• **Fig. 17.12** Complications of Porcelain Fused to Metal Prosthesis. (A) Porcelain fused to metal prostheses tends to be very heavy, especially if there are increased amounts of tissue loss (i.e., more metal substructure needed). This often results in patients reporting compromised opening or temporomandibular joint symptoms. (B) Porcelain fracture is the most common complication, often requiring the refabrication of the prosthesis. (C) Marginal integrity is a significant problem because of the difficulty in obtaining a passive casting, and (D) to increase the marginal integrity, the metal framework is often soldered; however, this results in an increased possibility of prosthesis fracture.
• **Fig. 17.13** Interocclusal Space. Interocclusal space is measured from the incisal edge to the alveolar crest. An FP-3 prosthesis requires a minimum of 10 mm for a monolithic zirconia, ~12 mm for a porcelain fused to metal prosthesis, and >15 mm for a hybrid prosthesis. The amount of space can be easily determined from the cone beam computed tomography images.

been shown with minimal complications.[17] Antagonistic wear is minimal and is advantageous to porcelain and natural teeth enamel. Lastly, there is less peri-implant disease, as lower thickness of biofilm accumulates in comparison with a porcelain product.

The crown height space determination for a hybrid prosthesis is approximately 15 mm from the bone to the occlusal plane. When less than this space is available, a porcelain-to-metal restoration is suggested. When a greater crown height space is present, a hybrid prosthesis is often fabricated. Implants placed too facial, lingual, or in embrasures are easier to restore when vertical bone has been lost and an FP-2 or FP-3 prosthesis is fabricated, because even extremely high smile lip lines do not expose the implant abutments. The greater crown heights allow the correction of incisal edge positions. However, the FP-2 or FP-3 restoration has greater crown height compared with the FP-1 fixed types of prostheses; therefore a greater moment of force is placed on the implant cervical regions, especially during lateral forces (e.g., mandibular excursions or with cantilevered restorations). As a result, additional implant abutments or shorter cantilever lengths should be considered with these restorations (Figs. 17.14 and 17.15).
• **Fig. 17.14** Techniques to Increase Interocclusal Space. Ideally the amount of interocclusal space is determined before the placement of implants. An osteoplasty is usually required before placement for an increased interocclusal space.

• **Fig. 17.16** The soft tissue profile may be changed or modified very easily with an RP-4 and RP-5 prosthesis. This can be completed by adding bulk to the flange areas of the prosthesis.

Removable Prostheses

There are two types of removable prostheses RPs (RP-4 and RP-5), based on support of the restoration (see Table 17.1). Patients are able to remove the prosthesis but not the implant-supported superstructure attached to the abutments. The difference in the two categories of removable restorations is not in appearance (as it is in the fixed categories). Instead, the two removable categories are determined by the amount of implant and soft tissue support.[18] The most common removable implant prostheses are overdentures for completely edentulous patients, which have been reported with high predictability.[6,19-23] One of the most significant benefits of a removable implant prosthesis (RP-4 and RP-5) is the ability to enhance the soft tissue profile. With an FP (FP-1, FP-2, or FP-3) in an edentulous patient, it is often difficult to increase the fullness of the soft tissue without overcontouring the prosthesis and making hygiene difficult (Fig. 17.16).

• **Fig. 17.15** FP-3 Hybrid Complication. When there exists insufficient interocclusal space, it is common for denture teeth to fracture or debond.

RP-4

RP-4 is an RP that is completely supported by the implants, teeth, or both with no soft tissue support. The prosthesis is rigid when inserted: Overdenture attachments usually connect the RP to a low-profile tissue bar or superstructure that splints the implant abutments. Usually five or six implants in the mandible and six to eight implants in the maxilla are required to fabricate completely implant-supported RP-4 prostheses in patients with favorable dental criteria.

The implant placement criteria for an RP-4 prosthesis are different from that for an FP. More interocclusal space is required to allow for sufficient space for acrylic and denture teeth. In addition, a superstructure and overdenture attachments must be added to the implant abutments. This requires a more lingual and apical implant placement in comparison with the implant position for an FP. If implant placement is not more lingually or apically positioned, insufficient space will be present to retain the denture teeth. The implants in an RP-4 prosthesis (and an FP-2 or FP-3 restoration) should be placed in the mesiodistal position for the best biomechanical and hygienic situation. On occasion the position of an attachment on the superstructure or prosthesis may also affect the amount of spacing between the implants. For example, a Hader clip requires the implant spacing to be greater than 6 mm from edge to edge, and as a consequence reduces the number

An FP-2 or FP-3 prosthesis rarely has the patient's interdental papillae or ideal soft tissue contours around the emergence of the crowns, because these restorations are used when there is more crown height space and the lip does not expose the soft tissue regions of the patient. In the maxillary arch, wide open embrasures between the implants may cause food impaction or speech problems. These complications may be solved by using a removable soft tissue replacement device or making overcontoured cervical restorations. The maxillary FP-2 or the FP-3 prosthesis is often extended or juxtaposed to the maxillary soft tissue so that speech is not impaired. Hygiene is more difficult to control, although access next to each implant abutment is provided.

The mandibular restoration may be left above the tissue, similar to a sanitary pontic. This facilitates oral hygiene in the mandible, especially when the implant permucosal site is level with the floor of the mouth and the depth of the vestibule. However, if the space below the restoration is too great, the lower lip may lack support in the labiomental region. Rarely can this space be left in the maxilla, because this will usually impact esthetics or affect the speech (e.g., the patient may exhibit "whistling" sounds or saliva extrusion through the spaces).

• **Fig. 17.17** RP-4 Prosthesis. An RP-4 prosthesis is a totally implant-supported prosthesis with no soft tissue support. (A) Usually this type of prosthesis is retained with a splinted bar. (B) A maxillary RP-4 is a palateless prosthesis that usually is reinforced with metal or fiber to increase strength. (C) The mandibular RP-4 prosthesis is totally implant supported with no soft tissue support (e.g., no buccal shelf extension).

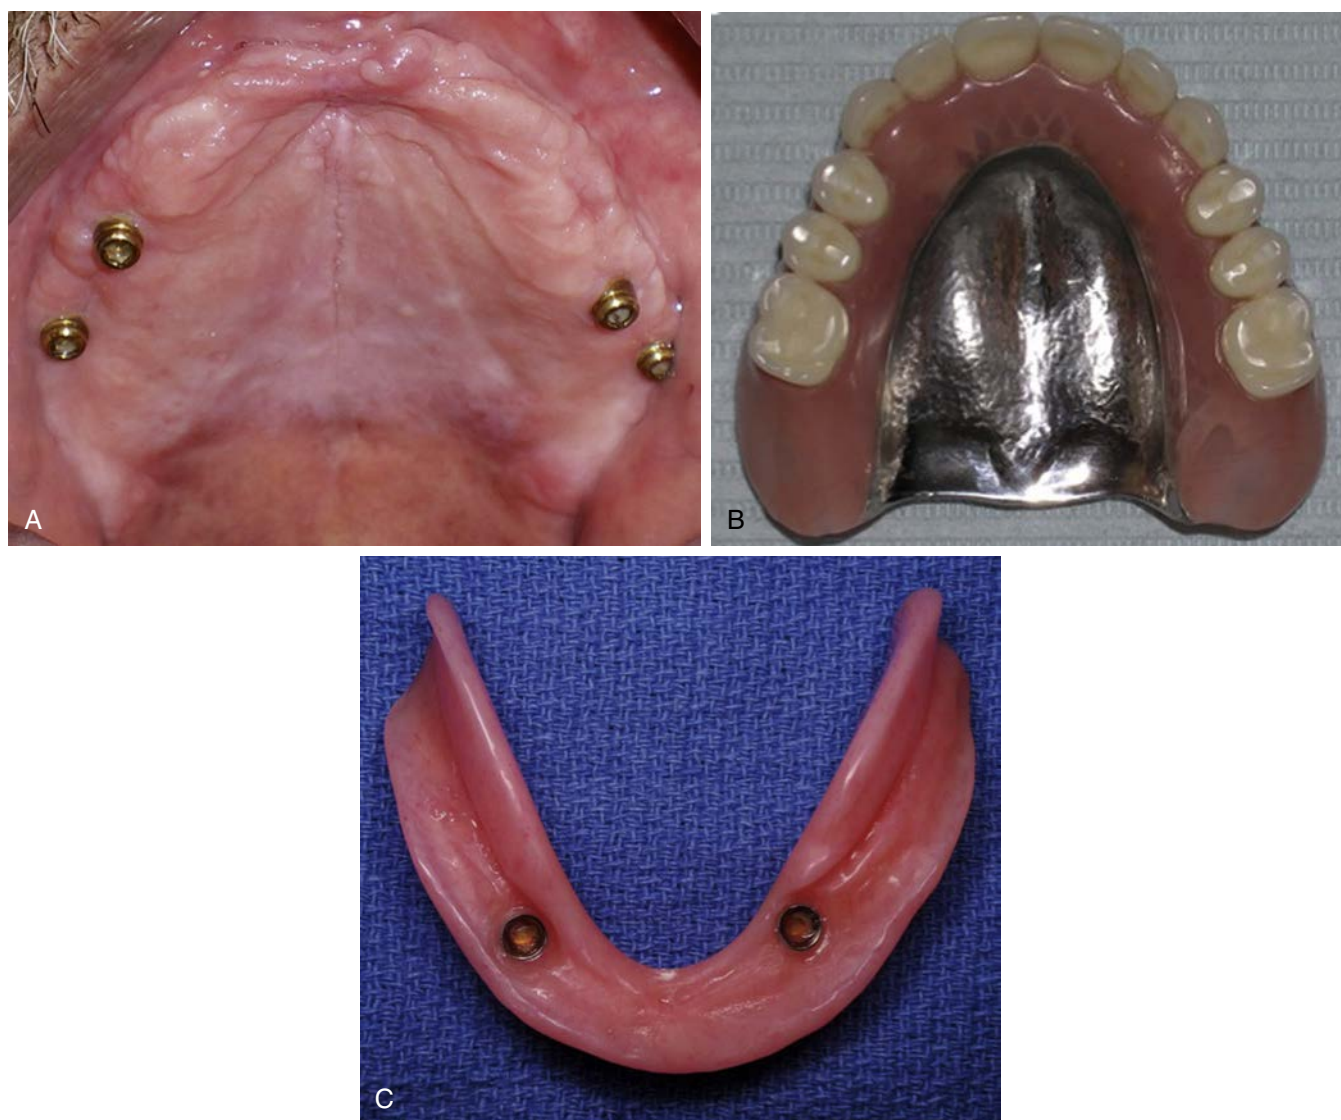
of implants that may be placed between the mental foramina. The RP-4 prosthesis may have the same appearance as an FP-1, FP-2, or FP-3 restoration. A porcelain-to-metal prosthesis with attachments in selected abutment crowns can be fabricated for patients with the cosmetic desire of an FP. The overdenture attachments permit improved oral hygiene or allow the patient to sleep without the excess forces of nocturnal bruxism on the prosthesis (Fig. 17.17).

RP-5

RP-5 is an RP with soft tissue (primary) and implant (secondary) support. There exist many options with an RP-5 prosthesis. For example, the completely edentulous mandibular overdenture may have: (1) two anterior implants independent of each other, (2) splinted implants in the canine region to enhance retention, (3) three splinted implants in the premolar and central incisor areas to provide lateral stability, or (4) implants splinted with a cantilevered bar to reduce soft tissue abrasions and to limit the amount of soft tissue coverage needed for prosthesis support. The primary advantage of an RP-5 restoration is the reduced cost. The prosthesis is similar to traditional overdentures supported by natural teeth (Fig. 17.18). In the maxilla, depending on the arch form, four, five, or six implants are indicated. The final prosthesis is a full-arch conventional denture that receives the primary support from the soft tissue and secondarily from the implants.

A preimplant treatment denture may be fabricated to ensure the patient's satisfaction. This technique is especially indicated for patients with demanding needs and desires regarding the final esthetic result. The implant clinician can also use the treatment denture as a guide for implant placement. The patient can wear the prosthesis during the healing stage. After the implants are uncovered, the superstructure is fabricated within the guidelines of the existing treatment restoration. Once this is achieved, the preimplant treatment prosthesis may be converted to the RP-4 or RP-5 restoration. The clinician and the patient should realize that the bone will continue to resorb in the soft tissue–borne regions of the prosthesis. Relines and occlusal adjustments every few years are common maintenance requirements of an RP-5 restoration. Bone resorption with RP-5 prostheses may occur two to three times faster than the resorption found with full dentures.[5] This can be a factor when considering this type of treatment in young patients, despite the lesser cost and low failure rate.

Summary

In traditional dentistry, the restoration reflects the existing condition of the patient. Existing natural abutments are first evaluated, and a removable or fixed restoration is fabricated accordingly.


• **Fig. 17.18** **RP-5 Prosthesis.** An RP-5 prosthesis is a soft tissue–supported prosthesis with secondary implant support. (A) Usually an RP-5 prosthesis is retained with nonsplinted attachments (e.g., no substructure bar). (B) A maxillary RP-5 prosthesis is a complete palate (e.g., must have full palatal support). (C) The mandibular RP-5 prosthesis is soft tissue supported with buccal shelf flange extension.

Implant dentistry is unique because an additional foundation base may be created for a desired prosthodontic result. Therefore both the psychological and anatomic needs and desires of the patient should be evaluated and determined. The prosthesis that satisfies these goals and eliminates the existing problems may then be designed. The prosthesis may be fixed or removable for the completely edentulous patient, whereas fixed restorations are planned for most partially edentulous patients.

If only one implant approach is used for all patients, the same surgical and prosthetic scenarios and flaws are invariably repeated. For example, if all edentulous mandibles are treated with two implants, not only are the implant and surgery similar regardless of intraoral or extraoral conditions, but an RP-5 prosthesis will usually result despite the patient's needs and desires. Many patients will accept an RP-5 prosthesis; however, many will not.

Therefore patients need to be educated on the advantages and disadvantages of the various types of prostheses.

The benefits of implant dentistry can be realized only when the prosthesis is first discussed and determined. An organized treatment approach based on the prosthesis permits predictable therapy results. Five prosthetic options postulated by Misch are available in implant dentistry. Three restorations are fixed and vary in the amount of hard and soft tissue replaced; two are removable and are based on the amount and type of support for the restoration (Figs. 17.19 and 17.20). The amount of support required for an implant prosthesis should initially be designed similar to traditional tooth-supported restorations. Once the intended prosthesis is designed, the implants and treatment surrounding this specific result can be established.
• **Fig. 17.19** Fixed restorations have three categories: FP-1, FP-2, and FP-3. The restoration type is related to the contour of the restoration. (FP-1 is ideal, FP-2 is hypercontoured, and FP-3 replaces the gingiva drape with pink porcelain or acrylic.) The difference between FP-2 and FP-3 most often is related to the high maxillary lip position during smiling or the mandibular lip position during sibilant sounds of speech. FP-2 and FP-3 restorations often require more implant surface area support by increasing implant number or size, or by adjusting design considerations.
• **Fig. 17.20** Removable prostheses have two categories based on implant support. RP-4 prostheses have complete implant support anteriorly and posteriorly. In the mandible the superstructure bar often is cantilevered from implants positioned between the foramina. The maxillary RP-4 prosthesis usually has more implants and little to no cantilever. An RP-5 restoration has primarily anterior implant support and posterior soft tissue support in the maxilla or mandible. Often fewer implants are required, and bone grafting is less likely indicated.

Bone Density: A Key Determinant for Treatment Planning

RANDOLPH R. RESNIK AND CARL E. MISCH[†]

Available bone is a crucial part of implant dentistry and describes the external architecture or volume of the edentulous area considered for implants. In the early days of oral implantology, the available bone was not modified in the implant candidate. Instead the existing bone volume was the primary factor used to develop a treatment plan. Short implants and fewer implants were used in less-available bone, and long implants in greater numbers were inserted in larger bone volumes. Today, the treatment plan should start with the determination of the final prosthesis first, then evaluate patient force factors followed by the bone density.

The internal structure of bone is described in terms of quality or density, which reflects a number of biomechanical properties, such as strength and modulus of elasticity. The external and internal architecture of bone controls virtually every facet of the practice of implant dentistry. The density of available bone in an edentulous site is a determining factor in treatment planning, implant design, surgical approach, healing time, and initial progressive bone loading during prosthetic reconstruction.[1,2] This chapter presents the aspects of bone density related to overall planning of an implant prosthesis.

Influence of Bone Density on Implant Success Rates

The quality of bone is often dependent on the arch position.[3-7] The densest bone is usually observed in the anterior mandible, followed by the anterior maxilla and posterior mandible, and the least-dense bone is typically found in the posterior maxilla. Following a standard surgical and prosthetic protocol, Adell et al.[8] reported an approximately 10% greater success rate in the anterior mandible compared with the anterior maxilla. Schnitman et al.[9] also noted lower success rates in the posterior mandible compared with the anterior mandible when the same protocol was followed. The highest clinical failure rates have been reported in the posterior maxilla, where the force magnitude is greater and the bone density is poorer.[5-7,9-13] Therefore, the literature is quite abundant on implant survival relative to the arch position.

In addition to arch location, several independent groups have reported different failure rates related to the quality of the bone.[3-21]

Engquist et al.[16] observed that 78% of all reported implant failures were in soft bone types. Friberg et al.[3] observed that 66% of their group's implant failures occurred in the resorbed maxilla with soft bone. Jaffin and Berman,[15] in a 5-year study, reported a 44% implant failure rate when poor-density bone was observed in the maxilla. The article documented a 35% implant loss in any region of the mouth when bone density was poor. Fifty-five percent of all implant failures within their study sample occurred in the soft bone type. Johns et al.[17] reported a 3% failure rate of implants in moderate bone densities but a 28% implant failure rate in the poorest bone type. Smedberg et al. reported a 36% failure rate in the poorest bone density.[18] The reduced implant survival most often is more related to bone density than arch location. In a 15-year follow-up study, Snauwaert et al.[12] reported early annual and late failures were more frequently found in the maxilla. Herrmann et al.[13] found implant failures were strongly correlated to patient factors, including bone quality, especially when coupled with poor bone volume (65% of these patients experienced failure). These reported failures are not primarily related to surgery healing but instead occur after prosthetic loading. Therefore over the years, many independent clinical groups, following a standardized surgical protocol, documented the indisputable influence of bone density on clinical success (Fig. 18.1). However, a protocol established by Misch, which adapts the treatment plan, implant selection, surgical approach, healing regimen, and initial prosthetic loading, has resulted in similar implant success rates in all bone densities and all arch positions.[22-25] This chapter proposes a scientific rationale for the modification of a treatment plan in function of implant density to achieve comparable success rates in all bone types.

Etiology of Variable Bone Density

Bone is an organ that is able to change in relation to a number of factors, including hormones, vitamins, and mechanical influences. However, biomechanical parameters, such as duration of edentulous state, are predominant.[26-30] Awareness of this adaptability has been reported for more than a century. In 1887 Meier[31] qualitatively described the architecture of trabecular bone in the femur. In 1888 Kulmann[32] noticed the similarity between the pattern of trabecular bone in the femur and tension trajectories in construction beams.

[†]Deceased.

450
● **Fig. 18.1** Over the years, several clinical reports observed higher success rates in better bone quality (bone I to III) and lower survival rates in poor bone quality (bone IV).
● **Fig. 18.2** The maxilla is a force distribution unit, which allows for force to be redirected away from the brain and orbit (A,B,and C). The mandible is designed to absorb force, thereby forming denser and thick cortical bone and courser trabecular bone.

● **Fig. 18.3** The trabecular bone in a dentate mandible is coarser compared with the maxilla (*green arrows*). The mandible, as an independent structure, is a force-absorbing element. In addition, the cortical bone is thicker and more dense (*red arrows*).

Wolff,[33] in 1892, further elaborated on these concepts and published, "Every change in the form and function of bone or of its function alone is followed by certain definite changes in the internal architecture, and equally definite alteration in its external conformation, in accordance with mathematical laws." The modified function of bone and the definite changes in the internal and external formation of the vertebral skeleton as influenced by mechanical load were reported by Murry.[34] Therefore the external architecture of bone changes in relation to function, and the internal bony structure is also modified.

MacMillan[35] and Parfitt[36] have reported on the structural characteristics and variation of trabeculae in the alveolar regions of the jaws. For example, the maxilla and mandible have different biomechanical functions (Fig. 18.2). The mandible, as an independent structure, is designed as a force absorption unit. Therefore, when teeth are present, the outer cortical bone is denser and thicker, and the trabecular bone is coarser and denser (Fig. 18.3). In contrast, the maxilla is a force distribution unit. Any strain to the maxilla is transferred by the zygomatic arch and palate away from the brain and orbit. As a consequence the maxilla has a thin cortical plate and fine trabecular bone supporting the teeth (Fig. 18.4). They also noted that the bone is densest around the teeth (cribriform plate) and denser around the teeth at the crest compared with the regions around the apices (Fig. 18.5). Alveolar bone resorption associated with orthodontic therapy also illustrates the biomechanical sensitivity of the alveolar processes.[37] Generalized trabecular bone loss in the jaws occurs in regions around a tooth from a decrease in mechanical strain.[38] Orban[39] demonstrated a decrease in the trabecular bone pattern around a maxillary molar with no opposing occlusion compared with a tooth with occlusal contacts on the contralateral side (Fig. 18.6). Bone density in the jaws also decreases after tooth loss. This loss is primarily related to the length of time the region has been edentulous and not loaded appropriately, the initial density of the bone, flexure and torsion in the mandible, and parafunction before and after tooth loss. In general, the density change after tooth loss is greatest in the posterior maxilla and least in the anterior mandible.
• **Fig. 18.4** The dentate maxilla has a finer trabecular pattern compared with the mandible. The maxilla is a force distribution unit and is designed to protect the orbit and brain.
• **Fig. 18.5** The trabecular bone of each jaw has structural variations. The trabecular bone is densest next to the teeth, where it forms the cribriform plate. Between the teeth the bone is usually densest near the crest and least dense at the apex.
• **Fig. 18.6** On the left the opposing mandibular tooth was removed. A lack of occlusal contact resulted in loss of trabecular bone around the maxillary tooth. The tooth on the right is from the same monkey, with the opposing mandibular tooth in place. The trabecular bone is much denser around the tooth. The disuse atrophy observed on the left is from inadequate microstrain conditions to maintain the bone. (*From Orban B.* Oral Histology and Embryology. *3rd ed. St. Louis, MO: Mosby; 1953.*)

Cortical and trabecular bone throughout the body are constantly modified by either modeling or remodeling.[40] Modeling has independent sites of formation and resorption, and results in the change of the shape or size of bone. Remodeling is a process of resorption and formation at the same site that replaces previously existing bone and primarily affects the internal turnover of bone, including that region where teeth are lost or the bone next to an endosteal implant.[41,42] These adaptive phenomena have been associated with the alteration of the mechanical stress and strain environment within the host bone.[43,44] Stress is determined by the magnitude of force divided by the functional area over which it is applied. Strain is defined as the change in length of a material divided by the original length. The greater the magnitude of stress applied to the bone, the greater the strain observed in the bone.[45] Bone modeling and remodeling are primarily controlled, in part or whole, by the mechanical environment of strain. Overall the density of alveolar bone evolves as a result of mechanical deformation from microstrain.

Frost[46] proposed a model of four histologic patterns for compact bone as it relates to mechanical adaptation to strain. The pathologic overload zone, mild overload zone, adapted window, and acute disuse window were described for bone in relation to the amount of the microstrain experienced (Fig. 18.7). These four categories also may be used to describe the trabecular bone response in the jaws. The bone in the acute disuse window loses mineral density, and disuse atrophy occurs because modeling for new bone is inhibited and remodeling is stimulated, with a gradual net loss of bone. The microstrain of bone for trivial loading is reported to be 0 to 50 microstrain. This phenomenon may occur throughout the skeletal system, as evidenced by a 15% decrease in the cortical plate and extensive trabecular bone loss consequent to immobilized limbs for 3 months.[47] A cortical bone density decrease of 40% and a trabecular bone density decrease of 12% also have been reported with disuse of bone.[48,49] Interestingly, bone loss similar to disuse atrophy has been associated with microgravity environments in outer space, because the microstrain in bone resulting from the Earth's gravity is not present in the "weightless" environment of space.[50] In fact, an astronaut aboard the Russian Mir space station for 111 days lost nearly 12% of his bone minerals.[51,52]

The *adapted window* (50–1500 microstrain) represents an equilibrium of modeling and remodeling, and bone conditions are maintained at this level. Bone in this strain environment remains in a steady state, and this may be considered the homeostatic window of health. The histologic description of this bone is primarily lamellar or load-bearing bone. Approximately 18% of trabecular bone and 2% to 5% of cortical bone are remodeled each year[26] in the physiologic loading zone, which corresponds to the adapted window. This is the range of strain ideally desired around an endosteal implant, once a stress equilibrium has been established (Fig. 18.8). Bone turnover is required in the adapted window, as Mori and Burr[53] provide evidence of remodeling in regions of bone microfracture from fatigue damage within the physiologic range.

The *mild overload zone* (1500–3000 microstrain) causes a greater rate of fatigue microfracture and increase in the cellular turnover rate of bone. As a result the bone strength and density may eventually decrease. The histologic description of bone in this range is usually woven or repaired bone. This may be the state for bone when an endosteal implant is overloaded and the bone interface attempts to change the strain environment. During the repair process the woven bone is weaker than the more mature, mineralized lamellar bone.[41] Therefore while bone is loaded in the mild overload zone, care must be taken because the "safety range" for bone strength is reduced during the repair.[42]
• **Fig. 18.7** Four zones for bone related to mechanical adaption to strain before spontaneous fracture. The acute disuse window is the lowest microstrain amount. The adapted window is an ideal physiologic loading zone. The mild overload zone causes microfracture and triggers an increase in bone remodeling, which produces more woven bone. The pathologic overload zone causes increase in fatigue fractures, remodeling, and bone resorption.
• **Fig. 18.8** An ideal bone–implant interface has organized: lamellar bone next to the implant. The adapted window zone of microstrain balances remodeling and allows the bone to maintain this condition.

Pathologic overload zones are reached when microstrains are greater than 3000 units.[46] Cortical bone fractures occur at 10,000 to 18,000 microstrain (1%–2% deformation). Therefore pathologic overload may begin at microstrain levels of only 18% to 40% of the ultimate strength or physical fracture of cortical bone. The bone may resorb and form fibrous tissue, or when present, repair woven bone in this zone, because a sustained turnover rate is necessary. The marginal bone loss evidenced during implant overloading may be a result of the bone in the pathologic overload zone. Implant failure from overload may also be a result of bone in the pathologic overload zone.

Bone Classification Schemes Related to Implant Dentistry

An appreciation of bone density and its relation to oral implantology has existed for almost 50 years. Linkow and Chercheve,[54] in 1970, classified bone density into three categories:

Class I bone structure: This ideal bone type consists of evenly spaced trabeculae with small cancelled spaces.
Class II bone structure: The bone has slightly larger cancelled spaces with less uniformity of the osseous pattern.
Class III bone structure: Large, marrow-filled spaces exist between bone trabeculae.

Linkow stated that Class III bone results in a loose-fitting implant; Class II bone was satisfactory for implants; and Class I bone was the most ideal foundation for implant prostheses. In 1985 Lekholm and Zarb[55] listed four bone qualities found in the anterior regions of the jawbone (Fig. 18.9). Quality 1 was composed of homogeneous compact bone. Quality 2 had a thick layer of compact bone surrounding a core of dense trabecular bone. Quality 3 had a thin layer of cortical bone surrounding dense trabecular bone of favorable strength. Quality 4 had a thin layer of cortical bone surrounding a core of low-density trabecular bone. Irrespective of the different bone qualities, all bone was treated
• **Fig. 18.9** Four bone qualities for the anterior region of the jaws. Quality 1 is composed of homogenous compact bone. Quality 2 has a thick layer of cortical bone surrounding dense trabecular bone. Quality 3 has a thin layer of cortical bone surrounded by dense trabecular bone of favorable strength. Quality 4 has a thin layer of cortical bone surrounding a core of low-density trabecular bone. (*From Lekholm U, Zarb GA. Patient selection and preparation. In: Brånemark PI, Zarb GA, Albrektsson T, eds.* Tissue Integrated Protheses: Osseointegration in Clinical Dentistry. *Chicago: Quintessence; 1985.*)

• **Fig. 18.10** The macroscopic structure of bone may be described, from the least dense to the most dense, as (1) fine trabecular (*red arrow*), (2) coarse becular (*yellow arrow*), (3) porous cortical (*green arrow*), and (4) dense cortical *(orange arrow)*.

• **Fig. 18.11** Four bone densities found in the edentulous regions of the maxilla and mandible. D1 bone is primarily dense cortical bone; D2 bone has dense-to-thick porous cortical bone on the crest and coarse trabecular bone underneath; D3 bone has a thinner porous cortical crest and fine trabecular bone within; and D4 bone has almost no crestal cortical bone. The fine trabecular bone composes almost all of the total volume of bone.

with the same implant design and standard surgical and prosthetic protocol.[8] Following this protocol, Schnitman and others[3,9,16] observed a 10% difference in implant survival between Quality 2 and Quality 3 bone, and 22% lower survival in the poorest bone density. Johns et al.[17] reported 3% failure in type III bone, but 28% in type IV bone. Smedberg et al.[18] reported a 36% failure rate in type IV bone. Higuchi and others also experienced a greater failure in the soft bone of the maxilla.[19] It is obvious that a standardized surgical, prosthetic, and implant design protocol does not yield similar results in all bone densities. In addition, these reports are for implant survival, not the quality of health of surviving implants. The amount of crestal bone loss also has been related to bone density[56-60] and further supports a different protocol for soft bone.

In 1988 Misch[1,2] proposed four bone density groups independent of the regions of the jaws based on macroscopic cortical and trabecular bone characteristics. The regions of the jaws with similar densities were often consistent. Suggested treatment plans, implant design, surgical protocol, healing, and progressive loading time spans have been described for each bone density type.[24,60,61] Following this regimen, similar implant survival rates have been observed for all bone densities.[22-24]

Misch Bone Density Classification

Dense or porous cortical bone is found on the outer surfaces of bone and includes the crest of an edentulous ridge. Coarse and fine trabecular bone types are found within the outer shell of cortical bone and occasionally on the crestal surface of an edentulous residual ridge. These four macroscopic structures of bone may be arranged from the least dense to the most dense, as first described by Frost[25,46] (Fig. 18.10).

In combination, these four increasing macroscopic densities constitute four bone categories described by Misch (D1, D2, D3, and D4) located in the edentulous areas of the maxilla and mandible (Fig. 18.11). The regional locations of the different densities of cortical bone are more consistent than the highly variable trabecular bone.

D1 bone is primarily dense cortical bone. D2 bone has dense-to-porous cortical bone on the crest and, within the bone, has coarse trabecular bone. D3 bone types have a thinner porous cortical crest and fine trabecular bone in the region next to the implant. D4 bone has very little to no crestal cortical bone. The fine trabecular bone composes almost all of the total volume of bone next to the implant (Table 18.1 and Fig. 18.12). A very soft bone, with incomplete mineralization and large intertrabecular spaces, may be addressed as D5 bone. This bone type is most often immature bone in a developing sinus graft.

TABLE 18.1	Misch Bone Density Classification Scheme		
Bone Density	**Description**	**Tactile Analog**	**Typical Anatomic Location**
D1	Dense cortical	Oak or maple wood	Anterior mandible
D2	Porous cortical and coarse trabecular	White pine or spruce wood	Anterior mandible Posterior mandible Anterior maxilla
D3	Porous cortical and fine trabecular	Balsa wood	Anterior maxilla Posterior maxilla Posterior mandible
D4	Fine trabecular	Styrofoam	Posterior maxilla Anterior maxilla
D5	Osteoid	Soft Styrofoam	Poorly mineralized bone graft

Determining Bone Density

The bone density may be determined by various techniques including tactile sensation, during surgery, the general location, or radiographic evaluation (CBCT).
• **Fig. 18.12** The four macroscopic bone qualities are (A) D1 (*arrow*), (B) D2, (C) D3 (*arrow*), and (D) D4. The bone-density variance is dependent on anatomic location and the local strain history of the bone after tooth loss.

TABLE 18.2	Usual Anatomic Location of Bone Density Types (% Occurrence)			
Bone	Anterior Maxilla	Posterior Maxilla	Anterior Mandible	Posterior Mandible
D1	0	0	92	8
D2	8	0	66	26
D3	75	22	0	3
D4	38	40	0	22
D5	Immature, poorly mineralized bone graft			

Location

A review of the literature and a survey of completely and partially edentulous patients postsurgery indicated that the location of different bone densities often may be superimposed on the different regions of the mouth[3-7,11-13,15-18,62-66] (see Tables 18.1 and 18.2). D1 bone is almost never observed in the maxilla and is rarely observed in most mandibles (Fig. 18.13). In the mandible, D1 bone is observed approximately 6% of the time in the Division A anterior mandible and 3% of the time in the posterior mandible, primarily when the implant is engaging the lingual cortical plate of bone. In a C–h bone volume (moderate atrophy) in the anterior mandible the prevalence of D1 bone approaches 25% in male individuals. The C–h mandible often exhibits an increase in torsion, flexure, or both in the anterior segment between the foramina during function. This increased strain may cause the bone to increase in density. D1 bone also may be encountered in the anterior Division A mandible of a Kennedy Class IV partially edentulous patient with a history of parafunction and recent extractions. In addition, D1 bone has been observed in the anterior or posterior mandible when the angulation of the implant may require the engagement of the lingual cortical plate.

The bone density D2 is the most common bone density observed in the mandible (Figs. 18.14 and 18.15). The anterior mandible consists of D2 bone approximately two-thirds of the time. Almost half of patients have D2 bone in the posterior mandible. The maxilla presents D2 bone less often than the mandible. Approximately one-fourth of patients have D2 bone, and this is more likely in the partially edentulous patient's anterior and premolar region, rather than the completely edentulous posterior molar areas. Single-tooth or two-tooth, partially edentulous spans in either arch almost always have D2 bone.

Bone density D3 is common in the maxilla (Fig. 18.16). More than half of patients have D3 bone in the upper arch. The anterior edentulous maxilla has D3 bone approximately 75% of the time, whereas almost half of the patients have posterior maxillae with D3 bone (more often in the premolar region). Almost half of the posterior mandibles also present with D3 bone, whereas approximately 25% of the anterior edentulous mandibles have D3 bone.

The softest bone, D4, is most often found in the posterior maxilla (approximately 40%), especially in the molar regions or after a sinus graft augmentation (where almost two-thirds of the patients have D4 bone) (Fig. 18.17). The anterior maxilla has D4 bone less than 10% of the time–more often after an onlay iliac crest bone graft. The mandible presents with D4 bone in less than 3% of the patients. When observed, it is usually Division A bone in a long-term, completely edentulous patient after an osteoplasty to remove the crestal bone.

Generalizations for treatment planning can be made prudently based on location. The bone density by location method is the first way the clinician can estimate the bone density in the implant sites to develop an initial treatment plan. It is safer to err on the side of less-dense bone during treatment planning, so the prosthesis will be designed with slightly more, rather than less, support. Therefore the initial treatment plan before computed tomography (CBCT) radiographic scans or surgery suggests the anterior maxilla is treated as D3 bone, the posterior maxilla as D4 bone, the anterior mandible as D2 bone, and the posterior mandible as D3
• **Fig. 18.13** (A–C) D1 bone: note the lack of trabecular bone. D1 bone has almost all cortical bone, leading to a tendency to overheat during preparation and compromised blood supply during healing.
• **Fig. 18.14** D4 Bone. (A) Cone beam computed tomography panoramic exhibiting very poor bone quality (minimal trabecular bone) in a patient with osteoporosis. (B) Cortical bone will be mottled in a patient with osteoporosis.

• **Fig. 18.15** A cross section of a D2 mandible in the region of the mental foramen. A thick cortical plate (*green arrow*) exists on the crest, and a coarse trabecular bone (*red arrow*) pattern exists within.
• **Fig. 18.16** A posterior maxilla demonstrating D3 bone with a thin porous cortical plate on the crest with fine trabecular bone underneath.

bone. A more accurate determination of bone density is made with CBCT images before surgery or tactilely during implant surgery.

Radiographic Evaluation

Periapical or panoramic radiographs are minimally beneficial in determining bone density, because of their two-dimensional nature and the lateral cortical plates often obscure the trabecular bone density. In addition, the more subtle changes of D2 to D3 cannot be quantified by these radiographs. Therefore the initial treatment plan, which often begins with these radiographs, follows the bone density by location method. Bone density may be more precisely determinedusing cone beam computerized tomography (CBCT).[67-70] With conventional computerized tomography (CT), each image is comprised of pixels. Each pixel in the CT image is assigned a number, also referred to as a Hounsfield or CT number. The CT Hounsfield scale is calibrated such that the Hounsfield unit values are based on water (0 HU) and air (–1000 HU). In general the higher the CT number, the denser the tissue. The HU is a quantitative measurement used in CT scanning to express CT numbers in a standardized form. The HU was created by Sir Godfrey Hounsfield and obtained from a linear transformation of the measured attenuation coefficients of water (0 HU) and air(-1000 HU).

When evaluating dental cone beam computed tomography (CBCT) images in regard to bone density, there does not exist a direct correlation (accuracy of measurement) compared with medical CT. Most dental CBCT systems inherently have an increased variation and inconsistency with density estimates.

The density estimates of gray levels (brightness values) are not true attenuation values (HU); thus inaccuracies in bone density estimates may result.[71] This is mainly due to the high level of noise in the acquired images and the slight inconsistencies in the sensitivity of the CBCT detectors. Dental imaging software frequently provides attenuation values (HU); however, such values should be recognized as approximations lacking the precision of HU values derived from medical CT units.

HUs have been correlated with bone density and treatment planning for dental implants.[72-74] In a retrospective study of CT scan images from implant patients, Kircos and Misch[69] established a correlation between CT HUs and density at the time of surgery. The Misch bone density classification may be evaluated on the CT images by correlation to a range of HUs (Box 18.1).[69] The very soft bone observed after some immaterialized bone grafts may be 50 to 180 units.[69] Even negative numbers, suggestive of fat tissue, have been observed with the cortical plates of some jaws, including the anterior mandible. Norton and Gamble[72] also found an overall correlation between subjective bone density scores of Lekholm and Zarb and the CT values. Several studies correlating torque forces at implant insertion with preoperative bone density values from CTs have reported similar conclusions.[75-77] Preoperative CT scan data of areas that lead to successful and unsuccessful implant placement have been reported. In the mandible, failed sites exhibited higher HUs than usual. This was correlated with failure in dense bone, possibly because of the lack of vascularization or overheating during surgery. By contrast, in the maxilla the bone density was low for the failed sites.[68] The bone density may be different near the crest, compared with the apical region where the implant placement is planned.[74] The most critical region of bone density is the crestal 7 to 10 mm of bone, because this is where most stresses are applied to an osteointegrated bone–implant interface. Therefore when the bone density varies from the most crestal to apical region around the implant, the crestal 7 to 10 mm determines the treatment-plan protocol (Figs. 18.18 and 18.19).

Many CBCT software programs are now available that allow for preoperative determination of bone density in the implant site area. Fig. 18.18 displays an implant ideally positioned in the bone within a CT scan image. An average HU is given inside the implant, which correlates to the bone density that the implant surgeon will be drilling into. The HU outside of the implant relays the average bone density around the periphery of the implant, which gives the clinician information on the bone–implant contact (BIC). This is especially important to determine the prosthetic protocol or progressive bone loading.

Tactile Sense

There is a great difference in the tactile sensation during osteotomy preparation in different bone densities, because the density is directly related to its strength.[1,2,77,78] To communicate more broadly to the profession relative to the tactile sense of different bone densities, Misch[1,2] proposed the different densities of his classification be compared with materials of varying densities. Site preparation and implant placement in D1 bone is similar to the resistance on a drill preparing an osteotomy in oak or maple wood (e.g., hard wood). D2 bone is similar to the tactile sensation of drilling into white pine or spruce (e.g. soft wood). D3 bone is similar to drilling into a compressed balsa wood. D4 bone is similar to drilling into a compressed Styrofoam. This clinical observation may be correlated to different histomorphometric

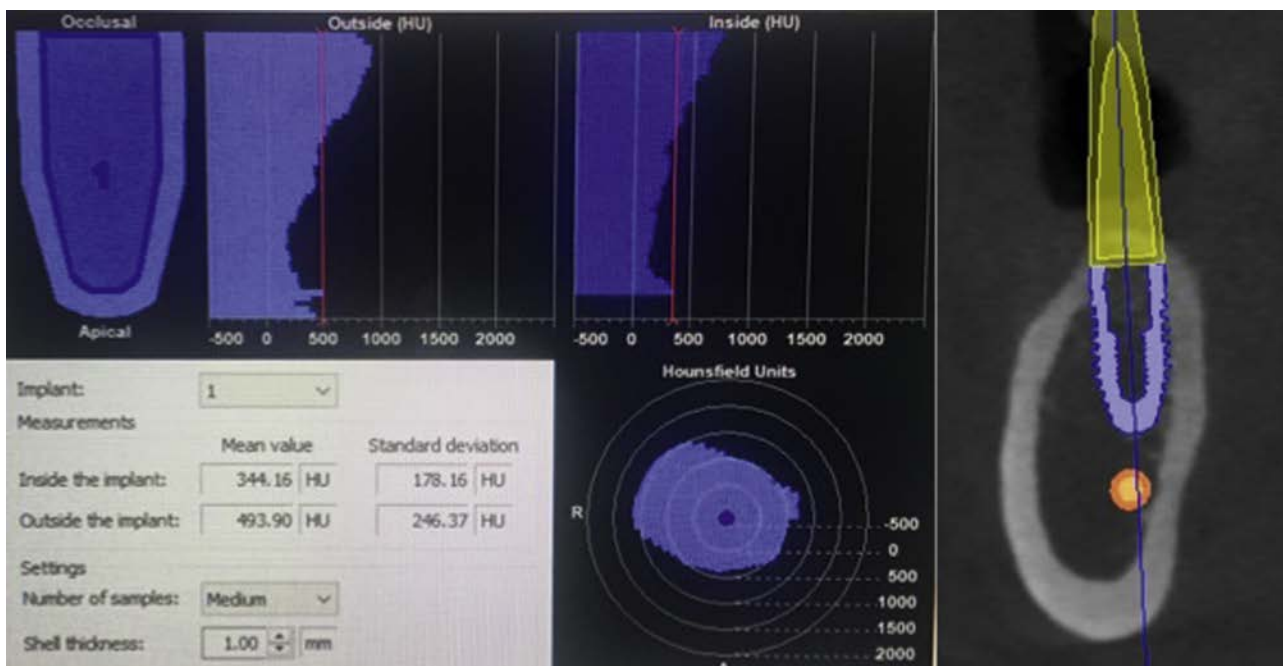
bone density determinations.[62] When an implant drill can operate at 1500 to 2500 rpm, it may be difficult to feel the difference between D3 and D4 bone. In D4 bone the drill may be inserted to the full desired depth without the drill rotating. In other words, a bone compression rather than extraction process may be used with the drill. D3 bone is easy to prepare but requires the drill to rotate while it is pressed into position. When this tactile method is the primary site, the surgeon should know how to modify the treatment plan if this bone density is different from first estimated when developing the treatment plan (Fig. 18.20).

Scientific Rationale of a Bone Density–Based Treatment Plan

Bone Strength and Density

Bone density is directly related to the strength of bone before microfracture.[79,80] Misch et al.[78] reported on the mechanical properties of trabecular bone in the mandible, using the Misch density classification. A tenfold difference in bone strength may be observed from D1 to D4 bone. D2 bone exhibited a 47% to 68% greater ultimate compressive strength, compared with D3 bone (Fig. 18.21). In other words, on a scale of 1 to 10, D1 bone is a 9 to 10 relative to strength. D2 bone is a 7 to 8 on this scale. D3 bone is 50% weaker than D2 bone and is a 3 or 4 on the strength scale. D4 bone is a 1 to 2 and up to 10 times weaker than D1 bone (Fig. 18.22). Misch and Bidez[81] performed three-dimensional, finite stress analyses on bone volumes of Division A, B, and C–w patients. Each model reproduced the cortical and trabecular bone material properties of the four densities described. Clinical failure was mathematically predicted in D4 bone and some D3 densities under occlusal loads (Fig. 18.23). The bone densities that originally relied on clinical impression are now fully correlated to quantitative objective values obtained from CT scans and bone strength measurements. These values can help prevent failure in specific situations of weak densities.


• **Fig. 18.18** Cone beam computed tomography determination of bone density inside and outside of implant. The inside density would correlate to the osteotomy preparation bone density. The outside density will correlate to the bone density that will encompass the implant after insertion.

(C) D3 bone (balsa wood), minimal cortical bone and course trabeculae. (D) D4 bone (Styrofoam), which has no cortical bone with minimal trabeculae.

Elastic Modulus and Density

The elastic modulus describes the amount of strain (changes in length divided by the original length) as a result of a particular amount of stress. It is directly related to the apparent density of bone.[80] The elastic modulus of a material is a value that relates to the stiffness of the material. The elastic modulus of bone is more flexible than titanium. When higher stresses are applied to an implant prosthesis, the titanium has lower strain (change in shape) compared with the bone. The difference between the two

• **Fig. 18.21** The ultimate compressive strength of D2 trabecular bone is greater than D3 trabecular bone. D4 trabecular bone is the weakest.

• **Fig. 18.22** The strength of bone is related directly to the density of bone.

materials may create microstrain conditions of pathologic overload and cause implant failure (Fig. 18.24A). When the stresses applied to the implant are low, the microstrain difference between titanium and bone is minimized and remains in the adapted window zone, maintaining load-bearing lamellar bone at the interface (Fig. 18.24B).

Misch et al.[78] found the elastic modulus in the human jaw to be different for each bone density (Fig. 18.25). As a result, when a stress is applied to an implant prosthesis in D1 bone, the titanium–D1 bone interface exhibits a very small microstrain difference. In comparison, when the same amount of stress is applied to an implant in D4 bone, the microstrain difference between titanium and D4 bone is greater and may be in the pathologic overload zone (Fig. 18.26). As a result, D4 bone is more likely to cause implant mobility and failure.[81] Several studies using finite element analysis models with various implant designs and bone qualities have evaluated the stress/strain distribution in the bone around the implants. Conclusions agree with the prior study to show the importance of bone quality in the treatment planning phase for long-term prognosis.[82-87]

Bone Density and Bone–Implant Contact Percentage

The initial bone density not only provides mechanical immobilization of the implant during healing but after healing also permits distribution and transmission of stresses from the prosthesis to the implant–bone interface. The mechanical distribution of stress occurs primarily where bone is in contact with the implant. Open marrow spaces or zones of unorganized fibrous tissue do not permit controlled force dissipation or microstrain conditions to the local bone cells. Because stress equals force divided by the area over which the force is applied, the less the area of bone contacting the implant body, the greater the overall stress, all other factors being equal. Therefore the BIC percent may influence the amount of stress/strain at the interface.

Misch[2] noted in 1990 that the bone density influences the amount of bone in contact with the implant surface, not only at first stage surgery but also at the second stage uncovery and early prosthetic loading. The BIC percentage is significantly greater in cortical bone than in trabecular bone. The very dense D1 bone of a C–h resorbed anterior mandible or of the lingual cortical plate of a Division A anterior or posterior mandible provides the highest

No failure predicted (A)   No failure predicted (B)   Failure predicted (C)

• **Fig. 18.23** (A) A finite element analysis study of D1 bone with a Division A, B, or C bone volume predicted no implant failure. (B) In a finite element analysis study of D3 bone of one-third the strength, no failure was predicted in Division A bone. (C) In a finite element analysis study, D4 bone was inadequate in strength for implant success, even in Division A bone volume.

• **Fig. 18.24** (A) When the microstrain is high (50×10^3 psi in this example), the change in shape difference of titanium and bone is large and may result in a pathologic overload zone. As a result, fibrous tissue at the interface and implant mobility is expected. (B) When the microstrain is low (10×10^3 psi in this example), the change in shape difference between titanium and bone is small and may result in the ideal adapted window zone. As a result, organized, lamellar bone may remain at the implant interface.
• **Fig. 18.25** The elastic modulus for D2 trabecular bone is greater than D3 trabecular bone, and D4 trabecular bone has the lowest elastic modulus.

percentage of bone in contact with an endosteal implant and may approximate more than 85% BIC (Fig. 18.27). D2 bone, after initial healing, usually has 65% to 75% BIC (Fig. 18.28). D3 bone typically has 40% to 50% BIC after initial healing (Fig. 18.29). The sparse trabeculae of the bone often found in the posterior maxilla (D4) offer fewer areas of contact with the body of the implant. With a machined-surface implant, this may approximate less than 30% BIC and is most related to the implant design and surface condition (Fig. 18.30). Consequently, greater implant surface area is required to obtain a similar amount of BIC in soft bone compared with a denser bone quality found around an anterior mandibular implant.

Bone Density and Stress Transfer

Crestal bone loss and early implant failure after loading results may occur from excess stress at the implant–bone interface.[49-52,56-59,82-86]

A range of bone loss has been observed in implants with similar load conditions.[59] Misch[2] noted in 1990 that part of this phenomenon may be explained by the evaluation of finite element analysis stress contours in the bone for each bone density. As a result of the correlation of bone density, elastic modulus bone strength, and BIC percent, when a load is placed on an implant, the stress contours in the bone are different for each bone density. In D1 bone, highest strains are concentrated around the implant near the crest, and the stress in the region is of lesser magnitude. D2 bone, with the same load, sustains a slightly greater crestal strain, and the intensity of the stress extends farther apically along the implant body (Fig. 18.31). D4 bone exhibits the greatest crestal strains, and the magnitude of the stress on the implant proceeds farthest apically along the implant body (Fig. 18.32). As a result the magnitude of a prosthetic load may remain similar and yet give one of the following three different clinical situations at the bone–implant interface, based on bone density: (1) physiologic bone loads in the adapted window zone and no marginal bone loss, (2) mild overload to pathologic overload bone loads and crestal bone loss, or (3) generalized pathologic overload and implant failure. Therefore to obtain a similar clinical result in each implant prosthesis, the variables in each patient must be either eliminated or accounted for in the treatment plan. Because the myriad of variables cannot be eliminated relative to bone density, the treatment plans (including implant number, size, and design) should be modified.

Treatment Planning

In oral implantology today, it is becoming more common for the initial radiographic survey to be with a CBCT scan. Therefore the implant clinician may use the location and radiographic survey
• **Fig. 18.26** The microstrain difference between titanium and D4 bone is great and may be in the pathologic overload zone, whereas at the same stress level, the microstrain difference between titanium and D2 bone may be within the ideal adapted window zone.
• **Fig. 18.27** D1 bone density has the greatest amount of bone–implant contact. Because stress equals force divided by area, the increase in the area of contact results in a decreased amount of stress.
• **Fig. 18.28** In D2 bone density, one finds primarily coarse trabecular bone next to the implant. The bone–implant contact is greater than D3 bone but less than D1 bone.

as indicators on the bone density qualitative evaluation of the patient. After the initial assessment of the bone density is determined, additional factors such as implant key position and number, implant size and design, and available bone are evaluated.

There exist four key principles that help form the basis for treatment-plan modification in function of the bone quality: (1) each bone density has a different strength, (2) bone density affects the elastic modulus, (3) bone density differences result in different amounts of BIC percent, and (4) bone density differences result in a different stress/strain distribution at the implant–bone interface when implants are loaded. Therefore bone density is an implant treatment-plan modifier in several ways—prosthetic factors, implant size, implant design, implant surface condition, implant number, and the need or method of prosthetic progressive bone loading.

As the bone density decreases, the strength of the bone also decreases. To decrease the incidence of microfracture of bone, the strain to the bone must be reduced. Strain is directly related to stress. Consequently, the stress to the implant system should also be reduced as the bone density decreases (Box 18.2). One way to reduce the biomechanical loads on implants is by prosthesis design to decrease force. The most ideal technique is the splinting of multiple implants. Additional techniques include the cantilever length being shortened or eliminated, narrower occlusal tables designed, and offset loads minimized, all of which reduce the amount of load.[45] RP-4 restorations, rather than fixed prostheses, permit the patient to remove the prosthesis at night and reduce nocturnal parafunctional forces. RP-5 prostheses permit the soft tissue to share the occlusal
• **Fig. 18.29** The fine trabecular bone of D3 initially heals next to the implant with 40% to 50% bone–implant contact.

• **Fig. 18.30** D4 bone has the least bone–implant contact. As a result the stress is greatest for the D4 bone-implant interface. Trabecular bone is fine, the strength is poor, and the modulus of elasticity microstrain difference is greatest. The microstrain difference for each bone density is not the same. D4 bone is most at risk, whereas D1 bone is least at risk.

force and reduce the stress on the implants. The use of occlusal guards help dissipate parafunctional forces on an implant system. As the bone density decreases, these prosthetic factors become more important.

The load on the implant may also be influenced by the direction of force to the implant body.[81] A load directed along the long axis of the implant body decreases the amount of stress in the crestal bone region compared with an angled load. Therefore as the bone density decreases, axial loads on the implant body become more critical. Bone grafting or bone spreading to increase

the width of bone and to better position the implant relative to the intended load is considered for soft bone types.

Stress may also be reduced by increasing the functional area over which the force is applied. Increasing implant number is an excellent way to reduce stress by increasing functional loading area. Three implants rather than two may decrease applied implant moments in half and bone reaction forces by two-thirds, depending on implant position and size.[45] An implant prosthesis

with normal patient forces in the bone should ideally have at least one implant per tooth. In the molar region, two implants for each missing molar may be appropriate. In D2 bone with normal patient forces a pontic may replace a tooth between two implants. In D3 bone, one implant per tooth is often appropriate.

The surface area of the implant macrogeometry may be increased to decrease stress to the implant–bone interface.[60,88] The width of the implant may decrease stress by increasing the surface area.[60,89] This may also reduce the length requirement. For every 0.5-mm increase in width, there is an increased surface area between 10% and 15% for a cylinder implant, and even greater difference is found with threaded-implant body designs. Because the greatest stresses are concentrated at the crestal region of the implant, width is more significant than length for an implant design, once adequate length has been established. D4 bone should often require wider implants compared with D1 or D2 bone. This may require onlay grafts or bone spreading to increase the width of bone when other stress factors are high. This implant length requirement may require sinus grafts in the posterior maxilla. However, because the crestal region is where pathologic overload of bone most often occurs after prosthetic loading, once initial healing is complete the length of the implant is not as effective to decrease crestal bone loss (and the quality of implant health) as other factors (e.g., implant design, implant width).

The macro design affects the magnitude of stresses and their impact on the bone–implant interface[10,82,90,91] and can dramatically change the amount and contour of the bone strains concentrated at the interface. Different implant design criteria respond to different bone densities. Bone densities exhibit a tenfold difference in strength, and the elastic modulus is significantly different between D1 and D4.

Coatings or the surface condition on an implant body can increase the BIC percentage and therefore the functional surface area. A rougher surface is strongly suggested in soft bone and has resulted in improved short-term survival rates compared with machined titanium.[11] After 1 to 2 years, the mechanical load on the overall implant design is more critical to the amount and type of bone contact compared with the surface condition on the implant body. Rough surface conditions also may have some disadvantages. Plaque retention when exposed above the bone, contamination, and increased cost are a few of the concerns with roughened surfaces. The benefit and risk of surface conditions suggest the roughest surfaces are most often used in only softer bone types.

Progressive bone loading provides for a gradual increase in occlusal loads, separated by a time interval to allow the bone to mature and accommodate to the local strain environment.[2] Over time, progressive loading changes the amount and density of

the implant–bone contact. The increased density of bone at the implant interface improves the overall support system mechanism. The softer the bone, the more important the need for progressive loading.[1,2]

Summary

A key determinant for clinical success is the diagnosis of the bone density in a potential implant site. The strength of bone is directly related to bone density. The modulus of elasticity is related to bone density. The percentage of BIC is related to bone density, and the axial stress contours around an implant are affected by the density of bone. As a consequence, past clinical reports that did not alter the protocol of treatment related to bone density had variable survival rates. To the contrary, altering the treatment plan to compensate for soft bone types has provided similar survival rates in all bone densities. Once the prosthetic option, key implant position, and patient force factors have been determined, the bone density in the implant sites should be evaluated to modify the treatment plan. The treatment plan may be modified by reducing the force on the prosthesis or increasing the area of load by increasing implant number, implant position, implant size, implant design, or implant body surface condition.

Treatment Plans Related to Key Implant Positions and Implant Number

CARL E. MISCH† AND RANDOLPH R. RESNIK

In the past, treatment planning for implant dentistry was primarily driven by the existing bone volume in the edentulous sites (i.e., bone-driven treatment planning). As a result, implants were placed in areas where bone was present, however not necessarily in the best position for prosthetic rehabilitation. Because of the nonideal positioning, atypical prostheses resulted that led to significant biomechanical issues. A second historical phase of treatment planning has since developed based on esthetics and ideal biomechanics. In this scheme, implant positions are primarily dictated and controlled by the teeth (prosthesis) being replaced. If the available bone is insufficient or in a nonideal position, bone augmentation is completed to increase the bone volume to position the implants more ideally.

It is generally accepted that when implants are inserted into abundant bone volume and allowed sufficient time to integrate before loading, the surgical success rate is greater than 98%. In most studies this success rate is not related to implant position, number, size, or design and, more importantly, prosthesis success.[1] Research has shown that when the implant is occlusally loaded with the prosthesis for a period, the failure rate may be greater than three to six times the surgical failure rate. For example, a metaanalysis reveals 15% failure rates (with several reports >30% failure) when the implant prosthesis is occlusally loaded in softer bone.[1] This failure most often occurs during the first 18 months of loading and is termed *early loading failure*. The primary cause of this complication in implant dentistry is related to biomechanical factors, with excessive biomechanical stress applied to the implant support system or bone too weak to support the load.[2]

Therefore it is imperative for the implant clinician to reduce the biomechanical stress to the implant prosthesis. This may be accomplished by several methods (e.g., eliminating cantilevers, ideal implant positioning, adequate implant number and splinting implants whenever possible).[1] Mechanical complications of the implant components or prosthesis far outnumber surgical failures, which may include abutment screw loosening, uncemented prostheses, and restorative material failure. These potential complications may be exacerbated by parafunctional habits, nonfavorable opposing dentitions, and improper occlusal schemes. Because mechanical complications are related to biomechanical factors,

Misch[2] developed a treatment plan sequence to decrease the risk for biomechanical overload, consisting of the following:
1. development of the prosthesis design
2. evaluation of patient force factors
3. determination of bone density in the edentulous sites
4. determination of key implant positions and implant number
5. determination of implant size
6. determination of available bone in the edentulous sites

This chapter will discuss the key implant positions and related treatment planning principles for an implant prosthesis to reduce the biomechanical stress to the system.

Key Implant Positions Rules for a Fixed Implant Prosthesis

The position of dental implants within the arch is crucial to long-term success. Some implant positions are more critical than others in regard to force reduction. For a fixed prosthesis, four general guidelines have been postulated to assist the clinician in treatment planning (Box 19.1):
1. Cantilevers on the prosthesis should be reduced and preferably eliminated (especially in the maxilla); therefore the terminal abutments in the prosthesis are key positions.
2. More than three adjacent pontics should not be designed in the prosthesis.
3. The canine and first molar sites are key positions, especially when adjacent teeth are missing.
4. The arch is divided into five segments. When more than one segment of an arch is being replaced, a key implant position is at least one implant in each segment.

• BOX 19.1   **Guidelines for Key Implant Positions**

- No cantilevers
- Maximum of three adjacent pontics
- Canine
- Molar rule
- Arch dynamics

---

†Deceased.
• **Fig. 19.1** Ideal key implant positions include the terminal abutment positions when adjacent teeth are missing. Without a terminal abutment, a cantilever situation will exist on the restoration, which increases biomechanical complications. This is particularly important when excessive forces are present.

Rule # 1: Minimize Cantilevers

The first rule for ideal key implant positions dictates that the use of cantilevers should be reduced and minimized in the design of the prosthesis (Fig. 19.1). Cantilevers are force magnifiers to the implants, abutment screws, cement or prosthesis screws, and implant–bone interface. Force magnifiers are variables that increase or potentiate force to the system. It is well accepted that cantilevers on fixed partial dentures supported by natural teeth have a higher complication rate than prostheses with terminal abutments, including unretained restorations. This is especially noted with parafunction or reduced crown height spaces.[3] Therefore the ideal key implant positions include the terminal abutment positions when adjacent teeth are missing.

The length of the cantilever is directly related to the amount of the additional force placed on the abutments of the prosthesis. For example, when a 25-lb force is placed along the long axis of an implant, the implant system (i.e., crown, cement, abutment, abutment screw, implant body, implant marginal bone, and implant–bone interface) receives a 25-lb load. When a force of the same magnitude (25 lb) is applied on a 10-mm cantilever, the moment force on the abutment is increased to a 250-lb millimeter force. As a result, any part of the implant system is at an increased risk for biomechanical failure (e.g., porcelain fracture, uncemented prosthesis, abutment screw loosening, crestal bone loss, implant failure, implant component or body fracture) (Fig. 19.2).

A cantilevered restoration on multiple implants may be compared with a class I lever. The extension of the prosthesis from the last abutment is the *effort arm* of the lever. The last abutment next to the cantilever acts as a fulcrum when a load is applied to the lever. The distance between the last abutment and the farthest abutment from the end of the cantilever represents the *resistance arm* and may be called the *anteroposterior distance* or *A-P spread* of the implants. The length (usually in millimeters) of the cantilever (effort arm) divided by the resistance arm represents the *mechanical advantage.* Therefore when two implants are 10 mm apart with a cantilever or extension of 20 mm, the mechanical advantage is two (20 mm/10 mm). In this example a 25-lb force on the cantilever results with a 50-lb force on the farthest abutment from the cantilever (25 lb × 2 = 50 lb). The abutment closest to the
• **Fig. 19.2** A cantilever on two implants may be considered a class 1 lever. For example, when the center of each implant is 10 mm apart, with a 20-mm cantilever, a mechanical advantage of 2 is created. Therefore the load on the cantilever will be multiplied by 2 on the posterior implant, and the implant close to the cantilever receives the majority of the stress of the two loads.

cantilever (fulcrum) receives a force equal to the sum of the other two forces, or in this example, 75 lb (25 lb + 50 lb). Therefore cantilevers magnify forces to all of the abutments that support the prosthesis.

Therefore the ideal treatment plan should minimize the use of cantilevers. However, in some clinical conditions a cantilever is the most prudent treatment option. For example, in an edentulous mandible, available bone in the posterior regions may be insufficient for root form implant placement, without advanced procedures (e.g., nerve repositioning, iliac crest bone grafts). An alternative treatment plan may be to cantilever pontics from anterior implants. However, when terminal abutments are not designed in the treatment plan and a cantilever is planned, other force and surface area factors should compensate for the increase in force (Fig. 19.3). When this option is considered, the force factors of parafunction, bone density, crown height, masticatory dynamics, implant location, and opposing arch are closely scrutinized. In addition to force modifiers, the A-P distance (A-P spread) of the distal and anterior implants is also a factor. When the implants are in one plane, the cantilever should rarely extend farther than the A-P distance, regardless of how low the patient force factors are. When the force factors are unfavorable, the cantilever length should be reduced or eliminated, the implant number increased, the implant size increased, or the implant design surface areas increased. The square arch form is the least desirable because this equates to a short, minimal A-P spread. The tapered arch form is the most ideal because the distance between the anterior and posterior implants is the greatest. The ovoid arch form is associated with an arch form between the square and tapered (Fig. 19.4).

Rule # 2: Limit the Number of Adjacent Pontics

In most prostheses designs, greater than three adjacent pontics are contraindicated on implants, just as they are contraindicated on natural tooth abutments.[4] The exception to this rule is when very
• **Fig. 19.3** (A) When three adjacent teeth are being replaced, the terminal abutments are key implant positions. When all patient force factors are low and bone density is good, two implants may be adequate to replace the three missing teeth. However, when force factors are high, an implant for each missing tooth is recommended. (B) When four adjacent teeth are missing, the terminal abutments are key implant positions. Rarely are these two implants sufficient to replace four posterior teeth (i.e., exception would be opposing a complete denture). More commonly, three implants are placed with the additional implant being placed ideally in the most available position because of higher occlusal forces.
• **Fig. 19.4** The anteroposterior distance (A-P spread) of five implants in the mandible is measured from the distal of the last two implants to the mid position of the most anterior implant. Because these splinted implants form an arch, the cantilever may extend up to 2.5 times the A-P distance (when patient force factors are low and bone density is good). Arch shape affects the A-P distance. The ovoid arch form (A) often has an A-P distance of 6 to 8 mm. A square arch form (B) often has an A-P dimension of 2 to 5 mm. A tapered arch form (C) has the greatest A-P distance, larger than 8 mm.

low force factors are present along with favorable implant conditions (i.e., bone density, available bone, minimal force factors). The complication resulting from multiple adjacent abutments is the additional force that is applied, especially in the posterior regions.

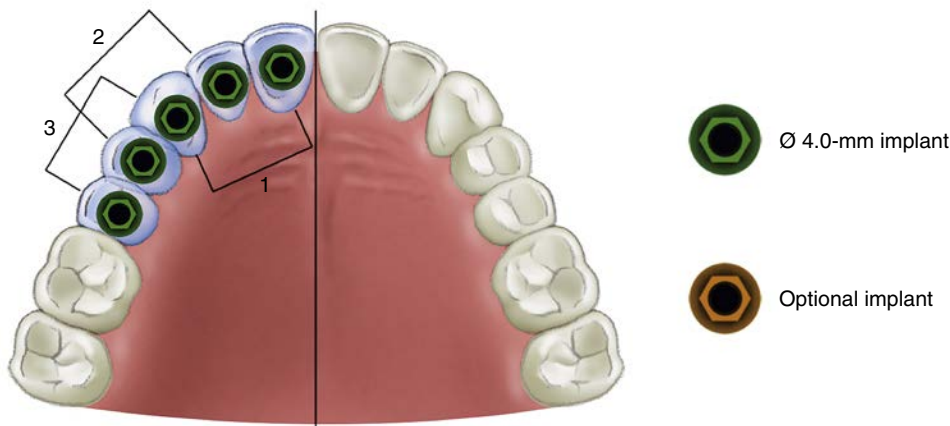
The adjacent abutments are subjected to considerable additional force when they must support three missing teeth, especially in the posterior regions of the mouth. In addition, all pontic spans between abutments flex under load. The greater the span between abutments, the greater the flexibility in the prosthesis. The greater the load, the greater the flexure. This resultant flexure places shear and tensile loads on the abutments.[5] In addition, the greater the flexure, the increased risk for porcelain/zirconia fracture, uncemented prostheses, and abutment screw loosening.

The flexure of restorative materials in a long span is more of a problem for implants than natural teeth. Because natural tooth roots have associated mobility both apically and laterally, the tooth acts as a stress absorber, and the amount of material flexure may be reduced. An implant is more rigid than a tooth (and also has a greater modulus of elasticity than a natural tooth), so the complications of increased load and material flexure are greater for an implant prosthesis. This is especially crucial with maxillary anterior prostheses, where angled forces magnify the amount of the force to the implant system.

The span of the pontics in the ideal treatment plan should be limited in size by reducing the occlusal table and cusp height. If replacing a molar-size space (mesiodistal), the size of two premolar-sized teeth may be used. By narrowing the occlusal table, the amount of damaging forces (i.e., shear, off-axis) will reduce the amount of force to the system. By decreasing the cusp height, the potential of shear forces is reduced significantly (Fig. 19.5).

Rule # 3: Implant Positioned in Canine Site

A fixed restoration replacing a canine is at greater risk than nearly any other restoration in the mouth. The maxillary or mandibular adjacent incisor is one of the weakest teeth in the mouth, and the first premolar is often one of the weakest posterior teeth. A traditional fixed prosthetic axiom indicates it is contraindicated to

replace a canine and two or more adjacent teeth.[4,6] Therefore if a patient desires a fixed prosthesis, and force factors are not favorable, implants are required whenever the following adjacent teeth are missing in either arch: (1) the first premolar, canine, and lateral incisor; (2) the second premolar, first premolar, and canine; and (3) the canine, lateral, and central incisors (Fig. 19.6). Whenever
• **Fig. 19.5** (A–C) A five- to seven-unit fixed prosthesis has three key positions for the abutments. The terminal abutment follows rule 1 (no cantilever), and a one-pier abutment is positioned following rule 2 (no three adjacent pontics). Rarely are these three abutments sufficient to support the prosthesis in the long term. Additional abutments are required when force factors are moderate to severe or bone density is poor around the implant.


these combinations of teeth are missing, implants are required to restore the patient because: (1) the length of the span is three adjacent teeth, (2) the lateral direction of force during mandibular excursions increase the stress, and (3) the magnitude of the bite force is increased in the canine region compared with the anterior region. Therefore under these conditions, at least two key implant positions are required to replace these three adjacent teeth, usually in the terminal positions of the span (especially when one of the terminal abutments is the canine position) (Figs. 19.7 and 19.8).

When the three adjacent teeth are the first premolar and canine and lateral incisors, the key implant positions are the first premolar and the canine. These positions result in an anterior cantilever to replace the lateral incisor. However, because the lateral incisor is the smallest tooth in the arch and in the anterior region has the least bite force, the cantilever is of limited negative impact. In addition, the canine implant is usually larger than a lateral incisor implant for the esthetic requirements of the restoration. This further reduces the effect of the cantilever (Fig. 19.9). In addition, the occlusion is modified so that no occlusal contact is present on the lateral incisor pontic in centric occlusion or excursions of the mandible. When force factors are greater than usual, a small-diameter implant may also be used to support the lateral incisor, and three implants with no cantilever reduce the increased force factor risks.

When there are multiple missing teeth and the canine edentulous site is a pier abutment position, the canine position is a key implant position to help disocclude the posterior teeth in mandibular excursions. As a result, when four or more adjacent teeth are missing, including a canine and at least one adjacent posterior premolar tooth, the key implant positions are the terminal abutments, the canine position, and additional pier abutments, which limit the pontics spans to no more than two teeth (Fig. 19.10).

The canine site is also crucial for the ideal occlusion. In most fixed-implant treatment plans an implant-protected occlusion is recommended. This occlusal scheme allows for disocclusion off of the canine (i.e., canine guidance), thereby protecting the teeth from harmful forces. Williamson and Lundquist[7] showed in electromyographic studies that when a mutually protected occlusion is present, two-thirds of the temporalis/masseter muscle fibers do

• **Fig. 19.6** Whenever the canine and three adjacent teeth are missing, implants are required to support a fixed prosthesis. Therefore when (*1*) the canine, lateral, and central; (*2*) the lateral, canine, and first premolar; or (*3*) the canine, first, and second premolar teeth are missing, an implant should always be placed in the canine position.

• **Fig. 19.7** When the canine, first premolar, and second premolar teeth are missing, key implant positions are in the canine and second premolar positions to support these three teeth.
• **Fig. 19.8** When the canine, lateral, and central incisor teeth are missing, key implant positions are in the central and canine positions to support these three teeth.

• **Fig. 19.9** When the first premolar, canine, and lateral incisors are missing, the key implant positions are the first premolar and canine position. Although this may result in a cantilever on the restoration, the lateral incisor is the smallest tooth, the anterior region has less bite force, and the canine implant may be larger than the lateral incisor implant for esthetic requirements.

not contract. Therefore by positioning an implant in the cuspid position, the resultant muscle activity from the temporalis and masseter muscles is greatly reduced.[7]

Rule # 4: Implant Positioned in Molar Site

The first molar is also a key implant position when three adjacent posterior teeth are missing. The bite force doubles in the molar position compared with the premolar position in both the maxilla and mandible. In addition, the edentulous span of a missing first molar is 10 to 12 mm, compared with a 7-mm span for a premolar. As a result, when three or more adjacent teeth are missing, including a first molar, the key implant positions include the terminal abutments and the first molar position (Fig. 19.11). For example, in a patient missing the second premolar, first molar, and second molars, three key implant positions are needed to restore the full contour of the missing molar teeth: the second premolar and second molar terminal abutments and the first molar pier abutment (Fig. 19.12). When one implant replaces a molar (for a span of less than 13 mm), the implant should be at least 5 mm in diameter. When a smaller-diameter implant is selected, the molar may be considered the size of two premolars.

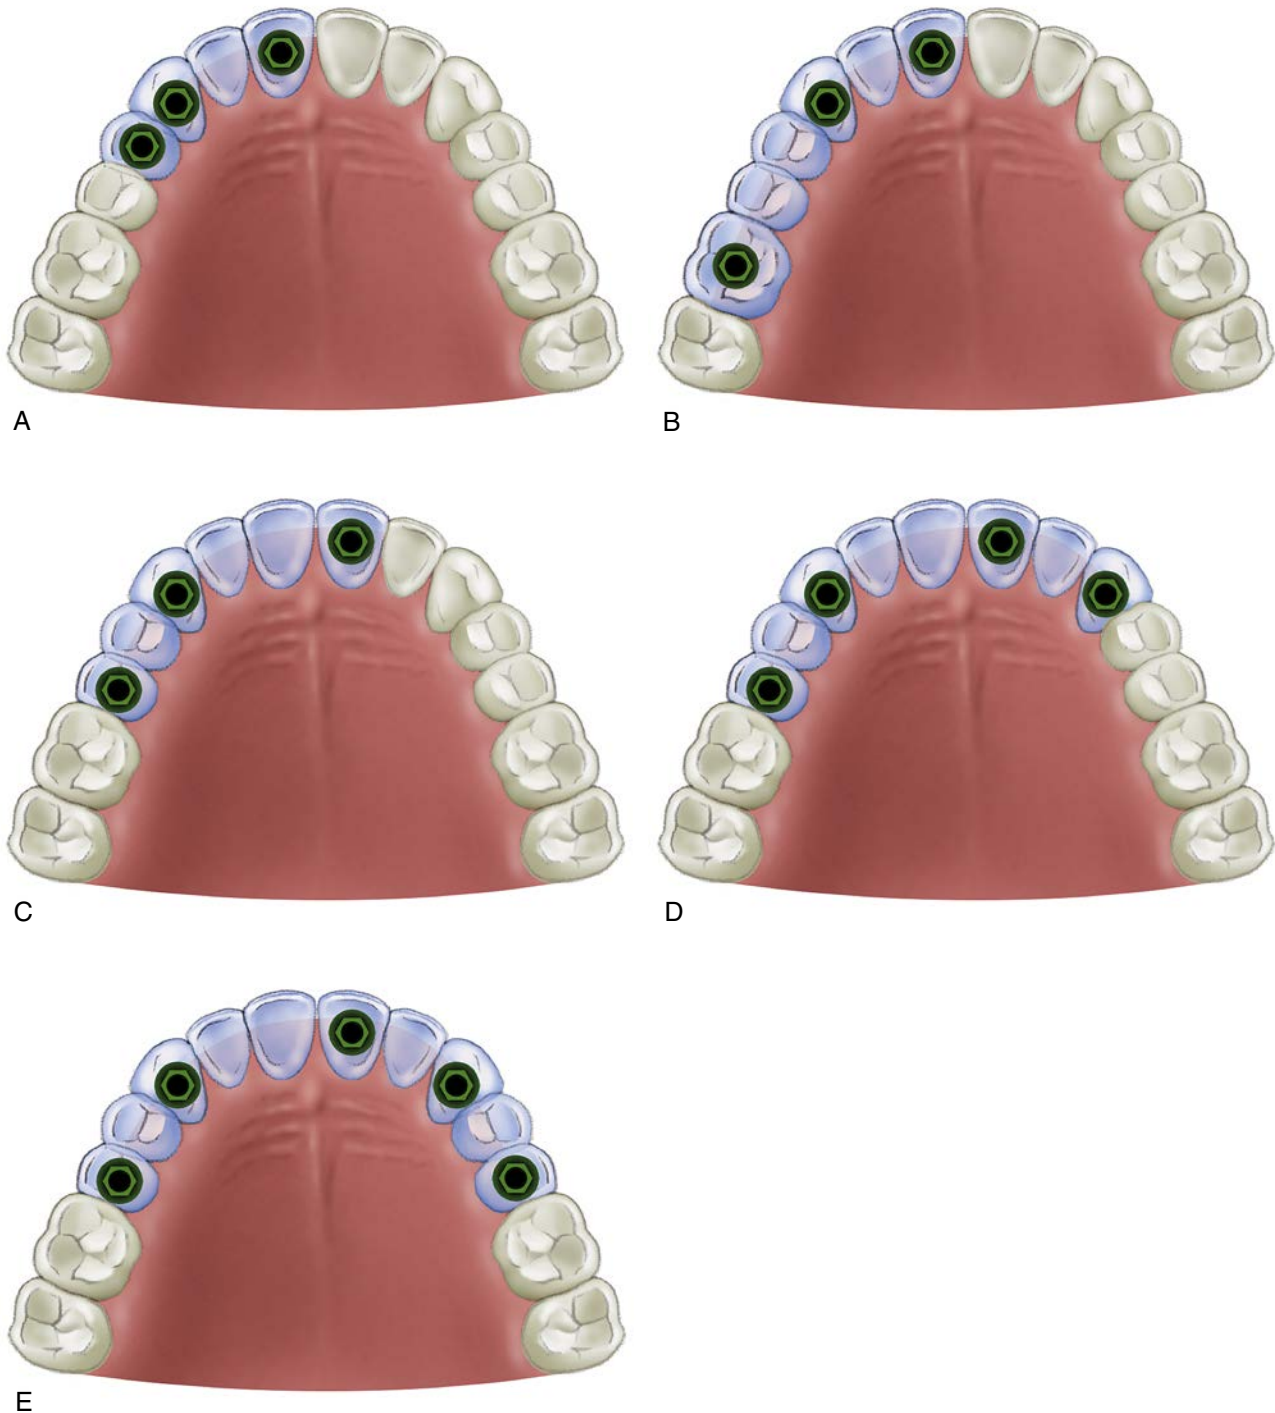
Rule # 5: Implant Positioned in Each Arch Segment

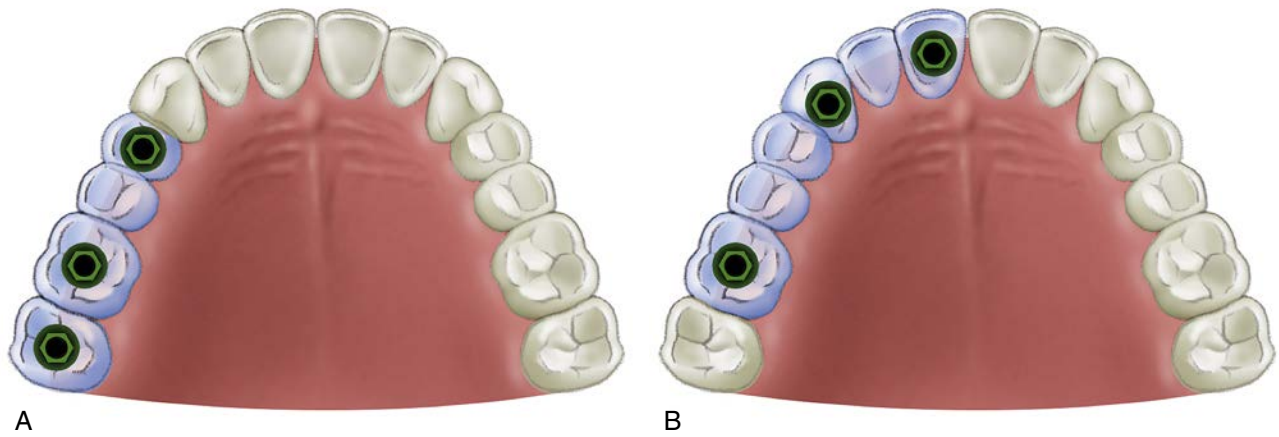
An arch (maxilla or mandible) may be divided into five segments, similar to an open pentagon (see Fig. 8.15). The two central and two lateral incisors are one segment, the canines are independent segments, and the premolars and molars on each side form a segment. In other words, each segment is essentially a straight line, with little inherent biomechanical advantage to a lateral force. However, when two or more segments of an arch are connected, the tripod effect is greater, and as a benefit, an A-P distance (A-P spread) is created from the most distal terminal abutments to the most anterior pier abutment (Fig. 19.13).

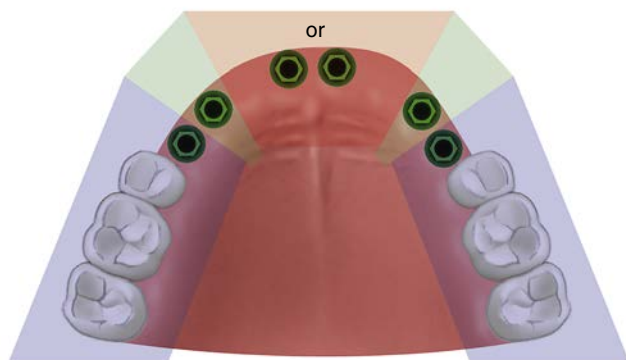
When multiple adjacent missing teeth extend beyond one of the open pentagon segments, a key implant position needs to be situated within each segment. Therefore if the patient is edentulous from first premolar to first premolar, the key implant positions include the terminal abutments (the two first premolars), the two canines, and either of the central incisor positions (Fig. 19.14). These implant positions follow the rules of (1) no cantilever, (2) no three adjacent pontics, (3) the canine position, and (4) at least one implant in each edentulous segment of an arch.

Implant Number

In the past the number of implants most often was determined by the amount of available bone in the mesiodistal dimension. For example, in an edentulous arch, five to six implants were often used in abundant bone between the mental foramina for a full-arch fixed prosthesis, whereas four implants were used in moderate-to-severe resorption for a fixed full-arch prosthesis (Fig. 19.15).[8] However, this treatment option does not consider the force magnifiers of crown or height space, or the A-P distance (A-P spread) of the implants in relation to the bilateral posterior cantilevers replacing the posterior teeth.

Usually a completely edentulous arch is supported by a 12-unit fixed prosthesis, extending from first molar to first molar. Rarely are second molars replaced in the prosthesis, unless the opposing arch has a second molar present. In this scenario the position of the implants cannot follow the four key implant position rules,


• **Fig. 19.10** (A) When the central, lateral, canine, and first premolar are missing, the ideal key implant positions are the central and first premolar (rule 1, no cantilever) and the canine position (rule 3, the canine and first molar position). (B) When the central, lateral, canine, first premolar, second premolar, and first molar are missing, the three key implants positions are the central and first molar sites (rule 1) and the canine site (rules 2 and 3, no three adjacent pontic and canine and first molar position). (C) When the central, central, lateral, canine, first premolar, and second premolar are missing, there are three key implant positions: the central and second premolar (rule 1, no cantilever) and the canine position (rule 3, the canine and first molar position). (D) When eight adjacent teeth are missing from second premolar to the opposite canine, there are four key implant positions: the canine and second premolar position (rule 1), the opposite canine (rule 3), and one of the central incisor positions (rule 2). (E) When 10 adjacent teeth are missing from second premolar to second premolar, there are five key implant positions: the two second premolar sites (rule 1), the two canine sites (rule 3), and one of the central incisor positions (rule 2).


• **Fig. 19.11** (A) When the patient is missing four teeth from the first premolar to second molar, there are three key implant positions to replace the four teeth: the first premolar and second molar sites (rule 1) and the first molar position (rule 3). (B) When the patient is missing six adjacent teeth from the central incisors to the first molar, there are three key implant positions: the central and first molar position (rule 1) and the canine position (rule 3). When a larger implant cannot be inserted into the molar site, an additional implant is required to follow rule 2. (C) When the patient is missing teeth from first molar to first molar, there are five key implant positions: the two first molars (rule 1), the two canines (rule 3), and a central incisor (rule 2). Additional implants in the posterior region are indicated when a larger-diameter implant is not positioned in the first molar sites (rule 2). Implants in the second premolar site are also usually indicated when force factors are moderate or bone density is D3. Even more implant support is suggested when force factors are severe or bone density is D4.
• **Fig. 19.12** In a patient missing the second premolar and first molar and second molars, three key implant positions are needed to restore the full contour of the missing molars: the second premolar and second molar terminal abutments and the first molar pier abutment.
• **Fig. 19.13** An arch may be considered as an open pentagon: the two premolar and molar sites, the two canine sites, and the central and lateral incisors represent the five sides.


• **Fig. 19.14** When a patient is missing eight teeth from first premolar to first premolar, there are five key positions: the first premolar sites (rule 1: no cantilever; and rule 4: one implant in each open pentagon segment), the two canines (rule 3: the canine and first molar rule; and rule 4: an implant in each pentagon segment), and an implant in one of the central incisor positions (rule 2: no three adjacent pontics; and rule 4: an implant in each open pentagon segment).

• **Fig. 19.16** When four adjacent teeth are missing from the canine to first molar, the two terminal key implant positions are usually inadequate to support the prosthesis. One or two additional implants are required in most clinical situations (depending on patient force factors and bone density). The additional implant of choice is in the second premolar site, especially when a larger-diameter implant is not placed in the molar site.

• **Fig. 19.15** In the past an edentulous arch used six implants to support a fixed prosthesis in abundant bone situations and four implants to support a complete full arch prosthesis when minimal bone volumes were present.

and include either four pontics between the anterior implants or three pontics cantilevered from the most distal implants. In addition, the number of implants in a treatment plan should rarely use a minimum number. There is no safety factor if an implant fails. For example, if 25 patients receive four implants to support a fixed prosthesis, there would be 25 fixed prostheses and 100 implants. If each patient lost one implant, there would remain only three implants and, as a result, nearly all 25 fixed prostheses would be at risk for overload failure. If 20% of the implants fail (with one failure per patient), only 5 of the 25 patients would have four implants to support the restoration (20% prosthesis success). This type of treatment planning may initially be less expensive for the patient, but an implant failure anytime after implant surgery places the patient's prosthesis at considerable risk.

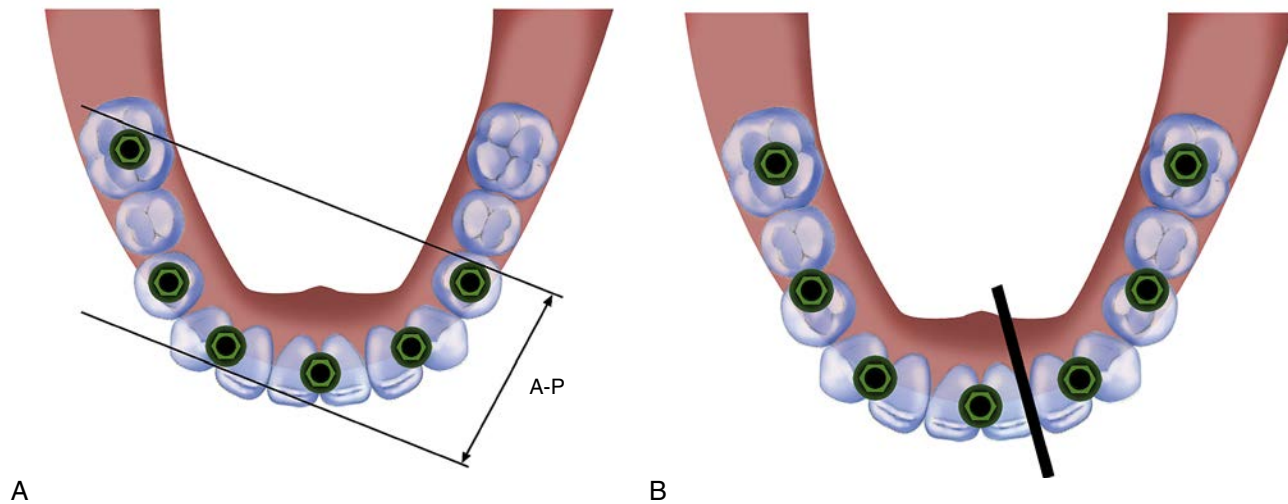
The key implant positions are often not enough support for the implant restoration, unless all patient force factors are low

(e.g., parafunction, masticatory dynamics, crown height) and the bone density is good (D1, D2). Therefore most often additional implants (besides the key implants) are added to the treatment plan.

One of the most efficient methods to increase surface area and decrease stress is to increase the implant number. For example, only two implant key positions as terminal abutments for a four-unit implant prosthesis in the canine and posterior region represent inadequate implant support, unless patient force factors are low, bone density is ideal, and implant size is not compromised. In most situations three implants to replace four missing teeth is an ideal implant number. When force factors are high and bone density is poor (i.e., posterior maxilla), four implants to replace four teeth is often appropriate (Fig. 19.16).

Previous studies have shown that three abutments for a five-tooth span distribute stress more favorably than do two abutments for the same span. The one additional implant may decrease the implant reaction force by two times and reduce metal flexure fivefold. In addition, in the three-abutment scenario, moment forces are reduced.[9,10] In full-arch prostheses, studies comparing six implants and four implant abutments show better distribution and reduced stress on the six-implant system components (crown, cement, abutment, abutment screw, marginal bone, implant–bone interface, and implant components).[11]

The decision on the number of implants in the treatment plan begins with the implants in the ideal key positions. Additional numbers are most often required and are primarily related to the patient force factors and to bone density in the edentulous sites. Therefore in a young, large man with severe bruxism with greater-than-normal crown height space in the posterior regions of the mouth, opposing an implant restoration will require one implant for each missing root (two implants for each molar). Likewise, patients with moderate force factors and poor bone density (D4 bone) in the implant sites may also require this many implants.

As a general observation the number of implants to replace all of the mandibular teeth range from five to nine, with at least four between the mental foramina. When fewer than six implants are used, a cantilever must be designed in a fixed prosthesis as a result of the mandibular flexure. Cantilevers in the mandible should


• **Fig. 19.17** (A) When six or more implants are positioned in the mandible (first molar, two first premolar, two canine, and one central incisor), a cantilever may be designed in the mandible because of the dynamics of an arch, with four of the five sections of an open pentagon joined, the large anteroposterior distance (A-P), and the favorable mandibular bone density. (B) When seven or more implants are placed in an edentulous mandible, two separate prostheses with no posterior cantilever may be designed. The mandible flexure and torsion are free to occur when the separation between the two prostheses is between the mental foramina.

ideally be projected in only one posterior quadrant to increase the A-P distance and reduce the force to the implants (Fig. 19.17). When implants are positioned in four of the five open pentagon positions in the mandible, a cantilever is at a reduced risk for overload because of favorable dynamics of an arch, increased large A-P distance, and favorable bone density. When seven or more implants are used, two separate restorations may be fabricated with no posterior cantilever to permit mandibular flexure and torsion (see Fig. 8.19B). Usually the second molar is not replaced in the edentulous mandible. A greater number of implants is generally required in the maxilla to compensate for the less-dense bone and more unfavorable biomechanics of the premaxilla, and range from 7 to 10 implants, with at least 3 implants from canine to canine (Fig. 19.18).

In most situations an implant should be positioned at least 1.5 mm from an adjacent natural tooth and 3 mm from an adjacent implant.[12-18] Using these guidelines, each 4-mm-diameter implant requires 7 mm of mesiodistal space (Fig. 19.19). Therefore the maximum number of implants between adjacent teeth can be calculated by taking the crest module of an implant (e.g., 4.0 mm) and adding these dimensions (Fig. 19.20). For example, an edentulous span of 21 mm is required for three adjacent implants 4 mm in diameter, and 28 mm for four adjacent implants between two teeth. As a general rule, it is better to err on the side of safety in numbers than on the side of too few implants. Therefore when in doubt, add an additional implant to the treatment plan.

Commonly, implant-supported crowns in the posterior regions of the mouth are the size of premolars. This concept often permits the placement of two implants to replace an intratooth molar, when the span is at least 14 mm for 4-mm-diameter implants (3 mm between each implant and 1.5 mm from the adjacent teeth). When the missing molar is the most distal in the arch, a 12.5-mm span is required for two 4-mm-diameter implants (3 mm between each implant and 1.5 mm from the anterior tooth), because the 1.5-mm distance from the last tooth is no longer required.

There are several advantages of a 7- to 8-mm-wide premolar and a molar-sized crown. More implants may be used to restore

   ● Primary site
   ● Secondary site
• **Fig. 19.18** The ideal seven-implant positioning for a maxillary edentulous arch includes at least one central incisor position, bilateral canine positions, bilateral second premolar sites, and bilateral sites in the distal half of the first molars. In the case of heavy stress factors, an additional anterior implant and bilateral second molar positions (to increase the anteroposterior distance) may be of benefit.

the missing teeth. Implants may range from 4 to 5 mm in diameter, which are the most common sizes, and often the available bone has adequate buccolingual bone dimension in this region. The emergence of the crown contours on implants of this dimension permit sulcular probing. In addition, the occlusal table width decreases mesial and distal moment forces compared with a molar-sized crown.[19]

Additional Treatment Planning Principles

Independent Prosthesis

As a general rule an implant-supported prosthesis should be independent from the natural adjacent teeth. This concept will
• **Fig. 19.19** The minimum mesiodistal dimension for two standard 4-mm diameter implants is 1.5 mm + 4 mm + 3 mm + 4 mm + 1.5 mm = 14 mm.

$$d = 1.5 \text{ mm} + \emptyset Z + 3mm + \emptyset Y + 3mm + \emptyset X + 1.5mm$$
• **Fig. 19.20** When three adjacent teeth are missing (two premolars and first molar), the mesiodistal dimension averages 7.1 mm + 6.6 mm + 10.4 mm = 24.1 mm. In this situation, planning 4-mm-diameter implants to fabricate two premolars of 7 mm each (1.5 mm + 4 mm + 1.5 mm) and one 5-mm-diameter implant for the first molar allows more bone around each implant.

reduce the risk for marginal decay on the natural teeth next to the adjacent pontic or abutment. The incidence of decay on a tooth splinted in a fixed partial denture accounts for 22% of the complications within 10 years, whereas individual crowns have less than 1% risk for decay within this time frame.[20] Unrestored natural teeth exhibit less risk for decay, and implants do not decay at all. A second common complication of teeth-supported fixed prosthetic restorations is endodontic-related factors that occur in approximately 15% of cases within 10 years.[21] Implant abutments
• **Fig. 19.21** Independent Implant Prosthesis. Ideally implants should always be kept independent from natural teeth because of numerous biomechanical differences. One of the most common complications is recurrent decay on the natural tooth abutment.

do not require endodontic procedures, and unsplinted natural tooth crowns have less endodontic procedures. Independent implant prostheses may also reduce or eliminate pontics, whereas simultaneously increasing the number of abutments and distributing forces more effectively. The increase in abutment number decreases the risk for an unretained restoration, which is the third most common fixed prosthesis complication supported by natural teeth. Therefore independent implant prostheses cause fewer complications and exhibit greater long-term success rates of the prosthesis and greater survival rates of the adjacent teeth.[22] However, when an implant restoration is joined to a natural tooth, an increased risk for abutment screw loosening, implant marginal bone loss, tooth decay, and unretained restoration occurs. In addition, the distribution of occlusal forces is optimized when independent implant prostheses are designed. As a result the ideal treatment plan for a partially edentulous patient includes an independent implant restoration (Fig. 19.21).

Splinted Implants

The splinting of dental implants is controversial. Many clinicians use the same existing treatment planning principles from natural teeth as they do for dental implants. However, implants and teeth are much different biomechanically. The fact that teeth adapt to forces much differently from implants is significant when deciding to splint versus nonsplint.

There exist many advantages to splinting implants. Splinted implants increase the functional surface area of support, increase the A-P distance (A-P spread) to resist lateral loads, distribute force over a larger area, increase cement retention of the prosthesis, decrease the risk for abutment screw loosening, decrease the risk for marginal bone loss, and decrease the risk for implant component fracture. In other words, the entire system benefits.[23-26]

In addition to biomechanical reasons, if an independent implant fails over time, the implant is removed, the site is grafted, the site is reimplanted, and a new crown is fabricated. When multiple splinted implants have an implant that fails, the affected implant may often be sectioned below the crown, and the implant or crown site converted to a pontic using the same prosthesis. As a result, rather than several surgical and prosthetic procedures over an extended period when independent units are restored, the

complication may be solved in one relatively short appointment when the crowns are splinted together.

The splinted implants distribute less force to the implant bodies, which decreases the risk for marginal bone loss and implant body fracture. In a report by Sullivan,[27] a 4-mm single implant replacing a molar had implant body fracture in 14% of the cases. In comparison, multiple implants splinted together had a 1% implant body fracture.[1]

Splinted implants reduce the risk for screw loosening. The highest prosthetic complication with single-tooth implants is abutment screw loosening. In a report by Balshi and Wolfinger,[28] single-tooth implants replacing a molar had 48% screw loosening over a 3-year period. When two implants were splinted together to replace a molar, the incidence rate of screw loosening was reduced to 8% over the same period.

The exception to the splinted implant rule is a full-arch mandibular implant prosthesis. The body of the mandible flexes distal to the foramen on opening and has torsion during heavy biting with potential clinical significance for full-arch implant prostheses.[29,30] As a result a full-arch mandibular implant prosthesis replacing the first or second molars should not be splinted to molars on the opposite side. Therefore full-arch mandibular restorations should have a cantilever or be made in two or three sections to accommodate the mandibular dynamics during function. The concept of flexure and torsion does not affect the maxilla, where all implants often are splinted together, regardless of their positions in the arch.

When implant crowns are splinted, they provide greater prosthesis retention and transfer less force to the cement interface. As a result a cemented implant restoration is less likely to become uncemented. This is especially significant when the abutments are short or lateral forces are present.

Many implant clinicians do not like to splint implants because of the associated technical complexities. The prosthesis path of insertion, the need for nonengaging abutments, and prosthetic insertion difficulties may deter many practitioners. However, with advancements in prosthetic and laboratory techniques and materials, this is becoming less of a concern in implant dentistry today.

When splinting implants, many clinicians and patients complain about the ability to perform interproximal hygiene. However, this concept is not as significant with implants for two reasons. First, a very low percentage of the population flosses regularly, especially if floss threaders are indicated.[31] Because the implants are usually 3 mm or more apart, if a patient does wish to perform interproximal hygiene, most aids (e.g., floss threader, proxy brush, water-pik) can easily clean this region.

A second reason that splinted units are not popular is the inability to repair restorative material fracture. However, when dental implants are splinted together, the crown marginal ridges between the implants are supported by metal/zirconia connectors; therefore the porcelain/zirconia is placed under compression. As independent units the margins of porcelain-to-metal crowns are most often placed under shear loads, which increase the risk for fracture. However, the increased use of monolithic zirconia has decreased material fracture significantly. Also, screw-retained prosthetic restorations are becoming more popular; therefore the prosthesis may be removed and repaired much easier.

And lastly, clinicians have the mindset of natural teeth and recurrent decay. A single crown on a natural tooth has a caries risk of less than 1% within 10 years. However, when natural teeth are splinted together, decay at the interproximal margin often occurs
• **Fig. 19.22** Splinted Prosthesis. Implants should be splinted together whenever possible, as the force (i.e., occlusal load) is distributed over a greater area. Note the fracture of the most posterior implant, which is likely due to occlusal force issues.

at a rate of approximately 22%.[32] In addition, the endodontic risk is increased when crowns are splinted. A single crown has an endodontic risk of 3% to 5.6%. Splinted teeth have an endodontic risk of 18%.[20] Therefore independent units reduce the incidence of complications and allow the practitioner to more readily treat these complications. However, implants do not decay or need endodontic therapy. As a result, independent units would not be required to address these complications (Fig. 19.22).

Treatment Planning Should Not Be Dictated by Finances

Many patients have unrealistic expectations with regard to treatment duration and implant treatment. It is not uncommon for a patient to demand that the treatment be "completed faster," especially when bone augmentation is ideally indicated. For example, a percentage of clinicians may not be comfortable with such procedures and may proceed with placing implants without bone grafting because the cost is greater and the procedure is more complex. Manufacturers have even further complicated the situation with questionable treatments of ultrashort implants, "mini-implants", excessive angled implants, or shortcut procedures.

Therefore because most biomechanical-related complications often occur within the first few years of function, the clinician may place themselves at significant risk when a nonideal or shortcut procedure is recommended. As a result, when failure occurs and remediation treatment is required, often the patient expects the clinician to repeat the treatment for no charge. Further, if the patient seeks care from another provider, this is often associated with a greater cost. As a result the patient is more likely to seek litigation-related remedies.

Summary

A biomechanical-based treatment plan reduces complications after implant loading with the prosthesis. To reduce stress conditions, there are key implant positions for a prosthesis replacing missing teeth: (1) minimize cantilevers in the design of the prosthesis, (2) greater than three adjacent pontics should be avoided, (3) the canine and first molar sites are vitally important positions

in an arch, and (4) the maxillary arch is divided into five segments. When more than one segment of an arch is being replaced, a key implant position is at least one implant in each missing segment.

Increasing the number of implants is the most efficient method to increase surface area and reduce overall stress. Therefore after the key implant positions are selected, additional implants are indicated to reduce the risks for overload from patient force factors or implant sites with reduced bone density. When in doubt of the number of implants required, adding an additional implant is advantageous.

Treatment Plans for Partially and Completely Edentulous Arches in Implant Dentistry

CARL E. MISCH† AND RANDOLPH R. RESNIK

Partially Edentulous Arches

A classification of patient conditions is necessary to organize treatment plans in a consistent approach. Because more than 65,000 possible combinations of teeth and edentulous spaces exist in a single arch, no universal agreement exists regarding the use of any one classification system. Numerous classifications have been proposed for partially edentulous arches. Their use allows the profession to visualize and communicate the relationship of hard and soft structures. This chapter reviews a classification for diagnosis and treatment planning for patients who are partially or completely edentulous and require implant prostheses. By using this classification, which Misch[1] first presented in 1985, the doctor is able to convey the dimensions of the bone available in the edentulous area and also indicate the strategic position of the area to be restored.

History

Cummer,[2] Kennedy,[3] and Bailyn[4] originally proposed the classifications of partially edentulous arches that are most familiar to the profession. These classifications were developed to organize removable partial denture (RPD) designs and concepts. Other classifications have also been proposed[5-12] (including one by the American College of Prosthodontists), none of which has been universally accepted. The Kennedy classification, however, has been most accepted in most American dental schools.

The Kennedy classification divides partially edentulous arches into four classes: Class I has bilateral posterior edentulous spaces, Class II has a unilateral posterior edentulous space, Class III has an intradental edentulous area, and Class IV has an anterior edentulous area that crosses the midline.

The Kennedy classification is difficult to use in many situations without certain qualifying rules. The eight Applegate rules are used to help clarify the system. They may be summarized in three general principles.

1. The first principle is that the classification should include only natural teeth involved in the final prosthesis and follow rather

†Deceased.

than precede any extractions of teeth that might alter the original classification. This concept, for example, considers whether second or third molars are to be replaced in the final restoration.

2. The second principles is that the most posterior edentulous area always determines the classification.

3. The third principle is that edentulous areas, other than those determining the classification, are referred to as modifications and are designated only by their number. The extent of the modification is not considered.

Classification of Partially Edentulous Arches

The implant dentistry bone volume classification developed by Misch and Judy[13] in 1985 may be used to build on the four classes of partial edentulism described in the Kennedy-Applegate system. This facilitates communication of teeth positions and the primary edentulous sites among the large segment of practitioners already familiar with this classification, and it enables the use of common treatment methods and principles established for each class. The implant dentistry classification for partially edentulous patients by Misch and Judy[13] also includes the same four available bone volume divisions previously presented for edentulous areas. Other intradental edentulous regions that are not responsible for the Kennedy-Applegate class determination are not specified within the available bone section, should implants not be considered in the modification region. However, if the modification segment is also included in the treatment plan, then it is listed, followed by the available bone division it characterizes.

Treatment Planning: Class I

In Class I patients, distal edentulous segments are bilateral, and natural anterior teeth are present (Fig. 20.1). The majority of these arches are missing only molars, and almost all have retained at least the anterior incisors and canines. Therefore once restored to proper occlusal vertical dimension, the natural anterior teeth contribute to the distribution of forces throughout the mouth in centric relation occlusion. More importantly, when opposing natural teeth or in fixed implant prosthesis, they also permit excursions
● **Fig. 20.1** A Class I, Division A dental arch has bilateral posterior missing teeth and abundant bone volume in the edentulous sites. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

during mandibular movement to disclude the posterior implant-supported prostheses and protect them from lateral forces. However, many of these mandibular Class I patients oppose a maxillary denture, in which case bilateral balance is more appropriate.

The Class I patient is more likely to wear an RPD than Class II or III patients because mastication and/or support of an opposing removable prosthesis is more difficult when not wearing a mandibular prosthesis. The posterior soft tissue–supported Class I partial dentures are designed to primary load either the edentulous regions or the natural anterior teeth. The clasp design, which places less force on the tooth (e.g., bar clasp), will ultimately place more force on the bone. The RPDs, which place more force on the abutment teeth (e.g., precision partial dentures), will place less force on the bone. In either case the removable prosthesis often accelerates the posterior bone loss. In addition, a partial denture that is not well designed or maintained distributes additional loads to abutment teeth and may even contribute to poor periodontal health. The combinations of these conditions lead to bone loss in the edentulous regions and poorer adjacent natural abutments.[14] As a result, it has been observed by authors that long-term Class I patients who have been wearing an RPD often exhibit Division C ridges and mobile abutment teeth.

Class I patients often have mobile anterior teeth, because long-term lack of bilateral posterior support caused by the wearing of a poorly fitting RPD, or none at all, has resulted in an overload to the remaining dentition. Therefore these patients often require a posterior implant prosthesis to be independent from the mobile natural teeth. In addition, the occlusal scheme must accommodate the specific conditions of mobile anterior teeth. This requires increased implant support in the posterior segments compared with most Class II or III patients, as well as greater attention and frequency for occlusal adjustments.

The treatment plan must consider the factors of force previously identified and relate them to the existing bilateral edentulous condition. Osteoplasty cannot be as aggressive in the Class I patient to increase bone width, compared with the Class IV or fully edentulous patient with implants primarily in the anterior regions, because of the opposing anatomic landmarks (maxillary sinus or mandibular canal). Augmentation procedures are often required to improve posterior bone volume, increase the implant surface area, and permit the fabrication of an independent implant restoration.

Financial concerns may require the staging of treatment over years. The posterior region with the greatest volume of bone usually is restored first, if no bone grafting is required. In this manner, implants of greater size and surface area can resist the unilateral posterior forces while the patient awaits future treatment. If many years pass before implants are to be inserted in the lesser available bone, then continued resorption may require augmentation before reconstruction. If both posterior segments require bone grafting, the patient is encouraged to have both posterior segments augmented at the same time. In this way the autologous portion of the graft may be harvested and distributed to both posterior regions, decreasing the number of surgical episodes for the patient.

Division A Treatment Plans

When patients are placed in a Class I, Division A category, an independent implant-supported fixed prosthesis is usually indicated. Two or more endosteal root form implants are required to replace molars with independent prostheses (Fig. 20.2). The greater the number of teeth missing, the larger the size and/or number of implants required. Posterior available bone is limited in height by the mandibular canal in the mandible or the maxillary sinus in the maxilla. The first premolar-positioned implants must avoid encroachment on the apex of the canine root and yet avoid the anterior loop of the mandibular canal or maxillary sinus (Fig. 20.3).

Division B Treatment Plans

Class I, Division B patients have narrow bone in posterior edentulous spaces and anterior natural teeth. A fixed prosthesis is also indicated in these categories. Available bone height is restricted by the mandibular canal or maxillary sinus. Therefore osteoplasty to increase bone width has limited applications. Endosteal small-diameter root form implants may be placed in the mandibular

• **Fig. 20.2** A Mandible with a Class I, Division A Classification. The key implant positions are deter-mined, and the implant sizes are ideal (4 mm × 10 mm in premolars and 5 mm × 10 mm in the molars). (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)
• **Fig. 20.3** A Maxilla with Class I, Division A Bone. The key implant positions and implant sizes are posi-tioned without limitation. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

posterior Division B edentulous ridge. If narrow-diameter root forms are used, then a greater number than for the Division A ridge is indicated, and the use of one implant for every missing tooth root with no cantilever is recommended.

The patient who is missing molars and both premolars requires additional implant support. Four Division B root forms may be the foundation of an independent fixed partial denture (FPD) in the mandible, depending on the other stress factors. If stress factors are too great (as a result of parafunction) or bone density is poor (as in the maxilla), then the Division B bone should be augmented to Division A before larger-diameter implant insertion. The anterior teeth in Class I patients should provide disclusion of the posterior implants during all excursions when opposing natural teeth or a fixed prosthesis. Molar endosteal implants should not be rigidly cross-splinted to each other in the Class I patient. Flexure of the mandible during opening may cause a rigid splint to exert lateral forces on the posterior implants. Therefore independent restorations are indicated (Fig. 20.4).

Division C Treatment Plans

When inadequate bone exists in height, width, length, or angula-tion, or if crown/implant ratios are equal to or greater than 1, the practitioner must consider several options. The first treat-ment option is not to use implant support but rather to orient the patient toward a conventional removable partial prosthesis. However, although this condition is easiest to treat with a tradi-tional soft tissue–borne restoration, bone loss will continue and can eventually compromise any restorative modality.

The second option is to use bone augmentation procedures. If the intent of the bone graft is to change a Division C to a Division A or B for endosteal implants, then at least some autogenous bone is indicated. Augmentation is used most often in the Class I max-illa, where sinus grafts with a combination of allografts and autog-enous bone are a predictable modality. Implants may be placed after the graft has created a Division A ridge, and the treatment plan follows the options previously addressed.

In the mandible the third option is nerve repositioning and endosteal implants in Class I patients who are poor candidates for bone augmentation. Risks of long-term paresthesia exist that may include hyperesthesia and pain. Reports in the literature con-cern dysesthesia and fracture of the severely atrophic mandible.[15] In addition, the gain of height in the C–h mandible may per-mit the placement of only implants 10 mm in height, still insuf-ficient to compensate for the increased crown height and resultant unfavorable crown/implant ratio. It is recommended that nerve repositioning be attempted only by clinicians with prior extensive training and experience with the procedures.
• **Fig. 20.4** A Class I, Division B dental arch has adequate height of bone but is barely sufficient in width. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)
• **Fig. 20.5** A Class I, Division D patient is usually seen in the maxilla when the maxillary sinus has expanded and less than 5 mm of bone is present in height under sinus. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

In the fourth option the mandibular anterior teeth are extracted and root form implants are placed between the mental foramens. This is especially a predictable treatment because the patient will benefit from increased masticatory efficiency and force along with improved esthetics.

Division D Treatment Plans

Class I, Division D usually occurs most often in the long-term edentulous maxilla. A sinus graft is usually performed before implant placement. Class I, Division D ridges are rarely found in the mandibular partially edentulous patient. When observed, the most common causes are from trauma or surgical excision of neoplasms. These patients often need autogenous bone onlay grafts to improve implant success and prevent pathologic fracture before prosthodontic reconstruction. After the bone graft is mature and the available bone improved, the patient is evaluated and treated in a manner similar to other patients with favorable bone volume (Fig. 20.5).

Treatment Planning: Class II

Kennedy-Applegate Class II partially edentulous patients are missing teeth in one posterior segment. These patients are often able to function without a removable restoration and are less likely to tolerate or overcome the minor complications of wearing the prosthesis. As a result, they are not as likely to wear a removable restoration. The available bone is therefore often adequate for endosteal implants, even when long-term edentulism has been present. However, the local bone density may be decreased. Endosteal implants with minimum osteoplasty are a common modality in these patients, who are more often Class II, Division A or B types.

Because the patient is less likely to wear the RPD, the opposing natural teeth have often extruded into the posterior edentulous region. The occlusal plane and tipped or extruded teeth should be closely evaluated and restored as indicated to provide a favorable environment in terms of occlusion and forces distribution. It is not unusual to require extraction of the second molar, endodontics, crown lengthening and a crown of the first molar, and enameloplasty for the second premolar (Fig. 20.6).

Division A Treatment Plans

When patients are placed in a Class II, Division A category, an independent implant-supported fixed prosthesis is usually indicated. Two or more endosteal root form implants are required to replace molars with independent prostheses. The greater the number of teeth missing, the larger the size and/or number of implants required. Posterior available bone is limited in height by the mandibular canal in the mandible or the maxillary sinus in the maxilla. The first premolar-positioned implants must not encroach on the apex of the canine root while still avoiding the anterior loop of the mandibular canal or maxillary sinus (Fig. 20.7).

Division B Treatment Plans

Class II, Division B patients have narrow bone in posterior edentulous spaces and anterior natural teeth. A fixed prosthesis is also indicated in these categories. Available bone height is restricted
Division A

• **Fig. 20.6** A Class II patient has posterior missing teeth in one quadrant. When the available bone is abundant, it is Division A. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.7** A maxillary arch that is Class II, Division A may have implants placed in the key implant positions and are of ideal sizes. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

by the mandibular canal or maxillary sinus. Therefore osteoplasty to increase bone width has limited applications. Endosteal small-diameter root form implants may be placed in the mandibular posterior Division B edentulous ridge. If narrow-diameter root forms are used, then a greater number than for the Division A ridge is indicated, and the use of one implant for every missing tooth root with no cantilever is recommended.

The patient who is missing molars and both premolars requires additional implant support. Four Division B root forms may be the foundation of an independent FPD in the mandible, depending on the other stress factors. If stress factors are too great (as a result of parafunction) or bone density is poor (as in the maxilla), then the Division B bone should be augmented to Division A before larger-diameter implant insertion. The anterior teeth in Class II patients should provide disclusion of the posterior implants during all excursions (Fig. 20.8).

Division C Treatment Plans

When inadequate bone exists in height, width, length, or angulation, or if crown/implant ratios are equal to or greater than 1, then the practitioner must consider several options. In the mandible the first treatment option is not to use implant support but to consider a posterior cantilevered FPD replacing one premolar-sized crown, using two or three anterior teeth as abutment support. This is the easiest option and is strongly recommended when only molars are missing.

The second option is to use bone augmentation procedures. If the intent of the bone graft is to change a Division C to a Division A or B for endosteal implants in the mandible, then autogenous bone is indicated. Augmentation is used most often in the Class II maxilla as the first choice, where sinus grafts with a combination of allografts and autogenous bone are a predictable modality. Implants may be placed after the graft has created a Division
• **Fig. 20.8** A maxillary Class II, Division B patient often has a membrane bone augmentation to increase width (pink) followed by implants in the key implant positions and of ideal sizes.

Division C

• **Fig. 20.9** A Class I, Division C–h arch has 7 to 9 mm of bone in height in the edentulous site. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

A ridge, and the treatment plan follows the options previously addressed.

The third option for the Division C mandibular patient is to place a Class II unilateral subperiosteal implant or a disc implant above the canal.

The fourth treatment option in the mandible is nerve repositioning and endosteal implants in Class II patients who are poor candidates for bone augmentation. Risks of long-term paresthesia exist that may include hyperesthesia and pain. In addition, the gain of height in the C–h mandible may permit the placement of only implants 10 mm high, which is still insufficient to compensate for the increased crown height and resultant unfavorable crown/implant ratio (Fig. 20.9).

Division D Treatment Plans

Class II, Division D usually occurs most often in the long-term edentulous maxilla. A sinus graft is usually performed before implant placement. Class II, Division D ridges are rarely found in the mandibular partially edentulous patient. When observed, the most common causes are from trauma or surgical excision of neoplasms. These patients often need autogenous bone onlay grafts to improve implant success and prevent pathologic fracture before prosthodontic reconstruction. After the graft is mature and the available bone improved, the patient is evaluated and treated in a manner similar to other patients with favorable bone volume (Fig. 20.10).

Treatment Planning: Class III

Typically the two most common Class III patients consulting for implants are either missing a single tooth or have a long posterior edentulous span. A multitooth posterior edentulous region most often can be restored as an independent prosthesis. A review of the literature demonstrates that joining implants in teeth in the same prosthesis under those conditions is possible.

A single-tooth implant is the treatment of choice when the bone and soft tissues are within normal range before or during implant treatment. Fixed prostheses increase the risk for decay, pulpal involvement, and periodontal disease on the natural abutment teeth.[16] Both the traditional prosthesis and the abutment teeth have a poorer survival rate than implant prostheses. As a result, single-tooth implants are often indicated (Fig. 20.11).

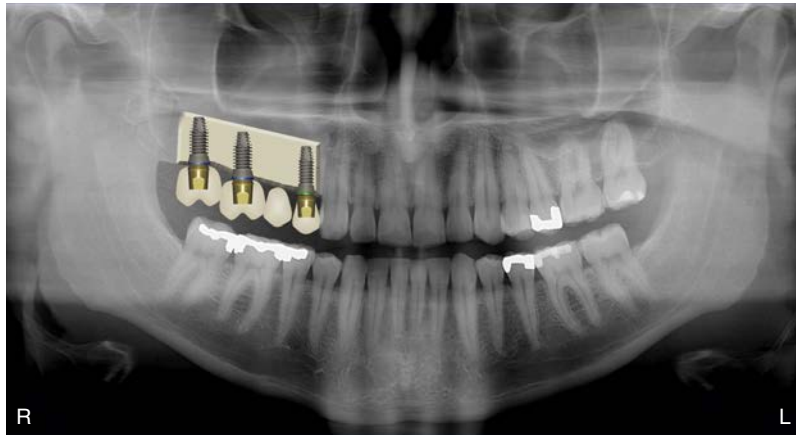
Division A Treatment Plans

Class III, Division A patients are usually excellent candidates for endosteal root form implant placement in the edentulous space. This will allow for the restoration of natural teeth to be independent and allow the fabrication of shorter span restorations. It is easier to obtain maximum available height of bone for implant placement anterior to the mandibular foramen or maxillary sinus. As a general rule the final prosthesis should be completely implant supported, and two implants should support each section of three missing tooth roots (not three missing crowns). Mobile natural teeth adjacent to the edentulous span cause greater loads on the implants; therefore one implant for each missing root may be indicated. If the adjacent teeth are mobile, then the implant must support both the missing teeth and mobile teeth during occlusion.

Division B Treatment Plans

In Class III, Division B patients, narrow-diameter endosteal implants may be placed in the mandibular long-span edentulous space. This treatment plan is primarily used for a fixed prosthesis when the span is too long or occlusal forces are too great for the natural abutments to act as sole support for the final prosthesis. The final implant prosthesis should be independent of these teeth (Figs. 20.12 and 20.13).

Division C or Division D Treatment Plans

When Division C is found in Class III patients the most common treatment plan in the maxilla is bone augmentation before implant insertion and an independent implant prosthesis. Sinus grafting in the posterior Division C ridge is predictable.


• **Fig. 20.10** A maxillary arch with Class II, Division C–h most often has a sinus bone graft (white) and then implants in the key implant positions and of ideal implant sizes. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)
Division B

• **Fig. 20.11** A Class III patient has an intratooth edentulous space. When it is adequate in height but barely sufficient in width, it is Division B bone. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.12** A Class III, Division B mandible may use smaller-diameter implants. When this option is used, one implant for each tooth root missing is often indicated. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.13** A Class III, Division B mandible may have a membrane bone graft to gain abutment width (gray) followed by ideal implant sizes in the key implant positions. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.14** A Class III, Division C–h patient may use 7- to 9-mm root form implants to support a fixed prosthesis. Incisal guidance on the anterior teeth during all mandibular excursions is indicated to eliminate greater forces on the extended crown heights. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

In the mandible, a traditional fixed prosthesis for Division C bone volume for Class III patients should often be considered, because bone grafting for height is difficult, requires an additional skill set, and is less predictable than in the maxilla (Figs. 20.14 and 20.15).

Treatment Planning: Class IV

In the Class IV patient the anterior edentulous space crosses the midline. In the past, traditional FPDs were often the treatment of choice when the canines were present. Today an independent implant prosthesis is often warranted. However, a lack of anterior bone volume in the maxilla is common, and bone grafts before implant placement are typically necessary to prevent the implants from being placed palatally in relation to the natural roots. A cantilever is often created off the implant bodies to place the maxillary incisor edge in proper position for esthetics and speech. The moment force generated is greater than when found in the mandibular counterpart. This, in addition to other factors, makes the premaxilla one of the more difficult regions of the mouth to treat successfully. As a general rule, one implant for each tooth is considered in the premaxilla unless facial bone

Division D

• **Fig. 20.15** A Class III, Division D patient is more often observed in the maxillary arch. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

loss has been significant that decreases the available length. In the mandible, usually one implant can replace two teeth, with the implants placed in the embrasure areas with a screw-retained prosthesis (Fig. 20.16).
Division B

• **Fig. 20.16** A Class IV patient has missing teeth that cross the midline. When the bone is adequate in height but barely sufficient in width, it is Division B. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

Division A Treatment Plans

Division A patients are good candidates for endosteal root form implant placement in the edentulous space. Ideally the prosthesis should be restored independently of the natural teeth. As a general rule the final prosthesis should be completely implant supported, and two implants should support each section of three missing tooth roots (not three missing crowns), as long as there are favorable force factors. Mobile natural teeth adjacent to the edentulous span cause greater loads on the implants. Therefore one implant for each missing root may be indicated (Figs. 20.17 and 20.18).

Division B Treatment Plans

The Class IV, Division B patient is most often treated with augmentation before implant placement. If the ridge is Division B and inadequate in width for Division A root form implants, then the narrow-diameter root forms compromise esthetics and oral hygiene procedures. Bone augmentation is more often used in anterior edentulous regions with narrow bone, and Division A implants are indicated to improve the final crown contour, esthetic appearance, and daily maintenance. Implant and tooth replacement should remain independent. The canine is an important natural abutment. When the canine and two adjacent teeth are missing, a fixed prosthesis is contraindicated (according to

• **Fig. 20.17** A Class IV, Division A patient has implants positioned in the key implant positions of ideal width and length. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.18** A Class IV, Division A mandible has implants positioned in the key implant positions. When force factors are low to moderate and bone density is good, the implant between the canine positions may be eliminated when posterior implants are connected to the canine implants. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.19** A maxillary Class IV, Division B patient usually has bone augmentation (pink) to increase the bone volume width. After augmentation the key implant positions and ideal implant sizes may be used to support a fixed prosthesis. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.20** A mandibular Class IV, Division B patient may use a narrower-diameter implant (3.0 to 3.5 mm) of ideal implant length (≥12 mm). The key implant positions should be selected, including an implant between the canine positions. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

basic prosthodontic principles). In other words an implant should replace a canine whenever multiple teeth are missing, which includes the canine (Figs. 20.19 and 20.20).

Division C and D Treatment Plans

The first option for a Class IV patient is to use bone augmentation procedures. If the intent of the bone graft is to change a Division C or D to a Division A or B for endosteal implants, then autogenous bone is indicated. Implants may be placed after the graft has created a Division A ridge, and the treatment plan follows the options previously addressed (Figs. 20.21 to 20.23).

Classification of Completely Edentulous Arches

Completely edentulous classifications in the literature include the classification of Kent and the Louisiana Dental School.[17] The classification was originally for ridge augmentation with

Division C

• **Fig. 20.21** A Class IV, Division C–h dental arch has compromised bone in height. If the bone is compromised in width, it is C–w. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.22** A maxillary Class IV, Division C–w patient should have block bone graft procedures to increase the width of bone followed by implants in the key implant positions. An additional implant may be necessary if bone density is poor or force factors are greater than normal. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)
• **Fig. 20.23** A mandibular Class IV, Division C–h mandible often may have implants positioned in key implant positions. Bone density is usually good, and in centric occlusion the implants may be loaded in their long axis. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

HYDROXYAPatite and a conventional denture. This classification treats all regions of an edentulous arch in similar fashion and does not address regional variation. Likewise the classification of Lekholm and Zarb[18] addressed only the anterior maxilla and mandible, always resulted in root form implants without regard for bone grafting, and always used a fixed prosthesis, regardless of biomechanical considerations. The divisions of bone previously presented by Misch and Judy[13] are the basis of the classification of the completely edentulous patient presented in this chapter. Its purpose is to allow communication of not only the volume of bone but also its location. It organizes the most common implant options of prosthodontic support for the completely edentulous patient.

The edentulous jaw is divided into three regions (one anterior and two posterior) and described according to the Misch-Judy classification.[19] In the mandible the right and left posterior sections extend from the mental foramen to the retromolar pad, and the anterior area is located between the mental foramina. The anterior section usually extends from first premolar (mesial) to first premolar (mesial) because of the foramen's most common

location (i.e., between the two premolar teeth). The right and left posterior regions of the edentulous maxilla also start from the first premolar (mesial) sites, where the maxillary sinus most often determines the height of available bone. The anterior section of the maxilla consists of the region between the first premolars and is usually anterior to the maxillary sinus (Fig. 20.24). The division of bone in each section of the edentulous arch then determines the classification of the edentulous jaw. The three areas of bone are evaluated independently from each other. Therefore one, two, or three different divisions of bone may exist. The term type is used in the completely edentulous classification, rather than class, as in the partially edentulous classification.

Type 1

In the Type 1 edentulous arch the division of bone is similar in all three anatomic segments. Therefore four different categories of Type 1 edentulous arches are present.
● **Fig. 20.24** A completely edentulous jaw is divided into three segments. The anterior component (Ant) is between the mental foramina or in front of the maxillary sinus. Right (RP) and left (LP) posterior segments correspond to the patient's right and left sides. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

Division A

In the Type 1, Division A ridge, with abundant bone in all three sections, as many root forms as needed may be placed to support the final prosthesis. As a general rule the range of 5 to 9 implants may be used in the mandible and 6 to 10 implants in the maxilla for a fixed prosthesis.

Division B

The Type 1, Division B edentulous ridge presents adequate bone in all three sections in which to place narrow-diameter root form implants. It is common practice to modify the anterior section of bone in the mandible by osteoplasty to a Division A and to place ideal size root form implants in this region. It is less common to have sufficient height in either the posterior maxilla or mandible to permit osteoplasty to improve the division. Therefore several narrower implants are often indicated in the mandible if posterior implants are inserted without grafting. One implant is used for every tooth root to compensate for the decrease in surface area of implant support. Augmentation by bone spreading may be indicated in the maxilla, if the patient desires a fixed prosthesis, especially when opposing natural teeth. If stress factors are great, then lateral augmentation may also be necessary in the posterior regions to increase implant diameter.

Division C

Type 1, Division C–w edentulous arches present adequate height of available bone but have inadequate width. If the patient desires an implant-supported removable prosthesis, then an osteoplasty may be used to convert the ridge to C–h. The treatment plan then follows a Type 1, Division C–h formula. When a fixed restoration is desired, an autogenous onlay graft in the C–w arch is usually warranted to restore the ridge to Division A before implant insertion.

Type 1, Division C–h edentulous arches often do not present all the essential requirements for predictable long-term implant support for fixed prostheses. An implant-supported RP-4 or RP-5 removable prosthesis is often indicated to reduce occlusal loads. The prosthesis should be completely implant supported (RP-4) to halt the continued bone loss in the posterior regions of the mouth. When only Division C anterior root form implants are inserted, posterior soft-tissue support (RP-5) may be required.

The edentulous maxilla is often treated with a conventional removable prosthesis until the mandible is completely restored. If
● **Fig. 20.25** (A) A Type I, Division C–h mandible and maxilla should be restored to Division A with autogenous grafts when a fixed prosthesis is desired. (B) Computer-assisted treatment plans with five to nine implants placed in the grafted bone volumes can be developed before treatment (XCPT, Naples, FL). (C) Panoramic radiograph of a patient with division C–h maxilla and mandible restored to division A arches with iliac crest grafts, endosteal implants, and fixed maxillary and mandibular prostheses. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

this denture needs additional retention or stability, then HA can be used to augment the premaxilla. This squares the ridge shape and provides resistance to occlusal excursions during function. Intramucosal inserts may also be used to increase the retention of the removable complete denture. However, the patient and doctor should realize that bone loss will continue and will make future implant placement even more difficult.

The C–h maxilla should often consider subnasal augmentation combined with root form implants in the canine eminence region and sinus graft with root form implants with an RP-4 prosthesis. Additional surgical training is required for these last two alternatives, and they have a greater incidence of complication.

Fixed prostheses may need autogenous iliac crest grafts to change the anterior division of bone and improve long-term success and esthetics. Sinus grafts are also indicated in these situations (Fig. 20.25).

The edentulous arches classified as Type 1, Division D are the most challenging to traditional and implant dentistry. If an implant fails in a Type 1, Division D patient, then pathologic fractures or almost unrestorable conditions may result; yet these are
• **Fig. 20.26** A Type 2, Division A, B arch has an anterior section classified as Division A (*A*) and posterior sections classified as Division B (*B*). The anterior region dominates the overall treatment plan in all edentulous arches and usually has a greater volume of bone than the posterior. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

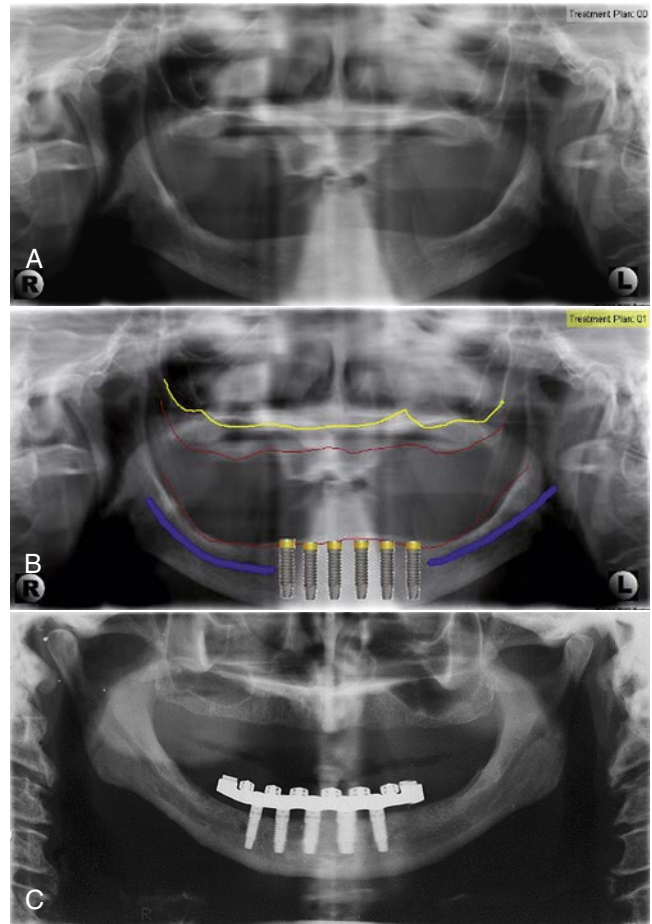
the patients who need the most help for support of their prostheses. The benefits versus risks must be weighed carefully for each patient. Endosteal implants may be placed in the anterior mandible. However, the unfavorable crown height of greater than 20 mm and mandibular fracture during implant placement or after implant failure may result in significant complications.[20]

Often the best solution is to change the division with autogenous grafts, then reevaluate the improved conditions and appropriately alter the treatment plan. The Type 1, Division D ridges most often use autogenous iliac crest grafts. After 6 months a total of five to nine implants may be placed in the anterior and posterior regions.

Type 2

In the Type 2 completely edentulous arch the posterior sections of bone are similar but differ from the anterior segment. The most common arches in this category present less bone in the posterior regions, under the maxillary sinus, or over the mandibular canal than in the anterior segment. These edentulous ridges are described in the completely edentulous classification with two division letters following Type 2, with the anterior segment being listed first because it often determines the overall treatment plan. Therefore a mandible with Division A between the foramina and Division C distal to the mandibular foramen is a Type 2, Division A, C arch. This condition is common in the mandible, because the posterior regions resorb four times faster than the anterior regions. Because onlay grafts in the posterior mandible are more difficult to perform predictably, the anterior region is often the only segment used for implant support.

In the Type 2, Division A, B arch the posterior segments may be treated with narrow-diameter implants, whereas the anterior section is adequate for larger-diameter root form implants to support the prosthesis (Fig. 20.26). When possible, the posterior Division B section is changed into Division A. Autogenous grafts are more debilitating and require extended healing periods but may be indicated for the benefit of increased posterior bone width when stress factors and patient desires are high. Smaller segments can be augmented with intraorally harvested block grafts. In the posterior maxilla, bone spreading and Division A root forms should be considered. The softer the bone is, the easier it is to spread.

Two primary modules exist to restore the Type 2, Division A, C edentulous ridge. In the mandible the most common option is the


• **Fig. 20.27** (A) A treatment option for Type 2, Division A, C. (B) A computer-generated treatment plan with favorable biomechanics places implants in the anterior section of the mandible and restores the arch with cantilevered posterior sections (XCPT, Naples, FL). (C) In a situation with higher masticatory dynamics or nocturnal parafunction, this type of arch may mandate the fabrication of a RP-4 prosthesis rather than a fixed restoration. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

use of the anterior section only for implant-supported root form implants (Fig. 20.27). The maxillary arch may be treated with a combination of sinus graft and endosteal implants if additional posterior support is required for the prosthesis. Because the bone density of the mandible is usually superior to that of the maxilla, and the moment forces remain directed within the arch form, rarely does the mandible require additional posterior support with grafts or circumferential subperiosteal implants. However, for a patient with a square arch form or high masticatory dynamics such as opposing natural teeth, posterior support may be required for an RP-4 or fixed prosthesis.

An edentulous ridge with severe posterior bone loss and abundant bone in the anterior region is uncommon and occurs more frequently in the maxilla. The Type 2, Division A, D patient is treated in a similar manner to the patient with a Type 2, Division A, C arch. Sinus grafts and endosteal implants in the maxilla or only anterior implants with or without an autogenous graft in the mandible are most often the treatment of choice.

The Type 2, Division B, C edentulous arch can be treated with two main treatment options. The anterior section may be changed
• **Fig. 20.28** This Type 3, Division A, B, D arch has abundant anterior bone (*A*), moderate atrophy of bone in the posterior right (*B*), and severe atrophy in the left posterior segment (*D*). Sinus grafting is a common treatment if posterior implants are required in the maxilla. However, bone augmentation in the posterior mandible for Division D is more unusual, and additional anterior implants in the Division A with a cantilever are more typical. Another option is to use narrower implants in the right posterior, splinted to the anterior implants. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 20.29** The square dentate maxilla with Type 3, Division C, D, E may require bilateral sinus grafts and implants in the canine with nasal elevation to support a fixed prosthesis. (*From Misch CE. Treatment plans for partially and completely edentulous arches in implant dentistry. In: Misch CE, ed.* Dental Implants Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

to Division A by osteoplasty if anatomic conditions permit. These patients are then treated exactly as the previously described Type 2, Division A, C. When the ridge does not present sufficient height after osteoplasty to upgrade the division, the posterior segments may be improved by sinus grafts and the whole arch treated in the same manner as Type 1, Division B or Type 2, Division B, A. Onlay grafts are less predictable than sinus grafts; therefore the anterior mandible may be changed to a Division C by osteoplasty, and a mandibular complete subperiosteal implant and RP-4 restoration or anterior root forms and RP-5 prosthesis may be selected for Type 1, Division C mandibular patients.

Patients who have advanced atrophy in the posterior segments and adequate ridge width and height in the anterior may be described as Type 2, Division B, D. This condition almost never occurs in the mandible, but it can be found on occasion in the maxilla. These patients are treated in a manner similar to patients with Type 2, Division B, C, as previously described. The primary difference is that the posterior graft is more extensive and requires additional months for healing before implant insertion and prosthodontic reconstruction. In the mandible, Type 2, Division C, D patients may be treated similar to a Type 1, Division D mandible with autogenous bone grafts before implant placement.

Type 3

In Type 3 edentulous arches the posterior sections of the maxilla or mandible differ from each other. This condition is less common than the other two types and is found more frequently in the maxilla than the mandible. The anterior bone volume is listed first, then the right posterior, followed by the left posterior segment. Therefore the edentulous maxilla with no bone available for implants in the left posterior section, abundant bone in the anterior section, and adequate bone in the right posterior segment is a Type 3, Division A, B, D edentulous arch (Fig. 20.28).

The patient with a mandible that has adequate bone in the right posterior segment and inadequate bone on the other side, but abundant bone in the anterior, is a Type 3, Division A, B, C edentulous ridge. A narrow-diameter implant may be placed in the right posterior segment, as well as root forms in the anterior section as indicated by the prosthesis. If additional prosthetic

support is needed in the left mandibular region, then in most cases additional anterior root forms are placed and splinted to the posterior implants and the teeth or bar cantilevered without implant support on the left posterior region. The Type 3, Division A, C, B patient is treated as a mirror image of Type 3, Division A, B, C.

The Type 3, Division A, D, C (or Type 3, Division A, C, D) patient receives a treatment plan similar to the plans discussed under Type 2, Division A, C. Endosteal root form implants are placed in the anterior section; if the prosthesis needs additional posterior support, then grafts are considered, especially in the posterior maxilla. Patients with Type 3 arches with anterior Division B or C are treated similar to the corresponding Type 2 patients with an anterior Division B or C. In the maxilla, it is not unusual that the premaxilla presents insufficient bone volume, and one posterior quadrant requires a sinus graft (Type 3, Division C, A, D). In that case and if appropriate bone volume is present in the cuspid area with favorable force factors, then a full-arch fixed prosthesis can be fabricated after sinus graft and implant placement in the posterior regions, bypassing the premaxilla (Fig. 20.29).

The arch is Type 3, even when the anterior region is similar to one of the posterior sections. For example, the Type 3, Division C, D, C ridge has Division C in the anterior, severe atrophy on the right section, and moderate atrophy in the left section. In a mandibular arch of this type, implant placement in the anterior section only may be sufficient to restore the patient, although a subperiosteal implant may be indicated. The maxilla usually requires sinus grafts and subnasal elevation because of the poor biomechanics and bone quality.

The anterior section usually determines the treatment plan. Rarely are posterior implants inserted without any anterior implant support. In traditional prosthetics, Kennedy-Applegate Class I, modification I patients with anterior missing teeth are often restored with an anterior FPD and posterior RPD. This limits rocking of the prosthesis and decreases the forces transmitted to the abutments. Conventional prosthetics also dictate that an FPD is not indicated when the canine and two adjacent teeth are missing. This applies also when the anterior six teeth are missing and implants cannot be inserted. These time-tested, traditional prosthodontic axioms indicate that posterior implants alone should not be placed without any anterior implant or natural tooth support. However, this concept is often ignored in the maxilla, where practitioners often rely solely on sinus grafts and implants in the posterior segments. If no canine implants are inserted, then the lack of anterior support can cause rotation of the prosthesis and accelerate posterior implant loss. The two posterior sections are

not connected because the span between the first premolars is too great, and the posterior implants are placed almost in a straight line with little biomechanical advantage. Anterior rocking and posterior lateral forces on these straight-line implants increase implant failure. The patient's condition is then often worse than before any implant therapy. It is usually far more prudent to convince the patient to be treated with an anterior onlay graft and anterior implants so that a full-arch restoration (RP-4 or fixed) may be fabricated.

Summary

An implant dentistry classification has been postulated that permits visualization of teeth and bone in partially edentulous arches. The foundation of this classification is the Kennedy-Applegate system, which is the most-used classification in prosthodontics. In addition, a classification for the completely edentulous arch is discussed, which is based on the quantity of available bone.

Preimplant Prosthodontic Factors Related to Surgical Treatment Planning

CARL E. MISCH[†], RANDOLPH R. RESNIK, AND FRANCINE MISCH-DIETSH

Implants serve as a foundation for the prosthetic support of missing teeth. However, in the partially edentulous patient, the existing teeth may often require restorations or treatment. The existing conditions of the stomatognathic system should be evaluated and treated, when indicated. As such, preimplant prosthodontic considerations are a vital phase of the overall treatment before implant surgery. For example, the surgical decision to augment or perform an osteoplasty before implant surgery is primarily dependent on the desired prosthetic result. Most all conventional forms of construction, from buildings to art form, require a detailed plan and a clear vision of the end result before the project is initiated.

Overall Evaluation

The preimplant prosthodontic evaluation of the patient's overall condition closely resembles traditional dentistry. When a restoring dentist first evaluates the prosthetic needs of a patient, an orderly process is required, regardless of the current state of the dentition. In other words, regardless of whether the patient has all teeth or is missing all teeth, after the dentist accepts the responsibility of long-term professional guidance and treatment as necessary, a consistent approach to care is beneficial. There are five initial elements that should be assessed in sequence and treated when indicated. These elements include maxillary anterior tooth position, the existing occlusal vertical dimension (OVD), the mandibular incisor edge position, the maxillary occlusal plane, and the mandibular occlusal plane (Box 21.1). These elements are evaluated in a partially edentulous patient during the initial clinical examination and on mounted diagnostic casts (which may also serve as diagnostic wax-up procedures).

Maxillary Anterior Tooth Position

The position of the existing maxillary anterior teeth is first assessed. Most often these natural teeth are adequate in location and incisal edge position. However, if their position is undesirable for any

†Deceased.

reason, orthodontics or conventional prosthetic intervention may be indicated. If the maxillary incisor edge is modified in either the horizontal or vertical plane, this may lead to changes in the other four elements of the stomatognathic system.

The labial position of the maxillary anterior teeth is first determined with the lip in repose (i.e., resting position). This is primarily evaluated by overall support of the maxillary lip and its relationship to the balance of the face, especially in relation to the nose and presence or absence of a philtrum in the midline (Fig. 21.1).[1-7] When the teeth are positioned more labial, the vertical position of the lip is elevated. Likewise, a more palatal position of the maxillary anterior teeth results in a more inferior or extended position of the lip. If the labial or horizontal position is going to be altered, then orthodontic therapy is ideally the treatment of choice. On occasion, a prosthetic or surgical approach may be indicated, with or without orthodontic treatment.

The next step in the evaluation process (when the labial position is acceptable) is the vertical position of the maxillary anterior teeth related to the lip in repose. The maxillary canine is the key for this position. Misch has suggested the canine tip be located approximately 1 mm level with the lip in repose, regardless of the age or sex of the patient (Fig. 21.2).[8] A horizontal line drawn from one canine tip to the contralateral side should be level to the horizon. Normally, the central incisors are 1 to 2 mm longer in a horizontal plane to the canines. If the patient is wearing a maxillary complete denture, then the maxillary anterior tooth position is often incorrect, compared with the natural tooth position. As a result of resorption of the premaxilla, the denture shifts apically and posteriorly after the bone loss pattern. No other region of the mouth should be restored until this position is corrected because it negatively influences the proper position of every other segment (e.g., OVD, mandibular anterior tooth position, posterior planes of occlusion).

The maxillary anterior horizontal and vertical tooth positions are evaluated before any other segment of the arches, including the OVD. If the maxillary anterior teeth are significantly malpositioned, the clinician should obtain further diagnostic studies, such as a cone beam radiograph, to determine the relationship of the maxilla to the cranial base. The patient may have unfavorable

Overall Evaluation
- Maxillary anterior tooth position
- Occlusal vertical dimension
- Mandibular incisal edge
- Maxillary posterior plane
- Mandibular posterior plane

Specific Criteria
- High and low lip line (maxillary and mandible)
- Maxillomandibular arch relationship
- Existing occlusion
- Crown height space
- Temporomandibular joint status
- Extraction of hopeless or guarded-prognosis existing teeth
- Existing prostheses
- Arch form (ovoid, tapering, and square)
- Natural tooth adjacent to implant site
- Soft tissue evaluation of edentulous sites

---

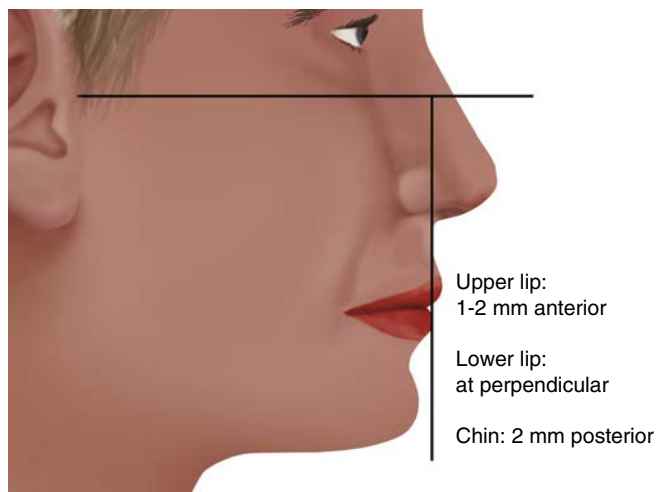
skeletal relationships (vertical maxillary excess or deficiency). If the position of the natural maxillary anterior teeth is undesirable for any reason, then orthodontics, orthognathic surgery, or prosthetic intervention may be indicated. After the position of the maxillary anterior teeth is acceptable, the next prosthetic step is the evaluation of the OVD.

Existing Occlusal Vertical Dimension

To determine the crown height space (CHS), the overall issue of OVD must be addressed. The patient's existing OVD should be evaluated early in an implant prosthetic treatment plan because any modification will significantly modify the overall treatment. Not only will a change in OVD require at least one full arch to be reconstructed, it will also affect the CHS and therefore the potential number, size, position, and angulation requirements of the implants. The OVD is defined as the distance between two points (one in the maxilla and the other directly below in the mandible) when the occluding members are in contact.[9] This dimension requires clinical evaluation of the patient and cannot be based solely on the diagnostic casts.

The determination of the OVD is not a precise process because a range of dimensions is possible without clinical symptoms.[10-23] At one time, it was believed OVD was very specific and remained stable throughout a patient's life. However, this position is not necessarily stable when the teeth are present or after the teeth are lost. Long-term studies have shown this is not a constant dimension and often decreases over time without clinical consequence in the dentate or partially or completely edentulous patient.

The OVD may be altered without the symptoms of pain or dysfunction however is case specific. However, this is not to say that altering the OVD has no consequence. A change in OVD affects the CHS. As such, it may affect the biomechanics of the support system of an implant prosthesis. In addition, any change in the OVD will also modify the horizontal dimensional relationship of the maxilla to the mandible; therefore a change in OVD will modify the anterior guidance, range of function, and esthetics.

The most important effect of OVD on tooth (implant) loading may be the effect on the biomechanics of anterior guidance. The more closed (decreased) the OVD, the farther forward the mandible rotates and the more class III the chin appears (Figs.


• **Fig. 21.1** Ideal soft tissue position. The labial position of the teeth is first evaluated relative to the support of the maxillary lip. A vertical line drawn through the subnasal point and perpendicular to the Frankfort plane can be used as a baseline. Ideally, the maxillary lip should be 1 to 2 mm anterior to this line, the lower lip even with the line, and the chin 2 mm behind the line.

Upper lip:
1-2 mm anterior

Lower lip:
at perpendicular

Chin: 2 mm posterior

• **Fig. 21.2** (A) Vertical position of the maxillary anterior teeth is assessed by evaluating the position of the canines. The ideal position is determined by the canine to lip in repose position: a horizontal line is drawn from canine tip to canine tip, and the central incisors are 1 to 2 mm longer. (B) This position is consistent (within 1 mm) regardless of the age or sex of the patient.

21.3 and 21.4). In a class II, division 2 patient, the more closed the OVD, the steeper is the anterior guidance and the greater the vertical overlap of the anterior teeth. Anterior guidance is necessary to maintain incisal guidance during mandibular excursions to decrease the risk of posterior interferences. In completely edentulous patients restored with fixed implant prosthodontics, a change
• **Fig. 21.3** Decreased vertical dimension. As the edentulous bite collapses, a closed occlusal vertical dimension results that rotates the chin farther forward. This gives a class III appearance.

• **Fig. 21.4** The more closed the occlusal vertical dimension, the farther forward the mandibular teeth occlude.

in OVD in either direction may affect biomechanics. Opening the OVD and decreasing the incisal guidance, with a resulting bilaterally balanced occlusion, may increase forces placed on posterior implants during mandibular excursion. Closing the OVD may increase the forces to anterior implants during any excursion. On occasion, a change in the OVD may also affect the sibilant sounds by altering the horizontal position of the mandible. According to Kois and Phillips, three situations primarily mandated the modification of the OVD: (1) esthetics, (2) function, and (3) structural needs of the dentition.[12] Esthetics is related to OVD for incisal edge positions, facial measurements, and the occlusal plane. Function is related to the canine positions, incisal guidance, and angle of load to teeth or implants. Structural requirements are related to dimensions of teeth for restoration, while maintaining a biological width.

Methods to Evaluate Occlusal Vertical Dimension

In traditional prosthodontics, a range of techniques has been described to establish the OVD. Objective methods use facial dimension measurements, whereas subjective methods rely on esthetics, resting arch position, and closest speaking space. There is no consensus on the ideal method to obtain the OVD; therefore this dimension is part art form and part science. However, it is a

crucial component of the rehabilitation process, so OVD should be determined before completion of a final treatment plan.

Subjective Methods

The subjective methods to determine OVD include the use of resting interocclusal distance and speech-based techniques using sibilant sounds. Niswonger proposed the use of the interocclusal distance ("freeway space"), which assumes that the patient relaxes the mandible into the same constant physiologic rest position.[13] The practitioner then subtracts 3 mm from the measurement to determine the OVD. Two observations conflict with this approach. First, the amount of freeway space is highly variable in the same patient, depending on factors such as head posture, emotional state, presence or absence of teeth, parafunction, and time of recording (greater in the morning). Second, interocclusal distance at rest varies 3 to 10 mm from one patient to another. As a result, the distance to subtract from the freeway space is unknown for a specific patient; therefore the physiologic rest position should not be the primary method to evaluate OVD. However, the distance should be evaluated once the OVD is established, to ensure a freeway space exists when the mandible is at rest.

Silverman stated that approximately 1 mm should exist between the teeth when making an S sound.[14]

Pound further developed this concept for the establishment of centric and vertical jaw relationship records for complete dentures.[15,16] Although this concept is acceptable, it does not correlate to the original OVD of the patient; therefore the speaking space should not be used as the only method to establish OVD. After the OVD has been determined, the speaking space should be observed, and the teeth should not touch during sibilant sounds. On occasion, a short adjustment period of a few weeks may be required to establish this criterion. Therefore a transitional prosthesis should be used to evaluate this position in case it must be modified before the final restoration.

Kois[12] has noted that the subjective method of esthetics to establish an OVD is the most difficult to teach inexperienced dental students and therefore is least likely to be initially addressed when teaching the concepts of determining OVD. However, experienced clinicians often value this method more than any other to assess OVD. After the position of the maxillary incisor edge is determined, the OVD influences esthetics of the face in general.

Objective Methods

Facial dimensions are directly related to the ideal facial esthetics of an individual and can be easily assessed regardless of the clinician's experience.[17-25] This objective evaluation is usually the method of choice to evaluate the existing OVD or establish a different OVD during prosthetic reconstruction. In addition, it may be performed without the need of additional diagnostic tests.

Facial measurements can be traced back to antiquity when sculptors and mathematicians followed the golden ratio for body and facial proportions, as described by Pythagoras. The golden ratio relates to the length and width of a golden rectangle as 1 to 0.618. Many human body proportions follow the golden ratio because it is considered the most esthetically appealing to the human eye.[18-20,25] Leonardo da Vinci later contributed several observations and drawings on facial proportions, which he called divine proportions.[21] He observed the distance between the chin and the bottom of the nose (i.e., OVD) was a similar dimension as

(1) the hairline to the eyebrows, (2) the height of the ear, and (3) the eyebrows to the bottom of the nose. Each of these dimensions equaled one-third of the face.

Many professionals, including plastic surgeons, oral surgeons, artists, orthodontists, and morticians, use facial measurements to determine OVD. A review of the literature found that many different sources reveal many correlations of features that may correspond to the OVD (Box 21.2; Fig. 21.5).

All these measurements do not correspond exactly to each other, but they usually do not vary by more than a few millimeters (with the exception of the vertical height of the ear) when facial features appear in balance. An average of several of these measurements may be used to assess the existing OVD. In a clinical study by Misch, the OVD was often slightly larger than the facial measurements listed (more in men than women), but it was rarely a smaller dimension.[22] The subjective criteria of pleasing esthetics may then be considered after the facial dimensions are within balance to each other.

Radiographic methods to determine an objective OVD are also documented in the literature. Tracings on a cephalometric radiograph are suggested when gross jaw excess or deficiency is noted. Such conditions may stem from vertical maxillary excess, vertical maxillary deficiency, vertical mandibular excess (long chin), vertical mandibular deficiency (short chin), and apertognathia or class II, division 2 (deep bite) situations. Orthodontic treatment planning of a dentate patient often includes a lateral cephalogram and may be used to evaluate OVD (glabella-subnasale, subnasale-menton). The same measurements may be performed on the edentulous patient.[26,27] Esthetics are influenced by OVD because of the relationship to the maxillomandibular positions. The smaller the OVD, the greater the class III jaw relationship becomes; the greater the OVD, the more class II the relationship becomes. The maxillary anterior tooth position is determined first and is most important for the esthetic criteria of the reconstruction. Alteration of the OVD for esthetics rarely includes the maxillary tooth position. For example, the OVD position may be influenced by the need to soften the chin for a patient with a large mental protuberance. After the OVD satisfies the esthetic requirement of the prosthetic reconstruction, it may still be slightly refined. For example, the OVD may be modified to improve the direction of force on the anterior implants.

In addition, anterior mandibular implants on occasion are too facial to the incisal edge position, and increasing the OVD makes them much easier to restore. Therefore because the OVD is not an exact measurement, the ability to alter this dimension within limits may often be beneficial. The evaluation of the pretreatment OVD is also very important for the patient wearing a complete maxillary denture opposing a partially edentulous mandible, especially in the case of edentulous posterior segments that are not compensated by a removable partial denture (Kennedy-Applegate class I). Under these conditions, a combination (Kelly) syndrome may be present and is especially noteworthy if the OVD is within normal limits.[28]

---

• Fig. 21.5 Occlusal vertical dimension (OVD) may initially be evaluated by objective measurements, comparing facial dimensions to the existing OVD. Leonardo da Vinci described divine proportions in the following way: (A) "The distance between the chin and the nose and the hairline and the eyebrows are equal to the height of the ear and a third of the face. From the outer canthus of the eye to the ear, the distance is equal to the height of the ear and to one-third of the face height." (B), In addition, facial height (from chin to hairline) is equal to the height of the hand, and the nose is the same length as the distance between the tip of the thumb and the tip of the index finger.

The clinical symptoms include (1) maxillary incisor denture position up and rotated back from ideal, (2) lower natural anterior teeth overerupted and beyond the mandibular occlusal plane, (3) horizontal occlusal plane tilted apically in the anterior and occlusally in the posterior regions, (4) enlarged tuberosities encroaching on the mandibular interarch space, (5) maxillary palatal hyperplasia, and (6) highly mobile tissue in the premaxilla. In addition, because the mandibular posterior teeth have been missing many years for this syndrome to develop, there is a lack of posterior bone in the mandible to place endosteal implants (Fig. 21.6).

The proper maxillary incisal edge position and OVD are especially critical for these patients because of the incidence of mandibular incisor extrusion beyond the maxillary occlusal plane. The extrusion is usually accompanied by the alveolar process. To position the maxillary incisors properly, the mandibular anterior teeth must be repositioned at the proper incisal plane. Endodontic therapy and crown lengthening procedures usually precede the restorations on the lower arch to obtain a retentive and esthetic restoration.

On occasion, the remaining roots of the mandibular anterior teeth are too short to consider for long-term prognosis after the crown lengthening is performed. Under these conditions, extraction of the mandibular anterior teeth, alveoloplasty, and implant placement may be indicated. When the arch shape is ovoid to tapered, five anterior implants may be adequate to serve as support for a full arch implant–supported restoration. Therefore the implants replace the teeth extracted from overeruption, and they can also replace the posterior missing teeth. This is usually very helpful because long-term edentulous posterior segments are usually deficient in bone volume. Thus this approach eliminates the need for posterior bone grafts to restore the lower arch with a fixed implant–supported restoration.

Mandibular Incisor Edge Position

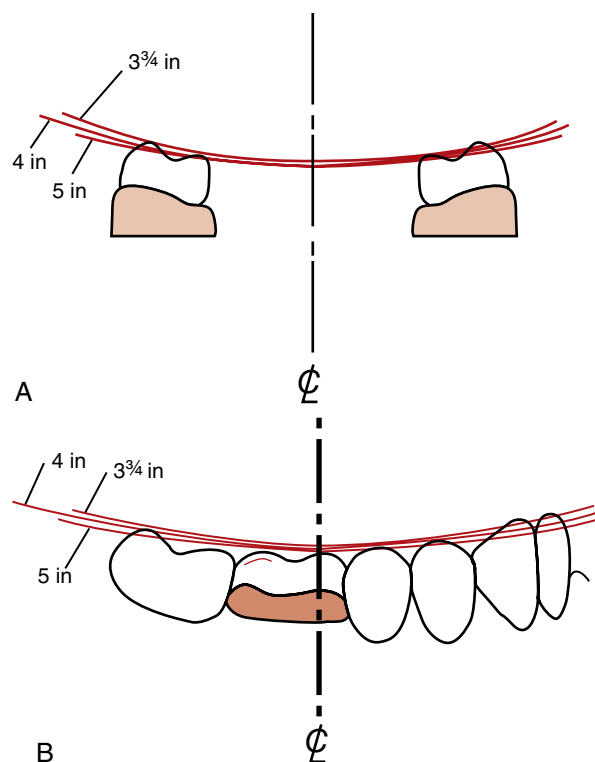
After the maxillary incisal edge and the OVD are deemed clinically acceptable, the position of the lower anterior teeth is evaluated. When natural teeth are present, or when a fixed prosthesis is planned in the anterior region, the mandibular teeth incisal edge should contact the lingual aspect of the maxillary anterior natural teeth at the desired OVD position. A vertical overlap with the maxillary anterior teeth is usually in the range of 3 to 5 mm. The incisal guidance is defined as the influence of contacting surfaces of the mandibular and maxillary anterior teeth on mandibular movements.[9] The incisal guide angle is formed by the intersection of the plane of occlusion and a line within the sagittal plane, determined by the incisal edge of the maxillary and mandibular central incisors when in maximal intercuspation (MI). The incisal guide angle is responsible for the amount of posterior tooth separation during mandibular excursions, and to do so, it should be steeper than the condylar disc assembly (Christensen phenomenon). Therefore any planned prosthesis and associated compensating curves should be developed within these confines. If they are not, then the maxillomandibular arch position may be improper (i.e., in the skeletal class II patient) and the posterior teeth may exhibit lateral contacts during mandibular excursions. Under these conditions, the masseter and temporalis muscles do not reduce their contraction force during these movements (as they do when only anterior teeth occlude in excursions), and the strong muscles of mastication continue to contract and place an increased force on the entire stomatognathic system.

The incisal guidance can be evaluated on the mounted diagnostic models. A steep incisal guidance helps in avoiding posterior interferences in protrusive movement. However, the steeper the incisal guide angle is, the greater force applied to anterior crowns. This may present a significant problem for an anterior single-tooth implant
● **Fig. 21.6** (A) Combination syndrome describes the clinical conditions occurring when a maxillary denture opposes mandibular anterior teeth and no partial denture. The mandibular teeth overerupt as the maxillary denture seats up in the anterior and down in the posterior. (B) Clinical view of retained maxillary anterior teeth with passive eruption of the mandibular alveolar bone with no posterior support, (C) Maxillary prosthesis showing extensive premaxilla atrophy and enlarged tuberosities, (D) In most cases of combination syndrome, tuberosity reduction is indicated prior to prosthetic treatment.
• **Fig. 21.7** Ala–tragus line (Camper plane) *(Line A)* is parallel to the occlusal plane of the maxillary teeth *(Line B).*

replacement. On occasion, the tooth is lost as a result of severe parafunction from a steep incisal guidance (usually from fracture after endodontic therapy). On the other hand, if the existing incisal guidance is shallow, it may be necessary to plan recontouring or prosthetic restoration of posterior teeth that exhibit contact during excursions.

Existing Occlusal Planes (Posterior Maxillary and Mandibular Planes of Occlusion)

After the maxillary anterior teeth position, OVD, and mandibular anterior teeth position are deemed acceptable, the horizontal occlusal planes are evaluated in the posterior regions of the mouth. Their position related to the curves of Wilson (mediolateral) and Spee (anteroposterior [A-P]) and to each other should allow harmonious occlusion, with maximum occlusal interdigitation and canine or mutually protected occlusion. Ideally, the maxillary posterior occlusal plane should be parallel to the Camper plane (i.e., to the midtragus position) (Fig. 21.7). The occlusal plane of existing teeth is critical in evaluating partially edentulous patients in relationship to the final implant prosthesis. Occlusal modification, endodontic therapy, or crowns are indicated to remedy tipping or extrusions of adjacent or opposing natural teeth. A pretreatment diagnostic wax-up is strongly suggested to evaluate the needed changes before implant placement. A proper curve of Spee and curve of Wilson are also indicated for proper esthetics and are reproduced in the compensating curves for complete denture fabrication (Fig. 21.8).

The occlusal plane seems like an obvious step in the patient dental evaluation; however, the existing occlusal plane is not routinely evaluated before the fabrication of the prosthesis. The restoring clinician should explain to the patient the existence of extrusion or exfoliation of the surrounding teeth, which is often obvious on radiographs or diagnostic casts. The need to restore the missing tooth sooner rather than later is apparent to the patient because the teeth are already shifting as a result of the arch collapse. If the patient cannot afford the complete treatment plan related to the missing teeth then the opposing arch with the poor occlusal plane should be treated first, and not the arch with the missing tooth. In this way, opposing quadrants will ultimately be restored to a proper relationship. An occlusal plane analyzer may be used on diagnostic casts to evaluate pretreatment conditions and assist in intraoral occlusal plane correction. Occlusal analyzers are fabricated in several sizes. The average size corresponds to a 4-inch sphere and provides a starting point for ideal curves of Wilson and Spee. Any discrepancy observed on the cast may be


• **Fig. 21.8** Occlusal planes. (A) The curve of Spee is also similar to the radius of a 4-inch sphere and is related to skull size. (B) The curve of Wilson is evaluated before reconstruction in the region. The radius of the average curve corresponds to the radius of a 4-inch sphere.

corrected in the mouth. A laboratory-assisted template may be fabricated with this intent. In the laboratory, a vacuum or press fit of an acrylic shell is prepared over the cast. The occlusal plane analyzer is then used to evaluate and correct an improper occlusal plane. A handpiece is used to grind the acrylic shell and protruding occlusal cusps on the duplicate diagnostic cast. The clear acrylic shell is then taken intraorally and inserted over the teeth. Any cusp extending through the acrylic shell is recontoured to the level of the surrounding acrylic. As such, the occlusal plane is rapidly corrected to an ideal condition (Fig. 21.9).

The natural dentition opposing a partially edentulous ridge also must be carefully examined, and often regions before surgical placement of the implants, especially in the posterior regions of the mouth. The opposing teeth have often drifted or tipped into the opposing edentulous site as a result of improper or missing opposing occlusal contacts.

The CHS in the edentulous site may be significantly reduced as a result of posterior extrusion or exfoliation. The implant drills and implant body insertion often require a posterior CHS of more than 8 mm from the ideal plane of occlusion so the handpiece, drill, or implant may be inserted at the correct position and angulation. This problem is increased when a guided surgical template is used.

The partially edentulous posterior ridge with facial resorption may require implant insertion more medial in relation to the original central fossa of the natural dentition. Enameloplasty of the stamp cusps of the opposing teeth is often indicated to redirect occlusal forces over the long axis of the implant body and may be determined with the diagnostic casts and modified in the mouth before the opposing arch impression and bite registration at the final impression appointment. Then, at the final prosthesis delivery, the final modifications of the opposing dentition are made. The goal of preprosthetic evaluation is to identify and restore the prosthetic parameters within normal limits. The correct tooth positions

• **Fig. 21.9** (A) Misch occlusal analyzer fabricated in three sizes as follows: ¾-inch, 4-inch, and 5-inch sphere. The occlusal plane of the patient is evaluated before the restoration of the opposing arch. (B) A press-form (vacuum) shell is placed over a duplicate study cast of the patient. The template and teeth are adjusted so the casts follow the Misch occlusal analyzer more accurately. (C) The areas on the cast are marked to indicate the areas to modify intraorally. The modified template is inserted in the mouth, and the dental regions above the template are recontoured. (D) Intraorally, the correction is performed using the template.

should be first determined so that, even if the total treatment time is extended over several years, at least each segment will aim toward a consistent goal. Too often the restoring dentist assumes the patient wants the cheapest or fastest treatment related to each treatment session. As a consequence, the mouth is restored one tooth at a time, fitting the restoration into the patient's present occlusal condition, which usually worsens over time and never improves on its own. As a result, after the patient has been in the same practice for several decades, the mouth is in poorer condition than when the patient started. Although it is easier to restore an entire mouth to the correct occlusal relationships at one time, it is also possible to obtain a similar result one tooth at a time, as long as each step proceeds along the predetermined course of treatment.

Specific Criteria

After the five elements of the existing teeth (restorations) have been evaluated and modified where necessary, several other conditions may modify and hinder the course of implant treatment if overlooked. These conditions should be considered before the final treatment plan is presented to the patient (Box 21.3) and include the following.

• **BOX 21.3** **Specific Criteria to Evaluate**

1. Lip lines
2. Maxillomandibular arch relationship
3. Existing occlusion
4. Crown height space
5. Temporomandibular joint status
6. Extraction of hopeless or guarded-prognosis existing teeth
7. Existing prostheses
8. Arch form (ovoid, tapering, and square)
9. Natural tooth adjacent to implant site
10. Soft tissue evaluation of edentulous sites

Lip Lines

Lip positions are evaluated, including resting lip line, maxillary high lip line (smile), and mandibular low lip line (speech) in relation to the vertical position of the teeth. The lip line positions are especially noted if anterior teeth are to be replaced. The resting lip positions are highly variable, but in general they are related to the patient's age. In general, older patients show less maxillary teeth at

rest and during smiling, but they demonstrate more mandibular teeth during sibilant sounds.[4] Prosthetic guidelines for incisal edge position established relative to esthetics, phonetics, and occlusion are applied.[1-8,29-35]

A common removable prosthetic guideline is a 1- to 2-mm incisal edge display with the lip at rest, regardless of the patient's age. Instead, the goal should be to position the prosthetic teeth in the most likely location for the patient's natural teeth. Males tend to show fewer teeth than a female of the same age. In a 50-year-old male, the maxillary incisal edge is often level with the upper lip at rest. This is a similar position for a 60-year-old female. The average upper lip is 20 to 22 mm for women and 22 to 26 mm for men. The maxillary incisal edge is usually at an average of 22 to 24 mm from the floor of the nose depending on the length and contour of the lip. For a short upper lip, the standard guideline for incisal edge of the central incisor would not be acceptable because this would decrease the height of the maxillary arch.

The position of the maxillary incisor in relation to the maxillary lip and the age of the patient is much more variable than the position of the canine. The lip bow in the center of the upper lip rises several millimeters on some females and is barely obvious on others. The higher the lip bow, the more central incisor surface is seen on the patient, regardless of age. Men rarely exhibit an exaggerated lip bow and therefore have a more consistent incisor edge to lip position. The canine position at the corner of the lip is not affected by the lip bow effect. As such, it is a more consistent position and usually corresponds to the length of the resting lip position from 30 to 60 years of age in both males and females.[8]

In the natural dentition, the maxillary lip is most often longer than the incisal edge after the patient turns 65 years old. However, most patients desire the maxillary teeth to be at least slightly visible. It is risky to extend the maxillary tooth position to decrease the age of the smile without considering the consequences of an increased crown height on moment forces (biomechanics). If pontics rather than implants support the anterior crowns, the poor biomechanical condition is magnified.

An alternative to increasing the length of the anterior teeth may be to increase the thickness of the alveolar ridge. This extra support brings out the lip and also raises the vermilion border. As a result, the teeth are not longer, but the border of the lip is higher. In addition, if the added width to the ridge is with autologous bone, replacing teeth with implants rather than pontics further improves the situation. The fuller maxillary lip may also look younger because vertical age lines may also be reduced.

High Lip Line

The maxillary high lip line is determined while the patient displays a natural, broad smile.[36,37] There are three categories of maxillary lip lines: low, average (ideal), and high ("gummy"). The low lip line displays no interdental papilla or gingiva above the teeth during smiling. The high lip demonstrates all of the interdental papilla and more than 2 mm of tissue above the cervices of the teeth. The clinical characteristics of the average or ideal esthetic smile include a full length of crown exposure (crowns of normal height), a normal tooth position and alignment (lateral incisors may not be completely straight), a normal tooth form, the interdental papilla, and minimal gingival exposure over the cervicals of the teeth (lip at the free gingival margin of the centrals and canines) (Fig. 21.10). Approximately 70% of the adult population has a smile line within a few millimeters of the free gingival margin.

● **Fig. 21.10** (A) An ideal high smile line, although this patient shows ideal clinical crown and the interdental papillae in the anterior, the right posterior shows less teeth than the posterior left. (B) Measuring the height of the exposed clinical crown.

The FP-1 prosthesis in implant dentistry attempts to reproduce a normal crown contour. However, with a high lip position during smiling, this goal must also include the soft tissue drape around the crown. As a consequence, the esthetic requirements are much more demanding and often mandate additional surgical steps to enhance the soft and hard tissues before the crown restoration. The selection of an FP-2 and an FP-3 fixed prosthesis is often based solely on the evaluation of the high lip line. An FP-2 prosthesis is easier to fabricate because it requires fewer porcelain bake cycles.

Approximately 15% to 20% of adults have a low lip line and do not show the interdental papilla when smiling (more males than females) (Fig. 21.11). In these patients, the soft tissue drape does not require a primary focus and can often be compromised with an FP-2 restoration, when the patient is notified before treatment. However, an average to high lip position during smiling contraindicates this restoration type because of poor cervical esthetics. The pink porcelain or zirconia restoration (FP-3) to replace the soft tissue may be esthetic, but it is rarely the treatment of choice for single-tooth replacement. On the other hand, in multiple missing adjacent anterior teeth, the pink porcelain or zirconia is often the treatment of choice because the soft tissue drape is usually unable to be ideal, even with bone and tissue grafts.

• **Fig. 21.11** (A) A low, high smile line shows no interdental papillae during smiling. (B) The patient in (A) has a full arch implant–supported FP-3 prosthesis.

• **Fig. 21.12** (A) A high smile line exposes all of the clinical crown, the interdental papillae, and the full gingival margin above the teeth. (B) Measurement of the high smile line. (C). Measurement of the low smile line.

In a completely edentulous patient, the labial flange of the patient's existing denture may be removed and the lip position evaluated before the completed treatment plan of a fixed restoration. When the lip needs the support of the labial flange for esthetics, yet a fixed restoration is planned, autogenous, allografts or hydroxyapatite (HA) may be indicated to increase labial tissue thickness for proper lip support.

A gummy or high smile line occurs in 14% of the young female patients and 7% of young male patients (Fig. 21.12).[36] The normal clinical crown width/height ratio is 0.86 for the central incisor, 0.76 to 0.79 for the lateral incisor, and 0.77 to 0.81 for the canine. If the patient demonstrates a band of gingiva over the cervical areas of the teeth, then the height of the clinical crowns are evaluated, relative to their width. Esthetic crown lengthening is often a good option when the height of the central clinical crown is less than 10 mm (and the width is greater than 8 mm). Often the effect of crown lengthening is a dramatic improvement and may be accomplished at the same time as the implant surgery.

In patients with a high lip line who are missing all their anterior teeth, the prosthetic teeth can be made longer (up to 12 mm) instead of the average 10 mm height to reduce the gingival display and result in a more esthetic restoration. Therefore the height of the maxillary anterior teeth is determined by first establishing the incisal edge by the lip in repose. Second, the high smile line determines the height of the tooth (from 9–12 mm). Third, the width of the anterior teeth is determined by the height/width ratios.

The cervical third of the maxillary premolars is also observed during a high smile line. It is not unusual to reveal the cervical third and gingiva of the premolar with a high lip line. These teeth should not appear too long or unnatural in height. Resorption may also cause the implants to be inserted more palatally in this area. The position of these crowns may then be too palatal and therefore affect the esthetic result. Bone grafts are the primary method to eliminate the need for ridge laps or the addition of pink porcelain at the gingiva. They are also indicated to reduce crown height.
Mandibular Lip Line

The mandibular low lip position is often neglected, with disastrous esthetic results. The mandibular incisors are more visible in middle age and older patients during speaking than maxillary teeth. In addition, lower central incisors are often visible in their incisal two-thirds during exaggerated smiles.[37,38] Although the maxillary high lip line is evaluated during smiling, the mandibular low lip position should be assessed during speech. In pronunciation of the S sound, or sibilants, some patients may expose the entire anterior mandibular teeth and gingival contour. Patients are often unaware of this preexisting lip position and blame the final restoration for the display of the mandibular gingiva, or complain that the teeth look too long. Therefore it is recommended to make the patient aware of these existing lip lines before treatment and emphasize that these lip positions will be similar after treatment. An FP-3 mandibular restoration may be indicated to restore the patient with a low mandibular lip position.

Maxillomandibular Arch Relationship

After the maxillary anterior teeth positions, OVD, and mandibular anterior teeth positions are evaluated, the maxillomandibular relationships are assessed in the vertical, horizontal, and lateral planes. An improper skeletal position may be modified by orthodontics or surgery. It is far better to discuss these options with the patient before implant surgery because the implant placement may compromise the final prosthetic result if the arch positions are altered after implant insertion. Specific compromises of the final result should be discussed with patients when orthognathic surgery or orthodontic therapy is declined by patients with skeletal discrepancies.

Arch relationships are often affected in edentulous ridges. The anterior and posterior edentulous maxilla resorbs toward the palate after tooth loss.[39] The width of the alveolar ridge may decrease 40% within a few years, primarily at the expense of the labial plate. Consequently, implants are often placed lingual to the original incisal tooth position. The final restoration is then overcontoured facially to restore the incisal two-thirds in the ideal tooth position for esthetics. This results in a cantilevered force on the implant body. The maxilla is affected more often than the mandible because the incisal edge position in the esthetic zones cannot be modified and is dictated by esthetics, speech, lip position, and occlusion. Anterior cantilevered crowns from maxillary anterior implants often require additional implants splinted together and an increase in the A-P distance between the most distal to most anterior implant positions to compensate for the increased lateral loads and moment forces, especially during mandibular excursions.

An anterior cantilever on implants in the mandibular arch may correct an Angle's skeletal class II jaw relationship. The maxillary anterior teeth support the lower lip at rest in both Angle's skeletal class I and II relationships. A traditional complete mandibular denture cannot extend beyond the anatomic support or neutral zone of the lips without decreasing stability of the prosthesis. However, with implants, the denture teeth may be set in a more ideal esthetic and functional position. The anterior cantilever in the mandible is also dependent on adequate implant number and A-P distance between the splinted implants. To counteract the anterior cantilever effect, the treatment plan should provide increased implant support by increasing the surface area by number, size, design, or A-P implant position. In these cases, an RP-4,

designed to prevent food impaction, may facilitate daily care and help control the occlusal forces, compared with an FP-3 prosthesis.

The palatal resorption pattern of the maxilla, paired with the anterior rotation of the mandible in long-term, complete denture patients, may mimic a class III relationship on a lateral cephalometric radiograph. However, in this condition, class III mandibular mechanics do not apply (primarily vertical chewers with little to no anterior excursions during mastication or parafunction). In contrast, these patients exhibit a full range of mandibular excursions and can contribute significant lateral forces on the maxillary restoration, which is cantilevered off the implant base to obtain a class I esthetic restoration. Therefore additional splinted implants are suggested in the maxilla, with the widest A-P distance available. This usually requires sinus grafts and posterior implants in the first or second molar position splinted to the anterior implant support.

Transversal arch relationships include the existence of posterior crossbites, which occur frequently in implant dentistry. Edentulous maxillary posterior arches resorb palatally and medially after tooth loss. Sinus grafts can restore available bone height, but the ridge still remains medial to the opposing mandibular tooth central fossa. This is especially pronounced when opposing a division C–h or moderate atrophic mandible because the mandible widens after the residual alveolar ridge resorbs. For example, when mandibular implants are used in C–h bone volume for implant support opposing a complete denture, the posterior teeth may be set in crossbite (especially when out of an esthetic zone) to decrease the moment forces developing on the maxillary posterior teeth, causing denture instability.

Existing Occlusion

MI is defined as the complete intercuspation of the opposing teeth independent of condylar position, which is sometimes described as the best fit of teeth regardless of the condylar position.[9] *Centric occlusion* is defined as the occlusion of opposing teeth when the mandible is in centric relation (CR).[9] This may or may not coincide with the tooth position of MI. Its relationship to CR (a neuromuscular position independent of tooth contact with the condyles in an anterior, superior position) is noteworthy to the restoring dentist because of the potential need for occlusal adjustments to eliminate deflective tooth contacts and the evaluation of their potential noxious effects on the existing dentition and for the planned restoration. Correction of the problems before treatment presents many advantages and may follow a variety of approaches, depending on the severity of the incorrect tooth position: selective odontoplasty (a subtractive technique), restoration with a crown (with or without endodontic therapy), or extraction of the offending tooth. The existing occlusion is best evaluated with facebow-mounted diagnostic casts and open-mouth bite registration in CR.

Controversy exists as to the necessity for MI to be harmonious with CR occlusion. A vast majority of patients do not have such a relationship, yet they do not exhibit clinical pathology or accelerated tooth loss. Therefore it is difficult to state that these two positions must be similar. What is important is to evaluate the existing occlusion and the mandibular excursions to consciously decide whether the existing situation should be modified or be maintained. In other words, dentists should determine whether they are going to ignore or control the occlusion of the patient (Fig. 21.13). As a general rule, the more teeth replaced or restored, the more likely the patient is restored to CR occlusion. For example, if a completely edentulous mandible is to be restored with

an implant-supported fixed prosthesis, then the CR occlusion position provides consistency and reproducibility between the articulator and the intraoral condition. Slight changes in OVD to position anterior implant abutments in a more favorable restoration position may be studied and implemented on the articulator without the need to record the new occlusal vertical position on the patient.

On the other hand, when one anterior tooth is being replaced, the existing MI position is often satisfactory to restore the patient, even though a posterior interference and anterior slide into full interdigitation may be present. The underlying question that helps determine the need for occlusal correction before restoration of the implant patient is the observation of negative symptoms related to the existing condition. This may include temporal mandibular joint conditions, tooth sensitivity, mobility, tooth fractures or abfraction, or porcelain fracture. The fewer and less significant the findings, the less likely an overall occlusal modification is required

before restoration of the patient. However, to properly assess these conditions, the dentist must not ignore them before treatment.

Crown Height Space

The interarch distance is defined as the vertical distance between the maxillary and mandibular dentate or edentate arches under specific conditions (e.g., the mandible is at rest or in occlusion).[9] A dimension of only one arch does not have a defined term in prosthetics; therefore Misch proposed the term *crown height space*.[40] The CHS for implant dentistry is measured from the crest of the bone to the plane of occlusion in the posterior region and the incisal edge of the arch in question in the anterior region (Fig. 21.14). The ideal CHS for an FP-1 fixed implant prosthesis should range between 8 and 12 mm. This space accounts for the biological width, abutment height for cement retention or prosthesis screw fixation, occlusal material strength, esthetics, and hygiene considerations

• **Fig. 21.13** Nonideal occlusion. The existing occlusion is evaluated to determine whether the maximal intercuspation is similar to centric relation. The mandibular excursions are also evaluated. The lack of canine contact and premature first premolar contact and the uneven occlusal plane indicated correction of the occlusion before final reconstruction.
• **Fig. 21.15** Crown height is not a multiplier of force when the load is in the long axis of the implant. However, any angled force or cantilever increases the force and the crown height magnifies the effect.
• **Fig. 21.14** (A) Crown Height Space The crown height space (CHS) is measured from the occlusal plane to the level of the bone. *CT,* Connective tissue; *JE,* junctional epithelium. Ideally a minimum of 8 mm is required between the bone level and the occlusal table, however id dependent on the type of prosthesis material. (B) CBCT cross-section depicting the available crown height space.
• **Fig. 21.16** The greater the crown height space (CHS), the more implants are required to restore the patient *(right).* The less the CHS (left side), fewer implants are required to restore the patient.

around the abutment crowns. Removable prostheses often require more than 12 mm of CHS for denture teeth and acrylic resin base strength, attachments, bars, and oral hygiene considerations.[41,42]

Excessive Crown Height Space

Mechanical complication rates for implant prostheses are often the highest of all complications reported in the literature [43,44] and are often caused by excessive stress applied to the implant-prosthetic system. Implant body or component failure may occur from overload and result in prosthesis failure and bone loss around the failed implants.[43] Crestal bone loss may also be related to excessive forces and often occurs before implant body fracture.

The biomechanics of CHS are related to lever mechanics. The issues of cantilevers and implants were demonstrated in the edentulous mandible in which the length of the posterior cantilever directly related to complications or failure of the prosthesis.[44] Rather than being a posterior cantilever, the CHS is a vertical cantilever and therefore is also a force magnifier. When the direction of a force is in the long axis of the implant, the stresses to the bone are not magnified in relation to the CHS (Fig. 21.15). However, when the forces to the implant are on a cantilever or a lateral force is applied to the crown, the forces are magnified in direct relationship to the crown height. Bidez and Misch have evaluated the effect of a cantilever on an implant and its relation to crown height.[45,46] When the crown height is increased from 10 to 20 mm, two of six of these moments are increased 200%. When the available bone height is decreased, the CHS is increased. An angled load to a crown also magnifies the force to the implant. Maxillary anterior teeth are usually at an angle of 12 degrees or more to the occlusal planes. Therefore even implants placed in an ideal position are usually loaded at an angle. In addition, maxillary anterior crowns are often longer than any other teeth in the arch, so the effects of crown height cause greater risk. The angled force to the implant may also occur during protrusive or lateral excursions because the incisal guide angle may be 20 degrees or more. Anterior implant crowns will therefore be loaded at a considerable angle during excursions, compared with the long axis of the

implant. As a result, an increase in the force to maxillary anterior implants should be compensated for in the treatment plan.

Most forces applied to the osteointegrated implant body are concentrated in the crestal 7- to 9-mm bone, regardless of implant design and bone density. Therefore implant body height is not an effective method to counter the effect of crown height. Moderate bone loss before implant placement may result in a crown height–bone height ratio greater than 1, with greater lateral forces applied to the crestal bone than in abundant bone (in which the crown height is less). A linear relationship exists between the applied load and internal stresses.[47,48] Therefore the greater the load applied, the greater is the tensile and compressive stresses transmitted at the bone interface and to the prosthetic components. The greater the CHS, the greater number of implants are usually required for the prosthesis, especially in the presence of other force factors. This is a complete paradigm shift to the concepts advocated originally with many implants in greater available bone and small crown heights and fewer implants with greater crown heights in atrophied bone (Fig. 21.16). Because an increase in the biomechanical forces are in direct relationship to the increase in CHS, the treatment plan of the implant restoration should consider stress-reducing options whenever the CHS is increased. Methods to decrease stress are presented in Box 21.4.[40,41]

CHS is defined as excessive when it is greater than 15 mm. Treatment of excessive CHS as a result of vertical resorption of bone before implant placement includes surgical methods to increase bone height or stress reduction methods to the prosthesis. Several surgical techniques may be considered to increase bone height, including block onlay bone grafts, particulate bone grafts with titanium mesh or barrier membranes, interpositional bone grafts, and distraction osteogenesis.[41,42,49]

Bone augmentation may be preferred to prosthetic replacement. Surgical augmentation of the residual ridge height will reduce the CHS, improve implant biomechanics, and often permit the placement of wider body implants with the associated benefit of increased surface area. Although prosthetics is the most commonly used option to address excess CHS, it should be the last option used. Gingiva-colored prosthetic materials (pink porcelain or acrylic resin) on fixed restorations or changing the prosthetic design to a removable restoration should often be considered when restoring excessive CHS.

In the maxilla, a vertical loss of bone results in a more palatal ridge position. As a result, implants are often inserted more palatal than the natural tooth position. Removable restorations have several advantages under these clinical circumstances. The removable
• **Fig. 21.17** Large crown height space requires a greater bulk of material (i.e., porcelain-metal prosthesis or zirconia), which increases the risk of possible prosthetic complications.

• **Fig. 21.18** Excessive crown height space. For an edentulous full arch prosthesis, a hybrid prosthesis (titanium milled bar + acrylic) may be used to decrease the thickness and weight associated with restoring a large space. Another prosthesis option is zirconia which is much lighter than conventional metal fused to porcelain.

prosthesis does not require embrasures for hygiene and may be removed during sleep to decrease the effects of an increase in CHS on nocturnal parafunction. The prosthesis may also improve the deficient lip facial support. The overdenture may have sufficient bulk of acrylic resin to permit denture tooth placement without infringement of the substructure and to decrease the risk of prosthesis fracture. However, it has identical requirements to a fixed prosthesis because it is rigid during function (hidden cantilever situation).

In the case of removable prostheses with mobility and soft tissue support, two prosthetic levers of height should be considered. The first is the height of the attachment system to the crest of the bone. The greater the height distance, the greater are the forces applied to the bar, screws, and implants. The second CHS to consider is the distance from the attachment to the occlusal plane. This distance represents the increase in prosthetic forces applied to the attachment. Therefore in a CHS of 15 mm, an O-ring may be 7 mm from the crest of bone, resulting in a lever action of 7 mm applied to the implants. The distance from the rotation point of the O-ring to the occlusal plane may be an additional 8 mm. Under these conditions, a greater lever action is applied to the prosthesis than to the implant interface. This results in increased instability of the restoration under lateral forces.[42]

A larger CHS results in the substructure requiring a greater bulk of material. This often may predispose the patient to fractured

• **BOX 21.5** **Reduced Crown Height Space**

1. Structural integrity problems of a restoration increase with a reduced CHS.
2. Surgical procedures during implant placement may increase a CHS, usually via osteoplasty procedures
3. Complications of an insufficient CHS may be increased by the surgical position of the implant (i.e., poor angulation, implant platform several millimeters above the bone).
4. Different implant systems have a different minimum CHS related to the height of the prosthetic components.
5. Esthetic issues may result from insufficient CHS.

CHS, Crown height space.

restorative material (Fig. 21.17). With metal based casted substructure, control of surface porosities after casting becomes increasingly difficult because their different parts cool at different rates.[50] If not controlled properly, both of these factors increase the risk of porcelain fracture after loading.[51] For excessive CHS, considerable weight of the prosthesis (approaching 3 ounces of alloy) may affect maxillary trial placement appointments because the restoration does not remain in place without the use of adhesive. Because noble metals must be used to control the alloy's heat expansion or corrosion, the cost of such implant restorations is dramatically increased. Proposed methods to produce hollow frames to alleviate these problems include using special custom trays to achieve a passive fit, which can double or triple the labor costs.[52]

An alternative method to fabricate fixed prostheses in situations of a CHS 15 mm or greater is the fixed complete denture or hybrid prosthesis, which has a smaller metal framework, denture teeth, and acrylic resin to join the materials together (Fig. 21.18). Unfortunately, this type of prosthesis has a high incidence of fracture/delamination. On occasion, undercontoured interproximal areas are designed by the laboratory in restorations of large CHS to assist oral hygiene, and they have been referred to as high-water restorations. This is an excellent method in the mandible; however, it results in food entrapment, affects air flow patterns, and may contribute to speech problems in the anterior maxilla.

Because crown height is a considerable force magnifier, the greater the crown height, the shorter the prosthetic cantilever should extend from the implant support system. In crown heights of more than 15 mm, no cantilever should be considered unless all other force factors are minimal. The occlusal contact intensity should be reduced on any offset load from the implant support system. Occlusal contacts in CR occlusion may even be eliminated on the most posterior aspect of a cantilever. In this way, a parafunction load may be reduced because the most cantilevered portion of the prosthesis is only loaded during functional activity while eating food.

Reduced Crown Height Space

Issues related to CHS are accentuated by an excessive CHS that places more forces on the implant and prosthetic system, and reduced CHS makes the prosthetic components weaker. A reduced CHS has biomechanical issues related to a reduced strength of implant material or prosthetic components, an increased flexibility of the material, and a reduction of retention requirement of the restoration. The fatigue strength and flexure of a material is related to its radius to the power of 4. In fixed restorations,
• Fig. 21.19 Reduced crown height space (CHS). (A) Panoramic radiograph depicting a compromised CHS (red arrows). (B) An osteoplasty using a ridge reduction bur is indicated to increase the CHS before implant insertion. (C) A cone beam computerized tomography reduction guide may be fabricated via interactive treatment planning software to simulate the amount of bone to be removed. (D) Stackable reduction surgical guide fixated onto host bone for preparation of ridge reduction.

the flexure of the reduced-diameter material may cause porcelain fracture, screw loosening, or uncemented restorations. Therefore in the situation of reduced CHS, material failures are more likely (Box 21.5).

Skeletal discrepancies (deep bite), reduced OVD from attrition or abrasion, minimal bone atrophy after tooth loss, and supraeruption of unopposed teeth may all result in less than ideal space for prosthetic replacement of the dentition. Traditional prosthetic and restorative procedures are indicated to restore the proper OVD and plane of occlusion. However, on occasion, even when the opposing arch is corrected, the CHS may still be less than ideal (<8 mm). The 8-mm minimum requirement for CHS consists of 2-mm occlusal material space, 4-mm minimum abutment height for retention, and 2 mm above the bone for the biological width dimension (which does not include the sulcus because a crown margin may be 1 mm subgingival for retention or esthetics). When the reduced OVD is in partially edentulous patients, the OVD may be restored by orthodontics, which is the preferred method. This correction may also require a surgical orthognathic surgery, such as a LeFort I osteotomy and superior repositioning. However, prosthetics is a common approach and may involve an entire arch.

When the opposing teeth are in the correct position and the CHS is insufficient, additional space may be gained surgically with osteoplasty and soft tissue reduction of one arch, provided adequate bone height remains after the procedure for predictable implant placement and prosthetic support (Fig. 21.19). If a removable implant-supported prosthesis is planned, an aggressive alveoloplasty should often be performed after tooth extraction to provide adequate prosthetic space.

Additional prosthetic space can also be obtained in many clinical situations by soft tissue reduction, especially in the maxilla. Soft tissue reduction should be performed in conjunction with second-stage surgery if the implants heal in a submerged location. This allows the thicker tissue to protect the implants from uncontrolled loading by a soft tissue–supported prosthesis during healing. If the implants heal permucosally, then the reduction procedures should be done during implant placement. Soft tissue reduction procedures may include gingivectomy, removal of connective tissue, or apical repositioning of flaps. Efforts should be made to maintain adequate keratinized tissue around the implants. Soft tissue reduction also has the benefit of decreased probing depths around the implants. However, the definition of

CHS is from the bone to the occlusal plane; therefore although the prosthetic space is improved, the CHS remains similar when only soft tissue reduction is performed. Too little CHS can be further complicated when the surgeon places the implant above the bone. When the CHS is less than ideal, the following prosthetic parameters should be identified[42]:

1. Available space
2. Abutment taper
3. Surface area of abutment
4. Cement type
5. Surface finish
6. Occlusal topography and material
7. Load on final restoration
8. Fit of restoration to abutment
9. Retention of prosthesis
10. Implant manufacturer
11. Implant platform to occlusal plane dimension

The consequences of insufficient CHS include a decrease in abutment height (which may lead to inadequate retention of the restoration), inadequate bulk of restorative material for strength or esthetics, and poor hygiene conditions compromising long-term maintenance.[53] In addition, the final restoration flexes inversely to the cube of the thickness of material. A fixed prosthesis half as thick will flex eight times as much and will further result in loss of cement retention, loosening/fracture of fixation screws, or porcelain fracture.[54] Inadequate thickness of occlusal porcelain or acrylic, or unsupported occlusal material caused by inadequate metal substructure design, may also result in complications such as component fracture.

Minimum restorative requirements vary in function of the implant system. The minimum restoration space may be determined by limiting the occlusal material to 1 mm and reducing the abutment height to the top of the retaining screw.

When fabricating a cemented restoration, the restoration technique (indirect versus direct) may be influenced by the CHS. Because additional abutment height for retention may be gained by a subgingival margin, the indirect technique (making an implant body level impression) may have an advantage over a direct intraoral impression. An implant body level impression permits the subgingival restoration to be placed more than 1 mm subgingival, with greater accuracy, representing benefit in a reduced CHS situation, especially when the soft tissue is several millimeters thick. The indirect technique is also used for custom abutments, which can be designed with increased diameter to increase the overall surface area for retention. A custom abutment may also be fabricated to decrease the total occlusal convergence angle to increase retention for cemented prostheses.

The retention and resistance difference between a 3-mm high and a 5-mm high implant abutment may be as great as 40% for a 4.5-mm-diameter abutment. Less than 3 mm of abutment height indicates a screw retained crown, 3 to 4 mm requires a screw retained or resin-cemented restoration, and greater than 4 mm of abutment height allows for clinician's preference. Splinting implants together, regardless of whether they are screw retained or cement retained, can also increase retention.

Conditions such as cement hardness, surface condition of the abutment, and occlusal material (zirconia vs. porcelain vs. metal) are also to be considered in limited CHS situations. The occlusal material is important to consider in reduced CHS for two primary reasons. When zirconia or metal is used as the occluding surface, it is possible to provide greater retention for the prosthesis as a result of an increase in abutment height. The abutment height may be greater because the occlusal space required above the abutment is only 1 mm, whereas porcelain requires 2 mm of occlusal space and acrylic resin requires 3 mm or more. When a screw is used to retain the crown, the strength of occlusal porcelain is reduced by 40%. Acrylic resin requires the most dimension for strength and is much more likely to fracture when the CHS is limited. This is why acrylic resin overdentures require more CHS than a porcelain-metal fixed prosthesis.

The surgeon may magnify the prosthetic problem of limited CHS by placing the implant at an angle to the ideal position. Angled abutments lose surface area of retention from the abutment screw hole and further compromise the limited space conditions. In addition, a 30-degree taper on an abutment to correct parallelism loses more than 30% of the abutment surface area and dramatically decreases the retention for the abutment.

Overdentures also exhibit greater complications in situations of reduced CHS. Removable prostheses have space requirements for elements such as a connecting bar and the type and position of attachments and restorative material (metal versus resin). According to English, the minimum CHS for individual attachments is 4.5-mm CHS for locator-type attachments and between 12 and 15 mm for a bar and O-rings.[55] Marinbach reported the ideal CHS for removable prostheses is >14 mm and the minimum height is 10.5 mm (i.e., nonbar overdenture).[42] The lowest possible profile attachment should be used in situations of reduced CHS to fit within the contours of the restoration, provide greater bulk of acrylic resin to decrease fracture, and allow proper denture tooth position without the need to weaken the retention and strength of the resin base.

Overdenture bars may be screw retained or cement retained. The most common current method of retention for a fixed prosthesis is screw retained. The most common method of bar retention by almost the same percentage for overdentures is screw retention; yet the advantages of cement retention for a fixed prosthesis also apply to an overdenture bar. Therefore in minimum CHS situations, the screw-retained bar has a clear advantage.

Temporomandibular Joint

The temporomandibular joint (TMJ) may exhibit signs and symptoms of dysfunction. Symptoms include pain and muscular tenderness experienced by the patient. Noises or clicking in the joint during opening, deviation of the mandible during jaw opening, and limited jaw movements are signs of potential dysfunction observed during the patient examination. Patient complaints or signs gathered during this phase should be carefully evaluated before further reconstructive treatment.

Palpation of the temporalis, masseter, and internal and external pterygoid muscles is part of the TMJ examination. The muscles should not be tender during this process. Parafunction may contribute to TMJ disorders and is a direct source of muscle tenderness. Under these conditions, the muscles are usually hypertrophied as a result of the excess occlusal forces. The masseter and temporalis muscles are easily palpated. The lateral pterygoid muscle is often overused in this patient profile, yet is difficult to palpate. The ipsilateral medial pterygoid muscles can be as diagnostic and are easier to evaluate in the hamular notch region. They act as the antagonist to the lateral pterygoid muscle in hyperfunction and, when tender, they are a good indicator of overuse of either muscle. Deviation to one side on opening indicates muscle imbalance on the same side as the deviation and possible degenerative joint disease.[56,57] The patient should also be able to perform unrestricted mandibular excursions. Maximal
• **Fig. 21.20** (A) A nonvital tooth with an endodontic lesion of more than 5 mm has less than an 88% treatment success rate. (B) The postoperative follow-up of the tooth indicates endodontic success. It may now be restored with less risk of failure. If not successful, extraction rather than retreatment is considered because the retreatment success rate is 65%.

opening is noted during this examination and is normally greater than 40 mm from the maxillary incisal edge to the mandibular incisal edge in an Angle's skeletal class I patient. If any horizontal overjet or vertical overbite exists, it is subtracted from the 40-mm minimum opening measurement.[58] The range of opening without regard to overlap or overbite ranges from 38 to 65 mm in men and 36 to 60 mm in women, from one incisal edge to the other. The practitioner is encouraged to carefully evaluate the TMJ status. It is beyond the scope of this text to address the methods of treatment of TMJ dysfunction. However, many patients with soft tissue–borne prostheses and TMJ dysfunction benefit from the stability and exacting occlusal aspects that implant therapy provides. As such, these patients may benefit from implant support to improve their condition.

Extraction of Teeth with Hopeless or Guarded Prognosis

Maintaining natural teeth in health, function, and esthetics is a primary goal of all dentists. In the past, the maintenance of a natural tooth was paramount because tooth replacement techniques were costly and not as predictable as repairing the natural tooth. However, advanced repair procedures such as apicoectomy, furcation treatment, or functional crown lengthening, may have a lower success rate than an implant to replace the tooth. Therefore on occasion, the natural tooth is significantly compromised and extraction with replacement of an implant is indicated. A tooth may be considered for extraction because of prosthetic, endodontic, or periodontal considerations. On rare occasions, extraction is considered rather than orthodontics to restore the teeth in a more esthetic or functional position.

Caries

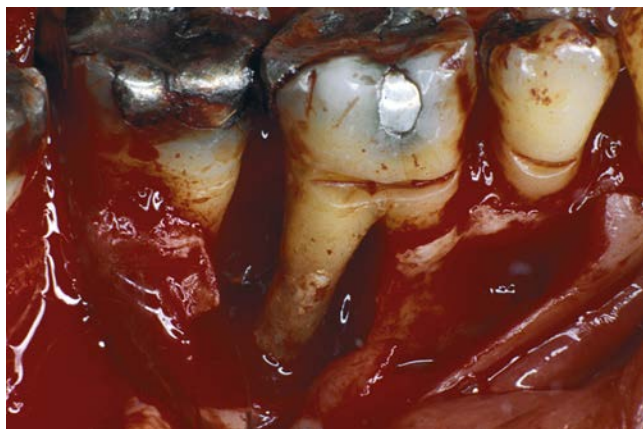
Caries on a natural tooth is most often able to be removed and the tooth restored. However, on occasion, the tooth is unrestorable

after the decay is removed. A prosthetic axiom is to have at least 1.5 to 2 mm of tooth structure for a crown with a cervical ferule effect. In addition, adequate retention and resistance from the tooth preparation should exist. As a result of the caries, endodontic therapy, post and core, and functional crown lengthening may be required. Thus the procedures to save the tooth are costly and not predictable. On occasion, the end result may not be predictable or esthetically pleasing. For example, when a central incisor requires considerable functional crown lengthening, the gingival margin may be compromised and have a poor esthetic result.

Endodontic Therapy

A patient with a history of an increased decay rate with recurrent caries under a crown, requiring endodontics with a post and core before restoration, may also be better served with an extraction and implant insertion. The repeated recurrent decay can be eliminated, at least for that tooth, with an implant. When caries extend within the root canal, the outer structural walls of the natural root may be too thin for a predictable post or restoration. As a result, extraction and implant insertion has a better prognosis.

Endodontic considerations may also consider tooth extraction rather than traditional treatment. When the root canal cannot be accessed because of abnormal root anatomy, an extraction and implant insertion may be considered. On occasion, the endodontic procedure is compromised or an apicoectomy has a moderate to high risk of paresthesia. An implant after extraction may be less invasive and have less risk of paresthesia. A tooth with "split root" syndrome may have undergone root canal therapy, with pain still present during function. Rather than an apicoectomy, an extraction and implant insertion is usually a definitive treatment that eliminates more predictably pain during function.

A vital tooth has endodontic success rates above 93%, whereas a nonvital tooth has an 89% rate. A large periapical lesion (larger than 5 mm) compromises the success rate of traditional


● **Fig. 21.21** Root resection prognosis. A mandibular first molar with a distal root resection generally has a success rate of 75%. Even when successful, the mesial root requires endodontic treatment, core, and crown and the distal root needs replacement. Therefore an implant or three-unit fixed partial denture is indicated. It is more cost-effective to extract, implant, and fabricate one crown, even when bone grafting is indicated.

TABLE 21.1	Extract or Maintain Natural Tooth: 0-, 5-, and 10-Year Rule	
Prognosis	**Protocol**
>10 years	Keep the tooth and restore as indicated
5–10 years	Ideally maintain the teeth and implants as independent prostheses
<5 years	Extract the tooth and graft or immediately place implant in site

endodontics. A nonvital tooth with large periapical pathology has a success rate of 78% (Fig. 21.20).[59,60] Therefore endodontic therapy should be performed and evaluated over several months before post, core, and crown treatment. A retreatment of an endodontic tooth with a periapical lesion has a reported success rate of 65%. As a result, consideration for extraction and implant replacement may be considered for nonvital teeth with more than 5-mm apical radiolucencies that do not resolve or endodontic retreatment when periapical lesions are present. The existing teeth in a partially edentulous patient should be evaluated for longevity and existing disease. Implant dentistry has modified the treatment plan philosophy in these patients.

Periodontal Disease

Advanced periodontal disease may be addressed with extraction of questionable abutments more frequently than in the past, provided the resulting edentulous area offers sufficient bone for predictable endosteal implant placement and a predictable prognosis.[61] Herodontics are discouraged when the prognosis is poor or failure of treatment may result in inadequate bone for implant placement. The cost of the questionable periodontal treatment may result in the patient's inability to afford the more predictable implant therapy later. This is especially noted when the existing available bone around the tooth roots is compromised in height, especially in the posterior mandible. Unsuccessful periodontal treatment and continual bone loss may render the remaining bone inadequate for extraction and placement of implants.

The etiology of furcation involvements includes bacteria and plaque in the furca, with extension of inflammation in the region with loss of interradicular bone. This leads to a progressive and site-specific loss of attachment in most individuals. A first molar furcation entrance cannot be accessed with hand instruments 58% of the time.[62] In addition, pulpal pathoses with accessory canals in the furca may cause problems. Vertical root fracture after endodontic therapy may also occur.

Furcation treatment of molars may include root amputation. The lowest success rate for root resection was found on mandibular distal root resection (75%) (Fig. 21.21). Even when successful, the missing root indicates endodontics, core and crown, and the replacement of the distal root. An implant replaces the entire

tooth, with a higher success rate and often lower cost. A maxillary molar that has lost bone to the furcation has lost almost 30% of the root surface area of support. Therefore when a tooth has a short root or is multirooted, a considerable functional crown lengthening may compromise the remaining support or result in a furcation involvement. The endodontics, post and core, and functional crown lengthening may not be as predictable as extraction and implant insertion. In addition, the cost of conventional treatment may be twice the cost of an implant. Traditional methods to save a tooth have increased in cost over the years. Multirooted endodontic therapy now approaches the cost of an implant surgery. When functional crown lengthening and endodontic post treatment is also required, the fees are usually greater than extraction and implant insertion. Therefore part of the equation of whether to extract or treat a tooth may also relate to the cost of the service provided. The natural molar tooth that requires endodontics, root amputation, post and core placement, and nevertheless a compromised root with poor root surface area may be cost prohibitive for the service provided.

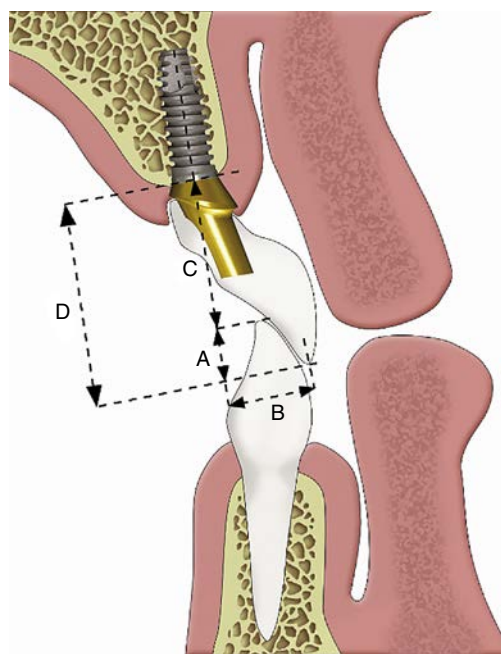
An implant in the site after tooth extraction is often less expensive and more predictable long term. However, the recent trend to extract teeth with a good prognosis after endodontic or periodontal treatment is discouraged. Implants are not yet 100% predictable, and implants should not be substituted for natural teeth presenting a good or even fair prognosis. Table 21.1 summarizes the decision-making protocol involving a natural tooth abutment. The dentist evaluates the natural teeth for their quality of health with widely used prosthetic, periodontal, and endodontic indexes. After this is accomplished, the dentist obtains an estimate of longevity and decides whether to extract or to treat and maintain the tooth, following a 0-year, 5-year, or 10-year rule. If the natural tooth has a favorable prognosis for more than 10 years, it is included in the treatment plan. The decision to use it or not as an abutment requires additional information, but few reasons support removal of the tooth to restore the partially edentulous patient.

If the natural tooth prognosis (after periodontal, endodontic, or restorative therapy when necessary) is in the 5- to 10-year range, independent implant-supported prostheses are indicated. If the edentulous region does not provide sufficient implant support for an independent restoration, then placement of as many implants as possible around the tooth, with treatment alternatives that will permit removal of the tooth without sacrificing the restoration, is indicated. For example, a coping may be placed on the tooth with a 5- to 10-year prognosis, and the tooth may act as "living pontic" in the final restoration, surrounded by sufficient implant support. Whether the tooth is missing or present does not matter. In this way, the prosthesis may be removed in the future and the tooth may be removed (if indicated). The prosthesis essentially is maintained without compromise.[63-65]

The copings on the teeth should be designed with a different path of insertion than fixed partial dentures (FPDs) and should be cemented with permanent cement, whereas the fixed implant prosthesis usually is cemented with a weaker (soft access) or temporary cement. Thus the FPD path of removal differs from that of the natural tooth coping and, along with the weaker cement, allows the prosthesis to be removed while the coping remains permanently cemented on the tooth. The preparation of copings on natural teeth often requires additional removal of tooth structure to prevent overcontoured restorations and, consequently, may mandate endodontic therapy. If hygiene is poor with patients with a high caries index or with grade II or grade III furca involvement in molars, the tooth most often is considered in the 0- to 5-year category and is considered for extraction, especially when other teeth in the same quadrant are missing or hopeless, or only 8 to 10 mm of bone remains between the crest of bone and the opposing landmark. A less than 5-year prognosis for a natural tooth adjacent to an edentulous site, despite restorative or periodontal therapy, warrants extraction of the tooth, with grafting and planning for additional implant abutment support as part of the initial treatment plan. This treatment scenario may often be faster, easier, and less costly over a 5- to 10-year period compared with maintaining a questionable adjacent tooth. Mandibular molars with grade I furcation involvement often are placed in the 5- to 10-year prognosis category. However, maxillary molars are at higher risk of furca complications and are lost 33% of the time within 5 years. Mandibular molars have a 20% failure at this same reference time. After the molar has a grade II or higher furca, it has a greater risk of failure and may be placed in the 0- to 5-year category.[66-69] The dentist should evaluate teeth especially next to multiple edentulous sites. A natural tooth distant from the future implant restoration site is less likely to affect the implant reconstruction and alter the treatment sequences in this site. However, failure of a natural tooth adjacent to an implant site may cause failure of the adjacent implant and almost always (whether failure occurs or not) causes the restoration to be delayed and compromised. Therefore if the practitioner is not sure whether the tooth is in the 0- to 5-year or 5- to 10-year category, the tooth more often should be considered to have the poorer prognosis.

Existing Prostheses

When present, existing prostheses are evaluated for proper design and function. A removable partial soft tissue–supported restoration opposing the proposed implant-supported prosthesis is of particular interest. The occlusal forces vary widely as the underlying bone remodels. The patient may not even wear the opposing removable partial denture in the future, which will dramatically modify the occlusal conditions. Therefore continued maintenance and follow-up evaluations are indicated, including relines and occlusal evaluation.

The patient should be asked whether esthetic desires are met with the current restorations. It is not unusual that the prosthesis is completely acceptable, yet the patient wishes a different shade or contour for the teeth. If unacceptable to the patient, the reasons for dissatisfaction are noted. In addition, the existing restorations are evaluated throughout the mouth for clinical harmony. It is better to leave a poor esthetic restoration that is in occlusal harmony than to provide one that is esthetic but improper in position because the latter may influence all future restorations. Pontic regions of existing prostheses may often be improved with the addition of connective tissue grafts.


● **Fig. 21.22** Dental arch form may be different than the arch form of the residual arch. A tapered dentate arch form on a square residual bone form is the worst combination because the anterior teeth are cantilevered from the implant abutments. (A) Amount of vertical overbite, (B) Amount of maxillary anterior cantilever, (C) Vertical crown height space minus overbite, (D) Maxillary bone level to incisal edge.

An acceptable preexisting maxillary removable prosthesis, which will be replaced with a fixed implant prosthesis, may be used as a template for implant reconstruction when fabricating an implant-supported fixed or removable implant prosthesis. The thickness of the labial flange of the existing denture is evaluated and is often removed to evaluate the difference in lip position and support. If implants may be correctly inserted, yet additional lip support is needed once the labial flange is eliminated, an HA, connective tissue, or acellular dermal onlay graft is usually indicated. This graft is not intended for implant support or placement; rather, it is intended to enhance the support of the labial alveolar mucosa to improve maxillary lip support.

Arch Form

The edentulous arch form in the horizontal plane is described as ovoid, tapering, or square. In the edentulous patient, the ovoid arch form is the most common, followed by the square, then the tapered form. The square arch form may result from the initial formation of the basal skeletal bone. However, the presence of a square arch form is more common in maxillary implant patients as the result of labial bone resorption of the premaxilla region when anterior teeth are lost earlier than the canine. The tapering arch form is often found in skeletal class II patients as a result of parafunctional habits during growth and development. It is common to find different arch forms in the upper and the lower arches.

Two different arch forms are to be considered for implant prostheses. The first arch form is of the residual edentulous bone and determines the A-P distance for implant support. The second arch form is of the replacement teeth position. The dentate and edentulous arch form are not necessarily related, and the worst situation in the maxilla corresponds to a square residual arch form that

supports a tapered dental restoration. The cantilever off the available bone is greatest in this combination (Fig. 21.22).

The most ideal biomechanical arch form depends on the restorative situation. The tapering residual ridge arch form is favorable for anterior implants supporting posterior cantilevers. The square dental arch form is preferred when canine and posterior implants are used to support anterior teeth in either arch. The ovoid arch form has qualities of both tapered and square arches.

The arch form is a critical element when anterior implants are splinted together and support a posterior cantilever restoration. For these conditions, a square arch form provides a poorer prognosis than a tapered arch form. The A-P distance or A-P spread is the distance from the center of the most anterior implant to a line joining the distal aspect of the two most distal implants.[55,70] The distance provides an indication as to the amount of cantilever that can be reasonably planned. When five anterior implants in the mandible are used for prosthesis support, the cantilevered posterior section of the restoration should not exceed 2.5 times the A-P spread, when all patient force and stress factors are low. The actual length of the cantilever depends on implant position and on other stress factors, including parafunction, crown height, implant width, and number. In other words, the predominant factors to determine the cantilever length are related to stress and not the A-P distance.[45,46] For example, the distance between two implants supporting a cantilever (C) form a class I lever. For implants 10 mm apart and a 10-mm posterior cantilever, the following forces are applied: a 25-pound force on cantilever C results in a 25-pound force on the most anterior implant from the cantilever (A) and 50 pounds for the nearest implant to the cantilever (B), which acts as a fulcrum. An interimplant distance of 5 mm with the same 10-mm cantilever and a 25-pound force applied on C results in a 50-pound force on A and a 75-pound force on B. The diminution in the distance between implants significantly increases the forces to both implants, but in the first example if a patient with parafunction bites with a 250-pound force on C, the force on implant A is 250 pounds and the force on implant B is 500 pounds. In other words, parafunction is much more meaningful in terms of force than the interimplant distance when designing a cantilever. Therefore A-P distance is only one stress factor to evaluate for cantilever length. Parafunction, crown height, masticatory dynamics, arch position, opposing arch, direction of force, bone density, implant number, implant width, implant design, and A-P distance are all factors to be considered. When the force factors are low and the area factors (implant number, width, and design) are high, the cantilever length may be as much as 2.5 times the A-P distance.

As mentioned previously, anterior endosteal implants often may not be inserted in their ideal location in the maxilla as a result of labial plate resorption and inadequate bone width at the implant site. This not only requires implant placement more palatally compared with the original natural teeth, but it may also negate the lateral and central positions and require the use of the canine regions in more advanced atrophic arches. The resulting restoration is a fixed, anteriorly cantilevered prosthesis to restore the original arch form. Under these conditions, greater stresses are placed on the dentate tapered arch forms compared with dentate square arch forms, with all other factors identical. The maxillary anterior cantilever to replace teeth in a dentate-tapered arch form requires the support of additional implants of greater width and number to counteract the increase in lateral load and moment force. For example, not only are the canine implants necessary, but two more anterior additional implants are suggested, even if bone grafting is required before their placement. In addition, additional posterior implants in the first

to second molar region splinted to the most anterior implants are highly suggested. Therefore if a maxillary arch form requires this treatment approach, at least eight implants (four on each side) and an increased A-P distance from molar implants splinted to incisor implants is suggested. In the maxilla, the recommended anterior cantilever dimension is less than for the posterior cantilever in the mandible because of poor bone density and forces directed outside the arch during excursions.

Natural Teeth Adjacent to Implant Site

A common prosthetic axiom is to provide the partially edentulous patient with a fixed prosthesis whenever possible. Implant dentistry often may provide the additional abutments necessary to fulfill this goal, regardless of the number of teeth missing. The ability to add abutments in specific locations, rather than being limited to a particular remaining natural abutment that may not always be in optimum health, enables the dentist to expand this prosthetic axiom to most patients. The dentist may use implants as independent support for the restoration or rarely, along with natural teeth in the same prosthesis. In either situation, the treatment plan is strongly influenced by the dental evaluation of the remaining natural abutments adjacent to the edentulous site. Natural teeth may require additional therapy before the final prosthesis can be completed. It is best to communicate with the patient regarding all required treatment involved in the rehabilitation process before the surgical placement of the implants. Otherwise, treatment outcome sequences and cost may conflict with the originally projected result and lead to dissatisfaction, the need to modify the original treatment plan, or a poorer prognosis.

Whether considered for abutment support or not, teeth adjacent to a partially edentulous site are evaluated thoroughly and from a different perspective than the rest of the dentition. Often the adjacent tooth exhibits bone loss next to the edentulous site and presents a less than optimal quality of health. In addition, the available bone characteristics immediately adjacent to the tooth are highly influenced by its presence. Often this is a determining factor in the choice between an independent implant prosthesis, a

traditional FPD, or a removable restoration. When multiple teeth are missing, the treatment becomes even more complex with additional restorative options, such as whether implants and natural teeth may serve as abutments in the same prosthesis.

The dental criteria of the adjacent tooth to an edentulous space addressed in this section are outlined in Box 21.6, as well as important parameters to evaluate in considering implants and teeth in the same restoration. Additional considerations to help assess the restorability of teeth adjacent to potential implant sites appear in Box 21.7.

Abutment Options

Several options are available for the restoration of an edentulous segment. Under ideal conditions, placing implant abutments in sufficient number to fabricate a completely implant-supported prosthesis has several advantages. The most common cause of failure of tooth-supported fixed prostheses is caries of the abutment teeth.[71-73] Unrestored natural teeth do not decay as often as restored teeth, and implant abutments do not decay. The second most common cause of fixed prosthesis failure is endodontic failure or complications of a natural tooth abutment. Implant abutments do not need endodontic therapy. As a result, the 10-year survival rates indicate a greater than 25% improved survival rate for implant prosthesis compared with FPDs supported by natural teeth.[74,75] Natural teeth abutments compared with unrestored natural teeth are more difficult to clean, collect and retain more plaque, are often more temperature or contact sensitive, and are more subject to future prosthetic periodontal or endodontic treatment. Caries, endodontic problems, or both may cause not only a loss of the fixed prosthesis more than 25% of the time within 10 years, but they almost as often lead to the failure and extraction of at least one of the natural tooth abutments. As a result, an independent implant restoration is the treatment of choice for almost every multiple-tooth edentulous site in a partially edentulous patient.[76]

Natural teeth respond to occlusal forces differently than implants. A light force produces most of the recorded movement of a tooth, whereas the amplitude of implant movement is related directly to the force applied.[77-79] In arches with implant and natural abutments, it is easier to adjust two independent prostheses. When planning an independent implant prosthesis, instead of using a natural tooth as one of the terminal abutments, the dentist usually requires the addition of at least one more implant. An increase in implant abutment number enhances the implant–bone interface and therefore reduces the stress to the support system and improves the ability of the fixed restoration to withstand additional forces, when necessary. In addition, because of the additional retentive units, uncemented or unretained restorations occur with less frequency. Unretained restorations are the third most common complication reported in fixed prosthodontics.[73,74] Abutment screw loosening is a common complication reported for implant prostheses, especially during the first year.[43,80-86]

The increase in implant number also decreases the amount of forces on the abutment screws, thus the risk of abutment screw loosening; as a result, many reasons justify the use of a sufficient number of implants for an independent prosthesis. So many advantages exist for an independent implant-supported fixed prosthesis with multiple units that such a treatment is always the first choice when possible. Unfortunately, completely implant-supported fixed prostheses in partially edentulous patients are not always feasible and carry a higher surgical risk. Thus the natural tooth occasionally may be considered a potential abutment. However, the dentist

should consider splinting of implants and natural teeth within the same prosthesis only when the surface area of the implant support does not permit replacement of the total number of missing teeth and additional implant placement is not a possibility.

Adjacent Bone Anatomy

The edentulous bony structure adjacent to a natural tooth varies in height, width, length, and angulation and is a reflection of the history of the former tooth. If the ridge topography is not ideal for endosteal implant placement in the site immediately adjacent to the natural abutment, then the dentist should consider a bone graft or a pontic. An osteoplasty needed to obtain adequate bone width in the area adjacent to a natural tooth may compromise the adjacent natural root support, increase the crown height of the final restoration, and affect the esthetic outcome. Therefore osteoplasty to gain additional width is rarely indicated in this situation.

If an ideal prosthodontic abutment position is adjacent to a natural tooth and inadequate bone width is available, augmentation of the edentulous site before implant insertion may improve the bone anatomy without compromising the natural abutment. However, inadequate bone height adjacent to a tooth offers a poorer prognosis for augmentation than in other situations. In general, to grow bone in height is more difficult than to grow it in width. However, when the inadequate bone height of the edentulous site includes the region adjacent to a natural root, the ability to grow additional bone height becomes even more unpredictable and usually unsuccessful. Bone height augmentation is not predictable on a natural tooth root with a horizontal defect. If the natural tooth root has lost bone adjacent to the site, then the bone augmentation in height usually will not occur above the position of bone on the root. An alternative for inadequate bone height next to a natural tooth is orthodontic extrusion, along with the bone graft. The orthodontic movement will increase bone height next to the tooth and improve the bone graft prognosis. However, the tooth usually requires endodontics and restoration after the orthodontic process. An implant apically positioned more than 3 to 4 mm below the cement-enamel junction (CEJ) and interproximal bone level of the natural tooth root presents potential soft tissue contour problems (Fig. 21.23). The soft tissue between the tooth and implant creates a more shallow slope, unlike the steep drop of the level of the bony crest between the elements. Under these conditions, a soft tissue pocket greater than 6 mm may result in the implant crown adjacent to the natural tooth. Therefore when a bone graft for height in a multitooth edentulous site is required to place an implant adequately adjacent to a natural root, the dentist should consider a pontic to replace the missing element next to the natural tooth. The pontic may be supported by a cantilever from implants or teeth or using dual support from teeth and implants. In case of inadequate bone volume adjacent to a tooth, the dentist considers treatment options in this order: (1) graft the site if inadequate in width to permit division A or division B implant placement, (2) cantilever a pontic from two or more natural teeth or two or more division A implants, and (3) fabricate a fixed prosthesis with one pontic connecting an implant with one or two teeth, depending on the adjacent tooth status (Fig. 21.24).

Cantilevers

Cantilevers in fixed prostheses result in moment loads or torque on the abutments.[87-91] They are used more frequently for implant-supported prostheses than natural teeth abutments, and several widely diverging guidelines have been recommended for their use,
• **Fig. 21.23** Apically positioned implant. (A) Maxillary implant insertion well below the ideal position (i.e., 3 mm below the free gingival margin). (B) Implant positioned too apical leading to crestal bone loss and peri-implant disease.
• **Fig. 21.24** (A) When inadequate bone adjacent to a tooth can be grafted for implant placement and an independent prosthesis, this is the ideal treatment of choice. (B) When inadequate bone adjacent to a tooth cannot be grafted, one option is to cantilever the missing tooth from the anterior teeth or from posterior implants. The posterior implants permit the replacement of more than one tooth but require at least two implants in most situations. (C) When the inadequate bone adjacent to a tooth cannot be grafted, another option is to insert an implant more distal and make a three-unit fixed partial denture by connecting the implant to the nonmobile tooth. (D) When the inadequate bone adjacent to a tooth cannot be grafted and the tooth is slightly mobile, one option is to insert an implant more distal and make a four-unit fixed partial denture by connecting the implant to two anterior teeth (when the most anterior tooth is nonmobile).
● **Fig. 21.25** Implant cantilever. (A) Maxillary central incisor implant with cantilevered lateral incisor. (B) Because of excessive horizontal forces, the implant prosthesis fractured at the abutment level.

ranging from no extension at all to several teeth.[87-93] The force on the cantilever may be compared with a class I lever. The distance between the most anterior and most distal abutments is divided into the length of the cantilever to determine the mechanical advantage to the farthest abutment from the cantilever. For example, if the implants are 10 mm apart and a distal cantilever of 15 mm is present, then the mechanical advantage is 1.5 times. A 25-pound compressive load (chewing force) is magnified to a tensile load of 37.5 pounds on the most anterior abutment. The abutment closest to the cantilever acts as a fulcrum and receives the sum of the two loads, or a compressive load of 62.5 pounds.

The most common complication for a cantilevered restoration is uncementation of the abutment farthest from the cantilever. This occurs because cement is about 20 times weaker in tension compared with compression forces. For example, the compressive strength of zinc phosphate cement is 12,000 pounds per square inch (psi), but its tensile strength before fracture is only 500 psi. Takayama has suggested that the cantilever should not extend beyond the distance between the implants to keep the mechanical advantage less than one times this distance.[94] The most common distance between two implant centers is 7 to 8 mm (i.e., for a 4-mm diameter implant) so that the outer dimensions of the implants may be 3 mm apart and the crowns on the implants are similar in size to a premolar. Thus the size of the cantilever should not be greater than a premolar of similar size when two implants support the prosthesis. Ideally, if present, a cantilever should extend mesially, rather than distally, to reduce the amount of occlusal force on the lever.[95] The most important factor in determining the length of the cantilever is the amount of force the patient places on the cantilever. In other words, the amount of force generated against the cantilever is more critical than the other factors, including the cantilever length and mechanical advantage. In addition, an angled force is more detrimental than a force in the long axis of the abutments.

The crown height also influences the amount of the force on the cement and bone interface. As such, the cantilever magnifies

any other force factor presented; therefore it should be used with caution. When cantilevers are used in the final restoration, the occlusion on the cantilevered pontics should be reduced, with no contact on the pontic during mandibular excursions. Cantilevers on two implants should not be used when force factors are moderate to severe or when other force factors are present (Fig. 21.25). Instead, additional implants or grafting and implants positioned without cantilevers typically reduce complications.

Attaching Implants to Teeth

Before 1988, many practitioners connected an implant to one or two natural teeth. These implants were designed to have either a fibrous tissue or a direct bone interface. When the root form osseointegration concept of Brånemark for full arch edentulous fixed prostheses became more dominant in the mid-1980s, these implants came to be used in partially edentulous arches. It was hypothesized at the time that joining a rigid implant to a natural tooth would cause biomechanical complications on the implant, implant prosthesis, or both. Since that time, several reports have indicated that a rigid implant may be joined to a natural tooth in the same prosthesis.[96,97] In fact, implant-cantilevered prostheses in partial edentulous patients have more reported complications than when implants are joined to teeth. There are more partially edentulous patients missing posterior teeth than anterior teeth. As a result, the most common scenario for which a root form implant may be joined to a natural tooth is in the posterior regions. Of these cases, the most common scenario is as a terminal abutment in a patient missing the molars. For example, if a patient is missing the first and second molars in a quadrant (with no third molar present), then the segment requires at least two implants of proper size and design to independently restore these two teeth. If adequate bone exists in the second molar and distal half of the first molar but inadequate bone exists in the mesial half of the first molar, then a premolar-size pontic is required. The pontic may be cantilevered from the anterior natural teeth or the posterior implants. Either of
• **Fig. 21.26** Splinting a rigid implant to a natural tooth has caused concerns relative to the biomechanical differential in movement between the implant and tooth. Because the tooth moves more than the implant, the implant may receive a moment force created by the "cantilever" of the prosthesis.
• **Fig. 21.27** Three- or four-unit precious metal prosthesis with an implant and a posterior tooth rigidly splinted has some inherent movement. The implant moves apically 0 to 5 mm, and the tooth moves apically 8 to 28 mm but can rotate up to 75 mm toward the implant because of a moment force. The metal in the prosthesis can flex from 12 to 97 mm, depending on the length of the span and the width of the connecting joints. The abutment-to-implant component movement may be up to 60 mm because of abutment prosthetic screw flexure. As a result, a vertical load on the prosthesis creates little biomechanical risk when joined to a nonmobile tooth because of the design.

these options may result in complications because of tensile forces on the cement seal of the abutment farthest from the pontic.

The connection of natural teeth and osseointegrated implants within a single rigid prosthesis has generated concern in publications, with studies and guidelines for both extremes.

In other words, some articles report complications, but others state that no problem exists. To be more applicable to a particular
• **Fig. 21.28** Tooth and implant movement. Under normal conditions, the same force applied to a tooth and an implant results in the tooth moving significantly more (28 μm) compared with an implant (5 μm).

situation, more information is required to design a successful treatment plan. Two prosthetic designs are available for the connection of implants and teeth within the same prosthesis: a conventional FPD or an FPD with a nonrigid connector. To address this issue, the mobility of the natural abutment should be assessed (Figs. 21.26 and 21.27).

Etiology

The mobility of potential natural abutments influences the decision to join implants and teeth more than any other factor. In the implant-tooth rigid fixed prosthesis, five components may contribute movement to the system: the implant, the bone, the tooth, the prosthesis, and implant and prosthetic components.

Existing Tooth Mobility

The tooth exhibits normal physiologic movements in vertical, horizontal, and rotational directions. The amount of movement of a natural tooth is related to its surface area and root design. The number and length of the roots; their diameter, shape, and positions; and the health of the periodontal ligament primarily influence tooth mobility. A healthy tooth exhibits no clinical mobility in a vertical direction. Actual initial vertical tooth movement is about 28 μm and is the same for anterior and posterior teeth.[98] The immediate rebound of the tooth is about 7 μm and requires almost 4 hours for full recovery, so additional forces applied within 4 hours depress the tooth less than the original force.[78] The vertical movement of a rigid implant has been measured as 2 to 5 μm under a 10-pound force and is mostly attributable to the viscoelastic properties of the underlying bone (Fig. 21.28).[79] The implant movement is not as rapid as the tooth movement because the tooth movement is a consequence of the periodontal ligament, not the surrounding bone elasticity.

Horizontal tooth mobility is greater than vertical movement. A very light force (500 g) moves the tooth horizontally 56 to 108 μm (Fig. 21.29). The initial horizontal mobility of a healthy, nonmobile
• **Fig. 21.29** Horizontal movement of teeth. A healthy natural tooth may move laterally from 56 to 108 mm, with anterior teeth moving significantly more than posterior teeth.
• **Fig. 21.30** Teeth have a primary tooth movement related to a periodontal ligament. This accounts for the 28-μm apical and 56- to 108-μm lateral movement. They also have a delayed secondary mobility related to the viscoelastic nature of bone.
• **Fig. 21.31** Implant movement is more mesiodistal than faciolingual, reaching values between 40 and 115 μm.
• **Fig. 21.32** Bridge flexure is related to the cube of the span between abutments. (A) Whereas a one-pontic prosthesis may flex 12 μm, (B) a two-pontic prosthesis flexes up to 97 μm. (C) Therefore the flexure will further increase the biomechanical mismatch between the teeth and implants.

posterior tooth is less than that of an anterior tooth and ranges from 56 to 75 μm, which is two to nine times the vertical movement of the tooth. Initial horizontal mobility is even greater in anterior teeth and ranges from 90 to 108 μm in healthy teeth.

Muhlemann found that tooth movement may be divided into initial mobility and secondary movement.[77] The initial mobility is observed with a light force, occurs immediately, and is a consequence of the periodontal ligament. If an additional force is applied to the tooth, then a secondary movement is observed, which is related directly to the amount of force. The secondary tooth movement is related to the viscoelasticity of the bone and measures up to 40 μm under considerably greater force (Fig. 21.30). The secondary tooth movement is similar to implant movement.

Prosthesis Movement

A fixed prosthesis that connects a tooth and implant also illustrates movement. Studies have shown that with a 25-pound vertical force, a prosthesis with a 2-mm connector fabricated in noble metal results in a 12-μm movement for one pontic and 97-μm movement for a two pontic span (Fig. 21.31).[99] The FPD movement helps compensate for some difference in vertical mobility of a healthy tooth and implant.

Rangert and colleagues reported an in vitro study of a fixed prosthesis supported by one implant and one natural tooth and showed that the abutment or gold cylinder screw joint of the system also acts as a flexible element. The inherent flexibility matched the vertical mobility of the natural tooth. The minimal movement of the tooth and the fact that implant, prosthesis, and abutment components have some mobility indicate that the risk is small in the vertical direction, with the biomechanical difference of an implant and a tooth in the same prosthesis when one or two pontics separate these units.[100]

Implant Mobility

The implant–bone interface also exhibits lateral movement. Sekine and colleagues evaluated the movement of endosteal implants with rigid fixation and found a range of 12 to 66 μm of movement in the labiolingual direction.[79] Komiyama measured 40 to 115 μm of implant movement in the mesiodistal direction under a force of 2000 g (≈4.5 psi) and a labiolingual range of 11 to 66 mm (Fig. 21.32).[101] The greater implant movement in the mesiodistal dimension corresponds to the lack of cortical bone around the implants in this direction, compared with the thicker lateral cortical plates present in the labiolingual dimension. The mobility

Mobility characteristics under loading
• **Fig. 21.33** Sekine compared tooth movement with a gradual load over 2 seconds *(left)* with implant movement. The secondary tooth movement was similar to implant movement.

of implants varies in direct proportion to the load applied and the bone density, which reflects the elastic deformation of bone tissue.

Although the implant has a range of mobility, the mobility is related to the viscoelastic component of bone, not the physiologic aspect of a periodontal membrane. As such, when the implant and tooth are loaded in the same prosthesis, the tooth immediately moves (primary tooth movement), and then the tooth and implant move together. In other words, secondary tooth movement is similar to implant movement because they both depend on the viscoelasticity of the bone. In a study by Sekine and colleagues[79] when a tooth was gradually loaded over a 2-second period, the tooth immediately moved 36 μm and then gradually moved an additional 6 μm. The implant gradually loaded had movement directly related to the amount of load and eventually moved as much as 22 μm. The secondary tooth movement was similar to the implant movement (Fig. 21.33).

In summary, when all factors are considered, an implant moves vertically and horizontally, the abutments and prosthesis flex, and the tooth has apical and lateral movements. However, the major difference in movement between implants and teeth is more related to the direction of movement (the horizontal dimension is more compared with much less difference in the vertical dimension).

Guidelines for Joining Implants to Teeth

No Lateral Force on Prosthesis. To decrease biomechanical conditions, which increase the risk of complications, a requisite to join an implant to a natural tooth is that no lateral force should be designed on a unilateral prosthesis. Lateral forces increase the amount of tooth movement and decrease the amount of implant movement (faciolingual versus mesiodistal). Horizontal forces placed on an implant also magnify the amount of stress at the crestal bone region.

Natural Tooth with No Clinical Mobility

A vertical movement or force placed on a posterior implant joined to a healthy posterior tooth causes mesial tension on the implant.

The implant can move vertically 3 to 5 μm and mesially 40 to 115 μm, and a noble metal–fixed prosthesis with one pontic allows mesiodistal movement of 6 μm. A natural tooth with

no clinical mobility could be connected rigidly to an osseointegrated implant with no lateral forces because the implant, bone, and prosthesis compensate for the slight tooth movement. Finite element, photoelastic, and clinical documentation confirm that implants can be connected rigidly to stable teeth.[102] However, the occlusion should be modified to allow the initial occlusal contacts on the natural tooth so that the implant does not bear the major portion of the initial load.[103]

The lateral mobility of healthy anterior incisor teeth often is recorded as (+) with a range of movement from 90 to 108 μm. Visual clinical evaluation by the human eye can detect movement greater than 90 μm. When the horizontal mobility of a natural tooth (anterior or posterior) can be observed, mobility is greater than 90 μm and too great to be compensated by the implant, bone, and prosthesis movement.

When the vertical posterior tooth movement, vertical implant movement, mesiodistal implant movement, and prosthesis movement are compared with the same conditions of a "mobile" tooth with lateral loads, the biomechanical risk factors are not the same. One of the primary conditions for joining an implant to natural teeth is the lack of observable clinical movement of the natural abutment during functional movement. Nonmobile posterior teeth with no lateral forces on the prosthesis may join rigid implants. However, implants rarely should be connected to an individual anterior tooth because (1) anterior teeth exhibit more than 10-fold greater clinical mobility than the implant, and (2) the lateral forces applied to the restoration during mandibular excursions are transmitted to the natural tooth and implant abutments.

When the natural abutment exhibits clinical horizontal movement or conditions promote horizontal forces against the abutment tooth, two options can be selected for the final prosthesis. The first, and the option of choice, is to place additional implants and to avoid the inclusion of natural abutments in the final prosthesis. This may include the extraction of the mobile tooth and replacement with an implant. The other option is to improve stress distribution by splinting additional natural abutments until no clinical mobility of the splinted units is observed.

Rigid Connectors Are Contraindicated

Implants should not be joined to mobile teeth with rigid attachments, which basically adds a cantilever on the implant (the tooth acting as a living pontic). If the natural teeth are mobile in relation to the implant in the same prosthesis, several complications may occur that may be detrimental to the tooth and implant.

If the prosthesis is cemented, movement may break the cement–implant abutment seal. Cement does not adhere as well to titanium as to dentin. In addition, the mobile tooth will move (which decreases the impact force) rather than break the cement seal on the tooth. However, the rigid implant will have greater stresses applied to the cement (or screw)-retained crown. After the prosthesis is loose from the implant, greater stress is applied to the natural mobile tooth. The tooth may increase in mobility as a result or fracture as a consequence (especially when endodontic procedures were performed) (Fig. 21.34).

Nonrigid Connectors Are Contraindicated

A mobile attachment between the implant and natural tooth is usually not a benefit. A mobile attachment moves more than an implant or a tooth; therefore it is not an "attachment." The pontic is cantilevered from the implant with little to no support from the tooth. It is usually better to have a rigid connector between implants and teeth than a mobile attachment.
• **Fig. 21.34** Rigid connection implant. (A and B) Treatment plan involving connecting posterior implant-supported crowns to natural teeth. Ideally, the implants should be independent from the teeth.

Although nonrigid connectors have been advocated in the literature, a nonrigid connector in a unilateral prosthesis rarely is indicated for implant-fixed prostheses and may be detrimental.[104] Nonrigid connection does not improve the stress distribution between the different abutments and has been reported to have caused migration of the natural teeth.[105,106]

If the nonrigid connector exhibits any clinically observed mobility, it moves more than the implant. As such, the implant-supported part of the restoration is cantilevered to the attachment. In addition, the nonrigid (or mobile) attachment adds cost, creates over contoured abutments, impairs daily hygiene, and does not decrease the clinical tooth movement.

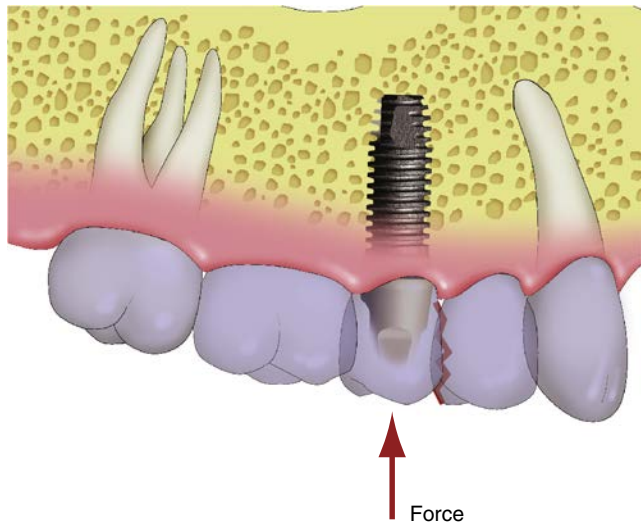
Prevent Tooth Intrusion. When implants are joined to teeth that act as a terminal abutment, a definitive cement should be used for the natural tooth. The tooth cannot intrude unless it becomes unretained from the abutment (or has a nonrigid connector between the units).

Reports of intrusion of the natural tooth connected to an implant usually include the use of temporary cement to lute a coping to the natural abutment, leaving the final restoration uncemented on the coping, or the use of a nonrigid connector.[107]

A possible explanation for tooth intrusion may be that the tooth is pushed vertically 28 μm but wants to rebound only 8 μm. The fixed prosthesis rebounds immediately and pulls on the tooth. The cement seal eventually breaks, causing a space to develop, which is first occupied by air. The prosthesis then acts as an orthodontic appliance and continually pushes the tooth in a vertical direction. Eventually, the space is occupied by saliva, and hydraulics continue the downward force during mastication. The tooth eventually submerges or intrudes from the prosthesis.

Ideal, Favorable Conditions. An alternative may be to join the implant(s) to a natural tooth if all other factors are favorable. This treatment option is more likely in the presence of a division C–h ridge in the pontic region when inadequate bone height adjacent to the natural tooth decreases the prognosis of a vertical bone graft. This option is also available when a posterior implant is positioned too distal to restore with a single crown. It is almost always better to splint the implant to the adjacent tooth rather than fabricating a cantilevered crown from one implant, especially when parafunction is present.

Pier (Intermediary) Abutments

A pier abutment is one between two other abutments, sometimes referred to as intermediate abutment. The intermediate abutment may be an implant or a natural tooth, and each type plays a different
• **Fig. 21.35** (A) When an implant acts as a pier abutment, the biomechanical risk of uncemented restorations is increased, especially under lateral loads. The more rigid implant may act as the fulcrum of a class I lever. The cement seal breaks on the more rigid tooth or the least retentive abutment. (B) This implant was overloaded and failed because the cement seal broke on the natural tooth. The compressive force on the pontic led to a tensile force on the tooth, and the implant acted as a fulcrum. Cement is 10 times weaker under tension. After the cement seal broke from the tooth, all the loads were applied to the implant only, which then failed from overload.
• **Fig. 21.36** Ideal option is to graft the sites and place implants in terminal abutment locations and to fabricate an independent prosthesis.


• **Fig. 21.37** When grafting and additional implants are not an option, an attachment should not be used to simulate the movement of the tooth.

role in the overall treatment. When an implant serves as a pier abutment between two natural teeth, the difference in movement between implant and tooth may increase the complication rate compared with one tooth joined to two implants. The pier implant exhibits less movement than a terminal abutment and acts as the fulcrum of a class I lever (Fig. 21.35). This problem is magnified by a longer lever arm such as a pontic between the implant and tooth. A pier implant abutment may cause complications even when joined to nonmobile teeth as terminal abutments. The cement tensile strength is often 20 or more times less than the compressive strength. Therefore when the implant acts as a fulcrum, an uncemented abutment (usually the least mobile tooth or least retentive crown) is a common consequence, with decay being the next most common occurrence. Uncemented restorations are a common complication in FPDs, even when all aspects of treatment are within acceptable limits. Any condition that may increase this problem, such as the one presently addressed, should be carefully avoided. For most clinical situations, an additional implant can be placed in at least one of the sites next to a tooth to provide the support needed to fabricate an independent, cantilevered, implant-supported prosthesis. The better option is to perform bone grafting, place implants in both terminal abutment locations next to the natural teeth, and avoid connecting implants to teeth (Fig. 21.36).When bone grafting is not an option and additional implants cannot be inserted, a mobile attachment can be used to restore the

• **Fig. 21.38** When a natural tooth serves as a pier abutment between two or more implants, the tooth may act as a living pontic. No stress breaker is needed in this situation.

implant pier abutment between two natural nonmobile teeth (Fig. 21.37). The nonrigid attachment may connect the implant and the least retentive crown to prevent the implant pier abutment from acting as a fulcrum. In conventional fixed prostheses, the "male" portion of a nonrigid attachment usually is located on the mesial aspect of the posterior pontic, whereas the "female" portion is in the distal aspect of the natural pier abutment tooth. This prevents mesial drift from unseating the attachment.[108] However, an implant does not undergo mesial drifting, and the nonrigid connector location is more flexible. When a natural tooth rather than an implant serves as a pier abutment between two or more implants, the situation is completely different from the previous scenario. When the two or more implants may support the load of the prosthesis alone, the natural tooth becomes a living pontic. In other words, in absence of the tooth, the dental unit would be a pontic. Because the tooth has greater mobility than the implant and does little to contribute to the support of the prosthetic load, it is referred to as a pontic with a root, or a living pontic (no more than one adjacent site should be a pontic) (Fig. 21.38). This scenario is best when no additional pontics are between the implants and the tooth. On occasion, multiple implants are splinted together to cantilever one or two pontics, yet a healthy, natural tooth is positioned among the implants. The tooth essentially is ignored in the development of the treatment plan, other than the dentist having to fabricate a crown rather than a pontic in the splinted prosthesis. For a natural pier abutment between two implants, a stress breaker is not indicated. One advantage of keeping the natural tooth, even though it does not contribute to the support of the prosthesis, is the proprioceptive aspect of the periodontal complex.[97-109] Implant prostheses have higher bite forces during mastication than natural tooth restorations because of the decrease in occlusal awareness. A living pontic may decrease the interaction of the forces found during function.

Natural Abutment Evaluation

The evaluation of a potential abutment adjacent to an edentulous site includes the following: (1) abutment size, (2) crown/root (implant) ratio, (3) tooth position, (4) parallelism, (5) caries, (6) root configuration, (7) root surface area, (8) endodontic status, and (9) periodontal status.

Abutment Size

Uncemented restorations are one of the most common complication of fixed prostheses.[71-73] After the crown on the natural abutment becomes uncemented, a significant concern is caries. Decay

may proceed rapidly and result in loss of the abutment, creating a need for endodontic treatment, post and core, a new prosthesis, or an abutment with even poorer retention. These same conditions exist if the natural retainer becomes uncemented from an implant-tooth restoration. In addition, the implant is at greater risk. The fixed prosthesis then acts as a cantilever with a dramatic increase in moment force on the implant. Crestal bone loss, prosthesis or abutment screw fracture, implant fracture, or mobility and failure of the implant are likely complications. When natural and implant abutments are combined in the same prosthesis, uncementation occurs more frequently on the implant. Tooth mobility fatigues the cement seal and increases the forces on the implant. The parameters of retention are similar for a tooth or implant and mainly are influenced by the diameter and height of the abutment.[110-112] Molars are more retentive than premolars because of their increased surface area, with all other factors being equal. Wider implant abutments are more retentive than narrower ones. Limited crown height because of limited interarch space also decreases retention. Splinting of teeth with limited crown height to improve retention often compromises access for hygiene in the interproximal areas. Instead, crown lengthening is often indicated in case of limited interarch space to improve the retention of the prosthesis and the esthetic result without compromising home care. A customized abutment of larger diameter can be used on an implant abutment of reduced height. Crowns of reduced size require minimal tapering and additional retentive elements, such as grooves or boxes to limit the path of insertion and direction of dislodgment.[111-113]

Crown/Root Ratio

The crown/root ratio represents the height of the crown from the most incisal or occlusal position to the crest of the alveolar ridge around the tooth compared with the height of the root within the bone. This criterion is most important when lateral forces are expected against the crown, as in mandibular excursions. The lateral forces act as a class I lever on the tooth, with the fulcrum at the crest of the bone. As the crown height increases, the root height decreases, creating a force multiplier.

The crown/root ratio is indicative of the risk of mobility and amount of additional stress the tooth may sustain when used as an FPD abutment. A patient with a history of periodontal disease may show an increased crown/root ratio, yet no abutment mobility. However, the long-term risk of mobility is increased if the tooth is used as an abutment for a prosthesis. Lateral forces are most detrimental in this situation because of the increased moment force. Splinting may be indicated to distribute stress, and occlusal schemes must be modified to protect these abutments from horizontal stresses.[114] The most ideal crown/root ratio for a fixed prosthetic abutment is 1:2, but this is rarely observed. A more common condition is 1:1.5, and a 1:1 ratio is the minimum requirement when opposing natural teeth or implants and when serving as an abutment for an implant-tooth prosthesis.[115] In addition, the doctor and patient must realize that teeth with an increased crown/root ratio often are restored with an FP-2 or an FP-3 prosthesis. A high lip line during smiling and low lip line during speech should be evaluated carefully to determine the prosthetic design. Crown/implant ratio is not considered in a similar way as a crown/root ratio. The implant does not rotate around a center located two thirds down the endosteal/root portion, as does a tooth. Instead, it captures the force at the crest of the ridge. The implant length does not affect its mobility and does not affect its resistance to a lateral force. Although a minimum

height requirement does exist and approaches 9 mm, implants greater than 12 mm in healed bone sites do not demonstrate clinical benefit. This is not to say crown height is not important. Crown height is a vertical cantilever on a tooth or implant and will magnify angled, lateral, or cantilever forces. However, the effect of crown height cannot be reduced by increasing the length of the implant. Instead, the dentist should consider reduced cantilever lengths or reduction of angled forces on the prosthesis.

Tooth Position

The dentist considers tooth position next to the edentulous site, including whether the tooth is in the anterior region of the mouth, the intermediate position, or the posterior region. Regardless of arch position, some considerations remain similar. When the natural tooth adjacent to the implant site is in the anterior region, greater mobility and often lateral directions of force are present. Therefore under these conditions the implant is rarely connected to a natural tooth as a terminal abutment. The most common situation in which an implant may be connected rigidly to a natural tooth as a terminal abutment is in a posterior edentulous site with a second or first premolar adjacent to the potential implant site.

The bone adjacent to a natural tooth often is compromised, especially in the long-term edentulous Kennedy-Applegate class I or class II patient. Under these conditions, the edentulous site is often deficient in width and height. As previously mentioned, bone grafting in width is much more predictable than height, especially in the posterior mandibular regions. A sinus graft may provide adequate height of bone for endosteal implants in the posterior maxilla, but onlay grafts on the posterior mandible are much less predictable, and nerve repositioning before implant placement is fraught with potential complications. Bone width augmentation is an usual treatment plan, and bone grafting for height in the posterior maxilla has become a routine procedure, but the posterior mandible is less often a candidate for height augmentation, unless block grafts or more advanced grafting techniques are selected.

When adjacent teeth have been missing for a long time period, the remaining natural abutment often has drifted from its ideal position and frequently exhibits tipping, tilting, rotation, or extrusion. The dentist should consider correction of the natural abutment position in the original treatment plan for the partially edentulous patient, whether or not the natural abutment is joined to the implant. A good habit to utilize is to evaluate and correct any dental unit that will contact the new restoration. Enameloplasty to improve the occlusion or change the contact shape and position next to the implant prosthesis is not unusual. The path of insertion of the implant prosthesis and the size and shape of the interproximal space also may require modification. Treatment also may consist of a crown when beyond the ability merely to reshape the tooth. Orthodontic movement to correct interarch or gross occlusal correction, especially when skeletal patterns require improvement, may be indicated. One can plan orthodontic treatment along with the healing phase for rigid fixated implants. One also may use orthodontic treatment to develop available bone for an implant next to a natural tooth. Moving the tooth slowly through the bone to a more remote position generates bone growth and an improved implant site.

Parallelism

As previously discussed, clinical movement can be eliminated by splinting natural abutments. As such, splinting mandibular incisors is more common in implant dentistry than traditional

prosthodontics. These teeth often are crowded or rotated. In addition, the path of insertion of a prosthesis that includes anterior and posterior dental units often requires more extensive tooth preparation. Some of the indications for attachments in a fixed or removable partial denture include joining nonparallel teeth or splinting anterior and posterior teeth in the same prosthesis. The attachment should usually be rigid in design, size, and fabrication. All of these factors limit the path of insertion of the final prosthesis. Several abutments may need endodontic therapy to achieve this goal. If this is not explained to the patient before treatment begins and endodontic therapy is required, the patient often feels that inadequate treatment has been rendered.

Endodontic therapy or posts and crowns for overlapping anteriors still may provide inadequate embrasures for hygiene. This condition not only compromises esthetics but also may result in the loss of more than one tooth because of periodontal disease. Selective extraction of incisors may even be indicated if rotations or overlapping of teeth create an unfavorable environment for daily maintenance.[116]

Caries

The dentist should eliminate all carious lesions before implant placement, even when the teeth will be restored with crowns after implant healing for the final prosthesis. Rigidly fixated implants usually require several months of healing after initial placement. The progression of the decay may alter the final treatment plan, with a decrease in crown retention and increased risk for endodontic therapy, posts, cores, or even loss of a desired abutment. Should endodontic therapy be indicated, the obturation of the canals ideally should be completed before implant surgery to avoid possible confusion in the differential diagnosis, if both treatments were overlapping in time and location. If caries are eliminated at the same time as implant surgery, then elimination of caries should be performed before reflection of any tissue.

Root Configuration

The natural root configuration may affect the amount of additional stress the tooth may withstand without potential complications.[116] Tapered or fused roots and blunted apexes are examples of decreased ability to withstand the additional occlusal loads required for a fixed prosthesis. The maxillary second molar often presents these varied root configurations. Additional implants and independent implant-supported restorations usually are indicated in the presence of these conditions, rather than the use of these teeth as terminal abutments. Root dilaceration or curvatures improve the support quality of an abutment tooth. However, such root morphology also is likely to encroach on the adjacent available bone volume and increase the risk of implant placement. This is exemplified best in the maxillary canine and first premolar region. The canine presents a distal angulation of 11 degrees and has a distal root curvature in 60% of the cases. As such, the first premolar edentulous site is limited. An implant inserted into this site usually should be shorter and should follow the angulation of the canine rather than that of the second premolar. The dentist must evaluate carefully any adjacent natural tooth with curved roots at the apex before implant placement.

Roots with a circular cross section do not represent as good a prosthodontic abutment as those with an ovoid cross section. Therefore the maxillary premolar is a better abutment than the maxillary central incisor, although their root surface areas are similar.[111] The maxillary lateral incisor may exhibit less lateral mobility than the central incisor as a result of its cross-sectional anatomy.[78]

All these factors from traditional prosthodontics are also part of the implant candidate's dental evaluation.

Root Surface Area

In general, the greater the root surface area of a proposed abutment tooth, the greater is the prosthetic support. Posterior teeth provide greater periodontal surface area and greater support than anterior teeth. Teeth affected by periodontal disease lose surface area and represent poorer support elements for a prosthesis. For a maxillary first molar, bone loss to the beginning of the root furcation corresponds to a root surface area loss of 30%.[117] Ante's law requires the root surface area of the abutment teeth to be equal to or greater than that of the teeth replaced by the pontics of the fixed restoration.[118] Although empirical at its inception, Ante's law has withstood the test of time and still serves as a clinical guideline.

Endodontic Evaluation

The natural abutment adjacent to or included in a combined tooth and implant-supported prosthesis should present a healthy pulpal status or successful endodontic treatment. If the pulpal or endodontic status of an abutment is questionable, then the prudent treatment is endodontic therapy. In this way, the abutment crown may be evaluated for retention, for need for post and core, and for any other related criteria before final prosthodontic treatment. Potential lesions of endodontic origin are evaluated best before implant surgery because an exacerbation of the lesion during early implant healing may result in a pathway of destruction to the adjacent implant site, implant failure, and extensive bone loss.

In the literature, success has been reported as low as 47% to as high as 98%. However, most studies report success in the range of 85% to 90% at 5 or more years.[117,119,120] As such, when endodontic treatment has a good prognosis and the tooth may be restored adequately, root canal treatment is in order. However, a number of implant failures each year are attributed to adjacent tooth endodontic failure. At first, this may seem contradictory. Implant healing failures are rare in most practices and account for less than 2% of implants inserted, when using a classic two-step approach. However, when these 2% failures are evaluated, a large number of failures occur next to natural teeth that had an endodontic complication during early implant healing.

Assessment of endodontic success before implant surgery often is difficult.[121-123] The patient may be symptom free, yet a low-grade infection is present at the apex. The healing implant interface is more prone to complications with such a tooth having this condition because the healing interface is weaker than the previous bone condition and a pathway may exist to the developing implant interface. If a tooth is asymptomatic, but has a past endodontic treatment and periapical radiolucency, consideration should be given to retreatment or extraction. When the periapical lesion is 5 mm or greater, the success of endodontic retreatment is not predictable. During the treatment planning phase, teeth adjacent to the edentulous segment should be scrutinized for potential endodontic problems, keeping in mind that the preparation of a tooth for a crown has a 3% to 6% risk of pulpal death as a consequence of the procedure. In addition, past periodontally involved teeth are at greater risk of pulpal disease after tooth preparation.

Periodontal Status

The periodontal evaluation of natural abutments to be connected to implants is identical to the evaluation of other FPD abutments. Special attention may be directed to the adjacent implant site, which may be contaminated by bacteria during periodontal

• **Fig. 21.39** Removable "treatment" prosthesis (A and B) To determine the ideal soft tissue profile, esthetics and jaw relationship, a temporary removable prosthesis may be used. Note how the facial flanges have been modified to reduced facial soft tissue profile.

surgery. The incision line and flap design for implant placement often includes the abutment teeth. The implant surgeon should decide whether periodontal therapy is indicated on the abutment teeth before or at the same time as implant placement. A reduction in the number of surgical procedures is a noteworthy benefit to the patient; however, active infection should be minimized during implant placement. Therefore the pathologic condition of the abutment teeth most often is addressed before the soft tissue reflection in the region of the implant osteotomy. Dental prophylaxis and oral hygiene considerations are usually scheduled before implant surgery. The use of 0.12% chlorhexidine to reduce the bacterial count is most beneficial.

In summary, a completely implant-supported prosthesis is desirable, independent of the natural teeth. Grafting the edentulous site or the use of additional implants is the usually treatment of choice. However, when insufficient implant support is available, the natural teeth may be considered as potential abutments. The most important natural tooth criterion for implant-tooth–supported restorations is tooth mobility. A clinical assessment of zero mobility often allows a rigid connection between the tooth and implant. However, if mobility is present, the practitioner should design the prosthesis to include more natural abutments and return the dental elements to zero mobility or consider an independent implant restoration. Splinting natural teeth is the usual method to reduce mobility.

Several additional factors are critical for dual implant-tooth support of a fixed prosthesis: crown size, crown/root ratio, tooth position, parallelism, caries, root configuration, root surface area, endodontics, and periodontal status. Although these same criteria are important for any fixed restoration, each presents unique aspects in implant- and tooth-supported prostheses.

Soft Tissue Support

The evaluation of the soft tissue support is a primary concern when evaluating potential implant sites. Of utmost importance is the soft tissue support when planning an RP-5 overdenture prostheses (i.e., gains primary support from the soft tissue and secondary support from the implants). The following factors need to be evaluated: ridge shape, size, parallelism, and palate shape. Large ridge forms with minimal resorption provide a better support than smaller ridge forms with greater atrophy, in either the maxilla or mandible (Fig. 21.39).

Prosthesis support depends on the shape of the residual ridge and, in the maxilla, the palatal vault. A square ridge form yields optimal resistance and stability. A relatively flat one represents a compromised factor for retention and stability, although support is still adequate. Tapering ridges on the palatal vault usually equate with poor stability.[124-126] Ridge parallelism is also evaluated. The edentulous ridge parallel to the occlusal plane is most favorable for soft tissue support. If ridges are divergent, stability of the denture will be greatly affected.

The lateral throat form in patients with a maxillary denture or RP-5 restoration should be evaluated. A soft palate slope is favorable when it has a long, gradual slope from the junction of the hard and soft palate,[127] which allows a greater extension of the posterior palatal seal and enhances retention. On the other hand, a soft palate class III, which drops abruptly, may lead to soreness, loss of valve seal, and gagging. These elements are of great diagnostic value in the evaluation of the maxillary fully edentulous patient who may consider an implant-supported overdenture. A greater number of unfavorable anatomic structures may direct the treatment plan toward an RP-4 prosthesis with greater implant support and no soft tissue support to address all the needs of the patient. It must be emphasized to the patient that a partial or total soft tissue–borne prosthesis will not stabilize bone loss. In contrast, bone loss will continue and may even be accelerated because the prosthesis is more often worn and bite forces are increased. As a result, all soft tissue–borne prostheses should be considered transitional dentures. Most of these prostheses require repeated relines, rebasing, and refabrication to replace the missing bone. A totally implant-supported prosthesis (fixed or removable) does not require soft tissue support and may be considered a definitive restoration.

Many soft tissue–supported restorations are fabricated because the patient cannot afford a totally implant-supported prosthesis especially in the completely edentulous patient. However, the clinician often forgets that if a patient cannot afford the ideal treatment today, it does not mean the patient cannot afford any further treatment later. For example, if a patient requires four first molars replaced, but cannot afford all restorations at this time, the doctor most often can still restore one of the molars. Then a few years later the next tooth may be restored. Eventually, the four molars are treated and the arch form and occlusion restored. In similar fashion, a patient who can afford only two implants to retain a

mandibular denture could possibly afford further treatment later. Therefore a lifetime strategy for health should be established, which may include the addition of more implants in the future to reduce and eventually halt the continued bone loss and consequences on esthetics and function.

Pretreatment Prostheses

Fixed Treatment Prostheses

Pretreatment prostheses in implant dentistry are often indicated to obtain a diagnosis, improve soft tissue health before fabricating soft tissue–borne restorations, reestablish or confirm the vertical dimension, evaluate esthetic considerations, or treat TMJ dysfunction (Fig. 21.40). In addition, the pretreatment prosthesis may be used to select a prosthetic option, to progressively load bone to improve its strength, and as a transitional restoration to protect a healing bone graft or implant. Immediate loading of an implant system often uses a transitional prosthesis out of occlusion in a partial edentulous situation. In the completely edentulous immediate load restoration, the transitional prosthesis has no cantilevers in nonesthetic areas.

Treatment prostheses may also help evaluate the psychological attitude of a patient before irreversible implant procedures (Box 21.8).

Diagnosis in medicine is the first step to establishing a treatment for a disease or disorder. Likewise, to establish a treatment plan for a partially or completely edentulous patient, a proper diagnosis should be established. A treatment prosthesis may be required to help in this process. For example, questionable teeth may require initial restoration to assess their prognosis related to whether or not the extraction of the tooth and implant replacement therapy is required. A treatment prosthesis may correct the existing occlusal plane, identify extruded teeth, and indicate whether endodontic therapy, crown lengthening, or extraction is required to complete the final treatment plan. Remember, after prosthetic crown lengthening is performed, usually at least 4 mm of tooth structure is supracrestal (2 mm for connective tissue and junctional epithelial attachment and 2 mm to create a ferrule effect with the crown to reduce the risk of root fracture). Also, the crown/root ratio is increased and the mobility of the tooth should be evaluated. Excessive mobility may require additional implants, splinting teeth, or even extraction and additional implant insertion. A long-span partially edentulous patient often wears a fixed-treatment prosthesis, which also acts as an interim prosthesis. Metal-reinforced transitional prostheses may be used when four or five pontics are present. These fixed, transitional treatment prostheses may be used during bone grafts or healing of implants to decrease forces on the soft tissues and on the graft or healing implants.

Removable Treatment Prostheses

Treatment prostheses may be used to improve the soft tissues used for support, stability, or retention before RP-5 overdenture or complete denture restorative procedures. The first evidence of residual ridge destruction by an ill-fitting denture is often deformed and traumatized overlying soft tissue.[128] The soft tissue bed may exhibit different degrees of redundant hyperplasia, epulis, hypertrophy, or abrasions.[129,130] A tissue conditioning treatment is usually indicated to restore soft tissue health before making the final impression for the soft tissue bone prosthesis. The soft tissue conditioner may need to be replaced every 2 to 3 days, although 10 to 14 days are usually sufficient to return the soft tissue to normal condition. The existing denture can often be used as the treatment prosthesis. Additional treatment such as surgical removal of excessive hypermobile tissues is often warranted before soft tissue conditioning.

It should be noted that soft tissue conditioners are different from soft liners used in soft tissue support areas of removable prostheses. Tissue conditioners usually change dimensions during the first 18 to 24 hours. As such, as the tissues return to a more normal condition,
• **Fig. 21.41** Polymethylmethacrylate prosthesis (PMMA). (A) From a diagnostic wax-up or scan of an interim prosthesis, a PMMA prosthesis is milled. (B) Prosthesis polishing. (C) Staining of the prosthesis. (D–F) Final interim PMMA prosthesis.

the material changes dimension to allow and encourage these changes. However, many tissue conditioners contain modifiers required for this reaction leach out of the material, halt the process within a day, and result in a stiff material. Soft liners, on the other hand, stay soft longer than tissue conditioners, especially when coated with a sealer. However, the material does not change dimension during the first day and therefore will not accommodate a changing tissue condition.

Most often, tissue conditioners are used to improve abused tissues before a final soft tissue impression for a removable prosthesis. In addition, these materials are used after implant surgery in regions under a removable prosthesis, while the implant–bone interface heals. The tissue conditioner may respond to the swelling and tissue changes immediately after soft tissue reflection. In

addition, it is relieved over the implant site. At the suture removal appointment, the tissue conditioner is removed and replaced with a sealed soft liner. This material remains soft during extended periods and is less likely to load the implant through the soft tissue.

Postimplant Placement Transitional Prosthesis

Usually for full arch prostheses, a transitional prosthesis maybe fabricated to function as a long-term provisional prosthesis. The most common transitional prosthesis is made of polymethylmethacrylate (PMMA). Because of advanced innovations in dental computer-aided design (CAD)/computer-aided manufacturing (CAM) technology, these prostheses can now be milled from a single block of

Fig. 21.41, cont'd (G) Intraoral insertion. (H) Occlusion verified. (I) Patient wears prosthesis to determine ideal esthetics, occlusion, and vertical dimension.

---

material, resulting in a strong, durable, and esthetic provisional that is resistant to wear, fracture, and staining. The patient may then adapt to the prosthesis with emphasis on the esthetics, occlusion, and vertical dimension before the completion of the final prosthesis (Fig. 21.41; Box 21.9). In addition, these type of prostheses allow the patient and clinician the latitude to determine if any changes such as vertical dimension, occlusion, esthetics, and soft tissue profile require changes to be made in final prosthesis.

Occlusal Vertical Dimension

Long-term edentulous patients who have been wearing the same denture may require a treatment prosthesis to restore the OVD and ridge relationship before implant treatment.[131] The OVD may gradually collapse, especially in the completely edentulous patient, as a result of continued bone loss and prosthesis occlusal wear. TMJ and myofascial dysfunction may be the further consequence of this condition. A treatment prosthesis to reestablish the proper OVD or assess a symptomatic joint helps determine the patient's specific needs regarding the dysfunction.

As the OVD decreases, the mandibular jaw rotates forward and closes in a more prognathic pseudo–class III relationship. To place the implants in the correct angulation, the OVD should be reestablished before implant surgery so the correct position of the teeth relative to the arch is established. In the case of immediate implant loading, a treatment prosthesis is delivered at or soon after the implant surgery. The design of the prosthetic superstructure concomitant with the implant substructure is necessary for immediate loading in implant overdentures. Therefore a treatment prosthesis is indicated to establish the proper OVD and tooth position before the placement of the implants and fabrication of the superstructure bar.

As the OVD increases, the maxillomandibular relationship evolves toward a class II relationship. This influences the position or angulation of the implant. In addition, the location of an overdenture bar may be equally influenced by variations of the OVD. The treatment prosthesis may be used to establish prosthetic position of teeth.

If a PMMA was prosthesis cannot be utilized, an alternative if for the placement of a conventional removable prosthesis. This type of prosthesis is most likely fabricated with acrylic teeth to facilitate recontouring and the addition of cold-cured acrylic for repairs or to change the OVD or lip support.

Esthetic Assessment

On occasion, a patient's desire for esthetic improvement may be very demanding or unrealistic. In the completely edentulous patient, a treatment denture (partial or complete) may be used to satisfy those esthetic concerns before implant surgery. Tooth

shape, surface quality, size and position, tooth color, lip and soft tissue contour, tooth position, gingival color, soft tissue contour, and papilla support may all be evaluated. If the patient cannot be satisfied with the pretreatment prosthesis, it is far better to realize this before implant placement or final prosthesis insertion. Although demanding patients may not be satisfied with the pretreatment prosthesis, they can decide to lower expectations and continue with treatment or be referred to another dentist. If the latter is chosen, it is prudent to contact the next practitioner and inform them that another pretreatment prosthesis is indicated before implant placement.

A high lip line in the maxilla or low lip line position in the mandible may influence the need for a specific gingival contour and color in the restoration, yet the maintenance needs of the restoration may compromise the final esthetic result. A fixed restoration must be designed to allow access for proper hygiene procedures around the teeth and implants. A pretreatment prosthesis may help determine whether an implant-supported removable prosthesis rather than a fixed restoration is required to satisfy the patient's esthetic goals and desires for the restoration, yet may be removed to allow proper daily maintenance. The maxillary vermilion border of this lip is usually altered by the loss of the maxillary anterior teeth. After bone is also lost, the natural support of the entire lip is often deficient and is dependent on the labial flange of the prosthesis. An FPD may require an anterior cantilever away from the soft tissue in a horizontal and vertical dimension to provide this support. A pretreatment prosthesis can provide the information required to determine whether a fixed prosthesis will compromise esthetics, support, or hygiene in this region above the teeth.

Another advantage of a transitional prosthesis is the ability to progressively load the implants. A prosthesis to improve the quality of bone is most always used in D3 or D4 bone-supporting implants before the fabrication of the final restoration. Interim (provisional) acrylic restorations that gradually load bone for progressive loading may be considered pretreatment prostheses. A decrease in crestal bone loss and decrease in implant failure, especially in soft bone types, are particular advantages with progressively loaded treatment prostheses. Pretreatment prostheses also assist in the determination of the final form and function of the final prosthesis, especially for completely edentulous patients. "Pretreatment" prosthesis may be the first full arch–fixed restoration they have worn after several years of wearing a complete denture, thereby allowing an easier transition period.

Summary

Preimplant prosthodontics for partial or fully edentulous patients include overall evaluation of five intraoral segments: (1) the maxillary incisal edge, (2) the OVD, (3) the mandibular incisor edge, (4) the maxillary occlusal plane, and the (5) mandibular occlusal plane.

In addition, there are 10 specific criteria that affect a treatment plan: (1) lip lines, (2) maxillomandibular relationships, (3) existing occlusion, (4) CHS, (5) TMJ status, (6) extraction of hopeless or guarded-prognosis teeth, (7) existing prosthesis, (8) arch form, (9) natural tooth adjacent to an edentulous space, and (10) soft tissue evaluation. Pretreatment prostheses are also used in an implant prosthetic evaluation process.

The prosthodontic evaluation of the implant candidate borrows several conventional criteria from the evaluation of natural abutments. In addition, many of these situations require a unique approach for implant prosthodontics and may influence the implant treatment plan. The goal of the implant surgeon is to achieve

predictable, rigid fixation of endosteal implants. The restoring dentist's responsibility is to maintain the implant–bone interface in an environment that satisfies all the traditional prosthodontic criteria.

Single and Multiple Tooth Replacement: Treatment Options

RANDOLPH R. RESNIK AND NEIL I. PARK

The introduction of the dental implant has greatly expanded the scope of services that clinicians can provide to restore dental patients to optimal form, function, and esthetics. Patients with missing teeth or pathology that necessitate tooth extraction now have numerous treatment options beyond fixed bridges or removable prosthetics. The progressive loss of bone as a consequence of tooth extraction can now be minimized. Implant technology has allowed practitioners to come much closer to the ideal goal of assisting patients with attaining or retaining dental health.

Clinicians are often confronted with patients with either an edentulous condition or a pathology that necessitates tooth removal. The clinician has an ethical and legal obligation to educate the patient as to the advantages and disadvantages of every therapeutic option available to restore the patient back to dental health.

The goal of this chapter is to provide clinicians with a comprehensive treatment protocol for common edentulous conditions, including advantages and disadvantages of each. By informing the patient of each option available (including no treatment), the dental professional can aid the patient in forming an educated choice for treatment that meets his or her needs and values.

Tooth Replacement

In the United States, 70% of the dentate population is missing at least one tooth. Single-tooth replacement will most likely comprise a larger percentage of prosthetic dentistry in the future, compared with past generations. In 1960 the average American older than 55 years had just seven original teeth. Currently, the average 65-year-old has 18 natural teeth, and baby boomers (those born between 1946 and 1964) can expect to have at least 24 natural teeth when they reach 65 years of age[1] (Fig. 22.1).

When evaluating options for tooth replacements, it is prudent of the clinician to use evidence-based medicine, which consists of conscientious, explicit, and judicious use of the best literature and research in making decisions concerning the care of individual patients. Over the years researchers have observed that external clinical evidence would both invalidate previously accepted treatment and allow replacement with new modalities that are more

efficacious and safer. Therefore an evidence-based approach should be applied to treatment planning for the replacement of teeth.[2]

When discussing a treatment plan with a patient, it is quite easy to get mentally focused on a certain treatment option, based on the actual needs and perceived values of the patient. Implant clinicians sometimes favor certain treatments (i.e., overdenture versus fixed prosthesis) according to their learning curve, training, or personal preferences. It is imperative from an ethical and legal perspective that the clinician discuss all treatment options, including a conversation concerning each option's advantages and disadvantages. Most state dental boards in the United States require as part of their dental law code that all patients be given all possible and viable options, including advantages and disadvantages.

In the treatment planning of a single edentulous site, five possible treatment options exist for the replacement of the missing tooth (Box 22.1). When evaluating single edentulous spaces, many factors must be taken into consideration when determining treatment options. One of the most important is the interocclusal space, which must be assessed carefully regardless of the treatment selected. Patients with insufficient vertical space may be contraindicated for any prosthesis without the prior correction of the occlusal plane and maxillomandibular relationships. In addition,
● **Fig. 22.1** The average number of missing teeth in a 20- to 64-year-old population is similar, regardless of income.

531

the condition, prognosis, and angulation of the adjacent teeth need to be evaluated to determine whether there are any factors that would contraindicate treatment.

Single Missing Tooth

No Treatment

Even though in most cases the option of no treatment is not ideal, the patient should always be informed of the possible ramifications that may occur if no treatment is rendered. Proposing this treatment option may seem counterintuitive to clinicians, because the goal of dentistry is to restore a patient to optimal function; however, the presentation of this option does allow the clinician to enter into a discussion as to the various consequences of tooth loss.

Advantages

The only advantages of no treatment are: (1) the patient will not have to undergo further procedures to address the situation; and (2) there will be no financial demands for the patient.

Disadvantages

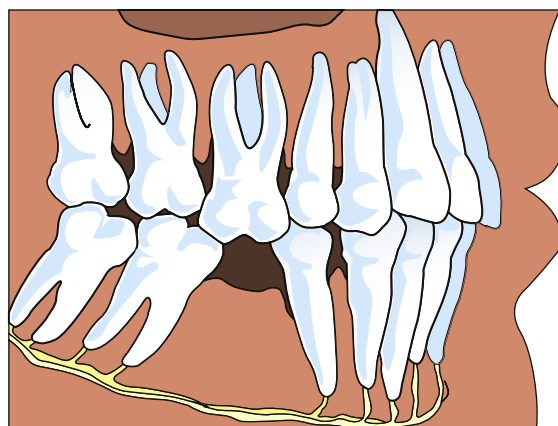
However, with no treatment, many disadvantages result.

Movement of Adjacent Teeth. When a patient loses a single tooth, numerous consequences may result that will create an occlusal disharmony and the potential for further dental complications. If a tooth is extracted in any position anterior to the second molars, the patient can expect for the tooth distal to it to begin tilting mesially into the edentulous space. This will most likely result in a change of the occlusal plane on that side. As the teeth experience this mesial tilt, the direction of load changes, which may cause excessive stress to the periodontal ligament. The contacting teeth in the opposing arch will begin to supraerupt in relation to the changes in the occlusal plane. The correction of future supraerupted teeth may require orthodontic or endodontic/crown therapy. In some situations extraction may be necessary.

Occlusal Force Issues. Another consequence of the single missing tooth is the patient will typically favor the fully dentate side to chew with, because of a decreased masticatory efficiency on the partially edentulous side. This situation results in the overuse of the fully dentate side, leading to fatigue-related issues with the teeth. Examples of these complications include fracture of crowns (porcelain, zirconia), fractures of enamel/existing restorations, significant occlusal wear, or myofascial pain syndrome (Fig. 22.2).

Removable Partial Denture

Advantages

The main advantages of the removable partial denture (RPD) in restoring a single missing tooth is based on convenience. The patient can receive a tooth-borne RPD after a few appointments, and there is a lack of invasive treatment in this modality. Most


• **Fig. 22.2** Consequences of No Treatment. Complications that may arise from not restoring a single edentulous site such as supraeruption of teeth, tipping of adjacent teeth, eventual loss of adjacent teeth from caries, and food impaction.

often there is a lower associated cost in comparison with most other treatment options.

Disadvantages

Decreased Acceptance. Removable partials dentures, even those that are primarily tooth borne, have a low patient acceptance rate compared with other treatment options. Patients experience difficulty in eating, because food debris may become trapped under the prosthesis. Speech patterns are often disrupted, because the patient must acclimate to the partial framework in the mouth. The prosthesis is often bulky, covering part of the palatal tissue on the maxilla or the lingual tissue on the mandible.

Increased Morbidity to Abutment Teeth. Reports of RPDs indicate that the health of the remaining dentition and surrounding oral tissues often deteriorates. In a study that evaluated the need for repair of an abutment tooth as the indicator of failure, the "success" rates of conventional RPDs were 40% at 5 years and 20% at 10 years.[3] Patients wearing partial dentures often exhibit greater mobility of the abutment teeth, greater plaque retention, increased bleeding on probing, higher incidence of caries, speech inhibition, taste inhibition, and noncompliance of use. A report by Shugars et al.[4] found abutment tooth loss for a RPD may be as high as 23% within 5 years and 38% within 8 years.

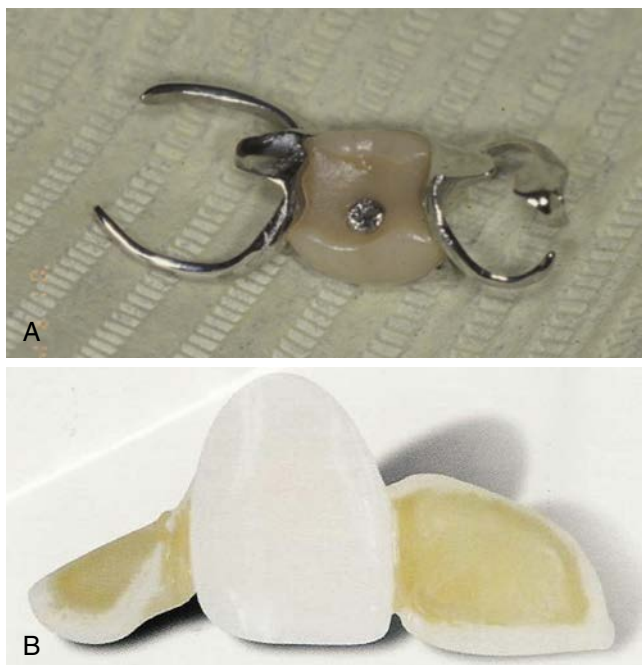
Increased Bone Loss. The natural abutment teeth, on which direct and indirect retainers are designed, must submit to additional lateral forces. Because abutment teeth are often compromised by deficient periodontal support, many partial dentures are designed to minimize the forces applied to them. The result is an increase in mobility of the removable prosthesis and greater soft tissue support. These conditions protect the remaining teeth but accelerate the bone loss in the edentulous regions.[5] Notably, bone loss is accelerated in the soft tissue support regions in patients wearing the removable prosthesis compared with patients not wearing the partial.

Accidental Swallowing of Prosthesis. Another drawback of the fabrication of a one-tooth RPD (Nesbit) is that no cross-arch stabilization exists; therefore accidental swallowing or aspiration may occur if it becomes dislodged. Numerous case reports have discussed the inadvertent swallowing of the prosthesis, which necessitated medical treatment, including removal from the esophagus.[6,7]

In conclusion, the evidence-based evaluation for the replacement of a single edentulous site with an RPD is not ideally

• BOX 22.2 Removable Partial Denture Treatment

Advantages
1. Ease of hygiene
2. Soft tissue replacement in esthetic areas
3. Soft tissue support
4. Minimal tooth preparation
5. Reduced cost
6. Reversible Treatment

Disadvantages
1. Material bulkiness—often requires cross-arch stabilization
2. Greater food debris and plaque accumulation
3. Inherent movement
4. Speech and function compromised
5. Accelerates bone loss in edentulous site
6. Abutment teeth loss
7. Possible aspiration


• **Fig. 22.3** Nonideal Single-Tooth Replacement Options. (A) Removable partial denture. (B) Resin-bonded prosthesis.

indicated. Partial dentures may accelerate the loss of adjacent teeth and allow for continued bone loss, along with predisposing the patient to increased morbidity (Box 22.2 and Fig. 22.3A).

Resin-Bonded Fixed Partial Denture

Another option to replace a missing tooth is with a resin-bonded prosthesis (i.e., Maryland bridge). Resin-retained bridges have been used clinically since the 1960s and have undergone many transformations over the years. This prosthesis type is used to replace a single missing tooth by cementing or bonding a pontic tooth to the adjacent teeth. This conservative treatment is usually not used as a first line of treatment because of an unpredictable longevity.

Advantages

Conservative Treatment. Almost no tooth preparation is indicated because retention does not rely on conventional retentive

• BOX 22.3 Resin-Bonded Prosthesis

Advantages
1. Minimal preparation of teeth
2. Conservative (reversible) treatment
3. Esthetics

Disadvantages
1. High debond rates (~50% within 3 years)
2. Risk for decay on abutment teeth when partially debonded
3. Movement of abutment teeth if dislodgement occurs

methods. Therefore even if preparation is required, it is usually restricted to the enamel.

Reversible Treatment. The prosthesis usually can be removed without damaging the abutment teeth. This is helpful especially if used as an interim treatment (i.e., future implant placement in a growing patient).

Conventional, Fast Treatment. Minimal appointments are required. Usually involves a conventional or digital impression followed by a second appointment insertion.

Inexpensive. Overhead costs, laboratory bills, and chair time are greatly reduced.

Disadvantages

Higher Failure Rate. There is a higher debond of the prosthesis in comparison with conventional bridges. Failure rates reported in the literature are greatly disparate, but the majority of reports indicate a failure rate of at least 30% within 10 years and as high as 54% within 11 months. Most failures occur from cement (bonding) failure during function.[8]

Higher Recurrent Caries. This type of prosthesis is highly susceptible to partial or total dislodgement, which may result in decay.[9]

Nonideal Space. In many cases diastemas are present or the pontic space is too large or small (nonideal space). This will result in difficulty in space distribution between pontic and abutment teeth. Often esthetic issues may result.

Relapse of Abutment Teeth. If the prosthesis is partially dislodged, it may result in one of the abutment teeth moving, especially if prior procedures have included orthodontic treatment (Box 22.3 and Fig. 22.3B).

Fixed Partial Denture

In the past the most common treatment for a single tooth was a fixed partial denture (FPD), which includes the preparation of the adjacent teeth. Because of the high success rates of this type of treatment, FPDs have been the treatment of choice since the 1950's.[10,11]

Advantages

Common Type of Treatment. A fixed prosthesis is a conventional and common type of procedure that most clinicians are comfortable performing. The prosthesis can be fabricated rather quickly, because a laboratory can generate a complete restoration in 1 to 2 weeks, and satisfies the criteria of normal contour, comfort, function, esthetics, speech, and health. Most patients have an increased compliance with this type of treatment, especially because no surgical intervention is needed.

Minimal Need for Soft and Hard Tissue Augmentation. With an FPD, augmentation of the edentulous area is uncommon. Because the pontic may be modified to encompass any defect, surgical augmentation procedures are usually not needed. In some

instances lack of attached tissue will be present on abutment teeth; however, this is rare.

Disadvantages

Increased Caries Rate. Despite the many advantages that an FPD has over its removable counterpart, the treatment modality does have inherent disadvantages. Caries and endodontic failure of the abutment teeth are the most common causes of FPD prosthesis failure.[12] Caries occurs more than 20% of the time, and endodontic complications to the abutments of an FPD 15% of the time. Caries on the abutment crown primarily occur on the margin next to the pontic. Fewer than 10% of patients floss on a regular basis, and those using a floss threader are even less.[13] As a result the pontic will act as a large overhang next to the crown and a reservoir for plaque. The long-term periodontal health of the abutment teeth may also be at greater risk as a result of the plaque increase, including bone loss.

Increased Endodontic Treatment. When a vital tooth is prepared for a crown, studies have shown that the patient has up to a 6% chance of experiencing an irreversible pulpal injury and subsequent need for endodontic treatment.[14] Not only does tooth preparation present a risk for endodontics on each of the vital abutment teeth, but the crown margin next to the pontic is also more at risk for decay and the need for endodontics as a result. Up to 15% of abutment teeth for a fixed restoration require endodontic therapy, compared with 6% of nonabutment teeth with crown preparations.[15]

Unfavorable Outcomes of Fixed Partial Denture Failure. Many issues may result when an FPD fails. This may include not only the need to replace the failed prosthesis but also the loss of an abutment tooth and the need for additional pontics and abutment teeth in the replacement bridge. Endodontic therapy is not 100% successful, and metaanalysis reports show a 90% success rate at the 8-year mark. Because approximately 15% of FPD abutment teeth require endodontics, many abutment teeth may be lost. In addition, an endodontic posterior tooth abutment is at a greater risk for fracture. Reports indicate that abutment teeth for an FPD fail because of endodontic complications (e.g., fracture) four times more often than those with vital pulps.[16] The fracture of the tooth may result in failure of the prosthesis and abutment tooth.

The abutment teeth of an FPD may be lost from caries, endodontic complications, or root fracture at rates up to 30% for 8 to 14 years.[17] Recent reports indicate 8% to 18% of the abutment teeth retaining an FPD are lost within 10 years. This is most alarming because 80% of abutments have no previous decay or are minimally restored before the fabrication of the FPD[18] (Box 22.4 and Fig. 22.4A).

Single-Tooth Implant

The last treatment option to replace a missing tooth is a single-tooth implant. In the past, patients were advised to set their desires aside and accept the limitations of an FPD. The primary reasons for suggesting the FPD were its clinical ease and reduced treatment time.

Ideally the primary reason to suggest or perform a treatment should not only be related to treatment time, cost, or difficulty to perform the procedure but also should reflect the best possible long-term solution for each individual.

Advantages

Higher Success Rate. Prior to the 1990's, few long-term studies focusing on single-tooth implant replacement with osseointegrated implants in any region of the mouth had been published. Early reports indicated that single-tooth implant results were less

• **Fig. 22.4** Common Single-Tooth Replacement Options. (A) Fixed partial denture. (B) Dental implant.

predictable than they have become in the "since the late 2000s". For example, in 1990 Jemt et al.[19] reported a 9% implant failure within 3 years of prosthesis completion on 23 implants (21 in the maxilla, 2 in the mandible). In 1992 Andersson et al.[20] published a preliminary report of a prospective study of 37 implants restored with single-tooth crowns in 34 patients. A 3-year follow-up included this "developmental group" and an additional 23 patients with 28 crowns. The cumulative success rate recorded was 93.7%, with 89% of the developmental group in function 3 to 4 years.[20] From approximately 1993 to present, single-tooth implants have become the most predictable method of tooth replacement, with success rates that exceed 95%.[21]

Hygiene. The dental implant treatment plan allows for easier hygiene because the proximal surfaces are able to be easily accessed for flossing. This acts as a preventative measure against periodontal and carious pathologies.

No Alteration of Adjacent Teeth. Adjacent teeth do not have to be altered with the implant option, which decreases the risk for recurrent caries or endodontic issues in these teeth. Because of these advantages, the patient is at a much lower risk for losing further teeth in the future.

Better Cost Comparison. Cost comparison studies conclude that the implant restoration demonstrates a more favorable cost-effectiveness ratio.[22] Even when the adjacent teeth are not lost, the conventional FPD often needs to be replaced every 10 to 20 years on average because of decay, endodontic complications, porcelain fracture, or unretained restoration (which may decay and require endodontics).

Higher Success Rate. The single-tooth implant exhibits the highest survival rates of the five treatment options presented for single-tooth replacement. In addition, the adjacent teeth have the highest survival rate and the lowest complication rate, which is a considerable advantage.

Disadvantages

Increased Treatment Time. The single-tooth implant procedure does take considerably longer for treatment than does the RPD or FPD. From the initial surgical placement the average implant requires 3 to 6 months for osseointegration to occur. This time frame is dependent on the patient's bone density in that area, as well as the volume of bone that was present at placement. In an effort to accelerate the process, immediate placement and loaded implants are a popular technique in implant dentistry today; however, limitations do exist.

Possible Need for Additional Treatment. Especially in esthetic areas, modifications to the soft tissue may be necessary in an effort to change the soft tissue drape or to enhance the patient's tissue biotype. In addition, in some cases the hard tissue (bone) may require augmentation for ideal implant placement and long-term success.

Esthetics. Based on available bone and crown height space (CHS), the final prosthesis may feature a traditional tooth contour (FP1), a longer crown form (FP2), or may require the addition of pink porcelain/zirconia to mimic normal soft tissue contours (FP3). The patient must be aware of these possible prosthetic outcomes because their esthetic values may dictate the need for adjunctive bone grafting procedures.

In conclusion, the single-tooth implant exhibits the highest survival rates of all treatment options presented for single-tooth replacement. The adjacent teeth have the highest survival rate and the lowest complication rate, which is a considerable advantage (Fig. 22.4B and Box 22.5).

• BOX 22.5 Implant

Advantages
1. Less risk for caries, endodontics, restoration and tooth fracture, unretained prosthesis
2. No preparation of adjacent teeth
3. Improved hygiene conditions
4. Improved esthetics: in most cases
5. Maintains hard and soft tissue bone at site
6. Decreases adjacent tooth loss

Disadvantages
1. Increased treatment time
2. Possible hard and soft tissue grafting

Specific Single-Tooth Implant Indications

Anodontia

The absence of one or more teeth is known as anodontia and may be complete (rare) or partial (also called *hypodontia*). It is many times more common than supernumerary teeth.[23] The primary cause of partial anodontia (third molars excluded) is familial heredity, and the incidence rate ranges from 1.5% to as high as 10% in the U.S. population.[24] Congenital absence appears to occur less often in Asians and African Americans (2.5%) than in whites (5.15%). The highest average has been reported in Scandinavian countries (10.1% in Norway and 17.5% in Finnish Skolt-Lapps). In addition, a number of syndromes exist in the literature that include multiple missing teeth, of which ectodermal dysplasia is the most common. A high correlation is found between primary tooth absence and a permanent missing tooth; however, a missing tooth occurs more frequently in the permanent dentition. Caprioglio et al.[25] evaluated the records of almost 10,000 patients between the ages of 5 and 15 years. Of all the missing single teeth, the mandibular second premolar was most often missing (38.6%), followed by the maxillary lateral incisor (29.3%), the maxillary second premolar (16.5%), and the mandibular central incisor (4.0%). The remaining teeth were absent at a rate of only 0.5% to 1.8%, with the maxillary first molar being the least affected. The missing mandibular second premolar primarily occurred in male patients, and the missing maxillary lateral incisor primarily occurred in female patients.[25] The most common multiple teeth lost (other than third molars) are the maxillary lateral incisors followed by the mandibular second premolars and maxillary second premolars (Figs. 22.5 and 22.6).

Congenitally missing teeth are therefore a common scenario in a general practice. Fortunately, fewer than 1% of those individuals who are missing teeth are missing more than two teeth, and fewer than 0.5% of this group is missing more than five permanent teeth. In the majority of children with more than five teeth missing, it is related to ectodermal dysplasia.[26]

A congenital missing mandibular second premolar most often has a deciduous second molar. In some cases, the deciduous second molar may be extracted at the approximate age of 5–6 years old. This may allow the permanent molar to then erupt in a more mesial position. When the first deciduous molar is lost naturally (around the age of 9–11 years), the first permanent premolar and first molar may be orthodontically positioned adjacent to each other. This approach eliminates the need for a second premolar replacement. Because the second premolar space is eliminated

• **Fig. 22.5** Congenitally missing mandibular left second premolar: the most common missing tooth. Note the increased mesial-distal distance due to retaining the primary molar.
• **Fig. 22.6** Congenitally missing maxillary lateral incisor: the most difficult missing tooth to be replaced by an implant. (A) Clinical image of missing lateral incisor. (B) Ideal implant placement being approximately 1.5 mm from roots.

with orthodontics, no bone graft, implant surgery, or crown (or combination of these treatments) is required to replace the tooth. Few disadvantages exist to the use of orthodontics to eliminate this posterior missing tooth space.

A common scenario is to maintain the deciduous second molar for as long as possible. Often the deciduous tooth will break down and need to be extracted. When the deciduous second molar is maintained, it may become ankylotic approximately 10% of the

time. As a result the opposing maxillary second premolar extrudes, and the adjacent teeth often tip over the deciduous tooth. In addition, because the deciduous molar is 1.9 mm larger than a premolar, the mesiodistal space is larger than the usual premolar space after the deciduous molar is lost at a later date in the adult patient's life.

An implant is usually the treatment of choice to replace the second premolar. However, the deciduous tooth does not have a buccolingual width of bone that is adequate for a larger-diameter implant. The crown for this larger tooth dimension is supported by a regular-size implant, which increases forces on the abutment screw and increases the risk for screw-loosening complications. However, this is most often the treatment of choice in adult patients rather than preparing the adjacent teeth for a traditional FPD. An alternative in an adult implant patient is to augment the site for width and place a larger-diameter implant (5 mm). This improves the emergence profile and decreases the risk for abutment screw loosening.

Another option in an adult patient missing a permanent premolar is orthodontic closure of the space. However, care is taken so the anterior component of teeth does not shift distally and open the centric occlusal bite relationship. To prevent this occurrence, an orthodontic implant (transitional anchorage device) may be inserted distal to the canine root and used as anchorage to pull the molars forward to close the space (Fig. 22.7). This approach may also negate the need to extract a third molar in that quadrant when performed on adolescents.

Single-Tooth Implant Size Specifics

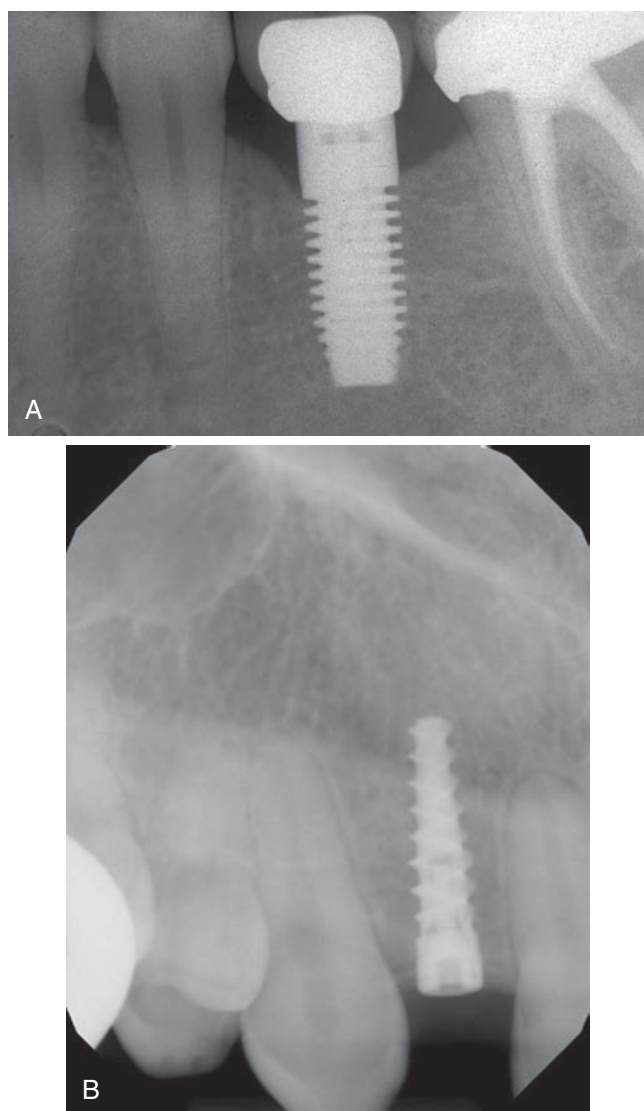
When an edentulous site is evaluated, the clinician must use specific parameters in determination if the site is an acceptable implant site. The ideal diameter of a single-tooth implant directly is dependent on the mesiodistal dimension of the missing tooth and the buccolingual dimension of the implant site. When evaluating the size of the dental implant, specific guideline measurements should be adhered to:

- 1.5–2.0 mm from an adjacent tooth
- 3.0 mm between implants
- 2 mm from a vital structure
- 1.5–2.0 mm mm of buccal bone (after implant placement)
- 1.0 mm of lingual bone (after implant placement)

Caution should be exercised in placing implants with compromised facial bone. When an implant has a facial bone thickness less than 1.0 mm of cortical bone, an increased risk for bone loss and implant failures may occur.[27] As a consequence the ideal implant diameter is 1.5 mm or more from each adjacent tooth, 1.5 mm or more from the facial plate, and 1.0 mm from the lingual plate (i.e., the lingual plate is always thicker and more resistant to bone loss in comparison with the facial plate).

Anterior Teeth Replacement

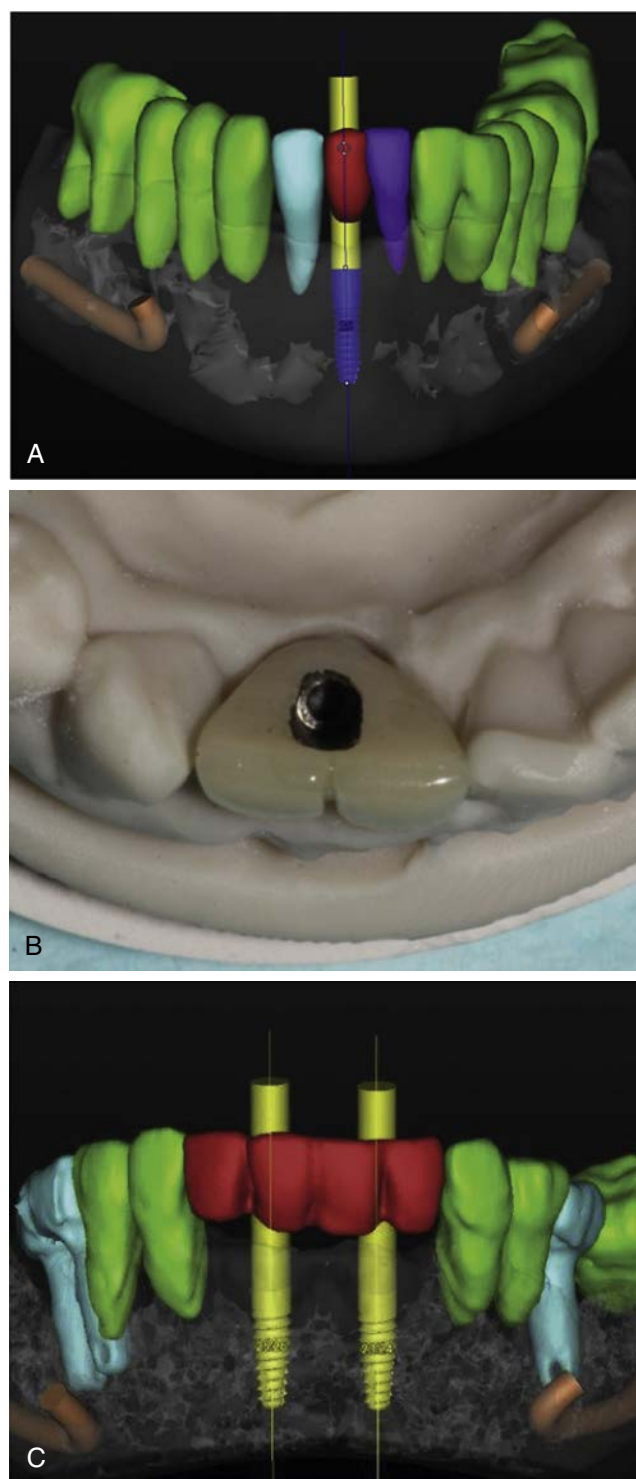
Mandible

One of the more difficult edentulous areas in the oral cavity to treatment plan is the mandibular anterior. Because of the compromised mesial-distal length, placing one implant for each missing tooth is difficult, if not impossible. When missing two mandibular incisors (~#24–#25), usually one implant may be placed interproximally, slightly lingual with a screw-retained prosthesis. If all four lower incisors are missing, two implants may be placed interproximally, distributing the cantilever amount equally. This


● **Fig. 22.7** (A and B) Postorthodontic treatment of the most common congenitally missing sites.

area involves lower force factors. When all of the lower incisors are missing (~#23–#26), then usually two implants are placed in the interproximal areas (#23–#24 and #25–#26), and a four-unit prosthesis is fabricated. This allows the implants to be far enough away from the mesial aspect of the cuspids, and therefore not causing a peri-implant problem. When mandibular cuspid to cuspid are missing, then usually four implants are placed, with the distal implants being in the #22 to #23 and #26 to #27 embrasure areas (Fig. 22.8). This prevents developing an osseous defect on the mesial of the cuspids.

Maxillary

The maxillary anterior edentulous spaces are one of the most difficult treatment areas. Contrary to missing posterior teeth, nearly all patients have an emotional response regarding a maxillary anterior missing tooth. No question exists regarding the need to replace the tooth, and financial considerations are less important. When posterior teeth are extracted, little resistance to the preparation of adjacent teeth may be given to the dentist. However, when anterior, normal-looking teeth must be prepared to serve as FPD abutments, the patient is more anxious and often looks for


● **Fig. 22.8** Treatment Plans for Mandibular Anterior. (a) Missing # 24 or # 25 - implant placement as long as ideal space is available. (b) Missing # 24 and # 25 - implant placed in the embrasure area with a screw retained prosthesis, (c) Missing # 23 - # 26 - two implants placed in the embrasure area.

an alternative. In the patient's perspective, anterior FPD restorations are never as esthetic as natural teeth. In part, this is because patients are able to distinguish between good and poor esthetic results. Because patients are able to notice only the restorations that are not natural in appearance, they believe anterior FPDs are not esthetic. In younger patients with congenitally missing

maxillary lateral incisors or with trauma to the maxillary central incisor (which resulted in its failure, often after endodontic therapy), parents are eager to provide the best possible replacement option. They often perceive this option to be a single-tooth implant. As a consequence of these psychological factors, a common site for a single-tooth implant in a restorative practice is the maxillary central or lateral incisor.

The highly esthetic zone of the premaxilla often requires both hard (bone and teeth) and soft tissue restoration. The soft tissue drape is often the most difficult aspect of treatment. As a consequence, maxillary anterior single-tooth replacement is often a challenge, regardless of the experience and skill of the dentist. Endodontic failure is less likely in the maxillary anterior region compared with posterior teeth, but the cause of pulp necrosis may more often lead to root resorption, compared with the posterior regions.

Before 1990 few long-term studies of anterior single-tooth implant replacement with osteointegrated implants were conducted. However, recently studies are becoming more prevalent. Misch et al.[28] reported on 276 anterior maxillary single implants to restore missing teeth from agenesia. In 255 adolescent patients the implants were monitored for a range of 2 to 16 years, with a 98.6% implant and prosthesis survival rate. In the same year, Wennstrom et al.[29] reported on a 5-year prospective study with 45 single-tooth implants, with a 97.7% implant survival rate with minimal bone loss. Zarone et al.[30] reported on lateral maxillary agenesis replacement with 34 implants, with a 97% survival rate at 39 months.

More clinical studies have been conducted for a maxillary anterior single-tooth replacement with an implant than any other treatment option. Retrospective reports are available, as with other modalities; however, of more importance is the fact that many prospective clinical studies confirm the data of previous reports. The maxillary anterior single-tooth implant has a very high success rate compared with any other treatment option to replace missing teeth with an implant restoration (i.e., overdentures, short-span FPD, full-arch FPD, or single-tooth implant).[31] In a systematic review of single-implant restorations in all regions of the mouth, Creugers et al.[32] reported a cumulative rate of 97% success at 4 years, with 83% reporting uncomplicated maintenance. Lindhe et al.[33] published a metaanalysis of implants with nine studies on single implants, with a total of 570 single crowns with a follow-up range of 1 to 8 years and a 97.5% survival rate. A review of the literature by Goodacre et al.[34] found single-tooth implant studies had the highest survival rate of any prosthesis type and averaged 97%.

More recently a trend toward single-stage and immediate-extraction implants has emerged. This appears especially attractive in the maxillary anterior region, where the soft tissue drape is ideal before the extraction and patients are more anxious to have a fixed replacement. In a prospective study of 102 single-tooth implants in the anterior maxilla, Kemppainen et al.[35] reported a 99% success rate using one-stage and two-stage implants. Other studies have recommended one stage and immediate load with some success in specific situations.

As important as implant versus prosthesis survival rates is the fact that the adjacent teeth prognosis is improved with single-tooth implants compared with any other option. In a 10-year report, Priest[36] indicated adjacent teeth next to implants have less decay, endodontic risk, sensitivity, plaque retention, and evidence of adjacent tooth loss over 10 years. Studies by Misch et al.[37] also resulted in similar conclusions. As such, the maxillary anterior single-tooth implant has become the treatment of choice when bone and space parameters are sufficient or may be created.

One of the most common procedures performed in implant dentistry is a single-tooth replacement. Although implant success rates are high in the maxillary regions, high patient expectations, high esthetic requirements, and sensitive soft and hard tissue management compound the complexity of the anterior teeth restoration. A single maxillary central crown on a natural tooth is often a difficult challenge for the restoring dentist. This challenge is significantly compounded when an implant serves as the prosthetic support. As a consequence, implants to replace a maxillary anterior single tooth remain one of the more difficult treatments to perform in implant dentistry.

Posterior Teeth Replacement

Premolar Replacement

The most ideal and easiest posterior tooth to replace with an implant is the first premolar in the maxillary arch (Fig. 22.9). When used as an abutment for a three-unit FPD, the canine is at an increased risk for material fracture or uncementation (because of the lateral forces applied) and is often more difficult to restore
• **Fig. 22.9** Premolar Replacement. (A) The maxillary first premolar is the safest and easiest position to place an implant. (B) In most cases an implant can be positioned anterior to the maxillary sinus in the second premolar position.

to its original appearance than are other anterior or posterior teeth. The vertical available bone is usually greater in the first premolar locations than in any other posterior tooth positions. In the maxilla, it is almost always anterior or below the maxillary sinus, and is the perfect site for a clinician initially learning implant placement. In the mandible the first premolar is almost always anterior to the mental foramen and associated mandibular neurovascular complex. The bone trajectory for implant insertion is more favorable in the mandibular first premolar than for any other tooth in the arch.

The maxillary premolars are often in the esthetic zone of patients with a high smile line. The need for bone grafting before maxillary first premolar implant placement is common because the extraction process of the thin buccal root often results in facial bone loss during or after the extraction. Implant placement without bone grafting may result in a recessed emergence profile, which in the past was corrected with a facial ridge lap to the crown. However, the crown with a ridge lap contour does not allow proper hygiene or probing of the facial sulcular region of the crown and should be used as a last resort.

To ensure a proper esthetic result and to avoid the need for a crown with a ridge lap, the implant body is often positioned similar to an anterior implant, under the buccal cusp tip (one-third buccal, two-thirds lingual) rather than midcrest (which is under the central fossa). The slight buccal implant placement improves the cervical emergence profile of the maxillary premolar crown.

The natural premolar tooth is 7 mm wide in the mandible and 6.5 to 7 mm in the maxilla. The premolar root is usually 4.2 mm in diameter on average at a distance of 2 mm below the cement-enamel junction (CEJ), which is the ideal position of the bone. As a consequence the most common implant diameter is usually 4 mm at the crest module. This also provides approximately 1.5 mm of bone on the proximal surfaces adjacent to the natural teeth when the mesiodistal space is 7 mm or greater. However, when the mesiodistal dimension is only 6.5 mm, a 3.5-mm implant is suggested.

The maxillary canine root is often angled 11 degrees distally and presents a distal curve 32% of the time, which may extend over the shorter root of the maxillary first premolar. With posterior implant insertion, the implant body is often longer than the natural tooth root. The surgeon may inadvertently place the implant parallel to the second premolar and, consequently, into the natural canine root. This may not only result in endodontic therapy of the canine but also may cause root fracture and loss of the tooth. Therefore in the maxillary first premolar region, care must be taken to evaluate the canine angulation and vertical height limitation. The first premolar implant may need to be placed parallel to the canine root, and a shorter implant than is considered ideal may be required (Fig. 22.10). A tapered implant body at the apical third may also be of benefit to avoid encroachment on the apical region of the canine.

The second premolar root apices may be located over the mandibular neurovascular canal (or foramen) or maxillary sinus. The foramen is often 2 mm or more above the neurovascular canal. Hence the second premolar available bone height may be less than the first molar region. This also results in a reduced height of bone compared with the anterior region of the jaws. As a result a shorter implant than ideal is a common consequence in the second premolar site.

First Molar Implant Replacement. The first molar is one of the most common teeth to be extracted. The natural molars receive twice the load of the premolars and have 200% more root surface area; therefore it is logical that the implant support in a molar region should be greater than in the premolar position. Its mesiodistal dimension usually ranges from 8 to 12 mm, depending on the original tooth size and the amount of mesial drift of the second molar before implant placement. It should be noted that the ideal size of the implant should be measured by the intratooth distance from the adjacent CEJ of each tooth, not the interproximal distance at the marginal ridges. A tipped adjacent tooth should be recontoured to a more ideal condition, so that food impaction does not occur under the interproximal contacts in the enlarged triangular interdental papilla space, which is formed after the implant crown is inserted.

When one 4-mm-diameter implant is placed to support a crown with a mesiodistal dimension of 12 mm, this may create a

A   B
● **Fig. 22.10** (A) The canine root is often angled to the distal 11 degrees and has an apical distal curve 32% of the time. As a consequence the first premolar implant may contact the canine root. (B) The first premolar implant may need to be angled so it is parallel to the canine rather than the second premolar.
● **Fig. 22.11** When a 4-mm-diameter implant replaces a molar, a mesial and distal cantilever is created on the crown, which is nonideal. In addition, if a large occlusal table exists (buccal-lingually), shear forces may result because of the mesial,distal, buccal, and lingual cantilevers.

● **Fig. 22.12** When the mesiodistal space in the posterior regions is 8 to 12 mm, a 5- to 6-mm-diameter implant is suggested.

● **Fig. 22.13** When the mesiodistal space is 14 to 20 mm, two implants should be used to support the crowns.

4- to 5-mm cantilever on the marginal ridges of the implant crown (Fig. 22.11). The magnified occlusal forces (especially important in parafunction) may cause bone loss (which may complicate home care), increase abutment screw loosening, and increase abutment or implant failure because of overload.

Sullivan[38] reported a 14% implant fracture rate for single molars fabricated on 4.0-mm implants composed of grade 1 titanium and concluded that this is not a viable treatment. Rangert et al.[39] reported that overload-induced bone resorption appeared to precede implant fracture in a significant number of 4.0-mm-diameter single-molar implant restorations. Therefore a larger-diameter implant should be inserted to enhance the mechanical properties of the implant system through increased surface area, stronger resistance to component fracture, increased abutment screw stability, and enhanced emergence profile for the crown.

When the mesiodistal dimension of the missing tooth is 8 to 12 mm with a buccolingual width greater than 7 mm, a 5- to 6-mm-diameter implant body is suggested (Fig. 22.12). Langer et al.[40] also recommended the use of wide-diameter implants in bone of poor quality or for the immediate replacement of failed implants. The larger-diameter implant does not require as long an implant body to result in a similar loading surface area, which is also a benefit because of the reduced posterior available vertical bone height because of anatomic limitations and landmarks present, such as the maxillary sinus or mandibular canal. When the mesiodistal dimension of the missing tooth site is 14 to 20 mm, two 4- to 5-mm-diameter implants should be considered to restore the region (Fig. 22.13). When two implants replace the molar region, the mesiodistal offset loads to the prosthesis can be eliminated because each implant may be placed 1.5 mm from the adjacent tooth. The total surface area of support is greater for the two implants, compared with the surface area provided by one larger-diameter implant (two 4-mm-diameter implants > one 5- or 6-mm-diameter implant). In addition, the two regular-size implants provide more stress reduction than just one larger-diameter implant, which in turn reduces the incidence of abutment screw loosening.
In 1996 Bahat et al.[41] reported on the results of various implant numbers and size selection. The overall failure rate was 1.2%, with the two 5-mm implants having 100% success. In 1997, Balshi et al.[42] compared the use of one implant and two implants to replace a single molar. The 3-year cumulative success rate was 99%. Prosthesis mobility and screw loosening were the most common complications for the one-implant group (48%); this complication rate was reduced to 8% in the two-implant group.

In a finite element analysis of three different implant-supported molar crown designs, Geramy and Morgano[43] showed a 50% decrease in mesiodistal and buccolingual stress between 5-mm and standard-diameter implants. The double-implant design had the least stress of all. Therefore, whenever possible, two implants should be used to replace a larger single-molar space to reduce cantilever loads and abutment screw loosening.

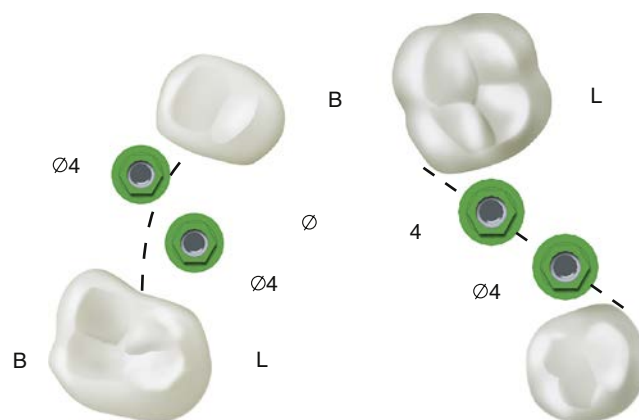
When the posterior space is 14 to 20 mm, the largest implant diameter for the two implants may be calculated by subtracting 6 mm (1.5 mm from each tooth for soft tissue and surgical risk and 3 mm between the implants) from the intratooth distance and
● **Fig. 22.14** When the space between natural teeth is 12 to 14 mm, the choice of implant size and number is less obvious.

● **Fig. 22.15** On the left (in the maxilla) the mesial implant is positioned more facial and the distal implant more palatal. On the right (mandible) the mesial implant is placed more lingual and the distal implant more buccal.

dividing by 2 to determine the size of each implant (16 mm – 6 mm = 10 mm ÷ 2 = 5-mm implants). Remember, when two adjacent molars are missing, it is advantageous to place each implant 1.5 to 2 mm from the adjacent teeth (or under the mesial of the first molar and distal of the second molar crown) and splint the implants together, rather than placing the implant in the center of each tooth. This eliminates the cantilever to the mesial and distal from the implants.

Ideally two implants should be 3 mm apart because crestal bone loss around each implant may occur. The width of the crestal defect is usually less than 1.5 mm. Therefore the two adjacent implants 3 mm or more apart will not convert an angular defect next to an implant to be a horizontal defect that may increase sulcus depths and cause loss of papilla height.[44] Although this region is often out of the esthetic zone, the loss of papilla height increases food impaction.

When the mesiodistal space is 12 to 14 mm from adjacent CEJs, the treatment plan of choice is less obvious. A 5-mm-diameter implant may result in cantilevers up to 5 mm on each marginal ridge of the crown. However, two implants present a greater surgical, prosthetic, and hygiene risk. Unfortunately the 12- to 14-mm space is not unusual. The primary goal is to obtain at least 14 mm of space instead of 12 to 14 mm (Fig. 22.14). Additional space may be gained in several ways. Orthodontics may be the treatment of choice to upright a tilted second molar or increase the intratooth space. One anterior implant may be placed and an orthodontic spring incorporated in the transitional crown; the spring pushes and uprights the distal tooth and moves it more distal. After orthodontic movement the second implant may be inserted with less risk and improved hygiene between each implant. Another option is to use orthodontics to reduce the space and place only one implant and crown.

The implants may not be centered in the crestal width of bone. Instead, one implant is placed buccal and the other on a diagonal toward the lingual (Fig. 22.15). The diagonal dimension increases the mesiodistal space by 0.5 to 1.0 mm. When implants are placed in such a way, consideration is given to oral hygiene and occlusion. In the mandible the most anterior implant is placed to the lingual aspect of the midcrest, and the more distal implant is placed to the facial aspect to facilitate access of a floss threader from the vestibule into the intraimplant space. The occlusal contacts are also slightly modified on the buccal aspect of the mesial implant to


occlude over the central fossa. In the maxilla the anterior implant is placed to the buccal aspect and the distal implant to the palatal region to improve the esthetics of the more visible half of the tooth. The distal occlusal contact is placed over the lingual cusp, and the mesial occlusal contact is located in the central fossa position. The cervical esthetics of the maxillary molar is compromised on the distal half of the tooth to the benefit of greater intratooth distance and easier access for home care. This maxillary implant placement requires the intraimplant furcation to be approached from the palate rather than the buccal approach as in the mandible.

Second Molar Implant Replacement. In general, when third molars are missing, the second mandibular molar is usually not restored. The mandibular second molar is not in the esthetic zone of the patient. Ninety percent of the masticatory efficiency is generated anterior to the mesial half of the mandibular first molar, so function is rarely a primary reason to replace the second molar. A 10% greater occlusal force is measured on the second molar compared with the first. As a result, biomechanical stress–related complications are more of a risk, including abutment screw loosening. This tooth is more likely to exhibit working or nonworking interfaces during mandibular excursions. As a result of the increased forces and occlusal interferences, a greater incidence of porcelain or zirconia fracture occurs.

The CHS decreases as it proceeds posteriorly, and represents limited access for implant placement, along with abutment screw and abutment insertion, especially when opposing natural dentition. A reduced CHS results in the abutment height being reduced, so the retention of the crown may be compromised. Cheek biting is more common in this region because of the proximity of the buccinator muscle.

The course of the mandibular canal anterior to the mid-first molar most commonly corresponds to the level of the mental foramen. However, in the region of the second molar, its course becomes highly variable, with less available bone height and an elevated risk for paresthesia and neurovascular bundle damage during implant surgery and insertion. The bone quality in the second mandibular molar region is often inferior to other regions of the mandible, with an increased risk for bone loss or implant failure as a consequence. The submandibular fossa topography is deeper in the second molar regions compared with the premolar or first molar sites, and mandates greater implant body angulation, with associated increased stresses at the crestal region of the implant, thereby increasing the risk for bone loss and abutment screw loosening. In addition, the

● **Fig. 22.16** Second Molar Replacement. Replacing second molar teeth is usually not recommended because of the compromised crown height space.

● **Fig. 22.17** Complications that may occur from the placement of second molars that result in neurosensory impairment.

TABLE 22.1	Disadvantages of Replacing Second Molars
1.	Not in esthetic zone
2.	Extruded maxillary second molar not esthetic or occlusal consequence
3.	Less than 5% of total chewing efficiency in this region
4.	A 10% higher bite force (increased bone loss risk, porcelain/zirconia fracture risk, and abutment screw–loosening risk)
5.	More often exhibits occlusal interferences during excursions
6.	Higher and less predictable location of mandibular canal in that site
7.	Less dense bone
8.	Submandibular fossa depth greater
9.	Angulation of bone to occlusal plane greater
10.	Limited to unfavorable crown height space for cement retention (increased risk for uncementation)
11.	Limited access for occlusal screw placement
12.	Limited access for correct implant body placement
13.	Crossbite position—implant placed more buccal than maxillary tooth
14.	Hygiene access more difficult
15.	Cheek biting more common
16.	More incision line opening after surgery
17.	Greater mandibular flexure during parafunction
18.	Greater cost to patient

facial artery is located in the submandibular fossa before it crosses the mandibular notch and crosses over the face. Perforation of the lingual plate in the region of the second molar may violate the facial artery and cause life-threatening bleeding. The mandible exhibits increased flexure and torsion in this area during opening or heavy biting on one side, and masticatory dynamics are less favorable. As a result the implant may not integrate in a patient with moderate-to-severe bruxism or clenching. Finally, the cost of an implant or fixed prosthesis to replace the second molar often does not warrant the benefits achieved. As a consequence the mandibular second molar is usually not replaced when the third molar and second molar are the only posterior mandibular teeth missing.

The primary disadvantage of electing not to replace a mandibular second molar tooth is the potential extrusion and loss of the maxillary second molar, or a loss of proper interproximal contact with the adjacent tooth, with increased risk for caries, periodontal disease, or both. The extrusion of the maxillary second molar is usually not an esthetic or occlusal concern. When the mandible moves into an excursion, the maxillary second molar is behind the mandibular first molar and does not alter the mandibular pathway of movement even if the maxillary second molar extrudes. If extrusion of the maxillary second molar is a concern for the patient or doctor, then a crown on the mandibular first molar may include an occlusal contact with the mesial marginal ridge of the maxillary second molar, or the maxillary second molar may be bonded to the maxillary first molar.

On the other hand, a missing maxillary second molar opposing a mandibular second molar with extrusion may result in occlusal concern when the mandible moves into an excursion. The extrusion of a mandibular second molar results in an occlusal interference when the mandible moves into protrusive or lateral excursion. Hence, as a general rule, maxillary second molars are usually replaced with an implant when opposing a natural tooth (Fig. 22.16).

The mandibular second molar is usually replaced when the third molar is in function and will remain present. In addition, some patients desire an intact dentition and wish to have the tooth replaced, regardless of whether they have a third molar. If the bone is abundant and no paresthesia or surgical risk is apparent, then the second molar may be replaced. However, this is usually the exception rather than the rule of treatment and usually replaces only a premolar-sized tooth (Fig. 22.17 and Table 22.1).

Multiple Missing Teeth

No Treatment

Advantages

There are no advantages to no treatment for multiple teeth other than finances and time. When a patient is missing multiple teeth, the education and communication to the patient is even more important. Although there is no financial or time commitment for the patient, the disadvantages are more significant in comparison with a single missing tooth.

● **Fig. 22.18** Multiple Implant Prosthesis: (a) Three cementable abutments for cement-retained prosthesis, (b) Buccal clinical view, (c) Occlusal view.

Disadvantages

Decreased Masticatory Function. The main disadvantage of not replacing multiple teeth is the decreased masticatory function. Patients will place more force and stress on their remaining teeth, which leads to an increased morbidity. The forces of mastication are transmitted to the remaining teeth, which results in a greater possibility of decay, mobility, periodontal issues, and loss of teeth. The longer the edentulous ridge remains without stimulation, the greater the chance that bone loss will occur. This may lead to the future need for hard and soft tissue augmentation procedures to increase hard and soft tissue volume for implant placement.

Tooth Movement. The remaining teeth may continue to shift in relation to the stresses of mastication, causing movement and tilting. Teeth in the opposing arch will supraerupt because of the lack of stimulation by an opposing tooth, causing root exposure and occlusal disharmony. These phenomena combine to drastically complicate the implant restoration.

Esthetics. If no treatment is rendered for the edentulous area, obvious esthetic issues will result. In most cases, patient acceptance of the edentulous areas is not well accepted, and esthetics is usually a motivating factor in seeking rehabilitation.

Removable Partial Denture

See Box 22.2 for the advantages and disadvantages of RPD treatment.

Implant-Supported Multiple Crowns (Fig. 22.18)

Advantages

Ideal Prosthesis. The implant-supported fixed prosthesis is the closest available treatment option for an edentulous patient to return to optimal form, function, and esthetics. Most patients who receive a fixed prosthesis will state that it "feels like normal teeth," which carries a profound psychological impact. The prosthesis does not require removal and is less likely to impact food in comparison with a removable prosthesis.

Less Bone Loss in Cantilevered Areas. Wright et al.[45] have evaluated posterior mandibular bone loss in implant overdentures (overdenture removable prosthesis [RP-5]) compared with cantilevered fixed prostheses from anterior implants. The annual bone loss index observed in the RP-5 overdentures ranged from +0.02 to –0.05, with 14 of 20 patients losing bone in the posterior regions. The fixed prostheses group had a range from +0.07 to –0.015, with 18 of 22 patients gaining posterior bone area. Reddy et al.[46] also found a similar clinical observation in 60 consecutively treated cantilevered fixed prostheses supported by five to six implants placed between the foramina. The mandibular body height was measured 5, 10, 15, and 20 mm distal to the last implant. The baseline measurements up to 4 years after function increased from 7.25 ± 0.25 to 8.18 ± 0.18 mm. Nearly all of the bone growth occurred during the first year of function. Therefore an important role for the complete implant-supported restoration is the maintenance and even regeneration of posterior bone in the mandible.

Decreased Maintenance. Because no attachments are used with a fixed implant prosthesis, far less maintenance is needed. This will also decrease the financial outlay the patient must commit to in comparison with an overdenture treatment.

Disadvantages

Cost. The cost of a fixed prosthesis is usually higher than other treatment plans, which may serve as a barrier to acceptance. In patients with severe parafunction the argument does arise for fabrication of a removable overdenture as opposed to the porcelain fixed restoration.

Esthetics. The esthetics for a fixed detachable prosthesis may be inferior to an removable prosthesis. Because soft tissue support for facial appearance often is required for an implant patient with advanced bone loss, a fixed prosthesis will usually not be as soft tissue supportive as an overdenture. Because there is no labial flange with a fixed prosthesis, compromises in the soft tissue may result. If overcontouring of the prosthesis is completed by the laboratory, this will often result in difficulty for hygiene access.

Food Impaction. With a fixed prosthesis a common complaint exists with an increase in food impaction. This will most likely result when custom abutments are used to offset nonideal implant positioning.

Types of Prostheses

The clinician should have a strong understanding of the various prosthetic options that may be used for single- or multiple-implant restoration in partially edentulous arches. The primary methods used for retention of these prostheses are cement and screw retention. Although other options exist, including friction-fit component systems, these methods find their greatest utility with the retention of removable prostheses.

Screw-Retained Restorations

Screw-retained restorations can be secured to the implant body directly (Fig. 22.19) or attached through the use of a standardized abutment, which is in turn held in place to the implant with a retaining screw (Fig. 22.20). The early work by Brånemark et al., which focused on the rehabilitation of the fully edentulous arch, featured screw-retained restorations exclusively (Fig. 22.21). The updated version of that type of restoration (Fig. 22.22) features a much lower profile for the abutment and provides the patient with a restoration that provides improved esthetics and function (Box 22.6).

Advantages

Retrievability. Screw-retained restorations are easily removed by the clinician at any time after delivery should there be a complication, such as prosthesis fracture or chipping, that requires intervention with the prosthesis outside the mouth. Although a
● **Fig. 22.20** Two splinted screw retained crowns. Note screw access channel (green arrows) and retaining screw (red arrows).

● **Fig. 22.21** Original Brånemark design "Swedish High-Water Bridge." *(From Misch CE. The completely edentulous mandible: treatment plans for fixed restorations. In:* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Elsevier; 2015.)*

● **Fig. 22.19** Screw-retained crown.

● **Fig. 22.22** Contemporary design of full-arch screw-retained bridge.

cement-retained prosthesis can also be removed by the clinician, it is a less predictable procedure and risks damage to the patient's restoration and implants. For this reason, screw retention is often recommended for long-span, full-arch, and cantilevered restorations, or in cases where the prosthesis may require removal in the future.

Lack of Cement. The absence of the cement interface between the restoration and the implant abutment is another important advantage of a screw-retained prosthesis. Excess cement at the margin has been shown to be an important iatrogenic contributing factor to implant complications, such as implant peri-mucositis and peri-implantitis. Although there are established techniques for mitigating that risk, it remains an important consideration. For example, in clinical situations where the soft tissue interface is part of the patient's smile, and it is necessary to place the margin of the restoration subgingivally, a screw-retained restoration is recommended.

Lack of Crown Height Space. In areas where there is minimal interocclusal space (i.e., CHS), a screw-retained restoration will provide better retention for the prosthesis. Cementation on short implant abutments provides the same risk for debonding as with restorations on natural teeth.

Disadvantages

Esthetics Is Dependent on Implant Positioning. For a screw-retained prosthesis, the esthetics of the prosthesis is highly dependent on the implant positioning in the x, y, and z axes. The most common area in the oral cavity that presents a problem is the maxillary anterior. Because of the inherent trajectory of the alveolus in this area, it is not uncommon for the implant to be facially positioned. Therefore the access hole would be required to be in the buccal aspect of the crown, which leads to an obvious esthetic issue.

• BOX 22.6   Screw-Retained Crowns

Advantages
- Retrievable
- Known retention
- No risk for leaving residual cement
- Limited interocclusal space

Disadvantages
- Highly dependent on implant position (unesthetic)
- Access hole
- More expensive
- Occlusion (access hole wearing)
- Multiple splinted units—passivity
- Porcelain fracture—unsupported porcelain
● **Fig. 22.23** Screw-retained prosthesis (bicuspid) with access hole filled with composite.

Access Hole. The greatest disadvantage to screw-retained restorations involves the screw access hole in the restoration. Particularly on ceramic or metal-ceramic restorations, the patient can often see the vestiges of this access and, without proper preoperative explanation, may be concerned. Fortunately this result can be largely mitigated by clinicians using newer composites that offer a remarkably good match to the restorative material used (e.g., opaque composite material) (Fig. 22.23).

Difficulty in Obtaining a Passive Fit. Some authors have reported increased difficulty in obtaining a passive fit for multiimplant screw-retained restorations compared with cement retained. The reasoning is that because there is some degree of spatial relief provided around each cement-over abutment, the overall restoration should be more forgiving of a minor misfit. Although there is some logic to this argument, it is fortunate that improved clinical and laboratory techniques, specifically the use of the implant verification jig and computer-aided design/computer-aided manufacturing (CAD/CAM) techniques, have made such challenges to passive fit increasingly rare.

Cement-Retained Restorations

Cement-retained restorations consist of a conventional crown or bridge prosthesis cemented over one or more abutments, which have been secured to the implant with an abutment screw (Fig. 22.24). The abutment for a cement-retained restoration can be either a

● **Fig. 22.24** Cement-retained crown, shown in position over a screw-retained custom abutment.

Advantages
- More passive
- Less expensive
- Enhanced esthetics
- Traditional prosthetics (conventional laboratory techniques)
- More freedom of implant position

Disadvantages
- Use of cement
- Unknown retention
- Can be difficult to remove

standardized abutment or a custom abutment. Standardized abutments have pre-prepared margins that attempt to mimic the soft tissue contours of the implant interface. Custom abutments, although originally fabricated with a waxing and casting technique, are now largely milled from precision titanium components using CAD/CAM methodology (Box 22.7).

Advantages

More Traditional Prosthetic Technique. Many clinicians prefer a cement-retained prosthesis because the prosthetic and laboratory procedures parallel traditional prosthetics. The preparation, impression, laboratory, and insertion techniques are similar to procedures completed on natural teeth. Therefore many clinicians and their office staff are comfortable completing cement-retained prostheses.

Passive Fit. A cement-retained prosthesis has been shown to be advantageous because a more passive fit is obtained. Because a cementable prosthesis contains a "cement space," the prosthesis will be more passive in comparison with a screw-retained prosthesis. The cement space is ideally approximately 40 µm and will compensate for any fit variation. When a screw-retained prosthesis is fixated to implants, permanent strain conditions develop as the force is transmitted from the prosthetic screws to the implant body. Therefore studies have concluded that most screw-retained prostheses exhibit some degree of nonpassiveness.[47]

No Access Hole. Another key advantage of cement-retained restorations is the lack of a screw access hole in the restoration. Although an occlusal access hole in a posterior crown can predictably be filled in a reasonably esthetic manner, angled implants where the screw access is from the facial or incisal can create esthetic challenges. Even though specially designed screw-retained components have been fabricated to correct these angles, many clinicians find the cemented restoration to be a more viable solution.

The screw access hole, even when correctly placed on the occlusal surface of the crown, may still present clinical difficulties. When using ceramic and metal-ceramic restorations, there may exist unsupported ceramic material around the screw channel that is susceptible to chipping. Although this complication rarely occurs in the now commonly used stronger monolithic materials like BruxZir zirconia (Glidewell Dental), it is still a risk when using layered ceramic materials. In addition, the occlusal contacts may fall in the area of a screw access hole, resulting in an occlusal scheme that varies from the original restorative plan.

Disadvantages

Retrievability Difficulty. Retrievability Cement-retained restorations are more difficult for the clinician to remove from the
• **Fig. 22.25** Natural tooth versus implant soft tissue attachments. There exists no attachment of the tissue to the implant surface as seen with a natural tooth (arrows).

patient after delivery. Even when a provisional cement is used, the clinician risks damage to the restoration or implant in the removal process. When using a cement-retained restoration, the clinician must follow the same retentive principles established for crowns on natural teeth. The preparation must be sufficiently retentive or there will be a significant risk for debonding. A cemented restoration also requires greater interocclusal distance than does a screw-retained restoration.

Requires Increased Crown-Height Space. A cement-retained restoration requires a minimum of 7 to 8 mm of CHS, whereas a screw-retained restoration can be successfully delivered with a space of 5 to 7 mm. (Internal data, Glidewell Dental).

Cement Retention. Perhaps the most significant disadvantage for the use of cement-retained implant restorations is the risk for excess retained cement and the peri-implant complications that could result. Because of the absence of strong fibrous attachments between the implant and the soft tissue, the peri-implant tissues are more easily displaced and retain cement easier in comparison with a natural tooth with its stronger fibrous connections (Fig. 22.25).

Miscellaneous Restorations

Angulated screw channel

In some clinical situations the angulation of the implant requires an access hole through the facial aspect of the implant restoration. New technology has led to the development of the angulated screw channel (ASC). The ASC allows a screw-retained prosthesis to be fabricated when angulations of the implant are less than 25 degrees. This is accomplished by using a lingual access to fixate the prosthesis.
• **Fig. 22.26** Combination Prosthesis. (A) Radiograph depicting #11/#12/#13 implant placement. (B) Intraoral view of # 11 custom abutment and #12 to #13 screw-retained abutments. (C) Combination screw-cement prosthesis with #11 (cementable) and #12 to #13 (screw-retained). (D) Final insertion of screw-cementable prosthesis.

Screw-cementable (combination) prosthesis

In clinical cases in which multiple implants are splinted together, and one or more of the implants are positioned with the screw access within the buccal aspect of the prosthesis, a combination prosthesis may be fabricated. This technique combines the advantages of cement and screw-retained prostheses into the same prosthesis. The combined prosthesis allows for the use of a temporary cement over the telescoped abutment (cement-retained) and fixation screws on the screw-retained part of the prosthesis. This allows for retrievability, along with ease of seating and enhanced esthetics (Fig. 22.26).

Ideal Positioning for Screw and Cement-Retained Prosthesis

Ideal implant positioning must be completed to optimize the esthetics of the implant restoration. The following are recommendations for ideal implant positioning (implant body long axis) for screw and cement-retained prostheses (Fig. 22.27):

Anterior

Cement retained: slightly lingual to incisal edge
Screw retained: cingulum area

Posterior

Cement retained: central fossa
Screw retained: central fossa

Abutment Options

Abutments for Cement-Retained Restorations

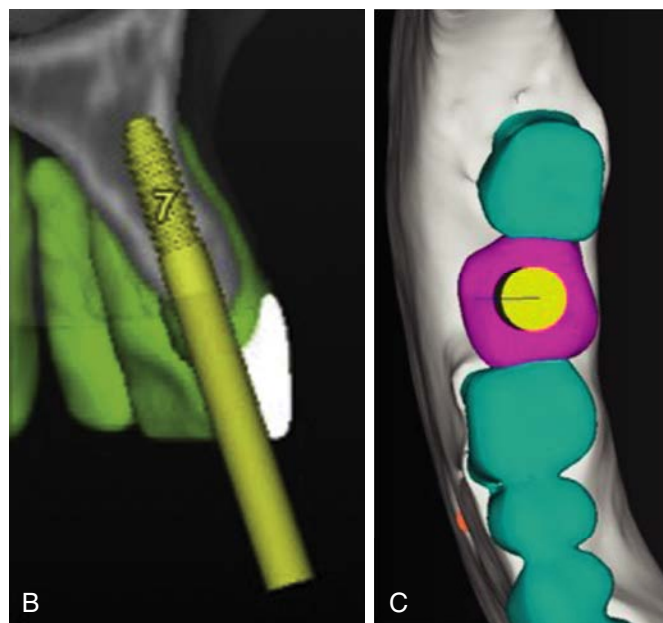
Standardized (Stock) Abutments

Standardized (stock) abutments are prefabricated components that are screw retained and intended to be connected directly to the endosseous implant platform. These abutments are used for the retention of a cemented prosthesis and are indicated for a single- or multiple-implant prostheses. Each stock abutment is specific for the restorative platform and the implant type. There are several common designs (e.g., straight, angled, esthetic), which vary based on the position and contours of the margins (Fig. 22.28).

Standardized abutments are advantageous in that they are inexpensive and often can be modified by the clinician or laboratory for the specific case. The disadvantages of these abutments are that they are more likely to allow tissue show-through (i.e., darkness because of tissue translucency) and have been associated with poorer tissue health.[48]

Custom Abutments

Custom abutments may be fabricated by using a castable abutment or through a CAD/CAM process. They may be produced from titanium, gold alloy, or milled zirconia with a titanium base (Fig. 22.29). These abutments can be designed with the margin in the ideal position with respect to the soft tissue drape around the implant.

Custom abutments allow for better soft tissue health, along with correction of nonideal implant placement. The disadvantage of custom abutments includes an increased laboratory cost.
• **Fig. 22.27** Ideal Positioning: (a) Cement-Retained - slightly lingual to incisor edge (green arrow) and Screw-retained - cingulum area (red arrow), (b) CBCT cross section depicting ideal placement for cement-retained prosthesis. and (C) posterior screw and cement retained.


• **Fig. 22.28** Standardized abutments for cemented restorations.

• **Fig. 22.29** Custom abutments for cemented restorations. Shown, left to right, are posterior titanium abutment, anterior titanium abutment, and anterior ceramic-titanium hybrid abutment.

Abutments for Screw-Retained Restorations

With few exceptions, most abutments for screw-retained restorations are standardized components (e.g., multiunit abutments). The contemporary design of today's multiunit abutment differs markedly from the component introduced in the original Brånemark protocol. Although the Standard Abutment once marketed by Nobelpharma (Fig. 22.30) provided the advantages of screw retention, the cylindrical design placed the restoration well above the soft tissue emergence of the implant, resulting in the Swedish high water design (Fig. 22.31). With the development of the multiunit abutments (Fig. 22.32), it is now possible to design prostheses that mimic a natural emergence profile from the soft tissue (Fig. 22.33).

Restorative Materials

There are few, if any, areas of restorative dentistry that have advanced as far in recent years as the choices of restorative materials that are

offered to the clinician providing implant restorations. Use of these materials is made possible by concomitant advances in CAD/CAM. In addition to the advanced computer-guided milling machines that enable the fabrication of these designs, there is rapid development in additive manufacturing, or three-dimensional printing, in providing implant restorations. In implant dentistry today the state-of-the-art esthetic restorative crown and bridge materials consist of monolithic ceramics such as zirconia (ceramic) and lithium disilicate (glass-ceramic), as well as porcelain fused to metal.

Zirconia

The use of zirconia is increasingly more popular than the traditional porcelain fused-to-metal prostheses. Most monolithic zirconia

• **Fig. 22.31** Swedish High Water Design: Standard abutments which attach to the implant place the prosthesis above tissue level.

• **Fig. 22.32** Multiunit Abutment (Glidewell Dental).

restorations are made of a partially stabilized zirconia (i.e., 3% yttria, 97% zirconia). Compared with other all-ceramic crown and bridge materials, monolithic zirconia exhibits a unique combination of high flexural strength, fracture toughness, and exceptional esthetics. Originally these restorations were specifically fabricated for posterior prostheses; however, with improved zirconia formulations and manufacturing processes, enhanced translucency and shading are present, which make them an anterior esthetic option as well.

The posterior monolithic zirconia (e.g., BruxZir Full Strength Solid Zirconia) can be used for screw-retained crowns in the

• **Fig. 22.33** Monolithic full-arch prosthesis, secured by multiunit abutments (BruxZir).

posterior, posterior bridges, and full-arch restorations (Fig. 22.34). Advanced staining techniques have enabled technicians to create a one-piece restoration with strength far exceeding hybrid restorations or layered restorations, while offering excellent esthetics. In the anterior regions of the mouth a third-generation material (e.g., BruxZir Esthetic) exhibits excellent translucency and shading and tensile strength that far exceeds other esthetic restorative materials. It can be used for anterior crowns, veneers, anterior screw-retained crowns, and short span bridges in the anterior (Fig. 22.35).

Lithium Disilicate and Lithium Silicate

Lithium disilicate, introduced by Ivoclar Vivadent as IPS e.max, and lithium silicate, manufactured by Glidewell Dental as Obsidian, are highly esthetic and versatile glass ceramic monolithic materials that can be milled or pressed to create veneers, crowns, and short span bridges. Although not providing the same flexural strength or fracture toughness shown by zirconia materials, they exhibit higher levels of translucency than the full-strength versions of these materials (Fig. 22.36).

Metal-Ceramic

Metal-ceramic restorations were developed in the 1970s to provide a higher-strength alternative to the feldspathic porcelains that were then available. By creating a cast metal framework that was layered with feldspathic porcelain, dental laboratories were able to significantly increase the strength of the restoration, and still maintain high esthetics. Two major technological advances have enabled the development of a new generation of metal-ceramic restorations that exhibit even greater strength, esthetics, and accuracy of fit. The advent of direct metal laser sintering, or three-dimensional printing of dental frameworks, provided a new level of fit and consistency for the metal underlying the metal-ceramic restoration. In addition, a pressable lithium silicate material, Obsidian, was developed that is significantly stronger than the feldspathic porcelains previously used for veneering. The combination created a strong and highly esthetic restoration that provides a better fit than a cast metal veneered restoration. Obsidian pressed to metal restorations can be used in the anterior or posterior for single crowns, short or long span bridges, and screw-retained implant crowns (Fig. 22.37).

Gold Alloy

For more than 100 years, gold alloy restorations have been a predictable and highly useful dental material. No dental material has more long-term documentation than gold alloy. This material has declined in popularity because of the increasing cost of noble metals, as well as patients' demand for more esthetic restorations. Gold alloy is primarily used for crowns, bridges, and screw-retained implant crowns in the posterior (Fig. 22.38).

• **Fig. 22.34** Monolithic Zirconia. (A) BruxZir SRC (screw-retained crown), (B) BruxZir bridge, and (C) BruxZir full-arch screw-retained bridge.

● **Fig. 22.38** Gold alloy crowns.

● **Fig. 22.39** Polymethylmethacrylate provisional full-arch bridge on implants.

Polymethylmethacrylate

Polymethylmethacrylate (PMMA) is a stable resin that demonstrates strength and translucency when milled using CAD/CAM technology. It is commonly used to create short- and medium-term provisionals for implant restorations to evaluate esthetics and phonetics, and to enable progressive loading treatment plans. It is also used for patient prototyping in the production of full-arch zirconia implant bridges, enabling the patient to wear a PMMA replica of his or her final zirconia bridge to provide a meaningful final approval for the design (Fig. 22.39 and Table 22.2).

TABLE 22.2	Current Recommendations for Single- and Multiple-Implant Crowns

Single-Implant Crowns

Anterior

1. Monolithic zirconia (BruxZir Esthetic)
2. Monolithic glass-ceramic (IPS e.max, Obsidian)
3. Metal-ceramic (Obsidian pressed to metal)
4. Metal-ceramic (porcelain fused to metal)

Posterior

1. Monolithic zirconia (BruxZir Full-Strength)
2. Metal-ceramic (Obsidian pressed to metal)
3. Metal-ceramic (porcelain fused to metal)

Multiple-Implant Crowns

Anterior

1. Monolithic zirconia (BruxZir Esthetic)
2. Monolithic glass-ceramic (IPS e.max, Obsidian)
3. Metal-ceramic (Obsidian pressed to metal: laser-sintered in non-, semi-, or precious)

Posterior

1. Monolithic zirconia (BruxZir Full-Strength)
2. Metal-ceramic (Obsidian pressed to metal: laser-sintered in non-, semi-, or precious)
3. Metal-ceramic (porcelain fused to metal)

Treatment Planning for the Edentulous Posterior Maxilla

RANDOLPH R. RESNIK AND CARL E. MISCH[†]

Historically the maxillary posterior region has been one of the most difficult regions in the oral cavity to treat. Maxillary posterior partial or complete edentulism is one of the more common treatment areas in implant dentistry. However, the maxillary posterior edentulous region presents many unique and challenging conditions in implant dentistry that many years ago led to an area with the highest implant failure rate. Over the years many new surgical protocols and technological advances have led to this region being as predictable as any other region in the oral cavity. Most noteworthy of these surgical methods includes sinus augmentation to increase available bone height, ridge augmentation to increase bone width, better-designed shorter implants, and modified surgical approaches to insert implants in poorer bone density.[1] Grafting of the maxillary sinus to overcome the problem of reduced vertical available bone has become a very popular and predictable procedure since the 1990's. After the initial introduction by Tatum in the mid-1970s and the initial publication of Boyne and James in 1980, many studies have been published about sinus grafting with results higher than 90%.[2-38] This chapter will address the various disadvantages inherent with the posterior maxilla, along with the treatment planning factors and concepts specific to the maxillary posterior partial or complete edentulous regions.

Inherent Disadvantages of Posterior Maxilla Treatment

Poor Bone Density

In general the bone quality is poorest in the edentulous posterior maxilla compared with any other intraoral region.[30] A literature review of clinical studies reveal poorer bone density may result in decreased implant loading survival by an average of 16% and has been reported to be as low as 40%.[31] The cause of the poorer success rate is related to several factors. Bone strength is directly related to its density, and the poor density bone of this region is often 5 to 10 times weaker in comparison with bone found in the anterior mandible (~ D2 Bone Quality).[32] Bone densities directly influence the percent of implant–bone surface contact (bone–implant contact or

BIC), which accounts for the force transmission to the bone. The bone–implant contact (~<30%) is the lowest in D4 (Type 4) bone compared with other bone densities. The stress patterns distributed within poor bone density migrate farther toward the apex of the implant. As a result, bone loss is more pronounced and occurs also deeper along the implant body, rather than only crestally as in other denser bone conditions. D4 bone also has been shown to exhibit the greatest biomechanical elastic modulus difference compared with titanium under load.[32] This biomechanical mismatch develops a higher strain condition to the bone, which may be in the pathologic overload range. As such, modified surgical protocols are warranted to increase bone-implant contact.

In the posterior maxilla the poorer deficient osseous structures and the minimal cortical plate on the crest of the ridge will compromise the initial implant stability (insertion torque) at the time of placement (Fig. 23.1). The labial cortical plate is usually thin, and the ridge is often wide. As a result the lateral cortical bone–implant contact to stabilize the implant is often insignificant because implant placement rarely engages the buccal plate. Therefore initial healing of an implant in D4 bone is often compromised, and clinical reports indicate a lower initial healing success than with D2 or D3 bone.

● **Fig. 23.1** D4 bone density, which is usually found in the posterior maxilla. This type of bone usually exhibits minimal cortical bone and has very fine trabeculae.

[†] Deceased
● **Fig. 23.2** As bone resorbs in the maxilla, the ridge shifts toward the lingual and encroaches on the maxillary sinus. This also will result in a change in the relationship of the maxilla and mandible.

Decreased Available Bone

In the posterior maxilla the implant clinician is often confronted with a decreased bone quantity, thereby compromising implant placement. The dentate maxilla is usually associated with a thinner cortical plate on the facial compared with the mandible. Because the trabecular bone of the posterior maxilla is finer than other dentate regions, the loss of maxillary posterior teeth usually results in an initial decrease in bone width at the expense of the labial bony plate. The width of the posterior maxilla will decrease at a more rapid rate than in any other region of the jaws.[25] The resorption phenomenon is accelerated by the loss of vascularization of the alveolar bone and the existing fine trabecular bone type. However, because the initial residual ridge is so wide in the posterior maxilla, even with a significant decrease in the width of the ridge, ideal size root form implants usually can be placed (Fig. 23.2).

Increased Pneumatization of the Maxillary Sinus

Pneumatization is a normal physiologic process that occurs in all paranasal sinuses during the growth period, which results in an increased volume. Histologic studies have shown that the pneumatization process occurs by osteoclastic resorption of the cortical walls of the sinus. However, the etiology of maxillary sinus pneumatization is poorly understood and has been associated with heredity, pneumatization drive of the nasal mucous membrane, craniofacial configuration, bone density, growth hormones, and intra-sinus air pressure.[39]

The pneumatization process has been shown to increase in size after tooth extraction. Most likely this is a result of a decrease in functional forces that are transferred to the bone after tooth loss and the remodeling process involving disuse atrophy according to Wolff's law.[40] Because of the proximity and possible protrusion of the maxillary sinus roots into the sinus, the lack of cortical bone lining after extraction will allow the sinus to expand. Studies have also shown that pneumatization is greater after molar extraction in comparison with premolar extractions, mainly because of the greater resultant defect.[41] Sharan and Madjar[39] in pneumatization studies showed that a preextraction curving sinus floor resulted in greater expansion. In addition, when two or more adjacent posterior teeth were extracted or when a second molar was extracted (in comparison with the first molar), greater expansion was reported (Fig. 23.3).
● **Fig. 23.3** Maxillary Sinus Pneumatization. (A and B) After tooth loss the maxillary sinus expands (non-uniformly) and approaches the maxillary sinus floor, which decreases available bone for implant placement.

Resultant Increased Crown Height Space

As the vertical bone loss increases, the crown height space increases. This most likely will result in implant placement inferior to the adjacent interproximal bone (if present) and inferior to the ideal apical-coronal position (i.e., 2–3 mm below the free gingival margin). The inferior positioning results in an increased crown height space, thereby increasing morbidity to the long-term prognosis of the implant prosthesis. Sevimay et al.,[42] in a three-dimensional finite element analysis, showed that when increasing the crown height from 10 to 20 mm, the strain values placed on the implant prosthesis increased 72% for tensile stress and 41% for compressive stress (Fig. 23.4). Therefore, implant prostheses in this area are at an increased risk in comparison to other areas of the oral cavity.

Lingual Oriented Ridge Position

As a result of the horizontal bone resorption process the ridge will progressively shift toward the palate until the ridge is resorbed into a medially positioned narrower bone volume.[29] The posterior maxilla continues to remodel toward the midline as the bone resorption
● **Fig. 23.4** Crown Height Space. (A) Measured from the top of the implant to the occlusal plane. (B) As bone resorbs from Division A to Division D, the vertical height position becomes more apical. This results in an increased crown height, even if vertical grafting is completed within the sinus.
● **Fig. 23.5** Another component of the maxillary posterior resorption process is the shifting of the ridge to the lingual. Because of the lingual positioning, implants are often placed in a nonideal buccal-lingual position.

process continues. Because of this resorption pattern, the buccal cusp of the final prosthesis will usually be cantilevered facially to satisfy the esthetic requirements at the expense of biomechanics in the moderate-to-severe atrophic ridges (Fig. 23.5).

Anatomic Location

Because of the maxillary posterior's anatomic location, access is a common problem. Especially when lack of opening is present,

surgical placement of implants in the posterior is sometimes difficult because of the lack of interocclusal space. Most commonly, maximum mouth opening is measured in the anterior by using the interincisal distance. Studies vary on the definition of a restricted opening; however, it is usually within the 35- to 40-mm distance.[43] Because the posterior opening is far less than the anterior, obtaining sufficient space for implant placement or prosthetic procedures is usually difficult. Insufficient space also becomes increasingly problematic when using a cone beam computed tomography (CBCT) surgical template for implant placement. In addition, the lack of space will increase the risk for swallowed or aspirated objects (Fig. 23.6).

Increased Biting Force

The occlusal forces in the posterior region are greater than in the anterior regions of the mouth. Studies have shown that the maximum bite force in the anterior region ranges from 35 to 50 lb/in^2. The bite force in the molar region of a dentate person ranges from 200 to 250 lb/in^2. Therefore, a 5:1 ratio exists between the maxilla and mandible. Parafunctional forces may increase the resultant force as much as threefold, which leads to greater implant and prosthetic morbidity.[44-46] As a consequence the maxillary molars of the natural teeth have 200% more surface area than the premolars and are significantly wider in diameter (Fig. 23.6).[1] Both of these features will reduce the stress to bone, which also decreases

● **Fig. 23.6** (A) It is often difficult to have adequate space for implant placement, especially in the posterior maxilla. With the popularity of guided surgery, it becomes even more difficult because greater space is required for implant placement. (B) Standard surgical drill, (C) Guided drill kits contain drills that are usually longer (~10 mm) than regular-size drills.
● **Fig. 23.7** Increased biting force may lead to accelerated crestal bone loss, along with mechanical stress complications such as fractured prostheses, screw loosening, and fractured implants.

Requirement of Greater Surface Area Diameter Implants and Minimized Occlusal Forces

When treatment planning in the posterior maxilla to combat biomechanical forces, ideally conditions should be simulated as those found with natural teeth. Because stresses occur primarily at the crestal region, biomechanical designs of implants to minimize their noxious effects should be implemented.[47] Implant diameter is an effective method to increase surface area at the crestal region and combat the forces.[47,48] Ideally Division B implants are not used in the posterior maxilla. A 12-year retrospective study of 653 sinus grafts performed by Misch revealed 14 implant failures.[49] Eight implant failures were caused by implant fracture at the neck of smaller-diameter implants. Therefore implants of at least 5 mm in diameter are suggested, or multiple splinted 4-mm implants in the molar area.

Over the years the concept of implant length has become less important to long-term implant success. Because the majority of force is transmitted only to the middle-crestal area of the implant, less emphasis is now placed on the need for longer implants. In general the better the bone quality, the less critical the implant length. However, with poorer bone quality, or extensive graft areas, greater length increases the surface area, allowing for better initial fixation or primary stability.

In certain cases, increasing implant number is an excellent method to decrease associated stresses. Normally one implant is indicated for each missing tooth. However, if narrower implants are indicated, then more implants should be placed and splinted

the strain of the bone. Following this natural selection, implant support should be greater in the posterior molar region than any other area of the mouth.[1] Therefore the decrease in bone quantity and quality and increased forces should be considered in the treatment plan of this region of the mouth (Fig. 23.7).[47]

Root Surface Areas of Maxillary Teeth
• **Fig. 23.8** Root surface areas are significantly greater in the posterior versus the anterior.

together to reduce stresses to the bone. If excessive force factors are present, two implants for each molar are then recommended.

And lastly, posterior cantilevers on implant prostheses should be minimized. Narrow occlusal tables with centered implant contact points prevent shear type of forces, which are detrimental to the implant interface (Fig. 23.8).

Maxillary Sinus Has High Incidence of Pathology

The maxillary sinus has the highest incidence of pathology in comparison with any of the other paranasal sinuses. Most studies report 30% to 40% of asymptomatic patients have some type of pathology present in their sinuses (i.e., inflammation, cysts, mucoceles, rhinosinusitis, fungal infections, carcinomas, antroliths). Therefore because many posterior maxillas require grafting, the presence of pathology results in complications and delayed treatment (Fig. 23.9).[51,52]

Treatment History

Treatment of the Posterior Maxilla—Literature Review

Over the years several strategies have been advocated to restore the posterior maxilla and address the deficiency of bone volume and poor bone quality. The various approaches can be categorized as follows:
- Avoid the maxillary sinus and place implants anteriorly, posteriorly, or medially.[52-54]
- Place implants and perforate the sinus floor.[55,56]
- Perform sinus augmentation procedures with simultaneous or delayed implant placement.[2-6,13,57-62]
- Elevate sinus floor during implant placement.[2,3,5,57-66]
- Use alternative types of implants.
- Use subperiosteal implants.[67,68]
- Perform horizontal osteotomy, interpositional bone grafting, and endosteal implants.[69,70]

In the early days of oral implantology, implants were inserted in the posterior maxilla without modifying the maxillary sinus topography. Shorter-length implants were often placed below the antrum. The decreased surface area, compounded by poor bone quality, resulted in poor implant stability and increased failure rates. Attempts to place larger endosteal implants posterior to the
• **Fig. 23.9** The maxillary sinus has a high incidence of pathology, which can range from (A) cystic lesions and (B) completely opacified sinus cavities.

antrum and into the tuberosity and pterygoid plates also resulted in compromised situations. Although feasible from a surgical standpoint, rarely are third- or fourth-molar abutments indicated for proper prosthodontic support. This approach often requires a greater pontic space (i.e., three or more pontics between the anterior and posterior implants). The resultant prosthesis span will result in excessive flexibility of the prosthesis, unretained restorations, excess stresses, and implant failure.

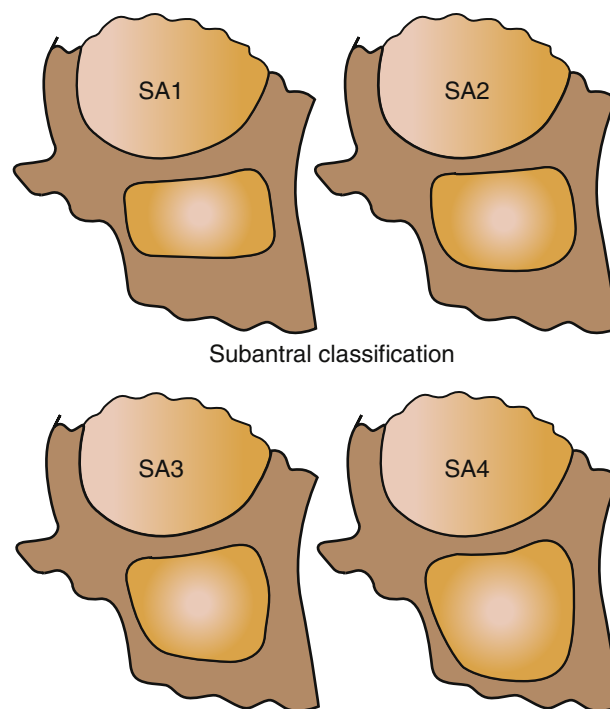
In the late 1960s Linkow reported that the blade-vent implant could be blunted and the maxillary sinus membrane slightly elevated to allow implant placement "into" the sinus in the posterior maxilla.[71] This technique required the presence of at least 7 mm of vertical bone height below the antrum.

Geiger and Pesch[55] reported that ceramic implants placed through the maxillary sinus floor could heal and stabilize without complication. Brånemark et al.[56] have shown that implants may be placed into the maxillary sinus without consequence if integration occurs between the implants and the bone below the sinus. Yet they also report a higher failure rate (70% success rate for 5–10 years) for this technique. Ashkinazy[54] and others have reported on using tomographic radiographs to determine whether adequate bone exists on the palatal aspect of the maxillary sinus for blade implants. However, Stoler[72] stated that after 25 consecutive computed tomographic scans of maxillae, adequate bone for implant support was not found on the medial aspect of the sinus. Thus it seems that if sufficient bone is present medial to the sinus, it is the rare exception.

In the early 1970s Tatum[2,3,58,63] began to augment the posterior maxilla with onlay autogenous rib bone to produce adequate vertical bone for implant support. He found that onlay grafts below the existing alveolar crest would decrease the posterior intradental height significantly, yet very little bone for endosteal implants would be gained. Therefore in 1974 Tatum developed a modified Caldwell-Luc procedure for elevation of the sinus membrane and subantral (SA) augmentation.[2,3] The Caldwell-Luc procedure was established by the American George Caldwell and the Frenchman Henry Luc, who in 1893 described a new technique and procedure to access the maxillary sinus using a lateral window.[73] The crestal ridge of the maxilla was infractured and used to elevate the maxillary sinus membrane. Autogenous bone was then added in the area previously occupied by the inferior third of the sinus. Endosteal implants were inserted in the grafted bone after approximately 6 months. Implants were then loaded with a final prosthesis after an additional 6 months.[2,3]

In 1975 Tatum developed a lateral approach surgical technique that allowed the elevation of the sinus membrane and implant placement in the same surgical appointment. The implant system used was a one-piece ceramic implant, and a permucosal post was required during the healing period. Early ceramic implants were not designed adequately for this procedure, and results with the technique were unpredictable. In 1981 Tatum[58] developed a submerged titanium implant for use in the posterior maxilla.[3] The advantages of submerged healing, the use of titanium instead of aluminum oxide as a biomaterial, improved biomechanics, and improved surgical technique made this implant modality more predictable.

From 1974 to 1979 the primary graft material for the sinus graft procedure was autologous bone. In 1980 the application of the SA augmentation technique with a lateral maxillary approach was further expanded by Tatum with the use of synthetic bone. That same year, Boyne and James[4] reported on the use of autogenous bone for SA grafts. Most of the data published in the 1980s were anecdotal or based on very small sample sizes. In 1987 Misch[5] organized a treatment approach to the posterior maxilla based on the amount of bone below the antrum, and in 1989 he expanded the treatment approach to include the available bone width related to the surgical approach and implant design (Fig. 23.10).[61,62] Since then, minor modifications regarding the graft materials or surgical approach have been proposed.

In the 1990s the profession developed a much greater interest in the sinus graft technique.[13] Several reports flourished in the literature, reporting on minor changes in the technique, different materials used in the graft, different origins for the autogenous portion of the graft, histomorphometric data relative to the graft healing, and other retrospective studies relative to the survival rates of implants placed in grafted sinuses with a simultaneous or delayed approach.[60-62,74-87]


● **Fig. 23.10** In 1987 Misch presented four subantral treatment options based on the amount of bone below the maxillary sinus. Subantral augmentation category 1 (SA-1) sinus used traditional implant approaches. SA-2 used a sinus lift procedure within the osteotomy. For SA-3 and SA-4 a Tatum sinus graft procedure is performed before implant insertion.

Long-term results have been reported by Tatum et al.[60] to be greater than 95% in more than 1500 SA augmentations performed. The sinus graft procedure has been the most predictable method to grow bone height from 5 to 20 mm compared with any other intraoral bone-grafting technique, with a graft success rate and an implant survival rate greater than 95%.

An alternative technique, which was a less invasive technique using osteotomes, was introduced in 1994 by Summers.[88] And more recently, newer techniques include the use of shorter implants, placement of implants to avoid the sinus, elongated zygomatic implants, and pterygoid plate implants.

Sinus Graft Options for the Posterior Maxilla

A classification based on the amount of available bone height between the floor of the antrum and the crest of the residual ridge in the region of the ideal implant locations was presented by Misch[5] in 1987 and later modified by Resnik in 2017 (Table 23.1). This protocol detailed a surgical approach, bone graft material, and timetable for healing before prosthetic reconstruction. In 1988 Cawood and Howell also classified the edentulous posterior maxilla, which included the loss of bone and pneumatization of the maxillary sinus.[89] In 1995 Misch modified his 1987 classification to include the lateral dimension of the sinus cavity, and this dimension was used to modify the healing period protocol, because smaller-width sinuses (0–10 mm) tend to form bone faster than larger-width (>15 mm) sinuses. Other classifications of the sinus graft procedure have been proposed by Jensen[90] in 1998 and Chiapasco[80,91] in 2003. In 2017 Resnik further modified the Misch classification to include different augmentation techniques and the use of short implants with regard to existing force factors.

TABLE 23.1	Healing Times for Treatment Categories			
Procedure	Height (mm): Favorable/ Unfavorable Conditions	Procedure	Healing Time (Months): Graft	Healing Time (Months): Implant
SA-1	≥ 8 / ≥ 10	Division A root form placement	No Graft	4–6 (no bone grafting)
SA-2	≥ 6 / ≥ 8	Sinus "bump"; simultaneous Division A root form placement	No Graft	6–8 (no bone grafting)
SA-3	≥ 5 / ≥ 8	Sinus graft (transcrestal or lateral wall + implant placement)	6–8	6–8[a]
SA-4	< 5 / < 5	Lateral wall approach sinus graft; delayed Division A root form placement	6–8	6–10[a]

[a]Evaluate at implant insertion.

SA, Subantral augmentation option.

Misch-Resnik Maxillary Posterior Classification

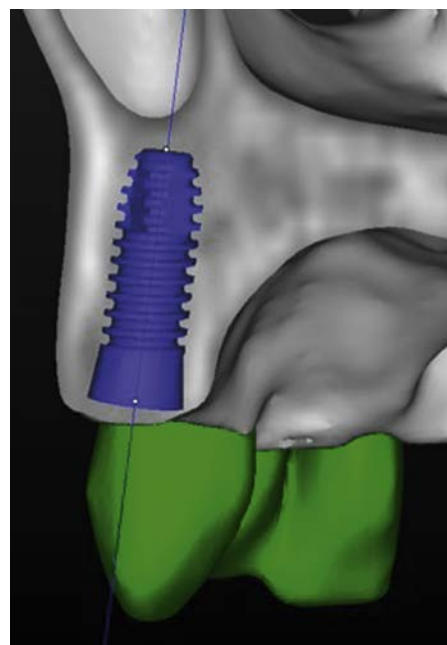
There exist four treatment classifications based on the amount of bone available below the maxillary sinus (i.e., SA-1, SA-2, SA-3, and SA-4). Because implants in the posterior maxilla are susceptible to biomechanical stress, each category has been further divided into two divisions: favorable and unfavorable force factors.

Favorable Conditions
- Good quality of bone (D2/D3 bone) with the presence of cortical bone
- Minimal occlusal force factors
- No parafunction
- Ideal crown/implant ratio

Unfavorable Conditions
- Parafunction, high force factors
- Poor quality of bone (D3/D4 bone) with no cortical bone
- Increased occlusal force factors
- Parafunctional forces present
- Poor crown/implant ratio

Subantral Option 1: Conventional Implant Placement

The first SA treatment option, SA-1, is applied when there exists sufficient available bone height to permit the placement of endosteal implants without entry into the sinus proper. The minimum "ideal" bone height is related to force factors and the bone density. For posterior maxillae with favorable force factors, a small-length implant (~ 8 mm) may be used as long as there exists sufficient bone for a minimum width to accommodate a 5-mm-diameter implant. For unfavorable force factors a minimum of 10 mm of height is required.

Patients with narrower bone volume (Division B) may be treated with osteoplasty or augmentation to increase the width of bone. The insertion of smaller surface area implants is not suggested because the forces are greater in the posterior regions of the mouth, and the bone density is less than in most regions. In addition, the narrow ridge is often more medial than the central fossa of the mandibular teeth and will result in an offset load on the restoration, which will increase the strain to the bone. Osteoplasty in the SA-1 posterior maxilla may change the SA category if the height of the remaining bone is less than 8/10 mm after the bone modification is completed. Augmentation for width may be accomplished with membrane grafting, bone spreading, and autogenous onlay or appositional grafts. Larger-diameter implants are often required in the molar region, and bone spreading to


- **Fig. 23.11** Subantral option 1 (SA-1) technique that includes implant placement that does not enter the sinus proper.

place wider implants is the most common approach when the bone density is poor. If less than 2.5 mm of width is available in the posterior edentulous region (Division C–w), the most predictable treatment option is to increase width with onlay autogenous bone grafts.[92] After graft maturation the area is then reevaluated to determine the proper treatment plan classification. However, Division C–w posterior maxillas are unpredictable and require an increased skill set.

Although a common axiom in implant dentistry is to remain 2 mm or more from an opposing landmark, this is not indicated in the SA region (i.e., inferior floor of the sinus). As long as pathology is not present in the maxillary sinus, there exist no contraindications for placement of implants at the level of or engaging the cortical plate of the sinus floor. Healing of implants in the SA-1 category is allowed to continue uneventfully for a minimum of 4 to 6 months, depending on the bone density. Usually progressive loading is recommended during the prosthetic phases of the treatment when D3 or D4 bone is present (Figs. 23.11 and 23.12; Box 23.1).

SA-1: Implant Placement – does not penetrate sinus

SA-1a   SA-1b

Unfavorable Conditions :
• D4 bone
• High force factors
• Increased C-I Ratio

Favorable Conditions :
• D2/D3 bone
• Minimal occlusal force factors
• Favorable C-I Ratio

• Implant Height:
    Host Bone ≥ 10 mm
• Implant Length:
    ≥ 10 mm

• Implant Height:
    Host Bone ≥ 8 mm
• Implant Length:
    ≥ 8 mm

Indications

Favorable conditions: >8 mm host bone (implant ≥8 mm in length)
Unfavorable conditions: >10 mm host bone (implant ≥10 mm in length)

See Surgical Protocol (Chapter 37)

Subantral Option 2: Sinus Lift and Simultaneous Implant Placement

The second SA option, SA-2, is selected when there is a minimum of 6/8 mm of vertical bone present (Fig. 23.11). In the SA-2 technique the sinus floor is elevated via the implant osteotomy 1 to 2 mm (Figs. 23.12 and 23.13). This technique was originally developed by Tatum[2,3] in 1970 and published by Misch[5] in 1987 and many years later by Summers[93] in 1994. The endosteal implant osteotomy is prepared as determined by the density of bone protocol. The depth of the osteotomy is approximately 1 to 2 mm short of the floor of the antrum. A cupped-shape osteotome of the same diameter (or slightly smaller) as the final osteotomy is selected.[94] It is of a different end shape than osteotomes used for bone spreading.[93] The osteotome is inserted and tapped firmly in 0.5- to 1-mm increments beyond the osteotomy until its final position up to 2 mm beyond the prepared implant osteotomy. This surgical approach causes a greenstick-type fracture in the antral floor and slowly elevates the unprepared bone and sinus membrane over the broad-based osteotome. The implant may be inserted into the osteotomy after the sinus membrane elevation and extend up to 2 mm above the floor of the sinus. The implant is slowly threaded into position so that the membrane is less likely to tear as it is elevated. The apical portion of the implant engages the denser bone on the cortical floor, with bone over the apex, and an intact sinus membrane. The implant may ideally extend up to 2 mm beyond the sinus floor, and the 1- to 2-mm bony covering over the apex may result in as much as a 3-mm elevation of the sinus mucosa (Fig. 23.14).
• **Fig. 23.13** Subantral option 2 (SA-2) technique with implant placement that includes a small bump into the sinus (~1 mm).

Because of the autologous bone present above the apical portion of the implant, along with the osteoprogenitor cell–rich sinus membrane, new bone formation is accelerated. The success of the intact sinus membrane elevation cannot be confirmed before or at the time of implant placement. Attempts to feel the elevation of the membrane from within an 8-mm-deep implant osteotomy that is approximately 3 mm in diameter may easily cause separation of the sinus lining.

The patient's prosthodontic treatment may proceed similar to that in the SA-1 category. If inadequate bone is formed around the apical portion of an implant after initial healing, the progressive loading protocol for D4 bone is suggested.

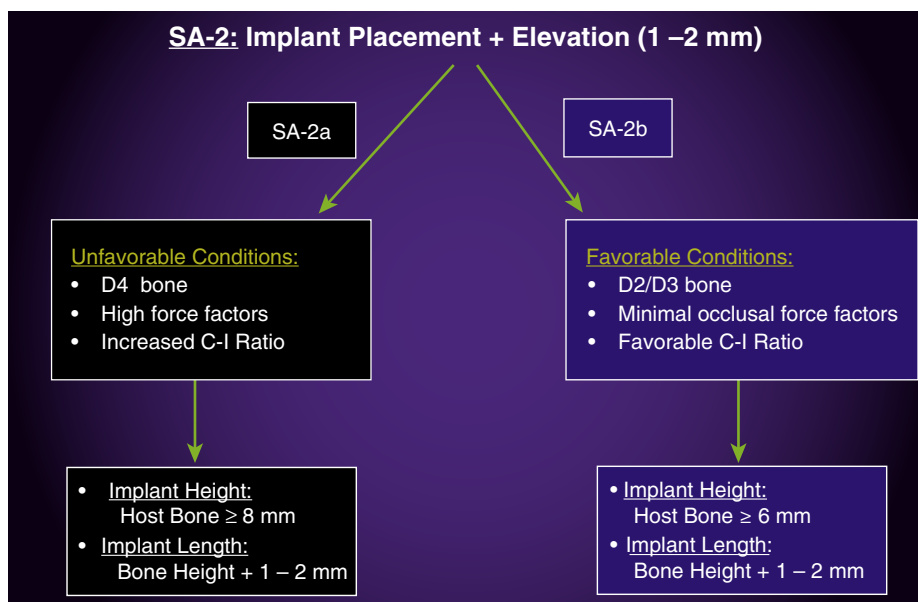
Some authors have reported the attempted SA-2 sinus lift procedure to gain more than 3 mm of implant vertical height.


Fig. 23.14 Subantral option 2 (SA-2) protocol decision tree related to favorable versus unfavorable factors.

• BOX 23.2   SA-2: Implant Placement: Membrane Bump 1-2mm No Graft (Osteotome Technique)

Indications

Favorable conditions: > 6 mm host bone (Implant length= Bone height + 1-2)
Unfavorable conditions: > 8 mm host bone (Implant length= Bone height + 1-2)

See Surgical Protocol (Chapter 37)

Blind surgical techniques such as the SA-2 technique increase the risk for sinus membrane perforation. When the sinus mucosa is perforated, the risk for postoperative infection increases. Membrane perforation is the primary reason why the SA-2 technique is restricted to elevating the membrane only 1 to 2 mm. In addition, the presence of a septum in the area of elevation increases the possibility of a perforation. If a sinus infection occurs, a bacterial smear layer may accumulate on the implant apex, which may precipitate mucociliary clearance issues and possible sinus infections.

Worth and Stoneman[95] have reported a comparable phenomenon of bone growth under an elevated sinus membrane, called *halo formation*. They observed the natural elevation of the sinus membrane around teeth with periapical disease. The elevation of the membrane resulted in new bone formation once the tooth infection was eliminated (Figs. 23.13 and 23.14; Box 23.2).

Subantral Option 3: Sinus Graft with Immediate Endosteal Implant Placement

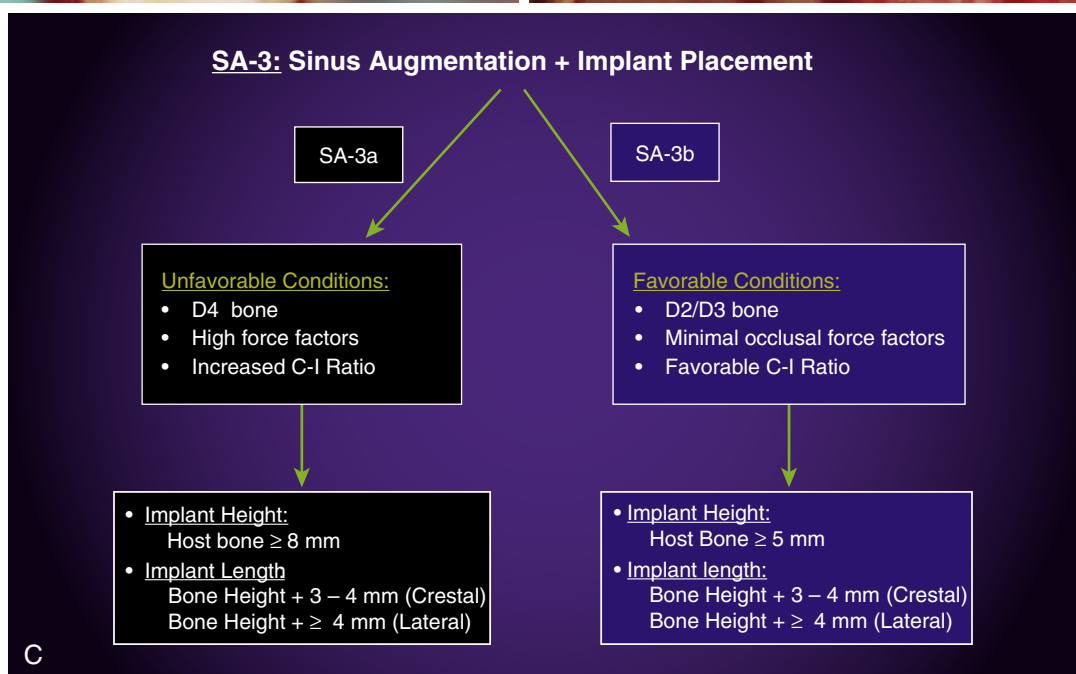
The third approach to the maxillary posterior edentulous region, SA-3, is indicated when at least 5 mm of vertical bone height and sufficient width are present between the antral floor and the crest of the residual ridge in the area of the required prosthodontic abutment (Fig. 23.15). The 5-mm minimum is necessary because this is the amount of bone needed to achieve rigid fixation for implant placement.

There exist two different options for the grafting of the sinus area in the SA-3 protocol. In the first technique the bone graft is performed transcrestally. The osteotomy is performed, and the floor is fractured similar to the SA-2 technique. Before the implant placement, the layering technique is used consisting of a collagen membrane (first layer) and allograft (second layer). Autogenous bone may be placed in SA-3 cases when poor bone quality is present.

The second technique is the Tatum lateral maxillary wall approach. With this procedure an osteotomy of the lateral maxillary wall is performed to allow for bone graft placement before dental implant insertion. This results in a lateral access window, which exposes the sinus membrane and allows for the lateral window to be rotated in and upward in a superior position. As long as there is sufficient width, the implant may be placed at the same time after the grafting is complete. The graft material selected is usually allograft, unless there is easy access to autogenous bone. Autogenous bone is of less importance because of the existing host bone (minimum 5 mm of height) (Boxes 23.1 and 23.2). When the original ridge width is Division B or C–w, membrane grafting or onlay graft in conjunction with the sinus augmentation is a possible treatment option, and usually the case is classified as SA-4 because implant placement will be delayed.

The 5-mm minimum of initial bone height in an SA-3 posterior maxilla may have cortical bone on the residual crest, and cortical-like bone on the original antral floor may stabilize an implant that is inserted at the time of the graft and permit its primary stability. Therefore an endosteal implant may be inserted at this appointment and has been advocated for many years by Misch[5] and others (Figs. 23.15 and 23.16; Box 23.3).[12,15,59]

Subantral Option 4: Sinus Graft Healing and Extended Delay of Implant Insertion

In the fourth option for implant treatment of the posterior maxilla, SA-4, the maxillary sinus region for future endosteal implant insertion is first augmented. This option is indicated when less than 5 mm remains between the residual crest of bone and the floor of the maxillary sinus. There is inadequate vertical bone in


● **Fig. 23.15** Subantral Option 3 (SA-3) Technique. (A) Implant placement with bone graft (crestal). (B) Implant placement with bone graft (lateral wall). (C) Decision tree related to favorable versus unfavorable factors and crestal versus lateral wall technique.

these conditions to predictably place an implant at the same time as the sinus graft and less recipient bone to act as a vascular bed for the graft and for primary stability (Fig. 23.17). The SA-4 protocol corresponds to a larger antrum and minimal host bone on the lateral, anterior, and distal regions of the graft, because the antrum generally has expanded more aggressively into these regions.

Unfortunately, in SA-4 posterior maxillas there is less autologous bone to harvest in the tuberosity, which further delays the bone regeneration in the site. In addition, there are usually fewer septa or webs in the sinus, which decreases complications, and it typically exhibits longer mediodistal and lateromedial dimensions. Therefore the fewer bony walls, less favorable vascular bed, minimal local autologous bone, and larger graft volume all mandate a longer healing period and slightly altered surgical approach.

The Tatum lateral wall approach for sinus graft is performed as in the previous SA-3 procedure (lateral wall). Most SA-4 regions provide better surgical access than the SA-3 counterparts because the antrum floor is closer to the crest compared with the SA-3 maxilla. The medial wall of the sinus membrane is elevated to the level of the height of the lateral window so that adequate height is available for future endosteal implant placement.

The combination of graft materials used and their placement are similar to those for the SA-3 technique. However, less autogenous bone is often harvested from the tuberosity, so in some cases an additional harvest site may be required, most often from the mandible (i.e., from the ascending ramus). Because of the compromised host bone present, more autogenous bone is required.

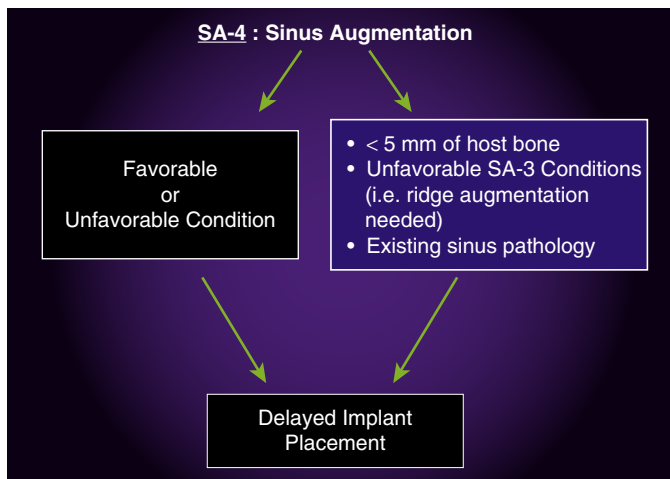
SA-4 : Sinus Augmentation

Favorable
or
Unfavorable Condition

• < 5 mm of host bone
• Unfavorable SA-3 Conditions (i.e. ridge augmentation needed)
• Existing sinus pathology

Delayed Implant
Placement


• **Fig. 23.17** Subantral Option 4 (SA-4) Bone-Grafting Indications.

The augmented region is left to mature for 6 to 10 months before reentry for placement of endosteal implants. The amount of initial healing is related to the antral size (including small, medium, or large lateral-medial size) and the amount of autologous bone used in the inferior third of the antrum. Typically the width of crestal bone is wide enough in SA-4 regions for the placement of root form implants after the graft matures.

The implant placement surgery at reentry for the SA-4 technique is similar to SA-1 with one exception. The previous access

window may appear completely healed with bone; soft and filled with loose graft material, or with cone-shaped fibrous tissue ingrowth (with the base of the cone toward the lateral wall); or in any variation states. If the graft site appears clinically as bone, the implant osteotomy and placement follow the surgical approach designated by the bone density. Usually with the SA-4 technique, implant placement is completed under a stage II process.

The time interval for stage II uncovery and prosthetic procedures after implant insertion is dependent on the density of bone at the reentry implant placement. The crest of the ridge and the original antral floor may be the only cortical bone in the region for implant fixation. The most common bone density observed is D4, and often it is softer than the region in general. Progressive loading after uncovery is most important when the bone is particularly soft and less dense.

The width of the host site for sinus grafts is most often Division A; however, when Division C–w to B exists, guided bone regeneration or an onlay graft for width is indicated. When the graft cannot be secured to the host bone, it is often ideal to perform the sinus graft 6 to 9 months before the bone graft for width. After graft maturation the implants may be inserted.

There are many advantages of the SA-4 technique over the SA-3 technique:

1. The healing of the graft may be assessed before the implant placement surgery via a CBCT scan. Because of the advances in CBCT technology, radiation exposure is not a significant disadvantage. In addition, the bone quality may be evaluated during the implant osteotomy before implant insertion. The healing time for the implant is no longer arbitrary but more patient specific.

2. Postoperative sinus graft infection occurs in approximately 3% to 5% of patients, which is much higher than the percentage for implant placement surgery. If the sinus graft becomes infected with an implant in place, a bacterial smear layer may develop on the implant and make future bone contact with the implant less predictable. The infection is also more difficult to treat when the implants are in place, and may result in greater resorption of the graft as a consequence. If the infection cannot be adequately treated, the graft and implant must be removed. Therefore there is also a decreased risk for losing the graft and implant if a postoperative infection occurs with a delayed implant insertion. Reports in the literature indeed indicate a higher failure rate of implants when inserted simultaneously compared with a delayed approach.[60,80,91,92]

3. Blood vessels are required to form and remodel bone. A titanium implant in the center of the sinus graft does not provide a source of blood vessels; therefore obtaining a vascular supply is more difficult and usually requires an increased healing time.

4. Bone width augmentation may be indicated in conjunction with sinus grafts to restore proper maxillomandibular ridge relationships or increase the implant diameter in the molar region. Augmentation may be performed simultaneously with the sinus graft. As a result, larger-diameter implants may be placed with the SA-4 technique.

5. The bone in the sinus graft will be much denser after ideal healing with the SA-4 approach. As such, implant angulation and position may be improved because it is not dictated by existing anatomic limitations at the time of the sinus graft.

The primary disadvantage of the SA-4 approach is the delayed implant placement, thereby requiring an additional surgery (Figs. 23.17 and 23.18; Box 23.4).

<5 mm	SA-4 Lateral wall
5 mm	SA-3 or SA-4
6 mm	SA-2, SA-3, or SA-4
7 mm	SA-2, SA-3, or SA-4
8 mm	SA-1, SA-2, or SA-3
9 mm	SA-1, SA-2
10 mm	SA-1 or SA-2
>10 mm	SA-1

SA, Subantral option.

Summary

In the past the posterior maxilla has been reported as the least predictable area for implant survival. Causes cited include inadequate bone quantity, poor bone density, difficult access, and high occlusal forces. Previous implant modalities attempted to avoid this region, with approaches such as excessive cantilevers when posterior implants are not inserted or an increased number of pontics when implants are placed posterior to the plantrum.

The maxillary sinus may be elevated and SA bone regenerated to improve implant height. Tatum began to develop these techniques as early as the mid-1970s. Misch developed four options for treatment of the posterior maxilla in 1987 based on the height of bone between the floor of the antrum and the crest of the residual bone. These options were further modified by Resnik to include specific bony dimensions dependent on favorable versus unfavorable conditions as well as the transcrestal augmentation technique and short length implants. Although management of the posterior maxilla presents many challenges for the implant practitioner, progress on a number of fronts has made it increasingly possible to create successful bone-supported prostheses in this region by adhering to the classifications described earlier in this chapter (Box 23.5).

The Edentulous Mandible: Fixed Versus Removable Prosthesis Treatment Planning

RANDOLPH R. RESNIK AND CARL E. MISCH[†]

Historically, the edentulous mandibular patient has been one of the most common patients to be treated with dental implants. The placement of dental implants in this area has been shown to be very successful in obtaining the support, retention, and stability of a mandibular prosthesis, whether it is fixed or removable. From a bone volume conservation standpoint, complete edentulous patients should be treated with sufficient implants to support a prosthesis in the maxilla or mandible. The continued bone loss after tooth loss and associated compromises in esthetics, function, and health make all edentulous patients possible implant candidates. The bone loss that occurs during the first year after tooth loss is 10 times greater than in the following years. In the case of multiple extractions, this often means an approximate 4-mm vertical bone loss within the first 6 months. As the bony ridge resorbs, the muscle attachments become level with the edentulous ridge, thereby compromising the fit of a mandibular prosthesis. Rather than waiting until the patient has lost most of the residual bone, the clinician should inform and emphasize to the patient the benefits of implants and why they should be inserted before the bone is lost. Therefore the profession should treat bone loss from extractions in a similar fashion as bone loss from periodontal disease. Rather than waiting until the bone is resorbed or the patient complains, the dental professional should educate the patient about the bone loss process caused not only by periodontal disease but also by the lack of stimulation and its consequences of bone resorption, and explain how implants are available to treat the condition. Therefore most completely edentulous patients should be informed of the necessity of dental implants to maintain bone volume, function, masticatory muscle activity, esthetics, and psychological health. Ideally patients who have non-restorable teeth should be given the option to include implants to support the future prosthesis. The traditional complete denture may be presented as a temporary measure to provide cosmetic and oral function during implant treatment. For an edentulous patient, two treatment options exist: (1) fixed (FP-1, FP-2, or FP-3) or (2) removable (RP-4 or RP-5) prosthesis (Fig. 24.1).

[†] Deceased

Mandibular Treatment Planning Principles

Anteroposterior Spread

The distance from the center of the most anterior implant to a line joining the distal aspect of the two most distal implants on each side is called the *anteroposterior* (A-P) *distance* or the *A-P spread*[1] (Fig. 24.2). In theory, the greater the A-P spread, the farther the distal cantilever may be extended to replace the missing posterior teeth. As a general rule, when five to six anterior implants are placed in the anterior mandible between the foramina to support a fixed prosthesis, the cantilever should not exceed two times the A-P spread, with all other stress factors being low.

The range of implant and prosthesis survival may be because of the broad application of the same implant position, regardless of crown height, opposing dentition, implant length, A-P position of implants, and parafunction. The arch form, the position of the mental foramina, force factors, and bone density are important criteria when four to six implants are placed only in the anterior segment to replace the entire mandibular arch. The anterior arch form and foramina position affect the position of the distalmost implants. Therefore a cantilever distance is variable for different patients.

The A-P distance is affected by the arch form. The types of arch forms may be separated into square, ovoid, and tapering. A square arch form in the anterior mandible has a 0- to 6-mm A-P spread between the most distal and most anterior implants (Fig. 24.3). An ovoid arch form has an A-P distance of 7 to 9 mm and is the most common type (Fig. 24.4). A tapering arch form has an A-P distance greater than 9 mm (Fig. 24.5).

Hence whereas a tapering arch form may support a 20-mm cantilever, a square arch form requires the cantilever to be reduced to 12 mm or less, however is directly dependent upon force factors. The position of the mental foramen can affect the A-P spread. The mental foramen is most often found between the root apices of the premolars. However, it may be located as far anterior as just distal to the canine and as far distal as the mesial of the first molar apex.[2] The farther forward the foramen, the shorter the cantilever length

567

• **Fig. 24.2** The anteroposterior (A-P) distance is determined by a line drawn from the distal portion of the distalmost implant on each side of the arch and another parallel line drawn through the center of the anteriormost implant from the cantilever.

• **Fig. 24.3** A mandibular square arch form has an anteroposterior (A-P) distance of 0 to 6 mm. As a result a cantilever is limited. (*From Misch CE. The completely edentulous mandible: treatment plans for fixed restorations. In:* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)
• **Fig. 24.4** A mandibular ovoid arch form has an anteroposterior (A-P) distance of 7 to 9 mm and is the most common type. A cantilever may extend to 18 mm with the ovoid-type arch. (*From Misch CE. The completely edentulous mandible: treatment plans for fixed restorations. In:* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

• **Fig. 24.1** Mandibular Edentulous Prostheses. (A) Fixed prothesis (FP-3), which is commonly fabricated from zirconia, porcelain fused to metal, or acrylic/denture teeth. (B) Removable prosthesis (RP-4), which is totally implant supported; note the flangeless nature of the prosthesis. (C) Removable prosthesis (RP-5), which is primarily supported by the soft tissue.

because the A-P spread is reduced. The A-P spread is only one of the force factors to be considered for the extent of the distal cantilever. If the stress factors are high (e.g., parafunction, crown height, masticatory musculature dynamics, opposing arch), the cantilever length of a prosthesis should be reduced and may even be contraindicated. The density of bone is also an important criterion. The softest bone types (D3 and D4) should not have as great of a cantilever than the denser types (D1 and D2).

Therefore, the length of the posterior cantilever depends on the specific force factors of the patient, of which A-P spread is

only one. The number and size of implants may also affect the cantilever length. Stress equals force divided by the area over which force is applied. The area over which the forces are applied from the prosthesis to the implants can be modified through the number, size, and design of the implants. A cantilever rarely is indicated on three implants even with a similar A-P spread as five implants.
• **Fig. 24.5** A mandibular tapered arch form has an anteroposterior (A-P) distance of greater than 9 mm and is the type least observed. A cantilever is least at risk for this arch form. (*From Misch CE. The completely edentulous mandible: treatment plans for fixed restorations. In:* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)
• **Fig. 24.6** The flexure of the mandible during opening and protrusive movements occurs distal to the mental foramina. The amount of flexure depends on the amount of the bone volume and the sites in question. The medial movement from the first molar to the first molar region may be 800 mm.

Mandibular Flexure

Medial Movement

Many reports have addressed the dimensional changes of the mandible during jaw activity as a result of masticatory muscle action.[3-6] Five different movements have been postulated.

Medial convergence is the one most commonly addressed.[7] The mandible between the mental foramina is stable relative to flexure and torsion. However, distal to the foramina, the mandible exhibits considerable movement toward the midline on opening.[8,9] This movement is caused primarily by the attachment of internal pterygoid muscles on the medial ramus of the mandible.

The distortion of the mandible occurs early in the opening cycle, and the maximum changes may occur with as little as 28% opening (or about 12 mm). This flexure has also been observed during protrusive jaw movements.[10] The greater the active opening and protrusive movements, the greater the amplitude of mandibular flexion. The amount of movement varies among individuals and depends on the density and volume of bone, and the location of the site in question. In general the more distal the sites, the more medial flexure. The amplitude of the mandibular body flexure toward the
• **Fig. 24.7** Unilateral molar biting causes the mandible to undergo torsion, with the bottom of the mandible expanding outward and the crest of the mandible rotating medially. (*From Misch CE. The completely edentulous mandible: treatment plans for fixed restorations. In:* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.*)

midline has been measured to be as much as 800 μm in the first molar-to-first molar region to as much as 1500 μm in the ramus-to-ramus sites (Fig. 24.6). In a study by Hobkirk and Havthoulas[11] on deformation of the mandible in subjects with fixed dental implant prostheses, medial convergence up to 41 mm was observed.

Torsion

Torsion of the mandibular body distal to the foramina has also been documented in both animal and human studies.[12,13] Hylander[14] evaluated larger members of the rhesus monkey family (macaque) and found the mandible twisted on the working side and bent in the parasagittal plane on the balancing side during the power stroke of mastication and unilateral molar biting (Fig. 24.7). Parasagittal bending of the human jaw during unilateral biting was confirmed by Marx,[15] who measured localized mandibular distortion in vivo in humans by using strain gauges on screws attached to cortical bone in the symphyseal and gonial regions. Abdel-Latif et al.[12] confirmed that the mandibles of patients with implant prostheses measured up to 19 degrees of dorsoventral shear. The torsion during parafunction is caused primarily by forceful contraction of the masseter muscle attachments (Fig. 24.8). Therefore parafunctional bruxism and clenching may cause torsion-related problems in the implant support system and prosthesis when the mandibular teeth are splinted from the molar-to-molar regions.

The posterior bone gain in edentulous patients restored with cantilevered prostheses from anterior implants may be a consequence of the mandibular flexure and torsion, which stimulate the bone cells in the region. Because the bite force may increase 300% with an implant prosthesis compared with a denture, the increased torsion may stimulate the posterior mandibular body to increase in size, as reported by Wright et al.[16] and Reddy et al.[17]

Misch[18] has observed the increase in flexure in the posterior mandible is a result of the mental foramen weakening of the facial cortical plate. As such, the mandible flexes and has torsion distal to the foramen. The most common position of the mental foramen is between the first and second premolar teeth. Therefore, when bilaterally
• **Fig. 24.8** The mandible flexes toward the midline on opening or during protrusive movements as a result of the internal pterygoid muscle attachments on the ramus (blue arrows). The mandible also torques, with the inferior border rotating out and up, and the crestal region rotating lingually. The movement is caused by the masseter muscles during forceful biting or parafunction (red arrows).

splinting teeth distal to the premolar positions, mandibular dynamics should be considered. Posterior rigid, fixated implants splinted to each other in a full-arch restoration are subject to a considerable buccolingual force on opening and during parafunction.[19,20]

A study by Miyamoto et al.[21] identified jaw flexure as the primary cause of posterior implant loss in full-arch splinted mandibular prostheses. The more distal the rigid splint from one side to the other, the greater the risk that mandibular dynamics may influence the implants or prosthesis prognosis. In addition, the body of the mandible flexes more when the size of the bone decreases. As a result the division C minus height (C–h) or division D mandible flexes or exhibits torsion more than the division A mandible, all other factors being similar.

The difference in movement between an implant and a tooth has been addressed as a concern for dentists when splinting these objects together. The natural tooth movement ranges from 28 μm apically and 56 to 108 μm laterally. In contrast, the rigid implant has movement up to 5 μm apically and 10 to 60 μm laterally. Yet the mandibular flexure and torsion may be more than 10 to 20 times the movement of a healthy tooth. Therefore the flexure and torsion of the mandibular body are more critical in the patient evaluation compared with whether an implant should be joined to the natural dentition.

Some authors have suggested four implants in the mandible with a full-arch splinted fixed restoration—two in the first molars and two in the canine regions (Fig. 24.9).[22] Additional implants have been used with this full-arch splinted restorative option, with up to four other implants in the premolar and the incisor regions.[23] However, complete cross-arch splinting of posterior molar implants with a rigid, fixated prosthesis should be reconsidered in the mandible. The flexure of the mandible is thwarted by the prosthesis, but this introduces lateral stresses to the implant system (cement, screw, crestal bone, and implant–bone interface).[24-26] These lateral stresses place the molar implants, screws, and bone at increased risk because of the mandibular flexure and torsion previously addressed.

In complete mandibular subperiosteal implants, pain on opening was noted in 25% of the patients at the suture removal appointment when a rigid bar connected molar-to-molar regions. When the connecting bar was cut into two sections between the foramina, the pain on opening was immediately eliminated. This clinical observation
• **Fig. 24.9** Some authors propose that the ideal implant positions to support a mandibular full-arch prosthesis are the bilateral molars and bilateral canines, splinted together with a rigid structure. These positions are not ideal because of the mandibular dynamics (flexure and torsion) during opening and function.

• **BOX 24.1** **Advantages of Mandibular Implant Overdentures**

1. Enhanced soft tissue support
2. Increased chewing efficiency compared with conventional dentures
3. Less expense/implants
4. Esthetics
5. Ease of hygiene
6. Parafunctional habits
7. Less food impaction

---

does not mean that the other 75% of patients did not have flexure of the mandibular arch on opening. The observation does demonstrate, however, that flexure may be relevant to postoperative complications.

Implant Overdentures Advantages (RP-4 and RP-5)

For an implant-supported overdenture the implants ideally should be placed in planned, specific sites, and their number should be predetermined by the clinician and patient. The primary indications for a mandibular implant overdenture (IOD) are problems often found with lower dentures, such as lack of retention or stability, decrease in function, difficulties in speech, tissue sensitivity, and soft tissue abrasions. If an edentulous patient is willing to remain with a removable prosthesis, an overdenture is often the treatment of choice. In addition, if cost is a concern for the patient, the overdenture may serve as a transitional prosthesis until additional implants may be inserted and restored. When evaluating mandibular IODs, many advantages exist (Box 24.1).

Enhanced Soft Tissue Support

Bone loss dictates the appearance of the inferior third of the face. A maxillary overdenture often provides improved support for the lips and soft tissues of the face compared with a fixed prosthesis because the prosthesis contour does not have to accommodate daily hygiene requirements. Denture teeth also provide an esthetic replacement for the natural dentition, which is more challenging for the technician to re-create with porcelain fused to metal restorations. For the laboratory to create pink

• **Fig. 24.10** (A and B) Soft tissue support: because of the ability to modify the flange of the prosthesis, ideal soft tissue support can be obtained.

• **Fig. 24.11** Hygiene: because of the removable nature of the overdenture, hygiene access is much easier to complete in comparison with a fixed prosthesis.

interdental papilla, as well as replace the soft tissue drape, is easier with an overdenture compared with porcelain-metal fixed restorations or zirconia prosthesis. In addition, the teeth can be positioned in the most esthetic position, without any restriction as to the relationship to the atrophied crest, because stability now is provided by the implant and does not depend on tooth position on the crest of the ridge (Fig. 24.10).

Increased Chewing Efficiency Compared with Conventional Dentures

A study of chewing efficiency compared wearers of complete dentures with patients with implant-supported overdentures. The complete-denture group required 1.5 to 3.6 times the number of chewing strokes compared with the overdenture group.[27] The chewing efficiency with an IOD is improved by 20% compared with a traditional complete denture.[28,29]

Less Expense/Implants

When cost is a factor, two implant-retained IODs may improve the patient's condition at a significantly lower overall treatment cost than a fixed implant–supported prosthesis. A survey by Carlsson et al.[30] in 10 countries indicated a wide range of treatment options. The proportion of IODs selected versus fixed implant dentures was highest in the Netherlands (93%) and lowest in Sweden and Greece (12%). Cost was cited as the number one determining factor in the choice. However, in general, overdenture treatment is less expensive than a fixed implant prosthesis, mainly because of the decreased number of implants required.

Esthetics

The esthetics for many edentulous patients with moderate-to-advanced bone loss is improved with an overdenture compared with a fixed restoration. Soft tissue support for facial appearance often is required for an implant patient because of advanced bone loss, especially in the maxilla. Interdental papilla and tooth size are easier to reproduce or control with an overdenture. Denture teeth easily reproduce contours and esthetics compared with time-consuming and technician-sensitive porcelain-metal or zirconia fixed restorations. The labial flange may be designed for optimal appearance, not daily hygiene.

Ease of Hygiene

Hygiene conditions and home and professional care are improved with an overdenture compared with a fixed prosthesis. Peri-implant probing is diagnostic and easier around a bar than a fixed prosthesis because the crown often prevents straight-line access along the abutment to the crest of the bone. The overdenture may be extended over the abutments to prevent food entrapment during function. Speech is not compromised because the denture may extend onto the soft tissues in the mandible and prevent air and saliva from escaping (Fig. 24.11).

Parafunctional Habits

An overdenture may be removed at bedtime to reduce the noxious effect of nocturnal parafunction, which increases stresses on the implant support system. The overdenture also may provide stress relief between the superstructure and prosthesis, and the soft tissue may share a portion of the occlusal load. The prosthesis
• **Fig. 24.12** (A) The mandible is divided into three regions for treatment planning. (B) The anterior mandible is positionally documented via *A*, *B*, *C*, *D*, and *E* positions.

is usually easier to repair than a fixed restoration. In most cases, there exists a reduced cost of overdenture treatment in comparison to a fixed prosthesis. In addition, long-term denture patients do not appear to have a psychological problem associated with the ability to remove their implant prostheses.[31,32] Therefore, denture patients usually adapt very well into an overdenture treatment.

Less Food Impaction

Especially with an RP-5 prosthesis, there is less food impaction with an overdenture in comparison with a fixed prosthesis. The flanges of the prosthesis (RP-5) usually extend to form a peripheral seal that minimizes food impaction. Because of the nature of the fixed mandibular prosthesis, it often is overextended for esthetic reasons. In comparison with a conventional denture, food particles migrate and become impacted under the prosthesis during swallowing. Because a lower denture "floats" and moves during function, the food more readily goes under and out, whereas the IOD traps the food debris against the implants, bars, and attachments.

Review of the Overdenture Literature

In 1986 a multicenter study reported on 1739 implants placed in the mandibular symphysis of 484 patients. The implants were loaded immediately and restored with bars and overdentures with clips as retention. The overall success rate was 94%.[33] Engquist et al.[34] reported a 6% to 7% implant failure for mandibular implant–supported overdentures and a 19% to 35% failure rate for maxillary IODs. Hyperplasia below the bar occurred in 25% of the patients. Jemt et al.[35] reported on a 5-year prospective, multicenter study on 30 maxillae (117 Brånemark implants) and 103 mandibles with 393 implants. Survival rates in the mandible were 94.5% for implants and 100% for prostheses; in the maxilla the survival rates were 72.4% for implants and 77.9% for prostheses. Higher failure rates in the maxilla were related directly to poor density and quantity of bone with a characteristic cluster failure pattern.[35]

Wismeijer et al.[36] reported on 64 patients with 218 titanium plasma-sprayed implants, with a 97% survival rate with overdentures in a 6.5-year evaluation. Naert et al. found 100% implant success at 5 years for overdentures with different anchorage systems. In Belgium, Naert at al. reported on 207 consecutively treated patients with 449 Brånemark implants and Dolder-bar

overdentures. In this report the cumulative implant failure rate was 3% at the 10-year benchmark.[37]

Misch[38] reported a less than 1% implant failure rate and no prosthesis failure over a 7-year period with 147 patients when using the organized treatment options and prosthetic guidelines presented in this chapter. Kline et al.[39] reported on 266 implant-supported overdentures for 51 patients, with an implant survival rate of 99.6% and a prosthesis survival rate of 100%. Mericke-Stern[40] reported a 95% implant survival rate with two IODs.

In a randomized clinical report Awad et al. compared satisfaction and function in complete dentures (48 patients) versus two IODs in 56 patients. There was significantly higher satisfaction, comfort, and chewing ability in the IOD group.[41]

Thomason et al.,[42] in the United Kingdom, reported a 36% higher satisfaction for the IOD patients than the complete denture wearers in the criteria of comfort, stability, and chewing.

In a 10-year study of IODs in Israel, with 285 implants and 69 IODs, Schwartz-Arad et al.[43] reported the implant survival rate was 96.1% with higher success rates in the mandible. Many reports have been published over the last two decades that conclude that implant-supported overdentures represent a valid beneficial option for denture wearers. It should be noted that the majority of reports are for IODs supported by only two implants.[44,45]

Mandibular Overdenture Treatment Planning (RP-4 and RP-5)

Anatomy of the Mandible

In treatment planning the mandible for a fixed or removable prosthesis, the mandible is divided into three regions: (1) anterior mandible, (2) posterior right, and (3) posterior left. The available bone in the anterior mandible is divided into five equal columns of bone serving as potential implant sites, labeled A, B, C, D, and E, starting from the patient's right side.[46,47] Regardless of the treatment option being used, all five implant sites are mapped out at the time of treatment planning and surgery (Fig. 24.12).

Mandibular Implant Site Selection

Anterior retention and stability for an overdenture offer several advantages. The greatest available height of bone is located in the anterior mandible, between the mental foramina. This

region also usually presents a favorable bone density (e.g., D2) for implant support. In addition, overdentures with posterior movement (RP-5) gain better acceptance than removable prostheses with anterior movement. An axiom in removable partial denture design is to gain rigid prosthetic support in the anterior region. When the prosthesis has poor anterior and poor posterior support, it rocks back and forth. This rocking action applies torque to the abutments and increases stresses on the overdenture components and bone–implant interface. Therefore anterior forces should be resisted by implants or bars, whereas posterior forces may be directed on a soft tissue area such as the mandibular buccal shelf (i.e., primary stress-bearing area). In addition, the IOD treatment options presented are designed for anterior implant placement with adequate bone quantity.

In this way the patient always has the option to obtain additional implant support in the future. For example, a patient may receive adequate support for an IOD with four implants. However, if the patient desires a fixed prosthesis in the future, these four implants may fall short of the new requirements. If the clinician did not plan an additional implant site at the initial surgery but instead placed the four implants an equal distance apart, the additional space may not be available without removing one of the present implants. In addition, a patient may desire a completely implant-supported restoration as an RP-4 or fixed prosthesis but cannot afford the treatment all at once. Three implants in the A, C, and E positions and an overdenture may be provided currently, two implants may be added in the B and D locations later, and a completely implant-supported overdenture or fixed restoration may be fabricated.

In addition, if an implant complication occurs that results in an implant failure, corrective procedures may be completed. If implants were placed in the A, B, D, and E positions, and an implant fails to achieve rigid fixation, the failed implant may be removed and an additional implant placed in the C position at the same time. This saves time as additional surgery is not required which eliminates the additional bone healing time before another implant can be reinserted.

Overdenture Treatment Options

In 1985 Misch[39,48] presented organized treatment options for implant-supported mandibular overdentures in the completely edentulous patient. The treatment options range from primarily soft tissue support with secondary implant retention (RP-5) to a completely implant-supported prosthesis (RP-4) with rigid stability (i.e., no soft tissue support) (Table 24.1). The initial treatment options are presented for completely edentulous patients with Division A (abundant) or B (sufficient) anterior bone, treated with Division A anterior root form implants of 4 mm or greater in diameter.

When evaluating the patient for an overdenture, the clinician should evaluate the patient's existing dentures concerning support, retention, and stability. Support is related to the resistance to occlusal load. Retention describes the resistance of the prosthesis to movement away from the tissues. Stability is the lateral resistance criterion. The patient's complaints, anatomy, desires, and financial commitment determine the amount of implant support, retention, and stability required to address these conditions predictably. The amount of resistance provided in IODs is related to the number and position of the implants.

TABLE 24.1	Mandibular Overdenture Treatment Options	
Option	**Description**	**Removable Prosthesis Type**
OD-1	2 implants (B and D positions) independent of each other	RP-5 Ideal posterior ridge form Ideal anterior and posterior ridge form Cost is a major factor (two-legged chair)
OD-2	3 implants (A, C, and E positions)	RP-5 Ideal posterior ridge form (three-legged chair)
OD-3	4 implants (A, B, D, and E positions)	RP-4 (favorable force factors) RP-5 (unfavorable force factors) Patient desires greater retention, major stability, and support (four-legged chair)
OD-4	5 implants (A, B, C, D, and E positions)	Patient has high demands or desires Retention, stability, and support (four-legged chair)

OD, Overdenture option.

Overdenture Option 1

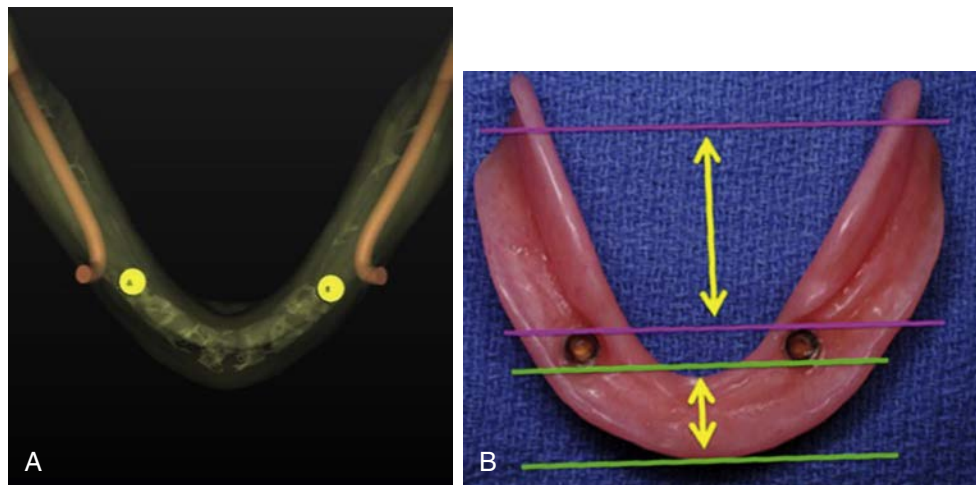
The first treatment option for mandibular overdentures (OD-1) is indicated primarily when cost is the most significant patient factor and minimal retention is required. The patient should be educated about the amount of retention that may be obtained. Most two implant overdentures can be correlated with a two-legged chair (i.e. rotation and hinging will occur). Bone volume should be abundant (Division A or B) in the anterior, and the posterior ridge form should be an inverted U shape, with high parallel walls for good-to-excellent anatomic conditions for conventional denture, support, and stability. The buccal shelf (primary stress bearing area) should be prominent to withstand the forces. Under these conditions, two implants may be inserted in the B and D positions. The implants usually remain independent of each other and are not connected with a superstructure. The most common type of attachment used in OD-1 is a Locator or an O-ring design, because there will be associated prosthesis movement.

Positioning of the implants in the B and D positions is a much better prosthetic option in OD-1 than positioning in the A and E regions (Fig. 24.13). Independent implants in the A and E positions allow a greater amplitude of rocking of the prosthesis compared with implants in the B and D regions (Fig. 24.14). When using B and D implants, the anterior movement of the prosthesis is reduced, and the prosthesis even may act as a splint for the two implants during anterior biting forces, thereby decreasing the stress to each implant. However, most situations do not allow the prosthesis to act as a true splint because a stress relief attachment permits movement in any plane. As a result, only one implant is loaded at a time in most situations. The stability and support of the prosthesis are gained primarily from the anatomy of the mandible and prosthesis design, which is similar to a complete denture. The implant support mechanism is poor because stress relief is permitted in any plane.

The primary patient advantage with OD-1 is cost. The existing restoration often may be adapted with an intraoral rebase and pickup procedure around the implants and attachments. Additional indications are when arch shape is considerably tapered such that a connecting bar would be cantilevered too far to the facial or would interfere with speech and mastication if too lingual. Hygiene procedures also are facilitated with independent attachments.

The disadvantages of the OD-1 relate to its relatively poor implant support and stability, compared with the other options, because of the independent nature of the two implants. The other disadvantages of OD-1 relate to an increase in prosthetic maintenance appointments. For the prosthesis to be inserted and function ideally, the two implants should be parallel to each other, perpendicular to the occlusal plane, at the same horizontal height (parallel to the occlusal plane), and equal distance off the midline. If one implant is not parallel to the other, the prosthesis will wear one attachment faster because of the greater displacement during insertion and removal than the other. If the angulation difference is severe, the prosthesis may not engage one attachment at all. The implants also should be perpendicular to the occlusal plane. Because the goal is to allow the posterior regions of the overdenture to rock downward and load the soft tissue over the mandibular buccal shelves for support, the hinge rotation should be at 90 degrees to the rotation path. In addition, because only two implants sustain the occlusal load during function or parafunction, minimization of the forces to the implant components and crestal bone by placing them in the long axis of the implant body and perpendicular to the occlusal plane is ideal (Fig. 24.15).

The two independent implants should be positioned at the same occlusal height, parallel to the occlusal plane. If one implant is higher than the other, the prosthesis will disengage from the lower implant during function and rotate primarily on the higher implant. This situation will accelerate the wear of the attachment on the lower implant. In addition, because the higher implant receives the majority of the occlusal load, an increased risk for complications may occur, including abutment screw loosening, crestal bone loss, and implant failure.

The implants should be equal distance off the midline. If one implant is more distal (farther from the midline), it will serve as the primary rotation point or fulcrum when the patient occludes in the posterior segments. As such, the more medial implant attachment will wear faster, and the more distal implant will receive a greater occlusal load (Box 24.2 and Fig. 24.16).
• **Fig. 24.13** Overdenture option 1 consists of two independent implants. These are best placed in the *B* and *D* positions (A) to limit the forward rocking of the restoration during function. Independent implants in the *A* and *E* positions (B) allow a greater rocking of the restoration and place greater leverage forces against the implants.


• **Fig. 24.14** Two-Implant Overdenture. (A) *A* and *E* position. (B) This position often results in an anterior and posterior "rocking" of the prosthesis. In addition, the attachment may impinge on the next phase tongue space requiring overcontouring of acrylic.
• **Fig. 24.15** (A) Treatment option 2 has implants in the *B* and *D* positions, and a bar joins the implants. The bar should not be cantilevered off the distal side of the implants. The prosthesis movement will be reduced, and too much force on the bar and implants will increase complications. Attachments such as an O-ring (B) or a Hader clip (C), which allow movement of the prosthesis, can be added to the bar. The attachments are placed at the same height at equal distance off the midline and parallel to each other.

Overdenture Option 2

Three root form implants are placed in the A, C, and E positions for the second overdenture treatment option (OD-2). The advantages of splinting A, C, and E implants compared with implants in the B and D positions are many. The additional implant provides a sixfold reduction in superstructure flexure

---

• **BOX 24.2** **Treatment Option 1: Two Implants (B-D)**

Advantages
- Decreased cost
- Greater prosthesis support than conventional denture
- Less invasive surgical and prosthetic procedures

Disadvantages
- May not meet patient expectations
- Increased maintenance appointments
- Continuous cost associated with attachment replacement
- Prosthesis reline must be completed more often
- Relies on soft tissue for primary support

Indications
- Lowest cost
- Less-complicated surgery
- Patient who needs minimal increased retention (RP-5)
• **Fig. 24.16** (A) When two implants are used in the treatment plan, the implants should be as parallel as possible. (B) Two implants that are not parallel and at different heights, which most likely will lead to prosthetic complications.

(i.e. if splinted bar is used) and limits the consequences previously discussed.[49] In addition, screw loosening occurs less frequently because three coping screws retain the superstructure rather than two. Implant reaction forces are reduced with a third implant compared with two implants. The greater surface area of implant to bone allows better distribution of forces. The risk for abutment or coping screw loosening is reduced further because force factors are decreased. Three permucosal sites distribute stresses more efficiently and minimize crestal bone loss. Because the crestal bone is the first region of the bone to be affected, this represents a major advantage. The reduction in the maximum moment of force is twofold with a three-implant system compared with two implants in the A and E regions (Fig. 24.17).[50] A three implant overdenture (RP-5) can be correlated to a 3-legged chair for patient educational purposes.
• **Fig. 24.17** Three-Implant Overdenture. (A) A-C-E positions. (B) B-C-D positions.

Ideally, the implants in the A, C, and E positions should not form a straight line. The C implant is anterior to the more distal A and E implants and directly under the cingulum position of the denture teeth. The prosthesis benefits from direct occlusal load to the implant support in the anterior arch. When more than two implants are in the anterior mandible, a tripod support system may be established. The greater the A-P spread of the A, C, and E implants, the greater the biomechanical advantage to reduce stress on the implant and the better the lateral stability of the implant bar and overdenture system. Rotation of the prosthesis may also be more limited compared with OD-1. Therefore the third implant for OD-2 is a considerable advantage for the mandibular edentulous patient. This is usually the first treatment option for a patient with minimal complaints who is concerned primarily with retention and anterior stability when cost is a moderate factor. The posterior ridge form determines the posterior lingual flange extension of the denture, which limits lateral movement of the restoration. If the anterior and posterior ridge form is favorable (Divisions A or B), the implants are placed in the A, C, and E areas, and a wide range of attachments is available (Fig. 24.18).[50]

If the posterior ridge form is poor (Division C–h), the lack of lateral stability places additional forces on the anterior implants. Implants then are best placed in the B-C-D position to allow greater freedom of movement of the prosthesis. The greater the stress to the system, the greater prosthesis movement/stress relief indicated. This increases the posterior movement of the prosthesis but decreases the amount of stress placed on the implants and screw-retained bar.

The prosthesis movement for three implants with C–h posterior bone should be greater to minimize forces on the implants and bar or individual attachment system. If the patient with poor posterior ridge form requires more stability, more than three implants are indicated. In Division D posterior mandibles, five anterior implants are indicated to support the prosthesis (Box 24.3).
• **Fig. 24.18** Overdenture option 3 corresponds to implants in the A, C, and E positions connected with a bar. The attachments should be positioned to allow movement of the distal section of the prosthesis (A). Two non-aligned Hader clips will not allow movement (B).

Overdenture Option 3

In the third mandibular overdenture option (OD-3), four implants are placed in the A, B, D, and E positions. These implants usually provide sufficient support to include a distal cantilever up to 10 mm on each side if the stress factors are low. The cantilevered superstructure is a feature of the four or more implant treatment option for three reasons: The first relates to the increase in implant support compared with OD-1 to OD-3. The second is that the biomechanical position of the implants is improved in an ovoid or tapering arch form compared with OD-1 or OD-2. The third is related to the additional retention provided for the superstructure bar, which limits the risk for screw loosening and other related complications of cantilevered restorations (Fig. 24.19).

In considering a distal cantilever for a mandibular overdenture bar, the implant position is the primary local determinant. Cantilevers may be compared with a class 1 lever in mechanics. The distalmost implant on each side acts as a fulcrum when occlusal forces are applied to the distal cantilever. Therefore the amount of the occlusal force is magnified by the length of the cantilever, which acts as a lever. For example, a 25-lb load to a 10-mm cantilever results in a 250-lb moment force.

This moment force is resisted by the length of the bar anterior to the fulcrum. Therefore if the two anterior implants are 10 mm from the fulcrum (distal implants), the effect of the posterior cantilever is countered. If the implants are 5 mm apart, the mechanical advantage of the lever is the 10-mm cantilever divided by the 5-mm A-P spread, which equals 2. A 25-lb distal force is magnified to 50 lb to the anterior implant and 75 lb (50 + 25 = 75) to the distal (fulcrum) implant.

The mandibular arch form may be square, tapering, or ovoid. Square arch forms limit the A-P spread between implants and may not be able to counter the effect of a distal cantilever. Therefore rarely are distal cantilevers designed for square arch forms. In a tapering arch form the A-P spread between implants in the A-E and B-D positions is greater and therefore permits a longer distal cantilever. This A-P spread is often at least 10 mm, and therefore often permits a cantilever up to 10 mm from the A and E positions. In an ovoid arch, which is most common, the A-P spread between AE and BD is usually 8 mm. Therefore the cantilever may be up to 8 mm long distally from the A and E implants.

The A-P spread is only one factor to determine the length of the cantilever. When stress factors such as occluding forces are greater, the cantilever is decreased. When the crown height is doubled, the moment forces are doubled. Therefore under ideal, low-force conditions (crown height less than 15 mm, no parafunction, older females, opposing maxillary denture), the cantilever may be up to 1.5 times the A-P spread for OD-3 overdentures.

The patient's indications for this OD-3 include moderate-to-poor posterior anatomy that causes a lack of retention and stability, soft tissue abrasions, and difficulty with speech. The edentulous posterior mandible resorbs four times faster than the anterior mandible. In the C–h posterior mandible the external oblique and mylohyoid ridges are high and often correspond to the crest of the residual ridge. The muscle attachments therefore are at the crest of the ridge. The patient's complaints and desires are more demanding than for the previous treatment options.

The OD-3 prosthesis is indicated to obtain greater stability and a more limited range of prosthesis motion. The overdenture attachments often are placed in the distal cantilevers. The prosthesis is still RP-5, but with the least soft tissue support of all RP-5 designs. The anterior attachment must allow vertical movement for the distal aspect of the prosthesis to

rotate toward the tissue. Clips, which permit rotation, are difficult to use on cantilevered superstructures. The clip must be placed perpendicular to the path of rotation to allow movement, not along the cantilevered bar, where its only function then is retention.

The patient benefits from the three implants because of greater occlusal load support and lateral prosthesis stability. The prosthesis loads the soft tissue over only the first and second molars and retromolar pad regions. Therefore the amount of occlusal force is reduced because the bar does not extend to the molar position, where the forces are greater. The amount of distal cantilever is related primarily to the force factors and to the arch form, which corresponds to the A-P spread from the center of the most anterior implants to the distal portions of the A and E implants. However, without the "C" implant position, the A-P spread is not as great (Box 24.4).

Overdenture Option 4

The fourth mandibular overdenture option (OD-4) is designed for three types of patients. This is a minimum treatment option for patients with moderate-to-severe problems related to a

traditional restoration. The needs and desires of the patient are often most demanding and may include limiting the bulk or amount of the prosthesis, major concerns regarding function or stability, posterior sore spots, and the inability to wear a mandibular denture.

The second patient condition is for the treatment of continued bone loss in the posterior mandible. If no prosthetic load is on the posterior bone, the resorption process is delayed considerably and usually is reversed. The third patient condition is a patient who suffers from severe soft tissue sore spots or a history of xerostomia. Because of the completely supported nature of this implant treatment plan, no resultant force will be applied to the soft tissue.

Therefore even when no posterior implants are inserted, the attachments, cantilevered bar, and overdenture avoid load to the residual ridge and often halt its resorption process. Studies have shown that completely implant-supported prostheses may increase the amount of posterior bone height, even when no posterior implants are inserted.[17,51] A better option to prevent this bone loss is the insertion of posterior implants before bone atrophy begins. This treatment option is more likely when the patient desires a fixed restoration or the arch form is square (Fig. 24.20 and Box 24.5).

Division C–h Anterior Mandibles

The four treatment options proposed for mandibular implant–supported overdentures provide an organized approach to solving a patient's complaints or anatomic limitations. The prosthesis support and range of motion should be part of the initial diagnosis. The treatment options initially proposed are designed for completely edentulous patients with Division A anterior bone in desire of an overdenture. These options are modified if the anterior bone is Division C–h. The increase in crown/implant ratio and decrease in implant surface area mandate modification of these initial options.

In the C–h anterior bone volume patient, one more implant is added to each option and OD-1 is eliminated completely. Ideally an RP-5 with good buccal shelf support is recommended.

• BOX 24.4   Treatment Option 3: Four Implants (A-B-D-E)

Advantages
- Increased anteroposterior spread from options 1 and 2
- May cantilever with bar
- May be used as an RP-4 or RP-5 according to force factors
- Possible no soft tissue support (RP-4)

Disadvantages
- More implants required
- More expensive treatment
- Surgical and prosthetic procedures more complicated

Indications
- Increased retention
- Decreased prosthesis movement
- More range of prosthetic options

• **Fig. 24.20** (A and B) Five-implant overdenture and a removable RP-4 prosthesis with implants in the A, B, C, D, and E positions.

Patient Education on Various Mandibular Overdenture Options

The clinician and staff can explain the amount of support each treatment option can provide by comparing them with the support system of a chair. Treatment option OD-1 is related to a two-legged chair. The prosthesis provides some vertical support but can rock back and forth. Option OD-2 with three implants is compared with a three-legged chair. This system provides further support but can be rocked one way or the other under lateral forces. A four-legged chair provides the greatest support and is similar to OD-3 and OD-4, which are stable, retentive prostheses.

Fixed Prosthesis

Fixed Prosthesis Advantages

Psychological

A fixed prosthesis provides the psychological advantage of acting and feeling similar to natural teeth, whereas an overdenture, even if fully implant supported, remains a removable prosthesis. In today's society, most patients do not want to be able to remove the prosthesis. A fixed prosthesis often is perceived as an actual body part of the patient, and if a patient's primary request is not to remove the prosthesis, an implant-supported overdenture would not satisfy the psychological need of this patient (Box 24.6).

Improved Speech

The complete mandibular denture, and overdentures to an extent, often move during mandibular jaw movements during function and speech. The contraction of the mentalis, buccinator, or mylohyoid muscles may lift the prosthesis off the soft tissue. As a consequence the teeth may touch during speech and elicit clicking noises. The retentive nature of a fixed prosthesis allows it to remain in place during mandibular movement. The tongue and perioral musculature may resume a more normal position because they are not required to limit the denture or overdenture movement.

Decreased Soft Tissue Irritation

Soft tissue abrasions and accelerated bone loss are more symptomatic of horizontal movement of the prosthesis under lateral forces.

A mandibular denture may move up to 10 mm during function. An implant-supported overdenture may limit lateral movements and direct more longitudinal forces. Under these conditions, specific occlusal contacts and the control of masticatory forces are nearly impossible. An implant fixed prosthesis provides ideal stability of the prosthesis, and the patient is able consistently to reproduce a determined centric occlusion.[52] A fixed prosthesis is especially beneficial in patients with xerostomia (i.e., dry mouth) because there is no tissue contact, which minimizes any possible soft tissue irritation (Fig. 24.21).

Increased Biting Force

Higher bite forces have been documented for mandibular fixed prosthesis on implants. The maximum occlusal force of a patient with dentures may improve 300% with an implant-supported prosthesis.[53] Jemt et al.[54] showed a decrease in occlusal force when the bar connecting implants was removed, which they attributed to the loss of support, stability, and retention. If enough implant support is provided, the resulting prosthesis may be completely supported, retained, and stabilized by the implant prosthesis (i.e., RP-4). Müller et al.[55] reported a greater masseter thickness, chewing efficiency, and bite force in edentulous patients with fixed implant–supported prostheses in a cross-sectional multicenter study.

Less Bone Resorption

When implants are placed in the anterior mandible, the resorption of bone is decreased. Studies have confirmed that after the extraction of mandibular teeth, an average of 4-mm vertical bone loss occurs during the first year after treatment. This bone loss will continue indefinitely, with the mandible experiencing a fourfold greater vertical bone loss than the maxilla.[56] The bone underneath an overdenture may resorb as little as 0.6 mm vertically over 5 years, and long-term resorption may remain at less than 0.05 mm per year.[57,58]

A more recent clinical study by Wright et al.[17] has evaluated the posterior mandibular bone loss in IODs (RP-5) compared with cantilevered fixed prostheses from anterior implants. The annual bone loss index observed in the RP-5 overdentures ranged from +0.02 to +0.05, with 14 of 20 patients losing bone in the posterior regions. On the other hand, the fixed prostheses group had a range from +0.07 to +0.015, with 18 of 22 patients gaining posterior bone area. Reddy et al.[18] also found a similar clinical observation in 60 consecutively treated cantilevered fixed prostheses supported by five to six implants placed between the foramina. The mandibular body height was measured 5, 10, 15, and 20 mm distal to the last implant. The baseline measurements up to 4 years after function increased from 7.25 ± 0.25 to 8.18 ± 0.18 mm. Nearly all of the bone growth occurred during the first year of function. Therefore

• **Fig. 24.21** Soft Tissue Irritation. Because there is no contact with the soft tissue for a fixed prosthesis, patients who have a history of soft tissue irritation or xerostomia benefit greatly from a fixed prosthesis.
• **Fig. 24.22** Fixed Implant Prosthesis. A net increase in bone is seen with an FP-3 prosthesis (red arrows). With a removable overdenture prosthesis, bone loss is seen and is continuous.

• **Fig. 24.23** Implant overdentures with posterior soft tissue support lose bone in the posterior regions almost 75% of the time. Fixed prostheses cantilevered from anterior implants gain bone in the posterior regions more than 80% of the time (right side of graph).

an important advantage for a complete implant-supported prosthesis is the maintenance and possible regeneration of posterior bone in the mandible. This is especially important because posterior bone loss in this region may lead to neurosensory changes and even mandibular body fracture (Figs. 24.22 and 24.23).

Less Soft Tissue Extension

The implant fixed prosthesis reduces the soft tissue coverage and extension of the prosthesis. This is especially important for new denture wearers, patients with tori or exostoses, or patients with low gagging thresholds. Also, the existence of a labial flange in a conventional denture may result in exaggerated facial contours for the patient with recent extractions. Implant-supported prostheses do not require labial extensions or extended soft tissue coverage. Fixed prosthesis should ideally be convex on the intaglio surface, not concave which leads to hygiene difficulty.

Less Long-Term Expenses

Mandibular overdenture wearers often incur greater long-term expenses than those with fixed restorations. Attachments such as Locator, O-rings, or clips wear and must be replaced regularly. Replacements appear more frequent during the first year, but remain a necessary maintenance step. Denture teeth wear faster on an IOD than with a traditional denture because bite force and masticatory dynamics are improved.

Walton and McEntee[59] noted that there were three times more maintenance and adjustments for removable prostheses compared with fixed restorations. IODs often require attachments to be changed on a regular basis, and denture teeth often wear, requiring a new prosthesis to be fabricated more often. In a review of literature by Goodacre et al., IODs have retention and adjustment problems 30% of the time, relines 19%, clip or attachment fracture 17%, and fracture of
• **Fig. 24.24** Crown/Implant Ratio. It is imperative that sufficient space is present to fabricate a fixed prosthesis, which is approximately 10 mm for a porcelain fused-to-metal prosthesis (i.e., 8 mm for a zirconia prosthesis).

the prosthesis 12%. A fixed prosthesis (FP-3) requires less repair and less maintenance. Patient education of the long-term maintenance requirement should be outlined at the onset of implant therapy.[60]

Less Interocclusal Space Requirement

The mandibular overdenture treatment plan may require up to 15 mm of space between crestal bone and the occlusal plane. When sufficient crown height space is lacking, the prosthesis is more prone to component fatigue and fracture. The required crown height space (i.e., 15 mm for a bar-retained overdenture and 9 mm for independent attachments) provides adequate bulk of acrylic to resist fracture, space to set denture teeth without modification, and room for attachments, bars, soft tissue, and hygiene. However, with a fixed prosthesis, only 8mm is required for a zirconia prosthesis and 10 mm for a porcelain fused to metal prosthesis. An osteoplasty to increase crown height space before implant placement or a fixed restoration is often indicated when abundant bone height and width are present (Fig. 24.24).

Patients with Limited Dexterity

A fixed implant prosthesis is ideal for patients with limited dexterity, such as patients with autoimmune disorders (e.g., rheumatoid arthritis, scleroderma). With a removable prosthesis, it may be difficult or impossible to remove a prosthesis because of the attachment fixation. Today, numerous hygiene devices are available to assist patients with daily hygiene.

Increased Chewing Efficiency

Gonçalves et al.[61] showed in studies that a fixed implant prosthesis results in significantly increased chewing efficiency in comparison with an IOD. In the fixed implant prosthesis group the masseter and temporalis muscle showed greater thickness and patient satisfaction was much greater than with a removable prosthesis.[61]

Mandibular Fixed Prosthesis (FP-1, FP-2, and FP-3)

In the past the functional and esthetic rehabilitation of edentulous patients have always been areas of frustration and challenge in the dental profession. However, with the use of dental implants, patients are now able to obtain clinically successful rehabilitation through the use of a fixed prosthesis. Currently, edentulous patients have a full array of treatment options for a fixed prosthesis in the mandibular arch.

Implant Treatment Options for Fixed Restorations

Treatment Option 1: The Brånemark Approach

Among the fixed implant–supported options, the prosthesis following the Brånemark protocol has been shown to have excellent longevity and clinical efficacy.[62] This classical treatment plan involves four to six implants between the mental foramina, and bilateral distal cantilevers replace the mandibular posterior teeth, usually to the first molar region. The mandible does not flex or exhibit significant torsion between the mental foramina. Therefore anterior implants may be splinted together without risk or compromise. The placement of four to six anterior root forms between the mental foramina and a distal cantilever posterior of the most distal implant to replace the posterior teeth was the treatment of choice for clinical reports from 1967 to 1981 with the Brånemark system.[62] This treatment approach resulted in an 80% to 90%

implant survival rate for 5 to 12 years after the first year of loading. In a long-term, 18- to 23-year study, Attard and Zarb[63] reported an 84% success rate using this treatment option (Fig. 24.25).

Treatment option 1 depends greatly on patient force factors; arch form; and implant number, size, and design. As a result, this option should be reserved for patients with low force factors, opposing a removable prosthesis, lower biting force, favorable bone density, and available bone for ideal implant dimensions (Box 24.7 and Fig. 24.26).

Treatment Option 2: Modified Brånemark Technique

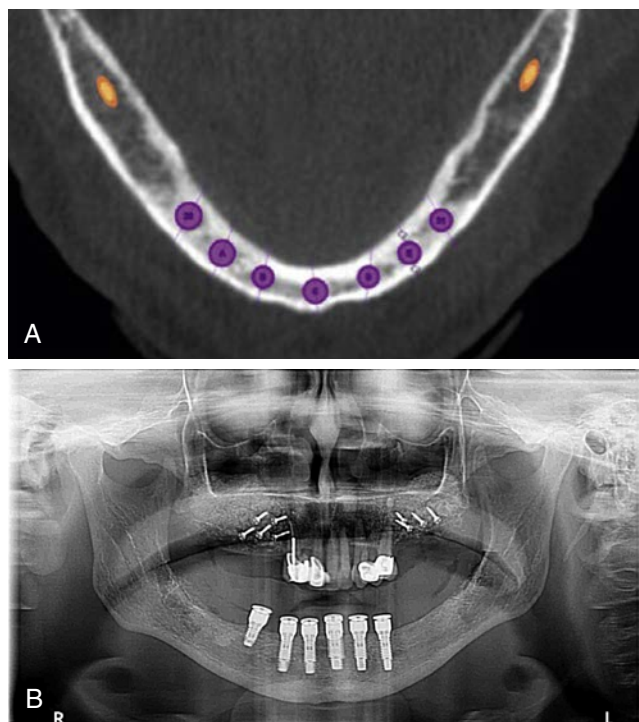
A second mandibular fixed treatment plan involves a modified Brånemark technique. Bidez and Misch[19] have evaluated dentate and edentulous mandibles, and developed a three-dimensional bone-strain model of flexure and torsion. Studies were performed to evaluate different splinted implant options that would not compromise the prosthetic foundation. As a consequence a number of implant site options have become available.[64]

A slight variation of the ad modum Brånemark protocol is to place additional implants above the mental foramina because the mandible flexes distal to the foramen. An implant above one or both foramina presents several advantages. First, the number of implants may be increased to as many as seven, which increases the implant surface area. Second, the A-P spread for implant placement is greatly increased. The more distal implant positions will reduce the class 1 lever forces generated from the distal cantilever prosthesis (Fig. 24.27). Third, the
• **Fig. 24.26** Treatment Option 1. (A) Clinical image of traditional Bråne-mark mandibular technique. (B) Five-implant FP-3 prosthesis. (C) Hybrid Brånemark fixed prosthesis.
• **Fig. 24.27** Treatment option 2 has five key implant positions: two implants placed over the mental foramina, two implants in the canine positions, and one implant in the midline. Secondary implants may be positioned in the first premolar sites. *FPD*, Fixed partial denture.

• **BOX 24.8** **Fixed Treatment Option 2: Implants Anterior and Over Foramina**

Advantages
• Decreased cantilever
• Increased anteroposterior spread

Disadvantages
• Must have adequate posterior bone
• More implants required

Indications
• Higher force factors
• Square arch forms


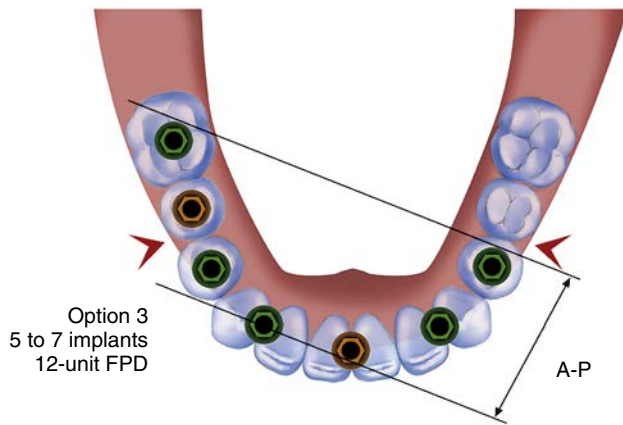
• **Fig. 24.28** Treatment Option 2. (A) Cone beam computed tomography treatment plan for implants over the foramen area. (B) Clinical image of adding an implant over the right foramen to increase the anteroposterior spread.

length of the cantilever is reduced dramatically because the distalmost implants are positioned at least one tooth more posterior.

A prerequisite for treatment option 2 is the presence of available bone in height and width over one or both foramina. When available bone is present, the foramen often requires implants of reduced height compared with the anterior implants. The most distal implant bears the greatest load when loads are placed on the cantilever (acts as fulcrum); therefore the greatest forces are generated on the shortest implants. A minimum recommended implant height of 8 mm and a greater diameter or an enhanced surface area design are recommended to compensate for the reduced implant length.

The key implant positions in treatment option 2 are the second premolar positions, the canine positions, and the central incisor or midline position. The two optional implant sites are the first premolar sites and are more often indicated when the patient force factors are greater than usual (Box 24.8 and Fig. 24.28).

Option 3
5 to 7 implants
12-unit FPD

A-P


• **Fig. 24.29** Treatment option 3 has key implant positions in one first molar site, bilateral first premolar positions, and two canine sites. Secondary implants may be used in the bilateral second premolar and midline position. The anteroposterior (A-P) distance is measured from the two distal-most implants to the anteriormost implant from the cantilever. *FPD*, Fixed partial denture.

Treatment Option 3: Anterior Implants and Unilateral Posterior Implant

The third fixed treatment option is used when inadequate bone is present over the foramina and support is required more posteriorly. The Bidez and Misch[65] strain model of an edentulous mandible indicated that implants in one posterior section may be splinted to anterior implants without compromise. Misch evaluated full-arch fixed prostheses on implants with one posterior segment connected to the anterior region over 20 years and found no additional complications experienced during this time frame compared with those with independent segments.[65]

Therefore an improved treatment plan option to support a fixed mandibular prosthesis consists of additional implants in the first molar or second premolar position (or both) connected to four or five implants between the mental foramina. Hence five to seven implants usually are placed in this treatment option (Fig. 24.29).

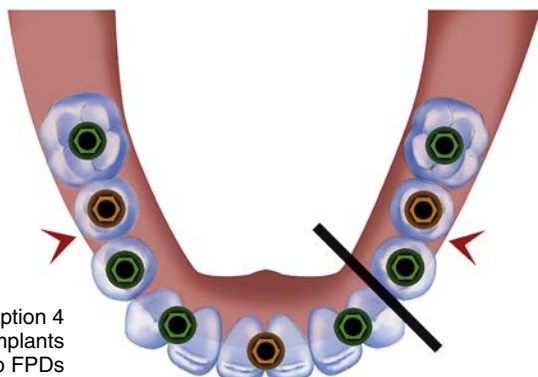
The key implant positions for treatment option 3 are the first molar (on one side only), the bilateral first premolar positions, and the bilateral canine sites. The secondary implant positions include the second premolar position on the same side as the molar implant and the central incisor (midline) position. On occasion an additional site may include the position over the mental foramen on the side of the cantilever. Although mandibular movement during function occurs, it has not been observed to cause complications, because the side opposite to the molar implant has no splinted implant(s).

Treatment option 3 is a better option than anterior implants with bilateral cantilevers (option 1 or 2) for several reasons. When one or two implants are placed distal to the foramina on one side and are joined to anterior implants between the foramina, a considerable biomechanical advantage is gained. Although the number of implants may be the same as option 1 or 2, the A-P spread is 1.5 to 2 times greater because, on one side, the distal aspect of the last implant now corresponds to the distal aspect of the first molar. In addition, only one cantilever is present rather than bilateral cantilevers. When force factors are greater, six to seven implants may be used for this option. Five implants between the foramina and one or two implants distal on one side encompass the most common placement.[66] This approach is superior to treatment option 1 or 2 with bilateral cantilevers because: (1) the A-P
• **Fig. 24.30** Treatment Plan 3 Options. (A) Two unilateral posterior implants. (B and C) Clinical images of one unilateral implant that increases the anteroposterior spread and reduces the bilateral cantilever effect.

spread is dramatically increased, (2) more implants may be used if desired, and (3) only one side has a cantilever. However, this option requires available bone in at least one posterior region of the mandible (Fig. 24.30 and Box 24.9).

Treatment Option 4: Anterior Implants and Bilateral Posterior Implants

Treatment plan options for fixed full-arch prostheses also may include bilateral posterior implants as long as they are not splinted together in one prosthesis. This option is selected when force factors are great or the bone density is poor. Poor bone quality most often is observed in the posterior maxilla, but on occasion it is also found in the mandible. Several options for fixed restorations are available when bilateral posterior implants are included; however, the prosthesis needs to be in more than one piece.[67]

In treatment option 4, implants are placed in all three segments of the mandible. Key implant positions for this treatment option include the two first molars, two first premolars, and two canine sites. Secondary implants may be added in the second premolars or the incisor (midline) position (or both) (Fig. 24.31).


• **Fig. 24.31** Treatment option 4 has implants in both molar sites. Other key positions include the two first premolar positions and the two canine sites. Secondary implants may also be positioned into second premolar locations and the midline. *FPD*, Fixed partial denture.

Option 5
8 to 9 implants
8-unit FPD
plus two 2-unit FPDs

• **Fig. 24.32** Alternative prosthetic design is for three separate prostheses, first premolar to first premolar supported by four or five implants, and two posterior segments. *FPD*, Fixed partial denture.

Prosthetically, all implants in the anterior and one posterior side may be splinted together for a fixed prosthesis. The other posterior segment is restored independently with an independent three-unit, fixed prosthesis supported by implants in the first premolar and first molar region.

Three implants (first premolar, second premolar, and molar) are used most often for the smaller segment to compensate for force factors and the alignment of the implants (because they are almost in a straight line). At least six implants typically are used in this option, but seven are more often used, so the smaller segment has three implants (Fig. 24.32).

The primary advantage of this treatment option is the elimination of cantilevers. As a result, risks for occlusal overload are reduced. Another advantage is that the prosthesis has two segments rather than one. The larger segment (molar to contralateral canine) has an improved advantage because it has implants in three to four different horizontal planes. Because no cantilever is present, less damaging forces are applied to the prosthesis. If the prosthesis requires repair, the affected segment may be removed more easily because only the segment requiring repair needs to be removed. The prosthesis should exhibit posterior disclusion in excursions to limit lateral loads, especially to the prosthesis supported by fewer implants.

Disadvantages for treatment option 4 include the need for abundant bone in both mandibular posterior regions and the additional costs incurred for one to four additional implants.

Another modification for the completely edentulous mandible is to fabricate three independent prostheses rather than two. The anterior region of the mandible may have four to five implants. The key implants are in the two first molar sites, the two first premolar sites, and two canine regions. Secondary positions are the two second premolar and central incisor (midline) sites. With this protocol, the posterior restorations extend from first molar to first premolar, and an anterior restoration replaces the six anterior teeth.

The advantages of this option are smaller segments for individual restorations in case one should fracture or become uncemented. In addition, if greater mandibular body movement is expected because of parafunction or a decrease in size of the body of the mandible, the independent restorations allow the most flexibility and torsion of the mandible.

The primary disadvantage of option 4 is the greater number of implants required. In addition, the available bone needs are greatest with this treatment option. Nine implants are rarely required to replace the lower teeth, regardless of the bone density or force factors present. Option 4 is the treatment of choice when force factors are severe (Box 24.10 and Fig. 24.33).

Treatment Option 5: All-on-Four Protocol

The treatment option 5 includes the "all-on-four" concept, which was developed to avoid regenerative procedures that potentially increase the treatment costs and patient morbidity. This protocol, developed

• **Fig. 24.34** All-on-Four Protocol. (A) Two implants are positioned in the anterior and two implants in the posterior at an angle to increase the anteroposterior spread and avoid the mental foramen. (B) Clinical image of mandibular all-on-four.

• **Fig. 24.33** Treatment Plan 4. (A and B) Clinical image of eight implant mandibular implants with two independent prostheses. (C) An additional prosthetic option is three independent prostheses with one anterior and two posterior.
• **Fig. 24.35** All-on-Four Complication. (A and B) If one or more of the implants fail, the prosthesis is lost, and new implants and bone augmentation may need to be completed to redo the prosthesis.

by Malo, uses four implants in the anterior part of a completely edentulous jaw to support a provisional, fixed, and immediately loaded prosthesis. Most commonly, the two most anterior implants are placed axially, whereas the two posterior implants are placed at an angle (i.e., usually at an approximately 45-degree angle) to increase A-P spread along with decreasing the cantilever length (Fig. 24.34).[68,69]

Tilted implants have been shown to generate favorable biomechanical outcomes[70] and in a metaanalysis, there was no significant difference in either failure rate compared with axially placed implants[71] or marginal bone loss.[72] The tilted implants offer several advantages, which include the use of longer implants (i.e., greater surface area and primary stability), reduced or eliminated cantilever length, and avoidance of vital structures such as the inferior alveolar canal.[73] This procedure has become popular among clinicians and patients because of the decreased treatment costs and treatment duration.[74] The literature has shown high survival rates and a low incidence of complications with this procedure (Fig. 24.35).[75,76] Most dental implant and prosthetic survival rates approach 98% (Box 24.11).[47,48,77,78] However, all-on-four protocols require the clinician to have additional surgical and prosthetic skills. Because of the increased skill level required, clinicians early on their learning curve should exercise caution in these cases.

Summary

The treatment of the edentulous mandible is a common procedure that implant clinicians see on a regular basis. There exists a full array of options for patients which include 5 fixed treatment plans and 4 removable overdenture treatment options. IODs borrow several principles from tooth-supported overdentures. The advantages of IODs relate to the ability to place rigid, healthy abutments in the positions of choice. The number, location, superstructure design, and prosthetic range of motion can be predetermined and based on a patient's expressed needs and desires. Two implants placed just anterior to the mental foramina rarely should be used. The overdenture should be designed to satisfy the patient's desires and anatomic limitations predictably.

Many completely edentulous patients desire a fixed restoration rather than a removable prosthesis. The financial cost for a fixed implant prosthesis often have been a deterrent but should be more similar to a completely implant-supported overdenture. The number and position of implants should be related to the amount of stress transmitted to the bone during occlusion and parafunction, and the density of the bone. Other considerations include mandibular flexure and torsion. Five treatment options generally are available for this fixed complete mandibular implant-supported restoration. These treatment options accommodate the stronger mandibular bone dynamics without affecting the prosthesis.

The Edentulous Maxilla: Fixed versus Removable Treatment Planning

RANDOLPH R. RESNIK AND CARL E. MISCH[†]

In all phases of implant dentistry the treatment planning of the edentulous maxilla is the most complicated for the long-term success of implants and the prosthesis. The maxillary arch is predisposed to inherent anatomic disadvantages, which has led to many studies verifying a much lower success rate in comparison with the mandible. Historically, most research studies on edentulous arches were completed on the mandible because most patients often described the instability of the mandibular denture in comparison with the maxillary. In general, patients are more likely to wear a maxillary denture in comparison with the mandibular edentulous prosthesis. Many patients often waited longer periods before seeking treatment in the edentulous maxilla, which resulted in extensive resorption.

The maxillary arch has a lower success rate mainly because in the past the maxillary arch principles followed the same principles that are used in the mandibular arch. The long-term prognosis for implants in the maxilla has been shown to be less predictable in comparison with the mandible. Because of the resorption pattern of the maxilla (i.e., horizontal bone loss twice as much as vertical resorption soon after extraction), anatomic structures such as the nasal cavity and the maxillary sinus play an important role in treatment planning. Because of the high prevalence of reduced quantity and quality of bone, along with increased esthetic demand, the maxillary arch requires more detailed approaches to treatment planning with respect to a fixed or removable prosthesis (Fig. 25.1).

Treatment Planning Factors

When evaluating a patient for maxillary implants, one of the most important diagnostic tools is the patient's existing denture. From the patient's denture, the smile line, amount of lip support, size and shape of the teeth, interocclusal space (crown height space), and the relative retention of the prosthesis can be determined.

Smile Line

The smile line is an important variable when evaluating the amount of teeth the patient should show with movement of the upper lip during
• **Fig. 25.1** The maxilla varies greatly, from abundant bone with attached tissue (A) to a severely resorbed maxilla with compromised hard and soft tissue (B).

[†] Deceased

589

speech and smiling. Tjan et al.[1] reported that the average smile allows approximately 75% to 100% of the maxillary incisors and interproximal gingiva to be visible. With an edentulous arch the clinician should evaluate the amount of ridge showing when smiling without the denture. If the residual ridge does show during smiling, the treatment planning for an implant prosthesis may be very challenging (Fig. 25.2).

Lip Support

The lip and soft tissue support is derived from the maxillary anterior teeth contours and also the position of the residual ridge. The lip and soft tissue support should be evaluated with the existing denture in place and not in place. This will give crucial information on whether a fixed or removable prosthesis would be more ideal. If the existing denture greatly supports the lip, then a fixed prosthesis may not be the most ideal because it is often difficult to obtain lip support from a fixed maxillary prosthesis. The soft tissue support is mainly from the buccal flange of the maxillary prosthesis as resorption in the maxilla proceeds in a cranially and medially direction.

In addition, a patient with a short upper lip will most likely show the maxillary teeth on repose. Therefore short upper lips are far more challenging than long upper lips. With a long upper lip, very little to none of the maxillary teeth will be visible (Fig. 25.3).

• **Fig. 25.2** Smile Line. When patients exhibit a high smile line, caution should be exercised in the treatment planning of the edentulous arch because the final esthetics may be problematic.

Ridge Position

Depending on the amount of bone resorption, the residual ridge is usually significantly lingual to the ideal position of the teeth in the maxillary anterior and posterior. This discrepancy must be taken into consideration when evaluating the ideal position of the implants so that a prosthesis may be fabricated that fulfills adequate lip support, phonetics, and patient approval, and allows for sufficient tongue space. When the difference between the ridge and the tooth position (i.e., square arch form and tapered tooth position) is present, significant prosthetic difficulties such as anterior force factors (i.e. from the cantilevered discrepancy between the ridge and tooth position) may predispose to complications.

Soft Tissue

The thickness and quality of the soft tissue should be evaluated both clinically and via a cone beam computed tomography examination. As the maxillary ridge resorbs, the tissue thins and is less dense with loss of keratinized tissue. In severely resorbed premaxillary regions, the tissue will become hypermobile, which leads to very little support for the prosthesis. Often maxillary edentulous patients seek an esthetic fixed prosthesis similar to natural teeth. Therefore it is imperative the patient understand the difficulty in achieving a papillary architecture similar to preextraction condition. Regenerating papilla, which would result in a FP-1 (fixed prosthesis with normal size clinical crown) prosthesis, is usually difficult and in some cases impossible to achieve.[2]

Crown Height Space (Interocclusal Space)

The amount of space between the residual ridge and the incisal edge is an important factor in the treatment planning of a maxillary prosthesis. For a fixed versus a removable implant prosthesis, there exist different dimensional tolerances to accommodate the prosthesis. Therefore a preoperative evaluation and determination of the amount of crown height space needs to be completed before any surgical placement of dental implants. In general this may be accomplished with an articulated setup of maxillary and mandibular arches. However, a study cast will not relate an accurate assessment of the thickness of the soft tissue. Therefore newer software programs that allow for the three-dimensional evaluation of the teeth in maximum intercuspation can easily be accomplished with a cone beam computed tomography survey.
• **Fig. 25.3** Lip Support. (A) The lip support should be evaluated with the denture in and the denture out to determine the future prosthetic demands (B).

Conventional screw-retained implant prostheses (i.e., zirconia or porcelain-fused prostheses) can be fabricated with 8-10 mm (zirconia) between the edentulous ridges and the opposing occlusal plane. For a hybrid prosthesis, approximately 15 mm of interocclusal room is required, as increased space is required to prevent acrylic material fracture.[3] Sufficient crown height space will allow for adequate bulk of material and permits for more ideal esthetics and hygiene ability. If space is compromised, an increase in prosthetic complications may occur.[4,5]

For a removable prosthesis in the maxillary arch, compromised space can be more problematic in comparison with the mandibular arch. When inadequate space is available for a removable prosthesis, fracture of the prosthesis or compromised esthetics may result. A significant variable is whether the implants would be independent or bar retained. For an independent attachment implant-supported overdenture (IOD), a minimum of 9 mm of space is required (i.e., Locator Attachment). If a bar-retained prosthesis is to be fabricated, a minimum of 12 to 14 mm of space is needed, depending on the attachment system.[6] To prevent fracture of the denture base or attachments, 2 to 3 mm is needed to provide adequate strength as a denture base material (Fig. 25.4) and prevent denture teeth dislodgement.[7]

Literature Review

In general, studies have shown the maxillary overdenture and maxillary fixed prosthesis to be less predictable and associated with a higher morbidity and failure rate in comparison with the mandibular arch prostheses. Jemt[8] evaluated maxillary fixed prostheses with 449 implants for a 5-year period and found a cumulative implant and prosthesis survival rate to be 92.1% and 95.9% for 5 years, respectively. The mean marginal bone loss was approximately 1.2 mm at the 5-year evaluation. In this study, speech problems were the most common patient complaints, followed by resin prosthesis fractures as the most common prosthetic complication.

Maxillary overdentures have been reported to have the highest failure rate in comparison with any other type of prosthesis. When evaluating maxillary overdenture success, Hutton et al.[9] showed a nine-times
• **Fig. 25.4** **Maxillary Crown Height Space.** Measured from the residual ridge to the incisal edge, the minimum space requirement is 8 to 10 mm for a fixed prosthesis, 9 mm for an independent attachment overdenture, and 12-14 mm for a bar-retained prosthesis.

greater failure in the maxilla compared with the mandible. Numerous studies have shown implant failure rates of 2% to 5% before loading, and up to 30% after loading.[10-13] For late failure, maxillary overdenture studies have shown failure rates up to 5% to 15%.[14-17]

Wilbom et al. evaluated maxillary fixed versus overdenture prostheses for a 5-year period. Interestingly, the survival rate was 77% in the overdenture group and 46% in the group originally treatment planned for a fixed prosthesis; however, it was then changed to an overdenture. With this study a very high failure rate was seen, especially with patients in whom the prosthesis was changed from a fixed to a removable prosthesis.[18]

Maxillary dentures have also been associated with various inherent disadvantages in comparison with a fixed prosthesis. Most of the issues stem from the increased palatal coverage that a conventional denture or RP-5 overdenture in comparison to a RP-4 overdenture. Shannon et al.[19] showed compromised parotid flow when palatal coverage was present, thereby decreasing salivary flow when wearing an RP-5 overdenture. Patients often report a lack of taste sensation when wearing a maxillary overdenture with palatal coverage. This has been shown with multiple studies.[20,21]

In addition, longitudinal studies on implant-supported maxillary overdentures have shown an increased frequency rate of maxillary hyperplasia of up to 30%.[22] In retrospective follow-up studies, hyperplasia was observed in more than 64% of the subjects originally planned for a fixed maxillary prosthesis but who had an overdenture treatment because of implant failure.[23] Most commonly, hyperplastic tissue is seen around the retaining bars.

Fixed Maxillary Treatment Plans

A review of the literature found many articles that indicate that full maxillary fixed implant–supported prostheses are fabricated on an average of six standard-diameter implants with posterior molar cantilevers. More recently, numerous articles have shown the success of a fixed prosthesis on four implants. However, the edentulous maxilla has been shown to have the lowest implant survival for either fixed or removable implant restorations, compared with mandibular prostheses.[24-27] All reports concur with the finding that maxillary bone tends to be of poorer quality and volume, and presents several biomechanical disadvantages. To compensate for the poor local conditions, a greater number of implants should be planned, along with a greater anteroposterior (A-P) distance. Therefore a number of core principles are used when treatment planning an edentulous maxillary arch for a fixed prosthesis; following these principles increases the success rate.

1. The number of implants is related to the dental arch form.
2. The arch form is dictated by the final dentition or prosthesis, not the edentulous ridge arch form.
3. Key implant positions exist: anterior, canine, premolar, and molar.
4. An RP-4 (totally implant supported removable prosthesis) prosthesis is treatment planned the same as a fixed prosthesis.

Three common dental arch forms for the maxilla exist: square, ovoid, and tapering. As a consequence of bone resorption the edentulous ridge arch form usually will differ from the dentate arch form. The dental arch form of the patient is determined by the final teeth position in the premaxilla and not the arch shape of the residual ridge. A residual ridge may appear square because of resorption or trauma. However, the final teeth position may need to be cantilevered facially with the final prosthesis. In other words, a dental ovoid arch form may be needed to restore a residual edentulous square arch form. The number and position of implants are related to the arch form of the final dentition (prosthesis), not the existing edentulous arch form (Table 25.1).

TABLE 25.1	Treatment Plan for Edentulous Premaxilla		
Arch Form	Anterior Cantilever (mm)	Number of Anterior Implants	Implant Position
Square	< 8	2	Canines
Ovoid	8–12	3	Two canines and one incisor
Tapering	>12	4	Two canines and two incisors

• **Fig. 25.6** Fixed Treatment Plan 1: When force factors are low, a square dentate arch form may use six implants for a fixed or RP-4 (totally implant supported removable prosthesis) prosthesis. *A-P*, Anteroposterior distance.

• **Fig. 25.5** Dental Arch Form Determination: Two horizontal lines are drawn. The first line bisects the incisal papilla and connects the tips of the canines. The second line is parallel and along the facial position of the central incisor. The distance between these lines determines whether the dentate arch form is square, ovoid, or tapering.

• **Fig. 25.7** Maxillary FP-3 (type 3 fixed prosthesis) Prosthesis. This prosthesis follows a square dentate arch form, and therefore is supported by six implants (canines, second premolars, and first molars). Because of the square arch form a minimal cantilever results.

lesser requirement of an implant in the central or lateral position. When maxillary fixed prosthesis treatment option 1 is used, mandibular excursions and occlusal forces exert less stress on the canine implants. As a result, implants in the canine position to replace the six anterior teeth may suffice when the force factors are low and if they are splinted to additional posterior implants (Figs. 25.6 and 25.7).

Maxillary Fixed Prosthesis Treatment Option 2

If the final teeth position is an ovoid arch form, at least three implants should be inserted into the premaxilla: one in each canine and preferably one in a central incisor position (Fig. 25.8). The central incisor position increases the A-P distance from the canine to central and provides improved biomechanical support to the prosthesis. In long-term edentulous maxillae with significant atrophy, treatment option 2 will most likely require bone augmentation before implant insertion (Box 25.2). When patient force factors are low to moderate, the anterior implant may be positioned in a lateral incisor site if the central site in nonideal. The three implant positions in the premaxilla will resist the additional forces created in this arch form, enhance prosthesis retention, and reduce the risk for abutment screw loosening.

The suggested locations for this treatment option are at least one central (or lateral) incisor position, bilateral canine positions,

The dental arch form in the anterior maxilla is determined by the distance from two horizontal lines. The first line is drawn from one canine (i.e., in a diagnostic wax-up or existing prosthesis if no teeth are present) incisal edge tip to the other. This line most often bisects the incisive papilla. The second line is drawn parallel to the first line, along the facial position of the anterior teeth (Fig. 25.5). When the distance between these two lines is less than 8 mm, a square dental arch form is present. When the distance between these two lines is 8 to 12 mm, an ovoid dentate arch form is present—the most commonly observed. When the distance between the two lines is greater than 12 mm, the dentate arch form is tapering.

Therefore with respect to dental arch form, the authors have postulated four different options for the maxillary fixed prosthesis.

Maxillary Fixed Prosthesis Treatment Option 1 (Box 25.1)

In a dental square arch form, lateral and central incisors are minimally cantilevered facially from the canine position, resulting in a

• **Fig. 25.8** Fixed Treatment Plan 2: In an ovoid dentate arch form, three implants should be planned in the premaxilla: one in each canine position and one additional implant. In addition, at least four posterior implants should be splinted to form an arch. *A-P*, Anteroposterior distance.

• **Fig. 25.9** Fixed Treatment Plan 3: In a tapered arch form the anterior cantilever is greater and should be supported by implants in the premaxilla. At least four posterior implants should be added to restore the completely edentulous arch. *A-P*, Anteroposterior distance.

    First molar

---

bilateral second premolar sites, and the bilateral distal half of the maxillary first molar sites. The seven implants should be splinted together to function as an arch. These implant positions create sufficient space between each implant to allow for greater implant diameters (i.e., when required for force or bone density factors). Implants should ideally be at least 3 mm apart after placement.

Maxillary Fixed Prosthesis Treatment Option 3

The prosthesis treatment planned in a tapered dental arch form places the greatest forces on the anterior implants, especially during mandibular excursions when the residual bone is an ovoid or square ridge form. The anterior teeth create a significant facial cantilever from the canine position, and anterior biting forces often lead to a shear type of forces. As such, four implants should be considered to replace the six anterior teeth (Figs. 25.9 and 25.10).

The bilateral canine and central incisor positions represent the best option. These positions are preferred when other force factors are greater, such as crown height, parafunction, and masticatory muscular dynamics. The worst-case scenario is a patient who requires restoration of a dental tapered arch form with a square residual ridge form. Not only are four implants then ideally required to compensate for the cantilevered tooth position, but these implants should be connected to additional posterior implants, which can extend to the second molar sites. Therefore in treatment plan 3, when force factors are moderate or the dental arch form is tapered, the minimum implant number should increase to eight implants (Box 25.3). When force factors are greater than usual or bone density is poorer, additional implants may be used in any of the arch forms. In the square and ovoid arch form, at least one additional implant is positioned in the premaxilla. For patients with higher force factors

or poor bone density, two additional implants are planned in the distal half of the second molar position to improve the arch form. This will result in an increased A-P distance compared with the first molar site, which will compensate for the increased force factors or poor bone density (Fig. 25.11). The implant number and position guidelines also may counter the effect of an incisal cantilever off the residual anterior bone for an esthetic tooth position and is indicated for patients with chronic parafunction (such as bruxism).

The disadvantage of second-molar implants for an ideal treatment plan is the additional cost of the second molar implant, possible bone grafting, and the prosthesis. In addition, many patients do not have an existing second molar in the mandibular arch. However, the reason for this implant position is for force transfer, not necessarily esthetics or functional purposes.

Primary site

Secondary site
• **Fig. 25.11** The ideal seven-implant positioning for a maxillary edentulous arch includes at least one central incisor position, bilateral canine positions, bilateral second premolar sites, and bilateral sites in the distal half of the first molars. In case of heavy stress factors, an additional anterior implant and bilateral second molar positions (to increase the anteroposterior distance) may be of benefit.

Maxillary Fixed Treatment Option 4: All-on-Four

In implant dentistry today a shift in treatment options has become popular to minimize treatment time, treatment costs, and decrease patient morbidity. The all-on-four treatment concept has been reported by Maló et al.[28] in many reports in an attempt to address these objectives in implant dentistry today. In general the all-on-four technique includes placing four implants in the maxillary arch, with two axially placed implants in the anterior and two posterior implants positioned angulated at 30 to 45 degrees.[28] Even though the placement of four implants is far less than what has been accepted for years (i.e., usually six to eight implants required for a fixed prosthesis in the maxilla) in implant dentistry, high success rates of 93% to 98% have been shown[29-32] (Box 25.4).

Maló et al.[28] state that the all-on-four technique in the maxilla uses a more favorable bone density in the anterior, along with longer implants in the posterior that are angulated, which increases the A-P spread. Zampelis et al.[33] concluded in a finite element analysis model that the tilted posterior implants have a biomechanical advantage in comparison with cantilevering axial placed implants. The all-on-four technique is most commonly used for immediate load situations (see Chapter 33).

In conclusion, the all-on-four technique has shown very promising results in the literature. However, careful patient selection, along with an experienced surgical and prosthetic clinician with an increased skill set, is essential for successful treatment results. Because of the pneumatization of the maxillary sinuses and the requirement of bone grafting in many cases,

the all-on-four technique allows for the avoidance of the sinus anatomy by tilting the implants, which ultimately increases the A-P spread (Fig. 25.12).

Removable Maxillary Treatment Plans

The primary advantage of a maxillary Implant Overdenture (IOD) compared with a fixed prosthesis is the ability to provide a flange for maxillary lip support and the reduced fee compared with a fixed restoration. As a consequence, before the selection of a specific prosthesis type and to facilitate the diagnosis, the labial flange above the maxillary teeth of the existing denture (or wax try-in of a new prosthesis) may be removed and the facial appearance of the maxillary lip without labial support assessed.

Maxillary IOD complications, such as attachment wear and prosthesis or component fracture, are more frequent than with a fixed restoration and primarily occur as a result of inadequate bulk of acrylic and minimal strength of the framework, compared with a fixed restoration (Table 25.2).

Fewer reports have been published for maxillary IOD compared with the mandible. Most of these reports discuss RP-5 restorations with posterior soft tissue support and anterior implant retention. According to Goodacre et al.,[34] the restoration with the highest implant failure rate is a maxillary overdenture (19% failure rate). In 1994 Palmqvist et al.[35] reported similar poor results in a 5-year prospective, multicenter study on 30 maxillae and 103 mandibles. Jemt and Lekholm[36] reported that the survival rate of mandibular implants was 94.5% versus 100% for mandibular prostheses. In the maxillae the implant survival rate was 72.4%, and the prosthesis survival rate was 77.9%. The authors suggested that the treatment outcome may be predicted by bone volume and quantity. A prospective study by Johns et al.[11] reported on maxillary IODs at 1, 3, and 5 years.[9,37] Sixteen patients were followed throughout the whole study with a cumulative success rate of 78% for prostheses and 72% for implants. A pooled implant survival rate of maxillary removable designs was reported at 76.6% at 5 years.[11,37-39]

Alternatively, Misch followed 75 maxillary IODs (RP-4) and 615 implants for 10 years with 97% implant survival rate and 100% prosthesis survival rate.[40] The primary differences in these treatment modalities have been a completely implant-supported, retained, and stabilized maxillary IOD (RP-4); a greater implant number; and key implant positions following the guidelines of treatment planning based on basic biomechanical concepts to reduce failure and decrease risks.

Maxillary Removable Implant Overdenture Treatment Options

Only two treatment options are available for maxillary IODs, whereas five treatment options are available for the mandibular IOD. The difference is due primarily to the biomechanical disadvantages of the maxilla compared with the mandible. As such, the two treatment options are limited to an RP-5 with four to six implants with soft tissue support, or an RP-4 restoration with six to eight implants (which is completely supported, retained, and stabilized by implants). The crown height space is critical for maxillary overdentures, and more often a lack of space may compromise tooth position compared with the mandibular situation. The maxillary anterior crown height space requirement is greater than the posterior dimension. A minimum of 14 mm of anterior crown height space and 12-14 mm of posterior space is required for IOD (i.e., bar-retained) because of the greater anterior teeth coronal dimensions and specific locations (Fig. 25.13).

• **Fig. 25.12** All-on-Four Protocol. (A and B) Two implants placed axially in the anterior and two implants placed posterior, which are angulated less than 45 degrees to avoid the maxillary sinus.

Option 1: Removable Maxillary RP-4 Implant Overdenture

The first option for a maxillary IOD is an RP-4 prosthesis with six to eight implants, which is rigid during function (i.e., primary support is by implants, no soft tissue support) (Box 25.5). This option is the preferred IOD design because it maintains greater bone volume and provides improved retention and confidence to the patient compared with a denture or RP-5 prosthesis. Because the palate is removed from this prosthesis (i.e., horseshoe-shaped),

soft tissue support is lost, thereby requiring increased number of implants. The cost of treatment is similar to a fixed prosthesis because of the increased number of implants required.

Unfortunately, many clinicians believe that the RP-4 overdenture requires fewer implants and less attention to the biomechanics of occlusal load, just because the prosthesis is removable. In the author's opinion, this is a primary reason for such a high implant failure rate in maxillary IODs. Combined factors such as reduced cost, patient fear of bone grafting, and lack of advanced training of the doctor are often the determining factors motivating the choice for a maxillary IOD.

Treatment planning for RP-4 maxillary overdentures is similar to a fixed prosthesis, because the IOD is fixed during function. Two of the key implant positions for the RP-4 maxillary IOD are in the bilateral canines and distal half of the first molar positions. These implant positions usually require sinus augmentation in the molar position. Additional posterior implants are located bilaterally in the premolar position, preferably the second premolar site. In addition, at least one anterior implant between the canines often is required. Six implants is the minimum number for an RP-4 treatment option. When force factors are greater, the next most important sites are the second molar positions (bilaterally) to increase the A-P spread and improve the biomechanics of the system. The occlusal scheme for the RP-4 prosthesis is similar to a fixed prosthesis: mutually protected occlusion (unless opposing a mandibular complete denture) (Fig. 25.14).

Option 2: Removable Maxillary RP-5 Implant Overdenture

The second treatment option for the maxillary arch is the RP-5 prosthesis (Box 25.6). A maxillary conventional complete denture usually has good retention, support, and stability. Although an RP-5 maxillary IOD is superior to a complete denture, many patients do not see much of a difference. The major advantages of an RP-5 maxillary IOD are the maintenance of the anterior bone and it being a less expensive treatment option in comparison with an RP-4 or fixed prosthesis. The treatment is far less expensive because bilateral sinus grafts are not required and molar implants are not indicated. Therefore this treatment plan is often used as a transition to an RP-4 or FP-3 prosthesis when financial considerations of the patient require a staged treatment over several years.
• **Fig. 25.13** Maxillary Overdentures. (A) RP-5: full palatal coverage for which the soft tissue provides primary support and the implants are for secondary support. (B) RP-4: horseshoe-shaped prosthesis that receives its primary support from the implants and no support from the soft tissue. Note the lack of palatal support (primary stress bearing area).

• **BOX 25.5** **Removable Maxillary Prosthesis Treatment Plan 1 (RP-4)**

Indications:
• Patients who cannot tolerate full palatal coverage
• Gag reflex
• Patients who require prosthesis with no movement
Prosthesis design: bar-supported horseshoe shape prosthesis

Advantages
• Less palatal coverage (horseshoe shape)
• Increased speech, taste
• No soft tissue support, completely implant supported
• Hygiene easier than fixed

Disadvantages
• Palate removed: lack of acrylic bulk > fracture
• Cost: more implants
• Posterior bone needed: sinus grafts

Positions (Based on Dental Arch Form)
• **Square:** 6 implants: bilateral canine, bicuspids, and first molar
• **Ovoid:** 7 implants: bilateral canines, bicuspids, and first molars
• **Tapering:** 8 implants: bilateral canines, bicuspids, first molars, and incisor

---

The first treatment option for a completely edentulous maxilla uses four to six implants supporting an RP-5 prosthesis, of which at least three are positioned in the premaxilla. Based on the poor success rates reported in the literature, specific biomechanical requirements, and poor bone quality, the fewest number of implants for an RP-5 maxillary overdenture should be four, with a wide A-P spread. The key implants are positioned in the bilateral canine regions and at least one central or lateral incisor position. In some cases, implant placement in the central incisor region may reduce the amount of available space for the prosthesis. Additional secondary implants may be placed in the first or second premolar region. In such cases, because of the reduced A-P spread and the lateral incisor in the anterior-most implant site, the second premolar position also should be used on the contralateral side (along with the canine) to improve the A-P spread. Six implants are often indicated for an RP-5 prosthesis when force factors are greater.

The maxillary RP-5 IOD is designed exactly as a complete denture with fully extended palate and flanges. When Locators or O-rings attachments are used to retain the prosthesis, they may be positioned more distal than a Hader clip, often immediately distal to the canine position. The prosthesis should be allowed to move slightly in the incisal region during function so that the restoration may rotate toward the posterior soft tissue around a fulcrum located in the canine or premolar position. The benefits of an RP-5 maxillary overdenture primary support from the soft tissue and secondary support from the implants. In addition, the benefit of premaxillary bone maintenance is seen because prosthesis of the implant stimulation (Figs. 25.15 and 25.16).

Summary

Maxillary IODs may be as predictable as mandibular overdentures when biomechanical considerations specific to the maxilla are incorporated in the treatment plan. In general this requires implants in greater numbers and a greater awareness of prosthetic principles.

Only two maxillary IOD treatment options are available. The fewest number of implants for this restoration is four to six implants to support an RP-5 prosthesis. A rigid IOD (RP-4) most often requires the placement of seven or more implants. In other words, maxillary IODs are completely different from their mandibular counterpart. In the completely edentulous maxilla, an IOD is often the treatment of choice. Unlike in the mandible, the maxillary lip often requires additional support as a consequence of bone loss. An ideal high lip line exposes the interdental papillae between the anterior teeth. Using overdentures to replace the hard and soft tissue is easier than attempting to do this with bone and soft tissue or zirconia prostheses.

A completely implant supported IOD (RP-4) requires the same number and position of implants as a fixed restoration. Thus sinus grafts and anterior implants usually are indicated, regardless of whether the prosthesis is fixed or removable. A common complication arises when four to six implants are placed, and an RP-4 palateless IOD is fabricated. Without the primary stress bearing area palatal support, the implants are often subjected to increased force factors, thus increasing complications and morbidity.
• **Fig. 25.14** RP-4 Overdenture Treatment Options. (A) Square arch—six implants. (B) Ovoid—seven implants. (C) Tapered—eight implants. An RP-4 is treatment planned similar to a maxillary fixed prosthesis.

Indications:
- Shorter treatment time required
- Contraindication to bone grafting

Prosthesis design: attachments only—complete palatal coverage (primary support from the soft tissue)

Advantages
- Increased retention and stability in comparison to a denture
- Maintain premaxilla bone
- Reduced fee (~RP-4)

Disadvantages
- Requires full palate (~soft tissue primary support)
- Must have adequate bone in anterior and bicuspid area
- Need adequate crown height space

Positions (Based on Dental Arch Form)
- **Square:** 4 implants: bilateral canine, bicuspids and/or incisor
- **Ovoid:** 5 implants: bilateral canine, bilateral bicuspid, and incisor
- **Tapering:** 6 implants: bilateral canines, incisors, and bicuspids
• **Fig. 25.15** RP-5 Treatment Options. (A) Four implants in canine and first premolar positions. (B) Five implants in canine, first premolars, and in the central/lateral incisor position. (C) Five implants in canines, one in premolar, and central/lateral incisors positions. Caution should be exercised to not remove palatal coverage from an RP-5 prosthesis.
• **Fig. 25.16** Central Incisor Implant Placement. (A) In tapered arch forms, placement of an implant in the central incisor region may impinge on the prosthesis. (B) Implant positioning that results in inadequate space for a prosthesis. Therefore, implants may be required to be positioned in the central-lateral or lateral position to allow for increased prosthetic room.

Implant Surgery

26

Basic Surgical Techniques and Armamentarium

CHRISTOPHER R. RESNIK AND RANDOLPH R. RESNIK

Basic dental surgical methods were practiced in the early Roman times when diseased gingival tissues were excised with instruments and no local anesthetic. Today, many of the principles of modern-day surgical procedures are based on the teachings of William Stewart Halsted, MD, the "Father of Modern-Day Surgery." Halsted, an American surgeon and cofounder of Johns Hopkins Hospital, developed surgical principles in the late 19th century that are still universally used today. He emphasized a strict aseptic technique and tissue-handling principles to obtain predictable soft tissue surgical success rates. He determined that the gentle handling of lacerated tissues would aid healing by causing less damage to the blood and nerve supply in the operative field. With his work, the "Tenets of Halsted" resulted that have helped to guide the principles of surgery in all medical disciplines[1] (Box 26.1).

Dental implant surgery encompasses a broad range of procedures involving the hard and soft tissues of the oral cavity. The procedures vary from simple exodontia to technically challenging full-mouth, bone augmentation and implant procedures. The implant clinician must have a strong foundation for basic surgical principles so that potential complications are avoided. For most implant procedures, specific instruments and armamentarium, as well as protocols, have been developed to facilitate the procedures. With these basic principles in mind, surgical protocols and biologic principles have been developed in the field of oral implantology. Over the years the surgical management of the dental implant patient has led to a more evidence-based practice and the introduction of improved techniques and instrumentation. Therefore this chapter will emphasize basic surgical principles that should ideally be used during implant-related procedures. In addition, a comprehensive review of the surgical armamentarium will be discussed.

Flap Design

Surgical flaps are made to gain access to a surgical area or to relocate tissue from one area to another. Over the years the mucogingival flap design used in oral implantology has changed dramatically. The use of technology has allowed for more accurate and ideal placement of implants and bone grafts, along with better techniques for handling tissue and preserving blood supply. In the early years of oral implantology, most surgeries were completed with an aggressive full reflection of the surgical area including full releasing incisions

that traumatized the tissue and compromised the blood supply. Following the original Brånemark protocol, implants were buried below the tissue and left to integrate for 4 to 6 months before a second surgery to uncover and place a healing abutment (stage 2 technique). In the 1990s a more conservative, one-stage surgery technique became popular that involved placement of a healing abutment at the time of implant placement. This procedure showed remarkable results, with decreased morbidity. Then in the 2000s immediate implant placement became popular, and advancements in guided surgery allowed the advent of "flapless" surgery, which resulted in much less trauma. With advanced technology, clinicians are now able to 3D print surgical guides in their office that are based on cone beam computed tomographic imaging for ideal implant placement and accurate anatomy, which has led to more accuracy with flapless techniques. However, flapless surgery is not indicated in all cases and certainly may lead to higher morbidity. Therefore it is imperative that the implant surgeon understand the basic principles of flap design.

The type of flap used in surgery varies dramatically, with much of the design criteria based on the purpose and anatomic area of the surgical site. Flap designs may be classified by the type of tissue (full versus partial thickness) and the number and type of incisions used to create them (envelope, papilla sparing, triangular, trapezoidal, vestibular, etc.).

When developing the ideal flap design, a few basic principles pertain to all flaps used in implant dentistry.

Maintain Blood Supply

The primary goal of any flap design is to retain and maximize the native blood supply to continuously nourish the

5. The obliteration of dead space in the wound
6. The avoidance of tension
7. The importance of trauma to the surgical site postoperatively
• **Fig. 26.1** Ideal flap design with broad base incision that preserves the blood supply. Note how the width of the incision base is much greater than the ridge.

• **Fig. 26.2** Flap design provides sufficient access to visualize the entire surgical field. Too small of a flap will lead to stretching of the tissue and an increase in inflammation.

• **Fig. 26.3** Full-thickness reflection with 2–4 Molt instrument.

surrounding tissue and bone.[2] If the blood supply is disrupted to the wound margin, in theory the health of the tissue may be compromised, which may lead to poor wound healing. It has been shown that three essential factors are required to maintain and regenerate soft tissue quality with implant-related procedures: (1) preservation of the blood supply to the adjacent papilla, (2) preservation of the bone on the adjacent teeth, and (3) minimal scar tissue formation during surgery.[3] When soft tissue becomes rigid and nonflexible as a result of traumatic surgical manipulation or previous surgical interventions, it may not allow for ideal adaptation or flexibility around the dental implant or prosthesis.[4]

Most importantly in the esthetic zone, it is imperative to maintain the papilla. The vascularity of the papilla tissue is supplied by various vascular anastomoses that cross the alveolar ridge. If repeated incisions and trauma to the vascular supply occur, scar tissue formation will result as fibroblasts become prematurely activated to form excess fibrotic tissue. This type of tissue is usually difficult to manipulate and may lead to recession and esthetic complications. An exaggerated level of erythema, edema, and discomfort may be indicative of compromised blood supply.[5]

The base of the flap is important in maintaining the blood supply. Ideally the flap should always be broader than the free margin (i.e., ridge area) to preserve the blood supply. All areas of the flap must have a source of uninterrupted vasculature to prevent ischemic necrosis of the flap.[6] Ideally flaps should have sides that converge, moving from the base to the apex (ridge). The length of the flap should generally not exceed twice the width of the base. The base of the flap should not have significant pressure or be excessively stretched or twisted, which may compromise the blood supply (Fig. 26.1).

Flap Design to Provide Access

The flap design must provide sufficient access to provide necessary visualization of the entire surgical area. Adequate access must also exist for the insertion of instruments required to perform the surgery and to reflect the tissue to maintain access. The flap must be held out of the operative field by a retractor that ideally would rest on intact bone without tension. Excess tension most likely will result in tissue trauma and an increase in swelling.[7] If increased edema is present, the patient may experience greater discomfort, and there is a greater possibility of incision line opening or compromised wound healing (Fig. 26.2).
Full-Thickness Reflection

The flap should be a full-thickness mucoperiosteal flap that will include the surface mucosa, submucosa, and periosteum. Because implant surgery usually requires access to the underlying alveolar bone, all tissue must be sufficiently reflected. In addition, full-thickness flaps are ideal because the periosteum is the primary tissue responsible for the bone healing process, and replacement of the periosteum in its original position hastens that healing process. In addition, torn, split, and macerated tissue heals much slower than a cleanly reflected full-thickness flap, thereby delaying the healing process.[8]

A sharp scalpel should be used to score the bone to obtain a full-thickness reflection, thus ensuring complete penetration through the tissue layers. When reflecting the tissue, the underlying bone should be "scraped," thus minimizing the possibility of a partial-thickness flap. Care must be taken when reflecting the tissue to separate the tissue away from the bone. When using a periosteal elevator (e.g., 2–4 Molt), the tip edge should always rest on the bone to prevent tearing through of the tissue flap (Fig. 26.3).

Minimize Trauma to Tissue

Meticulous handling is required to minimize trauma to the soft tissue. Proper use of appropriate tissue forceps, avoidance of excessive suctioning by the assistant, and "tieback" sutures all contribute to improved flap management. Nonlocking tissue pickups (e.g., Adson forceps) are commonly used to hold soft tissues in place when retracting tissue or during the suturing process. Various designs of tissue forceps exist, most commonly having smooth tips, cross-hatched tips, or serrated teeth (often called *mouse's teeth*). Serrated teeth forceps used on tissues will result in more tissue damage because they may tear the tissue, whereas smooth surface forceps tend to be much gentler to the tissue.

• **Fig. 26.4** Tissue retractors should ideally be positioned on bone to provide ideal access to the surgical field and minimize trauma to the tissue and vital structures.
• **Fig. 26.5** Vertical release incisions are required to provide access to the surgical field and prevent excess pressure on tissue flaps. The correct release incision is on the left which maintains the blood supply. The incorrect flap design is illustrated on the right as the blood supply is cut off because of the location of the release incision.

Tissue retractors should be selected and placed in a position to prevent undue pressure on the flap. Maintaining the retractors on bone and not on the tissue will minimize trauma to the tissue. Excessive pressure and tension on the tissue flap will impair blood circulation, alter the physiologic healing of the surgical wound, and predispose the wound to bacterial colonization, which may lead to incision line opening (Fig. 26.4).[9]

Vertical Release Incisions

Vertical release incisions may be used to maintain the blood supply and decrease the tension to the flap. Usually the primary blood supply is to the facial flap, which is from the unkeratinized mobile mucosa. Vertical release incisions are often made to the height of the mucogingival junction, and flared 45 degrees to allow for spreading of the tissue and maintenance of the blood supply.[10] Vertical release incisions should not be made over bony prominences (e.g., canine eminence) because this will increase tension on the incision line and may increase the possibility of incision line opening. In addition, it is often difficult to suture over these areas because the tissue tends to be very thin (Fig. 26.5).

Maintain Flap Margins Over Bone

The soft tissue flap design should also have the margins of the wound over host bone whenever possible. This is especially important when approximating tissue over bone grafts or barrier membranes. The host bone provides growth factors to the margins and allows the periosteum to regenerate faster to the site.[11] The margins distal to the elevated flap should exhibit minimal reflection. The palatal flap and the facial tissues distal to the reflected flap usually are not elevated from the palatal bone (i.e., unless augmentation is required) because the blood supply to the incision line
• **Fig. 26.6** Flap with excess tension increases possibility of incision line opening.

will be compromised. In some cases the soft tissue reflection distal to the surgery site may be split thickness to maintain periosteum on the bone around the incision line. This will improve the early vascularization to the incision line and adhesion of the margins to reduce retraction during initial healing.

Prevent Desiccation of Tissue

The tissues should be maintained in a moist environment without prolonged periods of desiccation.[12] If excessive drying of the tissues occurs, there is less likelihood that complete wound closure will occur. If the tissue margins become desiccated, periodic irrigations with sterile saline (0.9% sodium chloride) or saline-moistened gauze may be used.

Flap Mobility

The passivity of the flap is paramount for the successful wound healing of the soft tissues. When sutures are positioned too tight to overcome the residual tension of the flap, they may alter the blood supply, thereby reducing the vessel patency and impairing vascularization.[13] Excessive flap tension is the most frequent causative factor leading to incision line opening.[14] This is best prevented by appropriate incision and flap design, the use of periosteal releasing incisions (PRIs), and blunt dissection ("tissue stretching").

Past techniques to expand tissue primarily used a more apical tissue reflection and horizontal scoring of the periosteum parallel to the primary incision. Historically the vestibular approach by Brånemark allowed for optimal visualization of anatomic landmarks, suturing remote from the surgical area, complete tissue coverage, as well as predictable primary closure and healing.[15] The postoperative disadvantages of this approach include distortion of the vestibule and other anatomic landmarks, edema, difficult suture removal, and cumulative patient discomfort.[16]

Langer and Langer[17] documented the use of overlapping partial-thickness flaps. This approach results in extension of the coronal aspect of the buccal or palatal flap, allowing primary intention closure around the site in an overlapping manner. This is usually effective for primary closure when less than 5-mm advancement of the flap is necessary (Fig. 26.6).

A submucosal space technique developed by Misch[18] in the early 1980s is an effective method to expand tissue over

larger grafts (greater than 15 Å ~10 mm in height and width) (Box 26.2).

The utility of periosteal incision for gaining flap release was studied by Park.[19] He found flaps could be advanced up to 171.3% (more than 1½ longer than its original length) by two vertical incisions and a PRI under a minimal tension of 5 g, whereas one or two vertical incisions without PRI could advance the flap only 113.4% and 124.2%, respectively. These results suggested that PRI can be predictably used to attain tension-free primary closure under a minimal pulling tension of flaps (Fig. 26.7). A sharp scalpel blade at a 45 degree angle or Metzenbamm scissors are used to score the periosteum to create greater flap extension. This will allow tension-free primary closure.

• BOX 26.2 Submucosal Space Technique

Procedure

1. A full-thickness facial flap first is elevated off the facial bone approximately 5 mm above the height of the vestibule.
2. One incision with a scalpel, 1 to 2 mm deep, is made through the periosteum, parallel to the crestal incision and 3 to 5 mm above the vestibular height of the mucoperiosteum. This shallow incision is made the full length of the facial flap and may even extend above and beyond the vertical release incisions. Care is taken to make this incision above the mucogingival junction; otherwise the flap may be perforated and delay soft tissue healing.
3. Soft tissue scissors (e.g., Metzenbaum) are used in a blunt dissection technique to create a tunnel apical to the vestibule and above the unreflected periosteum. The scissors are closed and pushed through the initial scalpel incision approximately 10 mm deep, then opened slowly.
4. This submucosal space is parallel to the surface mucosa (not deep toward the overlying bone) and above the unreflected periosteum. The thickness of the facial flap should be 3 to 5 mm because the scissors are parallel to the surface. This tunnel is expanded with the tissue scissors several millimeters above and distal to the vertical relief incisions.
5. The submucosal space is developed and the flap is advanced the distance of the "tunnel" and draped over the graft to approximate the tissue for primary closure without tension. Ideally the facial flap should be able to advance over the graft and past the lingual flap margin by more than 5 mm. The facial flap may then be returned to the lingual flap margin and sutured. This soft tissue procedure is performed before preparing the host region for any type of bone grafting or augmentation around an implant.

Types of Flaps

Flapless

Flapless implant surgery has become popular because of the associated decreased pain and morbidity. In the flapless technique a tissue punch is used to remove the gingival tissue over the osteotomy site. Mainly this technique has been advocated because of the preservation of the blood flow to the papilla and decreased postoperative pain. Oliver[20] has shown that flapless surgery is advantageous for preserving the crestal bone and is reduced when the gingival tissue is thick (>3 mm).[21] However, when performing flapless surgery, adequate bone quantity must be present, along with sufficient keratinized tissue. The associated disadvantage of this technique is the inability to visualize the underlying bone. Cone beam computed tomographic imaging and guided surgery have made flapless surgery more predictable; however, inherent errors still exist. In most flapless surgery cases a tissue punch is used to expose the bone. The gingival tissue will be removed in the area of the osteotomy. Care should be exercised in using a tissue punch when an inadequate amount of keratinized tissue is present. Flapless surgery has been shown to result in overheating the bone because it is often difficult to irrigate the osteotomy adequately when a flap is not raised (Fig. 26.8 and Box 26.3).[22]

Papilla Sparing

The interproximal soft tissue in sites next to adjacent natural teeth may be classified into three categories: (1) papillae have an acceptable height in the edentulous site, (2) papillae have less than acceptable height, or (3) one papilla is acceptable and the other papilla is depressed and requires elevation.[23] When the interproximal papilla has an acceptable height, "papilla-saving" incisions are made adjacent to each neighboring tooth. The vertical incisions are made on the facial aspect of the edentulous site and begin 1 mm below the mucogingival junction, within the keratinized tissue. Extending the vertical incisions beyond the mucogingival junction increases the risk for scar formation at the incision site. The full-thickness incision then approaches the crest of the edentulous site, leaving 1.0 to 1.5 mm of the interproximal papilla adjacent to each tooth. This maintains the blood supply to the papillae and will help to preserve the papillae after healing. The goal is for the facial flap to be advanced over the implant or in approximation to a permucosal extension at the conclusion of the procedure, with no voids at the
● **Fig. 26.7** Tissue tension reduction: (A, B) Severing periosteal fibers with a 15 blade parallel; to the flap.

Advantages
- Less invasive
- Maintains tissue vasculature
- No vertical incisions
- Less patient discomfort

Disadvantages
- Limited visibility
- Overheating bone
- Limited access to evaluate bone
- Malpositioning is more common (unless guided)

---

incision line and primary closure (Fig. 26.9). Bilateral buccal vertical releasing incisions should extend obliquely at an angle and connect to the horizontal incision. This flap is indicated in the esthetic zone, areas where you need to increase the amount of keratinized gingiva on the buccal, or in patients with a thin gingival biotype (Box 26.4).

Envelope

An envelope flap is designed with a midcrestal incision over the implant site, followed by sulcular incisions on the buccal and palatal that extend at least one tooth to the mesial and distal. A full-thickness flap is reflected using blunt dissection. One of the benefits of this flap is that scarring from vertical incisions will be avoided. On reflection, if more access is required for osseous defects or implant placement complications, a vertical releasing incision may be added to create a triangular or trapezoidal flap. The envelope flap is contraindicated in cases where extensive bone grafting is required because of the limited access and the increased risk for tension on closure (Fig. 26.10 and Box 26.5).

Triangular and Trapezoidal

The triangular and trapezoidal incisions are more aggressive incisions that are initiated over the implant site and sulcular incisions that continue horizontally to at least one adjacent tooth. Both the triangular and trapezoidal incisions involve
• **Fig. 26.9** Papilla-Sparing Incision. (A) Incision maintaining 1 mm of papilla tissue. (B) Reflected flap maintaining papilla tissue intact.

• **BOX 26.4**   **Papilla-Sparing Surgery**

Advantages
- No disruption of the papillae
- Less morbidity
- Minimal disruption of vasculature

Disadvantages
- No access to additional sites
- Need additional skill set
- Minimal reflected space for implant placement
- Difficulty in bone grafting
- Possible scarring in nonkeratinized tissue

• **Fig. 26.10** Envelope Flap. Minimal flap that maintains blood supply.

- Easy to modify

Disadvantages
- Limited access
- Moderate disruption of vasculature
- Increased risk for tension upon closure
- Guided bone regeneration not possible

---

a sulcular incision and vertical releasing incisions (i.e., triangular: one vertical release; trapezoidal: two vertical release incisions). A vertical releasing incision is then extended apically above the mucogingival junction. By placing the vertical releasing incision as distal as possible, scarring may be spared that may occur during healing.[24] PRIs are placed to aid in flap advancement to gain tension-free primary closure. The main advantage of these flaps is direct visibility of the bone, which allows access to bone recontouring, as well as bone grafting. These flaps are contraindicated in patients with a thin gingival biotype because of the tension placed on the flap[25] (Fig. 26.11 and Box 26.6).

Vestibular

The vestibular flap incision is a minimally invasive technique that allows preservation of the interproximal tissue and allows access for buccal ridge recontouring and soft tissue grafting.[26] This technique involves one or more full-thickness vertical incisions in the vestibule away from the gingival margin and sulcus. After tissue elevation a subperiosteal pouch is created to allow space for a bone graft. The main limitation of this flap is the lack of visualization and access to the alveolar ridge (Box 26.7).

Proper Incision Technique

The design of the surgical incision is based on many factors such as anatomic location, tissue quality, type of procedure, and desired

• **Fig. 26.11** Examples are larger, more aggressive flap designs: (A) triangular and (B) trapezoidal.

• **BOX 26.6**　**Triangular/Trapezoidal Flap Surgery**

Advantages
- Better visibility
- Increased possibility of tension-free closure
- Access to additional sites

Disadvantages
- Increased bone loss and recession
- Increased disruption of blood supply
- Reflection/Suturing of adjacent papilla
- Increased patient morbidity

• **BOX 26.7**　**Vestibular Flap Surgery**

Advantages

---

healing outcome.[27] Flap designs may be further classified as to the type of tissue (full versus partial thickness), the number of incisions used to create them (envelope, papilla sparing, triangular, trapezoidal), or secondary incisions that dictate the flap's direction (rotating versus coronally versus apically advancing).[25]

Over the years the mucogingival flap design used in oral implantology has changed dramatically. Technology has allowed for the more accurate and ideal placement of implants and bone grafts. Better techniques and methods with tissue handling and preserving the blood supply have become reality. In the early years of oral implantology, most surgeries were completed with an aggressive full reflection of the surgical area with multiple release incisions. Most implants were placed with a submerged (stage 2) technique. In the 1990s a more conservative one-stage surgery technique became popular that involved placement of a healing abutment at the time of implant placement. This procedure showed remarkable results with a decreased morbidity. In the early 2000s advancements in guided surgery allowed the advent of "flapless" surgery, which resulted in much less trauma and patient complications.

With most dental implant procedures, surgical incisions are required. With a properly placed incision, the implant clinician may obtain adequate access to the surgical site for implant placement, identify necessary landmarks, and prevent unnecessary complications. The design of the surgical incision is based on numerous factors such as anatomic location, tissue quality, amount of keratinized tissue, procedure, amount of access required, and the desired healing outcome. There exist numerous principles that must be adhered to for the majority of incisions.

Proper Incision Positioning

The primary incision should ideally be located in keratinized tissue whenever possible. This will allow for an increased wound surface area and a resultant increase in vascularity to the incision line.[28] Not only does this reduce significant initial intraoral bleeding, it also will result in severing less blood vessels. A reduction in postoperative edema will result, which decreases tension to the incision line and possible incision line opening. If there exists 3 mm or more of attached gingiva on the crest of the edentulous ridge, the incision should ideally bisect the soft tissue. This places half of the attached gingiva width on each side of the incision (i.e., 1.5 mm), thereby strengthening the incision line. If there is less than 3 mm of attached keratinized tissue on the ridge crest, the incision should be made more lingually so that at least 1.5 mm of attached tissue is placed to the facial aspect of the implant. This concept is especially important in the posterior mandible because attached tissue is required to prevent tension and pulling from the buccinator muscle (Fig. 26.12).

Incisions made through attached gingiva and over healthy bone are more desirable than those through unattached gingiva and over unhealthy or missing bone contours. When osseous defects are present, properly placed incisions allow the wound margins to be sutured over intact, healthy bone that are a minimum of a few millimeters away from the bone defect. This will result in supporting the healing wound. In esthetic zones a papilla-sparing flap may be used to preserve the papilla and minimize possible tissue recession (Fig. 26.13).

In summary, the incision location may vary depending on multiple factors. The goal of any incision is to allow for adequate exposure of the operative field and to minimize possible damage or tearing of the tissue margins. This will lead to a better chance of obtaining primary closure, which results in better healing and less chance of postoperative complications.[29]
• **Fig. 26.12** Incision design based on amount of attached tissue. If less than 3 mm of attached tissue is present, then the incision is positioned more lingually.

• **Fig. 26.13** Incision made more lingual to increase attached tissue to the buccal. Note the broad based papilla sparing incision.

Use of a Sharp Scalpel Blade

A sharp scalpel blade allows incisions to be made cleanly without unnecessary damage from repeated strokes, especially if not in the same plane. Many factors dictate how fast the scalpel blade will dull, such as contacting teeth, titanium (e.g., implants, abutments, healing cover screws), and dense bone, which tend to lead to accelerated dulling. The resistance and thickness of the tissues may dull the blade at different rates; therefore the surgeon should change the scalpel blade whenever a difference is noted in the blade sharpness. Sharp dissections tend to minimize trauma to the incision line, which will result in less tissue trauma and postoperative swelling (Fig. 26.14).

Scalpel Technique

Clean, precise incisions allow for optimal wound closure. An ideal incision includes a single stroke through the tissue in one direction with firm, even pressure on the scalpel. Tentative strokes, especially in different planes, will increase the amount of damaged tissue and increase the amount of bleeding and inflammation. Long, continuous strokes are preferable to shorter,

• **Fig. 26.14** Incision should be made to "score" the bone; this allows for full-thickness reflection of the tissue.

• **Fig. 26.16** Incisions should be made to avoid any vital structures, for example, the mental foramen and lingual nerve in the mandible.
• **Fig. 26.15** Proper method of making incision using no. 15 scalpel blade. Note the scalpel motion is made by moving the hand at the wrist and not by moving the entire forearm. (*From Hupp JR, Ellis E, Tucker MR.* Contemporary Oral and Maxillofacial Surgery. *7th ed. Philadelphia: Elsevier; 2020.*)

inconsistent, interrupted strokes. Ideally the incision should always be over bone.

In most cases the blade should be held perpendicular to the epithelial surface. This will result in an angle that produces square wound margins, which are easier to reapproximate during suturing and less likely for surgical wound necrosis and incision line opening to occur[30] (Fig. 26.15).

Avoid Vital Structures

The incision and flap should be designed to avoid possible injuries to vital structures. The two most important structures in the mandible include the mental nerve and lingual nerve. When making incisions in the mandibular premolar area, care should be exercised with the anatomy of the mental nerve. Usually three to four branches of the mental nerve will ascend from the mental foramen and are superficially located in the soft tissue. In mandibular edentulous cases the scalpel blade should always remain on the bone. This will prevent "slipping" off the ridge and damaging

deeper vital structures. In mandibular severe atrophy cases the mandibular canal may be dehisced, which can lead to direct transection of the nerve fibers. In instances where the nerve lies on top of the ridge, the incision is carried lingual to the ridge to avoid severing the nerve. In the posterior mandible the lingual nerve may be closely adhered to the lingual aspect of the mandible. Therefore in the retromolar pad area, incisions should always be positioned lateral to the pad.

In the maxilla, rarely will an incision damage a vital structure. On the buccal, there exist no vessels that would be problematic, except for the infraorbital nerve, which exits the infraorbital foramen. However, direct trauma is usually rare in this area. On the palatal aspect the nasopalatine vessels exit the incisive foramen and supply the anterior palatal gingiva. If this area is incised, minimal bleeding will result, and the neural tissue regenerates rather quickly.[31] Posterior palatal release incisions should be avoided because the greater palatine nerve and artery may be traumatized, which may lead to increased bleeding episodes (Fig. 26.16).

Proper Scalpel Grip

Pencil Grip

The scalpel is grasped close to the blade between the tips of the thumb and the index finger, with the remaining handle resting on the web of the thumb, much like grasping a pencil. With this grip the motion is predominately from the thumb and index finger, allowing for precise cutting of tissue. A finger rest may be used to increase the accuracy of the fine cutting. This grip may also be "backhanded" by reversing the direction of the blade without changing the upper arm position. The pencil grip is best used for short, fine movements for precise incisions, because the muscles of the hand are used significantly more than the muscles of the forearm. The blade edge is usually held at 30 to 40 degrees to the tissue. One of the limitations of this technique is the greater angle, which results in less cutting-edge contact, and limits the depth of the incision (Fig. 26.17).

Fingertip Grip

With this technique the scalpel is held between the thumb and the middle finger, while the index finger is placed on the body of the

scalpel blade to apply downward pressure, much like grasping a butter knife. This grip technique uses more arm motion and is primarily used for making long skin incisions. The main advantage is the increased blade-to-tissue contact, which provides good depth and direction control. The greater the length of tissue contact with the scalpel, the more

the walls of the incision resist minute or sudden changes in direction, allowing for smoother, straighter incisions. The main disadvantage of the fingertip grip is that it does not allow for precise blade cuts.

Palm Grip

The palm grip is used when strong pressure in indicated to incise the tissue. The scalpel is held in the palm of the dominant hand with the index finger on top of the handle. The cutting pressure is derived from the palm and fingers as well as the entire arm. However, this grip is rarely used in implant dentistry (Fig. 26.17).

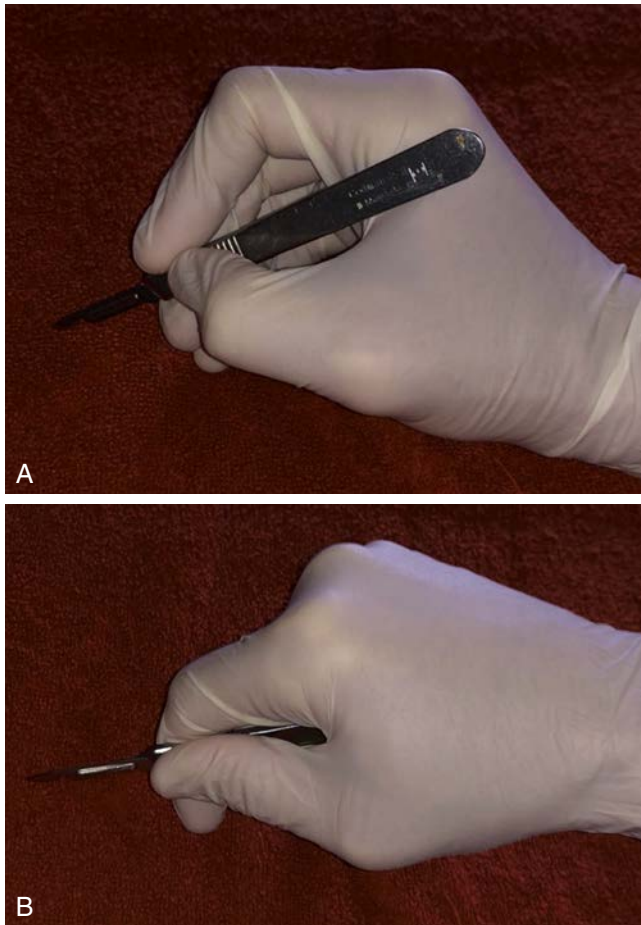
Surgical Armamentarium

A full array of instruments may be used in oral implantology, and usually the clinician will over time develop personal preferences with respect to various procedures. The following is a summary of some of the most popular instruments used today.

Instrument to Incise Tissue

Scalpel/Surgical Blades

The scalpel is the ideal instrument for making incisions and separating tissue. Scalpels are basically manufactured in two forms: disposable and metal reusable handle. The most used scalpel in oral implantology is the #3 scalpel, which commonly has a metric ruler on one side, which allows for intraoperative measurements. As stated earlier, the scalpel must be held in a way that permits full control of the instrument and at the same time freedom of movement. The handle of the scalpel is grasped between the thumb and the third and fourth fingers, and the index finger is placed over the back of the blade to provide firm control.

The most common scalpel blade used in oral implantology is the #15 blade or #15c blade. The #15 blade has a short, rounded cutting edge, combined with an angled point. In addition, the #12 or #12b blade is commonly used, mainly around teeth or in difficult access areas. These blades are small, pointed, and crescent shaped, which are end cutting on the inside edge of the curve. Blades can be either carbon steel or stainless steel. Carbon-steel surgical blades are sharper than stainless-steel blades but may dull quicker (Fig. 26.18).


A   B   #11   #12   #12B   #15   #15C

• **Fig. 26.18** (A) Scalpel handle: most common is the Bard-Barker. (B) Different scalpel blades: #11 is used for incision of abscesses or infections; #12 and #12b are used around teeth to connect incisions in difficult access areas; #15 is the most common blade used in oral implantology; and #15c has a smaller neck that allows for easier access around teeth.

Instruments to Reflect Tissue

Once the incision is made, the mucosa and periosteum must be reflected to expose the bone. The Molt periosteal elevator (#9) is one of the more common instruments to complete this task. The periosteal elevator usually has a sharp, pointed end and a broad, flat end. Normally the pointed end is used to initiate the reflection, followed by the broad end, which allows for a larger volume of tissue to be reflected. In the authors opinion an easier and more efficient instrument to use to reflect tissue is the 2/4 Molt. This double-ended instrument has two small, rounded, sharp areas, 2/4 (4 mm/6 mm), and is positioned in a dished-out fashion to allow for tissue to be reflected easier (Fig. 26.19).

In general, tissue can be reflected three different ways: (1) prying motion—pointed end used in a prying motion to elevate the soft tissue; (2) push stroke—used after full thickness incision to slide underneath the flap; and (3) pull or scrape stroke—used to remove tissue tags from the bone in a scraping motion (Fig. 26.20).

Instruments to Grasp Tissue

Tissue forceps are used to stabilize soft tissue flaps for suturing and reflection of flaps. The most common tissue forceps used in implant dentistry include the Adson and Allison forceps.

Adson forceps (pickups): to grasp and stabilize soft tissue flaps during suturing or implant and bone graft procedures. These delicate forceps have small teeth or serrations to gently hold tissue for stability. Care should be exercised to not crush the tissue because the tissue can be irreversibly damaged (Fig. 26.21).
Allison forceps: these forceps have larger and more aggressive teeth used to hold heavy or high-tension tissue. In implant dentistry these types of forceps are rarely used.

Instruments to Remove Bone/Tissue

Rongeur forceps

A rongeur is a heavy-duty surgical instrument with a sharp-edged, scoop-shaped tip, used for gouging or snipping away the bone. The word *rongeur* is a French word meaning "gnawer." In oral implantology the rongeur is used to cut or contour tissue, or to remove pieces of bone. Rongeur forceps have a spring between the handles, which increases the magnitude of the removal force. A common type used is termed *double-action* rongeur, which significantly generates more force than a single-action rongeur. Because the blades are concave toward the inside, harvested bone is easily retained to be used in grafting areas.

1. *Side Cutting* to cut and contour bone, remove sharp edges; will retain bone for grafting purposes
2. *End Cutting* to cut and contour bone; one beak may engage bone to shave bone from the ridge (Fig. 26.22)

Surgical burs

Surgical burs can also be used to remove bone. It is important to always use irrigation when using the surgical burs. The tissue must be adequately reflected to prevent trauma to the tissue with the burs. Cross-cut fissure burs may be used to make pilot holes in the host bone that will allow the bone to be removed with a chisel. Additional burs used to remove bone (i.e., alveoplasty) include special ridge reduction burs, straight handpiece (HP) acrylic barrel shaped burs, or HP round burs (Fig. 26.23).
• **Fig. 26.21** Adson Forceps. (A) Teeth: may perforate and tear thin tissue; however, it allows for better grasping of the tissue. (B) Serrated: less chance of perforating tissue.

• **Fig. 26.19** Reflection technique for full-thickness reflection with the 2/4 molt instrument.

• **Fig. 26.20** Recommended periosteal reflection instrument: 2 to 4 Molt.
• **Fig. 26.22** Rongeur. (A) Double-action rongeur allows for greater force for bone removal. (B) Bone removal using a "rocking" motion.
• **Fig. 26.23** Bone removal using carbide HP bur in a straight 1:1 handpiece.

Bone file

A bone file is a double ended serrated instrument used to remove sharp, spiny ridges within the bone (Fig. 26.24).

Instruments to Remove Tissue From Extraction Sockets or Bony Defects

The *surgical curette* is an instrument used to ensure removal of debris and diseased tissue. These instruments are usually spoon shaped and have sharp edges that allow scraping of the bony walls. Not only will the scraping remove soft tissue, the curettes will also initiate the regional acceleratory phenomenon (RAP). The most commonly used and recommended surgical curette has serrated edges (e.g., Lucas 86 Currette) (Figs. 26.25 and 26.26).

Bone-Grafting Instruments

Bone scrapers

Bone scrapers are mainly used by clinicians to harvest autogenous bone from the oral cavity and allow the collected bone particles to be delivered to the surgical site. These instruments consist of a harvesting blade and collection chamber, with a narrow-tipped syringe for access-restricted areas (Fig. 26.27).

Grafting spoon and condenser

These instruments hold bone to be placed at a specific area with a spoon-type of instrument. Usually a condenser is present on the other side of the instrument, which allows for the condensing of the bone graft material into the defect (Fig. 26.28).

Surgical Scissors

There exists a full array of scissors used in oral implantology: straight, curved, serrated, and nonserrated. Surgical scissors are used to cut tissue, spread tissue, and cut sutures. Usually the thumb and ring finger are placed in the scissor rings, with the index finger to steady the scissor. Curved scissors are usually preferred by most surgeons because they provide a better field of view and access to restricted areas.

Dean: the most commonly used scissors in oral implantology, which have slightly curved handles and offset serrated blades that allow for easy access to cut sutures and to remove diseased tissue. Dean scissors feature angled blades that are approximately 3 cm in length from midscrew. They have one serrated blade, with a slightly curved handle.

Iris: very small, extremely sharp scissors with a fine tip. Some iris scissors have curved blades for certain types of precision tasks, whereas others may have straight blades.

Kelly: commonly used to trim tissue or cut sutures because they have one serrated cutting side to the scissors.

Metzenbaum: surgical scissors that are designed for delicate tissue and blunt dissection. The scissors are available in variable lengths and have a relatively long shank-to-blade ratio. They are constructed of stainless steel and may have tungsten carbide cutting surface inserts. Blades can be curved or straight (Fig. 26.29).

Hemostats

The hemostat is an instrument that has serrated tips that allow for the "clamping" of tissue or small materials. Directly above the

finger rings is a ratchet to control the degree of force or restriction. In oral implantology, hemostats are used to constrict blood vessels (i.e., bleeding), retrieve loose objects in the oral cavity, and securely hold small items (Fig. 26.30).

Instruments to Retract Tissue

Retractors are used to hold back the cheek, tongue, or flap, which permit visibility to the surgical site. Examples include:

Mirror—conventional mouth mirror to retract tongue

Weider tongue retractor—broad, heart-shaped retractor with grooves and perforations that hold tongue and cheek away from surgical site

Seldin retractor—double ended with round blunted ends, used to retract a tissue flap from bone after an incision

Minnesota retractor—to retract tongue or cheek away from surgical site and has the advantage of reflecting both at the same time

Misch "Spoon" cheek and tongue retractor—to hold tongue or cheek away from surgical site, ergonomically designed to reduce hand fatigue

Sinus graft cheek retractor—broad-based flap retractor that reduces force to the infraorbital foramen area, thus reducing the possibility of a neuropraxia (Fig. 26.31)

Instruments to Hold Mouth Open

Bite block—sterilizable rubber block in multiple sizes to keep mouth open during procedures

Molt mouth prop—ratchet-designed instrument with rubber tips that allows variation on opening

Orringer retractor—spring-loaded mouth prop that self-maintaining spring-loaded mouth prop which maintains upper and lower soft tissue retraction (Fig. 26.32)

Suctions/Aspirators—suctioning is crucial to keeping the surgical field clear from debris to allow the surgeon to have clear visibility
• **Fig. 26.30** Hemostats. (A) Straight. (B) Curved. (C) Hemostats used to remove direct impression coping screws. (D) Curved hemostats used to hold abutment to prevent countertorque.

• **Fig. 26.32** Instruments to Hold Mouth Open. (A) Molt mouth prop. (B) Rubber mouth prop.

General surgical suction—used to clear the airway or surgical site; may be made of metal, which is autoclavable, or plastic, which is disposable

Fraser suction—suction that contains a hole in the handle that can be covered; vacuum relief hole controls suction by covering or uncovering the hole with fingertip; when uncovered, very little suction will result, which is important when working with bone or membranes (Fig. 26.33)

Yankauer tonsil aspirator—angled, long suction that has a perforated ball-type end for suctioning the posterior throat; a Yankauer is used to suction oropharyngeal secretions very effectively to prevent aspiration (Fig. 26.34)

Instruments to Hold Drapes

Towel clamp—a nonperforating clamp used to secure instruments and surgical materials, such as suction tubing to the surgical drapes (Fig. 26.35)

Handpieces/Motors

1. *Surgical motor console:* Composed of a console, foot pedal, and motor cord, which allows for the use of a contraangle or straight handpiece.
   - *1:1 handpieces*: usually straight handpieces that run at higher revolutions per minute (i.e., 40,000–50,000 revolutions/min); used for bone-grafting procedures
   - *16:1 or 20:1 handpieces:* contraangle reduction implant handpieces to drill osteotomies and/or place implants (Fig. 26.36)
2. *Piezosurgery units:* Piezoelectric bone surgery is an innovative technology that selectively cuts mineralized tissue without damaging soft tissue. This technology uses a high-frequency vibration (i.e., 25–35 kHz) that is transmitted to specialized surgical tips. The major advantages of this technology are the high precision accuracy, minimal thermal damage, increased healing, and less soft tissue trauma. There exist many uses of Piezosurgery in oral implantology, which

differ in various and versatile tips that are interchangeably used on the handpiece. This type of surgical unit may be used for atraumatic extractions, removal of implants, bone-grafting procedures, and sinus augmentation procedures (Fig. 26.37).

(Baxter, Deerfield, Ill.).

• **Fig. 26.37** (A) Piezosurgery motor console (Salvin, Charlotte, N.C.). (B) Vibrating handpiece that uses ultrasound frequency technology, resulting in precision and safe cutting of hard tissue.

Osteotomes

An osteotome is a surgical instrument which is used to cut, expand, or divide bone. There exists multiple types which are procedure specific.

Pointed: designed for progressive circumferential (circular) expansion (i.e., bone spreading) of the alveolar ridges which are compromised in width (i.e., Division B).

Progressive osteotomes: to incrementally widen or expand bone before implant placement

1. *Concave:* Concave osteotomes are used to infracture the floor of the maxillary sinus through the implant osteotomy. The concave tip retains bone graft material.
2. *Convex:* Convex osteotomes are used to raise the floor of the maxillary sinus after fracturing (SA-2 technique) (Fig. 26.38).

Sinus Curettes

Membrane curettes: Used to aid in the elevation of the sinus membrane, these curettes feature a rounder smooth tip for lifting the sinus with minimal puncture risk (Fig. 26.39).

Aseptic Technique

Ideally any surgical procedure where there may be an increased bacterial insult should use a sterile technique. There is much misunderstanding, though, when it comes to the terms *clean*, *aseptic*, and *sterile*.

- *Clean technique:* The clean technique includes routine hand washing, hand drying, and use of nonsterile gloves.
- *Aseptic technique:* The aseptic technique is used for short invasive procedures. It includes antiseptic hand wash, sterile gloves, antiseptic rinse, and use of a clean, dedicated area.
- *Sterile technique:* The sterile technique includes measures to prevent the spread of bacteria from the environment to the patient by eliminating all microorganisms in that environment.

This is mainly used for any procedure in which the bacterial count needs to be lowered and an increase in infection rate will lead to significant morbidity. This includes surgical hand scrub, hands dried with sterile towels, complete sterile field, sterile gown, mask, and gloves (Table 26.1; Boxes 26.8 and 26.9).

Achieving surgical asepsis requires multiple steps, including surgical gloving and gowning, along with maintaining a sterile field. Each member of the team involved in a sterile procedure is responsible for maintaining the aseptic environment.

Sterile Field

Sterile drapes are most often used within the sterile field to cover any surgical area used during the surgery (Fig. 26.40). Drapes come in various sizes and are most easily purchased in a kit. The inner surface of the sterile field, except for a 1-inch border, is considered the sterile field that may be used to add sterile items. This 1-inch

• **BOX 26.8** **General Principles for a Sterile Technique**

- Only sterile materials and instruments are placed within the sterile field.
- Check for chemical indicators to verify sterility of items placed onto the sterile field, along with package integrity and package expiration (if appropriate).
- Above and below the sterile field table is considered "nonsterile."
- Materials that display a manufacturer's expiration date should be considered unsafe for use after that date. (Rationale: Expiration dates do not guarantee either sterility or lack of sterility.)
- If any sterile item (material, instrument, gown, glove) has been compromised, the package contents, gown, or the sterile field is considered contaminated. This may happen when:
  - nonsterile items contact sterile items; or
  - liquids or moisture soak through a drape, gown, or package (strikethrough).
- Single-use materials should only be used on an individual patient for a single procedure and then discarded.
- Reusable medical devices shall be reprocessed and sterilized according to the manufacturer's directions.
- Any item that falls below table level is considered unsterile.

• BOX 26.9 **Sterile Scrub Technique**

Step 1: Prescrub Wash
A short prescrub wash is completed, including the hands up to the elbow. This is to remove superficial microorganisms and gross debris.
- Before the scrub, make sure surgical attire is worn and remove all jewelry. Glasses (loops, lights, etc.) should be placed in the ideal position.
- Perform a rinse from the fingertips to the elbows so the water flows from the cleanest area (fingertips) to the less clean area (elbows). Use a sink that is wide and deep so that both arms are contained within the borders so that water is not splashed out of the sink.
- Open the scrub brush and perform a preliminary scrub from fingers to the elbows. The next part of the prescrub is to clean the subungual area of each cuticle. With the disposable nail cleaning device, remove any debris from under each cuticle. The brush side of the scrub brush may be used over each cuticle.

Step 2: Primary Scrub
Depending on the hospital or surgical center, scrubbing methods and protocol will vary. The counted stroke method seems to be the most efficient to guarantee sterility. With the sponge side of the scrub brush, complete five strokes for each side of each finger (four sides), five strokes for each side of the hand, and five strokes for each forearm side. Rinse hands and arms under running water in only one direction, from fingertips to elbows. Care must be exercised to ensure fingers, hands, and arms do not touch any nonsterile surface (e.g., faucet). The hands should remain above the waist and below the axilla. If the water is controlled by hand-control levers, a nonsterile surgical assistant should turn the water off. Usually the prescrub and primary scrub will take approximately 3 minutes.

Step 3: Gowning
The hands should be dried with a sterile towel. Care should be exercised to prevent the sterile gown or gloves from water contamination. When moving

from the scrub sink to the sterile area, keep hands in front of the body, above the waist, and below the axilla. The neckline, shoulders, underarms, and sleeve cuffs are considered nonsterile.

The sterile gown should be immediately donned after complete drying of the hands and forearms, before gloving. Even though the complete gown is sterile when placed on the sterile table, once the gown is donned, only the front from the waist to the axilla is sterile. The gown should be lifted upward and away from the table, and allowed to open by locating the neckline and armholes. Hold the inside front of the gown at the level of the armholes to allow the gown to unfold. Do not touch the outside of the gown with bare hands. Extend both arms into the armholes, and the gown and sleeves will unfold. The gown is pulled onto the body with the cuffs of the sleeves extended over the hands. Do not push the hands completely through the cuffs.

Surgical gowns establish a barrier that minimizes the possibility of contamination from nonsterile to sterile areas, which is commonly referred to as a "strikethrough" barrier. They are made of a material that is resistant to blood and fluid penetration.

Step 4: Sterile Gloving
Sterile gloves are packaged in a sterile package. The closed gloving technique is most widely used. It ensures the hands touch only the inside of the gown and gloves. With the dominant hand, pick up the nondominant glove by the inner wrap straight up, placing it on the nondominant hand. Guide and wiggle the fingers into the glove. Using the gloved hand, pick up the remaining glove and guide it on the nondominant hand, making sure the gown cuff is covered. The nondominant glove will then pull the dominant glove cuff over the gown.

Step 5: Tying of the Gown
After the gown and gloves are in place, the front tie of the gown must be secured. The surgeon holds the left string with the left hand and holds the right large string and tag with the right hand. The tag is separated from the small string and handed to an assistant. The surgeon rotates 360 degrees and the assistant tears off the tag, leaving the right and left for the surgeon to tie.

---

border may also be used to position the drape within the surgical field. When placing sterile items onto the surgical field, items may be "dropped" from approximately 6 inches above the sterile field.

Surgical Scrub

The surgical scrub is the process that removes as many microorganisms as possible from the nail beds, hands, and forearms by mechanical washing and chemical antisepsis for a surgical procedure. This will result in a decrease in microbial count, and it inhibits the regrowth of bacteria. There are two different types of scrubbing techniques: a sterile sponge/brush with antimicrobial agent or a brushless technique with alcohol/chlorhexidine gluconate (Figs. 26.41 and 26.42). All rings, watches, bracelets, and jewelry should be removed before starting the hand scrub. Surgical hats, protective eyewear, headlights, and a surgical mask must be donned before surgical hand asepsis. Drying of the hands and arms is a priority because moist surfaces allow bacteria to multiply. Gowning, gloving, and tying the front tie of the gown occur after the hand scrub (Figs. 26.43 and 26.44).

Utilization of Ideal Suturing

Materials and Techniques

The objective of the proper suturing of the surgical wound is to position and secure the margins of the incisions to promote ideal

and optimal healing. The goal of the suture material and technique is to hold the margins of the wound in close apposition until the wound has healed enough to withstand normal functional tension and stress on the incision line.[32] If surgical wounds are not properly approximated, separation of the margins will occur, which leads to increased postsurgical morbidity. The clinician must select a suture with qualities that include high tensile strength,[33] tissue biocompatibility that prevents tissue irritation, ease of knot tying, and the ability to prevent minimal knot slippage (Table 26.2).

Suture Type

Absorbable

Absorbable sutures are popular and advantageous in implant dentistry because of the elimination of a suture removal appointment. There are two types of resorbable sutures: natural and synthetic.

Natural Natural sutures are mainly broken down by body enzymes. The most common natural sutures are plain and chromic gut (Fig. 26.45).

Plain gut. Plain gut is a monofilament derived from highly purified collagen from sheep intestinal submucosa. It is highly antigenic, losing 50% of tensile strength after 24 hours. Gut has unpredictable absorption because of the enzymes and macrophages that break it down. This type of suture has been shown to have a high incidence of tissue reactions, which impede healing.

• **Fig. 26.40** Sterile Operatory Setup. (A) A sterile surgical field includes sterile table drapes to cover any areas that are going to contain surgical materials. Ideally the chair is covered; however, it is considered nonsterile. (B) All sterile supplies are placed within the confines of the sterile drapes. (C) A sink area should be present to allow for a sterile scrub area and gowning.

Chromic gut. Chromic gut is also derived from purified collagen from sheep intestinal submucosa that is treated with chromic salts, which decrease absorption. This material is highly antigenic and loses 50% of tensile strength after 5 days. As a monofilament, it causes significant tissue reactivity. Chromic gut causes inflammation, loses tension, and resorbs too quickly to maintain soft tissue approximation over an augmented site. It is not recommended when the tissues are advanced for a bone augmentation. Hypersensitivity reactions have been shown to occur because of the chromate particles present in the suture.[34]

Synthetic Synthetic sutures are broken down by hydrolysis because of their hydrophobic nature. The most common synthetic, absorbable suture in implant dentistry is polyglycolic acid (PGA) (Fig. 26.46).

PGA (Vicryl). Because PGA sutures are absorbed by hydrolysis breakdown, they are not affected by a low pH. Because they are manufactured by synthetic polymers, their resorption is slower and they will maintain the incision line with a tensile strength much longer than most suture materials. This suture material will maintain sufficient tension over the first 2 weeks (75%), 50% after 3 weeks, and 25% after 2 weeks. PGA sutures have varying resorption rates, which consist of regular breakdown (≈21–28 days) and fast absorbing (≈7–14 days). The suture material is inert and has a relatively low tissue reaction.

Nonabsorbable

Nonabsorbable sutures are composed of human-made materials, which are not metabolized by the body. The most commonly used nonresorbable suture in dentistry is a natural fiber, silk, which undergoes a special manufacturing process to make it adequate for its use in surgery. Other nonabsorbable sutures are made of artificial fibers (e.g., polypropylene, polyester, nylon), which may contain coatings to enhance their performance characteristics (Fig. 26.47).

Silk: Over time, silk has been the most universally used suture material in dentistry because of its low cost and ease of handling. However, silk has many disadvantages with respect to implant dentistry. First, it is nonresorbable and must be removed. Because silk is a multifilament, is has been shown to "wick," which results

• **Fig. 26.41** Prescrub Technique. (A) Make sure hat, mask, glasses, and light source are worn and in place before the initiation of the scrub technique. (B) With lukewarm water, prerinse from fingertips to elbow. (C) Open surgical scrub brush with fingertip cleaner. (D) Complete a preliminary scrub from hands to the elbow with the soap brush. (E) Use fingertip cleaner to clean under fingernails, and (F) use the "brush" side of the scrub brush to complete fingernail cleansing.

in accumulating bacteria and fluid to the surgical wound.[35] And lastly, silk has been shown to release less tension during early retraction of the flap from healing, along with eliciting greater inflammation reactions, which may contribute to incision line opening more often than synthetic materials.[36,37]

Polypropylene (i.e., PROLENE): This suture, which is a mono-filament, will not lose tensile strength over time. It is inert, has very little tissue reaction, possesses a low coefficient of friction, passes through tissue very easily, and has good knot security. The main disadvantage of this suture material tissue is irritation from the cut ends of the suture material.

Polytetrafluoroethylene: The polytetrafluoroethylene (PTFE) suture material is a monofilament, which has a relatively high tensile strength and is nonwicking (low bacteria accumulation). In addition, PTFE sutures have good handling qualities, are easy to tie with excellent knot security, are soft and comfortable for patients, and are biologically inert.

The main disadvantage of PTFE is that it is very expensive. PTFE sutures are slippery and have poor frictional resistance to knot loosening. At least seven equally tensioned, flat square throws are required to produce a secure knot when using PTFE material.
• **Fig. 26.42** **Scrub Technique.** (A) Scrub each side of the finger approximately five times. (B) Scrub each side of hand. (C) Scrub up to the wrist, then up to the elbow. (D) Rinse from the fingertips to the elbows. The theory is to remove all debris/bacteria away from the fingertips to the wrist. The entire scrub process should take approximately 3 minutes.

Suture Qualities

The selection of the suture material should be made with regard to the location and type of surgical procedure provided. However, an ideal suture material should exhibit high tensile strength, low tissue reactivity, and be absorbable.

High Tensile Strength

High tensile strength is the measured force, in pounds, that the suture will withstand before breaking. A suture material with low tensile strength will lead to suture breakdown, which will most likely compromise the healing of the incision line. The tensile strength of the tissue to be sutured will ideally determine the tensile strength of the suture selected. The tensile strength of the suture should be at least as strong as the tensile strength of the tissue being sutured.

Low Tissue Reactivity

Tissue reaction from the suture material has been shown to be exhibited through an inflammatory response, which will usually develop during the first 2 to 7 days after suturing the tissue. The suture material selected should have an inherent low tissue reactivity.[38] Low tissue reactivity means that the suture material should exhibit a minimal inflammatory response, which will not delay wound healing or increase infection rate. Tissue reaction is reflected through

an inflammatory response, which develops during the first 2 to 7 days after suturing the tissue. Several studies published over the past forty years have reported that synthetic materials exhibit superior behavior to oral tissues in terms of tissue inflammatory reactions compared with nonsynthetic suture material.

Absorbable

Absorbable suture material allows for the convenience of no suture removal. These types of sutures undergo degradation and absorption in the tissues; thus the sutures do not have to be removed. There are two mechanisms of degradation of absorbable sutures: enzymatic breakdown or degradation by hydrolysis (PGA). Sutures derived from a biologic origin (i.e., plain and chromic gut) are digested by intraoral enzymes. Usually these types of sutures lose their tensile strength quickly (within days of surgery) and are not ideal for dental implant procedures. Secondly, these sutures may break down even faster when the intraoral pH is low. A decreased pH may result from infection, medications, metabolic disorders, or dry mouth. Trauma from suture removal may sometimes lead to incision line opening.

Treatment Implications

For dental implant procedures involving dental implant placement and bone grafting, the ideal suture material should exhibit a

• **Fig. 26.43** Sterile Gowning and Gloving. (A) Sterile gown and gloves (Sensicare, Medline, Northfield, Ill.). (B) Dry hands thoroughly, because moist hands will impair glove positioning; always maintain hands between waist and chin for sterility. (C) Pick up the gown from the sterile field from the inside surface of the gown; step back from the sterile field, allowing the gown to unfold from the body; and place arms into the sleeves of the gown. (D) When gown is in the ideal position, hands are at the seam of the inside cuff. Keep hands between waist and neck level to maintain sterility.

high tensile strength, low tissue reactivity, and be absorble or easily removed. The most common today include the use of PGA ("Vicryl"). A nonresorbable alternative would be a PTFE suture (e.g., Cytoplast), which exhibits a high tensile strength and is nonwicking.

Suture Size

Surgical threads are classified by diameter, ranging from 1 to 10, with the highest number being the smallest thread size. In implant dentistry the most common diameter is 3-0 for incision lines and 4-0 or 5-0 around tissue release margins or areas that exhibit thinner tissue. In some situations a 2-0 suture will be used, usually as a tie-back for the lingual tissue when performing mandibular surgery. Ideally the smallest-diameter suture material that will adequately hold the tissue in approximation should be used. As diameters of suture decrease, so do their respective tensile strengths (Fig. 26.48).

Suture Needle

The surgical needle is composed of three parts: (1) point, (2) needle body, and (3) swaged end. The needle type is classified by the curvature, radius, and shape. The most commonly used suture needles in implant dentistry are the 3/8 and 1/2 circle needles.[37] The 3/8 needle allows for the passage of the needle from buccal to lingual in one pass. The 1/2 is usually used in more restrictive

areas such as maxillary molars and in periosteal and mucogingival surgery.[39] The clinician should always be aware that there exist two types of needle designs: reverse cutting and conventional. In implant dentistry the reverse cutting should always be used because this will minimize severing of the tissues. The reverse cutting needle has a smooth inner curvature, with its third cutting edge located on its convex (outer) edge (Fig. 26.49).

Suturing Technique

Interrupted

Simple loop. The simple loop is the most common suture used in implant dentistry. It is used to approximate mobile surgical flaps in edentulous areas. Each suture is tied and cut after insertion through the tissue. The disadvantage of this suture is it is more time consuming than a continuous suture. However, it does have the advantage that, if one of the sutures would loosen or break, the remaining sutures would most likely hold the wound together to minimize wound dehiscence (Fig. 26.50).

Figure-eight. The figure-eight suture is placed as a simple loop on the buccal; however, on the lingual the needle passes through the outer aspect of the flap. The main disadvantage of the figure-eight is the suture material is interposed between the flaps after full closure. The figure-eight suture is most commonly used with extraction sites and around papilla (Fig. 26.51).

• **Fig. 26.44** Gloving and Gown Tying. (A) Pick up the first glove by the cuff, touching only the inside portion of the cuff. (B) While holding the cuff in one hand, slip your other hand into the glove. (C) Pick up the second glove by sliding the fingers of the gloved hand under the cuff of the second glove. (D) Put the second glove on the ungloved hand by using the cuff. (E) The surgeon holds left string (short) with left hand, holds tag and right string (long) with right hand, then pulls off tag with right hand. (F) The surgeon hands the tag to the assistant. (G) The surgeon spins around 360 degrees, and the assistant hands the long string to the surgeon, who ties the front of the gown. (H) The surgeon ties the front ties, and the assistant or circulator ties the Velcro back. (I) The surgeon is gowned and the hands are below the sterile area. The sterile area is below the axilla and above the waist.

TABLE 26.2 Suture Materials Used in Oral Implantology

Suture	Types	Color of Material	Raw Material	Tensile Strength Retention In Vivo	Absorption Rate	Tissue Reaction	Contraindications	Warnings
Surgical gut	Plain	Yellowish-tan Blue dyed	Collagen derived from healthy mammals (i.e., cow, sheep)	Lost within 3–5 days; individual patient characteristics can affect rate of tensile strength loss	Digested by proteolytic body enzymes within 7–10 days	Moderate	Should not be used in tissues that heal slowly and require support or under high-tension areas	Absorbs relatively quickly
Surgical gut	Chromic	Brown Blue dyed	Collagen derived from healthy mammals (i.e., cow, sheep); treated to resist digestion by body tissues	Lost within 7–10 days; individual patient characteristics can affect rate of tensile strength loss	Digested by body enzymes within 7–10 days	Moderate, but less than plain surgical gut	Being absorbable, should not be used where prolonged approximation of tissues under stress is required	Protein-based absorbable sutures have a tendency to fray when tied
Coated VICRYL (polyglactin 910)	Braided	Violet undyed (natural)	Copolymer of lactide and glycolide coated with polyglactin 370 and calcium stearate	Approximately 60% remains at 2 weeks; approximately 30% remains at 3 weeks (dependent on the type)	Minimal until about 40th day; essentially complete between 60 and 90 days; absorbed by slow hydrolysis	Mild	Even though a high tensile strength, may not be sufficient for high-stress areas	None known
PDS (polydioxanone)	Monofilament	Violet Clear	Polyester polyethylene terephthalate coated with polybutilate	Approximately 70% remains at 2 weeks; approximately 50% remains at 4 weeks; approximately 25% remains at 6 weeks	Minimal until about 90th day; essentially complete within 210 days; absorbed by slow hydrolysis	Slight	Being absorbable, should not be used where prolonged approximation of tissues under stress is required	None known
Surgical silk	Braided	Black White	Natural protein fiber of raw silk spun by silkworm (i.e., fibroin)	Loses all or most in about 1 year	Usually cannot be found after 2 years; encapsulation by fibrous connective tissue may result	Acute inflammatory reaction	Should not be used in any area where suture removal would be difficult	Slowly absorbs, tissue reaction
e-PTFE (expanded polytetrafluoroethylene)	Monofilament	White	Cytoplast	Nonresorbable	Nonresorbable	Biologically inert Comfortable to patients	None	None
Surgical steel	Monofilament Multifilament	Silver metallic	An alloy of iron-nickel-chromium	Indefinite	Nonabsorbable: remains encapsulated in body tissues	Low	Should not be used when a prosthesis of another alloy is implanted	May corrode and break at points of bending, twisting, and knotting

TABLE 26.2 **Suture Materials Used in Oral Implantology—cont'd**

Suture	Types	Color of Material	Raw Material	Tensile Strength Retention In Vivo	Absorption Rate	Tissue Reaction	Contraindications	Warnings
ETHILON nylon	Monofilament	Black Green Clear	Polyamide polymer	Loses 15%–20% per year	Degrades at a rate of about 15%–20% per year	Extremely low	None	None
NUROLON nylon	Braided	Black White	Polyamide polymer	Loses 15%–20% per year	Degrades at a rate of about 15%–20% per year	Extremely low	None	None
MERSILENE polyester fiber	Braided	Green White	Polyester polyethylene terephthalate	Indefinite	Nonabsorbable: remains encapsulated in body tissues	Minimal	None	None
ETHIBOND polyester fiber	Braided	Green White	Polyester polyethylene terephthalate coated with polybutilate	Indefinite	Nonabsorbable: remains encapsulated in body tissues	Minimal	None	Has not been evaluated in ophthalmic surgery
PROLENE polypropylene	Monofilament	Clear blue	Polymer of propylene	Indefinite	Nonabsorbable: remains encapsulated in body tissues	Minimal transient acute inflammatory reaction	None	None

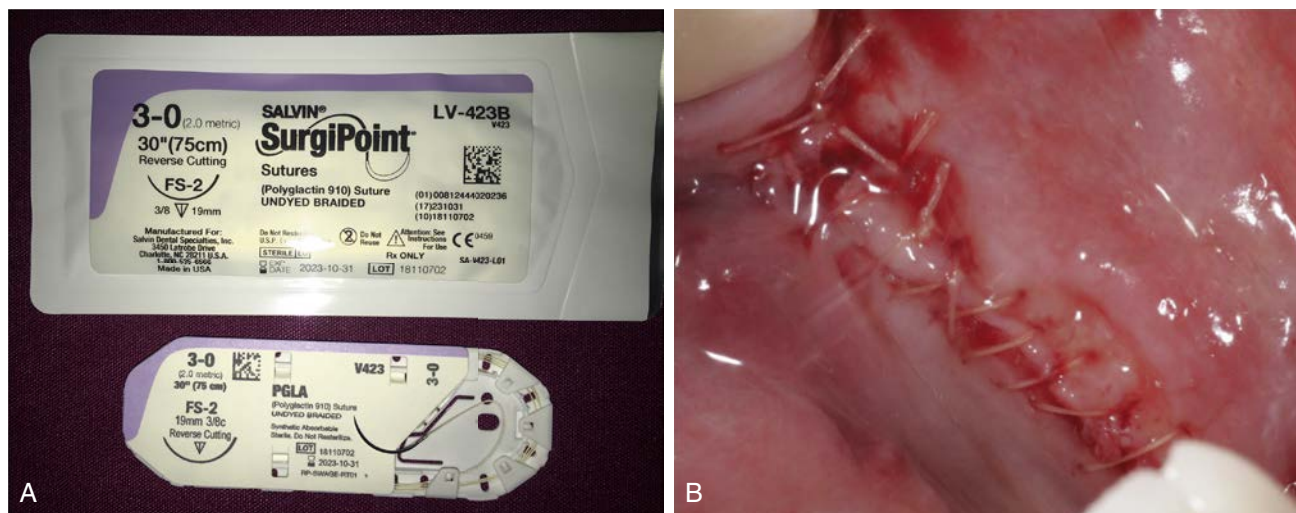
Second-Stage Surgery: Permucosal Abutment Suturing. A modification of the interrupted suture may be completed on second-stage surgery with a permucosal abutment that has a suture groove. A suture groove 3 to 5 mm above the platform connection may be incorporated in the healing abutment (e.g., External implant system, previously known as the Maestro dental system [BioHorizons IPH, Inc.]) (Fig. 26.52). When the tissue requires apical repositioning or when it is 3 to 4 mm thick and may grow over the healing abutment, the suture groove may be used. A suture is placed next to the healing abutment. Tissue forceps lift the suture from the incision line, and the suture is then rotated to form a loop. The loop is placed over the enlarged healing abutment and into the suture groove or under the healing cap. The suture may then be tied, securing the tissue at the height of the suture groove. A similar technique is used on the other side of the healing abutment. These two sutures (one on each side) hold the tissue at the level of the suture groove and prevent it from lifting up and over the healing cap during soft tissue healing.

Continuous

Soft tissue spans necessitating four or more interrupted sutures are best approximated with continuous nonlocking sutures. This suture design places less tension on the suture line and soft tissue, and allows faster vascularization of the reflected soft tissue flaps. However, whether locking or nonlocking, this suture knot has a tendency to loosen with uneven distribution of tension, which results in a compromise to the integrity of the suture knot (Fig. 26.53).

Horizontal/Vertical Mattress

Mattress sutures are a variation of the interrupted suture and are used most commonly where there exists muscle pull or


• **Fig. 26.46 Resorbable Fast-Resorbing Sutures With High Tensile Strength.** (A) Synthetic absorbable suture: polyglycolic acid (PGA) sutures, which are supplied in various resorption rates (Salvin, Charlotte, N.C.). (B) Clinical image of PGA suture, which has the advantage of being resorbable with excellent tensile strength.

high tension. This type of suturing technique will evert the surgical wound edges, which keeps the epithelium away from underlying structures and maintains the tissue flaps to the underlying structures (i.e., dental implant, graft material, membrane).[40]

There are two types of mattress suture, horizontal and vertical. Both of these suture types allow for greater tension to be applied on the soft tissue closure without risk for tearing the soft tissue flap. It should be emphasized they are not used to obtain primary closure when tension on the soft tissue flaps is present at surgery. The tissues should rest passively together before suturing. However, during functional/parafunctional movement of the tissues, the tension on the incision line may be reduced with a horizontal mattress suture. They are often used in the mandible when the floor of the mouth is in proximity to the lingual flap and the tissue is thin. They may also be used on a facial flap with a strong muscle pull on the soft tissue. In addition, horizontal mattress sutures evert the soft tissue margin and ensure primary closure without epithelium entrapment. A combination of a few horizontal mattress sutures with a continuous suture may be indicated to close large soft tissue spans (Figs. 26.54 and 26.55; Box 26.10).
• **Fig. 26.48** Suture Size Chart. Suture size increases in size with increasing number. The most common suture size in oral implantology is 3-0 and 4-0. For finer tissue procedures, 5-0 and 6-0 are most commonly used.

• **Fig. 26.55** Vertical Mattress Suture (Far-Far-Near-Near). (A) The needle should enter the tissue at 90 degrees approximately 5 to 6 mm from the margin of the incision and exits on the opposite side (same distance on the lingual aspect of the tissue as the facial). (B and C) The needle is placed backward in the needle holder and enters the lingual tissue toward the buccal (approximately the distance from the incision line). (D and E) The stitch is then tied off on the facial aspect.

1. Suture from mobile to immobile tissues: This allows for better control and manipulation of the tissue.
2. Do not hold needle at swage: This may result in bending of the needle.
3. Enter tissue at 90 degrees: This allows for easier passage of the needle through the tissue and prevents tearing.
4. Keep fingers in needle holder (index finger for security): Usually the thumb and index fingers are used to hold the needle holder. The fingers should always remain in the needle holders because this will expedite the suturing process, along with allowing for better control.
5. Enter 2 to 3 mm and exit from tissue margin: Less than 2 mm will lead to tearing of the tissue margin.
6. Suture 3 to 5 mm apart: Too many sutures will impair blood supply to the incision line and increase possibility of incision line opening (ILO).
7. First throw must lie flat: After the first loop is tied, it is mandatory the loop lie flat. If folded, the loop will lose tension and knot security will be lost. Final tension of the first tie should be as horizontal as possible.
8. Avoid excessive tension: Tying knots too tight leads to tissue ischemia and ILO. Knot tension should not cause tissue blanching. In tying the knot, a "sawing" motion should be avoided because this may result in weakening the integrity of the suture.
9. Evert tissue, not invert: This makes it less likely that ILO will occur.
10. Cut sutures approximately 2 to 3 mm at completion of knot: Less than 2 mm leads to loss of knot tension, and more than 3 mm leads to patient irritation. When the ends are too long, patients will tend to irritate the area with their tongue.
11. Complete knot: The final knot should be tight and firm so that slippage will not occur. Ideally the smallest knot possible should be used to prevent tissue and foreign body reactions.

• **Fig. 26.56** Tissue Pickups. (A) Serrated. (B) 1 Å~ 2 tips. (*Courtesy Salvin Dental Specialties, Inc., Charlotte, N.C.*)

Suturing Instruments

It is imperative that the implant clinician has a complete understanding of the instrumentation used in the suturing technique.

Tissue Pickups

The goal of the tissue pickup is to hold tissue (i.e., flap) while suturing. Care should be exercised not to crush or sever the tissue. There are various types of tissue pickups, with the serrated being the most popular. The 1 x 2 teeth pick-ups will usually result in tearing of the tissue, especially when the tissue is thin (Fig. 26.56).

Needle Holders

Most needle holders are made from stainless steel, titanium, and tungsten carbide tipped. The tungsten carbide tipped needle holders tend to deform the suture needle the least amount. Correct use of needle holders includes:
•   Always use the appropriate-size needle holder for the size of the needle. The larger the needle size, the wider and heavier

the needle holders should be. In contrast, with thinner tissue with a smaller size needle and suture material, smaller, more delicate needle holders are recommended (e.g., Castroviejo).
•   Avoid placement of the needle holders near the swage or eye of the needle. Needles should be grasped approximately one-fourth to half their length from the swaged area.
•   Check the alignment of the needle holder tips, making sure there is no opening between the tips. The needle should not be able to rock, twist, or turn within the needle holder tips.
•   Always close the needle holder on the first or second ratchet. If the needle is grasped too tightly, the needle may break or weaken. Hemostats should never be used as a replacement for needle holders because they will damage the suture needle and material (Fig. 26.57).

Suture Scissors

Many different types of scissors may be used in the suturing process. There are straight, curved, and special suture scissors that are used for cutting sutures, especially for removing sutures postoperatively (Fig. 26.58). When using suture scissors to cut the ends of the tied knot, make sure both tips of the scissors are visible to avoid inadvertently cutting tissue beyond the suture.

Suturing Knots

Surgical suture knot tying is the most important aspect of suturing and often the most common problematic area. Surgical knots in the oral cavity must be particularly secure to overcome the potential of loosening with saliva and normal function.[41] There are three components of a sutured knot: (1) loop, which is created by the knot; (2) knot, which is composed

of multiple throws, each of which represents a weave of two strands; and (3) ears, which are composed of the cut ends of the suture.[41] For knots to be effective, they must contain all three parts and possess attributes of both knot security and loop security. Knot security is defined as the efficacy of the knot at resisting slippage when load is applied. This depends on three factors: friction, internal interference, and slack between suture throws.

Loop security is the ability to maintain a tight suture loop as a knot is tied.[42] Any tied knot may have good knot security but poor loop security (a loose suture loop). Loose suture loops may be ineffective in approximating tissue edges to be secured. Ideally the knot should have minimal volume and be tied so that it fails only by breakage, rather than by slippage. A three-throw surgeon's knot square (2/1/1) should be used.[43] Security of the knot will depend on the material used, the depth and location of the wound, and the amount of stress that will be placed on the wound postoperatively. Operator experience is an important factor because considerable variation may result between knots tied by different surgeons and even between knots tied by the same individual on different occasions (Fig. 26.59).[44]

Treatment Implications

The type of surgical knot is directly related to the suture material being used. When using silk, expanded PTFE, chromic, or plain gut, a slip (granny) knot should be used. With synthetic resorbable and nonabsorbable synthetic suture materials, a modified surgeon's knot is recommended.[45]

For most dental implant procedures the surgical knot of choice is the modified surgeon's knot. The basic surgeon's knot is composed of two overhand knots. The first overhand knot is a double (i.e., composed of two loops or throws) and the second overhand knot is a single (loop) wound in the opposite direction. Additional knot security can be achieved with the common modification to the surgeon's knot, consisting of the addition of a third knot (composed of two loops) in the same direction as the first loop.[46]

Implant Placement Surgical Protocol

RANDOLPH R. RESNIK

Pre-Implant Placement Protocols

The technique for dental implant surgery has evolved over the years from the original protocol pioneered in the 1970s by Per-Ingvar Brånemark, a Swedish physician and researcher. With Brånemark's delayed approach, implant placement was completed, then after a healing period, the implants were exposed and prosthetically rehabilitated. Today, with the integration of computer and digitized technology, dental implant clinicians now have a full array of choices with the placement of dental implants.

Flap Design

Prior to the placement of implants, the underlying bone and osteotomy site must be exposed for implant osteotomy preparation and insertion (Chapter 26).

Full-thickness flap: The most common technique includes a mucoperiosteal flap, which may involve the buccal, lingual, and crestal areas.

Flapless: This technique does not reflect the crestal soft tissue. Instead, a core of keratinized tissue (the size of the implant crest module diameter) is removed over the crestal bone. The implant osteotomy is then performed in the center of the core of the exposed bone. This protocol requires no sutures around the healing abutment after implant placement. The advantages of this technique include less discomfort, tenderness, and swelling, which are usually minimal.

    The primary disadvantage of the flapless approach is the inability to assess the bone volume before or during the implant osteotomy or insertion. Therefore this technique should only be used when the bone width is abundant (>7 mm). In addition, bone grafting needs and procedures cannot be precisely evaluated. The soft tissue around the implant site should be ideal in the amount of attached keratinized mucosa because the soft tissue pouch is over the bone site, not in a region related to the soft tissue. Often, the keratinized tissue is reduced on the buccal half of the ridge and the tissue punch may inadvertently remove all the keratinized tissue on the facial aspect of the implant. Because the crest of the ridge is below the soft tissue, it is difficult to see lines on the drill to access the depth of drilling. Therefore stops on the drill are particularly beneficial. The clinician may have difficulty in assessing the location of the implant crest module in relation to the crest of bone because it is also below the soft tissue. And lastly, the interdental papillae may not be elevated with this technique. Therefore the soft tissue drape should be ideal in volume of keratinized tissue, both faciolingually and mesiodistally.

Surgical Approaches

Freehand surgery: This may include the flap or flapless technique, with the clinician placing the implant with the diagnostic information available (i.e., position of adjacent teeth, radiographs). Freehand surgery may include the use of nonlimiting surgical templates, which allow the surgeon the dimensional variability in implant location because the template will indicate the position of the final prosthesis; however, it will not specifically guide the placement of the implant (see Chapter 15 for surgical approaches).

Guided: This type of surgery, which may be performed flap or flapless, guides the osteotomy from a digitally designed and printed surgical template. This type of surgery allows the highest level of precision and control because the implant position is dictated via a comprehensive three-dimensional evaluation of the anatomy. Guided surgery may be differentiated by the type of support of the template:

Bone supported: The template rests on the alveolar bone and this technique requires the reflection of a full thickness flap.

Tissue (mucosa) supported: The template is supported by the soft tissue. This type of template is most commonly used with a flapless technique.

Tooth-supported: This is the most accurate technique and includes placement of the template directly on the natural teeth for support.

Guided surgery may also be classified according to the amount of drill guidance:

Pilot template: Allows guidance for the position and angulation for only the first drill in the surgical protocol. After the first drill, the osteotomy is completed freehand.

Universal template: This type of template is compatible with all implant systems and allows for depth, position, and angulation. However, the final osteotomy drill, along with implant placement, is completed freehand.

Fully guided template: Template that allows for depth, position, angulation, and implant placement via the guide.

Navigational directed surgery: Computerized navigation surgery has evolved from neurosurgical procedures into the field of dental implantology. This technique allows the clinician to precisely transfer a detailed presurgical implant plan to the patient. The clinician uses computerized navigation to adjust the position and angulation of the surgical drill according to the presurgical digital implant plan. The real-time imaging of the surgical drill allows for continuous updates on the positioning of the drill to avoid critical anatomic structures.

Dental Implant Osteotomy Preparation

Decreasing Heat During Osteotomy Preparation

The heat generated during an implant osteotomy is related to the presence and temperature of irrigation,[1-3] amount of bone being prepared,[4,5] drill sharpness and design,[5,6] time of preparation,[7] depth of the osteotomy,[8,9] pressure on the drill,[5] drill speed,[10] and variation in cortical thickness (bone density).[11]

Bone cell survival is very susceptible to heat. Eriksson has demonstrated that, in animal studies, bone temperature as low as 3°C above normal (40°C) can result in bone cell necrosis.[12] Therefore a conscious effort is made to control temperature elevation every time a rotary instrument is placed in contact with bone. Many dental implant preparation variables need to be addressed in understanding the reduction of heat during the osteotomy process.

Irrigation versus No Irrigation

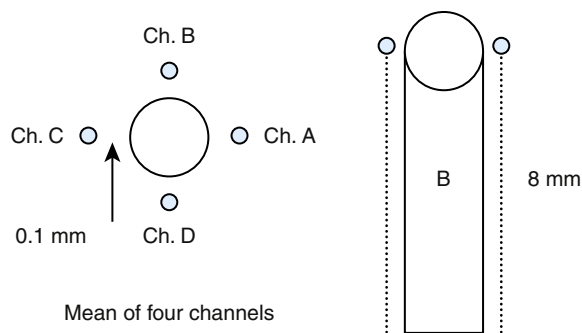
Although some authors have advocated implant osteotomy preparation without irrigation, the literature does not support it.[13] Yacker and colleagues showed that, without irrigation, drill temperatures greater than 100°C are reached within seconds of the osteotomy, and consistent temperatures greater than 47°C are measured several millimeters away from the implant osteotomy.[14] Benington and colleagues have reported that the osteotomy temperature may rise up to 130.1°C without irrigation after monitoring changes in bone temperature during the sequence of drilling for implant site preparation.[15]

To minimize heat generation, at least 50 mL/min of cooled irrigation of sterile saline (0.9% NaCl) should be used as a profuse irrigant and is a critical factor in the osteotomy process. The more dense the bone, the greater the need for copious irrigation. Distilled water should not be used because rapid cell death may occur in this medium.[4,9] The irrigant also may act as a lubricant and removes bone particles from the implant osteotomy site. The temperatures of the irrigant can also affect the bone temperature. Barrak and colleagues reported that cooling the irrigation fluid to 10°C, no mean temperature change >1°C will occur. Therefore placing the irrigation fluid into a refrigerator before implant surgery will help to prevent heat generation during implant placement[16,17] (Fig. 27.1).

Graduated versus One-Step Drilling

The amount of heat produced in the bone is directly related to the amount of bone removed by each drill.[18] For example, a 2-mm pilot drill generates greater heat than a 1.5-mm pilot drill.[4] As a result, most manufacturers suggest that the first drill (pilot) should be approximately 1.5 mm in diameter. In a similar fashion, the amount of heat generated by successive drills is also directly related to the increase in drill diameter.[19] For example, a 3-mm drill after a 2-mm drill removes 0.5 mm on each side of the drill. A 2.5-mm drill after a 2-mm drill only cuts 0.25 mm of bone on each side of

● **Fig. 27.1** Irrigation should use 0.9% NaCl (sterile saline), which may be cooled to reduce heat generation. The irrigation bags may be stored in a refrigerator.
● **Fig. 27.2** Number of steps in the preparation of the osteotomy is related to the bone density. Usually D1 will require all drills including the bone tap, the D2 protocol uses all drills except the bone tap, D3 requires the standard protocol stopping at the second to last drill, and D4 uses only the first or second drills.

the osteotomy. The smaller incremental drill size allows the clinician to prepare the site faster, with less pressure and less heat generation.[6] In addition, when larger increases in drill diameter are used to prepare bone, the clinician may inadvertently change the angulation of the drill because the larger drill is removing a greater bone volume and the tactile sense is decreased. As a result, an elliptical osteotomy may be prepared that does not correspond accurately to the round implant diameter. The gradual increase in osteotomy size also reduces the drill shatter at the crestal opening, which can inadvertently fragment the bony crest in which complete bony contact is especially desired. The gradual increase in drill diameter also maintains the sharpness of each drill for a longer period, which also reduces the heat generation (Fig. 27.2).


● **Fig. 27.3** Thermocouples were positioned within 1 mm of the drill site and inserted into bone for a depth of 8 mm. The wires were connected to a computer to measure the temperature, time of preparation, and time the bone temperature was elevated.

Drilling Speed

The subject of drilling speed has become very controversial in implant dentistry today. Eriksson and colleagues originally recommended drilling speeds of 1500 to 2000 rotations per minute (rpm) with irrigation.[20] Most recently in implant dentistry, the rotational speed of the drill has been suggested to be less than 2000 rpm, and several manufacturers have recommended speeds as low as 50 rpm. Kim and colleagues suggested drilling osteotomies at 50 rpm without irrigation and stated that the bone temperature may not significantly increase.[13]

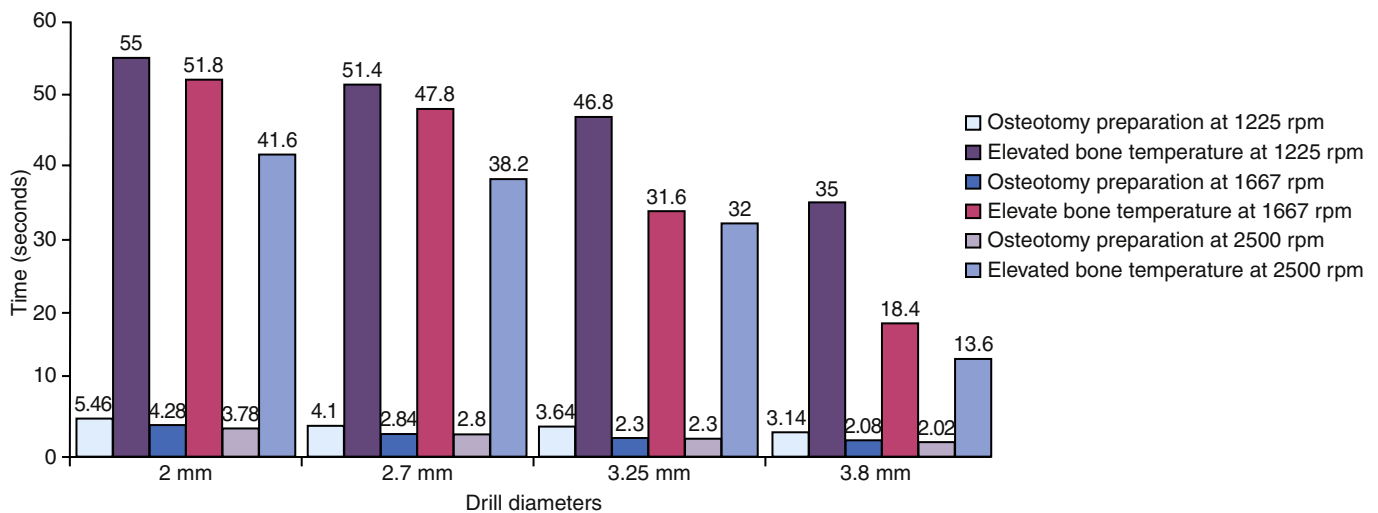
However, Yeniyol and colleagues showed that excessively low drilling speeds (less than 250 rpm) increased the degree of fragmentation of the osteotomy edge. It has been shown that low speed drills will "wobble," which leads to overpreparation of the osteotomy site.[21]

A controversial subject in implant dentistry is whether higher drilling speed is correlated with higher bone temperature during preparation. Although some reports have shown this, the majority of well-documented studies disprove this. For example, if high-speed preparation was detrimental, then slow-speed handpieces would be used to prepare natural teeth. A high-speed handpiece (~300,000 rpm) can remove bone over an impacted tooth or during an apicoectomy and still allow bone regeneration. Rafel prepared bone at 350,000 rpm in a human mandible and found a temperature of only 23.5°C at a distance of 3 mm from the drill periphery.[22] High-speed drills at 300,000 rpm have been used to prepare blade implant osteotomies for years, yet studies proved bone grew over the blade shoulder and was in direct contact with the implant.[23]

A study by Sharawy and colleagues compared four drill designs (two internal irrigated and two external irrigated) at speeds of 1225, 1667, and 2500 rpm.[4] Thermocouples connected to a computer to record temperature and time were placed within 1 mm of the osteotomy site in D2-type bone (Fig. 27.3). All drill designs in the study recorded lower bone temperatures with the greatest rotations per minute and, conversely, found the highest bone temperatures with the lowest rotations per minute (Figs. 27.4 and 27.5). As important, the slowest rotations per minute resulted in bone temperatures at or greater than 40°C, which may be a threshold of bone cell death. The highest rotations per minute (2500) increased the bone temperature by 2° to 3.5°C, whereas the 1225 rpm recorded a bone temperature greater than 41°C. Therefore the higher speed of 2500 rpm may prepare bone at a lower temperature than 1500 rpm, especially when in dense bone. The rotational speed of the drill is one of the more critical criteria to reduce bone temperatures.
● **Fig. 27.4** Internally cooled drill of the Paragon implant system recorded 41°C with the first drill at 1225 rpm; 2500 rpm reduced the bone temperature preparation for all drill diameters.
● **Fig. 27.5** Externally cooled drills of the Brånemark implant system recorded reduced temperatures at 2500 rpm, compared with slower speeds.

Sharawy and colleagues demonstrated that, regardless of the drill design or method of irrigation, 2500 rpm prepared bone at a lower temperature than slower speeds.[4] The clinician should allow the cutting surface of the drill to contact D1 and D2 bone fewer than 5 of every 10 seconds. Ideally, a pumping up-and-down motion (i.e., bone dancing) is used to prepare the osteotomy and provide constant irrigation to the drill cutting surface. It also maintains a constant drill speed and reduces the friction time against the bone, all of which reduce heat.

Drilling Time

Eriksson reported bone cell death when a temperature of 40°C was applied for 7 minutes, or when a temperature of 47°C was applied for 1 minute.[12] In other words, time and temperature are interrelated critical factors in implant site preparation. As the temperature increases, the time the bone temperature is elevated must be reduced. In the study by Sharawy and colleagues, the time the bone temperature remained elevated was recorded for each rotation per minute evaluated.[4] When the drill prepared an 8-mm depth osteotomy, the temperature remained elevated for 45 to 58 seconds (Fig. 27.6). The slower the rotations per minute (1225), the longer the bone temperature remained above the baseline. Because two to three drills are used to prepare an implant site, at 1225 rpm the first drill may increase the temperature to 41°C, the second drill to 45°C, and the third drill to 49°C, when the time between each sequence is not extended more than 1 minute. In the study by Sharawy and colleagues, the first drill diameter recorded the longest preparation time and the highest temperature, and the longest recovery time. Therefore to reduce the preparation time within the bone to a minimum in D1 bone, the clinician should not apply constant pressure to the drill, but "bone dance" with


● **Fig. 27.6** Internally cooled drills of the Nobel Biocare, Steri-Oss implant system demonstrate the temperature in the bone remains elevated for an extended period (up to 58 seconds) after site preparations in D2 bone. The lower the rotations per minute are the longer the temperature remains elevated.

intermittent pressure for 1 second in the D1 bone and 1 to 2 seconds out of the bone while the cooled irrigation is allowed to perfuse the site.

In summary, in D1 and D2 bone, a higher speed (1500–2000 rpm) should be used in the preparation of bone. In poorer quality bone (e.g., D3 and D4) drilling speed is not as crucial, therefore a lower speed maybe use (~1000 rpm).

Drilling Pressure

The pressure exerted when preparing the osteotomy should not result in heat generation. Hobkirk and Rusiniak found that the average force placed on a handpiece during preparation of an osteotomy is 1.2 kg.[11] Matthews and Hirsch concluded that the force applied to the handpiece was more influential than the drill speed in temperature elevation.[24] When the pressure on the handpiece was increased appropriately, drill speeds from 345 to 2900 rpm did not affect the temperature. Matthews and Hirsch found that increasing both speed and pressure allowed the drill to cut more efficiently and generated less heat. The effect of drill speed and pressure related to bone temperature was also reported by Brisman.[10] In cortical bone, speeds of 1800 rpm with a load of 1.2 kg produced the same heat as when speed increased to 2400 rpm with a pressure of 2.4 kg. The greater speed and greater pressure was more efficient than low speeds. Increasing pressure alone increased heat; increasing speed alone also increased heat. Different amounts of pressure are therefore used in response to the density of the bone. Sufficient pressure should be used on the drill to proceed at least 2 mm every 5 seconds. If this is not achieved, then new (sharper) or smaller diameter drills are indicated for each site preparation. The pressure on the drills should not reduce the rotations per minute, which makes the drill less efficient and increases heat. Handpieces of sufficient torque should be used to prevent this complication.

Intermittent versus Continuous Drilling

When preparing an osteotomy site, continuous drilling (i.e., no pumping motion) results in numerous possible negative consequences. When constant pressure is applied, irrigation cannot enter the osteotomy site; therefore this may result in heat-related damage. In addition, by not removing the drill from the osteotomy site during preparation, bone debris is maintained within the flutes of the surgical burs, resulting in potential heat generation. This also leads to less efficient drilling.

When intermittent drilling or bone dancing (i.e., continuously bringing the surgical bur in and out of the osteotomy site), less heat generation is seen. By bringing the bur in and out of the osteotomy site, irrigation may enter the site along with allowing any debris to be removed, thus making the cutting process more efficient. The only disadvantage of the bone dancing technique is the possibility of changing angulation or inadvertent widening of the osteotomy site.[25] Care should be exercised in withdrawing and inserting the implant drill at the same trajectory or angulation.

Insertion Torque

The insertion torque (IT) is the force used to insert a dental implant into a prepared osteotomy. The amount of torque is expressed in units of newton centimeters (N/cm), which ultimately determines the loading protocol. IT is the primary most important factor in determining primary stability, with higher torque values leading to higher primary stability.[26]

Lower values of IT have been shown to be associated with implant failures.[27]

Many studies have indicated IT near the range of 35-45 N/cm to be ideal for implant integration.[28,29] To standardize the amount of torque, calibrated torque wrenches, physiodispenser instruments with integrated electronic torque control settings, and pre-set torque settings on the implant electric motor systems should be used (Box 27.1).

Bone Density Factors Related to Implant Preparation

As discussed in Chapter 18, the density of the available bone has a significant effect on the predictability and success of dental implants. In the past, clinical reports that did not alter the surgical and prosthetic protocol had variable survival rates. In this chapter, a generic surgical protocol will be discussed, which is directly

- **Irrigation:** copious amounts of 0.9% NaCl
- **Irrigation solution temperature:** refrigerate before use
- **Drilling technique:** graduated protocol (more drills)
- Intermittent (bone dancing)
- **Drilling speed:** D1, D2 bone is 1500–2000 rpm; D3, D4 bone is ~1000 rpm
- **Drilling time:** greater drilling time, greater heat generation
- **Drilling pressure:** minimize pressure, never allow rotations per minute to decrease from excess pressure
- **Insertion torque:** 35-45 N/cm

• **Fig. 27.7** A study by the Dental Implant Research Group represented 33 different hospitals that place dental implants. The highest surgical failure rate was quality 1 bone, followed by quality 4 bone. The fewest surgical failures were observed in quality 3 bone.

related to bone density that has been shown to increase success of dental implants.

The density of available bone in an edentulous site has a primary influence on treatment planning, implant design, surgical approach, healing time, and initial progressive bone loading during prosthetic reconstruction. The quality of the recipient bone directly influences the amount of trauma generated during osteotomy preparation. This in turn provokes a cascade of reactions at the bone–implant interface that directly affect the quality of the load-bearing surface.

Once the implant is initially integrated with the bone, the bone-loading process from occlusal forces becomes a critical factor in long-term implant survival. The bone density under load is directly related to the bone strength and is therefore a critical parameter for long-term survival.[30,31] The occlusal stresses applied through the implant to the bone must remain within the physiologic to mild overload zone; otherwise, pathologic overload with associated bone loss and microfracture leading to implant failure may occur. The treatment planning and scientific rationale of strength, modulus of elasticity, bone-implant contact (BIC) percentage, and stress transfer difference related to bone density has been addressed in Chapter 18. This chapter addresses the modifications of the surgical and healing aspects related to each bone density in the oral environment.

Literature Review

Lekholm and Zarb listed four bone qualities found in the anterior regions of the jawbone: quality 1, comprises homogeneous compact bone; quality 2, a thick layer of compact bone surrounding a core of dense trabecular bone; quality 3, a thin layer of cortical bone surrounding dense trabecular bone of favorable strength; and quality 4, a thin layer of cortical bone surrounding a core of low-density trabecular bone.[32] Irrespective of the different bone qualities, all bone was treated with the same implant design and standard surgical and prosthetic protocols.

After the proposed protocols of Brånemark and colleagues, it was found that implant survival in initial surgical success was related to the quality of bone.[33] A higher surgical failure was observed in softer bone types, especially in the maxilla. For example, Engquist reported the surgical loss of 38 of 191 implants in the maxilla in D4 bone (20% loss) compared with 8 of 148 mandibular implants (5% loss) before stage II surgery.[34] Jaffin and Berman reported an overall 8.3% surgical and initial healing loss in 444 maxillary implants with softer bone.[35] Friberg and colleagues reported a 4.8% implant failure at stage II uncovery for 732 maxillary posterior implants, which was greater than mandibular failure.[36] Quirynen et al. also reported a 4.1% implant loss at stage II uncovery out of 269 implants in the maxilla.[37] Fugazzotto and
colleagues reported 22 failures out of 34 implants placed in quality 4 bone.[38] Hutton and colleagues identified poor bone quantity and quality 4 as the highest risk of implant failure in a study of 510 implants, with an overall failure rate in the maxilla nine times greater than in the mandible.[39] Sullivan and colleagues indicated a 6.4% stage II failure rate in the maxilla (12/188) and a 3.2% failure in the mandible (7/216).[40] Snauwaert and colleagues reported more frequent early failures in poor density maxillae.[41] Herrmann and colleagues correlated failure factors such as poor bone quality and volume. [42] A number of reports in the literature demonstrated that the greatest risk of surgical failure was observed in the softest bone type (D4), especially when found in the maxilla.

On the other extreme, a large clinical study from 33 US Department of Veterans Affairs (VA) hospitals by the Dental Implant Clinical Research Group (DICRG) states quality 1 bone had the highest surgical failure rate (4.3%), followed by quality 4 (3.9%), quality 2 (2.9%), and quality 3 with the fewest failures at 2.6% (Fig. 27.7). The overall implant surgical failure was 3%; the maxilla had better success at stage II surgery (98.1%) than the mandible (96.4%).[43] It must be emphasized that these reports only present implant failures up to stage II uncovery. The DICRG also noted that the failure rate was twice as great for surgeons who had placed fewer than 50 implants, compared with more experienced surgeons. The literature contains many published reports that indicated an implant surgical failure range from 3.2% to 5% in the mandible and 1.9% to 20% in the maxilla, with most reports indicating the greatest failure rates in maxillary implants with soft bone. It is clear from these reports that a wide range of results may be achieved; therefore consideration should be given to methods that improve surgical survival.

Misch developed a different surgical protocol for different bone qualities in 1988. The Misch classification of bone density includes four classifications, D1, D2, D3, and D4, which are based on the amount of cortical and cancellous bone. D1 bone is primarily composed of dense cortical bone and found mainly in the anterior mandible, with basal bone. D2 bone has dense-to-porous cortical bone on the crest and, within the bone, has coarse trabecular bone. D3 bone types have a thinner porous cortical crest and fine trabecular bone in the region next to the implant. D4 bone has almost no crestal cortical bone. The fine trabecular bone composes almost all of the total volume of bone next to the implant.

After these specific methods, prospective and retrospective multicenter clinical studies in a wide range of office settings found surgical survival to be greater 99%, regardless of the density type of bone, the arch (mandible versus maxilla), and gender and age of
● **Fig. 27.8** Multicenter study reported a surgical success of 99.6%, regardless of bone quality. (Data from Misch CE, Hoar JB, Beck G, et al. A bone quality based implant system: a preliminary report of stage I and stage II. *Implant Dent.* 1998;7:35–42.)

● **Fig. 27.9** Misch Classification for Bone Density. *D1,* dense cortical bone; *D2,* dense-to-porous cortical bone with coarse trabecular bone; *D3,* thinner porous cortical crest and fine trabecular bone; and *D4,* minimal crestal cortical bone with fine trabecular bone.

D4: 0 – 350

the patient.[44,45] Therefore a different surgical protocol for different bone densities appears warranted. The implant design, surgical protocol, healing, treatment plans, and progressive loading time spans are unique for each bone density type. More recently the use of improved rotary instruments, implant designs, and surgical approaches for different bone qualities has been recognized as a valid recommendation. A multicenter prospective clinical study by Misch and colleagues of 364 consecutive implants in 104 consecutive patients found a surgical survival rate (up to abutment connection) at stage II of 100% for D1, 98.4% for D2, 99.8% for D3, and 100% for D4 implants[46] (Fig. 27.8). Altering the surgical approach for each bone density can yield an overall implant surgical survival of 99.8% and a 2-year survival of 99.4%. In this chapter the surgical considerations and optimal healing time are discussed relative to each bone category, based on the literature, prospective clinical studies, and long-term experience.

Bone Density Classifications

Misch defined four bone density groups in all regions of the jaws that vary in both macroscopic cortical and trabecular bone types.[47] The regions of the jaws are divided into (1) the anterior maxilla (second premolar to second premolar), (2) posterior maxilla (molar region), (3) anterior mandible (first premolar to first premolar), and (4) posterior mandible (second premolar and molars). The regions of the jaws often have similar bone densities (Fig. 27.9).

In general, the anterior mandible is usually D2 bone, the posterior mandible is D3 bone, the anterior maxilla is D3 bone, and the posterior maxilla is often D4 bone. This generalization is used for the initial treatment plan. However, resorbed anterior mandibles may be D1 bone in approximately 25% of male patients and the posterior maxilla may have D3 bone after 6 months in the majority of sinus graft patients. The regional locations of the different densities of cortical bone are more consistent than the highly variable trabecular bone. Bone density may be most precisely determined before surgery by a computed tomography (CT) scan of the edentulous site (accompanied by Hounsfield values of the bone). Reformatted software allows "electronic surgery" of the CBCT images and relates the Hounsfield values at the implant–bone interface. Conventional dental radiographs, such as periapical, panoramic,

or lateral cephalometric images, are usually not diagnostic (Boxes 27.2 and 27.3) in the assessment of bone density.

A common point at which to evaluate bone quality is during surgery. The presence and thickness of a crestal cortical plate and the density of trabecular bone are easily determined during implant osteotomy preparation. The density of bone is determined by the initial bone drill, and evaluation continues until the final osteotomy preparation.

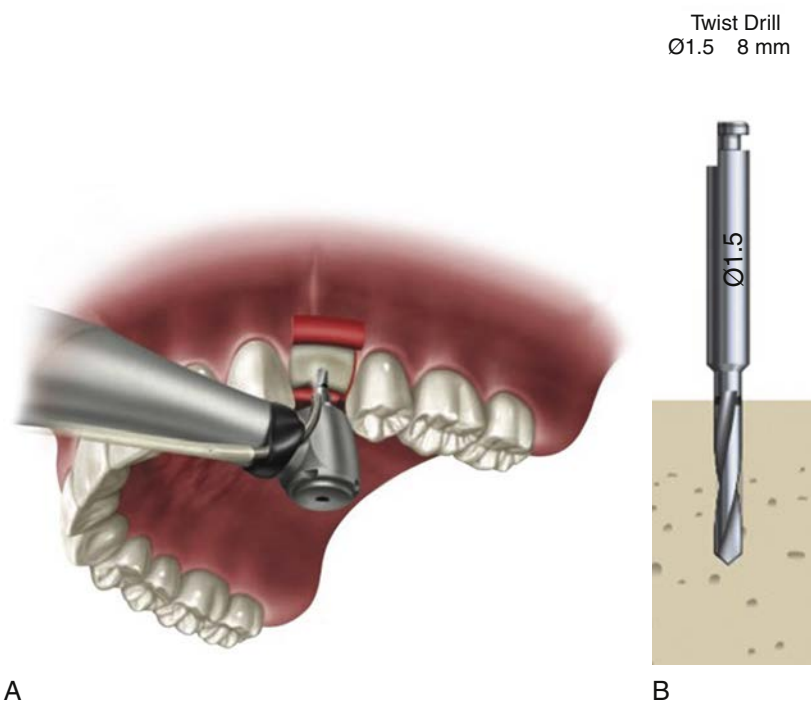
It should be emphasized that the bone density (D1–D4) classification of Misch is slightly different from Lekholm and Zarb's bone quality types (Q1–Q4). According to Misch and colleagues, D3 bone has fine trabeculae that is 47% to 68% weaker than D2 trabeculae, and 20% stronger than D4 trabeculae, whereas Lekholm and Zarb stated that Q3 bone has favorable-strength trabeculae similar to Q2.[34,36] In other words, the actual strength of the trabecular bone is different for each bone density, regardless of the presence or absence of cortical bone adjacent to the implant. In addition, the Lekholm and Zarb bone quality only evaluated bone in the anterior maxilla and mandible. The Misch bone density scale also evaluated the posterior molar regions of the jaws. As a result, a primary difference between D3 and D4 bone is also the presence of cortical bone in D3, which increases its overall strength and modulus of elasticity.[32] The quality 4 bone of Lekholm and Zarb is similar to Misch's D3, whereas D4 bone is even weaker because little to no cortical bone is present to improve the strength or the elastic modulus of the fine trabecular bone.

Osseodensification

A new method of implant preparation, termed osseodensification (OD), has recently been introduced to implant dentistry.

Twist Drill
Ø1.5   8 mm

Ø1.5

A   B


● **Fig. 27.10** Pilot drill. (A and B) With most surgical systems, the first drill includes a pilot drill with an approximate diameter of 1.5 mm. This initial drill is usually not prepared to final depth to allow for direction modification if needed.

Huwais and colleagues, in 2013, introduced a surgical protocol that includes the use of special densifying burs, which results with low plastic deformation of the bone. The specially designed burs (Densah burs) result in bone densification as the osteotomy is prepared, thereby increasing bone at the implant interface.[48]

The Densah burs utilize the concept of osteotomes, along with drilling speed to laterally compact bone during preparation. Bone is preserved and condensed through compaction autografting, increasing the bone density and improving the mechanical stability of the implant.[49] Conventional surgical drills excavate bone during implant osteotomies, which requires approximately 12 weeks of bone remodeling to repair. Because the OD protocol preserves bone while increasing density, the healing time may be shorter.[46]

Other methods of OD by use of undersizing the drills has been established. Degidi and colleagues showed a significant increase in primary stability by decreasing the preparation size by 10%.[50] Alghamdi and colleagues used an adapted bone site preparation technique by undersizing the osteotomy sites in poor bone density and showed favorable implant survival rates.[51] Therefore in the Misch implant placement protocol, the implant placement surgical protocol is specific for each bone density and varies with the amount of overpreparation and underpreparation of the osteotomy sites.

Generic Drilling Sequence

Before discussing the surgical implant protocol specific to bone density, the clinician must understand the generic protocol for dental implant osteotomy preparation and placement.

Step 1: Pilot Drill

With most surgical systems, a 1.5-mm or 2.0-mm surgical pilot drill is used to initiate the osteotomy. Pilot drills are end-cutting starter drills used to most commonly initiate an osteotomy in the center of the ridge in a mesiodistal and buccolingual dimension. The osteotomy should be completed with a reduction handpiece (e.g., 16:1 or 20:1 high-torque handpiece) and an electric motor at a preferred speed of 2000 rpm (i.e., for D1 and D2 bone) and >1000 rpm (i.e., for D3 and D4) under copious amounts of chilled saline irrigant. The osteotomy is made no greater than 7 to 9 mm deep in the bone (Fig. 27.10). The rationale for preparation of only 7 to 9 mm is if the angulation is determined to be nonideal, then it is easier to modify.

Step 2: Position Verification

Once the initial osteotomy is prepared, it is assessed for ideal position (see Chapter 28). If incorrect, the osteotomy location may be "stretched" to the proper location by a side-cutting Lindemann bur. This bur makes the hole oblong toward the corrected center position. After the new position is obtained, it should be deepened 1 to 2 mm beyond the depth of the initial osteotomy. This will prevent the second surgical bur from entering the first nonideal implant osteotomy.

Usually a direction indicator (depth gauge), which corresponds to the initial bur diameter, is then inserted into the osteotomy and the angulation and position assessed (Fig. 27.11). If direction indicators are not available, then older surgical burs may be used after slight modification (i.e., shortened 2–4 mm to allow for radiographic ease). A periapical radiograph should be obtained to determine proximity to any vital structures. The clinician should be well aware of the "Y" factor of their surgical drill system. The Y factor corresponds to the additional length of the bur that is inherent with surgical drills (i.e., a 10-mm depth drill may drill to a length that exceeds 11.0 mm).

Ideal final implant positioning should be a minimum of 1.5 mm from an adjacent tooth, 3.0 mm from another implant, and 2.0 mm from a vital structure such as the inferior alveolar canal or mental foramen.

Step 3: Second Twist Drill

The second drill used is approximately 2.5 mm in diameter, and is an end-cutting twist drill required for the initial osteotomy to the required depth. The osteotomy location and angulation are reassessed at this point. A slight correction of
position or angulation with a Lindemann drill may be completed; however, it should ideally be accomplished after the first drill (Fig. 27.12).

Step 4: Final Shaping Drills

Depending on the surgical system used, most shaping drills are used to sequentially widen the osteotomy to the matching diameter of the implant being placed. Depending on the diameter, multiple twist drills maybe used. The desired depth, along with the ideal location and angulation of the osteotomy, should be verified. Most implant drill kits will clearly identify the drill sequence and final osteotomy diameter related to each diameter implant (Fig. 27.13). Usually, the final drill will be within 1.0 mm of the final diameter of the implant diameter (i.e., a 4.0-mm implant will have a final drill size of approximately 3.2 mm).

Step 5: Crest Module and Bone Tap Drills

Most implant crest modules (implant neck) are larger in diameter than the implant body. The larger diameter often requires a side-cutting crest module drill in D1 (and some D2) crestal bone situations to prepare the crestal aspect of the implant osteotomy. This drill is not recommended when the bone density is poor (D3 and D4) (Fig. 27.14). This drill is used to open up the crestal area of the ridge to accommodate the wider crest module. When used, copious amounts of saline should be used.

In addition, usually in D1 bone, some implant systems will require the use of a bone tap or threadformer to prepare the threads in the bone before implant insertion. Most often for single-tooth implants, the threadformers or taps should use a high-torque, slow-speed handpiece and be rotated at less than 30 rpm into the bone. Irrigation also helps to lubricate and clean the bone tap and osteotomy site of debris during this process.

● **Fig. 27.14** Tap drill. (A and B) Used mainly in D1 bone at approximately 30 rpm.

Step 6: Implant Insertion

The implant site may then be prepared for implant insertion. The osteotomy is lavaged with sterile saline and aspirated to remove bone debris and stagnant blood. This reduces the risk of these materials being forced into the bone marrow spaces or neurovascular channels during implant insertion, causing hydrostatic pressure. This pressure may increase the devital zone of bone around the implant or even cause short-term neurosensory impairments when the implant site is in the vicinity of the mandibular canal.

The implant may be inserted with a hand ratchet or handpiece. The advantage of inserting an implant with a handpiece is that the placement will be more ideal and deviation is less likely, especially in poorer quality of bone (e.g., D3 and D4 bone). However, in better quality of bone, especially D1, difficulty in insertion may

A

B
• **Fig. 27.15** Implant insertion. (A) Placement of implant with a hand ratchet, which is usually used only in D1 and D2 bone. (B) Placement of implant with handpiece, which is usually indicated in D2, D3, and D4 bone.

sometimes occur. When placing an implant with a hand ratchet, good apical pressure should be used to decrease the possibility of deviating the path of the implant. If the implant is tightened into the osteotomy and significant stress occurs at the crestal area, pressure necrosis may occur and an increase in the devital zone of bone around the implant during healing will occur. If this should occur, the implant may be unthreaded 1 to 2 mm and then reinserted back into the osteotomy. When the implant is placed into the final position, a post-insertion periapical radiograph is taken to verify ideal positioning (Fig. 27.15).

Dental Implant Surgical Protocol 1 (D1 Bone)

Dense Cortical (D1) Bone

The dense D1 bone (i.e., similar to the hardness of oak or maple wood) is composed of almost all dense cortical bone. The maxilla almost never presents with D1 bone. In division A bone, approximately 4% of the anterior mandibles and 2% of the posterior mandibles have this dense bone category. In division C–h bone of an anterior mandible, these numbers increase and may reach 25% in males, whereas weaker bone density D3 and D4 bone are less commonly encountered.

The Hounsfield unit numbers are usually greater than 1250 HU.

Advantages of D1 Bone

The homogeneous, dense D1 bone type presents several advantages for implant dentistry. Composed histologically of dense lamellar bone with complete haversian systems, it is highly mineralized and able to withstand higher occlusal loads. The cortical lamellar bone may heal with little interim woven bone formation, ensuring excellent bone strength while healing next to the implant.[52,53]

D1 bone is more often found in anterior mandibles with moderate to severe resorption and greater crown/implant ratios. Implants placed into this bone density improve the dissipation of stresses in the crestal cortical region despite higher moments of force from the greater crown height to sustain long-term functional stress.

The percentage of light microscopic contact of bone at the implant interface is greatest in D1 bone type and greater than 80% (Fig. 27.16). In addition, this bone density exhibits greater strength than any other bone type. The strongest bone also benefits from the greatest BIC. Because of the density of this bone, less stress is transmitted to the apical third of the implants than in other bone types. As a result, shorter implants can better withstand greater loads than in any other bone densities. In fact, the placement of longer implants may decrease surgical survival rates because overheating during osteotomy preparation is a primary concern in this bone type. Greater heat is often generated at the apical portion of the osteotomy, especially when preparing dense cortical bone.[54]

Disadvantages of D1 Bone

Increased Crown-Implant Ratio. Dense cortical bone also presents several disadvantages. Because these cases are usually seen with mandibles with limited height (i.e., usually less than 12 mm), the crown height space is often greater than 15 mm. As a result, additional force-multiplying factors (i.e., such as cantilevers or lateral forces) are further magnified on the implant-prosthetic system. It is imperative that stress-reducing factors may be incorporated in the prosthesis design to reduce these effects, not only on the bone, but also on the prosthetic components (Fig. 27.17).

Poorer Blood Supply. D1 bone has fewer blood vessels than the other three types; therefore it is more dependent on the periosteum for its nutrition. The cortical bone receives the outer one-third of all its arterial and venous supply from the periosteum.[55] This bone density is almost all cortical, and the capacity of regeneration is impaired because of the poor blood circulation. Therefore delicate and minimal periosteal reflection is indicated. When D1 density is present, the bone width is usually abundant and the mandible widens apically. Fortunately, there are few occurrences when facial or lingual undercuts are observed with D1 bone densities, and flap reflection can be safely kept to a minimum. The precise closure of the periosteum and the overlaying tissue has been shown to help recover the blood supply and is encouraged.[56] Because of the compromised blood supply, this type of bone will actually take longer time to heal compared with D2 bone.

Overheating the Bone. The primary surgical problem of D1 bone is the dense cortical bone is more difficult to prepare for endosteal implants than any other bone density. The most common cause of implant failure in this bone quality is surgical trauma resulting from overheating the bone during the implant osteotomy procedures because surgical drills progress with more difficulty.
● **Fig. 27.16** D1 bone has the highest bone-implant contact (BIC), which is usually greater than 80% after initial bone healing. Thus the strongest bone is also the bone with the greatest BIC. Both these conditions make D1 bone the most suitable for occlusal loading.
● **Fig. 27.17** Division D mandible, which will usually be composed of D1 bone. Because of the extensive atrophy, the crown-implant ratio is increased.

The zone of devitalized bone that forms around the implant is larger in this bone density and must be remodeled and replaced by vital bone for the interface to be load bearing (Fig. 27.18). As a result, implant surgical failure may be greater in D1 bone than any other bone density. Therefore it is imperative the clinician strive to minimize the thermal trauma.

Pressure Necrosis. Because of the thick, dense cortical bone, placement of an implant may lead to an increase in internal stresses at the crestal area. Therefore after implant placement to the height of the bone level, the implant may be unthreaded 1 to 2 mm, the bone allowed to relieve the stresses, and then it is reinserted to the final placement level. By allowing the bone to expand from creep,
● **Fig. 27.18** Devital zone *(D)* of bone next to the implant *(I)* is primarily created by heat generated during surgery, which radiates from the site, especially in cortical bone. Other contributing factors include lack of blood supply, pressure necrosis from implant placement, microfracture from bone tapping, and implant insertion. *V,* Vital bone.

it is less likely that pressure necrosis, which leads to bone loss or die-back, will occur (Box 27.4).

Implant Osteotomy Drilling Sequence

In D1 bone, all the drills of the surgical system should be utilized. Because of the density of this bone type, more graduated drills will result in less heat generation. A secondary cause of lack of osseous integration may be related to mechanical trauma of the bone. There are several methods to reduce mechanical trauma in D1 bone, and one of these is related to final drill size selection. In D1 bone, the final bone preparation may be sized slightly larger in both width and height, especially for a threaded implant, than the manufacturer-recommended surgical protocol. This reduces the risk of microfracture trauma between the implant threads during insertion, which may lead to fibrous tissue formation at the bone–implant interface. In addition, a final drill dimension only used in D1 bone remains sharper for this critical step.

If a surgical drill of slightly greater diameter is not available with the implant system, the clinician can use the final drill size available and pass it within the osteotomy several times. By entering the osteotomy site multiple times, the osteotomy diameter will become slightly oversized. In fact, all drills for the D1 drilling sequence may use this method, therefore, less bone is removed with future drills, resulting in less heat generation.

A bone tap should be used in D1 bone before insertion of a threaded implant. There are several reasons for the use of a bone tap. Because the final drill osteotomy is almost 1 mm smaller than the outer diameter of the implant, the bone tap creates the space for the thread of the implant. This drill has open flutes, which permit the shaving of the bone to accumulate and be removed before placing the implant. A self-tapping implant insertion compresses the bone in the region of the threads. This is an advantage in softer bone types, but not in cortical bone. The tap reduces the mechanical trauma to the bone while the implant is inserted. The bone is also able to slightly recover from the trauma of the tap once it is removed and permits a more passive implant placement. Watzek and colleagues found a higher woven bone interface (i.e., a sign of bone trauma) when a self-threading implant design was used, compared with a pretapped implant site.[57] Satomi and colleagues found a higher BIC after initial healing with pretapped implant osteotomies compared with a self-tapping site, which is also indicative of less bone trauma. The use of a self-tapping implant insertion technique in dense bone

qualities has demonstrated a significantly higher degree of hard tissue trauma; therefore it is not recommended in D1 bone.[58]

The bone tap should be used with a hand ratchet and irrigation. The slow-speed, high-torque handpiece is very efficient and has several advantages in D2 bone. However, D1 bone is so strong that the handpiece gears may strip, and the handpiece is more likely to require repeated repair.

The hand position of the surgeon is important in maintaining constant force and direction on the hand ratchet during the bone-tapping process. When using a ratchet, the horizontal rotation on the tap causes it to tip back and forth around the vertical axis. Therefore, when using a ratchet the ratchet is held while the thumb of the other hand is placed directly over the bone tap, the index finger of the same hand retracts the lip for improved access and vision. The ratchet rotates the tap with one hand while the thumb and middle finger of the other hand apply constant pressure and direction to the tap so it does not tip back and forth or strip the osteotomy site (which may happen if the tap does not continue to advance within the osteotomy each turn of the tap).

A bone tap in D1 bone prevents the antirotational component of the implant body from being damaged during implant insertion in this dense bone type. A minor advantage to tapping may be the fact that drill remnants are more likely to be left in the implant osteotomy during preparation in dense bone or with a new drill and cutting edge. The bone tap may remove these remnants and decrease the risk of long-term corrosion from dissimilar metals contacting within the bone, although no reports in the literature have indicated this to be a problem.

Once the tapping process is complete, the osteotomy is irrigated and suctioned. The implant should be inserted with a hand ratchet, minimizing damage to the handpiece and allowing the clinician to gauge the IT of the implant. The implant should not be tightened with a high-torque pressure (>75 N/

cm) to the full depth of the osteotomy; this causes it to "bottom out" and may set up microfractures along the implant interface. Instead, once the threaded implant is introduced into the osteotomy and in final position, it is often unthreaded 1 to 2 mm to ensure that there is no residual pressure along the bone interface. Then, after 20 to 30 seconds, the implant may be reinserted to its final position. This step is primarily used in D1 bone because excessive initial strain may form at the interface of the cortical bone with even one extra rotation of the implant.[59] The rotational stress is usually highest at the crestal region, which may even cause mechanical bone microfracture and marginal bone loss.

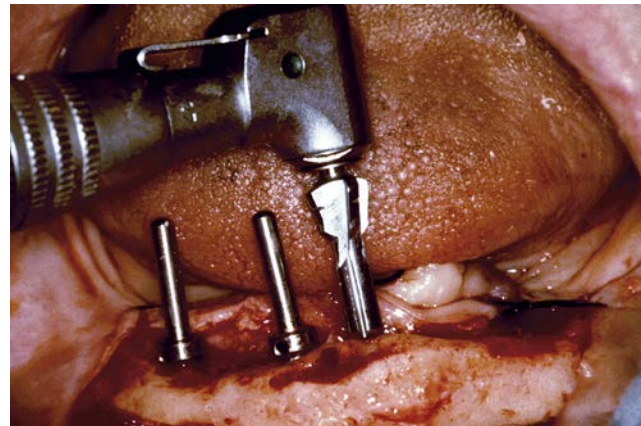
Use of Copious Amounts of Irrigation. As the depth of the osteotomy increases, the risk of the inadequate irrigation increases.[60] Therefore the bone dancing method of preparation is paramount, especially when reaching the apical area of the osteotomy. Copious amounts of either external irrigating drilling techniques should be used; however, many other factors should be understood. Irrigation, drill design, rotations per minute, and drill sizing are paramount to reduce heat. In addition, the chilling of the saline bags (i.e., placed in refrigerator before use) allow for the decrease in heat generation (Fig. 27.19).

Bone Debris Removal. During osteotomy preparation of D1 bone, fragments of bone often adhere to the flutes of the surgical burs. This bone is a great source for grafting around compromised sites after implant placement. Also, bone chips in the osteotomy may cause an increase in frictional heat and should be removed by irrigation in D1 bone to maintain optimal cutting action (Fig. 27.20). The bone debris should be frequently wiped off the cutting flutes of the drill with a surgical sponge. These bone shavings prevent coolant from reaching the bone and result in the drill being less efficient. The color of these bone shavings is important to evaluate. Any beige coloration to the bone debris indicates excessive heat is being generated and the bone debris is nonvital (Fig. 27.21). A brownish color indicates the bone cell death extends several millimeters away from the implant osteotomy. The color of the bone debris should be reddish or white, which indicates vital bone (Fig. 27.22).

Use of New Drills. The use of new drills with a sharp cutting flute is most critical for D1 bone surgery. Bone drills become dull after repeated use, especially if autoclaved frequently. Chacon and colleagues evaluated three different drill systems after repeated drilling and sterilization. The bone temperature 0.5 mm from the osteotomy preparation increased every 25 uses of the system, even though light microscopic evaluation showed little wear.[6] When the drills become dull, the clinician may not appreciate it in softer bone, but when D1 bone is prepared, the drill sharpness can become critical.

Larger Crest Module. Most implant designs have a larger crest module compared with the body of the implant. This design feature ensures a bone "seal" around the top portion of the implant after it is threaded into position. For example, a crest module is usually 4.1 mm for a 3.75-mm-diameter implant. Because the final osteotomy drill of many systems is in the 3.2-mm-diameter range, the 0.9-mm difference is substantial, especially in crestal cortical bone. As a result, a crestal bone drill is used in D1 bone, which prepares the larger diameter at the top of the osteotomy (Fig. 27.23). In a study by Novaes and colleagues, the difference in crestal bone loss after an initial healing period of 3 months was 1.5 mm between using a crestal drill compared with no crestal drill.[61] The additional bone trauma from compressing a larger crest module into the osteotomy is significant and may increase surgical
● **Fig. 27.19** (A) Pretapped bone site has less woven (newly generated) bone and illustrated less trauma on implant insertion. (B) A self-tapping implant insertion causes greater bone trauma and exhibits massive woven regenerative bone formation as a consequence. (From Watzek G, Danhel-Mayhauser M, Matejka M, et al. Experimental comparison of Brånemark and TPS dental implants in sheep [abstract]. In: *UCLA Symposium: Implants in the Partially Edentulous Patient*; 1990.)
● **Fig. 27.20** Bone chip debris should be frequently removed by irrigation in D1 bone to improve efficiency of the drill and before implant insertion after bone tapping.

● **Fig. 27.21** Bone debris in the drill should be evaluated. A brown or beige color indicates the temperature is too high and the bone is devitalized.

● **Fig. 27.22** Bone debris in the drill should be white or reddish, which indicates vital bone and ideal preparation conditions.


● **Fig. 27.23** Crestal bone tap should be used in D1 bone to prepare marginal bone to receive the crest module of the implant body, which is larger in diameter than the implant body.

bone loss around the implant (i.e., pressure necrosis). Therefore a crestal bone drill should be used in D1 bone as the last drilling step in the preparation of the osteotomy.

Final Implant Positioning. The ideal implant length for D1 bone is 10 mm for a 4-mm-diameter implant. There is little, if any, benefit to increased implant length beyond 10 mm in D1 bone for a threaded implant body because most all the stresses after healing are limited to the crestal half of the implant, with occlusal loading (Fig. 27.24). The longer implant makes bone preparation more difficult and generates more heat in this bone type. The final placement of the implant in relation to the crest of the ridge is related to its design and the bone density. A one-stage surgical approach is often used in D1 bone. A healing abutment may be added to permit the implant to heal above the soft tissue, thus eliminating a second-stage surgery.

The D1 dense compact bone is often of decreased height. Therefore the actual support system of the implant may be increased in

division C–h limited-height bone type by not countersinking the smooth portion of the implant crest module below the crest of the ridge. The smooth portion of the implant body may be placed above the ridge if no load is applied to the implant during initial healing, and the risk of micromovement during this period is minimal.

Bone Healing

Many of the cutting cones that develop from monocytes in the circulating blood and are responsible for bone remodeling at the implant interface. These blood cells originate from the blood vessels found in well-vascularized trabecular bone, which has a greater capacity for

regeneration than compact bone. Therefore in some aspects cortical bone requires greater healing time compared with trabecular bone.

On the other hand, because of the load-bearing capability of D1 bone and the excellent Bone-Implant Contact (BIC), prosthetic loading of D1 bone may start before the completion of the initial healing phase. Conditions that contribute to a lack of movement during healing are primordial to achieve a direct bone–implant interface. D1 bone is strong and often able to resist micromovement, regardless of whether an implant is loaded. As a result, immediate implant loading is often possible when multiple implants are splinted together, without compromise to the overall survival rate of the implant. However, most often, a blend of treatment conditions result in a minimum 3-month unloaded healing period in this bone type.
• **Fig. 27.24** D1 Bone: Mandibular cross-sectional image depicting mainly dense D1 bone.

Once the bone–implant interface is established, it exhibits the strongest load-bearing properties of any bone type. As a result, progressive bone loading is not necessary to develop a stable condition. The restoring clinician may proceed without delay as desired to the final prosthesis (Box 27.5; Fig. 27.25).

Dental Implant Surgical Protocol 2 (D2 Bone)

Dense-to-Thick Porous Cortical and Coarse Trabecular Bone (D2)

The second density of bone found in the edentulous jaws (D2) is a combination of dense-to-porous cortical bone on the crest and coarse trabecular bone within the cortical plates (Fig. 27.26). The Hounsfield values on reformatted CBCT images are 750 to 1250 units for this bone quality. The tactile feeling when preparing this bone density is similar to preparations in spruce or white pine wood (i.e. soft wood). The D2 bone trabeculae are 40% to 60% stronger than D3 trabeculae. This bone type occurs most frequently in the anterior mandible, followed by the posterior mandible. On occasion it is observed in the anterior maxilla, especially for a single missing tooth, although the dense-to-porous cortical bone is then found primarily on the lingual surface of the implant site.[62]

• **BOX 27.5** **implant Placement Surgical Protocols**

D1 Bone Surgical Protocol
- Drilling speed: ~2000 to 2500 rpm
- Bone tap: 25 rpm
- Irrigation: copious amounts of saline
- Bone dance: very critical to reduce heat
- Drill osteotomy multiple times with each drill to *oversize osteotomy*
- Ideally use new drills
- Always insert implant with hand wrench, not a handpiece
• **Fig. 27.25** D1 implant placement surgical protocol. In this protocol, all surgical burs, including a bone tap are used.

Advantages of D2 Bone

D2 bone provides excellent implant interface healing, and osteo-integration is very predictable; therefore it is the ideal type of bone. There exist no disadvantages in D2 bone.

Most implant systems refer to this density of bone for their generalized surgical protocol. The dense-to-porous cortical bone on the crest or lateral portions of the implant site provide a secure initial rigid interface. The implant may even be placed slightly above the crest of the ridge, with decreased compromise or risk of movement at the interface during healing compared with softer bone types. The intrabony blood supply allows bleeding during the osteotomy, which helps control overheating during preparation and is most beneficial for bone–implant interface healing.[63]

Implant Osteotomy Surgical Sequence

The drill sequence for D2 bone is similar to D1 bone, with a few exceptions. Therefore all drills in the surgical sequence are used except the bone tap. The use of a bone tap for D2 bone is dependent on the final osteotomy size, the implant body size, the depth of the thread, and the shape of the thread. A bone tap most often will lead to a decreased primary stability in D2 bone. A crestal bone drill should be used for most implant designs in D2 bone.[64] The osteotomy preparation should proceed at a higher speed (e.g., ~2000 rpm). Sharawy and colleagues showed that D2 bone with an osteotomy depth of 8 mm could be prepared in 4 to 8 seconds, dependent on drill design and rpm.[39] Therefore the osteotomy depth should not proceed slowly, creating additional heat. Enough pressure should be placed on the handpiece to proceed approximately at least 5 mm every 5 seconds.

The implant may be threaded into position with a low-speed (less than 30 rpm), high-torque (75 N/cm) handpiece, rather than using a hand ratchet. The handpiece allows a more precise implant rotation, and a constant pressure ensures the implant will progress into the site without risk of stripping the bone

● **Fig. 27.26** D2 bone has a dense to porous cortical crest, and inner trabecular bone is coarse. It is found most often in the anterior mandible.

within the threads. During this process, the irrigation may be stopped so the patient does not attempt to close the mouth and swallow, which may contaminate the implant and cause it to be pushed off the axis of the implant osteotomy. However, if minimal bleeding is present, then a small amount of irrigation may be used.

A threaded implant placed in the anterior mandible engages the cortical bone at the edentulous crest, and often the lingual lateral side. In division C–h bone, the implant may also engage the apical cortical region; however, in the mandible, care should be exercised to not perforate the inferior border. This provides immediate stability and proven long-term survival.

When the anterior maxilla presents this bone density, it is treated similarly to the D2 mandible. A threaded implant should engage the palatal cortical plate rather than the labial cortical bone, which is thinner and porous. However, care should be exercised because the implant may be pushed more labial, even stripping the facial plate. The anterior maxilla usually has less available bone height than does the anterior mandible. As a result, the apex of the implant may engage the thin cortical plate of the floor of the nose when a solid, traditional screw-type system is used. Because the greatest stresses after healing are primarily transmitted around the crest, the primary advantage of the apical end of the implant engaging cortical bone is initial stability during healing.

Healing

The excellent blood supply and rigid initial fixation of D2 bone permits adequate bone healing within 4 months. The lamellar bone–implant interface is more than 60% established at the 4-month healing interval. BIC is approximately 70% at this point in time, especially when cortical bone engages the lateral and lingual portions of the implant (Fig. 27.27). Abutment placement and prosthodontic therapy may then commence. It should be noted that the time frame for initial bone healing is based on the density of the bone and not on the location in the jaws. Therefore a 4-month rigid healing phase is adequate for porous cortical and coarse trabecular (D2) bone, even when found in the maxilla. Progressive bone loading is usually not required for D2 bone, although an increase in BIC takes place during the initial loading period (Box 27.6; Fig. 27.28).

Dental Implant Surgical Protocol 3 (D3 Bone)

Thin Porous Cortical and Fine Trabecular Bone (D3)

The third density of bone (D3) is composed of thinner porous cortical bone on the crest and fine trabecular bone within the ridge (Fig. 27.29). The CBCT-reformatted images may have a range of 375 to 750 HU. This bone quality provides the clinician with a tactile sense similar to drilling in compressed balsa wood. The trabeculae are approximately 50% weaker than those in D2 bone. D3 bone is found most often in the anterior maxilla and posterior regions of the mouth in either arch. It may also be found in the division B edentulous ridge, modified by osteoplasty to provide adequate width for a root-form implant placement. Sinus augmentation grafts are often D3 bone in the posterior maxilla after a healing period of 6 months or more.[65] D3 bone is least prevalent
● **Fig. 27.27** Bone-implant contact is approximately 70% in D2 bone after initial healing and is excellent for load-bearing capability.

in division C–h or division D anterior mandibles. Larger diameter implants (5 mm or 6 mm) are more essential in D3 bone in the molar regions than in the previous categories. A roughened implant body (i.e., such as acid-etched media or resorbable blast media) presents advantages in this bone density, regardless of design, to compensate for the limited initial bone contact and decreased bone strength inherent in the trabecular architecture.

The porous cortical layer is thinner on the crest and labial aspect of the maxilla, and the fine trabecular pattern is more discrete in wide edentulous sites. The D3 anterior maxilla is usually of less width than its mandibular D3 counterpart. The D3 bone is not only 50% weaker than D2 bone, but the BIC is also less favorable in D3 bone. These additive factors can increase the risk of implant failure. Therefore small-diameter implants are not suggested in most situations. Instead, bone spreading in this bone density is mechanically easier to perform (i.e. less cortical thickness) and allows the placement of greater diameter implants. The increased-diameter implants lead to improved prognosis, especially when lateral forces or greater force magnitudes are expected. In addition, bone spreading compacts the trabecular bone and increases its density after initial healing (e.g., OD).

Advantages of D3 Bone

The main advantage of D3 porous compact and fine trabecular bone is that the implant osteotomy preparation time and difficulty is minimal for each drill size and is usually less than 10 seconds. The crest module drill and bone tap may be eliminated in the surgical protocol. Blood supply is excellent for initial healing, and intraosseous bleeding helps cool the osteotomy during preparation. As a result, this bone density is usually associated with a high surgical survival rate.

Disadvantages of D3 Bone

D3 bone also presents several disadvantages. It is more delicate to surgically manage than the previous two bone density types as its preparation takes minimal effort.

● **BOX 27.6** **D2 Bone Surgical Protocol**

- Drilling speed: ~2000 to 2500 rpm
- Bone tap: usually not needed
- Irrigation: copious amounts of saline
- Bone dance: very critical to reduce heat
- Implant placement: with insertion wrench or handpiece

Twist Drill	Parallel Pin	Twist Drill	Twist Drill	Shaping Drill	Final Drill
Ø1.5 8 mm	Ø4.3 mm	Ø2.4/1.5 8 mm	Ø3.0 11.5 mm	Ø3.5 11.5 mm	Shaping Drill
					Ø4.3 11.5 mm

● **Fig. 27.28** D2 surgical protocol. Note the use of all surgical burs except the bone tap.

D3

● **Fig. 27.29** D3 bone exhibits minimal cortical bone and thin trabecular bone.

The motor speed in drilling the osteotomy is not as important as in D1 or D2 bone. Therefore bone preparation in D3 bone can range from 1000 to 2000 rpm and must be made with constant care of direction to avoid enlargement or elliptical preparation of the site.

A common mistake that causes an elliptical site (i.e., over-sized osteotomy) to form is the pronation of the wrist, which redirects the handpiece direction. In dense bone, the side of the drill encroaches on the dense cortical crest, which opposes the movement and stops the rotation before the crestal osteotomy is enlarged. In D3 bone the arc pathway is not stopped and the osteotomy at the level of the crestal bone is of greater diameter than the drill. If the implant design does not increase at the crestal region, then the surgical defect created around the crestal area of the implant may heal with fibrous tissue rather than bone and cause an initial bony pocket.

Therefore the osteotomy should be drilled with the arm in a "drill press" type of motion (i.e., in one plane). To improve rigid fixation of traditional root-form designs during healing, the opposing thin cortical bone of the nasal or antral floor is often engaged in the maxilla or the apicolingual plate in the mandible, when immediate loading (IL) is considered. If the original implant height determined before surgery does not engage the opposing cortical bone, then the osteotomy is increased in depth until it is engaged. Slightly longer implants may be placed in this approach to further increase surface area of support. However, it should be remembered that this technique improves stability during healing but does not decrease the crestal loads to bone after healing. Instead, implant crest module design and the crestal one-third of the implant body design are necessary to decrease stress when the implant prosthesis is loaded.

The clinician must be careful to avoid undesired lateral perforations of the cortical bone during osteotomy procedures, especially on the thin, labial porous cortical plate of the maxilla. A common mistake is the stripping of the thin facial plates during the osteotomy. The initial and intermediate drills proceed through the fine trabecular bone without incident. However, the lingual aspect of the end-cutting drill contacts the thick palatal cortical bone within the osteotomy, which resists preparation, and pushes the drill facially, which may strip the facial plate. A very firm hand, which prevents lateral displacement of the drill and handpiece during the implant osteotomy and does not permit the drill to move facially, is mandatory to prevent this unwanted complication.

Implant Osteotomy Surgical Sequence

In D3 bone, the final drill (i.e., in some systems the final two drills) is not used because the placement of the implant allows for the lateral displacement of the bone, increasing bone density. A crestal bone drill should not be used in D3 bone. The thin, porous cortical bone on the crest provides improved initial stability of the implant when it is compressed against the crest module of the implant. Unlike D1 and D2 bone, the final drill diameter (3.0–3.4 mm for a standard-diameter implant) is of benefit for the 4.1-mm to 4.2-mm crest module dimension to compress the weaker bone. The compressed soft bone not only provides greater stability, but it heals with a higher BIC, which is a benefit during the initial bone-loading process.

A bone tap is never indicated in D3 bone because the fine trabeculae are 50% weaker than D2 trabeculae, and when the implant is threaded into position, it compresses the bone. This provides improved initial stability and increases the BIC during initial healing. Bone compaction is a benefit when the bone density is poor. Because crest module drills and a bone tap are usually not used in D3 bone, the number of steps and time of preparation are reduced. With any drill in D3 bone, it should only be passed once in the osteotomy to avoid oversizing the preparation. On the other hand, a complication often occurs when inserting the threaded implant into the prepared bone site of the anterior maxilla. The threaded implant does not completely thread into the more dense palatal plate of bone in this region, and the implant may be pushed facially, often stripping the facial bone because the implant is threaded into position. This often occurs when a ratchet is used instead of a handpiece when placing the implant. A hand ratchet often will distort and widen the top of the osteotomy and impair proper bone contact with the crest module of the implant. In addition, the hand ratchet will often push the implant toward the facial bone, into the softer bone. This causes the implant to be positioned more facially than originally prepared and may even strip the thin cortical plate on the facial aspect of the osteotomy.

In abundant bone volume, the implant may self-tap the soft, thin, trabecular bone to enhance initial stability. An implant with a wider crest module can compress the crestal bone when inserted without using a countersink drill. The implant should not be removed and reinserted because initial rigid fixation may be compromised. If the only cortical bone is on the crest of the ridge, as in a posterior mandible, the implants are not countersunk below the crest in this density of bone. The thin, porous cortical plate provides greater initial stability than the fine trabecular bone underneath. This is especially important in the posterior mandible of a clenching parafunctional patient because bone torsion occurs during heavy biting pressures.

Therefore for placement of an implant in D3 bone, a low-speed (30 rpm), high-torque handpiece should be used rather than a hand wrench for self-tapping implant insertion. This

Twist Drill   Parallel Pin   Twist Drill   Twist Drill   Shaping Drill
Ø1.5 8 mm   Ø4.3 mm   Ø2.4/1.5 8 mm   Ø3.0 11.5 mm   Ø3.5 11.5 mm

decreases the risk of oversizing the osteotomy with an elliptical implant insertion, which usually results from hand wrench placement in softer bone. A firm hand during handpiece insertion also can prevent the implant from being pushed facially and away from the thicker lingual cortical plate. Tightening a threaded implant to increase fixation once completely inserted is not recommended because stripping of the threads and decreased fixation may occur.

A roughened surface condition or coating on a threaded implant body is advantageous in this soft bone condition to enhance initial stability and the amount of initial trabecular bone at the bone–implant interface. The amount of bone initially at the bone–implant interface is reduced compared with bone types D1 and D2. If the lingual and apical cortical bone are not engaged at the time of implant placement, then less than 50% of the implant surface may actually contact bone. An additional implant may be used to improve load distribution and prosthodontic support during the early loading period. Often a two-stage technique is recommended to minimize premature loading of the implant (Fig. 27.30; Box 27.7).

Healing

The time frame for atraumatic healing is usually 5 months or more. The actual implant interface develops more rapidly than D2 bone; however, the extended time permits the regional acceleratory phenomenon (RAP) from implant surgery to stimulate the formation of more trabecular bone patterns. In addition, the more advanced bone mineralization within the extra months also increases its strength before loading. An extended gradual loading period (e.g., progressive bone loading) is also recommended to further improve this bone density during the initial bone loading (Box 27.8).

• BOX 27.7   Disadvantages of D3 Bone

Bone-Implant Contact
- Approximately 50%
- Longer healing period
- Additional implants recommended

Implant Placement
- One chance, widen osteotomy
- Thin crestal cortical bone which decreases primary stability
- Greater risk of overload during healing

• BOX 27.8   D3 Bone Surgical Protocol

- Underprep: no last bur (osseodensification)
- Drilling speed: ~1000 to 2500 rpm (speed not as important in poorer quality bone)
- Final drill and bone tap: not used
- Irrigation: copious amounts of saline
- Bone dance: not as critical in comparison to better quality bone
- Implant placement: handpiece

Dental Implant Surgical Protocol 4 (D4 Bone)

Fine Trabecular Bone (D4)

Fine trabecular (D4) bone has very little density and little or no cortical crestal bone. It is the opposite spectrum of dense cortical (D1) bone. The most common locations for this type of bone are the posterior molar region of a maxilla in the long-term

edentulous patient, or in an augmented ridge in height and width with particulate bone or substitutes, or in a sinus graft. It is rarely observed in the mandible but on occasion does exist. These edentulous ridges are often very wide but have reduced vertical height. This bone type is also present after osteoplasty in wide D3 ridges because the crestal cortical bone is removed during this procedure.

The tactile sense during osteotomy preparation of this bone is similar to stiff, dense Styrofoam. The bone trabeculae may be up to 10 times weaker than the cortical bone of D1. The BIC after initial loading is often less than 25% (Fig. 27.31). A CBCT scan with reformatted images of D4 bone has a Hounsfield number of 0 - 350 HU. units.

Division B implants are not suggested in this bone type. Bone spreading is easiest in this bone density, and larger diameter implants are suggested whenever possible. A roughened implant surface coating is almost mandatory to improve the amount of BIC in this bone quality after initial healing.

Disadvantages of D4 Bone

Fine trabecular bone presents the most arduous endeavor to obtain rigid fixation. Bone trabeculae are sparse and, as a result, initial fixation of any implant design presents a surgical challenge (Fig. 27.32).

Additional implants are placed to improve implant-bone loading distribution and prosthodontic rehabilitation, especially during the first critical year of function. For fixed restorations, no cantilever on the prosthesis is used with this bone density. An additional implant may be placed at the time of surgery in the second molar region to further improve support. The implant of choice in the wide posterior maxilla with D4 bone is a greater diameter and roughened surface. or HA-coated threaded implant. When properly inserted, the-threaded implant can be more stable and provides greater surface area. The larger diameter implant offers greater surface area for support, further compresses the fine trabecular bone for greater initial rigidity, has a greater chance to engage the lateral regions of cortical bone for support, and improves stress transfer during loading (Box 27.9).

Implant Osteotomy Drilling Sequence

The initial drill and possibly the second drill are used to determine site depth and angulation is the only one that should be used in this bone type, after which osteotomes may be used with a surgical mallet or handpiece to compress the bone site, rather than remove bone, as the osteotomy increases in size (Figs. 27.33 and 27.34).

The compaction technique of the site is prepared with great care. The bone site may be easily distorted, resulting in reduced initial stability of the implant. The final osteotomy diameter is similar to the D3 preparation. The residual ridge is easily expanded in this bone type. The osteotomy may both compress the bone trabeculae and expand the osteotomy site.

The implant should self-tap the bone or shape the implant receptor site while being seated with a slow-speed, high-torque handpiece. A hand wrench is contraindicated because it may deviate the positioning of the implant. The pressure on the implant during insertion corresponds to the speed of rotation, and the implant proceeds to self-tap the soft bone. It is difficult to thread an implant in soft bone in difficult access regions. If there is any cortical bone in the opposing landmark, it is engaged to enhance stability and simultaneously ensure the maximum length of

● **Fig. 27.31** Posterior maxillary region may be D4 bone, with bone-implant contact after initial loading no greater than 25%.

Bone Anatomy
Location:
- Minimal cortical crest, decreased primary stability cortical crest
- Decreased bone height (i.e. maxillary posterior)
- Requires more implants

Osteotomy
- Must undersize osteotomy for osseodensification
- Surgical Access (i.e. posterior maxilla)

---

implant. An implant with a greater crestal diameter presents the added benefit to further compress the crestal bone for stability.

Once inserted, the implant should not be removed and reinserted; instead, one-time placement is mandatory. The implant is countersunk in this bone if any risk of loading is expected during healing (e.g.,
● **Fig. 27.33** Bone compaction technique to prepare the implant site, which results in osseodensification.

● **Fig. 27.34** Bone compaction instruments (osteotomes) are used after the initial pilot drill to prepare the osteotomy.

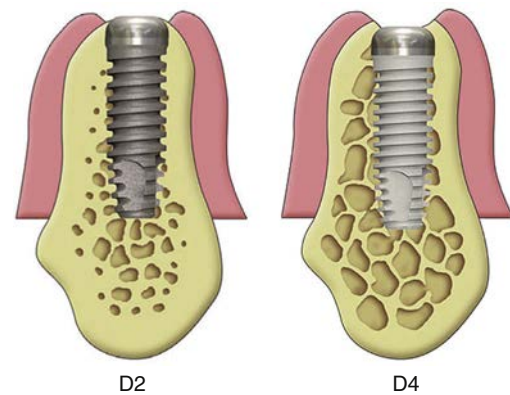
under a soft tissue–borne prosthesis). Countersinking the implant below the crest reduces the risk of micromovement during healing in this very soft bone No countersink drill is used before countersinking. A two-stage technique is recommended because this will minimize premature loading of the implant (Fig. 27.35; Box 27.10).

Healing

The healing and progressive bone-loading sequence for D4 bone require more time than the other three types of bone. Time is needed to allow bone to remodel at the surface and to intensify its trabecular pattern. The additional time also allows a more advanced bone mineralization and increased strength. Six or more months of undisturbed healing is suggested. The compression technique for surgery, the extended healing time, and progressive bone-loading protocol allow the remodeling of this bone into a more organized and load-bearing quality similar to D3 bone before the final prosthetic loading of the implants (Fig. 27.36).

Primary Stability

Accurate assessment of primary stability is crucial in the implant placement protocol. Methods of measuring implant stability

D2   D4


● **Fig. 27.35** In D4 bone, the implant is often countersunk below the crest of the ridge, wherever a soft tissue–borne restoration is worn during the initial healing phase. In D2 bone, the implant is usually placed at the crest of the bone.

• BOX 27.10 D4 Bone Surgical Protocol

- Underprep (osseodensification)
- Drilling speed: ~1000 to 2500 rpm (speed not as important in poorer quality bone)
- Irrigation: copious amounts of saline
- Bone dance: not recommended as will enlarge osteotomy
- Implant placement: handpiece (do not deviate from original osteotomy)

include percussion testing, IT, reverse torque testing, resonance frequency analysis (RFA), and surgical experience.

Periotest

In the early days of implantology, instrumented percussion testing used the Periotest system. Periotest evaluations have been used to gauge primary stability. The system is composed of a metallic tapping rod in a handpiece, which is electromagnetically driven and electronically controlled. Signals produced by tapping are converted to unique values called Periotest values. These results are expressed in arbitrary units with acceptable Periotest values in the ranges of –4 to –2 and –4 to +2. However, today this device has been supplanted by RFA because of the lack of reproducibility of results derived from Periotest measurements (Fig. 27.37).

Resonance Frequency Analysis

In implantology today, the more common method of determining primary stability is resonance frequency analysis (RFA). RFA is a testing method that provides objective and reliable measurements of lateral micromobility at various stages of the implant treatment process. The method analyzes the first resonance frequency of a small transducer attached to an implant or abutment. It can be used to monitor the changes in stiffness and stability at the implant–tissue interface and to discriminate between successful implants and clinical failures. The Implant Stability Quotient (ISQ) is the scale of measurement for use with the RFA method.

This more objective assessment of stability may help improve a clinician's learning curve and is useful for future comparison. Multiple studies[66,67] have determined that an acceptable stability range lies between 55 and 85 ISQ, with an average ISQ level of 70.[68]

Twist Drill Ø1.5 8 mm · Parallel Pin Ø4.3 mm · Twist Drill Ø2.4/1.5 8 mm · Osteotome Ø3.0 mm · Osteotome Ø3.5 mm
• **Fig. 27.36** D4 surgical protocol. Only one to two burs are used, then osteotomes osseodensify the osteotomy, which results in an increased bone density.
• **Fig. 27.37** Periotest, which uses a tapping rod to evaluate implant stability.

Various studies have shown that the RFA protocol can provide the clinician with important information about the current status of the bone-implant interface via ISQ values. In combination with clinical and radiographic findings, the use of RFA can be used as a valuable diagnostic adjunct with regards to the bone density, healing protocols, and loading protocols for dental implants, as well as recognizing the potential failure of implants.

Sennerby reported on a classification of ISQ values in relation to the health of dental implants. The ISQ values were placed into three zones based on RFA measurements at the time of implant placement. Recommendations include the "safe zone" which includes ISQ values of 70 or above. These high ISQ values are usually suitable for immediate load protocols. The second classification includes "questionable" implants, which represent values from 55 – 70 ISQ. Values in this range require continuous monitoring to determine if ISQ numbers increase after longer healing. It is recommended that implants with ISQ's in this range should undergo progressive bone loading techniques. The last zone includes implants with an ISQ value of less than 55. These implants are compromised and may be associated with an increased failure rate. Therefore, increased healing times are recommended along with progressive bone loading protocols. If subsequent readings still remain low after healing and progressive bone loading protocols, further healing may be warranted.[69]

Numerous studies have shown the successful use of RFA in the evaluation of implant health. Sjöström et al.[70] evaluated the primary stability of maxillary implants of successful vs. failed implants. The average ISQ for the successful implants were 62 ISQ and the failed implants were 54 ISQ. Turkyilmaz and McGlumphy in a retrospective study of 300 implants over three years showed failed implants with an average ISQ of 46 and successful implants an average of 67 ISQ. In the evaluation of Hounsfield units and insertion torque, similar significant differences were found.[71] (Fig. 27.38; Box 27.11).

In general, the RFA technique via ISQ values provide valuable information on the current status of the implant–bone interface. The ISQ values correlate to the micromobility of the implant, which is directly related to the biomechanical properties of the surrounding bone tissue and the quality of the bone-implant interface. Through various studies, it has been shown that lower ISQ values are directly associated with eventual implant failure. Therefore, the RFA technique is a valuable modality in evaluating dental implant health during any phase of the implant process.[72]

● **Fig. 27.38** Penguin RFA. (A) Penguin RFA measures implant stability and osseointegration. (B) Reusable MulTipeg is inserted into the implant body. (C) Penguin is placed in approximation to the reusable MulTipeg. (D) Final reading of the RFA, ideally the Implant Stability Quotient reading will be greater than 55.

One-Stage versus Two-Stage

The clinician is often confronted with the choice of completing the dental implant procedure with a one-stage or a two-stage protocol. Numerous studies have shown no difference in success rates between the two techniques.[73,74]

Two-Stage Surgery

The two-stage surgery technique involves the placement of the implant and a low-profile cover screw, which is inserted into the implant body. When the cover screw is in final position, it may be slightly tightened, loosened, and tightened again. No tissue, blood coagulants, or bone particles should prevent the complete seating of the cover screw. In addition, the cover screw should not be tightened with significant force because this may result in the implant rotating, which increases the possibility of nonintegration.

The two-stage surgical approach offers several advantages. By submerging the implant below the tissue, no pressure is placed on the surgery site, allowing the implant to heal undisturbed. In addition, there exists less chance of infection, and overloading the implant prematurely is less likely. However, with a two-stage approach, a second-stage surgery is required, which usually will lead to longer healing times. Studies have shown that less keratinized tissue is present compared with a one-stage protocol.

The indications for a two-stage surgery include anytime primary stability is in question, such as compromised bone density. If excessive parafunctional habits are present, then submerging the implant is an ideal treatment to minimize the possibility of biomechanical overloading. Last, if bone grafting procedures are used in conjunction with the implant placement, then undisturbed healing via a two-stage technique is ideal (Fig. 27.39; Box 27.12).

One-Stage Surgery

A one-stage surgical protocol involves the placement of a healing abutment that extends slightly above the crest of the tissue. The soft tissue is then sutured around the healing abutment to form a soft tissue drape during the healing period. There are numerous advantages to the one-stage surgery technique.

One advantage is that the soft tissue matures while the bone interface is healing. This permits the restoration to be fabricated with complete assessment of the soft tissue profile. In the two-step
● **Fig. 27.39** After implant placement, a cover screw is inserted into the implant. A second-stage surgery is indicated to expose the implant for prosthetic rehabilitation.
● **Fig. 27.40** After implant placement, a healing abutment is inserted into the implant to allow for ideal soft tissue healing.

● **BOX 27.12** **Two-Stage Surgical Protocol**

Advantages:
• Submerged implant
• No pressure on surgery site
• Less chance of infection

Disadvantages:
• Second-stage surgery needed
• Longer healing times
• Less keratinized tissue versus one-stage

Indications:
• ? Primary stability
• Bone grafting/membranes
• Parafunction/force issues

● **BOX 27.13** **One-Stage Surgical Protocol**

Advantages:
• No second surgery
• Shortens treatment time
• Better tissue health

Disadvantages:
• Healing abutments can be loose
• Force-related issues
• Less space for interim prosthesis

Indications:
• Favorable primary stability
• No bone grafting/membranes
• No parafunction/force Issues

---

procedure, the soft tissue is less mature when the prosthesis is fabricated because a stage II surgery is required to uncover the implant and place a healing abutment.

Because a healing abutment has been placed on the implant, a second surgical procedure and suture removal appointment are not necessary. This saves the patient discomfort and results in two less appointments (stage II uncovery and suture removal).

The abutment to implant connection may be placed above the crest of bone in the one-stage surgery. This higher location of the implant–abutment connection may reduce some of the early crestal bone loss in a developing implant interface. In addition, Weber observed an improved hemidesmosome soft tissue–implant connection when the components above the bone were not removed and reinserted, such as when the healing gap connection is below the bone.[75] Depending on the crest module design, the one-stage surgical approach may have less early crestal bone loss.

The one-stage technique also has numerous disadvantages. The higher profile permucosal extension (PME) is more at risk of loading during healing, especially when an overlying soft tissue–borne transitional restoration is worn. Therefore a disadvantage may be a higher healing failure rate. However, clinical studies of one-stage surgery indicate similar implant survival rates in good bone volumes and quality.

Because the healing abutment is placed with finger pressure, patients may tend to place unnecessary force on the abutment via their tongue. This may result in the loosening of the abutment and possible aspiration. If the healing abutment becomes partially loose, then soft tissue will often grow in between the abutment and implant, preventing complete seating of the prostheses. When a bone graft is placed at the time of implant insertion, primary closure of the soft tissues improves the environment to grow bone. Therefore the one-stage approach is indicated less often under these conditions.

A one-stage surgical protocol is indicated when implant placement involves excellent primary stability. The patient should not exhibit any parafunctional or force-related habits and there should be no bone grafting procedures completed in conjunction with the implant placement (Fig. 27.40; Box 27.13; Table 27.1).

Summary

Bone remodels in relation to the forces exerted on it. Depending on the location of the edentulous ridge and the amount of time the area has been edentulous, the density of bone is variable. Clinically, the surgeon can correlate the hardness of the trabecular bone and the presence of a cortical plate with four different densities of bone. The typical locations of these different densities, the alteration in surgical technique with each type, and the advantages and

TABLE 27.1   Surgical Preparation and Implant Insertion Protocol

Bone Density	Location	Similar Density	Drilling Protocol	Drilling Speed	Insertion Level	Insertion Technique	Ideal Healing
D1	Anterior mandible	Maple/oak wood	All drills + bone tap	2000 rpm (bone dancing)	At or slightly above crest	Hand ratchet	3–4 months
D2	Anterior mandible Posterior mandible, Anterior maxilla	White pine wood	All drills (possible bone tap)	2000 rpm (bone dancing)	Level with crest	Hand ratchet or handpiece	4 months
D3	Anterior maxilla Posterior mandible	Balsa wood	All drills except last shaping drill	~1000 rpm	At or slightly below crest	Handpiece (30 rpm)	4–5 months
D4	Posterior maxilla	Styrofoam	Only one to two beginning burs, then osteotomes	~1000 rpm	Slightly below crest	Handpiece (30 rpm)	5–6 months

disadvantages of each have been related to each density classification. The dense cortical bone of D1 is the strongest bone, approximately 10 times greater than D4 bone, and is the most difficult to prepare. The thick, porous cortical and coarse trabecular D2 bone is twice as strong as D3 bone and is ideal for implant support. The thin, porous cortical and fine trabecular D3 bone is similar to preparations in compressed balsa wood. The fine trabecular bone of D4 is similar to osteotomies in dense Styrofoam. The initial drills may be used to distinguish among the four bone density types.

A surgical preparation and implant insertion protocol has been discussed which relates specifically to the bone density. D1 bone heals with a lamellar bone interface and has the greatest percentage of bone at the implant body contact regions. D2 bone heals with woven and lamellar bone, is adequately mineralized at 4 months, and often has approximately 70% bone in initial contact after healing with the implant body. D3 bone has about 50% bone at the initial implant interface after healing and benefits from a roughened surface on the screw-shaped implant body to increase initial fixation and bone contact. An additional 1 month (total of 5 months) is used for initial bone healing, compared with D2 bone, to permit a greater percentage of bone trabeculae to mineralize and form around the implant. D4 bone density has the least amount of trabeculae at implant placement. Additional time for bone healing and incremental bone loading will improve the density and result in implant survival similar to that of other bone densities.

Ideal Implant Positioning

RANDOLPH R. RESNIK AND CARL E. MISCH[†]

To obtain ideal esthetics and function of an implant-supported prosthesis, the three-dimensional positioning of the dental implant within the bone is critical. The malposition of the dental implant can lead to significant implant complications and increased morbidity. Nonideal implant positioning may result in undesirable outcomes that may ultimately affect the success and longevity of prosthetic rehabilitation.[1] To achieve an ideal result for the patient, a clinician must be conscious of the implant placement with respect to the ideal and correct orientation of the final prosthesis design. Optimal dental implant positioning is dictated by the three-dimensional placement of implants with respect to the biomechanical and prosthetic principles related to the final implant prosthesis.

Recently advances in implant dentistry technology have created a greater appreciation for the esthetic results of the implant restoration. Implant dentistry has experienced a profound shift from a functional thought process with a surgical approach to esthetics, to a more prosthetically and biologically driven protocol.[2] The dental implant should be positioned in ideal relationship to the position of the existing teeth, vital structures, and other implants, as well as the buccolingual, mesiodistal, and apicocoronal dimensions. When implants are positioned with no emphasis to the three-dimensional location, any of the following detrimental effects may occur (Fig. 28.1) Box 28.1:

> • BOX 28.1 **Non-Ideal Implant Positioning Complications**
>
> - Increased implant morbidity
> - Increased prosthetic complications (e.g., esthetics, prosthesis)
> - Increased prosthetic costs (e.g., implant parts, laboratory costs)
> - Increased peri-implant complications
> - Decreased longevity of prosthesis
> - Less patient acceptance

The ideal three-dimensional positioning of a dental implant needs to be addressed before the surgical procedure. Lack of proper planning may lead to malpositioning which may be evaluated in the three spatial planes. The placement of a dental implant in available bone is comparable to an object in space that is defined by "x," "y," and "z" coordinates. In implant dentistry, the x-axis is defined by the mesiodistal plane, the y-axis is the buccolingual dimension, and the z-axis is known as the apicocoronal (length of implant body in relation to the osseous crest).[3] Unfortunately,

[†]Deceased

many dental implants are placed within the existing available bone without respect to the three dimensions. In this chapter, the proper positioning of implants will be discussed according to the final prosthetic needs and demands of the patient and the treatment protocols for implants that are placed in nonideal positions.

"X"-Axis (Mesial-Distal) Positioning

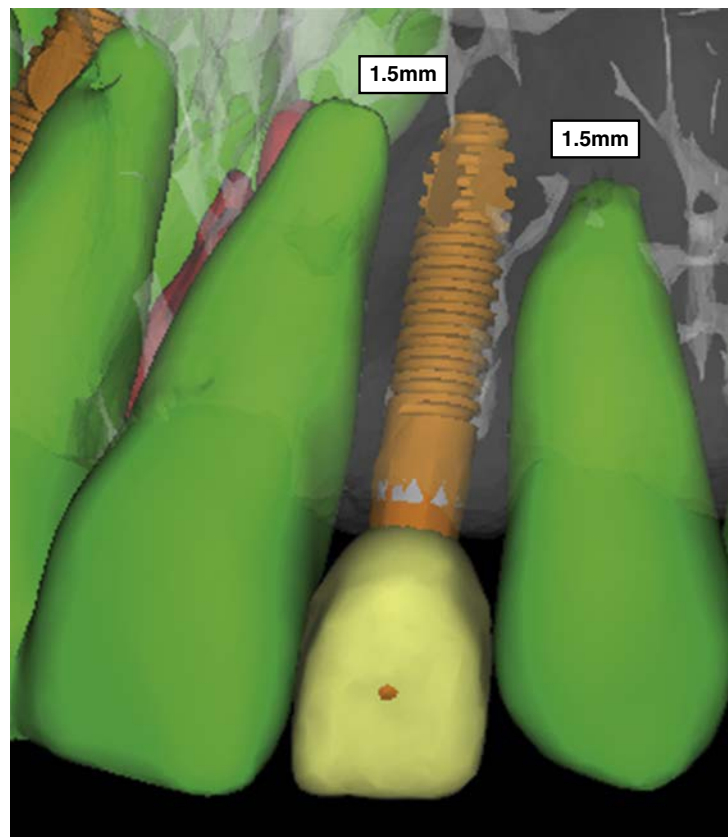
Insufficient Implant–Tooth Distance (Apical)

Ideal Positioning
Ideally, it is best to allow at least a minimum of 1.5 mm from the adjacent tooth root or tooth structure.[4] Maintaining this amount of space from a tooth root decreases the possibility of causing damage to the tooth and postoperative complications (Fig. 28.2).

Pretreatment Evaluation
Preoperatively, the most accurate technique to determine available space for an implant adjacent to a tooth is with a cone beam computerized tomography (CBCT) axial image. The ideal x-axis angulation and position needs to be determined via interactive CBCT treatment planning and transferred to the surgical procedure. This is most easily accomplished with a CBCT-generated surgical template. If the implant placement is being completed freehand, then an intraoral radiograph (e.g., periapical) should be used after the first pilot drill to determine ideal positioning with respect to the adjacent teeth. After initial evaluation, the osteotomy positioning may be changed or modified via a Lindemann drill (i.e., side-cutting bur) (Fig. 28.3).

Implants that are positioned too close to an adjacent tooth root are usually the result of poor treatment planning (inadequate space), poor surgical technique (improper angulation), or placement of an implant body that is too wide. This may also occur when root dilacerations of an adjacent tooth exist or if a tooth has been orthodontically repositioned to where the tooth root has encroached on the intraroot space.

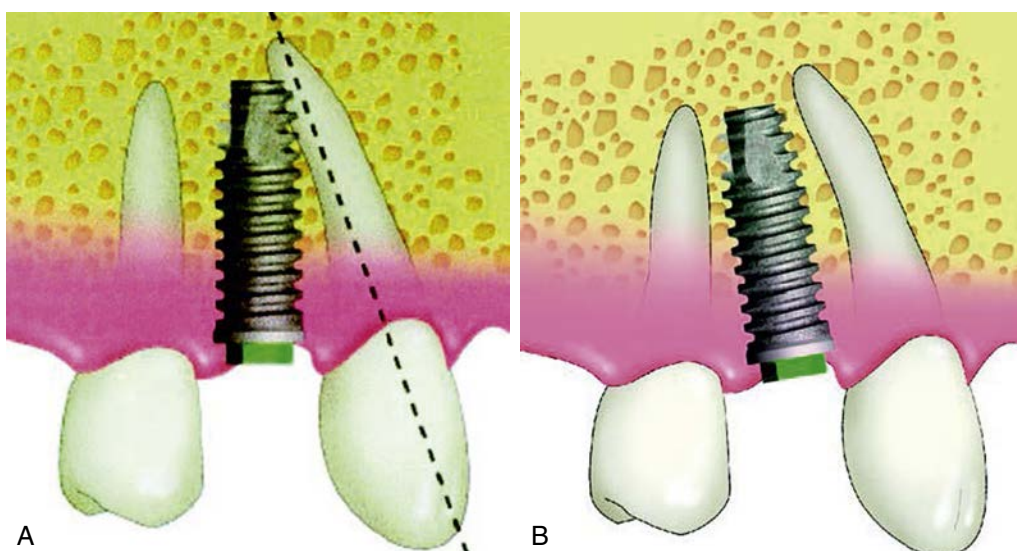
The maxillary lateral incisor position may pose a significant challenge in some cases, especially if the area is replacing a congenitally missing lateral incisor. Often, after orthodontic treatment, there exists an ideal mesiodistal distance of the clinical crowns; however, compromised intraroot distance may result because of tilting the teeth orthodontically into position (i.e., clinical crown of the central incisor moves mesially and apical root moving distally). Lack of space may contraindicate implant placement or require orthodontic treatment for repositioning of the roots (Fig. 28.4).

Another common area for root approximation complications is the maxillary first premolar edentulous site. Careful consideration for the angulation of a natural canine must be evaluated. The 11-degree
• **Fig. 28.1** Malpositioned implants. (A) Mandibular posterior implants placed too close together, too much distance from anterior adjacent tooth, and poor angulation. (B) Maxillary left implant with poor positioning and angulation. (C and D) Maxillary implant placement with no regards to positioning and final prosthesis.


• **Fig. 28.2** Ideal implant placement with regards to the apical area of the adjacent teeth (>1.5 mm). If the implant encroaches upon the root, complications may result.

average distal inclination and distal curvature of the canine root frequently place the apex of the root into the first premolar implant area. The implant should be angled to follow the root of the canine and prevent contact or perforation of the natural root. A shorter implant often is indicated, especially when a second premolar is also present. In some cases, an implant may be contraindicated (Fig. 28.5).

Complications

Implants positioned too close to a tooth risk damage to the periodontal ligament (PDL) and surrounding structures. This may cause displacement of bone into the PDL space and result in altered blood supply to the adjacent tooth, loss of tooth vitality, apical periodontitis, and internal or external resorption (Fig. 28.6).[5]
• **Fig. 28.3** Cone beam computerized tomography (CBCT) evaluation. (A) Axial three-dimensional CBCT view measuring midroot distance. (B) Axial view measuring at the most apical extent of the tooth roots.
• **Fig. 28.4** (A) Postorthodontic treatment exhibiting tilting of the maxillary central crown mesially, which results in the root apex tilting distally, resulting in less available space for a lateral incisor implant. (B) Poor treatment plan of two congenitally missing lateral incisors with insufficient space resulting in impingement on the adjacent tooth roots.


• **Fig. 28.5** Maxillary first bicuspid area. (A) Often the maxillary first bicuspid is placed and may encroach on the natural curvature of the maxillary cuspid. (B) Ideally the implant should be placed parallel to the cuspid root or a shorter implant to minimize the possibility of root encroachment.

Because of the close proximity of implants to an adjacent tooth, the implant may fail because of infection or bone resorption. If less than 1.5 mm of space exists between the implant and the root apex, then the PDL may be damaged, which can result in irreversible trauma and internal or external resorption of the natural tooth. Therefore placing an implant too close to the root surface may ultimately lead to implant or tooth loss, which can occur in the short term or the long term.

In the field of orthodontics today, temporary anchorage devices (TADs) have become popular for cases requiring anchorage. TAD implants are smaller diameter implants (<1.8 mm) that are inserted perpendicular to the long axis of the tooth in the interradicular spaces of the maxilla and mandible. TADs are used for tooth movement (e.g., labial segment retraction or mesial movement of teeth) or for intraoral anchorage, in which tooth movement in all three planes may be accomplished. Interradicular orthodontic implant complications may include loss of tooth vitality, tooth loss, osteosclerosis, and dentoalveolar ankylosis.[6,7] These implants should be cautiously placed because they often are positioned in areas of minimal intraroot distance and above the mucogingival line in attached tissue, which often leads to detrimental effects on adjacent tooth structure[8] (Fig. 28.7).

• **Fig. 28.6** Nonideal positioning with respect to the root apex. Implant has an ideal crestal positioning; however, apical positioning results in the implant being too close to the root apex.

Treatment

Initial placement. If there is insufficient space between an implant and the root apex after initial placement, then the implant should be removed and repositioned, especially if the adjacent tooth becomes symptomatic. If available space is compromised, then the roots should be repositioned via orthodontics or the treatment plan changed to a different type of prosthesis.

Past placement. If an implant has been restored and root approximation (<1.5 mm) exists, then the tooth/implant should be monitored on a more stringent clinical and radiographic recall basis along with informing the patient of possible morbidity. The patient should be made aware of the proximity and possible complications that may result. If symptomatic or radiographic pathology is present, then the implant should be removed and repositioned along with vitality testing of the tooth (Fig. 28.8; Box 28.2).

Insufficient Implant–Tooth Distance (Coronal)

Ideal Positioning

For tissue health and ideal emergence profile, a minimum of 2.0 mm should be present from the implant neck to the adjacent tooth[9] (Fig. 28.9). When the implant is closer than mm to the adjacent tooth, any bone loss related to the microgap, the biologic width, or stress concentration may cause the implant and adjacent tooth to lose bone. More space is required at the coronal area (1.5 mm vs. 2.0 mm) to accommodate a papilla.

Within an edentulous space, the implant should be placed in the middle of the space, with an equal amount of interproximal bone toward each adjacent tooth. Ideally, there should exist 2.0 mm or more from the adjacent cement-enamel junction (CEJ) of each tooth. When evaluating defect width around an implant with bone loss, it is usually less than 1.5 mm wide. Hence, if bone loss around the implant occurs, then the bone loss will remain a vertical defect and is less likely to cause bone loss on the adjacent natural tooth. If bone is maintained and no bone loss occurs around the adjacent tooth, then the interdental papilla height will be maintained.

Pretreatment Evaluation

The coronal implant–tooth distance may be determined by evaluating CBCT images (i.e., axial images) or the use of study casts in conjunction with diagnostic wax-ups. On preoperative evaluation, if inadequate space exists for implant placement, then the following treatment may be completed to increase mesiodistal distance:

1. Enameloplasty (modification of the interproximal contact areas) may be completed on the proximal contours of the

• **Fig. 28.7** Orthodontic implants (temporary anchorage devise [TADs]) that are used for anchorage usually will be very close to adjacent roots. (A) Clinical image depicting a TAD that is placed in between two tooth roots and perpendicular to the bone. (B) Intraoral radiograph showing minimal space for implant placement between tooth roots.

adjacent teeth to increase mesiodistal dimensions. However, care should be exercised in the amount of enamel removed because aggressive modification may lead to hypersensitivity and possible endodontic intervention (Fig. 28.10A, 28.10D).

2. Orthodontic intervention may be used to upright a tilted adjacent tooth to increase the intratooth space. For larger spaces (multiple spaces), one implant may be placed, and an orthodontic spring incorporated in the transitional crown. The spring pushes the distal tooth more distal and, after orthodontic movement, the second implant may be inserted with less risk and improved hygiene between each implant. Another option is to reduce the space orthodontically and place only one implant and crown (see Fig. 28.10B).

3. For larger spaces (multiple implants) the implants may be offset, with one implant placed buccal and the other implant on a diagonal toward the lingual.[9] The diagonal dimension increases the mesiodistal space by 0.5 to 1 mm. In the mandible, the most anterior implant is placed to the lingual aspect of the midcrest and
• **Fig. 28.8** Tooth root proximity existing on a final prosthesis. Patients should be informed and a more frequent evaluation should be completed along with regular pulp vitality testing.

• **BOX 28.2   Lack of Space Between Tooth/Implant (Apical)**

Complication:
• Tooth hypersensitivity
• Loss of tooth vitality
• Periapical pathology
• Tooth loss
• Implant loss

Prevention:
• Ideal positioning (>1.5 mm)
• Accurate radiographic evaluation (cone beam computerized tomography)
• Diagnostic wax-up/interactive treatment planning

Treatment:
• Preprosthetic
  • Remove implant
  • Check tooth vitality
• Postprosthetic
  • Strict recall evaluation
  • Monitor tooth vitality

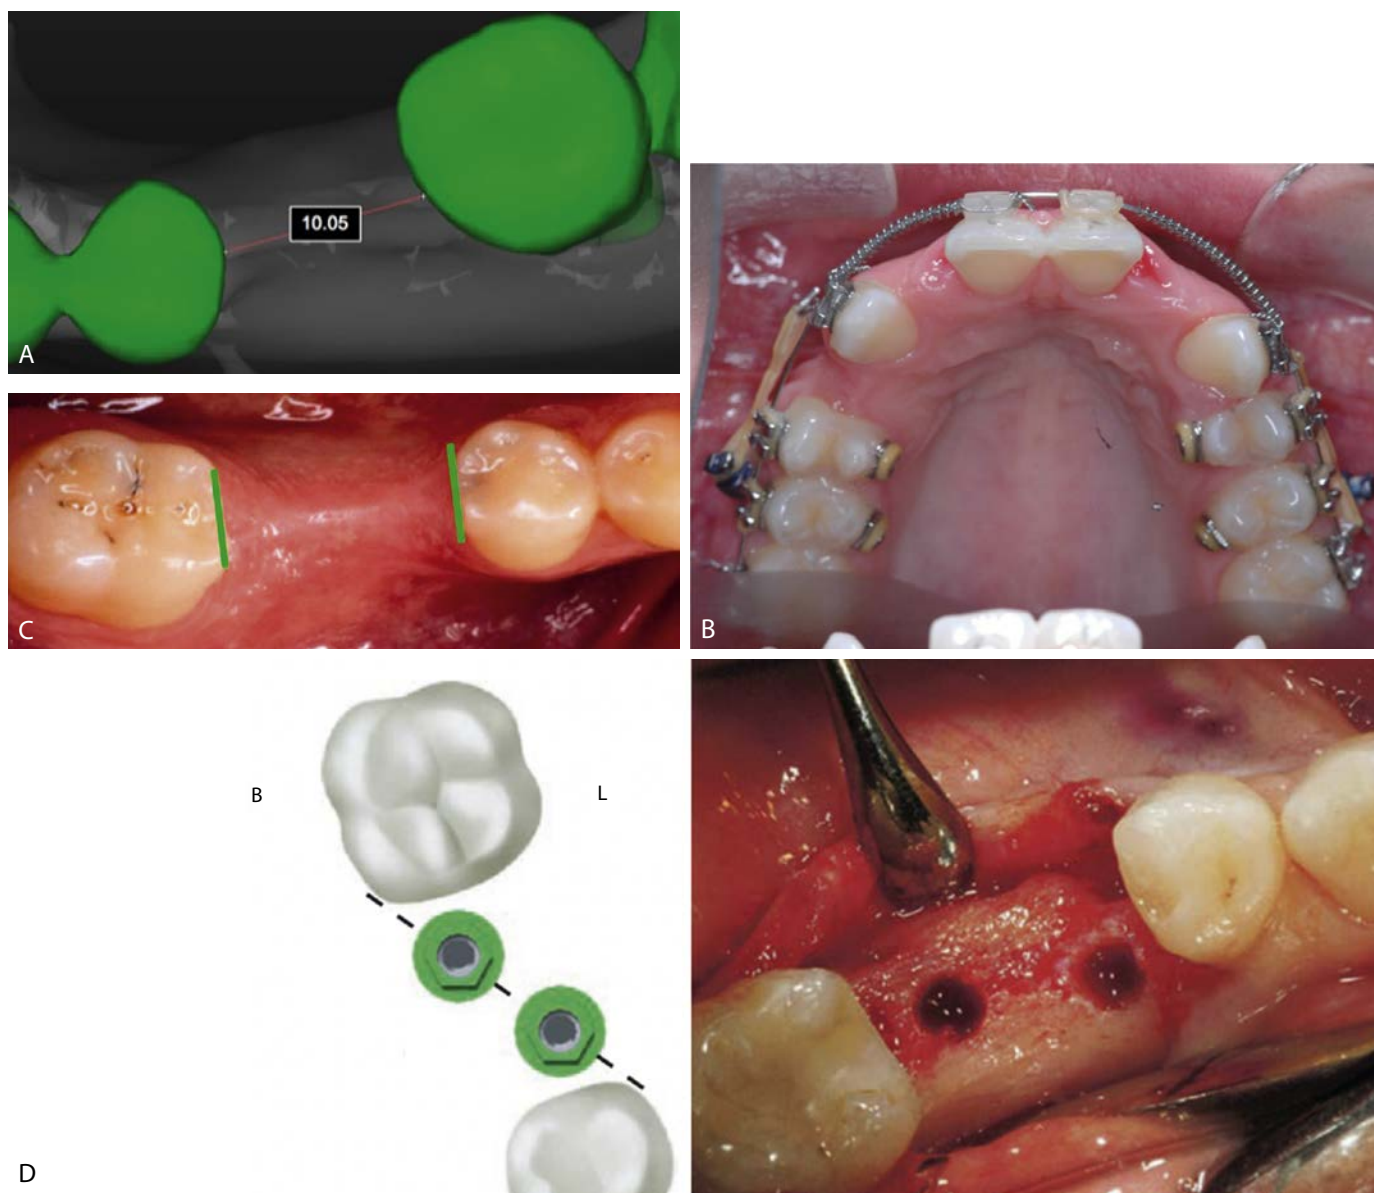
---

the more distal implant is placed to the facial aspect to facilitate access of a floss threader from the vestibule into the intraimplant space. The occlusal contacts also are slightly modified on the buccal aspect of the mesial implant to occlude over the central fossa. In the maxilla, the anterior implant is placed facially and the distal implant palatally to improve esthetics. The distal occlusal contact is placed over the lingual cusp, and the mesial occlusal contact is located in the central fossa position. The cervical esthetics of the maxillary molar are compromised on the distal half of the tooth to achieve greater intratooth distance and easier access for home care. This maxillary implant placement requires the intraimplant furcation to be approached from the palate, rather than the buccal approach, as for the mandible Fig. 28.10D.

Prevention

A common technique to avoid placing implants too close to a tooth is the use of a surgical template. A pilot, universal or fully guided surgical template may be used that will prevent the implant from being placed too close to the tooth. In addition, if a template is not used, there exist multiple positioning devices that allow for ideal osteotomy positioning (i.e., 1.5–2.0 mm from the adjacent tooth). A surgical spacer may be used, which enables the initial osteotomy site to be placed at the correct position, allowing for adequate space between the tooth and final implant position (Fig. 28.11A–B). Surgical guidance systems (Salvin, Charlotte, North Carolina) also may be used to ensure ideal implant placement (buccolingual and mesiodistal spacing) and may be used with any surgical drill system (see Fig. 28.11C–D). However, the most accurate positioning adjunct is the use of CBCT-generated surgical templates (tooth supported) (see Fig. 28.11E).

Complications

Lack of space between the implant platform and the coronal aspect of the adjacent tooth occurs most likely from poor initial osteotomy positioning, poor treatment planning, or the use of
• **Fig. 28.9** In some cases, insufficient mesial-distal space will be present which decreases clinical crown space. Ideally, 2.0 mm should be present between implant and adjacent tooth (crestally).


• **Fig. 28.10** Possible treatment options for inadequate spacing. (A) Determine the exact measurement of available space for an edentulous space via cone beam computerized tomographic images. (B) Orthodontic repositioning allowing additional spacing. (C) Enameloplasty of adjacent tooth allows for additional space for prosthesis emergence. (D) In some cases two smaller diameter implants may be placed to replace one molar, however care should be exercised not to position implants too close to each other or too close to adjacent tooth.

an implant body that is too large. This will lead to a situation in which the implant encroaches on the adjacent tooth. Implant clinicians must be aware that most implant crestal platforms are larger than the implant body, which will result in decreased space between the adjacent tooth (e.g., a 3.8-mm implant may have a 4.1-mm platform) (Fig. 28.12; Table 28.1).

Prosthetically, when there exists a lack of space between the adjacent clinical crown and implant, it may be difficult, if not impossible, to form an ideal emergence profile in the new final prosthesis. Lack of proper emergence profile leads to esthetic, hygienic, and soft tissue complications, which increases implant morbidity (Fig. 28.13A–C). Hygiene difficulties will become more frequent because of the unnatural contours of the prosthesis and the lack of space for cleansability. This usually will result in

plaque buildup and related peri-implant complications. Normal hygiene techniques will be modified to access the areas for proper cleansability.

Also, because of the lack of space between the implant and coronal portion of the tooth, bone loss will likely occur. Interproximal bone loss may result from lack of sufficient blood supply. Esposito and colleagues have shown a correlation between increased bone loss and decreased distance of the implant from the adjacent tooth.[10] They reported bone loss increased with decreasing distance, especially in the maxillary incisor region. Because of interproximal bone loss caused by the proximity of the implant to the coronal portion of the tooth, a lack of or reduction in the size of papilla will be present. This will result in peri-implant conditions and resultant esthetic issues (see Fig. 28.13D).
• **Fig. 28.11** Ideal implant placement. (A) Positioning device placed on the distal contact of the adjacent tooth allows for the ideal osteotomy site in the edentulous space. (B and C) Surgical guidance systems may be used for various situations and spacing between teeth. (Courtesy Salvin Dental Specialties, Inc., Charlotte, NC.) (D) Tooth-supported surgical template allowing for accurate implant positioning.)
• **Fig. 28.12** Implant placement too close to the clinical crown of the adjacent tooth (<2.0 mm).

Treatment

Initial placement. On surgical implant placement, if the position of the implant is less than 2.0 mm from the adjacent clinical crown, removal and reposition of the implant should be completed. If the implant is positioned 1.5–2.0 mm from the adjacent tooth,

TABLE 28.1	Average Mesiodistal Width of Permanent Teeth	
Tooth	**Mandibular (mm)**	**Maxilla (mm)**
Central incisor	5.3	8.6
Lateral incisor	5.7	6.6
Cuspid	6.8	7.6
First bicuspid	7.0	7.1
Second bicuspid	7.1	6.6
First molar	11.4	10.4
Second molar	10.8	9.8

a possible option would include modifying (enameloplasty) the adjacent tooth, as long as irreversible damage to the tooth is not done and an ideal emergence profile can be established.

Past placement. If the implant has been restored and approximation (<1.5 mm) exists, then the tooth/implant should be strictly monitored. If the natural tooth becomes symptomatic, then the implant should be removed and repositioned, along with long-term vitality testing of the tooth (Box 28.3).
• Fig. 28.13 Complications resulting from impingement on adjacent teeth. (A and B) Poor implant positioning resulting in inability to create an emergence profile for crowns. (C) Implant body that is too wide results in bone loss followed by tissue loss.

• BOX 28.3   Lack of Space Between Tooth/Implant (Coronal)

Complication:
- Interproximal bone loss
- Compromised emergence profile
- Complicates prosthetic procedures
- Reduced papilla height
- Hygiene difficulties

Prevention:
- Ideal positioning (~ 2.0 mm)
- Accurate radiographic evaluation (cone beam computerized tomography)
- Diagnostic wax-up/interactive treatment planning
- Use of a surgical template

Treatment:
- Preprosthetic
  - Enameloplasty, crown natural tooth
  - Possible removal of implant and reposition

Excessive Implant–Tooth Distance (Coronal)

Ideal Positioning

If excessive space (>4.0 mm) exists between the implant body and adjacent tooth, a biomechanical disadvantage will result because of the cantilever effect (i.e., contact area of the adjacent tooth). Ideally, the implant should be loaded along the long axis of the implant body. Because of the excessive space between the implant and tooth, overcontouring of the final prosthesis is required to achieve a contact area with the adjacent tooth (Fig. 28.14).

Pretreatment Evaluation

To prevent the placement of an implant too far from an adjacent tooth, a CBCT-generated template may be used to accurately place the implant. Because teeth are present, a tooth-supported guide would be the most accurate template compared with bone-borne or tissue-borne guides. In addition, special positioning devices allow for ideal osteotomy placement and adherence to the ideal placement of 1.5 to 2.0 mm from the adjacent tooth. These predetermined distance spacers will minimize the possibility of placing the implant too close or too far from the adjacent tooth (Fig. 28.15).

Complications

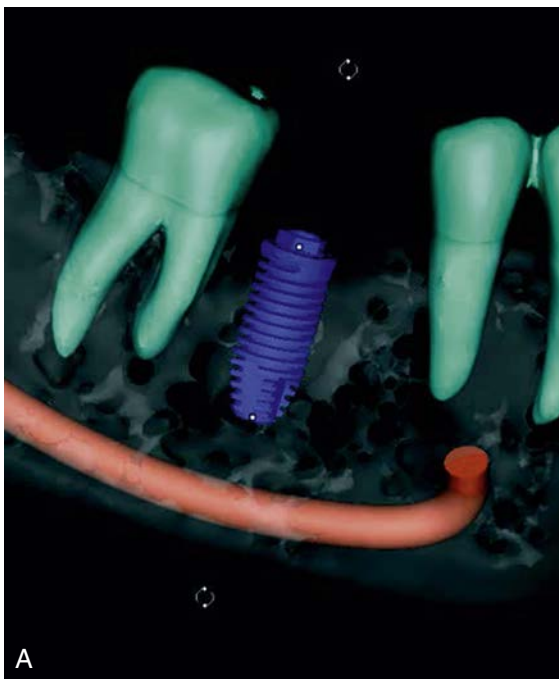
The excessive space present between the implant and adjacent tooth will result in biomechanical issues and possible esthetic complications. Loading of the cantilever area will produce - a resultant shear force. Because bone is weakest with shear forces, bone loss will most likely occur around the crestal area of the implant. Cantilevers present on implant prostheses are more problematic than on natural teeth for several reasons. Forces are magnified to the


Fig. 28.14 Implant placed too far from the adjacent tooth. (A) The implant should be placed at the midpoint of the mesiodistal distance. (B) Nonideal placement may result in cantilever effect biomechanical disadvantages.

Fig. 28.15 Implant should be placed in the midpoint of the mesiodistal distance via three-dimensional cone beam computerized tomographic interactive treatment planning.
Fig. 28.16 Clinical image depicting poor implant positioning leading to a significant cantilever effect. Forces placed on the mesial cantilever will result in shear forces to the implant crestal area.

entire implant system, which may result in implant screw loosening, cement retention failure, or even possibly the mobility and failure of the implant itself. Second, because the implant is void of a PDL, there is no stress release system in place to protect the implant. Studies have shown a 1-mm increase in the horizontal offset of an implant restoration may produce a 15% increase in torque during function, and a 1-mm increase in the vertical offset introduces a 5% increase.[11] The overcontoured crown leads to resultant shear forces, which may lead to component failure (i.e., screw loosening, screw fracture, implant fracture).

Because of the need to obtain interproximal contact, the final prosthesis will be atypical, which may lead to increased difficulty in prosthetic impression, laboratory, and insertion procedures (Figs. 28.16 and 28.17). Food impaction is a common complaint from patients with an increased implant–tooth distance because periodontal maintenance is difficult as a result of related soft tissue complications. The chronic soft tissue problems may lead to

peri-implant disease (i.e., peri-mucositis, peri-implantitis) which results in an increased implant morbidity.

Treatment

Initial placement. If nonideal placement is determined during surgery, the implant should be repositioned in the ideal position (i.e., 1.5–2.0 mm from the adjacent tooth). To prevent malposition the following osteotomy formula may be used: ½ diameter of the implant + 2.0 mm from tooth = osteotomy site initiation.

In other words, a 4.0-mm implant pilot osteotomy would be 2.0 mm + 2.0 mm = 4.0 mm from the adjacent tooth. If the initial osteotomy is not ideal, then a Lindemann drill (side cutting) is used to reposition the osteotomy into the correct position.
• **Fig. 28.17** Implant positioning too far from tooth. (A) Implant placement too far posterior leading to the implant being non-restorable, (B) Poor implant positioning resulting in prosthesis that has resultant anterior and posterior cantilevers. (C and D) Atypical prosthesis because of nonideal implant placement and need to obtain contact area, which results in biomechanical complications and food impaction.

Past placement. If the implant has already been placed and is ready to be restored, then the amount of occlusal force should be assessed to determine the ideal treatment:

Minimal occlusal forces: If favorable force factors exist (e.g., opposing removable prosthesis, lack of parafunction) then a cantilever (overcontoured crown) may be fabricated with (Fig. 28.18A) the following:
- Narrow occlusal table
- Minimal cusp height: It has been reported that every 10-degree increase in cusp inclination leads to a 30% increase in the torque applied to the restoration during function[10]
- No lateral contacts
- Strong, long contact area

High occlusal forces: If unfavorable forces (e.g., opposing fixed or implant prosthesis, parafunction) are present, then a cantilever is contraindicated and the mesiodistal distance is reduced by either:

- Overcontouring adjacent crown (e.g., crown, composite) (see Fig. 28.18B)
- Remove implant and reposition (Box 28.4).

Lack of Implant–Implant Distance

Ideal Positioning

The distance between two implants has been determined to be a significant factor with respect to crestal bone loss, the presence of interimplant papilla, and generalized tissue health. Ideally, there should exist 3 mm or more space between any two adjacent implants. This will allow adequate room for interdental papilla and tissue health, cleansability, transfer copings during prosthetic impressions, and minimizing horizontal bone loss. When implants are placed too close together, it is usually the result of poor treatment planning or surgical technique (Fig. 28.19).
• **Fig. 28.18** Treatment of excessive distance. (A) Prosthesis with narrow occlusal table, minimal cusp height, and no lateral contacts maintains implant-protected occlusion. (B and C) To decrease implant–tooth distance, the natural tooth may be elongated or overcontoured by the use of a crown or bonding.

• **BOX 28.4** **Excessive Space Between Tooth/Implant**

Complication
- Overcontoured crowns
- Atypical prosthetics
- Cantilever effect (biomechanics)
- Food impaction
- Periodontal complications

Prevention
- Ideal positioning (1.5–2.0 mm from tooth)
- Accurate radiographic evaluation (cone beam computerized tomography)
- Diagnostic wax-up/interactive treatment planning
- Parallel long axis of adjacent tooth
- Use of a surgical template

Treatment
Minimal occlusal forces:
1. Narrow occlusal table
2. Minimal cusp height
3. No lateral contacts
   - Cantilever (overcontoured crown)
   High occlusal forces:
1. Overcontour adjacent tooth
   - Reduce mesiodistal distance
2. Remove implant and reposition

Pretreatment Evaluation

The preliminary evaluation to determine distance for multiple implants is the evaluation and measurement of space in the axial dimension. This may be accomplished by use of a CBCT image (axial) depicting the adjacent tooth roots for measurement (Fig. 28.20).
• **Fig. 28.19** Ideal interimplant distance: 3.0 mm between implants and 1.5 mm 1.0-2.0 mm from adjacent teeth.

Osteotomy Measurement. A formula exists for ideal placement of initial osteotomies in anticipation of the final implants. For example, when placing 5.0- and 4.0-mm implants, add ½ diameter of implant + 3.0 mm between implants and 2.5 mm + 2.0 mm + 3.0 mm = 7.5 mm between osteotomy sites. In this example, the initial osteotomy sites may be placed at approximately 7.5 mm between the two pilot holes. In addition, special spacing guides may be used for ideal positioning. Ideally, the implant diameter width should correspond to the width of the natural tooth at the level 2 mm below the CEJ.
• **Fig. 28.20** Evaluation of intertooth distance. (A) Clinical crown measurement. (B) Cement-enamel junction measurement. (C) Midroot distance. (D) Apical distance.
• **Fig. 28.21** (A) Implants placed too close together. (B) Ideally, the space should be 3.0 mm.

Complications

When lack of interproximal bone (i.e., <3.0 mm) is present, a decreased blood supply will result, eventually leading to bone loss. Tarnow and colleagues have shown that implants placed less than 3.0 mm apart may have adequate stability and function; however, this placement will likely result in crestal bone loss. In this study, implants with a greater than 3-mm distance between implants resulted in a 0.45-mm bone loss, whereas implants positioned less than 3 mm had over twice the amount of bone loss, or approximately 1.04 mm[12] (Fig. 28.21).

In addition, when lack of space exists between the implants, the resultant bone loss will be responsible for the loss of the papilla. As the bone resorbs, the distance between the contact point of the crowns and the bone level increases. As this distance increases (i.e., >5 mm), the papilla will become smaller in size and contour.

Lack of space may also lead to difficulty in hygiene access, which will result in poor tissue health. The resultant tissue condition will most likely lead to peri-mucositis or peri-implantitis. Prosthetically, lack of space may result in difficulty in obtaining a final impression (i.e., placement of impression transfer copings) and seating the final prosthesis. With some implant systems, the transfer copings may be adjusted to allow for impression of the implant bodies. Additionally, an unconventional implant prosthesis (irregularly contoured) will most likely need to be fabricated (Fig. 28.22).

Treatment

Initial placement. If implants are not ideally positioned, then the osteotomy should be repositioned to ideal positions (3 mm between implants). The implant positions may be altered with the side-cutting Lindemann drill (Fig. 28.23).
● **Fig. 28.22** Complications. (A) Close proximity of posterior implants resulting in bone loss. (B and C) When implants are too close together, the prosthetic procedures may be difficult or impossible to complete. (D) Implant proximity resulting in hygiene difficulty and resultant peri-implant disease.

Past placement. If implants have been restored, then removal of implants and repositioning should be completed if the patient cannot adequately clean the prosthesis. In some situations, the abutment/implant body may be minimally modified to gain extra space, usually with a flame-shaped diamond bur. This is best completed with external hex implants because modification of internal hex implants may alter structural integrity of the implant, leading to possible fracture (Box 28.5).

Buccolingual Positioning("Y-Axis")

The faciopalatal (buccolingual) positioning of the dental implant is crucial to the esthetic and biomechanical effectiveness of the final prosthesis. Frequently, implant positioning is dictated by the resulting available bone, leading to angulation complications. Bone remodeling after tooth extractions is common, with resorption occurring from the buccal plate initially, decreasing the width of bone and shifting the ridge position more lingual. When evaluating the faciopalatal positioning, two dimensions need to be investigated:
1. Faciopalatal ridge position
2. Faciopalatal angulation position

Ideal Positioning (Faciopalatal Ridge Dimensions)

The faciopalatal position of the implant with adequate bone width is mid to slightly palatal of the edentulous ridge. This approach permits the use of the largest diameter implant to be placed in the space with respect to the natural tooth dimensions. Ideally, after implant placement, the crestal bone should be at least 2.0 mm wide on the facial aspect of the implant and 1.0 mm or more on the palatal aspect (Fig. 28.24).[13]

Pretreatment Evaluation

With this positioning protocol, if implant bone loss occurs, then the facial plate will remain intact and not cause recession on the facial aspect of the implant crown. Therefore for a 4-mm-diameter implant, a minimum of 7-mm faciopalatal width of bone is required (i.e., 4.0-mm-diameter implant + 2.0 mm buccal bone + 1.0 mm lingual bone). Bone spreading in conjunction with implant placement or bone grafting on the facial aspect of the edentulous site may be indicated when the ridge is compromised in width.

When evaluating the CBCT images, the available bone width may be determined via the cross-sectional images. With the use of interactive treatment planning, implant positions can be evaluated to ensure a minimum of 2.0 mm present on the buccal and 1.0 mm on the lingual aspects of the ridges (Fig. 28.25). The faciopalatal width is not as critical on the palatal aspect (i.e., with respect to the buccal bone) of the implant because it usually contains dense cortical bone, which is more resistant to bone loss and is usually not in the esthetic zone.

When present, the buccal cortical bone minimizes future hard and soft tissue recession. In this scenario, if bone loss occurs on the implant, the facial plate will remain intact, and minimal recession on the facial aspect of the implant will result. Spray and colleagues have shown that if the facial bone is more than 1.8 mm in
• **Fig. 28.23** Inadequate space between implants. (A) The prevention of multiple implants being placed too close together includes the use of interactive treatment planning (multiple cone beam computerized tomography views) to ensure ideal spacing. (B) Inadequate space between implants; ideally one of the implants should be removed and replaced in a more ideal position. (C) When implants are already restored, a strict recall should be followed to monitor bone loss and related periodontal complications. (D) Two implants placed in anterior mandible with insufficient space between implants (> 3.0mm) and lack of space between adjacent teeth (1.5–2.0 mm).

thickness (after implant placement), recession infrequently results. However, if the facial plate is less than 1.8 mm, vertical resorption occurs quickly, mainly because of the lack of blood supply.[14] Therefore improper buccolingual positioning has a direct effect on the long-term health of the implant and prosthesis.

A common mistake, especially with clinicians early on their learning curve, is to use solely two-dimensional radiographs or clinical evaluation of the soft tissue thickness. Often this is misleading and may pose a significant change to the implant placement or final prosthesis. Thus viewing the third dimension of bone (i.e., CBCT survey) will allow for the accurate assessment of available bone width and ideal position of the implant (Fig. 28.26).

Ideal Positioning (Faciopalatal Angulation)

The faciopalatal angulation is a crucial factor in the long-term success of the dental implant and prosthesis. One area that faciopalatal positioning is most critical is the maxillary anterior region. Because of the inherent angulation issues (i.e., trajectory of the natural teeth with respect to the available bone), coupled with being in the esthetic zone, there is very little room for error when placing implants in this area. In the literature, three different

protocols for the buccolingual (faciopalatal) angulations of the implant body have been discussed: (1) similar to the facial position of the adjacent natural teeth, (2) under the incisal edge of the final restoration, and (3) within the cingulum position of the implant crown (Fig. 28.27).

Facial Implant Body Angulation (Anterior). In theory, a maxillary anterior implant body angulation should be positioned at the facial emergence of the final crown, and this position should be in the same position as a natural tooth.

However, the facial crown contour of a natural tooth has two planes, and its incisal edge is palatal to the facial emergence of the natural tooth by 12 to15 degrees (Fig. 28.28). This is why maxillary anterior crown preparations are in two or three planes (Fig. 28.29). In addition, because the implant is narrower in diameter than the faciopalatal root dimension, when the implant body is oriented as a natural tooth and has a facial emergence, a straight abutment is not wide enough to permit the two-plane or three-plane reduction to bring the incisal edge of the preparation more palatal. As a result, the incisal edge of the preparation remains too facial and will require significant modification or an angled abutment.

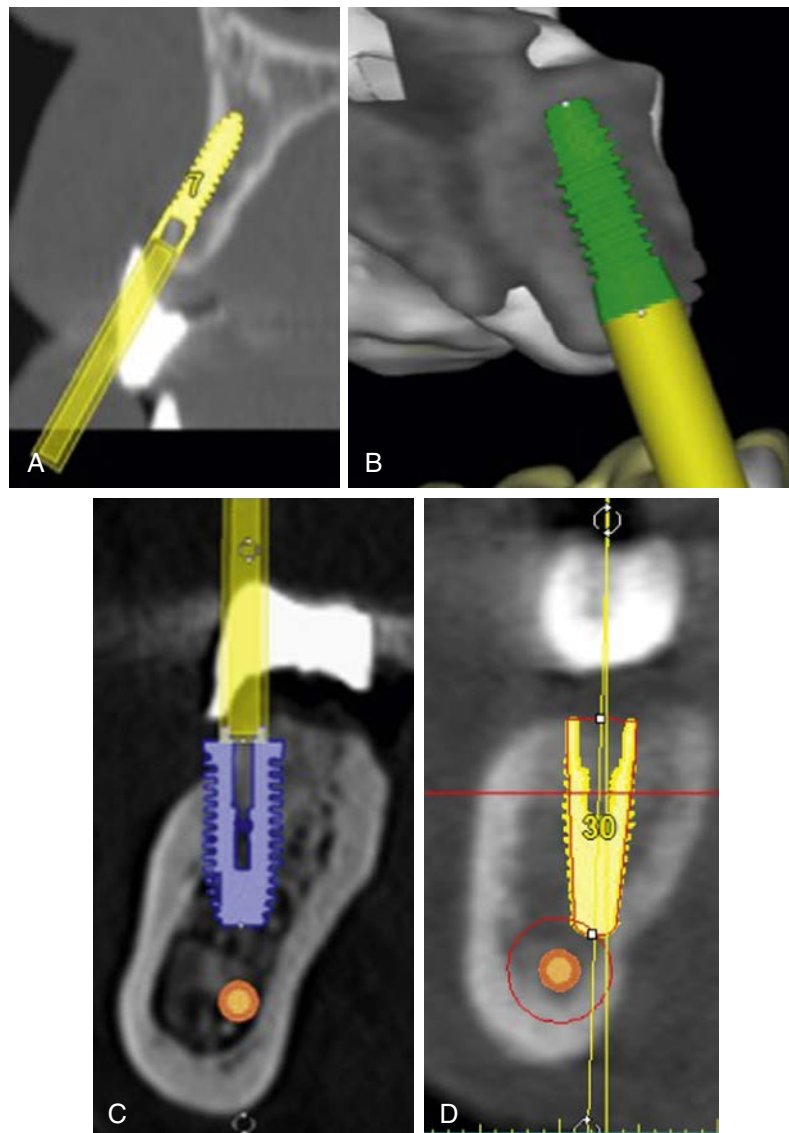
Therefore the implant body should be more palatal than a natural root, so 2.0 mm of bone exists on the facial aspect. Many

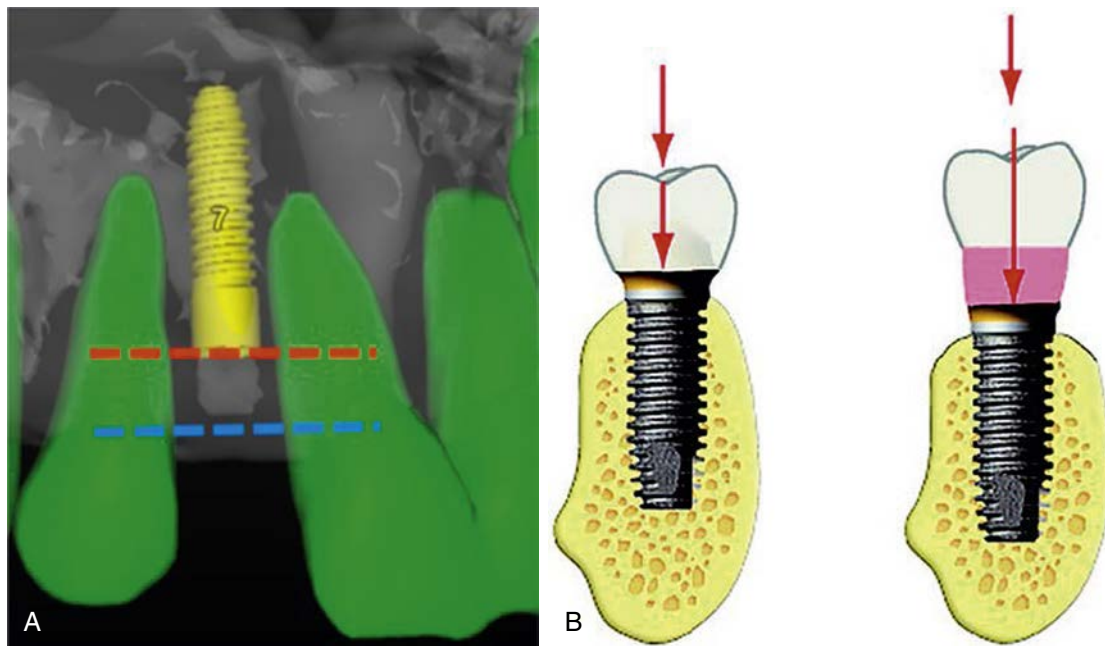
Complication:
- Increased bone loss
- Loss of interdental papilla
- Hygiene issues
- Prosthesis complications
(Poor emergence profile/impression)

Prevention:
- Ideal positioning (3.0 mm between implants)
- Accurate radiographic evaluation (cone beam computerized tomography)
- Diagnostic wax-up/interactive treatment planning
- Use of a surgical template

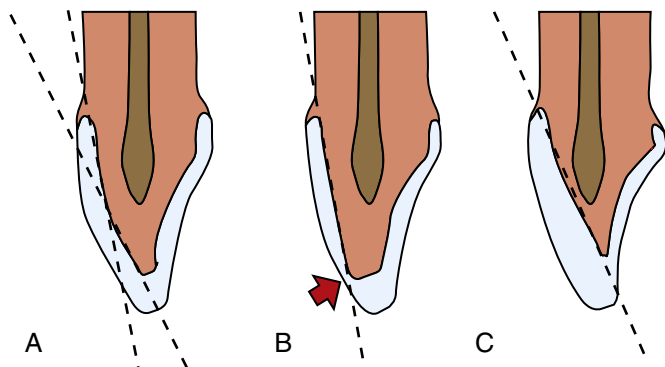
Treatment:
- Custom abutments
- Strict recall
- Remove implants and reposition
- Minimal occlusal forces

implant clinicians, especially early on their learning curve, will attempt to align the implant body with the facial aspect of adjacent teeth and the implant may inadvertently be inserted too facial. When this occurs, no predictable method exists to restore proper esthetics. At best, the final crown will appear too long. This problem is compounded when the implant is also inserted too shallow and insufficient room is present to obtain a proper emergence profile. To correct a maligned implant with soft tissue grafts or bone augmentation is rarely successful after the implant is already inserted in a final position (Fig. 28.30).

In the maxillary anterior area, natural teeth are loaded at an angle because of their natural angulation compared with the mandibular anterior teeth. This is one reason why maxillary anterior teeth are wider in diameter than mandibular anterior teeth (i.e., which are loaded in their long axis). The facial angulation position of the implant body often corresponds to an implant body angulation, often with up to 15 degrees off-axial loads. This angled load increases the force to the abutment screw–implant–bone complex by 25.9% compared with a long-axis load.[15] These offset loads increase the risks of abutment screw loosening, crestal bone loss, and cervical soft tissue marginal


• **Fig. 28.24** Buccal-Lingual Positioning: (A) Non-ideal maxillary positioning, (B) Ideal maxillary positioning, (C) Non-ideal positioning in mandible too facial, (D) Ideal positioning in central fossa of restoration.


• **Fig. 28.25** Implant placement too deep. (A) Implant placed greater than 4.0 mm from free gingival margin, which increases potential complications. (B) The crown height is not a multiplier of force when the load is in the long axis of the implant. However, any angled force or cantilever increases the force and the crown height magnifies the effect.
• **Fig. 28.26** (A) Two-dimensional radiograph not depicting the true bone dimensions because of inherent inaccuracies. (B) Cone beam computerized tomography cross-sectional image allowing for the accurate representation of bony dimensions.
• **Fig. 28.27** Three implant angulation positions are suggested in the literature for a maxillary anterior single-tooth implant. (A) Under the incisal edge. (B) Similar to the facial position of the adjacent teeth (B). (C) Under the cingulum position of the implant crown. (From Misch CE. Single-tooth implant restoration: maxillary anterior and posterior regions. *Dental Implant Prosthetics*. St Louis, MO: Elsevier Mosby; 2015.)

Fig. 28.28 Maxillary anterior teeth have an incisal edge 12 to 15 degrees more palatal than the facial emergence position of the crown. (From Misch CE. Single-tooth implant restoration: maxillary anterior and posterior regions. *Dental Implant Prosthetics*. St Louis, MO: Elsevier Mosby; 2015.)


• **Fig. 28.29** (A) Maxillary anterior crown preparations are made in two or more planes. (B, C) When the plane of the emergence profile is only used, the incisal edge of the preparation is too facial. (From Misch CE. Single-tooth implant restoration: maxillary anterior and posterior regions. *Dental Implant Prosthetics*. St Louis, MO: Elsevier Mosby; 2015.)

• **Fig. 28.30** Implant positioned too facial and too shallow. The angled abutment must be prepared to make room for restorative materials and to allow a more apical position of the crown margin. (From Misch CE. Single-tooth implant restoration: maxillary anterior and posterior regions. *Dental Implant Prosthetics*. St Louis, MO: Elsevier Mosby; 2015.)

• **Fig. 28.31** Implant placed too facial and the thin tissue receded after crestal bone loss. (From Misch CE. Single-tooth implant restoration: maxillary anterior and posterior regions. *Dental Implant Prosthetics*. St Louis, MO: Elsevier Mosby; 2015.)

shrinkage.[16] As a result, implants angled facially may compromise the esthetics and increase the risk of complications (Fig. 28.31).

Cingulum Implant Body Angulation. A second angulation suggested in the literature is more palatal, with an emergence under the cingulum of the crown. This may also be the result of an implant insertion in a width-deficient ridge (division B) because the bone is lost primarily from the facial aspect and the ridge shifts toward the lingual. This position is also often the goal when a screw-retained crown is used in the final restoration. The prosthesis fixation screw (i.e., to retain a maxillary anterior crown) cannot be located in the incisal or facial region of the crown because this will compromise the esthetics.

This position also is suggested to increase the bone thickness on the facial aspect of the implant body. However, the cingulum implant position may cause a considerable hygiene compromise.[17] The implant body in the anterior maxilla is round and usually 3.5 to 5.5 mm in diameter. The labial cervical contour of the implant crown must be similar to the adjacent teeth for the ultimate esthetic effect. Because the long axis of the implant for a screw-retained crown must emerge from the cingulum position, this requires a facial projection of the crown or "buccal correction" facing away from the implant body. The facial ridge lap must extend 2 to 4 mm and is often similar in contour to the modified ridge lap pontic of a three-unit fixed prosthesis.

The modified ridge lap crown has become a common solution to correct the esthetics of the restoration when the implant is placed in narrow bone or follows a palatal angulation position.[18,19] However, plaque control on the facial aspect of the implant is almost impossible. Unlike a pontic for a fixed partial denture (FPD), the ridge lap crown has a gingival sulcus that requires sulcular hygiene. Even if the toothbrush (or probe) could reach under the facial ridge lap to the gingival sulcus, no hygiene or measuring device could be manipulated to a right angle to proceed into the facial gingival sulcus. As a result, although an acceptable esthetic restoration may be developed, especially with the additional cervical porcelain, the hygiene requirements render this approach less acceptable (Fig. 28.32).

Some authors argue that an improved contour may be developed subgingivally rather than supragingivally with a palatal implant position. To create this contour, the implant body must be positioned more apical than desired. This position may prevent food from accumulating on the cervical "table" of the crown. However, the "subgingival ridge lap" does not permit access to the facial sulcus of the implant body for the elimination of plaque and to evaluate the bleeding index or facial bone loss (Fig. 28.33). Therefore the maintenance requirement for the implant facial sulcular region suggests this modality is not a primary option.

Greater interarch clearance is often needed with an implant palatal position because the permucosal post exits the tissue in a more palatal position. Inadequate interarch space may especially

• **Fig. 28.32** Implant crown with a "modified ridge lap." The tissue periodi-cally becomes inflamed because hygiene aids (or a dental probe) cannot enter the sulcus of the implant; instead, it can only slide along the facial ridge lap to the free gingival margin. (From Misch CE. Single-tooth implant restoration: maxillary anterior and posterior regions. *Dental Implant Pros-thetics*. St Louis, MO: Elsevier Mosby; 2015.)

• **Fig. 28.33** Implant with a "subgingival ridge lap crown" and an inflamed gingival sulcus. (From Misch CE. Single-tooth implant restoration: maxillary anterior and posterior regions. *Dental Implant Prosthetics*. St Louis, MO: Elsevier Mosby; 2015.)

hinder the restoration of Angle's class II, division 2 patients with the implant in this position.

Ideal Implant Angulation. The third implant angulation in the literature describes the most desirable implant angulation. The clinician determines the line for the best angulation by the point of the incisal edge position of the implant crown and the midfaciopalatal (i.e., or slightly palatal) position on the crest of the bone. The center of the implant is located directly under the incisal edge of the crown so that a straight abutment for cement can be used. Because the crown profile is in two planes, with the incisal edge more palatal than the cervical portion, the incisal edge position is ideal for implant placement and accommodates some of the facial bone loss that often occurs before implant placement.

The facial emergence of the crown mimics the adjacent teeth, proceeding from the implant body under the tissue (Fig. 28.34). The angle of force to the implant is less from the long axis, which decreases the crestal stresses to the bone and abutment screws. When in doubt, the implant surgeon should err toward the pala-tal aspect of the incisal edge position, not to the facial aspect,

• **Fig. 28.34** *Left:* Implant crown is positioned under the incisal edge and has a facial emergence profile similar to the adjacent teeth. *Right:* The implant was positioned under the cingulum and requires a screw-retained crown with a facial ridge lap to have a similar facial crown emergence as the adjacent teeth. (From Misch CE. Single-tooth implant restoration: max-illary anterior and posterior regions. *Dental Implant Prosthetics*. St Louis, MO: Elsevier Mosby; 2015.)

because it is easier to correct a slight palatal position in the final crown contour, compared with the implant body angled too facial.

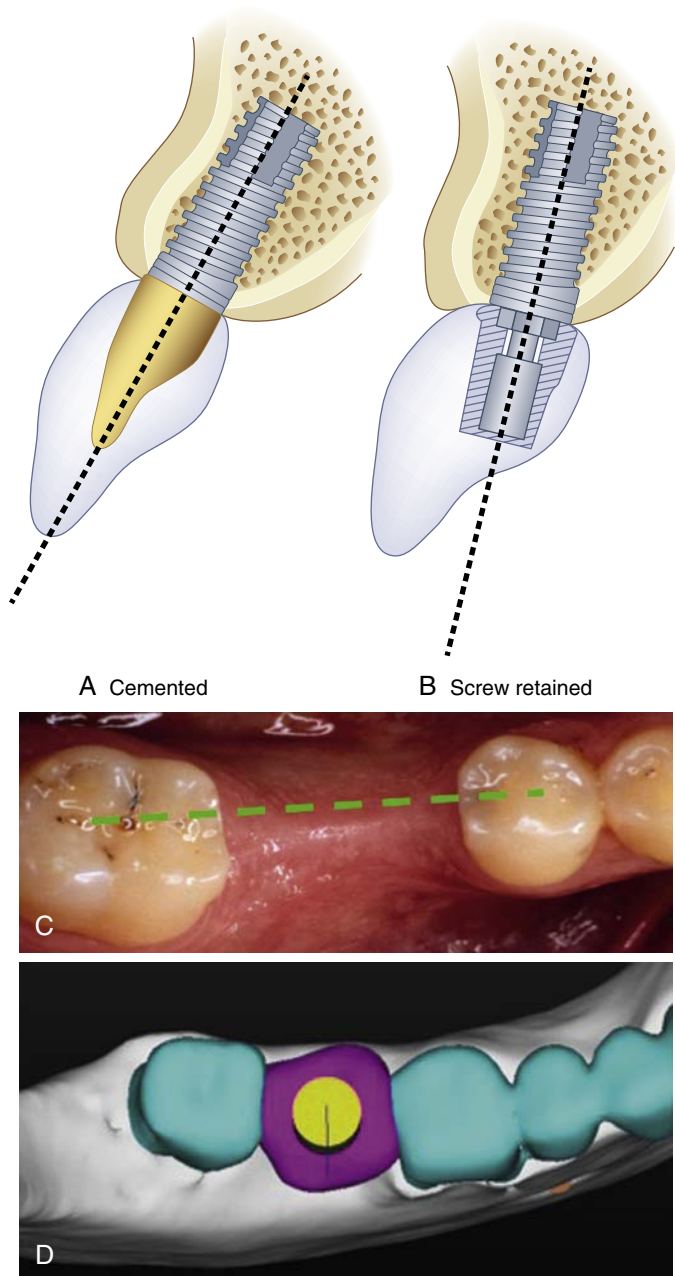
The implant body angulation slightly lingual to the incisal edge may also be used for cement or screw-retained restorations. In screw-retained restorations, an angled abutment for screw retention is inserted, and the coping screw for the crown may be located within the cingulum. This method does not require a facial ridge lap of the final crown, which decreases the risk of compromised hygiene. However, it should be noted that pros-thetic screw loosening is one of the more common complications of maxillary anterior screw-retained crowns.[20] When this occurs, there is an increased risk of marginal bone loss as a result of the crown movement and microgap created by the loose screw. When ideal bone volume is present, a surgical template that indicates the incisal edge and facial contour of the final prosthesis may be used.

Faciopalatal Positioning

A. Angulation with Respect to Prosthesis Type

1. FP-1 & FP-2 Prosthesis

Cement-retained (anterior). The ideal angulation for an FP-1 or
  FP-2 in the anterior is slightly lingual to the incisal edge.
  This is advantageous for two reasons. First, a straight abut-
  ment may be used, which is esthetically more pleasing and
  prosthetically less complex. When an FP-1/FP-2 prosthesis
  is indicated, precise buccolingual angulation implant place-
  ment is necessary to obtain an ideal esthetic result. In the
  anterior region, the ideal implant position allows the place-
  ment of a straight abutment slightly lingual to the incisal
  edge of the final crown for a cemented prosthesis. The re-
  sulting forces are concentrated along the long axis of the
  implant, minimizing damaging shear forces. In addition, if
  access is ever required to treat screw loosening, the existing
  crown may be retained, preventing a new crown from hav-
  ing to be fabricated.

A Cemented   B Screw retained


• **Fig. 28.35** (A, B) Ideal implant placement for a cement and screw-retained prosthesis in the anterior, (C, D) Ideal posterior implant placement in line with the adjacent teeth central fossa's.

Screw-retained (anterior). For screw-retained prostheses in the anterior, the implant should emerge within the cingulum area of the anterior tooth so the access hole does not affect the esthetics of the restoration. If the implant is placed too facially, then the access hole will impinge on the esthetics of the restoration (i.e., screw hole through the facial of the restoration). If the implant is placed too far lingually, overcontouring of the final crown may result in biomechanical issues and possible occlusal interferences (Fig. 28.35A–C).

Posterior region (cement retained or screw retained). In the posterior region, the long axis of the implant should emerge within the approximate center (central fossa) of the prosthesis for a screw-retained or cement-retained FP-1 or FP-2. This allows occlusal

forces to be directed ideally along the long axis of the implant (see Fig. 28.35D–E).

Complications

Facial. If the implant is placed too facial for an FP-1 or FP-2 prosthesis, then esthetic issues will result from overcontouring of the prosthesis. Bone dehiscence usually will be accompanied by tissue recession, and this complication is more pronounced in thin biotype patients. Facial positioning is often a complication when implants are placed in immediate extraction sites. To correct the facial position of the implant, an angled abutment must be used. However, because of the access hole, the facial of the abutment is more bulky. This results in overcontouring of the facial aspect of the prosthesis, which will lead to tissue recession and bone loss (Fig. 28.36).

Lingual. Implants placed too far to the lingual can result in facial overcontouring of the final prosthesis (ridge lap) for esthetic reasons. The prosthetic impression and placement of the prosthesis is also complicated, which results in difficulty with the seating of the abutments. Because of the overcontouring of the lingual contours, patients often complain of lack of space for the tongue, which may impede speech. In the anterior region, a lingual-placed implant may make the implant nonrestorable if the patient has a deep bite occlusion and insufficient interocclusal space (Fig. 28.37).

FP-3 Prosthesis

Screw retained. After evaluation of the articulated setup, arch form, available bone, and force factors, the FP-3 prostheses should be determined to be either screw retained or cement retained. For screw-retained prostheses, ideal positioning should be slightly lingual to the denture/porcelain/zirconia teeth to minimize tooth fractures and delamination in the anterior. In the posterior, the implant positioning should be within the central fossa of the Prostheses teeth.

Cement retained. For cement-retained restorations, implant positioning should be located slightly lingual to the incisal edge in the anterior region and in the central fossa area in the posterior. If force factors are a concern, then ideal implant placement is crucial to minimize biomechanical overload. However, if force factors are low, then nonideal placement is less of a problem with cement-retained prostheses because abutment angulation may be modified (Fig. 28.38).

Complications

Facial. Implants positioned too facially will impinge on the esthetics, complicate screw insertion, and result in increased prosthesis component fractures. Because the access holes will extrude through the facial contours of the teeth, the access will need to be covered with composite. This predisposes the prosthesis to loss or discoloring of the composite plugs. Also, facially inclined implants may lead to soft tissue irritation because of lack of attached tissue.

Lingual. Implants placed too far lingually will result in an overcontoured prosthesis, resulting in possible speech problems in the maxilla and crowding of the tongue in the mandible. Because the bulk of the material is needed for strength of the prosthesis, often this overcontouring results in an atypical prosthesis. In addition, lingually placed implants usually will result in lack of attached tissue, which may lead to chronic soft tissue problems (Figs. 28.39 and 28.40).
● **Fig. 28.36** Facially positioned implant complications. (A) Clinical image showing the facial positioning which results in peri-mucositis. (B) Pre-treatment evaluation should be completed to avoid malposition. (C) Facially positioned anterior implant often will require an angled or custom abutment. (D) Facially inclined implants resulting in esthetic and bone loss issues. (E) Facial positioning leading to the implant being non-restorable.

RP-4 and RP-5. The faciopalatal angulation for implants placed for removable overdentures should be positioned to emerge within the body of the denture base. This is crucial so the components (e.g., attachments, bar) that are attached to the implant do not impinge on the ideal setting of the denture teeth. Denture acrylic requires a minimum of 2.0 mm of bulk for strength and resistance form to prevent fractures and delamination.

Malpositioning

Lingual. Implants that are positioned too far lingually for an overdenture will result in overcontouring the lingual surface of the denture. This may interfere with phonetics, and often patients will complain of lack of space for the tongue. If the lingual aspect of the denture is thinned too much during adjustment, this will result in an area of possible fracture or loss of attachment.

Facial. Implants placed too far facially will interfere with ideal denture tooth placement, leading to possible denture tooth "pop offs." Often the esthetics are compromised because of the required malpositioning of the denture teeth. In addition, facially positioned implants often result in lack of adequate attached tissue and potential periodontal concerns because gingival irritation and recession are more likely to result. This may

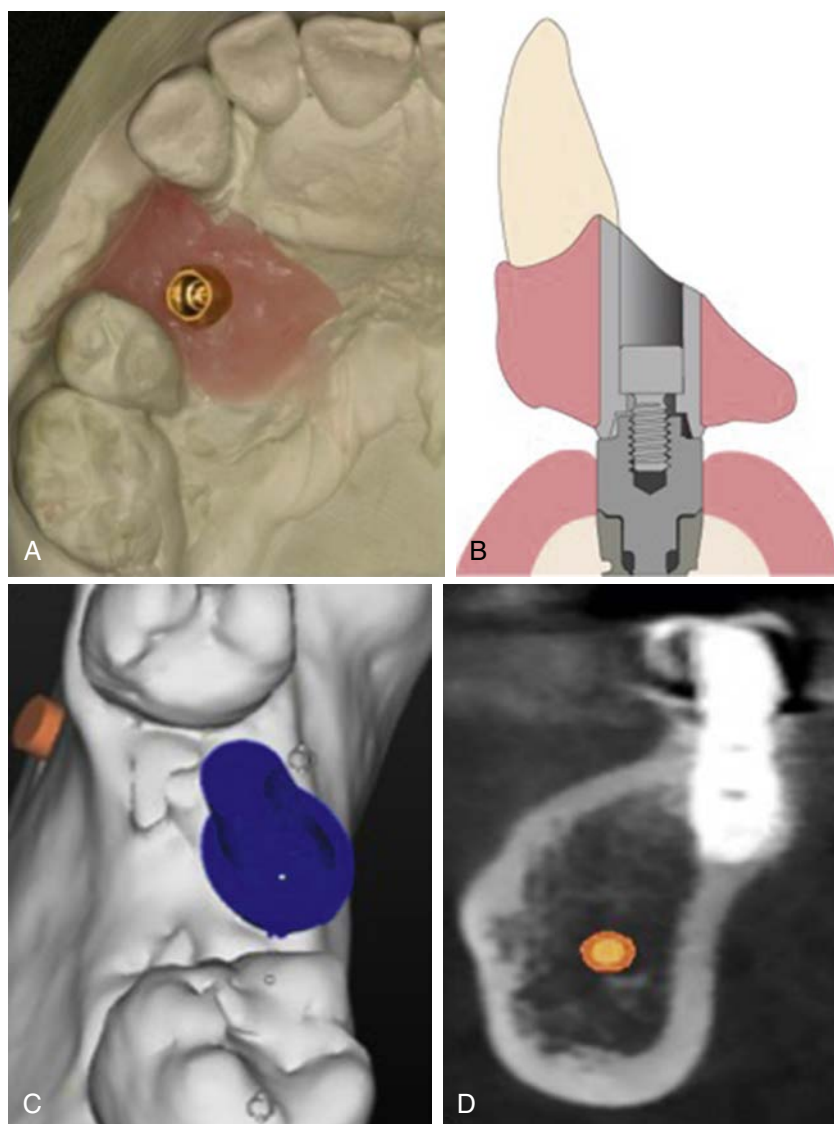
lead to chronic pain, and remediation is usually unsuccessful (Fig. 28.41; Boxes 28.6 and 28.7).

Apicocoronal (Z-Axis)

The depth of implant placement in the bone is a significant factor in relation to the longevity of the implants. Whether the implant is placed too deep or not apical enough, prosthetic and periodontal complications may increase implant morbidity.

Ideal Positioning

In most regions of the mouth, it has been suggested that the implant platform be placed approximately 2 to 4 mm apical to the adjacent cemento-enamel junction (CEJ) or free gingival margin (FGM). Most recently, the free gingival margin is used as the anatomic landmark as this will allow for more accurate representation when soft and hard tissue recession is present.[21] (Fig. 28.42).

The best platform level for a two-stage implant is similar to the most desirable bone level before the loss of a natural tooth, which is 2 mm below the adjacent tooth CEJ.[22] This positions the platform of the implant approximately 3 mm below the facial FGM


• **Fig. 28.37** Lingual positioned implant complications. (A) Lingually placed abutment requiring overcontouring and possible tongue impingement complications. (B) Usually lingually placed implants can be restored with a screw-retained prosthesis. (C) Posterior implant placed too far to the lingual requiring angled abutment. (D) Lingually placed posterior implant perforating the lingual plate.
• **Fig. 28.38** FP-3 Ideal Implant Positioning (A) Immediate placement/load positioning, (B) Final monolithic zirconia prosthesis.

of the implant crown. This position will allow for 3 mm of soft tissue for the emergence of the implant crown on the midfacial region and more as the soft tissue measurements proceed toward the interproximal regions. This depth also increases the thickness of the soft tissues over the facial aspect of the titanium implant
• **Fig. 28.39** (A and B) Facially positioned implants. (C) 3D CBCT image showing lack of bone from facially inclined implant.

body, which masks the darker color. It is easier to use the FGMs of the adjacent teeth to help determine the depth than it is to attempt to use the CEJ as a landmark (Fig. 28.43).

In conclusion, the ideal anterior and posterior implant body position is 2 to 4 mm below the facial FGM of the adjacent teeth. The depth of an implant platform greater than 4 mm below the adjacent CEJ is too deep. An implant platform position less than 2 mm below the FGM of the crown is too shallow. Therefore the ideal depth position of the implant platform is more than 2 mm and less than 4 mm below the FGM.

Excessive Depth

Some authors have suggested that the implant be deepened (countersunk) below the crestal bone more than 4 mm below the facial CEJ of the adjacent teeth to develop a crown emergence profile similar to a natural tooth (Fig. 28.44).[22,23] This provides a subgingival emergence transition of about 5 mm on the facial aspect to achieve the width of the natural tooth (4 mm below the CEJ, and the ideal FGM on the facial is 1 mm above the CEJ). This concept was originally developed for a 4-mm-diameter implant, and the diameter of a central incisor root is 4 mm at a position 4 mm below the CEJ[24] (Fig. 28.45). Very esthetic restorations may be fabricated with this implant depth position because the bulk of subgingival porcelain provides good color and contour for the crown. However, several concerns arise regarding the long-term sulcular health around the implant when it is seated greater than 4 mm below the CEJ.

Various studies have shown during the first year of function, a mean bone loss range of 0.5 to 3.0 mm, depending partly on implant design. The bone maybe lost at least 0.5 mm below the connection of the abutment to the implant body and extends to any smooth or machined surface beyond the crest module.[25] For example, Malevez and colleagues noted more pronounced bone loss for conical implants that had long, smooth, tapered crest modules.[26] This may lead to facial sulcular probing depths of 7 to 8 mm or greater. Grunder evaluated single-tooth

implants in function for 1 year and noted the bone levels were 2 mm apical to the implant–abutment connection, and sulcular probing depths were 9.0 to 10.5 mm, using a Brånemark implant design.[27] As a result, daily care devices cannot maintain the sulcus health, and anaerobic bacteria are more likely to develop. The interproximal regions of the implant crown, which correspond to the incidence or absence of interdental papillae, usually exhibit even greater probing depths. As a result, gingival shrinkage of the tissue is more likely to occur when the implant is placed more than 4 mm below the facial position of the adjacent CEJ.

• **BOX 28.6** **Excessive Angulation (Facially)**

Complication:
• Bone loss (dehiscence)
• Esthetics (overcontour)
• Thin tissue (recession)
• Prosthetic complications
• Implant failure

Prevention:
• Understand ideal angulation with respect to final prosthesis type
• Accurate radiographic evaluation (cone beam computerized tomography)
• Diagnostic wax-up/interactive treatment planning
• Use of a surgical template

Treatment:
• Custom abutments
• Possible removal of implant

• **BOX 28.7** **Excessive Angulation (Lingual)**

Complication:
Maxilla:
• Ridge-lap
• Crown bulky
Mandible:
• Lack of tongue space
• Speech issue
• Overcontour

Prevention:
• Understand ideal angulation with respect to final prosthesis type
• Accurate radiographic evaluation (cone beam computerized tomography)
• Diagnostic wax-up/interactive treatment planning
• Use of a surgical template

Treatment:
• Modified ridge lap screw retained
• Decrease occlusal force factors
• Remove/reposition implant

• **Fig. 28.44** Implant position too deep in apicocoronal position.

The attachment mechanism of the soft tissue above the bone is less tenacious compared with a tooth, and the defense mechanism of the peri-implant tissues may be weaker than that of teeth.[28] To err on the side of safety for the best sulcular health conditions, it is recommended that the clinician should limit sulcular depths adjacent to implants to less than 5 mm.[29] This may be even more relevant for single-tooth implants because of the devastating consequences of gingival shrinkage for long-term esthetics. In addition, the interproximal regions of the single-tooth implant crown is shared with the adjacent teeth, and anaerobic bacteria that form in the region next to the implant may affect the adjacent natural tooth as a result of a horizontal defect (especially when the implant is closer than 1.5 mm to the tooth).

When the implant is countersunk below the crestal cortical bone (as with this depth technique), the trabecular bone around the crest module is weaker against occlusal loads. In addition, when the implant is placed below the crestal bone, the resultant initial crown

height is increased, as are moment forces. An increased risk of additional bone loss also is present from the increased moment loads applied to weaker trabecular bone, which may also result in soft tissue shrinkage over the long term. The end result is longer clinical crowns, which also decrease gradually in width (as the narrowing dimensions approach the implant body). The interproximal region may result in black triangular spacings in lieu of interdental papillae.

The increased crown height also increases forces to the abutment screw and increases the risk of screw loosening.

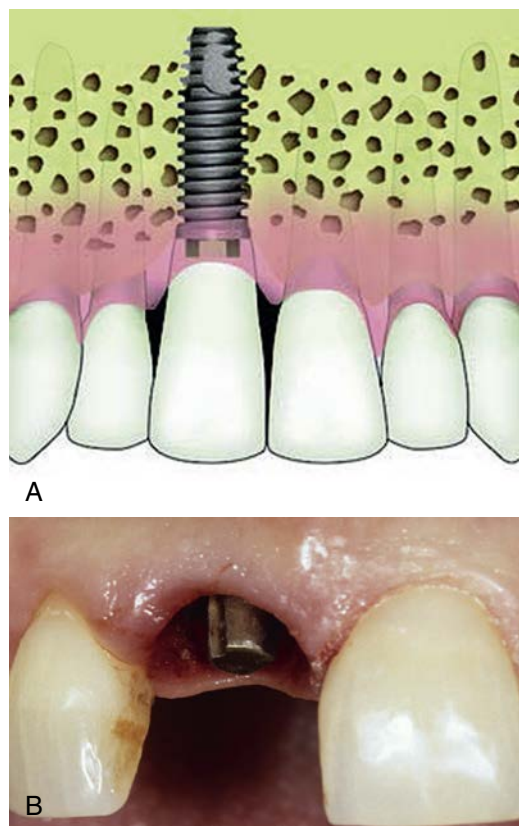
FP-1, FP-2, and FP-3

Placement Too Deep. When implant placement results in positioning deeper than 4 mm below CEJ or FGM, many complications may result:

1. Unfavorable crown height space (CHS; crown-implant ratio).
2. Periodontal complications because of the inability to perform proper hygiene and associated bone loss on adjacent teeth.
3. Higher moment forces, which cause biomechanical overload with resultant crestal bone loss.
4. Prosthetics are more complicated, with difficulty in impression taking, placing abutments, and seating the prosthesis.
5. With deeply placed implants, often the facial plate will resorb, especially if facial inclination is present.
6. Long-term sulcular health is decreased because there is minimal to no cortical bone present. The trabecular bone around the crest module is weaker against occlusal loads.
7. Resultant initial crown height and moment forces are increased. A further increased risk of soft tissue shrinkage occurs long term, with additional bone loss at the crest module. The result is longer clinical crowns, which also decrease gradually in width (as the narrowing dimensions approach the implant body), with resultant black triangular spacings in lieu of interdental papillae and compromised long-term esthetics (Figs. 28.46 and 28.47).

Treatment

Treatment planning phase. During the treatment planning phase, if it is determined there exist no alternatives to placing the implants at a compromised depth (i.e., bone grafting contraindicated), the following can be completed to decrease the possible of complications:

1. Increase the number of implants.
2. Increase the diameters of implants.
• **Fig. 28.46** (A) Apically positioned implant resulting in atypical prosthesis and predisposing the implant to bone loss and peri-implant disease. (B) Resultant prosthesis from apically positioned implant. (C) Mandibular implant apically positioned too close to mandibular canal.


• **Fig. 28.47** (A) Black triangle formation as a result of apical positioned implant. (B) Implant placement too deep resulting in significantly larger clinical crown.

3. Design implants to maximize the surface area.
4. Fabricate removable restorations (less retentive) and incorporate soft tissue support.
5. Remove the removable restoration during sleeping hours to reduce the noxious effects of nocturnal parafunction.
6. Splint implants together, regardless of whether they support a fixed or removable prosthesis (Fig. 28.48).
• **Fig. 28.48** The greater the crown-implant ratio, the greater is the need for more implants and splinting the implants.

At the time of surgery. If an implant is inserted and the position is known to be excessively deep, ideally the implant should be removed, site bone grafted, and then the implant replaced at an ideal position after sufficient healing. If rigid fixation cannot be accomplished, then the implant should be removed and grafting allowed to heal, with future implant placement.

Integrated implant. If it is determined after integration that the implant position is compromised, then the risk versus benefit of removing the implant needs to be determined. If the morbidity of removing the implant is too significant, then the implant may be restored with the following guidelines:
1. Shorten cantilever length.
2. Minimize buccal and lingual offset loads.

3. Ideal emergence profile.
4. Occlusal contact load should be reduced on any offset load from the implant support system.
5. Occlusal contact load should be reduced on any offset load from the implant support system.

Occlusal contacts in centric relation (CR) occlusion may be eliminated on the offset load area. A parafunction load may be reduced because the most cantilevered portion of the prosthesis is loaded only during functional activity while eating food.[30]

NOTE: Questionable treatments, including segmental osteotomies, are not recommended because of the invasiveness, length of treatment time, and questionable prognosis (Box 28.8).

Inadequate Depth

When the implant body is positioned less than 2 mm below the facial FGM of the crown, the cervical esthetics of the restoration are at an increased risk because limited space is present subgingivally to develop the facial emergence profile of the crown. The porcelain or zirconia of the crown may not be subgingival enough to mask the titanium color of the abutment or implant below the crown margin (Fig. 28.49A). If bone loss occurs, then the titanium implant abutment or body may

  - 3 mm below free gingival margin (2–4 mm)
- Options:
  - Graft
  - Change to fixed partial denture

Treatment:
1. Remove implant
2. Ideal emergence profile
3. Monitor
4. ? Treatment

• **Fig. 28.49** (A) An implant replacing a maxillary lateral incisor that is inserted too shallow. The implant crown is not placed subgingival enough to develop an emergence profile or to mask the color of the abutment. (B) The implant is positioned too shallow. (C) An abutment is inserted, and a subgingival margin is created on the implant body. (D) The final implant crown is inserted below the tissue 1.5 mm and on the implant body. (From Misch CE. Single-tooth implant restoration: maxillary anterior and posterior regions. *Dental Implant Prosthetics*. St Louis, MO: Elsevier Mosby; 2015.)

also cast a dark shadow on the gingival tissues. If apical shrinkage of tissue occurs, then the dark titanium abutment and implant body may become directly visible. Periodontal surgical procedures to position soft tissue over the exposed titanium are unpredictable.

On occasion, the crestal bone height is coronal to the ideal bone height (3 mm below the facial FGM). The two most common conditions that result in this finding are (1) when the adjacent teeth are closer than 6 mm (in agenesis of a lateral incisor) and (2) when a block bone graft regenerated excess width and height of bone. Ideally, the midcrestal bone is 3 mm below the interproximal bone and follows the interproximal scallop of the CEJ of the missing tooth. When the teeth are closer than 6 mm (i.e., a lateral incisor in the maxilla), the interproximal bone height of each adjacent tooth to the missing space is able to stimulate and maintain bone at the interproximal bone level. The same conditions may occur when bone augmentation gains height to the interproximal height of bone.

When a single-tooth implant replaces a missing tooth with these conditions, an osteoplasty should be performed so that the midcrestal region is 3 mm apical to the FGM of the adjacent tooth; otherwise, the implant position will be too shallow and result in a short crown height at the gingival margins.

To solve the problem of an implant body placed too shallow, the restoring dentist may need to prepare the implant crest module and place the margin of the crown directly on the implant body (even if esthetic crown lengthening of the surrounding bone and soft tissue is necessary) (see Fig. 28.49B–D). Also feather edge margin should be used to minimizes this weakening of the abutment or implant body.

The following may occur when implant positioning is not deep enough (<3 mm from CEJ, <2 mm from FGM):
1. Inadequate emergence profile (transition from the narrower diameter of the implant compared with the wider dimension of the crown).
2. Decreased retention of the implant, which may lead to uncementable restorations or component fracture.
3. Poor resultant esthetics because implant abutment or implant body will show through, resulting in cervical darkness, and if this occurs in the anterior region, it may be unpleasant for the patient. Normally, the facial margin of the crown will not be able to be placed subgingival enough to mask the titanium color of the abutment below the margin.
• **Fig. 28.50** Poor emergence profile as a result of inadequate implant depth.

4. Inadequate running room because the location of the crest module will leave inadequate room for adequate hygiene. An abrupt change from the prosthetic platform to the diameter of the restoration will result. Normally, this will most likely result in hygiene difficulty (Fig. 28.50).

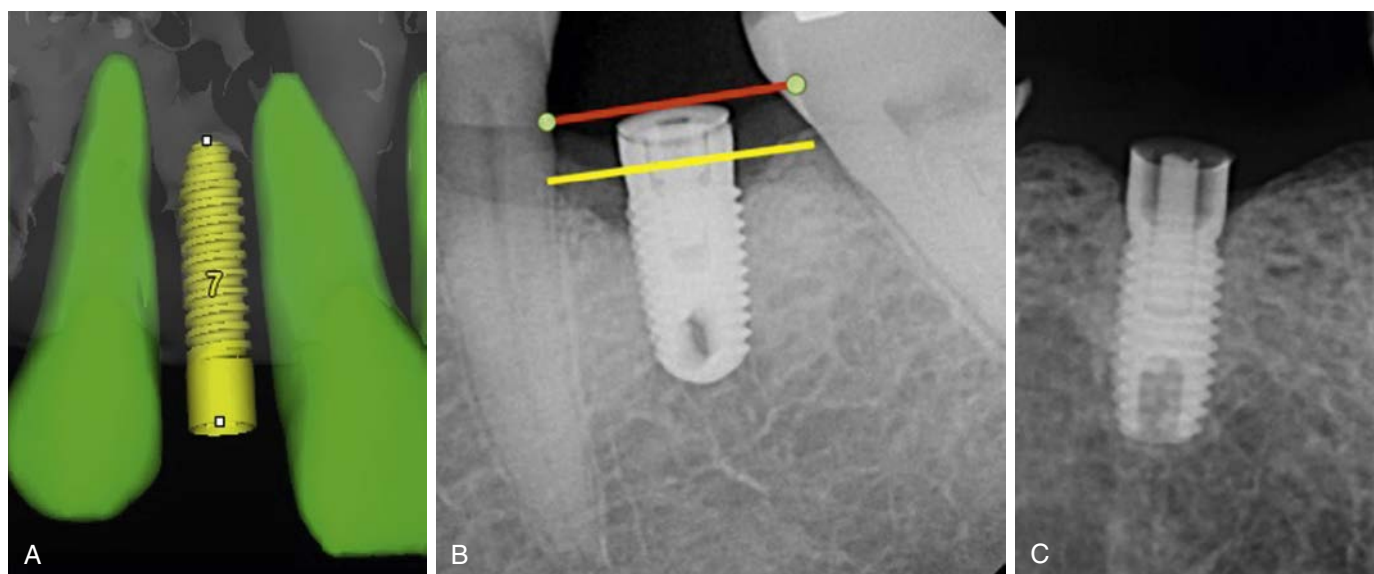
Treatment

Treatment planning phase. If it is determined during the treatment planning phase that implant positioning would result in an implant being in a nonideal location with respect to the FGM, modifications to the treatment plan or final prosthesis may be indicated. Skeletal discrepancies (deep bite), reduced occlusal vertical dimension (OVD) from attrition or abrasion, minimal bone atrophy after tooth loss, and supraeruption of unopposed teeth may all result in less than ideal space for prosthetic replacement of the dentition. Traditional prosthetic and restorative procedures are indicated to restore the proper OVD and plane of occlusion and increase the CHS:
1. Modification or adjustment of opposing occlusion should always be explained to the patient at the initiation of treatment to prevent miscommunication issues. This is extremely important, especially if alteration of the opposing tooth would result in the need for endodontic therapy.
2. Ideally, 8.0 mm of space is required for a cementable prosthesis. The 8-mm requirement for CHS consists of 2 mm of occlusal material space, 4 mm minimum abutment height for retention, and 2 mm above the bone for the biologic width dimension (which does not include the sulcus because a crown margin may be 1 mm subgingival for retention or esthetics). If this cannot be accomplished, a screw-retained prosthesis or change to an FPD treatment plan is indicated.

At time of surgery. If the implant is inserted and the position is known to be excessively shallow, removal of the implant is indicated, the osteotomy should be deepened if available bone is present, and the implant is reinserted at a more favorable depth. The location of vital structures should always be determined before deepening of the osteotomy.

Integrated implant. After implant integration, if the implant is determined to be of inadequate depth, the implant should be ideally removed. However, if the morbidity of removing the implant is too significant, then the following may be evaluated as possible treatment options:
- A screw-retained prosthesis
- Shorten cantilever length/Narrow occlusal table
- Minimize buccal and lingual offset loads
- Ideal emergence profile (Fig. 28.51)
- Increase mechanical and chemical retention of the abutment by roughening the abutment surface or retentive grooves.

RP-4 and RP-5

When evaluating a treatment plan for a removable implant prosthesis, numerous factors need to be addressed. First, it must be determined that adequate interocclusal space is present, especially is a connecting bar is to be utilized. For a bar and overdenture with attachments, 15 mm of space is required from the crest of the ridge to the incisal edge is suggested. If interocclusal space is insufficient, then an osteoplasty at the time of surgery should be completed to increase space for the final prosthesis. Interactive


• **Fig. 28.51** Implant positioning that is too shallow. (A) Cone beam computerized tomography image depicting an implant placement that is too shallow. (B) Periapical radiograph showing insufficient depth *(red)* and ideal placement *(yellow).* (C) Inadequate depth, which led to fracture of implant abutment screw.
• **Fig. 28.52** Interocclusal space (Crown-Height Space) evaluated via CBCT 3D imaging.

treatment planning may be used to fabricate a reduction guide, which will allow the implant clinician to remove the ideal amount of bone. A minimum of 2.0 mm of acrylic is required to adequately retain denture teeth and maintain structural integrity of the prosthesis.

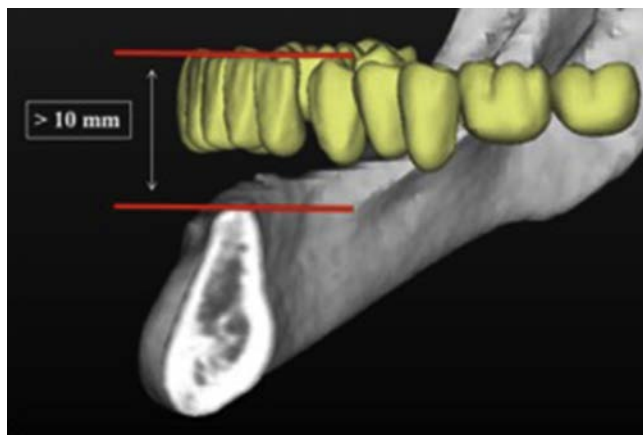
Complications: More than 15 mm

For an RP-5 prosthesis, greater interocclusal space is usually not problematic because of the soft tissue support. However, with an RP-4 (implant-supported) prosthesis, greater interocclusal space may pose a problem, with increased "rocking" of the prosthesis because of the lack of soft tissue support (i.e., RP-4 is completely implant supported). With removable prostheses, two prosthetic levels of height should be taken into consideration. The first is the height of the attachment system to the crest of the bone. The greater the height distance, the greater the forces applied to the bar, screws, and implant structures. The second CHS to consider is the distance from the attachment to the occlusal plane. This distance represents the increase in prosthetic forces applied to the attachment. For example, in a CHS of 15 mm, a locator attachment may be 7 mm from the crest of bone, resulting in a lever action of 7 mm applied to the implants. The distance from the rotation point of the locator attachment to the occlusal plane may be an additional 8 mm. Under these conditions, a greater lever action is applied to the prosthesis than to the implant interface. This results in increased instability of the restoration under lateral forces (Fig. 28.52).[30]

Treatment

If more than 15 mm of space is present, an RP-5 prosthesis should have ideal interocclusal space for the final prosthesis. Peripheral extension and the primary stress-bearing area support (maxilla–horizontal palate, residual ridge; mandible–buccal shelf) should be used to decrease excessive loading force. The occlusion should include bilateral balanced contacts with no occlusal prematurities. If excessive force exists (i.e., excessive CHS and/or parafunction), then an RP-4 (totally implant supported) may be changed to an RP-5 (soft tissue supported) to decrease the force.

Complications: Less than 15 mm

When sufficient CHS is lacking and the prosthesis is more prone to component fatigue and fracture, an overdenture is more difficult to fabricate than a porcelain-to-metal fixed prosthesis or zirconia monolithic prosthesis. The 15-mm minimum CHS provides an adequate bulk of acrylic to resist fracture; space to set denture teeth without modification; and room for attachments, bars, soft tissue, and


- **Fig. 28.53** Minimum interocclusal space for an FP-3 prosthesis.

hygiene. In the mandible (Fig. 28.53) the soft tissue is often 1 to 3 mm in thickness above the bone, so the occlusal plane to soft tissue should be at least 9 to 11 mm in height. An osteoplasty to increase CHS before implant placement or a fixed restoration is often indicated when abundant bone height and width are present (Fig. 28.54).

Treatment

If less than 15 mm of CHS is present, then an RP-4 and RP-5 may present issues. Without sufficient space for tissue health, attachment space, bulk of acrylic, and nonmodified denture teeth, the overdenture may undergo fatigue and possible fractures. An RP-4 may be changed to an RP-5 to obtain soft tissue support to minimize forces to the attachments. Additionally, the overdenture prosthesis should be changed to a metal base, metal reinforced, or fiber mesh to increase the strength of the prosthesis, to prevent prosthesis fracture (Box 28.9).

Implant Position with Respect to Vital Structures

Inferior Alveolar Nerve Canal or Mental Foramen

Accurate positioning of implants in approximation to the inferior alveolar canal and mental foramen is crucial in preventing neurosensory impairment. The correct location of the nerve and canal should be ascertained via three-dimensional imaging, especially when the implant may be within 2 mm of the nerve. After identification of the vital structures, the implant should be placed greater than 2 mm from the inferior alveolar canal or mental foramen. Implant placement less than 2 mm increases the risk of compression or traumatic injuries to the nerve trunk, which may result in neurosensory deficits (Fig. 28.55)

Inferior Border of Mandible

Placement of dental implants in the anterior mandible can lead to significant and even life-threatening complications. Care should be noted to evaluate the angulation and trajectory of the anterior mandible with three-dimensional imaging to minimize the possibility of perforating the lingual cortex. Two-dimensional radiographs (i.e., panoramic) may lead to false representation of the amount of bone available. If the inferior border of the mandible is perforated, then bleeding may become evident from the sublingual and submental blood vessels. Because this area is difficult to access, dangerous sublingual bleeding complications may arise (Fig. 28.56).

Nasal Cavity

The anterior maxilla is often a very challenging area to place implants. Because of the compromised bone in width and height, along with angulation issues, implants are often malpositioned. Placement of implants in the anterior maxilla may be very challenging, especially when a minimal height of bone is present. Ideally, implants should be positioned just short of the nasal floor, without engaging the thin inferior floor of the nasal cavity. There do exist more advanced surgical techniques in which the implants may extend into the nasal cavity 1 to 2 mm via a subnasal graft; however, these procedures should be completed with caution (Fig. 28.57).[31]

Distance from the Maxillary Sinus (Inferior Border)

One of the more challenging areas for implant placement involves the posterior maxilla. The implant dentist often encounters compromised bone height and poor bone quality in this area because of bone loss and pneumatization of the maxillary sinus. There are four treatment options (Misch classification) for implants placed in this area, with respect to the quantity of bone from the crest of the ridge to the inferior border of the sinus (Fig. 28.58):[32]

1. SA-1: Implant placement that does not penetrate the maxillary sinus proper
2. SA-2: Implant placement with penetration into the sinus approximately 1 to 2 mm without bone grafting.
3. SA-3: Implant placement along with bone grafting, either with the crestal or lateral approach
4. SA-4: Sinus augmentation from a lateral approach with delayed implant placement

Prevention of Implant Malposition

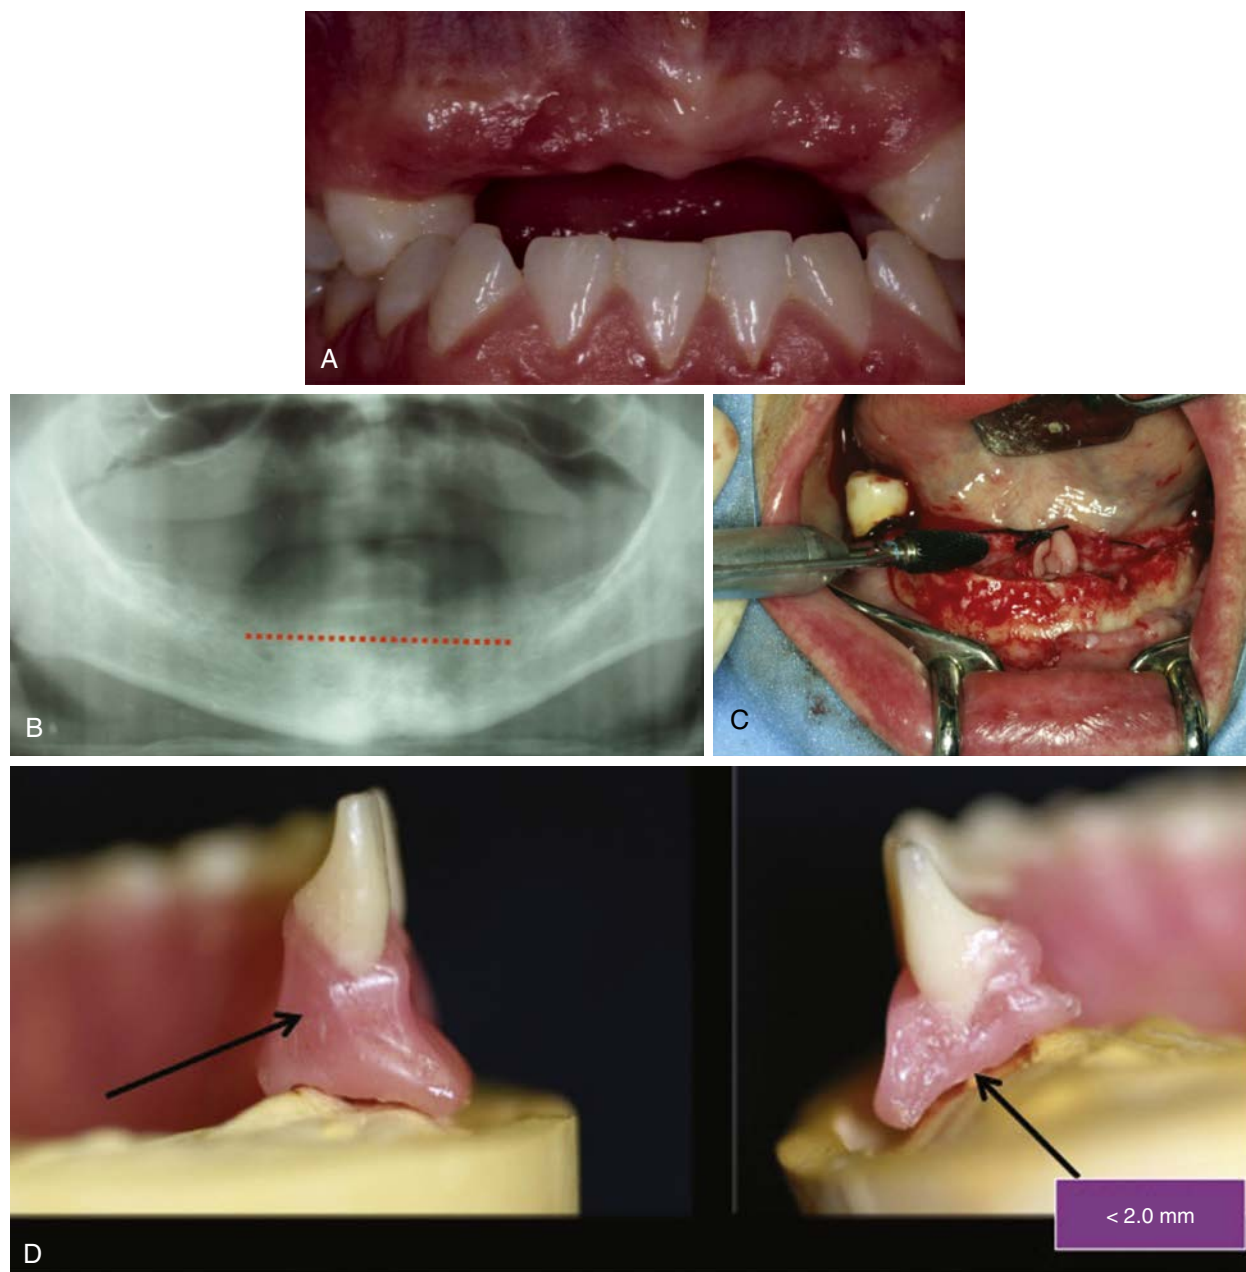
Ideal Treatment Planning

The surest way to minimize errors in positioning during implant surgery is to develop a comprehensive strategy during the preoperative assessment phase of treatment. CBCT analysis offers the clinician an excellent evaluation of the patient's anatomy to properly plan implant position, diameter, and length, which helps to prevent positional, spacing, and depth issues.

Ideal Available Bone

The amount of available bone width (faciopalatal) should be at least 3.0 mm greater than the implant diameter at implant insertion (i.e. 2.0 mm of buccal bone and 1.0 mm of lingual bone). For example, a 4.0-mm implant requires at least 7.0 mm of bone width (minimum). Augmentation has become very predictable and accepted in the profession, therefore the clinician should never compromise when adequate bone is not available. Various bone grafting techniques and materials are available that the clinician should implement in treating these compromised cases.

Understanding the Prosthesis Type and Associated Ideal Positioning

When treatment planning, the final prosthesis should always be evaluated first, before implant placement. The implant clinician must have a strong understanding of the various prosthesis types (e.g., FP-1, FP-2, FP-3, RP-4, RP-5) along with the positional and prosthesis demands and needs. The prosthesis type


• **Fig. 28.54** Lack of interocclusal space for removable prosthesis. (A) Evaluation in the treatment planning phase with patient occluding in centric occlusion. (B) The amount of osteoplasty should be determined preoperatively *(red line)*. (C) Osteoplasty via course acrylic bur. (D) Lack of acrylic bulk leads to poor retention of denture teeth and possible fracture of denture base (<2 mm); at least 2 mm of acrylic is required for adequate strength.

(fixed [FP-1, FP-2, FP-3] or removable [RP-4, RP-5]) dictates the ideal placement of implants. It is imperative the patient be fully informed of the various prosthesis types along with the advantages and disadvantages.

Soft Tissue Evaluation

The biotype (thin versus thick) tissue should always be evaluated before implant placement. Thin biotypes are at higher risk of gingival recession and esthetic issues, especially in the anterior part of the mouth. Thin biotype patients are more susceptible to malpositioning issues, and greater emphasis should be noted on

ideal conditions. If needed, soft tissue augmentation should be completed before implant placement.

Condition of the Adjacent Teeth

Before implant placement in edentulous sites, the adjacent natural teeth should be evaluated for restorability and existing pathology that may be present. A 5- to 10-year prognostic window should be established for each natural tooth before the completion of an implant treatment plan. If a tooth does not possess a favorable 5- to 10-year prognosis, extraction should be discussed or alternative treatment options.

Complication:
• Decrease retention
• Poor emergence profile
• Component fracture

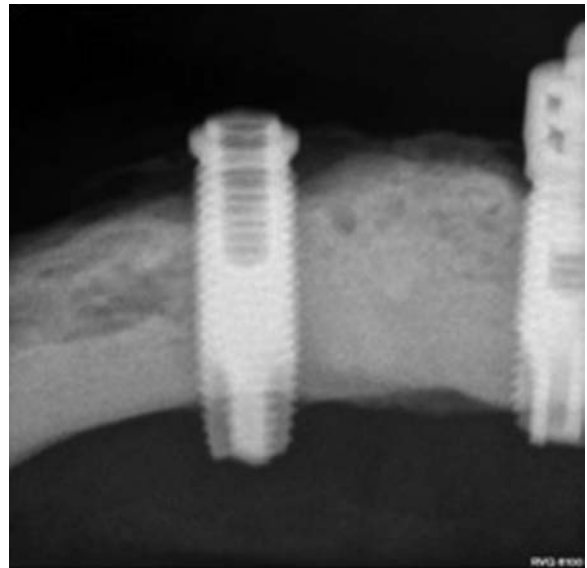
Prevention:
• Ideal:
  • 3 mm below free gingival margin (2–4 mm)
• Options:
  • Change to fixed partial denture

Treatment:
• Screw retained
• Remove implant, replace with deeper implant
• **Fig. 28.55** Poor positioning leading to inferior alveolar canal impingement.

Presence of Pathology

The intended implant site should be carefully evaluated for the presence of pathology at the site or latent adjacent pathology associated with natural teeth, which may lead to increased implant morbidity. It is common to have residual bacteria present, especially if a recently infected natural tooth extraction was performed. Additionally, the adjacent teeth should be evaluated for periapical pathology, because this may lead to a retrograde peri-implantitis.

Good Surgical Technique

To minimize the possibility of improper positioning, the implant clinician should evaluate the osteotomy location after the use of the first pilot drill. Usually, the pilot drill is used to a depth of 6 to 8 mm. A direction indicator is placed and should be evaluated both radiographically and with a surgical template for proper positioning. The position can also be evaluated by having the patient close lightly to determine the interocclusal positioning with the direction indicator. Any modifications of the angulation should be completed with a Lindemann drill.


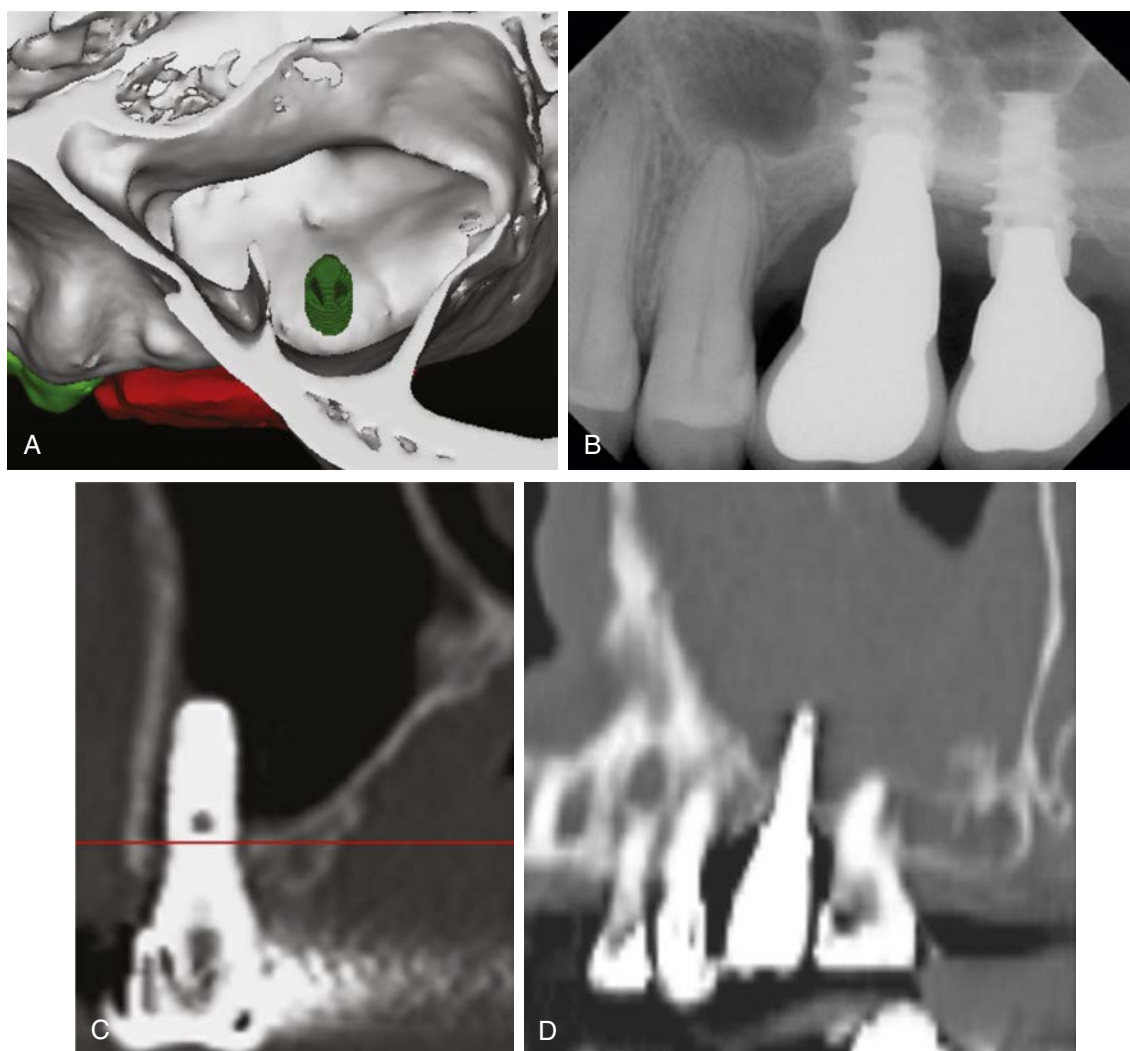
• **Fig. 28.56** Poor positioning leading to perforation of the inferior border of mandible.

• **Fig. 28.57** Poor positioning leading to perforation of the nasal cavity.

Poorly Dense Bone

In poorly dense bone (~D4), overpreparation of the osteotomy site may lead to redirection of the implant on placement. Additionally, implants should be inserted with a handpiece rather than a hand ratchet. When implants are placed in poorly dense bone with a ratchet, the implant may be easily redirectioned by placing it in a more elliptical direction.

Understand the True Location of Vital Structures

Knowing the exact location of the vital structures is paramount in avoiding complications. Impinging on vital structures such as the mandibular canal, maxillary sinus, or nasal cavity may


• **Fig. 28.58** Implant placement in posterior maxilla without bone grafting. (A and B) Implant penetration into the sinus cavity. (C) Implant placed into the sinus depicting no bone in the sinus, leading to inadequate support for the prosthesis. (D) Implant placed into sinus causing rhinosinusitis.

increase morbidity and place the patient at risk for irreversible complications.

Use of Surgical Templates

A surgical template is defined by the prosthodontics glossary as a guide used to assist in ideal surgical placement and angulation of dental implants.[21] The objective of using a surgical template is to provide accurate placement of the implant according to a surgical treatment. There are many different types of surgical templates used today. Stumpel classified surgical templates according to the amount of surgical restriction that is used in the template. The design categories are (1) nonlimiting, (2) partial limiting, and (3) complete limiting.[33]

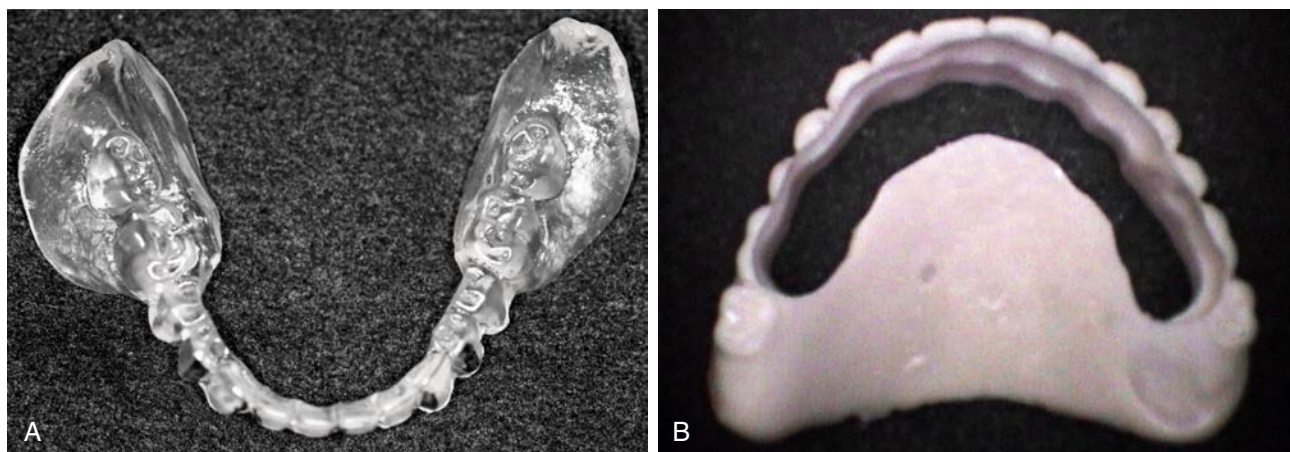
Non-Limiting Design

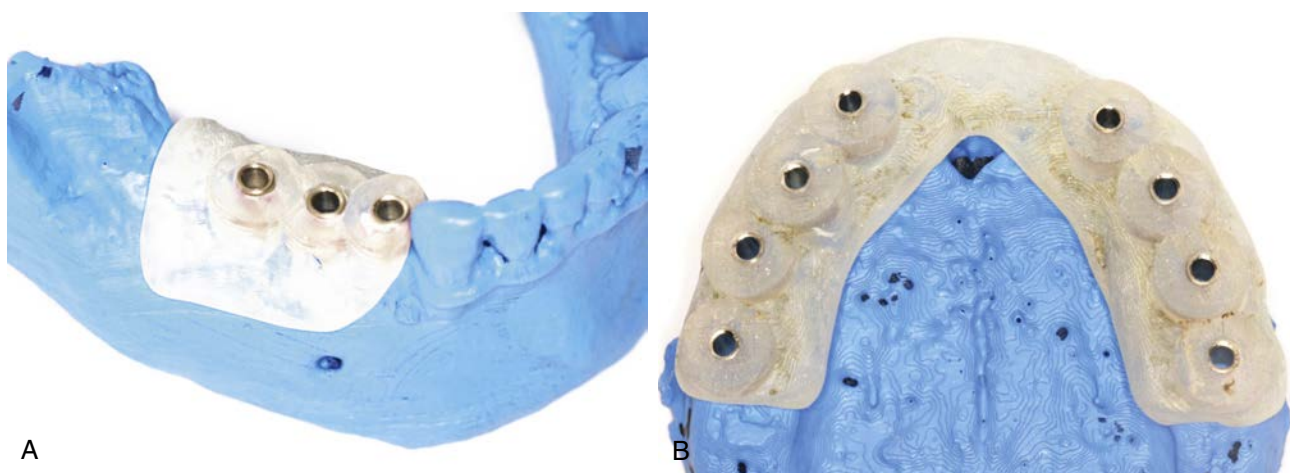
The nonlimiting template allows the implant surgeon dimensional variability in the implant location because the template indicates the ideal space (location) for the final restoration, not the actual mesiodistal angulation. The nonlimiting template is advantageous because of the ease in fabrication and the low cost involved.

These templates allow the implant surgeon only an initial location of the proposed prosthesis, not the exact angulation (buccolingual) and position (mesiodistal). A great deal of flexibility and latitude regarding the final position of the implant is inherent with this type of template (Fig. 28.59).

Partial Limiting Design

The partial limiting design incorporates a guided sleeve or a slot that allows for angulation of one drill size (usually the pilot drill). After the first drill is used, the rest of the osteotomy sites are completed freehand. Various techniques can be used in fabricating a partial limiting template, including manual laboratory-fabricated templates or templates fabricated from a radiographic template, which is then converted to a surgical guide template.

Complication. Although the partial limiting design is more accurate than the nonlimiting design, these templates still do not allow for final, positioning of the implant. Clinical studies have shown these types of templates to have a high degree of error in the buccolingual orientation (Fig. 28.60).[34]


• **Fig. 28.59** Nonlimiting surgical templates: (A) Mandibular prosthesis with lingual contour removed. (B) Maxillary prosthesis with lingual contour removed and retention of the palate for support.


• **Fig. 28.60** Complete limiting surgical templates. (A and B) Complete fabricated limiting templates, which allows for accurate placement in the mesiodistal and buccolingual dimensions.

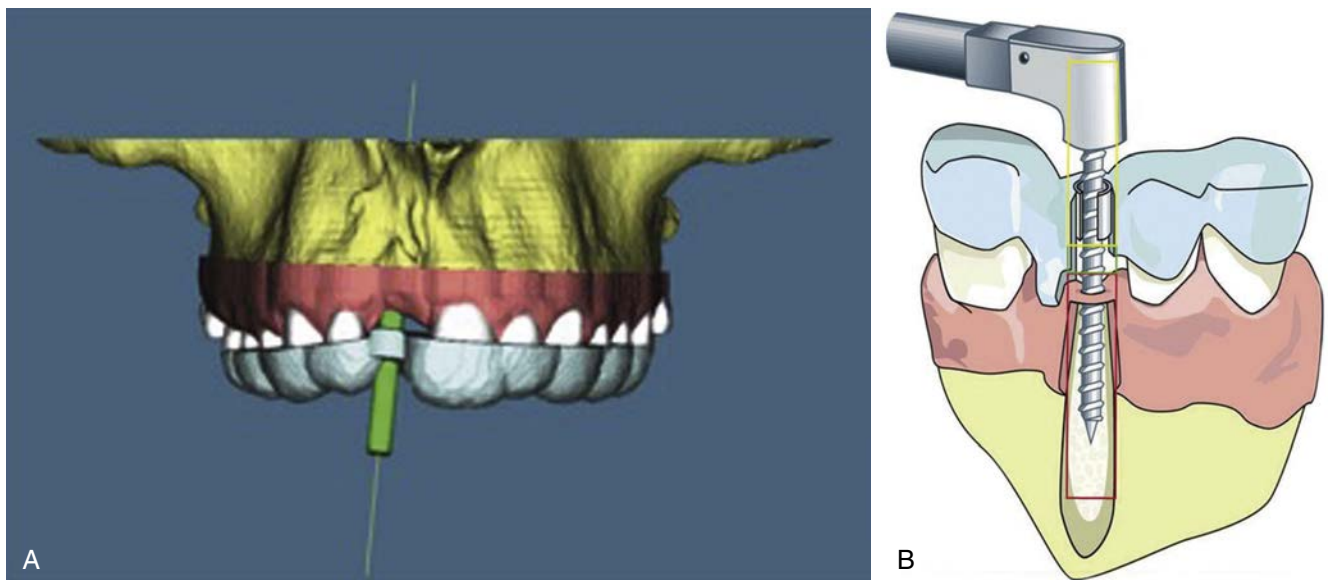
Complete Limiting Design

With the complete limiting template design, the position, angulation, and depth of the osteotomy are dictated by the guided tubes or sleeves, restricting any variation by the implant surgeon. This type of guide prevents any osteotomy error in the buccolingual and mesiodistal planes. Additionally, drill stops can be incorporated to prevent overpreparation in depth of the site. Basically, with the complete limiting design, the final position of the implant is known before the actual surgery. This technique is extremely popular because the prosthetic final abutment or provisional restoration can be prefabricated for immediate provisionalization after implant placement.

Complication. The use of complete limiting surgical templates that are fabricated from interactive treatment planning with cone beam technology has been shown to be highly accurate. However, caution must be used when employing surgical templates that are fabricated conventionally (not from CBCT) on dental study casts, which are rigid, nonfunctional surfaces without information of the soft tissue thickness and bone morphology. These types of surgical templates, usually made from study casts, allow for placement of implants according to an estimate of location of teeth, soft and hard tissue, and vital structures without three-dimensional guidance (Figs. 28.61, 28.62, and 28.63).[35]

Use of CBCT Surgical Guides

To overcome the limitations and complications inherent with conventional surgical templates, the use of CBCT-generated templates has evolved in implant dentistry today. A computer-generated surgical guide (partial limiting or complete limiting) provides a link between the CBCT treatment plan and the actual surgery by transferring the interactive plan accurately to the surgical site.

With the use of CBCT-generated software programs, this anatomic relationship can be predictably determined before surgery. After the scan is completed the data must be converted into a format that can be used by the scanning software. Every treatment-planning software program has its own specific protocol, but all software is compatible with Digital Imaging and Communication in Medicine (DICOM) files that are generated and downloaded from the scanner. Although many third party companies complete the interactive treatment planning process, it is highly recommended the implant dentist be involved in the process. After the files have been converted into the software program, evaluation of potential implant sites in the desired prosthetic locations can be completed. Virtual implants may be placed via comprehensive implant libraries, which include the implant brand, type, diameter, and length. The available bone
• **Fig. 28.61** Bone-supported surgical template. (A and B) Template requires the exposure of the bone and the complete seating of the surgical template.


• **Fig. 28.62** Tooth-supported surgical template. (A and B) Template requires adequate remaining teeth for complete seating and stabilization over the teeth.
• **Fig. 28.63** Soft tissue–supported surgical template. (A and B) Template requires adequate soft tissue to allow for complete seating and stabilization.

dimensions may be ascertained, along with the density and angulation with respect to the planned prosthesis. After completion of the final implant positions, the treatment plan is saved, and the surgical template is designed.[29] it is well documented in the literature that surgical templates are significantly more accurate than freehand insertion.[36] With all types of guides the implant clinician must show good judgment regarding the accuracy of the template and must be able to determine any discrepancies (especially in bone volume) between the intended osteotomy site and the actual current bony architecture of the patient.

Summary

One of the most critical skills in the practice of implant dentistry is the ability to place an implant in the ideal and correct position. The complexity of this skill set is underrated; the clinician needs to understand the three planes of placement, along with maintaining a safe distance from vital structures. Malpositioning may result in a successful integration of the implant, but it may place the intended restoration at significant risk for complication and/or failure. Technological advances such as guided surgery and surgical templates have proven to be helpful to implant clinicians, especially those early on their surgical learning curve or in cases in which space tolerances are low. However, even these techniques have margins of error and

tolerances that need to be fully understood. With a combination of proper treatment planning and ideal positioning guidelines, the implant clinician can ensure a predictable surgical and prosthetic outcome (Box 28.10).

• BOX 28.10 Ideal Implant Positioning Summary

Implant Distances:
- Implant-Tooth: 1.5 mm (apical), 2.0 mm (coronal)
- Implant–implant: 3.0 mm

Bone Thickness: (after implant placement)
- Buccal = 2.0 mm
- Lingual = 1.0 mm

Ideal Positioning:
- Apicocoronal: 2.0–3.0 mm apical to free gingival margin

Prosthesis Type: (Cement vs. Screw Retained)
- Anterior
  - Cement: Slightly lingual to incisal edge
  - Screw: Cingulum Area
- Posterior
  - Cement/Screw: Central Fossa

Interocclusal Space: (minimum)
- Cement-Retained Prosthesis
  - 7–8.0mm (Zirconia), 8–10.0 mm (Porcelain Fused Metal)
- Screw-Retained Prosthesis
  - 5.0–6.0 mm (Zirconia/PFM)
- Overdenture
  - Bar-Retained: 14–16 mm (depending on attachment)
  - Independent Attachment: 9 mm (e.g. Locator)

Vital Structure Distance:
- Nasal Cavity: may engage cortical bone without perforation
- Maxillary Sinus: (into sinus proper)
  - SA-1: Implant placement below sinus floor
  - SA-2: 1.0 – 2.0 mm membrane elevation
  - SA-3: Transcrestal (3.0-4.0 mm), Lateral Wall (> 4.0 mm)
  - SA-4: Lateral Wall: minimum of 5 mm host bone
- Mandibular Anterior: No cortical bone perforation
- Mandibular Posterior: 2.0 mm from mandibular canal/mental foramen

Maxillary Anterior Implant Placement

RANDOLPH R. RESNIK AND CARL E. MISCH[*]

Maxillary Anterior Implant Placement

Contrary to missing a posterior tooth, most patients have an emotional response regarding a maxillary anterior missing tooth. Because the premaxillary teeth are directly within the smile line, no question exists regarding the need to replace the tooth, and financial considerations are usually less important. When posterior teeth are extracted, little resistance to the preparation of adjacent teeth may be given to the dentist. However, when anterior, normal-looking teeth must be prepared to serve as fixed partial denture (FPD) abutments, the patient is more anxious and often looks for an alternative. In the patient's perspective, anterior FPD prostheses are never as esthetic as natural teeth. This in part is because they are able to distinguish between the esthetics of a natural tooth versus a porcelain/zirconia restoration.

Therefore the profession and patients are gravitating to implant replacement instead of conventional prosthetics. Single-tooth implants are now one of the most common implant procedures performed in the United States. In the nonesthetic posterior region, the single-tooth implant is one of the simplest procedures in implant surgery and prosthetics. However, it should be noted, the maxillary anterior single-tooth replacement is often the most difficult procedure in all of implant dentistry.

The highly esthetic zone of the premaxilla often requires both hard (bone and teeth) and soft tissue restoration. The soft tissue drape is usually the most difficult aspect of treatment to develop and maintain. As a consequence, maxillary anterior single-tooth replacement is often a significant challenge, regardless of the experience and skill of the clinician.

Maxillary Anterior Implant Studies

In general, the single-tooth implant has the highest success rate compared with any other treatment option to replace missing teeth with an implant restoration (e.g., short-span FPD, full-arch FPD, single-tooth implant).[1-4] Misch and colleagues reported on 276 anterior maxillary single implants used to restore missing teeth from agenesis. In 255 adolescent patients, the implants were monitored for a range of 2 to 16 years, with a 98.6% implant and crown survival rate.[5] In the same year, Wennstrom and colleagues

reported on a 5-year prospective study with 45 single-tooth implants, with a 97.7% implant survival rate with minimal bone loss.[6] In 2006, Zarone and colleagues reported on lateral maxillary agenesis replacement with 34 implants, with a 97% survival rate at 39 months.[7] A review of the literature by Goodacre and colleagues found that single-tooth implant studies had the highest survival rate of any prosthesis type and averaged 97%.[8] Therefore the maxillary anterior implant has been well researched and most studies show a very high success rate.

More recently, a trend toward single-stage and immediate-placement implants has emerged, appearing especially attractive in the maxillary anterior region. This is preferable because the soft tissue drape is easier to retain, and with this type of treatment shorter treatment time is advantageous. Kemppainen and colleagues in a prospective study of 102 single-tooth implants in the anterior maxilla, reported a 99% success rate using one- and two-stage implant protocols.[9] Other studies have recommended one-stage and immediate load with overwhelming success.[10,11]

Maxillary Anterior Teeth Evaluation

The maxillary anterior implant is successful only if the final restoration it supports is fully supported functionally and esthetically with the adjacent dentition. The exponential growth of the field of implant dentistry has been paralleled by exciting new advancements in esthetic dentistry and plastic regenerative surgery. This growth has made the profession realize that the restoration of the peri-implant soft and hard tissue to an optimal architecture is the key to a successful implant restoration. It is no longer acceptable practice to only achieve osteointegration with an implant. The implant restoration complex in the esthetic zone should ideally be achieved in a context that respects all biological tissues (Fig. 29.1).

When the goal for a maxillary incisor single-tooth replacement is to obtain an ideal result, the clinician should first evaluate not only the edentulous site but also the remaining anterior teeth. Because only one tooth is missing, the adjacent teeth most often dictate its length, contour, shape, and position. If this is not satisfactory, then a potential modification may need to be integrated into the overall treatment plan.

Parameters for a healthy esthetic anterior restoration have been established. The following guidelines have been proposed by esthetic and cosmetic dentistry colleagues. These parameters

[*]Deceased.

706

• **Fig. 29.1** Maxillary anterior implants that may be functional; however, in some situations (i.e., high smile line) they may not be esthetically pleasing to patients because of the addition of pink porcelain between the lateral and central incisor.

• **Fig. 29.2** Patient's left maxillary central incisor was replaced with an implant and crown. The tooth is wider than the right central incisor. Orthodontics could have reduced the horizontal overjet of the lateral and central incisors and resulted in more symmetric teeth. A second option is a veneer on the right central incisor to correct the rotation and make the natural tooth more symmetric to the implant crown.

play a determinant role in the final result and should not be overlooked. The patient must be educated about their present condition before the onset of treatment, and the starting point should be documented. The patient, once fully informed of the existing discrepancies and their potential negative effect on the envisioned result, may decide to address and correct the existing problems of the adjacent teeth or simply elect to accept the compromise. Correction may be as simple as bleaching the remaining teeth or as complex as full esthetic rehabilitation with crown lengthening, soft tissue plastic surgery, veneers or crowns, and orthodontic therapy (or a combination of these procedures).

Maxillary Tooth Size

The two maxillary central incisors should appear symmetric and of similar size, most importantly when the patient has a high smile line. This is most critical to evaluate when the missing tooth is one central incisor (Fig. 29.2). Outline asymmetry is visually acceptable the more distal from the midline the eye travels. When one maxillary tooth is missing, the remaining space may be compromised from drifting of the adjacent teeth. Orthodontic intervention may be indicated when the missing tooth is a central incisor with a mesiodistal space less or more than the size of the corresponding central incisor. The other option is to modify the existing central incisor with a veneer or composite to make it similar in size and shape to the missing tooth restoration. This has the advantage of lowering the mesial interproximal contact and making the two centrals more square shaped, which decreases the height requirement of the papilla. The shades of the two centrals is easier to match when made at the same time in the laboratory. To understand ideal tooth size, the clinician should have a clear understanding of the normal and average tooth dimensions.

Central Incisor. The average clinical crown length of the maxillary central incisor is 10.2 mm for a male patient and 9.4 mm for a female patient.[12] In some cases, surgical crown lengthening and longer anterior teeth may be indicated to reduce gingival exposure during a high-smile lip position. Because the clinical crown height of an implant-supported central incisor is often longer than the adjacent tooth, an esthetic crown lengthening on the natural tooth may be used to align the gingival margins. When an implant crown is longer than the corresponding natural tooth, a crown-lengthening procedure may be more predictable on the natural tooth than attempting to augment the implant crown with soft tissue.

However, the clinical crowns of natural teeth are rarely more than 12 mm high. The width of the average maxillary central is 8.6 mm for a male patient and 8.1 mm for a female patient. Although male teeth are usually slightly longer and wider, the length to width ratio is similar to female teeth, (0.85 for male patients and 0.86 for female patients). A ratio range of 0.70 to 0.86 has been reported to be acceptable for the central incisors when they are similar. When the anterior teeth are made longer and both centrals have the same width, an acceptable result may be obtained.

Lateral Incisor. The average clinical crown length of the maxillary lateral incisor is 8.7 mm for a male patient and 7.8 mm for a female patient. Therefore the average lateral incisor is almost 1.5 mm shorter than the central incisor (at both the gingival region and the incisal edge). Gingival margins of the maxillary lateral incisors may be similar to centrals and canines, but they should not be higher than the neighboring teeth. Therefore an implant crown on the lateral incisor should not be longer than the central or canine. The average width of a lateral incisor is 6.6 mm for a male patient and 6.1 mm for a female patient, but this is more variable than for any other anterior tooth. The length to width ratio is slightly greater for a female patient (0.79, compared with the male patient ratio of 0.76). A lateral incisor space may be slightly narrower than the other natural tooth; however, when replacing the lateral incisor, it may be preferable to perform a slight mesial stripping of the adjacent canine to duplicate and make symmetric the lateral incisors.

Canine. The average male canine clinical crown length is 10.1 mm and width is 7.6 mm, with a ratio of 0.77. The canine is usually the same height as the central but 1 mm narrower. Usually the lateral incisor is 1 mm narrower than the cuspid. The female canine height averages 8.9 mm (0.5 mm shorter than the central) and 7.2 mm in width (1 mm narrower), with a ratio of 0.81. As a general rule, regardless of sex, the central incisor is 2 mm wider than the lateral incisor and 1 mm wider than the canine. However, on the horizontal plane, the canine is 1 to 2 mm shorter than the central incisor and corresponds to the curvature of the lower lip during smiling.

Tooth Shape

Three basic shapes of maxillary anterior teeth exist: (1) square, (2) ovoid, and (3) triangular. The tooth shape will directly influence the interproximal contact area and the gingival embrasure. The

square tooth shape is the most favorable to obtain an ideal soft tissue drape and papillae around the crown because the interproximal contact is further apical and more tooth structure will fill the interproximal region. In contrast, a triangular tooth shape has a more incisal interproximal contact, a steeper gingival scallop, and is farther from the interproximal bone (Fig. 29.3). As a result, a space often exists between the interproximal contact and the interdental papilla of the remaining teeth. This is especially noteworthy to observe at the initial examination. When the soft tissue fills the interproximal space of the remaining anterior teeth that have a triangular shape, the tissues may be very liable and easily disappear during the healing phases after implant surgery. Care should be taken if the adjacent soft tissue requires reflection for a bone graft before the implant insertion. The ideal restoration of the soft tissue with a triangular-shaped tooth is less predictable.

The cervical embrasure of the adjacent teeth to the edentulous site should be particularly evaluated. A triangular tooth is narrow at the cervical embrasure, and the base of the interproximal tissue is wide. In addition, the adjacent tooth contact is often higher off the tissue, with an increased risk of a black triangular space. When such a condition is present on the adjacent teeth of the missing tooth, it is likely that the interdental papillae region will also be compromised on the implant crown. The tooth shape also affects the topography of the underlying hard tissues. The roots of triangular tooth shapes are positioned farther apart; therefore they have thicker facial and interproximal bone. This may decrease the amount of crestal bone loss after an extraction. In addition, the prognosis for an immediate implant insertion is more favorable in these situations because the bone defect is smaller in diameter and the interproximal bone more likely to provide the recommended 1.5 mm or more of interproximal bone from the adjacent tooth. The square-shaped tooth is more likely to have less interproximal bone between the roots. Therefore it presents a greater risk of crestal or interproximal bone loss with an immediate implant insertion, making it less favorable for immediate implant insertion after extraction.

Soft Tissue Drape

The height of the maxillary lip when smiling (high lip line) is one of the most important criterion to evaluate when observing the cervical region of the maxillary anterior teeth. Its position is usually related to age, with older men showing the least amount of teeth and soft tissue and younger female patients displaying the most. Some patients (15% of male patients and 6% of female

patients) show only the incisal half of the anterior teeth when they smile.[13] Those patients should be identified and it should be explained in detail that an ideal soft tissue result in the gingival region is not mandatory. Clinical results in emergence contours, interdental papilla presence, and even shade and contour of the crown are much less demanding. Therefore the additional surgical intervention and cost may not be necessary when these patients are willing to accept a slight compromise in ideal esthetics (Fig. 29.4).

Ideally the height of the maxillary lip should rest at the junction of the free gingival margin on the facial aspect of the maxillary centrals and canine teeth.[14,15] Thus the interdental papillae are visible, but little gingival display is seen over the clinical crowns. Almost 70% of patients have this ideal smile position. A "gummy" smile is defined as showing more than 2 mm of soft tissue above the clinical maxillary crowns and is more acceptable in the female patient. It may occur in more than 14% of the female population and 7% of the male population. The higher the high lip line, the more ideal the esthetic requirements are for the remaining teeth and the single-tooth replacement. Therefore the existing maxillary anterior teeth condition is closely scrutinized when a high lip line exists and ideal results are desired.

The soft tissue drape of the remaining teeth should be evaluated, especially if exposed during the high lip position of smiling. Under ideal conditions, soft tissue completely fills the interproximal space, with no dark triangles from the absence of light within the oral cavity. The interproximal contact between the maxillary central incisors should begin in the incisal third of the teeth and

● **Fig. 29.5** Interdental papillae are often highest between the central incisor, with progressively less height as they proceed distal. The high lip line during smiling shows the interdistal papillae in more than 85% of the patients. (Note: The maxillary right lateral incisor is an implant restoration.)

continue to the height of the central interdental papilla. In a healthy patient, very little to no space is seen between the papillae and interproximal contact. According to Kois, the distance from the facial free gingival margin to the height of the central midinterproximal papilla is usually 4 to 5 mm; therefore the interdental papilla height is approximately 40% to 50% of the exposed tooth length.[16] Interproximal contacts at the incisal position start progressively more gingivally from central to canine. The greatest papilla height is often between the centrals, slightly lower between the centrals and laterals, and even lower between laterals and canines (Fig. 29.5).

However, the papilla height is often similar between the centrals and from the centrals to the laterals. Under ideal conditions the osseous scallop of bone in the maxillary anterior region begins 2 mm below the cement-enamel junction (CEJ) midfacial to a point 3 mm more incisal in the interproximal region. The soft tissue follows this osseous scallop. A soft tissue biological dimension of approximately 3 mm in height above the bone is present at the midfacial position (1 mm above the CEJ) and 3 to 5 mm above the interproximal bone. Therefore if the interproximal contact is within 3 to 5 mm of the interproximal bone, then the interdental papilla will most often completely fill the space. Tarnow and colleagues[17] and Norland and Tarnow[18] measured the distance from the bottom of the interproximal contact to the vertical height of interproximal bone on natural teeth and observed how frequently the interproximal space would be completely filled by soft tissue. The distances ranged from 3 to 10 mm, with 88% of the contacts to the bone at 5 mm, 6 mm, or 7 mm; the most common measurement was 6 mm (40%), followed by 5 mm (25%), and then 7 mm (22%) (Fig. 29.6).

When the contact point to bone was 3 to 5 mm, the papilla almost always filled the space. When the contact was 6 mm, an absence of papilla was noted almost 45% of the time; at a 7-mm distance the papilla did not fill the space 75% of the time (Fig. 29.7). In other words, a difference of 1 to 2 mm from the interproximal contact to the interseptal bone is very significant in relation to the interproximal soft tissue. Therefore it is critical to evaluate this dimension before implant surgery. If the height of the interproximal bone is lost or the interproximal contact is more incisal, then the soft tissue will less likely fill the interproximal space. In addition, contact distances to bone of 7 mm sometimes present a papilla initially, but after surgical reflection the chance this papilla will return to the original position may be less than 25%.
● **Fig. 29.6** Distance from the interproximal contact to the crest of bone with natural teeth most often measures 5 mm, 6 mm, or 7 mm.[58] (Tarnow, D. P., Magner, A. W., & Fletcher, P. (1992). The effect of the distance from the contact point to the crest of bone on the presence or absence of the interproximal dental papilla. *Journal of periodontology*, 63(12), 995-996.)
● **Fig. 29.7** When the interproximal contact-to-bone distance is 5 mm or less, the interdental papilla completely fills (100%) the space between the teeth. When the contact–bone distance is 6 mm (the most common measurement), almost 40% of the time a black triangular space occurs between the teeth from the absence of papilla filling the space. A 7-mm or greater contact–bone distance nearly always has an incomplete fill of the interproximal space with the soft tissue. (From Tarnow DP, Magner AW, Fletcher P. The effect of the distance from the contact point to the crest of bone on the presence or absence of the interproximal dental papilla. *J Periodontol*. 1992;63(12):995-996.)

The higher the gingival scallop, or difference between the height of the papilla and the free gingival margin, the higher the risk for gingival loss after extraction. Likewise, once the tooth is extracted and an edentulous site is healed, the less likely the surgical and restorative procedures will be able to restore an ideal soft tissue contour. In contrast, a flatter gingival scallop and an interproximal tissue close to the osseous crest are conducive to minimal tissue shrinkage and a more ideal outcome. The height of the facial gingival contour is in the middle of the tooth for the maxillary lateral incisors and the four mandibular anterior teeth; however, it is slightly to the distal on the central incisors and canines. The height of the free gingival margins of the two centrals are similar to both canines. The cervical height of the lateral incisors may be level or below the centrals and canines but symmetric to each other. It may be easier to lengthen the cervical contour of the contralateral incisor when replacing a missing lateral incisor with an implant

• **Fig. 29.8** Single missing central incisor is often the most challenging surgical and prosthetic implant to complete. The soft and hard tissues need to be ideal to obtain an acceptable esthetic result.

• **Fig. 29.9** Maxillary left central incisor implant crown in position. The soft tissue drape is established through both surgical and prosthetic methods.

instead of attempting to lower the gingival contour on the implant crown when gingiva and bone shrinkage has occurred. The least desirable gingival contour is seen when one anterior tooth is higher than the rest. Unfortunately this is a common occurrence with an implant crown when the bone and/or soft tissue is not augmented in conjunction with implant insertion or uncovery.

The color and texture of the tissue is also evaluated in the edentulous tooth site. The attached keratinized gingival tone and coral-pink color should be similar around the implant abutment compared with the healthy adjacent teeth. The biotype of the gingiva is usually classified as either thick or thin. Thicker tissue is more resistant to the shrinkage or recession and more often leads to the formation of a periodontal pocket after bone loss. Thin gingival tissues around the teeth are more prone to shrinkage after tooth extraction and are more difficult to elevate or augment after tooth loss. Gingival recession is the most common esthetic complication of thin biotypes after anterior single-tooth extraction and is also a concern after implant surgery, uncovery, or both. According to Kois,[19] predictability of the maxillary anterior single-tooth implant is ultimately determined by the patient's own presenting anatomy. Favorable conditions include (1) when the tooth position is more coronal relative to the full gingival margin, (2) square tooth shapes, (3) flat scallop periodontium forms, (4) thick periodontium biotypes, and (5) high (<3 mm) facial osseous crest positions of the teeth and midcrestal. Unfavorable patient anatomy includes (1) aligned or apical preexisting tooth (relative to the free gingival margin), (2) triangular tooth shapes, (3) high scallop periodontium form, (4) thin periodontium types, and (5) low (>4 mm) facial osseous crest positions in relation to adjacent teeth and the midcrestal area.

Anatomic Challenges

Natural Tooth Size Versus Implant Diameter

The esthetics of a maxillary anterior single crown on a natural tooth is often one of the most difficult procedures in restorative dentistry. When an implant is being restored, the challenges are even greater (Figs. 29.8 and 29.9). When comparing the size and shape of an implant versus natural tooth, the implant is often 5 mm or less in diameter and round in cross section. A natural maxillary anterior crown cervix region is approximately 4.5 to 7 mm in mesiodistal cross section and is never completely round. In fact, the natural central incisor and canine teeth are often larger

in their faciopalatal dimension at the CEJ than in the mesiodistal dimension. Because the bone is lost first in the faciopalatal width, the greater width of implants in this dimension would require even greater augmentation than presently advocated. As a result, the cervical esthetics of a single-implant crown must accommodate a round-diameter implant and balance hygiene and esthetic parameters. Additional prosthetic steps and components with varied emergence profiles or customized tooth-colored abutments are often required to render the illusion of a crown on a natural abutment.

Compromised Bone Height

The available bone should be closely evaluated because it will greatly influence the soft tissue drape, implant size, implant position (angulation and depth), and ultimately the final esthetic outcome. Hard tissue topography is a prerequisite to an optimal, esthetic implant restoration. Therefore a comprehensive cone beam computerized tomography (CBCT) evaluation of the available bone volume present is mandatory to determine the ideal implant position. The osseous midcrestal position of the edentulous site should be approximately 2 to 3 mm below the facial CEJ or free gingival margin of the adjacent teeth. The interproximal bone should be scalloped 3 mm more incisal than the midcrestal position.

The position of the interproximal crest of bone is an important anatomic consideration, especially for the development of the interproximal soft tissue height. Becker and colleagues classified the range of interproximal bone height above the midfacial scallop from less than 2.1 mm (flat) to scalloped (2.8 mm) to pronounced scalloped (<4.1 mm).[20] The flat anatomy should correspond to a square-shaped tooth, the scalloped to an ovoid-shaped tooth, and the pronounced scalloped to a triangular-shaped tooth (Fig. 29.10). However, these relationships do not always exist. When a flat interdental-to-crest dimension is found on triangular teeth, the interproximal space will usually not be filled with soft tissue because the dimension of the interproximal contact to the bone will be greater than 5 mm (Fig. 29.11).[21]

Often the osseous crest may be more apical than ideal in both the implant site and the adjacent tooth roots. Under these conditions, ideal crown contour, soft tissue emergence, and interproximal tissue conditions are less likely (Figs. 29.12 and 29.13). Instead of the expected FP-1 prosthesis, most likely an FP-2 prosthesis will be the end result. Bone and soft tissue changes after maxillary anterior tooth loss are rather rapid and of considerable consequence. As a result, many maxillary anterior edentulous sites

require at least some bone and/or soft tissue modification before, in conjunction with, and/or at implant uncovery.

Compromised Mesiodistal Space

An adequate mesiodistal space is necessary for an esthetic outcome of an implant restoration and the interproximal soft tissue health of the adjacent teeth. A traditional two-piece implant should be a minimum of 1.5 mm from an adjacent tooth. When the implant is closer to an adjacent tooth, any bone loss related to the micro-gap, the biological width, and/or stress may result in loss of bone around the implant or adjacent tooth. This may compromise interproximal esthetics and/or sulcular health of the implant and natural tooth (Fig. 29.14).[22] In addition, when an implant is less than 1.5 mm from a natural tooth, inadequate room is available for an ideal emergence profile of the implant restoration.

Compromised Faciopalatal Width

In most cases in which a maxillary anterior single tooth is lost, the facial plate of bone will be compromised. Studies have shown a 25% decrease in faciopalatal width occurs within the first year of tooth loss and rapidly evolves into a 30% to 40% decrease within 3 years. As a result, even an intact alveolus 6 to 8 mm wide is often inadequate in width after 1 year for a division A root-form

• **Fig. 29.10** Triangular tooth form corresponds to the greatest width and height of interdental papillae and the most incisal interproximal contact position on the crown.
• **Fig. 29.11** When natural teeth have an interproximal crown contact to interseptal bone distance of 5 mm or less, the interdental papilla almost always fills the interproximal space. When the distance is 6 mm, the interproximal space is not filled with soft tissue almost 40% of the time; at 7 mm the interproximal space is filled with an interproximal papilla 25% of the time.

implant in a central incisor position, and after 3 years it almost never presents adequate available bone for an ideal sized implant. The bone width loss is primarily from the facial region, because the labial plate is very thin compared with the palatal plate, and facial undercuts are often found over the roots of the teeth (Fig. 29.15).[23] Studies have shown the median buccal alveolar thickness in the maxillary anterior region to be; 1 mm apical to alveolar bone margin = 0.83 mm, midroot = 0.70 mm, and 1 mm from the tooth apex = 0.88. A bone graft is often necessary to restore the
• **Fig. 29.12** Implant position slightly apical to the ideal 3 mm below the free gingival margin resulting in an FP-2 prosthesis (elongated clinical crown compared with adjacent teeth).
• **Fig. 29.13** Implant position significantly placed apical to the adjacent teeth, which will result in remodeling of the crestal bone. Note the increased crown height space leading to an FP-3 prosthesis (prosthesis replacing clinical crown and soft tissue with pink porcelain or zirconia).

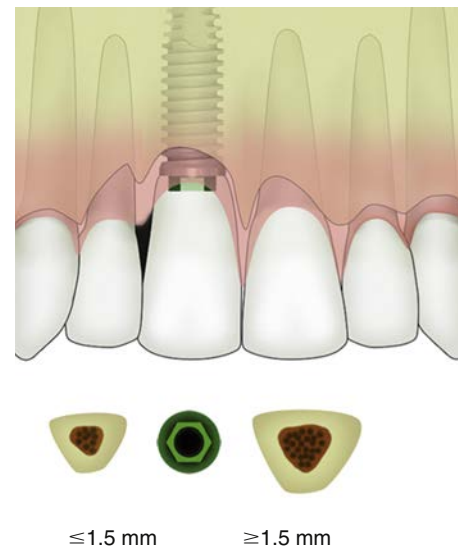
proper anatomy of the ridge and to avoid a compromised implant position more palatal and apical.

The amount of available bone width (faciopalatal) should be at least 3.0 mm greater than the implant diameter at implant insertion. Therefore a 3.5-mm implant requires at least 6.5 mm of bone width. Bone augmentation in width is very predictable. In many instances it is performed before implant placement; however, in some cases, it may be performed at the time of implant insertion, especially when minimal dehiscence of the implant is visible. It should be emphasized that the implant diameter measurement is at the crest module of the implant. Most 3.75-mm-diameter implant bodies are 4.1 mm at the crest module. In these situations, the mesiodistal limitation is 7.1 mm and the faciolingual width limitation is 7.1 mm.

Selection of the Implant Size

The first factor that influences the size of an implant is the mesiodistal dimension of the missing tooth. The average mesiodistal dimension of a central incisor is 8.6 mm (male) and 8.1 mm (female), a lateral incisor is 6.6 mm (male) and 6.1 mm (female), and a canine is 7.6 mm (male) and 7.2 mm (female). In general, the implant body should not be as wide as the natural tooth or clinical crown because the emergence contour and interdental papillae region cannot be properly established.

The mesiodistal dimensions of the maxillary central incisor at the cervix (preferably 1 mm below the free gingival margin) averages 6.4 mm, the lateral incisor dimension is 4.7 mm, and canine natural teeth at the cervix are 5.6 mm (Table 29.1).[24] However, these dimensions are also too large for an implant. The bone level on natural teeth is approximately 2 mm below the CEJ;

≤1.5 mm   ≥1.5 mm


• **Fig. 29.14** If bone loss occurs on an implant placed closer than 1.5 mm to a tooth (on the distal), then bone and soft tissue drape will also be lost on the tooth. As a result, the distance from the interproximal crown contact to the interproximal bone increases, and the risk of soft tissue shrinkage and loss of interdental papilla increases. When the implant is greater than 1.5 mm from the tooth (on the mesial); bone loss on the implants does not cause bone loss on the tooth root. The interproximal crown contact to interproximal bone relationship remains ideal, and the interdental papilla is maintained.

A   B   C   D   E
• **Fig. 29.15** Bone Resorption in the Maxillary Anterior (A) Before the loss of a maxillary anterior tooth, the bone around the roots most often is present. (B) Extraction often causes a loss of the thin labial plate of bone over the root. After extraction, the residual ridge most often is decreased in width (division B). (C) After 6 months to 1 year, the residual ridge continues to resorb and becomes division B–w. (D) Eventually, the residual ridge forms a C–w bone volume that is slightly deficient in height and less than 2.5 mm in width. (E) This bone volume often extends almost to the floor of the nose.

TABLE 29.1	Maxillary Teeth Dimensions				
Type of Tooth	Mesiodistal Crown (mm)	Mesiodistal Cervix (mm)	Faciolingual Crown (mm)	Faciolingual Cervix (mm)	2 mm Below Cement-Enamel Junction
Central incisor	8.6	6.4	7.1	6.4	5.5
Lateral incisor	6.6	4.7	6.2	5.8	4.3
Canine	7.6	5.6	8.1	7.6	4.6
• **Fig. 29.16** Compromised bone width. (A) Preoperative view is very deceiving and can give a false positive on the amount of bone present. (B) Reflection of the ridge tissue reveals a significant defect present.
• **Fig. 29.17** (A) Large ridge defect. (B) To gain adequate width of bone, a symphysis bone graft is completed.

the natural tooth dimensions at this bone level are reduced to 5.5 mm for central incisors, 4.3 mm for lateral incisors, and 4.6 mm for canines. Therefore, in theory, the latter dimensions most closely resemble the consummate implant diameter to mimic the emergence profile of a natural tooth. However, this dimension is usually too large to adequately restore the soft tissue drape of the missing anterior tooth.

The second factor that determines the mesiodistal implant diameter is the necessary distance from an adjacent tooth root.[25] Initial vertical bone loss around an implant during the first year of loading is variable and ranges from 0.5 to more than 3.0 mm. The height of the interseptal (interimplant) bone in part determines the incidence of presence or absence of the interdental papillae between the teeth. When the distance from the interseptal bone to interproximal contact is 5 mm or less, the papilla fills the space. When the distance is 6 mm, a partial absence of papilla is seen 45% of the time, and at 7 mm the risk of a compromise in the interproximal space is 75%.[26] Therefore the intraseptal bone height is relative to the maintenance of the interdental papilla and should be preserved. As a consequence, the implant should be at least 1.5 mm from the adjacent teeth whenever possible, and the interseptal bone on the adjacent teeth should be within 5 mm of the desired interproximal crown contact position.

In summary, two mesiodistal parameters determine the preferable implant size. The suggested width of the single-tooth implant should correspond to the width of the missing natural tooth, 2 mm below the CEJ. The distance between the roots of the adjacent teeth should also be measured. The implant diameter + 3 mm (1.5 mm on each side) should be equal to or less than the distance between the adjacent roots, at the crest of the ridge (which is 2 mm below the interproximal CEJ).

The next dimension that determines the width of an anterior implant is the faciopalatal dimension of bone. The width of bone should allow at least 1.5 mm on the facial aspect of the implant so that if a vertical defect forms around the crest module, then that defect would not become horizontal and change the cervical contour of the facial gingival (Fig. 29.16). Because of its initial reduced volume, facial bone tends to be labile, and its resorption is responsible for most of the compromised long-term esthetic results in the anterior maxilla. The faciopalatal width dimension is not as critical on the palatal aspect of the implant because it is dense cortical bone, more resistant to bone loss, and not within the esthetic zone. Facial bone grafting at the time of implant insertion is frequently indicated because the bone volume in width is often compromised (Figs. 29.17 and 29.18).

The width of the implant should mimic the emergence of a natural tooth and help preserve the bone and health of the adjacent teeth. The natural intraroot distance of the two central incisors distance is approximately 2 mm. However, the natural roots of the central to lateral and lateral to canine are usually less than 1.5 mm
• **Fig. 29.18** (A) Compromised ridge with significant deficiency in width. (B) Guided bone regeneration required to obtain sufficient width and height for implant placement.

Lateral incisor: 3.0–3.5 mm
Canine: 3.7–4.2 mm

---

apart and often only 0.5 mm of space exists between them. As a consequence, the typical size of the single-tooth implant is usually smaller in diameter than the natural tooth root.

The typical diameters of the implant used to replace the average-size tooth often results in a 4.0- to 5.2-mm implant for a central incisor, a 3.0- to 3.5-mm implant for a lateral incisor, and a 3.7- to 4.2-mm implant for a canine. The difference in the emergence profile of a 4-mm-diameter implant and a 5-mm-diameter implant is negligible and often not clinically relevant for an anterior tooth because a 0.5-mm difference occurs on each side of the implant. Therefore, when in doubt, the clinician should use a smaller diameter implant. As such, a 4-mm-diameter implant may often be used in the central-implant position for a single-tooth replacement. Likewise, a 3.0- to 3.5-mm implant is often used for a lateral incisor single-tooth restoration (Box 29.1).

Implant Position

The maxillary anterior single-tooth implant should be positioned precisely in three planes. From a mesiodistal aspect, the implant most often is placed in the middle of the space, with an equal amount of interproximal bone toward each adjacent tooth. On occasion, the central incisor implant is positioned slightly to the distal of the intratooth space (Fig. 29.19) when the incisive foramen is enlarged and encroaches on the ideal placement. When a central incisor implant is planned and the foramen between the existing central incisor root and implant site is larger than usual, the remaining bone may be inadequate for placement.

The nasopalatine foramen may also expand off to one side of the midline within the bony canal. When the central incisor implant is placed, the implant may encroach on the canal and result in a soft tissue interface on the mesiopalatal surface of the implant. As a precaution, the clinician should reflect the palatal tissue when placing a maxillary central incisor implant and, if necessary, place the implant in a more distal position (Fig. 29.20). This usually requires a smaller diameter implant than usual to remain 1.5 mm or more from the lateral incisor. On occasion, the contents of the foramen maybe be removed and a bone graft inserted to decrease the size of the incisive canal.

The midfaciopalatal position of the implant is in the middle to slightly palatal 0.5 mm of the edentulous ridge of adequate contour. This approach permits the use of the greatest diameter implant. The crestal bone should be at least 1.5-2.0 mm wider on the facial aspect of the implant and 1.0 mm on the palatal aspect. Therefore for a 4-mm-diameter implant, a minimum 6.5-mm faciopalatal width of bone is required for the central or canine position, and 6.0 mm of bone width is required for a lateral incisor with a 3.5-mm implant. Bone spreading in conjunction with implant placement or bone grafting on the facial aspect of the edentulous site may be indicated when the ridge is less wide than is desirable. The thickness of bone on the facial aspect of a natural root is usually 0.5-0.7 mm thick in the anterior region. As a result, if the implant is placed in the center of the ridge, the implant will be 1 mm or more palatal than the facial emergence of the adjacent crowns at the free gingival margin.

The implant center is positioned in the faciopalatal center of the edentulous ridge and the midmesiodistal position. The implant body angulation from this point is considered next. In the literature, three faciopalatal angulations of the implant body are suggested: (1) a facial angulation so that emergence of the final crown will be similar to adjacent teeth, (2) under the incisal edge of the final restoration, and (3) within the cingulum position of the implant crown (Fig. 29.21).

Facial Implant Body Angulation

Researchers often theorize that a maxillary anterior implant body angulation should be positioned at the facial emergence of the final crown. The facial implant position is predicated on the concept that the facial emergence of the implant crown at the cervical should be in the same position as a natural tooth. At first, this makes some sense. However, the crown of a natural tooth has two planes, and its incisal edge is palatal to the facial emergence of the natural tooth by 12 to 15 degrees (Fig. 29.22). This is why anterior crown preparations are in two or three planes. The implant body is more palatal than a natural root, so 1.5 mm of bone exists facially. In addition, because the implant is narrower in diameter than the faciopalatal root dimension, when the implant body is oriented as a natural tooth and has a facial emergence, a straight abutment is not wide enough to permit the two or three plane reduction to bring the incisal edge of the preparation more palatal. As a result, the incisal edge of the preparation remains too facial. Therefore when the implant is angled to the facial emergence of a tooth, an angled abutment of 15 degrees must be used to bring the incisal edge more palatal. Most two-piece angled abutments have a design flaw that compromises facial cervical esthetics. The metal flange facial to the abutment

A   B
• **Fig. 29.19** (A) The ideal mesiodistal implant position for a central incisor is 0.5 to 1.0 mm more distal than the midtooth position. This decreases the risk of encroachment on the incisive canal. (B) The best mesiodistal position for a cuspid is centered in the cuspid position.

screw is thinner than a straight abutment and may result in fracture (especially because angled loads are placed on the facial-positioned implant). The manufacturers thicken the profile of the abutment on the facial aspect to reduce the risk of fracture. However, this design flaw brings the cervical facial margin more facial and wider than the implant body, which is already as facial as the adjacent tooth. As a result, the implant crown margin is facially overcontoured. The restoring doctor then has to prepare the facial aspect of the abutment metal flange for esthetics, which weakens it and makes it prone to fracture. When the implant clinician attempts to align the implant body with the facial aspect of adjacent teeth, the implant may inadvertently be inserted too facial. No single method exists to restore proper esthetics when the implant abutment is located above the free gingival margin of the adjacent teeth. At best, the final crown appears too long and too facial. Soft tissue grafts and/or bone augmentation do not improve the condition once the implant is already incorrectly inserted (Fig. 29.23).

The natural maxillary anterior teeth are loaded at a 12- to 15-degree angle because of their natural angulation compared with the mandibular anterior teeth. This is one reason the maxillary anterior teeth are wider in diameter than mandibular anterior teeth (which are most commonly loaded in their long axis). The facial angulation of the implant body often corresponds to an implant body angulation, which leads to 15-degree off-axial loads and increases the force to the abutment screw-implant-bone complex by 25.9% compared with a long axis load. These offset loads increase the risks of abutment screw loosening, crestal bone loss, and cervical soft tissue marginal shrinkage. In summary, implants angled too facially compromise the esthetics and increase the risk of complications (Fig. 29.24).

Cingulum Implant Body Angulation

A second angulation suggested in the literature is more palatal, with an emergence under the cingulum of the crown. This also
• **Fig. 29.20** Complete reflection of lingual tissue to determine the position and size of the nasopalatine foramen and canal. The enlarged nasopalatine canal and foramen has led to compromised bone for implant placement.

may be the result of an implant insertion in a width-deficient ridge (division B) because the bone is lost primarily on the facial. This position is often the goal when a screw-retained crown is used for the prosthesis. The prosthesis fixation screw (to retain a maxillary anterior crown) cannot be located in the incisal or facial region of the crown as this will impinge on the esthetics.

The cingulum implant position may result in a considerable compromise. The implant body is round and usually 4.0 to 5.5 mm in diameter. The labial cervical contour of the implant crown must be similar to the adjacent teeth for the ultimate esthetic effect. Because the long axis of the implant for a screw-retained crown must emerge in the cingulum position, this most often requires a facial projection of the crown or "buccal correction" facing away from the implant body. The facial ridge lap must extend 2 to 4 mm and is often similar in contour to the modified ridge lap pontic of a three-unit fixed prosthesis (Fig. 29.25).

The modified ridge lap crown has become a common solution to correct the esthetics of the restoration when the implant is placed in narrow bone or follows a palatal angulation position. However, plaque control on the facial of the implant is almost impossible. Even if the toothbrush could reach the gingival sulcus, no hygiene device could be manipulated to a right angle to proceed into the facial gingival sulcus. As a result, although an acceptable esthetic restoration may be developed, especially with the additional cervical porcelain, the hygiene requirements and present implant dentistry standards render this approach nonideal (Fig. 29.26).

Some authors argue that an improved contour may be developed subgingivally with a palatal implant position. To create this contour, the implant body must be positioned more apical than desired. This position may prevent food from accumulating on the cervical "table" of the crown. However, the subgingival ridge lap does not permit access to the facial sulcus of the implant body for the elimination of plaque and to evaluate the bleeding index or facial bone loss. Therefore the maintenance requirements for the implant facial sulcular region do not permit the clinician to consider this modality as a valid primary option.

Greater interarch clearance is often required with an implant palatal position because the permucosal post exits the tissue in a more palatal position. Inadequate interarch space may especially hinder the restoration of Angle's class II, division 2 patients, with the implant in this position. The bony ridge should be augmented if too narrow for the ideal implant diameter and position, or an alternate treatment option should be selected.
• **Fig. 29.21** Three implant positions are found in the literature related to the final crown position. (A) A position below the incisal edge is best used for a cemented crown in the esthetic zone. (B) An implant is in the position of the natural root of the tooth. Although this makes sense, it places the implant too facial, and an angled abutment is usually necessary. (C) An implant in the cingulum position that is used when a screw-retained crown is the treatment of choice. This position requires a facial ridge lap of porcelain when used for FP-1 prostheses in the esthetic zone.

• **Fig. 29.22** Natural tooth has very thin facial cortical bone over the root, and the incisal edge of the crown is 12 to 15 degrees palatal to the facial emergence profile. This is not an ideal position for an implant. The bone to the palatal region is better suited for an implant and allows the implant to be positioned under the incisal edge.

• **Fig. 29.23** Implant placement too facially positioned. Soft tissue grafts will not correct the malpositioning and usually the most ideal treatment is implant removal and re-positioned in a more ideal position.

• **Fig. 29.24** Facially positioned implant leading to compromised esthetics.
• **Fig. 29.25** Implant placed in the cingulum position will usually require a ridge lap on the implant crown to restore the facial contour of the tooth.

Ideal Implant Angulation

The third implant angulation in the literature describes the most desirable implant angulation. A straight line is determined by connecting two points. The clinician determines the line for the best angulation by the point slightly lingual to the incisal edge position of the implant crown and the midfaciopalatal position on the crest of the bone. The center of the implant is located slightly lingual to the incisal edge of the crown so that a straight abutment for cement retention emerges directly below the incisal edge (Fig. 29.27). Because the crown profile is in two planes, with the incisal edge more palatal than the cervical portion, the incisal edge position is perfect for implant placement and accommodates some of the facial bone loss that often occurs prior to implant placement. The facial emergence of the crown mimics the adjacent teeth, proceeding from the implant body under the tissue. The angle of force to the implant is also improved, which decreases the crestal stresses to the bone and abutment screws. When in doubt, the

● **Fig. 29.26** (A) The maxillary left central incisor *(right side)* with a ridge lap crown presents acceptable esthetics. (B) However, probing on the facial aspect measures the distance to the implant but cannot evaluate facial bone loss because it cannot be directed apically to the pocket depth. (C) Periodically, the left central incisor implant becomes inflamed, and the bleeding index increases as a result of the inability to clean the implant sulcus on the facial.

clinician should err toward the palatal aspect of the incisal edge position, not to the facial aspect, because it is easier to correct a slight palatal position in the final crown contour compared with the implant body angled too facial.

The implant abutment selected for a maxillary anterior single-tooth implant is most commonly used for a cemented restoration; however, screw-retained prostheses are becoming more popular. A greater range of corrective options exists with a cement-retained crown for implants, especially if it is not ideally positioned. The location of the cervical margin of a cemented crown can be anywhere on the abutment post or even on the body of the implant provided it is 1 mm or more above the bone.

The implant body angulation under the incisal edge may also be used for screw-retained restorations. In these cases an angled abutment for screw retention is placed, and the coping screw for the crown may be located within the cingulum. This method does not require a facial ridge lap of the final crown, which decreases the risk of compromised hygiene. When ideal bone volume is present, a surgical template that ideally correlates the incisal edge and facial contour of the final prosthesis may be used.

Soft Tissue Incision: Surgical Protocol

Obtaining and maintaining the ideal tissue drape is often the most difficult aspect of maxillary anterior single-tooth replacement within the esthetic zone. Several different approaches

have been advocated to enhance the soft tissue appearance. The approaches may be surgical (addition or subtraction) or prosthetic and include (1) a soft tissue graft before bone augmentation, (2) a soft tissue augmentation in conjunction with a bone graft before implant insertion, (3) soft tissue augmentation in conjunction with implant insertion, (4) soft tissue manipulation at the implant uncovery procedure, (5) a prosthetic modification of interproximal contact position, (6) creeping attachment around the implant crown, or (7) a prosthetic replacement of the soft tissue with pink-colored porcelain (Box 29.2).

Surgical additive techniques such as pouch procedures, interpositional grafts, sliding flaps, and connective tissue grafts (autogenous or acellular dermal matrix) have all been proposed. A soft tissue graft may be performed as a separate procedure before any other surgery when the patient has a high lip dynamic and the soft tissue color and/or volume is grossly deficient. Most often, a connective tissue graft to improve the soft tissue drape is indicated.

A bone graft and soft tissue augmentation is indicated when the bone on the adjacent teeth is within normal limits (2 mm below the CEJ) but deficient in width and midcrestal volume. When the interproximal bone is not within normal limits, orthodontic extrusion maybe an option, followed by a crown and possibly endodontic therapy. The goal of a soft tissue augmentation for either of the two previous procedures is to obtain soft tissue on the crest of the ridge at the height of the interproximal papilla height.

• **Fig. 29.27** (A) The perfect position for an anterior single-tooth implant is under the incisal edge to the approximate midcrest position. A central incisor should have the position slightly distal and slightly toward the palate. (B) The implant crown has a 1.0- to 1.5-mm subgingival margin and begins a facial, mesial, and distal contour at this point to exit the tissue similarly to the contour of the adjacent tooth.

• **BOX 29.2** **Soft Tissue Contouring and Emergence Profile**

Preprosthetic Surgery
• Soft tissue graft before bone augmentation
• Soft tissue graft in conjunction with bone graft before implant surgery

Surgery Stage I
• Soft tissue augmentation
• Nonresorbable hydroxyapatite graft
• Lingually oriented incision to position more tissue to the facial
• Papilla saving incisions

Surgery Stage II
• Connective tissue graft (subepithelial)
• Soft tissue plastic surgery
• Gingivoplasty (coarse diamond)
• Prosthetics
• Wide healing abutment
• Temporary contouring through provisional restoration
• Anatomic abutment, tooth-colored abutment
• Pink porcelain/zirconia on abutment
• Lingually oriented incision to position more tissue to the facial

---

When elevating the interproximal tissue in the anterior maxilla, "papilla-saving" incisions are made adjacent to each neighboring tooth (Fig. 29.28). The vertical incisions are made on the facial aspect of the edentulous site and begin 1 mm below the macrogingival junction, within the keratinized tissue. Extending the vertical incisions beyond the macrogingival junction increases the risk of scar formation at the incision site. The full-thickness incision then approaches the crest of the edentulous site, leaving 1.0 to 1.5 mm of the interproximal papilla adjacent to each tooth. The vertical incisions are not wider at the base than the crestal width of tissue. This permits the facial flap to be advanced over the implant or short and adjacent to a healing abutment at the conclusion of the procedure, with no voids at the incision line and primary closure.

When the papillae are depressed in the edentulous site, vertical-release incisions are made along the root angle of each adjacent tooth, beginning 1 mm below the macrogingival junction and

in the sulcus of each adjacent tooth. Therefore the interproximal papilla region becomes part of the facial soft tissue flap.

The crestal incision is made on the palatal incline of the edentulous site to provide greater thickness of keratinized tissue on the facial aspect of the flap. This also allows more interproximal tissue to be elevated to enhance the papilla height.

The soft tissue is reflected, and the crestal bone width of the ridge is evaluated. When a central incisor site is reflected, the palatal flap is reflected to the incisive foramen for identification and evaluation. On occasion, its position may require the soft tissue to be enucleated and a graft positioned in its site. An initial pilot drill is positioned in the midmesiodistal and faciopalatal aspect of the ridge and proceeds approximately 7 to 9 mm within the bone under copious cooled sterile saline. A direction indicator is positioned into the site for evaluation to determine the implant position with respect to the facial, palatal, mesial, and distal implant position. A periapical radiograph is taken, and the initial osteotomy in relation to the adjacent roots and opposing landmark (i.e., floor of nose) is assessed. If adjustments are required, then a side-cutting drill (i.e., Lindemann drill) may be used.

The second drill is used to increase the depth and width of the osteotomy at approximately 2000 rotations per minute (rpm) (in D1 and D2 bone) under copious amounts of cooled sterile saline. The osteotomy drilling should be completed with a "bone-dancing" preparation to avoid overheating the bone. If the bone density is D3 or D4, lower rotations per minute may be used (~1000 rpm). If a surgical guide is not used, then the angulation of the drill should be within the long axis of the intended implant position to coincide with the lingual aspect of the incisal edge. If the osteotomy is not ideally positioned, then the side-cutting drill (Lindeman) is introduced into the osteotomy, and the palatal bone is removed by "shaving" up and down in the palatal aspect of the preparation.

The final size osteotomy drill is used to complete the osteotomy according to the bone density surgical protocol. In general, a crestal bone drill and bone tap should not be used in the maxillary anterior region because the maxillary bone usually has little to no cortical bone present on the bony crest. Using a crestal bone bur will often lead to a decreased primary stability of the implant and reduced facial bone thickness.

The threaded implant is inserted with a handpiece at 30 rpm because this is the most accurate insertion technique. Placing an

A   Papilla intact

Incision

B   Papilla depressed
• **Fig. 29.28** (A) When the interdental papillae are in an acceptable position, papilla-saving incisions are made to minimize soft tissue reflection. The incisions are vertical to allow primary closure. When the papillae are depressed, the vertical release incisions include the papilla in the edentulous site. (B) In situations with a more depressed soft tissue, facial soft tissue and papillae over each adjacent tooth are also reflected. The crestal incision is positioned towards the palatal incline on the ridge.

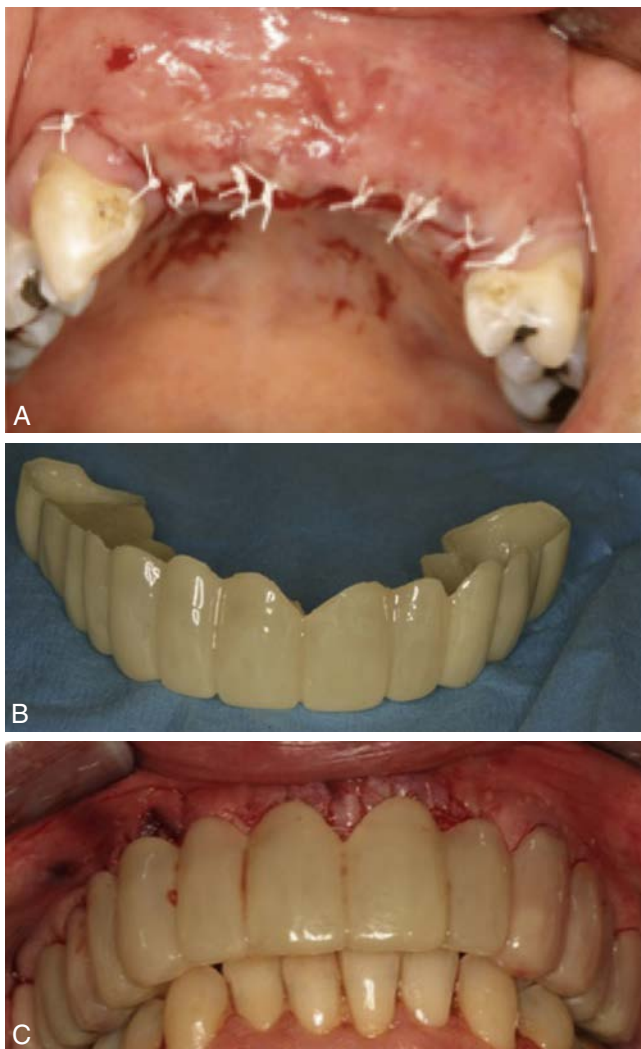
implant with an insertion wrench may lead to possible misdirection of the implant, most commonly being pushed to the facial. When a handpiece is used, counterforces on the handpiece handle and the fingers of the other hand on the handpiece head may permit the implant to be inserted without compromise to angulation or position.

The implant is rotated in final position, with a flattening of the antirotational component to the facial (i.e., depending on the implant type and design). The implant mount may be removed, and the clinician decides whether a low-profile cover screw (two stage) or healing abutment (one stage) is used within the implant. When the hard and soft tissue contours are ideal and a papilla-saving incision was made, a healing abutment may be used. When a bone graft is placed and/or the crestal tissue elevated to increase the height of the papilla, a low-profile cover screw is more often used to allow for undisturbed healing. Once the cover screw is inserted, the clinician decides whether a bone graft on the facial bone is indicated. When the facial bone over the implant is less than 1.5 mm thick, bone from the osteotomy is ideally used over the facial aspect along with a collagen membrane. If tissue thickness is required, an acellular dermal matrix may be used instead of the collagen membrane (Fig. 29.29) to increase the bulk of tissue, therefore allowing for a more esthetic result.

Soft Tissue Closure

The soft tissue is approximated and sutured with a resorbable suture material (most commonly 4-0 or 5-0) around the healing abutment or over the cover screw, depending on whether the tissue is at the ideal position or is being augmented. The increased tissue thickness from augmentation facilitates the sculpting of interdental papillae at stage II surgery, improves ridge contour, and prevents the grayish hue of the titanium implant body from showing through the labial mucosa in the event of crestal bone loss in the future.

Transitional Prosthesis

A soft tissue–borne transitional prosthesis is not recommended because this may increase crestal bone loss during the healing period. In addition, it may depress the interdental papillae of the adjacent teeth. For a single tooth edentulus area, a resin-bonded fixed restoration may be fabricated to provide esthetics and improve speech and function, especially when crestal bone regeneration is performed. When a resin-bonded restoration is used, the adjacent teeth are not prepared and the prosthesis is bonded to the tooth regions below the centric occlusal contacts of the teeth.


• **Fig. 29.29** Removable Interim Prosthesis: (A) Maxillary anterior surgery site, (B) Smile Transitions interim prosthesis which is durable and highly esthetic that prevents pressure on the surgical site, (C) Removable prosthesis in place.

• **Fig. 29.30** Hawley appliance with the addition of a denture tooth, may be used as an interim prosthesis

For multiple missing maxillary anterior teeth, a removable partial or full arch prosthesis (Smile Transitions™ - Glidewell Laboratories) maybe utilized during the healing period. The prosthesis is retained by the remaining natural teeth, thereby preventing pressure or impingement on the soft tissues overlying the surgery site. (Fig. 29.29).

Other options include an Essix appliance, which is an acrylic shell, similar to a bleaching tray, that has a denture tooth attached to replace the missing tooth. This prosthesis is the easiest for tooth replacement after surgical procedures. Another option may include a cast-clasp removable partial denture (RPD) with indirect rest seats to prevent rotation movements on the surgical site (Fig. 29.30).

In some cases, an immediate placement/loaded prosthesis may be used; however, this needs to be completed under ideal conditions (e.g., favorable primary stability and insertion torque, bone density, lack of parafunction). The benefits of immediate implant insertion after tooth extraction are related to an improved preservation of the soft tissue drape and the bone architecture compared with their collapse after tooth extraction. As a result, bone augmentation and soft tissue grafts may be avoided. The procedure has been described as a preservation technique aiming at maintaining the harmonious gingival architecture. The procedure also reduces the number of surgical procedures, which may decrease the cost to the patient.

Complications

The primary esthetic complications of maxillary anterior single-tooth implants include interdental papillae deficiency and gingival shrinkage after crown delivery.

Interdental Papilla Deficiency

The interproximal CEJ of a natural tooth exhibits a reverse scallop toward the incisal edge. The same pattern is followed by the alveolar interproximal bone, which is more coronal in the interproximal regions than in the facial or lingual plates. As a consequence, the probing depth in the papilla region of a natural tooth is quite similar to the facial or palatal probing depths. Interproximal bone around an implant does not follow such a contour. As a result, the interdental papillae, which look natural and rise to fill the interproximal regions between healthy adjacent teeth, exhibit greater probing depths than the other surfaces of the implant crown. In fact, because the interproximal bone height also may be lost next to the adjacent teeth, the dental and implant papilla also correspond to a greater proximal probing depth next to the natural tooth. A greater sulcus depth increases the risk of shrinkage after gingivoplasty, or later, even with good daily hygiene care. As a result, even years later the tissue may shrink and result in a poor interproximal esthetic situation (Fig. 29.31).

As previously addressed, four surgical time sequences exist to address the interproximal tissue height: (1) before a bone graft with a connective tissue graft; (2) in conjunction with a bone graft, often using an acellular tissue graft (i.e., OrACELL; Salvin, Charlotte, North Carolina); (3) at implant insertion, with an elevation of the tissue over a healing abutment and (4) at implant uncovery (i.e., split-finger technique). There are several other methods to improve the soft tissue drape. These approaches used to modify the soft tissue are prosthetic-related methods.

The most common prosthodontic solution to alleviate soft tissue limitations is helpful when soft tissue surgery has not recreated

• **Fig. 29.31** Most common esthetic complication in the premaxilla is the inadequate soft tissue drape around an implant crown. The patient's left central incisor exhibits black interproximal spaces.

• **Fig. 29.32** (A) A prosthetic solution for inadequate papilla height is to lower the interproximal contact of the crown by reshaping the adjacent teeth. (B) The canine implant crown fills the space and eliminates the interdental spaces caused by the lack of papilla height.

an ideal interproximal papilla height. The interproximal region may be treated similarly to the pontic interproximal region of a three-unit FPD (Fig. 29.32). Rarely are interdental papillae present next to the pontics of a fixed prosthesis. Instead, rather than raising the tissue to the interproximal contact of the crown, the interproximal contact is extended toward the tissue, and the cervical region of the pontic is slightly overcontoured. A similar approach may be applied to the single-tooth implant. The interproximal contacts of the adjacent teeth are recontoured, especially on the palatal line angle, to become oblong and extend toward the tissue. The contact areas of the single-tooth crown are extended, especially on the palatal line angle, toward the gingiva. The cervical region of the single-tooth implant is slightly overcontoured in width, similarly to the pontic of a fixed prosthesis. This concept does slightly compromise the interproximal esthetics. The papilla is not as high next to the implant crowns as it is between the natural teeth, and the cervical width of the crown is 0.5 mm wider.

However, the sulcus depth is reduced on the tooth and implant crown, and the daily hygiene conditions are improved. In addition, long-term shrinkage of the tissue is less likely to occur. This option should be the method of choice whenever possible and especially when the high lip position during smiling does not display the gingival regions around the teeth.

Nasopalatine (Incisive) Foramen and Canal

Anatomy

The nasopalatine (incisive) canal connects the oral cavity (nasopalatine foramen) with the floor of the nasal cavity. The soft tissue overlying the foramen is often associated with two lateral canals, which often fuse before exiting the foramen.[27] The maxillary division of the trigeminal nerve gives off the nasopalatine nerve branch, which enters the posterior nasal cavity via the sphenopalatine foramen, transverses the roof of the nose and proceeds along the nasal septum in between the periosteum and mucosa before exiting the nasopalatine foramen.[28] Mraiwa and colleagues reported that the nasopalatine foramen is located approximately 7.4 mm from the labial surface of an unresorbed maxillary anterior ridge and that the distance will vary after the amount of osseous resorption after extractions. The mean diameter of the nasopalatine foramen was shown to be approximately

4.6 mm (range, 1.5–9.2 mm).[29] The length of the nasopalatine canal has been reported to be approximately 9 mm, with a range of 3 to 14 mm.[30] The average height has been documented to be approximately 10.08 to 10.86 mm.[31,32] However, as the premaxilla resorbs, the nasopalatine canal decreases in size.[33] When the maxillary premaxilla alveolus resorbs in height, the incisive canal reduces in length; therefore division A, B, and C–w bone has greater canal length than division C–h and D bone. The angle of the nasopalatine canal has been shown to vary from 46 to 99 degrees with respect to the horizontal plane with a mean angulation of 66 degrees.[34] A vertical projection above the incisive canal along the nasal floor is called the premaxillary wing. The nasal process of the maxillary premaxilla rises 2 to 3 mm above the nasal floor (Fig. 29.33).

Surgical Approaches to the Nasopalatine Canal

In most cases, an implant may be positioned to replace a central incisor without encroaching on the nasopalatine canal. However, if extensive resorption or a large canal is present, then the nasopalatine canal may have a direct effect on the implant positioning. Therefore ideally the implant should never contact any soft tissue contents of the canal. To avoid this from occurring, there exist several approaches when the nasopalatine directly affects the implant positioning. Kraut et al reported that approximately 4% of nasopalatine canals directly affect the ideal positioning of implants in the premaxilla.
• **Fig. 29.33** Nasopalatine canal and foramen. (A) Large nasopalatine canal. (B) Large nasopalatine foramen. (C) Clinical image of nasopalatine foramen exposure, which compromises implant placement in the central incisor region. (D) Attempting to place implant in cases with large nasopalatine canal leads to penetration into the canal and a soft tissue interface.

Bone Grafting the Nasopalatine Canal with Delayed Implant Placement

One option when the size and position of the nasopalatine canal impinges on the implant placement is to enucleate and bone graft the canal. The nasopalatine canal is exposed by full-thickness reflection and the soft tissues within the canal are entirely curetted. Serrated spoon excavators (e.g. Lucas 86) may be used along with a round carbide bur to completely remove any soft tissue remnants from the canal. Rosenquist and colleagues first reported on removing the contents of the nasopalatine canal and autogenous bone grafting the area. Implant placement was delayed for approximately 5 months with a 100% success.[35] Since then, numerous additional studies have shown positive outcomes with this procedure including guided bone regeneration techniques along with grafting the nasopalatine canal (Fig. 29.34).[36,37]

Removal of the Canal Contents + Implant Placement

A second option includes the enucleation of the nasopalatine canal followed by immediate implant placement. The incisive foramen is first reflected and identified, and a periodontal probe evaluates the angle and depth of the bony canal to ensure a minimum length of 9 mm. The soft tissues in the incisive canal are curetted from the canal site, which is approximately 4 mm in diameter at its apex. A round carbide bur (e.g. # 6 or # 8 round bur) in a straight handpiece may be used to remove the soft tissue remnants. In addition, the trauma from the round bur initiates the regional acceleratory phenomenon (RAP), which allows for more predictable healing (Fig. 29.35).

Once the soft tissue is removed, drills progressively increase the diameter to the final implant osteotomy diameter 2 mm below the final height of the canal. A blunt osteotome and gentle, sudden impact force with a mallet then prepares the apical 2 mm of the implant site. A large-diameter threaded implant (>5 mm) is generally used and should be greater than the diameter of the foramen (Fig. 29.36). When the foramen diameter is greater than that of the implant available, the canal is augmented with an autologous or allograft bone graft, and the implant insertion is delayed for several months. This technique is often clinically challenging.

Positioning the Implant Away From the Nasopalatine Canal

In the literature, some authors have suggested placing the implant in a nonideal position to avoid the nasopalatine canal. If the intended prosthesis is an RPD, the implant may be positioned to avoid penetration into the canal. The most common position would be in the embrasure area of the central and lateral position. This would result in maintaining the anteroposterior spread, along with not penetrating into the canal. However, care should be exercised not to angulate the implant too far to the facial as this may impinge on the esthetics of the prosthesis.

Kraut and colleagues evaluated CBCT scans and found that 4% of the time the nasopalatine canal would interfere with the normal preparation of an osteotomy for an implant.[38]

Mardinger and colleagues reported that after extraction the average length of the canal shortened from 10.7 to 9 mm and the nasopalatine foramen encompassed 36.5% of the ridge width (range, 13%–58%) as it enlarges in all directions. In severely resorbed ridges, the nasopalatine foramen enlarged by 32%
• **Fig. 29.34** Bone graft with delayed implant placement. (A and B) Ridge augmentation to gain width of bone so implant placement does not impinge on the nasopalatine foramen. (C) Ideal implant placement.
• **Fig. 29.35** (A) Implant placement into the nasopalatine canal for a removable implant-supported overdenture. By placing an implant in the nasopalatine canal, the anteroposterior spread is increased. (B) Clinical image depicting implant in the nasopalatine canal.

(1.8 mm) and reached approximately 5.5 mm in diameter, which could occupy up to 58% of the ridge.[39]

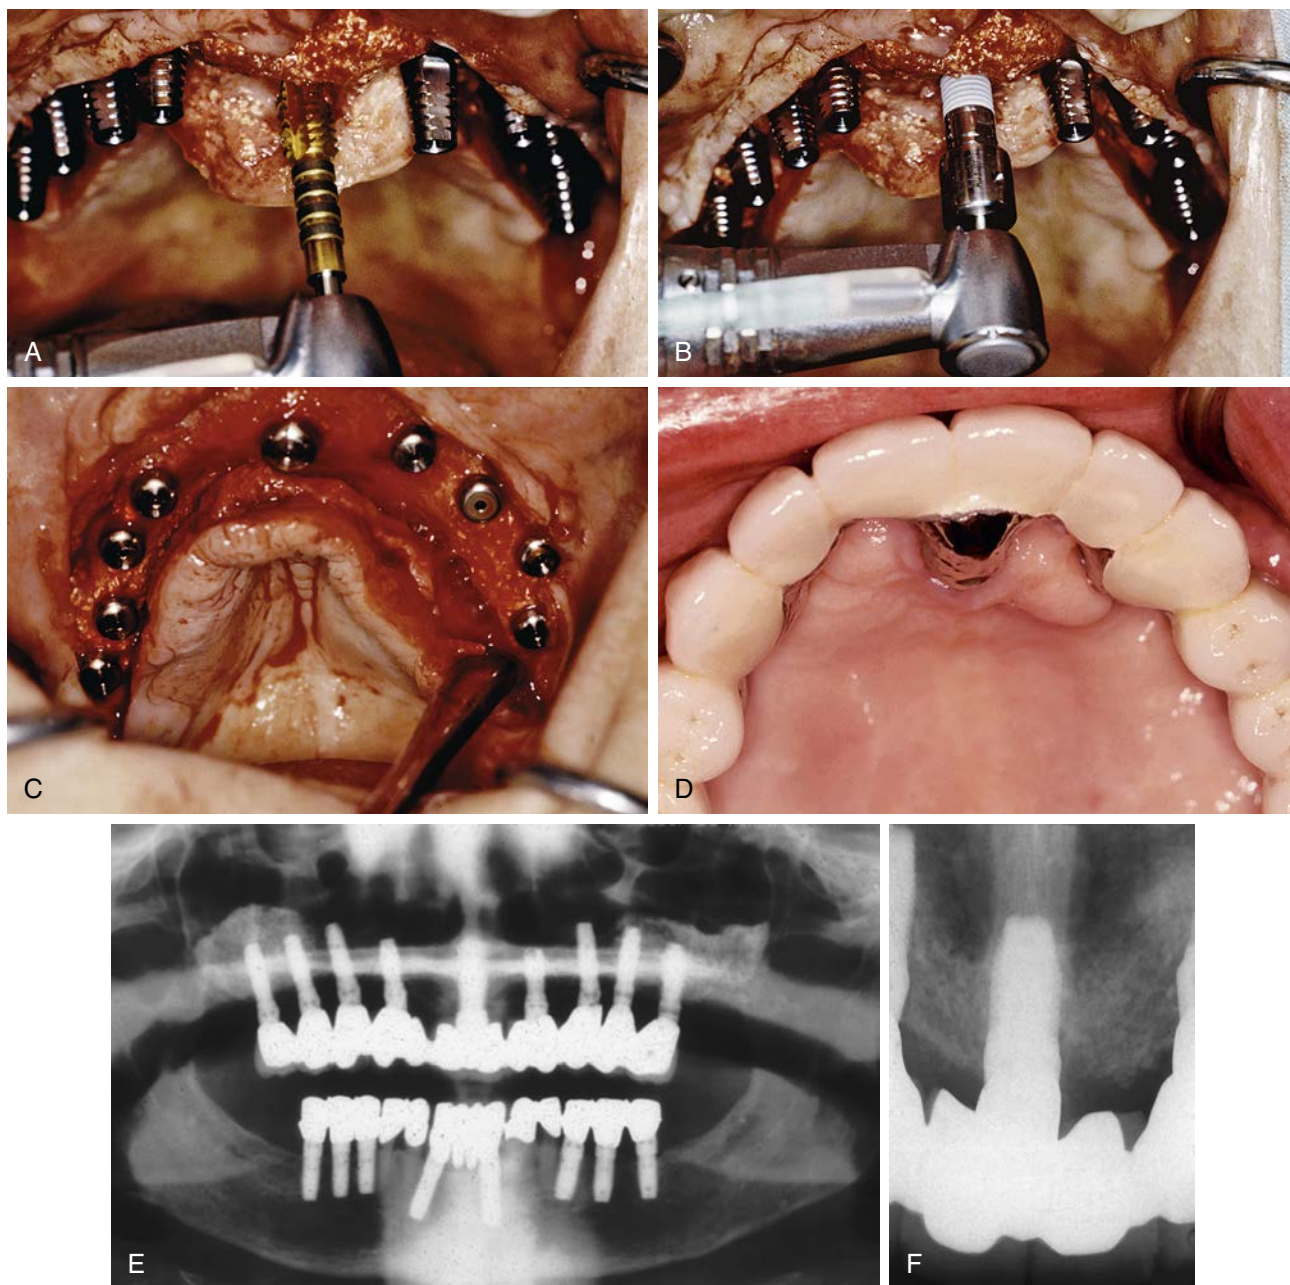
Another technique for a fixed prosthesis is to angulate the implant intentionally, often placing the implant at an increased apical position. The theory includes allowing more space (i.e., running room) for the prosthesis that creates a more favorable emergence profile. However, this technique does increase the crown height space, which is a force magnifier. In addition, adjacent teeth may be compromised periodontally.

Complications of Nasopalatine Implants

Migrated Implant

Some rather significant complications may be associated with incisive canal implants. The first surgical complication of an incisive foramen implant is related to the implant that is too small for the foramen and not properly fixated (i.e., inadequate primary stability). The implant may be inadvertently pushed through the incisive canal and into the nares proper. Because patients are in a supine position during the surgery, the implant may fall back into the soft plate, then into the trachea or esophagus. If the implant disappears from the oral site, the patient's head should be turned to the side immediately, then down and forward. A nasal speculum and tissue forceps may then be used to recover the implant or immediate medical referral.

Excessive Bleeding

A second surgical complication may include excessive bleeding from the incisive foramen. Although this complication is very rare, it is possible. When reflection of the palatal tissue off the incisive canal is associated with arterial bleeding, a blunt bone tap (mirror handle) may be placed over the canal and a mallet used to hit the instrument firmly, crushing the bone over the artery. After several minutes the procedure may continue, and the implant insertion


• **Fig. 29.36** (A) The incisive foramen was excavated and prepared for an implant. The site may be bone tapped before implant insertion. (B) A 5-mm-diameter implant is inserted into the incisive foramen after implant preparation. (C) A stage II reentry reveals bone around the incisive foramen implant. (D) On occasion, a fixed prosthesis may be fabricated with the anterior implants in the canine and incisive foramen position. (E) A panoramic radiograph of the incisive foramen implant, bilateral sinus grafts, and nine implants (including the canine positions). (F) A periapical radiograph of an incisive foramen implant after 5 years of function.

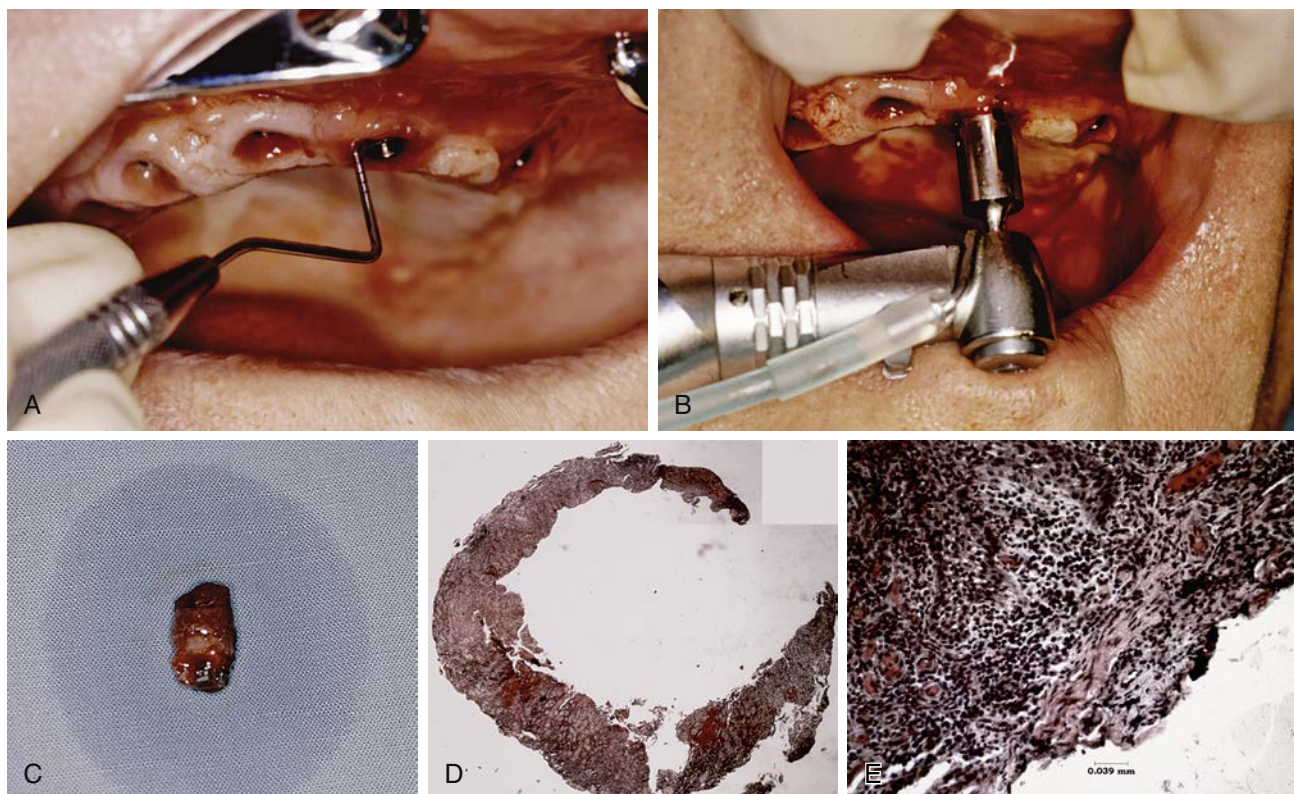
will obdurate the site and arrest the bleeding. Additional techniques include the use of injecting epinephrine 1:50,000 directly into the foramen. An electrocautery unit may also be used with a ball type of attachment.[40]

Neurosensory Impairment

A third complication of an nasopalatine foramen implant is associated with enucleation of the soft tissue from the foramen, which may result in neurologic impairment of the soft tissues in the anterior palate. These complications may be anesthesia or paresthesia to the soft tissue or a dysesthesia, resulting in a burning sensation,

which have been reported in numerous reports.[41,42] In most cases, collateral innervation from the greater palatine nerve to the anterior palate is present which eliminates any possible neurosensory disturbances.

Tissue Regeneration

The fourth complication is a long-term complication which may include the regeneration of the soft tissue in the incisive canal, resulting in bone loss and failure of the implant (Fig. 29.37). When the implant is removed and the soft tissue biopsied, nerve fibers can be seen reinvading the site. This most likely occurs because the implant


• **Fig. 29.37** (A) A long-term complication of an incisive foramen implant may be bone loss around the implant that extends the full length of the implant. (B) When more than 50% of the implant has been lost, it should most often be extracted. A trephine bur may remove the integrated portion of the implant. (C) The implant removed is surrounded by soft tissue. (D) Histologic examination of the soft tissue around the implant reveals that the contents of the incisive canal are reforming around the implant. (E) Histologic examination demonstrates nerve fibers in the soft tissue around the implant.

was too small for the size of the foramen, and the soft tissue can reform around the implant. Treatment of this complication includes removing the implant and, if necessary for the treatment plan, regrafting and/or reimplantation at a later date.

Implants in Approximation to the Nasal Cavity

Anatomic Considerations

The anterior nasal spine has an anterior component that averages 4.1 mm (0–9 mm) in adults.[27] Posterior and lateral to it, two flat processes, the alae of the premaxilla, project superiorly and laterally. The piriform aperture is bounded below and laterally by the maxilla. The breadth of the piriform aperture in adults ranges from 20 to 28 mm and averages 23.6 mm.[43,44] The lower border of the inferior piriform rim may be sharp or rounded. This border often rises from the premaxillary bone and ends anteromedially in the anterior nasal spine. The anatomy of the nasal floor is variable in relation to the inferior turbinate and is typically situated 5 to 9 mm below the level of this structure (Fig. 29.38).[45]

When maxillary anterior teeth are present or have maintained the residual bone, the inferior piriform rim is usually level or a few millimeters above the floor of the nose in the central and lateral region.[46] The inferior piriform rim above the nasal floor forms a prenasal fossa, which is found in 12% of patients.[47] In these cases a shallow depression extends toward the alveolar arch behind a sharp border of the inferior piriform rim. As a result, when the

• **Fig. 29.38** Natural canine root is distal to the lateral piriform rim of the nose. However, a nasal recess extends distal, behind the piriform rim and over the canine site of a resorbed maxilla, which is more palatal than the tooth root position. The inferior concha of the nose is 4 to 6 mm superior to this recess region.

inferior piriform rim is used as a guideline for the height of the opposing cortical plate from the crest of the ridge in the maxilla during surgery to determine implant length, the lowest portion of the nasal floor and nasal mucosa may be inadvertently perforated during the implant osteotomy and placement. Ideally, implant placement should be short of the nasal floor.
• **Fig. 29.39** (A and B) Implant placement into the nasal cavity proper is not recommended because irritation and nasal congestion problems may result.

The canine tooth position is immediately distal to the lateral piriform rim. The canine eminence in this area is lost after several years of edentulism, and the crest of the residual C–h bone volume ridge is palatal to the original tooth position. The nasal cavity is usually above, medial, and palatal to the canine position in the dentate patient. However, a nasal recess is present behind the lateral piriform rim. This nasal recess corresponds to the apical region of the canine position in the C–h maxilla, which has resorbed palatally and is now under the nasal cavity. Implants placed in the canine position of a C–h bone volume may extend more superiorly than the natural canine root.

The arterial blood supply to the nose is derived from both the external and internal carotid arteries. The terminal branch of the maxillary artery (a branch of the external carotid) supplies the sphenopalatine artery, which supplies the lateral and medial wall of the nasal chamber. The anterior and posterior ethmoid arteries (branches of the ophthalmic artery) supply the nasal vestibule and the anterior portion of the septum. In addition, a few vessels from the greater palatine artery pass through the incisive canal of the palate to reach the anterior part of the nose. At the junction between the squamous epithelium of the nasal vestibule and the respiratory epithelium of the nasal cavity lies a strip about 1.5 mm wide covering a region of wide and long capillary loops, known as Kiesselbach's plexus.[48] It extends to the lower and central part of the cartilaginous septum and is a common region for nose bleeds (Fig. 29.39).

Ideally, dental implants should be positioned short of the nasal cavity. Wolff and colleagues reported a case report describing an implant placed into the nasal cavity resulting in severe congestion postop. Therefore dental implants protruding into the nasal cavity may cause alterations in airflow. If this should occur, the implant should be removed or the apical portion of the protruding implant may be removed via a transnasal approach (Fig. 29.40).[49]

Maxillary Anterior Anodontia

The most common maxillary anterior tooth replaced by an implant is a central incisor lost from trauma (e.g., endodontic failure, fracture, root resorption) and/or a lateral incisor absent as a result of agenesis. The absence of one or more teeth is known as anodontia and may be complete (very rare) or partial (also called hypodontia). It is many times more common than supernumerary teeth. The primary cause of partial anodontia is familial heredity, and incidence ranges from 1.5% to as high as 10% in the US population.[50] The genetic predisposition has been associated with PAX9 promoter polymorphisms.[51] In addition, a number of syndromes exist in the literature that include multiple missing teeth, of which ectodermal dysplasia is the most common.

A high correlation is found between primary tooth absence and a permanent missing tooth; however, a missing tooth occurs more frequently in the permanent dentition. Caprioglio and colleagues[52] evaluated the records of almost 10,000 patients between the ages of 5 to 15 years of age. Of all the missing single teeth, the mandibular second premolar was most often missing (38.6%), followed by the maxillary lateral incisor (29.3%), the maxillary second premolar (16.5%), and the mandibular central incisor (4.0%). The remaining teeth were absent at a rate of only 0.5% to 1.8%, with the maxillary first molar being the least affected. The missing mandibular second premolar primarily occurred in male patients, whereas the maxillary lateral incisor primarily occurred in female patients. The most common multiple teeth lost (other than third molars) are the maxillary lateral incisors, followed by the mandibular second premolars and maxillary second premolars. Congenitally missing teeth are therefore a common scenario seen in dental practices today. Fortunately, less than 1% of those missing teeth are missing more than two teeth, and less than 0.5% of this group are missing more than five permanent teeth.

When acceptable conditions can be created, an anterior single-tooth implant is the treatment of choice for a congenitally missing anterior tooth. However, the treatment of congenitally missing teeth are very challenging with significant esthetic and functional demands.

The replacement of congenitally missing teeth usually occurs during the adolescence period. Because of this patient population, many issues complicate the treatment including (1) interdisciplinary approach, (2) postorthodontic retention, (3) implant placement timing, (4) ideal placement is required, and (5) associated esthetic and soft tissue problems exist.

This condition is especially beneficial for a lateral incisor because the ideal cervical region of the tooth is similar to the implant diameter. However, the roots of the adjacent natural teeth often impinge
• **Fig. 29.40** (A and B) Implant placement into the nasal cavity may result in compromised crown height space and irritation from violating the inferior meatus and turbinate. Note the implants are actually in contact with the turbinate.

on the edentulous space, resultying in insufficient mesial-distal space for a dental implant. As a consequence, orthodontic therapy before implant placement should often be considered. An additional advantage of orthodontics before or in conjunction with implant treatment for the congenital missing tooth is that the missing lateral incisor may be restored provisionally by a denture tooth attached to the orthodontic wire to provide an esthetic replacement without trauma to the augmented ridge or implant during healing.

The missing maxillary lateral incisor is most often replaced with a dental implant because the other orthodontic or prosthetic options are usually poor alternatives. The clinician should first determine whether space-opening (maintenance) procedures or space closure (orthodontics) is the treatment of choice for the missing tooth. The treatment options are usually different for a mandibular second premolar compared with a maxillary lateral incisor.

Graber[53] noted a strong correlation between a missing single tooth and altered tooth size, shape, or both. A common condition is a missing lateral incisor, in which the contralateral lateral incisor is smaller than usual or a peg lateral. As such, the mesiodistal space is often limited to less than 6.5 mm. In these instances, a nonfunctional, small-diameter implant of 3.0 mm may be considered. When the intratooth space is less than 5 mm, other treatment options should be considered including a cantilevered FPD from the canine abutment.

Congenitally Missing Lateral Incisor Treatment Protocol

In most cases of congenitally missing lateral incisors, orthodontic intervention is required. There usually are three phases of treatment for the replacement of congenitally missing lateral incisors, (1) orthodontic treatment, (2) postorthodontic treatment, and (3) final implant treatment.

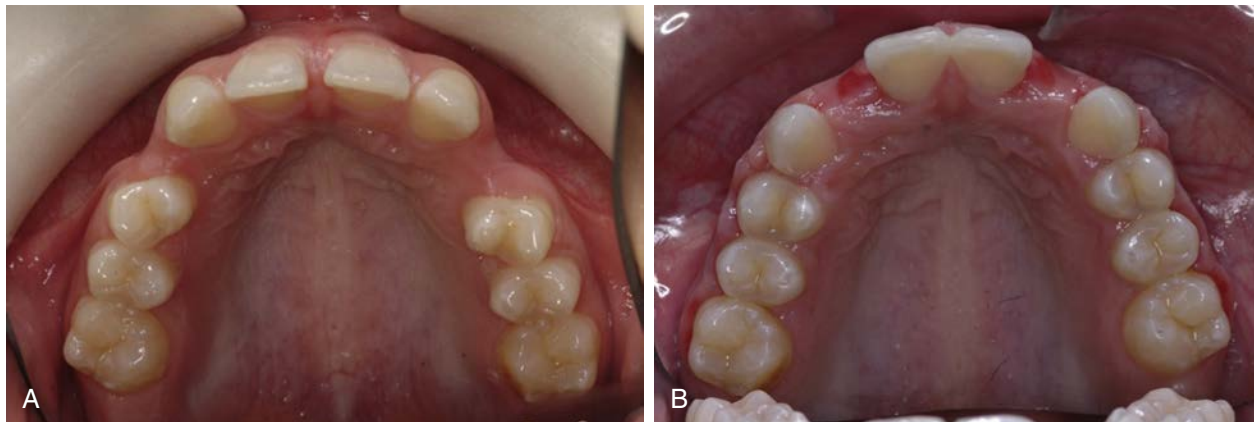
Orthodontic

There are two different orthodontic treatments for the restoration of a congenitally missing lateral incisor: cuspid substitution (space closing)[54] and conventional treatment (space opening).[55]

With cuspid substitution, the permanent cuspid is orthodontically repositioned into the lateral incisor space and the first premolar into the canine space. The advantage of this treatment is that it uses conventional orthodontic treatment, which usually entails comprehensive orthodontic care. The disadvantage of this treatment is that most patients end up with a class 1 occlusion, therefore a malocclusion results. Usually, the patient will not have a cuspid disocclusion, but a group function will result. In addition, esthetically, the cuspid differs greatly in shape, size, and color compared to a lateral incisor. Usually the cuspid shade is one to two shades darker than the lateral, and if recontouring of the cuspid is completed, usually the show-through of the dentin will make the tooth even darker. The canine is normally 1 mm wider than the lateral incisor; reducing the interproximal areas of the tooth will result in further darkening.[56] Last, the permanent cuspid is more convex than a lateral; therefore reshaping often will result in hypersensitivity and esthetic issues. The first premolar is normally shorter and narrower than the contralateral cuspid (Fig. 29.41).

Conventional orthodontic treatment includes opening the space to allow for a future restoration, which usually includes an endosseous implant. The goal of conventional orthodontic treatment is to achieve ideal coronal and apical space for an implant, along with a favorable occlusal scheme for the final prosthesis (Fig. 29.42).

The amount of space required is a minimum of 6 mm, which results from the "golden ratio."[57] The golden ratio describes the relationship between the central and lateral incisor, which states that the lateral incisor is ⅔ the size (mesiodistal width) of the central incisor. The average central incisor is 9 mm wide; therefore the lateral width would be 6 mm. Chu described another method of determining the width of the lateral incisor. With this method, the central incisor is determined to be "x." The lateral incisor then is calculated as "x – 2 mm" and the cuspid is "x – 1 mm."[58] Last, the author uses a method that measures the contralateral side and duplicates that space in the final restoration. In some cases, cosmetic bonding may need to be completed to make the spaces ideal.

• **Fig. 29.41** Canine substitution. (A) Preoperative image depicting congenitally missing lateral incisors. (B) Final postoperative image showing canine repositioned into the lateral position and first premolar repositioned into the cuspid position.


• **Fig. 29.42** Conventional orthodontic treatment, (A) Preoperatively, congenitally missing laterals. (B) Postoperatively, canines repositioned into their ideal position allowing for future implant placement.

Spacing Requirements

Before placing an implant into a congenitally missing space, a CBCT should be obtained to determine the exact space between the adjacent teeth, both coronally and apically. In many cases, clinicians will determine whether there is adequate coronal space; however, the apical space is compromised. This often occurs when space is obtained by use of a palatal expander, and then the central incisors are "tipped," instead of "bodily" moved back into position. By closing the space between the central incisors, the root apexes will be approximate, leaving inadequate space for a dental implant. In most cases, the interroot distance should be a minimum of 6 mm (Fig. 29.43).[59,60] The minimum space required should be verified via a CBCT examination by measuring the coronal, midroot, and apical areas.

Postorthodontic Retention

In most cases of postorthodontic treatment, the patient is usually too young for implant treatment. Therefore it is imperative that patients are maintained during this period to prevent relapse. Postorthodontic retention usually is via a removable or rigid prosthesis. Common removable prostheses include a Hawley appliance or an Essix appliance.[61] Unfortunately, apical relapse or reapproximation has been shown to occur in approximately 11% of postorthodontic cases because of retainer noncompliance, compensatory eruption, and increased vertical growth.[62] Ideally, to prevent root approximation, a rigid, nonremovable prosthesis should be used. Rigid retention usually involves the insertion of a resin-bonded bridge, which is advantageous because it is a nonremovable prosthesis; however, a high debonding rate is seen.[63]

Final Prosthesis

For a congenitally missing lateral incisor, an implant retained prosthesis is advantageous over all other options (e.g., resin-bonded prosthesis, FPD, cantilevered fixed prosthesis, RPD). The clinician must evaluate and take into consideration the following factors when treatment planning for an implant prosthesis: timing, available bone present, coronal and apical space, positioning, esthetics, and gingival contours.

Timing. A common complication occurs when clinicians use chronologic age as the determining factor for the timing of implant placement. Ideally, implant placement should be completed when the patient has facial growth cessation. In the literature, growth cessation has been documented to be determined with the use of dental development,[64] voice changes,[65] hand–wrist radiographs,[66] cervical vertebrae maturation,[67] and serial lateral cephalometric radiographs.[68] Unfortunately, most of the accurate options to determine growth cessation are via radiation exposure. Therefore to reduce the radiation exposure to adolescent implant patients, the author recommends measuring growth cessation by monitoring stature growth, usually with the assistance of the patient's pediatrician. Studies have shown that less than a 0.5-cm growth in a 6-month period is an ideal time to initiate dental implant treatment.[69]

If implants are placed before growth cessation, the downward growth of the maxilla results in the implants being in infraocclusion compared with the natural teeth. When facial growth occurs, changes will result in tooth position. Because of the osseointegration (i.e., ankylosis) of the dental implant, the dental implant cannot change position, which may result in esthetic complications.[70] Westwood and colleagues reported implants placed at age 12 will
● **Fig. 29.43** (A) Ideal implant placement for lateral incisor, 1.5 mm from teeth and a 3.0-mm implant diameter. (B) Nonideal space caused by orthodontic tipping of the central incisors.

● **Fig. 29.44** (A) Implant placement too early. Because of continued growth of the maxilla, the implant *(left central incisor)* is positioned in infraocclusion. (B) Bilateral lateral incisors in infraocclusion. Note the tissue recession and implant exposure of the maxillary right lateral incisor.

● **Fig. 29.45** Maxillary right lateral incisor showing compromised bone. Note the large concavity adjacent to the midroot of the adjacent teeth.

be in infraocclusion 5 to 7 mm 4 years later.[71] Ranly showed that at age16 teeth are located approximately 10 mm coronally from their position at age 7.[72] In general, implant submergence is not easily correctable. It may be possible to place a new prosthesis on the implant to correct the occlusal discrepancy, increased crown-implant ratio, and the poor esthetics. However, significant biomechanical issues along with potential peri-implant disease may result. If eruption of the adjacent teeth occurs, remediation of the implant usually involves explantation of the implant, bone augmentation, and placement of a new implant (Fig. 29.44).

Available Bone Present. Because the congenitally missing tooth does not have a permanent tooth bud, the available bone in the area most often is compromised in quality and quantity. In most cases, a division B or a division C–w is present. To obtain adequate bone for implant placement, bone augmentation is usually recommended. Bone augmentation maybe completed before growth cessation; however, it should be timed correctly with implant placement at the time of no future growth. In some cases, the permanent cuspid may be allowed to erupt mesially through the alveolus into the lateral incisor position. Because of its significant buccolingual dimensions, the edentulous ridge is maintained. When the permanent canine is moved orthodontically into the ideal canine position, an increased buccolingual width will be retained (Figs. 29.45 and 29.46).[73]

(B) Cone beam computerized tomographic three-dimensional image measuring ideal space for implant. (C) Nonideal space for implants. The placement of implants places the adjacent teeth at significant risk.

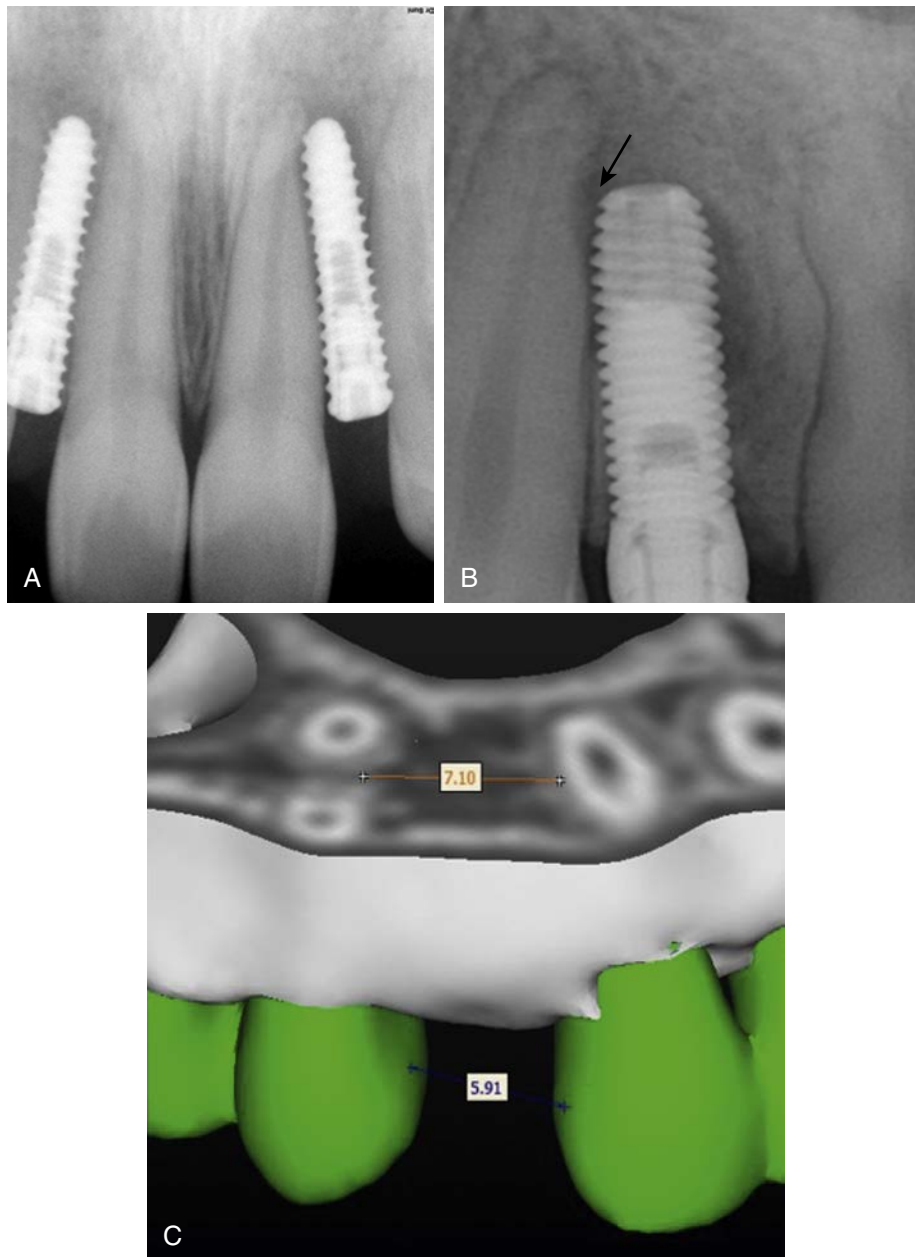
Coronal and Apical Space. A CBCT examination should be completed to verify that a minimum of 6 mm of space is present coronally and apically. A minimum of 1.5 mm of space needs to be present between the final implant position and an adjacent tooth root. If implant placement is too close to an adjacent tooth root, a number of complications may result, including devitalization of teeth, development of pathology around the teeth or implant, sensitivity of teeth, and loss of teeth or implant. If the coronal space is compromised, apical migration of the papilla will occur, leading to open gingival embrasures and compromised gingival scallop (Figs. 29.47 and 29.48).[74]

Implant Positioning. Often, implants placed in the premaxilla are positioned too facially. This occurs because of a thin buccal plate and the existing bone trajectory. If an implant is facially positioned, then esthetic issues may result including tissue show-through of the implant or abutment and gingival recession (Fig. 29.49). In addition, bone loss may occur from unfavorable force factors. For a cement-retained prosthesis, the implant should be placed slightly lingual to the incisal edge of the tooth. For a screw-retained prosthesis, the implant should be positioned in the cingulum area. In the apicocoronal position, the implant body should ideally be positioned 2 to 3 mm below the free gingival margins of the central incisor and cuspid (Fig. 29.50).[75]

Soft Tissue Complications. Usually when a tooth is missing congenitally, the associated papilla will not be present. To increase the thickness of the tissue, acellular dermis (OrACELL) may be used at the time of bone augmentation or implant placement.

After implant placement, tissue grafting is more difficult and less predictable. Another option to increase tissue thickness is the use of the split-finger technique, which is completed at the second-stage surgery appointment and uses a healing abutment to increase the size of the papilla.[76] Last, the tissue can be guided via a provisional restoration. After implant healing is complete, a provisional restoration may be placed on the implant to prosthetically guide the soft tissue into an ideal position. The subgingival contours of a provisional prosthesis have been shown to influence the final position of the prosthesis (Fig. 29.51).[77]

Summary

The replacement of missing teeth in the premaxilla is very challenging because of the highly specific soft and hard tissue criteria, in addition to all other esthetic, phonetic, functional, and occlusal requirements. Maxillary anterior tooth loss usually compromises ideal bone volume and position for proper implant placement. Implant diameter, compared with that of natural teeth, results in challenging cervical esthetics. Unique surgical and prosthetic concepts are implemented for proper results. In spite of all the technical difficulties that the surgical and restoring clinician may face, the anterior single-tooth implant is the ideal modality of choice to replace a missing anterior maxillary tooth. However, the clinician must have a strong foundation for the inherent complications that are involved with replacing maxillary anterior teeth.


• **Fig. 29.48** (A) Lack of Available bone for implants encroaching upon periodontal ligament space of adjacent teeth, (B) Poor positioning leading to pathology involving the implant and natural tooth, (C) A CBCT examination should always be utilized to determine the available bone for implant placement.
• **Fig. 29.49** Implant placement too facial leading to inability to fabricate a screw-retained prosthesis or requiring a custom angled abutment.

Mandibular Anatomic Implications for Dental Implant Surgery

RANDOLPH R. RESNIK

In dental implantology today it is imperative the clinician have a strong understanding of the surgical anatomy and variations with respect to implant placement in the mandible. Before the commencement of dental implant surgery, a careful and detailed evaluation should be completed of the mandibular vital structures. This may be accomplished by including a clinical evaluation, a visual examination, along with palpation of the anatomic areas. The clinician should have a clear and concise three-dimensional (3D) vision of the anatomic structures in relation to the intended implant surgical procedure.

A thorough radiographic examination needs to be completed to provide information concerning the location and topography of the 3D anatomy. In this chapter a comprehensive evaluation of the important mandibular anatomic areas will be discussed, together with their clinical relevance in dental implant surgery (Fig. 30.1).

Mandibular Anterior

Hourglass Anterior Mandibles

The mandibular anterior region has historically been considered one of the safest and most predictable regions for implant placement. The predictability stems from the favorable quality of bone (i.e., thick cortical and dense trabecular bone) most commonly present in this area. The morphology of the mandibular anterior has been classified as the following shapes: hourglass, ovoid, pear, sickle, and triangular. The pear shape, which is usually abundant with bone, has been shown to be the most common among edentulous and dentate patients.[1]

However, this anatomic area may be compromised by a narrow alveolar width or severe osseous constriction. These types of bony variations have been termed an *hourglass effect*, which is usually indicative of a developmental abnormality. Hourglass mandibles, which have been shown to have an incidence rate of approximately 4%, should always be concerning to the clinician because of possible perforations during implant placement surgery.[2] The position of the alveolar constriction may vary significantly because they have been shown to be high, low, or variable within the alveolus. A thorough 3D cone beam

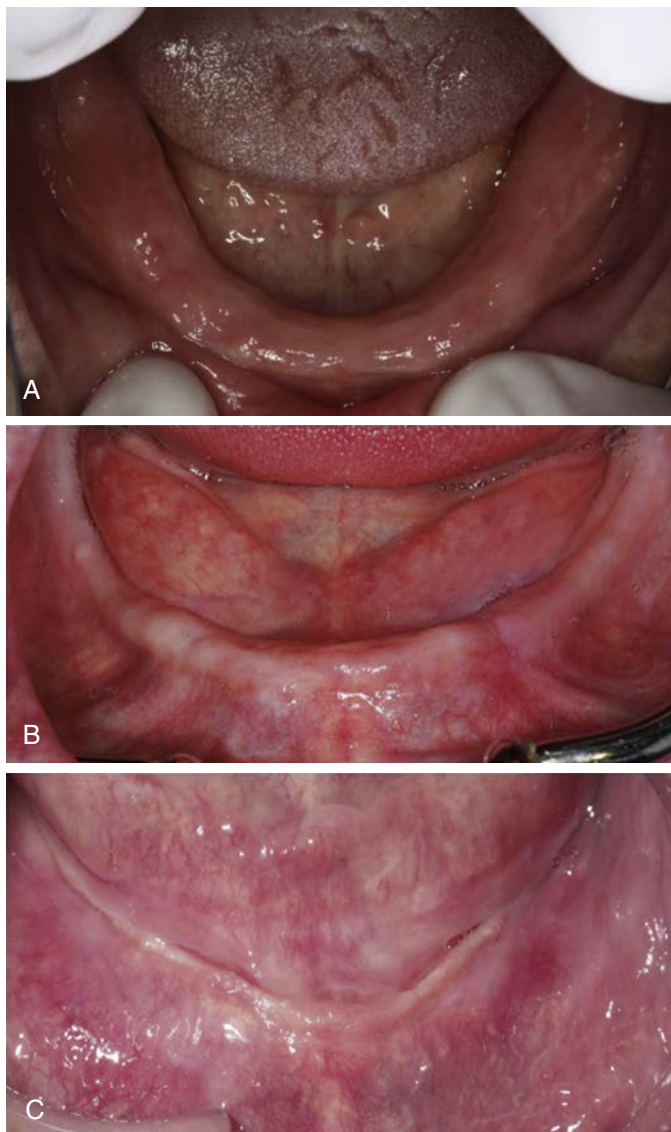
computed tomographic (CBCT) examination should be completed to prevent complications in this area, and guided surgery is recommended to minimize the possibility of perforations[3] (Fig. 30.2).

Butura et al.[4] classified mandibular anterior constrictions as: (1) facial constriction, (2) lingual constriction, and (3) hourglass constriction. They discussed various treatment options to include alveoplasty to a level beyond the constriction, staged bone graft reconstruction, posterior and anterior angled implants to avoid the site, and extra-long implants to bypass the constriction and engage the inferior border of the mandible.[4]

Clinical Relevance

Due to the variable expression of hourglass mandibles, treatment strategies are based on the location and extent of the undercut. In some cases implant placement in this area will be contraindicated. In less severe constrictions an osteoplasty may be performed, together with implant placement. However, the crown height space may be increased significantly, leading to possible biomechanical issues. In addition, other constrictions may require grafting procedures to increase bone volume for implant placement (Fig. 30.3).

If the positioning of a dental implant leads to perforation of the bony mandibular plates, possible life-threatening hemorrhage episodes may occur. These events have been reported when a drill perforates the lingual plate of the sublingual region of the mandible and traumatizes a sublingual or submental artery, especially in the canine region.[5,6] If perforation of the lingual cortical plate is associated with arterial bleeding, it is critical to identify its origin and treat aggressively. The origin of bleeding in the floor of the anterior region of the mouth may be from the lingual artery, facial artery, or one of its branches. Perforation of either the submental artery (originates from the facial artery) or the sublingual artery (originates from the lingual artery) may lead to bony perforation and bleeding, causing an expanding ecchymosis (sublingual hematoma) and compromising the airway. If this should occur, the patient should be repositioned in an upright position, and bimanual pressure should be applied to the area of bleeding. If the airway is compromised, immediate emergency assistance should be summoned (Fig. 30.4).

737


● **Fig. 30.1** Variable Mandibular Anatomy. The mandibular arch varies dramatically with respect to the amount of hard and soft tissue resorption. (A) Mandibular arch with a significant amount of bone and keratinized tissue. (B) As bone resorption occurs, the loss of the attached tissue results. (C) Advanced resorption of the hard and soft tissues resulting in a severely atrophic mandible with minimal attached tissue.

● **Fig. 30.2** Constricted Mandibular Anterior. (A) Cone beam computed tomographic panoramic image that depicts a significant amount of available bone; however, it does not indicate a constriction is present. (B) Cross-sectional images showing the hourglass appearance of the anterior mandible, which contraindicates implant placement.

Median Vascular Canal

In the mandibular midline, radiographic examination often reveals the presence of a radiolucent canal, which is termed a *median vascular canal*. This canal houses the bilateral sublingual arteries that enter the lingual foramen, which is located on the lingual aspect of the mandible. The lingual foramen is seen as a radiopacity below the genial tubercles, which is visible on approximately 52% of CBCT scans.[7] This arterial anastomosis may transverse anteriorly, inferiorly, or superiorly within the anterior mandible, in some instances exiting the facial aspect of the symphysis area. Various studies have shown median vascular canals to be present in 100% of cases, detected on CBCT examinations. Two-dimensional (2D) panoramic radiographs observe their presence only 4.2% of the

time.[8] This is most likely due to the superimposition of the cervical vertebrae and to the orientation of the panoramic beam in relation to the position of the canals. Gahleitner et al.[9] reported one to five canals per patient with an average diameter of 0.7 mm, with a range of 0.4 to 1.5 mm (Fig. 30.5).

The presence and size of the sublingual anastomosis and the median vascular canal are easily seen on a cross-sectional or axial image of a CBCT scan. In approximately 31% of lingual vascular canals the diameter exceeds at least 1 mm.[10] The sublingual artery is a branch of the lingual artery that originates from the external carotid artery. The lingual artery courses medially to the greater horn of the hyoid bone and crosses inferiorly and facially around the hypoglossal nerve. It then transverses deep to the digastric and stylohyoid muscles, and courses between the hyoglossus and genioglossus muscles. There exist four main branches of the lingual artery: the suprahyoid, dorsal lingual, deep lingual, and sublingual (Fig. 30.6).

Clinical Relevance

When planning implants in the anterior mandible, if a large anastomosis is present, the position may be modified to prevent encroachment on the structure. If this area is violated, excessive bleeding may result. The intraosseous bleeding is usually well controlled by placing an implant, direction indicator, or surgical bur in the osteotomy site. There will be no neurosensory issue with encroaching on this area because there are no sensory fibers within the canal (Fig. 30.7).

Severely Angled Anterior Mandible

There exists one uncommon subcategory of Division C, namely C–a (i.e. Division C bone with excessive angulation). In this category, available bone is adequate in height, but angulation is greater than 30 degrees regardless of implant placement. When present, this condition is most often found in the anterior mandible. For ideal implant placement, usually bone augmentation is required. However, a diagnostic wax-up should be completed first because Division C–a mandibles are usually associated with skeletal Class III patients (Fig. 30.8).

Clinical Relevance

Root form implants placed in Division C–a will lead to poorly positioned implants that will most likely be nonrestorable for a fixed prosthesis. This will most likely result in an overcontoured prosthesis, speech difficulty, compromised tongue space, and inability to obtain an ideal occlusion. Therefore in most cases, a staged bone graft and implant treatment plan should be formulated.

Lack of Keratinized Tissue

As the mandibular osseous process progresses, the presence of keratinized tissue becomes more compromised. In general, implants are healthiest when there exists sufficient keratinized tissue. Some reports indicate the lack of keratinized tissue may contribute to implant failure.[11] Mobile, nonkeratinized mucosa has been shown to exhibit greater probing depths, which has been confirmed histologically. The absence of keratinized mucosa also increases the susceptibility of peri-implant regions to plaque-induced destruction.[12] Additional studies have shown that mobile mucosa may disrupt the implant-epithelial attachment zone and contribute to an increased risk for inflammation from plaque.[13] For larger edentulous ridges the zone of attached tissue on the facial flap (mandible) provides greater resistance for the sutures against tension of the mentalis muscle in the anterior region and the buccinator muscle in the molar and premolar regions, which often cause

incision line opening. As a result, an incision made facial to the attached tissue may cause partial ischemia to some of the crestal tissue. In addition, the incision in unkeratinized facial tissue may sever larger blood vessels, which increases bleeding and decreases vision during surgery, while also potentially complicating final suturing (Fig. 30.9).

Clinical Relevance

For implant sites, an evaluation of the quality and quantity of keratinized tissue should be completed. If insufficient attached tissue is present, tissue augmentation procedures should be completed before implant placement. For larger edentulous sites, especially in the mandible, the incision may be modified to maintain the attached tissue in some cases. If the crest of the ridge is above the floor of the mouth, and there exists greater than 3 mm of attached, keratinized gingiva on the crest of the ridge, a full-thickness incision is made, bisecting the attached tissue. If less than 3 mm of attached gingiva exists on the ridge, the full-thickness incision is made more to the lingual so that at least 1.5 mm of the attached tissue is to the facial aspect of the incision line. Another treatment option includes the use of an acellular dermis (e.g., OraCell; Salvin Dental Corp.). Acellular dermis may be placed at the time of implant placement, thereby increasing the thickness and quality of the tissue while the integration of the implants is taking place (Fig. 30.10).
● **Fig. 30.4** **Mandibular Anterior Perforation.** (A) Implant treatment plan showing perforation of the inferior border of the mandible. (B) Lingual constriction that may lead to bleeding complications, along with chronic tissue irritation. (C to E) Implant placement in a constricted ridge leading to nonideal implant placement.
• **Fig. 30.5** Median Vascular Canal. (A) Canal extending close to buccal plate and then superiorly to almost the crestal area. (B) Canal extending inferiorly and then superiorly.
• **Fig. 30.6** Rare off-midline vascular canal.
• **Fig. 30.7** Implant placement into the canal may result in bleeding episodes.
• **Fig. 30.8** Division C–a Mandible. (A) Mandibular anterior Division C–a with extreme angulation. (B) Cross-sectional image of a Division C–a mandible.
● **Fig. 30.9** (A) Maxillary anterior ridge with compromised attached tissue. (B) When less than 3 mm of attached gingiva is present, the incision for a full-arch mandible should include making the incision more lingual and extending to the lingual aspect of the mandible when there is nerve dehiscence.

Inadequate Width of Bone

A common consequence of tooth loss and bone remodeling in the mandibular anterior region is the resultant narrowing and knife-edge configuration of the mandibular bony ridges (i.e., Division B available bone). Pietrokovski et al.[14] evaluated edentulous ridges in human jaws and found that 43% of mandibular anterior ridges were knife-edge and 38% in the premolar region. Nishimura et al.[15] reported a higher incidence of mandibular knife-edge ridges in females compared with males, mainly because of increased osteopenia changes with unfavorable bone mineral density values.

Clinical Relevance

Therefore before implant placement, it is often necessary to reduce the bone width (i.e., osteoplasty), which results in an increased horizontal width of available bone. An osteoplasty may be carried out with various methods, including osteoplasty burs, barrel burs (i.e., acrylic burs), rongeurs, bone chisels, and Piezosurgery units. By increasing the width of bone, dental implants may be placed with sufficient bone on the buccal (~2.0 mm) and on the lingual (~1.0 mm).

Although an osteoplasty increases available bone for implant placement, many detrimental effects may result. Reduction of a knifelike ridge will decrease the amount of cortical bone present. The cortical bone is a crucial component for primary stability of the implant and is responsible for a greater stress distribution. In addition, as the bony height is reduced, the crown height space increases. The increased crown/implant ratio results in greater strain at the peri-implant interface, which predisposes the implant to biomechanical complications.

The amount of osteoplasty required should be determined before surgery via the use of CBCT treatment planning. In general, if a fixed prosthesis (e.g., FP-1, FP-2, FP-3) is indicated, a minimal osteoplasty is recommended. By minimizing the reduction of bone height, the possibility of a crown/implant ratio problem resulting is decreased. In some cases bone augmentation may be required to maintain the height of bone and increase the bone width, rather than reducing the ridge by means of an osteoplasty. If a removable prosthesis (e.g. RP-4, RP-5) is indicated, a more aggressive osteoplasty is recommended, because this will allow for increased space for the removable prosthesis (i.e., thickness of acrylic, attachment space). In general, the greater the interocclusal space, the less likely a prosthesis or attachment fracture can occur (Box 30.1 and Fig. 30.11).

Mandibular Posterior

Although the posterior mandible is considered a predictable anatomic area for implant placement, there are many drawbacks that include compromised available bone in height and width, significant undercuts, difficult access, and numerous vital structures that may be damaged (e.g., inferior alveolar nerve [IAN], mental nerve, submandibular gland). Iatrogenic violation of these vital structures may result in neurosensory disturbance, pain, infection, excessive bleeding, and compromised implant positioning (Fig. 30.12).

Lack of Bone Height

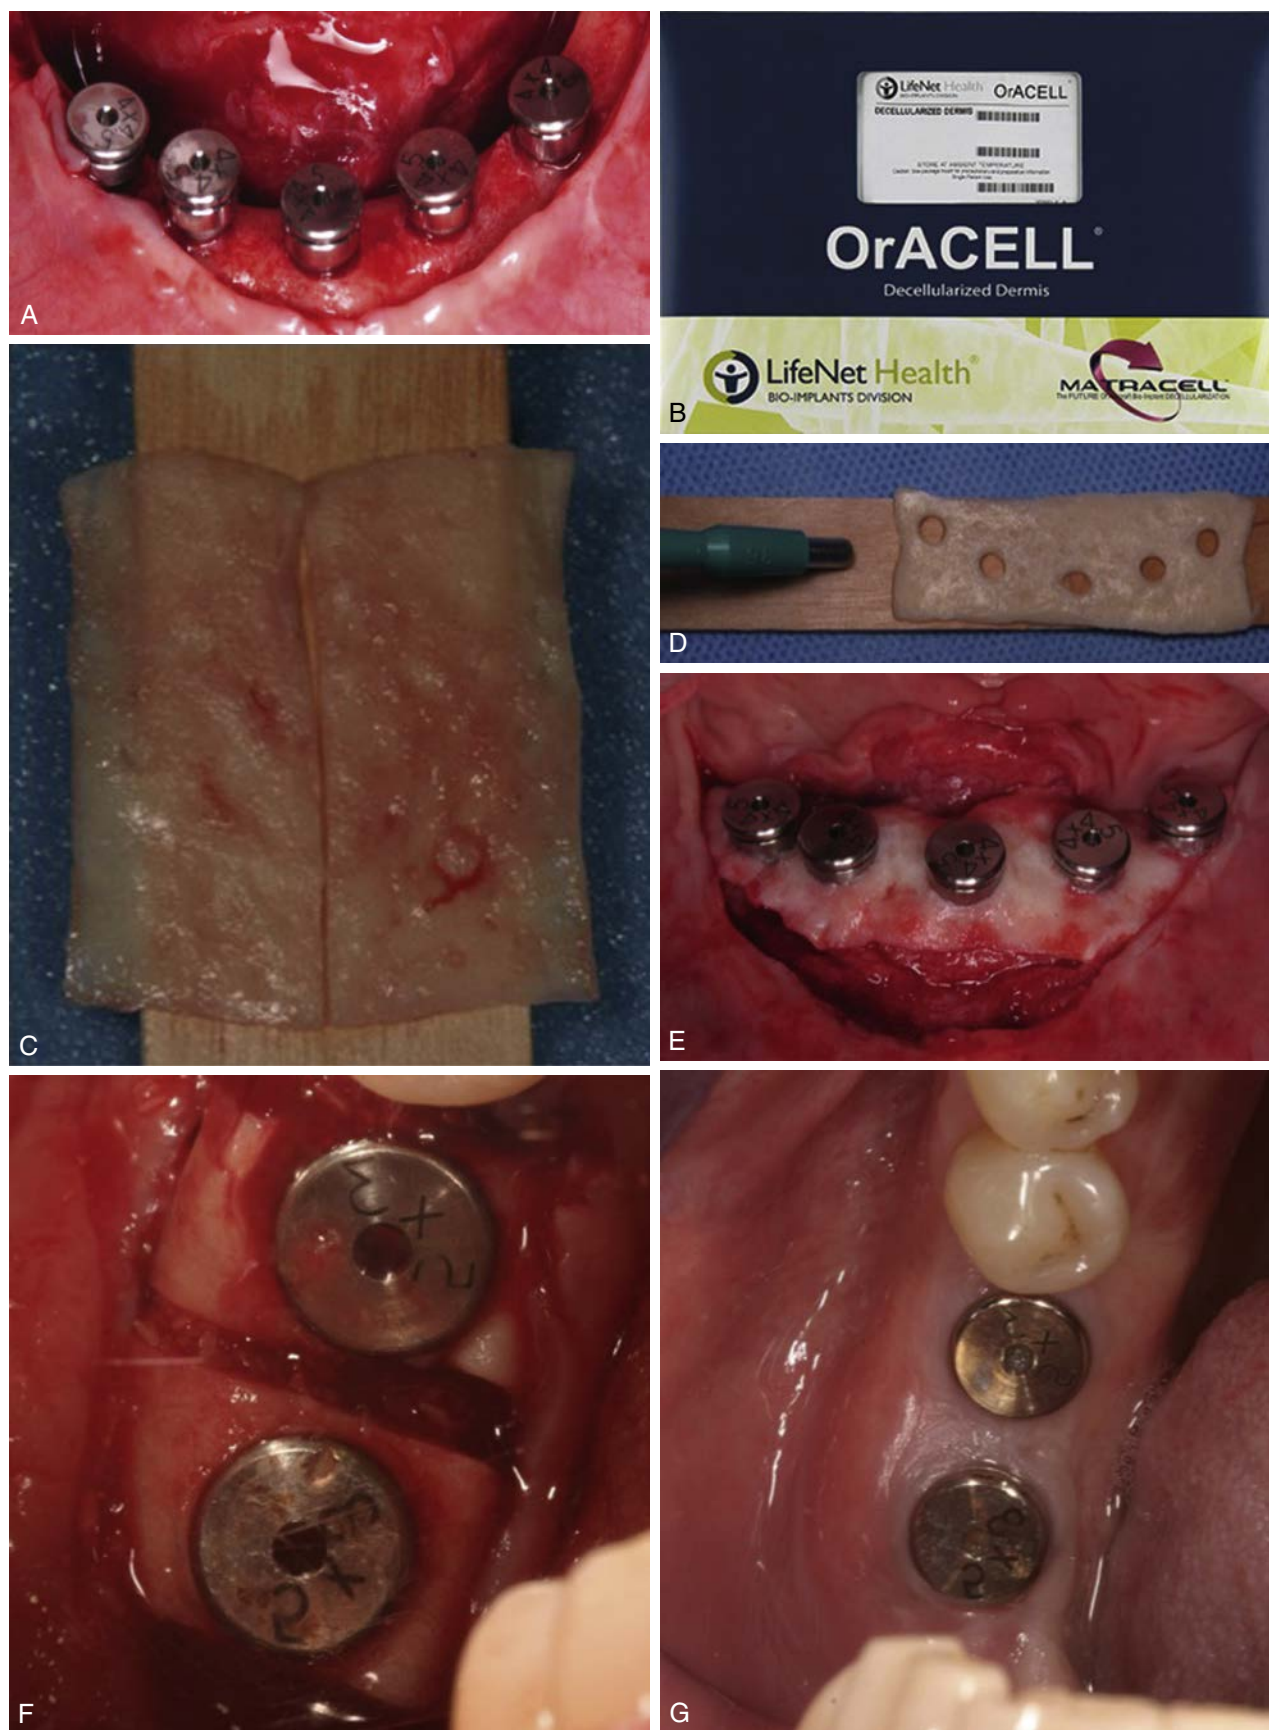
The posterior mandible resorbs from buccal to lingual, transforming from a Division A to a Division B rather rapidly. Because of the trajectory of the posterior mandible, implant placement in an ideal position for prosthetic rehabilitation may be difficult. When limited alveolar ridge height exists, four options are usually available: (1) no treatment, (2) vertical ridge augmentation with delayed implant placement, (3) vertical bone augmentation with simultaneous implant placement, and (4) the use of short implants.[16-19]

Vertical Bone Augmentation (With Simultaneous or Delayed Implant Placement)

With severely resorbed alveolar ridges in the posterior mandible, the available bone height for standard implant placement is often limited by the proximity of the mandibular canal. Vertical bone augmentation is an option for increasing the ridge dimensions, thereby allowing for placement of standard-length implants. By increasing the bone height, esthetics and biomechanical complications are less likely to complicate the longevity of the implant prosthesis.

However, increasing bone height in the posterior mandible is one of the most challenging procedures in implant dentistry. To increase the available bone, various techniques, including autogenous block grafts, guided bone regeneration, and distraction osteogenesis, have been discussed in the literature. However, an increased rate of surgical complications and enhanced patient morbidity have been associated with these types of procedures.

Shorter Implants

Recently the use of short implants (~8 mm) in the atrophic posterior mandible has been introduced to circumvent the need for vertical bone augmentation. Because the loss of vertical bone height is often associated with inadequate available bone for implant


• **Fig. 30.10** (A) Anterior mandible with minimal attached, keratinized tissue and implant placement. (B and C) OrACELL acellular dermis. (D) Four-millimeter holes are made with a biopsy punch to fit over the neck of the implants. (E) Acellular dermis placed with healing abutments. This technique has the advantage of increasing tissue quantity in conjunction with implant healing. (F and G) Before and after case of implant placement and acellular dermis.

placement, the safety zone (2-mm distance between the implant and nerve canal) is sometimes compromised with conventional length implants. If this occurs, an increased possibility of a neurosensory impairment may result.

Therefore the use of shorter length implants offers the clinician many advantages in comparison with vertical bone augmentation: it is a less invasive surgery, less surgical experience is required, it is less expensive, and it has a faster treatment time. However, shorter implants do have drawbacks: they may result in an increased crown height space, less surface area in comparison with standard length implants, and a possible higher rate of biological and technical complications from occlusal overload.

In summary, studies on the use of short implants (~8 mm) are promising.[20,21] Many factors should be evaluated when deciding whether short implants should be used instead of vertical bone augmentation. Force factors (e.g., opposing occlusion, parafunction) must be favorable, and an implant-protected occlusion should adhered to. In addition, with short implants, the widest diameter implant possible should be selected, along with an increased number of implants. The final prosthesis involving multiple implants should always be splinted for greater force distribution (Fig. 30.13).

Mandibular Deformation (Flexure of the Mandible)

Full-arch implant-supported prostheses with a rigid substructure have become controversial in implant dentistry because of the associated increased strain at the bone-implant interface. Because of the rigid bone-implant interface that is associated with dental implants, jaw deformation may transmit excessive stress, which can result in complications. In the literature, pain has been associated with full-arch rigidly splinted prostheses.[22,23] Gates and Nicholls[24] reported on deformation of impression material when full-arch impressions are taken with the mouth wide open. The inaccuracies may result in ill-fitting or nonpassive superstructures in different jaw positions. In addition, mandibular deformation has been associated with loosening of full-arch implant-supported prostheses and possible fractures of prostheses during mastication.[25,26]

Etiology

Flexure. The body of the mandible flexes distal to the foramen on opening and has torsion during heavy biting, with potential clinical significance for full-arch implant prostheses. Many reports have addressed the dimensional changes of the mandible during jaw activity as a result of masticatory muscle action. Five different movements have been postulated. Medial convergence is the one most commonly addressed.[27] The mandible between the mental foramina is stable relative to flexure and torsion. However, distal to the foramina, the mandible exhibits considerable movement toward the midline on opening.[28] This movement is caused primarily by the attachment of the internal pterygoid muscles on the

medial ramus of the mandible. The distortion of the mandible occurs early in the opening cycle, and the maximum changes may occur with as little as 28% opening (or about 12 mm). This flexure has also been observed during protrusive jaw movements.[29] The greater the active opening and protrusive movements, the greater the amplitude of mandibular flexion. The amount of movement varies among individuals and depends on the density and volume of bone and the location of the site in question. In general the more distal the sites, the more medial is flexure. The amplitude of the mandibular body flexure toward the midline has been measured to be as much as 800 μm in the first molar-to-first molar region to as much as 1500 μm in the ramus-to-ramus sites.

Torsion. Torsion of the mandibular body distal to the foramina has also been documented in both animal and human studies. Hylander[30] evaluated larger members of the rhesus monkey family (macaque) and found the mandible twisted on the working side and bent in the parasagittal plane on the balancing side during the power stroke of mastication and unilateral molar biting. Parasagittal bending of the human jaw during unilateral biting was confirmed by Abdel-Latif et al.,[31] who showed patients with implant prostheses measured up to 19 degrees of dorsoventral shear.

The torsion during parafunction is caused primarily by forceful contraction of the masseter muscle attachments. Parafunctional bruxism and clenching may cause torsion-related problems in the implant support system and prosthesis when the mandibular teeth are splinted from the molar-to-molar regions.

Implants placed in front of the foramina and splinted together or implants in one posterior quadrant joined to anterior implants have not shown these complications related to the flexure or torsion of the mandible. Complete implant-supported fixed restorations can halt the posterior bone loss associated with edentulism, improve psychological health, and produce fewer prosthetic complications than removable restorations. All edentulous mandibular patients should be given the option of having a fixed prosthesis. However, the increase in forces of mastication, increase in force with patients of greater force factors (e.g., parafunction, crown height space, opposing arch type), or reduced bone density in the implant sites warrant an increase in implant number or implant position in anterior and posterior implant sites (Fig. 30.14).

Prevention

The concept of flexure and torsion does not affect the maxilla, where all implants are often splinted together, regardless of their positions in the arch. Prevention of mandibular flexure should include the following treatment plans:

Bilateral posterior implants: If implants are positioned bilaterally in the premolar/molar regions of the mandible, the final prosthesis should be fabricated with two sections. This will minimize the possibility of flexure/torsion issues. Usually, the prosthesis is. splint in the premolar area.

Anterior implants with unilateral implants posterior: With implant support on only one posterior side, full-arch splinted prostheses will not be subject to the flexure/torsion problems.

Anterior implants with no posterior implants: With no posterior implant support, full-arch splinted prostheses may be fabricated without concern regarding flexure/torsion problems.

Treatment

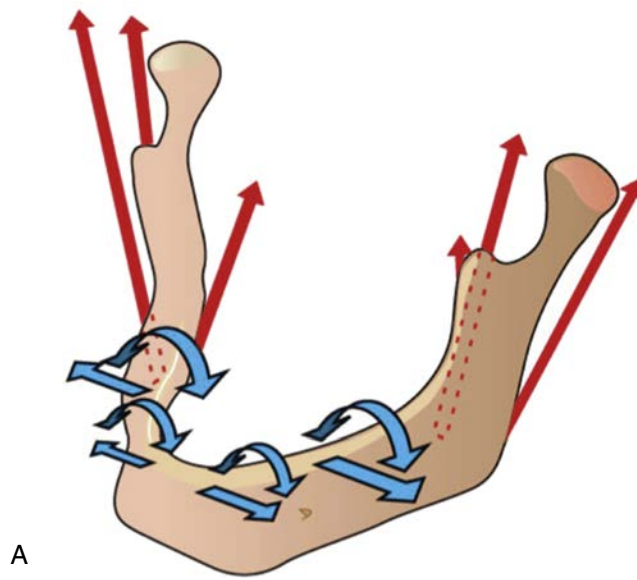
If a full-arch splinted prosthesis is fabricated and the patient exhibits complications (e.g. pain, difficulty opening, posterior
● **Fig. 30.11** Osteoplasty. (A) Because of bone resorption and resultant Division B ridge, it is often necessary to reduce the height of bone via osteoplasty. (B) Osteoplasty of the mandibular anterior ridge to gain width of bone and increase interocclusal space. (C) In general, for a fixed prosthesis (e.g., FP-1, FP-2, FP-3), minimal osteoplasty should be completed to minimize crown height space issues. For a removable prosthesis (e.g., RP-4, RP-5), a more aggressive osteoplasty should be performed to increase space for prosthetic rehabilitation. (D) Implant placement for a removable implant overdenture with insufficient interocclusal space leading to the nonrestorability of the implants.
● **Fig. 30.12** Posterior Mandible. Because of the bone morphology and resorptive patterns of the posterior mandible, this anatomic area is often difficult to treat.

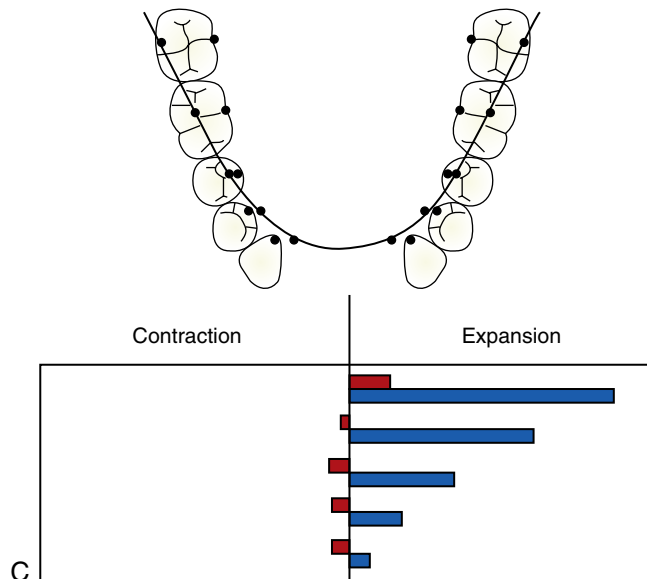
bone loss) related to the flexure/torsion of the mandible, the prosthesis should ideally be re-fabricated to allow for stress relieve for flexure and torsion forces. This is most likely completed by making the prosthesis in more than one piece.

Bony Anatomic Areas

Posterior Lingual Undercut

In the posterior mandible, it is imperative the implant clinician have detailed knowledge of the three-dimensional anatomy of the area. A lingual undercut is often present, which may lead to complications with life-threatening consequences.

Parnia et al.[32] classified posterior lingual concavities into three types: type 1 (20%): flat depressions less than 2 mm in depth, type 2 (52%) occur with 2 to 3 mm in depth, type 3 (28%) showed significant concavities of more than 3 mm. Nickenig et al.[33] classified posterior mandible morphology to be U-shaped (undercut), P-shaped (parallel), and C-shaped (convex). Lingual undercuts had a prevalence rate of 68% in the molar region, with the prevalence rate far greater in the second
● **Fig. 30.13** Augmentation Versus Short Implants. (A) Due to extensive atrophy, posterior resorption results in a Division D ridge that contraindicates bone augmentation. (B) Short implant placement that prevents nerve impairment, but predisposes patient to biomechanical issues. (C to E) Vertical augmentation graft: large defect augmented with autogenous bone, with delayed implant placement.




• **Fig. 30.14** (A) The mandible flexes toward the midline on opening or during protrusive movements as a result of the internal pterygoid muscle attachments on the ramus. The mandible also torques, with the inferior border rotating out and up, and the crestal region rotating lingually. The movement is caused by the masseter muscles during forceful biting or parafunction. (B) The amount of flexure depends on the amount of the bone volume and the sites in question. The medial movement from the first molar to the first molar region may be 800 μm. (C) Unilateral molar biting causes the mandible to undergo torsion with the bottom of the mandible expanding outward and the crest of the mandible rotating medially. (*Adapted from Hylander WL. Mandibular function in Galago crassicaudatus and Macaca fascicularis: an in vivo approach to stress analysis of the mandible.* J Morphol. *1979;159:253-296.*)

molar region (90%) than in the first molar region (56%).[33] Other studies have shown that lingual undercuts occur in approximately 66% of the population, with a mean undercut of 2.4 mm (Fig. 30.15).[34]

Clinical Relevance

If perforation of the lingual plate is made with either the surgical drill or implant placement, life-threatening situations may result from sublingual bleeding. Within the lingual undercut area, the sublingual and submental arteries are present. Trauma to either of these arteries can result in a sublingual hematoma and airway compromise.

If the perforation were to occur above the mylohyoid muscle, damage to the lingual nerve may result in a neurosensory impairment. If an implant is inserted in this area that extends into the undercut, constant irritation from the extruded implant in the soft tissue may cause the patient chronic pain. In some cases violation may predispose the patient to infection. A clinical examination should always be carried out to determine whether an osseous undercut exists. This may be confirmed with a CBCT examination because cross-sectional images are an effective way of observing lingual undercuts. Violation of this area may cause infection or constant irritation from the extruded implant in the soft tissue.

In addition to the blood vessels in the sublingual area, two salivary glands are also present. The submandibular fossa is a depression on the medial surface of the posterior mandible, which is inferior to the mylohyoid ridge. Within this fossa the submandibular gland is present. Anterior to the submandibular gland is the sublingual fossa, which is present on both sides of the mental spine. The sublingual gland is found in the sublingual fossa. The submandibular and sublingual fossae should be palpated and evaluated before implant osteotomies. In this area, perforation of the lingual plate may damage either of the glands, resulting in possible infection.

Accurate measurements must be determined to prevent over-preparation of the osteotomy site in the posterior mandible. This is most easily completed with a CBCT examination. A clinical examination and palpation of the bone ridge at the proposed implant sites should also be completed. Osteotomy angulation should be carefully evaluated because improper drilling angulation may also lead to perforations. Perforations may lead to infection that can spread to the parapharyngeal and retropharyngeal space. Infections in these spaces progress to severe complications, such as mediastinitis, mycotic aneurysm, internal jugular vein thrombosis, or upper airway obstruction.[35] These complications may occur immediately or can be delayed and should be treated aggressively.

Shorter implants with a tapered design have been shown to be beneficial in avoiding lingual bone perforations.[36] Ideally, implants should always be positioned along the long axis of the occlusal forces, therefore implants should not be placed at an excessive angulation (>30 degrees) to avoid undercuts. de Souza et al.[37] has shown that the submandibular fossa has a direct influence on implant placement (i.e., implant size, position, and angulation) 20% of the time (Fig. 30.16).

Vascular Considerations

Incisive Canal Vessels

The incisive artery is the second terminal branch of the inferior alveolar artery, which is a branch of the maxillary artery. The incisal branch continues anteriorly after supplying the mandibular

first molar area, where it innervates the incisor teeth and anastomoses with the contralateral incisal artery. In rare cases the incisive canal is large, lending to greater bleeding during osteotomy preparation or bone-grafting procedures. The exact location of the incisive canal is easily determined via a CBCT evaluation in the panoramic or sagittal views.

Clinical Relevance

Clinicians often confuse the incisive canal with an anterior loop of the mental nerve. The nerve, artery, and vein within this canal may cause bleeding episodes if traumatized. Usually the placement of the implant, a direction indicator, or surgical bur can be placed into osteotomy to apply pressure to allow for the clotting process.

Inferior Alveolar Artery

The inferior alveolar artery is a branch of the maxillary artery, one of the two terminal branches of the external carotid. Before entering the mandibular foramen, it gives off the mylohyoid artery. In approximately the first molar region, it divides into the mental and incisal branches. The mental branch exits the mental foramen and supplies the chin and lower lip, where it eventually will anastomose with the submental and inferior labial arteries. The exact location of the inferior alveolar artery is easily determined via a CBCT evaluation in the panoramic or sagittal views.

Clinical Relevance

Normally the inferior alveolar artery is located superiorly to the Inferior alveolar nerve (IAN) IAN within the bony mandibular canal. Drilling or placing an implant into the inferior alveolar canal may predispose to significant bleeding. Some authors have recommended the placement of an implant or direction indicator short of the canal to control the bleeding; however, this may lead to possible neurosensory disturbances from hematoma or local irritation to the IAN canal. A 2.0-mm safety zone should be established to prevent complications in this area. If bleeding does occur, follow-up postoperative care is essential because hematoma formation within the canal may lead to a neurosensory impairment. This condition should be monitored because it may progress to respiratory depression via a dissecting hematoma in the floor of the mouth.

Buccal Artery

A common donor site for autogenous grafting is the lateral ramus area in the posterior mandible. When making the incision lateral to the retromolar pad, a common blood vessel to sever is the buccal artery. The buccal artery is a branch of the maxillary artery and will most likely cause a significant bleeding episode. This artery runs obliquely between the internal pterygoid and the insertion of the temporalis on the outer surface of the buccinator.

Clinical Relevance

In most cases, damage to the buccal artery is very difficult to avoid. Incision and reflection will usually encompass the area of buccal artery location. When performing surgery in this area, a hemostat should always be available for immediate access to clamp the vessel. A curved hemostat should be used to clamp the vessel, thus decreasing the bleeding. It should be left in place for 3 to 5 minutes. If bleeding persists, a ligature may be placed with Vicryl suture material (i.e., resorbable) (Fig. 30.18).
• **Fig. 30.15** Posterior Lingual Undercut. (A) Large sublingual posterior undercut. (B) Of concern is the possibility of lingual perforation. (C and D) Implant dimension measurements should never be made from cone beam computed tomographic panoramic views because third dimension of bone needs to be determined. (E) Implant placement without regard to sublingual undercut results in migration of the dental implant into sublingual space.
● **Fig. 30.16** Variable Posterior Bony Anatomy. (A) Straight, no angulation. (B) Slight angulation with minimal lingual undercut. (C) Larger lingual undercut resulting from more extensive atrophy. (D) More significant angulation resulting from buccal bone resorption. (E and F) Extensive lingual undercuts.

Facial Artery

The facial artery is a branch of the external carotid artery, lying superior to the lingual artery and medial to the ramus of the mandible. It courses below the digastric and stylohyoid muscles, and passes through a groove in the submandibular gland before it becomes superficial around the inferior border of the mandible. There are two main branches of the facial artery: the facial and cervical. The facial branch encompasses five branches, which supply the eye, nose, and lips. There are four branches of the cervical region, supplying the pharynx, soft palate, auditory tube, and submandibular gland.

Clinical Relevance

Excessive retraction in this area may lead to trauma to the facial artery. If bleeding from the facial artery exists, pressure should immediately be applied to the angle of the mandible over the vessel. Usually immediate medical assistance will need to be summoned.

Neural Considerations

Lingual Nerve

The lingual nerve is a branch of the trigeminal nerve that provides sensory innervation to the mandibular lingual tissue and the

anterior two-thirds of the tongue. The lingual nerve is a concern for implant clinicians because it may be damaged during reflection of the lingual flap. The lingual nerve is most commonly found 3 mm apical to the alveolar crest and 2 mm horizontal from the lingual cortical plate. However, 22% of the time, it may contact the lingual cortical plate.[38] Variations of this nerve have reported it to be located lingual to the third molar area, at or above the crest of the bone.[39]

Clinical Relevance

When elevating tissue in the posterior mandible, always maintain the retractor on the bone and minimize stretching of the tissue on the lingual aspect of the mandible. The lingual nerve is very susceptible to neuropraxia types of nerve impairments. In addition, no lingual vertical release incisions should be used because of the variant lingual nerve anatomy. In addition, in the posterior ramus area, incisions shoudl always be lateral lateral to the retromolar pad because the lingual nerve transverses this area in 10% of cases (Fig. 30.17).

Inferior Alveolar Nerve

Prevention of iatrogenic injuries to the third division of the trigeminal nerve is paramount in implant dentistry today. A resultant neurosensory impairment in the head and neck region may affect the patient's quality of life and may present potentially significant medicolegal problems for the clinician. To prevent damage to these vital nerve structures, it is imperative for the implant dentist to have a comprehensive radiographic survey of the region, thorough knowledge of the normal versus variant anatomy, and awareness of intraoperative surgical techniques to minimize the possibility of nerve impairment (Fig. 30.19).

Radiographic Considerations

Two-Dimensional Radiography

Today the use of 2D radiography is becoming less common for dental implant treatment planning. Two-dimensional radiographs, mainly panoramic, have many inherent disadvantages in evaluating potential implant sites. All panoramic (2D) radiographs exhibit some degree of distortion, nonuniform magnification, and image superimposition, which can potentially lead to incorrect measurement and assessment of neural structures. Studies have shown periapical and panoramic radiography to be unreliable in assessing the true location of the inferior alveolar canal and the mental foramen.[40] Extreme caution should be exercised when using 2D radiography as the only modality for implant site evaluation (Fig. 30.20). Two-dimensional radiographs may be used for initial assessment of potential implants sites.

Even with the generalized acceptance of CBCT radiography in the diagnosis and treatment planning of dental implants, numerous manufacturers still make available to implant dentists magnification guides and digital software programs for intraoral
• **Fig. 30.19** Posterior Mandible Complication. (A) Implant osteotomy violating the inferior alveolar canal from poor preoperative planning. (B) Implant placement resulting in a neurosensory deficit.
• **Fig. 30.20** Two-Dimensional Radiographs. (A) Panoramic radiographs are inherently inaccurate and do not show the accurate position of the inferior alveolar canal or mental foramen. (B) Panoramic radiographs have a variable magnification factor in the vertical and horizontal planes.

radiographs to assist in the placement of implants over vital structures. The clinician should be aware that panoramic radiographs have variable magnification (i.e., not 25% as related by many implant and panoramic companies), and even calibrated intraoral software programs cannot accurately assess true distances because of their 2D origin. Both periapical and panoramic radiography are associated with magnification that is inconsistent and difficult to determine. Schropp et al.[41] have shown that in more than 70% of cases in which implant size was initially determined via panoramic radiographs, the implant size had to be altered after CBCT evaluation. Magnification guides should never be used as the sole criteria for implant site evaluation because they may lead to overestimation of available bone dimensions.

Three-Dimensional Radiography

In most cases a 3D radiographic modality is recommended for evaluation of the mandibular arch and related nerve anatomy. Studies have shown approximately 50% of nerve injuries resulted from inadequate radiographic assessment.[42,43] Therefore to determine the ideal location and measurement parameters associated with the dental implant placement, the clinician must be able to accurately measure the distance between the alveolar crest and the superior border of the mandibular canal, as well as the width of bone in the proposed implant site. Medical slice computed tomography (MSCT) and CBCT images have been shown to be the most accurate radiographic modalities in the assessment of available bone and identification of the IAN.[44] A thorough knowledge of the relative 3D position of the IAN is crucial in preventing mandibular nerve impairment before implant placement (Fig. 30.21).

Because MSCT and CBCT have been shown to be 1:1 (no magnification), the implant dentist has the ability to place implants, measure available bone, evaluate bone density, determine the prosthetic treatment plan, and order surgical templates directly from their computerized treatment plan. Interactive treatment planning software programs available today contain libraries of most implants systems, which allow the clinician to accurately access the size, type, and ideal placement of the implant in relation to anatomic structures. This virtual treatment plan may then be transferred to the patient's surgery by means of a surgical template or computer-assisted navigation system.

For clinicians early on their learning curve, the fabrication of a bone model can be an invaluable preoperative diagnostic tool. Bone models are made directly from the CBCT dicom (.dcm) data, which are easily fabricated with in-office 3D printers. The
• **Fig. 30.21** (A) Cone beam computed tomographic image depicting cross-sectional, axial, panoramic, and three-dimensional images. (B) Virtual treatment plan showing the mandibular nerve in relation to placement of an implant.

● **Fig. 30.22** Guided-Implant Surgery. With the use of surgical templates, implants may be positioned more accurately, thereby avoiding possible nerve complications.

clinician is able to evaluate the exact osseous morphology (width of bone, undercuts, bony landmarks) and location of vital structures (color coded within the model) before the actual surgery. Implant osteotomies may be performed in a laboratory setting to allow the implant dentist to complete the procedure before surgery.

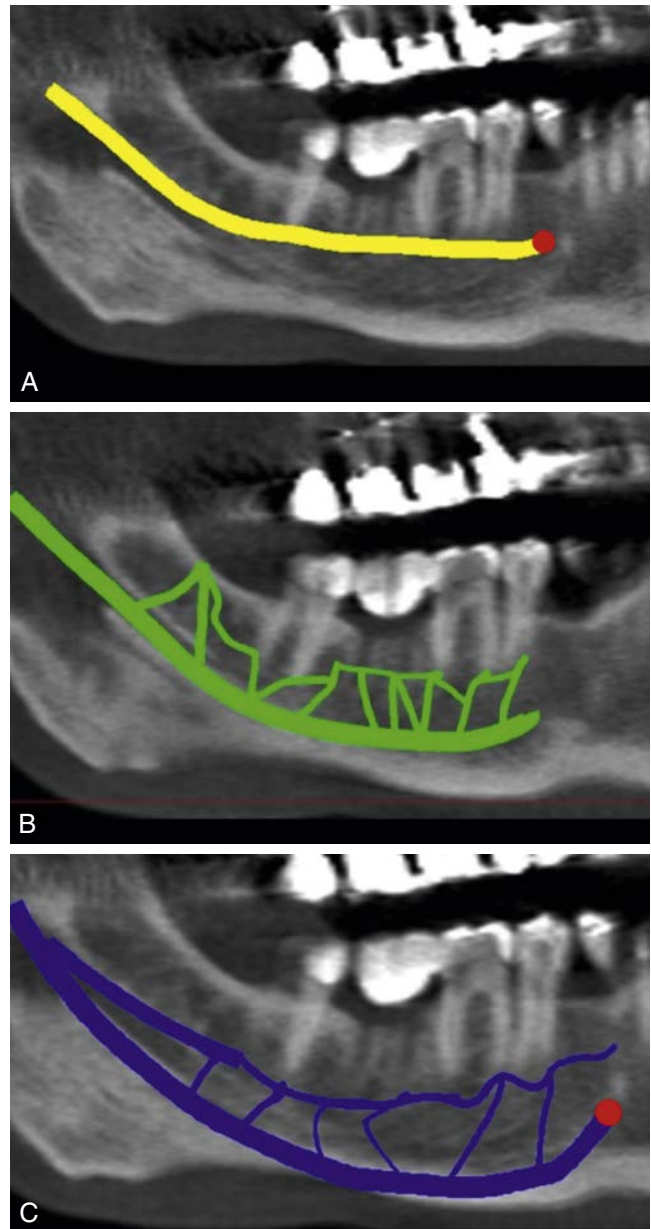
Neurosensory impairment issues are most frequently an inadvertent sequela of improper diagnosis, treatment planning, or surgical technique. Many of these complications can be overcome by using 3D surgical guides for the ideal positioning and placement of implants. Basically the surgical guide is the conduit for transferring the interactive treatment plan from the computer to the patient's actual surgical procedure. This allows the implant dentist to be able to place the implants in the exact location as per the treatment plan. Surgical guides are categorized based on method of retainment: tooth, bone, or mucosa supported. In addition, guides are distinguished by the surgical technique involved: fully guided—all osteotomies and implant placement is completed through the guide; universal guide—all osteotomies except for the final drill and implant placement are completed through the guide; and pilot—only the first or initial drill is used through the guide. Guided surgery with surgical templates has been reported to improve the accuracy of implant placement in clinical situations in comparison with conventional surgical methods (Fig. 30.22).[45] Nickenig et al.[46] showed that implants placed with surgical templates were within 0.9 mm of the planned positions, whereas free-hand placement resulted in deviations of approximately 2 to 3 mm.

Anatomic Considerations

To avoid damage to the IAN, the clinician must have a thorough understanding of the normal versus variant anatomy of the posterior mandible.

Inferior Alveolar Canal

Inferior-Superior Plane

There is a common belief that the vertical position of the IAN is relatively constant within the mandible. Normally the IAN runs a concave path from posterior to anterior, with anterior terminal segments exiting the mental foramen (mental nerve) and a branch that ascends to the midline of the mandible (incisive nerve). However, numerous anatomic studies have confirmed the


● **Fig. 30.23** Inferior Alveolar Nerve (Inferior-Superior Plane). (A) Type 1 (high): positioned close to tooth apex. (B) Type 2 (intermediate): most common position within the middle of the mandible. (C) Type 3 (low): positioned in the inferior border of the mandible.

inferior-superior (vertical) positions of the IAN are not consistent.[47,48] An early classification of the vertical positions of the course of the alveolar nerve was reported by Carter and Keen.[49] They described three distinct types: (1) in close approximation to the apices of the teeth, (2) a large nerve approximately in the middle of the mandible with individual nerves supplying the mandibular teeth, and (3) a nerve trunk close to the inferior cortical plate with large plexuses to the mandibular teeth. In type 1 nerves, impairment is common because of the close proximity to the nerve bundle. Three percent of patients can have the IAN directly contacting one or both of the roots of the mandibular first molar.[50] It is highly recommended that a comprehensive radiographic survey be completed to evaluate the IAN in a vertical plane, especially with type 1 and 2 nerves (Fig. 30.23). Juodzbalys et al.[51] categorized the inferior-superior positioning as either: (1)

high, within 2 mm of teeth apices; (2) intermediate; or (3) low. Heasman[52] reported that 68% of patients exhibit an intermediate zone path of the IAN canal, with an average distance of 3.5 to 5.4 mm from the first and second molar roots.

Buccal-Lingual Plane

Studies have shown the buccal-lingual location of the IAN as it progresses anteriorly is not constant. The nerve paths have been described in a buccal-lingual direction with a high degree of variability and are dependent on the amount of bone resorption, as well as age and race variables.[53]

Kim et al.[54] evaluated and classified the buccolingual IAN location into three types: type 1, IAN canal is in close proximity to the lingual plate (~70%); type 2, IAN canal follows the middle of the ramus from the second molars to first molars (~15%); and type 3, IAN canal follows the middle or lingual thirds of the mandible from the ramus to the body (~15%).

In addition, older and Caucasian patient groups have shown less distance between the buccal aspect of the nerve and the inferior border of the mandible. Other studies have shown the most common area for the IAN to be in the middle of the buccal and lingual cortical plates is the first molar region.[55] Thus, in the buccal-lingual plane, the IAN is highly variable, therefore 3D cross-sectional images should be used to determine the true position of the nerve (Fig. 30.24).

Mental Foramen

Determining the exact location of the mental foramen is crucial when placing implants in the posterior mandible. Although the foramen has been thought to be symmetric to the contralateral side in most patients, the location has been shown to be highly variable.[56] The mental nerve passes through the mental foramen with three to four nerve branches that exit with an average diameter of 1 mm.[57] This nerve will innervate the skin of the mental area, and the other two proceed to innervate the skin of the lower lip, mucous membranes, and the gingiva as far posteriorly as the second premolar. Any trauma to this nerve may result in neurosensory impairment in this area.

The size, shape, location, and opening angulation of the mental foramen are variable. Usually the mental nerve exits the mental foramen from the mental canal. The mental canal is most commonly angled in a superior direction from the mandibular canal (i.e., average is approximately 50 degrees, with a range from 11 to 70 degrees).[58] The size of the mental foramen in the literature has been reported to range from 2.5 to 5.5 mm. The most common shape is ovoid (~65%) and round (~23%).[59]

The positioning of the mental foramen is also extremely variable in the vertical and horizontal planes. Clinically there are many different techniques in identifying the foramen, with a wide variation of predictability.

Visualization of the Mental Nerve

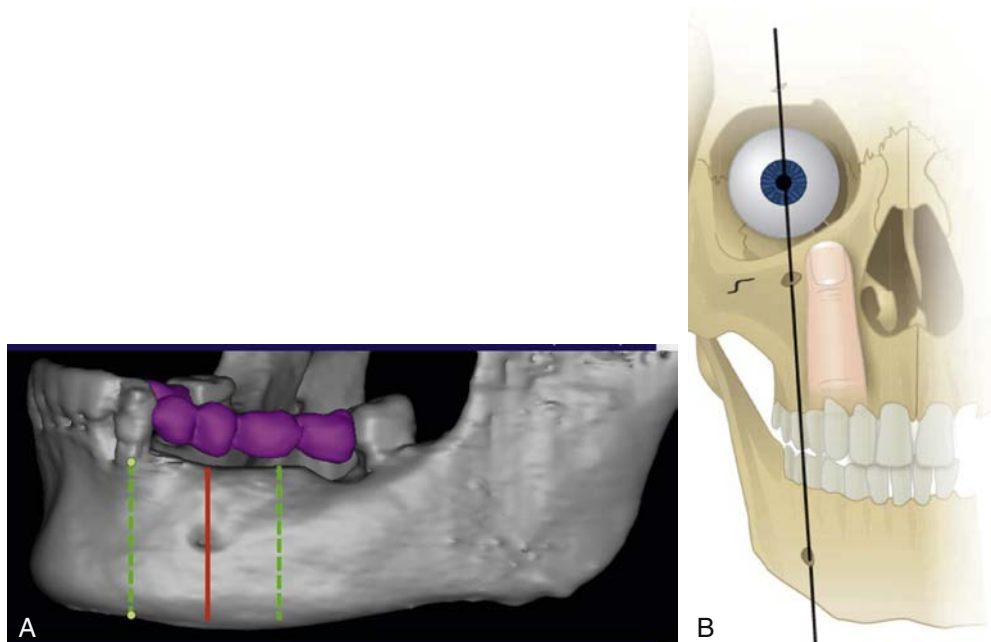
Two-dimensional Radiographs. Studies have shown that in more than 50% of periapical and panoramic radiographs the mental foramen is not in the location depicted on the 2D image.[60] Conventional 2D radiography should never be used as the sole diagnostic modality in evaluating the foramen position (Fig. 30.25).

Three-dimensional Radiography. The literature has shown that 3D imaging is the most accurate diagnostic tool to ascertain the exact location of the mental foramen. CBCT panoramic and cross-sectional images, together with 3D images, are the easiest
● **Fig. 30.24** Buccal-Lingual Inferior Alveolar Nerve Canal Position. The position in the buccal-lingual position is variable: (A) buccal positioned; (B) lingual positioned.

● **Fig. 30.25** Two-dimensional radiograph that has been shown to depict the true location of the mental foramen only 50% of the time.

and most accurate techniques in determining the exact foramen location (Fig. 30.26).[61]

Palpation. In rare cases the clinician may be able to palpate the location of the mental foramen. Most notably, when bone resorption has caused the nerve to be exposed on the residual ridge, the concavity formed by the exposure of the nerve can be determined. In these cases the location of the mental foramen may be marked with a surgical pen. When the nerve is located on the buccal surface of the mandible, the palpation method of identification has very low utility.

Anatomic Eandmarks. In the literature, many authors have postulated that landmarks such as teeth and mandibular bony areas may help identify the location of the mental foramen. With respect to teeth, the location cannot conclusively be associated with a particular tooth (e.g., first premolar, second premolar, between apices of the premolars) because studies have shown the location to be dependent on gender, age, and race.[62] In addition, patients exhibit different types of facial and skeletal growth, along with orthodontic factors that make dentition landmarks completely inaccurate. Numerous studies have shown a high correlation between mental foramen location and race. However, most of these studies associate the location of the mental foramen with a specific tooth[63-66] (Fig. 30.27).
● **Fig. 30.26** (A and B) Cone beam computed tomographic three-dimensional image showing true position and size of mental foramen. (C) Complete dehiscence of mandibular canal.


● **Fig. 30.27** (A) The position of mental foramen does not correspond to a specific anatomic landmark (e.g., first premolar, second premolar). The mental foramen may be positioned as far anterior as the cuspid and as far posterior as the first molar. (B) In the literature a vertical line drawn from the pupil of the eye and infra-orbital foramen will be in close approximation to the mental foramen. However, this technique has inherent inaccuracies because many patients have different skeletal relationships.
● **Fig. 30.28** (A) Incision outline to expose foramen consists of a crestal incision to the mesial of the canine and distal of the molar, with an anterior and a posterior vertical release incision. (B) After foramen exposure the height of available bone may be determined.

Direct Evaluation. The most precise technique available today to determine the exact location of the mental foramen is by direct evaluation. Exposing the mental foramen may be intimidating to some clinicians, especially early on their learning curve. This can be accomplished with very low morbidity; however, the technique's success depends on the clinician's training and experience.

Technique to Expose Mental Foramen

1. Crestal incision is made from the canine position (mesial) to the first molar position, with vertical 45-degree release incisions anterior and posterior (Fig. 30.28).
2. Full-thickness reflection is completed below the mucogingival junction: A moist 4 × 4 gauze is placed over the index finger, and the flap is elevated apically until the superior aspect of the foramen is located (Fig. 30.29).
3. The gauze may be used anterior and posterior to the foramen to confirm the foramen location.
4. Once the foramen is located, a periodontal probe may be used to measure the ridge height. The implant length is usually 2 mm less than the measured distance.

Three-dimensional Ultrasound. The most promising imaging technique for the future is ultrasound. Ultrasound has the advantage of no ionizing radiation and the ability to reconstruct 3D images of bone surfaces to within an accuracy level of 24 μm. At this time, ultrasound units are not available specifically for dental use.[67]

Mental Nerve Variants

Accessory and Double Foramen. Studies have shown that in approximately 6.62% to 12.5% of patients, an accessory foramen is present.[68,69] In the majority of cases, small accessory foramina usually contain a small branch of the mental nerve or a nutrient branch that supplies the teeth. These are usually not problematic because of cross-innervation or actually contain nutrient branches and no sensory fibers to the soft tissue. Accessory foramens are usually radiographically differentiated from a double foramen in the accessory foramen, which will be seen on a CBCT as a very small foramen, usually anterior to the larger main mental foramen.

However, in a small percentage of cases, a larger branch of the mental nerve (equal or larger-size foramen) may exit the second mental foramen, which is termed a *double foramen*. Special care should be extended in this situation because it may contain components of one of the three branches of the mental nerve. Accessory foramina are believed to be the result of early branching of the IAN, before exiting the mental foramen during the 12th week of gestation.[70] Double foramens are easily seen in 3D images, or the coronal CBCT images are depicted as two larger size foramens, often being of the same size (Fig. 30.30).

Anterior Loops of the Mental Nerve. As the mental nerve proceeds anteriorly in the mandible, it sometimes runs inferior and anterior to the mental foramen. This anterior and caudal component of the mental nerve will curve cranially back to the mental foramen and is termed the *anterior loop*.[71] Recently, CBCT and dissection studies have shown a rather high (70%) prevalence rate of anterior loops, with a mean of 1.16 mm distance anteriorly. The anterior loop may be depicted most predictably on axial CBCT images, with 2D radiographs being totally unreliable.

Determining the presence of an anterior loop is critical when placing implants anterior to the mental foramen. Inability to ascertain the presence of an anterior loop may result in damage to the mental nerve (Fig. 30.31). The anterior loop measurement should be added to the safe zone to avoid damaging the mental nerve. For example, if a 1.0-mm anterior loop is present, then the safety zone should be calculated to be 3.0 mm (1.0 mm anterior loop + 2.0 mm safety zone).

Incisive Nerve Branch. The incisive nerve branch, a continuation and terminal branch of the IAN, supplies the mandibular canine and incisor teeth, and is seen as a radiolucent canal in the anterior mandible. The canal is most commonly present in the middle third of the mandible and narrows toward the midline, reaching the midline only 18% of the time.[72] The incisive nerve is often mistaken for an anterior loop in the mandible. Because there is no soft tissue sensory component to this nerve, implants may be placed in proximity to it without nerve impairment. Studies have shown incisive canals have a mean diameter of 1.8 mm and location 9.7 mm from the lower cortical border.[73] The incisive nerve has been recognized as an important anatomic structure that must be taken into consideration when performing surgery in this area. Excessive bleeding has been reported as a significant intraoperative complication in this area when it is perforated during osteotomy preparation (Fig. 30.32). However, this is usually remedied by placing the implant, direction indicator, or surgical bur into the osteotomy site.
• **Fig. 30.29** **Exposure of the Mental Foramen.** (A) General incision outline with mental foramen high-lighted in yellow. (B) Anterior full-thickness reflection. Surgical Principles to Decrease Neurosensory Complications

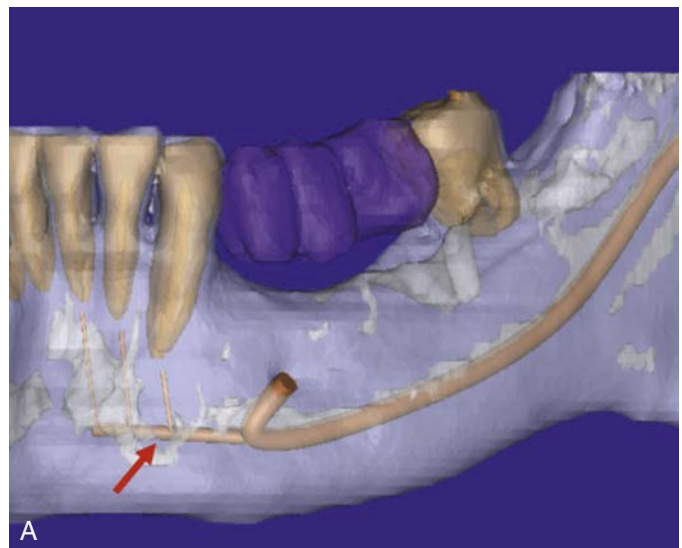
Safety Zone

A 2-mm safety zone with osteotomy preparation and final implant placement is paramount in preventing neurosensory impairments.[74] Therefore the final implant position should always maintain a minimum distance of 2 mm from the IAN canal. Compression-related injuries (neuropraxia) can occur by encroaching on the IAN without actual contact. Nerve impairments have been reported when implants are placed less than 2 mm from the canal without actual invasion of the canal.

Bleeding and resultant hematomas have been shown to cause nerve damage because of final positioning of the implant too close to the neurovascular canal.[75] In addition, the IAN superior cortical bone can be compressed, causing pressure necrosis with resultant nerve impairment.[76] Interactive treatment planning software programs allow the implant clinician to accurately assess the ideal placement with respect to this vital structure (Fig. 30.33).

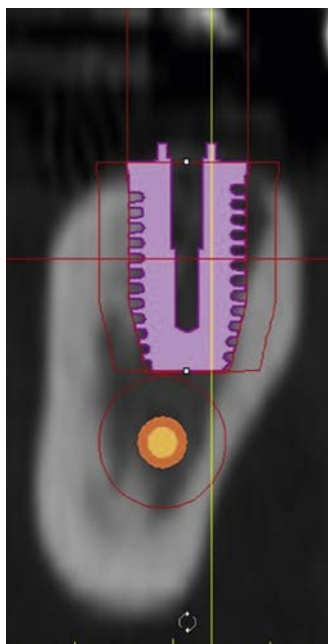
Always Take Into Account the Y Dimension of the Implant Burs

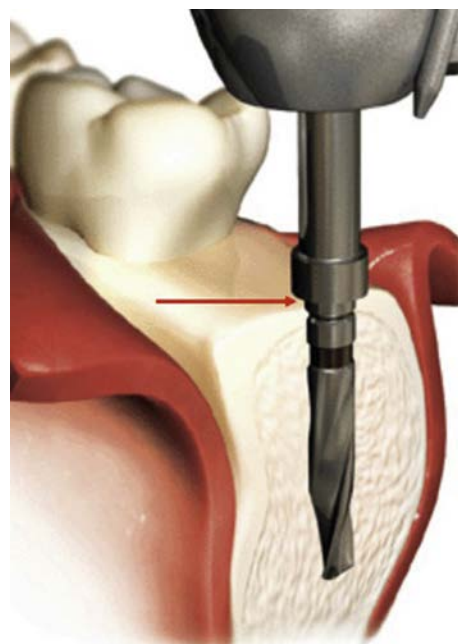
Care should always be exercised in knowing the exact drilling depth when performing osteotomies over vital structures, especially in the posterior mandible. The implant clinician should double-check the marking depth on the burs before initiating the osteotomy. The principle of "measure twice, drill once" should be followed to prevent iatrogenic overpreparation of the implant site.


- **Fig. 30.32** Incisive Nerve. (A) Three-dimensional image depicting the incisive nerve, which is the second terminal branch of the inferior alveolar nerve. (B) Cone beam computed tomographic panoramic and cross-sectional images showing the incisive nerve canal (green arrows).

In addition, the Y dimension of the implant system being used must be known. With many implant surgical systems, the depth of the millimeter lines inscribed on surgical drills do not always coincide with the actual depth of the drill. Most drills contain a V-shaped apical portion designed for cutting efficiency (Y dimension). Usually the wider the drill, the greater the Y dimension. The implant clinician should always evaluate the manufacturer's drill length with respect to the length of the implant before performing the osteotomy. If this concept is not adhered to, overpreparation of the site may occur, resulting in nerve damage (Fig. 30.34).

Use Drill Stop Burs to Prevent Overpreparation

An additional technique to prevent overpreparation of the osteotomy site is the use of stop drills. These drills have a predetermined depth marking that prevents overpreparation. Stop drills are beneficial in the mandibular posterior area, especially when visibility and access are compromised. Generic drill stop kits are also available that may be used with most implant surgical systems (Salvin Dental Corp.). These autoclavable, reusable kits


• **Fig. 30.33** Safety Zone. A 2-mm safety zone should always be present between the implant and the inferior alveolar canal.


• **Fig. 30.35** Drill Stops. To prevent overdrilling in depth, special drills have predetermined depth stops that correspond to the intended implant length.
Drill diameter	Y dimension
1.5 mm	0.43 mm
2.0 mm	0.58 mm
2.5 mm	0.74 mm
3.0 mm	0.86 mm
3.2 mm	0.94 mm
3.4 mm	0.99 mm
3.7 mm	1.07 mm
4.0 mm	1.17 mm
4.2 mm	1.22 mm
4.4 mm	1.27 mm
4.7 mm	1.35 mm

• **Fig. 30.34** "Y" Dimension. (A) All surgical drills have an inherent Y dimension, which results in a greater drill length to each drill. (B) Y dimension increases as the surgical drills increase in size.

may be used for any size length implant and corresponding drill (Fig. 30.35). Some surgical implant systems have specific depth burs that coincide with the actual implant depth (e.g., Hahn Implants; Glidewell Corp.).

Understand Bony Crest Anatomy

Due to resultant bone resorption after extraction, the alveolar ridge becomes compromised in width (Division B bone) at the expense of the buccal plate. When measuring available bone height, special consideration should be given to the final location of the superior aspect of the implant platform, not the existing crest of the ridge. It will often appear there is adequate vertical height for implant placement; however, when the osteotomy is initiated, the thin crest will be lost (i.e., because the diameter of the drill exceeds the width of the bone) and the implant will be placed inferior to where it was originally intended. This can lead to unexpected depth drilling and an implant that is placed too close to the vital structure. The clinician should either augment the ridge to maintain vertical height or reduce the height calculation by the amount of osteotomy-induced osteoplasty (Fig. 30.36).

Maintain Total Control of the Handpiece

When performing osteotomies in the posterior mandible, special care should be noted to maintain complete control of the surgical handpiece. Large marrow spaces (i.e., where there is a lack of or thin trabecular bone) are often present, which may allow the osteotomy site to become deeper than intended. This will result in the implant being placed more apically, leading to neurosensory impairment. A CBCT comprehensive evaluation allows the implant dentist to view the bone quality before surgery. Most software programs associated with CBCT units allow the clinician to ascertain the density in the intended site. The implant clinician may also determine the bone density by tactile sensation when drilling. In addition, when drilling the osteotomy near the mental foramen, care should be exercised not to bend the wrist. This can
● **Fig. 30.36** Division B Ridge. (A) Incorrect measurement from superior crest to inferior alveolar nerve (IAN) canal. (B) Because the thin crest was not taken into consideration, implant placement will lead to encroachment of the IAN canal. (C) Ideal selection of implant length and positioning.

potentially redirect the drill or implant placement in an unwanted direction (e.g., near the mental foramen, into a tooth root). Surgical templates and guides are beneficial in preventing this malpositioning complication.

Do Not Place Bone Graft Material in Close Approximation to Nerve

After tooth extractions, especially in the mandibular premolar areas, care should be exercised in placing bone graft material (autologous, allogenic, xenogenic) in direct contact with an exposed IAN. Whether socket grafting or in conjunction with implant placement, case studies have shown resultant neurosensory impairment from bone graft material causing compression, crushing, or chemical burn injuries.[77] When grafting sockets with an exposed IAN canal, excessive pressure should be avoided. In addition, a small piece of fast resorbing collagen (e.g., OraTape, OraPlug) may be placed before the addition of grafting material. This will decrease the chance of particulate graft being in direct approximation to the nerve canal (Fig. 30.37).

Use Copious Amounts of Irrigation

Overheating the bone during osteotomy preparation may produce thermal stimuli that may lead to peri-implant necrosis and secondary postoperative nerve damage. Neural tissue is extremely sensitive and may be damaged by heat stimuli. The thickness of the necrotic area is proportional to the amount of heat generated during preparation.[78] The implant dentist must be cautious not to overheat the bone. This can be minimized by "bone dancing," which involves drilling in short intervals and allowing irrigation to enter the osteotomy, preventing heat generation. In addition, new (sharp) and intermediate-size drill burs may be used to reduce heat generation. This is more crucial with harder bone density (e.g., D1 or D2) or bone with compromised vascularity.

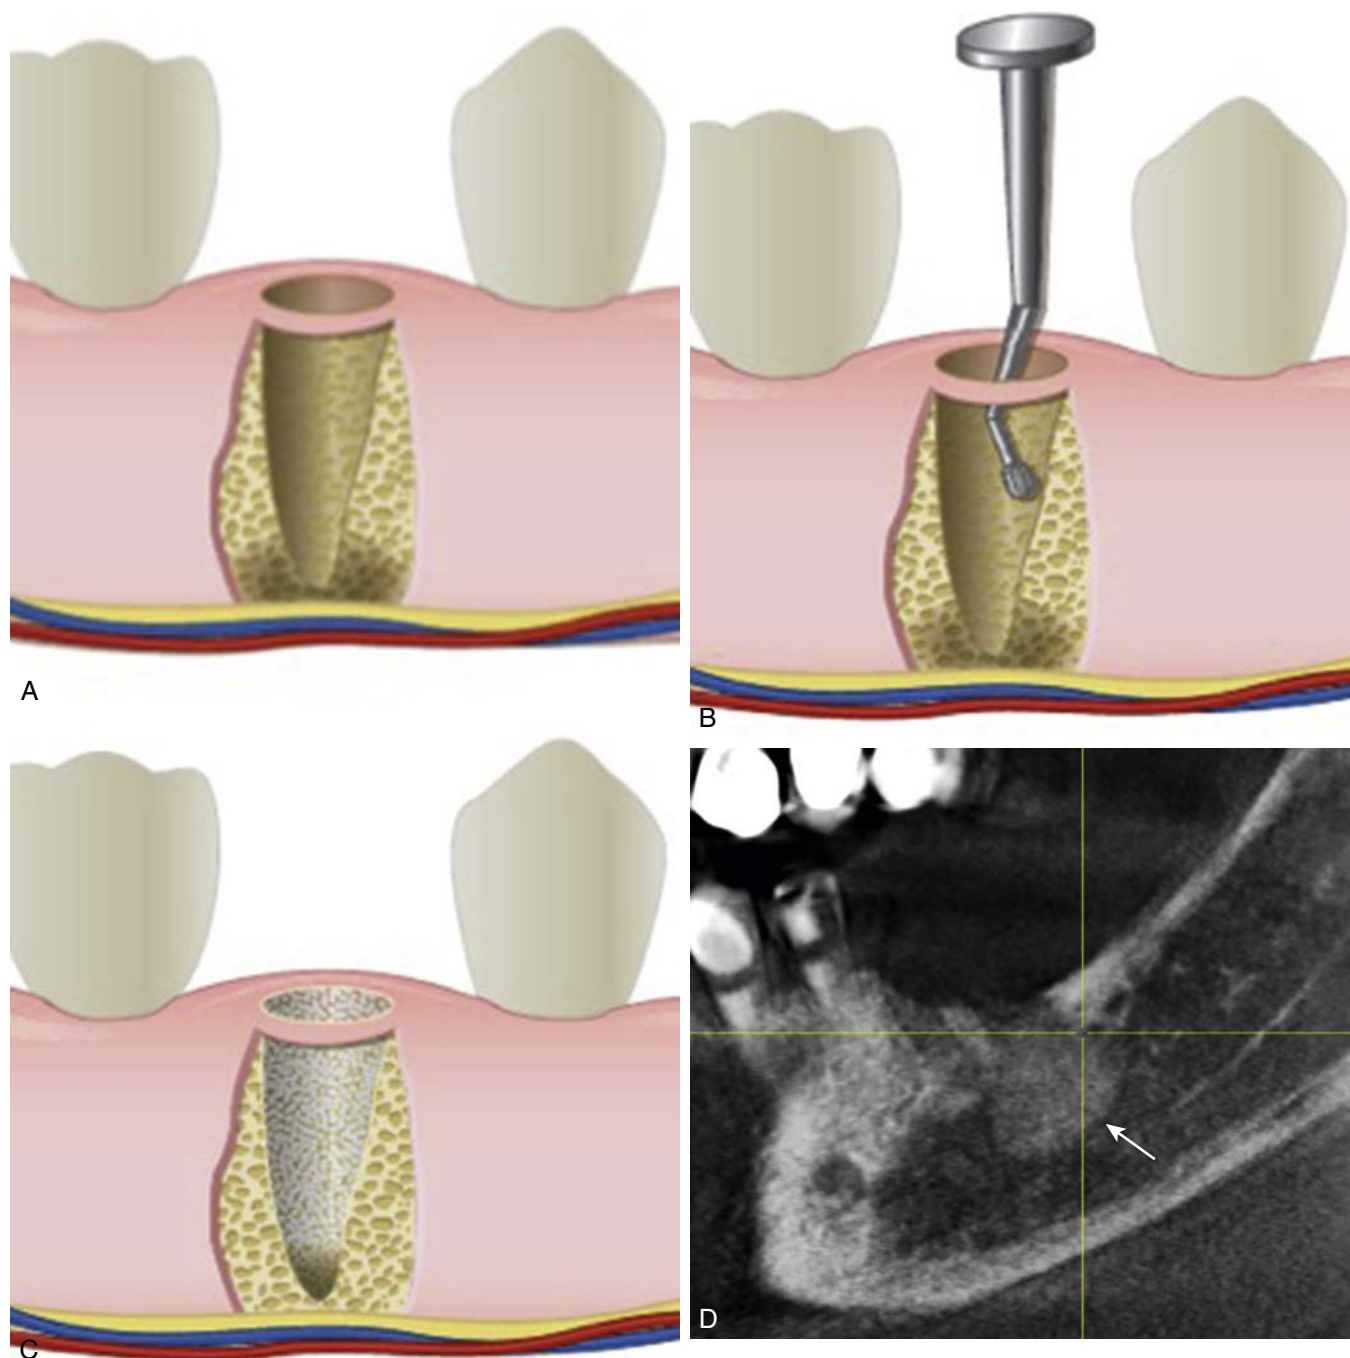
Avoid Incision-Related Injuries

Avoid incision-related injuries when making incisions in close approximation to the mental foramen and associated nerve structures in the posterior mandible. In cases of severe bone atrophy the presence of nerve dehiscence may inadvertently result in a transected nerve during the initial incision (i.e., making the incision on the crest of the ridge). Anatomic landmarks, 3D models, accurate measurements from CBCT scan, and palpation of the nerves are ways to avoid this complication. In addition, incisions in the posterior of the oral cavity should never be made over the retromolar pad. This can result in possible injury to the lingual nerve, which in 10% of cases transects this area[79] (Fig. 30.38).

Avoid Flap/Retraction–Related Injuries

Neurosensory impairments may also occur from overzealous use or incorrect placement of retractors. Broad-base (not sharp) retractors should be used to retract tissue that is not directly over the mental foramen because excessive stretching of the nerve trunk may cause irreversible damage. It is imperative that the mental foramen and associated branches of the mental nerve be identified in this area when placing retractors. Retractors should always be placed and held on the bone to prevent slippage or excessive soft tissue pressure, which can lead to a neuropraxia type of nerve damage (Fig. 30.39). Excessive stretching of the tissue may also lead to neurosensory impairments. It has been shown the perineurium protects the fascicles; however, if greater than 30% elongation of the nerve occurs, structural damage will occur to the nerve fibers.[80]

Use Special Care When Releasing Periosteum Over Mental Foramen

It is a common procedure during closure after implant placement or bone grafting to stretch the periosteal tissue to allow primary and "tension-free" closure.


• **Fig. 30.37** Postextraction Site. (A) Care should be taken when grafting an extraction site in close approximation to the inferior alveolar nerve. (B) A curette should be used with caution because direct damage to the nerve may occur. (C) Grafting in close approximation to the canal may lead to nerve trauma. (D) Bone graft material placed into an extraction socket resulting in a nerve impairment.

Various techniques are used to "release" the tissue to improve vascularization of the incision line and adhesion of the margins to prevent incision line opening. The submucosal technique developed by Misch in 1988 is an effective method to expand the tissue. This procedure involves the use of a #15 scalpel blade and soft tissue scissors (i.e., Metzenbaum) to create a blunt dissection. Knowledge of the location of the three mental nerve branches is necessary because inadvertent incisions over the mental nerve branches may result in neurotmesis (transection) types of nerve injuries (Fig. 30.40).

Careful Suturing

When the mental nerve is exposed, care should be exercised to prevent nerve tissue from being entrapped within the sutures. The mental nerve emerges from the mental foramen and divides into three branches below the depressor anguli oris muscle. Caution must be exercised to prevent any of the mental nerve branches from becoming entrapped within the suture material, potentially causing a neuropraxia (compression) type of nerve injury. In addition, nerve fibers may be damaged from the passage of the extremely sharp suture needle through the tissue.
● **Fig. 30.38** Incision-Related Injuries. In patients with significant mandibular atrophy and dehiscence of the nerve canal, possible incision-related injuries may result. The incision should be modified to avoid exposed nerves by extending to the lingual when approaching the exposed nerves.
● **Fig. 30.39** Flap Retraction–Related Injuries. Retractors should be carefully positioned to avoid stretching or damaging the inferior alveolar nerve.

Verify Correct Positioning of CBCT SurgiGuides

Studies have shown that the most precise and accurate surgical templates are tooth supported. When using bone- or tissue-supported surgical guides, care must be exercised to correctly position the guide because an error in placement may result in direct damage to the IAN. Tooth-supported guides should always be the first choice if possible because they are clinically proven to give rise to the fewest positioning errors. The least accurate is the

● **Fig. 30.40** (A and B) Periosteal release incision (A) and blunt dissection (B) should never be completed in close approximation to the mandibular nerve.

mucosa supported, which are usually used for flapless surgery.[66] Studies have shown that flapless surgical guides consistently show deviations of implant positions from ideal locations. Perforations of the buccal plate can be found in more than 50% of the flapless cases.[81] A very minor discrepancy (anteroposterior) in the placement of the guide can lead to impingement on vital structures. Therefore surgical templates should always be fixated and the ideal position verified.

Surgical Procedures That Increase Neurosensory Complications

Immediate Implants in the Mandibular Premolar Area

Immediate implants have gained overwhelming popularity in implant dentistry today. Extreme caution must be exercised when extracting and immediately placing implants in the mandibular premolar area. As noted earlier, many variables dictate the position of the mental foramen, with the foramen being highly variable. Studies have shown that 25% to 38% of the time the mental foramen is superior to the premolars apex.[82] Because most immediate implant osteotomy sites involve drilling the osteotomy site deeper for stability (~2–4.0 mm), the odds of nerve trauma are greatly increased. Because of this the implant clinician must be very selective in cases involving extraction and immediate implant placement in this anatomic area (Fig. 30.41).
● **Fig. 30.41** Mandibular Premolar Immediate Implants. (A) Approximately one-third of mandibular premolars root apexes are inferior to the mental foramen. (B and C) Implant placement into the mental foramina leading to neurosensory impairment.
● **Fig. 30.42** Superior Cortical Plate of Inferior Alveolar Nerve (IAN) Canal. (A) Mandibular canal with thick cortical plate, which is uncommon. (B) Thin to no cortical bone is present over the IAN canal.

Drill Until the Superior Cortical Plate Is "Felt"

It has been advocated in the literature that the osteotomy depth may be determined by "feeling" the superior cortical plate of the inferior alveolar canal. A 2-mm safety zone should always be adhered to because research has shown that in approximately 28% of posterior mandibles there is no superior cortical plate over the inferior alveolar canal.[83] In addition, studies have shown it to be impossible to use tactile sense to ascertain the presence of superior cortical bone surrounding the mandibular canal. Clinical reports have revealed hemorrhage into the canal, or bone fragments may

cause compression or ischemia of the nerve from engaging the superior cortical plate. Dependence on the ability to "feel" the superior cortical plate through tactile sense increases the likelihood of nerve complications (Fig. 30.42).

Infiltration Technique

An alternative technique in placing implants in the posterior mandible is not using mandibular nerve block anesthesia. Instead, infiltration is accomplished in the soft tissue surrounding the osteotomy site, and the patient is asked to alert the implant clinician

on the proximity of the drill to the nerve bundle.[84] This alternative technique results in a very high degree of subjectivity concerning patients' responses, because of varying degrees of pain thresholds. In addition, disadvantages of this surgical method include inconsistent mandibular nerve anatomy, with varying locations of dental-alveolar nerve branches. With the success of CBCT radiography in implant dentistry today in determining the exact location of the IAN, this technique should be avoided because of the high degree of false-negative and false-positive results from patients. Etoz et al.[85] showed this supraperiosteal infiltration technique to be safe in 91% of cases. However, according to this study, approximately 1 patient in 10 ended up with a neurosensory deficit.

Placing Implants Lingual to the Inferior Alveolar Nerve Canal or Foramen

Many authors have advocated placing implants lingual to the neurovascular bundle (Kumar; Stellar). As stated previously, the buccal-lingual nerve position within the mandible is extremely variable, along with the incidence and trajectory of lingual osseous concavities.

Attempting to place implants buccal or lingual to the inferior alveolar canal or mental foramen is associated with a high degree of morbidity, even with the use of CBCT-guided surgery. In addition, perforation of the cortical plate can occur, which may lead to sublingual bleeding or formation of a sublingual hematoma (Fig. 30.43).

Place Implants at the Depth of the Adjacent Root Apexes

Many implant clinicians use the location and length of the adjacent teeth as a guide in determining the size (length) of the implant to be placed. Usually a Panorex or periapical radiograph is used in determination of this length. When this technique is used in anatomic type 2 or 3 (i.e., more apically positioned in the vertical dimension) nerve courses, the incidence of nerve impairment is low. However, in mandibles that exhibit a type 1 nerve course (close to root apex), close approximation of the implant to the canal is likely, leading to a higher probability of neurosensory impairment. Ideally the implant clinician should ascertain the available bone above the mandibular canal via 3D radiographic analysis (Fig. 30.44).
• **Fig. 30.43** Lingual Placed Implant. (A and B) Implants should never be placed lingual to the inferior alveolar nerve canal because nerve injury or perforation of the lingual plate may occur.
• **Fig. 30.44** In type 1 nerves, placement of implants at the apex of the adjacent tooth may result in direct nerve trauma.

"As Long as There Is Not Excessive Bleeding, the Mandibular Canal Has Not Been Violated"

Another unconventional technique in avoiding nerve impairment is the evaluation of the amount of bleeding from the osteotomy site. Many practitioners correlate the amount of hemorrhage with the proximity of the neurovascular bundle (IAN, artery, vein, and lymphatic vessels). Anatomic studies have shown that the inferior alveolar artery may lie parallel to the nerve and lingual as it traverses anteriorly. Its position varies with respect to the IAN within the mandibular canal. Other studies show the inferior alveolar artery appears to be solitary and lies superior and lingual to the IAN, slightly above the horizontal position.[86] In addition, there exist multiple inferior alveolar veins positioned superior to the nerve, which may cause venous oozing if directly traumatized. A false-positive result may occur if this area is damaged because large marrow spaces, which can cause excessive bleeding, are common in the posterior mandible (D3 bone). The degree of bleeding should not be used as an indication of nerve proximity or violation of the mandibular canal.

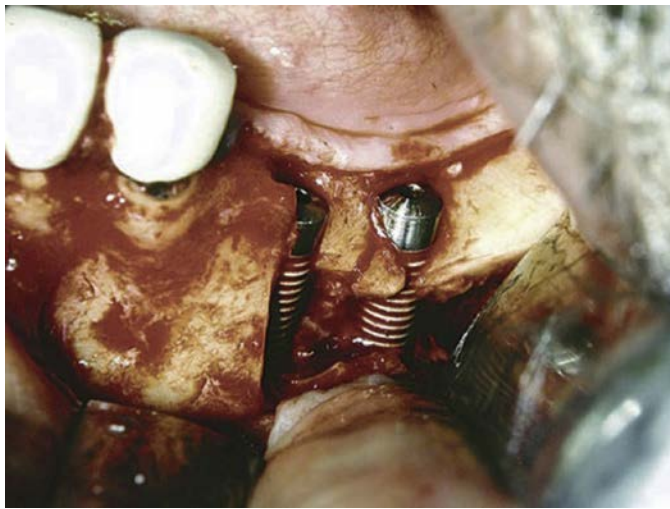
Replacing Second Molars

There are many prosthetic and surgical disadvantages when evaluating edentulous, second mandibular molar sites for implant placement. Disadvantages include high incidence of sublingual bony undercuts, which can result in perforation of the lingual plate or angulation issues, decreased interocclusal space (especially with supraeruption of the adjacent tooth), difficult access for surgery and prosthetic component insertion, and the fact that there is 10% greater occlusal force on the second molar versus the first molar. Function is not a primary reason for replacement because 90% of masticatory efficiency is generated anterior to the mesial half of the mandibular first molar, and cheek biting is more common in this area because of the proximity of the buccinators muscle. One of the most important disadvantages is the close approximation of the mandibular canal in the second molar area, which leads to difficulty in placement of implants in this area. When implants are placed, usually the available bone present is compromised in height. As a result the second molar is often not replaced when the only posterior teeth missing are the second and third molars. The primary disadvantage of not replacing the second molar is extrusion of the opposing maxillary second molar. If extrusion is a significant concern, a full-coverage crown on the mandibular first molar may include occlusal contact with the mesial marginal ridge of the maxillary second molar (Fig. 30.45).

Nerve Repositioning

Treatment of patients who exhibit compromised alveolar crest height in the posterior mandibular area can be very challenging. Techniques include the use of shorter implants, which become biomechanically compromised, or the use of bone grafting to increase available bone for future implant placement. An alternative technique is to reposition the IAN laterally, either by nerve lateralization or nerve transposition. In nerve lateralization the IAN is exposed and retracted laterally while the dental implants are placed. The transposition technique, first published in 1987 by Jensen and Nock,[87] includes the mental foramen in the osteotomy, resulting in the IAN being positioned more posterior. The inherent risk with these complex procedures is neurosensory impairment (anesthesia, paresthesia, or dysesthesia) to the mental nerve branch. Although this is a valid treatment option in significantly atrophied cases, this technique should be reserved for practitioners with advanced training and experience with these procedures (Fig. 30.46).

Conclusion

Prior to implant or bone grafting procedures in the mandible, a careful and detailed clinical and radiographic evaluation is paramount to identify vital structures in the mandible. The use of cone beam computed tomography is essential to determine the location of normal and variant anatomic structures such as bone undercuts, poor bone density, extreme bony angulation, blood vessels, and the mandibular canal and mental foramen. The complications that may result can range from very minor issues to life
• **Fig. 30.45** Second Molar Implants. (A and B) Implants in the second molar region have a high incidence of nerve trauma because of the location of the mandibular nerve in relation to the second molar implant site.


● **Fig. 30.46 Nerve Repositioning.** The repositioning of the inferior alveolar nerve should be completed only by experienced clinicians with advanced training in the technique.

threatening circumstances. Therefore, the clinician must understand the possible sequalae and management if violation of one of these mandibular vital structures is compromised.

Dental Implant Complications

RANDOLPH R. RESNIK

In implant dentistry today, most procedures are completed free of complications. However, complications do occur and may have devastating, long-lasting effects for the patient and the clinician. Ideally the clinician should have a strong understanding of surgical and prosthetic implant principles, which minimizes the possibility of complications. However, even if the clinician follows the most strict and predictable protocols, unexpected situations may occur. Therefore this chapter provides a comprehensive summary of the etiology, prevention, and management of possible complications resulting from the treatment planning, intra-operative, post-operative, and maintenance situations.

Intraoperative Complications

Malpositioned Initial Osteotomy Site

In performing the initial osteotomy for a dental implant, in some cases the initial implant position may not be placed in the ideal location. The osteotomy may need to be repositioned to allow for ideal placement. The use of a Lindemann bur (i.e., side-cutting fissure bur) is ideal for the repositioning of an osteotomy because of its side-cutting capabilities. Lindemann burs allow for easy and efficient positional change with minimal trauma to the bone.

Once the initial osteotomy is prepared, it is assessed for proper position with a direction indicator. If nonideal placement occurs, the osteotomy site may need to be "stretched" or repositioned to a more ideal location.

Prevention

Surgical templates or implant-positioning devices for ideal implant positioning should be used to prevent the improper placement of the initial osteotomy. A pilot surgical guide (i.e., guide that allows only for the drilling of the first pilot drill) can be used for the clinician to obtain the accurate mesial-distal and buccal-lingual position of the osteotomy site. This is especially useful for decreasing the possibility of malpositioning for clinicians who are early on their learning cure.

Treatment

The use of conventional drills (non-side-cutting) is difficult to horizontally reposition an osteotomy site because of the end-cutting capabilities of the burs. The use of a side-cutting Lindemann bur will allow for repositioning to a new, corrected site. It is imperative the new osteotomy position should be deepened so that subsequent end-cutting drills will not reposition back into the original osteotomy site.

However, when using the Lindemann bur, always use copious amounts of saline because this bur will generate a significant amount of trauma and heat to the bone[1] (Fig. 31.1).

Facial Dehiscence After Implant Placement

After implant placement, it is not uncommon to have facial plate dehiscence on the buccal aspect of the implant, usually in the crestal area. Because bone resorbs from the facial to lingual, in some cases after implant placement, less than 2.0 mm of facial bone is present. A minimum of 2.0 mm of bone is recommended to maintain ideal hard and soft tissue surrounding the implant. If the implant is allowed to heal with a known facial dehiscence, the implant will be more susceptible to peri-implant disease and increased implant morbidity.

Ridges that are compromised (i.e., Division B, C, or D) should be modified to obtain a Division A bone (e.g., >7 mm width and >10 mm of bone height) before osteotomy initiation. This may be accomplished by either osteoplasty or lateral bone augmentation. After implant placement, a minimum of 2.0 mm of facial bone should be present over the implant or the compromised facial area should be grafted.

Treatment

After implant placement, if there exists less than 2.0 mm of bone on the facial aspect of the ridge, the site may be grafted with autogenous bone (ideally). The autogenous bone is most easily obtained from bone fragments gathered from the flutes of the surgical drills during the osteotomy preparation. The consistency of this bone allows for ease of packing, and the graft will have less chance of migrating. Ideally, the autogenous bone should be red or white colored as this signifies live, viable bone. If the bone fragments are black or brown, the bone should be discarded as it is most likely necrotic. Allograft bone is not the most ideal bone to graft in this area as it tends to migrate easily after placement and is an added expense (Fig. 31.2).

Loss of Facial Plate When Placing an Implant

When placing implants in bone that is compromised in width (i.e., Division B bone), it is not uncommon to fracture or lose the facial plate of the supporting bone. This leads to a compromise in the healing of the implant and the longevity of the implant and final prosthesis.

771
● **Fig. 31.1** Repositioning Osteotomy Site. (A) Side-cutting Lindeman bur. (B) Use of a Lindeman bur to reposition the osteotomy should always deepen the new osteotomy site because this will prevent subsequent burs from falling into the original site. (C) Clinical image of repositioning osteotomy more distal.
● **Fig. 31.2** Facial Dehiscence. (A) Crestal bone is missing after implant placement, which often occurs because of buccal and lingual crestal height discrepancies. (B) Autogenous bone fragments within the bur flutes. (C) Grafting after implant placement.

Prevention

Ideally the width of bone needs to exceed 7.0 mm for placement of a 4.0-mm diameter implant. When compromised width of bone exists, the trauma of the osteotomy or the placement of the implant may fracture or "pop off" the buccal plate. This is most likely the result of the buccal plate being thinner than the lingual plate, which results in the facial plate being more fragile and susceptible to fracture (Fig. 31.3).

The available bone before implant placement should be evaluated via a cone beam computed tomography (CBCT) examination. If nonideal width of bone is present, site development, including grafting, is indicated to obtain a Division A bone. The osteotomy preparation should be in one plane, and care should be exercised not to deviate from the original angulation. If Division B bone is present, ridge augmentation is recommended to achieve a Division A ridge before implant placement.

Treatment

After implant placement, if a fracture or loss of the buccal plate exists, treatment will depend on the extent of the deficit.

Loss of Entire Buccal Plate. If the entire buccal plate is lost or if mobility of the implant exists, the ideal treatment should include removing the implant, followed by grafting the site. After sufficient healing occurs, implant placement may be completed.

● **Fig. 31.3** Implant placement with partial loss of the buccal plate. Note the fractures present in the host bone.

Partial Buccal Plate Still Intact. If no mobility of the implant is present and the facial plate is partially intact, the facial area can be grafted, ideally with autogenous bone from the osteotomy site (e.g., bone from the surgical drill).
● **Fig. 31.4** Overheating of the osteotomy site often occurs when using a surgical template. (A) With most surgical templates, minimal irrigation enters the osteotomy site. (B) Ideally supplemental irrigation can be used to decrease heat generation. Note the modification of the template which allows for external irrigation.

Overheating the Bone

One of the most common complications that has been associated with early implant failure and bone loss is overheating of the bone during the osteotomy preparation. This is usually the result of osteotomy preparation in dense bone with a nonideal surgical osteotomy protocol. The Misch osteotomy preparation protocol has been developed to minimize heat generation in D1 and D2 bone density types. Bone tissue has been shown to be very susceptible to thermal related injuries, with studies showing the temperature threshold to be 47 °C for tissue survival when drilling is maintained for more than 60 seconds. If heat generation is higher than this limit, then osseointegration is in question because of the resulting necrosis of the surrounding bone cells.[2] In addition, resultant hyperemia, fibrosis, osteocytic degeneration and increased osteoclast activity may occur which may lead to a necrotic zone around the implant.[3]

Prevention

Intermediate Burs. In addition to the surgical protocol, multiple intermediate drills may be used in the drilling protocol (See Chapter 27). A decrease in the heat and trauma generated is seen when gradual increases in drill diameter are used. This technique reduces the amount of pressure and heat transmitted to the bone, especially in the presence of dense and thick cortical bone.

Copious Amounts of Saline. Together with external irrigation from the surgical drills, increased irrigation may be obtained by using internal irrigation (through the surgical bur) or with supplemental irrigation via a syringe. In addition, the use of chilled saline allows for a significant reduction of heat generation.

Bone Dance. The bone-dancing technique was introduced by Misch in 1988 to reduce the amount of heat generation. When preparing the osteotomy, small increments of bone are removed by using an up-and-down motion of the drill. This will allow increased irrigation into the osteotomy, along with removing bone fragments, which decreases frictional heat.

Use of Sharp, New Drills. Drills that are dull will increase heat generation, causing the possibility of overheating the bone. Surgical drills should be replaced approximately every 20 to 30 autoclave cycles; however, this is highly dependent on past use.

Drill Speed. Sharawy et al.[4] have shown the drill speed in hard, dense bone (e.g. D1 and D2 bone types) should be approximately 2000 to 2500 rpm. Osteotomy preparation at higher speeds with sharp drills elicits less risk for osseous damage and a decreased amount of devitalized zone adjacent to the implant. Yeniyol et al.[5] have shown that drilling at very slow speeds results in a higher degree of bone fragmentation. However, in poorer bone density, lower speed (e.g., ~1000 rpm) may be used with little concern for overheating the bone.

Surgical Templates. Surgical templates often result in overheating of the bone because of the inability of saline to enter the osteotomy because of the minimal space between the guide tubes in the template and the drill size. Ideally the template should be modified to open up the facial aspect of the template so supplemental irrigation may be used (Fig. 31.4).

Treatment

If known excess heat generation occurs during implant placement, ideally the implant should be removed, regional acceleratory phenomenon (RAP) initiated, and the site grafted for future implant placement. If bone width is available after sufficient RAP is completed, a wider implant may be placed.
● **Fig. 31.5** Overheating the bone from improper surgical drilling protocol; note the lack of bleeding from the osteotomy site.

Implant Pressure Necrosis

When placing implants in bone with thick cortical components (i.e., D1 and D2 bone), possible early implant failure may occur from pressure necrosis. Numerous studies have shown that the overcompression of the crestal bone is a contributing factor in peri-implant disease and implant failure.[6] It is suggested that excessive tightening of the implant creates compression forces within the crestal bone around the implant. This may impair the microcirculation and lead to bone resorption.

Pressure necrosis from implant placement may increase the devital zone of bone around the implant, or even cause short-term neurosensory impairment when the implant site is in the vicinity of the mandibular canal. This most often occurs where there exists a cortical component of bone in the crestal region (~D1–D2 bone). If a crestal bone drill is not used or surgical steps to alleviate the internal stresses are not completed, excess stress will be generated on insertion of the implant, which will lead to "die-back" or a devitalized zone (Fig. 31.5).

Prevention

Torque. The implant should not be "tightened" into the osteotomy with excessive torque pressure. A torque value of 35 N-cm is considered safe with most threaded implant designs. If excessive pressure is present, the implant should be unscrewed 3 to 4 mm and then reinserted.

Crestal Bone Bur. Because most implants have a wider crest module (wider diameter of the neck of the implant in comparison with the implant body), greater stress can be concentrated upon placement in D1 and D2 types of bone. To decrease crestal pressure, a crestal bone bur can be used to minimize the stress at the ridge crest.

Use of Insertion Wrench. To decrease the crestal stress, the implant may be inserted with a hand ratchet to depth, then unthreaded 3 to 4 mm, and then reinserted to ideal depth. By unscrewing the implant 3 to 4 mm, the bone is given time to "creep," which on reinsertion, will have less force at the crestal region.

Treatment

Ideally the thickness of crestal bone and bone quality type should be ascertained before implant osteotomy preparation. This may be determined via a CBCT radiographic examination.

If a large cortical component of bone is present and the implant placed is known to contain excess pressure, the implant should be removed and the crestal bone modified. The implant then should be reinserted at a lower insertion torque.

Injury to Adjacent Teeth

Damaging adjacent natural teeth during dental implant placement may lead to adverse effects on adjacent tooth structures and can result in dental implant failure or adjacent tooth loss. The injury to the root structure of adjacent teeth may be direct (i.e., damage to tooth by the drill or implant) or indirect (i.e., thermal damage from the osteotomy process). The direct trauma may result in bone loss, natural tooth or implant loss, infection, internal or external resorption, loss of tooth vitality, or prosthetic failure.

Trauma to adjacent teeth may occur upon the placement of dental implants because of poor surgical technique including improper angulation, implant sites with insufficient available space or bone quantity, or placement of implants with an incorrect diameter. Dilacerated roots and excessive tilting of natural teeth in the mesiodistal direction may impinge on the intended implant space and prevent ideal placement. In addition, available space discrepancies often exist between the coronal space and the apical space. Studies of orthodontic mini-implants placed in contact with teeth (<1.0 mm) have been shown to cause root resorption. However, if the implant is removed in a timely fashion, cementum repair may occur.[7]

Prevention

The location of adjacent teeth to the implant site should be evaluated before implant placement. This is most accurately determined by evaluating CBCT images, usually in the axial plane. Accurate spacing is easily determined by measuring the intertooth distance. The angulation should always be evaluated after the initial osteotomy with a direction indicator (i.e., radiograph with known diameter and length guide pin in osteotomy) to assess proper positioning and angulation. CBCT surgical templates may be used to avoid damaging adjacent root surfaces. Ideally a minimum of 1.5 mm of space between the implant and root surface is recommended.

Treatment

Perioperative. If after placement of the dental implant, it appears the implant is too close (<1.5 mm) from the periodontal ligament or tooth structure, ideally it should be removed and repositioned. If the implant is removed and another is inserted, care should be exercised to verify adequate primary stability. If primary stability is not obtained, then an implant with a larger diameter or length may be inserted. If that is not feasible, then the osteotomy site should be grafted and implant placement delayed.

Postoperative/Post-healing. If the implant has been previously placed and is asymptomatic and not encroaching on the periodontal ligament/tooth structure, strict monitoring should be completed on a regular basis, with vitality testing of the adjacent teeth. If the adjacent tooth is sensitive to thermal stimulation or percussion, the implant should be removed immediately (Fig. 31.6).
● **Fig. 31.6** (A) Implant placement too close to a tooth root; implant should be removed and reinserted in a more ideal position. (B) Implant that was placed many years ago should be closely monitored clinically and radiographically.

Swallowing/Aspiration of Implant Components

Because of the nature of dental implant procedures, the aspiration or ingestion of dental components or materials may occur. Accidental inhalation of dental instruments (drills, burs, direction indicators, root tips, crowns, etc.) can result in many complications, including life-threatening situations. Because of the small size of abutments, screws, drivers, and other implant components, a significant risk for the implant clinician exists. This may occur during any dental implant procedure, including the surgical and prosthetic phases.

There is usually two possibilities: the patient may swallow the foreign object into the stomach or aspirate the foreign object into the lungs.

Swallow: If the object is swallowed, usually the patient will be asymptomatic. However, depending on the shape and size of the object, it may need to be removed because of the complication of blockage within the gastrointestinal system.

Aspiration: The object may be aspirated into the lungs, in which case the patient will usually be symptomatic. The patient will exhibit signs of coughing, wheezing, hoarseness, choking, stridor, or cyanosis. The patient will often complain of pain and discomfort.

Prevention

Various techniques are available for the implant clinician to prevent aspiration or swallowing of a foreign object. There is no one technique that will guarantee this complication will be avoided; however, extreme caution should always be exercised.

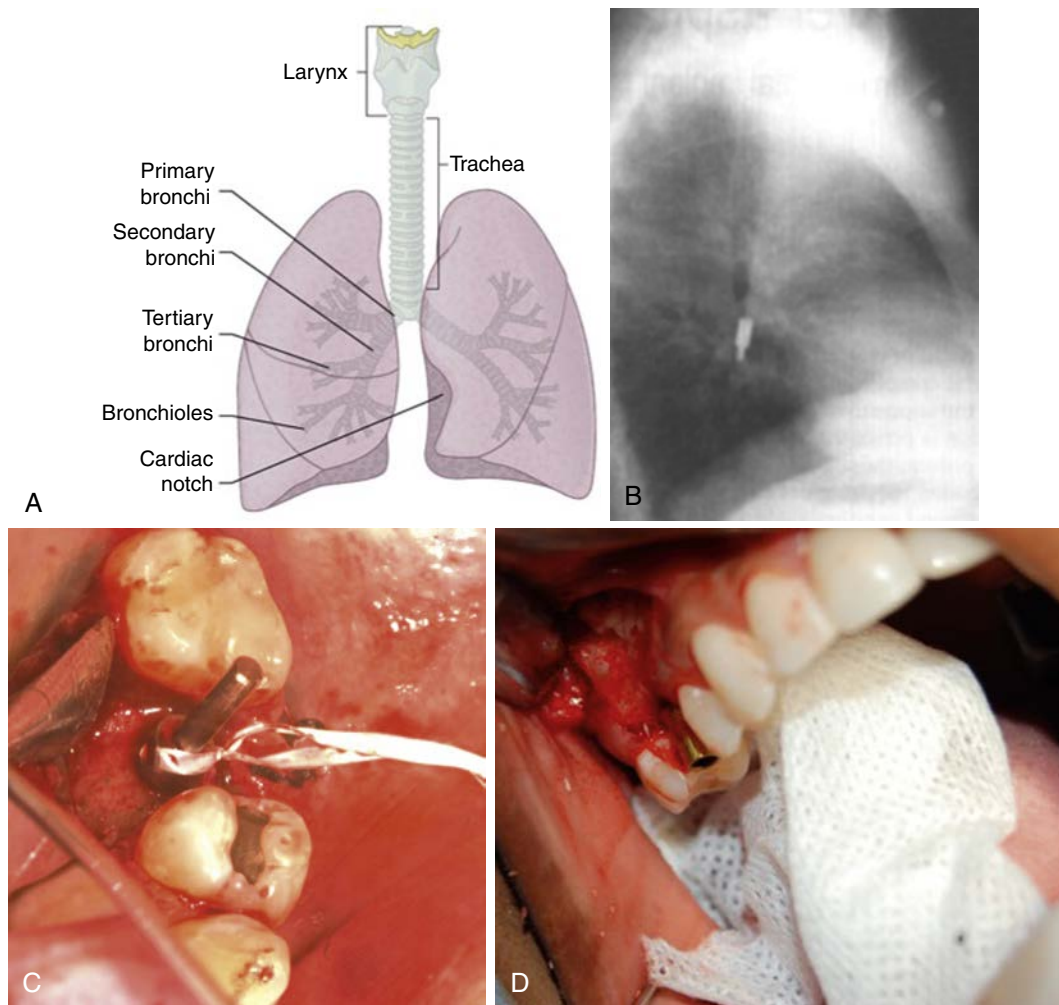
Techniques to prevent swallowing or aspiration include:
- Floss ligatures to all implant components.
- Use of special prosthetic instruments (e.g., EasyReach Wrench; Salvin Dental).
- Use throat packs (4 × 4 gauze) or pharyngeal screens.
- Utilize high-vacuum suction.
- Use curved hemostats for retrieval of objects.

Treatment

When swallowing or aspiration of implant components occurs, the clinician must act proactively to avoid complications and medicolegal issues. First, if an instrument is lost in the mouth, the patient should be instructed not to sit straight up because this will ensure the swallowing or aspiration of the instrument. The patient should turn to the side and attempt to "cough" the instrument up. If the instrument is lost, symptoms usually will determine whether aspiration into the lungs or swallowing into the stomach has occurred. If the instrument has been swallowed into the stomach, usually the patient will exhibit no symptoms. If the patient has aspirated the instrument, this will most likely be accompanied with coughing, wheezing, pain, and cyanosis. This may be life-threatening and should be treated accordingly as a medical emergency. In all swallowing/aspiration situations the patient should be referred immediately to his or her physician or emergency room for a chest x-ray. If the instrument has been aspirated, it will usually be located in the right bronchus because the right main bronchus has a more acute angle than the left. Rigid bronchoscopy is usually used for the removal of the instrument under general anesthesia (Fig. 31.7).

Air Emphysema

Because of the attachment apparatus difference between implants and teeth, air extruded into the sulcular area around implants may lead to air emphysema. Subcutaneous emphysema is a condition in which air is introduced into the subcutaneous or fascial spaces. The two most common ways for this to occur is the use of an air-driven handpiece or an air-water syringe in which air is forced into the sulcular area. Symptoms will include swelling that increases over time, with a "crackling" feeling with pain. Crepitus to palpation will confirm the diagnosis of air emphysema. The patient will usually be apprehensive, with a feeling of difficulty in breathing.

Subcutaneous air emphysema can lead to many devastating complications during and after dental implant surgery. Early recognition and management of this condition is crucial to preventing


● **Fig. 31.7** Aspiration of Foreign Bodies. (A) Pulmonary system anatomy. (B) Implant driver lodged in the right bronchus. (C) Floss should be tied to all implant components to minimize aspiration. (D) Use a 4 × 4 throat pack; never use a 2 × 2 pack because the patient can easily swallow it.

progression of the problem. As the air accumulates subcutaneously, dissection occurs along the connective tissue that joins the adjacent muscle planes. Via the fascial spaces, air from the oral cavity may extend into the mediastinum space, where it can communicate with parapharyngeal and retropharyngeal spaces, which leads to airway compromise. From the retropharyngeal space, air may lead into the pleural space and pericardium, which could result in heart and lung failure.

Prevention

When placing implants, modifying abutments in the oral cavity, or removing bone around an implant body, an electric handpiece should always be used (i.e., never use an air-driven handpiece). In addition, air-water syringes should never be used to place air into the sulcular area parallel to the long axis of the implant.

Treatment

Usually symptoms arise immediately; however, cases have been described in the literature that have occurred minutes to hours after a procedure. Patients with significant emphysema should be monitored closely before discharge, for respiratory or cardiac distress. Treatment should include supportive therapy with heat and analgesics. Antibiotic therapy should always be administered because infection may result from bacteria being induced into the

fascial spaces, with resultant cellulitis or necrotizing fascitis. Resolution usually occurs in 4 to 7 days, with minimal morbidity. In isolated cases, exploratory surgery, emergency tracheotomy, and the placement of chest tubes have been reported (Fig. 31.8).[8]

Electric Handpiece Burns

Electric handpieces, the most common type of handpiece used in implant dentistry today, have a tendency to overheat, which may result in significant soft tissue complications. In 2007 and 2010, the U.S. Food and Drug Administration (FDA) released warnings to health professionals concerning possible serious burns related to electric dental handpieces. The FDA has requested manufacturers to decrease these issues by design modification, overheating alarms, warning labels, and clinician training to avoid overheating.

Because electric handpieces have insulated housings, the clinician may not be aware of the extent of the heat generated in the handpiece. Compounding the problem is that the patient may be anesthetized and unaware of the thermal injury. Injuries have been reported ranging from first- to third-degree burns and may require reconstructive surgery. Unlike conventional air-driven handpieces that decrease efficiency when overworked, electric handpieces will maintain higher efficiency, thus generating a greater amount of heat.
● **Fig. 31.8** (A) Facial air emphysema. (B) Air-water syringes should never be directed along the long axis of the implant. (C) Proper air-water syringe positioning, perpendicular to the long-axis of the dental implant.
● **Fig. 31.9** (A) Implant site that was treated with an electrosurgery unit. (B) Implant loss and bone necrosis. (C) Resultant large bony defect.

Prevention

Awareness is most crucial for avoiding this complication. The clinician should be conscious of the possibility of the handpiece overheating, take frequent breaks during treatment, and check continuously for the implant motor becoming hot during treatment. Electric handpieces should have routine maintenance according to the manufacturer's recommendations. Usually the straight 1:1 handpieces have a greater incidence than the 16:1 or 20:1 reduction handpieces.

Treatment

If a burn occurs, treatment will vary depending on the severity. Treatments range from over-the-counter ointment to a physician referral. For severe burns, systemic antibiotics are warranted. If the burn does not penetrate the vermillion border, healing will usually result without a defect.

Monopolar Electrosurgery Units

Monopolar electrosurgical units are a common soft tissue modality used in dentistry today. However, in implant dentistry, when these units are used around dental implants, significant complications may arise. Monopolar electrocautery should never be used in the proximity of a dental implant or implant prosthesis.

Electrosurgery is defined as the controlled passage of high-frequency waveforms, or currents, for the purpose of altering the surrounding soft tissue. The action of monopolar electrocautery is cutting the tissue by means of an advancing spark with a grounded patient. This results in sparking, current spread, and thermal damage in the tissues because of the generation of heat.

Prevention

In implant dentistry, monopolar electrosurgery units are contraindicated. The monopolar electrodes should not contact an implant or electrical shock osteoradionecrosis and possible implant loss may result. However, bipolar electrosurgical units have been shown to be effective around dental implants. Bipolar electrocautery uses molecular resonance with a sine-wave current that prevents sparking and thermal damage. These types of units may be used continuously around implants because they produce progressive coagulation rather than a single high-output discharge, thus creating no spark.[9]

Treatment

Treatment is usually palliative in nature because electrosurgery damage is usually irreversible in nature (Fig. 31.9).

Salivary Gland Injury

The sublingual gland may be injured when an implant is poorly positioned in the posterior mandible, which may cause the formation of a ranula. Ranulas are defined as an accumulation of extravasated salivary secretions that form pseudocysts in the submandibular area. When the ranulas form above the mylohyoid muscle, they appear as a translucent, bluish swelling in the sublingual space. Most ranulas are visible on a clinical examination and are considered "plunging" when they extend inferiorly from the sublingual space into the neck area. Ranulas are usually not fixed, and they are rarely painful unless they become secondarily infected. In some cases they develop into larger lesions and may compromise the airway.

The proximity of the sublingual gland to the lingual cortical plate of the mandible makes it susceptible to injury. Trauma usually occurs from improper angulation during dental implant surgery, which perforates the lingual cortex and causes damage to the sublingual gland. In addition, the gland may be injured during aggressive reflection and retraction when working in the sublingual area.

Prevention

To prevent damage to the salivary glands, ideal preoperative treatment planning, good surgical technique, proper implant angulation, and careful retraction will avoid these complications.

In addition, the anatomy of the sublingual area must be understood. The sublingual gland is positioned adjacent to the lingual cortex and seated below the mylohyoid muscle.

The submandibular duct is positioned inferior and medial to the sublingual gland. The lingual nerve will cross the submandibular duct from medial to lateral and then cross back at the first premolar area, where it branches into the tongue musculature.

Treatment

Treatment should include referral to an oral and maxillofacial surgeon, which usually involves the complete removal of the sublingual gland. In some cases, where the ranulas are very small and asymptomatic, no surgery may be indicated or marsupialization to reestablish connection with the oral cavity (Fig. 31.10).[10]

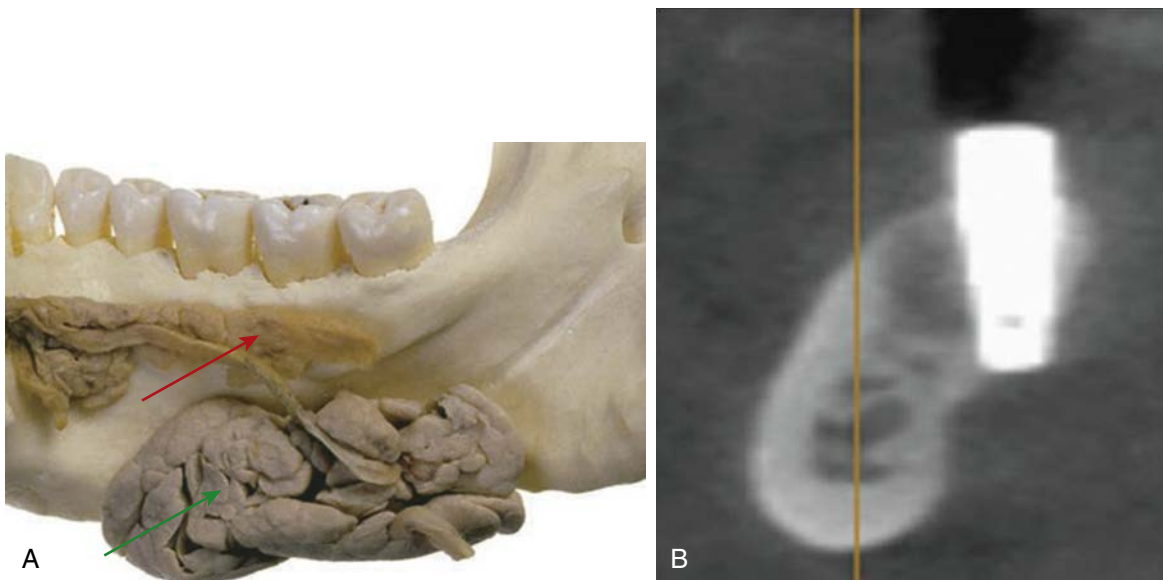
Bleeding-Related Complications

Prevention/Treatment of Bleeding

The ideal management of intraoperative hemorrhage is prevention. Although the clinician should be capable of handling potential bleeding complications, the best course of action is avoidance, which is aided by taking the appropriate preventive measures. A preoperative assessment of the patient is mandatory, including a thorough preoperative patient history, and medical consultation when indicated. The clinician also should be familiar with managing patients receiving anticoagulants and those who have bleeding issues, should use meticulous intraoperative surgical technique, and should provide appropriate postoperative instructions, care, and follow-up. Patients need to be instructed on the importance of compliance with prescribed medication and proper postoperative instructions and care.

Incision/Reflection of Tissue

The dental implant clinician must carefully plan the location of incisions with respect to surgical anatomy to maintain hemostasis and minimize bleeding. Ideally incisions should always be made over host bone when possible. This will allow for pressure to be applied over bone in the event of uncontrolled bleeding. The flap design should incorporate release incisions so that excessive pressure and stretching is reduced to decrease possible tearing of the tissue and resultant blood vessel trauma.

Reflection and elevation of the mucosa and periosteum should be carefully completed with full-thickness and atraumatic reflection. Split-thickness flaps should be avoided to minimize potential bleeding sites. Anatomic areas containing vital structures, which may be highly vascular, should be carefully evaluated and avoided if possible (Fig. 31.11).


• **Fig. 31.10** Salivary Gland Damage. (A) Anatomic depiction of the sublingual gland (red) and submandibular gland (green). (B) Implant perforation of the lingual plate may result in gland damage.
● **Fig. 31.11** (A) Ideal incision location and full-thickness reflection will reduce bleeding with atraumatic reflection of the tissue. (B) Split-thickness flap, which results in increased bleeding and tissue trauma.

Anatomy/Anatomic Variants

Strategic planning of potential implant sites is extremely important, with a thorough understanding of anatomic structures and variants with the use of CBCT. The lack of distortion of the CBCT images allows the clinician to better plan surgical sites, while maintaining relatively safe zones from anatomic structures.

Mandibular Anterior: Intraosseous Vessels

Median Vascular Canal. On occasion, in the mandibular midline, copious bleeding may be present (e.g., C position, even though no bone perforation has occurred). Bilateral sublingual arteries enter through the lingual foramen within the lingual plate below the genial tubercles in the mandible. As this anastomosis transverses within the anterior mandible, the canal is termed the *median vascular canal*. Bleeding in this area may be significant; however, it is not associated with any type of neurosensory impairment. The presence and size of the sublingual anastomosis and the median vascular canal is most commonly seen on a cross-sectional or axial image of a CBCT scan. If a large anastomosis is present, the position of the planned osteotomy may need to be modified.

Management. If significant bleeding occurs after implant osteotomy in the midline, a direction indicator or surgical bur can be placed in the osteotomy site to apply pressure. If the osteotomy is completed, an implant may also be introduced into the site, which will compress the walls of bone, thus slowing the bleeding process (Fig. 31.12). In most cases intraosseous bleeding is more easily controlled in comparison with soft tissue hemorrhage.

Inferior Alveolar Artery. The inferior alveolar artery is a branch of the maxillary artery, one of the two terminal branches of the external carotid. Before entering the mandibular foramen, it gives off the mylohyoid artery. In approximately the first molar region, it divides into the mental and incisal branches. The mental branch exits the mental foramen and supplies the chin and lower lip, where it eventually will anastomose with the submental and inferior labial arteries. The exact location of the inferior alveolar artery is easily determined via a CBCT evaluation in the panoramic or sagittal views.

Management. Normally the inferior alveolar artery is located superiorly to the inferior alveolar nerve within the bony mandibular canal. Drilling or placing an implant into the inferior alveolar canal may predispose to significant bleeding. Hemorrhage
● **Fig. 31.12** Median Vascular Canal. In the mandibular midline, the radiolucent canal that houses the right and left sublingual anastomosis.

may be controlled by placement of an implant or direction indicator short of the canal. A 2.0-mm safety zone between the implant and canal should be adhered to. If bleeding does occur, follow-up postoperative care is essential because hematoma formation within the canal may lead to a neurosensory impairment. This condition should be monitored because it may progress to respiratory depression via a dissecting hematoma in the floor of the mouth (Fig. 31.13).

Incisive Artery. The incisive artery is the second terminal branch of the inferior alveolar artery, which is a branch of the maxillary artery. The incisal branch continues anteriorly after supplying the mandibular first molar area, where it innervates the incisor teeth and anastomoses with the contralateral incisal artery. In rare cases the incisive canal is large, lending to greater bleeding during osteotomy preparation or bone-grafting procedures.[11] The exact location of the incisive canal is easily determined via a CBCT evaluation in the panoramic or sagittal views.

● **Fig. 31.13** Implant placement into the mandibular canal, which may result in excessive bleeding from the inferior alveolar artery.
● **Fig. 31.14** Incisive Canal Vessels. The incisive canal is the radiolucent canal extending anterior from the mental foramen and mandibular canal. Implants placed into this area may cause increased bleeding.

Management. Bleeding complications can occur when implants are placed into the mandibular incisive canal, which contains the incisive artery. If bleeding does occur during placement of the implant, a direction indicator, surgical bur, or implant can be placed into the osteotomy to apply pressure (Fig. 31.14).

Mandibular Anterior: Extraosseous Vessels

The anterior mandible is usually known as a safe area for implant placement, but in certain situations it may present with a significant undercut on the lingual aspect between the foramina. Life-threatening hemorrhage has been reported when a drill perforates the lingual plate of the sublingual region of the mandible and traumatizes a sublingual or submental artery, especially in the canine region.[12,13]

If perforation of the lingual cortical plate is associated with arterial bleeding, it is critical to identify its origin and treat aggressively. The origin of bleeding in the floor of the anterior region of the mouth may be from the lingual artery, facial artery, or one of its branches. The submental artery originates from the facial artery and courses along the inferior border of the mandible. The sublingual artery, a branch of the lingual artery, runs along the inferior border of the mandible and terminates in the midline. Perforation in this area may lead to bleeding, causing an expanding ecchymosis (sublingual hematoma) and compromising the airway.

Sublingual Artery (Lingual Artery). The lingual artery is a branch of the external carotid artery between the superior thyroid and facial arteries. The lingual artery courses medially to the greater horn of the hyoid bone and crosses inferiorly and facially around the hypoglossal nerve. It then transverses deep to the digastric and stylohyoid muscles, and courses between the hyoglossus and genioglossus muscles. There exist four main branches of the lingual artery: the suprahyoid, dorsal lingual, deep lingual, and sublingual.

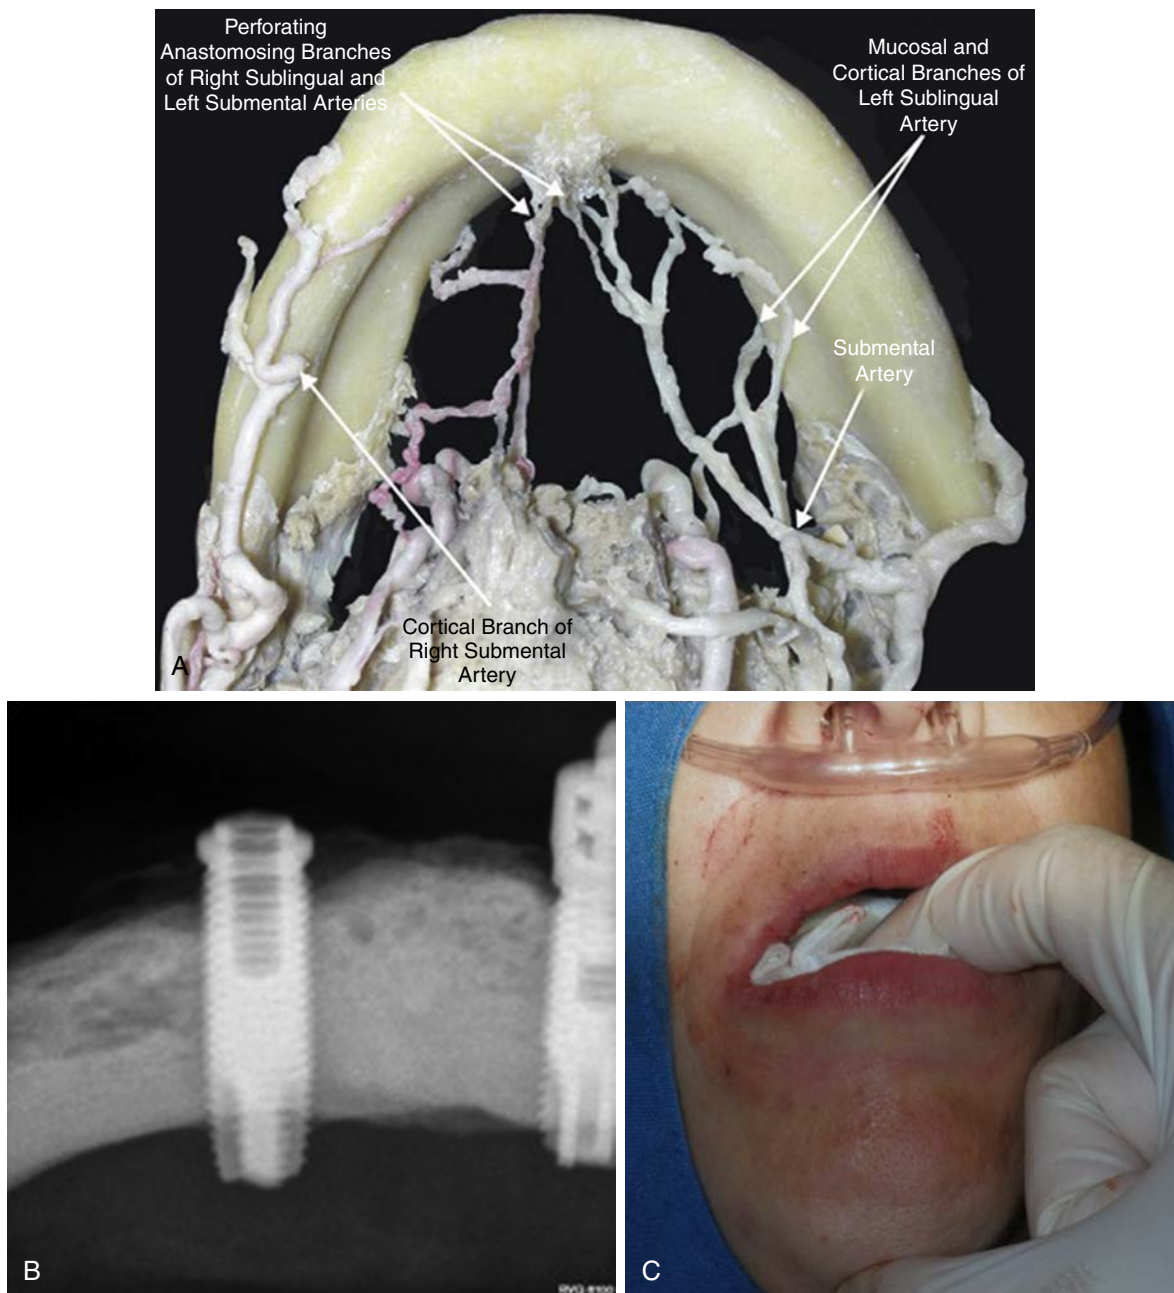
Of clinical significance to oral implantology is the sublingual artery, which supplies the sublingual salivary gland, mylohyoid and surrounding muscles, and the mucous membranes and gingiva of the mandible. A distal branch runs medially in the anterior lingual mandibular gingiva and anastomoses with the contralateral artery. An additional branch connects with the submental artery under the mylohyoid muscle.[14] The lingual artery will anastomose throughout the tongue area, with more anastomoses occurring anteriorly.[15]

Submental Artery (Facial Artery). The most important branch of the facial artery associated with oral implantology is the submental branch, which is the largest of the branches of the facial artery. The submental branch exits the submandibular gland and proceeds anteriorly on the surface of the mylohyoid muscle, just inferior to the body of the mandible. The submental branch terminates as an anastomosis with the sublingual branch of the lingual artery and the mylohyoid branch of the inferior alveolar artery.[14]

Studies have shown that the floor of the mouth and lingual gingiva are supplied approximately 53% by the submental artery and the remaining by the sublingual artery.[16] Perforation of the lingual cortical plate may result in trauma to the submental artery. Treatment should include immediate repositioning of the patient in an upright position followed by the application of bimanual pressure. This should be immediately applied, followed by airway management and emergency protocol.

Bleeding from the submental artery may be decreased by applying finger pressure over the lower border of the mandible. Doppler ultrasonography studies have shown this to reduce the arterial blood by 25% to 50% at the oral commissure level and 33% to 50% at the inferior border of the nares.[17]

Prevention. Clinical and radiographic evaluation should be completed to ascertain the amount of available bone and osseous angulation in the anterior mandible. The length of implants should be carefully evaluated because bicortical stabilization (which may lead to perforation of the lingual plate) is no longer advocated for implant success. This is most important in the mandibular canine position as the arteries are close to the lingual cortical plate. In addition, care should be exercised in elevation of the lingual flap and manipulation of the lingual tissue.

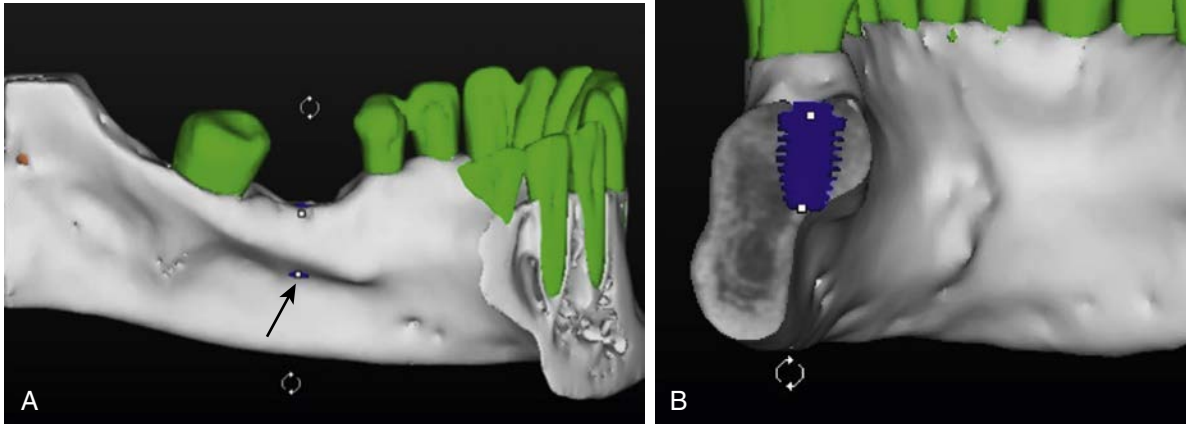
Clinical Significance. Bleeding into the sublingual and submaxillary spaces will cause elevation of the tongue and floor of the mouth. Bleeding in these spaces will proceed to airway obstruction because the anterior extension of the hematoma is limited by the superficial layers of the cervical fascia.[18] The signs and symptoms of sublingual swelling include immediate or delayed (up to 4–8 hours after surgery) elevation of the floor of the mouth, protrusion of the tongue, profuse intraoral bleeding, difficulty in swallowing, and respiratory depression. The submandibular swelling may dislocate the trachea to the contralateral side and compromise the airway.[19] In addition, pulsatile hematomas (pseudoaneurysms) of the lingual artery may result from the injury (Fig. 31.15).[20]


● **Fig. 31.15** (A) Sublingual and submental artery anatomy in the floor of the mouth. (B) Perforating lingual plate, which may cause sublingual bleeding. (C) To slow the bleeding, bimanual pressure with a 4 × 4 gauze on the lingual surface of the mandible and extraoral pressure on the inferior mandible. (*From Loukas M, Kinsella CR Jr, Kapos T, et al: Anatomical variation in arterial supply of the mandible with special regard to implant placement. Int J Oral Maxillofac Surg 37(4):367–371, 2008.*)

Management. Immediate bimanual pressure should be applied to the bleeding area if the location can be determined. A 4 × 4 gauze may be used to apply the bimanual compression downward from the floor of the mouth (lingual surface of the mandible) and in an upward direction from the submental skin area. The patient should be repositioned from a supine to an upright position. Young forceps may be used to pull the tongue outward, which will slow the bleeding. Airway obstruction should be of vital concern because this may lead to a life-threatening situation. If any clinical signs of airway obstruction exist (e.g., dyspnea, dysphagia, wheezing, stridor, cyanosis), emergency intervention should be summoned immediately. Ligation of the bleeding vessel is the ideal treatment to control the hemorrhage. This may be difficult in an office setting because of the location and surgical access of the bleeding vessel. To obtain definitive control of sublingual artery bleeding, surgical intervention with selective ligation of the branches, along with arterial embolization via interventional angiography, is indicated (Fig. 31.16).[21]
● **Fig. 31.16** **Sublingual Hematoma.** (A) Four implants placed flapless in the anterior mandible. (B) Resultant sublingual hematoma with airway compromise. (C) Axial computed tomography images showing extent of hematoma (blue arrows) with airway compromise. Note perforation of lingual cortical plate (red arrow). (D) Young forceps may be used to pull tongue out to decrease the bleeding and helps maintain airway until medical assistance arrives. (*From Limongelli L, Tempesta A, Crincoli V, et al: Massive lingual and sublingual haematoma following postextractive flapless implant placement in the anterior mandible.* Case Rep Dent. *2015;2015:839098.*)

Mandibular Posterior: Extraosseous Vessels

Posterior Lingual Undercut. In the mandibular posterior area a lingual undercut may be problematic and difficult to manage. In this area, perforation of the lingual plate can occur easily, thereby causing bleeding episodes, with an origin that may be difficult to locate. Life-threatening situations may result from sublingual bleeding. Violation of this area may cause infection or constant irritation from the extruded implant in the soft tissue. If the perforation were to occur above the mylohyoid muscle, damage to the lingual nerve could result in a neurosensory impairment.

Prevention. A clinical examination should always be carried out to determine whether an osseous undercut exists. This may be confirmed with a CBCT examination because cross-sectional images are an effective way of observing lingual undercuts. In addition, angulation and positioning must be continuously verified to prevent inadvertent perforation. Studies have shown that lingual undercuts occur in approximately 66% of the population, with a mean undercut of 2.4 mm.[22] Accurate measurements must be made to prevent overpreparation of the osteotomy site in the posterior mandible.


● **Fig. 31.17** Mandibular Posterior Undercut. (A) Three-dimensional image depicting the posterior under-cut. (B) When an undercut is present, limited available height is present for implant placement. This will often lead to a crown/implant ratio issue.

Accurate visualization of this area is most easily completed with a CBCT examination. Osteotomy angulation should always be carefully evaluated because improper drilling angulation may lead to perforations. In addition, hourglass mandibles, which have been shown to have an incidence rate of approximately 4%, should always be concerning because perforation will occur.[23]

In addition, clinical palpation of the ridge during osteotomy preparation will minimize perforations and decrease complications. During osteotomy preparation, handpiece control must be maintained to minimize inadvertent lingual plate perforation.

Management. If sublingual posterior bleeding (submental or sublingual arteries) occurs, the patient should be repositioned in an upright position and bimanual pressure should be applied to the area of bleeding. If the airway is compromised, immediate emergency assistance should be summoned (Fig. 31.17).

Buccal Artery. A popular donor site for autogenous grafting is the lateral ramus area in the posterior mandible. When making the incision lateral to the retromolar pad, a common blood vessel to damage is the buccal artery. The buccal artery is a branch of the maxillary artery and will most likely cause a significant bleeding episode. This artery runs obliquely between the internal pterygoid and the insertion of the temporalis on the outer surface of the buccinator.

Prevention. In most cases damage to the buccal artery is impossible to avoid. Incision and reflection will usually encompass the area of buccal artery location. When performing surgery in this area, a curved hemostat should always be available for immediate access to clamp the vessel.

Management. A curved Kelly hemostat should be used to control the bleeding. It should be left in place for 3 to 5 minutes until clotting is complete. If bleeding persists, a ligature may be placed with Vicryl suture material (Fig. 31.18).

Maxilla: Lateral Wall/Nasal Bleeding

Significant bleeding from the lateral approach sinus elevation surgery is rare; however, when it occurs, it has the potential to
● **Fig. 31.18** Buccal Artery. The buccal artery is often traumatized when making incisions in the retromolar area.

be troublesome. Three main arterial vessels should be of concern with the lateral approach sinus augmentation. Because of the intraosseous and extraosseous anastomoses that are formed by the infraorbital and posterior superior alveolar arteries, intraoperative bleeding complications of the lateral wall may occur. In some cases this bleeding may be significant.

Extraosseous Anastomosis. The soft tissue vertical release incisions of the facial flap in a resorbed maxilla may sever the extraosseous anastomoses during lateral wall osteotomy preparation for sinus graft surgery. The extraosseous anastomosis on average is located 23 mm from the crest of the dentate ridge; however, in the resorbed maxilla, it may be within 10 mm of the crest. When this artery is severed, significant bleeding has been observed. These vessels originate from the maxillary artery and have no bony landmark to compress the vessel. Vertical release incisions in the soft tissue should be kept to a minimum height, with delicate reflection of the periosteum. Hemostats are usually difficult to place on the facial flap to arrest the bleeding. Significant pressure at the
● **Fig. 31.19** Intraosseous Anastomosis. (A) Cross-sectional image showing radiolucent notch on the lateral wall of the sinus. (B) Intraosseous notch (red arrow). (C) Intraosseous anastomosis pulsating bleed (white arrows).
● **Fig. 31.20** (A) Posterior lateral nasal artery (red line) in close approximation to the lateral wall of the nasal cavity (medial wall of maxillary sinus). (B) Nasal bleed during sinus augmentation procedure.

posterior border of the maxilla and elevation of the head to reduce the blood pressure to the vessels usually slows the bleeding. The elevation of the head may reduce nasal mucosal blood flow by 38%.[24]

Intraosseous Anastomosis. The vertical component of the lateral access wall for the sinus graft often severs the intraosseous anastomoses of the posterior alveolar artery and infraorbital artery, which is on average approximately 15 to 20 mm from the crest of a dentate ridge. Methods to limit this bleeding, which is far less of a risk, include cauterization with the use of a handpiece and diamond bur without water, electrocautery, or pressure on a surgical sponge while the head is elevated. In some cases a second window is made distal to the bleeding area source for access to ligate (Fig. 31.19).

Posterior Lateral Nasal Artery. The third artery that implant surgeons should be cautious of is the posterior lateral nasal artery (Fig. 31.20). This artery is a branch of the sphenopalatine artery, which is located within the medial wall of the antrum. As it courses anteriorly, it anastomoses with terminal branches of the facial artery and ethmoidal arteries. A significant bleeding complication may arise if this vessel is severed during elevation of the membrane off the thin medial wall.

If the excessive bleeding occurs while the medial wall is elevated, the sinus may be packed with hemostatic agents, followed by packing with large 4 × 4-inch surgical sponges and elevation of the head. Once the bleeding is arrested, the sponges are removed, the layered graft materials may be inserted, and the procedure completed.

Epistaxis (active bleeding from the nose) after sinus graft surgery is rather common. This may occur with or without a known membrane perforation. Usually epistaxis is limited to the first 24 hours after surgery, and the patient should always be warned of this potential complication.

If bleeding should occur through the nose, there exist numerous techniques to obtain hemostasis. Placing a cotton roll, coated with petroleum jelly with dental floss tied to one end, within the nares may obtund nose bleeding after the surgery. After 5 minutes the dental floss is gently pulled and the cotton roll removed. The head is also elevated, and ice is applied to the bridge of the nose. If bleeding cannot be controlled, reentry into the graft site and endoscopic ligation by an ENT (ear, nose, and throat) surgeon may be required.

If the orbital wall of the sinus is perforated or if an opening into the nares is already present from a previous event (i.e., previous sinus surgery), the sinus curette may enter the nares and initiate bleeding. The arteries involved in this site are composed of branches of the sphenopalatine and descending palliative arteries, which are branches of the internal maxillary artery. The posterior half of the inferior turbinate has a venous network, the Woodruff plexus, which is highly vascular. A cotton roll with silver nitrate or lidocaine with 1:50,000 epinephrine is also effective in obtaining hemostasis.

Postoperative Bleeding Control

Patient Education

It is imperative that patients understand that minor oozing may persist for up to 24 hours after dental implant surgery. If the patient is taking anticoagulants, this may persist for up to 48 hours. The patient should be instructed on the use of pressure dressings, and special care should be taken to minimize any trauma to the surgical site (e.g., eating, pulling on lip to see surgical site). The patient should avoid rinsing the mouth vigorously. All postoperative instructions should be reviewed with the patient and given in writing before surgery.

Patients should be instructed to limit their activities for a minimum of 24 hours, depending on the extent of the surgery. The head should be elevated as much as possible during the daytime hours, and the use of two pillows (i.e., elevate head) during sleeping will reduce secondary bleeding episodes.

Postoperative hemorrhage in anticoagulated patients may lead to significant issues. Studies have shown bleeding episodes in anticoagulant patients will most likely occur within 6 days of the surgery.[25] In patients who have exhibited significant bleeding during surgery, hemorrhagic shock, although rare, should be evaluated. If the patient displays any signs or symptoms of shock (e.g., tachycardia, hypotension, lethargy, disorientation, cold/clammy skin), immediate medical assistance should be summoned. Treatment would include intravenous fluid replacement to replenish the intravascular volume and restore tissue perfusion. Finally, caution should be exercised on the postoperative use of medications that may increase bleeding. A comprehensive review of the patient's medications should be completed to determine whether any drug interactions may exist that would increase bleeding. Agents that interfere with platelet function should be avoided for routine analgesia (e.g., nonsteroidal antiinflammatory drugs [NSAIDs], aspirin) unless the benefit outweighs the increased risk for bleeding. The routine perioperative use of aspirin should usually be avoided because of an increased risk for bleeding and lack of benefit. However, if these medications are administered for a separate indication under the recommendation of a physician (e.g., recent stroke, acute coronary syndromes, implanted coronary stent), they should be continued.

Techniques to Decrease and Control Bleeding

The need to control gross bleeding is paramount for successful surgery because insidious and continuous loss of blood from arteries, veins, or capillaries can become significant if bleeding is not controlled. Dental implant clinicians have numerous options for maintaining hemostasis, which include mechanical, thermal, pharmacologic, and topical agents.

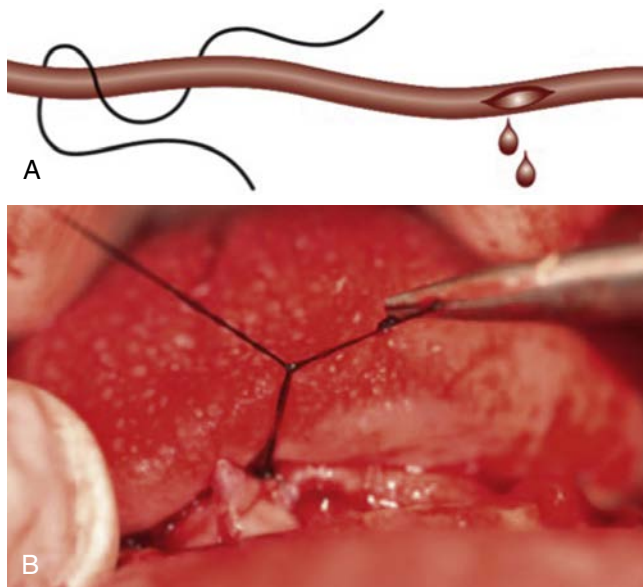
Mechanical Methods

The most common primary mechanical method to control bleeding is to apply direct pressure or compression on the bleeding site, along with repositioning the patient. Secondary mechanical methods include suturing, clamping the blood vessel with hemostats, and ligating the bleeding vessel with suture material.

Positional Changes. When significant bleeding occurs, maintaining the patient in a supine position is not recommended because of increased bleeding (head below the heart). Hydrostatic pressure occurs within the vascular system because of the weight of the blood vessels and is dependent on gravity. The pressure is decreased in any vessel above the heart and increased in blood vessels below the heart. Studies have shown that in an upright position, the average pressure at the level of the heart is 100 mm Hg. Vessels in the head and neck averaged 49 and 186 mm Hg, respectively, at the foot level.[26] Repositioning the patient to an upright position (head above the heart) will not stop the bleeding; however, it will significantly decrease the hemorrhage (studies have shown a decrease up to 38%).[27]

Direct Pressure. If significant intraoperative bleeding occurs, the ideal treatment should involve immediate application of pressure to the surgical site. Pressure or compression directly on the blood vessel will allow for platelet aggregation and initiation of the coagulation cascade. Pressure may be applied manually or by the patient biting forcefully on a gauze dressing. Pressure should be maintained for at least 3 to 5 minutes to allow the formation of a blood clot. Caution should be exercised not to remove the gauze too early because this may dislodge the clot.

Ideally 3 × 3 or 4 × 4 gauze should be used because 2 × 2 gauze may be accidentally aspirated. In primary bleeding, pressure is the simplest and fastest method to control bleeding before the use of hemostatic measures.

Suturing. Suturing plays a significant role not only in obtaining primary closure for ideal healing but also for maintaining hemostasis (direct versus indirect). Direct placement of a suture (ligation) is used when there is access to a deep bleeding vessel. The suture is placed by entering the tissue at least 4 mm from the bleeding vessel, 3 mm below the vessel, and 4 mm exiting the tissue. This will ligate or occlude the vessel as long as it is placed proximal to the bleeding area. A figure-eight suture technique is ideally used. Indirect suture placement is used to retract the tissue and minimize bleeding via pressure from the accumulated tissue. This is most often used as tie-backs when reflecting an edentulous mandible (cuspid to molar bilaterally). And lastly, good suturing technique is paramount for preventing reactionary bleeding after surgery. Ideally interrupted or mattress sutures should be placed in conjunction with continuous sutures to maintain closure. A suture material that exhibits high tensile strength is recommended, such as polyglycolic acid (e.g., Vicryl). The interim prosthesis should be modified to have no direct pressure on the wound site, as this may dislodge the sutures (Fig. 31.21).


● **Fig. 31.21** Suturing. (A) Direct ligation with figure-eight suturing technique. (B) Indirect tie-back of the mandibular lingual tissue from cuspid-molar contralaterally, which decreases bleeding, allows for ease of retraction, and prevents tissue trauma.

Clamped Vessel With Hemostat Forceps. When local measures are not successful in controlling bleeding, a hemostat may be used to clamp the blood vessel. Usually a curved Kelly hemostat may be used to clamp the vessel to control the bleeding via two mechanisms:

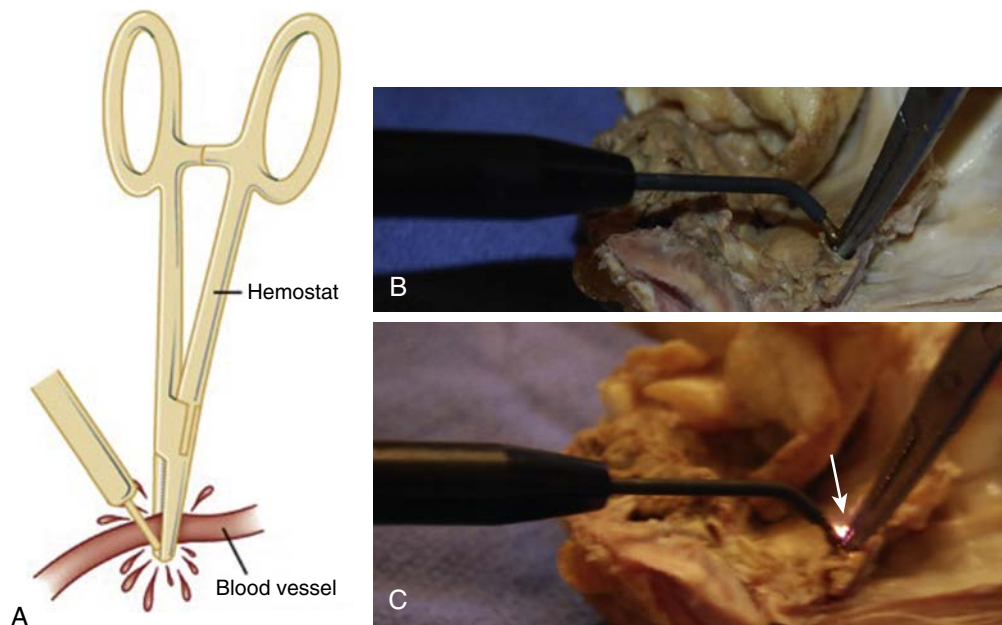
1. The first mechanism is occluding the vessel and damaging the blood vessel's wall to stimulate clotting. This clamping pressure should be maintained for approximately 2 to 3 minutes, which will usually allow for hemostasis. However, this method may be unreliable because the clot may become dislodged and postoperative bleeding may occur after removal of the hemostat.
2. A more successful technique in controlling bleeding is to use fine-pointed hemostats (Kelly hemostats) and ligate the bleeding vessel with suture material. The vessel should be clamped to obtain immediate hemostasis, with the tip of the hemostat extending beyond the vessel. A clamped vessel may be ligated with suture material such as an absorbable suture with high tensile strength (e.g., Vicryl). A tie should be placed around the hemostat, extending to the vessel. The hemostats are then removed, and two additional throws are made with the suture. Usually bleeding from vessels of 2 mm or greater diameter should be ligated. Direct ligation of the bleeding blood vessel is usually the most effective technique in stopping arterial blood flow. However, exposure and identification of the bleeding vessel may sometimes be extremely difficult. In addition, the bleeding may occur from multiple capillaries, which may result in difficult hemostasis.

Electrocautery. Electrocauterization, developed in the 1930s, has been one of the most common hemostatic techniques because of its low cost, accessibility, ease of use, and effectiveness. Electrocautery is the process of destroying tissue using heat conduction, with a probe that is heated by an electric current. Different procedures may be completed with the use of high radiofrequency alternating current for cutting, coagulating, and vaporizing tissues.
● **Fig. 31.22** Electrocautery. (A) Monopolar electrocautery, which uses current to establish hemostasis. A ball electrode is the most common to be used; however, access is sometimes difficult. (B) A battery-operated disposable cautery unit that does not use current, however generates heat to ligate the blood vessel.

Electrocautery is most effective on small vessels and may be used in two modes: monopolar and bipolar (Fig. 31.22).

Monopolar electrosurgery delivers current using different types of waveforms (i.e., modes). The coagulation mode uses an interrupted waveform, which generates heat, thereby coagulating a cell, a phenomenon also termed *fulguration*. The cutting mode is low energy, which produces a cutting effect to vaporize tissue with minimal hemostasis. The blend mode simultaneously cuts tissue and coagulates bleeding. This technique is often difficult to use in implant surgery because access and a relatively dry field is needed to cauterize the vessel. A dry field is needed for the effective electrical current to pass through the tissues. A high-speed plastic, not metal, suction tip should be used to maintain a dry field.

Buzzing the Hemostat (Electrocautery + Hemostat Ligation). Usually on larger vessels the combination of a clamped vessel (with curved hemostat) and electrocautery will allow for the cauterizing of the blood vessel, thus stopping blood flow in the vessel. The protocol is as follows:

1. Use the lowest possible setting to achieve the desired effect.
2. Use the CUT mode, not the COAG mode. COAG has a higher peak-to-peak voltage and is more prone to alternate (small) current pathways.


● **Fig. 31.23** (A–C) "Buzzing the hemostat" usually used for larger-vessel ligation (arterial). The vessel is clamped with the hemostat, and the electrocautery unit is placed on CUT mode and lightly touches the hemostat. A spark will usually result (arrow). Before its use, supplemental oxygen (nasal cannula) should be discontinued to prevent a patient airway fire.

3. After clamping the vessel, touch the active electrode to the hemostat closer to the patient (below the hand holding the hemostat) and then activate the electrode. This minimizes sparking and the subsequent demodulation of current, while encouraging a path of least resistance.

NOTE: Care should be exercised because the implant clinician may receive burns or be shocked even when wearing protective gloves. When the surgeon clamps a bleeding vessel and the electrode is touched to the hemostat, the tissue between the clamped hemostat is coagulated. The "buzzing" may cause high-voltage breakdown of the surgeon's glove, leading to a burn. To minimize this possibility, the surgeon's glove should be changed, if wet, because hydrated gloves show a lower resistance. In addition, the electrode should be placed in contact with the hemostat before activation of the electrosurgical current, to minimize the production of a spark (Fig. 31.23).

Lasers. Lasers, which are gaining popularity as a tool in dental surgery, may also be used to achieve hemostasis. Laser is an acronym for "light amplification by stimulated emission of radiation," which produces laser light energy. Laser energy delivered to an area of bleeding may be reflected, scattered, transmitted, or absorbed. The extent of the tissue reaction depends on the laser wavelength, power settings, spot size, and length of contact time with the bleeding area. Lasers have been shown to be a safe or useful modality in treating dental surgery patients with bleeding disorders.[28]

Pharmacologic Techniques

Although pharmacologic techniques may be used in implant dentistry to control bleeding, the success of maintaining hemostasis is questionable, with varying results.

Epinephrine. Epinephrine may be used to enhance hemostasis in combination with local anesthesia (e.g., 2% Lidocaine 100,000, 1/50,000 epinephrine). When locally placed, epinephrine will reduce bleeding, slow the absorption of the local anesthetic, and prolong the anesthetic and analgesic effect. The hemostatic properties are related to platelet aggregation, which leads to a decrease in the adrenoreceptors within the vessel walls, thus producing vasoconstriction. However, rebound hyperemia may result postoperatively, which will increase bleeding. Various studies have shown that topical application of a 1/100,000 concentration of epinephrine creates vasoconstriction and controls hemostasis with sinus graft procedures, with no appreciable changes in systemic hemodynamics.[29]

Tranexamic Acid Solution. Tranexamic acid 4.8% is an antifibrinolytic oral rinse that facilitates clot formation by inhibiting the activation of plasminogen to plasmin. Plasmin prevents the clotting process from initiating fibrinolysis. Tranexamic acid solution may be used as a mouthwash postoperatively and has been shown to enhance clotting in patients with coagulopathies or anticoagulant therapy. Sindet-Pedersen and Ramstrom[30] showed a significant reduction in postoperative bleeding with a 10-mL rinse, four times a day for 7 days postoperatively. Choi et al.[31] reported a significant decrease in bleeding during maxillary surgery after a bolus of tranexamic acid was given preoperatively (Fig. 31.24).

Topical Hemostatic Agents. Absorbable topical hemostatic agents are used when conventional methods of hemostasis are ineffective. These agents may be placed directly into the bleeding site to decrease bleeding during the procedure or during the postoperative interval. They work either mechanically or by augmenting the coagulation cascade. The topical hemostatic agents have the added benefit of minimizing the possibility of systemic blood clots, which are drawbacks of systemic hemostatic agents. There are two types: active and passive (Table 31.1).

Active Hemostatic Agents

Thrombin. Active topical hemostatic agents have biologic activity that induces clotting at the end of the coagulation cascade. Most active agents used in dental implant surgery contain the coagulant thrombin. Thrombin is a naturally derived
● **Fig. 31.24** Tranexamic Acid Injection. (A) Injection solution (Auromedics, East Windsor, N.J.). (B) Injectable tranexamic acid placed under bleeding flap.

TABLE 31.1	Active and Passive Hemostatic Agents		
COMMON HEMOSTATIC AGENTS			
Type	**Product**	**Advantages**	**Disadvantages**
Collagen	OraTape, OraPlug (Salvin), CollaTape, CollaPlug (Zimmer)	Inexpensive; resorbs in 10–14 days; highly absorbent to many times its own weight	None
Microcellular collagen	Avitene (Davol), Helitene (Integra), Instat (Ethicon)	Good application for large surfaces; superior hemostasis to gelatin and cellulose	Difficult to handle; expensive
Gelatin	GelFoam (Baxter), Surgiform (Ethicon)	Swelling after application results in tamponade effect; neutral pH	May cause tissue/neural damage due to compression from swelling; possible dislodgement from bleeding site
Cellulose	Surgicel (Ethicon), Blood Stop (Salvin), Oxycel (Becton Dickinson), ActCel (Coreva Health Sciences)	Easy to handle; low pH provides antimicrobial coverage; expands three to four times its original size and converts to a gel	Possible foreign body reaction; low pH may lead to possible postoperative irritation; needs to be removed
Thrombin	Thrombin-JMI Bovine (Pfizer), Evithrom-human (Ethicon), Recothrom-recombinant (ZymoGenetics)	Can be added to collagen products, good for small-vessel bleeding	Bovine has been shown to be immunogenic; leads to severe coagulopathy
Thrombin + gelatin	FloSeal (Baxter)	Very good for arterial bleeding areas because it acts as an adhesive	Can result in significant swelling from the compression; can cause neural disturbance
Fibrin sealant	Tisseel (Baxter) Evicel (Ethicon)	Good for larger bleeding areas because it acts as an adhesive	Expensive; preparation time
Kaolinite	QuikClot (Z-Medica)	Kaolin is a natural occurring mineral	Limited use in dental surgery; needs to be poured into wound; exothermic reaction causes heat
Synthetic bone hemostatic agents	Bone wax Ostene (Ceremed)	Ostene is soluble; it dissolves in 48 hours and is not metabolized, with a low bacterial adhesion and infection rate	Bone wax is insoluble; must be removed or will cause inflammation and a foreign body giant cell reaction; should not be used in implant dentistry
● **Fig. 31.25** (A) Topical thrombin (King Pharmaceuticals, Bristol, Tenn.). (B) Injected under a flap.

enzyme that is formed from prothrombin and acts as the basis for a fibrin clot by converting fibrinogen to fibrin. It is mainly used as a topical hemostatic agent in 5000- to 10,000-unit solutions, which accelerates capillary bleeding. It may be used as a powder or combined with a gelatin sponge during surgical procedures.

Thrombin bypasses the initial enzymatic process, thereby exerting its effect by impairing aspects of the coagulation cascade. For thrombin to maintain hemostasis, circulating fibrinogen is needed because it is necessary for the formulation of a clot. Therefore when a patient exhibits the absence of fibrinogen, thrombin will not be effective. Fibrinogen is less susceptible to coagulopathies caused by clotting factor deficiencies and platelet dysfunction.[32] However, thrombin does work in the presence of antiplatelet and anticoagulation medications, which are quite prevalent in the population (Fig. 31.25).

Types of Thrombin. Thrombin is available in many forms as a hemostatic agent and has been purified from numerous sources and classified according to the plasma used to create it. Bovine thrombin (e.g., Thrombin-JMI) is available as a powder that may be used dry, reconstituted with sterile saline, or added to gelatin sponges or collagen. Antibody formation has been associated with bovine thrombin, and this may lead to coagulopathies.[33]

Human plasma thrombin (e.g., Evithrom) is available as a frozen liquid that can be reconstituted via an absorbable gelatin sponge. Human plasma thrombin has been associated with the potential risk for viral or disease transmission.[34]

Recombinant thrombin (e.g., Recothrom) is a genetically engineered thrombin available in a powder form. It may be applied via a spray kit or with an absorbable gelatin sponge. The use of recombinant thrombin eliminates the risk for antibody formation and disease and virus transmission.[35]

Advantages. Thrombin use is advantageous in patients receiving antiplatelet or anticoagulation medications. Thrombin does not need to be removed from the bleeding site because degeneration and reabsorption of the fibrin clot is achieved during the normal healing process. Usually thrombin-containing active agents have a rapid onset of action, providing hemostasis within 10 minutes in most patients.[36]

Disadvantages. Thrombin is ineffective in patients who suffer from afibrinogenemia because fibrinogen will not be present in the patient's blood. Care should be exercised not to use thrombin directly on larger vessels because systemic absorption may lead to intravascular thrombosis.

Passive Hemostatic Agents. Passive hemostatic agents provide hemostasis by accelerating the coagulation process. These agents form a physical, lattice-like matrix, which activates the extrinsic clotting pathway and provides a platform for platelets to aggregate and form a clot. Passive hemostatic agents are effective only on patients who have an ideal coagulation process. If the patient suffers from any type of coagulopathy, other hemostatic techniques should be used.

Passive hemostatic agents are available in many different forms (e.g., bovine collagen, cellulose, gelatins) and application methods (e.g., absorbable sponge, foam, pads that may absorb several times their own weight). Expansion may lead to complications, specifically pressing on neural tissue (e.g., inferior alveolar nerve). Therefore after hemostasis is obtained, passive hemostats should be removed to minimize postoperative complications. Passive hemostatic agents are readily available and inexpensive.

Collagen. Collagen-based hemostatic agents work by contact activation and promotion of platelet aggregation, which occurs as a result of contact between blood and collagen. Collagen is available in many carrier forms such as a powder, paste, or sponge. Studies have shown that between 2% and 4% of the total population is allergic to bovine collagen.[37]

Bovine Collagen (OraPlug, OraTape; Salvin Dental Specialties, Inc.). Products such as OraPlug and OraTape are soft, white, pliable, nonfriable, coherent, spongelike structures that are fabricated from bovine collagen (usually from deep flexor tendons). They are nontoxic, nonpyrogenic, and highly absorbent. Indications include the control of oozing or bleeding from clean oral wounds. They help control bleeding, by stabilizing blood clots, and protect the wound bed to facilitate the healing process. When applied, the products should be held in place for approximately 2 to 5 minutes to achieve ideal hemostasis and then may be removed, replaced, or left in place. Most collagen materials are completely resorbed within 14 to 56 days (Fig. 31.26).[38]

Cellulose. The most common cellulose-based hemostatic agent is regenerated oxidized cellulose that initiates clotting via contact activation. Oxidized cellulose has been shown to be poorly absorbed and may cause healing complications postoperatively.

Regenerated Cotton Cellulose (BloodSTOP; LifeScience PLUS, Inc.). BloodSTOP is a biocompatible, nonirritating, water-soluble, regenerated cotton cellulose hemostatic agent that resembles traditional gauze. When applied to a bleeding surgical site, Blood-STOP quickly absorbs blood and transforms into a gel to seal the

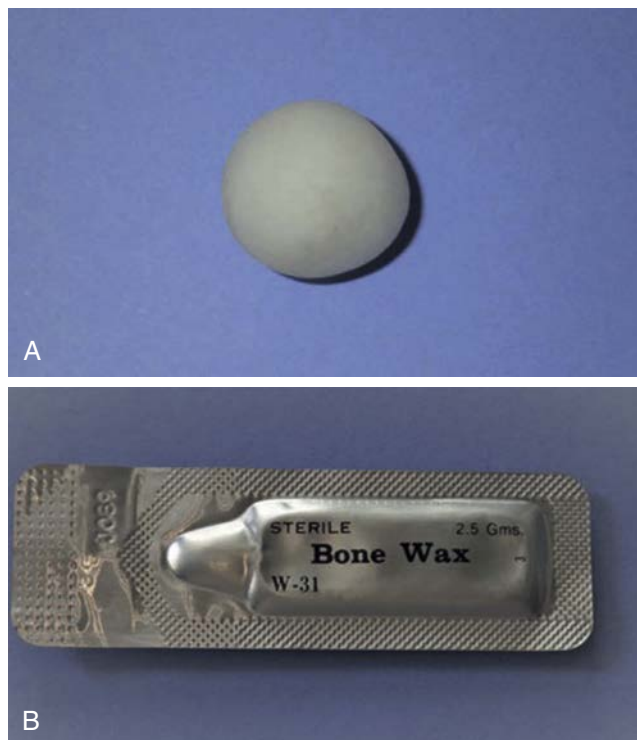
wound with a protective transparent layer, actively aids in blood coagulation, and creates a positive environment for wound healing. Because BloodSTOP is 100% natural cellulose and is water soluble, it is easily removed without disruption of the wound surfaces after hemostasis. It is manufactured in a single-use, sterile package with a 0.5 × ~2-inch size (Fig. 31.27).

Mechanical

Beeswax. Bone wax, a soft, malleable, nonbrittle wax, was invented in 1886 by Sir Victor Horsley. The material is a combination of beeswax, salicylic acid, and almond oil.[39] It is most commonly used when the bleeding is visualized as having an origin from within the bone. This type of bleeding most commonly occurs during osteotomy preparation and extractions. Bone wax exhibits no hemostatic quality; it obliterates the vascular spaces in cancellous bone. However, caution should be exercised with the use of bone wax because it is water insoluble and will not be absorbed. It may predispose the area to infection or inhibit bone healing. Studies have shown that bone wax, when removed from an osseous defect after 10 minutes, completely inhibited further bone regeneration.[40] Bone wax also increases inflammation, which may cause a foreign body giant cell reaction and infection at the site (Fig. 31.28).[41]

Synthetic Bone Hemostat Material (Ostene; Ceremed Inc.). Ostene is a synthetic bone hemostat material approved in 2004 by the FDA for use in cranial and spinal procedures. This material is a mixture of water-soluble alkylene oxide copolymers that elicits minimal postoperative inflammation. It has many advantages over


● **Fig. 31.28** (A and B) Bone wax. (*B: Courtesy Surgical Specialties, Wyomissing, Pa.*)

● **Fig. 31.29** Ostene (Bone Hemostasis Material) (Baxter). Ostene material is a sterile water-soluble surgical implant material. It can be used for the control of bleeding from bone surfaces by acting as a mechanical barrier.

bone wax because it is water soluble and dissolves in 48 hours. It has been associated with a decreased infection rate and positive bone cultures.[42] Ostene is supplied in sterile peel pouches and is applied in a manner similar to bone wax, without the associated disadvantages (Fig. 31.29).

Postoperative Complications

Edema (Postoperative) Surgical Swelling

Postoperative edema is a direct result of tissue injury and is defined as an accumulation of fluid in the interstitial tissue. Two variables determine the extent of edema: (1) the amount of tissue injury is proportional to the amount of edema; and (2) the looser the connective tissue at the surgery site, the more edema is most likely to be present. Because postoperative swelling can adversely affect the incision line (i.e., result in incision line opening [ILO]), measures should be taken to minimize this condition. Usually edema will peak at approximately 48 to 72 hours; therefore patients should always be informed. Increased swelling after the fourth day may be an indication of infection, rather than postsurgical edema.

Etiology

The mediators of the inflammatory process include cyclooxygenase and prostaglandins, which play a significant role in the development of postoperative inflammation and pain. When tissue manipulation or damage occurs, phospholipids are converted into arachidonic acid by way of phospholipase A_2 (PLA_2). Arachidonic acid, which is an amino acid, is released into the tissue, which produces prostaglandins via enzymatic breakdown via cyclooxygenases. The end result is the formation of leukotrienes, prostacyclins, prostaglandins, and thromboxane A_2, which are the mediators for inflammation and pain.

Prevention

Good surgical technique must be used with minimal tissue trauma to decrease postoperative swelling. Additional factors include patient systemic disorders, excessive retraction, and long surgical duration, which will all contribute to increased inflammation after surgery. Postoperative prophylactic medications such as ibuprofen (NSAIDs) and glucocorticosteroids (steroids) are used as prophylactic medications, which counteract the negative effects of the edema cascade.

Nonsteroidal Anti-inflammatory Drugs. NSAIDs have an analgesic effect, as well as an anti-inflammatory effect. This drug class reduces inflammation by inhibiting the synthesis of prostaglandins from arachidonic acid. Therefore the use of the popular analgesic drug ibuprofen has a secondary beneficial anti-inflammatory effect. NSAIDs do not have a ceiling effect for inflammation (i.e., ceiling effect for analgesia is 400 mg); however, higher doses to achieve anti-inflammatory qualities are accompanied by serious side effects.

Recommendation: Ibuprofen 400 mg for type 1 to 4 procedures (see Chapter 14).

Glucocorticosteroids. The adrenal cortex, which uses cholesterol as a substrate, synthesizes and secretes two types of steroid hormones—the androgens and corticosteroids. The corticosteroids are classified additionally by their major actions: (1) glucocorticoids, which have effects on carbohydrate metabolism and have potent anti-inflammatory actions; and (2) mineralocorticoids, which have sodium-retaining qualities. The use of synthetic glucocorticosteroids has become popular in the postoperative management of inflammation after oral surgical procedures. These synthetic glucocorticoids have greater anti-inflammatory potency in comparison with natural steroids, with very little sodium and water retention. Most steroids have similar chemical structures; however, they differ in their milligram potency.[43] The anti-inflammatory effects are achieved by altering the connective tissue response to injury, causing a decrease in hyperemia, which results in less exudation and cellular migration, along with infiltration at the site of injury.[44]

Glucocorticoids bind to glucocorticoid receptors within cells and form a glucocorticoid receptor (GR) complex. This complex alters the synthesis of messenger RNA from the DNA molecule, affecting the production of different proteins. By suppressing the production of proteins that are involved in inflammation, glucocorticoids also activate lipocortins, which have been shown to inhibit the action of Phospholipase A2 (PLA_2).

PLA_2 is a key enzyme involved in the release of arachidonic acid from cell membranes.

Arachidonic acid is an omega-6 fatty acid that is incorporated into cell membranes. When a cell is damaged, arachidonic acid is released from cell membranes and is converted into inflammatory and pain prostaglandins by cyclooxygenase-2 enzymes. The release of arachidonic acid requires the activation of enzyme PLA_2. However, lipocortins, which cause the inhibition of PLA_2, prevent the release of arachidonic acid, thereby reducing the amounts of inflammatory prostaglandins.

A wide range of glucocorticoid preparations are available for local, oral, and parenteral administration. In relation to the naturally occurring cortisol (hydrocortisone), synthetic glucocorticoids are longer acting and more potent. The main differences are based on the classification as short acting (<12 hours), intermediate acting (12–36 hours), and long acting (>36 hours). A summary of the most common glucocorticosteroids is shown in Table 31.2.

The ideal synthetic glucocorticoid for dental implant surgery should maintain high anti-inflammatory potency with minimal mineralocorticoid effects. The glucocorticoid that best suits the requirements is the long-acting glucocorticoid dexamethasone (Decadron). It is imperative this drug be administered before surgery so that adequate blood levels are obtained. Also, it should be given in the morning in conjunction with the natural release of cortisol (~8:00 a.m.). This timing will interfere the least with the adrenocortical system. Because inflammation usually peaks between 48 and 72 hours, the postoperative regimen of dexamethasone should

not exceed 3 days after surgery. This high-dose, short-term gluco-corticoid therapy has been shown not to significantly affect the hypothalamic-pituitary-adrenal axis, which controls many of the body's processes, including reactions to stress.[45]

A significant additional benefit of the administration of dexamethasone is the potent antiemetic effects for the prophylactic treatment of postoperative nausea and vomiting. This is now an accepted medication for hospital-based outpatient surgery, usually given in doses of 8 to 10 mg intravenously.[46]

Contraindications to the use of corticosteroids include active infections (viral, bacterial, fungal), tuberculosis, ocular herpes simplex, primary glaucoma, acute psychosis, and diabetes mellitus. Special attention must be given to patients with diabetes because glucocorticoids have an anti-insulin action that results in increased serum glucose and glycosuria.[47] Usually corticosteroids are contraindicated with patients with insulin-dependent diabetes. For patients with oral and diet-controlled diabetes, a medical consult should be completed before any treatment.

TABLE 31.2	Synthetic Glucocorticoids		
Glucocorticoids	Anti-inflammatory Potency	Equivalent Dose (mg)	Duration (hr)
Short acting			
Hydrocortisone	1.0	20	<12
Cortisone	0.8	25	<12
Intermediate acting			
Prednisone	4.0	5	24–36
Prednisolone	4.0	5	24–36
Long acting			
Dexamethasone	25	0.75	48

Recommendation: Decadron 4 mg for type 1 to 4 procedures (see Chapter 14).

Cryotherapy. Cryotherapy (application of ice) is one of the simplest and most economical modalities in the management of postoperative soft tissue inflammation. The use of ice to reduce pain and swelling dates back to the ancient Egyptians, more than 4000 years ago.[48]

The use of cryotherapy is highly advised in any dental implant procedure in which excessive inflammation is expected. The mechanism of action involves a reduction in fluid accumulation within the body tissues, slowing of metabolism, control of hemorrhage, and a decrease in the excitability of peripheral nerve fibers leading to an increase in pain threshold.[49]

Caution must be taken to limit the application of ice to no longer than 2 days because prolonged use may cause rebound swelling and cell destruction. Improper and prolonged use of ice may result in cell death caused by prolonged vasoconstriction, ischemia, and capillary thrombosis.[50]

After 2 to 3 days, moist heat may be applied to the region to increase blood and lymph flow to help clear the area of the inflammatory consequences. This also helps reduce any ecchymosis that may have occurred from the tissue reflection. Although usually safe, the application of ice is cautioned in patients suffering from cold hypersensitivities and intolerances and peripheral vascular diseases. In addition, ice application may be problematic in patients who are elderly or very young because they may have impaired thermal regulation and limited ability to communicate.

Care should be exercised in using facial bandages because prolonged ice administration may result in soft tissue injury.

Recommendation: Cold dressings (ice packs) should be applied extraorally (not directly on skin: place a layer of dry cloth between ice and skin) over the surgical site for 20 minutes on/20 minutes off for the first 24 to 36 hours (Fig. 31.30).

Decrease Activities. Patients should be instructed to decrease activities after surgery because this will minimize swelling postoperatively. The more active the patient and the more strenuous activity the patient engages in, the greater the extraoral swelling.
● **Fig. 31.30** (A and B) Common postoperative complications of (A) edema and (B) ecchymosis.

Recommendation: Activities should be limited for the first 3 days. Elevation of the head (sitting upright) and sleeping on multiple pillows will minimize the postoperative swelling.

Treatment

Swelling is self-limiting and once it occurs, it is usually difficult to treat (time dependent). The earlier mentioned medications/therapy (Decadron, NSAIDs, cryotherapy) will help to reduce postoperative inflammation, especially after longer, more invasive surgeries.

Ecchymosis (Bruising)

Ecchymosis is subcutaneous extravasation of blood within the tissues, which results in discoloration of the skin from the seepage of blood in the tissues. The location of the ecchymosis may be distant to the surgical site because of gravity (i.e., always inform patients preoperatively). Ecchymosis that presents in the inferior mandibular area or neck may be from bleeding under the flap and traveling via fascial spaces because of gravity.

Etiology

The cause of ecchymosis (bruising) is not confined to an existing hematologic disease or to medication-induced bleeding. Moderate bruising should be expected after dental implant surgery, especially after longer, more invasive surgeries. Female and elderly patients are more susceptible to bruising.

The ecchymosis cascade includes:
1. Blood vessels rupture.
2. Red blood cells die and release hemoglobin.
3. Macrophages (white blood cells) degrade hemoglobin via phagocytosis.
4. Hemo > bilirubin = bluish-red color.
5. Bilirubin > hemosiderin = golden-brown color.

Ecchymosis may appear as bright red, black, blue, purple, or a combination of the above colors. It usually consists of nonelevated, rounded, and irregular areas that increase in intensity over 3 to 4 days postsurgery and will diminish and become yellow as they disappear. It may take 2 to 3 weeks for complete resolution.

Prevention

Unfortunately, even with gentle handling of tissues and good surgical technique, ecchymosis may be unavoidable. To minimize ecchymosis, avoid postoperative aspirin, herbal remedies, and food supplements that may increase bleeding. Always inform the patient preoperatively (preferably in written postoperative instructions) that bruising may occur. Elderly patients are more susceptible to ecchymosis because of decreased tissue tone and weaker intracellular attachment.

Treatment

Ecchymosis is self-limiting and usually resolves without treatment. However, the patient may treat the ecchymosis in the following ways:

Rest/avoid strenuous activity: promotes tissue healing and decreases inflammation
Elevation: helps decrease inflammation, facilitates proper venous return, and improves circulation to the site
Analgesics: helps reduce pain associated with the onset of ecchymosis
Sun exposure: inform patient to avoid sun exposure to the area of bruising because excessive sunlight may cause permanent discoloration

Dental Implant Periapical Lesions (Retrograde Peri-implantitis)

After implant placement and recall examinations, case reports have shown the genesis of periapical lesions (radiolucency), which may suggest a possible precursor to failure of the endosseous implant.[51] These periapical lesions have been termed *apical peri-implantitis* and *retrograde peri-implantitis*.[52] The lesions have been defined as symptomatic or asymptomatic periapical radiolucency developing after implant placement with a normal coronal bone-to-implant interface.

Etiology

Asymptomatic. A clinically asymptomatic periapical radiolucency is considered to be inactive when radiographically there exists evidence of bone destruction with no clinical symptoms.

This may result from placing an implant into a site in which the osteotomy was prepared deeper than the implant length, resulting in an apical space. Also, when implants are placed adjacent to a tooth with an apical scar, this may result in a radiolucency. Inactive lesions may be caused by thermal bone necrosis, which is a direct result of overheating the bone. The thermal injury may result in a fibrous tissue interface, which may compromise the prognosis of the implant.

Symptomatic. A clinically symptomatic lesion is most commonly caused by bacterial contamination during implant placement. This may occur when an implant is placed into a preexisting area with bacteria (existing infection, cyst, granuloma, or abscess). When lesions are initiated at the apex, they may spread coronally or facially. Clinical symptoms with active lesions include intense pain, inflammation, percussion, mobility, or possible fistulas tract formation (Fig. 31.31).[53]

Prevention

Prevention of periapical lesions includes the following:
1. Clear evaluation of adjacent tooth structure to rule out preexisting infection or pathology
2. Pulp testing of adjacent teeth
3. Caution when placing immediate implants into sites with possible pathology
4. Extensive debridement of pathologic tissue and decortication of immediate extraction sites

Treatment

Because of the multifactorial etiology of periapical lesions around dental implants, there is no accepted general consensus on the treatment. Nonsurgical antibiotic treatment of periapical lesions has been shown to be unsuccessful.[54] The following have been shown to be effective treatments of periapical lesions:

Exposure: Tissue reflection is completed to expose the apical implant area (buccal or lingual access).
Debridement: The granulation tissue is completely removed to expose the bony walls of the apical area.
Removal of implant apex (elective): The apical portion of the implant may be removed to gain better access to the bony walls. This should be completed only if there is no biomechanical compromise for the implant.
Surface decontamination: The implant surface may be detoxified with various chemicals such as tetracycline (250 mg) grafting,[55] citric acid (40%),[56] chlorhexidine, and hydrogen peroxide.[57,58]
● **Fig. 31.31** Retrograde Periapical Lesion. (A) Radiolucency on mesial of implant of mandibular implant. (B) Radiolucency on mesial of maxillary implant.

Allograft: The defect area is grafted with allograft material, along with a resorbable membrane. A local antibiotic (e.g., Ancef, Cleocin) should be added to the graft for additional antimicrobial coverage.

Systemic antibiotics: Systemic prophylactic antibiotics (e.g., amoxicillin) should be used, together with 0.012% chlorhexidine oral rinse.

Titanium Allergy/Hypersensitivity

Hypersensitivity to titanium (Ti) is an ever-increasing reportable complication in medicine today that has been associated with a wide range of situations. In orthopedic medicine there are many case reports of titanium alloy hypersensitivity. Witt and Swann[59] reported 13 cases of failed total hip prostheses and concluded the tissue reaction in response to metal-wear debris may have been the causative factor of the failed implants. This process has been termed *repassivation* and may produce an oxide that surrounds and turns the peri-implant tissues black. Yamauchi et al.[60] reported a titanium-implanted pacemaker caused an allergic reaction. The patient experienced development of a distinct erythema over the implantation site, which resulted in a generalized eczema. Titanium sensitivity was confirmed by intracutaneous and lymphocyte stimulation testing.

In the dental literature, allergic reactions to pure titanium are rare. However, many authors have suggested there is a higher incidence of titanium alloy allergy with respect to dental implants; it is most likely underreported because of a poor understanding of failure or allergy.[61] Preez et al.[62] have reported a case of implant failure caused by a suspected titanium hypersensitivity reaction around a dental implant. Histologic results showed a chronic inflammatory reaction with concomitant fibrosis. Egusa et al. reported a titanium implant overdenture case that resulted in generalized eczema that fully resolved after implant removal.[46] Sicilia et al.,[63] in a clinical study of 1500 consecutive implant patients, reported approximately nine implants with a positive reaction to titanium allergy.

Etiology

Sensitivity to titanium has been shown to be a result of the presence of macrophages and T lymphocytes with the presence of B lymphocytes, which results in a type IV hypersensitivity reaction.[64] All metals, when in a biologic environment, undergo corrosion, which may lead to the formation of metallic ions and trigger the immune system complex with endogenous proteins.[65] Titanium alloy dental implants have been shown to contain many "impurities" that may trigger type IV hypersensitivity reactions. Harloff et al.[66] used spectral analysis to investigate various titanium alloy implants. The results showed that all of the titanium alloy samples contained small amounts of other elements such as beryllium (Be), cobalt (Co), chromium (Cr), copper (Cu), iron (Fe), nickel (Ni), and palladium. These impurity elements have been shown to be the cause of the hypersensitivity reactions.

Prevention

A thorough medical history involving any history of titanium hypersensitivity is strongly recommended.

Treatment

When titanium hypersensitivity is suspected the implants should be removed and the patient should be referred to his or her physician for appropriate testing. Case reports have shown that after complete removal of the implants, complete resolution results.[67] Metal sensitivity is usually diagnosed using a "patch test," which involves placement of titanium (allergen) to the skin for approximately 3 to 4 days. A positive test would include the appearance of an erythematous reaction. However, there is a possibility of false-negative results because the sealing qualities of the skin against direct contact may make the test unreliable (Fig. 31.32).

Incision Line Opening

ILO is one of the most common complications resulting from dental implant and bone graft surgery, occurring when a wound dehisces along a suture line (Fig. 31.33). The prevalence

● **Fig. 31.32** Titanium Dental Implant Allergy. (A) Facial eczema after implant placement. (B) Intraoral view of type IV hypersensitivity reaction. (C) Complete resolution after implant removal. > **• BOX 31.1**   **Clinical Dental Implant Wound Opening Categories**
>
> **Class 0:** The mucosa covering the implant is intact.
> **Class 1:** A breach in the mucosa covering the implant is observed. Oral implant communication may be detected with a periodontal probe, but the implant surface cannot be observed without mechanically interfering with the mucosa.
> **Class 2:** The mucosa above the cover screw is fenestrated; the cover screw is visible. The borders of the perforation do not reach or overlap the borders of the cover screw.
> **Class 3:** The cover screw is visible. In some areas of the cover screw the borders of the perforation aperture overlap the borders of the cover screw.
> **Class 4:** The cover screw is completely exposed.

rate of ILO has been shown in studies to range from 4.6% to 40% around submerged implants.[68,69] Mendoza et al.[70] reported 37% of postimplant surgery patients exhibited no ILO, whereas 43% had partial ILO and 20% had complete ILO. However, when evaluating soft tissue dehiscence around membranes (barriers), studies have shown a 30% incidence rate when part of guided bone regeneration procedures.[71] Therefore ILO is a common postoperative complication after dental implant and bone-grafting surgery. In this chapter the causative factors, prevention, and management of ILO will be discussed, together with a treatment protocol that is procedure and time specific.

Classification of Incision Line Opening Complications

When placing root form implants with a two-stage approach, spontaneous early exposure of submerged implants has the potential for complications that may affect healing and osseointegration of the implants. A classification and nomenclature system for these exposures is useful for communication and recordkeeping. Clinical wound opening has been categorized by Tal[69] (Box 31.1 and Fig. 31.34).

Considering that spontaneous early exposures are complications that can potentially lead to mucositis or peri-implantitis, Barboza and Caula[72] proposed classification for spontaneous early
● **Fig. 31.34** Incision Line Opening Classification. (A) Class 0 wound healing. (B) Class 1 wound healing.
(C) Class 2 wound healing. (D) Class 3 wound healing. (E) Class 4 wound healing.

exposure of submerged implants based on diagnostic methods and treatment modalities to prevent or intercept such complications. They suggested that implants with spontaneous exposure should immediately be surgically exposed as early as possible to prevent mucositis. A healing abutment should be placed after the cover screw is removed.[72]

Morbidity Consequences of Incision Line Opening With Implants and Bone Grafting

The resultant consequences of ILO can vary depending on the type of implant or bone-grafting procedure. For implant placement with good initial fixation, primary closure is favored for

one-stage surgery, with placement of a permucosal abutment. For bone augmentation procedures, primary closure is of paramount importance for clinicians when performing guided bone regeneration techniques and autogenous onlay grafting procedures. When ILO occurs during autogenous block grafting, there tends to be a greater potential for delayed healing, loss of graft into the oral cavity, and increased risk for infection.

Exposure of nonresorbable membranes adds additional risk for infection and unsatisfactory results. If guided bone regeneration is performed in conjunction with implant placement, ILO may also lead to loss of the implant. ILO most likely will result in a bacterial smear layer on the implant body, which may inhibit bone formation. Bone resorption resulting from infection may require implant removal. The same degree of ILO, without simultaneous implant placement, could possibly be managed and compensated for by bone expansion, use of slightly narrower implants, increased number of implants, and/or additional augmentation.

In addition, ILO can negatively affect esthetic clinical outcomes. The placement of implants simultaneous with regenerative procedures adds the risk for a functional and esthetically compromised result. For multistage bone augmentation procedures, primary soft tissue healing allows for the most predictable outcomes. Incision technique, flap design, soft tissue handling, and avoidance of transitional prosthesis pressure are key factors in avoiding ILO.

Wound dehiscence may be associated with increased discomfort and the need for closer monitoring. More postoperative appointments are required. These are financially nonproductive and negatively impact practice profitability. Some patients may seek care or a second opinion because of loss of confidence in the primary clinician. When ILO occurs, the clinician should be proactive in follow-up care and educating the patient on the complication consequences.

Prevention of Incision Line Opening

Good Surgical Technique

The implant clinician should adhere to the following surgical principles to minimize and promote optimum wound healing and decrease the possibility of ILO.

Incision in Keratinized Tissue. The primary incision should ideally be located in keratinized tissue whenever possible. This permits increased wound surface area and a resultant increase in vascularity to the incision. Not only does this reduce the initial intraoral bleeding, it also severs smaller blood vessels and reduces postoperative edema, which may add tension to the incision line. If there is 3 mm or more of attached gingiva on the crest of the edentulous ridge, the incision bisects this tissue. This places half of the attached gingiva width on each side of the incision. If there is less than 3 mm of attached keratinized tissue on the crest, the incision is made more lingually so that at least 1.5 mm of the attached tissue is placed to the facial aspect of the implant. This concept is very important in the posterior mandible because attached tissue is needed to prevent tension and pulling from the buccinator muscle (Fig. 31.35).[73]

Broad-Based Incision Design. The apex or tip of the flap should never be wider than the base (e.g., diverge from incision base to the apex). This will maintain adequate vasculature that will prevent ischemic necrosis to the flap, decreasing the possibility of ILO. The length of the flap should generally not exceed twice the width of the base. In addition, the base of the flap should not have significant pressure or be excessively stretched or twisted, which may compromise the blood supply (Fig. 31.36).[74]
● **Fig. 31.35** Incision should always maintain attached tissue on the facial.

● **Fig. 31.36** Anterior papilla-sparing incision with broad-based design.

Allow for Adequate Access. The flap should be large enough to provide adequate visualization of the surgical site and allow for the insertion of instruments to perform the surgical procedure. If the flap is too small, a retractor will not be able to maintain the flap without excessive pressure. Excessive retraction pressure will lead to increased inflammation, which may compromise the healing of the incision line.

Vertical Release Incision to Maintain Blood Supply and Decrease Tension on Flap. The blood supply to the reflected flap should be maintained whenever possible. The primary blood supply to the facial flap, which is most often the flap reflected for an implant or bone graft, is from the unkeratinized mobile mucosa. This is especially true where muscles of facial expression or functional muscles attach to the periosteum. Therefore vertical release incisions are made to the height of the mucogingival junction, and the facial flap may be reflected approximately 5 mm above the height of the mucogingival junction. Both of these incision approaches maintain more blood supply to the facial flap. In addition, incisions and reflection in the mobile alveolar mucosa increase flap retraction during initial healing, which may contribute to ILO and may increase risk for scar formation and delayed healing of the incision line as a consequence of reduced blood supply.

Vertical release incisions should not be made over bony prominences (e.g., canine eminence) because this will increase tension on the incision line and may increase the possibility of ILO (Fig. 31.37).
● **Fig. 31.37** Vertical release incisions to allow for tension-free closure.

Maintain Flap Margins Over Bone. The soft tissue flap design should also have the margins of the wound over host bone whenever possible. This is especially important when approximating tissue over bone grafts or barrier membranes. The host bone provides growth factors to the margins and allows the periosteum to regenerate faster to the site. The margins distal to the elevated flap should have minimal reflection. The palatal flap and the facial tissues distal to the reflected flap should not be elevated from the palatal bone (unless augmentation is required) because the blood supply to the incision line will be delayed. In addition, the unreflected flap does not retract during initial healing, which could place additional tension on the incision line. The soft tissue reflection distal to the graft site may be split thickness to maintain periosteum on the bone around the incision line. This improves the early vascularization to the incision line and adhesion of the margins to reduce retraction during initial healing.

Clean, Concise Incision. A clean incision is made through the tissue in one direction with even pressure of the scalpel. A sharp blade of proper size (i.e., #15 blade) should be used to be make clean, concise incisions without traumatizing the tissue from repeated passes or strokes. Tentative strokes, especially in different planes, will increase the amount of damaged tissue and increase the amount of bleeding. Long, continuous strokes are preferable to shorter, inconsistent, and interrupted strokes.[75]

Sharp dissection will minimize trauma to the incision line, which will result in easier closure. Care should be noted of vital underlying nerves, blood vessels, and associated muscles. Scalpel blades dull rather easily, especially when used on bone and tissue with greater resistance. The clinician should change blades when dulling is suspected to decrease tissue trauma. The incision should be made with the blade held perpendicular to the epithelial surface. This will result in an angle that produces square wound margins that are easier to reorient during suturing and less likely for surgical wound necrosis to occur.

Full-Thickness Reflection and Ideal Flap Elevation. Ideally the flap should be full thickness and include the surface mucosa, submucosa, and periosteum. The periosteum is necessary for healing; the replacement of the periosteum in its original position will increase healing.

Tissue elevation should be completed with extreme care. Meticulous handling is required to minimize trauma to the soft tissue. Proper use of appropriate tissue forceps, avoidance of excessive suctioning by the assistant, and "tie-back" sutures all contribute to improved flap management. Nonlocking tissue pick-ups, also called "thumb forceps," are commonly held between the thumb
● **Fig. 31.38** Full-thickness flap and reflection.

and two or three fingers of one hand. Spring tension at one end holds the grasping ends apart until pressure is applied. These forceps are used to hold tissues in place when applying sutures and to gently retract tissues during exploratory surgery. Tissue forceps can have smooth tips, cross-hatched tips, or serrated tips (often called "mouse's teeth"). Serrated forceps used on tissues will cause less tissue damage than smooth surface forceps because the surgeon can grasp with less overall pressure.

Smooth or cross-hatched forceps are used to move dressings, remove sutures, and perform similar tasks.

During flap elevation, elevators should rest on bone and not on soft tissue. Care should be exercised not to continuously suction the tissue because this may irritate and traumatize the tissue margins. Use of variable-suction tips with fingertip control can help minimize tissue damage. After flap replacement, it is advantageous to apply pressure to the tissue for several minutes to minimize blood clot thickness and to ensure bleeding has stopped.

Minimizing surgical operating time will directly benefit soft tissues and will reduce the risk for infection.[76] The tissue retractors should be selected and placed in a position to prevent undue pressure on tissues. Maintaining the retractors on bone and not on the tissue will minimize trauma to the tissue. Excessive pressure and tension on the tissue flap will impair blood circulation, alter the physiologic healing of the surgical wound, and predispose the wound to bacterial colonization (Fig. 31.38).

Papilla-Saving Incisions. The interproximal soft tissue in sites next to adjacent natural teeth may be classified into three categories: (1) papillae have an acceptable height in the edentulous site, (2) papillae have less than acceptable height, or (3) one papilla is acceptable and the other papilla is depressed and requires elevation.

When the interproximal papilla has an acceptable height, "papilla-saving" incisions are made adjacent to each neighboring tooth. The vertical incisions are made on the facial aspect of the edentulous site and begin 1 mm below the mucogingival junction, within the keratinized tissue. Extending the vertical incisions beyond the mucogingival junction increases the risk for scar

formation at the incision site. The full-thickness incision then approaches the crest of the edentulous site, leaving 1.0 to 1.5 mm of the interproximal papilla adjacent to each tooth. The vertical incisions are not wider at the base than the crestal width of tissue. This permits the facial flap to be advanced over the implant or short and adjacent to a permucosal extension at the conclusion of the procedure, with no voids at the incision line and primary closure.

Hemostasis. Hemostasis is important for many reasons, such as providing a clean surgical field for accurate dissection and flap elevation, along with decreasing trauma. Bleeding can occur from arteries, veins, or capillaries and may result in diffuse, continuous oozing. Ideally complete hemostasis should be achieved before the closure of the wound. If not, the continuous bleeding or hematoma will prevent the apposition of the surgical wound. There are many mechanical, thermal, and chemical methods that may be used to achieve adequate hemostasis. Care should be noted that the use of active or passive hemostatic agents, along with electrocauterization of the wound margins, may decrease the normal physiologic healing of the wound margins and predispose the site to infection and possible wound dehiscence. If hemostatic agents are used (e.g., cellulose), they should be removed after hemostasis is accomplished because this may interfere with surgical wound healing.

Prevent Desiccation of the Tissue. The tissues should be maintained in a moist environment without prolonged periods of desiccation. If drying of the tissues occurs, there is less likelihood that complete wound closure will occur. If the tissue margins become desiccated, periodic irrigations with sterile saline (0.9% sodium chloride) or a saline-moistened gauze may be used.

Relieving Tissue (Tension Free). Excessive flap tension is the most frequent causative factor of ILO. This is best prevented by appropriate incision and flap design, the use of periosteal releasing incisions (PRIs), and blunt dissection ("tissue stretching"). Past techniques to expand tissue primarily used a more apical tissue reflection and horizontal scoring of the periosteum parallel to the primary incision. Historically the vestibular approach by Brånemark allowed for optimal visualization of anatomic landmarks, suturing remote from the surgical area, complete tissue coverage, as well as predictable primary closure and healing.[77] The postoperative disadvantages of this approach include distortion of the vestibule and other anatomic landmarks, edema, difficult suture removal, and cumulative patient discomfort.[78] Langer and Langer[79] documented the use of overlapping partial-thickness flaps. This approach results in extension of the coronal aspect of the buccal or palatal flap, allowing primary intention closure around the site in an overlapping manner. This is usually effective for primary closure when less than 5-mm advancement of the flap is necessary.

A submucosal space technique developed by Misch[80] in the early 1980s is an effective method to expand tissue over larger grafts (greater than 15 × 10 mm in height and width) (Box 31.2).

The utility of periosteal incision for gaining flap release was studied by Park et al.[81] They found that flaps could be advanced up to 171.3% (>1.5 times longer than its original length) by two vertical incisions and a PRI under a minimal tension of 5 *g*, whereas one or two vertical incisions without PRI could advance the flap only 113.4% and 124.2%, respectively. These results suggested that PRI can be predictably used to attain tension-free primary closure under a minimal pulling tension of flaps (Fig. 31.39).

• BOX 31.2 Submucosal Space Technique[153]

1. The full-thickness facial flap first is elevated off the facial bone approximately 5 mm above the height of the vestibule.
2. One incision with a scalpel, 1 to 2 mm deep, is made through the periosteum, parallel to the crestal incision and 3 to 5 mm above the vestibular height of the mucoperiosteum. This shallow incision is made the full length of the facial flap and may even extend above and beyond the vertical release incisions. Care is taken to make this incision above the mucogingival junction; otherwise the flap may be perforated and delay soft tissue healing.
3. Soft tissue scissors (e.g., Metzenbaum) are used in a blunt dissection technique to create a tunnel apical to the vestibule and above the unreflected periosteum. The scissors are closed and pushed through the initial scalpel incision approximately 10 mm deep, then opened slowly.
4. This submucosal space is parallel to the surface mucosa (not deep toward the overlying bone) and above the unreflected periosteum. The thickness of the facial flap should be 3 to 5 mm because the scissors are parallel to the surface. This tunnel is expanded with the tissue scissors several millimeters above and distal to the vertical relief incisions.
5. The submucosal space is developed and the flap is advanced the distance of the "tunnel" and draped over the graft to approximate the tissue for primary closure without tension. Ideally the facial flap should be able to advance over the graft and past the lingual flap margin by more than 5 mm. The facial flap may then be returned to the lingual flap margin and sutured. This soft tissue procedure is performed before preparing the host region for any type of bone grafting or augmentation around an implant.

● **Fig. 31.39** Tension-Free Closure. Facial flap can be pulled over the lingual flap by a minimum of 5 mm.

Decreasing "Dead Spaces"

Gentle pressure is applied to the reflected soft tissue flaps for 3 to 5 minutes. This pressure may reduce postoperative bleeding under the flap, which may cause "dead spaces" and delayed healing. Any stagnant blood under the flap is "milked" from under the soft tissue by gentle pressure. This also allows the fibrin formation from the platelets to help "glue" the flap to the graft site.

Decrease Inflammation

Systemic corticosteroids or NSAIDs may be administered before and after surgery to decrease soft tissue edema because edema has been shown to contribute to ILO.

● **Fig. 31.40** Ideal Provisional Prosthesis. (A) Postsuturing image. (B) Snap-On Smile prosthesis. (C) Insertion of prosthesis.

● **Fig. 31.41** Essix Appliance.

Transitional and Interim Prosthesis Design

Occlusal forces applied to a removable prosthesis over a healing implant or graft site may also cause ILO of soft tissues and delay wound healing. Without appropriate adjustment, these forces can easily result in ILO by compressing the surgical area during function before suture removal. The potential for crestal bone loss is increased during any graft healing or around implants during stage I healing, which may lead to implant failure from early loading. Although use of such prostheses should be discouraged, other strategies to minimize or eliminate this possibility would include extensive relief of the intaglio surface, flange elimination, and use of tissue conditioners.

Much more preferable provisional tooth replacement(s) would be either tooth or implant (transitional) supported (Fig. 31.40).

Other examples of fixed transitional prostheses would include the bonding of natural tooth crowns or denture teeth to the teeth bounding the edentulous space and modification of existing fixed partial denture, that is, pontic shortening. Removable transitional prostheses, such as an Essix retainer or Snap-On Smile prosthesis, are frequently used because of their rigid support and resultant lack of pressure on the incision line. A resin-bonded fixed restoration can also be fabricated to provide improved function, especially when crestal bone regeneration is performed.

The prosthesis may depress the interdental papillae of adjacent teeth. As a result a resin-bonded fixed prosthesis is fabricated for the extended healing, and a removable device may be used short term for cosmetic emergencies (if the prosthesis debonds) (Fig. 31.41).

When a resin-bonded restoration is used, the adjacent teeth are not prepared and the device is bonded to teeth below the centric occlusal contacts. The interdental papillae are often depressed after initial socket healing. This type of transitional restoration for the single-tooth implant has the multiple benefits of being off the soft tissue drape, the developing bone augmented site, and the healing implant-bone interface.

Several options to the resin-bonded device permit these goals. An Essix appliance is an acrylic shell, similar to a bleaching tray, that has a denture tooth attached to replace the missing tooth. This prosthesis is the simplest treatment for tooth replacement postsurgery.

When an adjacent tooth requires a crown be added to the orthodontic wire, a cast-clasp RPD with indirect rest seats, which prevents rotational movements on the surgical site, is an excellent option.

Atraumatic Suture Removal

Removing sutures too early or traumatically may result in ILO and cause delayed healing, leading to morbidity of the implant or bone graft.

Normally nonresorbable sutures or extended absorbable sutures are removed within 10 to 14 days after surgery. Suture removal should include the following steps:

1. Patient rinses lightly with 0.12% chlorhexidine gluconate.
2. With tissue pick-ups, hold up the knot end of the suture and cut the suture closest to the tissue. Care should be exercised not to traumatize or irritate the surgical wound.
3. Gently pull the suture out with the knot outside of the tissue. Do not pull the knot through the tissue to remove.
4. Have the patient rinse with 0.12% chlorhexidine. Evaluate and make sure the interim prosthesis does not impinge on the surgical wound. The adjacent tooth may be prepared and a cantilevered transitional fixed partial denture with a pontic over the surgical site may be used. When the patient requires orthodontics, a denture tooth and an attached bracket may be added to the orthodontic wire.

Management of Incision Line Opening

In the dental implant literature there are two treatment recommendations discussed with respect to ILO. The first is to allow the surgical wound to heal via secondary intention with the use of antimicrobials and hygiene measures. The second treatment modality is to resuture the opened surgical wound, which is not recommended by the author (Table 31.3).

To allow the site to heal by secondary intention, there needs to be significant discipline and patient cooperation for a successful outcome. This treatment technique is dictated by many variables, such as the health of the existing tissue, tissue thickness, location, age of the patient, and size of the dehiscence.

For an incision line opening to heal correctly, strict post-op instructions and procedures must be adhered to by the clinician and the patient. First, the clinician should make sure that no external influence may directly traumatize or delay the healing. If an interim prosthesis is being used, care should be exercised to minimize any direct contact with the incision line. The intaglio surface of the prosthesis over the incision line should be modified

TABLE 31.3	Treatment of Incision Line Opening	
Surgical Procedure	**TREATMENT**	
	Early (<1 Week)	**Late (~>3 Weeks)**
Implant: One stage	Secondary intention protocol (resuture ONLY if favorable conditions)	Secondary intention protocol
Two stage	Secondary intention protocol	• Remove overlying tissue with tissue punch bur or scalpel • Place permucosal extension (≈1 mm above tissue; higher extension may lead to excessive force on the implant) (Fig. 31.42)
Bone Graft: Particulate graft	Secondary intention protocol	Secondary intention protocol
Block graft	Secondary intention protocol	• Check for mobility of graft • Reduce sharp bony edges • Freshen wound edges with diamond bur
Membrane: Collagen (regular)	Secondary intention protocol	Secondary intention protocol
Collagen (extended)	Secondary intention protocol	Secondary intention protocol • Trim excess membrane above tissue level with scissors
Acellular dermal matrix (AlloDerm)	Secondary intention protocol	Secondary intention protocol • Trim excess membrane above tissue level with scissors
Nonresorbable (cytoplast, titanium)	Secondary intention protocol	• Remove membrane if chronic tissue irritation or infection • Ideally attempt to maintain for at least 6 weeks

accordingly to be concave, not convex. The stress bearing areas (i.e. Maxilla – horizontal palate and residual ridge, Mandible- buccal shelf) should be maintained to absorb the occlusal forces. In addition, the ILO should be locally cleaned with 0.12% chlorhexidine. The patient should be placed on a strict recall, ideally seen every week for the first month.

The patient should be instructed to rinse non-vigorously with 0.12% chlorhexidine twice a day. Strict avoidance of smoking and alcohol use as this will delay healing. If an interim prosthesis is being used, no denture adhesive should be positioned over the ILO area. And lastly, the patient should be instructed to not evaluate the site, especially by pulling the lip up to inspect the area. This will stretch the incision line and most likely will result in further dehiscence (Box 31.3).

Resuturing Protocol

Resuturing is most often not recommended because it is an unpredictable technique and in some cases increases the amount of dehiscence. When attempting to resuture a fresh wound, usually the epithelium is thin and friable, which often leads to tearing of the incision line. This may result in a larger dehiscence or infection. If completed, the margins of the tissue should be "freshened" with a scalpel or a diamond bur. Greenstein et al.[82] have recommended that, when the dehiscence is small and occurs within 24 to 48 hours, the clinician may immediately resuture the dehiscence. Once the wound is large (2–3 cm) or the time elapsed is more than 2 to 3 days, it becomes more difficult for the margins of the wound to be excised and resutured. It is the author's recommendation to be cautious with resuturing incision lines that may end up resulting in increased morbidity of the surgical wound (Fig. 31.42).

• BOX 31.3 Secondary Intention Protocol

Clinician
1. Relieve prosthesis to have no buccal flange and no contact on the surgical wound area.
2. Maintain stress-bearing areas on the prosthesis with the use of a tissue conditioner; however, material should be removed from the dehisced area.
3. Locally clean the dehiscence area with 0.12% chlorhexidine.
4. Employ closer observation of the patient to include recall appointments a minimum of once a week for the first month.

Patient Instructions
1. Nonvigorous rinse with 0.12% chlorhexidine twice daily and plaque control.
2. Minimize the use of interim prosthesis.
3. No direct mastication on the area of dehiscence.
4. Avoid smoking and the use of alcohol.
5. Avoid peroxide and alcohol-based mouth rinses.
6. Avoid acidic foods.
7. Avoid inspection of dehiscent site (pulling on lip to see area).
8. Do not use any denture adhesive with the interim prosthesis.

Biomechanical Complications

Screw Loosening

Abutment screw loosening has been shown to be associated with an approximately 6% of implant prostheses fabricated.[83] Screw loosening is the most common implant prosthetic complication, accounting for approximately 33% of all post-implant prosthodontic complications.[84] More recent studies indicate this
● **Fig. 31.42** Resuturing Complication. (A) Two weeks postoperatively showing suture breakdown. (B) After resuturing, complete bone graft is exposed. This is why resuturing is not recommended.

complication occurs in approximately 8% of single crowns, 5% of multiple-unit fixed prostheses, and 3% of implant overdentures. De Boever et al.[85] have shown that 12% of prostheses exhibit loosening within 3 years, whereas Chaar et al.[86] have shown an incidence rate of 4.3% within 5 years and approximately 10% long term (5–10 years). Screw loosening may cause considerable complications. A loose screw may contribute to crestal bone loss because bacteria are able to colonize and harbor in the open interface. When an abutment screw becomes loose on a cemented crown, the crown may need to be cut off the abutment to gain access to the abutment screw, which results in patient disappointment and unproductive clinician time. If a loose abutment screw is not treated appropriately, fracture of the prosthesis, implant components, or the implant body may occur.

Etiology

External Force Factors. External forces that act on a screw joint greatly increase the risk for screw loosening. These forces may be called *joint-separating forces* when related to screw loosening; however, they are the same forces that are risk factors for implant failure, crestal bone loss, and component fracture. When

the external joint-separating forces are greater than the force holding the screws together (called *clamping forces*), the screw will become loose. The external forces from parafunction, crown height, masticatory dynamics, position in the dental arch, and opposing dentition are factors that can dramatically increase the stress to the implant and the screw joint. In addition, conditions that magnify or increase these factors are cantilevers, angled loads, and poor occlusal designs. External forces applied to the joint system are important to account for when the aim is to decrease the incidence of screw loosening. The endurance limit of a material is the amount of force required to fracture the object when enough cycles are applied. The greater the force, the fewer cycles required before fracture occurs. It is the combination and relationship of both the amount of force and the number of cycles that is the cause of the screw loosening complication.

Cantilevers/Increased Crown Height Space. One of the most common causative factors resulting in screw loosening is excessive continuous occlusal forces. The most common example occurs in prostheses with improper occlusal contacts. The greater the stress applied to the prostheses, the greater the risk for abutment screw loosening. A nonideal prosthetic design may potentiate the force applied. Cantilevers increase the risk for screw loosening because they increase the magnitude of forces to the implant system: there is a direct relationship between the length of the cantilever and force applied to the prosthesis.[87] Any of these external forces applied to a cantilever will further magnify the joint-separating forces. For example, cantilevers on prostheses lead to uneven occlusal loads. Uneven occlusal loads cause repeated cycles of compression and then tension and shear of implant components. Screws are especially vulnerable to tensile and shear forces. Both of these are dramatically increased with cantilever forces or angled loads. Because the screw is an inclined plane, the continued vibration causes it to unthread.

The greater the range of external forces, the fewer the number of cycles necessary before screw loosening. When an increased crown height space exists (poor crown/implant ratio), there is a resultant greater force applied to the screw. This usually results in a greater risk for screw loosening (or fracture). Boggan et al.[88] demonstrated that the force that is applied to the screw is directly related to the crown height. The crown height acts as a vertical cantilever, which magnifies the force on the abutment screw.

Parafunction. Of all the external forces that cause screw loosening, the primary factor is parafunction related. A horizontal bruxing patient loads the implant crown with an angled force repeatedly. This increases the magnitude of force, cycles to fatigue failure, and the angle of the force that places shear on the interface. Abutment screw loosening can be expected in a patient with a severe bruxing habit. A parafunction patient increases the amount of force to the system while also increasing the number of cycles to the system.

Hence fractures of porcelain and cement seals and also screw loosening or fracture are inevitable. When the adjacent natural teeth are mobile to lateral or angled forces, the rigid implant and implant crown may be overloaded. A heavy bite force occlusal adjustment, which allows the adjacent teeth to move before implant crown contact, is recommended to reduce the risk for overload. Continuous occlusal loads can have a cumulative effect on the preload, and the screw material may undergo deformation.[89] When the force exceeds the yield strength, plastic deformation occurs, and the screw begins to deform. This material deformation causes the screw to loosen and leads to potential failure of the prosthesis.
● **Fig. 31.43** (A) Nonpassive or improperly seated screw-retained restorations may be distorted when seated into position when the prosthetic screw is threaded. The distortion of the superstructure causes stresses that are concentrated at the crestal bone level and may result in bone loss. (B) Radiographic image depicting incomplete seating of abutment, which predisposes prosthesis to screw loosening.

Screw loosening is also affected by the amount of the force and the number of cycles, and is similar to fatigue. External methods to limit screw loosening include factors that reduce the biomechanical stress. These include key implant positions (i.e., to distribute forces evenly), sufficient number of implants (i.e., adequate surface area), passive prosthetic frameworks, and adequate occlusal schemes.[90]

Splinted Versus Nonsplinted Crowns. Screw loosening of abutment or prosthetic screws occurs more often on individual implant crowns than on crowns that are splinted together. For example, in a report for single molar replacement, the abutment screw-loosening rate was 40% during a 3-year period. When two splinted implants were used to replace the molar space, the screw loosening was reduced to 8%.[91] The stress distribution of splinted prosthetic units results in less force applied to the screw system. Studies have shown that splinted implant-retained overdentures have far less screw loosening in comparison with fixed prostheses.[92]

Crown/Abutment Not Fully Seated. If the abutment is not fully seated because of improper abutment placement, tissue impingement, or bone impingement, a poor distribution of force in the screw system will result, which leads to increased screw loosening. When the abutment is not fully seated and completely tightened, the prosthetic screw will be distorted, which leads to inadequate preload and subsequent screw loosening or fracture (Fig. 31.43).

Insufficient/Excessive Torqueing. When improper preload via the torqueing process is applied to the abutment screw, screw loosening will often occur. This may be caused by either excessive or insufficient tightening of the abutment screw. An implant screw is similar to a bolt joint in engineering. There is a preload (tightening force) placed on the screw, which develops a force within the screw. As the screw is tightened, it elongates, producing tension, which results in the implant screw acting like a spring. The preload stretch of the screw is maintained by frictional force, and the tension between the screw and the implant/abutment is termed a clamping force.

● **Fig. 31.44** Nonideal torque applied to the screw leads to a greater incidence of screw loosening. If the screw is not torqued sufficiently or overtorque occurs, insufficient preload will result, which will most likely result in screw loosening. The proper torque wrench and technique should be used according to the manufacturer's specifications because implant systems have various recommended torque values.

When insufficient preload is applied to the screw, there is insufficient clamping force, which ultimately leads to screw loosening, especially under occlusal loading. When excessive force is applied, the clamping force is easily released, and screw loosening will occur (Fig. 31.44).

Screw Diameter. The diameter of the abutment screw may have a significant effect on the amount of preload applied to the system before deformation occurs. The greater the screw diameter, the higher the preload that may be applied, which results in a greater clamping force on the screw joint. However, the coping and prosthetic screws vary greatly according to the type, size, and material. The strength of the material increases by a power of 4 when the diameter of the screw doubles (a screw with twice the diameter is 16 times stronger). As a result, abutment screws loosen less often because they can take a higher preload compared with coping and prosthetic screws. Some companies offer similar diameters for abutment and prosthetic screws. As a result a similar clamping force may be used for either component.

Screw Material. The composition of the screw is another factor that modifies its performance. The composition of the metal may influence the amount of strain in the screw from preload and the point of fracture, directly affecting the amount of preload that can be safely applied. Screw material and yield strength vary greatly when all other factors are similar (e.g., 12.4 N for a gold screw to 83.8 N for a titanium alloy screw fixation).[93]

The deformation or permanent distortion of the screw is the endpoint of the elastic modulus. Titanium alloy has four times the bending fracture resistance of grade 1 titanium. Abutment screws made of grade 1 titanium deform and fracture more easily than the alloy. Titanium alloy is 2.4 times stronger than grade 4 titanium. As such, a higher torque magnitude can be used on the titanium alloy abutment screw and female component (found within the implant body), less on grade 4 titanium, less on grade 1 titanium, and the least on gold screws.

The elongation of metal is related to the modulus of elasticity, which depends on the type of material, width, design, and the amount of stress applied. The material of which the screw is made (e.g., titanium alloy, titanium, or gold) has a specific modulus of elasticity. A prosthetic gold screw exhibits greater elongation than a screw made of titanium alloy but has a lower yield strength.

Although the strengths of titanium grades are dramatically different, the modulus of elasticity is similar for grade 1 to 4 titanium. Hence the strain of the abutment screw is similar with each grade of titanium, but the safety load relative to fracture is different. Titanium alloy (grade 5) has a slightly higher modulus of elasticity. Although not clinically relevant to metal-bone osseointegration, the titanium alloy screw should have a slightly higher preload value. This is not a consequence relative to permanent deformation or fracture because it is more than twice as strong as the other grades of titanium.

The metal for the screwdriver used in the torque wrench is also important to consider. Stripping of the screw head prevents the clinician from tightening or removing the screw. Some manufacturers fabricate the torque wrench driver out of titanium alloy, and the screw is made of gold or titanium. The concept is that the torque wrench will not deform the hexagon and will not strip, so the device lasts longer. However, this is not ideal. It is easier to replace the torque wrench driver than the abutment or prosthetic screw.

From a clinical standpoint the receptor site for the torque wrench is also a feature of the screw head to consider. The screw head has a rotation feature, most commonly a hexagonal design. The more sides to the rotation feature, the more often the head will strip. A slot or triangular feature will strip less than a hexagon.

Component Fit. In the science of machining metal components there is a range of dimensions that manufacturers use. For instance, an implant 4 mm in diameter may actually range from 3.99 to 4.01 mm. Likewise the abutment and prosthetic coping connection also has a range. As a result, if a smaller implant body hex dimension is mated with a larger abutment connection, the components may not ideally fit together. Most implant manufacturers allow for a misfit range that results in the abutment or coping being able to rotate 10 degrees on the implant body. Components between the abutment and implant body may have a misfit of 10 degrees in a rotational dimension, and horizontal discrepancies have been reported up to 99 μm.[94,95] These ranges are different with respect to each implant system. The more accurate the component fit, the less force is applied to the abutment or prosthetic screw.

The incidence of screw loosening is also a function of the accuracy of fit of the flat-to-flat connection of the implant and abutment or prosthetic component. Implant abutment connections or prosthetic connections with an unstable mating interface place undue stress on the screw that connects the components. Mechanical testing has demonstrated a direct correlation between the tolerance of the flat-to-flat dimension of the external hexagon and the stability of the abutment or prosthetic screw. Binon[96] showed that a mean flat-to-flat range of less than 0.005 mm exists on the hexagon, and a flat-to-flat range of less than 0.05 mm for the entire sample would result in a more stable screw joint. Studies have shown plastic castable patterns, which can be highly inaccurate, to have a vertical misfit as high as 66 μm.[97] The same manufacturing conditions apply to impression transfer copings and analogs. Many manufacturers have a wider machining range (+ or – variance) for the prosthetic components to reduce the cost of manufacturing. When transfer copings and analogs are used in impressions and then to fabricate the prosthesis in the laboratory and the implants are splinted together, the prosthesis may not passively seat.

Many manufacturers recommend the use of plastic (nonmetal) burnout posts. Plastic burnout prosthetic copings cost less, but they exhibit much greater laboratory variance and poor fit because of irregularities and settling of the superstructure. Besides cost, another advantage of a plastic burnout pattern for a coping is that one type of metal is used for the coping and superstructure, lessening the risk for metal corrosion or separation between the coping and superstructure.

A machined coping may be used to fit the implant abutment more accurately to reduce settling. Some manufacturers suggest a titanium coping to reduce the risk for misfit. However, oxides form on the titanium-machined coping surface and impair metal adherence when the prosthesis or abutment metal work is cast to the coping. Mechanical retentive features on the coping improve this metal-to-metal attachment. Laboratory studies demonstrate that an alloy-cylinder compatibility exists when noble-metal alloys are used rather than titanium for a superior metal-to-metal connection. A machine coping connection is still present, so it is superior to the plastic components used to cast one metal.[98] The risk of oxides forming between the coping and metal of the prosthesis is also reduced.

Implant Design. The type and design of the dental implant has a significant impact on screw loosening. As a general rule, most implant bodies have an antirotational feature for the abutment connection. The most common designs are an external hexagon, an internal hexagon, a Morse taper, and a Morse taper with threads.
• **Fig. 31.45** The higher (or deeper) the antirotational hexagon component (x component on the graph), the less the force applied to the abutment screw (Fs) on the y axis. A 0.7-mm hexagon height is standard in the industry and was used first by Nobel Biocare. A 1-mm hexagon height has less risk for screw loosening because the force on the screw is decreased.

• **Fig. 31.46** To reduce forces on the abutment screw, the platform diameter of the implant is more important than the hexagon height. The larger the diameter (x-axis), the less the force applied to the screw (y axis).

Factors that affect the abutment screw connection and screw loosening include the height (or depth) of the hexagon and the platform diameter. Boggan et al.[88] studied the influence of design factors on the mechanical strength and quality of fit of the implant abutment interface. Whereas failure mode for static test samples was bending or deformation of the abutment screw, fracture of the abutment screw was the common failure mode for the fatigue test samples. The static failure load was greater for the external hex implants of 1 mm in height, compared with implants with an internal hexagon of 1.7 mm. The larger-diameter implant had the greatest static load before failure.[88] As the hexagon height (or depth) increases, the load on the abutment screw decreases. Likewise, as the diameter of the implant platform increases, the force on the abutment screw decreases. Reduction of the lateral load (P) on the abutment screw is crucial to prevent the load on the screw to be beyond the yield strength of the material.

The height (or depth) of the antirotational hexagon is directly related to the force applied to the abutment screw with any lateral load. Because the crown is connected to the abutment and the abutment rests on the implant platform, a lateral force on the crown creates a tipping force on the abutment. This tipping force is resisted by the hexagon height or depth, the platform, and the abutment screw. When the arc of rotation is above the hexagon height, all of the force is applied to the abutment screw. For the hexagon height to be above the arc of tipping forces, the hexagon height must be at least 1 mm for a 4-mm-diameter implant. Yet many implant manufacturers feature a hexagon height of only 0.7 mm, so almost all of the force is directed to the abutment screw, increasing the occurrence of screw loosening and fracture (Fig. 31.45).

The difference between external (EC) versus internal connections (IC) has been well documented. Studies have shown that the incidence rate associated with EC implants was 18.3% at a mean of 5.3 years (217 of 1183 restorations; maximum, 59.9%).[99,100] The complication rate with internal connection (IC) implants was 2.7% at a mean of 4.5 years (142 of 5235 restorations; maximum, 31.6%).[101,102] Other studies have shown the external hex to have a significantly higher incidence of screw loosening than the internal hex (MA-EC, 15.1%; Zr-EC, 6.8%; MA-IC, 1.5%; Zr-IC, 0.9%).[103]

The platform dimension on which the abutment is seated is also an important factor in screw loosening. Larger-diameter implants, with associated larger platform dimensions, reduce the forces applied to an abutment screw and change the arc of displacement of the abutment on the crest module. For example, in a report by Cho et al.,[104] abutment screw loosening over a 3-year period was almost 15% for a 4-mm implant diameter but less than 6% for the 5-mm implant diameter (Fig. 31.46).
Screw Versus Cement Retained. When evaluating the prosthesis type (cement versus screw), studies have shown screw retained (8.5%) had a much higher incidence of screw loosening in comparison with cement retained (3.1%). These complications have a greater incidence with screw-retained restorations compared with cement-retained restorations because cement-retained restorations are more passive and have less strain on the implant system.[105] Although a cement-retained restoration is more common, screw-retained restorations are indicated when low-profile retention is necessary on a short abutment or when the implant bodies are more than 30 degrees from each other and splinting is required to restore the patient.

In addition, a screw-retained prosthesis has the advantage of less chance of tissue irritation because of the high incidence of retained cement with a cement-retained prosthesis. Screw loosening and partially unretained restorations are common complications of nonpassive castings. The more passive the fit on the implant abutment for screw retention and the more controlled the occlusal forces, the more secure is the prosthesis. The repeated compressive and tensile forces from nonpassive castings under occlusal loads cause vibration and loosening of the screw components. Accuracy in design and fabrication of the metal superstructure are determining factors for the reduction of forces at the implant abutment and implant-bone interface. Passive screw-retained restorations are more difficult to fabricate than passive cement-retained restorations. When the screw is threaded into position, the superstructure may distort, the implant may move within the bone, or the abutment screw may distort. The distortion of the superstructure and implant system may reach a level such that a 500-μm original gap may not be detectable.[106] As a result the casting may appear to fit the implant abutment for screw retention. However, the superstructure, bone, and components do not bend beyond their elastic limit, and compression, tensile, and shear forces are placed on the bone-implant interface.[107] The bone must remodel to eliminate these forces. If the forces are beyond physiologic or ultimate strength limits, resorption of the

bone-implant interface occurs. As a result, greater crestal bone loss has been associated with nonpassive castings. Creep (a constant force applied over time on a material) or fatigue also can contribute to fracture of the components over time because of a constant load or cyclic load frequency.

Anatomic Location. The location of the prosthesis in the oral cavity is also a significant factor in the incidence of screw loosening. Sadid-Zadeh et al.[108] showed a significant incidence difference with respect to anatomic locations, anterior (12.8%; 51 of 398 restorations) and posterior positioning (4.8%; 144 of 2972 restorations). However, when evaluating internal connection implants, they had an associated higher incidence of screw loosening in the posterior region (4.3%) than the anterior region (0.7%).

Prevention

Decreased Force. Because of the directional relationship between force and screw loosening, the evaluation, diagnosis, and modification of treatment plans related to stress conditions are of considerable importance. After the clinician has identified the source of excessive force on the implant system, the treatment plan is altered in an attempt to minimize the negative impact on the longevity of the implant, bone, and final restoration.

Prosthetic Design. The prosthetic design may be altered to minimize the possibility of screw loosening. Ideal implant placement in the key implant positions should be adhered to.

Cantilevers should be eliminated or reduced, especially when high occlusal forces are present. In addition, implant protection principles should be adhered to, including reduction of cuspal inclines of the prosthesis (decreased cusp height), decreased occlusal table, and no lateral contacts, especially in the posterior.

Ideal Preload. The ideal torque force on an abutment screw varies by manufacturer and may range from 10 to 35 N-cm. This preload is determined by many variables, including the screw material, screw head design, abutment material, abutment surface, and possible lubricant. To reduce the incidence of screw loosening, the abutment screw should be torqued by the following protocol:
1. Light finger-tighten with driver (~10 N-cm).
2. Maximum finger-tighten with driver (~20 N-cm).
3. Implant screw should be torqued to the manufacturer's specifications (~30-35 N/cm).
4. After 5 to 10 minutes, the screw should be retorqued to the same manufacturer's specifications.

NOTE: For cases of expected increased force, the implant screw may be retorqued a third time after 30 to 60 days.

Screw-Tightening Sequence. When screw-tightening a multiunit fixed implant prostheses, a proper sequence and technique is crucial to obtain the correct torque. The torque should be applied incrementally among all screws so that not one screw is tightened fully. This is based on the fact that a multi-unit prosthesis is unlikely to be "completely" passive. A nonideal tightening sequence will lead to either an insufficient or excessive amount of torque placed onto a specific screw thread. Undertorque will lead to insufficient clamping force and lack of ideal stretching of the screw. This will most often lead to screw loosening. Overtorque will lead to permanent deformation of the screw, which may lead to screw fracture.

Settling Effect. Settling is a term used to describe the effect of various implant parts wearing and fitting closer together. Minor irregularities on or within a casting that incorporates the top of an abutment or screw can cause slight elevation of the casting or the screw head. Over time, micromovement wears down the

irregularities, and the parts fit closer together. However, this settling relaxes the preload force on the prosthetic screw and is more likely to cause screw loosening. This embedment relaxation or loss of preload has been shown to be approximately 2% to 10% of the initial preload within the first few seconds or minutes after tightening. This is the reasoning for the earlier protocol to include a second retorque after 5 to 10 minutes to regain the lost preload due to settling.[109]

Torque Under Moist Conditions. Studies have shown when placing and torqueing abutment screws, more accurate torque values result under wet conditions versus dry.[110] Saline may be used to lubricate the screw before placement of preload to maximize the accuracy of the preload.

Wider Implant Bodies. The use of wider implant bodies results in decreased force on the screw. Graves et al.[111] have shown increasing implant size from 3.75 to 5.0 mm results in 20% greater strength, whereas increasing implant size from 3.75 to 6.0 mm increases the strength by 33%.

Treatment

When confronted with a mobile prosthesis, it is important to determine whether the mobility is a result of screw loosening or the actual implant being mobile (implant failure). Box 31.2 illustrates a technique to determine the cause of the prosthesis movement (Fig. 31.47).

Implant Movement. Mobility of the implant body indicates failure of the implant and necessitates immediate removal. A radiograph may reveal a circumferential radiolucency. The site should then be re-evaluated after adequate healing for the need of bone grafting, implant placement, or change in prosthetic treatment planning.

Abutment Screw Movement

Option 1. Removing a cemented crown from a mobile abutment is very challenging with conventional crown removal techniques (e.g., crown bumper). The impact force that is applied to the mobile crown is dissipated because of the loose screw. This may result in damage to the internal threads of the implant body. In addition, when an implant crown margin is subgingival, it is often difficult to obtain access for the crown remover. In poorer bone densities, overzealous use of a crown remover may result in loss of the bone-implant interface.

Option 2. The safest and most predictable treatment option to treat abutment movement is accomplished with making an occlusal access and transforming the cement-retained crown into a screw-retained crown (Fig. 31.48).

Following are the steps for completing this procedure:
1. Evaluate and determine the location and angulation of the implant abutment screw (buccal-lingually and mesial-distally). An intraoral radiograph is often helpful.
2. With a round diamond bur (≈#8 round), access is made through the occlusal surface to remove the abutment screw (i.e., central fossa: posterior teeth and lingual aspect of crown in anterior teeth).
3. After the screw is located, the screw is engaged with the appropriate hex driver, reverse-torqued, and the screw is removed.
4. Discard old screw and place new screw.
5. Torque to the manufacturer's specifications with ideal protocol.
6. Cover access hole with filler (polytetrafluoroethylene) and opaque composite.

In situations where the access hole is through the facial aspect of the prosthesis (i.e., anterior crowns), the crown will need to be removed and a new crown fabricated. Care should be exercised
● **Fig. 31.47** (A and B) Checking buccal-lingual mobility of the prosthesis with a mirror handle. (C and D) Palpation of buccal and lingual cortical plates to evaluate the presence of pain.

when cutting the crown off because in most cases it is difficult to determine the cement location (Fig. 31.49).

This may result in sectioning the crown too deep, causing damage to the abutment, abutment screw, or implant body. A safer method includes the earlier technique (access with screw removal) with fabrication of a new prosthesis. If the abutment remains fixated to the prosthesis, the prosthesis can be easily removed by gently heating the prosthesis with a Bunsen burner.

Screw Fracture

Etiology

The causative factor most likely to induce screw fractures is biomechanical stress to the implant system. The biomechanical stress leads to partially unretained restorations or fatigue, which is directly related to an increased amount of force. Prosthesis screw fracture has been shown to occur with a mean incidence rate of 4% with a range of 0% to 19%. Abutment screw fracture is directly related to the screw diameter, with larger-diameter screws fracturing less often, and a mean incidence rate of 2% and a range of 0.2% to 8% (Fig. 31.50).[112]

Prevention

Immediate Treatment of Loose Screw. If an abutment screw is determined to be mobile, immediate treatment is recommended. The longer the period that force is applied to a mobile prosthesis, the greater the chance the abutment screw will be deformed and possibly fracture. The loose screw follows a fatigue curve that is related to the number of cycles and the intensity of the repeated forces.

Treatment

Explorer Removal. The easiest method to remove a screw is to rotate the screw counterclockwise with a sharp explorer tip.

• **Fig. 31.48** Loose Screw Removal Technique. (A) Occlusal access is made with a #8 round diamond bur. (B) Screw is easily removed with implant driver. (C) Access needs to be large enough to allow for screw removal. (D) Chlorhexidine irrigation of the internal threads. (E) A new screw is torqued into position according to the manufacturer's recommendations. (F) Sterile polytetrafluoroethylene is placed in the access hole after final torque. (G) Opaque composite placed into access.

• **Fig. 31.49** (A) Most commonly in the maxillary anterior the access may need to be made through the facial surface. (B) Care should be exercised in cutting cement-retained crowns off because the abutment screw may be irreversibly damaged.

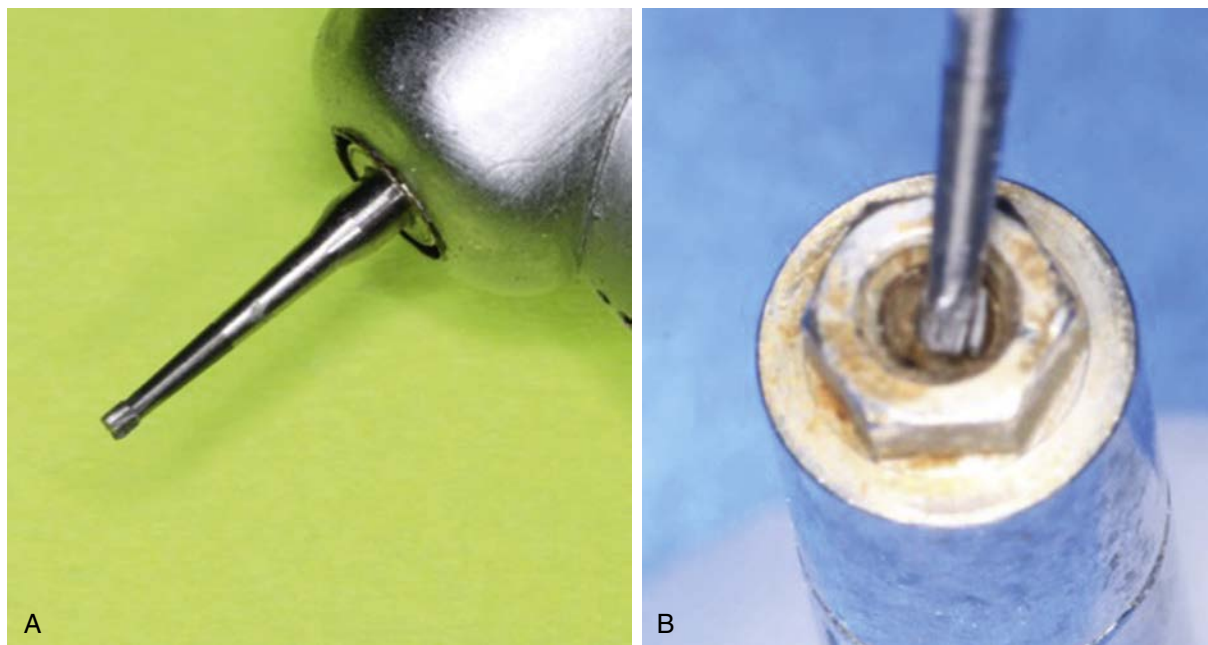
Because a loose screw has no preload, the fractured component remains passive in the implant body. If the screw has been deformed or debris has been introduced between the screw and the implant body, this technique may not be successful (Fig. 31.51).

Ultrasonic/Cavitron Device. If debris is present between the threads, an ultrasonic or Cavitron device may be used. The vibration (≈20,000–30,000 rpm) will usually dislodge the debris, and the screw can then be removed via the explorer method.

Round Bur (205LN). A very small round bur or 205LN can be used in a slow-speed handpiece or AS123 screwdriver. The tip of the bur is placed at the seam of the fractured screw and abutment (implant). As the bur spins clockwise, the friction placed on the screw makes it turn counterclockwise, and the screw unthreads.

Inverted Cone Bur (~33½ Bur). With an inverted cone bur in a high-speed handpiece (ideally electric handpiece in reverse), gently touch the top of the screw. This will usually result in the screw being extruded from the implant body. Care should be exercised to not touch the implant body with the bur because this will result in damage to the implant body threads. With this technique, always use a throat pack to prevent loss (Fig. 31.52).

Slot the Top of the Screw. A slot 1 mm deep is made through the center of the screw with a high-speed handpiece and a very narrow fissure bur (or 33½ bur). A small screwdriver is then used to unthread the screw. Be careful using this technique because the bur may inadvertently perforate the side of the implant body. There is no predictable method to repair the implant body if this occurs. The patient should be informed that implant failure may result as a consequence of this technique (Fig. 31.53).

Manufactured Retrieval Instruments. Multiple retrieval kits are on the market that are used to remove fractured screws. These are usually specific for the type of implant body type (internal, external, trilobe, etc.) (Fig. 31.54).
• **Fig. 31.50** (A and B) Fractured screws that usually occur from occlusal overload.
● **Fig. 31.51** Explorer Technique to Remove Broken Screw. (A and B) The screw may be easily removed if preload is lost by using the explorer in a counterclockwise direction.


● **Fig. 31.52** (A) Inverted cone (33½ bur) with handpiece. (B) The fractured screw is lightly tapped in the center of the screw, which will usually dislodge the screw. A throat pack should be used, and care should be exercised to not touch the internal walls of the implant.

● **Fig. 31.53** (A) Slot the top of the screw. A slot is made in the screw with a high-speed handpiece and narrow fissure bar. A screwdriver is then used to unthread the screw. (B) Use of an ultrasonic scaler to loosen debris between the screw and the internal threads of the implant.

Neurosensory Impairment

The iatrogenic injury of any of the branches of the trigeminal nerve is a major concern in implant dentistry. As the number of implants being placed each year keeps increasing, along with a greater number of clinicians performing the procedures, the incidence of nerve impairments will most likely continue to increase. The reported incidence of such nerve injuries after dental implant procedures is highly variable (0%–44%) in the literature.[113] Studies have shown that approximately 73% of doctors who perform implant surgery have experienced postoperative nerve complications.[114] Libersa et al.[115] evaluated transient versus permanent nerve injuries after implant placement and reported a permanent injury 75% of the time (Fig. 31.55).

When a nerve injury occurs, it is paramount the dental implant clinician be able to recognize the type and extent of injury, and provide the most appropriate postoperative care. Traumatic and iatrogenic nerve complications may involve total or partial nerve resection, crushing, thermal, stretching, or entrapment injuries. The resulting sensory deficits may range from a nonpainful, minor loss of sensation (hypoesthesia), to a more permanent and severe debilitating pain dysfunction (dysesthesia). The sensory complications from a nerve injury will usually result in an overall decreased quality of life for the patient and potential long-standing psychological problems.[116] Not only do these complications affect the patient, the clinician is often confronted with patient dissatisfaction, embarrassment, and possible medicolegal implications.

In the field of oral implantology today the clinician must have a thorough understanding of the cause, prevention, and treatment of neurosensory impairments. A postoperative classification and guidelines for the diagnosis and management of neurosensory deficits have been developed by the author, which is dependent on the history, type, and nature of the injury.

Specific Anatomic Areas Susceptible to Nerve Injury

Inferior Alveolar Nerve

Nerve impairment to the inferior alveolar nerve (mental nerve) is a common clinical complication with major medicolegal implications. Because of its anatomic location, the mental nerve is the most common nerve to be damaged via implants or bone graft procedures. Trauma usually occurs from placement of implants directly into the foramen or into the inferior alveolar canal in the posterior mandible. Sensory nerve injury may result in altered sensation, complete numbness, and/or pain, which may interfere with speech, eating, drinking, shaving, or makeup application and lead to social embarrassment.

The mandibular division of the trigeminal nerve (cranial nerve V) exits the skull base via foramen ovale and then divides into an anterior and posterior division. The anterior division of the mandibular nerve has mainly motor branches that innervate the temporalis, lateral pterygoid, and masseter muscles. The posterior division of the mandibular nerve is mainly sensory, which provides branches including the lingual nerve, inferior alveolar nerve, and auriculotemporal nerve. The inferior alveolar nerve divides into two terminal branches, the mental and incisive nerves.[117] The mental nerve courses anteriorly until it exits through the mental foramen, which is sensory to the soft tissues of the chin, lip, and anterior gingiva. The incisive nerve continues anterior and innervates the mandibular anterior teeth.

Most nerve injuries that occur in relation to dental implant surgery involve the inferior alveolar nerve. Accurately determining the exact location of the inferior alveolar nerve as it courses through the body of the mandible is imperative to avoid neurosensory disturbances secondary to implant placement. Histologically this inferior alveolar nerve consists of connective tissue and neural components in which the smallest functional unit is the individual nerve fiber. The inferior alveolar nerve fibers may be either myelinated or unmyelinated. The myelinated nerve fibers are the most abundant; they consist of a single axon encased individually by a single Schwann cell. The individual nerve fibers and Schwann cells are surrounded by the endoneurium, which acts as a protective cushion made up of a basal lamina, collagen fibers, and endoneurial capillaries.

Lingual Nerve

Within the infratemporal fossa the lingual nerve divides from the posterior division of the mandibular nerve (V3) as a terminal branch. As the lingual nerve proceeds anteriorly, it lies against the medial pterygoid muscle and medial to the mandibular ramus. It then passes inferiorly to the superior constrictor attachment and courses anteroinferiorly to the lateral surface of the tongue. As it runs forward deep to the submandibular gland, it terminates as the sublingual nerve.

● **Fig. 31.55** (A and B) Implant-induced nerve impairment.

The lingual nerve is sensory to the anterior two-thirds of the tongue, floor of the mouth, and lingual gingiva. It also contains visceral afferent and efferent fibers from cranial nerve VII (facial nerve) and from the chorda tympani, which relays taste information. With the prevalence of second molar implants, care should be taken to note the possible position of the lingual nerve on the medial ridge of the retromolar triangle, where it courses anteriorly along the superior lingual alveolar crest, which is slightly lingual to the teeth.[118]

Due to the lingual nerve's variable anatomic location, it may be iatrogenically traumatized during various implant surgical procedures. Usually the lingual nerve is not damaged from the actual osteotomy preparation of implants unless the lingual plate is perforated. This sensory nerve is most likely traumatized during soft tissue reflection during implant placement in the second molar area or incision/reflection over the retromolar pad for bone graft procedures.

In addition, the lingual nerve can suffer damage from lingual flap retraction and inferior alveolar nerve blocks. Studies have shown that lingual nerve impairment after nerve blocks occurs twice as often as inferior alveolar nerve damage.[119] This is most likely due to the fact the lingual nerve is most commonly unifascicular at the site of the injection. Sensory damage to the lingual nerve may cause a wide spectrum of complications ranging from complete anesthesia to paraesthesia, dysesthesia, drooling, tongue biting, change in taste perception, and change in speech pattern.

Nasopalatine Nerve

The incisive canals fuse and form a common Y-shaped canal that exits lingual to the central incisor teeth (incisive foramen or incisive fossa). The nasopalatine nerve passes through these canals and provides sensation to the anterior palate. These nerves (also termed *incisive nerves*) terminate at the nasal floor and enter the oral cavity via the incisive canal, which is underneath the incisive papilla. To prevent trauma to these nerves, ideal presurgical planning of implant placement in the maxillary incisor region should be carefully evaluated.

In the literature, many authors have advocated removing the contents of the nasopalatine canal and grafting with a high success rate.[120] Although this nerve is often affected by the placement of implants or bone grafting in the incisor region, sensory disturbances are rare. Nerve damage reported in the literature caused by complete removal[121] or flap surgery[122] is of short duration. This is most likely due to cross-innervation of the greater palatine nerve on the anterior palatal area.

Anterior Superior Alveolar Nerve

The anterior superior alveolar nerve branches from the infraorbital canal on the lateral face. This small canal may be seen lingual to the cuspid and is denoted as the canalis sinuosus. The canal runs forward and downward to the inferior wall of the orbit and after reaching the edge of the anterior nasal aperture in the inferior turbinate, it follows the lower margin of the nasal aperture and opens to the side of the nasal septum. Studies have shown that in approximately 15% of the population, this canal is approximately 1 to 2 mm in diameter. The canals present as a direct extension of the canalis sinuosus and may be clinically relevant when greater than 2.0 mm (Fig. 31.56).[123]

The canine pillar region is a key implant position for dental implants. Care should be exercised to evaluate for the presence of neurovascular bundles. Insertion of implants in approximation to the canal may be problematic because this may lead to a soft tissue interface and failure of the implant and temporary or permanent sensory dysfunction and possible bleeding issues. However, significant sensory impairments are rare because of cross-innervation. Many clinicians are unaware of the canalis sinuosus and may misdiagnose this radiolucency as apical pathology of the maxillary cuspid.

Infraorbital Nerve

The infraorbital nerve emerges from the infraorbital foramen and gives off four branches: the inferior palpebral, external nasal, internal nasal, and the superior labial branches, which are sensory to the lower eyelid, cheek, and upper lip. The inferior palpebral branches supply the skin and conjunctiva of the lower eyelid. The nasal branches
• **Fig. 31.56** Canalis sinuosus. (A) Anatomic variant that may lead to the placement of implants into the canal, leading to a soft tissue interface. supply the lateral nose soft tissue and the movable part of the nasal septum, and the superior labial branches supply the skin of the cheek and upper lip. Normally the average distance of the inferior border of the orbital rim to the infraorbital foramen is 4.6 to 10.4 mm.

Impairment of the infraorbital nerve may be very traumatic to patients. Damage to branches of the infraorbital nerve usually will result from retraction-related trauma (neuropraxia). Procedures involving the maxillary cuspid-bicuspid area are most susceptible to injuries. Anatomic variants of the infraorbital foramen have been shown to be up to 14 mm from the orbital rim. This is most likely seen in elderly female patients with extensive alveolar atrophy.

Etiology of Nerve Injuries

Most implant-related nerve impairments are the direct result of poor treatment planning and inadequate radiographic evaluation. Trauma to associated nerves in the oral cavity occurs when the implant clinician is not aware of the amount of bone or does not know the location of nerve canals or foramina. The preoperative evaluation and assessment are crucial to determine the amount of available bone in approximation to nerve anatomy. A CBCT examination is most commonly used for the three-dimensional planning in these areas.

Neurosensory impairment injuries may result from a wide array of intraoperative and postoperative complications. For example, nerves may be mechanically injured by indirect or direct trauma via retraction, laceration, pressure, stretching, and transection. Thermal trauma may cause inflammation and secondary ischemia injuries with associated degeneration. And lastly, peripheral nerves have been shown to be susceptible to chemical injuries, where the nerve is directly traumatized by chemical solutions.

Administration of Local Anesthesia

Adequate local anesthesia is paramount for successful dental implant surgery and stress reduction protocol. However, although rare, the use of nerve blocks may result in trauma to various branches of the trigeminal nerve. The exact cause of local anesthesia nerve damage is unclear, and various theories such as injection needle trauma, hematoma formation, and local anesthetic toxicity have been discussed.

Although the true incidence is difficult to quantify because of reporting difficulties, studies have shown permanent injury occurs in approximately 1 in 25,000 inferior nerve blocks. Most patients do recover fully without deficits, with full recovery in 85% of patients with complete remission in 8 to 10 weeks.[124]

Damage From Injection Needle. Complications resulting from needle trauma are likely the most common theory on why nerve injury results after administering nerve blocks. First, it is not uncommon for the tip of the needle to become barbed (damaged) when contacting bone. Stacy et al.[125] showed that 78% of needles became barbed after initial injection, increasing the possibility of damaging the nerve. Two-thirds of the needles developed outward-facing barbs, which have been shown to rupture the perineurium, damage the endoneurium, and cause transection of nerve fibers. The lingual nerve has been associated with the highest percentage of nerve impairment cases as a result of an anesthetic injection (~70%).[126] Because of the lingual nerve's anatomic location, it is predisposed to nerve injuries because it is commonly contacted when using the pterygomandibular raphe as an injection landmark because of the nerve being positioned shallow in the tissue (~3–5 mm from the mucosa).[127]

Hematoma. The anesthetic needle may also cause damage to the epineurial blood vessels, which may result in hemorrhage-related compression on the nerve fibers. The accumulation of blood may lead to fibrosis and scar formation, which may cause pressure-related trauma.[128] The extent of impairment to the nerve is directly related to the amount of pressure exerted by the hematoma and recovery time of the axonal and connective tissue damage.

Anesthetic Toxicity. If the anesthetic is injected within the fascicular space, chemical irritation and damage may occur. Studies have shown articaine to comprise 54% of mandibular nerve block injuries,[129] and it is 21 times more likely to cause injury in comparison with other nerve injuries.[130] Theories concerning articaine toxicity include the high concentration of articaine solution and the increased resultant inflammatory reaction.[131] Lidocaine has been shown to be the least toxic anesthetic, followed by articaine, mepivacaine, and bupivacaine.[132] Chemical trauma from local anesthetics has been shown to cause demyelination and axonal degeneration of nerve fibers.[134]

Soft Tissue Reflection

Injury to nerves and nerve fibers may occur during the reflection, retraction, or suturing of the soft tissue. This is most noted when the mental nerve is dehisced or exposed on the mandibular ridge. Special caution should be exercised when making incisions over these areas because complete transection injuries may occur from incisions through the nerve or foramen. Stretching injuries (neuropraxia) may occur from excessive retraction, so care should be noted as to the proximity of neural vital structures within the retracted tissue. A common stretching injury occurs with the infraorbital nerve, especially when implants or bone grafting are being performed in the canine and bicuspid region. Complete transection of the nerve may result from attempting to reduce the tissue tension over the surgery flap without regard to the anatomic location of the nerve (Fig. 31.57).

Implant and Implant Drill Trauma

The surgical drilling for implant placement may result in a direct or indirect neurosensory impairment.

Trauma. Direct trauma from surgical drilling may occur from overpreparation of the osteotomy site or lack of knowledge of the true bur length. The implant clinician must know and understand the true length of the surgical burs used in the osteotomy site preparation. For many surgical drill systems, the marked millimeter gauge lines inscribed on the shank of the drills most often do not include the cutting edge of the drill and do not correspond to the actual depth of the drill. Most surgical implant drills have a sharp, V-shaped apical portion to improve their cutting efficiency and allow adequate depth of drilling. The V-shaped apical portion of the drill (termed the *Y dimension* in engineering) is often not included in the depth measurements of the commercial drills and may measure as much as 1.5 mm longer than the intended depth. Therefore the clinician may inadvertently drill deeper than anticipated because of the drill design.

In addition, overpreparation may occur, especially in less dense bone. The implant clinician should use the initial implant osteotomy twist drill as a gauge for bone density type and for an evaluation of the position of the surgical drill relative to the mandibular canal or vital structure. In implant dentistry today the popularity of immediate placement implants has been associated with an increase in drilling-related trauma. To gain primary stability, most immediate implant osteotomy sites require drill preparation and implant placement apical to the extraction site. When placing implants in the mandibular premolar area, violation of the canal
● **Fig. 31.57** Periosteal release of the tissue to obtain tension-free closure, which may cause nerve injury. (A) The use of a #15 blade to release the periosteal fibers. (B) Blunt dissection to release tissue with Metzenbaum scissors.

● **Fig. 31.58** Drill Impingement Trauma. (A) Encroachment: even though the surgical drill is short of canal, thermal damage and bone necrosis (brown/green) result in nerve damage. (B) Partial penetration (hematoma): the surgical drill partially penetrates the superior aspect of the canal, resulting in bleeding and hematoma formation. (C) Partial penetration (laceration): the surgical drill penetrates deeper into the canal, which results in laceration of nerve fibers. (D) Transection: the surgical drill may penetrate the entire canal, leading to complete transection of the nerve fibers.

may occur, causing nerve damage. Therefore in this anatomic area, immediate implant placement is not recommended unless adequate bone is available below the root apex. The following subsections describe the various types of surgical drill trauma that may lead to a neurosensory impairment.

Thermal Trauma. The surgical drill may cause a nerve impairment from thermal damage even though the surgical drill does not violate the mandibular canal. Most commonly this is the result of insufficient irrigation, which leads to overheating the bone. The associated thermal trauma may lead to nerve impairment via bone necrosis from overheating the bone during preparation. Nerve tissue has been shown to be more sensitive to thermal trauma than bone (osseous) tissue. In the literature, excessive temperatures have been reported to produce necrosis, fibrosis, degeneration, and increased osteoclastic involvement.[30] To minimize this complication, the bone density should be evaluated preoperatively via CBCT examination, tactile evaluation, and location. In harder bone densities (e.g., D1 and D2), special care should be exercised in reducing the possibility of overheating the bone (see Chapter 27).

Partial Penetration. The surgical drill may also cause direct trauma to the neurovascular bundle by penetrating the mandibular canal or mental foramen. The neurosensory impairment will be directly related to the specific nerve fascicles that are damaged. Normally the vein and artery, which are positioned more superiorly than the nerve, will be damaged when penetration of the canal results. This indirect trauma leads to nerve damage from the excessive bleeding (hematoma), as well as thermal and chemical injuries from the penetration into the canal.

Transection. The most severe type of nerve injury, with the lowest probability of regeneration, is when the implant drill transects the canal. In a true transection the nerve is completely severed. When this occurs, repair and regeneration of the traumatized nerve are highly variable. Complete transection of the nerve occurs when surgical error involves the preparation of an osteotomy too deep because of inaccurate measurements or slippage of the handpiece. This type of injury results in the most severe of response, a total nerve impairment (anesthesia) and neuroma formation. Usually this type of nerve injury results in a complete anesthesia and retrograde degeneration, resulting in possible future dysesthesia.[135] The extent of neurosensory impairment is directly related to the extent of fascicle injury and is dependent on the time the implant is left to irritate the nerve fibers (Fig. 31.58).

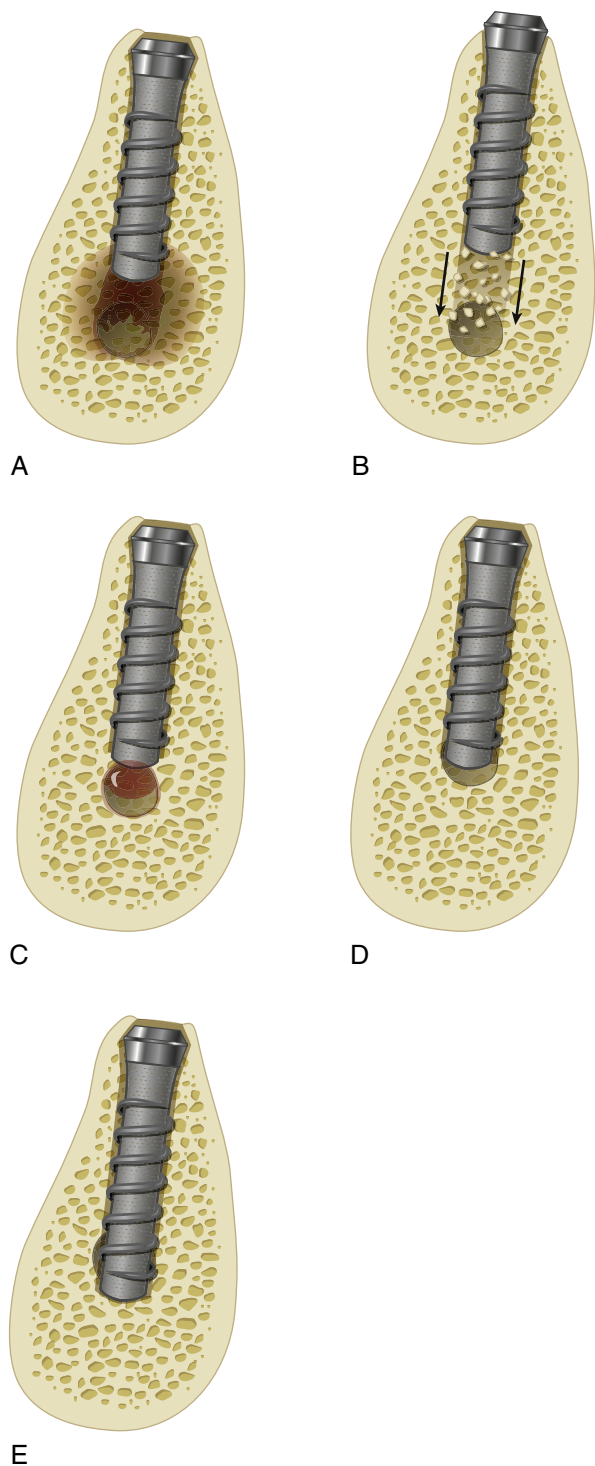
Implant Encroachment on the Mandibular Canal. Injuries to vital nerve structures caused by implant positioning are most common in the posterior mandible. These injuries may be caused by direct trauma (mechanical) and indirect trauma or infection (pressure). Placement of an implant into or near the mandibular canal is associated with many types of neurosensory impairments (Fig. 31.59). When an implant is too close to the mandibular canal, a compression or secondary ischemia injury may occur. To prevent these complications, the implant clinician should always adhere to a 2.0-mm safety zone of the implant in proximity to the canal or mental foramen. Studies have shown that implant pressure on the canal occurs with increasing stress as the bone density decreases.[136] Khaja and Renton showed that placing an implant too close to the canal may induce hemorrhage or deposition of debris into the canal, causing ischemia of the nerve. Even removing the implant or repositioning may not alleviate and decrease pressure-related symptoms. Additional studies have shown the presence of postoperative severe pain after implant placement in close approximation to the canal, resulting in chronic stimulation and debilitating chronic neuropathy.[137]

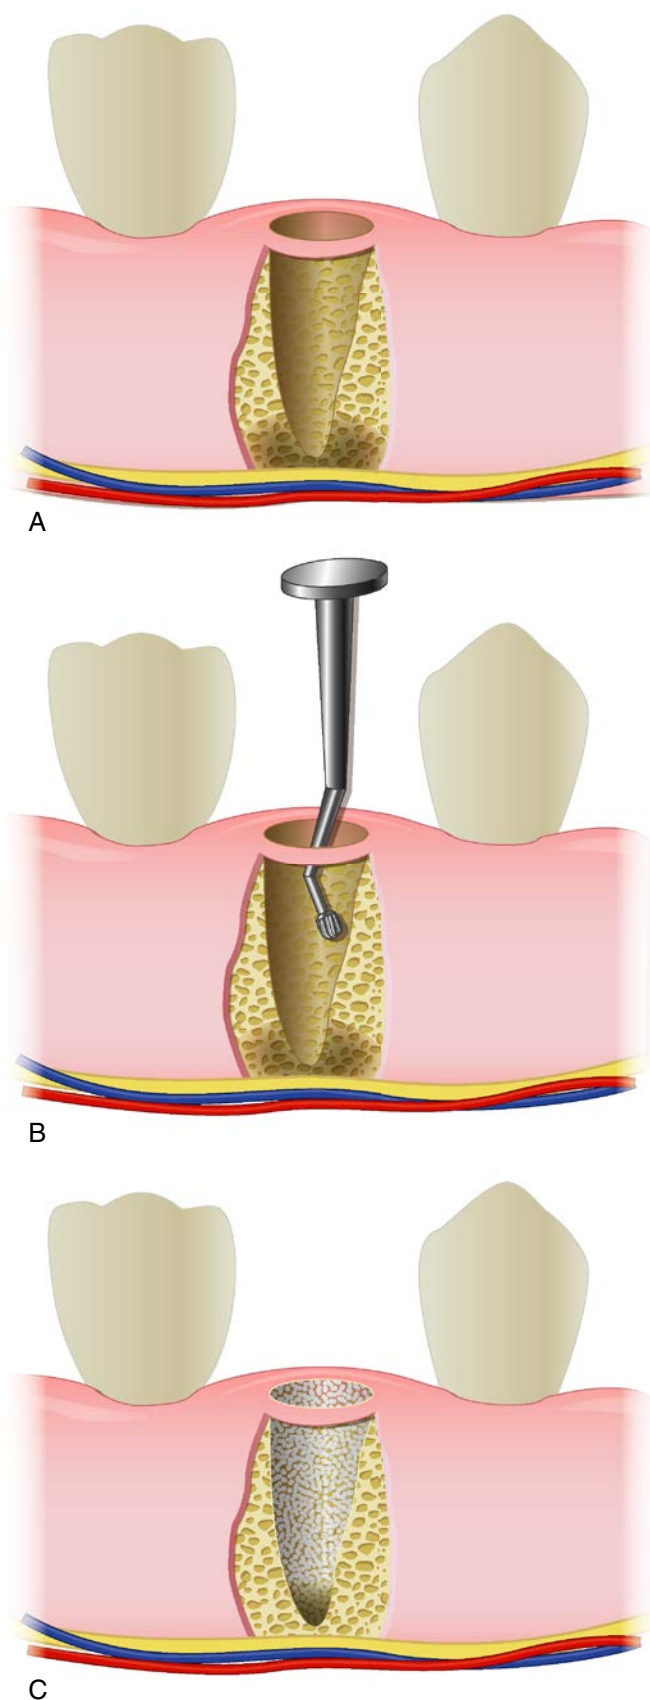
Partial Penetration Into the Mandibular Canal. Placement of the implant body into the mandibular canal is associated with a high degree of morbidity. Even though the sensory nerve fascicles are usually inferior to blood vessels within the canal, a partial penetration may result in an injury that is usually related to the fibers that are damaged. This is why in some clinical situations the implant is directly within the canal; however, no neurosensory symptoms exist.

In addition, implant placement into the canal may cause hematoma formation (severing of the inferior alveolar artery or vein), leading to a pressure-induced nerve impairment.

Infection. Placement of implants in approximation to the canal may cause neurosensory impairments via peri-implant infections. Infectious processes after implant placement may result from heat generation, contamination, or prior existence of bone pathology. This may lead to spread of infection that may extend into the neural anatomy. Case reports have shown nerve impairment issues resulting from an implant infected by chronic peri-implantitis.[33]

Mandibular Socket Grafting. After mandibular tooth extractions, grafting into the socket may effectively expose the inferior alveolar nerve to socket medicaments. This may lead to chemical neuritis, and if the irritation persists, an irreversible neuropathy may occur (Fig. 31.60). In addition, care should be exercised when removing pathology and granulation tissue from extraction sockets in close proximity to the nerve canal (type 1 nerve).[138] Overzealous curetting of the socket apex may lead to direct traumatic injury of the canal.

Delayed Nerve Damage (Canal Narrowing). Nerve damage may result even when ideal implant placement is performed (>2.0 mm from the nerve canal). Shamloo et al.[139] reported an implant placement case in which the implant body resulted in compression and bone to be forced into the superior aspect of the mandibular canal (canal narrowing). This led to delayed healing and remodeling within the canal and resulted in excessive narrowing of the canal, with compression of the nerve fibers. The narrowed aspect of the canal was shown be approximately 0.2 mm, with an average diameter in the nonaffected sites being approximately 3.2 mm.[139] The nerve impairment (paresthesia and anesthesia) occurred 2 years after implant placement surgery.


- **Fig. 31.59** Implant Impingement Trauma. (A) Encroachment: even though the implant body is short of the canal, thermal damage may occur from overheating the bone. (B) Bone fragments (trabeculae) may be pushed apically, resulting in a pressure necrosis nerve injury. (C) Partial penetration (hematoma): the implant body may partially penetrate the superior aspect of the canal, resulting in bleeding and hematoma formation. (D) Partial penetration (laceration): the implant body may penetrate deeper into the canal, which results in laceration of nerve fibers. (E) Transection: the implant body may penetrate the entire canal, leading to complete transection of the nerve fibers.


● **Fig. 31.60** Post-extraction Site. (A) Care should be taken when grafting an extraction site in close approximation to the inferior alveolar nerve. (B) A curette should be used with caution because direct damage to the nerve may occur. (C) Grafting in close approximation to the canal may lead to nerve trauma.

Nerve Healing Physiology

After nerve injury, there exist two phases of healing: degeneration and regeneration.

Degeneration

There are two types of nerve degeneration: segmental degeneration and Wallerian degeneration. Segmental demyelination occurs when the myelin sheath is damaged and causes a slowing of the conduction velocity, which may prevent the transmission of nerve impulses. The resulting effects will clinically be paresthesia, dysesthesia, or hyperesthesia. The second type of degeneration is termed *Wallerian degeneration*, in which the axons and myelin sheath distal (away from the central nervous system) to the injury undergo complete disintegration. The axons proximal to the site of injury (toward the central nervous system) undergo less degeneration, but many nodes of Ranvier (periodic gaps in the myelin sheaths of axons that facilitate the rapid conduction of nerve impulses) are affected. Wallerian degeneration usually occurs after complete transection of the nerve and results in a dysesthesia type of symptoms.

Regeneration

Usually regeneration occurs immediately after nerve injury. The proximal nerve area sprouts out new fibers that grow at a rate of 1.0 to 1.5 mm/day. This will continue until the site innervated by the nerve is reached or blocked by fibrous connective tissue, bone, or an object (e.g., dental implant). During the regeneration process, new myelin sheaths form as axons increase in size. In some situations the continuity of the Schwann cells is disrupted, and connective tissue may enter the area. The growth may find an alternative path, or it may form a traumatic neuroma, which is usually characterized by significant pain. Studies have shown that the administration of steroids may minimize the formation of neuromas, especially the administration of high doses within the first week of nerve injury (Fig. 31.61).[140]

Neurosensory Deficit Classification

There are two widely accepted classifications of nerve injuries. In 1943 Seddon[141] postulated a three-stage classification, which was later reclassified by Sunderland in 1951 into five different subclassifications. These nerve injury classifications are described by the resultant morphophysiologic type of injury, which is based on the time course and amount of sensory recovery (Fig. 31.62).

Neuropraxia, or first-degree injury, is characterized by a conduction block with no degeneration of the axon or visible damage of the epineurium. Usually this type of injury is consistent with stretching or manipulation (reflection of tissue) of the nerve fibers, which results in injury to the endoneurial capillaries. The degree of trauma to the endoneurial capillaries will determine the magnitude of intrafascicular edema, which results in various degrees of conduction block. Usually resolution of sensation and function will occur within hours to weeks.

Axonotmesis (second-, third-, or fourth-degree injury) consists of degeneration or regeneration axonal injuries. The injury classification depends on the severity of axonal damage. This type of injury involves the endoneurium, with minimum disruption to the perineurium and epineurium. The most common types of injury are traction, stretching, and compression, which can lead to severe ischemia, intrafascicular edema, or demyelination of the nerve fibers. Initially complete anesthesia is most common,
● **Fig. 31.61** Normal and abnormal nerve responses (degeneration, regeneration) to nerve injury. (*From Hupp JR, Tucker MR, Ellis E.* Contemporary Oral and Maxillofacial Surgery. *6th ed. St. Louis, MO: Mosby; 2014.*)

which is followed by paresthesia as recovery begins. Improvement of the related sensory deficits occurs within approximately 2 to 4 months, with complete recovery usually within 12 months. In some cases painful dysesthesias are possible, with resulting neuroma formation.

Neurotmesis (fifth-degree injury) is the most severe type of injury, resulting from severe traction, compression, or complete transection injuries. Initially patients exhibit anesthesia, followed by paresthesia with possible dysesthesia. A very low probability of neurosensory recovery exists, with immediate referral for a neurosurgical evaluation recommended.[142] The axon and encapsulating connective tissue will lose their continuity. There is usually complete loss of motor, sensory, and autonomic function. Neuroma formation is common if transection has occurred.

The literature involving peripheral nerve injuries is vast, with a significant variation in the nomenclature used to describe the associated clinical signs and symptoms. Neurosensory impairments are classified from complete numbness to severe pain of the facial soft tissues to the intraoral anatomy. Because of these deficits, severe complications result for the patient and the clinician. A thorough

understanding of the associated classifications and definitions is necessary (Tables 31.4 and 31.5).

To standardize the nomenclature concerning nerve injuries, the International Association for the Study of Pain reduced sensory impairment into three categories: anesthesia, paresthesia, and dysesthesia.[42] Anesthesia is characterized by the complete lack of "feeling," which is usually consistent with complete transection of the nerve. This type of altered sensation is most severe because anesthesias are the most difficult and unpredictable to treat, with a high incidence of neuroma formation. Paresthesia is defined as an altered sensation that is not unpleasant. It is usually characterized as a "pins and needles" feeling. Within the paraesthesia category, many subcategories exist, including hypoesthesia (decreased sensitivity to stimulation), hypoalgesia (decreased response to a stimulus that is normally painful), and synesthesia (sensation in an area when another is stimulated). Dysesthesias are classified as an altered sensation that is unpleasant. Usually pain is associated with this type of impairment, which may be spontaneous or mechanically evoked. Subcategories include hyperalgesia (painful response to nonpainful stimuli), hyperpathia (delayed or prolonged painful response), anesthetic dolorosa (pain in an area that

TABLE 31.4 Neurosensory Impairment Classification and Injury Response

Sunderland	Seddon	Description	Causes	Responses	Recovery Rate
I	Neurapraxia	Temporary interruption of nerve transmission (conduction block)	• Nerve compression • Edema • Hematoma • Minor stretching • Thermal	• Neuritis • Paresthesia	Complete (fast—days to weeks)
II	Axonotmesis	Endoneurium, perineurium, and epineurium remain intact; some axonal degeneration may occur	• Nerve compression • Traction • Hematoma • Partial crush • Edema • Stretching	• Paresthesia • Episodic • Dysesthesia	Complete (slow—weeks)
III		Disruption of axon and connective tissue (endoneurium), causing disorganized regeneration; Wallerian degeneration occurs	• Crush • Puncture • Severe hematoma • Stretching	• Paresthesia • Dysesthesia	Variable (slow—weeks to months)
IV		Damage involves entire fascicle; axonal, endoneurium, and perineurium changes occur; the epineurium is intact; scar tissue formation	• Full crush • Extreme stretching • High thermal • Direct chemical trauma	• Hypoesthesia • Dysesthesia • Neuroma formation	Unlikely
V	Neurotmesis	Complete transection or tear of the nerve with amputation neuroma forming at injury site	• Complete • Transection (overpreparation with implant drill)	• Anesthesia • Intractable pain • Neuroma	None

is anesthetized), causalgia (persistent burning pain), and allodynia (pain in response to a stimulus that usually does not provoke pain).

Treatment

Nerve Impairment at Time of Surgery

During surgery, if known traction or compression of the nerve trunk has occurred, the topical application of dexamethasone may be used to minimize deficits. Upon removal of the surgical deill or implant from the mandibular canal, 1 to 2 mL of the intravenous

TABLE 31.5	Description of Neurosensory Impairment Deficits[154]
Paresthesia	Abnormal sensation that is not unpleasant
Anesthesia	Total loss of feeling or sensation
Dysesthesia	Abnormal sensation that is unpleasant
Allodynia	Pain due to a stimulus that does not normally provoke pain
Hyperpathia	Abnormally painful reaction to a stimulus
Causalgia	Persistent burning pain
Anesthesia dolorosa	Pain in an area that is Anesthetized
Hyperesthesia	Increased sensitivity to stimulation
Hyperalgesia	Increased response to a stimulus that is normally painful
Hypoesthesia	Decreased sensitivity to stimulation
Hypoalgesia	Decreased response to a stimulus that is normally painful
Synesthesia	Sensation felt in an area when another area is stimulated

form of dexamethasone (4 mg/mL) is topically applied into the osteotomy site (Fig. 31.63). This direct steroid application will reduce neural inflammation and may enhance recovery from neurosensory deficits. Studies have shown no morbidity associated with the topical application of glucocorticoids at the injury site, and postsurgical recovery has also been shown to improve significantly.[143] No bone grafting or implant should be placed that may lead to irritation of the traumatized nerve fibers.

Postoperative Nerve Impairment

When a neurosensory deficit occurs postoperatively, a comprehensive sensory evaluation must be completed. This initial examination is used to determine whether a sensory deficit exists, to quantify the extent of injury, document a baseline for recovery, and determine whether referral for microneurosurgery is indicated.

Step 1: Clinical Assessment. The implant clinician must first determine whether a neurosensory deficit exists by mapping the area of deficit. This diagnostic examination consists of objective and subjective findings to determine the extent of impairment, to use as a baseline for future evaluation, and to determine when referral for surgical intervention is required. The subjective clinical sensory tests involve nociceptive and mechanoceptive examinations. Nociceptive tests trigger a variety of autonomic responses that result in the subjective experience of pain. Mechanoceptive tests use mechanical stimuli to trigger sensory neurons that elicit various responses such as touch, position, and motion (Table 31.6 and Fig. 31.64).

Clinical Examination Complications. There exist many inherent problems with relying on the credibility of the patient's subjective responses. Because there may exist a high degree of false-positive and false-negative results, clinicians should use clear and concise instructions when administering these tests. For instance, when administering the "directional movement" test, the clinician should complete this test on the contralateral side first so the patient understands the technique and response. The results of the subjective clinical examination will depend on good communication between the implant clinician and the patient, with the outcome of the results related to the patient's perceived interpretation and how to relate their

• **Fig. 31.63** (A) Dexamethasone 4 mg/mL (Mylan, Canonsburg, Pa.). (B) One to two milliliters of dexamethasone placed into the osteotomy site.

TABLE 31.6	Diagnostic Testing for Neurosensory Impairment	
Diagnostic Test	**Description**
Nociceptive	
Pin pressure (A-delta, C-fiber)	Determination of feeling from pin pressure using a blunted explorer. A normal response (distinct sharp pain) is a positive sign of feeling (in relation to an unaffected area) with no pain. If no feeling is present in comparison with an unaffected side, the area is termed *hypoalgesia*. If an exaggerated response is noted in relation to an unaffected side, the area is termed *hyperalgesia*.
Thermal discrimination (warm: A-delta, cold: C-fibers)	Ice chips or ethyl chloride spray and a heated mirror handle (warmed to 43°C) are used to determine the patient's ability to feel cold and hot.
Mechanoceptive	
Static light touch	Cotton tip applicator with the patient's eyes closed to test tactile stimulation by gently touching the skin and determining the threshold of the patient (A-beta afferent axons). Directional movement: Soft brush is used to determine the patient's ability to detect both sensation (A-beta and A-alpha axons) and direction of movement. The soft brush is swiped from left to right, as well as in the reverse direction.
Two-point discrimination	With the patient's eyes closed, the patient's ability to discriminate varying (myelinated A-alpha fibers) distances between two points is determined using a caliper. The normal values vary significantly, with the average being approximately 5 mm.[73]

perceptions. In addition, the tests should be administered with the patient's eyes closed, so as to minimize the possibility of incorrect responses.

Step 2: Radiographic Evaluation/Removal or Repositioning of the Implant. A thorough and comprehensive radiographic examination should be completed, including (ideally) a CBCT radiograph. If the implant (or bone screw) is in close approximation of the nerve bundle, removal or repositioning should be completed. Care should be exercised in "backing" the implant out (repositioning farther from the nerve) because trauma to the nerve may still be present from hematoma formation or pressure from cancellous bone crushed into the neural space. In addition, backing the implant out may lead to the implant being positioned undesirably because of lack of interocclusal space for the restoration (i.e., too coronally positioned). In these cases the implant should be removed and the osteotomy site irrigated with 4% dexamethasone (1–2 mL). No graft materials should be added to the osteotomy site because they may interfere with the reinnervation and repair of the nerve trunk.[144]

Step 3: Pharmacologic Intervention. Immediately after the nerve is traumatized, the inflammatory process begins with the activation of cytokines and inflammatory mediators. These inflammatory mediators will contribute to the development of nerve trauma by activating the neurons and their nociceptors.[145]

With any type of nerve impairment, corticosteroids or nonsteroidal anti-inflammatory agents should be used immediately. Studies have shown that the use of systemic adrenocorticosteroids (e.g., dexamethasone) minimizes neuropathic symptoms after nerve trauma if administered in high doses within 1 week of injury.[146] It has been advocated that a tapering dose of a corticosteroid for 5 to 7 days after trigeminal nerve injury is beneficial.[147] Dexamethasone (~8 mg) is specifically recommended because of its greater anti-inflammatory effects, in comparison with other corticosteroids such as methylprednisolone or prednisone. Additional pharmacologic agents include antidepressants, neurologic drugs, antisympathetic agents, and topical agents.

In addition, cryotherapy (ice packs) should be applied to the paraneural tissues for the first 24 hours and then episodically for the first week. Cryotherapy has been shown to be beneficial in minimizing secondary nerve injury from edema-induced compression, decreasing the metabolic degeneration rate of trigeminal ganglion cells, and slowing potential neuroma formation.[148] Additional physiologic agents include transcutaneous electric nerve stimulation, acupuncture, and low-level laser therapy.

Step 4: Possible Referral. In certain situations patients may need to be referred in a timely manner to a practitioner experienced in nerve injury assessment and repair. The decision and timing to refer should be based on the patient's symptoms and the type of injury, together with the experience of the implant dentist in treating nerve injuries. Usually sufficient time is given for neurosensory recovery. In cases of dysesthesia, anesthesia, or known nerve transection, prompt surgical intervention may allow for the best chance of neurosensory recovery. Early, aggressive treatment has been shown to minimize possible transition to chronic refractory neuropathies (Table 31.7).[149]

Step 5: Follow-Up Care. Follow-up care should always be a component of the treatment of a patient with nerve impairment. The interval between appointments is determined by the extent and type of nerve injury. Usually after the 1-week postoperative appointment, patients are seen every 2 weeks with mapping and documentation of the deficits noted.

Surgical Intervention. Surgical repair is indicated in some cases of neurosensory impairment. In general, early treatment is crucial to success and decreased morbidity. Microneurosurgical procedures include direct nerve repair via primary anastomoses of the two severed nerve ends for transection injuries. For nerve splits, reestablishment and proper alignment of nerve stumps will allow for the best chance to correct regeneration of the damaged nerves.

Fractured Implant

Although rare with today's dental implants, fractured implant bodies may cause significant problems for both clinicians and patients. Dental implant fractures may be one of the major causes of late implant failures and may include possible medicolegal issues. Studies by Goodacre et al.[150] relate the risk for implant body fracture in the early to intermediate period for implants 3.75 mm in diameter to be approximately 1%, the abutment screw fracture risk at 2%, and the prosthetic screw risk at 4% (Fig. 31.65).

Etiology

The incidence of implant body fracture dramatically increases when force conditions are greater. Cantilevers, angled loads, and parafunction increase the risk for fracture. The risk for fracture also increases over time. Typical mechanical failures are due to either

● **Fig. 31.64** Sensory Testing. (A) Mapping out deficit with eyeliner. (B) Light touch with cotton applicator. (C) Directional test with brush. (D) Two-point discrimination using calipers. (E) Thermal test with mirror handle. (F) Pinpoint tests with explorer or dull needle.

static loads or fatigue loads. Static load (i.e., one load cycle) failures cause the stress in the material to exceed its ultimate strength after one load application. Fatigue load failures occur if the material is subjected to lower loads but repeated cycles of that load. The endurance limit or fatigue strength is the level of highest stress a material may be repetitively cycled through without failure. The endurance limit of a material is often less than half of its ultimate tensile strength. Therefore fatigue and ultimate strength values are related, but fatigue is a more critical factor, especially for patients with parafunction because they impose higher stress magnitude and greater cycles of load. Different materials have varying degrees of resistance to repeated loading and subsequent fatigue-related failures. The

fatigue strength of titanium alloy (Ti-6Al-4V) is four times greater (and safer) than grade 1 titanium and almost two times greater than grade 4 titanium. Long-term fracture of implant bodies and components may be dramatically reduced with the use of titanium alloy rather than any grade of commercially pure titanium.

Prevention

A titanium alloy implant should ideally be used to reduce the possibility of implant body fracture. Parafunctional habits should be addressed with occlusal guards, narrow occlusal tables, no lateral contacts, and an ideal occlusal scheme.

TABLE 31.7	Neurosensory Impairment Treatment Protocol			
NEUROSENSORY DEFICIT TREATMENT ALGORITHMS				
Postsurgery	**Documentation**	**Pharmacological Intervention**	**Treatment**	**Referral**
~48 hours	Three-dimensional radiographic examination (cone beam computed tomography); neurosensory examination	Corticosteroids: (dexamethasone 4 mg) 2 tabs a.m. for 3 days 1 tab a.m. for 3 days	Implant evaluation: • Removal and reposition if impingement within the mandibular canal • No bone grafting • Cryotherapy (1 week)	None, unless unfamiliar with neurosensory testing
1 week	Neurosensory examination (testing should be continued every 2 weeks thereafter)	High-dose NSAIDs (600–800 mg ibuprofen TID)	Palliative	Refer to oral surgeon or neuro-surgeon if: • Known nerve transection • Dysesthesia • Complete anesthesia
8 weeks	Neurosensory examination	NSAIDs PRN	Palliative	IF NO SIGN OF IMPROVEMENT, refer to OMFS or microsurgeon

● **Fig. 31.65** Fractured Implants. (A) Midimplant fracture. (B and C) Implant neck fracture. (D) Crestal implant fracture. (E) Clinical image of implant neck fracture.

Treatment

The ideal treatment for a fractured implant includes the removal and possible replacement of the implant. Alternative treatments include modification of the prosthesis to not include the implant and possible modification of the fractured implant (cementable abutment).

Explantation of Dental Implants

In some situations a failing implant or the position of the implant necessitates removal with reinsertion in an ideal position. The following are possible reasons why dental implants may need to be removed:

- Mobility of the implant
- Extensive bone loss
- Chronic pain
- Advanced peri-implantitis
- Fractured implant
- Malpositioned implant

Potential Complications

Taking an aggressive approach to removing an implant may lead to further bone loss and jeopardize the future site for reimplantation. Because an implant does not contain a periodontal ligament, placing too much force and pressure on it may lead to buccal or lingual plate failure. Loss of bony plates or excessive bone loss may result in the need for extensive bone augmentation in the future.

Treatment

The removal of dental implants is dictated by the location, amount of bone present, type of implant, and presence of mobility.

Mobile Implant

The loss of the bone-implant integration necessitates immediate removal because infection and further loss of bone may result. In certain cases the implant may migrate within tissue spaces or may be swallowed or aspirated.

Countertorque Ratchet. This technique involves placing an abutment or an engaging extraction tool into the implant and reverse torqueing the implant counterclockwise. This technique is usually atraumatic, however caution should be exercised to not use excess force as this may lead to bony plate fracture.

Convention Extraction Techniques. This method uses conventional forceps and elevators, and should be used only with minimal luxation to prevent possible fracture of the buccal or lingual plate. After removal, all soft tissue should be removed from the implant site before grafting or reimplantation. A throat pack should always be used to minimize the possibility of aspiration of the implant upon removal.

Nonmobile Implant

A partial or fully integrated implant is usually more problematic and can be in some cases very difficult to remove. Conventional extraction techniques should never be used because they may lead to significant bone loss or fracture. If a final crown and abutment is present, they should be removed to allow for easier access.

Countertorque Ratchet. This technique involves placing an abutment or an engaging extraction tool into the implant and reverse torqueing the implant counterclockwise. This should be used only in poorly dense bone (~maxilla). Care should be exercised in higher-density bone because damage or fracture of the implant body or adjacent bone may occur with this type of removal technique. The existing bone density is the most critical factor which affects the ease of implant removal via the countertorque technique.

Implant Type. In general, an internal hex implant is easier to remove via the countertorque method. External hex implants, because they engage coronal to the implant body, are more difficult to remove because of lack of leverage. Trilobe internal connections, especially those with smaller diameters, have been shown to fracture when greater than 45 N-cm of torque is applied.[151] Care should be exercised to prevent fracturing the implant on removal.

Implant Thread Shape. There are generally four types of implant thread designs: buttress, square, V-shaped, and reverse buttress. The square thread shape has the highest bone-implant contact and will be the most difficult to remove via the countertorque method.

Implant Body Design. A tapered implant design will be easier to remove than a square implant design. The thread depth and surface area decrease in the apical area, which minimizes the torque force necessary for removal. In addition, less chance of fracturing the bony plates exists.

Antirotational Design. Some implant designs contain a vent or opening, usually at the apical end, that will allow for bone growth integration. This will complicate the removal of a partially or fully integrated implant. A trephine or surgical bur technique may be indicated in the removal of these types of implants.

Reverse Screw Techniques. A reverse screw removal drill is usually inidcated when the internal aspect of the implants (threads) are damaged or when the countertorque method is unsuccessful. Caution should be exercised with smaller-diameter internal implants (~3.0 mm) because fracture of the implant body may occur (Fig. 31.66).

High-Speed Burs. The use of a high-speed bur is a fast, efficient technique to remove an integrated implant. Ideally a tapered surgical bur (extra long: 700 XXL) is used to minimize bone removal. The bur is used 360 degrees around the implant to a depth of half to three-fourths the length of the implant to be removed. Copious amounts of saline should be used to minimize thermal damage and the possibility of osteomyelitis. This helps to maintain bone and minimize damage to vital structures. After removal, the implant site should be irrigated to remove any particles (Fig. 31.67).

Piezo Surgical Units. A piezo surgical unit uses piezoelectric vibrations to cut bone tissue. By adjusting the ultrasonic frequency of the unit, it is possible to remove hard tissue while leaving soft tissue untouched by the process. Studies have shown that piezo units cause less soft tissue damage compared with other extraction techniques.[151]

Trephine Burs. Trephine burs are barrel-shaped burs that are available in various diameters. The bur selected should be slightly larger than the implant crest module because too large of a trephine bur will result in excessive bone removal. Too small of a trephine may result in implant body particles being removed and becoming embedded in the implant site. Copious amounts of saline should
● **Fig. 31.66** Reverse Screw Technique. (A) Implant with more than 50% bone loss. (B) Implant insertion tool inserted into implant. (C) Reverse torque with hand ratchet.
● **Fig. 31.67** (A) 700XXL bur. (B) Mesial and distal slot around implant.

be used to minimize thermal damage and the possibility of osteomyelitis. If the apex of the implant is in approximation to a vital structure, the trephine bur should not be used at the apex to avoid vital structure damage.

After the implant is removed, the implant site should be irrigated to remove any retained titanium particles (Fig. 31.68).

Combination of Techniques. In some cases it is prudent to remove bone half to three-fourths the length of the implant (using a trephine, piezo, or high-speed bur), together with the use of conventional extraction techniques or the countertorque method.

Immediate Implant Placement Surgical Protocol

RANDOLPH R. RESNIK

The traditional dental implant placement protocol is a proven and reliable treatment modality to restore edentulous spaces. However, a healing period is usually required after extraction and/or graft, which delays the implant placement and ultimately the placement of the final prosthesis. This extended treatment time leaves the patient without teeth and usually an interim prosthesis. Since the 1980s these conventional treatment protocols have been challenged to be replaced with other options that are geared toward shorter treatment times. Classifications have been reported to clarify the placement of dental implants according to various time intervals after tooth extraction.

The placement of dental implants at the time of tooth extraction (immediate implants) has been shown to be a viable treatment protocol in implant dentistry today.[1-4] The objectives of immediate implant placement are the same as for conventional staged treatment: implant primary stability, sufficient rigid fixation after healing, ideal positioning for implant restoration, and an ideal esthetic result. Immediate implant placement has become extremely popular because these objectives can be obtained with fewer procedures, less treatment time, and less cost to the patient. However, immediate placement implants are more demanding and require a special skill set from the implant clinician. The surgical procedure and prosthetic rehabilitation are more complex, with multiple factors that may lead to an increased morbidity or complications. Therefore this chapter will address the immediate placement protocol with a comprehensive evaluation of treatment planning and specific factors related to site-specific recommendations and the prevention of complications (Fig. 32.1) Box 32.1.

• BOX 32.1 Implant Placement Definitions[1]

- Immediate = at time of extraction
- Early = 4–6 weeks after extraction
- Delayed = 3–4 months after extraction
- Late = >4 months after tooth extraction

Advantages of Immediate Implant Placement

Decreased Treatment Time and Cost

The immediate placement procedure reduces the number of surgical appointments because no postoperative healing period is required. Because of the decreased number of surgical appointments, patient discomfort and morbidity are decreased. In addition, less chair time is required, which reduces the overall cost of the procedure.

Decreased Need for Bone Augmentation

Because the implant is placed at the same time as extraction, the bone remodeling process does not take place in which bone resorbs from the facial to the lingual, often resulting in compromised bone dimensions. If no immediate implant or grafting is completed at the time of extraction, resorption has been shown to result in approximately 1 to 2 mm of vertical bone height and 4 to 5 of horizontal bone width within 1 to 3 years.[5] Additional studies have shown that at 6 months after extraction, bone healing averages approximately 1.24 mm vertical bone loss (range 0.9–3.6 mm) and 3.79 mm horizontal bone decrease (range 2.46–4.56 mm) (Fig. 32.2).[6]

Preservation of the Soft Tissue Drape

An additional benefit of immediate implant insertion after tooth extraction is related to the preservation of the soft tissue drape. Most often after tooth extraction, the soft tissue drape is lost and becomes compromised. The immediate implant placement technique has been described as a "preservation technique," because the gingival architecture is preserved. If the soft tissue drape is not maintained, "black triangles" will result in the interproximal areas, which compromises long-term esthetics and/or contributes to peri-implant disease (Fig. 32.3).

Improved Implant Positioning

Because the implant is placed into the existing extraction site, the ideal implant positioning is much easier for the clinician. In a staged implant protocol, often the available bone is not in the

---

ideal position (i.e., the ridge is positioned more lingually), which leads to nonideal implant placement, with resultant implant prosthesis complications (Box 32.2).

Disadvantages of Immediate Placement

Site Morphology

After tooth extraction the dimensions of the remaining socket (i.e., mesial-distal and buccal-lingual dimensions) are usually much different from the implant diameter. Therefore a discrepancy is present between the implant diameter and the morphology of the socket, which results in bony defects. For example, the maxillary molar has an 8.0-mm mesial-distal average cervix diameter and a 10.0-mm buccal-lingual diameter. After extraction, usually a 5.0- or 6.0-mm diameter is inserted that leaves a 2.0- to 3.0-mm (mesial-distal) and a 4.0- to 5.0-mm buccal-lingual discrepancy (Fig. 32.4).

Surgical Technique Is More Complicated

Placement of an implant into an extraction site is usually much more surgically demanding. The techniques are site specific and usually do not follow standard manufacturers' surgical placement protocols. Most notably, it is often difficult to achieve primary stability because of poor bone density or compromised bone quantity (Fig. 32.5).

Anatomic Limitations

It is often necessary to deepen the osteotomy 2 to 4 mm apical to the existing extraction socket (apical wall) to obtain primary stability. This may result in impingement on vital structures, resulting in neurosensory impairments, perforation into the maxillary sinus or nasal cavity, or perforation of the cortical plates. In the maxillary anterior the nasal cavity may be penetrated, and in the posterior the maxillary sinus may be violated, which can predispose the patient to rhinosinusitis. In the mandibular posterior, extending the osteotomy deeper may lead to violation of the mandibular canal and resultant nerve damage (i.e., especially common in type 1 nerve positions) or lingual plate perforation (Fig. 32.6).

Lack of Primary Closure

It is usually difficult or even impossible to obtain primary closure after tooth extraction and immediate implant placement. Unless a large incision is made and the tissue stretched, it is often challenging to approximate the tissues. Therefore usually a membrane will be required to be placed over the extraction site. Making larger broad-based incisions with vertical releases incisions results in compromised blood supply and is usually not

• Fig. 32.4 Poor Site Morphology: Mandibular extraction resulting in minimal bone for immediate implant placement.

• Fig. 32.5 Surgical placement into an extraction site requires an increased skill set.

warranted. In some cases, when compromised keratinized tissues exist, free tissue, subepithelial, or connective tissue grafts may be indicated after stage I healing to restore the facial attached keratinized tissue.

Presence of Acute/Chronic Pathology

Although studies have shown immediate implants may be successfully placed after extraction of teeth into infected sites, there is obviously an increased risk. Because residual bacteria may be present after an extraction, healing may be affected and morbidity higher. If exudate is present, the pH is lowered, which
• **Fig. 32.6** Anatomic Limitations. (A) Maxillary implant penetrating the nasal cavity. (B) Maxillary molar showing no host bone present for immediate implant placement because of the maxillary sinus location. (C) Implant placement positioned more apical to root socket, which impinges on the mandibular canal.

may cause solution-mediated resorption of the grafted bone and contamination of the implant body because of a bacterial smear layer. Therefore implant placement into an infected site is a controversial topic in implant dentistry, and the implant clinician must be conscious of the possible associated complications (Fig. 32.7).

Consequences of Implant Failure

If implant failure results from an immediate implant, significant complications may occur. Usually the need for bone augmentation will result, which delays treatment and increases costs. Studies have shown that a replacement implant (second time) has a success rate of approximately 71%, and a third replacement has a success rate of approximately 60% (Fig. 32.8 and Box 32.3).[7,8] Therefore, implant failure may lead to many financial and patient related issues.

Immediate Implant Studies

Immediate placement implants were first reported by Lazzara in 1989.[1] In his studies, he documented the placement of implants at the time of extraction with the use of barrier membranes. Becker et al.[9,10] in 1999 reported a 93.3% survival rate for implants placed at the time of extraction and grafted with barrier membranes after 1 and 5 years after loading. Since then, a full array of studies has confirmed the success and predictability of placing implants at the time of extraction.[11,12] Peñarrocha-Diago et al.[13] evaluated immediate versus nonimmediate placement of implants for full-arch fixed restorations. They determined that the immediate group had a higher success rate (97.7%) versus the nonimmediate group (96.3%).

Treatment Planning Considerations

Available Bone

The concept of available bone is generally accepted as a primary determinant of implant placement viability. Available bone describes the amount of bone in an extraction site considered for implantation. It is measured in width, height, length, angulation, and crown height space (Fig. 32.9). As a general guideline, 1.5 to 2 mm of surgical error is maintained between the implant

and any adjacent landmark or vital structure. This is especially critical when the opposing landmark is the mandibular inferior alveolar nerve.

When evaluating available bone in an immediate extraction site, the implant clinician must consider the dimension of the extraction socket and the defect between the labial plate of bone and the proposed position of the implant. The resultant defect may be deceiving. For example, most anterior teeth have a faciopalatal dimension that is far greater than its mesiodistal dimension. When an anterior tooth requires extraction, during the extraction process the thin facial cortex often becomes compromised or lost. As a result the buccal cortex is almost always several millimeters apical to the palatal cortical plate, and frequently bone grafting and/or membrane placement in conjunction with the implant insertion are indicated.

Bone Height

The height of available bone is measured from the crest of the edentulous ridge to the opposing landmark. The anterior regions are limited by the maxillary nares or the inferior border of the mandible. The anterior regions of the jaws have the greatest height because the maxillary sinus and inferior alveolar nerve limit this dimension in the posterior regions. The maxillary canine eminence region often offers the greatest height of available bone in the maxillary anterior.[1] In the posterior jaw region there is usually greater bone height in the maxillary first premolar than in the second premolar, which has greater height than the molar sites because of the concave morphology of the maxillary sinus floor. Likewise, the mandibular first premolar region is usually anterior to the mental foramen and provides the most vertical column of bone in the posterior mandible. However, on occasion, this premolar site may present a reduced height compared with the anterior region because of the presence of an anterior loop of the mandibular canal. The nerve courses anteriorly below the foramen and proceeds superiorly, then distally, before its exit through the mental foramen. Posterior nerve anatomy has particular significance with regard to immediate implant placement. Primary stability for immediately placed implants is frequently achieved using bone apical to the extraction site. In the posterior mandible the course of the inferior alveolar nerve can vary from type 1 to type 3, with associated available apical bone ranging from nonexistent to sufficient and surgical risk varying accordingly. In addition, variants of the mental foramen exist that can increase the possibility of injury to the inferior alveolar nerve during immediate implant placement in the region (Fig. 32.10). The available bone height in an edentulous site is the most important dimension for implant consideration because it affects both implant length and crown height. Crown height affects force factors and esthetics. In addition, vertical bone augmentation, if needed, is less predictable than width augmentation.

Bone Width

The width of available bone is measured between the facial and lingual plates at the crest of the potential implant site. It is the next most significant criterion affecting long-term survival of endosteal implants. The crestal aspect of the residual ridge is often cortical in nature and exhibits greater density than the underlying trabecular bone regions, especially in the mandible.

Accordingly, the lack of crestal bone at an extraction site makes the achievement of primary stability more challenging for immediate implant placement. Facial dehiscence defects commonly found after tooth extraction and immediate implant placement
• **Fig. 32.9** Anatomic limitations for immediate implant treatment planning: (A) Floor of the nasal cavity. (B) Inferior border of the maxillary sinus. (C) Lingual cortical plate of the inferior mandible. (D) Inferior alveolar canal.

have been shown to have more compromised healing compared with infrabony defects (Fig. 32.11).[9]

Bone Length

Bone length is defined as the mesiodistal length of bone in a postextraction area. It is most often limited by adjacent teeth or implants. As a general rule the implant should be at least 1.5 mm from an adjacent tooth and 3 mm from an adjacent implant. These measurements not only allow surgical error but also compensates for the width of an implant or tooth crestal defect, which is usually less than 1.4 mm and may vary with implant diameter and thread design. As a result, if bone loss occurs around the crest module of an implant or around a tooth with periodontal disease, the associated vertical bone defect will not typically expand into horizontal defect and thereby cause bone loss on the adjacent structure (Fig. 32.12).

Bone Angulation

Bone angulation is an additional determinant for available bone (Fig. 32.13). The initial alveolar bone angulation represents the natural tooth root trajectory in relation to the occlusal plane. Ideally it is perpendicular to the plane of occlusion, which is aligned with the forces of occlusion and is parallel to the long axis of the prosthodontic restoration. The incisal and occlusal surfaces of the teeth follow the curve of Wilson and curve of Spee. As such, the roots of the maxillary teeth are angled toward a common point approximately 4 inches away. The mandibular roots flare, so the anatomic crowns are more lingually inclined in the posterior regions and labially inclined in the anterior area compared with the underlying roots. The mandibular first premolar cusp tip is usually vertical to its root apex. The maxillary anterior teeth are the only segment in either arch that does not receive a long axis load to the tooth roots, but instead are usually loaded at a 12-degree angle. As such, their root diameter is greater than the mandibular anterior teeth. In all other regions the teeth are loaded perpendicular to the curves of Wilson or Spee. The anterior sextants may have labial undercuts that often mandate greater
● **Fig. 32.12** Cone beam computed tomographic three-dimensional axial image measuring the length between two root tips.

angulation of the implants or concurrent grafting of the site after insertion. The narrower width ridge often requires a root form implant design that is likewise narrower. Compared with larger diameters, smaller-diameter designs cause greater crestal stress and may not offer the same range of custom abutments. In addition, the narrower width of bone does not permit as much latitude in placement regarding angulation within the bone. This limits the acceptable angulation of bone in the narrow ridge to 20 degrees from the axis of the adjacent clinical crowns or a line perpendicular to the occlusal plane.[14] The angulation of available bone in the maxillary first premolar region may place the adjacent cuspid at risk during implant placement.

Esthetic Risk

Especially in the anterior region, extracting a tooth with the immediate implant placement may result in nonideal esthetic issues. Therefore the patient should be evaluated preoperatively for the following esthetic parameters: lip line in relation to the
● **Fig. 32.13** Cone beam computed tomographic image determining ideal angulation.

● **Fig. 32.15** Immediate placement resulting in poor esthetics and periodontal complications because of positioning too deep and poor angulation.

● **Fig. 32.14** Maxillary lateral incisor resulting in poor esthetics because of a facially placed immediate implant placement.

teeth and gingival margins, presence and position of interproximal papilla, shape and shade of adjacent teeth, presence of restorations on adjacent teeth, and a hard and soft tissue thickness analysis. In some cases, even with an ideal esthetic result, possible limitations may deem the placement of implants nonideal (Fig. 32.14).

Type of Prosthesis

The clinician must always be proactive in the evaluation and anticipation of the final prosthesis and its associated dimensions of crown height space, whether for a single-tooth crown or full-arch prosthesis. In clinical situations where tooth extraction will

result in an edentulous arch, an alveoloplasty may need to be completed to satisfy the need for additional space. In completely edentulous patients, alveoplasty may result in the complete obliteration of the residual socket. This is imperative because sufficient crown height space is needed for an overdenture and attachment, whereas minimal reduction is required when a type 3 fixed prosthesis (FP-3) is treatment planned. When considering immediate implant placement for partially edentulous patients, the anatomic dimensions of the edentulous space must be evaluated. In some cases the opposing arch may need to be modified, or possible orthodontic treatment to realign or reposition the dentition (Fig. 32.15).

Bone Density

Bone quality or density refers to the internal structure of bone and reflects a number of its biomechanical properties, such as strength and modulus of elasticity. The density of available bone in a potential implant site is a determining factor in treatment planning, implant design, surgical approach, healing time, and initial progressive bone loading during prosthetic reconstruction. The quality of bone is often dependent on the arch position. The densest bone is usually observed in the anterior mandible, with less dense bone in the anterior maxilla and posterior mandible, and the least dense bone typically found in the posterior maxilla. In addition to arch location, several authors have reported different failure rates related to the quality of the bone. Johns et al.[15] reported a higher failure rate in the maxilla (poorer bone quality) in comparison with the mandible (more favorable bone density). Smedberg et al.[16] reported a 36% failure rate in the poorest bone density. The reduced implant survival most often is more related to bone density than arch location. In a 15-year follow-up study, Herrmann et al.[17] found implant failures were strongly correlated to patient factors, including bone quality, especially when coupled with poor bone volume. Bone quality is directly related to the ability to achieve an acceptable level of primary fixation for
• **Fig. 32.16** Poor Bone Quality. (A) D4 bone has an increased failure rate with immediate placement. (B) D4 bone has less than 30% bone-implant contact.

immediate implant placement, as well as long-term success for all placement protocols (Fig. 32.16).

Existing Crown Form

When evaluating teeth for immediate placement, tapered crown forms usually are associated with a higher risk for soft tissue compromise after extraction. The tapered crown also has more interproximal bone between the teeth and more facial bone over the tapered root. As such, under perfect conditions, the tapered tooth form may be more advantageous for extraction and immediate implant insertion. A square tooth form has less gingival shrinkage after extraction and exhibits less scalloping of the interproximal and facial bone with adjacent tooth roots. There is also less bone between the roots and larger spaces between the extraction site and the implant. As a result an immediate implant insertion after extraction offers less benefit for the soft tissue and greater risk for the implant-bone interface.[18]

Anatomic Location

For immediate implant placement an awareness of the bone characteristics of the proposed anatomic location will help dictate the appropriate treatment plan modifications for short- and long-term success. Regional variations in both available bone and bone density have already been described. The initial treatment plan before surgery suggests the anterior maxilla be treated as D3 bone, the posterior maxilla as D4 bone, the anterior mandible as D2 bone, and the posterior mandible as D3 bone. Bone remodeling, including loss of bone density, is primarily related to the length of time the region has been edentulous and therefore not loaded, the initial density of the bone, and mandibular flexure and torsion.

Immediate implant placement can take advantage of the fact that implant placement can be performed before the bone density in the jaws begins its usual decline after tooth loss.

Tissue Thickness

The patient's biotype is crucial in evaluating the susceptibility to increased tissue recession. Patients with a thin biotype are more predisposed to gingival recession and bone loss. Usually patients

• **Fig. 32.17** Thin biotype leads to postoperative tissue recession and black triangles.

with a thin biotype will require bone and possible tissue grafting to minimize recession.

Kan et al.[19] reported marginal tissue levels around immediate implants may continue up to 8.2 years (mean 4 years) after placement. In addition, thin biotypes were found to recede three times more than thick biotypes. For patients exhibiting a thin biotype, the use of orthodontic forced eruption procedures before tooth removal and implantation. This will result in bone and soft tissues to move coronally, thereby increasing mucosal tissue adjacent to the implant (Fig. 32.17).

Buccal Bone Thickness

In general the buccal bone is thinner than the lingual bone, and the buccal bone is usually compromised after extraction. For example, Januario et al.[20] evaluated facial bone thickness in the anterior maxillae at various measurements from the bone crest. They determined the bone thickness in the tooth sites to be approximately ≤1 mm thick (≤0.6 mm on average). In addition, they found the marginal portion of the wall was <0.5 mm wide.[20] After extraction, bone resorbs naturally from buccal to the lingual. There exist three main sources of blood supply to the bone surrounding the teeth: the periodontal ligament blood vessels, the periosteal blood vessels,

and the alveolar bone blood vessels. After an extraction, 20% of the blood supply from periodontal ligament blood vessels is lost and over the buccal plate of bone loses 50% of its blood supply.[21] In addition, if a buccal flap is elevated on the buccal side, the periosteal blood supply will be discontinued for approximately 4 to 6 days, until the formation of a new anastomoses. The cortical bone buccal plate contains no endosteal blood vessels; therefore, complete resorption of the buccal plate may occur after extraction if implant placement or grafting is not completed. Socket grafting is frequently used in the treatment postextraction to prevent collapse and to minimize resorption of the thin buccal plate (Fig. 32.18).

Implant Position

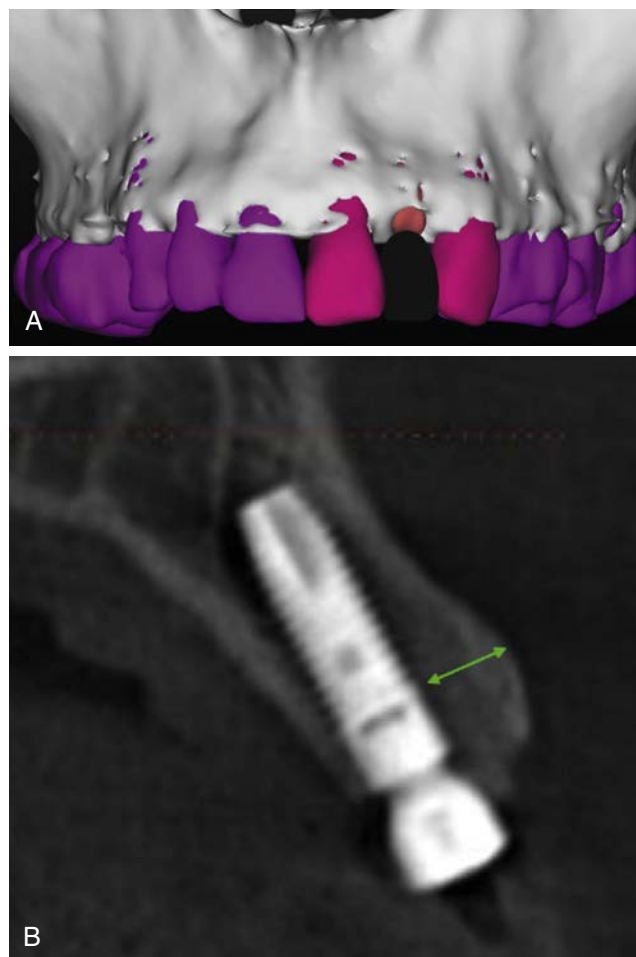
The immediate implant positioning is dictated by the anatomic position. For implants placed in the maxillary anterior, immediate implants should not be placed close to the buccal plate; instead they should be positioned more in the lingual aspect of the extraction socket. Evans and Chen[22] evaluated the esthetic outcomes of immediate anterior implants and found implants placed more buccally had three times more soft tissue recession than lingually placed implants (1.8 versus 0.6 mm). Spray et al.[23] reported that when 2 mm of facial bone thickness was present, vertical bone loss height was minimal. When <2 mm of bone thickness was present, tissue recession and failure resulted. In the mandibular anterior, implants should be positioned more toward the lingual, but not as much lingual version as the maxillary anterior. In the maxillary and mandibular posterior region the implants should be positioned in the center of the extraction socket, with a buccal lingual trajectory similar to the central fossas of the adjacent teeth.

Requirements for Immediate Implant Placement

1. A CBCT evaluation confirms sufficient bone quantity (buccal plate bone, bone apical to root apex, palatal bone); in addition, sufficient proximal bone to avoid encroachment on adjacent roots
2. An esthetic risk evaluation should be completed before immediate implant placement. The following factors should be taken into consideration (i.e., smile line, soft tissue drape, adjacent teeth shade stable and free of large restorations)
3. Ability to position implant in an ideal location for prosthetic rehabilitation, which is dependent on the anatomic location and the available bone.
4. Ideal primary implant stability is achieved (35–45 N/cm), which is dictated by bone density, surgical technique (i.e., drilling and osseodensification protocols), and implant design
5. If any of the above requirements are not satisfactory, the clinician should determine if other treatment options exist.

Immediate Implant Placement Technique

Step 1: Clinical and Radiographic Examination

A thorough clinical and radiographic examination should be completed as the first step of the immediate placement technique. Preferably a comprehensive CBCT scan is taken of the associated areas in question. The type of extraction defect (e.g., walls of bone present) may be anticipated with a careful preoperative clinical examination that includes periodontal probing, evaluation


• **Fig. 32.18** Buccal Bone Thickness. (A) Thin buccal bone leading to poor immediate implant candidate. (B) Postoperative radiograph depicting thick buccal bone, which results in higher success and better soft tissue healing.

of mobility, infection, and fractures, along with two- and three-dimensional radiographs. These collective clinical data are useful in evaluating for possible factors that would lead to immediate placement contraindications (Fig. 32.19).

Step 2: Atraumatic Tooth Extraction

Once the extraction of a natural tooth is indicated, methods to maintain or preserve the surrounding hard and soft tissues should be of utmost importance. Avoiding soft tissue injury reduces the dimensional loss of the underlying bone as the periosteum supplies more than 80% of the blood supply to surrounding cortical bone.[24] The atraumatic extraction of a natural tooth should ideally begin with a sulcular incision, preferably with a thin scalpel blade or periotome 360 degrees around the tooth. This will ensure all connective tissue attachment fibers above the bone level are severed. Failure to cut these fibers before extraction will result in increased tissue trauma and possible fracture of the buccal plate of bone. For an atraumatic extraction, the less soft tissue reflection the better as to minimize disruption of the blood supply.

The next step in an atraumatic extraction process is to evaluate the crown and root anatomy for ease of removal, especially with multirooted teeth. Proximal reduction of the tooth will increase the space so bone expansion can be completed and also will prevent damage from the adjacent teeth. If the roots of the tooth to
• **Fig. 32.19** Cone Beam Computed Tomography (CBCT) Interactive Treatment Planning for Immediate Implant. (A) CBCT cross section of maxillary central incisor. (B) Interactive treatment plan depicting implant length coinciding with root length. Placement of implant this length would lead to decreased prognosis. (C) Measurement of apical bone is available. (D) Ideal-length immediate implant.

be extracted are divergent, they should be sectioned and removed as individual units, because this will decrease the risk of fracturing a root or the surrounding bone. Elevation from the mesiolingual, direct lingual, or distolingual is most beneficial in avoiding the alteration of the buccal hard and soft tissue including the papillae.

Periotomes and dental elevators, which both use the mechanical advantage of a wedge, can then be used to initiate the luxation of teeth for their removal. A traditional dental forceps is used to grasp the tooth for any needed additional luxation before tooth removal. Ideally forceps should not be used until mobility of the tooth is present. Alternatively, a biomechanically based forceps (physics forceps) can be used. Its increased mechanical advantage may allow for tooth removal without application of rotational forces, minimizing potential fracture of the facial plate of bone (Fig. 32.20).[25]

Step 3: Curetting the Extraction Socket

The debridement of the extraction socket is imperative in the immediate implant process. Any remnants of periodontal ligament, bacteria, residual infection, dental material (i.e., gutta percha), and tooth fragments may affect the osseointegration process. Therefore the extraction socket should be thoroughly debrided and irrigated with saline to ensure the socket is free of contaminants.

A serrated spoon curette (Salvin Dental) should be used to scrape the walls of the socket (degranulation) and also initiate the regional acceleratory phenomenon (RAP), which enhances the healing process. This will initiate multiple areas of bleeding, which will promote a greater initiation of angiogenesis to the area (Fig. 32.21).

Step 4: Evaluating the Extraction Socket for Remaining Walls

The easiest and simplest technique for evaluating the remaining walls of bone after an extraction is with a blunted probe. The index finger may be placed over the buccal plate of bone, and the probe is introduced into the socket and run up and down within the socket. If the probe is felt (i.e., most commonly on a missing buccal plate), then no bone is present and the socket is missing a wall of bone (Fig. 32.22).

Classification of Bony Defects

Thick Five-Bony-Wall Defects. The most ideal condition for a successful immediate implant is the presence of five thick, bony walls around the extraction site. Most of the keys for predictable bone formation are present under these conditions, and the socket usually will form bone in the extraction socket without loss of width or height (Fig. 32.23).
• **Fig. 32.20** (A and B) Periotome atraumatic extraction; note minimal tissue reflection and damage.
• **Fig. 32.21** (A) Curetting the extraction socket with serrated spoon. (B) #10 round bur to remove soft tissue within the extraction socket and to initiate the regional acceleratory phenomenon technique.

Four-Wall Bony Socket. When a labial plate around a socket is missing, the absence of the wall prevents space maintenance, reduces host bone vascularization, and is replaced with soft tissue. In most cases bone augmentation procedures must be used to obtain an ideal volume and contour of bone. Sockets with a missing wall are significantly compromised and heal by repair rather than regeneration.

The first determination after the tooth extraction is complete is the assessment of the thickness of labial and palatal plates of bone and their relative height to the ideal volume desired. When one of the plates of bone is thinner than 1.5 mm or when height is desired, a socket graft is indicated, even in the presence of five bony walls (Fig. 32.24).

There exist three treatment options after tooth removal and bony wall evaluation:
1. *No treatment:* The most likely reason the option of no treatment would be chosen is if there is active infection present in the extraction site that cannot be completely eradicated.
2. *Bone grafting:* If the remaining walls of bone are not advantageous, then grafting the socket is completed. Usually one- to three-wall, and in many cases four wall defects should be grafted instead of attempting immediate placement.
3. *Immediate implant placement:* If favorable conditions exist, the implant is placed immediately after the extraction of the tooth.

● **Fig. 32.22** Evaluating the number of walls remaining with a colored periodontal probe. Note the lack of buccal plate.

● **Fig. 32.24** Four-Wall Extraction Socket (Mesial, Distal, Lingual, and Apical Present). The buccal plate is missing which is the most common wall to be lost after extraction.
● **Fig. 32.23** Five-Wall Extraction Socket (Mesial [*M*], Distal [*D*], Buccal [*B*], Lingual [*L*], and Apical [*A*] Present).

Step 5: Immediate Implant Placement Technique

Flap Design

Three types of flap designs are used for immediate implants: open (buccal and lingual tissue reflected), minimal flap (no buccal or lingual reflection, but minimal flap to expose crestal area), or flapless (tissue punch). Caneva et al.[26] evaluated flap versus flapless implant placement into extraction sockets and determined there is no difference in bone loss between the two techniques (Fig. 32.25).

Implant Osteotomy

The immediate implant placement surgical technique is initiated with either a surgical template or freehand technique.

a. *Surgical template:* If a surgical template is used, it should be placed over the adjacent teeth (i.e., ideally tooth supported) and standard drilling procedures completed according to the manufacturer's instructions (i.e., pilot, universal, fully guided surgical templates.) (Fig. 32.26).

b. *Freehand:* The initial osteotomy is directly related to the anatomic area and remaining socket anatomy. For example, in the maxillary anterior region it is crucial to avoid placing the implant directly in the center of the extraction socket. Placement of the implant in this position may perforate the buccal plate and increase morbidity. In addition, the implant is often too facial, which compromises esthetics. It is imperative the implant's final trajectory is within the incisal edge.

In the posterior regions, implants usually may be placed within the extraction site, along a trajectory in line with the central fossa of the adjacent teeth (Fig. 32.27 and Table 32.1).

Heat generation. Site preparation should always be performed with copious amounts of irrigation with cold saline (i.e., refrigerated) to reduce heat generation. It is often difficult to avoid heat generation when using a guided template or a flapless procedure. Therefore, a "bone dancing" technique should always be followed to allow saline to enter the osteotomy site.

Prevention of perforation. During the osteotomy process for an immediate implant placement, the clinician should use their index finger over the buccal plate for tactile sense to confirm no buccal vibration or fenestration.[27]

Ideal Positioning

Ideal depth. In general it has been accepted in the literature that 2 to 4 mm of bone is ideally required apical to the inferior part of the socket to obtain primary stability for an immediate implant.[28] Madani et al.[29] reported in a retrospective study that implant placement 1.08 mm subcrestally is the ideal depth of the neck of the implant. Subcrestal placement of the implant greater than 2 mm led to and increased bone loss. The vertical position of the implant shoulder should be 1 mm apical to the buccal crest to allow for adequate space for an emergence profile of the final restoration. Ideally a tapered design implant is used to avoid buccal fenestration, which is highly likely with a straight-walled design (Fig. 32.28).[30,31]

• **Fig. 32.25** Flap Design. (A) Flapless. (B) Minimal flap. (C) Open flap is usually utilized when a wall of bone is missing and bone grafting is indicated.

• **Fig. 32.26** Surgical placement with cone beam computed tomography tooth-supported template into the immediate extraction site.

• **Fig. 32.27** Freehand Surgical Placement Into Immediate Extraction Site.

TABLE 32.1	Surgical Protocol for Various Anatomic Areas			
Anatomic Area	**Initial Osteotomy Location**	**Apical Implant positioning**	**Horizontal Implant Positioning**	**Miscellaneous**
Maxillary anterior	Engage lingual plate	Engage 2–4 mm of bone past apex	Engage mesial, distal, and palatal	No engagement of buccal wall
Maxillary premolar	First: palatal socket Second: lingual of socket	Engage 2–4 mm of bone past apex	Engage mesial, distal, and palatal	No engagement of buccal wall
Maxillary molars	Lateral to septal bone in "sawing" motion	Rarely can engage apically without sinus penetration	Difficult to obtain because of socket morphology	Use extreme caution because rarely sufficient bone is present
Mandibular anterior	Center to lingual of socket	Engage 2–4 mm of bone past apex	Engage mesial, distal, and palatal	Angulation and thin buccal bone are of concern
Mandibular premolar	Center to lingual of socket	Difficult to engage more apical because of mental foramen	Engage mesial, distal, and palatal	Use extreme caution as close proximity to mental foramen
Mandibular molars	Lateral to septal bone in "sawing" motion	Difficult to engage more apical because of mandibular foramen	Difficult to obtain because of socket morphology	Use extreme caution as close proximity to mandibular canal
• **Fig. 32. 28** (A, B) Ideal depth to coincide with 2 to 3 mm below the free gingival margin.

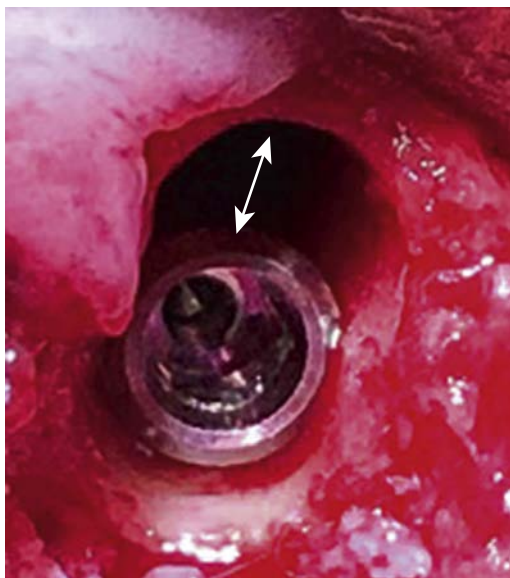
Jumping distance (maxillary anterior). The horizontal bone defect ("Jumping Distance," "Gap") is defined as the distance between the implant and the surrounding wall of the defect. Multiple animal and human studies have shown that the gap will fill with bone, regardless of whether graft materials and barriers are

used.[32-35] Botticelli et al.[33-35] reported that in defects of 2 mm or larger, no grafting was needed to grow bone. Tarnow et al.[36] concluded that as long as the buccal plate is intact after the extraction, no bone graft, membrane, or primary closure is needed, irregardless of how large the defect is. In most cases, care should be exercised not to completely fill the extraction socket with the implant. Many studies have shown conflicting results with the aftermath of filling the void between the implant and buccal socket wall.[26,37] In the author's opinion, the gap should always be grafting with a bone substitute that will maintain the space long enough for bone to regenerate, which ultimately will maintain the hard and soft tissue. Therefore a slower resorbing material (i.e., mineralized freeze-dried bone or xenograft), not a faster resorbing material (i.e., demineralized freeze-dried bone and autograft), should be used to augment the gap.

Too large an implant diameter for the tooth in question should not be used because they will reduce the gap space, thereby risking future soft and hard tissue recession (i.e. immediate implant placement in maxillary central incisor should not exceed 5 mm in diameter) (Fig. 32.29).[38] In addition, if the diameter of the implant is too large, a compromised emergence profile will result with the final prosthesis.

Lindeman drill. In most extraction sites the standard round or starter drill will have a tendency to "chatter," which makes initial placement of the osteotomy difficult. The author advocates the use of a Lindeman drill (side cutting surgical bur) to initiate osteotomies in extractions side. This type of bur when used in a "sawing" motion allows for an initial groove to be made that provides for proper and more precise positioning (Fig. 32.30).

Maxillary anterior position. Multiple studies have shown that postoperative gingival recession in the anterior region is associated with buccal implant positioning, which usually occurs when the implant is placed in the center of the extraction socket.[22] In the most esthetic area of the oral cavity (maxillary anterior), it is imperative that the positioning of the implant be lingually oriented. This will allow the buccal gap to be >2 mm, which has been shown to be vital in preventing hard and soft tissue recession.[39,40] A lingually placed implant will also minimize the possibility of apical perforation, which is common when implants are placed in the socket and a parallel walled implant is used.[41] In addition,

oversize implants should not be placed in the maxillary anterior because the buccal gap will be obliterated and the implant will encroach on the proximal area.[42] If the proximal area is compromised, a poor emergence profile will result, which may lead to peri-implant disease (Fig. 32.31).


● **Fig. 32.29** Jumping Gap Present on Facial of Implant.

Minimum torque. To achieve primary stability, a minimum torque value has been shown to be one of the most important factors in the success of immediate implants. The minimum torque has been shown to be approximately 35-45 N/cm in the literature.[43,44]

Final Emergence Position Based on Prosthesis. For a cement-retained prosthesis, the implant should exit slightly lingual to the incisal edge in the anterior and in the central fossa in the posterior. For a screw-retained prosthesis, the implant should exit in the cingulum area in the anterior and in the central fossa of the posterior. For a removable prosthesis, the implants should exit slightly lingual to the anterior teeth and within the central fossa of the posterior teeth.

Implant Design

Tapered versus parallel. Many studies have evaluated the implant design (tapered versus parallel) in the immediate implant protocol. McAllister et al.[45] showed a high success with tapered implants with a high initial implant stability. Tapered implants have been reported to be superior with immediate implants because the implants are narrow apically, which result in less chance of perforation. Because they are wider coronally, their jumping distance is less, therefore requiring less augmentation. However, Lang et al.[46] found that parallel and tapered implants have very positive short-term success rates with improved wound healing and primary stability.

Implant surface. Many researchers have evaluated rough versus machined surfaces for immediate implants. Wagenberg and Froum[47]

completed a clinical study with 1925 implants and reported higher success rates with roughened surfaces. Results concluded machined-surface implants were twice as likely to fail as roughened surface implants (4.6% versus 2.3%). In addition, studies have verified that roughened surfaces with a microthreaded neck result in less crestal bone loss than implants with non-microthreaded necks.[48]

Implant neck/collar design. When evaluating the implant collar or neck of the implant to be placed in an immediate extracting

• **Fig. 32.32** Tapered and platform switch implant has been shown to be the ideal implant for immediate implants.

site, studies have shown a tapered platform-switched internal connection to be superior for healing and implant survival.[49-52] Linkevicius et al.[53] determined that the use of a platform switching implant in a one-stage implant placement approach does not prevent crestal bone loss when the tissue is thin (≤2 mm). However, when the tissue is thick (>2 mm), use of a platform-switch implant shows minimal bone recession at the 1-year time frame.[53] Puisys and Linkevicius,[54] in a two-stage protocol, showed similar results with the thin versus thick tissue. Thin tissues (≤2 mm) lost minimal amount of crestal bone, whereas thick tissues (>2 mm) or thin tissues augmented with acellular dermal matrix (LifeNet; Salvin) had similar crestal bone maintenance with minimal bone loss at 1 year postoperatively (Fig. 32.32).[54]

Implant length. Schnitman et al.[55] reported that implant lengths greater than 10 mm provide significantly higher success rates for immediate implants. However, the implant length is directly related to the bone density. In favorable bone densities (e.g., D1, D2), implant length is not as important. When poor bone density is present (e.g., D3, D4), longer implants are required because of the greater need for primary stability and rigid fixation (Fig. 32.33 and Box 32.3).

Implant Stability

The initial stability of the immediate implant is one of the most critical factors in the success of the implant. When micromovement occurs, the implant-bone interface is reduced, thereby resulting in loss of primary stability. Micromovement greater than 100 μm may cause fibrous encapsulation of the implant.[56] There exist two types of implant stability, primary and secondary.

Primary. Primary stability is defined as the stability of the dental implant immediately after placement; it is derived from mechanical friction of the implant threads and the surrounding bone. Several methods have been advocated in the literature to determine primary stability.

a. *Percussion* is the first test method in the literature to be used to assess primary stability and estimate the amount of bone-implant contact. This technique is based on vibrational-acoustic science, where a "high pitched" sound signifies integration and a "low-pitched" sound may be indicative of lack of integration.

Unfortunately, this test is highly dependent on the clinician's experience level and subjective beliefs. Therefore although still used, it is not the most ideal testing method (Fig. 32.34).[57,58]

b. *Periotest* (Seimens, Bensheim, Germany) is a testing method that has been proposed to be a more objective method for assessment of implant stability. Although much better than the percussion test, the Periotest has been shown to have inaccuracies in the lack of resolution, poor sensitivity, and subject to operator variability (Fig. 32.35).[59]

c. A more recent method is the use of *insertion torque* that can be measured with low-speed insertion tools (i.e., surgical handpiece) or manual wrench ratchet. It has been shown that for a successful immediate loading protocol, the insertion torque should be between 35 and 45 N/cm.[60,61]

d. *Resonance frequency analysis* (RFA) is a diagnostic tool that allows for detecting implant stability as a function of the stiffness of the bone-implant interface. This test can be used in a continuous and objective manner during the healing phases of the implant. RFA was initially presented by Meredith et al.[62] in 1996. RFA has been shown to have quantitative and reproducible measurements on the presence of integration, immediate load feasibility, and follow-up evaluation at the prediction of an implant failure.[63]

RFA is a technique that is based on continual excitation of the implant interface through the use of dynamic vibration analysis (piezo effect). A specialized transducer, which contains two

piezoceramic elements, is either attached directly to the implant or abutment. The first piezo element generates an excitation signal that is a sinusoidal wave (5–15 kHz), leading to vibration of a whole transducer-implant-tissue complex. The oscillation response is measured by the second piezo element.[64]

The RFA technique measures implant stability as a function of stiffness of the bone-implant complex. The health of the implant is measured on an implant stability quotient (ISQ) that is calculated on a scale from 1 to 100. The full integration of an implant is usually measured in the range from 45 to 85 ISQ. Measurements of less than 45 are indicative of implant failure, whereas an ISQ value of 60 to 70 indicates success.[65]

● **Fig. 32.36** Resonance Frequency Analysis (RFA). The Penguin RFA (Glidewell) is a noninvasive resonance frequency analysis test that results in reliable, accurate numerical results concerning the stability of immediate placed implants.
● **Fig. 32.37** (A) Grafting of the jumping gap and other bony defects. (B) Membrane placement to prevent migration of bone graft material.

Secondary. During the healing process, the primary stability process is replaced by the biological process of bone healing. The main factors that influence secondary stability are the initial primary stability, bone remodeling process, bone-implant contact, and implant surface characteristics.

The use of RFA after the initial healing has shown great success. Han et al.[66] reported a decrease in ISQ values within the first 3 weeks after implant placement; then a return to the original ISQ values is observed approximately 8 weeks after surgery.

When comparing implants placed into immediate extraction sites vs. healed sites, Han et al.[67] showed implants immediately loaded performed the same, whether in postextraction or healed sited. In addition, they showed that tapered implants with strong self- cutting threads provides an excellent initial stability, with high insertion torque and ISQ values (Fig. 32.36).

Grafting/Membrane

After implant stability is confirmed, the present osseous defects are evaluated and grafted accordingly. Ideally the bone-grafting material should include a slower resorbing material that will maintain the space to allow for bone regeneration (e.g., demineralized/mineralized allograft, allograft + autograft, or xenograft). The membrane selection is dictated by the defect present. If the buccal wall is missing or very thin, then a longer-acting collagen membrane is recommended. It is more predictable if the membrane is placed on the buccal along with grafting before implant placement. If all five walls are present, then a collagen plug (or collagen tape) is placed over the socket (Fig. 32.37).

Closure

In most immediate placement sites it is difficult to obtain primary closure unless the flap is advanced. However, advancement of the flap will result in less keratinized tissue to the facial of the prosthesis. When inadequate keratinized tissue results, tissue grafts are usually indicated (Fig. 32.38).

Immediate Load or Staged Treatment

After implant placement a healing abutment (1-stage) or a cover screw (2-stage) may be placed. In immediate load cases a provisional restoration may be inserted, allowing the pontic (ovate design) to heal the soft tissue. De Rouck et al.[68] demonstrated that using single immediate implants with immediate provisionalization aids in

● **Fig. 32.38** Closure. Usually primary closure is not completed, and extending the flap to obtain primary closure is not generally recommended.

optimizing the esthetic results. They concluded that the provisional will mold the soft tissue and will limit the amount of soft tissue loss. Tarnow et al.[69] reported that immediate implant placement with a bone graft and a well-contoured provisional crown resulted in the least amount of facial-palatal contour change (<1 mm).

Immediate Implants Into Infected Sites

Placing implants into infected sites has been controversial. Villa and Rangert[70] reported on a series of cases where implants were placed immediately after extraction and had exhibited periodontal or endodontic infections. After 2 years the cumulative survival rate was 100%. The theory includes that after extraction, infections and microorganisms present can be eliminated with proper socket degranulation. Novaes et al.[71] evaluated immediate implant placement of implants placed in chronically infected sites. They determined that as long as antibiotics are used, meticulous debridement is completed, and alveolar bone preparation before implant placement is properly performed, immediate implants in infected sites are not contraindicated. Crespi et al.[72] evaluated immediate implant associated with a chronic periapical lesion; they did not demonstrate an increased rate of complications, and showed favorable soft and hard tissue postoperatively (Fig. 32.39).
● **Fig. 32.39** (A and B) Extreme caution should be exercised when placing immediate implants into sites with active infection.

Complications

Not Recognizing 4-Wall Socket

One of the most common complications for immediate implant placement is for the clinician to not diagnosis the loss of the buccal socket wall. A five wall socket is ideal and is treated with the conventional surgical technique (Fig. 32.40). In contrast, a four-wall socket requires a longer acting collagen membrane that is positioned over the buccal aspect of the extraction site. (Fig. 32.41).

Not Understanding Specific Anatomical Factors

Each tooth in the maxillary and mandibular arch is associated with factors which may make conditions ideal for an immediate implant placement or contraindicate placement. The author has formulated a protocol for each tooth based on specific anatomic and treatment planning criteria. Each speciifc tooth has ideal conditions (green), cautious conditions (yellow), or contraindication (red). (Fig. 32.42 and Fig. 32.43).

Inability to Obtain Primary Stability

Primary implant stability may be difficult to achieve in extraction sites where the trabecular bone density is less than ideal. Unlike a healed ridge of desirable bone volume, primary stability in fresh extraction sites is more difficult to achieve in general because of the lesser quantity of native bone present, as well as the fact that the anatomic challenge of the coronal aspect of the extraction site is often wider than the implant being placed. Potential variations in bone density may necessitate multiple modifications to osteotomy preparation and implant placement protocols compared with procedures performed in homogeneous bone density. As a result, after attempted implantation, the clinician may be faced with an implant with a questionable level of primary stability (Fig. 32.44).

Prevention

Complete Osteotomy Preparation in Appropriate Location and Surgical Sequence. Depending on the size of the extracted tooth and the implant to be placed, the implant in most cases extend past the original dimensions of the root apex and provide mechanical retention of the implant. In the anterior maxillary region, immediate implant placement often requires the osteotomy and implant insertion engage the lingual wall of the alveolus for rigid fixation. For maxillary posterior teeth the initial bur should be positioned off-center toward the lingual side of the interradicular septum. For mandibular posterior teeth the initial bur should be positioned on the mesial aspect of the interradicular septum. A Lindemann bur is useful for initiating and modifying osteotomies. The objective of this multiplane preparation process is to create an osteotomy in a prosthetically correct position without compromising the buccal wall of bone.

Underprepare Osteotomy Width and Overprepare Osteotomy Length. Misch[14] initially outlined a protocol that adapts the treatment plan, implant selection, surgical approach, healing regimen, and initial prosthetic loading to all bone densities and all arch positions, which resulted in similar implant success for all bone densities. The density of the residual native bone can influence the ability to achieve adequate primary fixation. With anterior single-rooted teeth, using bone beyond the apex and the lateral engagement of some or all of the tooth socket walls is instrumental in obtaining sufficient primary stability. With

posterior implants, vital structures such as the inferior alveolar nerve and the maxillary sinus limit stability derived from bone beyond the tooth apices. Furthermore, the limited native bone present undergoes remodeling after the surgical trauma of osteotomy preparation and implant insertion. This trauma leads to a weakening of the bone-implant interface and may have an adverse effect on the initial implant stability (Fig. 32.45).

Often inadequate primary stability may manifest itself only after 4 to 6 weeks; the bone interface is stronger on the day of implant placement compared with 3 months later. The surgical process of the implant osteotomy preparation and implant insertion cause a RAP of bone repair around the implant interface. As a result of the surgical placement, organized, mineralized lamellar bone in the preparation site becomes unorganized, less mineralized, woven bone of repair next to the implant. The implant-bone interface is weakest and most at risk for overload at 3 to 6 weeks after surgical insertion because the surgical trauma causes bone remodeling at the interface that is least mineralized and unorganized during this time frame. A clinical report by Buchs et al.[73] found immediately loaded implant failure occurred primarily between 3 and 5 weeks after implant insertion from mobility without infection. At 4 months the bone is still only 60% mineralized, organized lamellar bone. With time, bone formation and mineralization will lead to increased interlocking with the implant surface and a stronger implant-bone interface. However, this has proved to be sufficient in most bone types and clinical situations
• **Fig. 32.40** Five Wall Socket Immediate Implant Placement. (A) Maxillary second premolar depicting sufficient apical bone for immediate implant placement. for two-stage healing and delayed implant loading. The relative lack of native bone (compared with a healed site) suggests the osteotomy should frequently be undersized in width, the degree of which is dependent on bone density. In addition, for less dense bone, immediate implant fixation can be facilitated if the clinician can use osteotomes or osseodensification techniques for radial compaction. Dependent on tooth socket size and anatomy, sufficient implant stability can sometimes be achieved by lateral wall engagement only. However, extending the osteotomy 2 to 4 mm past the socket apex (without encroaching on vital structures) is more commonly completed for primary stability.[74]

Implant Design and Initial Stability. The clinical perception of primary implant stability is frequently based on the cutting resistance of the implant during its insertion. The feeling of "good" stability may be accentuated if there is the sense of an abrupt stop at the seating of the implant. Although root form tapered implants often have a geometry that will provide a firm stop, the resultant stability may be a false perception.[75] In addition, in a tapered, threaded implant, threads at the apical half are often not as deep because the outer diameter of the implant body continues to decrease. This limits the initial fixation of the implant and further reduces the functional surface area. For immediate implant placement, the tapered/conical body design may be of benefit during initial insertion because it is positioned within the osteotomy halfway before engaging bone. The choice of implant body with regard to primary stabilization is equivocal and may be more influenced by osteotomy preparation than implant body design. A study by Sakoh et al.[76] concluded that the combination of both conical implant design and the procedure of under dimensioned drilling appeared to be associated with increased primary stability (Fig. 32.46).

Treatment Options

Redirection dependent on bone density. If the implant has poor primary stability, the implant can sometimes be redirected into denser bone; the redirection may be needed in more than one plane and kept within the ideal three-dimensional boundaries for prosthetic reconstruction. Often a subtle tap of the (threaded) implant in an axial direction will gain the needed initial primary stability without putting the implant at risk from excessive apical positioning relative to the osseous crest and any adjacent teeth. A mallet and straight or offset osteotome can be used over top of the implant body.

Use of larger diameter implant. The dimensions, longer and/or wider, of the "rescue" implant may allow for satisfactory better primary fixation; however, it must still be in an acceptable position in relation to the crestal bone, adjacent teeth, and planned final prosthesis.[77] This may be placed in a redirected manner described earlier. An increased implant surface area can engage more cortical bone. It has also been shown in an experimental study in rabbit tibia that wider implant diameters resulted in increased removal torque values.[78] Matsushita et al.[79] used a two-dimensional finite element method to analyze the effect of different implant diameters on stress distribution within the alveolar bone using HA-coated implants. They found that stress in cortical bone decreased with increased implant diameter. Ivanoff et al.,[80] however, reported a lower survival rate and a tendency for higher bone loss for 5.0-mm-diameter implants, compared with 3.75-mm- or 4.0-mm-diameter implants. Resultant decreased facial bone dimensions associated with wider implant dimensions increase the probability of soft tissue recession. However, caution should be exercised in placing too wide of an implant because it

may encroach on the buccal plate or result in a nonideal prosthetic outcome.

Leave implant in place. An implant with loss of rotational stability (spinner) and minimal, if any, surrounding ridge deficiencies may be left in place. If replacement is not possible (e.g., in cases of inadequate bone dimensions or where a larger implant is unavailable), the implant clinician must then decide whether to leave the implant in place or remove it and reevaluate the site for further implant therapy after healing is complete. Ivanoff et al.[81] reported osseointegrated implants that have been mobilized because of a traumatic disruption of the bone-implant interface may reintegrate if allowed to heal for an additional period. Orenstein et al.[82]

reported a 79.8% survival rate after 3 years of implants that were mobile at placement. A significant factor for most of these implants was the presence of a HA coating. Almost half of the noncoated, initially mobile implants failed by 3 years postplacement. Even if initially mobile implants are found to integrate, precautions are advised to avoid implant overload. Clinicians may want to use strategies such as long-term temporization to promote bone maturation and evaluate the viability of initially mobile implants in function before inserting the definitive prosthesis.

Abort the procedure. The clinician may consider aborting the procedure and proceeding with bone grafting and delayed implant placement (Fig. 32.47).
● **Fig. 32.41, cont'd** (J) Positioning of collagen along buccal wall. (K) Implant placement. (L) Abutment placement to check angulation. (M) platelet rich fibrin (PRF) placed underneath the flap. (N) Final closure.

Postoperative Complications

Transitional Prosthesis Impingement

The transitional prosthesis over an immediate implant should not rest or apply pressure to the soft tissue over the site. Implants and particulate grafts are more prone to movement during healing, which prevents blood vessels from entering and forming bone in the site. If possible, a fixed provisional or a pressure-free prosthesis is ideal for successful healing (Fig. 32.48).

Neurosensory Impairment

The close proximity of inferior alveolar nerve to the apices of the mandibular posterior teeth poses the possibility of neurosensory impairment when preparing osteotomies and during implant insertion. In most cases, the immediate implant gains its primary stability from the bone beyond the root apices. This risk is greater in the posterior mandible extraction site than in a healed site with its increased volume of bone and associated likelihood of the more abundant bone achieving primary stability without nerve encroachment. Preventive strategies include preoperative three-dimensional imaging, guided surgery, and having a heightened awareness of local anatomy (Fig. 32.49). Neurosensory impairment is most common in Type 1 nerve positions (i.e. anterior posterior position close to root apexes.

For this discussion, care must be taken to distinguish between a compromise(s) that could be present after a delayed/two-stage procedure (e.g., increased final crown height) versus a compromise that could be solely attributed to implant placement at the time of extraction. Examples of the latter are characterized by excessive positions in

one or more of the potential three reference planes. Nonideal positioning can also result after multistage procedures; however, the need for native bone for primary stability in immediate placement cases increases the likelihood of positioning error. Management of cases with resultant excessive mesial-distal space/length can be frequently treated by placement of additional (usually narrower-diameter) implants. Use of surgical templates or guided surgery are recommended for clinicians desiring physical reference points during surgery (Fig. 32.50).

Conclusion

Placement of immediate implants into an extraction site has been shown through the literature to be very successful. Technological advances have led to an array of options for the patient and clinician as an alternative to the traditional two-stage technique. Immediate placement implants pose many challenges to clinicians, especially when treating patients with preexisting hard and soft tissue deficiencies. In this chapter, the advantages and disadvantages of immediate implants were explained in detail along with numerous treatment planning factors that should be ideally evaluated prior to treatment. With appropriate patient selection and treatment planning, complications may be minimized, and success rates increased with immediate placement implants. In addition, each specific tooth position is discussed in detail with a treatment planning protocol which allows the clinician to understand when ideal conditions exist, cautious variables are present, and when immediate placement is contraindicated.

Immediate Load/Restoration in Implant Dentistry

RANDOLPH R. RESNIK AND CARL E. MISCH

For years the two-stage surgical protocol established by Brånemark et al.[1] to accomplish osseointegration was considered a prerequisite for achieving osseointegration and long-term success. This traditional surgical protocol consisted of placing dental implants slightly below the crestal bone, obtaining and maintaining a soft tissue covering over the implant, and allowing for a nonloaded implant environment for 3 to 6 months. The success of the two-stage technique was highly documented; however, many in the field still strived for shorter treatment times and fewer surgical interventions. With advances in implant technology, the traditional protocol in implant dentistry has been reevaluated, which has led to a growing interest in the immediate-loading protocol. An abundance of clinical studies have shown positive outcomes and success with loading implants immediately or within a short period after implant placement.[2,3]

The immediate-loaded implant concept has become popular in the dental profession because it allows patients to have the ability to combine the surgical and prosthetic procedures into a single appointment. As a result of the immediate-loading technology, advances have led to an array of new implant designs and treatment protocols. In this chapter the concept of immediate-loading protocol will be discussed in detail, together with various immediate-loading protocols for single-tooth replacement, multiteeth replacement, and full-arch rehabilitation.

Immediate-Loading Terminology

The concept of immediate-loading implants involves a nonsubmerged first-stage surgery, with the immediate loading of the implants with an interim or final prosthesis. The terminology and nomenclature for these techniques are poorly understood, with little consistency. Therefore in an attempt to standardize the language in which immediate loading is discussed, Misch et al.[4] suggested a terminology for immediate restoration and/or occlusal loading (Box 33.1).

Advantages of Immediate Load Protocol

Less Discomfort for Patients

When the immediate loaded principle is used, patient discomfort and morbidity are reduced. No second-stage surgery (i.e., uncover) is required, therefore fewer appointments will be necessary for the patient. In many delayed loading situations, it is necessary for the patient to wear a removable prosthesis throughout the healing period. Not only does this lead to increased discomfort and inconvenience for the patient, but also the possibility of overloading the tissue and/or implant is greater. With the immediate load technique, a removable prosthesis is not worn, therefore decreasing the morbidity to the patient.

Faster Treatment

The immediate-loading protocol reduces the need for second-stage surgery and subsequent healing of the tissue. Therefore a more simplified surgical workflow is indicated that leads to shorter treatment time. In addition, in most cases, surgical intervention and complex bone augmentation procedures are not required to restore resorbed ridges that result from the postextraction bone remodeling process. This results in far fewer appointments and shorter treatment time.

More Ideal Soft Tissue Drape

In some clinical situations, placing a prosthesis at the time of surgery will allow for better soft tissue healing. The surrounding tissue is given the opportunity to mature and heal to the existing prosthesis. This is most important in esthetic areas, where soft tissue shrinkage after second-stage surgery may compromise the soft tissue margins and papilla contours.

Immediate Satisfaction and Patient Acceptance

Placing a prosthesis immediately after implant placement has been associated with increased psychological acceptance and patient satisfaction. In cases of full arch extractions, inserting a prosthesis immediately not only improves esthetics, but also will maintain masticatory function and muscle mass. Blomberg and Lindquist[5] evaluated patients undergoing extractions and immediate placement of an implant-supported bridge and their overall satisfaction to the procedure. Overwhelmingly, patients stated a significant improvement in their quality of life and increased self-confidence.[5]

Immediate occlusal loading: Insertion of an implant-supported interim prosthesis (e.g., polymethylmethacrylate [PMMA] temporary) or final restoration in occlusal contact within *2 weeks* of the implant insertion.

Early occlusal loading: Refers to an implant-supported prosthesis in occlusion between *2 weeks and 3 months* after implant placement (i.e., occlusal loading implants after a short healing period, ~5 weeks).

Delayed or staged occlusal loading: An implant prosthesis with an occlusal load after *more than 3 months* after implant insertion. The delayed occlusal loading approach may use either a two-stage surgical procedure that covers the implants with soft tissue or a one-stage approach that exposes the implant with a healing abutment.

Nonfunctional immediate prosthesis: This describes an implant prosthesis with no direct occlusal load *within 2 weeks* of implant insertion and is primarily considered in partially edentulous patients (i.e., congenitally missing maxillary lateral incisor).

Nonfunctional early prosthesis: Describes a prosthesis delivered between 2 weeks and 3 months after the implant insertion.[114]

Occlusal loading: The prosthesis is in contact with the opposing dentition in centric occlusion.

Nonocclusal loading: The prosthesis is not in contact in centric occlusion with the opposing dentition in the natural jaw position.

Provisional prosthesis: A fixed or removable dental prosthesis designed to enhance esthetics, stabilization, and/or function for a limited period, after which it is to be replaced by a definitive dental prosthesis. This type of prosthesis assists in the determination of the therapeutic effectiveness of a specific treatment plan or the form and function.[115]

Greater Bone-Implant Contact

Numerous studies are available that report positive success rates with immediate-loaded implants that are exposed to the oral cavity during the healing phase.[6,7] Histologic studies have shown an improved bone-implant contact (BIC) with immediate-loaded implants compared with conventional protocol implants.[8,9] Piattelli et al.[10] evaluated the histology of nonsubmerged, unloaded, and early-loaded titanium implants in monkeys. They determined that early-loaded implants exhibited lamellar cortical bone that was thicker in comparison with unloaded implants.[10] Testori et al.[11] reported a BIC of 64.2% for a single immediate-loaded implant and a BIC of 38.9% for a single submerged implant.

Disadvantages of Immediate Load Implants

Increased Skill Level Required

Especially when extracting teeth and placing implants at the same time, an increased skill level is required. These types of cases require significant preplanning, most commonly with advanced cone beam computed tomography (CBCT) interactive treatment planning. In addition, CBCT bone reduction and placement guides may be indicated, which increases the complexity of the surgery and prosthetic protocols.

Initial Surgical/Prosthetic Appointment Longer

In some cases the surgical placement of implants and the prosthetic procedures may require a longer appointment duration than normal. This may lead to increases exceeding the patient's tolerance for appointment length. With some patients, this may predispose them to an increased possibility of medical complications.

Possible Increased Implant Morbidity

An often talked about disadvantage for the immediate load concept is the risk for implant bone loss or implant failure. In general this is not supported by clinical studies and research. Chen et. al. in a systemic review and meta-analysis compared immediate loaded implants vs. conventional loading and found no difference in marginal bone loss between the two techniques. However, if failure does occur, this will often lead to the patient's loss of confidence in the doctor, increased costs and treatment time, together with a longer treatment period.

Prerequisites for Immediate-Loading Protocol

For the immediate-loading protocol to be successful, various treatment planning and patient factors need to be taken into consideration implemented in the patients treatment.

Adequate Bone Density

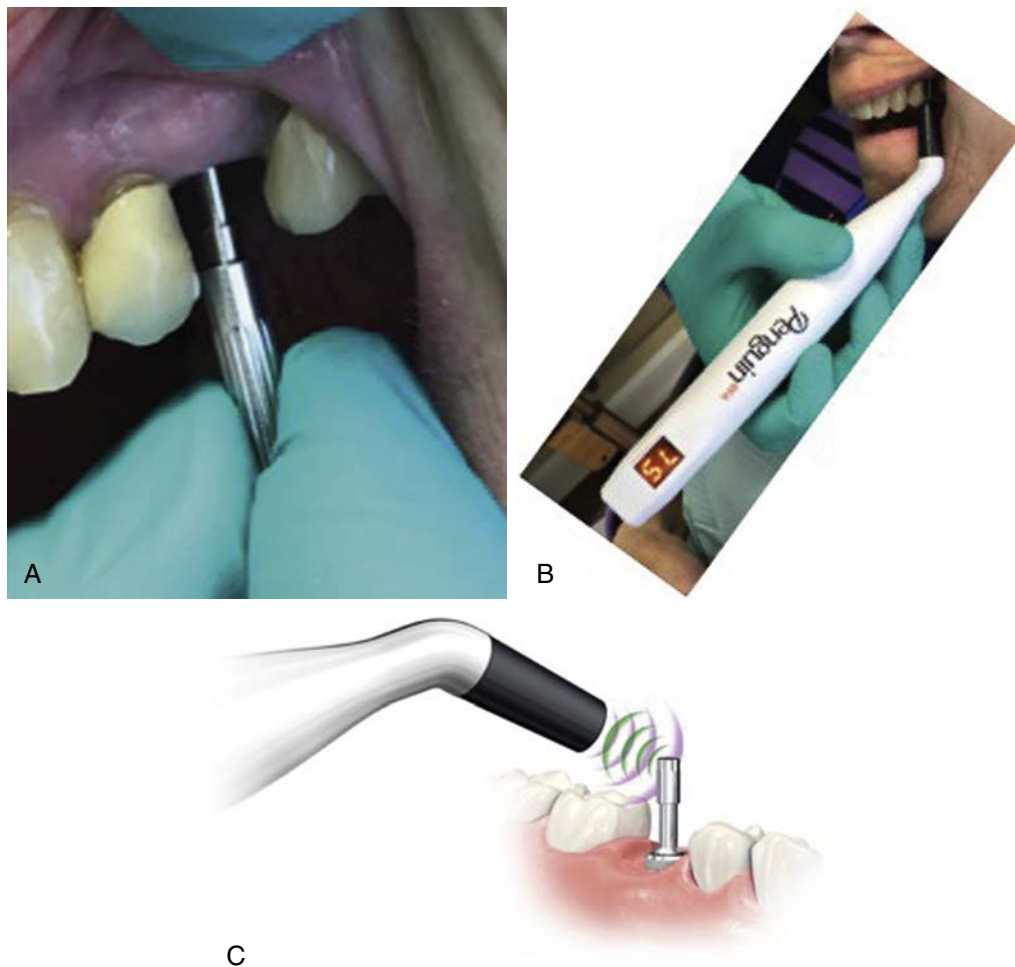
Ideally the bone density should be favorable for an immediate-loaded prosthesis (~D1, D2, D3). However, in some cases of poor bone quality, even with modified surgical protocols, achieving an insertion torque greater than 35 N-cm is unachievable. In these clinical situations the immediate-loading protocol is not recommended, and a healing period of 4 to 6 months is suggested before loading the dental implants. In addition, the prosthetic rehabilitation should include a progressive bone-loading protocol, which increases bone density around the implants.[12]

Sufficient Bone Dimensions

For immediate load cases, it is imperative that sufficient height and width of bone are available for the placement of implants. Lazzara et al.[13] stated that 12 mm of available bone height is recommended (i.e., for a 10-mm implant) and 6 mm of available bone width is required for adequate support. In clinical cases of compromised bone quantity, immediate-loaded implants may be at higher risk for bone loss or failure, therefore more implants or implants with a greater surface area are recommended.

Ideal Insertion Torque

In the literature it is generally accepted that the immediate-loading concept is based on obtaining an insertion torque of greater than 35 N-cm to provide sufficient implant stability when the prosthesis is placed under loading situations.[14-16] However, studies have shown successful implant integration at insertion torques of 30 N-cm or less.[17] Maló et al.[18] stated that implants inserted with <30 N-cm of torque in an All-on-4 protocol have similar short-term success outcomes and marginal bone loss compared with implants inserted with ≥30 N-cm of torque.

In most clinical situations with favorable bone quality (i.e., D1, D2, D3), insertion torque of greater than 35 N-cm is usually attainable. In clinical situations of less dense bone (i.e., D3, D4), this is often difficult, if not impossible, to obtain without surgical placement protocol revision. Therefore modified surgical drilling protocols should be used in less dense bone, which may include underpreparation of the osteotomy sites, use of osteotomes, or osseodensification protocols.


• **Fig. 33.1** Resonance Frequency Analysis with Penguin RFA. (A) MultiPeg placed into Implant Body, (B) Penguin RFA reading, (C) The Penguin RFA measures the resonance frequency of the reusable Multipeg. The frequency is displayed as an ISQ-value (Implant Stability Quotient).

Ideal Resonance Frequency Analysis Readings

The primary stability of an inserted dental implant can be measured via resonance frequency analysis (RFA). The RFA values will give a numerical assessment on the lateral movement (i.e., micromotion) of the implant during the healing phase. The micromotion differs for each implant system, mainly dictated on the implant design. For example, for implants with roughened surfaces, tolerance is in the range of 50 to 150 μm,[19,20] and with machined surfaces is approximately 100 μm of micromovement.[21] Studies have confirmed an implant stability quotient (ISQ) of 70 or greater is needed for an immediate-loaded prosthesis, 65 to 70 for early loading, and 60 to 65 for traditional healing (Fig. 33.1).[22,23]

Ability to Achieve an Adequate Anteroposterior Spread

The anteroposterior (A-P) spread (i.e., distance between the middle of the most anterior implant and the distal of the posterior implants) is important in increasing the mechanical advantage and force distribution of the prosthesis. In general the A-P spread is related to the ability to cantilever the prosthesis. The larger the A-P spread distance, the greater the force distribution for forces applied to the immediate-loaded prosthesis. However, force factors play a significant role in determining if a prosthesis may be cantilevered.[24]

Rational for Implant Immediate-Loading Protocol

Effect of Surgical Trauma on Healing

The immediate implant-loading concept challenges the conventional healing period of 3 to 6 months of no loading before the restoration of the implant. Often the risks of this procedure are perceived to be during the first week after the implant insertion surgery. In reality the bone interface is stronger on the day of implant placement compared with 3 months later[23] (Fig. 33.2).

The surgical process of the implant osteotomy preparation and implant insertion result in a regional acceleratory phenomenon of bone repair around the implant interface.[24] As a result of the surgical placement, organized, mineralized lamellar bone next to the implant site becomes unorganized, less mineralized, and mainly made up of woven bone.[25] The implant-bone interface is weakest and most at risk for overload at 3 to 6 weeks after surgical insertion because the surgical trauma causes bone remodeling at the interface that is least mineralized and unorganized during this
Fig. 33.2 (A) A densitometry profile of an implant 10 days after insertion. The two parallel lines at the interface represent the bone-implant contact. (B) After 3 months the densitometry profile was repeated. The implant interface is weaker at this time than the initial radiograph showed. (*Data are from Strid KG: Radiographic results. In Brånemark PI, Zarb GA, Albrektsson T, eds.* Tissue Integrated Prostheses. *Chicago: Quintessence; 1985.*)

time frame. A clinical report by Buchs et al.[27,28] found immediate-loaded implant failure occurred primarily between 3 and 5 weeks after implant insertion from mobility without infection. At 4 months the bone is still only 60% mineralized, organized lamellar bone.[28] However, this has proved to be sufficient in most bone types and clinical situations for two-stage healing and delayed implant loading.

One method to decrease the risk for immediate occlusal overload is to decrease the surgical trauma and amount of initial bone remodeling at implant placement. Roberts et al.[29,30] reported a devital zone of bone for 1 mm or more around the implant as a result of the surgical trauma (Fig. 33.3). Causes of trauma include thermal injury and microfracture of bone during implant placement. Excessive surgical trauma and thermal injury may lead to osteonecrosis and result in fibrous encapsulation around the implant.[31] Eriksson and Albrektsson[32,33] have reported bone cell death at temperatures as low as 40°C, which relate to surgical factors of the amount of bone prepared, drill sharpness, depth of the osteotomy, and variation in cortical thickness.

Studies have shown a self-tapping implant causes greater bone remodeling (woven bone) around the implant during initial healing compared with a bone tap and implant placement technique.[34] The implant should be nonmobile on insertion; however, pressure necrosis from increased torque may increase the risk for microdamage at the interface and result in bone loss. Pressure necrosis may occur from placing excessive torque on the implant, which results in an increased amount of strain at the interface. When this occurs, an increase in the amount of bone remodeling will take place, which decreases the strength of the bone-implant interface. Therefore it is prudent to minimize factors related to thermal injury and surgical trauma when considering the immediate-loading protocol.

Bone-Loading Trauma

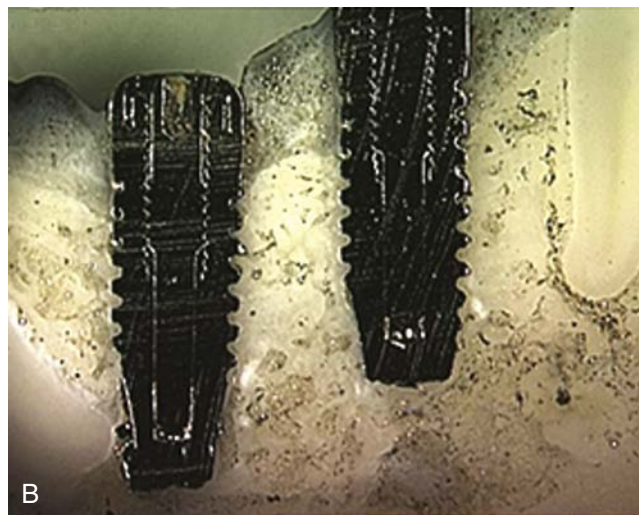
Cortical and trabecular bone have been shown to be modified by modeling or remodeling.[25] Remodeling, or bone turnover, permits

the repair of bone after trauma or allows the bone to respond to its local mechanical environment. The bone most often is lamellar in nature; however, it may become woven bone during the repair or remodeling process. Lamellar bone and woven bone are the primary bone tissue types found around a dental implant. Lamellar bone is organized, highly mineralized, is the strongest bone type, has the highest modulus of elasticity, and is called load-bearing bone. By comparison, woven bone is unorganized, less mineralized, weaker, and more flexible (lower modulus of elasticity). Woven bone may form at a rate of 60 µm/day, whereas lamellar bone forms at a rate of 1 to 5 µm/day.[28] The classic two-stage surgical approach to implant dentistry permitted the surgical repair of the implant to be separated from the early loading response by 3 to 6 months. Therefore the majority of the woven bone that formed to repair the initial surgical trauma was replaced with lamellar bone. Lamellar bone is stronger and able to respond to the mechanical environment of occlusal loading. The rationale for immediate loading is not only to reduce the risk for fibrous tissue formation (i.e., which results in clinical failure), but also to minimize woven bone formation and promote lamellar bone maturation to sustain occlusal load.

The woven bone of surgical trauma has been called *repair bone*, and the woven bone formed from the mechanical response may be called *reactive woven bone*.[35] Remodeling also is called *bone turnover*, and not only repairs damaged bone but also allows the implant interface to adapt to its biomechanical situation (Fig. 33.4). The interface-remodeling rate is the period of time for bone at the implant interface to be replaced with new bone. Once the bone is loaded by the implant prosthesis, the interface begins to remodel again. However, this time the trigger for this process is strain, rather than the trauma of implant placement. Strain is defined as the change in length of a material divided by the original length, and it is measured as the percentage of change. When the surgical trauma is too great or the mechanical stress is too severe, fibrous tissue may form rather than bone. Fibrous tissue at an implant interface will usually result in clinical mobility rather than rigid fixation.
• **Fig. 33.3** Bone remodeling around an implant after surgery replaces a 1-mm or more devital zone of bone. Arrows indicate the devital zone of bone replacement. *O*, Original bone; *T*, implant.
• **Fig. 33.4** Bone remodeling replaces the existing bone with new bone and is controlled primarily by the amount of microstrain within the bone. The rate of the bone remodeling also is related directly to the amount of microstrain.

Histologic Evaluation of Immediate-Loaded Implants

Short-Term Evaluation

General agreement is that excess stresses to an implant interface may cause overload and implant failure. However, immediate loading of an implant does not necessarily result in excessive stresses. The initial histologic response of bone at the implant interface has been evaluated on immediate-loaded implants. A direct BIC with favorable bone quality around the implants has been reported. Romanos et al.[25] demonstrated no statistical difference between immediate- and delayed-loaded implants. Sharawy[27] evaluated the immediate- versus delayed-healing interface of 20 dental implants


• **Fig. 33.5** (A,B) Paired implants inserted into a canine model, with one implant not loaded and the other immediately placed into function for 4 weeks.

in five adult beagle dogs (Fig. 33.5). All implants were inserted into premolar grafted bone defect sites. The implants were paired, so half of the implants were submerged, and the adjacent implants received an abutment and were subjected to immediate function for 4 weeks. The implants then were evaluated with histometric analyses of plastic embedded calcified sections. No statistically significant difference ($P > 0.05$) was found in the BIC ratios between the submerged and loaded implants (Fig. 33.6). Similarly, the volume fractions of the interface bone were not significantly different. The bone next to the implants appeared mature and showed evidence of remodeling.[27]

Suzuki et al.[28] performed a clinical and histologic evaluation of immediate-loaded posterior implants in nonhuman primates. After loading 10 implants for 90 days, they were compared with 5 control implants with no loading. The BIC percentage ranged from 50.3% to 64.1%, with an average of 56.3% for the controls. The immediate-loaded group had one implant failure, seven implants with an average of 67.6% BIC, and two implants with 43.2% and 45.6% BIC, respectively. Therefore the study demonstrated immediate-loaded implants may have a higher BIC than nonloaded implants, most likely a response to the strain conditions in the bone. However, three implants had less BIC or failure compared with controls. Although benefits exist related to immediate loading, it appears some risks are involved in the procedure.[28]

Testori et al.[30] reported on the histologic interface of two implants in humans that were immediately loaded after 4 months.
● **Fig. 33.6** No statistical difference in bone-implant contact percent and the volume fractions of the interface were found between the implants immediately loaded and those with no load for 1 month.

The bone contact ranged from 78% to 85%, with no epithelial migration. Therefore immediately loading an implant interface apparently does not necessarily place the interface at increased risk for fibrous tissue formation.[30]

Long-Term Evaluation

Piatelli et al.[31] evaluated bone reactions and the bone and titanium interface in early loaded implants in monkeys, compared with unloaded implants in the same arch several months after immediate loading. No statistically significant differences were detected in the BIC after 8 months.[31] However, loaded implants had less marrow spaces and more compact bone. A later study by the same group demonstrated greater bone contact in immediately loaded implants at 9 months.[33] No fibrous tissue was found at the interface. After 15 months, unloaded and immediately loaded implants were compared, and loaded implants exhibited greater (almost twice) direct bone contact at the interface. In particular, early loaded screws demonstrated thicker lamellar and cortical bone than unloaded implants. This finding suggests that early occlusal loading may enhance bone remodeling and further increase bone density.[36]

Randow et al.[39] evaluated the bone interface in a human patient after 18 months in an immediate-loading situation. They noted a direct bone-implant interface. Ledermann[37,38] confirmed these results in a 95-year-old patient who had an immediate-loaded, bar-connected overdenture in function for 12 years. Thus a long-lasting direct BIC relationship appears to be possible.[39]

Immediate Occlusal Loading: Factors That Decrease Risks

Bone Microstrain

When bone is loaded, its shape may change. This change may be measured as strain. Microstrain conditions 100 times less than the ultimate strength of bone may trigger a cellular response. Frost[40] has developed a microstrain language for bone based on its biological response at different microstrain levels (Fig. 33.7). Bone fractures at 10,000 to 20,000 microstrain (me) units (1%–2% strain). However, at levels of 20% to 40% of this value, bone

already starts to disappear or form fibrous tissue and is called the *pathologic overload zone*. The ideal microstrain for bone is called the physiologic or adapted zone. The remodeling rate of the bone in the jaws of a dentate canine or human that is in the physiologic zone is about 40% each year.[42] At these levels of strain, the bone is allowed to remodel and remain an organized, mineralized lamellar bone. This is called the *ideal load-bearing zone* for an implant interface. The mild overload zone corresponds to an intermediate level of microstrain between the ideal load-bearing zone and pathologic overload. In this strain region, bone begins a healing process to repair microfractures, which are often caused by fatigue. Histologically the bone in this range is called *reactive woven bone*. Rather than the surgical trauma causing this accelerated bone repair, the microstrain causes the trauma from overload. In either condition the bone is less mineralized, less organized, weaker, and has a lower modulus of elasticity.

One goal for an immediate-loaded implant-prosthesis system is to decrease the risk for occlusal overload and its resultant increase in the remodeling rate of bone. Under these conditions the surgical regional acceleratory phenomenon may replace the bone interface without the additional risk for biomechanical overload. When strain is placed on the horizontal axis and stress is positioned on the vertical axis, the relationship between these two mechanical indexes results in the flexibility or modulus of elasticity of a material. Therefore the modulus conveys the amount of deformation in a material (strain) for a given load (stress) level. The lower the stress applied to the bone (force divided by the functional surface area that receives the load), the lower the microstrain in the bone (Fig. 33.8). Therefore one method to decrease microstrain and the remodeling rate in bone is to provide conditions that increase functional surface area to the implant-bone interface.[43] The surface area of load may be increased in a number of ways: implant number, implant size, implant design, and implant body surface conditions. The force to the prosthesis also is related to the strain and may be altered in magnitude, duration, direction, or type. Methods that affect the amount of force include patient conditions, implant position, and direction of occlusal load.

Increased Surface Area

Implant Number

The clinician may increase the functional surface area of occlusal load at an implant interface by increasing implant number. Therefore rather than three to five implants to support a fixed prosthesis, use of additional implants when immediate loading is planned is more prudent. Immediate-loading reports in the literature with the lowest percentage survival correspond to fewer implants loaded.[34,44]

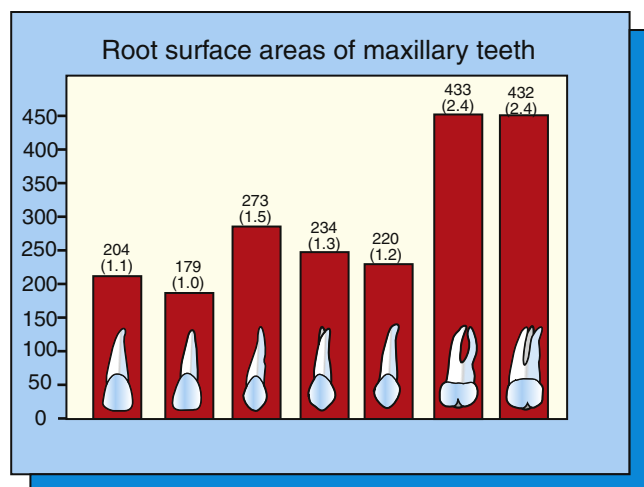
In numerous studies, 10 to 13 implants were inserted and splinted together per arch, and implant survival rate may be greater than 97%.[35,40-42] The increased number of implants also increases the retention of the restoration and reduces the number of pontics. The increased retention minimizes the occurrence of partially unretained restorations during healing, which can overload the implants still supporting the restoration. The decrease in pontics may decrease the risk for fracture of the transitional prosthesis, which also may be a source of overload to the remaining implants supporting the prosthesis. In general the maxilla typically requires more implants in comparison with the mandible. This approach helps compensate for the less dense bone and increased directions of force often found in the maxillary arch.
• **Fig. 33.7** Frost has reported on four distinct microstrain patterns within the bone. The acute disuse window results in atrophy, the adapted window is the physiologic response of organized bone, the mild overload zone corresponds to fatigue fractures with reactive woven bone formation, and the pathologic overload zone causes bone resorption. (*Data are from Frost HM. Mechanical adaption of Frost's mechanostat theory. In: Martin DB, Burr DB, eds.* Structure, Function and Adaption of Compact Bone. *New York: Raven Press; 1989.*)

Implant Size

The surface area may also be increased by the size of the implant. Each 3-mm increase in length can improve surface area support by more than 20%.[48] The benefit of increased length is not found at the crestal-bone interface but rather in initial stability of the bone-implant interface. Most of the stresses to an implant-bone interface are concentrated at the crestal bone, so the increased implant length does little to decrease the stress that occurs at the transosteal region around the implant.[49] Therefore length is not an effective method to decrease stress because it does not address the problem in the functional surface area region of the bone-implant interface. However, because the implant is loaded before the establishment of a histologic interface, implant length is more relevant for immediate-load applications, especially in softer bone types. The additional implant length also may permit the implant to engage the opposing cortical plate, which further increases the initial stability of the implant.

The functional surface area of each implant support system is related primarily to the width and the design of the implant. Wider root form implants provide a greater area of bone contact than narrow implants (of similar design). The crest of the ridge is where the occlusal stresses are greatest. As a result, width is more important than length of implant (once a minimum length has been obtained for initial fixation). Bone augmentation in width may be indicated to increase implant diameter when forces are greater, as in cases of moderate-to-severe parafunction. The major increase in tooth size occurs in the molar regions for natural teeth, where root surface area doubles compared with the rest of the dentition (Fig. 33.9). Therefore implant diameter often is increased in the molar region. When a larger-diameter implant is not possible without additional augmentation surgery, more implants may be inserted (i.e., two for each molar), which also is a method to double the overall surface area in the posterior region.
• **Fig. 33.8** When stress is applied to a material, a change in shape occurs (strain). The modulus of elasticity of a material represents the interaction of stress and strain. Titanium (Ti) has a higher modulus of elasticity than bone. When stress is applied to both of these materials, the microstrain difference between the two in the Frost microstrain zone at the interface at 50 units or less is disuse atrophy. When the microstrain difference is 50 to 2500 units, the ideal loading zone is present; between 2500 and 4000 units, the zone is in mild overload; and at more than 4000 units, the zone is in pathologic overload.

Implant Body Design

The implant body design should be more specific for immediate loading because the bone has not had time to mature and grow into recesses or undercuts in the design or attach to a surface condition before the application of occlusal load. For a threaded implant, bone is present in the depth of the threads from the day of insertion. Therefore the functional surface area is greater during the immediate-load format. The number of


• **Fig. 33.9** The natural dentition root surface area is two times greater in the molar region compared with any other tooth position. Treatment plans for immediate loading should consider implant size or number to increase surface area in this region, especially in the maxilla.

the threads also affects the amount of area available to resist the forces during immediate loading. The greater the number of threads, the greater the functional surface area at the time of immediate load.

Another variable in implant design is the thread depth, which varies in implant design. The greater the thread depth, the greater the functional surface area for immediate-load application. In general the thread depth of most threaded implants is approximately 0.2 mm, whereas the thread depth of other implant designs may reach 0.42 mm.[49] Therefore one threaded implant may have more than two times the overall functional surface area compared with other implants of similar length and width.

The functional surface area of an implant body may affect the remodeling rate of bone during loading. A macrosphere implant with reduced surface area may have twice the remodeling rate of a typical threaded implant design. A square-threaded implant design, with deeper threads in greater number, is reported to have a 10-fold reduction in remodeling rate under similar loading conditions and approximates 50% per year. The higher the remodeling rate, the weaker is the bone interface. The teeth have a bone remodeling rate of 40% per year, which maintains lamellar bone at the interface.[50]

The thread geometry also may affect the strength of early osseointegration and the bone-implant interface. Steigenga[51] placed 72 implants into 12 rabbits and reverse-torque tested the unloaded implants after 12 weeks. One-third of the implants had a V-thread, one-third had a reverse buttress shape, and one-third had a square thread. The number and depth of threads were the same, as were the width and length of each implant. The V-thread and reverse buttress thread geometry yielded similar values for reverse-torque and BIC values. The square thread demonstrated statistically significantly higher values for both of these evaluations.

Implant thread design may affect the bone turnover rate (remodeling rate) during occlusal load conditions. For a V-shaped thread design, a 10-fold greater shear force is applied to bone compared with a square thread shape.[49] Bone is strongest to compression and weakest to shear loading.[52] Compressive forces decrease the microstrain to bone compared with shear forces. Therefore the thread shape and implant design may decrease the early risks of immediate loading while the bone is repairing the surgical trauma.

A few clinical trials have compared immediate loading with different implant thread designs and tapered-implant bodies in the completely edentulous patient. The short-term clinical reports indicate a high success rate, regardless of implant design. As a result, overall shape and thread geometry apparently may not be the most important aspects for immediate occlusal load survival. Implant number, implant position, and patient factors most likely are more relevant components of success. Future studies in this area certainly are needed.

Decreased Force Conditions

The clinician may evaluate forces by magnitude, duration, direction and type. Ideally these conditions should be reduced to minimize the magnification of noxious effects of these forces.

Patient Factors. The greater the occlusal force applied to the prosthesis, the greater is the stress at the implant-bone interface and the greater the strain to the bone. Therefore force conditions that increase occlusal load increase the risks of immediate loading. Parafunction such as bruxism and clenching represents significant force factors because magnitude of the force is increased, the duration of the force is increased, and the direction of the force is more horizontal than axial to the implants with a greater shear component.[38] Balshi and Wolfinger[41] reported that 75% of all failure in immediate occlusal loading occurred in patients with bruxism. In their report, 130 implants were placed in 10 patients, with 40 implants immediately loaded and 90 implants following the traditional two-stage approach. The authors reported an 80% survival rate for immediately loaded implants compared with 96% for the traditional protocol. Grunder[42] appraised immediate loading in eight edentulous patients, four of whom exhibited bruxism. Overall success rates were 87% in the maxilla and 97% in the mandible, with five of the seven implant failures in the bruxism group. Parafunctional loads also increase the risk for abutment screw loosening, unretained prostheses, or fracture of the transitional restoration used for immediate loading. If any of these complications occur, then the remaining implants that are loaded are more likely to fail.

Occlusal Load Direction. The occlusal load direction may affect the remodeling rate. An axial load to an implant body maintains more lamellar bone and has a lower remodeling rate compared with an implant with an offset load. In an animal study, Barbier and Schepers[43] observed osteoclasts and inflammatory cells at the interface of offset-loaded implants and noted lamellar bone and a lower remodeling rate around axially loaded implants in the same animal. Therefore the clinician should eliminate posterior cantilevers in the immediate-load transitional restoration because they magnify the detrimental effects of force direction.

Implant Position. Dental implants have been used widely to retain and support cross-arch fixed partial dentures (FPDs). Implant position is often as important as implant number. For example, elimination of cantilevers on two implants supporting three teeth is recommended, rather than positioning the implants next to each other with a cantilever.[53] The cross-arch splint forming an arch is an effective design to reduce stress to the entire implant support system. Therefore the splinted-arch position concept is advantageous for the immediate-load transitional prosthesis in completely edentulous patients.

Implant position is one of the more important factors in immediate loading for completely edentulous patients. The mandible may be divided into three sections around the arch: the canine-to-canine area and the bilateral posterior sections. Several clinical reports discuss immediate load in a mandible with only three
● **Fig. 33.10** The modulus of elasticity is related to the bone density. Therefore the microstrain mismatch between titanium (Ti) and Division 4 (D4) bone is greater than that between titanium and D1 bone, even when the stress amount is the same. Force/Area (F/A)

implants, as long as the implants are positioned in the midline and each posterior region.[54,55]

The maxilla requires more implant support than the mandible because the bone is less dense and the direction of force is outside of the arch in all eccentric movements. The maxilla is usually divided into five sections, depending on the intensity of the force conditions and the shape of the arch. The minimum five sections include the incisor region, the bilateral canine areas, and the bilateral posterior regions. At least one implant should be inserted into each maxillary section and splinted together during the immediate-loading process.

Concerns have been raised regarding cross-arch splinting in the mandible because of mandibular flexure and torsion distal to the mental foramens. Clinical reports indicate the acrylic used in the transitional prosthesis is flexible enough to alleviate these concerns. However, the final restoration should be fabricated in at least two independent sections when implants are placed in both posterior molar positions.[56]

Mechanical Properties of Bone

The modulus of elasticity is related to bone quality (Fig. 33.10). The less dense the bone, the lower is the modulus. The amount of BIC is also less for less dense bone. The strength of the bone also is related directly to the density of the bone. The softer the bone, the weaker are the bone trabeculae.[56,57] In addition, the remodeling rate of cortical bone is slower than that of trabecular bone. As such, the cortical bone is more likely to remain lamellar in structure during the immediate-loading process, compared with trabecular bone.

The bone in the anterior regions of the jaw may have cortical bone at the crestal and apical region of the root form implant, whenever the implant is long enough to engage both cortexes. The anterior root form implants should attempt to engage the opposing cortical plate when immediate load is contemplated. The improved biomechanical condition of the cortical bone and the additional implant surface area are advantageous. The maxillary cortical bone is thin compared with the mandibular counterpart at the crestal region and the opposing landmark. In the posterior regions the maxillary sinus and mandibular canal usually negate the apical engagement of the opposing cortex of bone, which is also thin in the maxilla.

Cortical bone is also present on the lateral aspects of the residual ridge. Root form implants do not typically engage these plates unless the edentulous ridge is narrow. Bone grafting must depend on several factors to be predictable. Adequate blood supply and a

lack of micromovement are two important conditions. The developing bone is woven bone and more at risk for overload. The bone graft in the region of the implant body may lead to less fixation and lower initial BIC. Bone augmentation is more predictable when soft tissue completely covers the graft (and membranes when present). All of these conditions make bone grafting, implant insertion, and immediate loading more at risk. Therefore the suggestion is that implants that are immediately loaded be placed in an existing bone volume adequate for early loading and the overall proper prosthetic design. Bone grafting, before implant placement and immediate loading, is suggested when inadequate bone volume is present for proper reconstructive procedures (Fig. 33.11).

Immediate-Loading Protocol: Partially Edentulous Patients

Single Implants

Immediate dental implants for single implants is well documented in the literature, with numerous clinical trials showing satisfactory survival and success rates. However, a major difference with the longevity of single immediate implants is the loading protocol. In a meta-analysis study there was a five times higher failure rate with immediate-load single implants in comparison with delayed healing. No evaluated studies showed superior soft tissue and esthetic advantages in comparison with delayed surgical protocols. In 1998 Misch[58,59] published the first article during the "reinvention" of immediate "load" for partially edentulous patients. Because most patients have adequate remaining teeth in contact to function, his protocol included a provisional prosthesis primarily for esthetics, and the implant prosthesis is completely void of any occlusal contacts. This concept was termed N-FIT, or nonfunctional immediate teeth (Boxes 33.2 to 33.4).

Literature Review for Single Implants

Early Loading With Single Implants

Andersen et al.[60] evaluated early loading of eight implants in the maxilla. After implant placement, impressions were completed and interim acrylic resin restorations were fabricated approximately 1 week after surgery. At 6 months the interim crowns were removed and a final single tooth prosthesis was inserted. After 5 years a 100% success rate was reported, along with a 0.53-mm bone gain between the implant placement and final evaluation. Cooper et al.[61] reported on the 3-year implant success rate of immediate placed maxillary anterior implants after surgery. Peri-implant bone levels, along with papilla growth, were evaluated. The authors concluded that the gingival zenith increased from year 1 to 3, and marginal bone loss was minimal at an average of 0.42 mm.

Immediate Loading With Single Implants

Gomes et al.[62] published an initial report of immediate loading on a single implant. This report included the fabrication of a screw-retained provisional crown on an immediate-placed implant. Ericsson et al.[63] reported on a prospective study with single tooth implants with an immediate loading protocol compared with a two-stage implant procedure. In the immediate-loaded group, an interim single crown prosthesis was inserted within 24 hours of placement. Within 6 months the implants were restored with a final prosthesis. Two implants (14%) in the

(B) Eleven implants were inserted, and an impression was made for the delivery of the temporary restoration at the suture removal appointment. (C) The final restoration is fabricated after at least 6 months. This intraoral photograph illustrates the definitive maxillary porcelain-metal restoration. (D) A panoramic radiograph of the final maxillary restoration and the corrected mandibular occlusal plane.

• **BOX 33.2** **Nonfunctional Immediate Teeth**

Indications
- Edentulous area with favorable available bone and bone density
- Partially edentulous patients with centric occlusal contacts and excursions on natural teeth (or healed implants)
  - No parafunctional habits
  - Ideal implant position and implant dimensions (i.e., diameter and length)

Contraindications
- Patients with parafunctional oral habits (i.e., anterior and lateral tongue thrust, or biting on a pipe while smoking)
- Occlusal contacts that would result in functional contacts on implant prosthesis

---

• **BOX 33.3** **Advantages of Nonfunctional Immediate Teeth**

- Patient has a fixed esthetic tooth replacement after stage I surgery.
- No stage II surgery is necessary (eliminates discomfort for the patient and decreases overhead for the doctor).
- The soft tissue emergence may be developed with the transitional prosthesis and the tissue allowed to mature during the bone-healing process.
- The soft tissue hemidesmosome attachment on the implant body below the microgap connection may heal with an improved interface.
- The patient is able to evaluate the esthetics of the provisional prosthesis during the healing phase.

• **BOX 33.4** **Disadvantages of Nonfunctional Immediate Teeth**

- If force is applied to the provisional prosthesis, micromovement of the implant may cause crestal bone loss or implant failure.
- Parafunction from tongue or foreign habits (i.e., pen biting) may cause trauma and crestal bone loss or implant failure.
- Impression material or acrylic may become trapped under tissue or between the implant and crestal bone.
- Bone that is too soft, small implant diameters, or implant designs with less surface area may cause too great crestal stress contours and cause bone loss or implant failures.
- The duration of the surgery and/or postoperative appointment is longer.

---

immediate-loaded group failed, and no implant loss was seen in the two-stage protocol. Average bone loss was approximately 0.1 mm for both implant groups. Hui[65] evaluated 24 patients who received implant restorations on single teeth after tooth extraction in the esthetic zone. After a 1.5-year follow-up, all implants remained integrated.[63]

Degidi et al.[65] evaluated single implants that were nonfunctionally immediately loaded. All implants were placed with a minimum insertion torque of 25 N-cm, and after 5 years of follow-up a 95.5% survival rate was reported. When comparing healed versus immediate extraction sites, 100% and 92.5% success rates,

respectively, were reported. A 100% success rate was reported in favorable bone quality (type 1), whereas a 95.5% rate was found in poor bone quality (type 4).[65]

Chaushu et al.[66] compared the success of immediate-loaded implants in fresh extraction sites compared with sites that were healed. Provisional restorations were placed immediately the day of surgery. The authors concluded that immediate loading in an extraction site did increase the failure rate (i.e., approximately 20%) in comparison with immediate-loaded healed sites. Mankoo[67] described the immediate implant placement and provisionalization in the anterior region of the oral cavity. He reported this technique was advantageous, not only because of the lack of a stage 2 surgery required, but also the esthetic benefits provided from a provisional restoration.

In addition, a removable prosthesis is not required, which is usually difficult for the patient to adapt to and has associated esthetic issues.

A meta-analysis identifying more than 5000 studies was completed by Pigozzo et al.[68] and concluded no significant differences between immediate- and early-loading protocols with single-implant crowns. The success and survival rate together with marginal bone loss was evaluated up to 3 years.

Surgical/Prosthetic Protocol for Single Implants

After placement of a single tooth implant the clinician has three options at his or her disposal:
1. *Two-stage technique:* involves delayed healing and a second surgery to expose the implant before prosthetic rehabilitation
2. *One-stage technique:* a healing abutment is placed after implant placement, healing is completed, and prosthetic rehabilitation is delayed
3. *Immediate restoration with a provisional prosthesis:* may be loaded or nonfunctional; rarely will a single-tooth immediate implant be placed directly into function because of increased biomechanical forces that may result in poor healing or failure of the implant

Single-Tooth Nonfunctional Immediate-Restoration Procedure

The N-FIT concept presents a similar approach to the immediate-loading technique, except the implant-supported transitional prosthesis is placed out of all direct opposing occlusal contacts during the bone healing period. As a result the implant clinician may fabricate an esthetic tooth replacement immediately for the patient, but with no occlusal contact. By placing an immediate prosthesis, the soft tissue contours, as well as the esthetics, may be developed via the provisional prosthesis and bone-healing process (Fig. 33.12).

After implant placement, there exist multiple treatment options for the clinician to provisionalize the implant restoration.
1. Implant crown fabricated by the dental laboratory where the clinician relines the provisional prosthesis to a stock type abutment placement; this may be a cement or screw-retained prosthesis.
2. Prefabricated crown that is relined by the clinician; usually a stock or prefabricate abutment is inserted and prepared, after which the provisional restoration is fabricated to the esthetics and functional demands of the area
3. Composite that is bonded to a stock or prefabricated abutment and the adjacent teeth

4. The clinician takes an impression of the implant after insertion, together with jaw records and opposing impressions; a healing abutment is placed; at the suture removal, which is usually 2 weeks after placement, the healing abutment is removed and replaced with a laboratory-modified abutment and provisional prosthesis; this is an example of early loading

No matter what technique is used to fabricate a provisional prosthesis, it is imperative that the occlusion is strictly monitored. After placement of the interim crown the prosthesis should be evaluated in all centric and eccentric excursions to verify no contact. Of special concern is in the maxillary anterior region, because horizontal movement of the anterior teeth is far greater than the posterior teeth. Therefore the excursive movements should be evaluated with all degrees of force (i.e., clenching and bruxing movements) (Fig. 33.13 and Box 33.5).

Partially Edentulous (Greater Than One Edentulous Space)

With partially edentulous spaces, immediate-loaded implants is a controversial topic. Most studies consist of patient treatment in load-based areas such as the posterior part of the oral cavity. Few studies have been completed in the esthetic zone. Until more detailed studies are available, clinicians should be conscious of placing immediate implants, especially in the esthetic in partially edentulous patients.

Literature Review of Partially Edentulous Arches

Early Loading in the Partially Edentulous Arch

Testori et al.[69] reported on a 3-year 97.7% success rate in a longitudinal, prospective, multicenter study of early implant loading. All implants were placed in the posterior region of the oral cavity and were loaded within 8 weeks. Cochran et al.,[70] in a longitudinal, prospective, multicenter study, reported a 99.1% success rate after 1 year. Implants were placed in the posterior regions of the jaws, with various healing times based on the density of bone. Luongo et al.[71] evaluated the immediate and early loading (11 days) of implants in the posterior maxilla and mandible. A 98.8% success rate was reported, and the results were similar to those with delayed-loaded implants. Vanden Bogaerde et al.,[72] in a multicenter study, placed interim prostheses between 9 and 16 days after implant placement in the maxilla. An implant survival rate of 99.1% after 18 months was reported, with bone loss less than 0.8 mm.

Immediate Loading in the Partially Edentulous Arch

Drago and Lazzara[73] related a study involving restored fixed provisional implant crowns without occlusion immediately after implant placement. The implants were immediately restored with prefabricated stock abutments and cement retained. No occlusal contacts or interferences were present. Final prostheses were inserted 8 to 12 weeks after implant placement. After 18 months the implant survival rate was 97.4%, and an average bone loss of 0.76 mm was reported.[73] Interestingly, Machtei et al.[74] evaluated implants placed in the mandible in patients with chronic periodontitis. They concluded that immediate-loading protocols are a predictable treatment; however, caution should be exercised in the molar regions. Schincaglia et al.[75] reported a split-mouth study with bilateral, partially edentulous posterior mandibles. The overall success rate was 95%; an insertion torque of 20 N-cm or greater and an ISQ value more than 60 N-cm was recommended (Fig. 33.14).

• **BOX 33.5** **Protocol for Stage I Nonfunctional Early Loading Immediate Teeth**

Appointment #1: Surgery
1. Make impression of opposing arch and obtain tooth shade and centric bite registration.
2. Perform stage I implant surgery (use wider implants when possible).
3. Make an impression with additional silicone material or polyether. Verify that no impression material is entrapped underneath the flap.
4. Place a healing abutment approximately 2 mm above the tissue.
5. Suture (tissue thickness should be less than 4 mm).

Laboratory Procedure
1. Impressions are mounted on an articulator with correct jaw records.
2. An abutment is selected and prepared for either a cement or screw-retained prosthesis.
3. Provisional prosthesis is fabricated with narrow occlusal table, minimal cusp height, and no occlusal or excursive contacts.

Appointment #2: Suture Removal/Prosthesis Insertion
1. Sutures are removed atraumatically.
2. The healing abutment is removed and the internal opening of the implant is irrigated with chlorhexidine.
3. The laboratory-fabricated abutment is inserted (if cement retained).
4. Use countertorque (hemostat) and tighten to abutment screw 20 to 30 N-cm (which is less than final preload).
5. Insert provisional prosthesis and evaluate contour and occlusion (no occlusal contacts).
6. Instruct patient to eat soft foods (e.g., pasta, fish, cooked meat). No raw vegetables or hard bread are allowed until final prosthesis delivery. No oral habits, such as gum chewing, are permitted. When possible the patient should avoid chewing food in implant regions.
• **Fig. 33.14** (A) A panoramic radiograph of a patient with partial anodontia missing the bilateral permanent canines, first premolar, and second premolars. (B) The deciduous teeth have been extracted. (C) Two implants are used to support the prosthesis on each side. The mesiodistal space is inadequate for three implants. (D) The four implants are prepared for a cemented transitional prosthesis. (E) The transitional N-FIT restorations are primarily for esthetics and are completely out of occlusion in centric relation and all excursions. (F) The final restoration is made after 4 to 6 months. At this point the soft and hard tissues are mature. (G) The final restoration of the three-unit fixed partial denture supported by two immediate-loaded implants.

Completely Edentulous Arches

The immediate placement and loading of implants in the edentulous arches has become popular in implant dentistry today. In comparison with conventional implant procedures, the success of immediate placement and loading in the maxilla and mandible is dependent on patient selection, the preoperative treatment planning, and the skill set of the clinician in completing the surgical and prosthetic phases of treatment. These types of procedures tend to be more complex and can be associated with a higher degree of complications. The concept of immediate placement/load first originated with the mandibular arch and has been well studied. However, even though studies are limited in the maxilla, the maxillary arch is becoming more popular in implant dentistry today.

Literature Review of Edentulous Arches

Early Loading in the Mandibular Edentulous Arch

Numerous studies have shown favorable results with the early loading of the mandibular edentulous arch. Engquist et al.[76,77] reported on more than 100 edentulous mandible patients. Each patient was treated with four Nobel Biocare implants in the anterior mandible for a fixed implant prosthesis. They evaluated four groups: one-stage surgery, two-stage surgery, one-piece abutments, and early loading. The permanent prosthesis was loaded between 10 days and 3 weeks. With the early loading group, approximately 7% of the implants failed; however, this group exhibited less marginal bone loss than the control group.[76,77] Friberg et al.[78] evaluated more than 750 implants in the edentulous mandible, with the fixed prosthesis being placed approximately 13 days after implant placement. A 97.5% success rate was reported, with mean marginal bone resorption of approximately 0.4 mm.

Immediate Loading in the Mandibular Edentulous Arch

In 1990 Schnitman et al.[79] reported for the first time the immediate loading of dental implants in the anterior mandible. Five to six implants were placed in the interforaminal region, with additional implants placed posterior. Three of the implants were used for an interim prosthesis, which was converted from the patient's denture. The authors concluded the immediate loading of implants was a viable treatment option for patients because the long-term success was not impacted by the early loading of the implants. In a follow-up study, Schnitman et al.[80] treated 10 patients with an immediate-loaded fixed prosthesis. About 15.3% of the immediate implants failed, and all conventional loaded implants were successful. Schnitman et al.[80] concluded that immediate-loaded implants in the short term are successful; however, in the long term, they may have a questionable prognosis. Tarnow et al.[81] evaluated patients treated with a minimum of 10 implants, with 5 of the implants submerged, with no loading. A fixed interim prosthesis was inserted and later replaced with a fixed provisional prosthesis. Although three of the implants failed (two immediate loaded and one submerged), Tarnow et al. concluded that immediate implants splinted together are a viable treatment option.

More recently, studies have shown four to six implants placed in the mandible have favorable success rates. Chow et al.[82] placed four implants in patients with a screw-retained interim prosthesis. After 1 year the implants had a 100% success rate. In a prospective four-center study, Testori et al.[83] evaluated 62 patients in which an interim prosthesis was inserted within 4 hours of implant surgery. A success rate of 99.4% was reported, with crestal bone loss similar to the traditional delayed technique. Aalam et al.[84] evaluated 16 patients who received mandibular implants for screw-retained hybrid prostheses. After 3 years the implant success rate was 96.6%, and the prosthetic success rate was 100% (Fig. 33.15).

Early Loading in the Maxillary Edentulous Arch

Fischer and Stenberg[85] reported on early implant loading of 24 maxillary edentulous patients. After 3 years the implant success rate was 100%, and a 3-year study showed less radiographic bone loss in the early loaded than the control group.

Olsson et al.[86] studied for 1 year 10 patients who had received a fixed full-arch provisional prosthesis 1 to 9 days after implant placement. A permanent prosthesis was placed 2 to 7 months after implant placement. About 6.6% of the implants failed, all from infection, and an associated 1.3-mm marginal bone loss was reported.

Immediate Loading in the Maxillary Edentulous Arch

Bergkvist et al.[87] reported on a provisional prosthesis placed on immediate-loaded maxillary implants. After a mean healing period of 15 weeks, a final screw-retained prosthesis was fabricated. Approximately 2% of the implants failed during the healing period, and the mean marginal bone loss was 1.6 mm after 8 months.[87] Ibanez et al.[88] evaluated 26 patients who had fully edentulous maxillae, with implants that were loaded within 2 days of placement with either a provisional or final prosthesis. The success rate was 100% after a healing period of 1 to 6 years. The radiographic bone level change was a loss of 0.56 mm at 12 months and 0.94 mm at 72 months. Degidi et al.[89] reported on a 5-year follow-up of implants immediately loaded with an interim prosthesis followed by a final prosthesis. A 98% success rate was shown, with most failures occurring in the first 6 months of healing. In addition, they concluded that wider implants were associated with an increased failure rate. Balshi et al.,[90] in evaluation of 55 patients who received immediate implants, along with immediate-loaded implants, found a 99.0% survival rate of the implants and a 100% survival rate of the prosthesis. The interim prostheses consisted of an all-acrylic screw-retained prosthesis that was replaced approximately 4 to 6 months later (Fig. 33.16).

Provisional Implants

The use of provisional implants, which are defined as implants placed to retain an interim prosthesis, are not necessarily indicated for a permanent prosthesis. Originally these implants were thought not to achieve osseointegration. However, Balkin et al.[91] evaluated miniimplants for light microscopy evaluation after 4 to 5 months of immediate function. They reported that osseointegration did occur with mature and healthy bone. Iezzi et al.[92] reported on three provisional implants that were placed to retain a provisional prosthesis for 4 months. They concluded the existence of bone trabeculae around the implants, as well as the occurrence of the bone remodeling process. Heberer et al.[93] followed 254 provisional implants that were placed in 64 patients and remained functional up to 462 days. The total success rate reported was 82%, and patient factors such as gender, opposing occlusion, and implant position did not appear to be significant. Simon and Caputo[94] completed removal torque tests on provisional implants in 31 patients. They concluded that osseointegration may pose

• **Fig. 33.17** Provisional Implants. (A and B) Implants placed into "B," "C," and "D" implants with two miniimplants between the implants to retain an interim prosthesis (O-Ring Attachments).

an increased possibility of fracture in the mandible because they reported that implants left in after 10 months showed a higher possibility of fracture on removal (Fig. 33.17).

All-on-4 Surgical/Prosthetic Protocol

Malo et al.[95,96] originally introduced the concept of the All-on-4 protocol, which involves the immediate loading of a fixed prosthesis on four implants placed in the maxilla or mandible. Although numerous options are available, in general two parallel implants are placed anteriorly and two angled implants are placed posteriorly. The posterior implants are accurately positioned to avoid key vital structures (e.g., maxillary sinus, inferior alveolar canal), increase A-P spread, and minimize cantilever length. Because of these positioning protocols, a significant treatment time savings is seen as sinus augmentation and bone-grafting procedures in the mandible are avoided. Usually in the maxilla, two posterior implants are positioned at up to 45 degrees of angulation to avoid the maxillary sinus. In the mandible the position of the implants is dictated by the mental foramen position (i.e., possible anterior loop); however, they are usually angulated anteriorly 30 to 45 degrees. Multiunit abutments are placed into the implants with varying degrees of angulation, usually consisting of 0, 17, or 30 degrees.[95,96]

Requirements of the All-on-4 Technique

1. Minimum of 35 N-cm insertion torque: If this cannot be achieved, then a conventional healing phase is recommended.
2. No significant parafunction habits

3. Available bone dimensions:
   Maxilla: >5 mm of width and >10 mm of height
   Mandible: >5 mm of width and >8 mm of height
4. Favorable bone density of D1, D2, or D3

Advanced Fully Guided Immediate Placement/Loading Protocols (Box 33.6, Box 33.7, Fig. 33.18)

There exist various surgical/prosthetic protocols (e.g., 3D Diagnostix, nSequence) that allow a fully guided surgical and prosthetic protocol, which combines three-dimensional CBCT-guided surgery with a definitive fixed immediate prosthesis. These protocols allow the clinician to maximize the precision of CBCT technology, together with having the capability of delivering a provisional fixed prosthesis with precision and accuracy. These techniques, compared with a freehand two-dimensional approach, have increased precision, predictability, and time-saving consistency. The fully guided, immediate placement/loading protocols allow for three-dimensional (3D) precision digital implant planning with virtual surgical and prosthetic protocols, 3D modification of bony anatomy to optimize implant placement and positioning, implant placement with a fully guided technique, and same-day delivery of a screw-retained immediate fixed prosthesis. In addition, this protocol allows for definitive control for surgical treatment planning, especially in immediate extraction cases where the bony anatomy requires alteration[97] Fig. 33.19 (Box 33.8; Figs. 33.20 through 33.22).

Generic All-on-4 Protocol

1. Preoperative Records

Initially, maxillary and mandibular impressions are obtained conventionally or digitally (i.e., intraoral scanner), along with an accurate bite registration. A tooth shade is selected. Intraoral and extraoral photographs may be taken to assist in the diagnosis and treatment planning. Maxillary and mandibular cone beam computed tomography (CBCT) scans are obtained, with the patient wearing the bite registration in maximum intercuspation. The impressions, along with the CBCT scans are uploaded to a third-party manufacturer for processing.

2. Three-Dimensional Data Conversion

The digital three-dimensional (3D) data are merged with the 3D bony anatomy, which results in the formation of a 3D-specific dataset of tooth position, bony anatomy, occlusal considerations, prosthesis fabrication, and ideal biomechanical implant positioning. This is usually accomplished with a specialized software and third-party manufacturer (e.g., 3D Diagnostix).

3. Prosthetic and Surgical Treatment Plan

With an interdisciplinary team approach, the 3D data is used in formulating a prosthetic and surgical treatment plan. The prosthesis type should always be identified first and then the surgical plan formulated to fulfill the requirements of the prosthesis. The treatment planning factors should include: (1) type of prosthesis; (2) available bone; (3) bone density; (4) parafunctional forces; (5) anteroposterior spread; (6) occlusion; (7) implant dimensions and positions; (8) osteoplasty, if indicated; (9) path of prosthesis insertion; and (10) multiunit abutments and access holes.

4. Fabrication of Surgical Guides and Provisional Prosthesis

After treatment planning is complete, the finalized data set is sent for milling and rapid prototyping by the third-party manufacturer. A bone reduction guide (if indicated), implant surgical guide, and abutment guide are usually fabricated via stereolithography. The provisional prosthesis is most commonly milled in a monolithic polymethylmethacrylate (PMMA) block material. The manufacturer will provide a detailed surgery report on the guide sequence, along with implant size and position protocols.

5. Surgery

After anesthesia a bone reduction guide or bone foundation is positioned, usually with the aid of a registration and existing teeth. In some cases this guide will be fixated to the bone. The teeth are then extracted. After extraction a surgical implant guide will be positioned, which will assist in implant placement. This may include a universal or a fully guided template. After implant placement, multiunit abutments, which have been predetermined from the CBCT plan, are placed into the implant bodies.

6. Provisional Prosthesis Insertion

Temporary, stock abutments are placed into each multiunit abutment. The PMMA provisional prosthesis is then inserted and evaluated for fit. The PMMA prosthesis is then luted to the temporary abutment via light-cured acrylic. The PMMA can then be removed and polished for final insertion. Soft tissue closure is accomplished with a resorbable suture material with high tensile strength (e.g., Vicryl).

7. Final Prosthesis Fabrication

After sufficient healing a final prosthesis (i.e., monolithic zirconia) is fabricated. The function, phonetics, and design of the PMMA provisional can be used as a guide for any future modifications of the permanent prosthesis.

All-on-4 Surgical/Prosthetic Approaches

The All-on-4 treatment may be performed with two approaches:
1. **Conventional surgery:** full-thickness flap and freehand implant placement
   a. After flap elevation a midline osteotomy is completed in which the All-on-4 guide is placed.
   b. *Posterior surgical osteotomy:* The posterior sites are prepared at approximately 45 degrees, using the guide as an angulation tool. Implants are inserted at a final torque of 35 to 45 N-cm. Thirty-degree multiunit abutments are placed into both posterior sites. The abutments are tightened to the manufacturer's recommendations.
   c. *Anterior surgical osteotomy:* Prepare and place two anterior implants in the approximate "B" and "D" positions. Implants are inserted at a final torque of 35 to 45 N-cm. Multiunit abutments are placed into both anterior sites. The abutments are tightened to the manufacturer's recommendations.
2. **Guided: tissue- or bone-supported guide**
   a. Implant placement: Four implants are placed according to the type of guide (tissue supported—flapless) or bone supported (flap is raised to expose residual ridge). The four implants are placed according to the interactive CBCT treatment plan. NOTE: the angulation of the posterior implants is dictated by anatomic landmarks evaluated on the 3D CBCT.

Prosthetic Procedure

1. Temporary multiunit abutment copings are placed on each implant and hand tightened.
2. The fabricated prosthesis is tried in to verify proper seating and occlusion. Light-cured composite/acrylic is used fixate the interim prosthesis to the temporary abutments. The prosthesis is removed, and any voids present between the abutments and prosthesis are filled with composite/acrylic.
3. The prosthesis is polished and reinserted for final insertion. The abutment screws are placed with a final torque as per the manufacturer's recommendations. Polytetrafluoroethylene (PTFE) tape is placed in the access holes and light-cured composite/acrylic is used to cover the holes (Fig. 33.18).

A. Bone-Supported Surgical Guide

Clinician (Preoperative Appointment #1)
1. Conventional impressions + bite registration or digital impressions
2. Obtain cone beam computed tomographic (CBCT) scan
   • Make sure bite registration is in place and patient closes into centric occlusion.
3. Tooth shade is selected

Preplanning
1. The case is reviewed via three-dimensional interactive CBCT software and preplanned according to ideal implant position, biomechanical force factors, and prosthesis type (Fig. 33.19A, B, C,D).
2. The treatment planned case, along with impressions (or digital impressions), is sent to a laboratory or manufacturer for fabrication of the following:
   • The working study casts are fabricated and mounted on an articulator, using the surgical template as a reference.
   • The surgical template is fabricated from the CBCT plan via CAD/CAM or a 3D printer.
   • Multiunit abutments and prefabricated temporary abutments are attached to the implant analogs on the working cast.
   • A polymethylmethacrylate (PMMA) is fabricated and hollowed out, which correspond to the abutment positions.
   The laboratory furnishes the implant clinician with:
   a. *Bone foundation guide*—Fixated guide that is bone supported and is used as the primary guide that holds all additional stackable guides that are used. In addition, if ridge reduction is indicated, this guide may be used as a stackable bone reduction guide (Fig. 33.19E).

b. *Stackable surgical guide*—This stackable (i.e., attaches into the bone foundation guide) template is fabricated from the CBCT treatment and corresponds to the position of the implants. Usually this is a fully guided template, which allows for all osteotomy preparation and implant placement through the guide (Fig. 33.19H, I, J).
c. *Multiunit abutments*—Prefabricated abutments are specific to the implant system being used, which allows for the ideal angulation correction between the implants. Usually multiunits can be standard (no angulation) or angled with various angles (Fig. 33.19K, 33.20A).
d. *Temporary abutments*—These are nonengaging screw-retained abutments placed into the multiunit abutments that are used to allow for fixation of the prosthesis to the multiunit abutments (Fig. 33.19L, 33.20B).
e. *Stackable abutment guide*—A stackable abutment guide fits into the foundation guide and allows for the final positioning of the abutments, which are inserted into the implants and used to fixate the prosthesis.
f. *Silicone gasket*—This is a flexible gasket that is placed over the temporary abutments to prevent flow of acrylic/composite into the tissue space when fixating the provisional prosthesis into the abutments (Fig. 33.19M, N).
g. *Bite registration*—Used to verify proper positioning and seating of the provisional prosthesis (Fig. 33.19P, Q).
h. *Provisional prosthesis*—This prosthesis (usually a PMMA prosthesis) is inserted at the time of implant placement. It is used during the healing period to verify esthetic, vertical dimension, occlusion, and patient acceptance (Fig. 33.19O, R).

    i. *Fixation Pins*—usually 3 -4 fixation pins are used to fixate the foundation guide to the bone. The pins prevent any movement of the guide during the osteotomy process. (Fig. 33.19F, G).

Clinician (Surgery: Appointment #2)
1. Remaining teeth are extracted if indicated, along with debridement of the extraction sockets (Fig. 33.21A–C).
2. The tissue is reflected to expose the residual ridge. The flap design is dictated on the size of the guide.
NOTE: The guide should be evaluated so that it is fully seated, with no rocking or movement. Caution should be exercised to verify no tissue impingement underneath the guide. The *bone foundation guide* is fixated with fixation pins to prevent movement of the guide during osteotomy preparation. Usually three to four fixation pins are used, which are based on the implant positions (Fig. 33.21D).
3. If bone reduction is indicated, the bone is reduced to the level of the guide with bone reduction burs. Therefore the bone foundation guide acts as a bone reduction guide.
4. The *stackable surgical guide* is placed over the bone foundation guide. The osteotomies are prepared according to the fully guided surgical protocol that is specific to the implant system being used. All implants are placed into the final position and the stackable surgical guide is removed (Fig. 33.21E–G).
5. The *stackable multi-unit guide* is then positioned onto the bone foundation guide. This guide allows for the ideal positioning and placement of the multiunit abutments. Note that multiunit abutments may be straight or angled depending on the implant system being used. The multiunit abutments are torqued according to the manufacturer's instructions and the stackable guide is removed.
NOTE: A periapical radiograph may be taken to verify complete seating of the abutments.
6. The *temporary screw-retained abutments* are placed into the multiunit abutments. The abutment screws should not be finally torqued into place and only tightened with finger pressure (Fig. 33.21H).
7. The *soft silicone jig* is positioned over the temporary abutments. Complete seating of the jig should be verified because this may prevent complete seating of the interim prosthesis (Fig. 33.21I).
8. The *interim prosthesis* (e.g., PMMA, acrylic) is positioned over the temporary abutments and gasket. Complete seating of the prosthesis is verified, along with ideal occlusion. The *bite registration index* is inserted to confirm ideal vertical dimension and centric occlusion. Adjustments are made accordingly to the PMMA prosthesis or occlusal anatomy (Fig. 33.21J).
    • Alternative technique: A duplicate prosthesis may be used to obtain a bite registration or esthetic modification to be used in the final prosthesis.

9. Fixating Interim Prosthesis to Temporary Abutments: The interim prosthesis is then luted to the temporary abutments via light-cure composite (i.e., also may use self- or dual-cure acrylic) through injection vents present in the interim prosthesis. Patient closes in centric occlusion; light-cured composite is flowed through predrilled holes. The flowable acrylic is cured via a curing light. The silicone jig will prevent composite/acrylic from flowing into the abutment/sulcus area (Fig. 33.21K and 33.21L).
10. The screws holding the interim prosthesis to the abutments are loosened and removed. The prosthesis is inspected for voids between the temporary abutments and the interim prosthesis. Composite/acrylic is added accordingly. The prosthesis is then polished and reseated, with screws torqued to the manufacturer's recommendations. Access holes are filled with sterilized polytetrafluoroethylene tape (plumber's tape) and light-cured composite.
    • NOTE: Alternative treatment: Before the final seating of the interim prosthesis, a clear duplicate prosthesis can be used to obtain jaw records and final impression for the final prosthesis fabrication.

Clinician (Prosthetic: Appointment #3)
• After sufficient healing, the clinician confirms the correct vertical dimension, occlusion, shade, and contours of the prosthesis. The interim prosthesis is removed and a final impression completed. A verification jig maybe used for the obtaining an accurate impression. Sectioned acrylic blocks which contain titanium cylinder are secured onto each implant. Each cylinder is luted together and the final impression is taken. If no changes are indicated, the laboratory is instructed to complete the final prosthesis, which most commonly is a monolithic zirconia full-arch prosthesis.

Clinician (Prosthetic: Appointment #4)
• The clinician inserts the final prosthesis after removal of the interim prosthesis.
• The interim prosthesis is saved as a backup prosthesis or may be used as a possible future provisional if the need should arise (Fig. 33.21M).

B. Tissue-Supported Surgical Guide
Same procedure as described in part A with the following exceptions:
1. Dual Scan CBCT is utilized for the fabrication of the tissue supported guide.
2. A tissue foundation guide is used instead of the bone foundation guide (Fig. 33.2L).
3. The tissue is not reflected and the procedure is completed flapless.
4. No bone reduction guide is used.

Complications of Fixed Provisional Prostheses

If basic prosthodontic principles are not adhered to when placing a provisional prosthesis, complications may become more prevalent. Ideally the prosthesis should not interfere with soft tissue healing, cantilevers should be limited and avoided if possible, occlusal tables narrowed buccal-lingually, and even and ideal occlusal contacts. Suarez-Feito et al.[98] evaluated the complications in 242 consecutively treated patients, with more than 1000 implants supporting a provisional prosthesis. During the first 60 to 90 days, 8.3% of patients had at least one fracture, with 7.4% occurring within the first 4 weeks. In total, 8.3% of the patients had at least one fracture and 7.4% of the restorations fractured, of which more than half occurred during the first 4 weeks. When the opposing occlusion was an implant-supported prosthesis, the fracture risk

was 4.7 times higher. The maxillary arch had a 3.5 times greater fracture risk.[98] Nikellis et al.[99] reported similar results, which included a 16.6% fracture rate with provisional prostheses when the opposing dentition was an implant-supported prosthesis. To combat the higher complication rate in the maxilla, Collaert and De Bruyn[100] suggested a metal framework to reinforce the provisional reconstruction, as their study showed seven out of nine provisional prostheses resulted with early fractures. After changing their protocol to include a cast metal bar, no additional fractures were seen.[100] In addition, speech-related issues have been shown to be problematic. In the maxilla, usually because of implant position and increased structural reinforcement, compromised space for the tongue has been shown. Therefore because of the bulkiness, patients often reported this problem. Molly et al.[101] reported that
• **Fig. 33.20** (A) Multiunit abutments with varying angulations that depend on implant trajectory. Most commonly, the multi-unit abutments are available in 0°, 17°, and 30° (B) Temporary abutments that insert into the multiunit abutments that secure the prosthesis to the implants. Usually, non-engaging abutments (arrow) are used for full arch cases.

10% of maxillary immediate-loaded implant prostheses resulted in patients exhibiting nonadaptable speech deterioration. Van Lierde et al.[102] showed similar results with immediate-loaded All-on-4 prostheses, where 53% of patients had related speech issues. The most common reason was the palatal positioning of implants with angulated abutments (Fig. 33.23).

Immediate Load Implant Overdentures

The immediate-load concept for mandibular overdentures has been discussed in the literature for more than 50 years. The subperiosteal implant and the mandibular staple implant were loaded immediately after insertion and fulfilled the immediate-load definition. Babbush et al.[103] reported on immediate-loaded overdentures in the early 1980s, with threaded root form implants. More recently, Chiapasco et al.[104] documented implant success rates of 88% to 97% over 5 to 13 years. In theory the risk of joining implants together with a bar for an implant overdenture is less than for a fixed prosthesis, because the patient may remove the restoration at night to eliminate the risk for nocturnal parafunction. In addition, the overdenture may have some inherent movement and load to the soft tissue, which adds a stress relief system for the rigid implants.

The treatment plan for implant number and position for implant overdentures that are completely implant supported (i.e., RP-4 prosthesis) should be similar to a fixed restoration. If the prosthesis has no movement while in place, then it cannot gain support from the soft tissue. Although the prosthesis may be removed, it is completely implant supported during function or parafunction.

In contrast, a RP-5 prosthesis primarily loads the soft tissue with secondary support from the implants. Implant overdentures with hard and soft tissue support may be at increased risk for immediate loading because the biomechanical torque to the implants may be increased compared with completely implant-supported restorations. One should exercise care relative to the amount and direction of prosthesis movement during the initial loading period.

The use of a single immediate implant has been documented by numerous authors in the literature. Cordioli et al.[105] and Krennmair and Ulm[106] both concluded that one implant placed in the mandibular midline was a credible treatment, in particular for elderly patients with dentures who are experiencing masticatory complications. In addition, positive outcomes such as satisfaction and improved health-related quality of life, along with good functional outcomes, were reported to be greater.

(L) Final insert of maxillary and mandibular zirconia prostheses. (M) Final postoperative prosthesis panoramic radiograph.

Liddelow and Henry[107] reported on a 36-month prospective study evaluating a single-implant overdenture that is restored immediately into function. They concluded that a single implant with an oxidized surface may provide beneficial outcomes with minimal financial outlay for the patient (Fig. 33.24).

Ormianer et al.[108] reported on a modified loading protocol with two implants that were immediately loaded in the mandible. A success rate of 96.4% was achieved with a modified fixation technique. Impregum (3M ESPE) was used to provide retention for the prosthesis during the early phases of treatment, as the impression material was changed every 2 weeks for the first 3 months (Fig. 33.25).

● **Fig. 33.22** A Tissue-supported immediate implant placement is a flapless procedure which has a high incidence of complications and does not allow for ideal bone grafting of defects around placed implants.

Immediate Load Overdenture Treatment Protocol

Immediate Load Implant Overdentures

a. *Immediate loading:* After implant placement, abutments are placed into the implant bodies. The patient's current prosthesis is modified to seat completely, without interferences from the denture. The appropriate female attachment is directly secured to the denture base with light-cured attachment acrylic/composite. After adequate healing, conventional prosthetic protocols may be used to fabricate a new prosthesis with either single or splinted implant attachments.

b. *Early loading:* At the time of implant placement a final impression is made of the existing implants. At the postoperative appointment, jaw records are completed, with the correct vertical dimension and bite registration. Conventional prosthetic protocol is then adhered to complete the final prosthesis with either single or splinted attachments.

Immediate Loading: Postoperative Instructions

Diet

If the immediately loaded prosthesis becomes partially uncemented or fractures, the remaining implants attached to the restoration are at increased risk for overload failure. Therefore the diet of the patient should be limited to only soft foods during the immediate-loading process. Pasta and fish are acceptable, whereas hard crusts of bread, meat, and raw vegetables or fruits are contraindicated.

Final Prosthesis

After sufficient healing is completed (~ 4 - 8 months), The interim prosthesis is removed and a final impression is obtained to fabricate the final prosthesis.
● **Fig. 33.23** Fractured Polymethylmethacrylate (PMMA) Prosthesis. (A to C) The most common complication for a PMMA interim prosthesis is a fractured substructure. The enclosed images depict a fracture, mainly because of the large cantilever that is present.
Fig. 33.24 Immediate Single-Implant Overdenture. (A) One implant placed in the midline that results in varying results of patient satisfaction. (B) O-ring attachment placed. (C) Prosthesis with O-ring attachment.

Immediate Loading: Postoperative Complications

Full-Arch Immediate Prosthesis (Multiunit Abutments)

Göthberg et al.[109] compared two types of multiunit abutments (one oxidized and the other machined) versus implant prostheses without abutments supporting fixed prosthesis (i.e., FP-3) with either an immediate- or delayed-loading protocol. There was no significant difference in marginal bone loss between the distinct loading protocols. However, implants with machined multiunit abutments presented significantly less marginal bone loss after 3 years in comparison with oxidized abutments or no abutments.
Fig. 33.25 Immediate-Loading Overdenture. (A) Mandibular Two-Implant O-Ring Attachment Overdenture, (B) Maxillary Two Implant Overdenture which is usually inadeqaute support for a Maxillary Overdenture, (C) Four Implant Overdenture will allows for greater support.

Full-Arch Immediate Prosthesis (Connection/Disconnection of Healing Abutments)

Numerous researchers have evaluated the effect of placing the definitive (final) abutment at the time of the implant placement versus at a later stage on the soft and hard tissues. Molina et al.[113] evaluated the connection and disconnection of healing abutments versus the final abutment being placed at the time of insertion with early-loaded implants. They determined that the continued connection/disconnection of the abutment led to bone loss during the healing phase. This study supported other immediate-placed implant studies with similar outcomes.[110-112] Therefore throughout the full-arch immediate prosthesis protocol, the fewer the number of times healing abutments are connected/disconnected, the less bone loss will result. The connection of the abutment at the time of implant placement seems to reduce bone level changes during the 6- month healing period, compared with the use of standard healing abutments (which are continuously removed during the prosthetic process).

Summary

The delivery of care for patients missing one or all of their teeth often requires implants to restore function, esthetics, bone and soft tissue contours, speech, and intraoral health. The delayed occlusal-loading protocol, either the one- or two-stage approach, has been evaluated for more than 30 years by a number of clinical settings and situations. However, in some patient conditions the delayed healing process can cause psychological, social, speech, and/or function problems. A full range of treatment options relative to the initial hard and soft tissue healing is available. Immediate restoration of a patient after implant surgery is one of these alternatives.

A benefit/risk ratio may be assessed for each patient condition to ascertain whether immediate occlusal loading is a worthwhile alternative. The greater the benefit and/or the lower the risk, the more likely that immediate loading is considered. A complete edentulous mandible restored with an overdenture supported by four or more implants is a very low-risk condition. If the patient cannot tolerate a mandibular denture and does not wear the device, then an immediate-load protocol would be a high benefit. The highest risk for immediate loading would be a posterior single-tooth implant. Implant number cannot be increased, and implant length cannot engage cortical bone. When the single-tooth replacement is out of the esthetic zone, very low benefit is obtained with the immediate-restoration approach.

Additional clinical studies to evaluate the associated risks, especially in the maxillary arch, are expected over the next several years. Until the profession has longer-term evidence and more multicenter studies, immediate occlusal loading will be a secondary treatment option, restricted on a case-by-case basis.

A biomechanical rational for immediate loading may decrease the risk for occlusal overload during initial healing. The stresses applied to the implant support system result in strain to the bone interface. The greater the stress, the higher is the strain. Increasing implant area and/or reducing the forces applied to the prosthesis may reduce stress. The implant size, design, and surface condition all affect the area over which the occlusal forces are dissipated. The forces may be reduced by patient factors, implant position, reducing force magnifiers such as crown height or cantilever length, reducing the occlusal contacts, decreasing angled forces to the prostheses, and altering the diet. The mechanical properties of bone also affect the risk for overload, because the bone density is directly related to the strength of bone, its elastic modulus, and the amount of BIC. All of these factors are important in the traditional two-stage approach. They are especially noteworthy for immediate loading, because the surgical trauma of placing the implant also modifies the mechanical properties of bone during initial healing.

The majority of clinical reports reveal similar survival rates between immediate-loaded and two-stage unloaded healing approaches in the completely edentulous patient. Nonetheless, these findings do not imply that a submerged surgical approach is no longer necessary or prudent in many cases. Future studies may find indications based on surgical, host, implant, and occlusal conditions more beneficial for one versus the other. For example, the strength of bone and the modulus of elasticity are related directly to bone density. The softest bone type may be 10 times weaker than for the densest types. The microstrain mismatch of titanium and the softest bone is much greater than the densest bone. As a result, higher implant failure and greater crestal bone loss seem likely but as yet are not reported in the literature. The biomechanical treatment approach to increase surface area and decrease forces applied to the immediate restorations is most likely the major reason for the high implant survival.

Soft and Hard Tissue Rehabilitation

34

Atraumatic Tooth Extraction and Socket Grafting

RANDOLPH R. RESNIK AND JON B. SUZUKI

It is imperative that the implant clinician has a strong understanding of the extraction socket healing process and options for the socket graft site preservation technique. In most cases the extraction process will initiate a sequence of bony resorptive morphologic changes that negatively alters the alveolar ridge. This chapter will discuss the process of atraumatic extraction and a decision process on when no graft is indicated and when to graft (i.e., protocol on various bone substitutes, membranes, and healing periods).

Extraction Socket Healing

In understanding the healing process of the extraction site, the terminology is often misrepresented (Box 34.1). The process of bone repair occurs when there is injury or conditions of the bone that cause incomplete bone volume to form in the residual ridge. The most common conditions that cause bone repair are the absence of a labial plate before or as a consequence of tooth extraction. Other factors include a bony wall that is less than 1.5 mm thick (usually the facial), exudate, gross apical pathology, or excessive heat from a dental drill during root extraction.

The tooth socket with five bony walls (i.e., mesial, distal, buccal, lingual, and apical) will heal by bone regeneration (Fig. 34.1). The process of bone regeneration heals by secondary intention, and bone healing in many aspects is similar to secondary intention soft tissue healing. The healing sequence in both hard and soft tissue includes inflammation, epithelialization, fibroplasia, and remodeling. However, socket healing presents unique microvascular features and a sequential pattern of bone formation before remodeling.

Numerous authors in the literature have proposed the healing sequence and various stages of bone regeneration after a tooth is extracted with a healthy surrounding alveolus.

Stage 1: Granulation Stage: After a tooth is extracted, an initial clot forms within the socket which consists of a "coagulum" of red and white blood cells. At approximately the third day, the coagulum is slowly replaced by highly vascular granulation tissue. The blood clot begins to shrink, and capillaries form sinusoids and granulation tissue, starting from the socket apex and spreading laterally and crestally along the socket walls. Granulation tissue replaces the clot over a 4-to 5-day period.[1, 2]

Stage 2: Initial Angiogenic Stage: The initial angiogenic stage starts approximately a week after extraction. This stage develops from the broken ends of blood vessels in the residual periodontal ligament covering the cribriform plate. Blood plasma leaks from the broken vessels, and immature fibroblasts aggregate at the plasma-rich regions. Fibroplasia begins early in the sequence during the first week as a result of the ingrowth of capillaries and fibroblasts. White blood cells kill bacteria and begin to dissolve foreign bodies and bone fragments. With few exceptions the angiogenesis begins at the bottom of the socket because this area is not severely injured during the extraction and has the greatest source of blood vessels.[3]

Stage 3: Early Bone Formation Stage: This stage starts approximately three to four weeks after extraction. The granulation tissue gradually is replaced by connective tissue (collagen fibers, spindle shaped fibroblasts). The capillary activity begins the early phases of trabeculae development. This capillary activity is initiated at the socket apex, and trabeculae of woven bone growth will occur following the formation of blood vessels. During this stage, the cortical bone of the crestal area of the socket will start to resorb, along with the interseptal regions and the thinner facial plate.[4]

Stage 4: Bone Growth Stage: The bone growth stage starts at approximately four to six weeks after the extraction. This period demonstrates the greatest sinusoid formation activity. The forming trabeculae of woven bone first start from the bottom of the socket after the meshwork of newly formed anastomosing sinusoidal capillaries. Bone formation is more rapid at this point, creating a three-dimensional lattice pattern of woven bone. New bone trabeculae form on the walls and approximately two-thirds of the socket is filled at four – five weeks. At this stage, the center of the socket is primarily composed of woven bone. The more-organized lamellar bone starts to form from the lining of the socket, moving toward the center. At approximately 6 weeks, bone trabeculae almost completely fill the socket.[5]

Stage 5: Bone Reorganization Stage: The bone reorganization stage starts at about 6 weeks after extraction. Usually complete epithelial closure of the socket is completed by this time. The primary bone trabeculae remodel to form thicker secondary cancellous bone. This process always begins at the apex of the extraction socket. At approximately 60 days, woven bone has completely bridged the defect and at 90 days, woven bone is resorbed by osteoclasts which is replaced by lamellar bone. The bridged woven bone is usually completely remodeled to lamellar bone by 16

- **Bone remodeling**—the replacement of old bone tissue by new bone tissue; natural phenomena to maintain healthy bone mass
- **Bone modeling**—adapts bone size and shape to stress or loading
- **Bone repair**—a physiologic process in which the body facilitates the repair of a bone fracture
- **Bone regeneration**—requires the use of surgical protocols that enable bone growth within deficient sites, using the principles of osteogenesis, osteoinduction, and osteoconduction
- **Socket restoration versus preservation**—difficult to differentiate; both terms are used
    - Bone is restored in the socket (generally for the placement of an implant)
    - Bone preservation indicates long-term stability of the alveolar ridge
• **Fig. 34.1** The treatment plan and protocol for a post-extraction socket is dictated by five bony walls: mesial (*M*), distal (*D*), buccal (*B*), lingual (*L*), and apical (*A*).

weeks and most osteogenic activity is complete at this time. A new periosteum is established by 180 days.[6,7,8]

The timing for these stages varies among individuals and clinical situations. The number of bony walls around the socket and size of the alveolus greatly influence the regeneration process. In general, larger molar extraction sites (i.e. molar) take longer to completely form bone compared with smaller-diameter anterior sites. Although the period of regeneration for an extraction socket is variable, the clinical sign that the socket regeneration is complete is when the radiographic lamina dura (which represents the cribriform plate) is no longer present. This healing period usually takes between 3 to 6 months, dependent on tooth size, root number, and extent of trauma during the extraction (Fig. 34.2).

Importance of the Buccal Plate

One of the most important factors in the regeneration and repair of bone is the buccal plate. The buccal plate of bone is more susceptible to bone loss. Studies have shown the buccal plate may lose up to 56% horizontal bone loss and 30% vertical bone loss within the first year after extraction.[9,10] In addition, when the

buccal plate is thicker, the ridge tends to resorb less. The buccal plate is also more susceptible to trauma. When iatrogenic buccal plate damage occurs, the socket no longer heals by regeneration, however will heal by repair. This is usually a slower healing process and more unpredictable (Fig. 34.3).

Atraumatic Tooth Extraction

Theory of Atraumatic Tooth Extraction

There exists a full array of reasons teeth are deemed unrestorable; periodontal, endodontic, prosthetic, or orthodontic failures. Once the extraction of a natural tooth is indicated, methods to maintain or obtain the surrounding hard and soft tissues are indicated. It is the primary goal of the implant clinician to extract the nonrestorable tooth while minimizing associated trauma and maintaining the hard and soft tissue.

The atraumatic tooth extraction technique and socket grafting has become a popular procedure in implant dentistry. The process of atraumatic tooth extraction and preservation of soft and hard tissues begins with the surrounding soft tissue. The cells of the inner layer of the periosteum are responsible for bone remodeling. When the bone volume is ideal, the periosteum should be minimally reflected in preservation of the blood supply. However, the periosteum can also be a limiting factor in the volume of bone formation. When the periosteum is separated from the bone graft by a barrier membrane, more volume of bone is regenerated. The periosteum helps bone remodeling or bone repair, but may also limit bone modeling and regeneration.

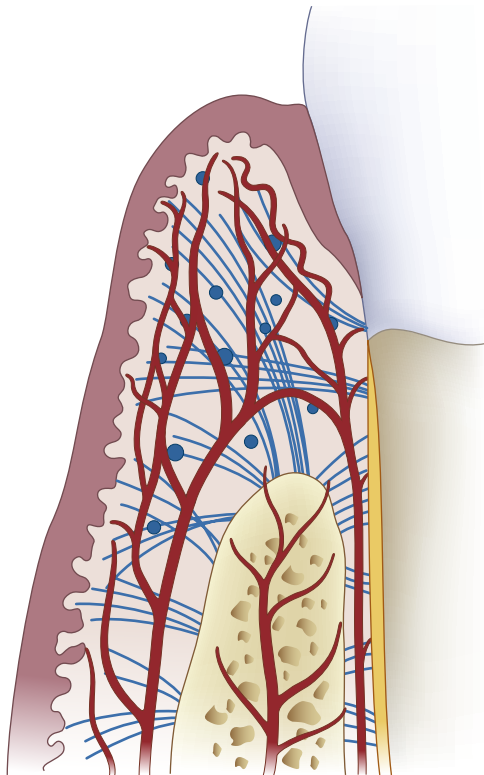
Atraumatic Tooth Extraction Technique

Many techniques and protocols exist for removing teeth; however, some basic principles should be applied to all extractions.

Severing the Connective Tissue Fibers

The soft tissue drape surrounding the teeth is affected by the reflection of the periosteum and often shrinks to adapt to the residual ridge form. In fact, the soft tissue is more labile to the trauma and reflection of the tissues than the hard tissues. Therefore the sulcular and surrounding soft tissue should ideally remain undisturbed during tooth extraction to prevent further dimensional loss. The extraction of a natural tooth begins with an incision within the sulcus, preferably with a thin scalpel blade or a blunt periotome. The incision should encompass the entire tooth (i.e., 360 degrees around the tooth) to sever the connective tissue attachment fibers above the bone (Fig. 34.4). There exist 13 different connective tissue fiber groups around a tooth, of which 6 directly insert into the cementum of the tooth above the bone. If these fibers are not severed before the extraction, trauma to the soft tissue is imminent. The soft tissue may tear, causing a delay in the healing process and increases bleeding (Fig. 34.5).

Minimizing Soft Tissue Reflection

The soft tissue should ideally be minimally reflected, because soft tissue retraction and shrinkage during initial healing are more evident, especially in the interdental papilla region. Usually a flap is raised when the buccal plate is not intact or surgical extraction of the tooth is indicated. If a tissue flap needs to be raised, an envelope flap (no vertical extension) is used. The vertical
• **Fig. 34.2** The Five Stages of Extraction Site Healing: (A) Granulation Stage: Initial blood clot forms and is gradually replaced with granulation tissue, (B) Initial Angiogenic Stage: Blood vessel formation integrates into the graft which starts at approximately one week, (C) Early Bone Formation Stage: At approximately 3-4 weeks, the granulation tissue is replaced by connective tissue. Woven bone starts to form at apex, (D) Bone Growth Stage: Greater woven bone growth continues as the center of the socket is primarily woven bone. Lamellar bone starts to form around the apex and lining of the socket, (E) Bone Reorganization Stage: Complete epithelial closure is usually complete by week 6. Woven bone is gradually replaced by lamellar and is complete by 16 weeks.
• **Fig. 34.3** The buccal plate is susceptible to fracture during extraction because the buccal plate is usually thinner than the lingual plate.
• **Fig. 34.4** The extraction of the tooth begins with a scalpel to incise the sulcular connective tissue fibers above the bone, which are attached to the cementum of the tooth.


● **Fig. 34.5** Illustration depicting the soft tissue attachment to a natural tooth. Thirteen different fibers insert into the tooth root and if not severed during the atraumatic extraction technique, hard and soft tissue damage will result.
● **Fig. 34.6** When a bone supported and reduction guide is indicated, a more extensive reflection is required for access and seating of the template.

incisions may compromise the blood supply and may delay the healing of the area. Whenever the periosteum is reflected, the cells are injured and need to regenerate before the remodeling process begins. The cortical bone receives more than 80% of its arterial blood supply and facilitates 100% of its venous blood return through the periosteum.[11] In some situations reflection of the tissue is necessary such as the use of bone-supported surgical templates (Fig. 34.6).

Evaluating the Anatomy of the Tooth to Be Extracted

The next step in the atraumatic extraction process is to evaluate the crown and root anatomy. This is especially important for divergent, multirooted teeth. If the roots of the tooth to be extracted are divergent, they should be sectioned and removed as individual units, rather than risking fracture of the roots or surrounding bone (Fig. 34.7). When the roots are fractured, there is an increased risk for bone fracture/removal to retrieve them. If bone removal around the tooth is necessary (because the tooth is fractured or decayed to the bony crest), it ideally should be at the expense of the lingual alveolus, not the more labial bone. The buccal plate of bone is almost always thinner than the lingual plate. Another option to reduce trauma when taking out teeth is modification of the contact (proximal) areas. When adjacent teeth are present the pathway of removal is often obstructed by the position of the adjacent tooth. If the tooth to be extracted is not reduced (i.e., mesial and distally), instruments or pressure may chip the enamel (or restoration) of the adjacent tooth and may cause the extraction of the tooth to take an altered pathway of removal, which is more likely to fracture the roots, bone, or both (Fig. 34.8).

Atraumatic Removal of the Tooth

Basic Principles. Biomechanic concepts have been used to extract teeth for thousands of years and date back to the days of Aristotle (384–322 BCE),[12] who described the mechanics of the extraction forceps, including the advantages of "two levers acting in contrary sense having a single fulcrum." This was 100 years before Archimedes reported on the principles of the lever. Pierre Fauchard[13] (1678–1761) is credited with being the pioneer of scientific dentistry and gave specific instructions for extracting teeth using a dental elevator, a "pelican," or pincers (forceps). He describes loosening the tooth with an elevator, then using the claw of the "pelican" (invented by Chauliac[14] in the fourteenth century). The pelican handle was positioned both on the tooth and on the gum below the tooth while it was rocked back and forth (which he called "shaking") before the extraction. Taft described a similar technique using the dental key, which had
● **Fig. 34.7** Atraumatic Extraction: (A) Mandibular first molar to be extracted, (B) Proximal contacts removed to allow for easier extraction, (C) Sectional of roots to minimize trauma, (D) Use of periotome to remove roots.

• **Fig. 34.8** (A) The maxillary lateral incisor requires extraction. The pathway of removal may restrict the extraction or chip an adjacent tooth. (B) The distal portion of the lateral incisor was reduced to allow the tooth to move distal, which allows pressure to the periodontal ligament and bone. In addition, there is less risk for adjacent tooth damage.

• **Fig. 34.9** Improper Extraction Technique: may often lead to retained fractured root tips or loss of buccal plate.

• **Fig. 34.10** Conventional extraction forceps often will result in the fracture the buccal plate leading to a compromised future implant site.

left and right claws that provided twisting and rocking in both directions.[15] This allowed the tooth to be loosened sufficiently to be pulled from the socket with "pincers" (forceps). Modern extraction forceps date from Tomes in 1840, with the development of the anatomic forceps, complete with a handle and beak to fit the neck of the tooth.

Biomechanics of Tooth Removal. The principle of the dental elevator is also not a modern development. Abulkasim (AD 1050–1122) was the first to apply a single lever (elevator) under the tooth to force it from its "bed." It was improved by Ambroise Paré in the sixteenth century to lift out the tooth before using the pelican. Although these biomechanical methods to remove teeth are effective, a review of the biomechanical principles is in order to decrease the trauma during the tooth extraction process.

The term "simple machine" is often used to describe basic devices that increase the amount of force applied (e.g., the lever, inclined plane, wheel, screw, pulley). They each transmit or modify force or torque. The most common devices used in the extraction of teeth include levers and inclined planes.

The wedge is technically a moving double inclined plane, which overcomes a large resistance by applying a relatively smaller force than the load necessary to move an object. The mechanical advantage of a wedge depends on the ratio of its length to its thickness. A short wedge with a wide angle moves an object faster; however, it requires more force than a long wedge with a smaller angle. Dental elevators use the mechanical advantage of a wedge to initiate the luxation of teeth for their removal (Figs. 34.9 and 34.10).

Periotomes. Periotomes are usually longer and thinner wedges compared with dental elevators and often are used to begin the atraumatic extraction process. Periotomes may be used in a similar manner for extraction of intact teeth or removal of retained root fragments.

Technique.

1. The long axis of the periotome blade should be inserted into the interproximal region along the root long axis (to protect the facial plate of bone), with the tip of the periotome blade located within the crest of the alveolar bone. The instrument is then pushed or tapped with a mallet into the periodontal ligament space along the mesial and distal root, severing the periodontal
• **Fig. 34.11** (A) A periotome is inserted along the tooth root on the mesial and pushed (or tapped with a mallet) to wedge the tooth against the opposing cribriform plate. A similar process is performed on the distal interpositional region of the tooth root. (B) Once the periotome acts as a wedge and is in place for 10 to 30 seconds, it is tapped (with a mallet) farther down along the mesial and distal interproximal root surface. (C) The periotome is converted into a lever by rotating the handle several degrees, which magnifies the force against the root. The tooth becomes slightly mobile at this stage. (D) A traditional dental forceps may remove the tooth after initial mobility is created by the periotome.

ligament immediately below the alveolar crest and wedging the tooth against the opposing cribriform plate (Fig. 34.11A). The periotome should never be used on the facial plate because this may damage the host bone.

2. A period of 10 to 30 seconds is allowed to elapse while the instrument is in place. This allows biomechanical creep to occur to the ligament and reduces its strength, and because the tooth is pushed against the opposing alveolus, it also will begin to expand the bone. This process is much more effective when there is no adjacent tooth contact. Reducing the mesial and distal proximal contacts of the tooth to be extracted not only decreases the risk for damage to the adjacent tooth crown, but also aids in the extraction hopeless tooth.

3. The periotome is then pushed farther down into the periodontal ligament space toward the root apex, often using a mallet and light tapping force. This process continues along the crestal third of the tooth. At the completion of this step the tooth is often slightly mobile (Fig. 34.11B).

4. Once the periotome is used as a moving wedge, it may then be converted to a lever (Fig. 34.11C). The blade of the periotome is often 3 to 4 mm wide. When the handle is rotated, one side of the periotome is applied to the tooth root, the other side to the cribriform plate, and the width of the "wedge" is now the length of a lever, which magnifies the rotation force (moment). The rotation of the periotome handle increases both tooth

mobility and the force against the opposite cortical plate to further expand it within physiologic limits.

5. A single-rooted tooth is most often tapered. As the periotome is tapped further apically toward the cribriform plate, it is slightly rotated. Because the socket is tapered, the lateral force on one side of the tooth is converted to a coronal direction force on the other side and the root is pushed out of the socket. As a result the periotome may now be pushed farther apical, toward the root apex. When time elapses between each force application, the tooth may even slide up and completely out of the socket. Additional time and elevation may be required if significant tooth mobility is not achieved.

Use of Conventional Forceps. Traditional dental forceps should not be applied to the tooth until significant tooth mobility is achieved. Once the wedge and lever action of the dental elevator is applied to a tooth, most often dental forceps are used to ultimately grasp and deliberately rock the tooth back and forth, and to rotate it as much as conditions will allow. The combination of these tooth movements expands the bony socket and separates the periodontal ligaments. As a consequence the tooth may be removed (Fig. 34.11D). Conventional dental forceps are actually two first-class levers connected with a hinge. The forces applied to the forceps handles are the long side of the lever and the beaks on the tooth are the short side of the lever, with the hinge acting as a fulcrum. The force on the handles is magnified to allow the
• **Fig. 34.12** The Physics (Atraumatic) Forceps. (A) A "bumper" (one beak) is placed on the facial of the tooth to be extracted at or below the mucogingival junction. The second beak is placed on the lingual, engaging the tooth root. The handles of the forceps act as a lever to rotate (avulse) the tooth from the socket. The bumper is placed below the tooth, usually at or above the mucogingival junction. The beak is placed low on the tooth root in the gingival sulcus. (B) Once the forcep is in position on the tooth root, the Physics Forceps is used as one unit (no squeezing of the handles). A few degrees of rotation to the facial places moment force on the tooth, which is held for 30 to 60 seconds. (C) Once the tooth releases from the socket, it is removed with a pincer-like device (e.g., pick-ups, extraction forceps, hemostat). (D) After removal of the tooth root, inspection of the root is completed to verify complete removal.

beaks of the forceps to grasp the tooth with great force. None of the force on the forceps handles is used to extract the tooth. Rather, the increased force on the forceps beaks often crushes or fractures the tooth. The forceps hold the tooth, and the surgeon's hand, wrist, and arm are used to move and extract the tooth. This action would be similar to forcibly pulling a bottle cap off a bottle or pulling a nail from a piece of wood using only a pair of pliers.

Alternative Extraction Forceps. The principles of biomechanics are the basis for the development of a different type of dental forceps called *Physics Forceps* (Golden-Misch Instruments, Detroit, Mich.). A *moment of force* in physics represents the magnitude of force applied to a rotational system at a distance from the axis of rotation. The principle of moment M is derived from Archimedes' discovery of the operating principle of the lever and is defined as

$$M = rF$$

where F is the applied force and r is the distance from the force applied to the object. The concept of a moment arm is key to the operation of the lever, which is capable of generating mechanical advantage. This means that the force applied to an object is affected by the length of the lever arms. The lever arm is the distance from the force input to the fulcrum or from the fulcrum to the force output.

The Physics Forceps is a dental extractor that uses first-class lever mechanics. One beak of the forcep is connected to a "bumper," which acts as a fulcrum during the extraction. The bumper is placed most often on the facial aspect of the dental alveolus, at or above the mucogingival junction. The second beak of the forcep is positioned as low as practical on the tooth root, most often on the palatal (lingual) into the gingival sulcus.

Once the forcep is in position around the tooth root, no squeezing pressure is applied to the tooth. Instead, the handles, once in position, are rotated as one unit facially for a few degrees and stopped for approximately 30-60 seconds (Fig. 34.12). The torque force generated on the tooth, periodontal ligament, and bone is related to the length of the handle to the bumper (8 cm), divided by the distance from the bumper to the forceps beak (1 cm). As a result a force on the handle connected to the bumper will increase the force on the tooth periodontal ligament and bone by eight times. No force is required to be placed on the forceps beak,
● **Fig. 34.13** Postextraction Debridement. (A) Serrated curette removing debris and soft tissue from within the socket. (B) Round carbide bure debriding the socket.

which is on the tooth. Therefore the tooth does not split, crush, or fracture. The 30-60 seconds of constant force cause biomechanical creep into the bone and periodontal ligament. Once creep has expanded and weakened the periodontal ligament and bone, the forceps handle may be slowly rotated another few degrees. This usually releases and elevates the tooth a few millimeters from the socket within an additional 10 seconds. At this point the tooth is loose and ready to be removed from the socket using any pincer-like device (e.g., pick-ups, an extraction forceps, a hemostat).

The extraction of a tooth using the Physics Forceps is similar to the removal of a nail from wood with use of a carpenter's hammer (instead of pliers). The handle of the hammer is a lever, and the beaks of the hammer fit under the head of a nail (they do not squeeze the head). The hammer head acts as a fulcrum. A rotational force applied to the hammer handle magnifies the force by the length of the handle, and the nail is elevated from the wood. Unlike a nail in wood, which is parallel and has friction for its full length, a tooth is tapered. Therefore after it is elevated a few millimeters, the periodontal ligament fibers are broken, and the tooth may be easily removed, without additional rotational force. This is important to note, because further rotational force on the forceps may fracture the facial plate of bone.

Creep is a phenomenon whereby a material continues to change shape over time under a constant load. In a tooth extraction, creep may occur to bone and the periodontal ligament. Reilly established the creep curve of bone, whereby under a constant load of 60 MPa, the bone over time responds in three different stages.[12] The majority of bone changes occur within the first minute, whereby the initial strain of bone (the change of length divided by the original length) is modified. The greater the force, the greater the deformation of the bone. This process allows the tooth socket to expand and the tooth to exit the socket. A secondary creep curve allows the bone to further deform when the force is applied for 1 to 5 minutes. The longer the time, the greater the deformation. However, the secondary deformation is only a 10% to 20% difference compared with the initial strain over the first

minute. Eventually the bone will fracture if the load is applied over a longer time frame, representing creep rupture.

The creep curve of the periodontal complex is similar to the creep curve of the bone, whereby the constant load on a tooth over time increases the strain and decreases the strength of the periodontal complex. Therefore the clinician should not underestimate the values of time and constant force to the tooth ligament and bone in the extraction process.

Socket Debridement After Extraction

Once the tooth is extracted, the tooth socket should be thoroughly debrided to remove all remnants of the periodontal ligament and any other soft tissue debris (e.g., granulation tissue). In addition, all fibrous tissue from periodontal disease or endodontic origin should be completely removed, because these tissues impair bone formation and delay bone healing for extended periods. Bleeding must ideally be present to allow for bone growth factors to enter the site. If bleeding is inadequate, the cribriform plate should be perforated with either a periodontal curette or a small carbide bur (i.e., #2 round bur) to promote bleeding and potentiate the healing process. Care should be exercised to not fenestrate the buccal or lingual walls and Fig. 34.15 or penetrate any vital structures (e.g., teeth, nerves, sinus, nasal cavity). A serrated curette (i.e., Lucas 86; Salvin Dental) can be used to remove the soft tissue and, secondarily, initiates bleeding. If lateral ridge augmentation is required, then bone decortication holes should be made over the recipient site to initiate angiogenesis and the regional acceleratory phenomenon (RAP) (Figs. 34.13 and 34.14).

Socket Grafting of the Extraction Site

Socket-Grafting Technique. Multiple bone graft procedures and studies have been evaluated for socket augmentation at the time of extraction. In most cases clinicians use one technique for socket grafting, without regard to the number of walls of bone remaining. Therefore rather than using the same technique regardless of clinical conditions, when bone repair rather than
● **Fig. 34.14** Care should be exercised when debriding sockets in the mental foramen area because this may cause neurosensory impairment.

● **Fig. 34.15** The proximity of the maxillary posterior teeth to the maxillary sinus may lead to perforation of the sinus and possible infectious episodes.

regeneration is likely, the clinician should provide as many keys to bone grafting as possible to increase the socket.

What Type of Bone?. Misch and Dietsh[16] have suggested different graft materials and techniques based on the number of bony walls that remained after the tooth is removed. A thick five bony wall defect will grow bone with almost any resorbable graft material, for example, an alloplast, allograft, or autograft. When a wall of bone is less than 1.5 mm or a labial plate is missing (four bony wall defect), an autograft or freeze-dried bone (FDB) with barrier membrane (BM) and guided bone regeneration increased the predictability of restoring the original bony contour. Becker et al.[17] evaluated demineralized freeze-dried bone (DFDB) alone in extraction sockets, and no evidence of bone formation was observed. It appears DFDB alone may be a poor choice for socket grafting. LeKovic et al.[18] compared extractions alone with BM with extractions. At 6 months, crestal bone loss (0.38 versus 1.50 mm) and horizontal ridge resorption (–1.31 versus –4.56 mm) were found.[18] A two or three bony wall defect usually will require the placement of a regenerative material, and autogenous bone or possibly a block graft of cortical autogenous bone fixated into the host bone position is suggested for one bony wall defect therefore, debridement should be completd with great care (Figs 34.16).

In the literature there exists no consensus with respect to the type of bone and the ideal membrane. Most studies completed on the type of bone include either allografts or xenografts. Allografts include demineralized (DFDBA) or mineralized freeze-dried bone allograft (FDBA). Because of the remaining calcium and phosphate salts, FDBA tends to resorb much slower and therefore maintains space much better than DFDBA. Xenografts resorb very slow, as some studies have shown them to last more than 44 months.[19]

What Type of Membrane?. The indication for the ideal membrane is dictated on the presence of a buccal wall. If all walls of the extraction socket are intact, then a fast-acting collagen is used (e.g., CollaTape, CollaPlug). If the buccal plate is missing, the membrane must be placed olver the buccal wall and should consist of a longer-acting material (e.g., longer-acting collagen or
● **Fig. 34.16** The graft materials and techniques for socket grafting are related to the remaining number of bony walls. (A) A thick, five-wall bony socket may remain ungrafted or use of an allograft. A thin wall bony socket used an allograft and collagen membrane. (B) Four-wall socket requires an allograft and a longer-acting membrane. (C, D) A Three-Two- or One wall socket will most likely require autogenous bone, usually in the form of an onlay block.

polytetrafluoroethylene [PTFE]). The advantage of the absorbable membrane (i.e., collagen) is that no reentry is required. The use of a dense PTFE attracts bone cells more readily; however, it is nonresorbable and needs to be removed.

Thick Five Bony Wall Socket (>1.5 mm). The bone regeneration process will restore complete morphology and bone volume to the residual ridge. This most often occurs when there are five thick bony walls around the extraction site (i.e., all remaining walls intact). Most of the keys for predictable bone formation are present under these conditions, and the socket often forms bone in
• **Fig. 34.17** Five-Walled Socket (< 1.5 mm). (A) Atraumatic Extraction. (B) Grafting with allograft. (C) Condensation of the graft. (D) Collagen membrane. (E) Final closure. (F) Six-week healing.

the extraction socket without loss of width or height. The atraumatic extraction of a tooth without pathology provides many of the keys necessary for predictable bone regeneration. The extraction process sets up the regional acceleratory phenomenon (RAP) for healing (which increases the rate of repair and adds bone morphogenetic protein to the site); the five bony walls protect the graft from mobility; the torn blood vessels in the periodontal complex leak growth factors into the region (platelet-derived growth factor, transforming growth factor); the space is maintained by the five walls of the bone; the bony walls provide blood vessels from bone into the site; and the defect size is small (i.e., one tooth). As a result the only key initially missing is soft tissue closure. The soft tissue around the extraction site begins to grow over the clot, and granulation tissue of the socket and within 2 to 3 weeks covers the extraction site (Fig. 34.17). There exist three treatment options for a few thick five bony wall socket;

Treatment Options (Five-Walled) ->1.5 mm)
1. Immediate Placement Implant.
2. No Treatment (Delayed implant Placement). In most thick bony wall sockets, bone will regenerate without bone graft material added; however, if the buccal plate is less than 1.5 mm, a socket graft is indicated to minimize collapse of the socket and to ensure adequate bone for future implant placement.
3. *Socket Grafting:* When the extraction socket is grafted, the selection of bone graft material is very important. The graft material

selected should coincide with the normal regeneration process. Therefore a material that resorbs too fast (e.g., autogenous bone, demineralized bone) or a material that resorbs too slow (e.g., cortical mineralized graft, xenograft) is not ideal for use in a five-walled defect. A much better choice would include a mineralized freeze-dried graft (cortico-cancellous 50-50) or a 70% mineralized/30% demineralized graft material that will maintain the space.

Five-Walled Bone-Grafting Technique. After complete socket debridement the socket is filled with the bone graft material in small increments. The bone graft material is compressed into the socket to avoid air spaces (i.e., should have "pushback"). Once the socket is completely filled, a collagen plug is hydrated in saline and then cut in half and compressed. The collagen is then inserted over the bone graft. Another option is cutting a piece of collagen tape (i.e., small oval piece) and positioning it over the grafted socket. The collagen is placed over the coronal aspect of the socket and the reflected tucked under the minimal flap on the buccal and lingual. The tissue is then closed with a crisscross suture. Ideally the suture technique should include the use of a high-tensile suture material (Fig. 34.18 and Box 34.2) similar to vicryl or PTFE.

Thin Five Bony Wall Socket (< 1.5 mm). For thin five bony wall sockets, the lack of socket grafting will result in unpredictable healing results. Therefore, it is recommended that these types of sockets be treated with a conventional socket grafting technique (# 3 Treatment Option for Thick Five Bony Wall Socket).
• **Fig. 34.18** Five Wall Socket: (A, B) All five walls remaining.

• BOX 34.2 Five-Walled Socket (> 1.5 mm)

Three Treatment Options:
1. Immediate Implant Placement
2. No Socket Graft (delayed implant placement)
3. Socket Graft

Reflection: conservative
Allograft: cortico-cancellous mineralized allograft or 70% mineralized/30%demineralized allograft
Membrane: regular collagen (~collagen plug)
Closure: primary closure is unachievable
Suture: crisscross suture (polytetrafluoroethylene or Vicryl)
Immediate implant: fair to good candidate
Prosthesis: Usually an FP-1 fixed prosthesis

*Thin Five-Walled Socket is treated with option # 3.

Four-Wall Bony Socket. Most often in a four-walled defect, the buccal wall is missing. When a labial plate around a socket is missing, the absence of the wall prevents space maintenance, reduces host bone vascularization, and replaces it with soft tissue vascularization. The facial bone level will never regenerate above the height of bone on the facial cortical plate of the tooth. Bone augmentation procedures must be used to obtain an ideal volume and contour of bone. Sockets with a missing lateral wall are significantly compromised and heal by repair rather than regeneration.

When conditions of repair instead of regeneration are present, socket grafting for ridge augmentation at the time of extraction is indicated.[20] Tooth extraction without grafting in four-walled defects will result in residual bone loss from resorption. For example, the maxillary anterior region may be reduced 23% in the first 6 months after an extraction and another 11% over the following 5 years.[21] Within 2 years an average of 40% to 60% of the original height and width of bone may be lost with multiple extractions.[22]

The first determination after the tooth extraction is complete is the assessment of the thickness of labial and palatal plates of bone and their relative height to the ideal volume desires. A curette or explorer may be used with the index finger over the buccal plate. If the buccal plate is missing, it will be easy to detect by tactile sensation. When the buccal plate is missing or when it is less than 1.5 mm thick, a socket graft is indicated. The two techniques of choice include a bone graft or a modified socket seal surgery (Figs. 34.19 and 34.26).

Four-Walled Bone-Grafting Technique. After complete debridement, a collagen membrane is contoured into a modified "V-Shape Cone," where the narrow part is placed on the inner surface of the buccal wall. Placing the membrane on the external aspect of the remaining buccal wall may compromise the blood supply and healing. The wider part of the membrane is trimmed to cover the socket opening and extend slightly to the lingual to "tuck" under the lingual marginal tissue. After the membrane is in place, the socket is filled with the bone graft material in small increments. The material is compressed into the socket to avoid air spaces (i.e., should have "pushback"). The suture technique should include the use of a high-tensile suture material. A crisscross suture is recommended, which encompasses the membrane and graft material. This will prevent the loss of the membrane and will contain the graft material. In some cases the membrane may be sutured to the tissue (Fig. 34.20 and Box 34.3).

NOTE: The membrane should cover only the missing buccal wall; the other walls should not have membrane coverage as this will decrease the healing of the area. The goal of the membrane is to prevent the soft tissue from repopulating the defect. If a membrane is not used, there is a greater chance of the graft particles migrating, resulting in unpredictable results.

One, two, and three bony wall sockets. When multiple walls of bone are missing, the greater the need for autogenous bone. A particulate graft is unpredictable in these situations. Therefore a donor site is most often used to obtain the autogenous bone: mandible (i.e., ramus, symphysis) or maxilla (i.e., tuberosity). In some cases (i.e. three bony wall sockets) a membrane tent screw may be used for space maintenance (Fig. 34.21) via guided bone regeneration protocols (GBR).

Obtaining Autogenous Grafting: Secondary Sites

Mandibular Ramus Donor Site: "Scraping Technique"

When autogenous bone is indicated, there exists many possible locations to harvest. One option which is easy, simple, and minimal morbidity is to obtain autogenous bone is to expose the mandibular ramus and remove bone from the external oblique ridge with double-action rongeurs. The "scrapings" may be placed in a surgical bowl with sterile saline. A second option to obtain smaller autogenous chips is to remove a block graft from the lateral ramus. Ramus block grafts may be taken; however, the blocks need to be reduced into smaller pieces, which is rather time consuming. In addition, a ramus block graft (i.e., veneer graft of the lateral ramus) has a greater morbidity rate and far greater postoperative complications (Fig. 34.22).
• **Fig. 34.19** Four Wall Socket: (A, B) Buccal wall missing.
• **Fig. 34.20** Four-Walled Socket. (A) Postextraction. (B) Extended collagen membrane. (C) Membrane in place. (D) Postsuturing.

Mandibular Ramus Donor Site: "Trephine Bur Bone Harvest"

A more aggressive technique to obtain autogenous bone cores from the ramus with trephine burs. Trephine burs are end-cutting burs that are available in various diameters with the 6- to 8-mm

trephine being the most popular to harvest bone from the ramus. For this technique, the ramus has become a more popular site in comparison with the symphysis area because of less morbidity. Once the ramus site (i.e., external oblique) is reflected, the trephine bur is used to harvest the autograft. Half of the trephine bur

Reflection: conservative
Allograft: cortico-cancellous mineralized allograft or 70% mineralized/30% demineralized allograft
Membrane: extended collagen or cytoplast (PTFE), (acellular dermis—thin biotype)
Closure: primary closure is usually unachievable
Suture: crisscross Suture (PTFE or Vicryl)
Immediate implant: poor to fair candidate
Prosthesis: Most likely a FP-2 or FP-3 prosthesis

*Autogenous bone can be used with allograft bone to accelerate healing and increase predictability.

is placed over the external oblique bony ridge, whereas the other half is lateral to the bone and above the reflected masseter muscle, which is elevated off the anterior lateral aspect of the ramus. Strict reflection of the soft tissues is warranted. The trephine bur is used with latch type angled surgical drill at 2000-2500 rpm with copious saline irrigation, 5 to 8 mm deep, making sure it is above and lateral to the position of the inferior alveolar nerve, artery, and vein. The inferior alveolar canal position may be identified via a cone beam computed tomography (CBCT) examination survey.

After the first trephine osteotomy is completed, the second site is completed above the half circle created by the first osteotomy and overlays the circle in the top third, or 3 mm from the top. This is repeated in the bottom third of the initial half circle, 3 mm above the bottom. Three interlacing semicircles are created along

• **Fig. 34.24** The maxillary tuberosity region is a common bone donor site for bone grafting when trabecular bone is the desired product. Trabecular bone has growth factors for blood vessels and for regeneration of a bone defect.

the external oblique of the ascending ramus. A large No. 8 round carbide in a straight handpiece then may score the lateral aspect of the ramus, corresponding to the depth of the trephine bur semicircle cuts. A chisel or surgical curette then may greenstick fracture the donor bone pieces from the ramus. These harvested pieces are usually an ideal size to use in the graft site, because they are approximately 5 × 3 × 5 mm large. A collagen sponge (e.g., OraTape, OraPlug) may be placed in the donor site and the tissues approximated for primary closure. One disadvantage of the trephine ramus technique is the loss of bone from the multiple osteotomies of the burs (Fig. 34.23).

Maxillary Tuberosity Donor Site

The tuberosity offers a variable amount of trabecular bone, which is dependent on the amount of maxillary bone atrophy and maxillary sinus pneumatization. This area is convenient and often the first choice of autogenous donor sites for maxillary sinus grafting[23,24]; it also may be considered for smaller areas of ridge augmentation[25,26] (Fig. 34.24). The cancellous nature of the bone allows it to be molded into an alveolar defect, such as an extraction socket.[17] The trabecular graft will more often require the use of a barrier membrane to minimize resorption and stabilize the graft.[27] The tuberosity autograft has growth factors for osteoinduction and to accelerate blood vessel growth in the host site.

The thicker soft tissue in the tuberosity region can mislead the assessment of this donor site. The tuberosity should be evaluated with a CBCT survey to determine the maxillary sinus location and the amount of host bone present. The anatomic limitations of this area include the maxillary sinus, pterygoid plates, adjacent teeth when present, and the greater palatine canal.

The tuberosity technique includes making a vertical incision a posteriorly at the lateral aspect of the maxilla and is extended anteriorly across the tuberosity into the molar region. After reflection of a mucoperiosteal flap, bone may be harvested from the tuberosity with a rongeur or chisel. Removing the graft with a chisel will allow the harvesting of a larger piece of bone. However, the sinus may inadvertently be entered during removal of the graft, with resultant oroantral communication. If this is observed at suture removal, the patient is instructed to avoid creating high nasal
● **Fig. 34.25** Tuberosity Harvest with Double Action Rongeurs.

pressures and should be placed on antibiotics to prevent infection and ensure normal drainage. Most often, the oroantral opening will close on its own (Fig. 34.25). If the oral-antral opening does not close, surgical closure is usually indicated.

Socket Seal Surgery

A composite graft socket seal surgery was developed by Misch et al.[28,29] composed of connective tissue, periosteum, and trabecular bone used to seal a fresh extraction socket. A connective tissue graft has the advantage over a keratinized graft by blending into the surrounding attached gingival regions, offering similar color and texture of the epithelium. This is most advantageous in the maxillary anterior region and other esthetic areas. The composite graft also contains autogenous bone. The major advantage of autologous bone is a more rapid and predictable bone formation via osteogenesis. The main disadvantage is the tuberosity bone resorbs rather fast, therefore unpredictable bone growth in quantity may result.

First, a CBCT evaluation should be completed to determine if adequate bone is present in the tuberosity location. A 6- to 10-mm trephine bur corresponding to the extraction site diameter is used in a slow-speed, high-torque handpiece (e.g., 16:1 or 20:1) to harvest a gingival graft with underlying bone. The most common site for the intraoral composite graft harvest is the maxillary tuberosity region (see Fig. 34.10). The trephine bur will drill through the unreflected, keratinized, attached gingiva and into the bone of the tuberosity region at the prescribed depth related to the thickness of the tissue and the amount of donor bone available. Care should be exerted not to enter the antrum. A trephine bur may be used as a lever to greenstick fracture the bone core from its base, once it is in position within the bone. A Molt elevator may also be used for this purpose. The bone core (usually 5–10 mm in height) and the attached soft tissue (about 3 mm in height) is trimmed of its epithelium with tissue scissors, leaving 3 to 6 mm of connective tissue attached to the bone core. If the bone core does not fill the extraction socket completely, a mineralized bone graft material (e.g., cortico-cancellous FDBA) may be used in the apical portion of the socket, provided the labial plate is still intact. Because the new bone forms from the apical portion of the socket, this is the least important region to augment.

If no bone plate remains in the apical half of the socket, additional autogenous bone should be harvested from an additional intraoral site to overfill the apical half of the socket. The bone of the composite graft (connective tissue attached to periosteum and bone) is compressed and fitted into the remaining portion of the socket.

The tissue of the composite graft will seal the socket and remain above the surrounding gingiva. A mallet and blunt instrument should be used to lightly tap it into place and compress the bony core to conform to the crestal contour of the socket. The connective tissue portion of the graft is then sutured to the surrounding gingival tissue with facial and palatal interrupted 4–0 PTFE or Vicryl sutures (Fig. 34.26). A removable transitional prosthesis should not be permitted to load the tissue during the first 6-8 weeks after extraction; otherwise the composite graft may become mobile and sequestrate.

The benefits of the composite graft socket seal surgery technique permit the surrounding keratinized gingival tissues to migrate and form a similar color and texture of keratinized tissue over the socket. The blood supply to the composite graft is established from the surrounding soft tissue. In addition, because autogenous bone is used as the graft in the coronal half of the socket, where the facial bone is most often very thin or absent, more predictable results will occur than if an allograft were used. The transfer of the bone graft with an intact periosteal layer expedites revascularization and may decrease the healing time.[30,31] As a result, reentry may be in in 4 to 5 months, and placement of an ideal implant diameter is often made possible.

Use of Bone Growth Factors in Extraction Site

Blood Concentrates

An option for faster healing and possibly better bone regeneration is the use of blood concentrates alone or in combination with bone graft material. Many authors have discussed the use of blood concentrates in the post-extraction site. Choukroun et al. described the use of his second generation platelet concentrate platelet rich fribrin (PRF) with socket grafting.[32] PRF is a natural fibrin biomaterial that allows for greater microvascularization and cell migration into the wound. Growth factors have been shown to be released up to 28 days after placement in extraction sites.[33] Histologically, the fibrin clot stimulates the extraction socket environment for more ideal bone regeneration and remodeling.[34,35] Rao et al. reported better bone regeneration and increased bone density in extraction sites with PRF alone compared to a control group.[36] However, the authors advocate if PRF is to be used, it is combined with bone graft material, which has been shown in the literature to facilitate more ideal and faster bone regeneration.[37]

Bone Morphogenic Protein

The use of bone morphogenic protein (BMP) has been investigated with the treatment of post-extraction sockets. BMP's are members of a family of proteins that are highly osseoinductive and stimulate mesenchymal cells to enhance bone growth. Fiorellini et al.[38] conducted controlled studies with the use of rhBMP-2 (bone morphogenic protein) with acellular collagen sponge in extraction sites. They concluded the use of BMP induced significant bone formation for the future placement of dental implants. Histologically, the bone was similar to native bone and was load bearing. Rh-BMP is commercially availability as an osteoinductive alloplastic bone graft material (Infuse Bone Graft, Medtronic Spinal and Biologics, Memphis, TN, USA).
• **Fig. 34.26** (A) The left maxillary central incisor has an absence of facial cortical plate (a four bony wall defect). (B) A trephine bur diameter is selected that corresponds to the size of the extraction site (Biohorizons, Birmingham, Ala.). (C) The trephine bur performs an osteotomy directly through the keratinized attached gingiva and into the tuberosity, and proceeds to the floor of the antrum. (D) The keratinized tissue, mucosa, periosteum, and bone of the composite graft are removed from the trephine bur. The tissue thickness is reduced to 2 to 3 mm above the bone. The surface of the tissue is connective tissue. (E) The composite graft is inserted into the extraction socket, and a blunt instrument (e.g., mirror handle) and mallet taps the composite graft into the socket so that the connective tissue is level with the surrounding tissues. (F) Sutures are positioned to maintain the composite graft in place.

Provisional Restorations

In most cases of socket-grafting site preservation, the patient will require a provisional restoration to maintain esthetics and function, and to protect the surgery site. For an interim removable prosthesis the implant clinician should ensure the prosthesis is tooth supported (i.e., has vertical stops on the adjacent teeth to prevent the partial denture tooth from exerting pressure directly on the tissues around the extractions site), and the surface area over the surgical site should be hygienic in contour. If a fixed prosthesis is used (e.g., resin bonded bridge), the undersurface should not impinge on the tissue (Fig. 34.27).

Socket Graft Healing

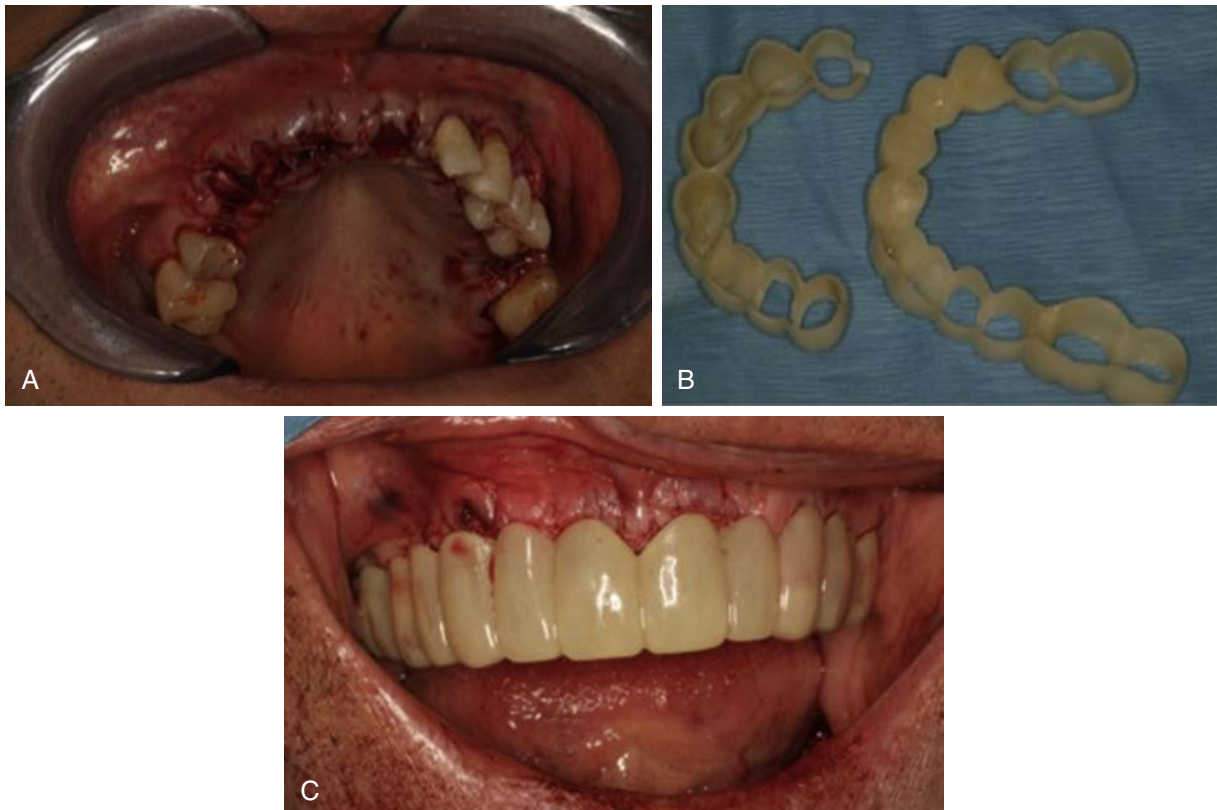
There exist many variables when determining when a socket graft site is healed for implant placement. Care should be exercised to place the implant only after adequate hard and soft tissue healing is obtained. Healing of the hard and soft tissues is determined by the size of the defect, type of graft material, type of bone graft, use of a membrane, and blood supply to the area. Usually a healing time ranging from 4 - 8 months is required. Radiographically, usually when the cribriform plate is not seen on the x-ray, adequate healing is achieved (Fig. 34.28).

Socket Grafting Contraindications

Infected Site

A relative contraindication to the socket-grafting protocol is the presence of an acute infection. A tooth demonstrating active infection (i.e., exudate or fistula) should be extracted without placement of bone graft material. The patient's acute infection should be managed by drainage of the infection, lavage of the infected area, and the use of systemic antibiotics. The bone grafting may be delayed for a minimum of 8 weeks postextraction to decrease the possibility of a graft infection. In addition, this delay will ensure better tissue quality (i.e., primary closure of the grafted site with keratinized tissue), elevated osteoblast activity, and a newly formed woven bone within the socket. The disadvantage of this surgical approach is the need for an additional surgery and a extended total treatment time (Fig. 34.29).

Proximity to Vital Structure (Mental Foramen, Mandibular Canal)

In the mandibular premolar area, 25% to 38% of the time the mental foramen is superior to the apex of either of the premolars. The location of the mental foramen is highly variable; however, it is most commonly located in the first or second premolar area. If a premolar is extracted, CBCT measurements need to confirm adequate bone below the apex. The clinician must be careful in debriding this area because nerve impairment may occur.
● **Fig. 34.28** Healed graft site exhibiting lack of cribriform plate present.


● **Fig. 34.27** Provisional Restoration. (A) Postextraction. (B) Overlay temporary bridge (i.e., Snap-On Smile). (C) Interim prosthesis inserted placing no pressure on extraction site.

In the mandibular molar area, especially in type 1 nerve locations (i.e., mandibular canal close to mandibular teeth apexes), after extraction it is important not to curette or place graft material in close proximity to the nerve canal (Fig. 34.30). In many cases, no superior cortical bone is present over the mandibluar canal.

Maxillary Sinus

In the maxillary first molar area, approximately 42% of the maxillary roots are located in the sinus proper.[39] When the tooth is extracted the sinus membrane may be perforated, and an exposure may occur. If grafting is completed, bone graft material may be introduced into the sinus proper, leading to the possibility of acute rhinosinusitis or oral-antral fistula formation (Fig. 34.31).
• **Fig. 34.29** Tooth With Apical Infection. Care should be exercised in grafting into an infected socket.

Socket Graft Complications

Inadequate Fill

Care should be exercised in filling the entire socket from the apex to the ridge with no voids. This is most often to occur in multirooted teeth, especially when root diameter is small. Small increments of graft material should be introduced into the socket at a time to avoid inadequate fills. Complications occur when too large of a syringe or too much volume of material is introduced into the socket and it becomes difficult to condense properly. Amalgam carriers with small amalgam pluggers can be used to graft smaller sized sockets (Fig. 34.32).

Too Dense of Socket Fill

Avoid excessive pressure when condensing the graft material into the socket. Too dense of a particulate graft fill may compromise the vascularity within the socket and final healing (Fig. 34.33). Usually when "push-back" of the material occurs, the socket is grafted sufficiently.

Overfilling the Extraction Socket

Excess graft material in height placed in the socket may compromise the soft tissue healing over the extraction socket. The graft material should be placed into the socket to the level of the surrounding socket walls. When excess bone is placed into an extraction site, it will usually be slowly lost postoperatively (Fig. 34.34). In addition, soft tissue healing over the extraction site will be delayed.

Leaving Soft Tissue or Root Fragment

After extraction the tooth and root structure should always be evaluated to verify no tissue or root tip is inadvertently left in the socket. Grafting over soft tissue or a root tip will increase the possibility of infection, decrease the amount of bone formation, and delay the healing process (Fig. 34.35).

Use of Incorrect Bone Graft Material

Certain bone substitutes are not ideal for socket grafting. Some of these materials include nonresorbable hydroxyapatite, calcified copolymer alloplast (Bioplant HTR; Bioplant
• **Fig. 34.30** Neurosensory Impairment (A and B) Socket graft material in close approximation to the mandibular canal. Care should be exercised in type 1 nerve paths.
• **Fig. 34.31 Maxillary Sinus Approximation.** Approximately 42% of molar roots are into the sinus floor, leading to possible perforation and extrusion of graft material into the sinus. Note the lingual root perforation into the maxillary sinus.
• **Fig. 34.32** (A and B) Inadequate socket fill (arrows). Graft material should be placed into the extraction sockets in small increments so that voids and inadequate fill do not occur.
• **Fig. 34.33** (A) Fill should be completed in small increments to allow for an ideal fill. (B) Adequate density is achieved when "pushback" occurs when packing the graft material.
• **Fig. 34.34** Overfilling the Extraction Socket. Bone should not be grafted above the cortical plate levels. This will result in poor wound healing migration of the graft material and incision line opening.
• **Fig. 34.35** Retained Root Tip. After the extraction, radiographic evidence should verify no retained roots in the socket.

Inc.), and "bioactive" glasses. Most of the alloplasts either do not resorb or resorb slowly with a fibrous encapsulation, thereby making them nonideal for subsequent implant placement (Box 34.4). Ideally, the bone graft material should resorb at the same rate that bone formation occurs (i.e. mineralized cortico-cancellous allograft or 70% mineralized/30% demineralized allograft).

Conclusion

The extraction of a natural tooth is one of the most widely performed procedures completed in dentistry today. After tooth extraction, it is well documented in the literature significant morphologic and dimensional changes occur to the extraction socket. When hard and soft tissue is lost, an increased difficulty in implant placement results, which compromises the final prosthetic outcome. Therefore, it is imperative that extraction sites are treatment predictably to maintain the hard and soft tissue volume. Many clinicians treat all sockets the same, with a set treatment

• **BOX 34.4**   **Summary of Post-Extraction Options**

1. Immediate implant placement (Usually for 5-walled sockets)
2. No Socket Graft - Delayed Implant Placement
   a. Five-walled socket (> 1.5 mm of buccal plate)
   b. Infected site
3. Socket graft—five-walled socket (< 1.5 mm of buccal plate)
   • Allograft + CollaTape/CollaPlug
4. Socket graft—four-walled socket
   • Allograft + extended collagen/dense polytetrafluoroethylene membrane
5. Socket graft—one-, two-, three-walled socket
   • Autograft + allograft

---

protocol to provide for placement of a future implant. However, the morphology, most specifically the number of remaining bony walls, play a significant role in the amount of resorption after extraction. Therefore, an extraction socket treatment protocol has been established which is dictated on the number of remaining walls. Each classification involves a different treatment protocol with the goal of maintaining the available bone and regenerating bone within the socket area so that ideal implant placement may be completed at a later date. In addition, the clinician must have a strong understanding of the indications and contraindications of socket grafting along with the ideal treatment of associated complications.

Bone Substitutes and Membranes

RALPH POWERS

Since acknowledging titanium as an inert substance capable of binding to bone in humans, implant dentistry has flourished.[1,2] Dr. Per-Ingvar Brånemark is known as the "father of the modern dental implant" for taking a serendipitous finding in orthopedic research and applying it to dentistry.[3] It took decades for him to convince the medical and dental communities that titanium could be integrated into living tissues, a process he called *osseointegration*. Now dental implants are considered a standard of care and enjoy a very high success rate. Having a reliable implant system is only part of the equation. It is well understood that both bone volume and bone quality are essential for implant placement and survival.[4]

Most dental implants require some type of bone augmentation. For many years autograft (considered the gold standard) was the only material available as a bone void filler, and it still has a place in many applications.[5] However, dramatic discoveries in biomaterials and improvements in processing, preservation, and packaging have made bone graft substitutes (BGS) available that are safe, effective, accessible in sufficient quantities, and suitable for almost all clinical situations. In fact, the global BGS and dental membrane market is expected to grow at a compound annual growth rate of 9.9% per year through 2025.[6] Much of this increase is driven by the large expected increase in dental implant and prosthetics work. The key factors driving the growth of this market include the growing geriatric population and corresponding dental disorders, rising incidence of tooth decay and edentulism, and the ability for more dental practitioners to place implants and provide more complete treatment solutions.

It is up to the clinician to create an osseo-adaptive situation when grafting, that is, having a host site prepared and a patient sufficient in health to allow for natural and predictable healing after any type of augmentation procedure. The wise clinician will be familiar with many types of BGS, as well as membranes, and their properties. The clinician should develop a decision tree for every clinical scenario based on a combination of empirical and scientific support. It is hoped the following information will provide a basis for understanding the many bone graft and membrane materials currently available.

Terminology for Bone Repair and Regeneration

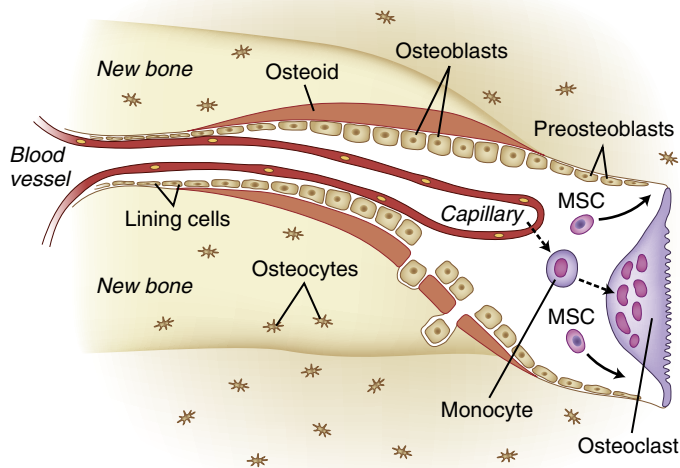
Bone remodeling is the ongoing process by which bone is resorbed and replaced in a dynamic steady-state process that maintains the health of bone. The process affects the entire skeleton all of the time. Although bone may appear superficially as a static tissue, it is actually very dynamic, undergoing constant remodeling throughout the life of the vertebrate organism. Bone remodeling is triggered by a need for calcium in the extracellular fluid, but it also occurs in response to mechanical stresses (microfracture) on the bone tissue.

For the remodeling to occur, appropriate cell signaling occurs to trigger osteoclasts to resorb the surface of the bone, followed by deposition of bone by osteoblasts. Together the cells in any given particular region of the bone surface that are responsible for bone remodeling are known as the basic multicellular unit (BMU). The action of osteoclasts and osteoblasts is synchronized: cells that resorb and deposit bone, respectively.

To understand bone remodeling, you need to know about three cell types found in bone:

- Osteoclasts are bone-resorbing cells (-*clast* means "to break"; osteoclasts break down bone). They are large, multinucleate cells that form through the fusion of precursor cells. Unlike osteoblasts, which are related to fibroblasts and other connective tissue cells, osteoclasts are descended from stem cells in the bone marrow that also give rise to monocytes (macrophages). One essential feature is the ingrowth of vascular tissue (neovascularization); this is an essential feature of remodeling in that the new vessels will carry cells and nutrients.
- Osteoblasts are bone-forming cells. They are connective tissue cells found at the surface of bone. They can be stimulated to proliferate and differentiate as osteocytes. They are recruited to the area and form the lining of the newly created tunnel.
- Osteocytes are mature bone cells. Osteocytes manufacture type I collagen and other substances that make up the bone extracellular matrix. Osteocytes will be found enclosed in bone[7] (Fig. 35.1).

Fig. 35.2 includes multiple cells and shows the phases of bone remodeling. The group of cells creating the tunnel through the bone is the BMU (forming the "cutting cone"). Osteoclasts are followed by preosteoblasts that adhere to the new wall of the area resorbed. As they mature to osteoblasts, they begin to secrete osteoid (immature bone matrix) in which they eventually are trapped and where they live out the remainder of their existence as osteocytes. This marks the start of reversal of the resorptive phase. The final product is the formation of Haversian canals (Fig. 35.3), or "osteons," familiar to all as a normal observation in bone histology.

913


• **Fig. 35.1** The Basics of Bone Remodeling. Involved are osteoclasts (removing old or impaired bone), preosteoblast and osteoblasts (forming new immature bone), and osteocytes trapped within the new bone matrix. None of this can occur without new vasculature to bring in essential cells and fluids. Mesenchymal stme cells (MSC) are the precursors to the bone forming "blast" cells.
• **Fig. 35.2** This is a more advanced look at the basic multicellular unit forming the "cutting cone." (*Adapted from: Roberts WE Garetto LP, Arbuckle GR et al: What are the risk factors of osteoporosis? Assessing bone health, J Am Dent Assoc 122:59-61, 1991. Source:* https://basicmedicalkey.com/functional-anatomy-of-the-musculoskeletal-system/)
• **Fig. 35.3** Osteons, or Haversian canals. Evidence that bone remodeling occurred in the area.

In infants, bone "turnover" is rapid and may result in a 100% new skeleton within 1 year; in adults, it is approximately 10%.[8] Statistics of adult bone remodeling are as follows:

• Life span of BMU is ~6 to 9 months.
• Speed of BMU is ~ 25 μm/day.
• Bone volume replaced by a single BMU is ~0.025 mm³.
• Life span of osteoclasts is ~2 weeks.
• Life span of osteoblasts is ~3 weeks.
• Interval between successive remodeling events at the same location is ~2 to 5 years.
• Rate of turnover of whole skeleton is ~10% per year.

The 10% per year approximation for the entire skeleton is based on an average 4% turnover per year in cortical bone, which represents roughly 75% of the entire skeleton, and an average 28% per year in trabecular (cancellous) bone, which represents roughly 25% of the skeleton. As you can see, remodeling occurs slowly and continuously.

Bone modeling adapts structure to loading and removes damage as to maintain bone strength. It involves independent sites of resorption and formation that change the size and shape of bones. The stimulus is additional localized stress (as in orthodontic tooth movement and weight training). This is described by Wolff's law, which proposes that bone in a healthy person or animal will adapt to the loads under which it is placed.[9] Modeling occurs at the cellular level in a fashion similar to that described for remodeling.

Bone repair is a proliferative physiologic process in which the body facilitates the repair of a bone fracture. Repair occurs in response to trauma (fracture or overuse) and is the result of a complicated cascade of events.

Bone regeneration is the regrowth of lost tissue. This requires the use of surgical protocols that enable regeneration of the deficient sites, using the principles of osteogenesis, osteoinduction, and osteoconduction (see more detailed definitions later in this chapter).

• *Guided bone regeneration* (GBR) refers to alveolar ridge augmentation or bone redevelopment (for implant placement or to preserve the site for fixed or removable bridgework); this often requires the presence of a membrane to protect the grafted area and restrict the entrance of unwanted cells. When a graft is placed into a site (in, for example, a fresh extraction socket), a competition occurs between soft tissue and bone-forming cells to fill the surgical site. Soft tissue cells (epithelial cells and fibroblasts) migrate at a very fast rate compared with bone-formers. A properly chosen and placed membrane

will reduce the competition. Below the membrane, regeneration occurs. It involves the proliferation of new blood vessels (angiogenesis) and the migration of bone-forming cells (osteogenesis). An initial blood clot will form, which is replaced by fibrous bone. This material (called *woven bone*) is characterized by a haphazard organization of collagen and is mechanically weak. Later this will be transformed into a better organized, load-bearing "lamellar bone" (via normal bone remodeling).[10]

- *Guided tissue regeneration* (GTR) involves the same techniques used in GBR, but for redeveloping (regenerating) lost periodontal tissues (cementum, periodontal ligament, alveolar bone) to retain the natural dentition. Early research in this area was instrumental in the development of the modern membrane.[11]

The concept of GBR was described first in 1959 when cell-occlusive membranes were employed for spinal fusions.[12] The terms *guided bone regeneration* (GBR) and *guided tissue regeneration* (GTR) often are used synonymously and rather inappropriately. GTR deals with the regeneration of the supporting periodontal apparatus, including cementum, periodontal ligament, and alveolar bone, whereas GBR refers to the promotion of bone formation alone. GBR and GTR are based on the same principles that use barrier membranes for space maintenance over a defect, promoting the ingrowth of osteogenic cells and preventing migration of undesired cells from the overlying soft tissues into the wound. Protection of a blood clot in the defect and exclusion of gingival connective tissue and provision of a secluded space into which osteogenic cell from the bone can migrate are essential for a successful outcome. The sequence of bone healing is affected not only by invasion of nonosteogenic tissue but more so by the defect size and morphology.

Bone preservation indicates long-term stability of the alveolar ridge. This is a general term for all of the previous terms in this section.

Mechanisms of Bone Repair and Regeneration

From the time of Hippocrates it has been known that bone has considerable potential for regeneration and repair. Nicholas Senn,[13] a surgeon at Rush Medical College in Chicago, described the utility of antiseptic decalcified bone implants in the treatment of osteomyelitis and certain bone deformities. Pierre Lacroix[14] proposed that there might be a hypothetical substance, osteogenin, that might initiate bone growth.

Marshall R. Urist provided the biological basis of bone morphogenesis. Urist[15] made the key discovery that demineralized, lyophilized segments of bone induced new bone formation when implanted in muscle pouches in rabbits. This discovery was published in 1965 in *Science*.[15] The term *bone morphogenetic protein* (BMP) first appeared in the scientific literature via the *Journal of Dental Research* in 1971.[16] Bone morphogenetic (or morphogeneic) proteins are now referred to as BMPs for convenience.

Bone induction is a sequential multistep cascade. The key steps in this cascade are *chemotaxis*, *mitosis*, and *differentiation*. Chemotaxis is movement of a motile cell in a direction corresponding to a gradient of increasing or decreasing concentration of a particular substance (such as a BMP). Mitosis is a type of cell division that results in two daughter cells each having the same number and kind of chromosomes as the parent nucleus. This is typical of ordinary tissue growth. Differentiation is the process by which a

cell becomes specialized to perform a specific function, as in the case of a bone cell, a blood cell, or a neuron. There are more than 250 general types of cells in the human body. For bone induction, BMPs (uncovered by normal bone remodeling or exposed in the matrix of a properly demineralized graft) signal for chemotaxis of bone-forming cells to the bone void. The cells divide to increase their number and mature to a more specialized form to produce new immature bone material (osteoid). Over time this area is remodeled to provide a better structure.

Early studies by Hari Reddi unraveled the sequence of events involved in bone matrix–induced bone morphogenesis. On the basis of this work, it seemed likely that "morphogens" were present in the bone matrix. A systematic study, using a battery of bioassays for bone formation, was undertaken to isolate and purify putative bone morphogenetic proteins.[17] It is well recognized that BMPs can be found in properly prepared demineralized bone products in the correct proportion to induce the sequential steps needed for bone regeneration. To date, 20 BMPs have been identified.[18] Now laboratory-produced recombinant human BMPs (rhBMPs) are used in orthopedic applications (rhBMP-2 and rhBMP-7), such as spinal fusions and nonunions. rhBMP-2 is U.S. Food and Drug Administration (FDA) approved for some dental use.

In general, osteoinduction is the process by which osteogenesis is induced. It is a phenomenon regularly seen in any type of bone healing process. Osteoinduction implies the recruitment of immature cells and the stimulation of these cells to develop into preosteoblasts. In a bone healing situation such as a fracture the majority of bone healing is dependent on osteoinduction. Osteoconduction means that bone grows on a surface.

Currently *osteogenesis* can occur only with autografts. Examples are the use of the rib, grafts from the chin, ascending ramus, ilium, tibia, or outer table of the cranium, or from bone collected during extraction or other dental procedure. Osteogenesis occurs when vital osteoblasts originating from the bone graft material contribute to new bone growth along with bone growth generated via osteoinduction and osteoconduction.[19]

Osteoinduction has a rich research history and has been well studied. Osteoinductive materials will recruit the proper bone cells to a site, and these cells will form bone. Osteoinduction can produce bone where bone is not normally found (ectopic or heterotropic sites). In fact, the early tests for a material's osteoinductive "potential" were placement of that material into the muscle pouch of an animal. An example of a test animal is the "nude" mouse. A nude mouse is a laboratory mouse from a strain with a genetic mutation that causes a deteriorated or absent thymus, resulting in an inhibited immune system because of a greatly reduced number of T cells. The phenotype (main outward appearance) of the mouse is a lack of body hair, which gives it the "nude" nickname. The nude mouse is valuable to research because it can receive many different types of tissue grafts, as it mounts no rejection response. Therefore if new bone forms in the muscle pouch of a nude mouse, it provides evidence of the potential for osteoinductivity. Now *in vitro* tests have been developed to assess potential osteoinductivity, although the *in vivo* animal assay is considered the gold standard.[20]

Osteoconduction is the formation of bone on a surface. All inert materials possess this characteristic. In bone regeneration, healthy bone must be present adjacent to the site where the graft is placed. Because bone will move from the healthy host site through the grafting material placed in the bone void, this is commonly referred to as "creeping substitution." Fig. 35.4 illustrates this phenomenon with a cancellous-based product.
- **Fig. 35.4** "Creeping substitution." This occurs with all materials to some extent because all BGSs are osteoconductive. It requires the presence of healthy host bone in close proximity to the graft. Neovascularization occurs in cells that will remove/repopulate the space. (*Source:* https://pocketdentistry.com/basics-of-bone-grafting-and-graft-materials/)

It occurs similarly with a cortical material, but at a slower rate. The rate of creeping substitution is based on the available space for vascular ingrowth. Available space is based on particle spacing (if a "powder" type material is used), as well as macroporosity and microporosity of the material.[21]

- Macroporosity (pore size greater than 100 μm) is usually required to facilitate the osteogenesis and angiogenesis. Interconnected macropores are necessary to promote body fluid circulation and cell migration to the core of the implant. An example of macroporosity is the normal marrow space formed by trabeculation in the cancellous portion of bone, or the interparticle spacing that is created when particulate grafts are placed.

- Microporosity (pore size less than 10 μm) has importance, as does the unique surface properties of microporous scaffolds. These have considerable influence on fluid distribution and protein adsorption. Moreover, capillary force generated by the microporosity can improve the attachment of bone-related cells on the scaffolds surface and even make the cells achieve penetration into the micropores smaller than them (Fig. 35.5).

Osteopromotion involves the enhancement of osteoinduction without the material possessing osteoinductive properties. As an example, enamel matrix derivative (xenograft based) has been

Granules

Macropore (>100μm)

Mesopore (10 - 100μm)

Micropore (<10μm)

shown to enhance the osteoinductive effect of demineralized freeze-dried bone allograft (DFDBA) but will not stimulate new bone growth alone.[22] Platelet-rich plasma and other substances derived from the patient's own blood are also examples.

Ideal Bone Graft Substitute

Reconstruction of bone defects or preparation of a site for implant placement remains a challenge. On the one hand, autografts harbor most features of "ideal" BGS; on the other hand, they have a lot of insurmountable disadvantages (higher level of surgical skill needed, insufficient quantity, second-site morbidity, increased operative time, etc.). An ideal bone graft substitute should:

- be biomechanically stable;
- degrade within an appropriate time frame;
- exhibit osteoconductive, osteogenic, and osteoinductive properties; and
- provide a favorable environment for invading blood vessels and bone-forming cells.

Even though osteoconductivity of biomaterials for bone tissue engineering (BTE) strategies can be directed by their composition, surface character, and internal structure, osteoinductive and osteogenic features (discussed later) can be enhanced by the addition of osteopromotive materials.[23]

Having the ideal substitute would address only a part of what is needed for successful bone regeneration. As illustrated in Fig. 35.6, the bone healing triad is based on the complex process involved in tissue repair, wherein the matrix/scaffold (osteoconductive materials), signaling proteins (osteoinductive, located within the matrix), and tissue-forming cells (osteogenic, osteoclasts and osteoblasts) work in concert to form new tissue (bone) in the healthy (osseo-adaptive) host over time.

Ideal Membrane Material

GBR is a common technique in implant dentistry for the treatment of bone defects. As discussed earlier, a critical component of the GBR procedure is the use of a barrier membrane. These materials are used to prevent the invasion of cells that are not needed or would interfere with bone formation. The primary goal is selective cell repopulation.[24] An ideal barrier membrane should:

- Be biologically compatible. There should be no inflammation or interaction between the barrier material and the host.
- Provide space maintenance. When desired, the membrane should have the ability to prevent defect collapse.

- Stabilize the blood clot that forms as part of natural healing. This will allow the regeneration process to progress and reduce unwanted tissue integration into the defect.
- Provide cell occlusion. This is the primary function of the membrane, but many membranes allow the passage of fluid that may assist in healing.
- Have some degree of mechanical strength (based on end-user needs). Strength is needed, and in some cases shape memory is desired.
- Resorb predictably, per the end-user requirements. Fortunately, many configurations with varying rates of resorption exist.
- Be easy to modify and manipulate.

As you will see, there are many types of membranes to choose from, most of which possess those properties. It is up to the clinician to choose the barrier membrane that best provides for the desired clinical outcome.

Classification of Bone Graft Substitutes and Membranes

Transplant refers to the transfer of an organ from one body to another, or from a certain section of the patient's own body to another area. This procedure is usually performed to replace a damaged or missing organ. Tissues can be transferred from one individual to another, and because they are generally placed to encourage the body to heal itself, thus being incorporated into the host, they are considered transplants.

Implants are medical devices intended to replace a missing body part, support a damaged part, or enhance the body in some way. Titanium dental implants are a good example. Some researchers consider allografts and xenografts (biological material) to be implants because they are nonliving. It is acceptable to call them either transplants or implants.

Autograft (or autotransplantation) is the transplantation of functioning organs, tissues, or even particular proteins from one part of the body to another in the same person. Examples in implant dentistry are grafts from the ascending ramus, chin, or iliac crest.

Allograft (or homograft) is the transplantation of cells, tissues, or organs to a recipient from a genetically nonidentical donor of the same species. It can also be called an *allogeneic transplant*. Related to this are isografts—a graft of tissue between two individuals who are genetically identical (i.e., monozygotic twins). Demineralized freeze-dried bone and acellular dermis are examples used in implant dentistry.

Xenograft (or heterograft) is a tissue graft or organ transplant from a donor of a different species from the recipient. Bovine or porcine sourced materials (cancellous bone or collagen membranes) are good examples. An interesting example of xenografts is coral-derived materials. These are considered xenografts (as opposed to alloplasts) because of their organic nature.

Alloplast is an inorganic material used as a bone substitute or an implant. Hydroxyapatite (HA) and tricalcium phosphate (TCP) materials are examples.

Oversight

A *510(k)* is a premarket submission made to the FDA to demonstrate that a medical device is as safe and effective, that is, substantially equivalent, as a legally marketed device. Once the device is determined to be substantially equivalent, it can then be marketed

in the United States. Two years after the Medical Device Amendments of 1976 were enacted, the FDA issued its final draft of the medical device Good Manufacturing Practice (GMP) regulation, a series of requirements that prescribed the facilities, methods, and controls to be used in the manufacture, packaging, and storage of medical devices. All 510(k) products must be manufactured under GMP, and proof that they are is part of the process for obtaining approval. Xenograft and alloplast materials fall under the 501(k) requirements. Products going through the 510(k) pathway can have intended applications or claims.

An *investigational device exemption* (IDE) allows the investigational device to be used in a clinical study to collect safety and effectiveness data. Clinical studies are most often conducted to support a premarket approval. Only a small percentage of 510(k)s require clinical data to support the application. Investigational use also includes clinical evaluation of certain modifications or new intended uses of legally marketed devices. All clinical evaluations of investigational devices, unless exempt, must have an approved IDE before the study is initiated. It is rare that a product intended to be used as a BGS or membrane in dentistry requires an IDE and premarket approval. If the device does need clinical evaluation and has not been cleared for marketing, these are required:

- an investigational plan approved by an institutional review board
- informed consent from all patients
- labeling stating that the device is for investigational use only
- monitoring of the study
- required records and reports

Good Clinical Practice refers to the regulations and requirements that must be complied with while conducting a clinical study. These regulations apply to the manufacturers, sponsors, clinical investigators, institutional review boards, and the medical device.

Products containing or consisting of human cells or tissues that are intended for implantation, transplantation, infusion, or transfer into a human recipient, and are considered minimally manipulated, are called *human cellular and tissue-based products* (HCT/Ps). HCT/Ps must also be intended for homologous use and cannot be combined with another article (except for water, crystalloids, or a sterilizing, preserving, or storage agent). The product must have no systemic effect and cannot be dependent on the metabolic activity of living cells for the primary function.

Allograft products are considered medical devices when the FDA determines that they have been more than minimally processed. To be considered beyond minimally processed, an original characteristic of a structural tissue must be altered, and that characteristic has to be relevant in that it has a potential effect on the utility of the tissue for reconstruction, repair, or replacement.

Manufacturers of HCT/Ps (i.e., tissue processors) are required by the FDA to comply with Current Good Tissue Practice. This includes proper handling, processing, labeling, and recordkeeping procedures. Under these regulations, tissue banks must screen and test all donors for risk factors and clinical evidence of relevant communicable disease agents.

With the rapid growth of all areas of tissue banking, there has been an increasing need for accountability and for measures that ensure that safe, quality tissues are available for clinical use. Quality improvement can be affected through voluntary standards, and most tissue banks have incorporated the achievement of high standards into their goals. The American Association of Tissue Banks (AATB) has established comprehensive standards for donor screening, recovery and processing of musculoskeletal, cardiac,

vascular, and skin tissues, and reproductive cells.[25] In addition, the standards contain institutional requirements; descriptions of required functional components of a tissue bank; requirements for construction and management of records and development of procedures; requirements for informed consent, tissue labeling, storage, and release; expectations for handling adverse outcomes, investigations, and tissue recalls; requirements for establishment of a quality program; specifications for equipment and facilities; and guidelines for tissue-dispensing services and tissue distribution intermediaries. AATB's *Standards for Tissue Banking* are consulted not only by tissue bankers but also by end-user healthcare facilities, other standard-setting organizations, and regulators worldwide. In 2018, more than 100 tissue banks in North America held AATB accreditation. Best practice for checking a tissue bank's accreditation status is to perform an accredited bank search on the AATB website.[26]

The Joint Commission has standards for storage and issuance of tissue for hospitals and ambulatory surgery centers. These standards apply to bone, tendon, fascia, and cartilage, as well as cellular tissues of both human and animal (xenograft) origin. The standards address key functions, including the need to develop procedures for tissue acquisition and storage, recordkeeping and tracking, and follow-up of adverse events and suspected allograft-caused infections, which must be reported to the tissue bank from which the tissue was obtained. Similar to federal regulations and AATB *Standards*, the minimal record retention period is specified to be 10 years from the date of transplantation, distribution, other disposition, or expiration, whichever is latest.

FDA authority to create and "enforce regulations necessary to prevent the introduction, transmission, or spread of communicable diseases between the States or from foreign countries into the States" under Section 361(a) of the U.S. Public Health Service Act (42 USC 264) applies to human tissue intended for transplantation. Formal enforcement policy and regulations did not exist until December 14, 1993 (codified in 21 CFR Parts 16 and 1270), when the "Interim Rule: Human Tissue Intended for Transplantation," which required donor screening, infectious disease testing, and recordkeeping "to prevent transmission of infectious diseases through human tissue used in transplantation," was adopted in response to reports of HIV transmission by human tissue and of potentially unsafe bone imported into the United States.[27]

These regulations were supplanted by a series of federal regulations, published in stages, first announced in the Proposed Approach to the Regulation of Cellular and Tissue-Based Products in March 1997. A final rule, "Human Cells, Tissues, and Cellular and Tissue-Based Products: Establishment Registration and Listing," published in January 2001, required organizations that are engaged in tissue recovery, donor qualification, tissue processing, and/or tissue-related laboratory testing to register as a tissue establishment with the FDA. The rule (21 CFR Part 1271) became effective for all tissue banks on March 29, 2004.

A final rule, "Eligibility Determination for Donors of Human Cells, Tissues, and Cellular and Tissue-Based Products," published May 25, 2004, set forth donor eligibility requirements, including health history screening and laboratory testing. Another final rule, "Current Good Tissue Practice for Human Cell, Tissue and Cellular and Tissue-Based Product Establishments; Inspection and Enforcement," published on November 24, 2004, established elements of good tissue practice, analogous to GMP for blood banks. Both rules became effective May 25, 2005.

Sterility

Sterility will be discussed from the viewpoint of allografts because they are the most difficult to sterilize because of their fragile biologic nature and variety.[28]

Tissue sterilization is defined as the killing or elimination of all microorganisms from allograft tissue, whereas disinfection refers to the removal of microbial contamination. The Association for the Advancement of Medical Instrumentation, a standard-setting organization for the medical instrumentation and technology industry, defines sterility assurance level (SAL) as the probability that an individual device, dose, or unit is nonsterile (i.e., one or more viable microorganisms being present) after it has been exposed to a validated sterilization process. Although absolute sterility in theory would represent an absence of any pathogen, SAL is generally applied only to the level of possible contamination with bacteria or parasites. In contrast with log reduction of viruses determined in assessments of virus reduction methods, SAL is an absolute determined by the ability of the method to eradicate or reduce microorganisms, the susceptibility of organisms that may be present to the sterilization method applied, and the maximal bioburden that could occur in the initial material. For example, a SAL of 10^{-6} means that there is less than a 1 in 1,000,000 chance of a viable microorganism remaining after the sterilization procedure. The FDA requires that medical devices be sterilized using a method validated to achieve a SAL of 10^{-6}. A medical device derived from or that includes a biological product component must also meet a SAL of 10^{-6} if it is to be labeled sterile. A SAL of 10^{-3}, or a 1 in 1000 chance of a viable microorganism being present, is a more achievable goal selected by some processors for aseptically processed tissues if the processor has been unable to validate their process to the more stringent SAL of 10^{-6} level, or if the tissues are unable to withstand the harsh treatment needed to achieve a more restrictive SAL without an impairment of tissue function. Such tissues may not then be labeled as sterile.

The complex physical structures and density of musculoskeletal tissues pose challenges for adequate penetration of antimicrobial agents to eradicate microorganisms. Allografts will not tolerate methods usually applied to metal and plastic medical devices because such treatment would impair the mechanical and biologic properties necessary for clinical utility. As an alternative, sterilization of tissues has been accomplished by several methods, including heat, chemicals, ethylene oxide gas, supercritical CO_2, and gamma or electron beam irradiation. However, not all sterilants have adequate tissue penetration. This is particularly the case for gases and liquids. The initial bioburden, which may be high in some tissues, must be considered. Some tissues are treated with antibiotics in vitro before storage, but this treatment decontaminates only the surface and may be effective against bacteria only.

A variety of methods, including chemical treatments and irradiation, has been used to reduce or eliminate pathogens in tissue intended for transplantation. The introduction of bone sterilization by ethylene oxide gas simplified bone processing and facilitated the widespread use of sterilized air-dried and lyophilized bone products. The effects of ethylene oxide treatment on the biomechanical and osteoinductive capacity of bone allografts have been questioned, although animal studies have yielded inconsistent results. These concerns, combined with those regarding the carcinogenic potential of ethylene oxide and its breakdown products, have largely led to abandonment of this method in the United States and the United Kingdom.

First introduced in the 1960s, gamma irradiation of bone is still used widely, usually employing a cobalt-60 source. The gamma rays penetrate bone effectively and work by generating free radicals, which may have adverse effects on collagen and limit utility in soft tissues unless performed in a controlled dose fashion at ultra-low temperature. The minimal bactericidal level of gamma irradiation is 10 to 20 kGy (1 kGy = 100,000 rad). Uncontrolled human studies have shown irradiated, calcified, and demineralized bone grafts to be clinically effective. Numerous studies have shown that mineralized bone allografts irradiated at 25 to 30 kGy are also clinically effective, with high success rates reported. In controlled studies the clinical effectiveness of bone allografts subjected to 25 kGy irradiation was comparable with that of nonirradiated bone grafts, although doses exceeding 25 kGy for cortical bone and 60 kGy for cancellous bone have been found to induce cross-linking of collagen and to impair mechanical function in a dose-dependent fashion. There is *in vitro* evidence that high irradiation reduces osteoclast activity and increases osteoblast apoptosis (programmed cell death), and that residual bacterial products induce inflammatory bone resorption after macrophage inactivation. However, the clinical significance of these findings has not been established. Newer processes employing radioprotectants have preserved bone allograft integrity when doses ≥25 kGy are applied, and controlled-dose methods permit successful irradiation at lower doses (see Proprietary Sterilization Methods to follow). Irradiated demineralized bone has potential osteoinductive activity and has been effective in nonstructural clinical applications.

Concerns about pathogen transmission and the limitations of irradiation, especially for soft tissues, have prompted improvements in sterilization methods and in the validation of these methods. A number of proprietary chemical-based processing methods have been developed with aims of effectively penetrating tissues and reducing, killing, or inactivating microorganisms and viruses without unacceptable adverse effects on the tissue's biomechanical properties. In addition, for use in transplantation, the agents must either be able to be effectively removed or be nontoxic. All methods in current use are applied only to tissue from donors who have met stringent criteria for medical history and behavioral risk assessment as well as negative results on infectious disease marker testing.

Proprietary Sterilization Methods

The Tutoplast process (Tutogen Medical, Gainesville, Fla.) was the first process to sterilize and preserve tissue without affecting biological or mechanical properties. The process has been in use since the early 1970s for a variety of hard and soft tissues, including bone, fascia lata, pericardium, skin, amniotic membrane, and sclera. Initially lipids are removed in an ultrasonic acetone bath that also inactivates enveloped viruses and reduces prion activity. Bacteria are destroyed using alternating hyperosmotic saline and purified water baths that also wash out cellular debris. Soluble proteins, nonenveloped viruses, and bacterial spores are destroyed in multiple hydrogen peroxide baths, and a 1N sodium hydroxide treatment further reduces prion infectivity by 6 logs. A final acetone wash removes any residual prions and inactivates any remaining enveloped viruses. Vacuum extraction dehydrates the tissue before the grafts are shaped and then double-barrier packaged. Terminal sterilization using low-dose gamma irradiation yields a SAL of 10^{-6}.

The Allowash XG process (LifeNet Health [LNH], Virginia Beach, Va.) employs six steps: (1) bioburden control, (2) bioburden assessment, (3) minimization of contamination during processing, (4) rigorous cleaning, (5) disinfection steps, and (6) a final

step of low-temperature, controlled-dose gamma irradiation. The process has been validated to achieve a SAL of 10^{-6}. Holtzclaw et al.[29] in 2008 compared the Allowash XG and Tutoplast methods, and found that each achieved medical-grade sterility with no effect on biological or biomechanical properties.

The BioCleanse process (Regeneration Technologies, Alachua, Fla.) uses low-temperature addition of chemical sterilants, such as hydrogen peroxide and isopropyl alcohol, which permeate the tissue's inner matrix, followed by pressure variations intended to drive the sterilants into and out of the tissue. Regeneration Technologies reports a SAL of 10^{-6} for soft tissues without adverse effects on the initial allograft mechanical properties.

The Clearant process (Clearant, Los Angeles, Calif.) is designed to avoid the negative effects of gamma irradiation through addition of free radical scavengers, using pretreatment dimethyl sulfoxide and propylene glycol as radioprotectants. Although the process subjects tissue to 50 kGy radiation and achieves a SAL of 10^{-6} for bacteria, fungi, yeast, and spores, the tissue's biomechanical properties are retained.

The Musculoskeletal Transplant Foundation (Edison, N.J.) uses a series of chemicals, including nonionic detergents, hydrogen peroxide, and alcohol, to treat cortical and cancellous bone grafts. For soft tissues an antibiotic mixture containing gentamicin, amphotericin B, and Primaxin is added and then washed out to a nondetectable concentration. The Musculoskeletal Transplant Foundation claims a SAL of 10^{-3} for its products. Incoming tissues whose bioburden exceeds prescribed parameters are pretreated with low-dose gamma irradiation.

NovaSterilis (Lansing, N.Y.) has developed a sterilization technique that uses supercritical carbon dioxide at low temperatures and relatively low pressures, resulting in transient acidification, which is lethal to bacteria and viruses, with good penetration reported. However, this technique only recently became available for clinically available allografts, and data on clinical efficacy and retention of allograft mechanical properties are limited.

End-User Responsibilities

Informed Consent. The clinician is, as defined by the AATB and other organizations, the end-user. As such, the clinician's responsibility is the safest and most efficacious treatment for his or her patient. This begins with a complete understanding of the characteristics and limitations of any material used in treatment. Second, the patient expectations and concerns must be assessed. This is part of the process of informed consent. It is important that proper informed consent is obtained.

The Doctrine of Informed Consent[30] is based on significant history:
- *Schloendorff* v. *Society of New York Hospital* in 1914: An operation was performed against the patient's wishes.
- *Salgo* v. *Leland Stanford Jr. University Board of Trustees* in 1957: The patient had not been informed of the risks involved with the surgery performed.
- *Natanson* v. *Kline* in 1960: This verdict established a standard that the risks as understood by a reasonable practitioner must be disclosed.
- *Canterbury* v. *Spence* in 1972: This verdict required practitioners to disclose the risks that a reasonable patient would want to know.
- AMA Position Paper on "informed consent" in 1981: This document established the "best standards" concerning informed consent in medicine.

Consent is to reflect all applicable local, state, and federal laws and regulations, as well as internal policies and evolving best practices. The informed consent discussion has several components[31]:
- the nature of the proposed treatment, including necessity, prognosis, time element, and cost;
- viable alternatives to the proposed treatment, including what a specialist might offer or the choice of no treatment; and
- what are the foreseeable risks, including things likely to occur and risks of no treatment?

When obtaining informed consent, the dental professional should:
- Use language that is easily understandable.
- Provide opportunities for patient questions, such as "What more would you like to know?" or "What are your concerns?"
- Assess patient understanding by stating, "If I have not explained the proposed dentistry clearly or if you have difficulty understanding, please tell me so we can discuss anything you do not understand."

When gaining consent for the use of allografts, please use language that does not degrade the spirit of the gift of donation (i.e., use "deceased donor" instead of "cadaver" and "recovered" instead of "harvested"). Remember that all tissue is recovered "aseptically" (not "sterile" and not necessarily in an operating room). For all types of materials (allograft, xenograft, alloplast), processors and manufacturers often provide patient education materials for use by the end-user. These do not replace the informed consent discussion but exist to augment the effort. In addition, most companies that provide materials have a toll-free number or website for answering patient inquiries. Patients' ability to recollect and comprehend treatment information plays a fundamental role in their decision making.[32] Although patients in general report that they understand information given to them, they may have limited comprehension. Additional media may improve conventional informed consent processes in dentistry in a meaningful way.

Proper Handling of Materials. The end-user is responsible for reviewing the "product insert" (also known by other names, e.g., "instructions for use," "package insert"). This document provides valuable information on storage, indications, contraindications, tracking, among others. Some materials have been treated with chemicals or antibiotics, and this must be listed to avoid allergic reactions in their patients.

Materials should be inspected on receipt. Are the materials the ones ordered? Is the packaging intact? Were the materials protected from extremes in temperature during shipment? What is the expiration date? If the material appears to be compromised in any way, or is not what was expected, the distributor should be notified.

Materials should be stored as indicated until time of use. It is imperative that certain material not be frozen or kept in areas with extreme heat (both conditions can destroy the characteristics of some materials). In addition, materials should be "logged" or tracked internally at time of receipt, when used on a patient, or when discarded or returned. All materials bear a unique identifier, and it is the responsibility of the end-user to have a system for identifying when and where each material is used. In the case of allografts, federal law states that each allograft unit have a distinct identifier, and that a system exists to track the graft from processor to consignee (and back). This makes it the responsibility of the end-user to track from his or her office inventory to the patient, meaning that the unique identifier can be associated with the patient's unique identifier (chart number, etc.).[33]

Tracking of xenograft and alloplast, although not always required, is a good practice. Take the example of a patient who experiences a localized reaction at a site where augmentation occurred; allograft bone was mixed with alloplast, and the site was covered with a xenograft membrane. Identification numbers for each material would be needed to determine, with the help of the individual processors, the root cause of the localized reaction. In this case, having the information at hand as part of the patient surgical notes would be a great advantage.

In the unlikely chance that a recall occurs, it is much easier to determine patients receiving affected units if that information is in a central database or log. Therefore in addition to information in the patient's operative note, it is wise to have a central log where grafts received into inventory are logged (date and time), as well as their final disposition (used on a patient [and ID of that patient], returned to distributor, discarded, etc., noting date and time).

Expiration Dates. Materials are not to be used past their expiration date. Disposition should be recorded in the office log, and the material should be discarded in a proper manner.

Material Safety Data Sheets. Material Safety Data Sheets (MSDS) are not required for BGSs and membranes. The Occupational Safety & Health Administration requires chemical manufacturers and importers to develop an MSDS for each hazardous chemical produced or imported, and these must be provided to a distributor or end-user before or at the time of shipment. "Hazardous" chemicals are defined as any chemical that is a physical or health hazard. A "physical hazard" is a chemical where scientific evidence shows that it is combustible, a compressed gas, explosive, flammable, an oxidizer, or unstable (reactive). A "health hazard" is a chemical for which statistical evidence exists that shows acute or chronic health effects in exposed individuals. BGSs and membranes do not pose a physical or health hazard.

As always, refer to the Instructions for Use document accompanying any BGS or membrane. This will contain specific information on indications for use, contraindications, precautions, and preparation instructions.

"Single-Patient Use". All BGSs and membranes, if packaged individually, are designated for single patient use. This means that the material cannot be used for treatment of more than one patient. The AATB demands that "Single-Patient Use" appears on the label of every allograft produced by AATB-accredited tissue processors. Processors are working with the AATB to ensure that each graft is used for treatment of only one patient, and that each graft can be tracked (personal communication, Jon Boyd, Director of Certification and Online Learning, AATB, McLean, Va.). Although the terminology may differ (e.g., "single use"), similar intent exists for xenografts and alloplasts (and this information may appear on a package insert). Consider the following:

- To reuse a single-use device or material without considering the consequences could expose patients and staff to risks that outweigh the perceived benefits.
- A device or material designated as "single use" must not be reused. It should be used only on an individual patient during a single procedure and then discarded. It is not intended to be reprocessed and used again, even on the same patient.
- The reuse of single-use devices can affect their safety, performance, and effectiveness, exposing patients and staff to unnecessary risk.
- The reuse of single-use devices has legal implications: Anyone who reprocesses or reuses a device intended by the manufacturer for use on a single occasion bears full responsibility for its safety and effectiveness.
● **Fig. 35.7** Photographs from the first tissue bank, U.S. Navy at Bethesda Naval Hospital in Bethesda, Maryland. The picture on the left shows technicians at work processing deceased donor material. Out of respect for the donor, processing was done in silence with technicians communicating nonverbally. The sign on the door translates to "from death, life." The right photograph shows a technician removing frozen grafts from a –80°C chest freezer. (*From Strong DM. The US Navy Tissue Bank: 50 years on the cutting edge.* Cell Tissue Bank. *2000;1:9-16.*)

End-User Queries. When in doubt, the end-user should contact his or her product distributor for additional information. It is the responsibility of the distributor to find answers, or to refer the end-user to a subject matter expert, which may include direct discussion with the manufacturer. In most cases the well-trained distributor representative or customer service representative can answer questions related to manufacture, clinical use, and safety.

Allograft Source, Processing, and Distribution

Allograft tissue banking has a rich history. The first tissue bank was established by the U.S. Navy in 1949 by Dr. George Hyatt.[34] Hyatt was an orthopedic surgeon at the Naval Medical Center in Bethesda, Maryland. The navy program was the first of its kind in the world and established many of the standards that are followed today (Fig. 35.7). During the 1950s, the identification of appropriate donor criteria for tissue donation, the development of procurement and processing methods, the establishment of a graft registry and documentation, and the clinical evaluation of a variety of tissues were pioneered at this facility. Cryopreservation, freeze-drying, irradiation sterilization of tissue, and immunologic principles of tissue transplantation were developed during the 50 years of research and development by navy scientists. Organ preservation, cadaveric bone marrow recovery, and immunosuppressive protocols were also developed at the Navy Tissue Bank. The navy was also instrumental in the establishment of the National Marrow Donor Program and the AATB in the United States. Although the Navy Tissue Bank has ceased activity after 50 years of excellence, it should be recognized as the first standard setter for the world community of tissue banks. The first civilian tissue banks were formed by ex-navy surgeons who trained at Bethesda.

At this time, all tissue banking in the United States is dependent on organ procurement organizations (OPOs). The OPOs are the mechanism through which families can elect to donate not only their loved one's lifesaving organs but also eyes, skin, heart valves, veins, arteries, bone, tendon, ligaments, and other "tissue" that can be used to improve health.

OPOs represent a unique component of health care.[35] By federal law, they are the only organizations that can perform the lifesaving mission of recovering organs from deceased donors for transplantation. When the National Organ Transplant Act was signed into law in 1984, it created the national Organ Procurement and Transplantation Network (OPTN) for matching donor organs to waiting recipients. The OPTN both standardized the process through which organs are donated and shared across the country, and created the system of federally designated OPOs throughout the United States and its territories. The OPTN includes all OPOs and transplant centers, and is managed under contract by the United Network for Organ Sharing located in Richmond, Virginia. There are currently 58 OPOs in the United States, and all are nonprofit entities.

Because the focus of the OPO is organ donation, tissue recovery and processing are managed by separate entities (tissue, eye, skin, heart valves) as designated by each OPO (through a contract). It is the responsibility of the OPO to make sure *every* family has the opportunity to fulfill their loved one's donation wishes.

Tissue processors may use either the OPO or regional recovery programs for the recovery of tissue. All donor suitability assessment, recovery, transport, storage, processing, postproduction testing, and distribution are the responsibility of the tissue processor.

Donor suitability is standardized throughout the United States and consists of three parts: initial medical interview with next of kin, physical assessment by the recovery team, and laboratory testing for communicable disease. The medical history and history of present illness are critical, and findings result in a high number of decisions not to proceed with tissue donation. When a potential donor is approved for recovery, they are assigned a unique identifier; this number will be associated with all tissue grafts subsequently produced. Tissue recovery *must* take place quickly: within 15 hours from time of asystole, or up to 24 hours from asystole if the deceased donor was refrigerated within 12 hours of death. Therefore laboratory testing is performed after recovery has occurred. The laboratory assessments not only test for donor suitability (communicable disease and systemic infection), but a representative culture from each piece of tissue is tested for microbiologic contamination via aerobic and anaerobic means at both room and body temperatures. Any biologic contaminant found is known as bioburden.

Recovery occurs, when possible, in an operating room at the hospital of the deceased donor. Many recovery programs and OPOs have dedicated recovery facilities, and the donor can be transported there for recovery. Some medical examiner offices have dedicated facilities in cooperation with the local recovery program or OPO. Recovery is done under aseptic conditions just like any surgical procedure. The donor is prepped, draped, and recovery occurs in a particular sequence via zones. Each zone uses new equipment. Tissue removed is swabbed for culturing, wrapped in special materials (impervious to fluids), tagged with the assigned unique identifier, and placed on ice for transport to the tissue processor.

After arriving at the processor, tissue is placed in quarantine (–80°C) until all serologic and microbiologic tests are complete. In addition, some donors have autopsies, the results of which must be obtained before processing. A final chart review and additional information must be assessed and approved before processing into usable grafts. The tissue bank medical director has full responsibility for release of tissue for processing.

Processing occurs in clean rooms or laminar flow hoods under strict aseptic conditions. One set of technicians processes one donor at a time—no donor pooling or cross-contamination is allowed. Different tissues undergo processing in different ways. Regardless of the tissue processor, the end product is the same: preparation and preservation of tissue without changing the biochemical or biological characteristics.

Grafts (now in quarantine) undergo postproduction review and testing (e.g., residual moisture if freeze-dried, residual calcium if demineralized) before final "in-package" sterilization (see earlier Sterility section). Poststerility review occurs (review of dosimetry and last look at all processing records) before approval by the quality team for release into the "bank" for distribution. Finished grafts are based on surgeon demand. Because the demand in many cases outweighs the supply, every effort is taken to maximize the donor gift. The time from receipt of donor tissue to grafts ready to distribute, at most tissue processors, takes approximately 90 days.

Regarding the "average donor" and the types of grafts produced for dental use, my research shows that two tissue banks provide the majority (>50%) of "full-line" allograft offering to the dental implant community. These two are Community Tissue Services (CTS) based in Dayton, Ohio, and LNH in Virginia Beach, Virginia. In addition, both offer branded and private label allograft options to the two largest dental implant suppliers in the world (Nobel Biocare and Straumann, respectively). Both use similar processing technology, and both have a long history of cooperation in tissue banking (CTS was founded in 1986, and LNH was founded in 1982). These two nonprofit organizations are innovative and active as leaders in AATB. I queried both processors regarding donors and grafts produced for the dental segment in 2017 (personal communication, Paul Lehner, Dental Product Manager, CTS, and David Adamson, General Manager Dental and Craniomaxillofacial, LNH).

Regarding donors, it is interesting that if you look at all donors received, the range is 12 to 80 years old (these are "musculoskeletal" donations that can be turned into grafts for a variety of surgical specialties, including dental). An average age cannot be calculated because the distribution is bimodal, that is, with two different "peaks." One peak occurs from about age 18 to 24 years, and the other appears from age 45 to 65 years. About 86.5% of the donors were younger than 70 years, and nearly three of every four donors are male. What is most interesting is that the donor age and gender statistics have not changed since the late 2000s (compared with my data from 2007), except that the number of donors has greatly increased. The increase is due to active donation awareness programs[36] and an increase in the number of individuals signing up on the national donor registry—that number is currently 130 million.[37] There were approximately 30,000 tissue donors in the United States in 2017.

Finally, all dental allograft processors in the United States are AATB accredited. Accreditation is a rigorous program that requires adherence to AATB standards, membership in the national organization, and periodic inspections. The AATB restricts distribution of allografts to hospitals, certain healthcare facilities, dentists, and podiatrists. Distribution intermediaries can receive and store allografts for redistribution, but they must follow AATB guidelines, be registered with the FDA, and are subject to state registration(s) and inspection(s).

Xenograft Source, Production, and Distribution

Clinicians and researchers have experimented with ways to correct skeletal defects in the modern era. Nothing exemplifies this

search better than the early experiences with xenografts. Orell[38] in 1937 reported his clinical experiences with the surgical grafting of os purum, os novum, and boiled bone. Os purum was ox bone prepared by a complicated physicochemical procedure that freed the bone of lipids, connective tissue, and some protein but still left some of the collagen matrix. It was used to fill various skeletal defects, and the author claimed that it was resorbed and replaced by host bone in 2 to 3 years.[38] In 1956, Forsberg[39] used finely ground, sterile os purum as an implant material for periodontal osseous defects. He reported 11 cases and claimed excellent results in 1, satisfactory results in 7, and poor results in the remaining 3 cases after a postoperative period of up to 12 months.[39]

University studies on laboratory-produced anorganic xenograft bone began in earnest in the 1950s. Anorganic means that the organic portion (~40% by weight) is totally removed, leaving pure HA. Scopp et al.[40,41] in the 1960s reported experimental and clinical work with the first commercially available xenogeneic implant material called Boplant (Squibb Pharmaceuticals; this product is no longer available). It was derived from calf bone, and processing consisted of detergent extraction, followed by chloroform and methanol extraction to reduce the lipid content, washing with sterile deionized water, sterilization by immersions in a liquid sterilizing agent, and finally lyophilization and vacuum packaging.[40,41] This work was the precursor to the modern xenograft. Notably, xenografts can be demineralized, freeze-dried, and/or deproteinized, but most distribution is of a calcified matrix form. To date, sources for xenograft material used in dentistry include bovine, porcine, equine, and species of coral. In general, bovine and porcine use cancellous bone. Both materials mimic human bone in density, porosity, and calcium content.[42-44]

The best example of xenograft processing and use can be seen with anorganic bovine materials such as Bio-Oss (Geistlich Pharma North America, Inc.).[45] The Geistlich Pharma website includes a searchable database for Geistlich Pharma materials and associated clinical studies. Of all of the available BGS materials, Bio-Oss has the greatest number of published studies. Since its beginnings in 1851 the company has dealt with the processing and refining of bone and collagen materials, and up to now they have the most researched biomaterials.

Geistlich Pharma manufactures its biomaterials in its own production department at the company's headquarters in Switzerland. The entire production process is subject to the strictest safety standards and quality checks: from the selection of the raw material suppliers to the delivery of the end products. Safety during the manufacture of the products is guaranteed thanks to extensive hygiene measures in a sophisticated zone system with different safety levels and permanent controls.

Geistlich Bio-Oss is made from the mineral part of bovine bone (and is also known as deproteinized bovine bone material). The strictly controlled manufacturing process ensures high quality and safety standards by:
- a defined origin of the raw material;
- a restricted country of origin, for example, Australia, which is historically and currently free of bovine spongiform encephalopathy (a prion disease, or "mad cow");
- using selected and certified slaughterhouses;
- performing of pre and post mortem health inspection for each individual animal;
- restricting source to extremity bone (according to World Health Organization Guidelines on tissue infectivity classified as tissues with no detected infectivity or infectious prions), as opposed to axial skeleton bones that may be associated with the spinal column;

- effective inactivation methods with 15-hour treatment at high temperature and cleaning with strong alkaline solutions;
- medical-grade sterilization and double sterile packaging; and
- official controls by international authorities.

Many of the controls placed on xenograft production are similar to what is seen with allograft. GMP must be followed and international manufacturers are subject to International Organization for Standardization rules.[46] International materials coming to the United States must obtain FDA clearance, most often via 510(k) approvals. Distribution of most xenograft materials in dentistry is accomplished through dental supply companies.

Alloplast Production and Distribution

The category of alloplastic implants includes any nonosseous material placed into a bony defect for the purpose of stimulating repair or regeneration. It includes a very wide range of materials, both biologically and nonbiologically derived, and is limited only by the imagination of the investigator and the tolerance of living host tissue. Albee[47] in 1920 reviewed the literature to date and reported that osmic acid, fibrin, blood, gelatin with lime salts, zinc chloride, thyroidin, glacial acetic acid, tincture of iodine, adrenaline, extract of hypophysis, copper sulfate, oil of turpentine, ammonia, lactic acid, silver nitrate solution, alcohol, carbolic acid, oak bark extract, vaccines, and sera had been used to stimulate bone growth without any appreciable success.

Historically the oldest known alloplast used in medicine is calcium sulfate. Calcium sulfate, also known as "gypsum" or "plaster of paris," was first implanted in humans by Dreesman in 1892 as a void filler of tuberculous osteomyelitis.[48]

A great many materials are used today as the basis of alloplasts. These include (but are not limited to): HA (and its many derivatives), tricalcium phosphates, biphasic configurations, calcium sulfates, bioactive glass (BG), polymer-based materials, and composite materials.[49] In recent years more attention has been placed on macroporosity and microporosity (and interconnectivity of pores), interparticle spacing, mechanical qualities, and rate of resorption.

Alloplast production follows the guidelines of the pharmaceutical industry. Materials are "manufactured" under GMP, subject to FDA and International Organization for Standardization regulations, and their use is restricted to medical facilities and licensed health professionals. Distribution to dental practitioners in the United States is predominantly through medical and dental supply companies.

Graft Descriptions[50-60]

Allograft

Mineralized Cortical Particulate. Also known as freeze-dried bone allograft (FDBA) (Fig. 35.8), mineralized cortical particulate grafts still contain all of the natural bone components (inorganic and organic including BMPs hidden within the bone matrix). Even though it is called *mineralized*, there is no mineral added; it is simply "not" demineralized. FDBA is sourced from extremity bone (femur, tibia, fibula, humerus, radius, ulna, etc.). It can be processed, ground, and sieved to any desired particle range. A common range is 250 to 1000 μm. Particles smaller than 50 μm are quickly removed from the site by macrophages. Some processors offer particles up to 3 mm for filling of larger defects. Because FDBA still contains its calcified portion, it has mechanical strength. For that reason it is a popular graft material in implant dentistry. FDBA is osteoconductive.
● **Fig. 35.8** This is a common allograft from the ilium. It is shown as a reminder that there are only two types of bone—cortical and cancellous—from which bone grafts are fashioned. Cortical has little macroporosity, whereas cancellous has much. The cancellous portion is made of interconnecting pores and is created from trabeculae oriented as per Wolff's law (form and function). New vessel formation can occur much quicker in cancellous bone. (*From Sfasciotti GL, Trapani CT, Powers RM. Mandibular ridge augmentation using a mineralized ilium block: A case letter. J Oral Implantol 42(2):215-219, 2016.*)

Mineralized Cancellous Particulate. Also known as FDBA, mineralized cancellous particulate is made solely from the cancellous portion of bone. Graft source is the metaphyseal region of long bones. It shares many of the characteristics of mineralized cortical particulate but has greater macroporosity because of the marrow space. In addition, the trabecular surface of cancellous is covered with endosteum that, like periosteum, probably plays a role in bone regeneration. Because of the porous nature of cancellous bone, new vessel growth (in theory) is more rapid through the graft; therefore regeneration will be quicker. Another benefit is that cancellous particles tend to lock together better than equivalently sized cortical particles, and this will reduce micromotion in a graft site. Mineralized cancellous grafts are osteoconductive.

Mineralized Cortical/Cancellous Mix. The mineralized cortical/cancellous mix is a combination of the two previous graft types. It can be manufactured in two ways: first is mixing together each component 50:50 (v/v), which requires cortical and cancellous material from a single donor, which requires additional quality-control measures; and the second way is to grind and sieve bone from the metaphysis of a long bone, which is known as a "natural" mix (called *corticocancellous*) and results in a graft with varying and undetermined proportions of cancellous component. Cortical/cancellous mix is gaining in popularity because these grafts provide good mechanical support and provide for faster incorporation.

According to information provided by tissue processors CTS and LNH (personal communication, Paul Lehner and David Adamson), in 2017 the previous three graft types (combined) accounted for >80% of the total allograft units distributed. In contrast, in the early 1990s >80% of the grafts distributed were demineralized cortical particulate (unpublished data). This shift is directly related to the increase in graft use to support implant placement.

Demineralized Cortical Particulate. Demineralized cortical particulate is also known as DFDBA or demineralized bone matrix (DBM). This historically was the first graft produced in great numbers by tissue processors for the periodontal market. Demineralized grafts have osteoinductive potential because processing removes the mineralized portion of the graft, thus exposing the noncollagenous proteins (e.g., BMPs) associated with the collagen matrix. These proteins recruit bone-forming cells to the site, thus inducing new bone growth. To be called *demineralized*, the AATB specifies that residual calcium in the final graft cannot exceed 8% by weight. Normal cortical bone, for example, has ~30% residual calcium. If a graft is over- or under-demineralized, it will not possess its full osteoinductive potential. DFDBA is often just called *demineralized*. The other term, *DBM*, is reserved for DFDBA that is put with a carrier or is packaged in a convenience device such as a syringe. When reading market reports, DFDBA is considered nonproprietary, made by many processors; DBM is proprietary and made by few processors, usually under patent protection. Because DFDBA (and DBM) have their mineral component removed, they have little mechanical strength and often will not maintain space. Both forms, if prepared correctly, are compressible, have osteoinductive potential, and are osteoconductive.

Mineralized Cortical/Demineralized Cortical Combination. One of the newest grafts, mineralized cortical/demineralized cortical combination (70:30 v/v) takes advantage of the best characteristics of its components. Unlike DFDBA, this version will maintain space and incorporates quickly compared with mineralized graft forms. It is both osteoconductive and osteoinductive.

Laminar Bone. Laminar bone is a graft form that was popular in the 1990s that has undergone a resurgence. It is made by preparing cortical sheets (from the diaphysis portion of long bones) and demineralizing. This flexible graft not only induces new bone to grow but acts as its own membrane.

Irradiated Cancellous (Vertebral Body). Vertebral bodies possess marrow and cancellous with extremely dense trabeculation (per Wolff's law). Cortical particulate, cancellous particulate, and block grafts can be produced from vertebral materials. These materials receive a 25 to 38 kGy gamma irradiation.

Mineralized Cortical and Cancellous Blocks and Cubes. Blocks and cubes in almost any dimension can be made from solid sections of cortical and cancellous bone. These would be used in larger cases where missing walls must be replaced, among other cases. These materials arrive freeze-dried, and clinicians must take care when rehydrating and during fixation. In the freeze-dried state, these grafts are brittle. When properly rehydrated, these have the same biomechanics as natural bone. Most often, fixation is by a lag screw method.

Gel, Pastes, and Putties. Gel, pastes, and putties are all made with DBM as the main component with an inert carrier substance. The first such graft came out in the early 1990s and used glycerol as a means of dispensing the DBM particles. This was formulated for convenience: the DBM needed no rehydration, there were no loose particles to deal with, and the graft was ready to go off the shelf. Many gels, pastes, and putties currently exist in the market. There is overlap in the naming of these materials. In general, gel means very thin (low viscosity), with the possibility of being delivered via a syringe or other device. Paste is thicker and may lend itself to delivery in an open-bore device. Putty is moldable and can be hand-delivered to a site. Many describe it like the modeling compound Play-Doh (Hasbro Corp., Cincinnati, Ohio) used by children and artists. Putty has additional utility in that it can often be combined with other graft materials (e.g., autograft) or osteo-promotive materials. Gels, pastes, and putties also may come in various formulation. Some have only DBM and a carrier, whereas others have DBM, a mineralized component, and a carrier. These materials would maintain space much better than a pure demineralized material.

Rib, Mandible, Bone Pins, and Sheets. A variety of additional skeletal grafts can be found at different tissue processors. Ribs are processed by most tissue banks. Mandibles are restricted to a few banks—these being difficult to recover and process. Bone pins

(solid cortical) have become more popular in recent years and are used much like tenting screws. Cortical sheets are available, but not by all tissue processors. Most tissue banks, if contacted, will work to assist a clinician in finding who has the graft available.

Cell-Based Materials. Osteocel (Nuvasive, Inc., distributed by ACE Surgical, Brockton, Mass.) is an excellent example of a cell-based material. From a single donor, DFDBA, mineralized cancellous, and cells from the bone marrow are processed and recombined into this specialized graft. The resulting material is osteoinductive, osteoconductive, and osteogenic. Other processors are researching similar solutions, and this is a fast-growing area of tissue regeneration.

Placental Tissues. The placenta is the source of valuable membranes and cells. Human amniotic membrane is the most commonly used and is derived from the fetal membranes. It consists of the inner amniotic membrane made of single layer of amnion cells fixed to collagen-rich mesenchyme. Human amniotic membrane has low immunogenicity, antiinflammatory properties, and can be isolated without the sacrifice of human embryos. Amniotic membrane has various clinical applications in the field of dermatology, ophthalmology, ENT (ear, nose, and throat) surgery, orthopedics, and dental surgery.

Fascia Lata. Fascia lata is the deep fascia of the thigh. It invests the whole of the thigh but varies in thickness in different parts (the section used for dentistry is around 1 mm thick). Since the 1920s, fascia lata from deceased donors has been used in reconstructive surgery. In 1993, Callan[55] described cases where freeze-dried fascia lata was used as a membrane. Although still available from many tissue banks for orthopedic applications, it has largely been replaced by acellular dermis in dental applications.

Pericardium. Pericardium is the membrane enclosing the heart, consisting of an outer fibrous layer and an inner double layer of serous membrane. The material resembles fascia lata and can be used in a similar fashion. Pericardium is recovered from only heart valve donors; therefore it is in short supply and not processed by most tissue banks. Xenograft pericardium can be substituted (see later discussion).

Acellular Dermis. Acellular dermal matrix has been used as a soft tissue replacement since its introduction in 1994. Its first dental use was correcting areas with insufficient attached gingiva, but in 1999, Crook[56] reported using it as a barrier membrane. Even though the material is in high demand, few tissue banks produce acellular dermis because most methods of production are proprietary. Acellular dermal matrices are soft tissue matrix grafts created by a process that results in decellularization but leaves the extracellular matrix intact. It starts with a full-thickness skin graft from a deceased donor. The full-thickness graft is exposed to chemicals that remove the epidermis. A secondary step exposes the remaining dermis to chemicals (detergents and endonucleases) that removed the cells and DNA. This is the "decellularization" step that renders the graft acellular. As a result, an immunologic response in the host is unlikely. Extracellular matrix is preserved, as well as biomechanical properties. These materials have found great use in burns treatment, plastic and reconstructive surgery, podiatry, orthopedics, and dentistry.

Xenograft

Particulate Form. Processing and production considerations for xenograft is similar to what has been described for allograft. However, cancellous (also known as spongiosa or trabecular bone) seems to be the preferred form. Xenograft is most often deproteinized (removing all immunogenic factors) by a variety of methods. What is left is a calcified matrix resembling natural inorganic component (HA) in all ways. Macroporosity and microporosity are preserved. As discussed previously, both bovine and porcine bone resemble human bone from a biochemical and biomechanical perspective. Xenograft particulate is available in a variety of particle ranges. Because xenograft is pure mineral, it does resorb slowly and is an excellent material for long-term space preservation.

Block Form. Solid and porous blocks of xenograft HA can be formed based on desired characteristics. These will function to preserve space for much longer than with an allograft. Macroporosity and microporosity can be controlled, as well as surface characteristics. As a pure HA product the grafts tend to be more brittle than natural bone, so care should be taken when modifying shape or using fixation screws.

Pericardium. As mentioned previously, allograft pericardium is in short supply. As a result, bovine and porcine pericardium substitutes have been developed and introduced into the dental market. Bovine has a greater collagen content than the porcine version. They generally consist of three layers with collagen and elastic fibers in an amorphous matrix. Their surface is porous, which allows for cellular attachment and proliferation, yet has an increased density for soft tissue exclusion. Pericardium membranes have shown a prolonged resorption in comparison with collagen membranes.

Collagen-Based Products. Resorbable collagen membranes (Fig. 35.9) are manufactured from xenogeneic tendon and skin to manage oral wounds such as extraction sockets, for sinus-lift procedures and repairs, and for periodontal or endodontic surgeries. They act as scaffolds for bone deposition in GBR, promote platelet aggregation, stabilize clots, and attract fibroblasts, facilitating wound healing. They are designed to resorb within 2 weeks to 6 months and are biocompatible, easy to manipulate, and only weakly immunogenic. For ease of use, collagen-based products are available in a wide variety of forms such as membranes, plugs, or tape. Extended collagen membranes resorb in 4 to 6 months and are used for larger bony defects that require longer healing periods. These membranes are modified by increasing the cross-link density.

Coralline Grafts. *Madrepore* ("stone coral") and *millepora* ("fire coral") are harvested and treated to become "coral-derived granules" and other types of coralline xenografts. Coral-based materials are mainly calcium carbonate (and an important proportion of fluorides, useful in the context of grafting to promote bone development), whereas natural human bone is made of HA, along with calcium phosphate and carbonate. The coral material is transformed industrially into HA through a hydrothermal process, yielding a nonresorbable xenograft. If the process is omitted, the coralline material remains in its calcium carbonate state for better resorption of the graft by the natural bone.

Alloplast

Hydroxyapatite. HA is a commonly used calcium phosphate biomaterial for bone regeneration applications due to having a composition and structure similar to natural bone mineral. HA-based grafts form a chemical bond directly to bone once implanted. Synthetic HA is available and used in various forms: (1) porous nonresorbable, (2) solid nonresorbable, and (3) resorbable (nonceramic, porous). HA functions as an osteoconductive graft material. These grafts show slow and limited

• **Fig. 35.9** Collagen Membrane. Collagen materials come in a variety of shapes and vary in their resorption time. (*Courtesy Humanus Dental AB, Malmö, Sweden:* *https://www.humanusdental.com/conform-resorbable-collagen-membrane-1520-mm*)

resorptive potential and generally are dependent on passive dissolution in tissue fluid and cell-mediated processes such as phagocytosis of particles for resorption. The degradation rate of HA depends on the method of ceramic formation, the calcium/phosphate ratio, crystallographic structure, and porosity. The ability of HA to resorb is also heavily dependent on the processing temperature. HA grafts synthesized at high temperatures are very dense with very limited biodegradability. These dense grafts are usually used as inert biocompatible fillers. At lower temperatures the particulate HA is porous and undergoes slow resorption.

Tricalcium Phosphates. Over the last few years, TCP has been used and extensively investigated as a bone substitute. TCP has two crystallographic forms: α-TCP and β-TCP. β-TCP exhibits good biocompatibility and osteoconductivity, and is used commonly as a partially resorbable filler allowing replacement with newly formed bone. Resorption of TCP grafts is thought to be dependent on dissolution by biological fluids and by presence of osteoclast-mediated resorption. In terms of bone regenerative potential, β-TCP grafts have been shown to be similar to autogenous bone, FDBA, DFDBA, and collagen sponge.

Biphasic Configurations. Biphasic configurations refer to grafts made from biphasic calcium phosphate, material composed of HA and β-TCP. The combinations are interesting in that the ratio of HA to β-TCP can be modified to provide for desired (slow versus fast) resorption. Also, by modifying the carrier and the characteristics of the granules, macroporosity and microporosity can be affected. These materials have a long history of use in orthopedics.

Calcium Sulfate. Calcium sulfate compounds have a compressive strength greater than that of cancellous bone. Calcium sulfate is usually applied as a barrier material to improve the clinical outcomes of periodontal regeneration therapy. When used as a barrier, calcium sulfate materials work as an adjunct with other graft materials.

Bioactive Glass. BG is a wide-open and fast-growing field in tissue engineering. BG has been widely studied since the 1970s. Since 45S5 BGs were discovered by Hench in 1969, they have been used for interface bonding of implant, and tissue repair and regeneration of bone. Glasses are noncrystalline amorphous solids that are commonly composed of silica-based materials with other minor additives. Compared with soda-lime glass (commonly used, as in windows or bottles), Bioglass 45S5 (trademarked by the University of Florida) contains less silica and higher amounts of calcium and phosphorus. The 45S5 name signifies glass with 45 weight % of SiO_2 and a 5:1 molar ratio of calcium to phosphorus. This high ratio of calcium to phosphorus promotes formation of apatite crystals. Lower Ca:P ratios do not bond to bone. Bioglass 45S5's specific composition is optimal in biomedical applications because of its similar composition to that of HA, the mineral component of bone.

The necessity of finding a material that forms a living bond with tissues led Hench to develop bioglass repair tissues during the Vietnam War. Bioglass offers advantages such as control of rate of degradation, excellent osteoconductivity, bioactivity, and capacity to deliver cells, but they present limitations in certain mechanical properties, such as low strength, toughness, and reliability. It can chemically bond with host tissue by forming a bonelike apatite layer between materials and bone tissue. Ionic dissolution products of BG can promote proliferation and differentiation of osteoblasts by activating a series of genes that regulate cellular behaviors. The first generation of BG was prepared by the melting-quenching method. Although traditional melting-derived BGs have excellent bioactivity, it was fired at a very high temperature (>1300°C), so it had a dense structure and small specific surface area, which limits its application. Compared with the melting-quenching method, the sol-gel method is a chemistry-based synthesis route, of which a solution containing the compositional precursors undergoes polymer-type reactions at room temperature to form a gel. The second generation of sol-gel BGs possesses uniform composition, composed of numerous nanoparticles with microporous and mesoporous structure, and thus it has high specific surface area. These advantages grant sol-gel BGs excellent bioactivity. However, up to now, there is no commercial product made of pure sol-gel BG in clinical application.

Synthetic Polymers. Synthetic polymers are discussed later in the Membranes section.

Titanium Mesh. Guided bone regenerative membranes can help in treating moderate-to-severe osseous defects, but the inherent physical property of the membrane to collapse toward the defect because of the pressure of the overlying soft tissues (thus reducing the space required for regeneration) makes the overall amount of regenerated bone questionable. The use of titanium mesh, which can maintain the space, can be a predictable and reliable treatment modality for regenerating and reconstructing a severely deficient alveolar ridge. The main advantages of the titanium mesh are that it maintains and preserves the space to be regenerated without collapsing, and it is flexible and can be bent. It can be shaped and adapted so it can assist bone regeneration in non-space-maintaining defects. Due to the presence of holes within the mesh (Fig. 35.10), it does not interfere with the blood supply directly from the periosteum to the underlying tissues and bone-grafting material. It is also completely biocompatible to oral tissues. Titanium mesh performs dual duty as a bone replacement and a barrier product.

Membranes

GTR and GBR membranes can be found in every graft source category previously listed. Each can be viewed as being either "resorbable" or "nonresorbable" based on whether the membrane can be left in the surgical site. There are advantages and disadvantages to each, and it is up to the clinician to understand where each type will have applicability.
● **Fig. 35.10** Titanium Mesh. This can be used in place of a bone graft substitute when severe defects are encountered. The material acts as its own membrane. (*Courtesy Salvin Dental*)

Resorbable Membranes. There are three types of biologically resorbable (degradable) membranes: (1) polyglycolide synthetic copolymers, (2) collagen, and (3) calcium sulfate.

The most commonly used biodegradable synthetic polymers for three-dimensional scaffolds in tissue engineering are saturated poly(α-hydroxy esters), including poly(lactic acid) (PLA) and poly(glycolic acid) (PGA), as well as poly(lactic-coglycolide) copolymers. The chemical properties of these polymers allow hydrolytic degradation through deesterification. Once degraded, the monomeric components of each polymer are removed by natural pathways. PGA is converted to metabolites or eliminated by other mechanisms, and PLA can be cleared through the tricarboxylic acid cycle. Due to these properties, PLA and PGA have been used in biomedical products and devices, such as degradable sutures, which have been approved by the FDA. Their properties can be highly modified through each product's final material design, surface topography, and porosity. In addition, dissolution rates can be controlled with resorption occurring in weeks to months.

Collagen membranes, as well as all resorbable membranes, do not normally require a second surgery for retrieval. Patients appreciate the elimination of a second surgery, in addition to less morbidity. Collagen is the principal component of connective tissue and provides structural support for tissues throughout the body. Collagen is a hemostatic agent. It possesses the ability to stimulate platelet attachment and to enhance fibrin linkage, which may assist initial clot formation and stabilization, leading to enhanced regeneration. In addition, collagen is chemotactic for fibroblasts. Collagen membranes are easy to manipulate and adapt nicely to the alveolar topography. Although collagen is a weak immunogen, it is very well tolerated by patients.

Calcium sulfate with its long use in medicine provides an inexpensive solution in a variety of clinical situations. As previously discussed, when used as a resorbable barrier, calcium sulfate materials work as an adjunct with other graft materials.

Nonresorbable Membranes. Materials such as cellulose acetate laboratory filters (Millipore; Merck KGaA, Darmstadt, Germany, operating as MilliporeSigma in the United States), silicone sheets, and expanded polytetrafluoroethylene (e-PTFE) laboratory filters were the first nonresorbable biomaterials used for investigating barrier membranes for regenerative therapy. Although these materials demonstrated some therapeutic potential, limitations such as inability to integrate with surrounding tissue, brittleness, and the need to remove them after a certain period were observed. The function of nondegradable (nonresorbable) membranes is temporary, as they maintain their structural integrity on placement and are later retrieved via surgery. Although this gives the clinician greater control over the length of time the membrane will remain in place, the retrieval procedure increases the risk for surgical site morbidity and leaves the regenerated tissues susceptible to damage and postsurgery bacterial contamination. However, in situations such as alveolar ridge augmentation before placement of dental implants, it may be desirable for the membrane to retain its functional characteristics long enough for adequate healing to occur, and then be removed. Hence in specific situations a nonresorbable membrane provides more predictable performance.

e-PTFE was originally developed in 1969, and it became the standard for bone regeneration in the early 1990s. The e-PTFE membrane was sintered (sintering is the process of compacting and forming a solid mass of material by heat or pressure without melting it to the point of liquefaction), and it had pores between 5 and 20 μm in the structure of the material. The most popular commercial type of e-PTFE was Gore-Tex (W.L. Gore & Associates, Newark, Del.). The e-PTFE membrane acts as a mechanical hindrance. Fibroblasts and other connective tissue cells are prevented from entering the bone defect so that the presumably slower migrating cells with osteogenic potential are allowed to repopulate the defect.

In time, clinicians discovered that e-PFTE exposed to the oral cavity resulted in migration of microorganisms through the highly porous membrane. With an average pore size of 5 to 20 μm and the diameter of pathogenic bacteria generally less than 10 μm, migration of microorganisms through the highly porous e-PTFE membrane at exposure was a common complication. A high-density polytetrafluoroethylene (d-PTFE) membrane with a nominal pore size of less than 0.3 μm was developed (Cytoplast; Osteogenics Biomedical, Lubbock, Tex.) to address this problem. The increased efficacy of d-PTFE membranes in GTR has been proved with animal and human studies. Even when the membrane is exposed to the oral cavity, bacteria is excluded by the membrane, whereas oxygen diffusion and transfusion of small molecules across the membrane is still possible. Thus the d-PTFE membranes can result in good bone regeneration even after exposure. Because the larger pore size of e-PTFE membranes allows tight soft tissue attachment, it usually requires sharp dissection at membrane removal. On the contrary, removal of d-PTFE is simplified because of lack of tissue ingrowth into the surface structure. In 1995, Bartee[58] reported that the use of d-PTFE is particularly useful when primary closure is impossible without tension, such as alveolar ridge preservation, large bone defects, and the placement of implants immediately after extraction. In those cases d-PTFE membranes can be left exposed, and thus preserve soft tissue and the position of the mucogingival junction.

Comparing Bone Graft Substitutes and Membrane Characteristics

When comparing bone graft substitutes and membrane characteristics, the choices are many. Fortunately there are suppliers who have developed regenerative portfolios that offer a "full range" of choices, allowing the clinician latitude in providing their patient with the best treatment. Fig. 35.11 illustrates a small sample of available material diversity from one such supplier.

• **Fig. 35.11** Today's clinician has many products to choose from. (*Courtesy Salvin Dental*)

The clinician is faced with a wide variety of materials in the market. Many appear to be similar, whereas many others appear to be markedly superior or inferior. As pointed out in this chapter, there are but a few product categories. The products in all categories are made under the strictest of regulations. Industry strives to provide safe and effective grafts for all surgical specialties.

Information on any graft type is easy to find thanks to the World Wide Web. The end-user has a responsibility to keep up to date on materials and techniques. Companies supplying the specialty of implant dentistry have expanded their regenerative portfolios and gained the technical knowledge to support the doctor in making grafting choices. This ensures the best treatment option for every patient.

The following tables are provided as a quick summary of materials covered in this chapter. Table 35.1 examines the materials regulated as HCT/Ps (donated human tissue). Table 35.2 lists the materials that are on the market via the 510(k) route (xenografts and alloplasts).

Looking to the Future

In the area of hard tissue replacement, significant advancements are being made related to milled "custom" graft materials. Most of the strides are a result of improvements in scanning, tomography, and manufacturing technologies. Also, advances in cell culture and the ability to create three-dimensional print scaffolds from biologic materials provide unlimited opportunities for both hard and soft tissues. Soft tissue augmentation shows promise in several areas, mainly from improved understanding in the area of wound healing and improved manufacturing. Cell-based grafts will play a big part in regeneration.

Milling of "custom" blocks is currently available.[61] Patient selection is a great part of the success and at the time of this writing, only dental surgeons who have received special training on the technique can use the service. Fabrication requires cone beam computed tomography and a tissue processor with the ability to mill bone using computer-aided design and computer-aided manufacturing (Fig. 35.12). The technology originated in Europe, is now available in the United States, and resultant grafts:
• are sourced from processed human allograft;

• are composed of natural mineralized collagen (normal trabecular bone);
• have 65% to 80% macroporosity, pore size 100 to 1800 μm (mean 600 to 900 μm);
• can be produced to a maximum size: 23 × 13 × 13 mm;
• show fast graft incorporation and complete remodeling potential;
• possess no antigenicity;
• result in no donor site morbidity;
• heal/integrate in 5 to 6 months;
• can be stored at ambient temperature for long periods; and
• are safe and sterile.

Cell culture technology is one of the fastest-growing areas of regenerative innovation.[62] It is part of BTE, the specific field of tissue engineering that mainly focuses on enhancing bone regeneration and repair by creating substitutes to traditional bone-grafting materials. BTE started about three decades ago and has witnessed tremendous growth ever since. Bone serves as a paradigm for general principles in tissue engineering because of its high regenerative potential compared with other tissues in the body. Classic BTE paradigm includes the following three key components: biomaterials to provide a scaffold for new tissue growth, cells, and signaling molecules. It is quite possible that components can be made from different classes of materials (e.g., a xenograft combined with an alloplast), thus taking advantage of the best properties of each.

Scaffolds can be either acellular or cellular on implantation within this model. In the former, the architecture and geometry promote the recruitment of local stem cell and or/osteoprogenitor cells, which could be possible with attachment motifs and chemical "smart" cues placed within the scaffold architecture. On the other hand, the latter strategy involves implantation of a scaffold combined with stem cell and or/osteoprogenitor cells, which can be incorporated by two methods: (1) cell seeding into a "prefabricated" scaffold, a commonly applied tissue engineering strategy; and (2) cell encapsulation during scaffold fabrication made of hydrogel polymer matrix, based on the immobilization of cells within a semipermeable membrane. This technique protects cells from the immune system and permits uniform cell distribution within the construct.[63]

TABLE 35.1   **Allograft-Derived Materials**

HCT/P Products	Function	Space Maintaining	Mode	Time to Remodel
Mineralized cortical	BGS particulate	Yes	Osteoconductive	6 months
Mineralized cancellous	BGS particulate	Yes	Osteoconductive	<6 months
Mineralized cortical/cancellous mix	BGS particulate	Yes	Osteoconductive	<6 months
Demineralized cortical	BGS particulate	No	Osteoconductive/osteoinductive	4–5 months
Mineralized cortical/demineralized cortical mix	BGS particulate	Yes	Osteoconductive/osteoinductive	4–5 months
Laminar bone	BGS structural	N/A	Osteoconductive/osteoinductive	4–5 months
DBM gel, putty, paste	BGS particulate	Varies	Osteoconductive/osteoinductive	Varies
Mineralized block, cube, rib, mandible, pins	BGS structural	Yes	Osteoconductive	Slow
Cell-based material	BGS particulate	Yes	Osteoconductive/osteoinductive/osteogenic?	Varies
Placental tissue	Membrane	N/A	Resorbable	Fast
Fascia lata	Membrane	N/A	Resorbable	4–6 months
Pericardium	Membrane	N/A	Resorbable	4–6 months
Acellular dermis	Membrane	N/A	Resorbable	4–6 months

BGS, Bone graft substitutes; *DBM*, demineralized bone matrix; *N/A*, not applicable.

TABLE 35.2   **Xenograft- and Alloplast-Derived Materials [510(k) Regulated]**

510(k) Products	Function	Space Maintaining	Mode	Time to Remodel
Xenograft mineralized cancellous	BGS particulate	Yes	Osteoconductive	Slow
Xenograft mineralized cancellous block	BGS structural	Yes	Osteoconductive	Slow
Xenograft pericardium	Membrane	N/A	Resorbable	4–6 months
Xenograft collagen forms	Membrane	N/A	Resorbable	Varies, weeks to months
Coralline based	BGS particulate	Yes	Osteoconductive	Slow to medium
Hydroxyapatite	BGS particulate and structural	Yes	Osteoconductive	Varies (generally slow)
Tricalcium phosphates	BGS particulate	Yes	Osteoconductive	Varies (generally fast)
Biphasic (hydroxyapatite + tricalcium phosphate)	BGS particulate	Yes	Osteoconductive	Varies (can be controlled by ratio of mix
Calcium sulfate	BGS (additive) and membrane	Yes	Osteoconductive (resorbable when used as membrane)	Fast
Bioactive glass	BGS (mainly as particulate)	Yes	Osteoconductive	Varies (generally slow)
Synthetic polymers	Membrane	N/A	Resorbable and nonresorbable forms	Varies based on composition
Titanium mesh	BGS (in severe cases) and membrane	Maintains space	Nonresorbable	Never resorbs

BGS, Bone graft substitutes; *N/A*, not applicable.
● **Fig. 35.12** A custom solution created from cone beam computed tomography and computer-aided design/computer-aided manufacturing milling (botiss.com).

Regarding BTE created scaffolds, the following characteristics are desired:

- hydrophilicity, roughness, and surface topography
- porosity, pore size, and interconnectivity
- mechanical strength close to native tissues and a predictable degradation rate (5 to 6 months is desired for dental use)
- biocompatible and bioactive
- ability to bind and release drugs or chemicals that can affect the healing microenvironment

Much work remains in this area, but the technologies show great promise.

Soft tissue grafts and membranes will benefit from a better understanding of clinical need. Manufacturers now know that collagen-based membranes can be modified by cross-linking to affect the rate of resorption. In addition, collagen-based materials can be preformed in molds to increase utility in cases with extreme anatomic variations. Thickness can be modified to produce "dead soft" materials that lack any memory and adhere perfectly to local anatomy. Naturally, research is going on with all material types for membranes that can be left "predictably" exposed to the oral cavity in cases where primary closure cannot be achieved. Much work with d-PTFE has already occurred in this area.[64]

Rowe et al.[65] in 2016 discussed work with electrospinning. This is a process by which microfibers/nanofibers can be formed from a viscous polymer solution exposed to an electric field. Although widely used in tissue engineering applications, biocompatible PLA and poly(ε-caprolactone) electrospun meshes have displayed properties that might enable its application as a GTR/GBR membrane. In initial tests it performed better than a current commercially available product.

Controllable osteoinduction maintained in the original defect area is the key to precise bone repair. In 2018, Ma et al.[66] reported on research involving the development of a dual-sided ("Janus") membrane that acts as a membrane on one side and is osteoinductive on the other.

Allografts (acellular dermis, fascia lata, and pericardium) are constantly being modified. The main focus for the future will be processing innovations resulting in consistency of thickness, sterility of the product (to a SAL 10^{-6}—not all products are at this desired level), and an increase in the length of time materials can be stored at ambient temperature. Acellular dermis will be highly studied because of its unique makeup and utility in many surgical disciplines. A unique reticular dermis is already available that retains architectural elements (open structure), mechanical properties (elasticity, organized collagen, and elastin), and key matrix proteins to support physiologic cellular responses during regenerative remodeling.[67] Of course a great deal of attention is being given to placental-based materials (chorion and amnion), with many products being marketed at the time of this writing.

Cell-based products for use in dentistry are currently available.[68] These feature (generally) three components: demineralized cortical bone, mineralized cancellous bone, and marrow cells; therefore these products mimic the biologic profile of autograft (osteoinductive, osteoconductive, and osteogenic). Currently these products require special shipping and storage at ultracold temperatures (not usually available in the typical dental office). Future efforts with these grafts will be to create shipping solutions that can act as short-term storage for those offices without ultralow-temperature freezers or the ability to store at lower temperatures for short periods. In addition, ways to increase the number and viability of bone-forming cells are being studied. Cell-based grafts are the most difficult of all BGS materials to produce because each component must come from a single donor, and processing must occur quickly to protect the viability of the osteogenic component.

Summary

Bone graft substitutes and membranes make up a significant portion of the dental implant market. Most patients who need implant therapy will need either an autograft or a substitute. The industries and regulatory bodies responsible for the manufacture of these materials, and instruments and technologies that augment their use, have reached a high level of maturity. Patient safety and graft performance are the focus of industry while always striving for improvement. Patients are active participants in their own treatment, and the most appropriate grafting decisions can be made collaboratively through the informed consent process.

The use of autografts, allografts, xenografts, or alloplasts, alone or in combination, should be based on the individual's systemic healing capacity, the osteogenic potential of the recipient site, time available for graft maturation, and the patient's expectations. Clinicians have a responsibility to their patients to understand the many products available for use in GBR. It must also be understood that no one ideal BGS or membrane exists.

Although product comparisons may seem difficult, the process is made easier by realizing the best patient outcome. Each graft class has characteristics unique to that group, and it is up to the end-user to evaluate each characteristic against patient needs. Also, the end-user has a responsibility to handle and use each material as intended to protect his or her patients and staff.

What has been presented in this chapter covers the basics of BGS and membranes. The next 10 to 15 years will see dramatic changes in biomaterials and techniques, and will provide the clinicians even more options for successful implant treatment.

Particulate Membrane grafting/ Guided Bone Regeneration

C. STEPHEN CALDWELL

The field of restorative dentistry has been through a paradigm shift in recent years that has completely changed treatment planning and the prospects for reconstruction of severely compromised dental cases. The use of dental implants in most treatment plans today offers the possibility of restorative success using fixed prostheses in many situations that would have previously been impossible. Meeting the demands and expectations of our enthusiastic patient population requires the multidisciplined implant team to perform at new and challenging levels of sophistication. As we attempt to restore these progressively more difficult cases, the severely compromised bony ridge defects that we encounter will continue to challenge team members to develop new and predictable grafting techniques (Fig. 36.1).

The goal of any dental implant procedure is to restore the patient to optimal form, function, and esthetics. Through the combined efforts of a great number of clinicians and researchers, guidelines have been established in regard to proper implant numbers and positioning based on possible prosthetic designs. The patient's existing bone volume often makes the proper placement and positioning of implants difficult, if not impossible. Ideal treatment planning in implant dentistry often requires the correction of significant alveolar ridge defects in regions where dental implants are indicated to support critical prostheses. Alveolar ridge defects are caused by a variety of factors including developmental anomalies, trauma, and most commonly, tooth extraction. After tooth loss a predictable resorptive process of the alveolar bone occurs in both a horizontal and a vertical dimension[1] (Fig. 36.2).

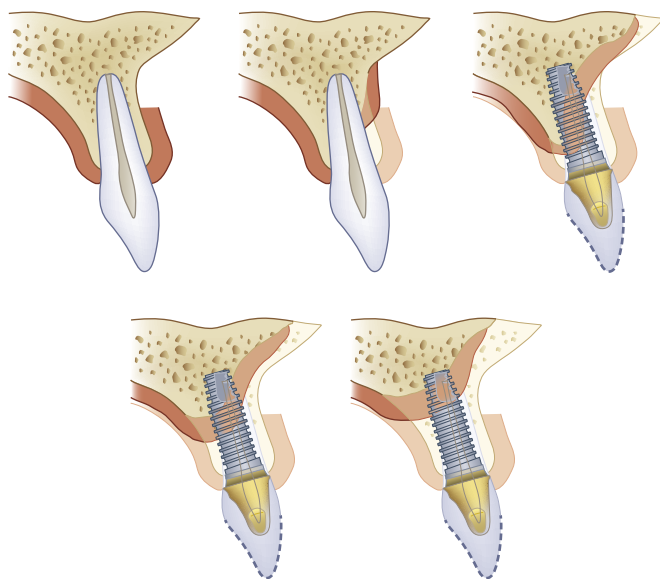
The loss of alveolar bone can pose a challenge both from the perspective of supporting a conventional removable prosthesis or placement of dental implants in an ideal position for functional and esthetic results. Before development of effective bone-grafting techniques, implants were placed in regions where there was available bony support, often leaving the restorative dentist with the task of restoring an implant in a less than ideal position within the arch. The success of implant dentistry today has been largely related to the advent of bone augmentation techniques that allow regeneration of an ideal ridge form and placement of implants in their ideal functional and esthetic positions[2–6] (Fig. 36.3).

The augmentation of bone volumes through grafting is an effective, but technique-sensitive process. It requires meticulous surgical skill, practice, and knowledge to become proficient in creating predictable bone growth before implant placement. Complications are plentiful in this discipline, leading to treatment delays, patient and provider frustration, as well as possible neurosensory, vascular, and infectious issues. The dental implant surgeon must have a firm understanding of the limitations encountered in various bone-grafting techniques to develop appropriate treatment plans. Clinicians must be able to not only prevent complications during the procedure, but also properly address complications related to these issues should they arise (Box 36.1).

Indications for Bone Grafting

The presence of an adequate volume of available bone is one of the most important prerequisites for predictable implant placement and osseointegration. Although loss in bone volume may result from trauma, bone deficiency is most frequently due to the normal physiologic process that occurs after tooth loss or extraction. Studies have shown that resultant bone resorption after tooth removal can be approximately 1.5 to 2 mm vertically and 3.8 mm in the horizontal plane within 6 months.[7,8]

Currently, bone regeneration procedures are widely accepted as a viable option for the treatment of edentulous deficiencies to be restored with an implant-supported prosthesis. Implant clinicians have a wide range of bone-grafting materials and procedures at their disposal. For years the gold standard in bone regeneration has been the use of autogenous (autograft) bone because of its inherent osteoconductive, osteoinductive, and osteogenic properties (Box 36.2). Because autogenous bone is composed of the patient's own tissue, there is a reduction in the likelihood of immunoreactions and possible infectious transmission. However, autogenous bone grafting has disadvantages, including the need for a secondary surgical site, a potential increase in pain and discomfort, bone-harvesting quantity restrictions, increased costs, and longer surgical procedures. Studies have shown that only 61% of patients accept grafting with autogenous bone.[9] Methods
• **Fig. 36.1** Careful planning and surgical execution can provide patients with the opportunity to replace their missing teeth with restorations that are not only functional, but also esthetically pleasing. (A Preoperative CBCT Cross-section of severely compromised central incisor B) Cross-section of the same site after completing a large ridge augmentation. (C and D) Final restorations in the anterior graft site.
• **Fig. 36.2** The progressive resorption of the bony ridge after an extraction leads to a situation that compromises all aspects of the restorative process. As resorption advances, less bone is available for implant placement, thus compromising the final result.

that minimize the inconvenience related to autogenous bone harvests allow the surgical team the opportunity to use the boost of autogenous grafts without putting their patients through excessive discomfort. As tempting as it may be, the lack of incorporation of at least some autogenous bone in a large ridge augmentation (> 3 mm) can ultimately change the density of the final graft, its resistance to unpredictable remodeling, the overall ability to regenerate vertical volume, and to some degree the width of a


• **Fig. 36.3** Loss of Soft and Hard Tissue. After tooth loss, bone loss occurs with respect to the prosthesis position. As the bone resorbs, the vertical and horizontal soft tissue support around teeth and implants disappears. This results in the exposure of the failing implant body, together with a future nonesthetic implant prosthesis.

- Bony undercuts/defects
- Maxillary Sinus pneumatization
- Available autogenous donor sites

• **BOX 36.2** **Biologic Bone Healing Classification**

1. **Osteogenic Grafts**
- Osteogenic bone grafts originate from autogenous origin and are comprised of live, viable cells capable of differentiation and formation of bone.

2. **Osteoinductive Grafts**
- Osteoinductive grafting materials provide a biological stimulus (proteins and growth factors) that *induce* the progression of mesenchymal stem cells and other osteoprogenitor cells toward osteoblast lineage.

3. **Osteoconductive Grafts**
- Osteoconduction is the process that allows the bone graft to be conducive to forming bone, thereby acting as scaffolding for bone growth.

---

large horizontal graft site. Therefore ideally 50% autogenous bone should be used in vertical regeneration cases and in large-volume horizontal grafts.

Success in any implant prosthesis requires the implants to be placed in positions that provide ideal esthetics, function, comfort, and support. To be successful in the development of a favorable prosthesis, the number and positions of implants in an edentulous space must be determined with a careful analysis of the relationship between the restorative prosthesis and the forces that will be exerted on the final prosthesis. This is then combined with the functional and esthetic aspects of the case, ultimately dictating the relationship between the implants, bone, and opposing forces. All of these factors must be considered in planning support for a prosthesis that functions well while maintaining the bone volume around its implant abutments. Clinicians too often try to bypass the grafting process, either to save time or because they are not experienced in advanced grafting techniques. Insufficient bone in recipient sites leads to placement of implants with inadequate diameters, shorter lengths, insufficient numbers, or less than ideal angulations. Compromises such as these can eventually lead to significant damage around an implant and the prosthesis it supports. Due to the fact that resorption and remodeling occur in every edentulous site, the need for adjunctive bone grafting must be considered and is often vital for a successful outcome.

Failure to recognize the need for bone grafting leads to numerous treatment issues, ranging from esthetic complications to implant and prosthetic failure. Placing implants of suboptimal sizes or in less than ideal numbers to bypass the grafting process is a compromise that often leads to force-related failures of implant components, failure of the prosthesis itself, or accompanied bone loss. Ultimately, prosthetic and implant morbidities may result. A multidisciplinary approach should be taken to assess the optimal prosthetic solution for the patient, based on the patient's wishes, available bone, and other factors. After a prosthetic plan has been established, the clinician should begin planning the implant positions required to execute the prosthetic option. Once the sites for the specific implants have been determined, the associated regions are evaluated for bony foundational support in that specific site. If inadequate bone is available to successfully place an implant in a key location for the prosthesis, grafting should then be included in the treatment plan to build the appropriate bone volumes (Fig. 36.4).

Cellular Bone Regeneration Process

The cellular development of bone in a deficient site involves a delicate process that occurs over an extended period. This series of steps can be easily disrupted by cellular ingrowth, micromovement, infection, or bacterial contamination. Therefore the process of guided bone regeneration (GBR) is always carried out in a protected space where the natural step-by-step process of bone development can occur. The first phase of this regeneration process involves the recruitment of osteoblast precursors and growth factors to the recipient area. This is accomplished primarily through the existing bony recipient bed, its vasculature, and the graft material (i.e., autograft, allograft, xenograft). The second phase of the process is the resorption/deposition process. Host osteoprogenitor cells will infiltrate the graft within 7 days, and resorption and deposition will occur via creeping substitution and osteoconduction. The osteoblast precursors differentiate into mature osteoblasts under the influence of osteoinductors and synthesize new bone during the first weeks. Growth factors involved in the bone formation process act on fibroblast and osteoblast proliferation, extracellular matrix deposition, mesenchymal cell differentiation, and vascular proliferation (Fig. 36.5 and Box 36.3).

• **Fig. 36.4** Malpositioned Implants. (A) Implants placed in compromised bone sites result in a compromised final prosthesis. (B and C) Implants positioned too far facially will increase prosthesis morbidity and compromise esthetics. (D and E) Implants positioned too far lingual will result in an overcontoured prosthesis, but also will place the implants at a biomechanical disadvantage.

• **Fig. 36.5** Guided bone regeneration combines the science of bone regeneration with the management of space maintenance for development of planned bony configurations. With the use of bone screws and a barrier membrane, bone regeneration may take place.

Treatment Planning in the Compromised Edentulous Ridge

Treatment planning for implant-supported restorations in edentulous spaces requires a clear understanding of the resorptive patterns of bone loss. As a ridge resorbs, available bone for support of dental implants disappears, preventing placement of implants in key locations for restorative success. After tooth loss the initial pattern of bone resorption starts with loss of the lateral (buccal) aspect of the ridge, eventually leading to a decrease in

---

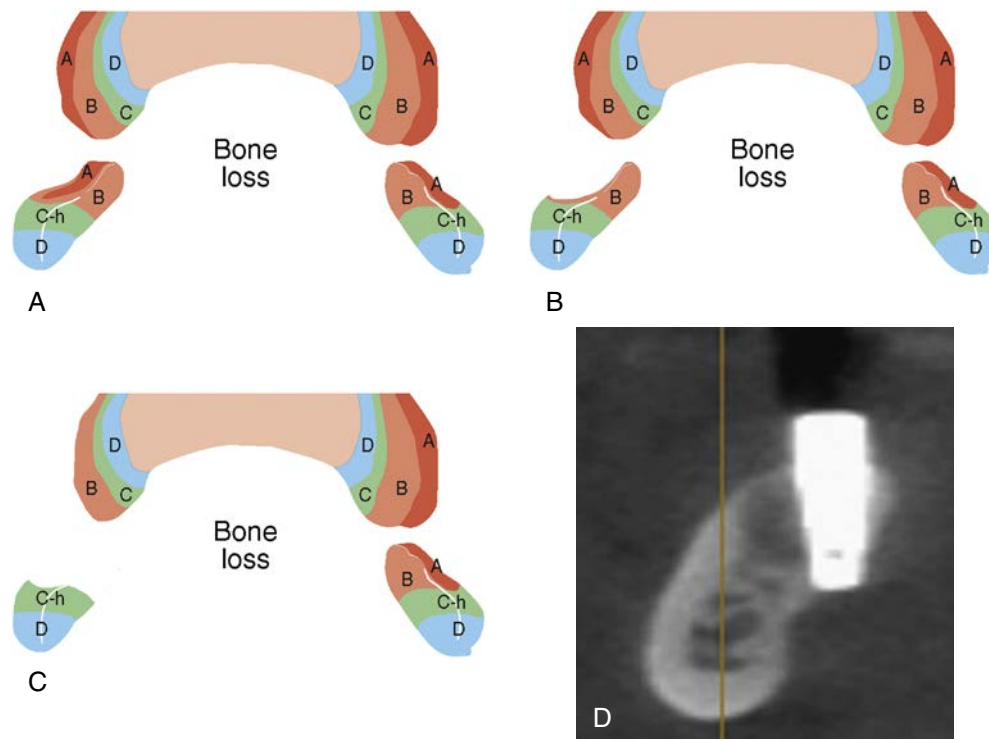
vertical ridge height. As this resorptive process occurs, the position of implant-supported restorations can change substantially secondary to the new interarch relationship between the maxilla and the mandible. For instance, the loss of maxillary posterior teeth with the accompanied loss of the buccal bony ridge width will often lead to development of a posterior crossbite. This is compounded as the mandible deteriorates into a division C or D ridge, resorbing until the remaining mandibular basal bone is actually positioned laterally, away from the remaining maxillary bone. Treatment planning must combine final restorative loading of implants in a manner that will not place unreasonable forces on the implant-bone interface leading to excessive bone remodeling and implant failure. The current ability of the implant team to regenerate bone in critical sites has increased the predictability of final prostheses and in doing so has reduced the number of implant failures (Fig. 36.6).

Edentulous Site Assessment

The treatment planning process begins with a reasonable assessment of the extent of the bony deficiency and the capacity of a regenerative procedure to create adequate support for implants in their ideal positions for comfort, esthetics, function, and support. As the extent of bone regeneration is evaluated, care must be taken in the beginning stages to identify the expected positions of each restoration or prosthesis using accurate restorative wax-ups. Evaluation of the relationship between the required restorative positions and the bony deficiency will then provide insight into the volume and shape of the bone that will need to be regenerated. At this


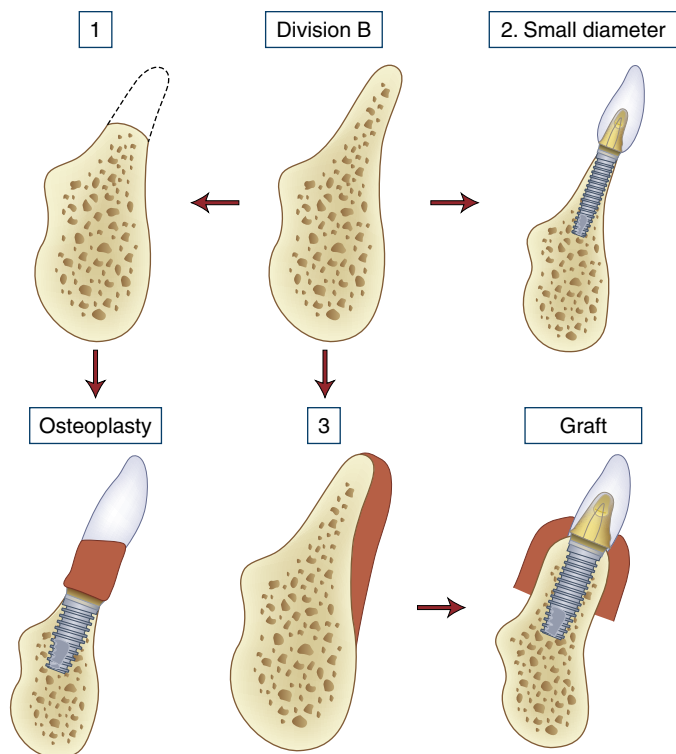
• Fig. 36.6 Resorptive Pattern in Posterior Mandible. (A) The normal bony contours in a coronal view of the maxillary and mandibular arches. (B) The initial resorption of bone in the mandibular arch from Division A to Division B. (C) As bone resorbs further (Division B to Division C), the resultant mandibular position is more lingually (medially) inclined in comparison with the maxillary arch. Further loss in the lower arch leaves the remaining bone in a more lateral position than the maxillary arch. (D) Often when bone resorbs, the position of the implant is compromised, as can be seen by the cross-sectional image depicting a perforation.

• **Fig. 36.7** (A) Maxillary left lateral and canine implants were placed in a poorly executed bone graft site, leading to a devastating esthetic situation. (B) Because of the malpositioned implants, a removable partial denture was placed to hide the implant position. (C) Maxillary left lateral incisor replacement resulted in a defect after two unsuccessful attempts to graft a missing facial cortical plate. (D) The loss of the cortical bone raised the defect to the level of the apices of the adjacent teeth. (E) The only remaining bone is found along the palatal cortical plate.

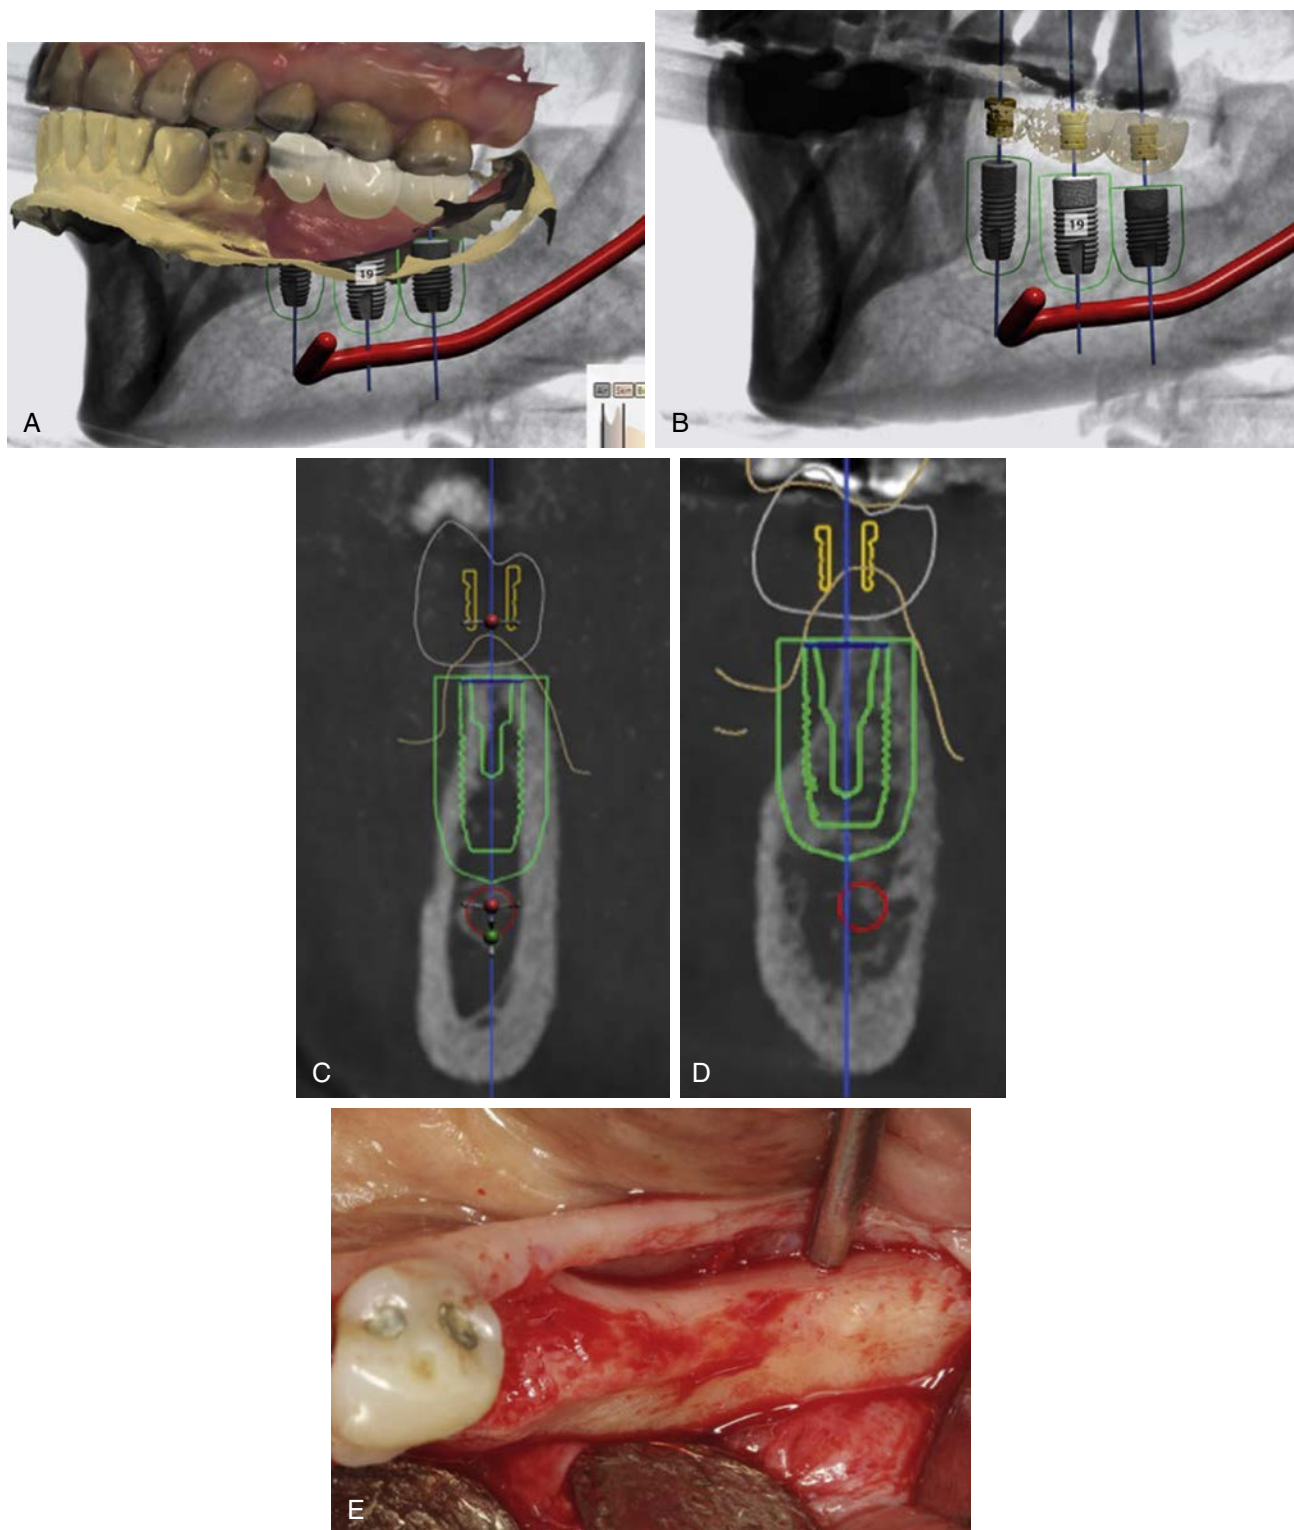
stage the most predictable surgical approach and bone graft material (e.g., autograft, allograft, xenograft) is selected to ensure adequate bone support can be developed for ideal implant placement.

In site assessment treatment planning, complications often result when the clinician fails to understand the relationship between the limitations of various regenerative grafting techniques and the predictable development of the required bone contours and bone volume needed for overall restorative success. It is not possible to treat every bony defect with simple or limited techniques that a clinician learns early in his or her learning curve. This discipline requires a variety of approaches to meet the reality of advanced bone resorption, and as the surgeon gains experience, correct application of techniques will lead to predictable outcomes. When the incorrect technique is used, inadequate bone volume will be regenerated, leading to either compromised restorative results or a potential failure of the prosthesis. These problems not only compromise the local grafting site, but they can also destroy bone around surrounding teeth, creating a worse situation than was originally encountered (Fig. 36.7).

In an ideal setting, prevention of ridge resorption starts with awareness of ridge preservation and limiting bone loss before major ridge defects occur. This starts with atraumatic extraction techniques, aggressive socket grafting, and communication among the members of the implant team in respect to the need for timely preservation of the ridge. The longer the patient remains without an implant in an extraction site, the greater the chance that adjunctive grafting procedures will be necessary. Use of effective grafting materials is critical for successful results. For patients with long-term edentulism, the surgeon needs to be fully aware of the patterns of bone resorption to understand the current underlying bony architecture and to correctly choose a grafting protocol that will build the correct volume for the intended prosthesis. This working knowledge of ridge resorption and expertise in the use of effective diagnostic imaging to accurately assess bone volumes gives the clinician the opportunity to correctly organize a reasonable and predictable implant treatment plan (Fig. 36.8).

The use of cone beam computed tomographic (CBCT) imaging, together with proper diagnostic digital or cast models, allows the clinician to create a clear prosthetic plan. The restorative wax-up can easily be interlaced into computed tomographic (CT) imaging software for assessment of the bone volumes needed for proper implant support in key positions. This whole process has been advanced with digital scans and virtual crowns/implants. The digital plans, once integrated into CBCT images, allow the team to visualize the relationships between bone volume and restorative components. Once the dimensions and volume of the graft have been determined, proper application of bone-grafting techniques and materials is necessary to ensure that the intended volume can be achieved. At this point the patient should be educated on the details of the regenerative procedures and a timeline of treatment. Advanced grafting procedures delay completion of the final prosthesis, and patients should be aware of the extent of the inconveniences that will need to be tolerated during this surgical sequence (Fig. 36.9, Fig. 36.10).


• **Fig. 36.8** Treatment Planning Decision Tree. In a Division B ridge, various treatment options are possible, including osteoplasty, Division B implants, or bone grafting. However, each treatment plan has advantages and disadvantages that should be taken into consideration with respect to the final prosthesis (e.g., type 1 fixed prosthesis [FP-1], FP-2, or FP-3).

• **Fig. 36.9** (A) Use of three-dimensional imaging allows the implant team the opportunity to visualize the relationship between the osteotomy and the surrounding bone and teeth. (B) Examination of cone beam computed tomography cross sections allows assessment of proposed implant sites and their relationship to available bone. In this case there is not enough bone to support an implant without additional grafting in the site. (C) The absence of adequate buccal bony support indicates the need to regenerate at least 5mm of bone. Bone around this coronal 5mm of the implant is critical for functional support during loading.


• **Fig. 36.10** (A) Planning a case in three-dimensional software starts with incorporation of the restorative wax-up into the cone beam computed tomographic image. (B) Implants are then introduced in positions that will support the crowns in their required restorative positions. (C and D) As the cross sections are evaluated in this particular case, it is apparent that there is not enough ridge width for placement of implants in the existing bone. This preliminary view indicates that augmentation of the ridge will be necessary for proper implant alignment and support. (E) Evaluation of the actual bony ridge at the time of surgery confirms the previous digital assessment of the bony deficiency.
• **Fig. 36.11** This series of cross sections was prepared from a mandible showing a patient who has a very thin overall ridge width throughout the anterior and posterior regions. As this case is considered for augmentation, concern should be directed to the potential for graft failure because of the overall discrepancy between the thin basal bone width and the required width for implant positioning.

Bony Defect Morphology Considerations and Classification

One of the most difficult components of bone augmentation treatment planning is learning how to predict the amount of bone that will actually be required to develop the proper foundational support that the restorative treatment plan requires. Evaluation of the clinical situation, review of two-dimensional radiographs, assessment of models with restorative wax-ups, and information from CBCT all play a role in determining where bone will be required and how much bone will be needed to successfully graft the site. The concept of determining graft volume is even more important when autogenous bone is incorporated into the regenerative process. The location of an autogenous bone harvest often determines how much volume of bone can be retrieved. The chin and ramus are the primary sites for significant donor volumes used in block grafting, but these sites can provide only a limited volume of bone. If these local donor sites are inadequate, bone can be taken at the apex of many osteotomy sites. In addition, the use of a Piezosurgery unit and bone scrapers may be utilized to harvest cortical shavings. (Fig. 36.11)

In cases where a previous procedure fails to properly develop adequate bone volumes for ideal implant positioning, reflection of tissue over the grafted site will reveal inadequate bony support for the intended implant size and position. At this time, critical decisions must be made to prevent the chance of compromising the overall case success because of this shortfall. The easiest solution is to stop and regraft the site, but this causes inconvenience for the patient, embarrassment for the surgeon, and an overall increase in the treatment time and expense. The alternative is to either ignore the deficiency, placing the implant in a deficient site or attempting supplemental grafting around the exposed implant surfaces. Implant placement in compromised sites without grafting ultimately limits the implant size or forces improper positioning of the implant in the alternative position. This option then leads to a compromised result and incurs unnecessary risk for future failure. For more experienced surgeons, simultaneous implant placement with additional grafting can be attempted, but this is limited to cases where the surrounding basal bone allows proper implant positioning application of grafting principles. (Fig. 36.12), (Fig. 36.13).

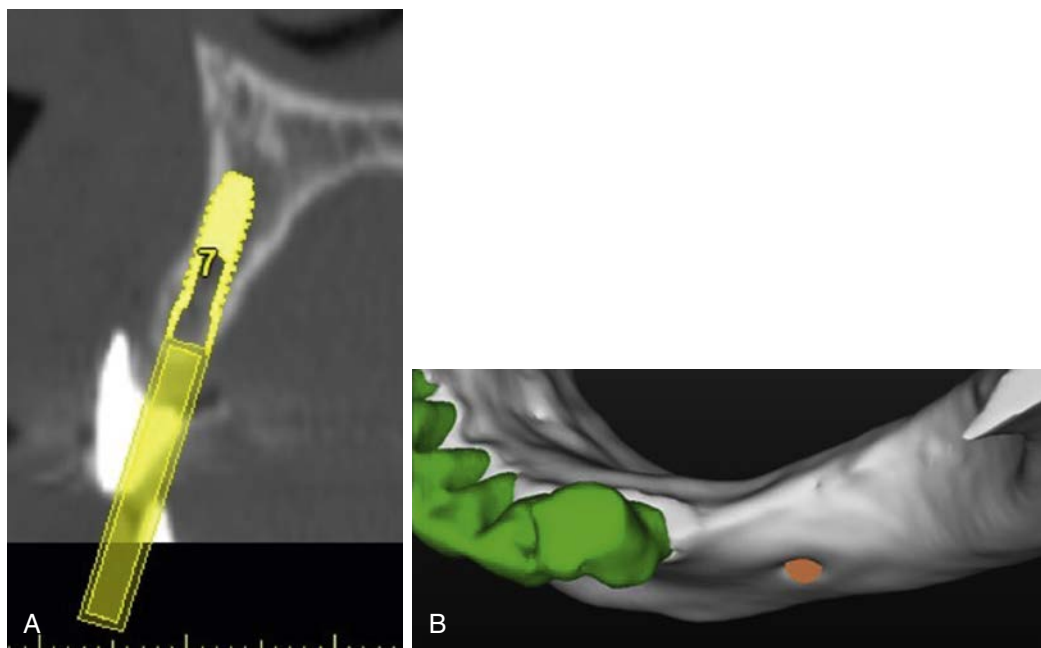
Bony Defect Classification

Determining if an edentulous site will require augmentation should start with an initial assessment of the bony defect. Careful review of the topography of the recipient site includes review of the bone levels on adjacent teeth, bony protuberances, the depth of the actual defect itself, variations in the vertical height of the remaining walls of the ridge, and the condition of the surrounding soft tissue. A successful graft depends on the passage of various cellular components from the surrounding recipient site's bony walls and vascular components into the developing graft site. The larger the distance from these bony surfaces to the peripheral graft components, the greater is the challenge for the various cells to migrate to the outer limits of the particulate graft. The surrounding prominent bony contours also provide additional support and protection for the graft particles, limiting micromovement that usually results in compromised bone growth. These fixed bony surfaces can also help with containment of graft particles and eventual support of membranes. Depending on the morphology and topography of the defect, the clinician may determine the difficulty and potential success of augmentation procedures. The following classification system is based on the bony contours of the deficient area.
• **Fig. 36.12** Osseous Defects. (A) When evaluating osseous defects, the three-dimensional relationship of bone loss versus adjacent tooth positioning is crucial. (B) Severe vertical resorption requires regeneration to avoid complications with support, esthetics, and poor healing. (C) The position of the adjacent teeth and roots should be evaluated to determine the prognosis of an implant-related restoration. (D) Defects that destroy both the facial and palatal cortical plates limit the choice of regenerative procedures that can be used. (E and F) When there is a sharp declining ridge adjacent to a natural tooth, placement of an implant 1.5 mm away creates a failing situation beginning at time of the initial implant placement. As time passes, both the tooth and the implant will be compromised. Positioning the implant away from the natural tooth can limit this proximity problem; however, the implant body position will be too apical, which affects the esthetics and biomechanics.

Bone Defect Classification

1. Depression
2. Concavity
3. Trough
4. Elevation/Prominence
5. Vertical (Height)
6. Buccal & Lingual Cortical Destruction
7. Complex/Multi-Dimensional
   (Fig. 36.14), (Fig. 36.15).

Depression

A simple depression in a potential implant site is a bony defect measuring less than 3.0 mm. If these types of defects are left untreated, they can contribute to either a ridge dehiscence or a fenestration when an implant is placed in the region. These depressed areas are usually grafted at the time of implant placement and they do not require the use of extensive space maintenance techniques. When a depression is noted, it can


• **Fig. 36.13** Cone Beam Computed Tomography (CBCT) Evaluation of Osseous Defects. (A) The use of interactive treatment planning should be completed to determine any possible bony deficiencies. (B) Three-dimensional CBCT can be used to obtain a better ideal of the bone morphology.
• **Fig. 36.14** (A) Evaluation of the clinical appearance of an edentulous space can easily mislead clinicians with respect to the underlying bony contours. (B) Flap reflection reveals a severely resorbed facial aspect of the edentulous ridge.
• **Fig. 36.15** (A) Facial and palatal ridge resorption with coronal and apical defects. This will require facial and palatal regeneration. (B) Severe facial resorption with some remaining palatal bony cortical plate.

be covered with a layer of allograft material and covered with a collagen membrane. Long-term isolation of the particles is not as critical in these situations as compared to larger defects where fibrous in-growth can be catastrophic. Depression type bony defects are the most predictable types of grafts and advanced surgical expertise is not as critical as in other defect types.

Concavity

The concave shaped ridge defect has a significant horizontal depression or bony defect in the middle of the ridge that exceeds 3.0 mm in overall depth. These defects have reasonable remnants of bone surrounding the site that can be used for graft support, containment of particles, and delivery of an adequate supply of cells for angiogenesis. Regeneration in these sites is relatively predictable and most of the implant support will still be provided by the surrounding autogenous bone. A concave defect will require adequate space maintenance for the development of significant horizontal bony growth requiring the use of a static support system (e.g. bone screws, a titanium supported membrane) that is maintained for at least 5 months. (Fig. 36.16A, Fig. 36.16B).

Trough

Severe ridge defects may on occasion destroy the ridge to the depth of the lingual/palatal cortical plate. These are most commonly seen in single tooth defects, especially after a traumatic extraction. The resulting defect provides clearly defined lateral walls of bone formed by the roots of the adjacent teeth and most of these sites also have an apical wall of bone that approximates the prior apex of the tooth. Although these are deep and involved defects, they provide protection for the graft components through their actual configuration. Fixation of tenting screws in the middle of these defects assures maintenance of the needed space for regeneration. The presence of four actual bony walls provides a ready source of cellular components and the resulting regenerative potential is excellent. Therefore, grafting in these defects can be completed more predictably than a wide and exposed concave defect that requires complex vertical support for development of graft depth,

protection from removeable prostheses, and general exposure to micromovement (Fig. 36.17).

Elevation/Prominence

When ridge defects extend across the span of several teeth, the topography of the lateral and vertical surfaces of potential graft sites can vary significantly. A horizontal concavity or isolated depression in a recipient site can be complicated by adjacent elevated prominences of cortical bone. The maxillary cuspid region would be a typical site where the original tooth extended beyond the surrounding basal bone. The loss of the cortical plate on an adjacent premolar would be a distinct contrast to the prominent cortical support over a cuspid. Other examples would be changes in the overall facial contours created by malpositioned teeth. Situations like this also can develop as various teeth are lost over an extended period of time and the resulting loss of ridge support emphasizes the facial contours of the remaining compromised teeth. Grafting around these prominent regions does not require much support in the elevated area, but good space maintenance is needed directly adjacent to the elevated portion of the recipient site (Fig. 36.18).

Vertical (Height)

Accurate assessment of the vertical ridge height in a potential augmentation site is critical from a treatment planning standpoint. As the vertical defect height is increased, the crown-implant ratio becomes problematic with respect to esthetics and biomechanical factors. Regeneration of vertical height is a complex grafting procedure and that is usually reserved for clinicians with advanced experience and skills in complex soft tissue manipulation. A true vertical defect is in essence a through and through defect with the loss of both cortical plates. These defects will require that the concept of space maintenance be moved into a 3rd dimensional skill. A thin sharp-edged ridge top is usually present, with two dense cortical surfaces approximating each another with little to no medullary component between them. The resulting surface area requiring regeneration involves the palatal/lingual aspect, the vertical height defect region, and the highly resorbed facial/buccal portion of the ridge. The limiting factor with these types of defects is the level of the bone on the interproximal aspect of the adjacent
• **Fig. 36.16** (A). Concave Ridge Defect: This ridge has multiple contours to the generalized horizontal defect. There is an angular coronal defect at the top of the ridge, as well as a serious apical defect that leaves a large region that will need to be regenerated. (B). This Concave defect requires significant support for the membrane to regenerate adequate bone in the deeper portions.
• **Fig. 36.17** Trough Defect Type: (A) 3D CBCT image demonstrating the loss of interproximal bone. This will greatly limit development of adequate height of the interproximal papilla in the final restoration. (B and C) Three-dimensional and clinical images of severe horizontal defect with loss of bone on adjacent teeth. There is still fairly good vertical height of the palatal cortical plate.

• **Fig. 36.18** This ridge defect has a complex nature to its topography. The prominent portions of the facial aspect of the ridge will help with support and regenerative components to the more compromised adjacent areas. Careful evaluation of the remaining surfaces demonstrate examples of other defect types.
• **Fig. 36.19** Vertical Ridge Defect Type: Lower anterior complex ridge defect with serious vertical component that destroyed both the facial and lingual cortical plates. The precipitous vertical drop in bone height from the interproximal tooth bone to the base of the defect requires correction of the vertical defect for reasonable implant placement and bone esthetics. Placement of an implant in the middle of the depressed region would still involve a horizontal deficiency. Preservation of the bone levels on the adjacent teeth is a priority.

teeth. Clinicians must understand that it is not possible to raise a ridge higher than the adjacent bony level. In complex cases, this limitation can often require removal of an adjacent tooth to provide a higher adjacent interproximal height for potential vertical development. This is most often seen in anterior areas of the maxilla and mandible where the aesthetic demands of a case require as much vertical regeneration as possible (Fig. 36.19).
• **Fig. 36.20** Hour-glass Ridge Defect: The images in examples (A) and (B) demonstrate the destruction of the facial and palatal cortical plates. Regeneration in these sites will require growth in both dimensions. Failure to regenerate the palatal portion of the site will lead to facial positioning of the implant and most likely, a facial bony deficiency.

Buccal/Lingual (Palatal)

Ridge assessment must include a three-dimensional review of the bony resorption on the lingual/palatal aspects as well as on the facial and vertical regions. Severe ridge defects can often include a significant lingual/palatal component that moves the regenerative procedure into a complex surgical category. The most common site for a true "Hour Glass" ridge defect is in the anterior portion of the maxilla or mandible. Unfortunately, these sites are technically challenging with respect to tissue release, space maintenance, and graft containment. In general, the palatal tissue is very thick and dense, limiting any significant stretching or expansion of tissue over a graft and membrane. For example, the lingual tissue in the mandible is paper-thin and procedures to release and extend lingual tissue over a graft has a potential for button-holing a flap or for potential complications in the region of vessels, salivary components, and muscle attachments. Fixation of tenting screws in palatal defects requires extensive reflection of the palatal tissue and accurate anchorage of the membrane beyond the borders of the bony defect. Membrane fixation on the lingual aspect of the mandible is a delicate process and awareness of the vital structures if critical. Regeneration in these sites is limited to clinicians with extensive surgical and bone grafting experience (Fig. 36.20 A, B).

Complex/Multi-Dimensional

Complex ridge defects are made up of a combination of the configurations described above. These sites will more than likely have deep horizontal destruction that is combined with at least one vertical component. These type of defects vary from a severe single tooth site to a complete section of a quadrant. It is the recognition of the complexity of these situations that is critical for success. The sheer volume of bone that needs to be regenerated can only be determined with advanced integration of 3D Imaging and CBCT surveys. The restorative requirements then dictate the actual locations for implant support and subsequently the areas where specific volumes of bone will be need to be regenerated. At that point, the specific technique can be chosen by its potential for development of large volumes of bone. These cases require harvesting significant volumes of autogenous bone and use of isolating membranes capable of separating the developing graft sites from soft tissue infiltration. Complex cases should be avoided until a clinician has extensive experience in development of bone in each of the basic situations described above (Fig. 36.21).
• **Fig. 36.21** Complex Ridge Defect: The images in (A) and (B) demonstrate the severity of bone loss that can occur over time and in highly destructive situations. These defects require advanced training and experience for predictable grafting success.

Soft Tissue Considerations

Patient-to-patient comparisons of the soft tissue drape surrounding the natural teeth often demonstrate significant differences in color, surface consistency, tissue thickness, and overall esthetics. This is emphasized when a very thin and friable tissue drape surrounds an anterior tooth. Differentiation of patients into either a "thick biotype" or a "thin biotype" is a critical tool that should be used during routine restorative care and anterior implant–related treatment planning. Cook et al.[10] demonstrated the simplest way to determine a patient's tissue biotype is through the evaluation of the visibility of a periodontal probe in the sulcus of an anterior tooth. A patient with a thick biotype will not show any translucence of the probe through the sulcular tissue. In contrast, a thin biotype will allow visualization of the coloration of a probe through the sulcular tissue.[10]

A patient with a thick biotype has tissue with a robust pink stippled appearance. This dense tissue drape forms a thick layer of tissue that is very forgiving when dental restorations are placed around natural teeth and when dental implants are involved. The thin biotype patient, however, presents a much more difficult challenge. These patients often have a thinner labial plate thickness, a narrower keratinized tissue width, and a greater distance from the cement-enamel junction to the initial alveolar crest. This delicate layer of tissue is so thin that the periodontal probe can be visualized when it is lightly placed in the sulcus. Patients with a thin biotype are also more prone to tissue recession, complicating the predictability of restorative esthetics around anterior teeth. As teeth migrate out of position or rotate in the arch, the prominence of the roots can increase, complicating the soft tissue situation even more. Thin layers of tissue around the maxillary anterior teeth require meticulous planning to hide underlying crown margins (Box 36.4 and Fig. 36.22).

Patient biotype and bony architecture must be considered early in all implant treatment planning to avoid a variety of issues that become very complex compared with similar situations around natural teeth. This early planning allows the surgical team the opportunity to incorporate tissue grafting into each surgical stage, allowing deficiencies to be avoided or to at least be minimized. These problems can be significantly complicated when major bone grafting has been completed in the region, resulting in elevation of the mucogingival junction and repositioning of the mucosa into the zone surrounding implant restorative margins. The tissue thickness in postoperative graft sites is often very thin, and development of an adequate emergence profile for crowns requires development of at least 3 mm of keratinized tissue thickness over the top of the implant body prior to restoring the implant. Restorative dentists often find it difficult to mask the dark tones in the coronal portions of natural teeth with endodontic-related color changes. This problem is compounded in a patient with a thin biotype as the color passes through the thin facial bone and thin tissue consistency. This problem with translucence is a reoccurring issue with implant restorations. Problems related to the translucence of the dark hue of the implant body and the abutment through thin tissue can significantly complicate the esthetics surrounding the final restoration.[11] A patient with a thick biotype and thick facial cortical

bone makes an ideal implant patient when restorations are placed and minor deficiencies can be hidden behind the thickened tissue mass. A patient with a thin biotype does not usually have a robust facial bone thickness, and any remodeling changes in facial bone density or thickness can greatly alter the restorative esthetics (Fig. 36.23).

Additional problems related to tissue thickness develop in implant cases as time passes and bony changes occur around the implant body. Esthetics around an implant restoration often change because there is an active bone remodeling process around implants that often results in a loss of facial cortical thickness. This can be a serious problem if an implant is placed in a site with very thin facial bone or in a site where the quality of bone lateral to the implant resorbs as the prosthesis is loaded and the functional forces are centered on the coronal 5 mm of the implant body. If recession or slight bone loss occurs, the facial aspect of the implant can be exposed, creating a dark hue that shows through the overlying tissue and contributes to a poor esthetic situation.

As anterior immediate implants are considered, recommendations for the actual location of the implant in the socket have changed significantly as resorptive patterns in immediate implants have been studied over time. An immediate implant currently should be placed significantly palatal to the facial cortical plate to allow for bone remodeling. This paradigm shift has occurred over time as the recommendations for implant diameters in anterior spaces have steadily decreased to accommodate for these changes in facial bone thickness and complications related to color translucence through the soft tissue. Current recommendations specify that the facial aspect of the implant body should be placed at least 3 mm palatal to the inner edge of the facial cortical plate. Additional authors currently recommend grafting on the facial aspect of anterior immediate implant sites with

bovine particulate grafts and connective tissue graft to minimize long-term changes.

When a clinician is preoperatively aware of a problem related to tissue biotype, it is possible to plan ahead procedurally to maintain or possibly change the biotype, leading to optimal esthetic outcomes. Patients with a very thin biotype can be evaluated for intraoperative supplementation using connective tissue grafts and facial bone grafts to create a more forgiving tissue drape over the implant site. Because thicker cortical bone volumes promote thicker biotypes, the bony architecture and soft tissue drape may be modified in an esthetic zone before implant placement and restoration. Advance planning also provides the implant team an opportunity to inform the patient about these issues and to point out potential esthetic complications before commencing treatment. Any compromise in a patient's expectations must be addressed, especially if the patient is not interested in grafting to modify the tissue type.

Implant restorative care in thin biotypes often requires tissue augmentation as the case ages to create a thick, dense layer of fibrous tissue over the implant body and any deficiencies involving the adjacent natural teeth. Connective grafting procedures are readily available to increase the thickness of the tissue drape in situations such as this. Subepithelial connective grafting procedures may use palatal connective tissue, dense connective tissue from the maxillary tuberosity, or acellular dermal matrix (i.e., OrACELL [Salvin Dental Specialties], AlloDerm [BioHorizons IPH, Inc.], PerioDerm) as the source of donor tissue. A thick layer of connective tissue is inserted into the deficient regions with tunneling procedures, allowing the repositioned tissue flap to provide the blood supply to the developing graft site. The use of the subepithelial approach allows the implant clinician to produce a final tissue tone and color that matches the adjacent natural tissue (Fig. 36.24A, B and C).

• **Fig. 36.24** Soft Tissue Augmentation over the facial aspect of an implant site with "grey tone" to the overlying soft tissue. (A). Grey coloration over the facial of the implant site. (B) A connective tissue graft is drawn into a tunnel prepared over the facial of the implant site. (C). The final restoration in place following the successful grafting procedure.

Large edentulous regions in the posterior portions of both arches often have little, if any, remaining keratinized tissue. These deficient regions can be augmented "before" the bone grafting procedure using "free tissue grafting techniques." In these cases, the epithelial layer of the palate is used as the source of the donor tissue. This usually creates large zones of thicker keratinized tissue with a distinct pinkish white color, duplicating the color of the tissue where the graft was harvested. This dense tissue is not always acceptable from an esthetic standpoint when it is placed in the anterior maxilla. Some of this color issue can be reduced by taking the graft from the posterior portion of the vault of the palate, away from the rugae found in the anterior palate. Use of thinner palatal grafts can also limit some of these annoying color issues. It is still important to keep in mind that the actual "thickness of the tissue" is important in the development of an emergence profile for the final restorations. At least 3 mm of tissue thickness is needed for not only this emergence pattern but is also important from the standpoint of implant health as the implant is restored and maintained.

The importance of the depth of soft tissue above the platform height has been described by Linkevicius et al.[12] in respect to maintenance of crestal bone height. Implants with less than 3 mm of tissue height over an implant were shown to be susceptible to crestal bone loss. The authors compared both regular root form implant and platform switch designs, and all implants were shown to be susceptible to this specific soft tissue related bone loss.[12]

Most anterior treatment plans involving major bone-grafting today incorporate the addition of layers of connective tissue, allograft, or bovine graft particles with membrane coverage to limit excessive bone remodeling in these critical regions. These concepts are critical in "immediate implant" cases, where many cases require both soft tissue and hard tissue supplementation.

Augmentation and implant treatment planning should include a careful assessment of any frenum attachments that could interfere with the grafting process. Grafting in regions where there is still a highly placed frenum can be compromised during the healing phase when remnants of the frenum place tension on the closed incision line, contributing to incision line opening. The maxillary frenum should routinely be removed if it appears to be problematic for future tissue health. The lower frenum and lateral frenum attachments can create a similar tension effect, but the routine periosteal release incision in these graft sites usually eliminates this particular problem in most cases (Fig. 36.25).

Guided Bone Regeneration Protocol

Regeneration of bone in a specified area requires that a protected zone be created where the development process can be completed without interference. Block grafting and other approaches have previously been described for development of significant amounts of bone regeneration in appropriate sites. This chapter describes various protocols that use the principle of "space maintenance and tissue exclusion" for defined bone development. One of the most important components of the GBR process is space maintenance via the use of barrier membranes. Dahlin et al.[13] and many other authors have described the
• **Fig. 36.25** (A) High frenum attachment. (B to D) Removal of frenum and placement of healing abutment.

Primary closure
Angiogenesis for necessary blood supply and undifferentiated mesenchymal cells
Space maintenance/creation to facilitate adequate space for bone ingrowth
Stability of wound to induce blood clot formation

• **BOX 36.6** Growth Rates of Soft Tissue Versus Hard Tissue

---

development of new bone growth using membranes that contained grafts materials, allowing only neighboring bone or bone marrow cells to migrate into the bony defect, without ingrowth of competing soft tissue cells from the overlying mucosa.

In general, membranes are used in GBR procedures to act as biological and mechanical barriers, preventing the invasion of non–bone-forming cells (e.g., epithelial cells), whereas slower-migrating bone-forming cells are drawn into the defect sites.[14] As bone defects heal over time, there is a competition between soft tissue ingrowth and slower action bone-forming cells that are trying to migrate into the area. Soft tissue cells tend to migrate at a much faster rate than bone-forming cells and if left unchecked, they will infiltrate the developing site. Therefore the primary goal of barrier membranes is to allow for selective cell repopulation and to guide the proliferation of various tissues during the healing process.[15] Below the protective membrane, the regeneration process proceeds with angiogenesis and migration of osteogenic cells into the site. This initial blood clot is replaced by woven bone after vascular ingrowth, and later is transformed into load-bearing lamellar bone. This ultimately assists in the support of hard and soft tissue regeneration.[16] If a barrier membrane is not used, the bony defect will fill in with soft tissue, resulting in compromised bone growth (Boxes 36.5 and 36.6).

In the following guided bone regeneration protocol, there exists nine distinct steps for successful and predictable outcomes;
1. Incision and Flap Design
2. Flap Reflection
3. Removal of Residual Soft Tissue
4. Recipient Bed Preparation
5. Tissue Release
6. Membrane Placement
7. Space Maintenance
8. Bone Graft Placement
9. Closure

Step 1: Incision and Flap Design

Incision design is one of the keys to a predictable regenerative result. Ideal incision designs provide complete access to the surgical site without compromising the integrity of the

surrounding tissue. As the incision is planned the anatomy of the adjacent papilla must be considered to prevent any damage that will compromise the esthetics and function of the tissue postoperatively. The patient's biotype and the amount of keratinized tissue is always reviewed, and any deficiencies in attached tissue must be accounted for in the incision design. The incision must be planned in a way that keeps incision lines away from critical regions where graft particles or blocks could become exposed. Observation of sound surgical principles in preparation of incisions is critical for maintenance of the blood supply to all of the involved tissues. Wide-based incisions are always important to prevent interruptions in the vascular supply to the flap.

Failure to properly plan the incision design of a flap during grafting can pose numerous issues, mainly related to incision line opening postoperatively. Incision line opening exposes the regeneration site to an influx of oral pathogens, soft tissue ingrowth, and loss of the graft materials that were intended to be isolated during the maturation process (Fig. 36.26A, B and C and Box 36.7).

The coronal incision is usually placed on the crest of the ridge, favoring a location closer to the palatal aspect if possible. It is important that the scalpel make a continuous full-thickness cut through the tissue and the periosteum, ending on the actual bone. Incisions that are irregular and leave regions of attached tissue and periosteum will lead to maceration of the flap as it is reflected. This shredding of tissue also compromises the periosteal layer that is the primary source for blood to the underlying bone. A survey of the available keratinized tissue must be completed before making an incision. In regions of bountiful attached tissue, the surgeon can use his discretion in the location of the incision through the keratinized regions. In regions where the keratinized tissue is limited, the incision should at least "split" the distance between the two edges of the keratinized tissue. It is always best to try to keep incision lines away from areas that are key to regenerative volume and protection (Fig. 36.27A,B, C, D).

When possible, the papillae should be preserved while incisions are prepared. If there is a good papilla adjacent to a graft site, the incision should be designed to avoid involvement of the papilla or it should be moved to the adjacent interproximal space. If the papilla is absent or is flat, the incision can be directed to the root approximating the graft or it can be moved to the adjacent space. It should be kept in mind that regeneration of a compromised interproximal papilla is still one of the most difficult endeavors in soft tissue surgery today. An incision in the middle of an anterior space of a "thin biotype" patient can either permanently scar the region or can completely destroy the papilla form and esthetics in the final restoration.

The positioning of vertical releasing incisions is one of the most important parts of the incision. A broad-based releasing incision should be prepared to maintain the blood supply to the flap and to allow elevation, retraction, repositioning, and suturing without tension. It should be kept in mind that most graft sites have a compromised soft tissue component that becomes a greater issue as the complexity of the underlying architecture increases. Most of these sites have a minimal keratinized band of tissue at the crest of the ridge, tapering quickly to the mobile mucosa of the vestibule. Full-thickness vertical release incisions should generally be planned to extend to the apical portion of mucogingival junction. In larger bone graft sites the vertical release will often extend deeper into the vestibule to help with complete release of the flap
• **Fig. 36.26** Incision Design. (A) Ideal crestal incision when adequate attached tissue is present. (B) Crestal or more lingually placed incision that preserves the limited amount of keratinized tissue. (C) Crestal full-arch incision designed to preserve the limited facial zone of keratinized tissue.

• **BOX 36.7** **Principle Concepts to Be Practiced in Grafting Incisions**

- Consideration of tissue biotype as incision is planned
- Maintain ideal papilla forms and levels
- Preservation and utilization of keratinized tissue in region
- Maintain the integrity of the full-thickness flap during reflection
- Design of lateral releasing incisions in locations that minimize exposure of graft particles
- Maintaining wide-based incisions to provide adequate blood supply to flap

• **Fig. 36.27** Design for Papilla Preservation. (A and B) Ridge incision, making sure to "score" the bone to obtain full-thickness flap; (C and D) incision continued to include a vertical release.

• **Fig. 36.28** Papilla-Sparing Incision. (A) Initial incision. (B) Full-thickness reflection.

during a tension-free closure. The location of vertical releases should be moved away from the most critical zones of the graft, limiting encroachment of the incision closure on the bulk of the graft particles and membrane margin. This is very important in cases where the barrier membrane is nonresorbable and exposure of a margin of the membrane can contribute to graft failure. In those cases, it is best to completely move the release to a completely different interproximal space. Properly placed incisions will position the margins of the flap over host bone instead of the graft particles and the membrane (Figs. 36.28 A and B). Vertical incisions have been related to scar formation in the surgical sites

after healing. Most scars are related to irregular incisions and poor adaptation of the wound edges at the time of suturing.

The goal of any implant treatment plan would be placement of restorations in the middle of a zone of attached keratinized tissue that is at least 3 mm thick from the level of the platform of the implant to the margin of the tissue surrounding the implant. Few resorbed ridges have an abundance of keratinized, and in most situations the surgeon will need to incorporate development of a thick tissue zone that will provide an emergence profile for the restoration and protection of the implant-bone interface. As the incision is prepared, the keratinized tissue dictates the path of the
• **Fig. 36.29** Alternative Release Incisions. (A) The vertical releasing incision is often moved laterally to the adjacent papilla space to obtain adequate access. This will minimize incision line opening when larger graft volumes are obtained. (B) Extending the incision to an adjacent tooth also minimizes the possibility of the incision over top of the graft site.
• **Fig. 36.30** Poorly Placed Release Incision. The incision should be positioned away from the graft site and also be more lateral to obtain a more broad-based flap design.

incision line and often determines how easily the wound will be to close and to withstand the strain on the incision line during healing. If adequate attached tissue is not present, soft tissue grafting should be completed either before the augmentation procedure, as a portion of the grafting protocol, or after the implants are placed. Tissue development options include autogenous free tissue grafts, autologous connective tissue grafts, acellular dermal matrix (Allo-Derm, OrACELL), or combinations of Mucograft and soft tissue grafts. In addition, when inadequate keratinized tissue is present, the incision should be placed toward the lingual portion of the remaining keratinized tissue, preserving as much attached tissue on the facial as possible. This allows for greater resistance to muscle pull and will decrease incision line opening (Fig. 36.29 A and B) (Fig. 36. 30).

Step 2: Flap Reflection and Site Preparation

Full-Thickness Reflection

Elevation of the tissue to expose the recipient site requires reflection of a full-thickness mucoperiosteal flap. This should be completed in an uninterrupted release of the flap that includes the surface mucosa, submucosa, and periosteum. This initial release is accomplished with

an angled curette or a scalpel that is used to score the bone, ensuring complete penetration through the tissue layers and the periosteum. As the tissue is reflected, the underlying bone should be "scraped" with the curette or periosteal elevator in a side-to-side motion. It is important to confirm at this stage that the complete flap has been freed from the bone and that it is freely drawing away from the bony surface. Partial-thickness reflection leads to tissue trauma or shredding of the flap itself. Tissue that has been compromised in this manner results in slower healing and a higher morbidity. When using a periosteal elevator (i.e., 2–4 Molt) for this flap release, the edge should always rest on the bone to prevent tearing through of the tissue flap.

The tissue thickness on the lingual aspect of the mandible is very thin and friable. This tissue can be easily torn during reflection of the flap and manipulation of the tissue during the grafting procedures. Resulting "buttonhole" openings compromise the blood supply to the surrounding tissue that is needed for coverage over the graft site, leading to compromised results postoperatively. Tearing or buttonholing the lingual flap may also expose the graft site and increase the possibility of margin necrosis coronal to the tear. This exposure may lead to a total graft failure (Fig. 36.31 A and B).

If the lingual flap is torn during the procedure, it can sometimes be repaired using 5–0 chromic suture, approximating the edges of the tear and preventing tension on the weak site. It is recommended to use a collagen membrane below these fenestrations to assist with healing and to isolate the graft materials. Maintenance of the blood supply to the tissue flap is important, requiring that all tension on the flap be minimized.

A flap covering a graft that does not have complete release of pressure on the two margins of the flap will often pull open during the healing process (incision line opening). Tension on the flap compromises the blood supply to the tissue along the suture line that is under pressure. This pressure leads to necrosis and eventual separation of the two edges of the flap closure. Once this has occurred the flap cannot be sutured back into place, and the graft site is open for contamination and tissue ingrowth. The success of bone grafting is largely dependent on the maintenance of space for bone development and isolation of the graft particles during the slow process of osteogenesis. Soft tissue ingrowth, bacterial contamination, and migration of graft particles predictably compromise regenerative results.
• **Fig. 36.31** Lingual Flap Design and Exposure. (A) The lingual should be reflected to expose the entire lingual surface; however, care must be exercised not to tear the flap. Perforating or a buttonhole in the flap will compromise the graft site. (B) If this occurs, it is very difficult to mend the tear, potentially compromising the closure of the graft site or predisposing the region to incision line opening over the healing graft. Incision line opening leads to an increased morbidity of the graft site.
• **Fig. 36.32** (A and B) Removal of fibrous/soft tissue with course barrel bur.

The typical graft site requires that the overlying flap be released enough for extension of the flap at least 5 mm beyond the edge of the adjacent margin for a tension-free flap closure. The only way to achieve this free flap release is complete release of the periosteal layer, allowing the elastic fibers of the underlying flap to stretch as the flap is drawn over the graft site.

Step 3: Removal of Residual Soft Tissue and Pathology

Before bone grafting, all evidence of soft tissue remnants should be eradicated. Soft tissue fibers left on the recipient site can limit proper attachment of the newly regenerated bone to the underlying basal layer. These fibrous tissue remnants are the same tissue that the barrier membrane is attempting to exclude from the site. Early fibrous tissue growth in the wound simply bypasses that critical barrier and starts fresh tissue development right in the center of the graft site (Fig. 36.32 A and B).

Step 4: Recipient Bed Preparation

Preparation of the recipient site for an augmentation is very important in the development of a healthy ridge. The recipient site is usually covered with a dense layer of cortical bone that does not easily provide a blood supply to a developing graft. The process of decortication of the recipient base is used to open multiple pathways through this thick layer of bone. These pilot holes create an open pathway to the underlying trabecular bone where blood flow into the graft site will increase revascularization (angiogenesis) and introduce bone growth factors into the graft site.[17] The decortication is usually accomplished with the use of cross-cut fissure burs or small, round burs that are used to perforate the cortical plate. Copious amounts of chilled saline should be used to prevent thermal trauma (Fig. 36.33 A and B).

The decortication process initiates the regional acceleratory phenomenon, which describes the cellular stimulating technique used to accelerate the healing rate of a graft site. In this process, bone decortication is used as a "noxious stimulus," and it has been shown that the healing rate of a graft site can be increased 2 to 10 times the normal healing rate by initiating the regional acceleratory phenomenon (RAP).[18] This acceleration is accomplished by the introduction of platelets to the area that ultimately release growth factors including platelet-derived growth factor (PDGF) and transforming growth factor (TGF). Ultimately the decortication process will lead to better integration of the graft to the host bone.
● **Fig. 36.33** Host Site Decortication. (A) The host site is prepared with a tapered cross-cut fissure bur (e.g., 169 L) to initiate angiogenesis. (B) The decortication must be deep enough to initiate bleeding, thus allowing blood vessels into the area (i.e., angiogenesis).

Step 5: Tissue Release

Successful augmentation procedures require maintenance of an intact tissue closure along the incision line during the healing process. One of the most common surgical complications that clinicians will experience early in their learning curve is incision line opening. The failure of maintaining this tissue union is directly related to an inadequate release of tension on the tissue flap as it is stretched over the widened graft space. Clinicians will find that it is highly unlikely to pull a tissue flap over any sizable graft site without first altering the integrity of the flap itself.

The most important concept in augmentation procedures is total membrane coverage of grafting materials from the time of membrane placement to completion of the graft maturation process. Success is directly related to the overall management of the soft tissue flap during flap closure. A successful case starts with the incision and continues with proper flap reflection of an intact periosteal layer, proper membrane positioning, and completion with a tension-free flap closure.

Tissue Release Technique

Examination of the exposed inner surface of a reflected flap will reveal a smooth, shiny layer of the periosteum. The periosteum is composed of a thin, firm layer of dense tissue that has no elastic fibers. This binding layer limits any significant elongation of the flap as it is stretched over a graft site. A shallow incision through the dense tissue "releases" the tight band of pressure on the underlying tissue flap. The tissue directly below the periosteum is primarily composed of elastic-type fibers, and once the periosteum has been released, the entire flap can be stretched. This simple releasing incision ultimately allows tension-free closure over the graft site (Fig. 36.34 A B and C) site (Fig. 36.35 A and B).

Step 6: Membrane Selection and Placement

Barrier membranes are generally used in guided bone regeneration procedures to act as biological and mechanical barriers against the invasion of fibrous tissue into the developing graft site. The membrane also will allow for the migration of the slower-migrating bone-forming cells into the defect sites During the bone regeneration process, there is a competition between soft-tissue and bone-forming cells to invade the surgical site. In general, soft-tissue cells migrate at a much faster rate than bone-forming cells. Therefore, the primary goal of barrier membranes is to allow for selective cell repopulation and to guide the proliferation of various cells during the healing process. Below the protection of the membrane, the regeneration process is allowed to continue unchecked with early angiogenesis and migration of osteogenic cells. The initial blood clot is replaced by woven bone after vascular ingrowth, which later is transformed into load-bearing lamellar bone. This will ultimately support the hard- and soft-tissue regeneration. If a barrier membrane is not utilized, lack of isolated space maintenance will result in soft-tissue integration and compromised bone growth.

Types of Membranes

Membranes are typically classified as resorbable or nonresorbable. Nonresorbable membranes have included titanium foils, expanded polytetrafluoroethylene (e-PTFE), and dense polytetrafluoroethylene (d-PTFE) with or without titanium reinforcement. Resorbable membranes are typically made of polyesters (e.g., polyglycolic acid, polylactic acid) or tissue-derived collagens (e.g., AlloDerm GBR, Pericardium, Ossix Plus). Non-resorbable membranes are bio-inert materials and require a second surgical procedure for removal after bone regeneration is complete. Resorbable membranes are naturally biodegradable and have varying resorption rates. However, all membranes, non-resorbable or resorbable, differ in their biomaterial and physical characteristics. These varied characteristics can often be associated with advantages and disadvantages in various clinical situations (Box 36.8).

Non-Resorbable Membranes. Non-resorbable membranes exhibit excellent biocompatibility, superior mechanical strength, increased rigidity, and generally achieve more favorable space maintenance than unsupported resorbable membranes. However, wound dehiscence is more common with non-resorbable membranes, and these membranes have the disadvantage of the need for a second surgery. This second procedure can result in an increased morbidity, higher costs, and over-all patient discomfort. The most common types of non-resorbable membranes include polytetrafluoroethylene (PTFE) and titanium mesh.

a. **Expanded PTFE membranes** — The expanded PTFE membrane (e-PTFE) was the first type of membrane used in implant dentistry and was the gold standard for bone regeneration in the 1990s. The e-PTFE membrane was advantageous as it prevented fibroblasts and connective-tissue cells from invading the
• **Fig. 36.34** Tissue Release Procedure. (A) Adequate flap release around bone graft sites is the most critical step for tension-free flap closure and predictable graft success. (B) A single shallow incision through the periosteum is prepared inside the flap while maintaining tension from elevating the flap. (C) The clear separation of the periosteal edges as the flap is extended and the elastic fibers allow the flap to stretch (i.e., tension-free).
• **Fig. 36.35** Extended Periosteal Release Procedures. (A) The incision may be extended on the mesial and distal aspect of the graft site to allow increased mobility of the flap when it is extended. (B) After blunt dissection of the periosteal release with scissors (i.e., scissors should be parallel to the flap), the flap can be freely extended over the graft site. This release must be completed until the flap can be repositioned at least 5 mm beyond the lingual aspect of the graft site.

bone defect, yet they allowed the osteogenic cells to repopulate the graft area. The most common e-PTFE membrane in implant dentistry was GORE-TEX® (W.L. Gore & Associates, Inc.; Flagstaff, Ariz.).

The two sides of e-PTFE membranes were composed of different layers. One side was approximately 1 mm thick with 90 percent porosity, which impeded the growth of epithelium; The other side was approximately 0.15 mm thick with 30 percent

1. *Tissue compatibility* — Ideally, the membrane should be biocompatible, resulting in no inflammation or interaction between the membrane and the host tissue that could lead to wound dehiscence or a local infection.
2. *Space maintenance* — The membrane should have a generally firm consistency to help maintain the regenerative space and to prevent loss of the defined ridge shape required by the restorative plan.
3. *Stabilization of the blood clot* — The membrane should provide stabilization of the blood clot, allowing the regeneration process to progress and reducing connective tissue integration into the defect.
4. *Cell Occlusiveness* — The porosity of the membrane should prevent fibrous tissue from invading the graft site. A larger pore size may inhibit bone formation by allowing the in-growth of faster-growing soft tissue cells. When the pore size is too small, limited cell migration inhibits collagen deposition and ultimately contributes to poor graft development.
5. *Mechanical Strength* — The membrane should have high durability and mechanical strength to protect the blood clot and resist passage of unwanted cells and bacteria. This same material strength is important when the membrane is tacked to the apical portion of the recipient site. A fragile membrane can easily tear around the fixation tack, releasing the anchorage of the membrane.
6. *Predictable resorption rate* — The resorption time of the membrane should coincide with the regeneration rate of bone tissue. The continued presence of the membrane is dependent on the location of the graft, the available vascularity in the region, and the quantity of graft material.
7. *Easy to modify and manipulate* — The membrane should be capable of size and shape alteration while maintaining adequate stiffness to prevent collapse into the graft site.

• **Fig. 36.36** D-PTFE membrane with titanium reinforcement depicting space maintenance principle, which allows for angiogenesis and the bone regeneration to progress. (Image adapted from Osteogenic Biomedical).

• **Fig. 36.37** Polytetrafluoroethylene (d-PTFE) Membrane. Clinical view of d-PTFE membrane.

porosity, which provided space for new bone growth and limited fibrous tissue ingrowth.[19]

The e-PTFE membranes had a high incidence of exposure, thereby resulting in an increased infection rate because of the ingrowth of bacteria into the highly porous structure. Additionally, the porous structure, with an approximate pore size of 5–20 micrometers, allowed for soft-tissue ingrowth, leading to increased difficulty in removal.

b. **High-density PTFE membranes** — Because of the associated complications of e-PTFE membranes, a higher density material — less than 0.3 microns — was developed in the early 1990s under the name Cytoplast™ (Osteogenics Biomedical; Lubbock, Texas). This high-density PTFE (also termed dense PTFE or d-PTFE) has been shown to have a lower risk of bacterial colonization in comparison to e-PTFE membranes, therefore resulting in fewer infections. The high density and small pore size of the membrane prevents passage of bacteria through the membrane, while allowing oxygen diffusion and passage of small molecules. Because of the lack of tissue ingrowth into the 0.3 micron pores, d-PTFE membranes are much easier to remove. Clinical use of d-PTFE has demonstrated that localized membrane exposure does not always dictate failure of the developing graft. If the d-PTFE membrane can be maintained for at least 6 weeks, removal at that time or later will often be followed with development of a reasonable bony ridge. (Fig. 36.36).

c. **Titanium-reinforced PTFE membranes** — The addition of a Titanium strut to a PTFE membrane allows the membrane to be shaped into a form that will develop bone in the contour and volume required by the restorative plan. These types of membranes are especially useful in the treatment of large osseous defects where varied thicknesses of bone are dictated by
an irregular recipient topography. Studies of GBR procedures using titanium-reinforced nonresorbable membranes have shown great success with horizontal and vertical alveolar ridge augmentation because of their ability to maintain space, minimize graft mobility, and exclude soft tissue ingrowth.[20–24] (Fig. 36.37) (Fig. 36.38).

d. **Titanium Mesh** Titanium mesh is a non-resorbable barrier that has been shown to be effective in maintaining space without collapsing. Titanium foils are flexible and can be bent and manipulated to mold around a bony defect. Titanium mesh has demonstrated predictable biocompatibility and features holes within the mesh that allow for maintenance of the blood supply from the periosteum. The primary disadvantage of titanium mesh is related to an increased incidence of wound dehiscence's and overall difficulty in maintaining soft-tissue coverage during the lengthy healing process. Exposure of the mesh may lead to an increased rate of infection and patient discomfort, leading to early removal of the mesh.

Resorbable Membranes. Resorbable membranes exhibit the advantage of no second-stage surgery for removal, thus decreasing discomfort and morbidity to the patient. However, the drawbacks of collagen include an unpredictable resorption time, which may adversely affect the amount of bone formation. Resorbable membranes derived from xenogeneic collagen for use in GBR procedures are the most popular membranes utilized in implant dentistry today. The various types of resorbable membranes include collagen, pericardium, and acellular dermal matrix.

Resorbable collagen membranes consist of either type I or type III collagen from bovine or porcine origin. Collagen membranes are easy
● **Fig. 36.38** Polytetrafluoroethylene (PTFE) Membrane: Clinical image depicting dense PTFE membrane prior to modification of the 2mm free zone adjacent to each tooth (Photo courtesy of Dr. John Hamrick).

to manipulate and have favorable effects on coagulation and wound healing, variable cross-linking, low antigenicity and high tensile strength.[25] Additionally, they inhibit epithelial cells, promote the attachment of connective-tissue cells, and increase platelet aggregation, which leads to wound stabilization and increased healing.

Collagen constitutes over 50 percent of the proteins in the human body. As the collagen membrane is degraded through enzymatic reactions, the process resembles normal tissue turnover.[26–33] Today, most collagen membranes are derived from allogenic or xenogeneic sources, which have become popular in implant dentistry. They act as scaffolding for osteoconduction, increase platelet aggregation and stability of clots, and allow for the attraction of fibroblasts for healing. Collagen membranes are manufactured with a variable resorption rate, which occurs through inflammatory cell biodegradation. The resorption rate is altered via the manufacturing process by the amount of cross-linking.

Collagen barriers are available in various forms:

a. **Collagen tape / plugs** are mainly used to control bleeding and maintain the blood clot within extraction sites. Collagen tape/plugs are usually a soft, pliable, sponge-like material that rapidly absorbs blood, thereby creating an artificial clot. The collagen allows aggregation of platelets, which results in the degranulation and release of bone-growth factors. Collagen tape/plugs have a resorption time of approximately 10–14 days are not indicated for guided bone regeneration procedures.

b. **Regular collagen membranes** resorb in three to four months and are mainly used in guided bone regeneration for small- to medium-size bony defects. Ideally, primary closure is recommended to decrease graft morbidity.

d. **Extended collagen membranes** resorb in four to six months and are used for larger bony defects that require longer healing periods. These membranes are modified by increasing the cross-link density. Cross-linked collagen membranes are most commonly used in guided bone regeneration procedures for larger bony defects requiring longer healing time and graft containment.

e. **Pericardium Membranes** are most commonly of either bovine or porcine origin, with bovine having a greater collagen content. They generally consist of three layers with collagen and elastic fibers in an amorphous matrix. Their surface is porous, which allows for cellular attachment and proliferation, yet has an increased density for soft-tissue exclusion. (Fig. 36.39 A, B, and C).

f. **Acellular Dermal Matrix (ADM)** is a biocompatible human (allograft) connective-tissue matrix derived through a process of removing all cells within the dermis. Because of the cells being removed during the manufacturing process, no viruses may be transmitted. Additionally, because of the acellular nature of this membrane, no inflammatory reactions or rejection will occur. The inert allograft, when used as a membrane, acts as an architectural framework that allows for fibroblast migration and vascularization. Allo-Derm is an acellular dermal matrix originally developed in 1994 to be used as a skin allograft for burn patients.[34] It has been used in the medical and dental literature as an allograft for various procedures because of its ability to rapidly vascularize and to increase soft tissue thickness. In the dental literature, AlloDerm has been successfully used for root coverage, thickening of soft tissues, and GBR.[35,36] AlloDerm GBR is a thinner version (thickness ranges from 0.5 to 0.9 mm) of the original AlloDerm product (thickness ranges from 0.9–1.6 mm), specifically designed for GBR. AlloDerm GBR has been successfully used as a barrier membrane and has also been shown to significantly increase soft tissue thickness by 45% and 73% from baseline at 6 and 9 months, respectively (baseline 0.55 ± 0.16 mm to 0.80 ± 0.26 mm at 6 months and 0.95 ± 0.28 mm at 9 months; P < 0.0033), when used as a barrier membrane for GBR of horizontal alveolar ridge deficiencies.[37,43] (Fig. 36.40 A, B, and C).

Sizing and Positioning of Membranes

The selection of the membrane type is one of the most important aspects of bone regeneration protocol. The choice of a specific type of barrier membrane is directly related to the ultimate success of the regenerative process. With numerous resorbable and non-resorbable membranes available, each one has specific properties that either help or hinder the isolation properties of the procedure. These properties relate ultimately to the workability of the material and the longevity of its protection of the underlying graft particles.

The size of the membrane must be large enough to completely cover the entire graft site after the bulk of the graft has been placed in the recipient site. As the membrane is then stretched over the graft, it must be wide enough and long enough to guarantee that all of the graft particles will be isolated from any soft tissue or bacterial ingrowth. Experience indicates that the minimum membrane will be 20 × 20 mm and in almost all large graft sites, use of a 20 × 40 mm membrane will be needed. Attempting to piecemeal two or three small membranes together is not only difficult, but also introduces another variable into the concept of graft isolation over an extended time frame. The most efficient way to trim and shape a large piece of dermal matrix or connective tissue is to wet a tongue depressor in saline and then use this as a "cutting board" for the membrane (Fig. 36.41).

Positioning of membranes around teeth is very critical to reduce complications. The use of d-PTFE requires a minimum of 2 mm between the edge of the membrane and the side of an adjacent root surface. d-PTFE membranes with titanium struts should be trimmed in a manner that prevents a lateral extension of the strut
• **Fig. 36.39** Pericardium Membrane. (A) Fixation of membrane. (B) Autogenous bone being placed under tent screws. (C) Final veneer graft of allograft bone.

in the region of the coronal aspect of the graft site. Titanium struts that are positioned close to the interproximal root surfaces will often lead to membrane exposure and a compromised graft volume in the region. Newer d-PTFE membranes are designed to keep these lateral extensions located away from these critical regions. Specific elimination of all sharp edges or rough margins is critical in the elimination of membrane perforation through thin regions of the overlying flap. GBR techniques using titanium mesh require 2 mm of clearance from the root of a tooth because of similar issues.

When using resorbable membranes around teeth, the 2-mm rule is not a critical factor, and resorbable membranes can be placed directly against the roots of the adjacent teeth without causing a membrane failure. Acellular dermal matrix does not need to be separated from root surfaces, keeping in mind that this same membrane is used in routine periodontal procedures for root coverage. The only complication with placing resorbable membranes directly against natural roots is related to primary wound closure in the root proximity. Membranes must be smooth, and they should allow the overlying flap to be adapted evenly around the neck of a tooth root.

Initial Placement of Membrane

After preparation of the recipient site, the barrier membrane may be initially fixated. The initial fixation may be completed either apically or on the lingual aspect of the ridge. Fixation of the membrane before placing the particulate graft assures that the membrane will not shift after the bulk of the graft has been placed and that it defines the apical extent of the graft itself. In situations where tacks cannot be used the membrane can be fixed both apically and palatally/lingually with sutures. It should be kept in mind that definition of this space is established by the membrane. If the thickness of the graft narrows as the graft extends toward the apex of the regenerative site, the thickness of the bony support of the implant itself will also be reduced. In that instance an apical fenestration often occurs, introducing one of a number of variables that can complicate the predictability of an implant over time (Figs. 36.42 and 36.43).

Step 7: Space Maintenance

Aside from the soft tissue exclusion and clot stability, space maintenance is key to the success of the GBR process. The creation and continued unmoving support of the graft "space" can be accomplished with membranes supported by tenting screws/pins, titanium-reinforced membranes, molded titanium mesh, block grafts, dental implants, or the bulk of particulate graft material.[44–48] Most of the new techniques in GBR protocols require specific support of this area where bone is needed. Simply filling the defect space with bone particles has been shown to greatly limit the final bone volumes, and definition of the actual shape of the ridge is really not predictable. As this protected "free zone" is defined, possibilities of successful development of new bone have been greatly improved.
● **Fig. 36.40** Collagen Membranes. (A) Bone screws placed in defect area. (B) Collagen membrane hydrated and fixated with tacks. (C) Site grafted and membrane positioned over graft.
● **Fig. 36.41** Modification of membrane to encompass defect using a #15 blade.

Space Maintenance Options

1. **d-PTFE integrated with titanium struts**
2. **Titanium Mesh**
3. **Tent Screws**

Tent Screw Technique

To support the membrane support and prevent collapse of the graft in most particulate membrane techniques, tenting screws are used. The principle of tenting screws utilizes the "head" of the screw for vertical and horizontal support. This support system literally creates the surface countour of the membrane and bone graft material, which allows for the bone regeneration process to proceed in a predictable manner.

Size of Fixation Screws. Bone fixation screws on the market today are generally non-resorbable screws that either have threads from the head to the tip of the screw or a smooth neck with 3 mm of thread design at the tip of the screw.[47,48,50,51] Use of resorbable screws has been described, and this possibility gives the surgeon the option to avoid a reentry procedure to remove the fixation screws.[41] As the variety of fixation screws is explored, choices of screws with large-head diameters are preferred. The wide head is important with this technique because the primary purpose of the screw is to support the membrane during the complete bone maturation process. If the head of the screw perforates through the membrane, the vertical support will be lost and the particulate graft is subject to pressure and micromovement. When support is lost, the final volume and consistency of the matured ridge will be altered.

Use of narrow-diameter (small) screw heads that are used in block grafting procedures was found to periodically result in compromised and decreased bone growth. Most likely, the membrane will lose its vertical support after the small screw head perforates through the membrane.

Ideally, bone fixation screws with a shaft diameter of 1.5 mm are recommended instead of thicker screws because it decreases the
• **Fig. 36.42** Membrane Placement in Proximity to Teeth. (A) Titanium-reinforced membrane. (B) Extended collagen membrane. (C) Acellular matrix.

overall post-grafting bone volume when larger-diameter screw shafts are used. Most screws today are self-threading and are easily inserted into decortication holes. The most common length of tent screws is approximately 6 mm, however the clinician should anticipate screw lengths of 10 -12 mm for larger osseous defects (Fig. 36.44).

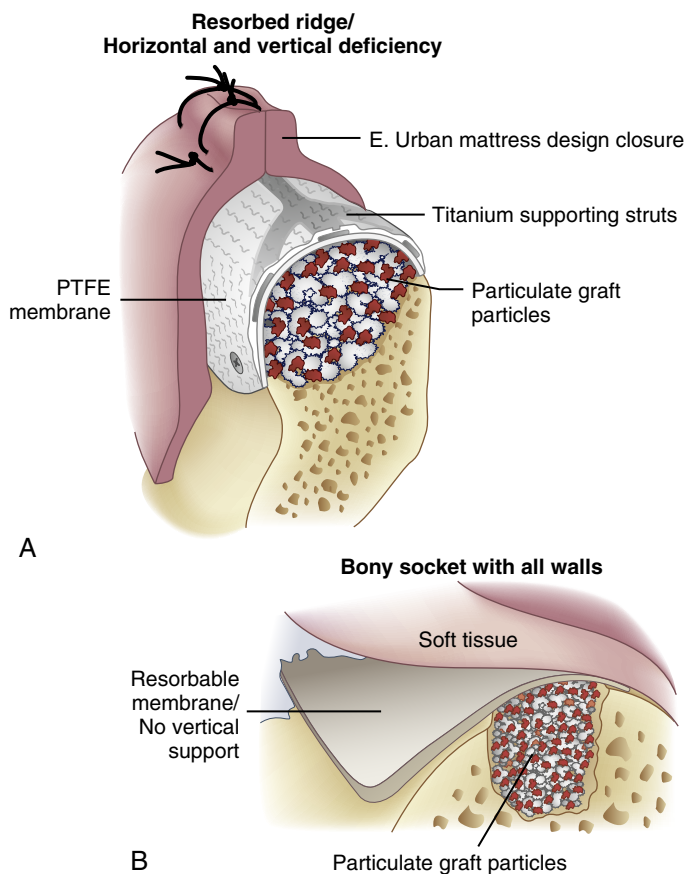
Tent Screw Numbers. The amount of support required to maintain the spatial dimensions of the graft site determine the number and positioning of these screws. Screws are anchored in the recipient site as needed to form a dome over the graft site that replicates the height of bone needed for ideal implant placement. Ultimately the tenting screws act as "tent poles" to support the membrane, decrease graft mobility, and relieve external pressure on the graft.[49] Placement of simple membranes over graft materials without defining space maintenance will usually lead to variable postoperative bone volumes and often deficient bony support on the facial and lingual aspect of the coronal aspects of the implant platform (i.e., membrane collapse) (Fig. 36.45).

Tent Screw Positioning. The positioning of the screws should be planned in a manner that will result in a dome shape that is formed by the "heads of the screws" matching the required contour of the final ridge form. The use of multiple screws in this technique creates very specific ridge forms that cannot be attained with unsupported membranes. Screws are placed 3 to 4 mm apart to allow solid bone formation between the screws. Basically, the number and position of tent screws is directly related to the size and the required contour of the bone graft.

Clinical situations where screws have been placed too close together periodically demonstrate weaker zones of bone formation which may result in difficult implant positioning. This can be important because lateral forces are placed on mature bone graft sites during implant osteotomy preparation and implant placement. Postoperative bony ridges using this specific technique have been found to easily tolerate the lateral forces of bone spreaders and wide body implants without any significant problems related to flaking or granular bony ridge forms. The only problem encountered with respect to screw positioning has been related to screw positions that were too close to the crest of the ridge. In these situations, an osteotomy diameter can encroach on the unfilled screw hole and the thin fragment of bone can become detached (Figs. 36.46 A, B, C, and D) (Figs. 36.47 A, B, C, and D).

Care should also be exercised in placing tent screws in approximation to adjacent teeth. The location and trajectory of adjacent tooth roots should be determined to prevent screw placement into a tooth root. Ideally, post-operative radiographs should be taken to verify ideal positioning in relation to tooth roots.

Step 8: Bone Graft Placement

The success of a bone graft is very dependent on the proper application of the basic principles of bone development. This has been emphasized as surgeons attempt to regenerate large bony defects that require development of a viable graft that can be far from the recipient bone, where all of the regenerative components originate.


• **Fig. 36.43** Resorbable vs. Non-resorbable membrane (A)This figure represents a nonresorbable dense polytetrafluoroethylene (d-PTFE) barrier membrane (provided by Osteogenics Biomedical) that has titanium supporting struts to prevent collapse into the regenerative space fill the underlying space with a bony matrix that can be replaced with viable bone as the regenerative process is completed. (B) This figure demonstrates the use of a resorbable barrier membrane with no supporting components. In this situation the membrane functions as a protective layer that prevents ingrowth of soft tissue into the underlying space. Membranes should generally be elevated above the ridge deficiency with screws or titanium to prevent collapse into the space or shifting of the graft particles.

This is even more important in vertical regeneration because the graft particles contact the host bone only at the base of the defect, and the other three sides of the graft are totally separated from this natural source of cells for angiogenesis and cellular ingrowth.

Prior to placement of the graft material, the recipient site should be free of soft tissue remnants, bone decorticated, and initial fixation of the membrane should be completed. When placing graft material into a bony defect, ideally a systematic layered approach should be utilized consisting of three layers which is dependent on the size and location of the graft site.

Layer # 1: Autograft (Optional)

The first layer of the guided bone regeneration graft is comprised of autogenous bone. Autogenous bone is usually indicated in any bony defect which requires horizontal bone growth of greater than 3 mm or in all cases of vertical regeneration. Autogenous bone harvesting today is typically harvested from any exposed region of cortical/cancellous bone present in the oral cavity. In the maxilla, donor sites are often available apical to most implant sites and in the tuberosity area. In the mandible, in the lateral aspect of the

ramus provides a bountiful source of cortical bone which may be harvested via numerous techniques.

Ramus Graft Harvest

Incision and Reflection. The incision for harvesting a graft in the ramus region starts at the level of the occlusal plane and proceeds down the external oblique ridge a short distance until it extends medially to the distal buccal aspect of the second molar or that same region if the area is edentulous. The incision continues anteriorly, following the crest of the ridge or following the sulcus to the distal aspect of the first molar or premolar, where a vertical release is usually prepared. The incision should always be located lateral to the retromolar pad to avoid any possible damage to the lingual nerve. The flap is reflected laterally to expose the cortical bone distal to the terminal molar and a minimal exposure of the lateral aspect of the ramus.

Ramus Harvesting Techniques. To harvest cortical bone from the ramus, numerous techniques are available;

Lateral Ramus Block: A cortical block may be harvested from the ramus and broken into smaller cortical particles. The amount of surface area obtained from smaller particles is much greater than what could be obtained by fixating an entire harvested block. The harvested block is processed by breaking the block into small pieces using double-action rongeurs. Use of large particles is not recommended, and complete destruction of the block with a bone mill has also not produced the results found with reasonable sized particles. The preparation of dense cortical bone has always presented a challenge in block grafting when an irregularly surfaced cortical graft needs to be trimmed and reshaped for adaptation in a graft site. In the case of particulate grafting, the complete piece of cortical bone must be broken into small pieces before it can be used. Control of the graft particles during this process is critical because loose particles can be easily lost or contaminated as the graft is processed. Autogenous bone harvests are challenging, and loss of critical bone particles or blocks can cause unnecessary time delays and patient discomfort if additional bone needs to be harvested to replace a contaminated block.

The particulate grafting technique described in this chapter requires that a piece of a cortical block be completely broken up into small particles that are then packed into irregular bony defects. These small particles tend to "shoot out" of the rongeurs if they are not carefully contained. The best way to eliminate the loss of these cortical particles is to fill a clear, shallow glass beaker or bowl with saline. The block is then submerged in the saline, and double-action rongeurs are used to break it up into the particle size needed for the procedure. The saline slows escaping particles in the same manner that water slows the movement of a bullet that is fired into water. The bone is typically broken up into 1 × 2 mm particles for placement in the graft site. (Figs. 36.48).

Scraping Technique: Another option of obtaining autogenous bone is removing cortical bone chips from the external oblique ridge. A double action rongeur may be used to remove small fragments from the exposed bone. The scrapings may be placed into a sterile surgical bowl with sterile saline. Another option of obtaining cortical chips is with the use of specific manufactured "scrapers", which not only harvest the bone, but also collect it within the scraper device. And lastly, piezosurgery units may be used with dedicated scraper tips. (Fig. 36.49).

Trephine Technique: The use of trephine burs (i.e. cylindrical end-cutting burs) have been advocated to harvest bone from the ramus area. These end-cutting burs that are available in various diameters, with the 6–8 mm trephine being the most popular for

• **Fig. 36.44** Tent Screw Size (A) Older generation tent screws of various diameters and head size, (B) Newer tent screws with larger, convex head which allow for more ideal space maintenance.
• **Fig. 36.45** (A). Tent screws used to stabilize membrane to achieve desired contour. (B) Postoperative results of bone growth to ideal contours.

harvesting bone from the ramus. One half of the trephine bur is placed over the external oblique bony ridge, while the other half is lateral to the bone and above the reflected masseter muscle, which is elevated off the anterior lateral aspect of the ramus. The trephine bur is used with an angled surgical drill at 2,000 rpm with copious saline irrigation, to a depth of approximately 5–8 mm, making sure the cuts are above and lateral to the position of the inferior alveolar nerve (IAN), artery and vein. The IAN position should be identified via a CBCT exam survey.

Ramus Recipient Site Closure. After removing the harvested donor bone the donor site is filled with a double layer of collagen tape before closing the wound with a combination of interrupted and mattress sutures. This closure is monitored as each suture is tied to confirm that there is no flap tension. The use of Vicryl or Teflon (Cytoplast) sutures is recommended to allow the implant clinician the opportunity to remove the sutures when he or she feels the wound

has adequately healed. Due to the nature of soft tissue in the ramus region, overlapping tissue margins can contribute not only to postoperative opening of wounds, but also to a lengthy recovery process.

Additional Harvest Sites. Maxillary Tuberosity Donor Site: The maxillary tuberosity offers a variable amount of trabecular bone, which is dependent on the extent of maxillary bone atrophy and maxillary sinus pneumatization. The cancellous nature of the bone allows it to be molded into the extraction socket. The tuberosity should be evaluated with a CBCT survey to determine the maxillary sinus location and the amount of host bone present.

Tori: The use of cortical bone harvested from lingual tori has been shown to produce excellent results. This is dense cortical bone, and large amounts of bone can be harvested from the typical lingual donor site. The use of Piezosurgery techniques allows the tori to be separated from the mandible without the threat of injury to underlying anatomic regions. There has been no noted difference
• **Fig. 36.46** (A to D) Screw placement literally determines the final contours of the augmented graft site. The screw head should never be placed higher than the level of the adjacent interproximal bone. When large head screws are used on the buccal aspect, the uppermost edge should be angled slightly to prevent its sharp edge from perforating the membrane. The best location for the largest diameter screw heads is lower down in the graft site where lateral support is needed.
• **Fig. 36.47** (A-D) The screws have been used in these varied surfaced defects to define a smooth final ridge contour that will allow implant placements in proper locations specified by the restorative wax-up.
• **Fig. 36.48** Ramus Autograft Harvest With Piezosurgery Unit. (A) Piezo cuts made in ramus bone. (B) Block removed. (C) Harvested block. (D) Block bone made into particulate chips.

in the final graft quality when tori were used as the donor source in regeneration cases (Fig. 36.50).

Placement of Layer # 1. The small autograft chips or small particulate pieces are placed directly on the host bone surrounding the bone screws. Because of the extensive nature of grafts requiring autogenous bone, at least 50% of the graft volume should be made up of this autogenous bone, with allograft compromising

the second layer. Graft particles are transferred from the bowl to the graft site with cotton forceps or a Molt curette. A bone or amalgam plugger with a small end can be used to manipulate the particles between the various screws. This process fills most of the defect and voids, regardless of the topography of the recipient site. It should be kept in mind that the volume of this graft is clearly defined by the levels of the heads of the bone screws. The screws have been positioned in a manner that defines the outermost borders of the desired bony ridge, corresponding to the requirements of the restorative plan and the needed sites for implant placement (Fig. 36.51).

Particulate Graft Material Options. There are many optional techniques and materials for use in regenerative graft procedures. Successful application of these techniques requires that the clinician have a comprehensive understanding of the various types of bone grafts and bone substitutes available, and the inherent advantages and disadvantages of each material. The ideal characteristics of a bone substitute include biocompatibility, low incidence of infection and immunogenicity, predictable maintenance of space over time, and the ability to be replaced entirely with new, viable bone growth. To comprehend the concept of bone regeneration and to select the ideal bone graft material, the implant clinician should have a strong understanding of bone biology.

Allograft Bone. Allogenic bone is harvested from an individual of the same species and transplanted to a genetically different individual. Allografts are considered to be one of the best sources for supplementation of an autograft or as an alternative to an autograft. Allografts are available in many different preparations, with the most common being FDBA and demineralized FDBA (DFDBA). Although their biological properties vary, they

• **Fig. 36.50** Tori Bone Harvest: (A) Tori Exposure (B) Harvested Tori.
• **Fig. 36.51** Delivery of bone particulate around the tenting screws: (A) Autogenous cortical particles have been placed around the screws on each side of the defect. The allograft application has been started in the center region and it will then be placed over the autogenous particles. (B) Autogenous bone particles have been placed around the fixation screws and the screw lengths are visible in the adjacent region where graft has not been positioned yet. (C) The allograft is placed over the autogenous bone on the right side before the layers are started on the opposite side. (D). The particulate has been placed over the entire recipient site and the membrane is ready to be drawn over the entire region.

generally exhibit osteoconductive qualities with reduced osteoinductive properties found in DFDBA. FDBA and DFDBA offer the advantage of decreased patient morbidity secondary to the elimination of the need for a second surgical site.

Allografts undergo extensive and rigorous processing procedures. First, allografts are processed by freeze-drying the graft at approximately –15°C to –20°C, allowing for easier handling and a decreased antigenicity. The main drawbacks of freeze-dried bone include the potential risk for cross-infection and the possibility of immunologic reactions because of its protein content. The possibility of disease transmission cannot be completely eliminated; however, there are no documented cases of disease transmission related

to the use of allografts in dentistry after completion of more than 1 million cases in a 25-year period.[57] In addition, allografts have been related to variations in sample quality related to age and the health variations of the donor. These variations in the regenerative properties of a specific sample indicate the possible importance of using a sample from a single donor rather than a donor pool. Allografts are primarily osteoconductive materials, with some reduced osteoinductive properties in demineralized bone matrix preparations.

Types of Allografts. The most common allografts used in implant dentistry have varying characteristics. For example:

- DFDBA is osteoconductive and osteoinductive. The material consists of highly processed bone with at least 40% of the mineral content of the bone matrix being removed by 0.5 to 0.6 M hydrochloric acid until the calcium content is reduced to less than 2%.[58] This allows for increased availability of matrix-associated BMPs or growth factors that allow the graft to become osteoinductive.
- FDBA is an allogenic bone that does not undergo the demineralization process. Also referred to as "mineralized" because the mineral content has not been reduced, FDBA has the same BMP content in its organic matrix. However, it does not have the same osteoinductive capability as DFDBA. FDBA has been shown to be a better scaffold for osteoconduction than DFDBA, which allows for superior space maintenance.[59] Eventually osteoclasts break down the mineral content of FDBA until demineralization occurs, inducing new bone formation and a prolonged protein release.

Particle Form and Size. The allograft particle form and size contribute to the predictability of bone regeneration.

- **Ideal particle form:** Allografts are available in three particle forms: cortical, cancellous, and cortico-cancellous. Cortical allografts are associated with an increased density and greater space maintenance properties, subsequently allowing a slower resorption rate. Cancellous chips are advantageous because they allow for osteoconductive scaffolding and deposition of osteoblasts while also allowing a faster resorption rate. The cortico-cancellous mixture allows for the benefits of both cancellous and cortical bone.
- **Ideal particle size:** The particle size of the allograft material is very important in the bone regeneration process, because a particle size that is too small (less than 125 μm) leads to fast resorption with inconsistent bone formation. A larger particle size (greater than 1000 μm) restricts resorption and may be sequestered or result in delayed healing. Studies have shown an ideal particle size for predictable bone regeneration to be approximately 250 to 1000 μm.[60]

Xenografts. Xenografts are bone grafts originating from a different species. Most commonly, xenografts are derived from bovine (cattle) origins, with less common sources including equine (horses) and porcine (pigs). The most common xenografts are natural hydroxyapatite (HA) derived from animal bone and anorganic bone matrix produced from bovine sources. Xenogenic bone grafts exhibit excellent osteoconductive properties and act as a scaffold for newly deposited bone. Although xenografts are available in greater supply than allograft materials, they have been shown to exhibit elevated inflammatory responses, along with a slow and inconsistent resorption process. Consideration must also be given to the risk for cross-contamination with bovine spongiform encephalopathy or porcine endogenous retroviruses. Unfortunately it has been shown to be difficult to adequately screen xenografts for the possibility of a viral presence[61] (Fig. 36. 52).

Alloplasts. Because of the remote possibility of disease transmission from allografts and xenografts, some in the literature have advocated alternative bone substitute options. Alloplasts, which are synthetic, are a biocompatible option for the implant clinician. Alloplasts have the advantage of relatively no immunogenic responses, and there is no risk for disease transmission. These materials have been shown to be osteoconductive, with an interconnecting pore system that serves as a scaffold for the migration of bone-forming cells.[62] Unfortunately many alloplastic grafts do not allow the graft material to be replaced with vital bone cells, which results in nonvital bone at the implant interface.

Types of Alloplasts. A wide range of synthetic materials for allografts have been developed, such as synthetic HA, β-tricalcium phosphate, calcium-phosphate cements, and glass ceramics.

- HA is the basic component of inorganic bone and exhibits a similar chemical composition to natural bone. HA is most commonly processed from natural reef coral skeletons or homogenized calcium-phosphate powder. It is not only biocompatible and osteoconductive, but also has excellent space-maintaining qualities. However, synthetic HA has shown unpredictable and slow degradation after approximately 1 to 2 years.[63]
- Tricalcium phosphate has a calcium-to-phosphate ratio of 1.5, which is much lower than HA and results in less compressive strength. Calcium phosphates resorb 10 to 20 times faster than HA, and their macroscopic mechanical properties are inadequate for load-bearing surfaces because of their inherent brittleness. Because of the fast biodegradation rate, this bone can be unpredictable and is not consistent with adequate bone deposition.
- Carbonate apatite with collagen has been shown to resemble bone more than any other calcium phosphate available. The inorganic content of bone contains approximately 7% carbonate by weight.[64] Studies have shown that carbonate apatite exhibits a more controlled resorptive pattern, as well as excellent osteoconductivity and biocompatibility.[65] When carbonate apatite is combined with collagen, the biological stability and strength are increased, which allows the scaffolds to act as a delivery vehicle for growth factors and living cells for bone formation.[66] Scanning electron microscopy studies have shown that the highly porous and interconnected structure ensures a biological environment that is conducive to cell attachment, proliferation, angiogenesis, and tissue growth.[67]
- Bioactive glasses are ceramic substitutes that are reinforced by oxides—sodium oxide, calcium oxide, phosphorus pentoxide, and silicon dioxide—and exhibit questionable mechanical strength. They are absorbable and have no risk for disease transmission or immune responses. The bioactive ceramics exhibit improved mechanical properties relative to bioactive glass, but they are still brittle enough to fracture when subjected to cyclic loading. To improve their resistance to fracture, methods of incorporating stainless-steel and zirconia fibers have been performed. Studies have shown questionable efficacy of bioactive glasses with respect to osteoconduction qualities and the ability to bond to tissues (bioactivity).[68]

Layer # 2 Summary. The second layer of the graft is ideally made up of particulate allograft that is placed over the top of the autograft (i.e. or 100% allograft for smaller defects < 3 mm). The allograft should veneer over the screw heads, however care should be exercise to not "overfill" the graft site. The recommended allograft bone type is either 70% mineralized / 30% demineralized or a cortical/cancellous mixture of mineralized bone. It is highly recommended that the ridge be overdeveloped rather than underdeveloped. Excessive overfilling of the graft site may lead to difficult tissue closure and increases the possibility of incision line opening.
• **Fig. 36.52** There can be very substantial variations in the density of matured graft sites, depending on what type of graft was used initially. The delayed turn-over of bovine particulate can greatly affect the density when an implant is placed before the complete substitution cycle has been completed. (A) PepGen15. (B) OsteoGraf 300/FDBA. (C) 90% autogenous/FDBA. (D) Mix of autogenous/bovine/FDBA.

Layer # 3: Final Implant Placement

After the graft material (Layers # 1 and # 2) is ideally positioned, the membrane (previously fixated apically or lingually) is stretched over the graft site. The membrane should be of sufficient size to totally encompass the entire graft. The goal of the membrane fixation is to not allow any movement, which could negatively affect the wound healing. In most cases, the final fixation is on the palatal aspect of the ridge with two tacks. Additional fixation can be used as needed in large graft sites to limit membrane movement.

Bone Growth Factors

Bone growth factors can be a significant part of the bone-grafting process as they may enhance the formation and mineralization of bone. In addition, bone growth factors may induce undifferentiated mesenchymal cells to differentiate into bone cells that trigger a cascade of intracellular reactions for the release of additional bone growth and cell-enhancing factors. These growth factors actually bind to specific receptors on the surface of target cells directing a more timely healing process. More than 50 known growth factors have been identified and categorized according to their specific contributions to the functions in bone healing. The two most common bone growth factor techniques utilize blood concentrates and recombinant human Bone Morphogenetic Protein-2.

Blood Concentrates. Most blood concentrates used in implant dentistry today are direct derivatives of platelets. The platelet, also called a thrombocyte, are blood cells that are primarily involved in the blood clotting process. A unique secondary function of a platelet is to release a wide range of growth factors that enhance collagen production, cell mitosis, blood vessel growth, cell recruitment, and cell differentiation.[69]

The two most utilized and studied platelet concentrates in implant dentistry today are platelet-rich plasma (PRP) and platelet-rich fibrin (PRF). The first-generation blood concentrate, platelet-rich plasma, was first introduced by Marx in 1998. His studies showed bone maturity to be twice as effective with the use of PRP in grafted sites, and the addition of PRP increased bone density up to 30% in healed sites.[70]

A second-generation blood substitute, platelet-rich fibrin, was first described by Choukroun in 2001. This concentrate has been shown to exhibit a much simpler processing protocol in comparison to PRP. PRF is very effective in the release of important growth factors present in platelets, such as platelet-derived growth factor (PDGF), transforming growth factor beta (TGF-ß), insulin-like growth factor (IGF), fibroblast growth factor (FGF), and epithelial growth factor (EGF). [71] (Box 36.9) Multiple clinical studies have shown increased soft tissue healing, enhanced healing of grafted bone, promotion of angiogenesis, and faster wound healing.[72–74]

The internal organization make-up of platelet rich fibrin is rather unique as it contains three adhesive molecules (fibrin, fibronectin, and vitronectin) that result in a highly elastic, matricial mesh architecture. This complex three-dimensional structure allows for a longer release of growth factors. As the platelets degranulate, a sustained release of growth factors may range from a time period of one to four weeks.[75]

1. **Platelet-derived growth factor (PDGF)**
   - Stimulates fibroblast mitogenesis and collagen synthesis
2. **Transforming growth factor beta (TGF-β)**
   - Enhances wound healing via endothelial angiogenesis
3. **Insulin-like growth factors (IGF)**
   - Enhances rate and quality of wound healing via bone matrix formation and cell replication
4. **Epithelial growth factor (EGF)**
   - Increases angiogenesis and epithelial mitogenesis
5. **Fibroblast growth factor (FGF)**
   - Increases angiogenesis, epithelialization, and fibroblasts
6. **Vascular Endothelial Growth Factor (VEGF)**
   - Increases endothelial growth factor and angiogenesis

PRF is an autologous fibrin matrix that incorporates platelets, leukocytes, cytokines, and circulating stem cells that are gradually released to accelerate physiologic healing. It is easily obtained and does not require any biochemical blood handling.[52] After drawing blood and placing in a centrifuge for 12 minutes, the coagulation cascade will be triggered. The end result is a fibrin clot in the middle layer, situated between the acellular platelet-poor plasma and the red blood cells. When this fibrin clot (PRF) is used as a membrane, it will help isolate and protect the wound while serving as a matrix to accelerate healing. When the PRF is mixed with the graft material (allograft), the fibrin clot acts as a biological connector between all of the elements of the graft, while also acting as a matrix that initiates angiogenesis, stem cell accumulation, and migration of osteoprogenitor cells to the graft. Thus the synergistic effects of the fibrin matrix and growth factors allow for the enhanced healing of the hard and soft tissues. Studies have shown that PRF with freeze-dried bone allograft (FDBA) heals faster than FDBA alone.[53]

The second-generation blood concentrate platelet rich fibrin (PRF) has been shown to be advantageous in comparison to platelet rich plasma (PRP):

- Is naturally polymerized and requires no chemical use
- Requires a conventional, single spin centrifuge
- Has a slower release of growth factors
- Is more efficient with cell migration and proliferation
- More advantageous fibrin network that stores cytokines and growth factors
- Better healing properties
- Less disposables required resulting in less expense

Platelet Rich Fibrin Uses. With bone augmentation procedures, PRF may be used as either a membrane or added to the particulate bone grafting material. Studies have shown that PRF is advantageous in healing during regenerative procedures either as a membrane or when added to particulate bone.[76] Because the PRF membrane resorbs rather fast (~ 7 days), it is not the most ideal membrane to be used to prevent soft tissue invasion. Therefore, usually the PRF membrane is placed over the primary membrane (e.g. collagen) to aid in hard and soft tissue healing (Figs. 36.53).

Recombinant human bone morphogenetic protein-2. Recombinant human bone morphogenetic proteins (rhBMPs) are a group of sequentially arranged amino acids and polypeptides that are osteoinductive proteins, acting to initiate, stimulate, and amplify bone morphogenesis. BMPs stimulate mesenchymal stem cells to induce bone formation via differentiation to osteoblasts, which form and mineralize new bone. BMP-2 has been purified,

sequenced, and cloned, and is marketed as rhBMP-2 (recombinant human bone morphogenetic protein-2; Infuse; Medtronic, Inc., Minneapolis, Minn.). Infuse bone graft consists of two components: a 1.5 mg/mL concentration of rhBMP-2 and an absorbable collagen sponge. Studies have shown rhBMP-2 with titanium mesh to be an effective treatment for augmentation of the deficient bony ridge before implant placement.[54] The new bone formed by rhBMP-2 has been shown to be similar to native bone and can withstand the stresses of implant placement and prosthetic function.[55]

Step 9: Closure

The final closure of the bone graft site is one of the most important steps of the grafting process. Ideally, a tension-free flap adaptation is the key to predictable results. If a poor suturing technique is used, incision line opening may result, which significantly increases the morbidity of the procedure. Therefore, meticulous principles should be adhered to with respect to a tension-free flap, ideal suture technique, and the close post-operative evaluation of the surgical site.

The type of suture selected should include a high tensile strength material. The most common suture materials used today include vicryl (absorbable) or PTFE (nonmabsorbable). The primary principle of wound closure in GBR cases is attaining a completely "tension-free" closure over the submerged graft. Specific attention must be directed to proper approximation of the margins of the flap to confirm there is no overlapping of the tissue flaps.

Usually the combination of horizontal mattress and interrupted sutures are used to close these graft sites. One of the primary advantages of using the horizontal mattress sutures is the ability to "evert" the tissue margins. By everting the margins of the flap outward, the connective tissue layers will be approximated against each other. A flap closure that "overlaps" two flaps is actually placing the connective tissue layer of the first flap over the epithelial layer of the adjacent flap. This type of poor approximation leads to at best a weak suture line and most often an open margin postoperatively. Additional interrupted sutures may be used to approximate all edges of the wound. The vertical incisions may be closed with 5-0 Chromic, as they may greatly reduce the post-op formation of tissue scars.

(Fig. 36. 54). (Fig. 36.55 A, B, and C) (Fig. 36. 56).

Postoperative Treatment

Provisional Restoration

The successful maturation of a bone graft site requires that the area be completely protected from micromovement of the isolating membrane and the underlying graft material. A successful graft is totally dependent on blood clot adhesion, capillary ingrowth, and the introduction of associated growth factors for predictable healing. It has been estimated that micromovement of 25 μm over a graft site can decrease the final graft volume as much as 40%. Therefore, disruption of any kind will consistently yield compromised results in mature graft development, if not full graft failure.

The most common source of daily pressure on a site occurs when the patient's transitional appliance has contact with the surface of the graft site. If possible, a fixed bonded transitional bridge should be placed over the graft site because it totally prevents contact with the underlying graft site. If this is not possible and the patient insists on a temporary prosthesis, plans for a carefully constructed removable partial denture should be formulated. A transitional prosthesis (flipper or removable partial
• **Fig. 36.53** (A) PRF used as a secondary membrane over the primary membrane, (B) PRF may be added to the graft material, (C) Sticky Bone, (D) Platelet Poor Plasma may be used to hydrate the primary (collagen) membrane

denture) must be modified to eliminate any significant contact with the graft site. If a removable prosthesis is absolutely necessary, all buccal flanges should be removed, and if possible, the acrylic should be altered to create regions of support on the lingual surfaces of the adjacent teeth. Occlusal rests should be used, or in cases where this is not possible, there must be good adaptation of the prosthesis to direct the forces to alternative stress-bearing areas (i.e., tissue areas away from the graft site that take the pressure off the graft site).

Essix appliances allow temporary replacement of teeth in narrow span regions, allowing long-term prostheses to be fabricated after the initial healing process has been completed. However, the Essix appliance does have disadvantages related to esthetics, fracture, wear issues, and discoloration. The Snap-On Smile appliance (Den-Mat Holdings, LLC) has been used successfully over longer-span edentulous regions with more pleasant esthetics that and increases patient acceptance (Figs. 36.57) (Fig. 36. 58) (Fig. 36.59).

Development of Ideal Bone Density in Regeneration Sites

The sole purpose of ridge augmentation and bone grafting is to develop a dense, stable volume of bony support for implants of appropriate sizes and numbers that are placed in the locations specified by the restorative plan. The quality and density of the

• **Fig. 36.54** Bone Graft Suturing. Polytetrafluoroethylene (PTFE) sutures over ridge with minimal tension from the vertical release incisions.

final graft development are important because a weak and granular implant osteotomy site is more susceptible to crumbling during implant insertion. These granular ridges can also resorb when the implant is loaded and stress is placed on the coronal aspect of the implant-bone interface. As clinicians plan augmentation procedures, they must understand the limitations of the materials that they are using and the techniques that are going to be used.

• **Fig. 36.55** (A, B, C) Polytetrafluoroethylene sutures over ridge with minimal tension from the vertical release incisions.
• **Fig. 36.56** Alternative Lingual Suture Membrane Fixation. (A) Tack placed in palatal cortical plate with suture started through the palatal flap, passing below the flap and back through the membrane. (B) The suture is then passed back from beneath the flap and out again.

Misch[56] created a system of bone densities for implants, ranging from D1 (hardest) to D4 (softest/most porous). These divisions encompass the acceptable ranges for the placement and rigid fixation of implants. Successful regeneration procedures develop a final osteotomy site that provides adequate bone volume in a dense, firm, manageable form that has a large number of vital bone cells that will easily integrate with the titanium implant body.

Success in bone grafting requires a thorough knowledge of the variety of grafting materials that are available and their capacity to be readily replaced with vital bone on a timely basis. The ultimate goal is a clear understanding of the concepts of osteoinduction and osteoconduction, which is critical for predictable grafting success. It is easy in the incorporation of regeneration into a practice routine to simply open a bottle of bone for use in a surgical procedure, instead of preparing to open a second site for a cortical bone harvest. Unfortunately, the characteristics of different types of bone graft vary greatly and in the long term this can significantly affect the volume and quality of the regenerated bone. It is vitally important that the clinician have a strong understanding

and foundation of the use and indications of the available bone grafting materials (Box 36.10).

Graft Maturation Healing Times

As time frames for graft maturation are considered, it must be kept in mind that this whole approach to grafting is a "substitution" process where the grafted bone is eventually going to be replaced with newly developed natural bone. For adequate healing the graft must be given sufficient time to resorb and for new bone to be regenerated in its place. This process varies considerably as different graft types are considered. A common issue with clinicians early in their learning curve is trying to use a "fixed" healing time period for all particulate grafts.

Ideally many factors must be taken into consideration when determining the healing time. One of the most important

---

• **BOX 36.10** GBR Bone-Grafting Options

1. **Autogenous Grafts:** a graft removed from one anatomic location and placed in another location in the same individual
   Donor sites: tuberosity, ramus, symphysis, iliac crest, etc. (coagulum, particulate, block grafts)
   Indications: used as the 1st layer in GBR procedures which require > 3 mm of bone growth (horizontal) or vertical bone growth
2. **Allograft**: grafts taken from the same species—human cadaver
   a. **Osteoinductive Allografts**: grafting materials that provide a biological stimulus (proteins and growth factors) that induce the progression of mesenchymal stem cells and other osteoprogenitor lineage. (Example: Demineralized Freeze Dried Bone Allograft {DFDBA})
   b. **Osteoconductive Allografts:** relatively inert filling materials that integrate with new forming bone. Osteoconduction is the process that permits osteogenesis when cells already committed to bone formation are also present in a closed environment.
   (Example: Mineralized Freeze-Dried Bone Allograft {FDBA})
   Indications: used as 2nd layer for grafts > 3 mm or as sole grafting material for grafts < 3 mm
      Options: 1. 70% FDBA / 30 DFDBA
               2. 100% FDBA (Cortico-Cancellous)
3. **Xenograft:** osteoconductive graft from another species
   (Examples: Bovine {Bio-Oss, Bio-Oss porcine, and equine)
   Indications: rarely used in GBR protocols
4. **Alloplast:** osteoconductive—a chemically or naturally derived nonanimal material
   (Examples: Hydroxyapatite, Bioglass, calcium sulfate)
   Indications: rarely used in GBR protocols
5. **Biologics:** cell-based therapies, growth factors, and osteoconductive matrices, that clinically enhance bone regeneration
   (Example: Emdogain, recombinant human bone morphogenetic protein-2, platelet-rich plasma, platelet-rich fibrin)
   Indications: elective use, however highly recommended in larger graft cases

---

factors is the number of remaining walls of bone that surround the recipient site. In general the larger the number of walls surrounding the graft, the shorter the healing time. The second factor is the use of autogenous bone within the graft. The more autogenous bone used, the shorter is the healing time. The quantity of allograft is a significant factor because the greater the amount of allograft, the longer the required healing period. This is directly tied to the time needed for adequate angiogenesis. The type of bone used is also significant with the healing time: autogenous (fast), allograft (moderate), xenograft (slow), and alloplast (slow to unpredictable bone turnover). Lastly, systemic diseases such as diabetes, hyperparathyroidism, thyrotoxicosis, osteomalacia, osteoporosis, and Paget's disease may all affect the healing response. (Box 36.11)

In summary, it is always best to err on the side of safety and allow for more bone healing time. For most cases involving graft sites composed entirely of allograft, 6 to 8 months is recommended when graft volumes are less than 4 mm in dimension. In similar sites with larger graft volumes (>4 mm), 6 to 10 months is highly recommended. Premature reentry into the graft may initiate many complications. In cases of poor or delayed healing, the quality of bone will be very weak and granular, similar to D5 bone. This type of bone is very soft and prone to overpreparation, ultimately resulting in a poor bone-implant contact. If this situation is encountered, the surgical implant placement protocol should be altered with underpreparation of the osteotomy, osseodensification techniques

---

> • **BOX 36.11** **Factors That Affect the Healing Time of Particulate Grafts**

and/or the use of osteotomes. The concepts of ridge remodeling after loading should be seriously considered, and placement of additional layers of xenograft with membrane coverage should be used. Overall, patience in graft maturation is critically important.

Bone-Grafting Complications

Incisive Canal Involvement in Regeneration Sites

Implant restorations in the anterior maxillary region present one of the most difficult challenges in dentistry today. The combination of esthetic demands, biomechanical/functional issues, and phonetic challenges require implant placement in ideal positions. The incisive foramen is the exit point of the nasopalatine canal, where the terminal branch of the descending palatine artery and nasopalatine nerve pass into the oral cavity. The proximity of the incisive foramen and the path of the canal must be evaluated in all maxillary incisor implant treatment plans because there can be significant variations in the size, position, and angulation of the nasopalatine canal and the exiting foramen. As the bone around the maxillary central incisors resorbs, the zone of available bony support moves palatally, frequently encroaching on the incisive foramen.

Defining the dimensions and pathway of the nasopalatine canal with CBCT imaging allows the surgeon to decide whether implants can be placed within the required restorative space or whether augmentation will be needed for ideal placement. This is particularly important in cases involving immediate implants because the lingual angulation of the immediate implant osteotomy could potentially fenestrate into the incisive canal. A fenestration in the side of an osteotomy allows neural/fibrous tissue invasion into the osteotomy, retarding bone growth and rigid fixation of the implant.

Axial CBCT images provide the most accurate view of the size, shape, and location of the canal in respect to the possible implant sites. Use of CBCT cross sections and three-dimensional images can also help determine the positions and dimensions of this important anatomic variant. The clinician must be aware of a possible widening of the canal above the level of the foramen, creating a fenestration between the canal and the osteotomy in the more apical regions of the osteotomy. As the cross sections of the CBCT are reviewed, the possible presence of a nasopalatine cyst should be ruled out, and edentulous arches should be reviewed for an enlarged foraminal dimension, as is often noted. The positions of implants in central incisor regions where the foramen is involved should be adjusted distally where an FP-1 restoration does not require a specific placement. This slight adjustment distally prevents fenestration on the mesiopalatal line angle, where this deficiency most likely will occur.

Severe bone resorption on the facial aspect of the maxilla reduces the ridge thickness to surprising extents, often leaving only a thin ridge that is positioned well to the palatal aspect of the required location for a central incisor implant. It should be kept in mind that a line between the cingula of the two cuspids passes directly over the incisal foramen. Subsequently, if an implant is placed this far palatally, the emergence profile will originate at a significantly proclined angle and the complete restoration will be palatally positioned. Cases such as this require that the seriously deficient ridge be regenerated before implant placement.

Regions that are determined to be deficient will require facial augmentation using techniques that are capable of generating sufficient lateral/vertical bone volume for proper implant placement and restorative success. Cases where the implant can be moved slightly in a distal direction can sometimes prevent the need for major augmentation. Another option in a FP-3, RP-4, or RP-5 case is the obliteration and grafting of the nasopalatine canal, which can aid in providing significant bone volume for implant placement into vital bone and potentially creating a better ridge consistency on maturation. (Fig. 36.60)

Releasing the Tissue Flap From Underlying Tenting Screws

Flap reflection is a basic procedure that is common in all surgical applications. Correct tissue manipulation allows the flap to be released and reflected without tearing or damaging the underlying periosteal layer. The use of bone fixation screws in particulate grafting techniques creates a complicated situation for flap reflection because the fibrous tissue layer of the periosteum surrounds the head of the screw and any exposed portion of the neck of the screw. As the flap is reflected away from a screw insertion site, this fibrous layer must be released before the flap can continue to be drawn away from the region.

This binding attachment cannot be easily drawn over the screw heads, and there is a potential to create perforations or tears in the flap as it is released. Flap reflection in this situation starts with a simple full-thickness crestal incision that is prepared over the graft site. Flap release is initiated with a sharp curette that is used to release the flap and to reflect the periosteum, scraping side to side until the full flap can be elevated. As the flap is released, the bone fixation screws must be freed from the thick layer of fibrous tissue that adheres to the screw head. A #12 scalpel maybe used to sever the fibrous layer over the screw, and a sharp curette is then used to continue the flap release until another screw is encountered. Once the flap has been completely released, the fixation screws are accessible for removal before placing the implants (Fig. 36.61).

Exposure of the Bone Fixation Screw During the Healing Process

Bone fixation screws in regeneration sites sometimes become exposed during the healing process, potentially leading to bacterial invasion around the neck of the screw. Careful attention to the time lines of the screw exposure and the type of regenerative process is important in these situations. It is not uncommon for the tissue covering the heads of the fixation screws to become very thin. This paper-thin tissue allows the color and contour of the screw heads to be visible and palpable. This is of no significant concern, and the only precaution is directed to relief of any removeable appliance that could be placing pressure on the
• **Fig 36.60** Incisive Canal Approximation (A) Two implants in # 8 and # 9 positions after significant bone augmentation, note that even with augmentation, implant placement impinging on incisive canal, (B) After extensive maxillary grafting, anatomical limitations of the incisive canal contraindicates implant placement.
• **Fig. 36.61** Bone Screw Removal. (A and B) The flap has been completely released and the fixation screws are accessible for removal (before placing the implants). (C and D) Bone must be removed from inside the screws before attempting removal with either a 12 blade or periodontal scaler.

already tender and thin tissue. If at any time the actual head perforates through the tissue, it should be considered for removal.

Exposure of fixation screws in particulate grafting occurs when the head of the screw works its way through the overlying membrane and eventually perforates through the thin layer of the mucosa that covers the graft site. This typically happens when the screw head has a thin diameter that perforates through the membrane and eventually through the tissue. Particulate grafting techniques use these fixation screws to support the membrane and to define the shape of the desired bony contours. The use of a

screw with a "wide head" is found to be important for predictable results. The type of membrane used for graft isolation also makes a significant difference when perforation of the screw through the membrane is a concern. Acellular dermal matrix and pericardium tend to be very resistant to membrane perforation during the healing process, whereas collagen membranes are soft when moistened and tend to perforate and tear if strain is placed on the hydrated membrane. Perforation of a membrane allows the ingress of foreign matter and fibrous soft tissue cells into the graft site, causing a disruption in the bone regeneration process. If the head of the

screw pushes through the soft tissue and is exposed, bacterial contamination may result, potentially leading to graft infection and possible failure.

The head of the bone fixation screws should have a wide and smooth diameter that provides enough surface area to support the membrane and to limit abrasion against the overlying mucosal layer. A small head will tend to work its way through a membrane when it is placed under tension or where a delicate membrane is being used. The typical bone fixation screw has a diameter of 1.5 mm, and the head of the screw should be as wide as possible. Newer generations of fixation screws have been designed specifically for membrane grafting, and they provide a very wide surface area for even support of a membrane. These larger heads also support such a large surface that the actual number of fixation screws can be reduced significantly.

Exposed screw heads should be maintained with chlorhexidine rinses until the surrounding soft tissue has healed. It is recommended that the screws in particulate techniques be removed at this time to eliminate the possibility of contamination of the graft through the opening around the shaft of the screw. If the screw is preventing pressure on the graft in respect to the use of a removable prosthesis, retention of the screw could be considered. Under no circumstances should efforts be made to cover the screw by repositioning the soft tissue (Fig. 36.62).

Incision Line Opening in Bone-Grafting Sites

Maintenance of complete soft tissue coverage over healing bone-grafting sites is one of the most important principles that must be observed for predictable grafting success. Any time that the healing graft site is exposed to the oral flora during the healing process, there will be some type of compromised change in the final graft site volume and in its overall integrity. Incision line opening with compromised graft results can often be a major limiting factor in successful implant placement.

Incision line opening can compromise even the most carefully planned regeneration site, and most of these graft sites will require additional grafting at a later time if an actual complication develops. An open incision line introduces numerous potential complications into the healing process. First, the introduction of microorganisms into a graft site through an open incision can lead to an infection in the healing graft site. Exposure of the graft particles and the presence of purulence is an indication of impending failure of the graft. The infection reduces the pH in the graft site, causing a breakdown of the graft particles and eventually compromising the resulting ridge volume. Second, an open incision line may allow exposure and breakdown of the barrier membrane, contributing to fibrous tissue ingrowth into the graft site. Lastly, there exists a potential for particulate graft materials to escape the graft site, resulting in an inadequate bone volume in the final proposed implant site.

The most important concept in maintaining incision line integrity is consistent tension-free wound closure. This protective seal can be most effectively managed from the standpoint of overall flap management throughout the surgical procedure. A clinician's experience in manipulation of soft tissue affects this aspect of bone regeneration more than any other part of bone regeneration surgery. As the clinician gains more experience in delicate tissue management and begins to understand the maintenance of a tension-free flap closure, problems with graft and membrane exposure will become an uncommon occurrence.

All regeneration sites require that the overlying tissue flap be stretched over the wide bulk of the graft at the completion of the procedure. Unfortunately there is a finite distance that a tissue flap can be freely stretched, and at this point the wound closure is placed under tension. Even though pressure can be exerted on the stiches to force closure of the wound, the incision line is put under an unreasonable amount of stress. The continual tension and pressure will eventually lead to necrosis of the tissue around the sutures, leading to an open incision postoperatively.

The inner surface of a reflected flap is lined with the periosteum: a thin, dense binding layer of tissue that cannot be stretched. The tissue directly below the periosteum is very loose mobile tissue full of elastic fibers. This disparity in tissue types can predictably be neutralized with a shallow incision through the dense periosteal layer. This "tissue release" is accomplished by preparing a clear and continuous releasing incision through the periosteum, exposing the underlying elastic layers of tissue that can then be released for expansion of the flap over the enlarged graft site. As this incision perforates the periosteal layer, the two edges clearly separate, allowing the elastic tissue below the periosteum to stretch. A sharp pair of Metzenbaum scissors is then placed into the space below the periosteum, and as the scissor tips are opened, the tissue easily releases and the edges separate further. This is repeated until the complete flap is stretched over the graft site and 5 mm beyond the opposite flap margin.

In the event of an incision line opening, the patient should be placed on a frequent monitoring protocol to observe the status of the graft material and any grafting hardware present. The oral microflora must be managed with the use of daily chlorhexidine rinses. The clinician must not attempt to suture the site again because healing margins along incision lines feature tissue that cannot, at that time, support the pressure of another suture under tension (Figs. 36.63 and 36.64).

High Mucogingival Junction Following Ridge Augmentation

Major ridge augmentation requires that the soft tissue flap be stretched over the enlarged graft site. Through the process of extending this tissue laterally over a large and bulky graft, the mucogingival junction is elevated to a level that often surrounds the abutment with mucosa. Various approaches are available to prevent or repair this deficiency of keratinized tissue, but the addition of pre-surgical procedures to an already involved series of surgical appointments often prevents implant teams from coping with this situation.

The simplified approach is to place a very wide autologous tissue graft from the palate over the mucosal region prior to the actual augmentation procedure. The main complaint about this approach is the fact that palatal grafts like this have a whiter color after the graft is placed and it really does not match the thin and pink color of anterior restorative sites. Those grafts are better indicated for use in posterior regions.

The best method available in this situation was described by Dr. Esteban Urban who recommends releasing the loose mucosal tissue with a split thickness flap, leaving the underlying periosteum and fibrous tissue intact. The released mucosal flap is sutured apically with multiple 5-0 Chromic sutures, creating an exposed zone of exposed tissue from the top of the ridge to the newly sutured tissue. A thin strip of palatal tissue is removed, and it is sutured along the apical suture line to fixate the repositioned tissue. This technique will ultimately prevent relapse of the mucosal tissue level. A large piece of mucograft (i.e. resorbable collagen matrix - Geistlich Mucograft®) is placed over the exposed periosteum and
• **Fig. 36.62** Membrane Tent Screws. (A) Larger screw heads are more likely to grow bone than smaller screw heads. Note the lack of bone around the small-headed screw on the far right side of the photo. (B) Wide-head bone screw. (C) Tent screws are available in various width shanks and lengths. (D) As the graft heals and the membrane resorbs, the head of the fixation screws are often visible through the thin mucosa covering the healing graft site. This is not a complication, and no special treatment is necessary. (E) Screw perforation through thin tissue. (F) Screw removal before implant placement.

sutured with chromic sutures. This arrangement of tissue, mucograft, and tissue graft create a predictable zone of keratinized tissue on the facial aspect of the implant restoration and the addition of the mucograft basically eliminates any discomfort related to the repositioning of the mucosal flap. (Fig. 36.65 A, B, C, D, and E)

Graft Infection

Graft materials resorb rapidly at a lower pH condition, with HA crystals dissolving at pH 5.5 or less. Infectious environments may contain a pH of 2 or less, which can cause the rapid dissolution of

a graft. Infection may be caused by lack of aseptic surgical technique, incision line opening, or infection from adjacent dental sources. The presence of a localized infection in a bone graft will cause dissolution of the graft material, contributing to graft failure. The severity of this failure can vary depending on the duration of the infection and the onset of the contamination.

The use of proper surgical technique is vital in the prevention of surgical contamination. Preoperative antibiotic regimens, chlorhexidine scrubs, and aseptic technique will limit bacterial contamination at the time of surgery. Proper suture technique and flap design are grafting fundamentals that

Split thickness release of the mucosa, with apical fixation using 5 0 Chromic sutures. (D). Fixation of the free tissue graft at the depth of the newly defined vestibule. The exposed tissue between the tissue graft and the top of the ridge is covered with "Mucograft". (E). Three week post operative image is graft site with new zone of keratinized attachment.

prevent incision line opening that can also expose the graft to the oral microflora. Lastly, the clinician should ensure that all space maintenance components (nonresorbable membranes, titanium mesh, tenting screws) are free from sharp edges that may perforate the mucosa postoperatively, allowing the ingress of bacteria into the graft.

Postoperative examinations must be routinely scheduled, especially during the initial stages of wound healing. The patient must be instructed in hygiene techniques that minimize strain on the incision line, and postoperative chlorhexidine rinses can be used to manage the bacterial microflora. If incision line opening occurs, the patient must be placed on a chlorhexidine rinsing protocol to keep the graft site clean until the granulation is complete. If the patient experiences purulence from the site or general malaise, antibiotic protocols must be commenced immediately. Nonresorbable membranes should be maintained for at least 6 weeks unless the site becomes infected. If this occurs, the membrane should be removed before the situation advances.
• **Fig. 36.66** Piezoelectric Handpiece Trauma. (A and B) The shaft of the handpiece (A) and the insert (B) should not be allowed to contact the soft tissue because soft tissue burns or trauma may result. (C) Ideal position of handpiece and insert with no contact to adjacent tissues.

Ultrasonic Piezosurgery-Related Tissue Injury

The use of ultrasound technology in dentistry first began in the 1950s, and newer Piezosurgery units have been developed using low-frequency ultrasound (10–60 kHz) for the selective cutting of bone. Traditional bone drilling with motorized drills is easily available to clinicians; however, cutting bone with a drill can generate excessive amounts of heat in dense bone, potentially damaging the surrounding tissue. A surgical drill that comes in contact with blood vessels, nerves, or sinus membranes can also cut or damage adjacent vital structures. The use of Piezosurgery in implant surgery has been a welcome alternative to motorized drills in many applications. At the lower ultrasonic frequencies used for Piezosurgery, surgical inserts cut through hard, mineralized bone but do not damage the surrounding soft tissue or generate high amounts of heat. Piezosurgery has been especially useful in implant surgery, where bone must be cut in close proximity to a nerve or blood vessel.

As Piezosurgery has been performed, it has been reported by practitioners that the inserts should not be allowed to function while in direct contact with the soft tissue flap. Earlier surgical units were reported to "heat up the insert tip" during use, and irritations or burns on the soft tissue flap were sometimes detected. This altered tissue issue has not been evident in updated Piezosurgery units, but careful attention must be directed to protection of surrounding soft tissue during ultrasonic insert use. Instructors describe this as an abrasive phenomenon caused by the rapid ultrasonic movement of the tip against the soft tissue. Care must be taken to keep the tissue flap away from the ultrasonic inserts.

Development of any abrasive or burn-type lesion should be treated symptomatically, just as any other oral burn or abrasive lesion would be treated. If there are any signs of more serious damage, more involved treatment may require appropriate referrals for wound care (Figs. 36.66 A, B, and C and 36.67).

Summary

To satisfy the ideal goals of implant dentistry, the hard and soft tissues need to be present in ideal volume and quality. After tooth loss, the resorption of the alveolar process occurs so often that augmentation procedures are often necessary to restore the hard and soft tissues. This becomes especially significant when the edentulous areas are in the esthetic zone. Augmentation procedures not only enhance the final esthetic result, but also will make a more predictable biomechanical foundation to minimize possible complications. In implant dentistry today, there exist a vast array or procedures and protocols to augment deficient implants sites. This chapter presented an overview of the indications for guided bone regeneration techniques along with a classification of differing ridge morphology that will allow the clinician to understand the predict ability and difficulty based on the bony ridge deficiency. The following images demonstrate the regenerative potential of current approaches to bone augmentation. Jensen and Terheyden[78] in 2009 reviewed 108 articles and concluded that the mean average of particulate grafting with a membrane was 2.6mm and 24.4% required additional grafting post operatively. As the concept of "Space Maintenance" has been explored over recent years, techniques and barrier materials have improved significantly, changing the ability of surgeons to regenerate ridge defects. The following cases are examples of the ability of these techniques to regenerate large amounts of bone in critical regions. These are not a few "rare cases" that have been cherry picked for this publication. Careful application of the principles described in this chapter have demonstrated similar results on a very predictable basis (Box 36.12 and Figs. 36.68-36.72).
• **Fig. 36.67** Ideal Retraction. (A) The piezoelectric inserts are separated from the surrounding soft tissue with "Pritchard retractors" and wide flap access. (B) Two retractors retract the tissue, whereas the piezo insert prepares the bone.

• BOX **36.12** **Guided Bone Regeneration Protocol**

Step 1: Incision

a. Position—ideally bisect the attached tissue; if compromised keratinized tissue, incision should be made more to the lingual
b. Broad based—release incisions should always be broad based to maintain adequate blood supply to allow for ideal healing
c. Papilla sparing—when possible around adjacent natural teeth, incisions should be made maintaining the papilla; this reduces the chance of altering or losing the papilla and the development of a "black triangle"

Step 2: Reflection

A full-thickness reflection is recommended. The amount of reflection is related to development of adequate exposure to the graft site for placement of bone grafts and barrier membranes. It is also important in preparation of the site for tension-free primary closure.

Step 3: Removal of Recipient Site Soft Tissue

It is imperative that all soft tissue is removed from the recipient site because soft tissue remnants will prevent bone formation. This may be accomplished in various ways including: (1) hand instrument removal, (2) small round burs (#8 carbide), or (3) laboratory straight handpiece burs (carbide, diamond).

Step 4: Decortication

The recipient site should be decorticated to increase bleeding (angiogenesis) and to allow bone growth factors to enter the area, enhancing bone formation. When decorticated, bleeding must be visible through the decortication sites. Cross-cut fissure burs or small, round burs may be used to perforate the cortical plate.

Step 5: Tissue Release

It is imperative the tissue is prepared prior to graft placement to prevent disruption of the graft material. Therefore, the flap is prepared to minimize any tension on the incision line. Ideally, the facial flap should extend a minimum of 5 mm over the lingual flap. There are two techniques which include (1) periosteal release - # 15 blade, and (2) blunt dissection – Metzunbaum scissors.

Step 6: Membrane Placement

a. Membrane selection—the type of membrane will depend on the shape and volume of bone required, the predictability of soft tissue closure (resorbable vs. nonresorbable), and the experience of the surgeon.
b. Hydration—most membranes will need to be hydrated to allow for proper placement and to minimize the possibility of poor closure
c. Fixation—the membrane should be apically fixated with tacks or sutures to minimize movement. Usually the facial/buccal tacks are placed before grafting. This initial stabilization of the membrane allows the site to remain undisturbed after graft placement. It is highly recommended to fix the membrane on the lingual/palatal aspect with tacks or sutures.
d. Adequate periosteal release over the graft site—the tissue should be released enough for the flap to be stretched freely, allowing tension-free closure. Ideally the facial flap should extend a minimum of 5 mm beyond the lingual flap.

Step 7: Space Maintenance

For predicatble bone growth, the space must be maintained to allow the bone grafting material to heal undisturbed. Placement of a support system (tenting screws, polytetrafluoroethylene (PTFE) membrane with titanium, titanium mesh) must be used. Collapse of the graft site will result in compromised bone growth.

Step 8: Graft Material Placement

a. **Autogenous:** Usually, autogenous bone is recommended when bone growth of greater than 3 mm is required. When indicated, autograft should be the first layer (against the host bone). The autograft shavings should cover the complete recipient bed below the screws.

Continued

• BOX 36.12 Guided Bone Regeneration Protocol—cont'd

b. **Allograft:** The allograft should be placed as the second layer in larger bone graft cases (> 3 mm). For smaller graft cases, 100% allograft may be used (i.e. 70% FDBA / 30 DFDBA or 100% FDBA Cortico-Cancellous). The particulate bone should be densely packed to avoid air spaces which tend to harbor bacteria.

• After the bone graft is placed, the membrane is drawn completely over the graft material with 2 to 3 mm of overlap over native bone to limit exposure of the particulate during the healing process. The membrane should be fixated (on the free end) with tacks or sutures. In situations where the membrane cannot be fixated, it can be tucked under the lingual flap and the coronal surface can be included in the closure sutures to limit movement. If platelet-rich fibrin or platelet-rich plasma is being used, it should be placed over the membrane (in between the tissue and membrane).

Step 9: Closure

a. *Suture selection*: The most ideal sutures for tissue closure are Vicryl (resorbable) or PTFE (Cytoplast, nonresorbable). The PTFE suture allows adjustment of the suture tension as the knot is being tied, and results in minimal inflammation around a healing incision line.

b. *Primary sutures:* the crest or ridge area should be closed first with a tension-free suture line. Mattress sutures should be placed at intervals that distribute the pressure on the incision over a large surface area. Mattress suture evert the tissue flaps, thereby decreasing the possibility of incision line opening. Interrupted sutures may be used between the mattress sutures. A common mistake is to close the vertical releasing incisions first, thereby placing tension on the crestal suture line.

c. *Secondary sutures:* After the crestal area has been closed, the releasing incisions may be closed passively. Care should be exercised not to place too much tension on the releasing flaps, thereny limiting tension on the crestal sutures.

Maxillary Sinus Anatomy, Pathology, and Graft Surgery

RANDOLPH R. RESNIK AND CARL E. MISCH

The posterior maxilla has been described as one of the most challenging and complex intraoral regions that confronts the implant clinician. There exist many treatment planning and patient factors that contribute to these problems in this area, which in many cases require the clinician to have additional training and an increased skill set:

- Poor bone density
- Compromised available bone
- Increased pneumatization of the maxillary sinus
- Increased crown height space
- Ridge position shifts toward lingual (medial)
- Difficult access because of anatomic location
- Increased biting force
- Requirement of wider diameter implants and increased number

Before discussing the various treatment options of the posterior maxilla, it is imperative that the implant clinician have a strong foundation for maxillary sinus anatomy, anatomic variants, pathology, and a comprehensive understanding of the various treatment approaches.

Maxillary Sinus Anatomy

The maxillary sinuses were first illustrated and described by Leonardo Da Vinci in 1489 and later documented by the English anatomist Nathaniel Highmore in 1651.[1] The maxillary sinus, or antrum of Highmore, lies within the body of the maxillary bone and is the largest and first to develop of the paranasal sinuses (Fig. 37.1). Adult maxillary sinuses are pyramid-shaped, air-filled cavities that are bordered by the nasal cavity. There is much debate about the actual function of the maxillary sinus. Possible theorized roles of the sinus include weight reduction of the skull, phonetic resonance, participation of warming humidification of inspired air, and olfaction. A biomechanical adaptation of the maxillary sinus directs forces away from the orbit and cranial cavity when a force is delivered to the midface.

Development and Expansion of the Maxillary Sinus

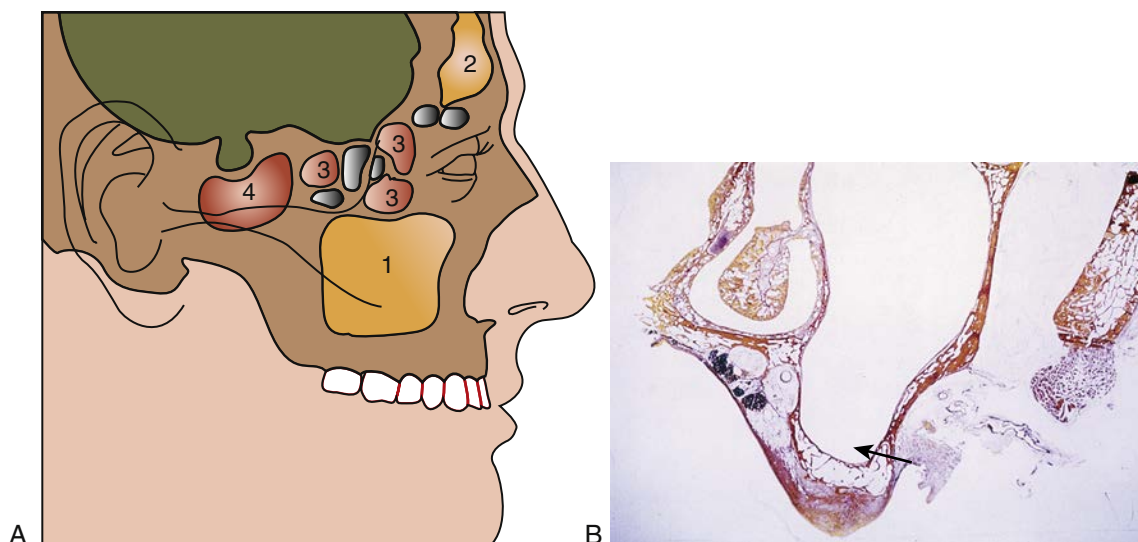
A primary pneumatization occurs at approximately 3 months of fetal development by an outpouching of the nasal mucosa within the ethmoid infundibulum. At that time, the maxillary sinus is a bud situated at the infralateral surface of the ethmoid infundibulum between the upper and middle meatus. Prenatally, a secondary pneumatization occurs. At birth, the sinus is still an oblong groove on the mesial side of the maxilla just above the germ of the first deciduous molar.[2]

At birth, the sinus cavities are filled with fluid. Postnatally and until the child is 3 months old the growth of the maxillary sinus is closely related to the pressure exerted by the eye on the orbit floor, the tension of the superficial musculature on the maxilla, and the forming dentition. As the skull matures, these three elements influence its three-dimensional (3D) development. At 5 months, the sinus appears as a triangular area medial to the infraorbital foramen.[3]

During the child's first year, the maxillary sinus expands laterally underneath the infraorbital canal, which is protected by a thin bony ridge. The antrum grows apically and progressively replaces the space formerly occupied by the developing dentition. The growth in height is best reflected by the relative position of the sinus floor. At 12 years of age, pneumatization extends to the plane of the lateral orbital wall, and the sinus floor is level with the floor of the nose. During later years, pneumatization spreads inferiorly as the permanent teeth erupt. The adult sinus has a volume of approximately 15 mL (34 mm height x 33 length x 23 mm width). The main development of the antrum occurs as the permanent dentition erupts and pneumatization extends throughout the body of the maxilla and the maxillary process of the zygomatic bone. Extension into the alveolar process lowers the floor of the sinus approximately 5 mm. Anteroposteriorly, the sinus expansion corresponds to the growth of the midface and is completed only with the eruption of the third permanent molars when the young person is about 16 to 18 years of age.[4]

In the adult, the sinus is pyramid shaped with consisting of four bony walls, the base of which faces the lateral nasal wall and the apex of which extends toward the zygomatic bone (Fig. 37.2). The floor of the maxillary sinus cavity is reinforced by bony or membranous septa, joining the medial or lateral walls with oblique or transverse buttress-like webs. They develop as a result of genetics and stress transfer within the bone over the roots of teeth. These have the appearance of reinforcement webs in a wooden boat and
● **Fig. 37.1** Maxillary sinus *(1)* is the largest of the four paranasal sinuses. The initial maxillary sinus formation is completed at age 16 to 18 years. *2,* Frontal sinus; *3,* ethmoid sinus; *4,* sphenoid sinus.

rarely divide the antrum into separate compartments. These elements are present from the canine to the molar region and tend to disappear in the maxilla of the long-term edentulous patient when stresses to the bone are reduced. Karmody found that the most common oblique septum is located in the superior anterior corner of the sinus or infraorbital recess (which may expand anteriorly to the nasolacrimal duct).[5] The medial wall is juxtaposed with the middle and inferior meatus.

Although the maxillary sinus maintains its overall size while the teeth are present, an expansion phenomenon of the maxillary sinus occurs with the loss of posterior teeth.[6] The antrum expands in both inferior and lateral dimensions. This expansion may even invade the canine eminence region and proceed to the lateral piriform rim of the nose. The dimension of available bone height of the posterior maxilla is greatly reduced as a result of dual resorption from the crest of the ridge and pneumatization of the sinus after the loss of teeth. The sinus expansion is more rapid than the crestal bone height changes. As a result of the inferior sinus expansion, the amount of available bone in the posterior maxilla greatly decreases in height (Fig. 37.3). The maxillary sinus tends to enlarge with age, as well as with edentulism, which further
● **Fig. 37.2** Maxillary sinus begins to form in the fetus and by 5 months is the size of a pea, under the eye, and close to the ostium for drainage. By 16 years of age, the maxillary sinus has four thin, bony walls around it. The superior wall separates it from the floor of the orbit. The medial wall contains the ostium to drain the sinus and separates it from the nasal fossa. The lateral wall forms the maxillary bone below the zygomatic arch. The floor of the antrum rests above the roots of the teeth.


• **Fig. 37.3** (A) The fourth expansion phenomenon of the maxillary sinus occurs with the loss of the posterior teeth. The anterior portion of the sinus may expand to the piriform rim of the nose. The inferior expansion may approach the crest of the ridge. *1,* Maxillary sinus; *2,* frontal sinus; *3,* ethmoid sinus; *4,* sphenoid sinus. (B) Coronal section of the posterior region of the edentulous human maxilla. Note expansion of the sinus floor inferiorly far below the level of the floor of the nose. (Courtesy Mohamed Sharawy, Augusta, Georgia.)

decreases the amount of available bone. In addition to the diminished quantity, bone in the posterior maxilla often is softer and of poorer quality. Radiographs typically reveal sparse trabeculations, and the tactile experience of drilling in this bone resembles a Styrofoam type of material (D4 Bone).

After normal sinus expansion, with periodontal disease and tooth loss increasing the bone loss, inadequate bone will result between the alveolar ridge crest and the floor of the maxillary sinus. In most cases, bone quantity will be compromised for implant placement. The limited available bone is compounded by a decrease in bone density and the shifting of the residual ridge in a medial direction. Therefore this area of the maxilla is often reported with an increased incidence of implant malpositioning and morbidity.

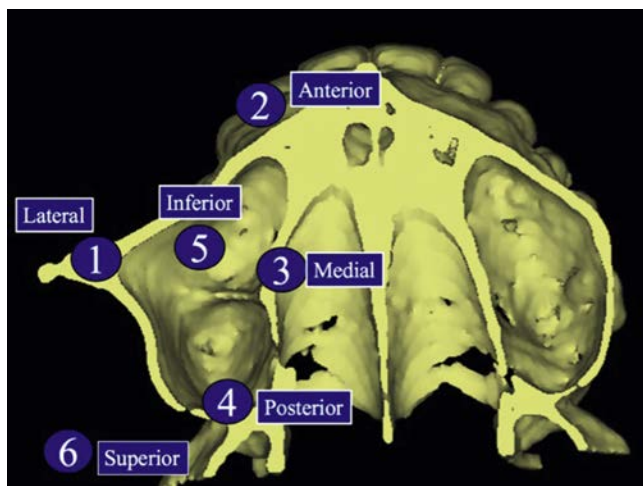
Bone Resorption Process

The maxilla generally has a thinner cortical plate facially compared with any region of the mandible, and very minimal cortical bone is present on the ridge. In addition, the trabecular bone in the posterior maxilla is finer (less dense) than other dentate regions. When maxillary posterior teeth are lost, an initial decrease in bone width at the expense of the labial bony plate results. The width of the posterior maxilla has been shown to decrease at a more rapid rate than in any other region of the jaws.[7] The resorption phenomenon is accelerated by the loss of vascularization of the alveolar bone and the existing fine trabecular bone type. However, because the initial residual ridge is inherently wide in the posterior maxilla, even with a significant decrease in the width of the ridge, adequate-diameter root-form implants (~5mm) usually can be placed. However, as the resorption process continues, the residual ridge continues to progressively shift toward the palate until the ridge is significantly resorbed into a medially positioned narrower bone volume.[8] This results in the buccal cusp and central fossa of the final restoration being cantilevered facially to satisfy esthetic requirements at the expense of biomechanics in the moderate to severe atrophic ridges. This cantilevered part

of the prosthesis is usually in the form of a ridge lap pontic area, which in most cases results in hygiene difficulties.

Resultant Poor Bone Density

In general, the bone quality is poorest in the posterior maxilla, compared with any other intraoral region.[9] A literature review of clinical studies reveals that the poorest bone density may decrease implant loading survival by an average of 16%, and it has been reported as low as 40%.[10] The cause of these failures is related to several factors. Bone strength is directly related to its density, and the poor-density bone of this region is often 5 to 10 times weaker, compared with bone found in the anterior mandible. Bone densities directly influence the bone-to-implant contact percentage (BIC), which accounts for the force transmission to the bone. The BIC is least in D4 bone, and the stress patterns in this bone migrate farther toward the apex of the implant (Fig. 37.4). As a result, bone loss is more pronounced and also occurs along the implant body, rather than only crestally, as in other denser bone conditions. D4 bone also exhibits the greatest biomechanical elastic modulus difference compared with titanium under load.[11] Earlier studies and surgical protocols did not take into consideration the poor BIC in this area.

In the posterior maxilla, the deficient osseous structures and an absence of cortical plate on the crest of the ridge is often observed, which further compromises the initial implant stability at the time of insertion. The labial cortical plate is thin, and the ridge is often wide. As a result, the lateral cortical BIC to stabilize the implant is often insignificant. The implant placement protocol often uses bone compression (osseodensification) rather than bone extraction (removal) to create the implant osteotomy to compensate for these deficiencies. If the surgical protocol is not modified, the initial healing of an implant in D4 bone will be compromised.
● **Fig. 37.4** Bone–implant contact percent is often reduced in the posterior maxilla because the quality of bone is poorer than other regions of the mouth. This histologic slide depicts the numerous areas of no bone contact at the implant interface.


● **Fig. 37.5** Maxillary sinus is comprised of six walls that contain significant anatomic and vital structures, which are important in the placement of implants. *1,* Lateral, *2,* anterior, *3,* medial, *4,* posterior, *5,* inferior, *6,* superior.

Bony Walls

The maxillary sinus features six bony walls, each of which contain important anatomic structures that play a significant role in the treatment of the maxillary posterior region. The implant clinician must have a strong understanding and foundation of the bony walls associated with the posterior maxilla in the preoperative assessment before surgical procedures (Fig. 37.5)

Anterior Wall

The anterior wall of the maxillary sinus consists of thin, compact bone extending from the orbital rim to just above the apex of the cuspid. With the loss of the canine, the anterior wall of the antrum may approximate the crest of the residual ridge. Within the anterior wall and approximately 6 to 7 mm below the orbital

rim, with anatomic variants as far as 14 mm from the orbital rim, is the infraorbital foramen (Fig. 37.6A). The infraorbital nerve runs along the roof of the sinus and exits through the foramen. The infraorbital blood vessels and nerves lie directly on the superior wall of the maxillary sinus and within the sinus mucosa.

Tenderness to pressure over the infraorbital foramen or redness of the overlying skin may indicate inflammation of the sinus membrane from infection or trauma, which may contraindicate graft surgery until resolution. In patients exhibiting anatomic variants of the infraorbital foramen, neurosensory impairment may occur during retraction of this area, leading to neurapraxia type injuries. The use of worn, sharp-edged retractors should be avoided when reflecting tissue superiorly in this area to avoid potential injuries. Within the anterior wall of the sinus, the thinnest part is the canine fossa, which is directly above the canine tooth. The anterior wall of the maxillary sinus may also serve as surgical access during Caldwell-Luc procedures to treat a preexisting or post–sinus graft, pathologic condition.

Superior Wall

The superior wall of the maxillary sinus coincides with the thin inferior orbital floor. The orbital floor slants inferiorly in a mediolateral direction and is convex into the sinus cavity.

A bony ridge is usually present in this wall that houses the infraorbital canal, which contains the infraorbital nerve and associated blood vessels. Dehiscence of the bony chamber may be present, resulting in direct contact between the infraorbital structures and the sinus mucosa.

Ocular symptoms may result from infections or tumors in the superior aspects of the sinus region and may include proptosis (bulging of the eye) and diplopia (double vision). When these problems occur, the patient is closely supervised, and a medical consult is advised to decrease the risk of severe complications that may result from the spread of infection in a superior direction. Superior-spreading infections may lead to significant ocular problems or brain abscesses. As a result, when ocular or cerebral symptoms appear, aggressive therapy to decrease the spread of infection is indicated. Overpacking the maxillary sinus with bone graft material during a sinus graft may result in pressure against the superior wall if a sinus infection develops (see Fig. 37.6B).

Posterior Wall

The posterior wall of the maxillary sinus corresponds to the pterygomaxillary region, which separates the antrum from the infratemporal fossa. The posterior wall usually has several vital structures in the region of the pterygomaxillary fossa, including the internal maxillary artery, pterygoid plexus, sphenopalatine ganglion, and greater palatine nerve. The posterior wall should always be identified radiographically because when the wall is not present, a pathologic condition (including neoplasms) is to be suspected (see Fig. 37.6C).

Common donor sites to obtain autogenous bone for sinus augmentation procedures include the tuberosity area. Special consideration should be taken for the posterior extent of the tuberosity removal. Aggressive tuberosity removal may lead to bleeding in the infratemporal fossa (pterygoid plexus), resulting in life-threatening situations.

It should be noted that pterygoid implants placed through the posterior sinus wall and into this region may approach vital structures, including the maxillary artery. A blind surgical technique to place a pterygoid implant through the posterior wall may have increased surgical risk. However, they are of benefit primarily
● **Fig. 37.6** Six bony walls of the maxillary sinus. (A) Anterior. (B) Superior. (C) Posterior. (D) Medial. (E) Lateral. (F) Inferior.

when third or fourth molars are needed for prosthetic reconstruction or sinus grafts are contraindicated and available bone posterior to the antrum is present.

Medial Wall

The medial wall of the antrum coincides with the lateral wall of the nasal cavity and is the most complex of the various walls of the sinus. On the nasal aspect, the lower section of the medial wall parallels the lower meatus and floor of the nasal fossa; the upper aspect corresponds to the middle meatus. The medial wall is usually vertical and smooth on the antral side (see Fig. 37.6D).

The main drainage avenue of the maxillary sinus is through the maxillary ostium. The primary ostium is located in the superior aspect of the sinus medial wall and drains its secretions via the ethmoid infundibulum through the hiatus semilunaris into the middle meatus of the nasal cavity. The infundibulum is approximately 5 to 10 mm long and drains via ciliary action in a superior and medial direction. The ostium diameter averages 2.4 mm in health; however, pathologic conditions may alter the size to vary from 1 to 17 mm.[12]

The maxillary ostium and infundibulum are part of the anterior ethmoid middle meatal complex, the region through which

the frontal and maxillary sinuses drain, which is primarily responsible for mucociliary clearance of the sinuses to the nasopharynx. As a result, obstruction in one or more areas of the complex will usually result in rhinosinusitis or lead to morbidity of the graft or implant. Patency of the maxillary ostium is most crucial preoperatively and postoperatively during maxillary graft sinus surgery to prevent infection and morbidity of the graft. Evaluating the patency of the ostium via cone beam computerized tomography (CBCT) is easily accomplished with evaluation of serial cross-sectional images. The patency of the ostium must be ascertained before surgery to prevent or minimize postoperative complications. This is easily verified via coronal or cross-sectional images on CBCT surveys. Of utmost importance when performing any procedure involving the maxillary sinus, the patency of the ostium must be maintained throughout the postoperative period. If ostium patency is compromised, increased morbidity of the implant or graft will occur because the mucociliary action of the maxillary sinus will be compromised.

Smaller, accessory or secondary ostia may be present that are usually located in the middle meatus posterior to the main ostium. These additional ostia are most likely the result of chronic sinus inflammation and mucous membrane breakdown. They are present in approximately 30% of patients, ranging from a fraction of a millimeter to 0.5 cm, and are commonly found within the membranous fontanelles of the lateral nasal wall.[13] Fontanelles are usually classified either as anterior fontanelles (AFs) or posterior fontanelles (PFs) and are termed by their relation to the uncinated process. These weak areas in the sinus wall are sometimes used to create additional openings into the sinus for treatment of chronic sinus infections. Primary and secondary ostia may, on occasion, combine and form a large ostium within the infundibulum.

Lateral Wall

The lateral wall of the maxillary sinus forms the posterior maxilla and the zygomatic process. This wall varies greatly in thickness from several millimeters in dentate patients to less than 1 mm in an edentulous patient. A CBCT examination will reveal the osseous thickness of the lateral wall, which is crucial in defining the osteotomy location and preparation technique. Patients exhibiting increased parafunction forces will have thicker lateral walls (see Fig. 37.6E). The lateral wall thickness of the maxilla has been noted to be extremely variable, with some cases being nonexistent. This will lead to an increased possibility of membrane perforation, even occurring on reflection. In contrast, the lateral wall may be very thick, which is usually seen with patients that exhibit parafunction and have just recently lost the posterior teeth. In these situations, lateral wall sinus grafting becomes very difficult because of the cortical thickness. The lateral wall houses the intraosseous anastomosis of the infraorbital and posterior superior alveolar artery, which may lead to a bleeding complication because this area is the site for osteotomy preparation of the lateral wall sinus graft procedure.

Inferior Wall

The inferior wall or floor of the maxillary sinus is in close relationship with the apices of the maxillary molars and premolars. The teeth usually are separated from the sinus mucosa by a thin layer of bone; however, on occasion, teeth may perforate the floor of the sinus and be in direct contact with the sinus lining. Studies have shown that the first molar has the most common dehiscent tooth root, occurring up to approximately 30% to 40% of the time.[14] In dentate patients the sinus floor is approximately at the level of

the nasal floor. In the edentulous posterior maxilla the sinus floor is often 1 cm below the level of the nasal floor (see Fig. 37.6F).

Radiographically, the sinus inferior floor morphology is easily seen via 3D imaging. The floor is rarely flat and smooth; the presence of irregularities and septa should be determined and their exact locations noted. Irregular floors are most often seen after teeth are extracted, leaving residual bony crests that increase risk of perforation because of the difficulty in membrane reflection. In some cases, the bony crests are not even seen on the CBCT evaluation.

Complete or incomplete bony septa may exist on the floor in a vertical or horizontal plane. Approximately 30% of dentate maxillae have septa, with three-fourths appearing in the premolar region. Complete septa separating the sinus into compartments are very rare, occurring in only 1.0% to 2.5% of maxillary sinuses.[15] The presence of septa complicate lateral wall sinus graft procedures, which leads to an increased likelihood of membrane perforation.

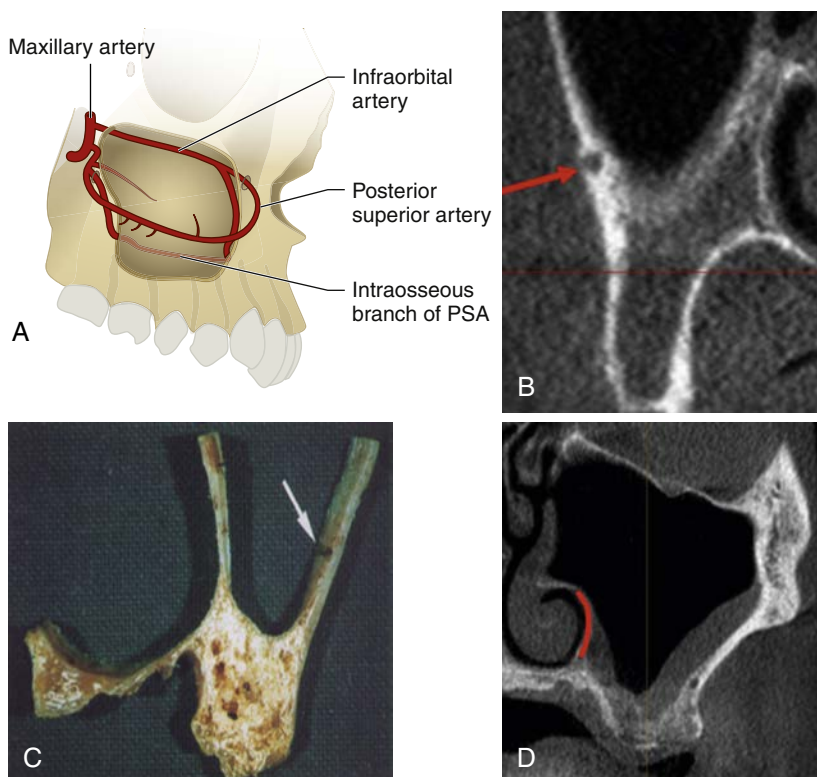
Ostiomeatal Complex

The ostiomeatal unit is composed of the maxillary ostium, ethmoid infundibulum, anterior ethmoid cells, hiatus semilunaris, and the frontal recess, which encompasses the area of the middle meatus. This common channel allows for air flow and mucociliary drainage of the frontal, maxillary, and anterior ethmoid sinuses. Blockage in this area leads to impaired drainage of the maxillary, frontal, and ethmoid sinuses, which may result in rhinosinusitis and postoperative complications after implant or grafting procedures.

Radiographic identification of the ostiomeatal complex and related structures must be evaluated to prevent potential postoperative complications. Pathology or variations within the ostiomeatal complex may lead to postoperative sinus graft morbidity or implant complications caused by compromised mucociliary drainage (alteration of normal sinus physiology) of the maxillary sinus.

Blood Supply and Sensory Innervation

The vascular supply in the maxillary sinus is a vital part of the healing and regeneration of bone after a sinus graft and healing of a dental implant. The blood supply to the maxillary sinus is derived from the maxillary artery, which emanates from the external carotid artery. The maxillary artery supplies the bone surrounding the sinus cavity and also the sinus membrane. Branches of the maxillary artery, which most often include the posterior superior alveolar artery and infraorbital artery, form endosseous and extraosseous anastomoses that encompass the maxillary sinus. The formation of the endosseous and extraosseous anastomoses in the maxillary sinus is termed the double arterial arcade. Studies have shown vascularization of postgraft material to depend on the intraosseous and extraosseous anastomoses, along with the blood vessels of the Schneiderian membrane, which is supplied by the posterior superior alveolar artery and the infraorbital artery along the lateral wall.[16]

There exist different factors that alter the vascularization in this area. With increasing age, the number and size of blood vessels in the maxilla decrease. As bone resorption increases, the cortical bone becomes thin, resulting in less vascularization. As the lateral wall becomes thinner, the blood supply to the lateral wall and lateral aspect of the bone graft comes primarily from the periosteum, resulting in a compromised vascularization to the region.


• **Fig. 37.7** Blood supply of the maxillary sinus. (A) Extraosseous and intraosseous anastomosis, which is made up of the infraorbital and posterior superior artery. (B) Cross-sectional cone beam computerized tomography image depicting intraosseous anastomosis *(arrow)*. (C) Intraosseous notch *(arrow)* containing the intraosseous anastomosis, which comprises the posterior superior artery and infraorbital artery. (D) Posterior lateral nasal artery location in the medial wall of the maxillary sinus. *PSA*, Posterior Superior Artery.

Extraosseous Anastomosis

The extraosseous anastomosis is found in approximately 44% of the population and is usually in close approximation to the periosteum of the lateral wall.

The extraosseous anastomosis is superior to the endosseous unit, which is approximately 15 to 20 mm from the dentate alveolar crest. To minimize vascular trauma to the extraosseous anastomosis, surgical and anatomic considerations should be addressed. Ideally, vertical incisions should be made as short as possible to decrease the possibility of blood vessel damage. It is crucial to gain adequate access to the lateral aspect of the maxilla, and the periosteum should be reflected full thickness with great care. Haphazard reflection may lead to severing or damage to the anastomosis, with resultant postoperative edema. Severing of the extraosseous anastomosis may result in significant increased bleeding during the surgical procedure. This intraoperative complication may give rise to impaired visibility for the clinician, along with increased surgery duration. Additionally, postoperative complications such as pain, edema, and ecchymosis may result from the severing of these blood vessels. If trauma to these vessels occurs, direct pressure or the use of electrocautery may be used. However, electrocautery may potentially cause membrane damage or necrosis. If severe bleeding occurs, curved Kelly hemostats are used to clamp the bleeding vessel, followed by ligature placement. A slowly resorbable suture with high tensile strength such as Vicryl is recommended.

Intraosseous Anastomosis

The intraosseous anastomosis is found within the lateral wall of the sinus, which supplies the lateral wall and the sinus membrane. In an edentulous maxilla with posterior vertical bone loss, the endosseous anastomosis may be 5 to 10 mm from the edentulous ridge. The endosseous artery has been shown to be observed on CBCT scans in approximately one-half of the patients requiring a sinus graft.[17] However, anatomic cadaver studies have shown the prevalence to be 100%.[17] In 82% of cases, the most common anatomic location was observed between the canine and second premolar region.[18] However, with a long-term edentulous patient with a thin lateral wall, the artery may be atrophied and almost nonexistent.

Surgical, radiographic, and anatomic considerations should be addressed to minimize trauma to these blood vessels. The CBCT radiographic identification is extremely important in identifying these blood vessels before surgery so preparation may be made. Radiographically, smaller anastomoses will not be seen if the pixel size (~1.0 mm) is less than one-half the size of the anastomosis vessel. Studies have shown that the use of a 0.3 or 0.4 CBCT pixel size for radiographic evaluation will most likely show the smaller anastomoses.[19]

Studies have shown that in 20% of lateral wall osteotomies significant bleeding complications may occur,[20] mainly because the anastomosis is greater than 1.0 mm in diameter. It has been shown that vessels larger than 1.0 mm are more problematic and associated with significant bleeding, whereas smaller vessels (<1.0 mm) are usually insignificant and easily managed (Fig. 37.7; Box 37.1).

In most cases, bleeding is a minor complication and of short duration; however, in some instances it may be significant and difficult to manage. To control bleeding, there are many possible treatments: (1) the patient should be repositioned into an upright

• BOX 37.1 **Arterial Supply to Posterior Maxilla (Double Arterial Arcade)**

- Endosseous anastomosis (within the lateral wall of sinus)

position and pressure applied with a surgical gauze; (2) electrocautery may be used, although this may lead to membrane necrosis and perforation, with possible migration of graft material; (3) a second window may be made proximal to the bleeding source to gain access to the bleeding vessel, especially if location cannot be obtained from the original window; and (4) cutting the bone and vessel with a high-speed diamond with no irrigation (which cauterizes the vessel).

Posterior Lateral Nasal Artery

A posterior lateral nasal artery (branch of the sphenopalatine artery that also rises from the maxillary artery) supplies the medial aspect of the sinus cavity. The medial and posterior walls of the maxillary sinus mucosa receive their blood supply from the posterior lateral nasal artery.

During sinus graft surgery the clinician may be in close approximation to this artery when elevating the membrane off the medial wall. Care should be exercised to minimize trauma to this area because aggressive reflection of the membrane may result in trauma to the blood vessel or perforation into the nasal cavity.

Trauma to this artery may cause significant bleeding in the sinus proper and also within the nasal cavity. Because the medial sinus wall is very thin (usually one-half the thickness of the lateral wall), aggressive membrane reflection may result in trauma, leading to bleeding issues.

Sphenopalatine/Infraorbital Arteries

The sphenopalatine artery is also a branch of the maxillary artery and enters the nasal cavity through the sphenopalatine foramen, which is near the posterior portion of the superior meatus of the nose.

As the sphenopalatine artery exits the foramen, it branches into the posterior lateral nasal artery and the posterior septal artery.[21] Additionally, the infraorbital artery enters the maxillary sinus via the infraorbital fissure in the roof of the sinus and ascends cranially into the orbital cavity. Because of the anatomic locations of these blood vessels, it is rarely a concern with respect to sinus graft surgery.

The sphenopalatine and infraorbital blood vessels are usually not problematic for bleeding complications during lateral-approach sinus elevation surgery because of their anatomic locations. However, incorrect incision locations and aggressive reflection may damage the blood vessels. If bleeding does occur, it is usually easily controlled with pressure and local hemostatic agents.

Maxillary Sinus Mucosa

The epithelial lining of the maxillary sinus is a continuation of the nasal mucosa and is classified as a pseudostratified, ciliated columnar epithelium, which is also called the respiratory epithelium.

The epithelial lining of the maxillary sinus is much thinner and contains fewer blood vessels than the nasal epithelium. This accounts for the membrane's pale color and bluish hue. Five primary cell types exist in this tissue: (1) ciliated columnar epithelial cells, (2) nonciliated columnar cells, (3) basal cells, (4) goblet cells, and (5) seromucinous cells. The ciliated cells contain approximately 50 to 200 cilia per cell. In a healthy maxillary sinus the cilia cells assist in clearing mucus from the sinus and into the nasopharynx. The nonciliated cells compose the apical aspect of the membrane, contain microvilli, and serve to increase surface area. These cells have been theorized to facilitate humidification and warming of inspired air. The basal cell's function is similar to that of a stem cell that can differentiate as needed. The goblet cells in the maxillary sinus produce glycoproteins that are responsible for the viscosity and elasticity of the mucus produced. The maxillary sinus contains the highest concentration of goblet cells compared with the other paranasal sinuses. The maxillary sinus membrane also exhibits few elastic fibers attached to the bone (no tenacious attachment is usually present), which simplifies elevation of this tissue from the bone during grafting procedures. The thickness of the sinus mucosa in health varies, but it is generally 0.3 to 0.8 mm.[22] In smokers, it varies from very thin and almost nonexistent to very thick, with a squamous type of epithelium.

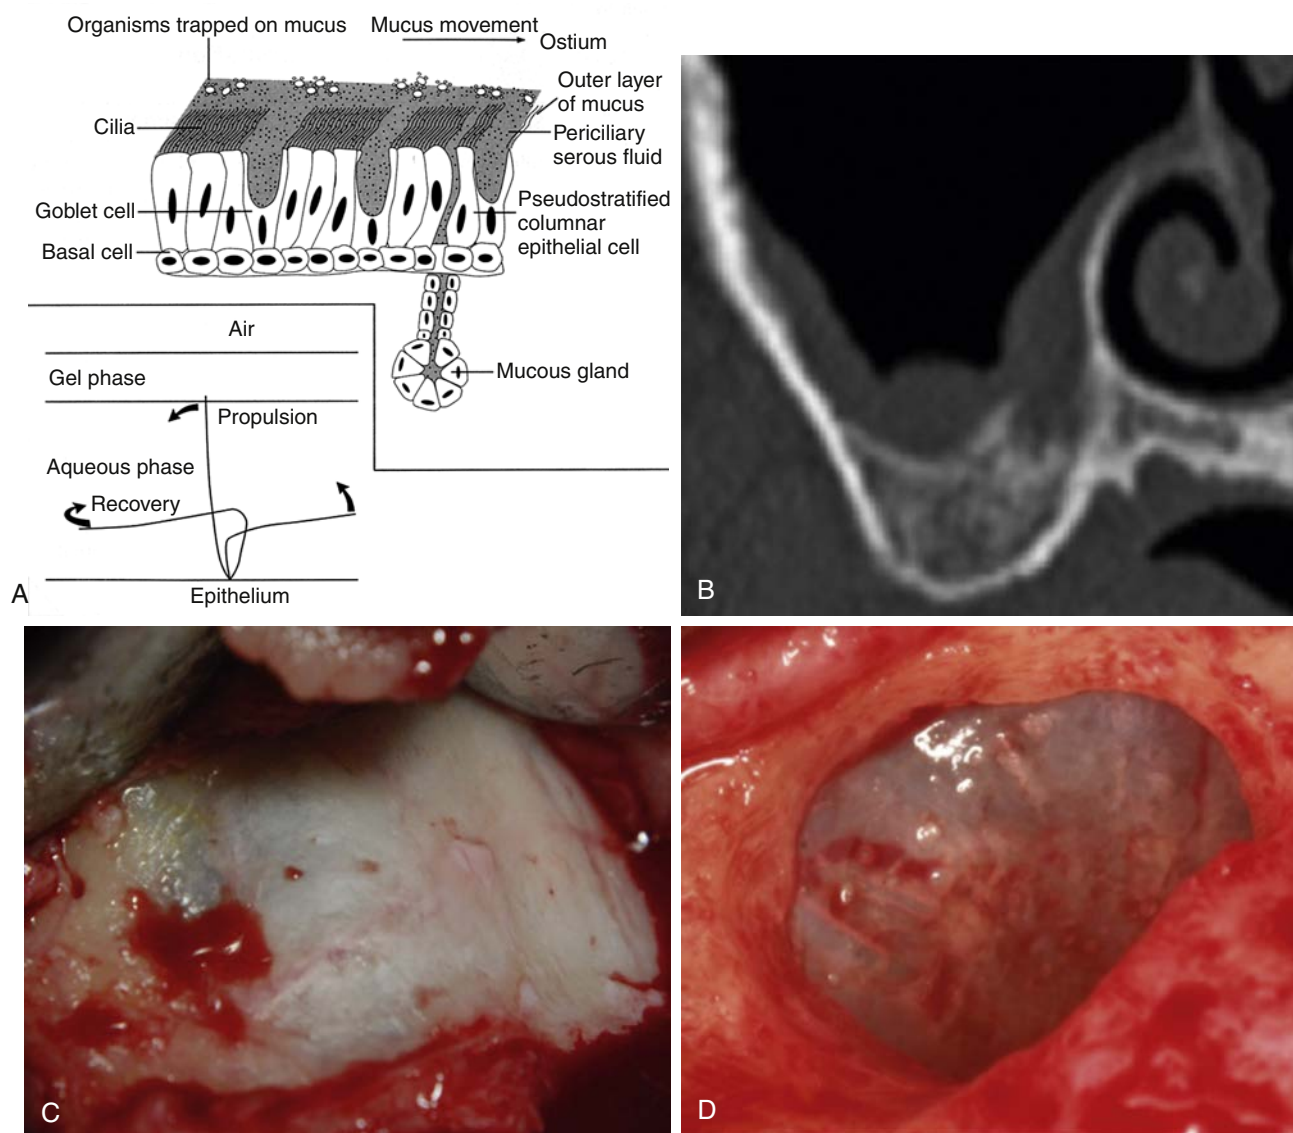
Radiographically, normal, healthy paranasal sinuses reveal a completely radiolucent (dark) maxillary sinus. Any radiopaque (whitish) area within the sinus cavity is abnormal, and a pathologic condition should be suspected. The normal sinus membrane is radiographically invisible, whereas any inflammation or thickening of this structure will be radiopaque. The density of the diseased tissue or fluid accumulation will be proportional to varying degrees of gray values.

Maintaining the integrity of the sinus membrane is crucial in decreasing postoperative complications, including loss of graft material and the possibility of infection.

Many factors may alter the physiology of the sinus mucosa, such as viruses, bacteria, and foreign bodies (implants). Care should be taken to minimize membrane perforations during surgery. If perforations occur, appropriate repair treatment protocols should be followed.

Maxillary Sinus Mucociliary Clearance

Normal mucociliary flow is crucial to maintaining the healthy physiology of the maxillary sinus. In a healthy sinus an adequate system of mucus production, clearance, and drainage is maintained. The key to normal sinus physiology is the proper function of the cilia, which is the main component of the mucociliary transport system. The cilia move contaminants toward the natural ostium and then to the nasopharynx. The cilia of the columnar epithelium beat toward the ostium at approximately 15 cycles per minute, with a stiff stroke through the serous layer, reaching into the mucoid layer. They recover with a limp reverse stroke within the serous layer. This mechanism slowly propels the mucoid layer toward the ostium at a rate of 9 mm per minute and into the middle meatus of the nose.[22]

In health, mucoid fluid is transported toward the ostium of the maxillary sinus and drains into the nasal cavity, eliminating inhaled small particles and microorganisms. This mucociliary transport system is an active transport system that relies heavily on oxygen. The amount of oxygen absorbed from the blood is not adequate to maintain this drainage system; additional oxygen has to be absorbed from the air in the sinus. This is why the patency of the ostium is crucial in maintaining the normal transport system.


• **Fig. 37.8** Maxillary sinus membrane (Schneiderian Membrane). (A) The pseudostratified columnar epithelium cells have 50 to 200 cilia per cell that beat toward the ostium to help clear 1 L of mucus from goblet and mucous glands each day from the sinus. In health, the mucous has two layers: a bottom serous layer and top mucoid layer. The cilia beat with a stiff stroke in the mucoid layer toward the ostium and a relaxed recovery stroke within the serous layer. (B) Cross-sectional image depicting an inflamed Schneiderian membrane. If the sinus membrane is of normal thickness, it will not be visible on a radiograph. (C) Clinical image depicting the thinness of the lateral wall and show through *(dark blue)* of the Schneiderian membrane. (D) Bluish hue of the membrane after lateral wall window preparation.

Various elements may decrease the number of cilia and slow their beating efficiency. Viral infections, pollution, allergic reactions, and certain medications may affect the cilia in this way. Genetic disorders (e.g., dyskinetic cilia syndrome) and factors such as long-standing dehydration, anticholinergic medications and antihistamines, cigarette smoke, and chemical toxins also can affect ciliary action[23] (Fig. 37.8).

An alteration in the sinus ostium patency or the quality of secretions can lead to disruption in ciliary action, which may result in rhinosinusitis. For clearance to be maintained, adequate ventilation is necessary. Ventilation and drainage are dependent on the ostiomeatal unit, which is the main sinus opening. Ciliary movements of ciliated epithelial cells dictate clearance of the maxillary sinus. It is important to maintain the patency of the maxillary ostium and the ostiomeatal complex in the postoperative period to minimize the possibility of complications.

The physiologic mucociliary transport system may be compromised by abnormalities in the cilia, which include a decrease in overall ciliary number and poor coordination of their movement. This altered physiology may result in an increased morbidity of implant placement or bone graft healing. Therefore it is crucial that the mucociliary drainage mechanism be maintained throughout the postoperative treatment period. This is most likely accomplished with good surgical technique, evaluation and treatment of prior drainage issues, and strict adherence to the use of pharmacologic agents (e.g., antibiotics, corticosteroids).
● **Fig. 37.9** Subantral augmentation classification. (A) SA-1: implant placement that does not extend into the maxillary sinus proper. (B) SA-2: implant placement that elevates the sinus membrane approximately 1 to 2 mm without bone grafting. (C) SA-3: implant placement and simultaneous bone grafting by either a crestal or lateral-wall approach. (D) SA-4: lateral wall sinus augmentation with delayed implant placement.

Maxillary Sinus Bacterial Flora

There is much debate on the bacterial flora of the maxillary sinus. Maxillary sinuses have been considered to be generally sterile in health; however, bacteria can colonize within the sinus without producing symptoms. In theory, the mechanism by which a sterile environment is maintained includes the mucociliary clearance system, immune system, and the production of nitric oxide within the sinus cavity. In recent endoscopic studies, normal sinuses were shown to be nonsterile, with 62.3% exhibiting bacterial colonization. The most common bacteria cultured were *Streptococcus viridans, Staphylococcus epidermidis,* and *S. pneumoniae.*[24] The culture findings for secretions in acute maxillary sinusitis yielded high numbers of leukocytes, *S. pneumoniae,* or *S. pyogenes,* with *Haemophilus influenzae* being recovered from the purulent exudates with lower numbers of staphylococci. Other reports have indicated the bacterial flora of the maxillary sinus consists of nonhemolytic and alpha hemolytic streptococci, as well as *Neisseria* spp. Additional microorganisms identifiable in various quantities belong to staphylococci, *Haemophilus* spp., pneumococci, *Mycoplasma* spp., and *Bacteroides* spp. This is important to note because the sinus graft procedure often violates the sinus mucosa, and bacteria may contaminate the graft site, leading to postoperative complications.

The implant clinician must understand the importance of reducing the bacterial count and possible microorganisms that may initiate infections in the maxillary sinus. A strict aseptic technique should be adhered to during any surgical procedures that invade the maxillary sinus proper. This will minimize the possibility of bacterial colonization within the graft, which may lead to increased morbidity. The type of bacteria inhabiting the sinus is very important because it dictates what antibiotic is prescribed preoperatively, postoperatively, and therapeutically in case of infection. The most common bacteria present in the sinus must be susceptible to the specific antibiotic to prevent infection and decrease the morbidity of the graft. The antibiotic selected should not be the clinician's "favorite"; instead it should be the most ideal antibiotic, which is specific for the involved bacteria. Ideally, Augmentin (875/125 mg) has been shown to be most effective antibiotic for bacterial infections in the maxillary sinus.

Maxillary Sinus: Clinical Assessment

To establish adequate osseous morphology for the placement of endosteal implants in the resorbed maxillary posterior region, various grafting techniques have been developed to increase bone volume. In 1987 Misch[25] developed four different categories for the treatment of the posterior maxilla (termed subantral [SA]) as SA-1 through SA-4 and was later modified and updated by Resnik in 2017 (Fig. 37.9). The SA-1 posterior maxilla allows implant placement inferior to the sinus cavity, without penetration into

TABLE 37.1	Preoperative and Postoperative Physical Examination	
Site	**Signs of Infection**	
Inferior wall	Bulge in hard palate, ill-fitting denture, loose teeth, hypesthesia or nonvital teeth, bleeding, palatal erosion, oroantral fistula	
Medial wall	Nasal obstruction, nasal discharge, epistaxis, cacosmia, visible mass in nostril	
Anterior wall	Swelling, pain, skin changes	
Posterior wall	Midface pain, hypesthesia of one-half of face, loss of function of lower cranial nerves	
Superior wall	Diplopia (double vision), proptosis (eye bulging out), chemosis, pain or hypesthesia, decreased visual acuity	

the sinus proper. Because the sinus floor is not altered, a preexisting sinus pathology or anatomic variant will be less likely to affect the healing process. As such, if the patient has a preexisting maxillary sinus condition or develops a sinus infection after implant placement, then implants are not at risk of becoming contaminated. However, the SA-2 to SA-4 surgical procedures do alter the sinus membrane and sinus floor. With these treatment options, a thorough preoperative evaluation is completed to rule out any existing pathologic condition in the maxillary sinus. In this way, the risk of possible mucus or bacteria contaminating the graft and creating a bacterial smear layer on the implant is reduced. Therefore the possibility of impaired bone formation during healing is reduced. In addition, because of the proximity of the maxillary sinus to numerous vital structures, postoperative complications can be very severe and even life-threatening.

Pathologic conditions associated with the paranasal sinuses are common ailments and afflict more than 31 million people each year. Approximately 16 million people will seek medical assistance related to sinusitis; yet sinusitis is one of the most commonly overlooked diseases in clinical practice. Potential infection in the region of the sinuses may result in severe complications. Infections in this area have been reported to result in sinusitis, orbital cellulitis, meningitis, osteomyelitis, and cavernous sinus thrombosis. In fact, paranasal sinus infection accounts for approximately 5% to 10% of all brain abscesses reported each year.[26]

A physical examination of the maxillary sinus evaluates the middle third of the face for the presence of asymmetry, deformity, swelling, erythema, ecchymosis, hematoma, or facial tenderness (Table 37.1). Nasal congestion or obstruction, prevalent nasal discharge, epistaxis (bleeding from the nose), anosmia (the loss of the sense of smell), and/or halitosis (bad breath) are noted.

The clinical examination for maxillary rhinosinusitis concerns the regions surrounding the maxillary antrum. The examination is conducted to assess each wall surrounding the maxillary sinus separately. The infraorbital foramen on the facial wall of the antrum is palpated through the soft tissue of the cheeks or intraorally to determine whether tenderness or discomfort is present. The intraoral examination assesses the floor of the antrum by alveolar ulceration, expansion, tenderness, paresthesia, and oroantral fistulae. The eyes are examined to evaluate

the superior wall of the sinus for proptosis, pupillary level, lack of eye movement, and diplopia. The nasal fluids may be used to evaluate the medial wall of the sinus by asking the patient to blow the nose in a waxed paper. The mucus should be clear and thin in nature. A yellow or greenish tint or thickened discharge indicates infection. Infected maxillary sinuses typically are symptomatic, which can exhibit exudate in the middle meatus and may be inspected with a nasal speculum and headlight (rhinoscopy) through the nares. The methods of examination of the infected maxillary sinus may include transillumination, nasoendoscopy, bacteriology, cytology, fiberoptic antroscopy, and radiography CBCT, or magnetic resonance imaging [MRI]).

Maxillary Sinus Radiographic Evaluation

Various radiographic techniques have been used in implant dentistry to evaluate the maxillary posterior region. In the early days of oral implantology, evaluation of this area was limited to 2-dimensional (2D) radiographs. However, these types of radiographs have inherent disadvantages that are affected by magnification and distortion, which leads to errors in diagnosis and treatment planning. Currently, this anatomic area is evaluated mainly by the use of 3D radiographic techniques (CBCT) or medical CT because they have become more accurate and efficient, with a significant reduced radiation.

Cone Beam Computerized Tomography

CBCT surveys have allowed the implant clinician to evaluate anatomic structures, anatomic variants, and pathologies more accurately. Many software programs are available that allow combining 3D images with computer software and allow an accurate assessment of the maxillary sinus. Because visualization of the maxillary sinus and surrounding structures are crucial for the proper diagnosis and treatment planning, it is highly suggested the implant clinician utilize CBCT anytime procedures involve the maxillary sinus.

Presently, no radiographic modality provides more information about the paranasal sinuses than CBCT. This type of radiography provides much more detailed information about the anatomy and pathologic condition of the sinuses compared with 2D radiography. Studies have concluded that CBCT is the best option for viewing the surrounding osseous structures and pathologic condition in the maxillary sinuses.[27,28]

The maxillary sinus can be evaluated with most CBCT images, including reformatted axial, panoramic, cross-sectional, sagittal, and 3D images. Most physicians use the coronal radiographs to evaluate the paranasal sinuses. The implant clinician must have a clear understanding of the CBCT radiographic anatomy and the pathologic conditions associated with the posterior maxilla and maxillary sinus regions.

Normal Anatomy

Maxillary Sinus Membrane (Schneiderian Membrane)

A CBCT scan of normal, healthy paranasal sinuses reveals a completely radiolucent (dark) maxillary sinus. Any radiopaque (whitish) area within the sinus cavity is abnormal, and a pathologic condition should be suspected. The normal sinus membrane is radiographically invisible, whereas any inflammation or thickening of this structure will be radiopaque. The density of the diseased tissue or fluid accumulation will be proportional to varying degrees of gray values.
● **Fig. 37.10** (A) Normal paranasal anatomy. (B) Paranasal pathology and anatomic variants.

Ostiomeatal Complex

The ostiomeatal unit is composed of the maxillary ostium, ethmoid infundibulum, anterior ethmoid cells, and the frontal recess. The main drainage avenue of the maxillary sinus is through the ostium. The maxillary ostium is bounded superiorly by the ethmoid sinuses and inferiorly by the uncinate process. The uncinate process is a bony knifelike projection that is attached inferiorly to the inferior turbinate and posteriorly has a free margin. Drainage continues through the ostium into the infundibulum, which is a narrow passageway leading into the middle meatus. The middle meatus is the radiolucent space bounded by the middle and inferior turbinates.

Nasal Cavity

Within the nasal cavity, three nasal turbinates or conchae (superior, middle, and inferior) exist Hard are small downward projections of bone. Between the turbinates is a space or recess termed a meatus. The respiratory epithelium covers the turbinates and

meatus and warms, moistens, and cleans the air that is respirated into the lungs.

The nasal septum is the bony partition that creates a barrier between the right and left sides of the nasal cavity. Obstructions within any aspect of the nasal system predispose the area to pathologic conditions (Fig. 37.10).

Maxillary Sinus: Anatomical Variants

Numerous anatomic variants arise that can predispose a patient to postsurgical complications. When these conditions are noted, a pharmacologic protocol may need to be altered and/or implants may be placed after the sinus graft has matured, rather than predisposing them to an increased risk by inserting them at the same time as the sinus graft. As stated previously, patency of the ostium is paramount to maintain drainage. Preexisting skeletal and bony abnormalities of the ostiomeatal complex may compromise the patency of the maxillary ostium, thereby, predisposing patients to maxillary rhinosinusitis.
● **Fig. 37.11** Nasal septum deviation is a common variant. Extreme cases may obstruct the ostiomeatal unit and increase the risk of sinusitis after a sinus graft.

Nasal Septum Deviation

A nasal septum deviation is a very common anatomic variant, occurring in as much as 70% of the population older than 14 years. This bony variant in extremes may cause obstruction of the ostiomeatal unit, which results in inflammation from air turbulence, causing increased mucosal drying and particle deposition. If the deviation is long-standing, then atrophy of the middle turbinate may occur, resulting in narrowing of the ostiomeatal complex (Fig. 37.11).[29]

Timmenga and colleagues[30] evaluated 45 patients who received 85 sinus grafts with endoscopy postsurgery. Of the 45 patients, five were found to have sinusitis postsurgery; all five of those patients had a nasal deviation or oversized turbinate. Therefore when these conditions are observed, consideration should be given to not place the implant at the same time as the sinus graft, and the recommended preoperative and postoperative pharmacologic protocol is especially warranted.

Middle Turbinate Variants

The middle turbinate plays a significant role in proper drainage of the maxillary sinus. A concha bullosa is a pneumatization within the middle turbinate and may occlude the ostiomeatal complex, compromising adequate drainage. This variant is seen in approximately 4% to 15% of the population (Fig. 37.12).[31] Another variant in this anatomic structure is a paradoxically curved middle turbinate, which presents a concavity toward the septum, decreasing the size of the meatus. This also predisposes the patient to a higher incidence of sinus disease.

Uncinate Process Variants

The uncinate process is a projection of the ethmoid bone which is located in the wall of the lateral nasal cavity. This bony process is an important anatomic structure in the patency of the ostium. A deflected uncinate process (either laterally or medially) can narrow the ethmoid infundibulum, affecting the ostiomeatal complex. Perforations may also be present within the uncinate process, leading to communication between the nasal cavity and ethmoid infundibulum. In addition, the uncinate process may be pneumatized. Although this is rare, it may compromise adequate clearance and drainage of the maxillary sinus.

Supplemental Ostia

A supplemental ostium or secondary ostia may occur between the maxillary sinus and the middle meatus, which is often found in
● **Fig. 37.12** (A) Nasal cavity anatomy: inferior turbinate *(IT),* middle turbinate *(MT),* inferior meatus *(red arrow),* middle meatus *(yellow arrow).* Note the paradoxical middle turbinate. (B) Coronal image depicting concha bullosa *(arrow)* and deviated septum.

the posterior fontanelles (PF). This may be found in approximately 18% to 30% of individuals. Because these secondary openings are usually located posterior and inferior to the natural ostium, they may predispose the patient to sinusitis by the recirculation of infected secretions from the primary meatus back into the sinus cavity. On occasion, these secondary ostia may be encountered during the elevation of the medial wall of the antrum before placement of the sinus graft. When observed, a piece of collagen is placed over the site to prevent graft material from entering the nasal cavity.

Maxillary Hypoplasia

Hypoplasia of the maxillary sinus may be a direct result from trauma, infection, surgical intervention, or irradiation to the maxilla during the development of the maxillary bone. These conditions interrupt the maxillary growth center, producing a smaller than normal maxilla. A malformed and positioned uncinate process is associated with this disorder, leading to chronic sinus drainage problems. Most often, these patients have adequate bone

• **Fig. 37.13** Maxillary hypoplasia. Coronal cone beam computerized tomographic view of an abnormally small sized maxillary sinus
• **Fig. 37.14** Inferior meatus pneumatization (big nose variant). Cone beam computerized tomographic panoramic image depicting the abnormally large nasal cavity extending into the molar area.

height for endosteal implant placement, and a sinus graft is not required to gain vertical height (Fig. 37.13).

Inferior Turbinate and Meatus Pneumatization (Big-Nose Variant)

Misch had observed, on rare occasion, that the inferior third of the nasal cavity pneumatizes within the maxilla and resides over the alveolar residual ridge. An evaluation of 550 computerized tomography (CT) scans of complete or partially edentulous maxillae found this condition in 18 patients (3% incidence). When the patient has this condition, the maxillary sinus is lateral to the edentulous ridge. When inadequate bone height is present below this structure, a sinus graft does not increase available bone height for an implant. This condition is difficult to observe on a two-dimensional panoramic radiograph. If unaware, then the implant can be placed into the nasal cavity above the residual ridge and even penetrate the inferior turbinate. A sinus graft is contraindicated with this patient condition because the sinus is lateral to the position of the implants. Instead, in most cases an onlay graft is required to increase bone height (Fig. 37.14).

Maxillary Sinus Pathology

A pre-existing, pathologic, maxillary sinus condition may be a relative or absolute contraindication for many procedures that will alter the sinus floor before or in conjunction with sinus grafting and/or implant insertion. The risk of postoperative infection is elevated and may compromise the health of the implant and the patient. Therefore pathologic conditions, either preoperative or postoperative, of a maxillary sinus should be evaluated, diagnosed, and treated.

Pathologic conditions of the maxillary sinus may be divided into four categories: (1) inflammatory lesions, (2) cystic lesions, (3) neoplasms, and (4) antroliths and foreign bodies. Studies have shown that 20% to 45% of the asymptomatic population has a subclinical pathologic condition in the maxillary sinus. The author has evaluated approximately 2000 prospective candidates for maxillary sinus augmentation procedures at the Misch International Implant Institute for signs of pathology. The results concluded 38.7% of asymptomatic patients had maxillary sinus pathologic conditions on CBCT scan evaluation. Manji and colleagues evaluated 275 patients and concluded that 45.1% were classified as exhibiting sinus pathology (i.e., 56.5% had mucosal thickening (≥5 mm), 28.2% with polypoidal thickening, 8.9% partial opacification and/or air/fluid level, and 6.5% complete opacification).[32] Because of this increased incidence, it is highly recommended that a thorough radiographic evaluation be completed on all prospective sinus elevation patients.

Inflammatory Disease

Inflammatory conditions can affect the maxillary sinus from odontogenic and nonodontogenic causes.

Odontogenic Rhinosinusitis (Periapical Mucositis)

Odontogenic sinusitis describes a type of sinus disease in which radiographic, microbiologic, and/or clinical evidence indicates it is of a dental origin (i.e., from a tooth). The close proximity of the roots of the maxillary posterior teeth to the floor of the sinus suggest any inflammatory changes in the periodontium or surrounding alveolar bone may result in pathologic conditions in the maxillary sinus.

Etiology. Odontogenic sinusitis is usually the result of an infected tooth (e.g., periapical abscess, cyst, granuloma, periodontal disease) that causes an expansile lesion within the floor of the sinus. Periapical inflammation has been shown to be capable of affecting the sinus mucosa, with and without perforation of the cortical bone of the sinus floor. Infection and inflammatory mediators are capable of spreading directly or via bone marrow, blood vessels, and lymphatics to the maxillary sinus, causing an inflammatory response.[33] Additional etiologic factors include sinus perforations during extractions and foreign bodies (e.g., gutta-percha, root tips, amalgam). Odontogenic rhinosinusitis is often polymicrobial, with anaerobic streptococci, *Bacteroides* spp., *Proteus* spp., and coliform bacilli involved. Studies have shown 10% to 40% of all rhinosinusitis sinusitis cases may have an underlying dental pathology.[34,35]

Radiographic Appearance. The radiographic evaluation of patients with odontogenic sinusitis will most commonly demonstrate a unilateral maxillary sinusitis. A unilateral maxillary odontogenic sinusitis is often overlooked on CBCT scans because they are frequently asymptomatic. Involvement of the ostiomeatal complex may result in extension to adjacent paranasal sinuses (e.g., ethmoid, frontal, sphenoid), ranging from 27% to 60% among patients with odontogenic sinusitis.[36] Odontogenic sinusitis has been shown to exhibit bilateral involvement in 20% of
• **Fig. 37.15** Odontogenic rhinosinusitis. Cone beam computerized tomographic panoramic view showing molar roots extending into the maxillary sinus, resulting in inflammation of the sinus membrane. Note the communication between the maxillary molar roots and the maxillary sinuses.

• **Fig. 37.16** Mild mucosal thickening. Three-dimensional axial view showing bilateral mucosal thickening (gray area surrounding the bony walls of the maxillary sinus).

patients. In some cases, a slight thickening of the sinus membrane may be present adjacent to the offending tooth.[37] Usually the radiographic appearance will be a radiopaque band that follows the contours of the sinus floor.

Differential Diagnosis. Odontogenic sinusitis may be confused with acute rhinosinusitis sinusitis; however, acute rhinosinusitis is almost always symptomatic. Mild mucosal thickening from a nonodontogenic origin (e.g., smoking, allergy) may also show similar radiographic signs. However, the nonodontogenic origin may be confirmed from lack of radiographic evidence of a diseased or painful tooth.

Treatment. Before any type of sinus augmentation or implant placement into the sinus, the tooth or teeth involved should be treated periodontally, endodontically, or extracted. After intraoral soft tissue healing and resolution of the pathologic condition (i.e., a minimum of 6 weeks), the bone graft and/or implant may be performed with minimal morbidity. The removal of unhealthy teeth decreases sinus membrane thickening, but most of the time it does not completely resolve it. In addition, epithelial metaplasia with the ciliated mucosa changing to simple cuboidal and stratified squamous keratinized tissue may result. Therefore, depending on the severity, in some cases the mucosal thickness may remain because of the change in epithelia structure and metaplasia changes[6] (Fig. 37.15).

Mild Mucosal Thickening (Nonodontogenic)

Sinus membrane thickening has been shown to be present in approximately 46.7% of patients, with equal distribution between healthy and unhealthy natural teeth.[38] The most common area for the mucosal thickening has been shown to be in the midsagittal sinus region, which is adjacent to the first and second molars. In the literature, it is accepted that mucosal thickening greater than 2 mm is considered a pathologic sinus membrane.[39-42]

Etiology. Local odontogenic issues, such as periapical pathology, periodontal disease, and the health of the adjacent dentition, have been shown to be the etiologic factor in the inflammatory response to the sinus membrane in approximately 50% of cases.[43] However, nonodontogenic factors such as smoking,[44] allergies, sinus congestion, mold, and air pollution may aggravate the sinus mucosa, resulting in mild thickening. Chronic inflammatory conditions may result in altered bacterial flora, along with mucociliary clearance and cilia changes.
Radiographic Appearance. On a CBCT image, usually thickened mucosa will appear as a radiopaque widened membrane. Thickened mucosa can easily be seen when evaluating axial images.

Treatment. Usually no treatment is necessary because mild mucosal thickening is asymptomatic. Studies have shown that slight mucosal thickening allows for sinus grafting procedures to be completed with a decreased incidence of membrane perforation (Fig. 37.16).

Acute Rhinosinusitis

A nonodontogenic pathologic condition may also result in inflammation in the form of sinusitis. The most common type of sinusitis is acute rhinosinusitis (i.e., sinusitis symptoms of less than 3 months). The signs and symptoms of acute rhinosinusitis are rather nonspecific, making it difficult to differentiate from the common cold, influenza type of symptoms, and allergic rhinitis. However, the most common symptoms include purulent nasal discharge, facial pain and tenderness, nasal congestion, and possible fever.

Acute maxillary rhinosinusitis results in 22 to 25 million patient visits to a physician in the United States each year, with a direct or indirect cost of $6 billion. Although four paranasal sinuses exist in the skull, the most common involved in rhinosinusitis are the maxillary and frontal sinuses.[45]

Etiology. An inflammatory process that extends from the nasal cavity after a viral upper respiratory infection often causes acute maxillary sinusitis. Microbiological cultures have shown the most common pathogens causing acute rhinosinusitis are *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis*. These pathogens include approximately 20% to 27% β-lactamase–resistant bacteria. *S. aureus* has also been cited, with the microbiology of acute rhinosinusitis. However, this pathogen is usually only seen in nosocomial (hospital-induced) sinusitis and is unlikely to be seen in an elective sinus graft patient.

The most important factor in the pathogenesis of acute rhinosinusitis is the patency of the maxillary ostium.[46,47] Local predisposing causes of sinusitis include inflammation and edema associated with a viral upper respiratory tract infection or allergic rhinitis. As a consequence, mucous production within the sinus may be abnormal in quality or quantity, along with a compromised
• **Fig. 37.17** Acute rhinosinusitis. (A and B) Flat radiopaque (gray) line within the maxillary sinus, which is termed an air-fluid level and consistent with acute rhinosinusitis.

mucociliary transport. In an occluded ostium, an accumulation of inflammatory cells, bacteria, and mucus exists. Phagocytosis of the bacteria is impaired with immunoglobulin (Ig)-dependent activities decreased by the low concentration of IgA, IgG, and IgM found in infected secretions.

The oxygen tension inside the maxillary sinus has significant effects on pathologic conditions. When the oxygen tension in the sinus is altered, resultant sinusitis occurs. Growth of anaerobic and facultative organisms proliferate in this environment.[48] Many factors may alter the normal oxygen tension within the sinuses. A direct correlation exists between the ostium size and the oxygen tension in the sinus. In patients with recurrent episodes of sinusitis, oxygen tension is often reduced, even when infection is not present. As a consequence, a history of recurrent acute rhinosinusitis is relevant to determine whether a bone graft or dental implant may be at increased risk of morbidity.

Radiographic Appearance. The radiographic hallmark in acute rhinosinusitis is the appearance of an air-fluid level. A line of demarcation will be present between the fluid and the air within the maxillary sinus. If the patient is radiographically positioned supine, then the fluid will accumulate in the posterior area; if the patient is upright during the imaging survey, the fluid will be seen on the floor and horizontal in nature. Additional radiographic signs include smooth, thickened mucosa of the sinus, with possible opacification. In severe cases, the sinus cavity may fill completely with supportive exudates, which gives the appearance of a completely opacified sinus. With these characteristics, the terms pyocele and empyema have been applied.

Treatment. Because acute rhinosinusitis is one of the most common health problems today, patients having sinus grafting procedures should be well screened for a past history and current symptoms. Even though acute rhinosinusitis is a self-limiting disease, a symptomatic patient should be treated and cleared by their physician before any grafting procedures. These patients are also more prone to postoperative rhinosinusitis. As a result, a sinus graft is performed and given a longer healing period before placement of an implant. In addition, the suggested antibiotic coverage may be altered and extended, both before and after the sinus graft procedure (Fig. 37.17).

Chronic Rhinosinusitis

Chronic rhinosinusitis is a term used for a sinusitis that does not resolve in 3 months and also has recurrent episodes. It is the most common chronic disease in the United States, affecting approximately 37 million people. Symptoms of chronic rhinosinusitis are associated with periodic episodes of purulent nasal discharge, nasal congestion, and facial pain.

Etiology. As maxillary rhinosinusitis progresses from the acute phase to the chronic phase, anaerobic bacteria become the predominant pathogens. The microbiology of chronic rhinosinusitis is very difficult to determine because of the inability to acquire accurate cultures. Studies have shown that possible bacteria include *Bacteroides* spp., anaerobic gram-positive cocci, *Fusobacterium* spp., and aerobic organisms (*Streptococcus* spp., *Haemophilus* spp., *Staphylococcus* spp.).[49] A Mayo Clinic study showed that in 96% of patients with chronic rhinosinusitis, active fungal growth was present.[50]

Radiographic Appearance. Chronic rhinosinusitis may appear radiographically as thickened sinus mucosa, complete opacification of the antrum, and/or sclerotic changes in the sinus walls (which give the appearance of denser cortical bone in the lateral walls).

Treatment. Medical evaluation and clearance by an experienced physician in sinus pathology (e.g., otolaryngologist [ENT]) is highly recommended for patients with chronic maxillary rhinosinusitis before any sinus grafting, because significant bacterial resistance and fungal growth is highly probable. Fungal infections are often difficult to treat and control, and serious complications may result in postoperative sinus graft patients. In many chronic rhinosinusitis patients, a sterile and nonpathologic sinus is difficult to obtain, contraindicating (absolute) sinus grafting and/or implants.

Allergic Rhinosinusitis

Etiology. Allergic sinusitis is a local response within the maxillary sinus caused by an irritating allergen in the upper respiratory tract. Therefore allergens may be a cause of acute or chronic rhinosinusitis. This category of sinusitis may be the most common form, with 15% to 56% of patients undergoing endoscopy for sinusitis showing evidence of allergy. Allergic rhinosinusitis often leads to chronic sinusitis in 15% to 60% of patients.[51] The sinus mucosa frequently becomes irregular or lobulated, with resultant polyp formation.

Radiographic Appearance. Polyp formation related to allergic sinusitis is usually characterized by multiple, smooth, rounded, radiopaque shadows on the walls of the maxillary sinus. Most commonly, polyps initially are located near the ostium and are easily observed on a CBCT scan. In advanced cases, ostium occlusion, along with displacement or destruction of the sinus walls, may be present with a radiographic image of a completely opacified sinus.

Treatment. When patients have a history of allergic rhinosinusitis, special attention must be given to a patent ostium, bacterial resistance, and close postoperative supervision. Polyps, if enlarged or too numerous, may be required to be removed before the sinus
• **Fig. 37.18** Allergic rhinosinusitis. (A) Bilateral polypoid inflammation consistent with allergic rhinosinusitis. (B) Polyp removal on a patient with chronic allergic rhinosinusitis. Unfortunately the polyps have a high incidence of recurrence, and in many cases this contradicts implant treatment.

graft. This may be performed through an anterior Caldwell-Luc approach or by an endoscopic procedure via the maxillary ostium.

Allergic sinusitis patients often have a greater risk of complications related to an increase in allergen production. Because sinus grafting is an elective procedure, the time of year for the surgery may be altered to decrease the postoperative infection risk. For example, if hay fever or a grass allergy is related to the patient's sinusitis, then the sinus graft surgery should be performed in the season or seasons that have least risk to aggravate the sinus mucosa (i.e., winter or fall). In severe cases of polyposis, any procedure violating the sinus proper may be an absolute contraindication (Fig. 37.18).

Fungal Rhinosinusitis (Eosinophilic Fungal Rhinosinusitis)

Granulomatous rhinosinusitis is a very serious (and often overlooked) disorder within the maxillary sinus. Patients who exhibit signs of fungal rhinosinusitis may indicate an extensive history of antibiotic use, chronic exposure to mold or fungus in the environment, or history of immunosuppression. Fungal rhinosinusitis has been categorized into five types: acute necrotizing (fulminant), chronic invasive, chronic granulomatous invasive, fungal hall (sinus mycetoma), and allergic. The first three types are classified as tissue-invasive and the last two are noninvasive fungal rhinosinusitis.[52]

Etiology. Fungal infections are usually caused by aspergillosis, mucormycosis, or histoplasmosis. Chronic rhinosinusitis patients should always be evaluated for granulomatous conditions because a high percentage of fungal growth exists in this patient population. Of concern in these patients is eosinophils are activated that release major basic protein (MBP) into the mucus, which attacks and destroys the fungus. However, this may result in the membrane being irritated and possibly irreversibly damaged, which allows bacteria to proliferate. Three possible clinical signs may differentiate fungal rhinosinusitis from acute or chronic rhinosinusitis; however, a positive diagnosis requires mycological and histologic studies.[53]

1. No response to antibiotic therapy
2. Soft tissue changes in sinus associated with thickened reactive bone, with localized areas of osteomyelitis
3. Association of inflammatory sinus disease that involves the nasal fossa and facial soft tissue

Radiographic Appearance. Granulomatous rhinosinusitis is extremely variable and may appear radiographically as mild
• **Fig. 37.19** Fungal rhinosinusitis. Coronal cone beam computerized tomographic image of fungal rhinosinusitis, which has the radiographic appearance of an opacified sinus with localized highly densified areas.

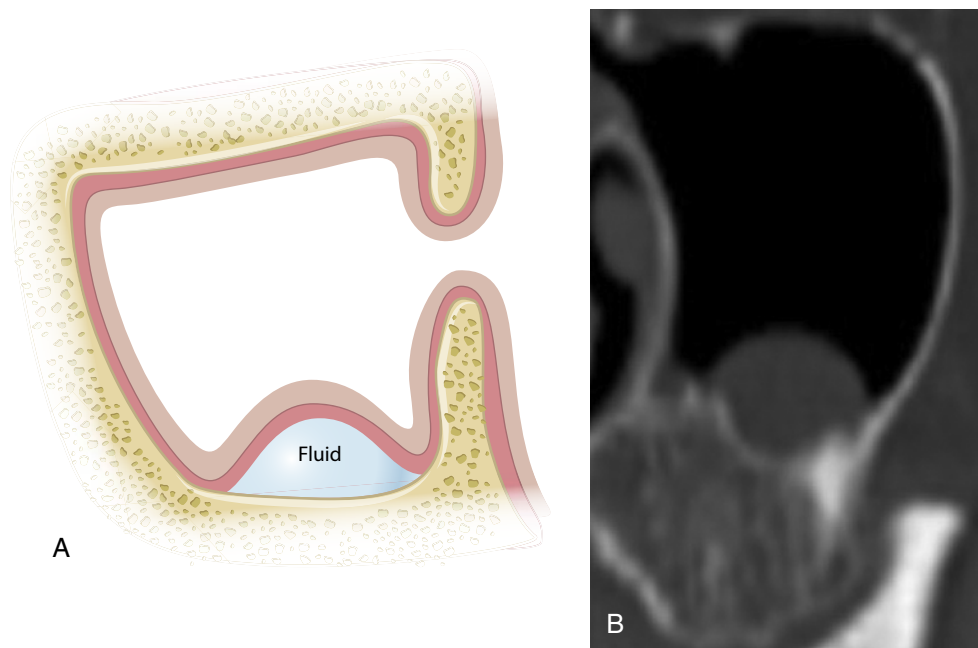
thickening (less common) to complete opacification (more common) of the sinus. The majority of sinuses show complete opacification with hyperdense areas.[54] Extension beyond the maxillary sinus to other sinuses is common and expansion and erosion of a sinus wall may be present.

Treatment. Patients with a history or current knowledge of fungal rhinosinusitis should be referred to their physician or an ENT for treatment and surgical clearance (i.e., in most cases clearance will not be given because fungal rhinosinusitis is rarely curable). Treatment usually involves debridement and therapy with an antifungal agent, such as amphotericin B (Fig. 37.19).

Cystic Lesions

Cystic type lesions are a common occurrence in the maxillary sinus. They may vary from microscopic lesions to large, destructive, expansile pathologic conditions. Cystic lesions may include pseudocysts, retention cysts, primary mucoceles, and postoperative maxillary cysts.

Pseudocysts (Mucous Retention Cyst)

The most common cysts in the maxillary sinus are mucous retention cysts. After much controversy, in 1984, Gardner[55] distinguished these cysts into two categories: (1) pseudocysts and (2)


• **Fig. 37.20** Pseudocyst. (A) Diagram showing fluid accumulation underneath the membrane. (B) Radiograph showing the dome-shaped characteristics of a pseudocyst.

retention cysts. Pseudocysts are more common and of much greater concern during sinus graft surgery, compared with retention cysts. Pseudocysts recur in approximately 30% of patients and are often unassociated with sinus symptoms. As a consequence, many physicians do not treat this condition. However, when their size is larger (approximately >10 mm in diameter), pseudocysts may occlude the maxillary ostium during a sinus graft procedure and increase the risk of postoperative infections. Studies have shown successful bone graft and implant placement in maxillary sinuses with pseudocysts.[56]

Etiology

A pseudocyst is caused by an accumulation of fluid beneath the periosteum of the sinus mucosa. This elevates the mucosa away from the floor of the sinus, giving rise to a dome-shaped lesion. Pseudocysts have also been termed mucosal cysts, serous cysts, and nonsecreting cysts. Pseudocysts are not true cysts because they lack an epithelial lining; however, they are surrounded by fibrous connective tissue.[57] The cause of the fluid is thought to result from sinus mucosa bacterial toxins or from odontogenic causes (Fig. 37.20).

Radiographic Appearance

Pseudocysts are depicted radiographically as smooth, homogenous, dome-shaped, round to ovoid, well-defined radiopacities. Pseudocysts do not have a corticated (radiopaque) marginal perimeter and almost always located on the floor of the sinus cavity. In some cases, pseudocysts may encompass the entire maxillary sinus, making diagnosis difficult because it may be radiographically similar to rhinosinusitis.

Treatment

Pseudocysts are not a contraindication for sinus graft surgery, unless their approximate size increases the possibility of occluding the maxillary ostium. If a large pseudocyst (i.e., greater than 8 mm) is present, then the elevation of the membrane during a sinus graft may raise the cyst to occlude the ostium. In addition, on elevation or placement of the grafting material, the cyst may be perforated, allowing fluid within the cyst to contaminate the graft. Large cysts of this nature should be drained and allowed to heal before or in conjunction with sinus elevation surgery. Most often, an ENT physician should evaluate to determine any intervention. If a pseudocyst is less than 8 mm, then less concern is needed and the fluid may be drained in conjunction with sinus grafting, depending on the surgeon's experience in the treatment of this condition. Caution should be exercised to prevent membrane perforation. A strict recall evaluation of this area during the follow-up period of the sinus graft surgery is in order because reoccurrence of pseudocysts is common.

Retention Cysts

Retention cysts may be located on the sinus floor, near the ostium, or within antral polyps. Because they contain an epithelial lining, researchers consider them to be mucous secretory cysts and "true" cysts. Retention cysts are often microscopic in size.

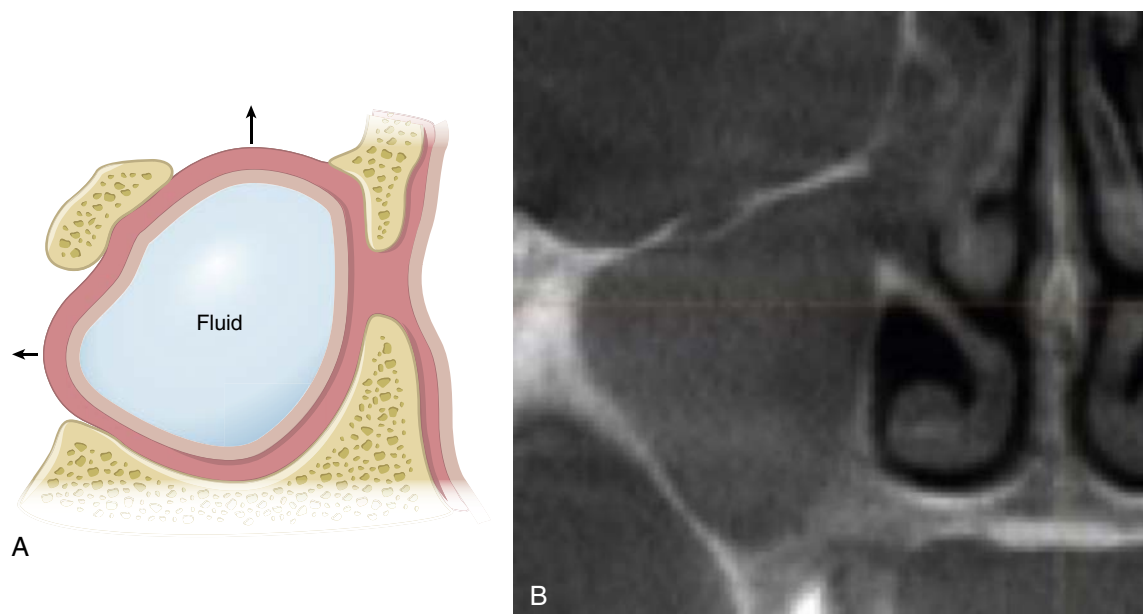
Etiology

Retention cysts result from partial blockage of seromucinous gland ducts located within the connective tissue underlying the sinus epithelium. As the secretions collect, they expand the duct, producing a cyst that is encompassed by respiratory or cuboidal epithelium. They may be caused by sinus infections, allergies, or odontogenic reasons.

Radiographic Appearance

Retention cysts are usually very small and not seen clinically or radiographically. In rare instances, they may achieve adequate size to be seen in a CT image and may resemble the appearance of a small pseudocyst.

Treatment

No treatment for retention cysts exist before or in conjunction with a sinus graft and/or implant insertion.


• **Fig. 37.21** Primary maxillary sinus mucocele. (A) Diagram showing expansive nature of a primary maxillary sinus mucocele. (B) Radiograph showing the initial stage of complete opacification and later stages including expansion of the bony plates.

Primary Maxillary Sinus Mucocele

A primary mucocele is a cystic, expansile, destructive lesion that may include painful swelling of the cheek, displacement of teeth, nasal obstruction, and possible ocular symptoms.[58] The primary mucocele is more commonly found in the ethmoid sinus (45.5%) versus the maxillary sinus (18.3%).[59]

Etiology

The primary mucocele arises from blockage of the maxillary ostium by fibrous connective tissue. Because of the compromised drainage, the mucosa expands and herniates through the antral walls. This mucocele is classified as a cyst because it is lined by antral epithelium, which contains mucin.

Radiographic Appearance

In the early stages, the primary mucocele involves the entire sinus and appears as an opacified sinus. As the cyst enlarges, the walls become thin and eventually perforate. In the late stages, destruction of one or more surrounding sinus walls is evident.

Treatment

Surgical removal of this cyst is indicated prior to any bone augmentation procedures (Fig. 37.21).

Secondary Maxillary Sinus Mucocele (Postoperative Maxillary Cyst)

A postoperative maxillary cyst of the maxillary sinus is a cystic lesion that usually develops secondary to a previous trauma or surgical procedure in the sinus cavity. It also has been termed a surgical ciliated cyst, postoperative maxillary sinus mucocele, or a secondary mucocele.[60-62] Secondary mucoceles occur most commonly in the maxillary sinus (86%) versus the ethmoid sinus (7.1%).[59]

Etiology

A postoperative maxillary cyst is a direct result of trauma or past history of surgery within the maxillary sinus. The cyst is derived from the antral epithelium and mucosal remnants that previously were entrapped within the prior surgical site. This separated mucosa results in an epithelium-lined cavity in which mucin is secreted. The antrum becomes divided by a fibrous septum in which one part drains normally, whereas the other part is composed of the mucocele. It is relatively rare in the United States; however, it constitutes approximately 24% of all cysts in Japan. At least three reported cases exist of a postoperative maxillary cyst forming after a sinus graft procedure, including one by the author of this chapter.[63]

Radiographic Appearance

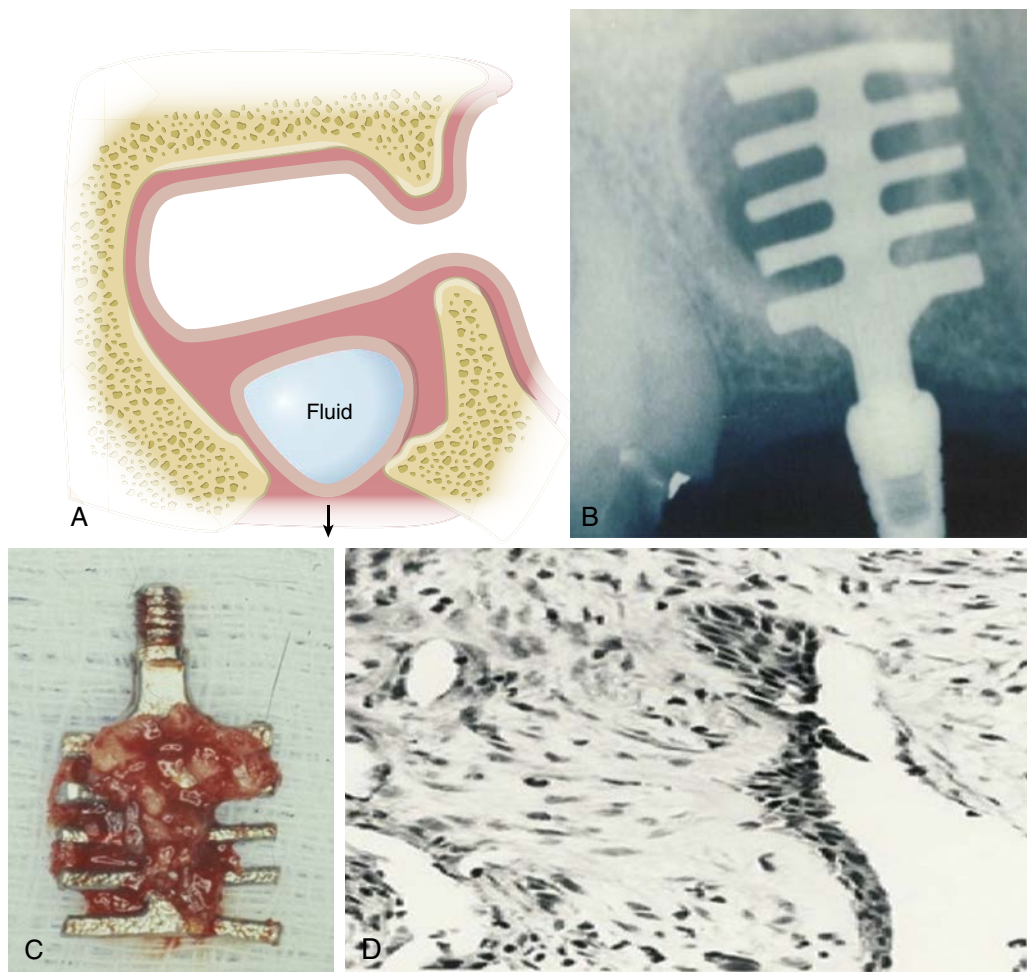
The cyst radiographically presents as a well-defined radiolucency circumscribed by sclerosis. The lesion is usually spherical in the early stages, with no bone destruction. As it progresses, the sinus wall becomes thin and eventually perforates. In later stages, it will appear as two separated anatomic compartments.

Treatment

Surgical ciliated cysts should be enucleated before any bone augmentation procedures. If observed after the sinus graft, then the cysts should be enucleated and regrafted in the site (Fig. 37.22)

Neoplasms

Etiology

Primary malignant tumors within the maxillary sinus are usually caused by squamous cell carcinomas or adenocarcinomas. Signs and symptoms of malignant disease are related to the surrounding sinus wall that the tumor invades and includes swelling in the cheek area, pain, anesthesia or paresthesia of the infraorbital nerve (e.g., anterior wall), and visual disturbances (e.g., superior wall). These tumors in the sinus are usually nonspecific and give a variety


• **Fig. 37.22** Secondary maxillary sinus mucocele. (A) Diagram showing cystic nature of a secondary mucocele, which divides the sinus into two compartments. (B) Radiograph of blade implant with well-defined radiolucency around the implant. (C) Blade implant removed with associated pathology. (D) Histology revealing a secondary maxillary sinus mucocele.

of consequences, including opacified sinuses; soft tissue masses in the sinus; and sclerosis, erosion, or destruction of the walls of the sinus. Sixty percent of squamous cell carcinomas of the paranasal sinuses are located in the maxillary sinus, usually in the lower one-half of the antrum. Clinical signs in the oral cavity reflect the expansion of the tumor and an increased mobility of the involved teeth. Invasion of the infratemporal fossa is also possible.[1]

Radiographic Appearance

Radiographic signs of neoplasms may include various-sized radiopaque masses, complete opacification, or bony wall changes. A lack of a posterior wall on a panoramic radiograph should be a sign of possible neoplasm (Fig. 37.23).

Treatment

Any signs or symptoms of a lesion of this type should be immediately referred for medical consultation. Sinus graft surgery is absolutely contraindicated while this condition exists.

Antroliths and Foreign Bodies

Maxillary sinus antroliths are the result of complete or partial encrustation of a foreign body. These masses found within the maxillary sinus originate from a central nidus, which can be endogenous or exogenous.[64]

Etiology

The majority of endogenous sources are from dental origin, including retained roots, root canal sealer, fractured dental instruments, and dental implants. Additionally, bone spicules, blood, and mucus have been reported to cause antroliths.[65] Reports in the literature of exogenous sources include paper, cigarettes, snuff, and glue.[66] Although most antroliths are asymptomatic, they often are associated with sinusitis.

Radiographic Appearance

The radiographic appearance of a maxillary antrolith resembles either the central nidus (e.g., retained root) or appears as a radiopaque, calcified mass within the maxillary sinus (Fig. 37.24).

Differential Diagnosis

Because the calcified antrolith is composed of calcium phosphate ($CaPO_4$), calcium carbonate salts, water, and organic material, it will be considerably more radiopaque than an inflammatory or cystic lesion.[67] The central nidus of the antrolith is similar to its usual radiographic appearance.
• **Fig. 37.23** Axial contrast-enhanced computerized tomography (bone window) shows almost complete radiopacification of the right maxillary sinus by squamous cell carcinoma. There is destruction of the walls of the sinus and an air-fluid interface in the left sinus. (From Koenig LJ, et al. *Diagnostic Imaging: Oral and Maxillofacial.* 2nd ed. Philadelphia, PA: Elsevier; 2017.)
• **Fig. 37.24** Antroliths. Any object left in the sinus will calcify and is termed an antrolith. Antroliths usually will result in mucociliary clearance issues.

Treatment

Before sinus augmentation and implant placement, the antrolith should be surgically removed. If sinusitis exists, then the sinus cavity should be allowed to heal completely before sinus augmentation procedures. A nonsymptomatic condition may have the antrolith removed and sinus graft performed at the same surgery, only if the sinus membrane is not compromised.

Miscellaneous Factors That Affect the Health of the Maxillary Sinus

Smoking

The use of tobacco is one of the main factors that may lead to an increased morbidity after sinus graft procedures. Smoking is known to be associated with an increased susceptibility to allergies and infections because it interferes with ciliary function and secretory immunity of the nasorespiratory tract. In the maxillary sinus, this may have direct effects on both immune exclusion and suppression because IgA and IgM responses are reduced, whereas IgE responses are increased. Smoking is believed to interfere with bone graft healing because it reduces local blood flow by increasing peripheral resistance and causing an increased platelet aggregation. By-product chemicals of smoking, such as hydrogen cyanide and carbon monoxide, have been shown to inhibit wound healing, as does nicotine, which inhibits cellular proliferation. Tobacco may interfere directly with osteoblastic function, and strong evidence exists of decreased bone formation in smokers. In addition, smokers have a significant reduction of bone mineral content. Bone mineral density can be reduced two to six times in a chronic smoker. Overall, smoking may contribute to poor available bone quality and poor healing capacity resulting from vascular and osteoblastic dysfunction.[68]

There exist many clinical studies with smoking and sinus graft procedures. Klokkevold evaluated the success rate of dental implants placed in the posterior maxilla; it showed a 7% greater failure rate compared with nonsmokers.[69] Lindquist showed that smokers can also suffer detrimental effects around successfully integrated maxillary implants, with a significantly greater bleeding index, greater mean peri-implant pocket depth, more frequent peri-implant inflammation, and radiographically greater mesial and distal bone loss.[70] Olson and colleagues found an association between dental implants placed in augmented maxillary sinuses and history of smoking.[71] Widmark reported a higher failure rate in smokers after rehabilitation of severely resorbed maxillae with and without bone graft.[72] Schwartz-Arad and colleagues evaluated 212 implants in the posterior maxilla, resulting in a 95.5% success rate with nine failures. Of the nine failures, five were in patients that smoked.[73]

In summary, smoking is not an absolute contraindication for sinus graft procedures. However, patients should be instructed to cease smoking before and after sinus graft procedures because of the literature-based studies showing a higher risk of wound dehiscence, graft infection and/or resorption, and a reduced probability of osseointegration. It is recommended, however, that if a decision to proceed with surgery has been made, then patients refrain from smoking at least 15 days before surgery (i.e., the time it takes for nicotine to clear systemically) and 4 to 6 weeks after surgery. Moreover, smokers should sign a detailed informed consent in which risks connected to smoking are clearly defined and explained.

Relative and Absolute Contraindication to Maxillary Sinus Graft Procedures

In general contraindications for implant surgery also apply to sinus graft procedures. However, additional specific and local conditions may exist that increase morbidity. Several conditions related to the maxillary sinus are a concern, but they are not necessarily contraindications to the sinus graft procedure. The implant clinician, after evaluation of the CBCT scan and evaluation of the maxillary sinus, will in some cases need further medical evaluation before proceeding with procedures that may invade the sinus proper. There exists a wide variation in the severity of the possible pathologic conditions that may be present in the maxillary sinus. For example, a patient may have a mild deviated septum. Because it does not affect the mucociliary clearance of the maxillary sinus

and there is no associated pathology, no medical consultation by an ENT is warranted. However, if a deviated septum is present and severe, resulting in a nonpatent ostium, an ENT referral would be highly recommended.

A list of relative and absolute contraindications is listed in Boxes 37.2 and 37.3.

Reduction of Sinus Graft Complications

Even though sinus graft procedures have high success rates, these procedures tend to have a higher risk of infection than implant placement surgery because the patient is predisposed to infections originating from the oral surgical procedure (i.e., intraoral infection originating from the surgical site) or from the sinus graft procedure (i.e., infection within the sinus proper). Therefore a surgical environment that includes a strict aseptic technique including intraoral and extraoral scrubbing with chlorhexidine, scrubbing and draping the patient, and gowning the doctor and assistant should be considered in addition to sterile gloves and sterile instruments. The risk of postoperative sinus infection is generally less than 5% when these procedures and a preoperative and postoperative pharmacologic regimen are used.[73,74]

Prophylactic Medications

Systemic Antimicrobial Medications

The risks of bacterial contamination before and after sinus graft procedures are much different than routine implant surgical procedures. Therefore the pharmacologic protocol for sinus graft procedures should be effective against the organisms in this surgical site. The recommended pharmacologic regimen includes a prophylactic antibiotic, anti-inflammatory medications, and antimicrobial rinses.

Compared with routine dental implant surgery, sinus augmentation has a greater chance of morbidity because of the possible additional routes of infection. Bacterial invasion may originate from different sources such as (1) intraoral surgery, (2) bone graft material, and (3) bacteria from the sinus cavity. Additionally, it has been well documented that the inclusion of foreign bodies (e.g., implants, autografts, allografts) increases infection rates.[75,76] Because a greater chance of infection and morbidity exists with this type of surgical procedure, a strict antibiotic protocol is of benefit. Antibiotic medications have been shown to significantly reduce the number of sinus graft or implant failures caused by infection.[77]

Following the principles of prophylactic antibiotic administration, the antibiotic should be effective against the bacteria most likely to cause infection. The most likely contaminating organisms after intraoral surgery are primarily streptococci, anaerobic gram-positive cocci, and anaerobic gram-negative rods. *S. pneumoniae, H. influenzae,* and *M. catarrhalis* are the three most common pathogens found within the maxillary sinus that may lead to acute sinus infections.[78] *S. aureus* is not common with acute episodes; however, it has been shown to have a significant role in causing chronic rhinosinusitis disease, along with anaerobic bacteria. The organisms associated with infection in general oral surgical procedures include α-hemolytic streptococci and *S. viridans.*[79] Therefore a pharmacologic protocol should be effective against these organisms.

When evaluating various classes of antibiotic medications used for treatment of maxillary sinus infections, the antibiotic class of choice is the β-lactam antibiotic drugs. With the wide range of possible routes of bacterial invasion and types of bacteria, the antibiotic drug must be broad spectrum to account for all these possibilities. However, bacterial resistance has become a significant problem in the treatment of these pathogens. Bacterial resistance is initiated by two common mechanisms: (1) production of antibiotic-inactivating enzymes (*S. aureus, H. influenzae,* and *M. catarrhalis*) and (2) alteration in target site (*S. pneumoniae*). Studies have shown the following resistance (i.e., β-lactamase production) results[80]:

H.*influenzae:* 36.8%
M.*catarrhalis:* 98%
S.*pneumoniae:* 28.6%

Because of the high rate of bacterial resistance, amoxicillin (the drug of choice for many years) is no longer recommended for antibiotic prophylaxis for the sinus graft surgery. Instead, amoxicillin-clavulanate (Augmentin) is used because the addition of clavulanic acid enhances amoxicillin's activity against the β-lactamase–producing strains of bacteria.

The patient with a history of nonanaphylactic allergic reaction to penicillin may take cefuroxime axetil (Ceftin) as an alternative.[81] Ceftin is a second-generation cephalosporin that possesses good potency, efficiency, and strong activity against resistant *S. pneumoniae* and *H. influenzae.* If a patient has a true history of anaphylactic reaction to penicillin, recurrent sinus infections, or

a recent history of antibiotic use, then doxycycline may be used. In the past, the quinolone class of antibiotics (e.g., Levaquin, Avelox) have been used with excellent success because they exhibit superior activity against most types of involved bacteria. However, recently the Food and Drug Administration (FDA) has recommended the adverse effect of tendon damage does not warrant its routine use anymore.

Maximum effectiveness of prophylactic antibiotic drugs occurs when the antibiotic is in adequate concentrations in the tissue before bacterial invasion is initiated. Because the sinus mucosa has limited blood supply when infection and inflammation is present, poor antibiotic blood levels are achieved. Therefore to combat possible bacterial invasion from the sinus surgery, antibiotic medications should be administered at least 1 full day (24 hours) before surgery and extended for approximately 5 days after surgery.

Local Antibiotic Medications

The antibiotic concentration within a blood clot of the sinus graft depends on the systemic blood titer. After the clot stabilizes, further antibiotic drugs do not enter the area until revascularization.[82] The bone graft is a dead space with minimum blood supply and absence of protection by the host's cellular defense mechanisms. This leaves the graft prone to infections that would normally be eliminated by either the host defenses or the antibiotic. The osteogenic induction of autografts and allografts is greatly retarded when contaminated with infectious bacteria.[83] To ensure adequate antibiotic levels in an SA graft, it is recommended to add antibiotic to the graft mixture.[84,85] This local antibiotic may protect the graft from early contamination and infection. Numerous studies have shown that an antibiotic added to graft material has no deleterious effects on bone growth. Antibiotic drugs such as penicillin, cephalosporin, and clindamycin, even in high concentrations, have not been found to be destructive to bone-inductive proteins.[86]

The locally delivered antibiotic should have efficacy against the most likely organisms encountered. Because the incidence of allergy is so high with β-lactam antibiotic drugs, the parenteral form of cefazolin (Ancef) is recommended. If there exists a true allergy to penicillin (i.e., anaphylactic), then Cleocin may be used as an alternative. Orally administered capsules and tablets should not be used within the graft because they contain fillers that interfere with bone regeneration.

Clinical experience indicates that less risk of infection exists when preoperative and postoperative antibiotic drugs are used both orally and in the graft. Because infection considerably impairs bone formation for patients undergoing sinus graft procedures, oral antibiotic coverage is continued for approximately 5 days after the surgery. Recommended antibiotic drugs are shown in Box 37.4.

Oral Antimicrobial Rinse

An additional antimicrobial medication used with respect to sinus augmentation surgery is chlorhexidine gluconate. This category of antimicrobial rinse has been shown to successfully decrease infectious episodes and minimizes postoperative complications from the incision line.[87] Gentle oral rinses of chlorhexidine gluconate 0.12% should be used twice daily for 2 weeks after surgery or until the incision line is completely healed.[88]

Glucocorticoid Medications

Sinus augmentation surgery usually results in increased postoperative inflammation. Therefore a pharmacologic regimen

is recommended to decrease postoperative edema. Glucocorticoids have been well documented to decrease inflammation of the soft tissue and minimize postoperative pain, swelling, and incision line opening. In addition, the clinical manifestations of surgery on the sinus mucosa also can be decreased by use of a glucocorticoid medication.[89] Therefore the usual surgical protocol for most implant surgeries, including sinus grafts, includes a short-term dose of dexamethasone (Decadron) (Box 37.5). To ensure patency of the ostium and minimize inflammation in the sinus before surgery, steroid medications are initiated 1 full day before surgery. This medication should also be extended 2 days postoperatively because edema peaks at 2 to 3 days postsurgery.

Decongestant Medications

Sympathomimetic drugs that influence α-adrenergic receptors have been used as therapeutic agents for the decongestion of mucous membranes. Both systemic and topical decongestant medications are useful in reopening a blocked sinus ostium and facilitating drainage. Oxymetazoline 0.05% (Afrin or Vicks Nasal Spray) and phenylephrine 1% are useful topical decongestant medications. The vasoconstrictor action of oxymetazoline lasts approximately 5 to 8 hours, which is preferred compared with 1 hour for phenylephrine. However, decongestant drugs have many disadvantages. Topical decongestant drugs can cause a rebound phenomenon and the development of rhinitis medicamentosa if used more than 3 to 4 days. The effectiveness of the topical decongestant is markedly enhanced by proper position of the patient's head during administration of the drug. It should

- Two tablets (8 mg) in the morning of surgery
- One tablet (4 mg) in the morning, the day after surgery
- One tablet (4 mg) in the morning, the second day after surgery

also be noted that the pulse amplitude and blood flow in the sinus mucosa is reduced with decongestant drugs, such as oxymetazoline. This may, in turn, decrease the defense mechanism within the tissues.[90]

As a consequence of the medical and local risks of decongestant medications, the modified sinus graft pharmacologic protocol no longer recommends the prophylactic use of decongestant medications.

Analgesic Medications

In most cases, sinus graft procedures usually require very minimal postoperative analgesic coverage. If a narcotic is required, any analgesic combination containing codeine, such as Tylenol 3, is prescribed postoperatively because codeine is a potent antitussive, and coughing may place additional pressure on the sinus membrane and introduce bacteria into the graft. The patient is instructed to cough (if necessary) with the mouth open so excessive air pressure does not occur through the ostium.

Cryotherapy

With sinus elevation procedures, postoperative inflammation in the posterior maxilla is very common because of the extent of tissue reflection. Because postoperative swelling can adversely affect the incision line, measures should be taken to minimize this condition. Application of cold dressings and cold oral liquids, along with elevation of the head and limited activity for 2 to 3 days, will help minimize the swelling. The applied cold dressing and liquids will cause vasoconstriction of the capillary vessels, reducing the flow of blood and lymph, resulting in a lower degree of swelling. Ice or cold dressings should only be used for the first 24 to 48 hours. After 2 to 3 days, heat may be applied to the region to increase blood and lymph flow, which helps to clear the area of the inflammatory consequences. This also assists in the reduction of ecchymosis that may have occurred from the bleeding and tissue reflection.

Aseptic Technique

Because of the extent of tissue reflection, technique sensitivity of sinus surgery, and need for asepsis, oral or conscious sedation is usually recommended for sinus graft procedures. After sedation and adequate infiltration anesthesia (i.e., posterior and middle alveolar nerve, greater palatine nerve) are obtained, the patient is prepared for surgery. Preparation of the surgical site is important in sinus manipulation surgery to reduce contamination by the patient's own normal flora. The oral cavity cannot become a sterile environment for surgery. However, intraoral preparation before surgery may significantly reduce the bacterial count in the mouth. Studies reveal a significant reduction in bacteremia during extractions and implant surgery complications after preparation with antiseptic mouth rinse.[89,90]

Iodophor compounds (Betadine) are a most effective antiseptic. However, because the iodine is complexed with organic surface-active agents, it has been shown to inhibit the osteoinduction of allograft bone. Therefore the use of 0.12% chlorhexidine gluconate (Peridex) scrub and rinse is most often used as intraoral preparation of the surgical site requiring a bone graft. Extraoral presurgical scrubbing of the skin should also be performed with chlorhexidine antiseptics prior to surgery.

Surgical Treatment of the Maxillary Sinus: History

In the early 1970s, Tatum began to augment the posterior maxilla with autogenous rib bone to produce adequate vertical bone for implant support.[91,92] He found that onlay grafts below the existing alveolar crest would decrease the posterior intradental height significantly, yet very little bone for endosteal implants would be gained. Therefore in 1974 Tatum developed a modified Caldwell-Luc procedure for sinus augmentation (SA) grafting. The crest of the maxilla was infractured to elevate the maxillary sinus membrane. Autogenous bone was then added in the area previously occupied by the inferior third of the sinus. Endosteal implants were inserted in this grafted bone after approximately 6 months. Implants were then loaded with final prostheses after an additional 6 months.

In 1975 Tatum developed a lateral-approach surgical technique to elevate the sinus membrane and place implants simultaneously. The implant system used was a one-piece ceramic implant, and a permucosal post was required during the healing period. Early ceramic implants were not designed adequately for this procedure, and results with the technique were unpredictable. In 1981 Tatum developed a submerged titanium implant for use in the posterior maxilla and achieved predictable results.

From 1974 to 1979, the primary graft material for sinus grafts was autologous bone. In 1980 Tatum[55,93] further expanded the application of the SA augmentation technique with a lateral maxillary approach and the use of synthetic bone. The same year, Boyne and James first reported on the sinus graft technique using autogenous bone for SA grafts.[60] Most of the publications in the 1980s were anecdotal or based on very small sample sizes.

Treatment Classifications for the Posterior Maxilla

In 1984, Misch[61] organized a treatment approach to the posterior maxilla based on the amount of bone below the antrum, and in 1986 he expanded the treatment approach to include the available bone width that was related to implant design. In 1987 Misch included the technique of the sinus floor elevation through the implant osteotomy before implant placement.[62] He reported on 170 sinus graft cases, with two complications and an uneventful resolution.

In the Misch SA classification, the treatment modality is dependent on the available bone height between the floor of the antrum and the crest of the residual ridge in the region of the ideal implant locations. The SA protocol also suggested a surgical approach, bone graft material, and a time table for healing before prosthetic reconstruction. In 1995 Misch[94] modified his 1987 classifications to include the lateral dimension of the sinus cavity; this dimension was used to modify the healing period protocol because smaller width sinuses (0–10 mm) form bone faster than larger width (>15 mm) sinuses. The Division A–width ridge was also increased to 6 mm to permit more bone to encompass the implant on each side. In 2017 Resnik modified the Misch classification to include alternative treatment options with short implants, crestal grafting approaches, and treatment plan modifications based on force-related factors, which are detailed in Box 37.6 (Figs. 37.25–37.28).

Surgical Technique

Subantral Option One: Conventional Implant Placement

The first Misch SA treatment option, SA-1, occurs when suffi-cient bone height is available to permit the placement of endosteal implants following the usual surgical protocol, with no maxillary sinus involvement. Because the quality of bone in the posterior max-illa often is D3 or D4 bone, bone compaction or osseodensification to prepare the implant site is common. This technique permits a more rigid initial insertion of the implant and also increases the BIC.

Required Bone Dimensions

In the abundant bone volume (Division A),the minimum ideal bone height for the SA-1 is related to the associated force fac-tors. Under favorable conditions, a minimum of 8 mm of bone is required from the crest of the ridge to the inferior floor of the sinus for the placement of an 8-mm implant. The literature has concluded that short implants (8 mm) have been shown to be successful in the posterior maxilla. If multiple implants are placed, then ideally the implants should be splinted for force distribution. For unfavorable conditions, greater than 10 mm of bone is required in height to allow for placement of an implant so it does not invade the maxillary sinus. This will allow an implant of 10 mm in length to be placed that will allow for a greater insertion torque and BIC. Therefore the implant will be less likely to have force-related effects that may cause micromovement during the healing phase and poorer healing (Fig. 37.29).

Because the maxillary sinus proper is not invaded during an SA-1 approach, it is less critical if preexisting pathology in the sinus is present. However, if pathology is present that warrants medical referral, then this should be completed before any implant placement. Therefore in general the sinus pathologic contraindi-cations for sinus graft surgery do not apply for implant insertion when adequate bone is present below the sinus for implants of adequate size to support the load of the prosthesis. Although a common axiom in implant dentistry is to remain 2 mm or more from an opposing landmark, this is not necessary in the SA region.

Narrower bone volume patients (Division B) in SA-1 may be treated with osteoplasty or augmentation to increase the width of bone. The insertion of smaller surface area implants (as small-diameter root-form implants) are not suggested because the forces are greater in the posterior regions of the mouth, and the bone density is less than in most regions. In addition, the narrow ridge is often more medial than the central fossa of the mandibular teeth and will result in an offset load on the res-toration, which will increase the strain to the bone. However, multiple narrow diameter implants may be placed to support one tooth (i.e., two narrow diameter implants to support one molar).

Osteoplasty in the SA-1 posterior maxilla may change the SA category if the height of the remaining bone is sufficient to allow for adequate bone postosteoplasty. Augmentation for width may be accomplished with bone spreading, membrane grafting, or autogenous grafts. Larger diameter implants are often required in the molar region, and bone spreading to place wider implants is the most common approach when the bone density is poor. If less than 2.5 mm of width is available in the posterior edentu-lous region (C–w), then the most predictable treatment option is to increase width using onlay autogenous bone grafts. After graft maturation the area is reevaluated to determine the proper treat-ment plan classification.

Endosteal implants in the SA-1 category are left to heal in a nonfunctional environment for approximately 4 to 8 months (depending on bone density and force factors) before the abut-ment post(s) are added for prosthodontic reconstruction. Care is taken to ensure that the implants are not traumatized during the initial healing period. Progressive loading during the pros-thetic phases of the treatment is suggested in D3 or D4 bone (Box 37.7).

• **BOX 37.6**   **Force-Related Factors**

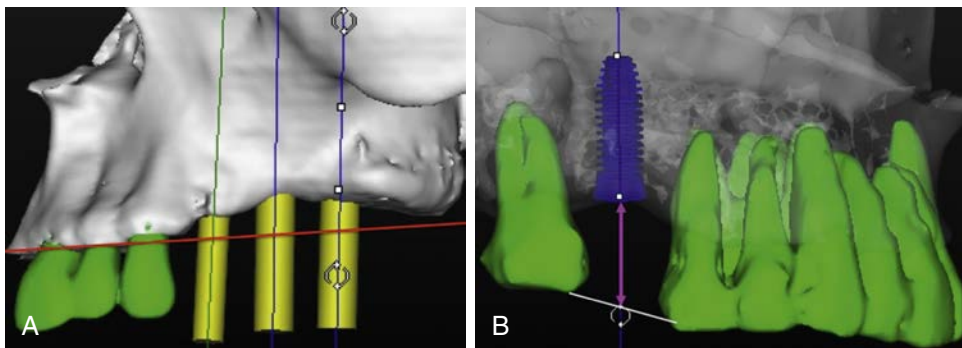
Favorable Conditions
- Good quality of bone (D2/D3 bone) with the presence of cortical bone present
- Minimal occlusal force factors
- No parafunction
- Ideal crown/implant ratio

Unfavorable Conditions
- Poor quality of bone (D3/D4 bone) with no cortical bone present
- Increased occlusal force factors
- Parafunctional forces present
- Poor crown/implant ratio

• **Fig. 37.25** Bone quality. (A) Thick cortical bone and a dense cancellous bone, which is consistent with a D2 type of bone, (B) No cortical bone present, with very fine trabecular bone, which is usually consistent with D4 bone and mainly found in the posterior maxilla.

Subantral Option Two: Sinus Lift and Simultaneous Implant Placement

The second SA option in the Misch SA classification, SA-2, is selected when the intended implant length is 1 to 2 mm greater than the vertical bone present (Fig. 37.30). In this technique, 1 to 2 mm may be achieved via elevating the sinus membrane without bone grafting. Tatum[95] originally developed this technique in 1970, and Misch[96] first published it in 1987. Summers[97]
• **Fig. 37.26** Force factors. The posterior maxilla is very susceptible to force-related issues because of strong muscles such as the temporalis (green) and masseter (red).

• **Fig. 37.27** Parafunction. Forces are significantly increased in patients who exhibit parafunction. In this radiograph, the prominent antegonial notch is consistent with parafunctional forces and masseter hypertrophy.


published a similar procedure in 1994, 24 years after Tatum's first presentation.

Because the SA-2 surgical approach modifies the floor of the maxillary sinus, a preexisting pathologic condition of the sinus should not be present because it may affect the implant site by retrograde infection.

This technique is reserved for 8 to 10 mm of host bone below the sinus in which an implant is placed via an osteotome technique that elevates the membrane approximately 1 to 2 mm with the use of no grafting. Ideally, an 8-mm implant is used with caution in these cases.

Rationale

In some situations, a longer implant may be required for prosthetic support and initial fixation. Worth and Stoneman[98] have reported a comparable phenomenon of bone growth under an elevated sinus membrane called a "halo formation". They observed the natural elevation of the sinus membrane around teeth with periapical disease. The elevation of the membrane resulted in new bone formation once the tooth infection was eliminated. In an article by Palma and colleagues[99] the elevation of the sinus membrane in implant insertion, with or without a graft material below the mucosa, gave similar results in primates regarding implant stability or BIC after healing. As a result of the autologous bone present above the apical portion of the implant with an SA-2 technique, and the sinus floor fracture (which increases the regional accelerated phenomenon of bone repair and formation), new bone formation over the implant apex is predictable.

Incision and Reflection

In an edentulous posterior maxilla, a full-thickness incision is made on the crest of the edentulous ridge from the tuberosity to the distal of the canine region. A vertical, lateral relief incision is made at its distal and anterior extension of the crestal incision for approximately 5 mm. If minimal attached tissue exists on the crest of the ridge, which is more often observed in the premolar region, then the primary incision is made more palatal to place more keratinized tissue on the facial aspect. When teeth are present in the region, the crestal incision extends at least one tooth beyond the edentulous site. If one tooth is missing, the reflection is similar to a single-tooth replacement option, and even a direct (flapless technique) may be used.

A full-thickness palatal flap is first reflected because the palatal dense cortical plate facilitates soft tissue reflection. Special attention is given to avoid the pathway of the greater palatine artery or to remain completely subperiosteal so that this structure remains

• **Fig. 37.28** Crown/implant ratio. The maxillary posterior region often is confronted with a an increased interocclusal space because of the vertical and horizontal bone resorption. (A) Three-dimensional image showing the apical positioning of implants caused by vertical bone resorption. (B) Cone beam computerized tomography interactive treatment planning evaluating the increased crown height space.

• **Fig. 37.29** SA-1 (A and B) Treatment plan which includes implant placement below the maxillary sinus proper.

within the soft tissue. The labial mucosa is reflected off the edentulous ridge, rather than elevating the tissue from the bone. The crest should not be used to leverage the tissue because the ridge may have minimal cortical bone and a perforation may result. This could result in damage to the residual ridge or possibly even penetrate the sinus or nasal cavity. Once the tissue is reflected, the width of the available bone is evaluated to ensure that it is greater than 6-7 mm wide and allows the placement of Division A root-form implants.

Osteotomy and Sinus Elevation (SA-2)

The endosteal implant osteotomy is prepared as determined by the density of bone protocol, which is usually D3 or D4 bone. The depth of the osteotomy is approximately 1 to 2 mm short of the floor of the antrum. When in doubt of the height dimension, the osteotomy should err on a shorter length. The implant osteotomy is prepared to the appropriate final diameter, short of the antral floor, by approximately 1 mm.

A flat-end or cupped-shape osteotome is selected for the infracture of the sinus floor. Usually in D3 bone, an osteotome of the same diameter as the final osteotomy is selected. In D4 bone, an osteotomy one to two sizes smaller than the final implant size maybe used, performing an osseodensification technique. The osteotome is inserted and tapped firmly in 0.5- to 1.0-mm increments beyond the osteotomy until reaching its final vertical position, up to 2 mm beyond the prepared implant osteotomy. A slow elevation of the sinus floor is less likely to tear the sinus mucosa. This surgical approach compresses the bone below the antrum, causes a greenstick-type fracture in the antral floor, and slowly elevates the unprepared bone and sinus membrane over the broad-based osteotome. If the osteotome cannot proceed to the desired osteotomy depth after tapping, then it is removed and the osteotomy is prepared again with rotary drills an additional 1 mm in depth. The osteotome is then reinserted to attempt the greenstick fracture of the antral floor.

Care should be exercised when removing the osteotomes from the osteotomy site. The osteotome should never be luxated

because this will increase the width of the final osteotomy, leading to less insertion torque. Once the osteotome prepares the implant site, the implant may then be threaded into the osteotomy and extended up to 2 mm above the floor of the sinus. The implant is slowly threaded into position so the membrane is less likely to tear as it is elevated. The apical portion of the implant engages the more dense bone on the cortical floor, ideally with bone over the apex, and an intact sinus membrane. The implant may extend 0 to 2 mm beyond the sinus floor, and the 1 mm of compressed bone covering over the implant apex results in as much as a 3-mm elevation of the sinus mucosa (Fig. 37.31). Ideally, the implant design should include a convex apex with no apical openings as this design will be less likely to cause a membrane perforation.

Modified SA2 Techniques

Rosen and associates[100,101] developed a modification to the SA-2 treatment approach for use at the time of an extraction of a maxillary molar. The technique is indicated when the maxillary molar is extracted, the surrounding walls of bone are intact, and no periapical pathologic condition is present. The crest of the ridge to the antral floor should be 7 mm or more in height. Once the tooth is extracted and the surrounding bony walls confirmed, a modification of the SA-2 technique is in order. A 5- to 6-mm trephine bur is used in the center of the extraction site and prepares the bone 1 to 2 mm below the antral floor. A 5- to 6-mm-diameter, flat-ended or cup-shaped osteotome and mallet intrudes the core of bone 2 mm above the sinus floor, creating 9 mm or more of vertical bone. A socket graft may be used within the extraction socket but is not pushed into the surgical space of the sinus because it may perforate the sinus mucosa. After 4 months, an implant may be inserted.

Some authors have used the SA-2 sinus lift procedure to gain more than 2 mm of implant vertical height. However, these blind surgical techniques increase the risk of sinus membrane perforation.

The success of the intact sinus membrane lift cannot be confirmed before or at the time of implant placement. Attempts to "feel" the elevation of the membrane from within an 8-mm-deep implant osteotomy may cause tearing of the sinus lining.

Attempting to elevate the sinus mucosa more than 2 mm through an implant osteotomy 3 to 4 mm wide and 8 mm deep is not predictable. Reiser and colleagues[102] reported that when the sinus elevation was 4 to 8 mm in cadavers, almost 25% resulted in sinus perforation. The implant osteotomy sinus floor
• **Fig. 37.30** SA-2. (A) Radiograph depicting an SA-2 (maxillary second premolar) and SA-1 (maxillary first molar). (B) SA-2 implant that includes implant insertion with penetration into the maxillary sinus proper 1 to 2 mm without bone grafting.
• **Fig. 37.31** (A) SA-3 crestal. Treatment plan that includes implant insertion with bone grafting via the crestal (osteotomy) approach gaining approximately 3 to 4 mm of height. (B) Lateral wall. Treatment plan that includes implant insertion with bone grafting via the lateral-wall approach gaining more than 4 mm of height (i.e., amount of height is determined by size of lateral wall).

technique is often attempted because of the perceived ease of surgery of an SA-2 technique versus a lateral-wall or transcrestal approach.

Complications

If a sinus membrane perforation occurred during the initial implant placement procedure, then bone height growth is less likely to occur. This is the primary reason why only **0 to 2 mm** of additional bone height is attempted with this technique. However, even when membrane perforation occurs and/or no bone grows around the apical end of the implant, the SA-2 technique is of benefit because the apical end of the implant is surrounded by denser bone. This enhances rigid fixation during healing and increases BIC, leading to improved loading conditions. If inadequate bone is formed around the apical portion of an implant, then a progressive-loading protocol for D4 bone is suggested during prosthetic reconstruction (Box 37.8).

• **BOX 37.8**   **SA-2 Requirements**

- **Favorable conditions:** (>8 mm host bone, ideally 10-mm implant)
- **Unfavorable conditions:** (>10 mm host bone, ideally 12-mm implant)

Subantral Option Three: Sinus Graft with Immediate Endosteal Implant Placement

The third approach to the maxillary posterior edentulous region, SA-3, is indicated when at least 5 mm of vertical bone and sufficient width are present between the antral floor and the crest of the residual ridge in the area of the intended prosthesis abutment (Fig. 37.32).

A residual height of 5 mm for the SA-3 category has been selected for two main reasons: (1) this height (in adequate bone

width and quality) can be considered sufficient to allow primary stability of implants placed at the same time as the sinus graft procedure, and (2) because of the amount of residual bone (5mm), greater blood supply is present, which allows for more predictable and faster healing.

Anesthesia

Infiltration anesthesia has been used with success for sinus graft surgeries in the past; however, more profound regional anesthesia is achieved by blocking the secondary division of the maxillary nerve (V2). The sinus graft surgery often requires the reflection of the soft tissue extending to the zygomatic process. In addition, several branches of the maxillary division of the fifth cranial nerve innervate the sinus mucosa. As such, a V2 block is advantageous for patient comfort, and this achieves anesthesia of the hemimaxilla, side of the nose, cheek, lip, and sinus area.
• **Fig. 37.32** SA-4. Treatment plan that includes bone grafting via the lateral-wall approach with no implant placement. Implant placement is delayed according to the healing of the sinus graft sites.

Two options exist for V2 block anesthesia: (1) high and within the pterygomaxillary tissue behind the posterior wall of the maxilla or (2) at the depth of approximately 1 inch with a long-gauge needle within the greater palatine foramen (Fig. 37.33). The first method is easier to perform but may injure the pterygoid plexus or the maxillary artery and result in hematoma, or it may fail to reach the proper landmark. With the second option, it is more difficult to locate the foramen and negotiate up the canal. It may also injure the greater palatine artery or nerve. Too deep an administration with a greater palatine approach may result in the penetration of the orbit floor. Possible sequelae include periorbital swelling and proptosis, diplopia, retrobulbar block with dilated pupil, corneal anesthesia, motionless eye, retrobulbar hemorrhage, and optic nerve block with transient loss of vision. However, the success rate is greater, and the clinical risks appear minimal. Therefore most often, the first attempt for block anesthesia is within the greater palatine foramen; if unsuccessful, then the high posterior approach is used. Prevention of these complications is ensured by reduction of the needle depth measurement for smaller patients and the strict application of the technique. Proper angulation during soft tissue penetration prevents possible entrance into the nasal cavity through the medial wall of the pterygopalatal fossa.

Infiltration anesthesia is first administered to the posterior and middle alveolar nerve and greater palatine nerve. Scrubbing, gowning, and draping of the patient is next. Then after the infiltration is effective, the V2 block is administered. A long-acting anesthetic such as bupivacaine 0.5% (Marcaine) is preferred. Block anesthesia with these agents is longer acting than infiltration in the maxilla.[103]

The greater palatine foramen is found using an open-bore instrument (i.e., the handle of a mouth mirror with the mirror portion removed). Pressure is applied with this instrument along the palatal tissue, at the union of the residual ridge and hard palate, in the region of the second molar. Most often, the open-bore handle will feel and recede into the foramen. Slight pressure for a few seconds then marks the tissue over the opening of the foramen. A long, 1.5 inch needle is introduced into the foramen from the opposite side of the mouth and negotiates the canal for approximately 1 inch.

Surgical Approaches

There exist two options for grafting the sinus along with simultaneous implant placement.
• **Fig. 37.33** Anesthesia, V2 block. (A) Greater palatine foramen approach through the greater palatine foramen located 1 cm medial and adjacent to the second molar teeth. (B) Cotton swab may be pressed at the junction of the hard palate and the maxillary alveolar process until it falls into the foramen depression. The needle is advanced perpendicular until bone is contacted slowly at an angle of 45 degrees to the long axis of the hard palate.
• **Fig. 37.34** Incision/reflection. Full-thickness reflection is necessary to expose the lateral wall. (A) For a single-tooth sinus augmentation, usually the incision extends one tooth on each side of the edentulous site. (B) For a large SA4 edentulous area, the anterior incision must extend 5-10 mm anterior to the anterior wall (approximately distal of cuspid) and posteriorly to the tuberosity.

Lateral Wall. A Tatum lateral maxillary wall approach is performed by performing an osteotomy over the lateral wall of the maxillary sinus, infracturing the window, elevating the sinus membrane and window, grafting to the medial wall, and then placing the implant (SA-3).

Incision and Reflection. A crestal incision is made on the palatal aspect of the maxillary posterior edentulous ridge from the tuberosity to one tooth anterior to the anterior wall of the maxillary sinus, leaving at least 2 mm of attached tissue on the facial aspect of the incision. Because ridge resorption occurs toward the midline at the expense of the buccal dimension, the incision is made with awareness of the greater palatal artery, which proceeds close to the crest of the ridge in the severely atrophic maxilla. If bleeding from the palatal flap occurs, then a hemostat may be used to constrict the blood vessels distal to the bleeding, pressure may be applied over the greater palatine foramen with a blunt instrument, or electrocoagulation at the bleeding site may be used.

A vertical relief incision is made on the distal of the incision to enhance surgical access to the maxillary tuberosity. A broad-base anterior vertical relief incision is also made at least 10 mm anterior to the anterior vertical wall of the sinus. This may result in the incision being made over the distal aspect of the first bicuspid or canine. The facial soft tissue flap is designed, following general principles, with a base wider than the crest to ensure proper blood supply. The palatal portion of the flap is first reflected, followed by the facial crestal tissue, which is reflected off the crest.

The facial full-thickness mucoperiosteal flap is reflected to expose the complete lateral wall of the maxilla and a portion of the zygoma. The facial flap should be reflected to provide complete vision and access to the maxillary lateral wall. The superior aspect of the flap should never approach the infraorbital foramen because aggressive reflection of the facial flap may cause a neuropraxia type of nerve impairment and damage to this nerve structure. The reflected labial tissue can be sutured to the cheek mucosa, carefully avoiding the parotid duct. All fibrous and soft tissue should be removed from the lateral-wall access site to avoid soft tissue contamination of the bone graft. Entrapping soft tissue within the sinus may lead to formation of a secondary mucocele or surgical ciliated cyst. A moist 4 x 4 gauze or a 2-4 molt with a scraping motion easily removes this tissue (Fig. 37.34).

Access Window. The overall design of the lateral-access window is determined after the review of the CBCT scan, which helps determine the thickness of the lateral wall of the antrum, the position of the antral floor from the crest of the ridge, the posterior of the anterior wall in relationship to the teeth (if present), the presence of septa on the floor and/or walls of the sinus, and any associated pathology within the maxillary sinus.

The outline of the Tatum lateral-access window is scored on the bone with a rotary handpiece under copious cooled sterile saline. It is often easier to perform this step at 50,000 rpm (1:1 handpiece), but it is possible even at 2000 rpm, depending on the lateral-wall bone thickness. There exist multiple techniques to score the sinus window: (1) carbide bur (No. 6 or No. 8), (2) diamond bur, (3) bone removal burs (e.g., Dask bur), or (4) Piezosurgery units. With experience, the first bur is usually a No. 8 round carbide, which scratches the bone and designs the overall window dimension. This bur is followed with a No. 8 round diamond, which "polishes" away the bone within the groove made by the carbide bur. A No. 8 round diamond bur for the entire process is of benefit for an early learning curve because carbide burs "chatter" more and may tear the sinus membrane if the bur inadvertently comes in contact with it.

The inferior score line of the rectangular access window on the lateral maxilla is placed approximately 1 to 2 mm above the level of the antral floor (i.e., which in an SA-3 is >5 mm from the crest). If the inferior score line is made at or below the level of the antral floor, then infracture of the lateral wall will be impossible because the score line will be over host bone. If the inferior score line is made too high (>4 mm) above the sinus floor, then a ledge above the sinus floor will result in a blind dissection of the membrane on the floor, which may also lead to perforation.

The most superior aspect of the lateral-access window should be approximately 2-3 mm above the planned implant length (i.e., 12-mm implant would require the window to be 15 mm from the ridge crest). A soft tissue retractor placed above the superior margin of the lateral-access window (i.e., always maintained on bone, not soft tissue) helps retract the facial flap and prevents the retractor's inadvertent slip into the access window, which may damage the underlying membrane of the sinus.

The anterior vertical line of the access window is scored approximately 1 to 2 mm from the anterior sinus border. The
● **Fig. 37.35** Window preparation. (A) Window osteotomy should be made just through the cortical bone. (B) Initially, an outline form should be completed with a round carbide (No. 8), (C) Final preparation should be completed through the cortical bone with a round diamond (No. 8). (D and E) Osteotomy is complete when the window is free 360°.

distal vertical line should be made approximately 5 mm distal to the most posterior planned implant site (i.e., this will allow for adequate space if the implant position is changed more distally). If the patient is fully edentulous, the distal vertical line should be made approximately 5 mm distal to the first molar position. If the sinus access window outline is difficult to determine in relation to the sinus cavity, then it should err over the antrum rather than over the bone around this structure.

In general, a larger access window offers many advantages, including easier access, less stress on the membrane during initial elevation, and ease of additional membrane elevation with instruments because of the direct access that facilitates graft placement. The corners of the access window should always be rounded, not right or acute angles. If the corner angles are too sharp, then membrane perforation may occur from the use of a surgical curette at the corner or during the infracture of the lateral wall. Once the lateral-access window is delineated, the rotary bur continues to scratch the outline with a paint-brush stroke approach under cooled sterile saline irrigation, until a bluish hue is observed below the bur or hemorrhage from the site is observed. The expansion of the maxillary sinus after tooth loss pushes the arteries of the membrane to the outside of the structure and just below the surrounding bone. Therefore either the bluish hue of the membrane or bleeding in the area are signs of approaching the sinus membrane. This observation should be achieved circumferentially around the access window. The access window should not be overprepared in depth because direct contact with the membrane with rotary burs may cause a perforation (Fig. 37.35).

Complications

Endosseous Anastomosis. It should be noted that the largest blood vessel in the lateral wall is from an endosseous anastomosis from the posterior superior alveolar and the infraorbital artery. However, when the lateral wall is very thin in the edentulous patient, the anastomosis will atrophy and become nonexistent. The anastomosis has been shown to be located approximately 15 to 20 mm from the alveolar crest.

The horizontal lines of the access window should ideally not be positioned directly over this structure. The vertical lines of the access window often cut through the artery. Because the blood supply may be from either direction, both vertical access lines may have bleeding. This is rarely a concern for vision or blood loss during the procedure. If intraosseous bleeding is a problem, then the high-speed diamond used to score the window may be used without irrigation and polish the bleeding site, which cauterizes the vessel from the heat on the bony wall. Electrocautery may also be used on this vessel, if necessary. A hemostat maybe used; however, care should be exercised to avoid fracturing the lateral wall and/or perforating the sinus mucosa. Elevating the head and a surgical sponge applied to the site for a few minutes also aides in the control of hemorrhage.

Sinus Membrane Elevation. The first step in elevating the window is to ensure that the lateral window is completely "free" from the host bone. A flat-ended metal punch (or mirror handle) and mallet may be used to gently infracture the lateral-access window from the surrounding bone while still attached to the thin sinus membrane. The flat-ended punch is first positioned in the center of the window. If light tapping does not greenstick fracture the bone, then the flat-ended punch is placed along the periphery of the access window and tapped again. If the window does not separate easily, then the punch is rotated so that only an edge comes in contact with the scored line. This decreases the surface area of the punch against the score line of the window and increases the
● **Fig. 37.36** Sinus membrane reflection. (A) Membrane reflection starts on the floor, (B) is extended to the anterior wall, (C) extended to the posterior, (D) and then to the superior. Curette should always be maintained on the bone to prevent perforation.

stress against the bone. Another light tap with the mallet will most likely cause greenstick fracture of the bone along the scored line. If this still does not free the window, then further scoring of the bone with the handpiece and diamond bur is indicated, and the tapping procedure is repeated.

A short-bladed soft tissue curette designed with two right-angle bends is introduced along the margin of the window (i.e., Salvin Sinus Curette No. 1). The curved portion is placed against the window, whereas the sharp edge is placed between the sinus membrane and the margin of the inner wall of the antrum for a depth of 2 to 4 mm. The curette should always stay on the bone and be used in a scraping motion. If any sharp edges of bone remain on the bone's margin, then they may be flicked off with the curette. The curette is slid along the bone margin 360 degrees around the access window. This ensures the release of the membrane from the surrounding walls of the sinus without tearing from the sharp bony access margins. The sinus membrane may be elevated from the antral walls easily because it has few elastic fibers and is not attached to the cortical wall. Specially designed and shaped curettes are available to facilitate this surgical maneuver. A larger curved periosteal or sinus membrane elevator is then introduced through the lateral-access window along the inferior border (i.e., Salvin Sinus Curette No. 2). Once again, the curved portion is placed against the window, and the sharp margin of the curette is dragged along the floor of the antrum while elevating the sinus membrane. The curette should always be maintained on the bony floor to avoid a membrane perforation. The curette is never blindly placed into the access window. The implant clinician should see and/or feel the curette against the antral floor or sinus walls at all times. Once the mucosa on the antral floor is elevated, the lateral, distal, and medial wall of the sinus is addressed. The

curette is pushed against the bone that easily reflects the membrane. The sinus membrane is inspected for perforations or openings into the antrum proper.

It is easier to gain direct vision and access to the distal portions of the antrum than the anterior portions when the sinus area expands beyond the access window. Therefore whenever the periosteal elevator or curette cannot stay against the bone with good access in the anterior area, the access window should be increased in size toward the anterior. A Kerrison rongeur or a second window similar to the initial score-and-fracture technique may be used to expand the size of the access window.

The periosteal elevators and curettes further reflect the membrane off the anterior vertical wall, floor, and medial vertical wall. It is better to err on the high side to ensure that ideal implant height may be placed without compromise (i.e., always maintaining a patent ostium). The lateral-access window is positioned as part of the superior wall of the graft site, once in final position. The SA space has the original sinus floor as the base; the posterior antral wall, medial antral wall, and anterior antral wall as its sides; and the lateral-access window and elevated sinus mucosa as its superior wall (Figs. 37.36 and 37.37).

Sinus Graft: Layered Approach.

Top Layer: Collagen and Antibiotic. A resorbable collagen membrane (Oratape) soaked with a parental form of antibiotic (Ancef 0.2 mL) is then prepared (Box 37.9). The collagen and antibiotic are placed onto the elevated antral floor region and attach to the sinus mucosa on the superior part of the graft site. The collagen is a carrier for the antibiotic to decrease the risk of postoperative infection. In addition, in case of membrane tearing or separation of the sinus mucosa (with or without the awareness of the clinician), the collagen membrane seals the opening (Fig. 37.38). It is imperative that a portion of the membrane be left
• **Fig. 37.37** Window elevation. (A and B) The window should not be "intruded" but elevated. When complete, the lateral wall will be at 90 degrees and the medial bone exposed (green arrow).

outside of the sinus, preventing "intrusion" of the entire membrane into the sinus during bone placement.

Second Layer: Sinus Graft Materials. The second layer of the sinus graft layered approach is the most abundant and consists of the allograft bone grafting material. Many materials have been proposed in single or combination mixes, including mineralized and demineralized freeze-dried bone,[104,105] β-tricalcium phosphate (β-TCP),[106] xenograft hydroxyapatite (HA) (bovine anorganic bone), and calcium carbonates (bioactive glass).[107] In addition, more recent research has focused on combining "traditional" bone substitutes with bone growth factors.[108] Each graft material used in the sinus graft technique presents a similar, yet distinct, biological approach to the healing process.

What Type of Graft Material? Autogenous bone for years has been considered the gold standard of grafting material. Tatum first developed and reported the use of autogenous bone for sinus grafts in the 1970s, and Boyne[109,110] and James first published the information in 1980. In primates (*Macaca fascicularis*), Misch[111,112] found the use of iliac crest or tail bone in sinus grafts produced bone slightly denser than typical in the region, as evidenced from histology sections harvested at the reentry procedure. Similar findings have been observed during case series studies, with patients undergoing sinus grafts with autologous bone from the iliac crest or intraoral donor sites.[113]

It is interesting to note that sinus grafts in the literature that have used 100% autogenous bone have lower success rates than sinus grafts with synthetic substitutes (e.g., Del Fabbro and colleagues[114] reported 87.70% versus 95.98%).[115] Many additional studies have concluded that 100% autogenous bone results in less

bone formation that a composite type of graft. Hallman and colleagues showed that sinuses grafted with 100% xenograft compared with 100% autogenous exhibited greater healing and higher implant survival rates.[116] Froum and colleagues reported that if 20% autogenous bone was added to other bone substitutes, a greater mean vital bone formation was found.[117]

Demineralized freeze-dried bone (DFDB) has been shown to be osteoinductive, which is capable of inducing undifferentiated mesenchymal cells to form osteoblasts. The mechanism for this process appears to relate to the bone morphogenic protein (BMP) found primarily in cortical bone. In animal and human studies, DFDB allograft (DFDBA) powder used alone in sinus grafts did not provide satisfactory results. Bone was present but not in sufficient volume as the graft material originally placed. Speculation exists that the material resorbs more rapidly than the bone formation process, resulting in less bone formation. In addition, studies have shown that DFDB, when placed into an area of low-oxygen tension (hypoxic or hypocellular tissue), results in fibrous or cartilage tissue rather than bone.[118] Other authors have observed similar conclusions on the poor performance of DFDB used alone in animal and human studies.[119] At the Sinus Graft Consensus Conference,[14] high success rates were reported for all materials and combinations, with the exception of DFDB when used alone.

Mineralized freeze-dried bone allografts (FDBAs) are an allogenic bone that does not undergo the demineralization process. FDBA has the same BMP content in its organic matrix; however, it does not have the same osteoinductive capability as DFDBA. FDBA has been shown to be a better scaffold (osteoconduction) than DFDBA, which allows for superior space maintenance.[120] Eventually, osteoclasts breakdown the mineral content of FDBA until demineralization occurs, inducing new bone formation and a prolonged protein release.

Cammack and colleagues examined mineralized and demineralized freeze dried allograft used in sinus augmentation procedures and found no statistical significance between the two bone substitutes. A histomorphometric study by Froum and colleagues[121] at 26 to 32 weeks after grafting evaluated mineralized cancellous bone allograft (MCBA) and anorganic bovine bone material (ABBM) for sinus augmentation. Bilateral sinus grafts, one filled with MCBA and the other with ABBM, were compared. The average vital bone content of the MCBA was 28.25%, compared with the ABBM of only 12.44%. Therefore mineralized corticocancellous bone of approximately 250 to 1000 μm is advantageous for
● **Fig. 37.38** Top layer. (A and B) Fast-resorbing collagen (e.g., Collatape) is used with antibiotic as the top layer. The collagen membrane should be positioned to the medial wall and with a small segment exposed outside the superior aspect of the window. A longer acting collagen may be used if a known membrane perforation is present.
● **Fig. 37.39** Middle layer. The middle layer consists of allograft (i.e., 70% mineralized, 30% demineralized) plus antibiotic. (A) Allograft syringed into the sinus proper. (B) Packing of the sinus with a packer.

bone graft material because it fulfills space maintenance requirements and allows for cell migration.[122]

Allograft bone material is available in three particle forms: cortical, cancellous, and corticocancellous. Cortical allografts are associated with an increased density and greater space maintenance properties, which allow for slower resorption. Cancellous chips are advantageous because they allow for osteoconductive scaffolding and deposition of osteoblasts while being faster resorbing. Ideally, the use of corticocancellous bone is advantageous because it allows for both the benefits of cancellous and cortical bone to be used in the grafting process.

The ideal particle size of the allograft material is very important in the bone regeneration process because too small (<125 μm) particle size leads to fast resorption, with an inconsistent bone formation. A larger particle size (>1000 μm) restricts resorption and may be sequestered or result in delayed healing. Studies have shown an ideal particle size for predictable bone regeneration to be approximately 250 to 1000 μm.[123]

In addition to the mineralized bone, bone graft factors in the form of platelet-rich fibrin may be used. Whole blood is drawn (approximately 10 ml) from the patient and placed into a centrifuge for 10 to 15 minutes at 3000 rpm. The blood is separated by the centrifuge into three layers: (1) red blood cells, (2) platelet-rich fibrin (PRF), and (3) platelet-poor plasma (PPM). The PRF layer contains many growth factors that are involved in the cascade of bone mineralization.[124] The PRF is added to the bone substitutes, along with a local antibiotic to be added into the sinus proper. A parenteral form of antibiotic is used rather than a tablet form because oral antibiotic drugs often have fillers in the product that are not osteoconductive. The most common antibiotic is Ancef 500 mg/mL, and 0.8 mL of solution is added to the graft (Fig. 37.39).

Summary: 2nd Layer. The second layer of the lateral-wall sinus graft will consist of the following:

1. a. 70% mineralized FDBA, 30% demineralized DFDBA OR
    b. Mineralized FDBA: (Corticocancellous)
        - Particle Size = 250–100 µm
        - Approximately 250–1000 µm
2. PRF
3. Local antibiotic (Ancef)

These materials are mixed in a surgical bowl and filled into a bone grafting syringe or 1 cc hypodermic syringe. When placing the graft material, insert the syringe into the sinus proper in approximation to the medial wall and material is extruded as the syringe is removed. The grafting material should be deposited in an anterior and inferior direction. This will ensure material raises the lateral window instead of intrusion toward the medial wall. Intrusion will lead to lack of bone formation near the medial wall and may affect implant placement and post-sinus mucociliary function. By extruding the material in the anterior direction, bone graft material will be placed into the anterior segment of the sinus incorporating graft material in contact with the anterior wall and increasing blood supply for healing. The material should be condensed with a serrated packer, and packing pressure should be firm but not excessive. Inadequate pressure will result in airspaces, which may predispose the graft to future infection. Excessive condensation may lead to perforation of the membrane and extrusion of material into the sinus proper.

Bottom Layer

Regional Acceleratory Phenomenon. The third or bottom layer will consist of multiple steps to enhance bone growth. First, especially if little bleeding is present from the sinus floor and the anterior wall, a sharp instrument (e.g., scaler, curette) is used to scratch the bone. This trauma will initiate the regional acceleratory phenomenon (RAP), which introduces more growth factors into the site and starts the angiogenesis process. The blood vessels allow migration of osteoclasts and osteoblasts that resorb and replace the graft with live, viable bone. In addition, the blood vessels provide blood supply to the autologous bone portion of the graft, which is required for initial osteogenesis. The medial wall should not be scratched because it is very thin and perforation may occur.

Autogenous Bone. The second part of the third layer is the use of autogenous bone. Osteogenic material is capable of producing bone, even in the absence of local undifferentiated mesenchymal cells. Autogenous bone predictably exhibits this activity in the sinus graft. Misch has performed reentry of more than 1500 sinus grafts (at implant placement) accompanied by more than 50 human histologic sections and 18 primate sinus grafts and histology. A consistent histologic and clinical finding is that bone grows into the augmentation region from the surrounding walls of the maxillary antrum in which the sinus membrane was elevated.[125] In other words, the bone growth came from the surrounding walls of bone, similar to an extraction socket. The last regions to form bone are usually the center of the lateral-access window and the region under the elevated sinus membrane. In fact, no new bone at time intervals up to 12 months was found to grow immediately under the sinus membrane.

The most common harvest site for the lateral-wall approach is the maxillary tuberosity on the same side of the patient that the sinus is being augmented. In this way, an additional surgical site is not required, which decreases morbidity to the patient. Additional sources of bone to be added to the graft site may be any bone fragments from implant osteotomy sites, bone cores over the roots of anterior teeth, sinus exostoses, and cores from the mandibular symphysis or ramus region. The autogenous bone is placed on the original bony floor in the area most indicated for implant insertion. A blood supply from the host bone can be established earlier to this grafted bone and maintains the viability of the transplanted bone cells and the osteogenic potential of the transplanted bone growth factors. Autogenous bone represents an important component of the sinus graft, and is of more importance in an SA-4 approach compared with an SA-3, which has more host bone present (Fig. 37.40).

The harvest of the tuberosity bone is initiated with the exposure of the tuberosity bone; however, care should be exercised to not extend the incision to the hamular notch area because this may result in potential bleeding episodes. Once there is full-thickness reflection of the tuberosity bone, double-action rongeurs may remove small pieces of the mainly cancellous bone. The tuberosity bone is usually soft and therefore is compressed to form more cells per volume. Usually, rotary burs or bone chisels are not recommended because this reduces the amount of bone grafted and increases the possibility of perforation into the sinus proper. Additional autogenous bone may be harvested intraorally or extraorally, as indicated on a case-by-case basis (Fig. 37.41).

The autogenous bone is then placed on the floor by making small spaces with a curette within the allograft material. Ideally, a space should be made to the medial wall because it is advantageous for autograft chips to be placed in approximation to the medial wall. After placement of the autogenous bone, the grafted area is veneered with the allograft material to fill any voids that are present.

Implant Insertion. A review of the literature by Del Fabbro and colleagues[126] notes success rates of implants placed at the same time as the graft have a survival rate of 92.17%, whereas a delayed implant insertion has a survival rate of 92.93%. The 5 to 10 mm of initial bone height in an SA-3 posterior maxilla, the cortical bone on the residual crest, and the cortical-like bone on the original antral floor may stabilize an implant that is inserted at the time of the graft and permit its rigid fixation. Therefore when the conditions are ideal for the SA-3 sinus graft, the implant may be inserted at the same appointment. When inserting implants into an SA-3 sinus graft, the sinus should always be completely filled prior to implant placement. Attempting to graft after implant insertion is very difficult and will lead to voids. When preparing the osteotomy into the grafted sinus, a finger rest should be maintained so that control of the handpiece is maintained upon perforation into the sinus. Care should be exercised to not extend the osteotomy into the grafted material. This will result in dispersion of the graft material. Penetration though the inferior floor should only be approximately 1 mm, as there will be no resistance from the graft material when placing the implant. In most cases, the osteotomy will be underprepared to allow for osseodensification (D4 bone). Implant placement is more accurate when inserted with a handpiece (Figs. 37.42 and 37.44).

The advantage of the SA-3 technique is the decreased treatment time because the implant and sinus graft are completed at the same time. In addition, there exist several disadvantages of immediate implant placement compared with delaying implant placement (i.e., SA-4 approach):

1. The individual rate of healing of the graft may be assessed during the healing period, while the implant osteotomy is being prepared and the implant inserted. The healing time for the implant is no longer arbitrary, but it is more patient specific.
2. Under ideal conditions, postoperative sinus graft infections occur in approximately 3% to 5% of patients, which is greater than the percentage for implant placement surgery or intraoral onlay
• **Fig. 37.40** Autogenous bone harvest. (A) Usually because of access, the maxillary tuberosity is the most ideal location for autogenous harvest. (B) Harvest can be completed with a double-action rongeur. (C) Usually large autogenous pieces may be obtained without penetration into the maxillary sinus.
• **Fig. 37.41** Bottom layer. The bottom layer consists of any autogenous bone obtained because the importance of autogenous bone is inversely proportional to the amount of host bone present. (A) harvested bone placed into window. (B) Final bone packing of autogenous bone.
• **Fig. 37.42** SA-3 implant placement. (A) After lateral-wall sinus grafting, the osteotomy is completed, usually after the initial surgical drill, osteotomes are used to widen the osteotomy. (B) Implant placement into graft material. (C) Final veneer grafting over implant site.
• **Fig. 37.43** Membrane. (A) Collagen membrane positioning over the lateral window (i.e., may use platelet-rich fibrin over collagen). (B) Final suturing of surgical site.
• **Fig. 37.44** SA-3 lateral wall. (A) The sinus should always be grafted before implant placement (B) because grafting is difficult to complete after implant is placed (i.e., cannot graft on medial aspect of implant).

bone grafts. If the sinus graft becomes infected with an implant in place, then a bacterial smear layer may develop on the implant and make future bone contact with the implant less predictable. The infection is also more difficult to treat when the implants are in place and may result in greater resorption of the graft as a consequence. If the infection cannot be adequately treated, then the graft and implant must be removed. Therefore a decreased risk of losing the graft and implant exists if a postoperative infection occurs with a delayed implant insertion. Some reports in the literature indicate a slightly higher failure rate of implants when inserted simultaneously compared with a delayed approach.

3. Blood vessels within the graft are required to form and remodel bone. An implant in the middle of the sinus graft does not provide a source of blood vessels. It may even impair the vascular supply.

4. Bone width augmentation may be indicated in conjunction with sinus grafts to restore proper maxillomandibular ridge relationships and/or increase the implant diameter in the molar region. Augmentation may be performed simultaneously with the sinus graft. As a result, larger diameter implants may be placed with the delayed technique.

5. The bone in the sinus graft is denser with the delayed implant placement. As such, implant angulation and position may be improved because it is not dictated by existing anatomic limitations at the time of the sinus graft.

6. The clinician may access the sinus graft before implant insertion. On occasion, the sinus graft underfills a region, and the lack of awareness of the condition during implant insertion at the same time results in an implant placed in the sinus proper, rather than the graft site.

7. On reentry to a sinus graft, it is not unusual to observe a crater-like formation in the center of the lateral-access window, with soft tissue invagination. If the implant is already in place, then it may be difficult to remove the soft tissue and assess its precise extent. When soft tissue is present at a delayed implant insertion, the region is curetted and replaced with a bone graft before implant placement. The healing time for the implant is related to the developing bone assessed at the delayed surgery, not an arbitrary period that may be, on occasion, too brief.

Membranes. After implant placement, a thin layer of graft material may be veneered over teh lateral access opening. A resorbable membrane (e.g., Collatape) is then placed over the lateral-access window (Fig. 37.43). A membrane will delay the invasion of fibrous tissue into the graft and will enhance the repair of the lateral bony wall. A nonresorbable membrane should not be used because reentry would be required and the possibility of postoperative sinus infection will increase. A bacterial smear layer may accumulate in the nonresorbable material and contribute to the infection process. Rarely will a resorbable membrane become infected.

PRF may be used as a double membrane by placement over the lateral collagen membrane to increase the amount of growth factors for bone formation and to increase the growth factors for tissue healing. If inadequate PRF is available because it was used in the second layer of the graft, then PPP may be used because platelets are present but in lower quantities. Froum and colleagues[127] evaluated sinus grafts with barrier membranes over the lateral-access wall compared with no barrier membrane. All sinus graft combinations in the study demonstrated higher vital bone percentage on the cores when a barrier membrane was used. Misch observed a higher vital bone percentage even when collagen was used over the lateral-access site compared with no collagen. Tarnow and colleagues completed a split-mouth design study with bilateral sinus grafts, with or without covering the lateral window with a membrane. Histologic samples revealed a higher percentage of bone with a membrane (25.5%) compared with no membrane (19.9%).[128]

Soft Tissue Closure. The soft tissues and periosteum should be reapproximated for primary closure without tension, with care to eliminate graft particles in the incision line. Because of the access window grafting, along with the double layer membrane, it is often necessary to stretch the tissue to allow for tension-free closure. Therefore the facial flap must often be expanded, which usually can be completed by periosteal release incisions. A tissue pickup holds the facial flap to the height of the mucogingival tissues junction. The flap is then elevated, and a No. 15 blade is used to incise the tissue 1 mm deep through the periosteum above the mucoperiosteum. Tissue scissors are then introduced into the incision parallel to the facial flap at a depth of 3 to 5 mm. A blunt dissection under the flap releases the periosteum and muscle attachments to the base of the facial flap. The flap may then be advanced over the graft site to the palatal tissues.

It should be noted that horizontal vascular anastomoses are located lateral to the maxilla, within the soft tissue (extraosseous anastomosis), and approximately 20 mm above the crest of the ridge. A blunt dissection does not violate these vessels. No tension should exist on the facial flap with primary closure of the site. Interrupted horizontal mattress or a continuous suture (3-0 polyglycolic acid [PGA]) may be placed. Suturing is more critical with this procedure than with many other implant placements. Incision line opening may contribute to infection, contamination, or loss of graft materials. The borders and flange of an overlaying soft tissue–borne denture or partial denture are aggressively relieved to eliminate pressure against the lateral wall of the maxilla.

Crestal Approach. The second option for an SA-3 sinus augmentation and implant placement is the use of the crestal approach. This approach has become more popular for reducing complications from lateral-wall sinus augmentation procedures. The crestal approach sinus augmentation uses an osteotome to break through the floor and then graft below the sinus membrane. The following are the five steps used in the procedure:

Step 1: A conventional full-thickness flap with crestal incision is completed to gain access to the bony ridge. A pilot drill is used to perform the initial osteotomy 1 to 2 mm short of the sinus floor. The exact measurement of the available bone is completed via CBCT images. Incrementally larger surgical drills or osteotomes should be used to widen the osteotomy, at least one drill short of the final implant width.

Step 2: A small diameter osteotome is inserted into the prepared site to compress the sinus floor using a surgical mallet. A slight

"give" will occur when the bone is breached. A periapical radiograph may be taken to verify positioning. Incremental wider osteotomes are inserted to expand and to obtain vertical expansion of the bone height to accommodate the implant diameter.

Step 3: After the last osteotome is used, bone graft material is slowly introduced into the osteotomy site. First, a PRF coagulant maybe placed into the osteotomy site. This will allow for enhanced soft tissue healing via penetration through the collagen membrane to increase bone growth. Second, collagen is tapped into position to elevate the membrane. A small piece of collagen (i.e., approximately 1½ larger than the osteotomy hole) is placed into the osteotomy site, with the last osteotome. The collagen will act as a buffer between the bone graft material and the sinus membrane. The collagen is less likely to perforate the membrane.

Step 4: The graft material is slowly introduced into the sinus osteotomy with a bone graft spoon or an amalgam carrier. The sinus floor is then elevated by repeated increments of bone graft material and placed into position with an osteotome.

Step 5: Once the osteotomy is widened and sinus membrane is elevated to the desired height, the implant may be inserted.

This SA-3 crestal technique has the advantage of surgical simplicity, which decreases possible surgical morbidity. The main disadvantage of this technique is the unknown perforation of the sinus membrane. Ideally, the sinus membrane integrity should be maintained during the procedure. The limitations of this technique include elevating the membrane approximately 3 to 4 mm. If greater height is required, the lateral-wall approach may be used (Figs. 37.45 and 37.46; Box 37.10).

Subantral Option Four: Sinus Graft Healing and Extended Delay of Implant Insertion

In the fourth option for implant treatment of the posterior maxilla, SA-4, the SA region for future endosteal implant insertion is first augmented, then after sufficient healing, implant placement is completed. This option is indicated when less than 5 mm remains between the residual crest of bone and the floor of the maxillary sinus (Fig. 37.47). In addition, if an SA-3 approach is warranted because only 5 mm of bone is present, but pathology is present, it is often advantageous to complete an SA-4 technique. The SA-4 corresponds to a larger antrum and minimal host bone on the lateral, anterior, and distal regions of the graft because the antrum generally has expanded more aggressively into these regions. The inadequate vertical bone in these conditions decreases the predictable placement of an implant at the same time as the sinus graft, and less recipient bone exists to act as a vascular bed for the graft. In addition, in most cases, less autologous bone exists in the tuberosity for harvesting, and fewer septa or webs will exist in the sinus (and typically exhibit longer mediodistal and wider lateromedial dimensions). Therefore the fewer bony walls, less favorable vascular bed, minimal local autologous bone, and larger graft volume all mandate a longer healing period and slightly altered surgical approach.

The Tatum lateral-wall approach for sinus graft is performed as in the previous SA-3 procedure without the implant insertion (Fig. 37.48). Most SA-4 regions provide better surgical access than their SA-3 counterparts because the antrum floor is closer to the crest, compared with the SA-3 posterior maxilla. However, in Division D maxillae, it is usually necessary to expose the lateral maxilla and the zygomatic arch. The access window in the severely atrophic maxilla may even be designed in the zygomatic arch. In general, the medial wall of the sinus membrane is elevated approximately
● **Fig. 37.45** Crestal approach. (A) Step 1: Initial osteotomy short of sinus floor. (B) Osteotome used to widen osteotomy. (C) Platelet-rich fibrin and collagen membrane placement. (D) Allograft material placement. (E) implant placement.

12 mm from the crest so that adequate height is available for future endosteal implant placement. The combination of graft materials used and their placement are identical to the SA-3 technique lateral-wall approach. However, because less autogenous bone is often harvested from the tuberosity, an additional harvest site may be required, most often above the roots of the maxillary premolars or from the mandible (i.e., ascending ramus).

The width of the host site for most edentulous posterior maxillae is Division A. However, when Division C–w to D exists, a membrane or onlay graft for width is indicated. When the graft cannot be secured to the host bone, it is often better to perform the sinus graft 6 to 9 months prior to the autogenous graft for width. After the graft maturation, the implants may be inserted (Box 37.11).

Vascular Healing of Graft

Healing of the sinus graft takes place by several vascular routes, including the endosseous vascular anastomosis and the vasculature of the sinus membrane from the sphenopalatine artery. In mildly resorbed ridges, the host bone receives its blood supply from both centromedullary and mucoperiosteal vessels. However, as age and the resorption process increases, the bone gradually becomes totally dependent on the mucoperiosteum for the blood supply. The periphery of the graft is mainly supplied by vessels of the sinus membrane and by intraosseous vascular bundles. The central portions of the graft receive blood from collateral branches of the endosseous anastomosis. The extraosseous vascular anastomosis may enter the graft from the lateral-access window.

Many local variables are related to sinus graft maturation, including healing time, the volume of the SA graft, the distance from the lateral to medial wall (small, average, or large), and the amount of autologous bone in the multilayered approach, all of which relate to the speed and amount of new bone formation.

The time of evaluation of the sinus graft is perhaps the greatest variable of all. Froum and colleagues[129,130] evaluated a sinus graft from the same patient at 4 months, 6 months, 12 months, and 20 months. The amount of new bone continuously increased, compared with the amount of graft material in the antrum. In addition, the additional time allowed the graft to mature into a load bearing type of bone. In summary, the more time that elapsed from sinus graft to implant loading, the more vital bone was available to support the occlusal load.

The type of bone graft material used in the sinus graft may affect the rate of bone formation. Bone formation is fastest and most complete within the first 4 to 6 months with autogenous bone, followed by the combination of autogenous bone, porous HA, and DFDB (6–10 months); alloplasts only (i.e., TCP) may take 24 months to
• **Fig. 37.46** Crestal approach. ---

form bone. The time required before implant insertion for SA-4 or implant uncovery is dependent on the volume of the sinus graft. Most healed sinus augmentations (i.e., especially SA-4) will be the D4 type of bone; therefore osseodensification surgical approach and progressive bone loading techniques should be strictly followed.

Postoperative Instructions

The postoperative instructions are similar to those for most oral surgical procedures. Rest, ice, pressure, and elevation of the head are particularly important. Strict adherence to the pharmaco-logic protocol as mentioned previously is vital to decrease postop morbidity is of major importance. Although smoking is not an absolute contraindication for sinus grafting, smoking during the healing period may negatively affect the healing and increase the possibility of postoperative infections.

Blowing the nose and/or creating negative pressure while sucking through a straw or cigarettes should also be eliminated for the 2 weeks after surgery. Block and Kent[131] reported on a patient who lost the entire sinus graft 2 days after surgery from

blowing the nose. Sneezing, if it occurs, should be done with the mouth open to relieve pressure within the sinus. Swelling of the region is common, but pain is usually less severe than after anterior implants in an edentulous mandible. In addition, the patient should be warned against lifting and pulling on the lip to observe the surgical site or during oral hygiene procedures to reduce the

risk of incision line opening. The patient should be notified that small bone particles or synthetic bone found in the mouth or expelled from the nose with bleeding is not unusual (Box 37.12).

Implant Insertion

The implant surgery at reentry after successful sinus grafts is similar to SA-1, with a few exceptions. The periosteal flap on the lateral side is elevated to directly allow inspection of the previous access window of the sinus graft. The previous access window may appear completely healed with bone, soft and filled with loose graft material, or with cone-shaped fibrous tissue in-growth (with the base of the cone toward the lateral wall).

> ## • BOX 37.12   Sinus Graft Postoperative Instructions
>
> 1. Do not blow your nose.
> 2. Do not smoke or use smokeless tobacco.
> 3. Do not take in liquids through a straw.
> 4. Do not lift or pull on lip to look at sutures (stitches).
> 5. If you must sneeze, then do so with your mouth open to avoid any unnecessary pressure on the sinus area.
> 6. Take your medication as directed.
> 7. You may be aware of small granules in your mouth for 2 to 3 days after surgery.
> 8. Bleeding from the nostril may be present for the first 24 hours after surgery.

If the graft site on the lateral-access wall appears clinically as bone, then the implant osteotomy and placement follow the approach designated by the bone density. If soft tissue has proliferated into the access window from the lateral-tissue region, then it is curetted and removed. The region is again packed to a firm consistency with autologous bone from the previously augmented tuberosity and mineralized freeze-dried bone. The implant osteotomy may then be prepared and the implant placed a the D4 bone protocol. Additional time (6 months or more) is allowed until the stage II implant uncovery is performed and progressive bone loading is used during prosthetic reconstruction. The time interval for stage II uncovery and prosthetic procedures after implant insertion of a sinus graft is dependent on the density of bone at the reentry of implant placement. The crest of the ridge and the original antral floor may be the only cortical bone in the region for implant fixation. The most common bone density observed for a sinus graft reentry is D3 or D4. Most often, mineralized bone graft (or xenograft) material in the sinus graft has not converted to bone. The tactile sense and the CBCT evaluation interpret the mineralized graft material as a denser bone type; therefore a tactile or radiographic D3 bone may actually be D4-like bone. It is prudent to wait longer (rather than shorter) for implant uncovery. An SA-4 sinus graft has a recommended healing time at least 4 to 6 months for implant insertion and another 4 to 8 months for implant uncovery. Therefore the overall graft maturity time is 4 to 10 months for SA-3, and SA-4 healing time is 8 to 14 months before prosthetic reconstruction. Progressive loading after uncovery is most important when the bone is particularly soft and less dense. Inadequate bone formation after the sinus graft healing period of SA-4 surgery is a possible, but uncommon, complication.

Intraoperative Complications Related to Sinus Graft Surgery

Membrane Perforations

The most common complication during sinus graft surgery is tearing or creation of an opening in the sinus membrane (Box 37.13). This has several causes, which include a preexisting perforation, tearing during scoring of the lateral window, existing or previous pathologic condition, and elevation of the membrane from the bony walls. According to studies, membrane perforations occur about 10% to 34% of the time. It has been reported with a higher frequency in smokers. If membrane perforation occurs more often than this, then the clinician should give consideration to alter or reevaluate the surgical technique used in sinus grafting.

Sinus membrane perforation usually does not affect the sinus graft. However, in a report of the Sinus Consensus Conference,

> ## • BOX 37.13   Membrane Perforations
>
> - Small (<2 mm) fast-resorbing collagen (e.g., Collatape, Oratape)
> - Medium (2–4 mm) regular collagen (e.g., OraMem)
> - Large (>4 mm) longer acting collagen (e.g., Renovix, OraMem Extend)

analysis of failed sinus grafts found 48% (79 of 164 failures) were attributed to sinus membrane perforations.[130] In an endoscopic evaluation after sinus grafts, macrolaceration of the sinus membrane resulted in a typical sinusitis appearance, even when clinical conditions of infection were not present.[132] Once the tear or perforation is identified, the continuation of the sinus elevation procedure is modified. The sinus membrane should be elevated off the bony walls of the antrum, despite the mucosal tear. If a portion of the membrane is not elevated away from a sinus wall, then the graft material will be placed on top of the membrane, preventing the bone graft from incorporating with the bony wall.

The perforation of the sinus membrane should be sealed to prevent contamination of the graft from the mucus and contents of the sinus proper and to prevent the graft material from extruding into the sinus proper. When graft materials enter the sinus proper, they may become sources for infection or may migrate and close off the ostium to the nasal cavity and create an environment for an infection.

Numerous studies have shown a very low probability of sinus infections after perforations in the sinus membrane. Jensen and colleagues[133] reported that graft maturation occurred and no sinus infections were observed despite a 35% incidence of sinus perforation during the procedure in 98 patients.

The surgical correction of a small perforation is initiated by elevating the sinus mucosal regions distal from the opening. Once the tissues are elevated away from the opening, the membrane elevation with a sinus curette should approach the tear from all sides so that the torn region may be elevated without increasing the opening size. The antral membrane elevation technique decreases the overall size of the antrum, thus "folding" the membrane over on itself and resulting in closure of the perforation. A piece of resorbable collagen membrane (e.g., Collatape) is placed over the opening to ensure continuity of the sinus mucosa before the sinus bone graft is placed. The collagen will stick to the membrane and seal the SA space from the sinus proper.

If the sinus membrane tear is larger than 6 mm and cannot be closed off with the circumelevation approach, then a resorbable collagen membrane with a longer resorption cycle (e.g., Renovix, BioMend), may be used to seal the opening.

The remaining sinus mucosa is first elevated as described previously. A piece of collagen matrix is cut to cover the sinus tear opening and overlap the margins more than 5 mm. It should be noted that when a sinus tear occurs, it is sealed with a dry collagen membrane so that it may be rotated into the lateral-access opening, gently lifted to the mucosal tissue around the opening, and allowed to stick to the mucosa. Once the opening is sealed, the sinus graft procedure may be completed in routine fashion. However, care should be taken when packing the sinus with graft material. After a perforation, the graft is easily pushed through the collagen-sealed opening and into the sinus proper. The graft material is then gently inserted and pushed toward the sinus floor and sides but not toward the top of the graft. A sinus perforation may cause an increased risk of short-term complications. A greater bacterial penetration risk exists into the graft material through

the torn membrane. In addition, mucus may invade the graft and affect the amount of bone formation. Graft material may leak through the tear into the sinus proper, migrate to and through the ostium, and be eliminated through the nose or obstruct the ostium and prevent the normal sinus drainage. Ostium obstruction is also possible from swelling of the membrane related to the surgery. These conditions increase the risk of infection. However, despite these potential complications, the risk of the infection is low (less than 5%); therefore the sinus graft surgery should continue, and the patient should be monitored postoperatively for appropriate treatment (Figs. 37.49 and 37.50).

Antral Septa

Antral septa (i.e., also termed buttresses, webs, and struts) are the most common osseous anatomic variants seen in the maxillary sinus. Underwood,[134] an anatomist, first described maxillary sinus septa in 1910. He postulated that the cause of these bony projections derived from three different periods of tooth development and eruption. Krennmair and colleagues[135] further classified these structures into two groups: primary structures, which are a result of the development of the maxilla, and secondary structures, which arise from the pneumatization of the sinus floor after tooth loss.

Misch[136] postulated that septa might be bone reinforcement pillars from parafunction when the teeth were present. He noticed these structures occur more often in SA-3 sinuses and after a shorter history of tooth loss. Long-term edentulous sites and SA-4 sinuses have fewer septa. The prevalence of septa has been reported to be in the range of 33% of the maxillary sinuses in the dentate patient and as high as 22% in the edentulous patient.[137] The septa may be complete or incomplete on the floor, depending on whether they divide the bottom of the sinus into compartments. The septa may also be incomplete from the lateral wall or, the medial wall, or it should extend from the floor.

The shape of an incomplete maxillary sinus septum often resembles an inverted gothic arch that arises from the inferior or lateral walls of the sinus. In rare instances, they may divide the sinus into two compartments that radiate from the medial wall toward the lateral wall.

The most common location of septa in the maxillary sinus has been reported to be in the middle (second bicuspid–first molar) region of the sinus cavity. CBCT scan studies have shown that 41% of septa are seen in the middle region, followed by the posterior region (35%) and the anterior region (24%). For diagnosis and evaluation of septa, CBCT scans are the most accurate method of radiographic evaluation.[138] Panoramic radiography has been shown to be very inaccurate, with a high incidence of faulty diagnoses.

Sinus septa may create added difficulty at the time of surgery. Maxillary septa can prevent adequate access and visualization to the sinus floor; therefore inadequate or incomplete sinus grafting is possible. These dense projections complicate the surgery in several ways. After scoring the lateral-access window in the usual fashion, the lateral-access window may not greenstick fracture and rotate into its medial position. The strut reinforcement is also more likely to tear the membrane during the releasing of the access window. The sinus membrane is often torn at the apex of the buttress during sinus membrane manipulation because difficulty exists in elevating the membrane over the sharp edge of the web, and the curette easily tears the membrane at this position. However, because septa are mainly composed of cortical bone, immediate implant placement may engage this dense bone, allowing for strong intermediate fixation. Moreover, septa allow for faster bone formation because they act as an additional wall of bone for blood vessels to grow into the graft.

Management of Septa Based on Location

The use of CBCT radiographs before sinus graft surgery permits the surgeon to observe and plan the necessary modifications to the sinus graft procedure as a result of the septa. The modification to the surgery is variable depending on its location. The septa may be in the anterior, middle, or distal compartment of the antrum. When the septum is found in the anterior section, the lateral-access window is divided into sections: one in front of the septa and another distal to

• **Fig. 37.49** Maxillary sinus perforation from window outline osteotomy.
• **Fig. 37.50** Perforation repair. (A and B) Extended collagen membrane fixated on the superior aspect of the sinus cavity.

the structure. This permits the release of each section of the lateral wall after tapping with a blunt instrument. The elevation of each released section permits investigation into the exact location of the septa and to continue the mucosal elevation.

The mucosal tissue may often be elevated from the lateral walls above the septa. The curette may then slide down the side walls and release the mucosa from the bottom half of the septum on each side. The sinus curette should then approach the crest of the buttress from both directions, up to its sharp apex. This permits elevation of the tissue over the web region without tearing the membrane. When the strut is located in the middle region of the sinus, it is more difficult to make two separate access windows within the direct vision of the clinician. As a result, one access window is made in front of the septa. The sinus curette then proceeds up the anterior aspect of the web, toward its apex. The curette then slides toward the lateral wall and above the septal apex. The curette may then slide over the crest of the septum approximately 1 to 2 mm. A firm, pulling action fractures the apex of the septum. Repeated similar curette actions can fracture the web off the floor. Once the septum is separated off the floor, the curette may proceed more distal along the floor and walls. When the septum is in the posterior compartment of the sinus, it is often distal to the last implant site. When this occurs, the posterior septum is treated as the posterior wall of the sinus. The sinus membrane manipulation and sinus graft are placed up against and anterior to the posterior septum (Figs. 37.51–37.53).

Bleeding

Bleeding from the lateral-approach sinus elevation surgery is rare; however, it has the potential to be troublesome. Three main arterial vessels should be of concern with the lateral-approach sinus augmentation. Because of the intraosseous and extraosseous anastomoses that are formed by the infraorbital and posterior superior alveolar arteries, intraoperative bleeding complications of the lateral wall may occur. The soft tissue vertical-release incisions of the facial flap in a resorbed maxilla may sever the extraosseous anastomoses. The extraosseous anastomosis on average is located 23 mm from the crest of the dentate ridge; however, in the resorbed maxilla, it may be within 10 mm of the crest. When this artery is severed, significant bleeding has been observed. These vessels originate from the maxillary artery and have no bony landmark to compress the vessel. Therefore vertical release incisions in the soft tissue should be kept to a minimum height with delicate reflection of the periosteum. Hemostats are usually difficult to place on the facial flap to arrest the bleeding. Significant pressure at the posterior border of the maxilla and elevation of the head to reduce the blood pressure to the vessels usually stops this bleeding. The elevation of the head may reduce nasal mucosal blood flow by 38%.[139,140]

The vertical component of the lateral-access wall for the sinus graft often severs the intraosseous anastomoses of the posterior alveolar artery and infraorbital artery, which is on average approximately 15 to 20 mm from the crest of a dentate ridge. Methods to limit this bleeding, which is far less of a risk, have been addressed and include cauterization by the handpiece and diamond bur without water, electrocautery, or pressure on a surgical sponge while the head is elevated (Fig. 37.54).

The third artery of which the implant surgeon should be cautious is the posterior lateral nasal artery. This artery is a branch of the sphenopalatine artery that is located within the medial wall of

the antrum. As it courses anteriorly, it anastomoses with terminal branches of the facial artery and ethmoidal arteries. A significant bleeding complication may arise if this vessel is severed during elevation of the membrane off the thin medial wall.

Epistaxis (active bleeding from the nose) is a common disorder; however, it has been reported that 6% of patients who experience this in the general population require medical treatment to control and stop the hemorrhage because it lasts longer than 1 hour. Treatment options to treat epitasis include nasal packing, electrocautery, and the use of vasoconstrictive drugs. Vessel ligation and/or endoscopic surgery are necessary on rare occasions.

The most common site (90%) of nasal bleeding is from a plexus of vessels at the anteroinferior aspect of the nasal septum and the anterior nasal cavity (which is anterior to the sinus cavity and within the anterior projection of the nose). The posterior nasal cavity accounts for 5% to 10% of epitasis events and is in the region of the sinus graft. If the orbital wall of the sinus is perforated, or if an opening into the nares is already present from a previous event, then the sinus curette may enter the nares and cause bleeding. The arteries involved in this site are composed of branches of the sphenopalatine and descending palliative arteries, which are branches of the internal maxillary artery. The posterior half of the inferior turbinate has a venous network called the Woodruff plexus. Lavage of the nares with warm saline and oxymetazoline decongestant sprays provides excellent vasoconstrictive activity to treat the condition. A cotton roll with silver nitrate or lidocaine with 1:50,000 epinephrine may also be effective.

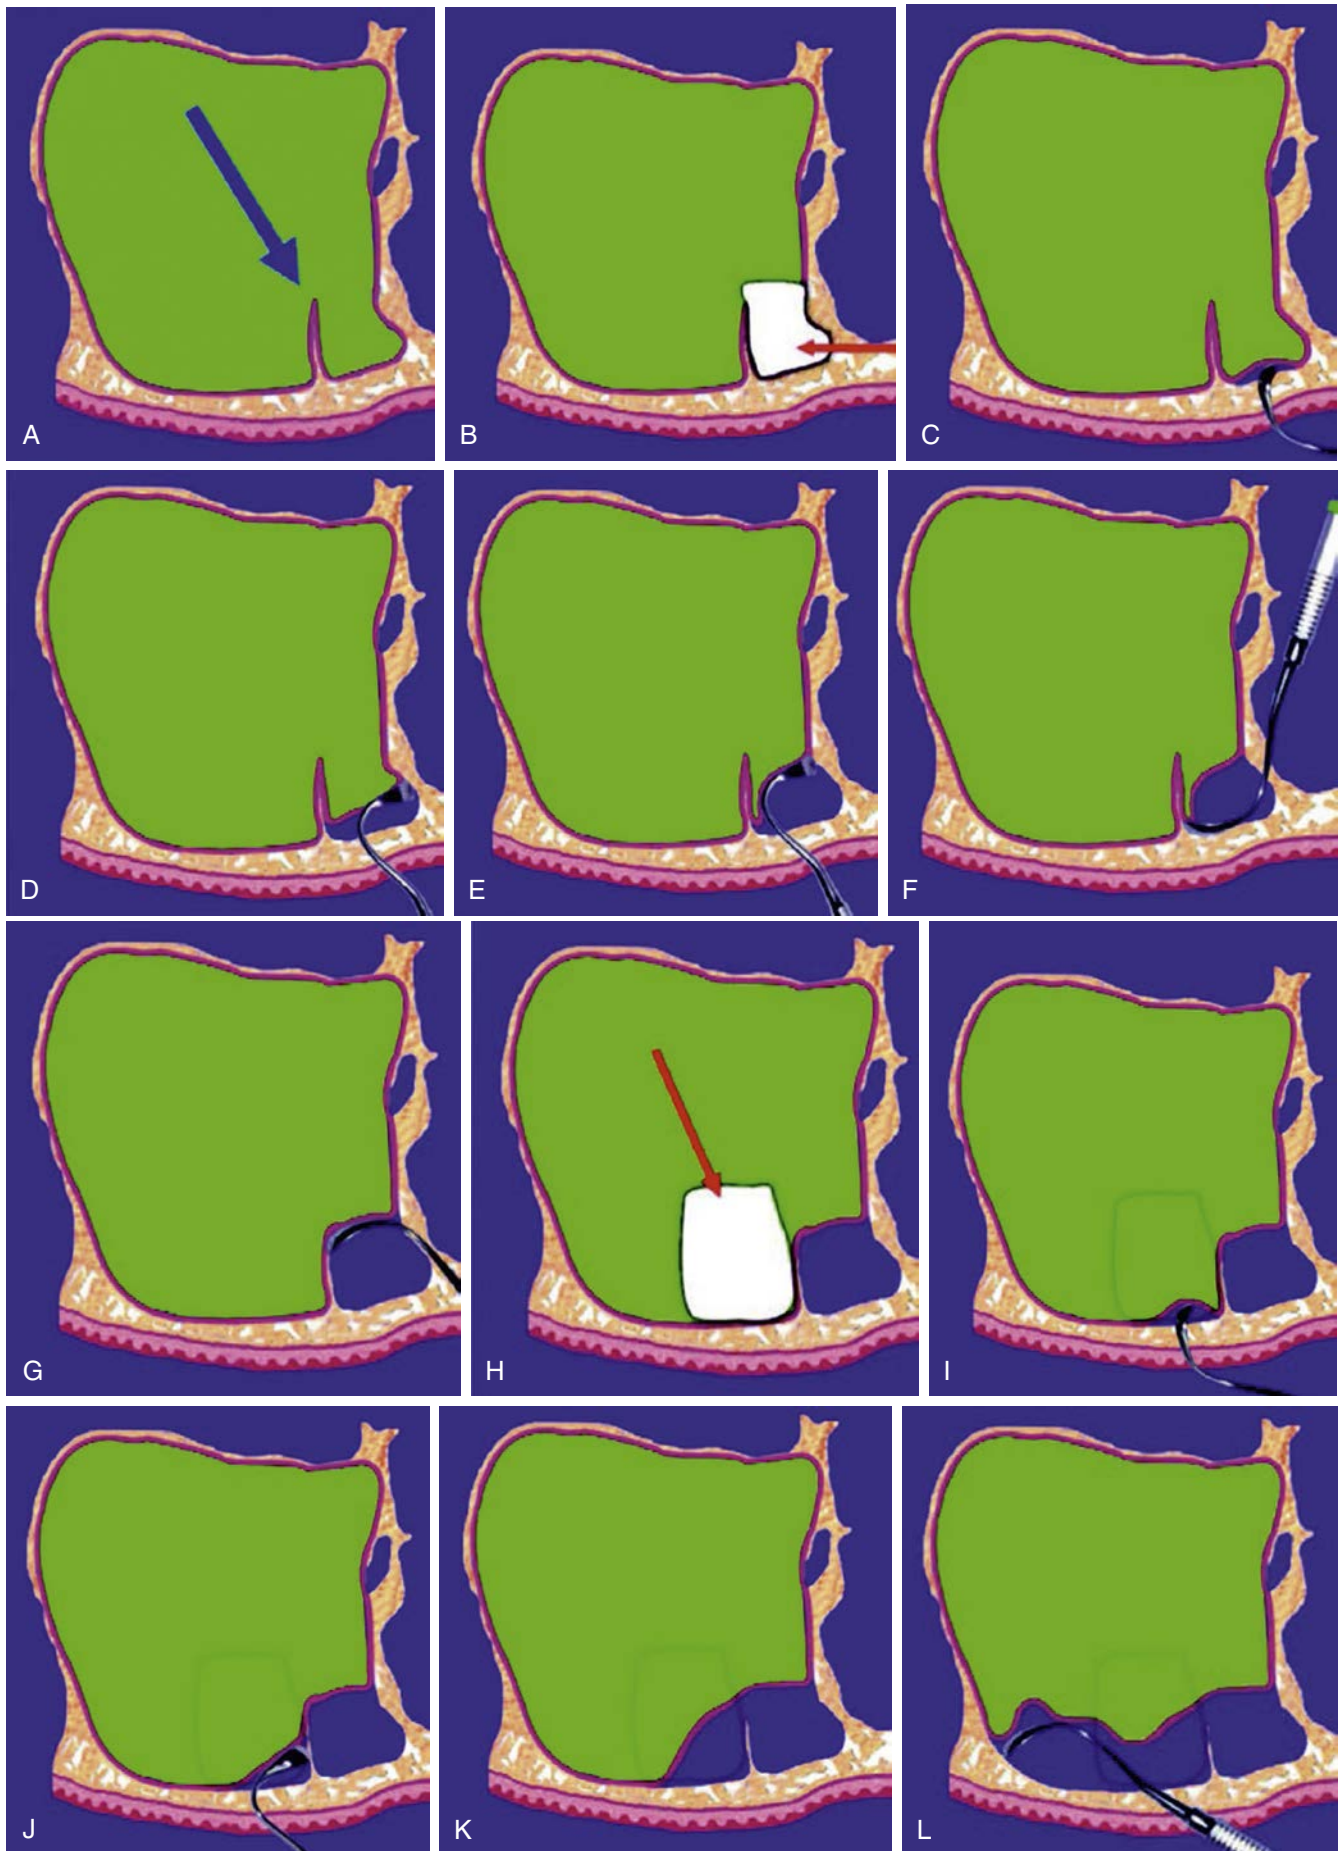
Bleeding from the nose may also be observed after sinus graft surgery. Placing a cotton roll, coated with petroleum jelly with dental floss tied to one end, within the nares may obtund nose bleeding after the surgery. After 5 minutes the dental floss is gently pulled and removes the cotton roll. The head is also elevated, and ice is applied to the bridge of the nose. If bleeding cannot be controlled, then reentry into the graft site and endoscopic ligation by an ENT surgeon may be required (Figs. 37.55 and 37.56).

Short-Term Postoperative Complications

Short-term complications are defined as those that occur within the first few months after surgery.

Incision Line Opening

Incision line opening is uncommon for this procedure because the crestal incision is in attached gingiva and usually is at least 5 mm away from the lateral-access window. Routinely, the soft tissue requires release before primary approximation and suturing. Because a collagen membrane is placed over the window, the soft tissue will usually not approximate without tension unless the surgeon expands the facial flap by releasing the periosteum above the mucogingival junction (where the tissue becomes thicker). Incision line opening occurs more commonly when lateral-ridge augmentation is performed at the same time as sinus graft surgery, or when implants are placed above the residual crest and covered with the soft tissue. It may also occur when a soft tissue–supported prosthesis compresses the surgical area during function before suture removal.

The consequences of incision line opening are delayed healing, leaking of the graft into the oral cavity, and increased risk of infection. However, if the incision line failure is not related to a lateral onlay graft and is only on the crest of the ridge and away from the


• **Fig. 37.51** Large septum in center of sinus. (a) Septum. (B) Window made anterior to septum. (C) Membrane is elevated off of floor. (D–G) Membrane is exposed anteriorly, posteriorly and to the medial wall. (H) Posterior window is outlined. (I–L) Membrane exposed on second window allowing for grafting around the septum.

sinus access window, then the posterior crestal area is allowed to heal by secondary intention. During this time, a soft tissue–borne prosthesis should be aggressively relieved, with no reline material in contact with the ridge. If incision line opening includes a portion of a nonresorbable membrane (i.e., for lateral-ridge augmentation), then the membrane should be cleaned at least twice daily with an oral rinses of chlorhexidine.

Nerve Impairment

The infraorbital nerve is of concern in sinus elevation surgery because of its anatomic position. This nerve enters the orbit via the inferior orbital fissure and continues anteriorly. It lies in a groove in the orbital floor (which is also the maxillary sinus superior wall) before exiting the infraorbital foramen. The infraorbital nerve exits the foramen approximately 6.1 to 7.2 mm from the orbital rim. Note that anatomic variants have been reported to include dehiscence and malpositioned infraorbital foramina, along with the nerve transversing the lumen of the maxillary sinus rather than coursing through the bone within the sinus ceiling (orbital floor). Malpositioned nerves have been reported as far as 14 mm from the orbital rim in some individuals. In the severely atrophic maxilla, the infraorbital neurovascular structures exiting the foramen may be close to the intraoral residual ridge and should be avoided when performing sinus graft procedures to minimize possible nerve impairment. This is of particular concern on soft tissue reflection and the bone preparation of the superior aspect of the window. Special considerations should be taken during reflection of the superior flap, and sharp-ended retractors should be avoided. Usually, those most at risk have a small cranial base (i.e., elderly females).

Complication

Because the infraorbital nerve is responsible for sensory innervations to the skin of the molar region between the inferior border of the orbit and the upper lip, iatrogenic injury to this vital structure can result in significant neurosensory deficits of this anatomic area. Most often the nerve is not severed, and a neuropraxia results. Even though this injury is sensory and there is no motor deficit, patients usually have a difficult time adapting to this neurosensory impairment (Fig. 37.57).

Management

If an infraorbital nerve impairment occurs, the implant clinician should immediately follow the clinical and pharmacologic neurosensory impairment protocol.

• **Fig. 37.53** Septum in posterior part of sinus. (A) Maxillary septum found on the floor in the posterior of the sinus. (B) An access window and curette elevates the mucosa anterior to the septum. The posterior septa is used as a posterior wall to contain the graft material.

Revision Surgery

When failure or compromise of the sinus graft occurs, reentry procedures are sometimes required to correct deficits. Failed or compromised sinus grafts result in altered soft and hard tissue characteristics, mainly the formation of adhesions of the Schneiderian membrane to the buccal flap. This results in difficulty with reflecting the buccal flap during the reentry procedure. Studies have shown that separation of the adhesions from the sinus mucosa led to a 47% perforation rate. In addition, it has been shown that altered characteristics of the Schneiderian membrane result in a nonflexible thick fibrotic membrane. In some cases, in which voids are present but have difficult access, regrafting procedures may need to be accomplished via a closed approach through the osteotomy site.[101]

Treatment Implications

Because of access issues, along with the higher perforation rate and fibrotic changes in the Schneiderian membrane, patients need to be informed of a higher postoperative complication rate involving questionable reentry bone growth and implant success. If reentry is necessary, usually bony adhesions and bony fenestrations of the lateral walls will be present.

The combination of fibrotic changes of the Schneiderian membrane, increased chance of perforation, and altered sinus physiology lead to a high complication rate. The continuation of the sinus mucosa and oral mucosa make reentry revision surgery problematic and difficult. This will require the separation of the oral and sinus mucosa to gain access to the sinus proper (Fig. 37.58).
• **Fig. 37.54** Intraosseous anastomosis. (A) Significant bleed from anastomosis (B) controlled by crushing bony area in which bleeding originated.

• **Fig. 37.55** Nasal bleeding. (A) Nasal bleeding immediately postop (B) usually may be controlled by gauze pressure packs.

Edema

Because of the extent of tissue reflection and manipulation, sinus graft surgery often results in significant edema. The resultant postoperative swelling can adversely affect the incision line, leading to greater morbidity.

Prevention

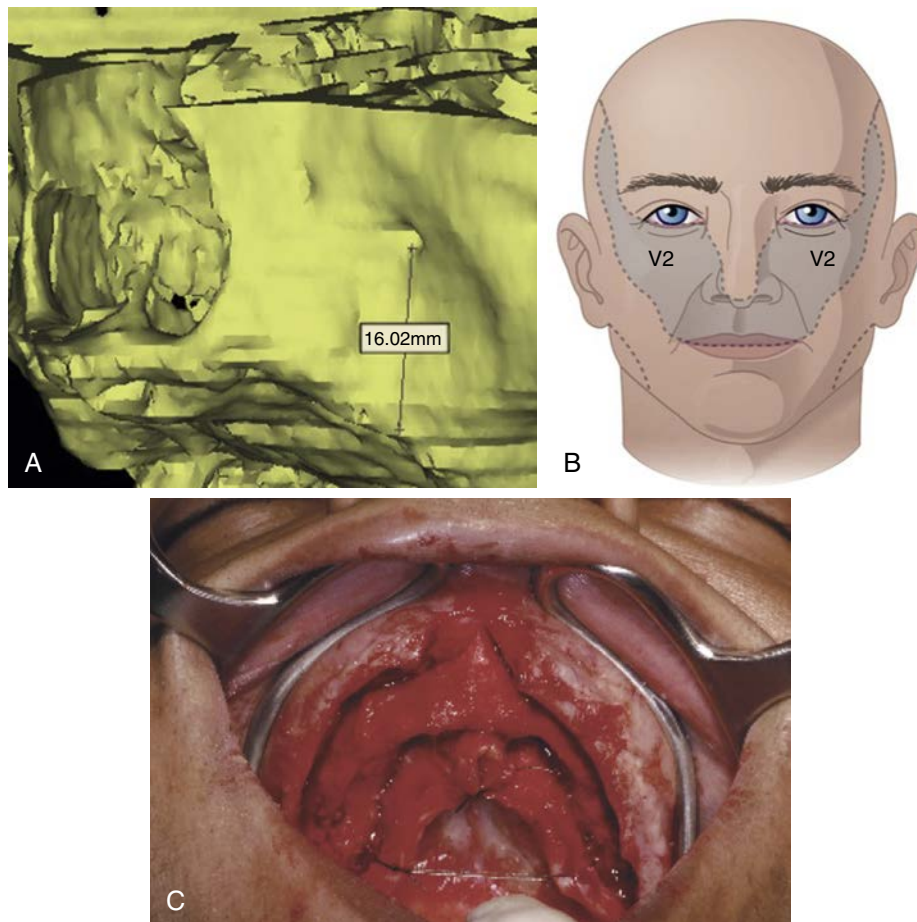
The use of good surgical technique that involves careful reflection and retraction will decrease the amount of postoperative edema.
• **Fig. 37.56** Bleeding control. Bleeding may be controlled by electrocautery.

The greater the surgery duration, the greater is the chance of edema. Caution should be used to decrease the amount of surgical duration and should not exceed the patient's tolerance. To minimize edema, corticosteroid use is used 1 day before and 2 days after surgery. This short-term prophylactic steroid use will allow for adequate blood levels to combat edema, which usually will peak at 48 to 72 hours. Dexamethasone is the ideal drug of choice because of its high antiinflammatory potency.

Cryotherapy

Application of an ice pack, along with elevation of the head and limited activity for 2 to 3 days, will help minimize the postoperative swelling. This cryotherapy will cause vasoconstriction of the capillary vessels, reducing the flow of blood and lymph and resulting in a lower degree of swelling. Ice or cold dressings should only be used for the first 24 to 48 hours. After 2 to 3 days, heat (moist) may be applied to the region to increase blood and lymph flow to help clear the area of the inflammatory consequences. This will also help reduce the possibility of ecchymosis that may result.

Ecchymosis

Sinus graft surgery also increases the possibility of bruising or ecchymosis. Because of the extent of reflection, bone preparation,


• **Fig. 37.57** Nerve impairment. (A) Infraorbital foramen anatomic variants that are close to the residual ridge. (B) V2 sensory impairment. (C) Special broad-based retractor which minimizes trauma to the infraorbital nerve.

and the highly vascular surgical area, ecchymosis will occur more often with this procedure compared with other implant related surgeries.

Etiology

The etiology of ecchymosis includes the following: blood vessels rupture → red blood cells die and release hemoglobin → macrophages degrade hemoglobin via phagocytosis → production of bilirubin (bluish-red) → bilirubin is broken down to hemosiderin (golden-brown).

Prevention

In most cases, ecchymosis will not be able to be completely prevented; however, the goal should be to minimize the extent of bruising. Additionally, good surgical technique, shorter surgical duration, the avoidance of anticoagulant analgesics, and postoperative cryotherapy all aid in the control of this phenomenon. Patients should always be informed of the possibility of ecchymosis. This is easily accomplished by having it be part of the postoperative instructions (Fig. 37.59).

Pain

Minimal discomfort and pain is usually associated with sinus graft surgery. However, if narcotics are indicated, any analgesic combination containing codeine, such as Tylenol 3, is prescribed postoperatively because codeine is a potent antitussive, and coughing

may place additional pressure on the sinus membrane and introduce bacteria into the graft. The patient is instructed to cough (if necessary) with the mouth open to minimize possible air pressure changes within the sinus cavity.

Oroantral Fistulae

Oroantral fistulae may develop postoperatively, especially if the patient has a history of past sinus pathology or infection. Small oroantral fistulae (<5 mm) usually will close spontaneously after treatment with systemic antibiotic drugs and daily rinses with chlorhexidine. However, larger fistulae (>5 mm) will normally require additional surgical intervention (Fig. 37.60). Larger fistulae are associated with an epithelialized tract, which is the result of the fusion of the sinus membrane mucosa to the oral epithelium. When this occurs, patients will most likely complain of fluids entering the nasal cavity on eating or drinking. Caution should be exercised in using the Valsalva maneuver (i.e., nose blowing test) to confirm the presence of an oroantral fistula at the time of surgery. The patient is asked to pinch their nostrils together to occlude the nose. The patient blows gently to see if air escapes into the oral cavity via the sinus. This is not recommended because this test may create an opening or make a small opening larger. The Valsalva maneuver may be used postoperatively to diagnose a suspected communication.

Management

Closure of oroantral fistulae can be accomplished by using broad-based lingual or facially rotated flaps (Figs. 37.61 and 37.62). Buccal flaps to close the fistula may be more difficult after a sinus graft because of the location of the graft site. In addition, the buccal tissue is very thin, and rotated or expanded buccal flaps usually result in loss of vestibular depth. Before the initiation of the flap design, the soft tissue around the fistula is excised and the sinus floor curetted to ensure direct bone contact. A tension-free rotated
• **Fig. 37.58** Revision surgery. (A) Postoperative infections often result in the sinus and nasal epithelium being continuous, (B) Reentry into sinus requires incising the tissue to separate the oral and nasal epithelium.
• **Fig. 37.59** Postoperative edema and ecchymosis. One of the most common postoperative complications is edema and ecchymosis, which often may extend into the mandible and neck area.
● **Fig. 37.60** Oroantral fistula: (A) Postoperative fistula resulting from poor wound healing. (B) Radiograph showing communication between the sinus and oral cavity.

flap is then made for complete covering of the communication. For oroantral closure after sinus graft procedures, a lingual flap is recommended because of the abundance of keratinized mucosa with an adequate blood supply. Flap designs include island flaps, "tongue-shaped" flaps, or rotational and advanced flaps, depending on the size of the exposure. A key to closing the oroantral opening is the dissection of the buccal flap lateral to the fistula. An incision that extends 15 mm anterior and posterior to the fistula is of benefit. The fistula then has an elliptical incision on each side of the opening. The core of tissue and the fistulous tract are excised. The facial flap is undermined and expanded well into the tissues of the cheek. The palatal aspect of the incision is adjacent to the tongue-shaped flap. Placement of the incision for the pedicle flap should be split thickness and take into account the location and depth of the greater palatine artery. Once the attached palatal pedicle graft is rotated to the lateral and attached to the facial flap, horizontal mattress sutures are placed to invert the flap to achieve a watertight seal. Sutures with high tensile strength (Vicryl) should be used and allowed to remain in place for at least 2 weeks (Fig. 37.63).

Post-Operative Infection

When evaluating postsurgical infectious complications after sinus graft procedures, the implant clinician must differentiate the type, location, and etiology of the infectious episode. The infection may originate within the graft site or may originate in the maxillary sinus proper. It could also be a combination of both (Table 37.2). Very few studies have evaluated these different processes. Postsurgically, there exist many reports with varying results

(approximately 0%–27%) on the incidence of infection leading to acute rhinosinusitis.[141] Postoperative infections after sinus graft surgery may result from the following:
- **Acute rhinosinusitis:** infection within the sinus proper
- **Graft site:** infection within the graft area
- **Combination infection**: from acute rhinosinusitis and graft site

Graft Site Infections

Etiology of Graft Site Infection

The graft site may become infected from many sources: (1) preexisting site bacteria, (2) bacterial contamination of the surgical site, (3) graft material, (4) surgical technique, (5) bacterial contamination from acute rhinosinusitis, (6) lack of systemic and local prophylactic antibiotics, and (7) systemic, mediation, or lifestyle factors (Fig. 37.64).

Additionally, studies have shown a direct correlation between an increased infection rate with simultaneous implant placement and with simultaneous ridge augmentation.

One such study showed that simultaneous ridge grafting increased the infection rate significantly (15.3%) versus sinus grafting alone (3%).[142] Most often, the infection begins more than 1 week after surgery, although it may begin as soon as 3 days later.

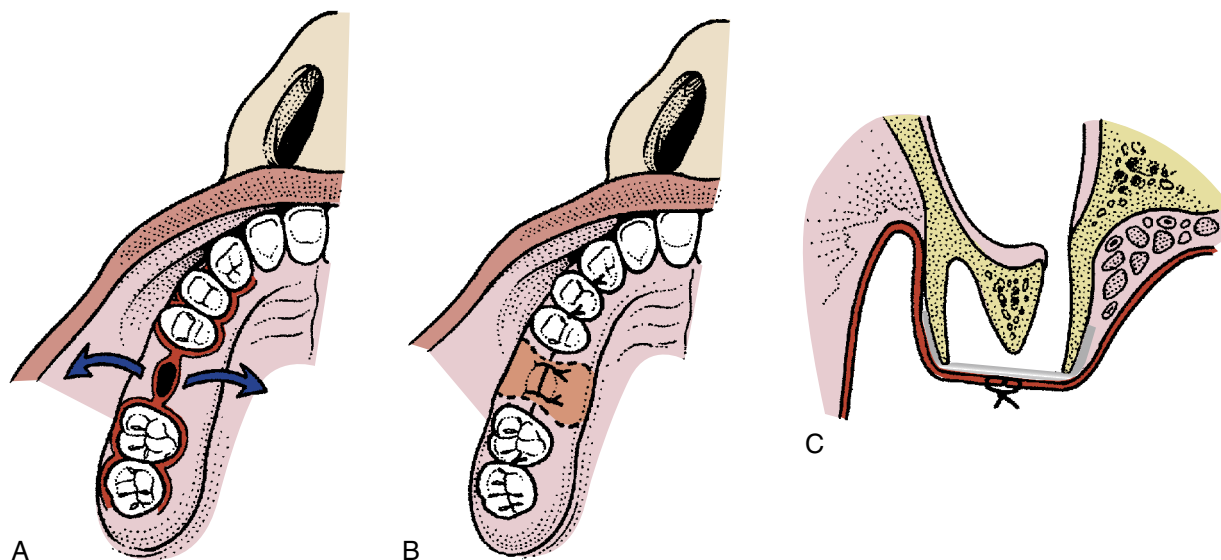
Diagnosis

The most common sign of graft site infection is swelling, pain, dehiscence, or exudate near or including the grafting surgical site. Patients may complain of poor taste and loss of graft particles in their mouth. Incision line opening is a common sequalae with exudate discharge. Graft site infections usually occur within days to weeks of the surgery and are less common as a late infection. Initially, the infection may start as a graft site infection (localized to the graft), which then leads to an acute maxillary rhinosinusitis (Fig. 37.65).

Treatment

Although the incidence of infection after the procedure is usually low, the damaging consequences on osteogenesis and the possibility of serious complications require that any infection be aggressively treated. In case of postoperative infection, it is recommended that the clinician perform a thorough examination of the area by palpation, percussion, and visual inspection to identify the area primarily affected. Infection will usually follow the path of least resistance and is observed by changes in specific anatomic sites to which it spreads.[143]

Early, aggressive treatment is crucial for graft site infections to prevent the loss of graft or extension of the infection into the sinus proper, causing an acute rhinosinusitis or spread of infection to other vital areas. Initially, systemic antibiotics along with antimicrobial rinses should be used. If infection persists, debridement and drainage should be completed, along with the use of sterile saline and chlorhexidine. A Penrose drain may also be used in cases that do not respond to systemic antibiotics. In some instances, oroantral fistulae result after infection cessation (see the section "Oroantral Fistulae").

Antibiotic treatment in the maxillary sinus, both prophylactically and therapeutically, is much different than for most oral surgical procedures. When selecting antibiotic medications for sinus infections, a variety of factors must be evaluated. These include the most common type of pathogens involved, antimicrobial resistance, pharmacokinetic and pharmacodynamic properties, and
• **Fig. 37.61** Oroantral fistula repair. (A) oroantral fistula, (B) flap extension for tension-free closure, (C) Extended collagen membrane, (D) Membrane positioned, (E) Lateral sliding flap to obtain primary closure.


• **Fig. 37.62** Membrane-assisted closure of oroantral communications. (A) Oroantral fistula in the right maxillary alveolar process in the region of the missing first molar, which is to be closed with subperiosteal placement of alloplastic material such as gold or titanium foil or a resorbable collagen membrane. Facial and palatal mucoperiosteal flaps are developed. Extension of the flaps along the gingival sulcus one or two teeth anterior and posterior allows some stretching of the flap to facilitate advancement for closure over the defect. The fistulous tract is excised. Osseous margins must be exposed 360 degrees around the bony defect to allow placement of the membrane beneath the mucoperiosteal flaps. The flap is supported on all sides by underlying bone. (B) Closure. Ideally, the flaps can be approximated over the defect. In some cases, a small gap between the flaps will heal over the membrane by secondary intention. Even if the intraoral mucosa does not heal primarily, the sinus lining usually heals and closes, and the membrane is then exfoliated or resorbed, and mucosal healing progresses. (C) Cross-section of membrane closure technique. Buccal and palatal mucoperiosteal flaps are elevated to expose osseous defect and large area of underlying alveolar bone around the oroantral communication. The membrane overlaps all the margins of the defect, and the facial and palatal flaps are sutured over the membrane. (From Hupp JR, et al. *Contemporary Oral and Maxillofacial Surgery.* 5th ed. St Louis, MO: Elsevier; 2009.)

the tissue (sinus) penetration of the various antibiotic drugs. The antibiotic medication of choice should be effective against respiratory and oral pathogens while exhibiting known activity against resistant strains of the common pathogens. Two such factors are used when evaluating sinus antibiotic medications: (1) the minimum inhibitory concentration (MIC) and (2) the concentration of antibiotic drugs penetrating inflamed diseased sinus tissue. The MIC is the lowest concentration of the antimicrobial agent that results in the inhibition of growth of a microorganism. The MIC is usually expressed by MIC 50 or MIC 90, meaning that 50% or 90% of the microbial isolates are inhibited, respectively. Previous studies and treatment modalities used amoxicillin as the first drug of choice. However, with the increasing prevalence of penicillinase- and β-lactamase–producing strains of *H. influenzae* and *M. catarrhalis*, along with penicillin-resistant strains of *S. pneumoniae*, other alternative antibiotic drugs should be selected.

β-Lactam Medications. The most common β-lactam antibiotic drugs used in the treatment of rhinosinusitis and graft site infections are penicillin (amoxicillin, Augmentin) and cephalosporin (Ceftin, Vantin). Amoxicillin has been the drug of choice for years to combat the bacterial strains associated with rhinosinusitis and infections in the oral cavity. However, its effectiveness has been questioned recently because of the high percentage of β-lactamase–producing bacteria and penicillin-resistant *S. pneumoniae.* Augmentin (amoxicillin-clavulanate) has the added advantage of activity against β-lactamase bacteria. It has been

associated with a high incidence of gastrointestinal side effects. However, with the dosing regimen (twice a day [bid]), these complications have been significantly decreased. Two recommended cephalosporin medications have also been suggested to treat rhinosinusitis: cefuroxime axetil (Ceftin) and cefpodoxime proxetil (Vantin). Other cephalosporin drugs fail to achieve adequate sinus fluid levels against the causative pathogens. Ceftin and Vantin have good potency and efficacy, while exhibiting strong activity against resistant *S. pneumoniae* and *H. influenzae.*

Macrolide Medications. Macrolide drugs are bacteriostatic agents that include erythromycin, clarithromycin (Biaxin), and azithromycin (Zithromax). Macrolide medications have good activity against susceptible pneumococci; however, with the increasing rate of macrolide resistance, their use in combating sinus pathogens is becoming associated with a high likelihood of clinical failure. These antibiotic drugs are very active against *M. catarrhalis,* although their activity on *H. influenzae* is questionable. These antibiotic medications are not suggested to treat postoperative sinus infections.

Lincosamide Medications. Clindamycin (Cleocin) is the primary lincosamide drug used in clinical practice today that is considered to be bacteriostatic. However, in high concentrations, bactericidal activity may be present. Clindamycin is mainly used for the treatment of gram-positive aerobes and anaerobes. With acute sinus disease, clindamycin is usually not indicated because it exhibits no activity against
• **Fig. 37.63** Postsinus graft infection. (A) Preoperative radiograph. (B) Postoperative sinus augmentation. (C) 4-week postop with graft site infection and acute rhinosinusitis.

H. influenzae and *M. catarrhalis.* This drug may be used in chronic sinus conditions because anaerobic organisms play a much larger role in the disease process.

Tetracycline-Derived Medications. Doxycycline (Vibramycin) is a bacteriostatic agent with adequate activity against penicillin-susceptible pneumococci and *M. catarrhalis.* This drug does not exhibit any activity against penicillin-resistant bacteria and is not effective against *H. influenzae.* However, doxycycline may be used as an alternative antibiotic for the treatment of acute rhinosinusitis infections.

Sulfonamide Medications. The most common sulfonamide drug, trimethoprim-sulfamethoxazole (Bactrim) is bacteriostatic. Recently a high rate of resistance to these drugs has been seen with *S. pneumoniae, H. influenzae, M. catarrhalis,* and other sinus

pathogens. This drug should not be considered to treat postoperative infections unless a culture and sensitivity test has been performed and susceptibility is shown.

Metronidazole Medication. Metronidazole is the most important member of the nitroimidazole group. It is bactericidal and is effective against gram-positive and gram-negative anaerobic bacteria. Its main use would be in the treatment of chronic sinus (not acute) conditions. The medication should be used with another antibiotic drug to be effective against aerobic bacteria.

Antibiotic Conclusion. In the evaluation of different antibiotic drugs used for the treatment of pathologic conditions of the sinus, meticulous analysis of the activity against the most common pathogens must be evaluated. With all of the antibiotic medications evaluated, amoxicillin-clavulanate, and cefuroxime axetil

TABLE 37.2	Types of Postoperative Sinus Infections		
	Acute Rhinosinusitis	**Graft Site Infection**	**Combination**
Etiology	• Preexisting pathology • Nonpatent ostium • Anatomic variants • Graft overfill • Postsurgery physiologic alteration • Spread of infection from graft site • History of chronic rhinosinusitis • Preexisting odontogenic or allergic rhinosinusitis	• Preexisting pathology • Oral pathogen contamination • Untreated periodontitis • Perforation • Lack of asepsis • Long duration surgery • Simultaneous ridge augmentation • Simultaneous implant placement • Lack of prophylactic medication • Lack of local graft antibiotics • Systemic diseases, smoking/alcohol	Primary site could be sinus proper or graft site
Bacteria	Aerobic gram-positive cocci *(Streptococcus pneumoniae)* Aerobic gram-negative rods *(Haemophilus influenzae)* *(Staphylococcus epidermidis, Streptococcus viridans, Branhamella catarrhalis)*	Aerobic gram-positive cocci *(S. viridans)* Aerobic gram-positive cocci *(Staphylococcus aureus)* Aerobic gram-negative rods *(Bacteroides)* Aerobic gram-positive cocci (peptostreptococcus)	Any combination of pathogens
Prevention	CBCT: Confirmation of ostium patency Confirmation of no pathology or anatomic variants Prophylactic medications	Prophylactic medication Good surgical technique Aseptic technique Short surgical duration No membrane perforation	Any combination of preventive measures
Symptoms	Mild: Facial pain/edema Congestion Nasal drip/blockage Cough Severe: Significant facial pain/edema Fever Headache Proptosis/diplopia Malaise	Site pain/edema Incision line opening Exudate Bad taste Bleeding Intraoral swelling	Any combination of symptoms
Ideal antibiotic	β-Lactam	β-Lactam Lincosamide	β-Lactam
Initial treatment	Antibiotic: 1. Augmentin 2. Ceftin Nasal saline	Antibiotic: 1. Augmentin 2. Clindamycin Chlorhexidine	Antibiotic: 1. Augmentin 2. Ceftin Nasal saline/rinse
Secondary treatment	Referral, especially if cerebral/ocular symptoms	Debridement/irrigation Possible culture	Debridement Possible culture Referral, especially if cerebral/ocular symptoms

CBCT, Cone beam computerized tomography.

show excellent MIC 90 blood levels against the most common pathogens associated with sinus infections.

Decongestant Medications. Recent recommendations in the medical literature state that nasal decongestants (sympathomimetic drugs) should not be used except in severe cases of congestion and infection. Nasal decongestants have been shown to impair blood flow, decreasing antibiotic levels to the site. Additionally, it may cause a rebound phenomenon and the development of rhinitis medicamentosa. This rebound phenomenon has been theorized to occur as a negative feedback vasodilation after repeated introductions of the sympathomimetic (vasoconstricting) drug.

Saline Rinses. An important treatment for the patient with the presence of acute rhinosinusitis and graft infections is the use of saline rinses with a bulb syringe or a squeeze bottle in the nostril used to lavage the sinus through the ostium. The nasal saline rinse has a long history for treatment of sinonasal disease. Hypertonic and isotonic saline rinses have proven to be effective against chronic rhinosinusitis. These techniques of nasal irrigation have been evaluated, with the best option of a positive-pressure irrigation using a squeeze bottle that delivers a gentle stream of saline to the nasal cavity (NeilMed's Sinus Rinse; NeilMed Pharmaceuticals Inc.). The syringe or squeeze bottle should not seal the nasal

● **Fig. 37.64** Graft site infection showing exudate and incision line opening.

opening because this may force bacteria up toward the ethmoidal sinus. Instead, a gentle lavage with sterile saline rinses the sinus and flushes out the mucus and exudate. Ideally, the head is placed down and forward so that the saline can reach the ostium in the superior and anterior portion of the sinus. The course of therapy should continue for at least 7 days.[144] Another option is the Neti Pot, which is very common among chronic rhinosinusitis patients (Fig. 37.66).

Acute Rhinosinusitis Infections

Etiology of Acute Rhinosinusitis

There are two causes of acute maxillary rhinosinusitis after sinus graft surgery: (1) preexisting maxillary sinus pathology or (2) progression of sinus graft surgery to involve the maxillary sinus proper (Fig. 37.67).

Diagnosis

Maxillary rhinosinusitis is a complication that arises when the patient postoperatively complains of any of the following symptoms: (mild) headache, pain, or tenderness in the area of the maxillary sinus; rhinorrhea; or (severe) fever, headache, or ocular symptoms. Studies have supported the fact that patients who had predisposing factors for rhinosinusitis were more at risk of developing postoperative transient rhinosinusitis.

The wide range of reported percentages (3%–20%) may be the result of different methods used for diagnosis (i.e., clinical, radiographic, endoscopic). Cases of maxillary sinusitis after dental implant surgery have rarely been reported in the dental literature. However, recently in the medical literature, numerous cases of minor to severe complications after sinus surgery have been documented. Although very infrequent, severe infections may lead to more severe complications, such as orbital cellulitis, optic neuritis, cavernous sinus thrombosis, epidural and subdural infection, meningitis, cerebritis, blindness, osteomyelitis, and, although rare, brain abscess and death.[145]

Treatment

If infection occurs postoperatively, treatment must be aggressive because of the possible complications that may arise to close anatomic structures. Systemic antibiotic therapy is the first line of treatment, along with close observation of symptoms. Recent medical literature discourages the use of systemic decongestants and highly recommends the use of saline lavage and rinses. Systemic decongestants have been shown to impair site antibiotic

delivery and also have a high degree of rebound effect (rhinitis medicamentosa).

If symptoms are not alleviated with antibiotic and decongestant medications, possible referral to the patient's physician or ENT is warranted. Emergency consultation should be considered if the patient complains of a severe headache that is not relieved by mild analgesics, as well as persistent or high fever, lethargy, visual impairment, or orbital swelling.

The authors highly recommend that a professional association with an ENT be obtained. Because the possible morbidity of these infections and causative pathogen is not easily determined, referral is sometimes needed. Additionally, if mild sinus symptoms persist or signs of severe infection are present, immediate referral is recommended. Resolution of these conditions has been accomplished with the use of antibiotic drugs, endoscopic treatment, or Caldwell-Luc procedures (Fig. 37.68).

Combination (Graft Site Infections/Acute Rhinosinusitis)

Etiology

The etiology of a combination infection can either be initiated from the graft site or the sinus proper.

Diagnosis

The diagnosis for a combination type infection can parallel a combination of graft site symptoms and/or acute rhinosinusitis.

Treatment

The treatment of a combination type infection should include the use of a β-lactam antibiotic (e.g., Augmentin) followed by the use of debridement and nasal saline rinses. If ocular or cerebral symptoms persist, or the patient does not respond to antibiotic treatment, referral is recommended.

The most current, comprehensive study on the treatment of sinus disease involves guidelines established by the Sinus and Allergy Health Partnership, Centers for Disease Control and Prevention, and the FDA in 2000. With this information as a guide, the following recommendations for antibiotic use in the treatment of infections after sinus graft are suggested (Box 37.14).

Spread of Infection

Because of the anatomic and topographic location of the maxillary sinus, infections from oral or sinus pathogens may spread quickly to adjacent sites.

Sinus-related pathologic conditions are the most common cause of orbital infection, accounting for 60% to 84% of cases. Because of the seriousness of ocular infections, early diagnosis and aggressive treatment is paramount.

Various routes may predispose this area to infection from the maxillary sinus and include the following:
1. The venous plexus of the maxillary sinus drains through the posterior wall into the deep facial vein, through the pterygoid plexus, and finally into the cavernous sinus.
2. Veins also perforate the osseous roof of the maxillary sinus, entering the orbit through the superior and inferior ophthalmic vein. These veins also are connected to the pterygoid plexus and cavernous sinus.

• **Fig. 37.65** Postgraft infection. (A) Cone beam computerized tomographic (CBCT) coronal image showing implant with associated infection. (B) Axial CBCT image showing a completely opacified sinus. (C) Intraoral view of draining fistula tracts *(green arrows).* (D) Incision and drainage. (E) Exudate and infected tissue removal.

● **Fig. 37.66** Neti Pot. Used for nasal irrigation resulting in flushing out the nasal passages.
● **Fig. 37.67** Culture and sensitivity. In some cases of rhinosinusitis, a culture and sensitivity test may be administered. (A) Swab sealed and sent to laboratory for culture and sensitivity testing.(B) Culture swab placed into the infected site.

3. Additionally, numerous veins perforate the anterior wall that drain into the superior ophthalmic vein and into the cavernous sinus. From the cavernous sinus, drainage through the deep middle cerebral vein communicates with the white substance of the brain's superficial venous system.

Because of the elaborate maxillocerebral venous anastomoses, spread of infection from the maxillary sinus may result in possible sequelae such as brain abscesses, intraorbital abscesses, orbital cellulitis, cavernous sinus thrombosis, and osteomyelitis.

Implant Penetration Into the Sinus

Bränemark and colleagues[146] reported on animal histologic studies and 44 clinical cases of implants penetrating the maxillary sinus. They reported success rates comparable to other maxillary implants, and no postoperative signs or symptoms were found with these implants. An animal study by Boyne[147] led to the same conclusion. The assumption was that direct connection between hard and soft tissues to the integrated implant created a barrier to the migration of microorganisms. However, it should be noted these animals do not have the same incidence of maxillary sinusitis comparable to humans.

It is possible that an implant that penetrates the sinus floor may contribute to a source of periodic sinusitis because a bacterial
● **Fig. 37.68** Functional endoscopic sinus surgery (FESS). (A) FESS scope. (B) Surgical placement of FESS.

Mild Infection

Symptoms
- Purulent and nonpurulent nasal drip
- Nasal blockage
  - Facial pain and pressure
  - Intraoral and extraoral swelling
- Cough

Treatment
1. Amoxicillin-clavulanate (Augmentin) 825 mg/125 mg (1 tablet bid for 10 days)
   a. If nonanaphylactic allergy to amoxicillin:
      cefuroxime axetil (500 mg) 1 tablet bid for 10 days
   b. True anaphylactic allergy to amoxicillin:
      doxycycline (100 mg) 1 tablet bid for 10 days
2. Nasal saline rinses

Moderate to Severe Infection

Symptoms
- Mild infections symptoms
- Severe headache
- High persistent fever (>102.5°F)
  - Periorbital swelling
  - Ocular symptoms (diplopia, proptosis)
  - Altered mental status
- Infraorbital hyperesthesia

Treatment
1. Immediate physician referral (emergency room or ENT Physician)

Bid, Twice daily; ENT, ear, nose, and throat (physician).

• **Fig. 37.69** Implant penetration into sinus. Coronal image showing implant placement into maxillary sinus leading to a completely opacified maxillary sinus.

smear layer would be difficult to remove through regular phagocytic activity. When this is suspected, removal of the implant or an apicoectomy of the implant apex, from a lateral-access window, may be of benefit (Fig. 37.69).

Overfilling of the Sinus

The goal of the sinus graft is to obtain sufficient vertical height of bone to place endosteal implants with long-term success. The maximum length requirement of an implant with adequate surface of design is rarely more than 15 mm, and as a result, the goal of the initial sinus graft is to obtain at least 16 mm of vertical bone from the crest of the ridge. This usually means the bottom one-half of the sinus is filled with graft material because most sinuses approximate 35 mm in height. A CBCT scan of the sinus before surgery may be used to estimate the amount of graft material required for the ideal volume of sinus graft material. Care should be given to the amount of graft material placed into the sinus. Overfilling the sinus can result in blockage of the ostium, especially if membrane inflammation or the presence of a thickened sinus mucosa exists.

The majority of sinus graft overfills do not have postoperative complications. If, however, a postoperative sinus infection occurs without initial resolution, reentry and removal of a portion of the graft and changing the antibiotic protocol may be appropriate (Fig. 37.70).

Postoperative Cone Beam Computerized Tomographic Mucosal Thickening (False Positive for Infection)

Immediate postoperative radiographs may reveal significant mucosal thickening within the sinus. The clinician should not determine this to be infection unless the previously mentioned signs of infection are noted. Normally, elevation of the sinus mucosa and bone grafting does alter the overall maxillary sinus environment by reducing the size of the sinus and repositioning the mucociliary transport system. In spite of this, only short-term clearance impairment exists, resulting in only subclinical effects on the sinus physiology. However, in cases of preoperative sinusitis histories, elevation surgery may predispose a patient to sinus-related complications. It has been shown that these procedures do alter the microbial environment. Studies reveal at 3 months after surgery, positive sinus cultures were present compared with cultures taken for the same patients preoperatively. However, after 9 months the cultures were similar to the preelevation results. The key is maintenance of the ostiomeatal opening between the maxillary sinus and the nasal cavity.

Migration of Implants

In 1995 the first case of a displaced (migrated) implant into the maxillary sinus was documented. Since then, an increased number of reports are coming to light, documenting an ever-increasing problem. Reports have shown that implants migrating from the maxillary sinus have been found in the sphenoid sinus, ethmoid sinus, orbit, nasal cavity, and anterior cranial base.

Etiology

The etiology of implant displacement or migration from the maxillary sinus includes many possibilities. The timing of

● **Fig. 37.70** Overfilling of the sinus. (A) Cone beam computerized tomographic coronal scan image depicting excess graft material occluding the maxillary ostium. (B) Significant overfill of maxillary sinus leading to an acute rhinosinusitis.

implants ending up in the maxillary sinus proper varies from intraoperative displacement to migration years later. Many etiologic factors have been suggested, according to the timing (early versus late) (Table 37.3).

Prevention

For early migration/displacement complications, most likely the cause is surgical error or incorrect treatment planning. When evaluating late migration/placement complications, the majority of issues are a direct result of postoperative prosthetic errors (too early loading) or factors that are precipitated by lack of integration or minimal bone at the implant interface.

Management

The management of displaced or migrated implants into the maxillary sinus should be treated with urgency. Leaving implants in the maxillary sinus may lead to acute rhinosinusitis complications. Additionally, implants left in the maxillary may become calcified (antrolith) or become displaced into other anatomic areas (e.g., sinuses, orbit, nasal cavity, brain).

The patients should be referred as soon as possible for removal via a Caldwell-Luc approach or endoscopy (functional endoscopic sinus surgery [FESS]) (Figs. 37.71–37.77).

Postoperative Fungal Infection

Fungal infection after sinus bone grafting is rarely reported; however, with the increased number of sinus graft procedures being performed, inevitably more will be reported in the literature. Fungal sinusitis is a destructive, invasive disease that is mostly caused by *Aspergillus*. *Aspergillus* spp. is a fungus of the Ascomycetes class, which is one of the most commonly encountered in the human environment. In the diagnosis of fungal sinusitis, there exist two forms: noninvasive and invasive. The invasive form is rare and is almost always associated with immunocompromised patients. Erosion and osseous destruction occurs that may be fatal. However, this form has not been associated with dental implants or sinus graft surgery.

Case studies have shown postoperative complications after sinus graft surgery[148] and overextension of root canal filling involving the noninvasive form. This type of fungus growth is also

TABLE 37.3	Migration of Dental Implants	
Early	**Late**
• Poor initial stability • Overpreparation of osteotomy site • Poor quality of bone • No crestal cortical bone • Implant placement into sinus without bone graft • Incorrect treatment planning • Surgical inexperience • Untreated antral preparation • Postoperative sinus infection • Immediate placement implants	• Too early loading • Changes in intranasal or intrasinus pressure • Peri-implantitis • Autoimmune reaction

termed fungus balls or aspergilloma and is associated with immunocompetent patients.

Diagnosis

Usually, the patient will present with clinical symptoms of frontal headache, orbicular pain, nasal congestion, and bleeding, with signs of chronic rhinosinusitis. Radiographically, a distinctly increased soft tissue density mass (radiopacity) is seen on CBCT scans.

Management

Referral to an ENT for evaluation and confirmation of diagnosis. Usually, treatment involves surgical removal via Caldwell-Luc or FESS techniques because systemic antimycotic drugs are ineffective.

Summary

In the past, implant treatment in the posterior maxilla was reported as the least predictable region for implant survival. Causes cited include inadequate bone height, poor bone density, and high occlusal forces. Past implant modalities attempted to avoid this region, with procedures such as excessive cantilevers from anterior implants or excess numbers of pontics when implants are placed anterior and posterior to the antrum.
● **Fig. 37.71** Migrated implants into maxillary sinus. (A and B) Implants displaced into maxillary sinus. (C) Implant obstructing the maxillary ostium.

● **Fig. 37.72** Migrated implant into nasal cavity. Implant that was displaced into the maxillary sinus and eventually eroded through the medial wall of sinus into the nasal cavity.

The maxillary sinus may be elevated and SA bone regenerated to improve available bone height. Tatum began to develop these techniques as early as the mid-1970s.[3] Misch[149] developed four options for treatment of the posterior maxilla in 1984 based on the height of bone between the floor of the antrum and the crest of the residual bone. These options were further modified to reflect the width of available bone, once adequate height was obtained. Root-form implants of adequate size are indicated in the posterior maxilla. The higher forces and less dense bone often require larger diameter implants.

It is the observation of the authors, using the sinus graft procedures described in this chapter for more than 30 years, in clinical practice, universities, and private implant institutes, that the sinus graft procedure is more than 97% effective. This region of the mouth predictably grows more bone in height than any other intraoral region. However, an organized approach needs to be completed with respect to patient selection, pathology evaluation, pharmacologic management, and surgical and prosthetic protocol to increase success and decrease potential morbidity of the procedures.

Intraoral Autogenous Bone Grafting

C. STEPHEN CALDWELL AND CARL E. MISCH

Treatment plans in implant dentistry in the past used existing bone volume to determine the location and type of implant and restorations were adapted to accommodate irregularities related to implant locations. In abundant bone (Division A), endosseous root form implants were inserted; in bone of moderate width (Division B), blade implants were placed; and in inadequate height of bone (Division C–h), subperiosteal implants were the treatment of choice.

Treatment planning has dramatically changed. The final prosthesis type and design is first determined, followed by determining the ideal implant positions, numbers, and sizes. The available bone is often inadequate to provide the foundation required for a predictable treatment plan. As a consequence, bone grafting has become a more frequent solution for achieving long-term success.

In addition to the biomechanical and functional needs significant esthetic considerations need to be included in planning a case. Bone grafting is often indicated to allow placement of an implant in the proper location for an ideal esthetic result. In addition, the soft tissue drape often requires enhancement in the esthetic zone as the bone foundation sets the tone for the soft tissue drape. Therefore when ideal crown contours (FP-1) and soft tissue are desired, bone augmentation is an important aspect of the treatment plan. As a result of biomechanical-based foundations and esthetic desires, a primary diagnostic consideration for implant prostheses is the available bone in the edentulous span. The placement of endosteal dental implants requires adequate bone volume at the desired locations for ideal prosthetic support. With insufficient bone volume, several surgical techniques may be used to reconstruct the deficient ridge in preparation for implant placement, including bone spreading (ridge splitting), bone growth factors, particulate grafting (allograft, xenograft, alloplast), and autogenous grafting (intraoral or extraoral donor sites).

The number of key factors present and the geometry of a bony defect are important considerations in the selection of a modality for ridge augmentation.[1] In general the fewer the number of remaining bony walls, the greater is the need for osteopromotive techniques. Although allografts and guided bone regeneration techniques have been used predictably in slight-to-moderate bone regeneration (primarily for inadequate width in the horizontal dimension), these methods have limitations and have been found to produce less favorable results in the treatment of larger bone deficiencies.[2-13] Ideally the most predictable bone graft material possesses osteoconductive, osteoinductive, and osteogenic

properties. The only type of bone-grafting material that maintains all three of these regenerative properties is autogenous (autologous) bone. Therefore autologous cortical/trabecular bone grafts may be considered and have been proved to be highly successful for the repair of moderate-to-severe alveolar atrophy and bone defects (Fig. 38.1).[14-28]

History of Autogenous Bone Grafts

The use of iliac crest autologous bone blocks with osteointegrated implants was initially described by Brånemark et al.[29] and is now an accepted procedure in oral and maxillofacial rehabilitation. Although the iliac crest is often used in oral and maxillofacial reconstruction with dental implants,[30-34] there are many disadvantages related to harvesting bone from the ilium. The surgery is far more aggressive than intraoral techniques and it must be performed in a hospital setting under general anesthesia. This ultimately will increase patient cost, and complications from the surgery, such as neurosensory and gait disturbances are increased.[35] As an alternative to the iliac crest, there are multiple autogenous donor graft sites that originate intraorally; these include the mandibular symphysis, mandibular ramus, and maxillary tuberosity.

In the literature the mandibular symphysis was one of the first intraoral donor sites reported. Early case reports described its use in the repair of intraoral birth defects, such as cleft palates.[36,37] In 1992 Misch et al.[38] expanded the indications for use of the mandibular symphysis and ramus block bone grafts with endosteal dental implants. In the repair of localized alveolar defects of the jaws, bone grafts harvested from the intraoral sites known to offer several advantages.[20,38-41] The main advantage of intraoral versus extraoral donor grafts is their convenient surgical access and lower morbidity. The proximity of donor and recipient sites can reduce operative and anesthesia time, making them ideal for outpatient implant surgery. In addition, patients report minimal donor site discomfort compared with bone harvested from the iliac crest or other extraoral donor sites.[19,20,38-45] Bone harvested from the maxillofacial region appears to have inherent biological advantages in bone graft augmentation. This may be attributed to the embryologic origin of the donor bone.[43,46-51] The majority of bones in the human skeleton are of endochondral origin (from a cartilaginous precursor). With the exception of alveolar bone and the mandibular condyles, the maxilla and body of the mandible develop intramembranously.[52] It has been demonstrated that membranous
• **Fig. 38.1** Autogenous Bone Grafting: (A) Clinical image depicting block grafting to a large defect in the maxillary left central and incisor area. (B) Post-graft healing allows for ideal placement's of dental implants.

• **Fig. 38.2** (A) The symphysis block graft is usually harvested approximately 5 mm below the roots of the anterior teeth and extends to the lingual plate. (B) The symphysis and ramus region are two of the most popular sites that are harvested for intraoral defects.

bone grafts show less resorption in comparison with endochondral bone grafts.[46,47,49,53-56] Although cancellous grafts revascularize more rapidly than cortical grafts,[14] cortical membranous grafts revascularize more rapidly than endochondral bone grafts, with a thicker cancellous component.[48,57] Early revascularization of membranous bone grafts results in an improved maintenance of graft volume.[48,56-58] It is also theorized that bone of ectomesenchymal origin, such as the mandible, has a better potential for incorporation in the maxillofacial region because of a biochemical similarity in the protocollagen of the donor and recipient bone.[59] More recent research suggests that grafted bone independent from its embryogenic origin will mimic the properties of the recipient bone.[60] The inductive capacity of cortical grafts is explained by their higher concentration of bone morphogenetic proteins.[60-62] Bone from the maxillofacial skeleton contains increased concentrations of growth factors, which may lead to a greater capacity for bone repair and graft retention.[63] Another hypothesis is that the improved survival of craniofacial bone grafts is simply caused by their three-dimensional structure.[64,65] Because these grafts have a thicker cortical volume, they resorb at a slower rate.[53,54,57,66] In bone graft reconstruction, an emphasis has been placed on the transplantation of viable osteoprogenitor cells from cancellous marrow grafts, because the majority of osteoblasts are present in cancellous bone.[18] However, because of significant graft resorption associated with cancellous block grafts from endochondral

donor bone, they are not the primary donor bone in reconstruction of mandibular discontinuity defects and ridge augmentation for soft tissue–supported prostheses.[16,18,55-57,67,68] In contrast, corticocancellous block grafts harvested from the ilium have greater bone volume compared with particulate cancellous grafts.[57] When endosteal implants are surgically placed in corticocancellous bone, it has been observed that bone resorption is slower. This may be because of the microarchitecture of the bone graft (i.e., cortical compared with cancellous).

Cortical bone harvested from the mandible exhibits slower graft resorption and excellent graft incorporation into the host bone compared with cancellous bone grafts.[57] This is due to the vast amounts of osteocytes, growth factors, and bone morphogenetic protein contained in cortical bone. This facilitates angiogenesis and osteoblast migration into the graft site.[69-72] It has also been shown that the dense structure of the cortical grafts offers improved implant stability and interfacial stress transmission on implant loading.[73-75] When used in block bone grafting, the results have been consistent, with excellent graft stability.[19-23,25,26,38-45,76-91] Mandibular block bone grafts may be harvested from the residual ridge, symphysis, body, and ascending ramus (Fig. 38.2).

Preoperative Evaluation of Recipient Site

A preoperative, comprehensive evaluation of the host graft site is extremely important. The implant clinician must identify any esthetic concerns, the graft dimensions needed to reconstruct the osseous deficiency or zone of atrophy, the soft and hard tissue topography, and the periodontal and endodontic health of the adjacent teeth.[38,92,93] The host site should ideally be evaluated in width, height, and length. In general the most predictable bone augmentation sites require only the width dimension and extend for one tooth. This provides mesiodistal and apical walls of host bone. A one-tooth span provides ease
● **Fig. 38.3** Clinical evaluation of the underlying bone is often misleading. (A) Clinical evaluation of edentulous site. (B) After mucoperiosteal flap, tissue is reflected to reveal significant bony defect.

of soft tissue manipulation and minimal risk for incision line opening. The least predictable bone graft sites are more than four teeth in length and require more than 5 mm of height and width of bone (Fig. 38.3).

The implant clinician must always take into consideration the final prosthesis in the treatment planning of osseous defects. When an FP-1 prosthesis is the treatment of choice, the adjacent teeth next to the host graft site should ideally have bone on the roots to a level within 2 mm of the cement-enamel junction. When a bone graft is placed adjacent to a tooth root (rather than bone), the graft most often resorbs to the level of the existing bone on the adjacent tooth root. Therefore in a one-intratooth defect, a line drawn from each bone level on the adjacent roots is the maximum bone height that can be predictably expected.

In selection of the donor bone for a graft site the graft recipient site needs to be evaluated in terms of width and height graft requirements. When greater than 4 mm of donor bone graft width is required (C–w bone volume), the mandibular symphysis is the preferable donor site because of the corticocancellous nature of the graft. When donor graft requirements are less than 4 mm in width, the ascending ramus of the mandible should be considered (Division B to B–w bone volume). When considering atrophy in the vertical dimension, the symphysis of the mandible is a good source of bone because of the greater volume of bone that can be acquired.

An accurate radiographic assessment is imperative for complete assessment of the osseous defect. Ideally preoperative imaging studies should include a cone beam computed tomographic (CBCT) scan because they have become the standard of care in preoperative implant surgical planning and in the evaluation of the recipient and donor sites.[94-96] Mounted study casts on a semiadjustable articulator of the patient's jaws allow the implant team to fully evaluate the anatomy of the jaws and teeth that cannot be fully appreciated while examining the oral cavity. In addition to mounted study models, a diagnostic wax-up of the reconstructed jaw and dentition will help to determine graft dimensions such as width, height, and implant positioning in relation to the opposing dentition. From this information, surgical templates may be fabricated with respect to the ideal implant position in relation to the position of the final prosthesis (Fig. 38.4).[38,41,94,95]

Preparation of Recipient Site

The recipient graft site should be clinically evaluated before bone harvesting is initiated. This assessment allows the clinician to obtain accurate graft dimensions that are required to reconstruct osseous defects or zones of atrophy in preparation for future implant placement. Soft tissue incisions to expose the recipient site are made within attached keratinized tissue. In an edentulous ridge the soft tissue incision is made slightly lingual to the gingival crest to reduce the risk for incision lines opening from jaw movement and postsurgical edema. When harvesting a monocortical block of bone, vertical releasing incisions are made anterior and posterior to the crestal incision line to provide good visualization of the surgical site and ease of graft harvest, and to avoid tearing of the soft tissue flap. The soft tissue reflection of the flap distal to the graft site may be a full- or split-thickness reflection to facilitate soft tissue healing and reduce incision line opening (Figs. 38.5 and 38.6).

Selection of Intraoral Donor Site

After the recipient site has been reviewed, the selection of the donor site can be determined. The severity of the defect basically determines if this graft can be taken from the ramus or in major defects, from the mandibular symphysis. In minor defects where cancellous bone is applicable, bone form the maxillary tuberosity can be considered. It is always preferable to use autogenous bone as the graft material in this type of case.

Mandibular Symphysis Donor Site

Anatomy

The mandibular symphysis describes the area in the midline of the mandible where the two lateral halves of the mandible fuse at an early period of life. The median ridge divides and encloses the triangular eminence or mental protuberance. The base of the protuberance is depressed in the center and is raised on either side to form the mental tubercle. The most inferior aspect of the mandibular symphysis is termed the "menton," and this area serves as the origin of the geniohyoid and genioglossus muscles (Fig. 38.7). Because the average interforaminal distance is greater than 4 cm, the symphysis is ideal for recipient sites that require large intraoral grafts. In general the symphysis has proven to be a good graft choice for graft reconstruction cases that require graft sizes of four or more teeth, especially when both vertical and horizontal deficiencies are present.

Radiographic Evaluation

As part of the treatment planning process, CBCT imaging studies are recommended to evaluate the symphysis to determine the anatomic bone morphology, which includes the approximate length of the mandibular teeth, the distance between the mental foramina, and the vertical height of bone between the root apices and the inferior border of the mandible. CBCT imaging allows comprehensive three-dimensional visualization of the graft site, avoidance of unwanted complications, especially violation of the floor of the mouth with its highly vascular structures (e.g., sublingual and submental arteries). CBCT imaging is superior to plain film radiographs (e.g., panoramic) because it can provide the clinician with anatomic information in three dimensions that are not available on two-dimensional films. However, intraoperative periapical radiographs may be used to ascertain the apical location of the incisor teeth to prevent injury to the roots of the anterior teeth.

It is imperative to determine the buccal-lingual dimension of available bone throughout the symphysis area. Great care should be exercised to avoid hourglass mandibles because perforation of the lingual plate may lead to fracture or damage to blood vessels. The width of the mandible in the midline is usually the greatest dimension and decreases toward the mental foramen area. Mandibular symphysis width is several millimeters narrower in the region of the premolar and canines, compared with the midline (Fig. 38.8).

The average dimension of the anterior mandible between the mental foramina is approximately 44 mm, with African American males having the greatest distance, followed by white

males, and African American females.[97] It is recommended that all osteotomy cuts remain a minimum of 5 mm from the anterior aspect of the mental foramen to avoid injury to the mental neurovascular bundle and mental nerve. In a study by Montazem et al.,[98] dentate cadaver mandibular blocks were harvested from the mandibular symphysis to evaluate the maximum bone quantity without causing damage to the mental nerve. When two symmetric blocks were measured from each site, the average was 21 × 10 × 7 mm, the largest was 25 × 13 × 9 mm, and the smallest measured 21 × 6.5 × 6 mm.[98] Therefore the mandibular symphysis is an ideal donor site for harvesting cortico-cancellous blocks (Fig. 38.9).

Anesthesia

The anterior symphyseal region of the mandible is innervated by the mandibular branch of the fifth cranial nerve (V3) and cervical nerves from C-3 and C-4. Bilateral dental or Akinosi (closed-mouth) blocks with lidocaine 2% (1:100,000 epinephrine) and Marcaine 0.5% (1:200,000 epinephrine) can be used to obtain V3 innervation anesthesia. Infiltration anesthesia is then performed anterior and inferior to the mental foramen and in the midline at the base of the mental protuberance.

Incision and Reflection

Surgical access to the symphysis is accomplished using crestal or vestibular incisions. When incisor teeth are present, a vestibular approach is recommended as reflection of the soft tissue around the anterior teeth may result in tissue recession and root exposure soft tissue healing.[99] In addition, a vestibular incision is less traumatic and results in reduced postoperative discomfort. However, the vestibular incision will usually result in more intraoperative bleeding and the highest risk for incision line opening, but the least risk for soft tissue changes around the teeth and root exposure after healing. It also creates much simpler access to the symphysis area and allows for easier suturing of the incision line. Limiting the distal extent of the vestibular incision to the canine tooth area (i.e., mesial of the canine) will reduce the incidence of mental nerve neurosensory impairment.[38,39,44] When there is a high mucogingival junction (MGJ) or high muscle attachments, a sulcular incision may be indicated because a vestibular incision would have a higher incidence of incision line opening. In addition, sulcular incisions are advantageous when less than 4 mm of keratinized gingival height is found around the lower anterior teeth because incision line opening is a greater risk. This is often seen when the mentalis muscle is large and parafunctional forces in this region exist. The sulcular incision carries the least risk for incision line opening after healing but has an increased risk for root exposure. The sulcular approach is also the most time consuming approach from the standpoint of suturing (Fig. 38.10).

Using a scalpel or electrocautery, an incision is made through the mucosa and periosteum down to the symphysis bone between the bilateral canine teeth. Using a periosteal elevator, the soft tissue flap is reflected (full-thickness) off of the anterior mandible. Full-thickness reflection is required so that no soft tissue remains on the donor bone that could interfere with healing (Figs. 38.11 and 38.12).

To avoid ptosis of the chin, it is recommended that soft tissue dissection to the inferior border of the mandible be avoided. This limited reflection prevents complete reflection of the mentalis muscle from its lower attachment to the bone.
• **Fig. 38.8** Cone Beam Computed Tomography Evaluation. (A) It is very important not to solely treatment plan the anterior mandible via the two-dimensional or three-dimensional panoramic image. (B) Three-dimensional image depicting hourglass anatomy. (C) Cross section showing severe undercuts.
• **Fig. 38.9** The average interforaminal distance between the mental foramen is greater than 44 mm, and accurate measurements should be determined before graft harvesting.
• **Fig. 38.10** (A) Sulcular incisions are usually made in the anterior mandible for a symphysis harvest when the keratinized tissue is less than 4 mm in height or when a heavier musculature is observed. (B) The incision extends distal to the canines, and a vertical release incision is made anterior and above the height of the mental foramen. A full-thickness mucoperiosteal flap reflection exposes the symphysis for the harvest. (C) A sulcular incision has less risk for postoperative incision line opening; however, there is a greater risk for root exposure after healing.

• **Fig. 38.11** (A) A vestibular incision is made 5 to 10 mm below the mucogingival junction when 4 to 9 mm of keratinized tissue height is observed on the facial of the mandibular anterior teeth. (B) The incision extends to the distal of the canines, and a vertical release incision is made for approximately 10 mm (above the height of the mental foramen). A full-thickness mucoperiosteal reflection exposes the mandibular symphysis. (C) Vestibular incisions often heal with scar formation.

Donor Site Osteotomy Harvest

After the symphysis is exposed, the osteotomy for the graft harvest is planned. The dimensions of the block bone graft are determined by the size of the host bone defect. The osteotomies may be performed with a surgical fissure bur (557, 702—straight 1:1 handpiece), oscillating saw, or Piezotome unit. In general the Piezosurgery unit allows more efficient and bone-saving osteotomy cuts (Fig. 38.13).

Piezotome surgery (Acteon Corp.) is a technology that uses a modulated ultrasonic frequency to cut or sever mineralized tissue. This ultrasonic surgery technique uses microoscillations (i.e., 60–200 m/sec at 25–29 kHz) to cut hard tissue, without damaging soft tissue. With this type of surgical modality, precision cuts can be prepared and greater bone graft quantities can be harvested on a predictable basis. In addition, visibility is improved because a cavitation effect is created from the irrigation/cooling solution that is used. Numerous studies have shown the ultrasonic bone cutting technique to be more favorable than conventional rotary instruments.[100]

The harvesting of the symphysis block includes four different osteotomy cuts: (1) superior, (2) inferior, (3) right vertical, and (4) left vertical (Figs. 38.14 and 38.15).

Superior Cut. The superior bone cut is usually made first and is dictated by the location of the mandibular incisor and canine teeth. To avoid root injury of the incisor teeth, when harvesting blocks of bone from the symphysis, it is recommended to remain a minimum of 5 mm apical to the apices of the incisor and canine teeth. Usually the canine teeth are much longer than the incisor teeth (i.e., incisors: ~12–14 mm, canines: ~16 mm).[101] The angulation of the superior cut is slightly converging (i.e., with respect to the lingual plate) because this will minimize injury to the tooth roots and allow for easier removal of the bone. The depth of the osteotomy should always be through the labial cortex; however,

● **Fig. 38.12** When there exists an abundant amount of attached keratinized tissue on the facial aspect of the mandibular anterior teeth, an incision in the keratinized tissue is of benefit. The incision is made to the distal of the canines. In this case a midline vertical incision was made, because the symphysis harvest was limited in size.

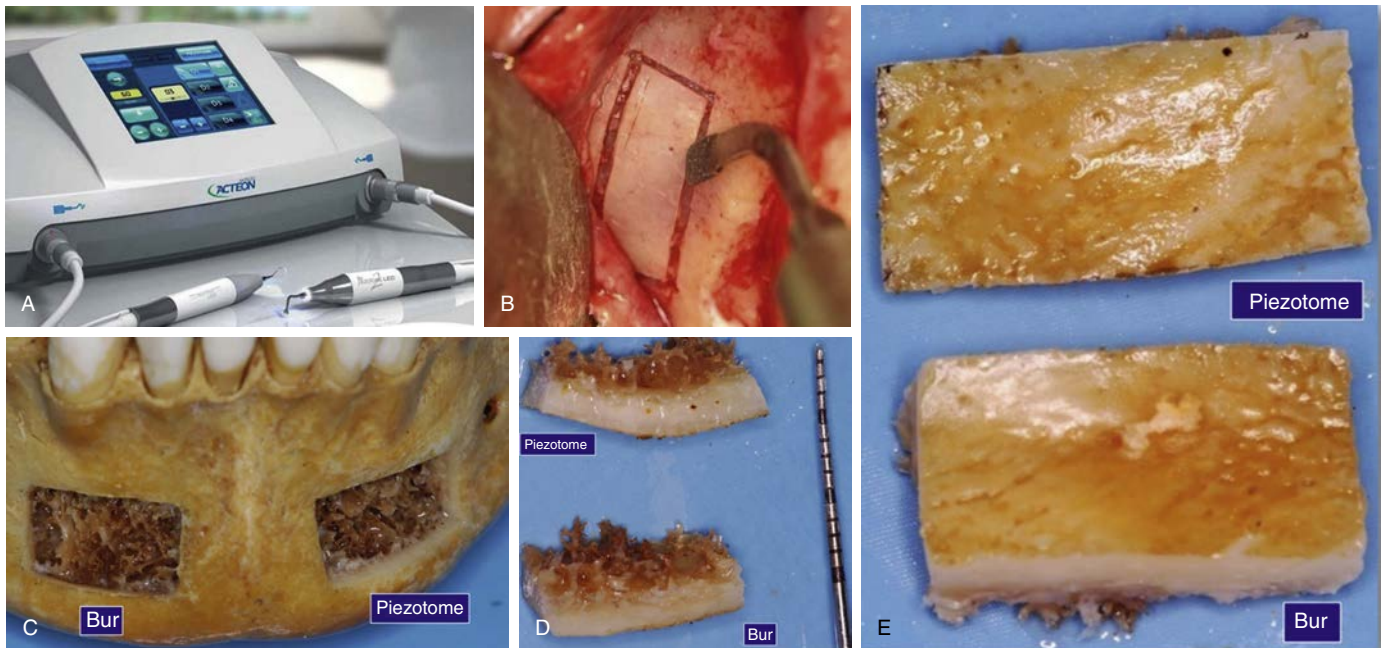
it should never be extended lingually to the lingual cortical plate (Fig. 38.16).

Inferior Cut. The inferior bone cut is often the most difficult to perform because access is always difficult and challenging. Care should be exercised not to compromise the inferior border of the mandible because this may cause iatrogenic fracture of the symphysis area and possibly create a discontinuity defect. The horizontal inferior osteotomy should be at least 5 mm or more superior to the inferior border of the mandible, and the lingual cortical plate should be preserved so that the lingual plate does not fracture off during the harvest.

Vertical Cuts. Bilateral vertical cuts are made to connect the horizontal superior and inferior cuts. The location of these cuts must be at a minimum 5 mm anterior to each mental foramen. The presence of an anterior loop should always be evaluated and when present, proper modification to the location of the cuts should be adjusted. As the horizontal and vertical cuts are connected, care should be taken to make sure all four cuts are completely through the cortical plates and that they each connect with the adjacent cut. Small islands of intact bone can prevent the block from freely being removed from the donor site. (Fig. 38.17).

Block Removal

Block removal from the symphysis is usually completed with a straight/curved bone chisel and mallet or a Potts elevator. The chisel/elevator is usually placed in one of the vertical cut areas, and an elevated force is applied to verify movement of the block. If no movement of the block is present, the osteotomies may be deepened slightly and reverification that all cuts are continuous. The chisel can be used with the mallet; however, the mandible should be stabilized to prevent any damage to the temporomandibular joint. Ideally the patient should maintain his or her teeth in maximum intercuspation.

After block removal, cancellous bone may be available (i.e., determined by CBCT cross-sections) to harvest to supplement


● **Fig. 38.13** Piezotome (Acteon) versus Bur. (A) Piezotome surgical unit. (B) Surgical image showing the superior osteotomy cut with the Piezotome. any voids in the block graft. Bone curettes of varying sizes will allow for the available cancellous bone to be removed from the donor site.[102] Care must be exercised not to perforate the lingual cortical plate. In some cases, because of the size of the block or the acute angle of the symphysis, the block outline may require sectioning into two sections. This will allow for easier block removal because two blocks of bone can be harvested from the symphysis instead of one large block of bone. Another option is to maintain a section of bone in the midline of the symphysis because this will decrease the risk for altering the postoperative appearance of the chin, especially when the patient has a prominent chin point. After the bone block is harvested, the defect can be filled with a particulate graft material (e.g., microporous hydroxyapatite and a collagen membrane) to minimize the possibility of a defect and to help to restore the contour of the mandible (Fig. 38.18; Boxes 38.1 and 38.2).

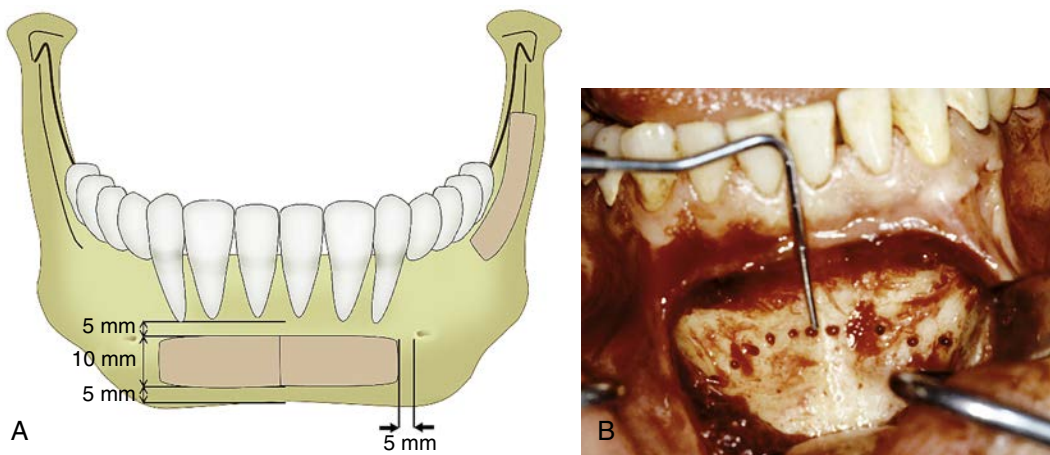
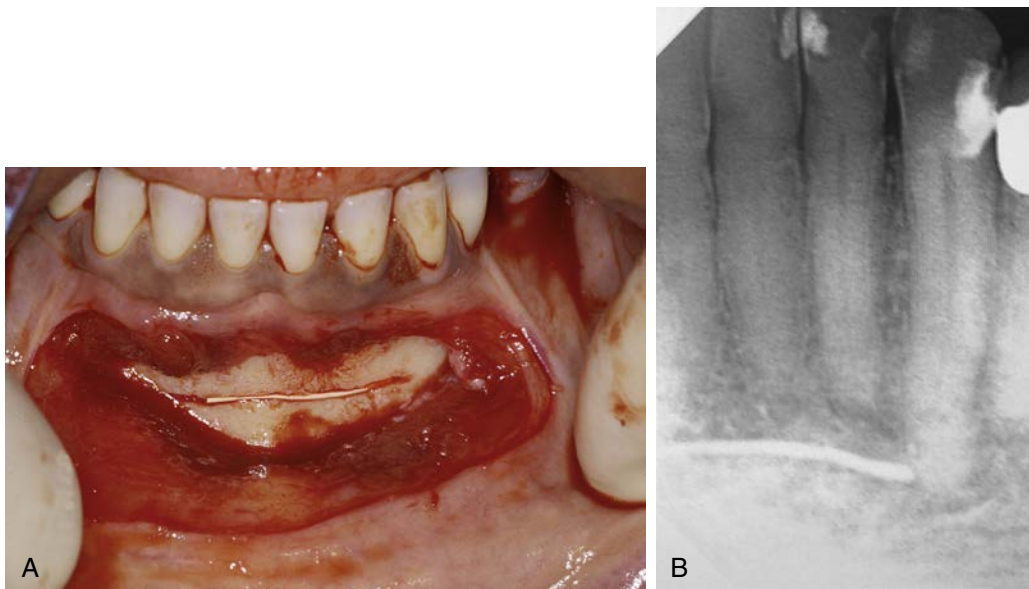
Closure

If a vestibular incision is used, a two-layered soft tissue closure is recommended for suturing. The periosteum is first closed with resorbable suture (e.g., 4–0 or 5–0 Vicryl), as well as the mentalis muscle and vestibular mucosa. This is followed by the outer tissue closure with a high tensile strength suture material (e.g., Vicryl, PTFE). To allow for ease of closure, the patient should bite into the centric occlusion, which also decreases tension on the flap. Postoperative pressure dressings in the form of pressure


● **Fig. 38.14** (A) The guidelines for the symphysis block harvest are usually 5 mm from each mental foramen, 5 mm below the roots of the anterior teeth, and 5 mm from the inferior border of the mandible. (B) The superior osteotomy for the bone block is made 5 mm from the apex of the mandibular anterior teeth. The block margin slopes down in the canine region because of the longer roots.
● **Fig. 38.15** (A) Cone beam computed tomography cross section in midline showing buccal and lingual contours. (B) Osteotomy cuts should not be perpendicular to the outer buccal plate because block removal will be difficult. (C) Osteotomy cuts should converge toward the lingual to allow for easier removal.


• **Fig. 38.16** (A) When in doubt on the location of the superior cut, a radiopaque material may be placed in the osteotomy and evaluated radiographically. (B) The radiograph reveals the initial osteotomy is too close to the canine root and should be 6 mm more apical in this region.

• **Fig. 38.18** In some cases, involving large blocks, the bone should be sectioned in half to allow for easier removal.

• **BOX 38.1**   **Symphysis Bone Graft**

Indications
- Horizontal and vertical ridge augmentation
- Thicker graft required (corticocancellous)
- Maximum: $0.7 \times 1.5 \times 6$ cm

Advantages
- Easy access
- Can obtain large amount of cancellous bone
- Usually a corticocancellous graft

Disadvantages
- Altered sensation of mandibular anterior teeth
- Inferior alveolar nerve damage
- Patient cosmetic concerns
- More challenging closure
- Greater possibility of incision dehiscence

• BOX 38.2 Symphysis Graft Osteotomy Technique

Incision: vestibular—depending on access, slightly apical to mucogingival junction from mesial of cuspid to mesial of cuspid; an alternative incision is a sulcular incision
Superior: 5 mm below apices of anterior teeth
Inferior: 5 mm superior to the inferior border of mandible
Vertical: 5 mm anterior to mental foramen
Bone harvest: chisel and mallet, or Potts elevator

tapes placed over the skin of the chin can reduce the development of hematoma formation, incision line dehiscence, and infection (Figs. 38.19 and 38.20).

Alternative Symphysis Procedures

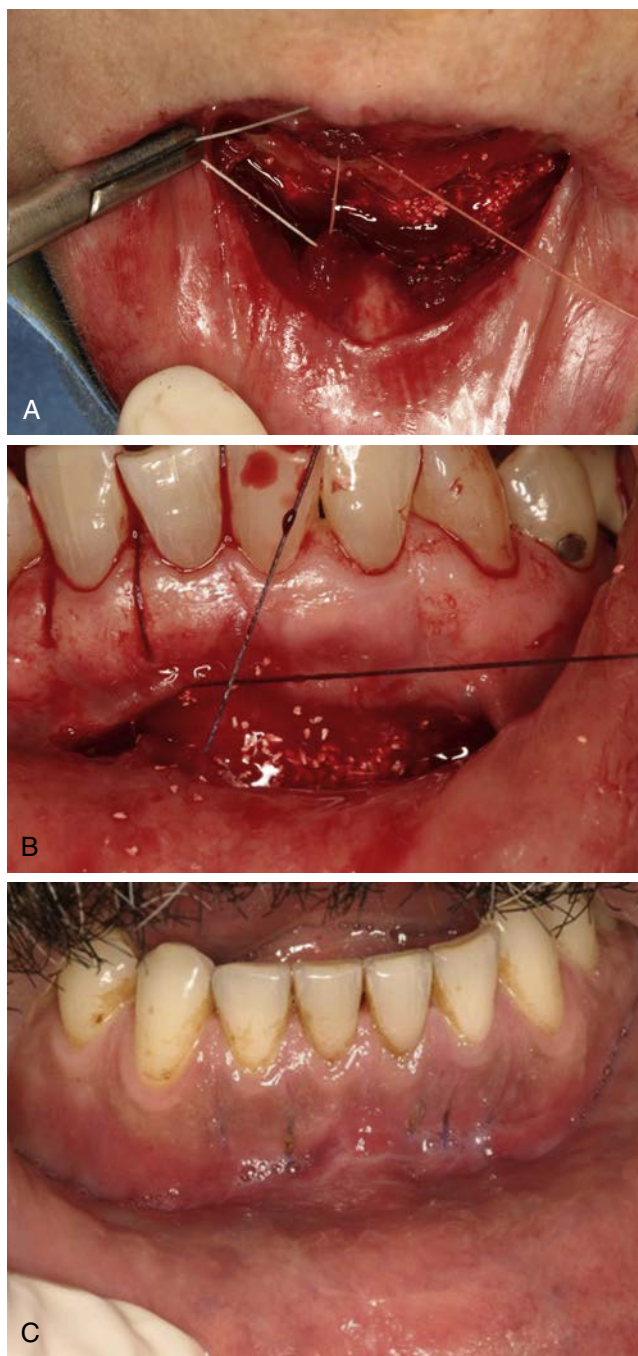
If a large monocortical bone block is not indicated, circular-shaped bone cores ranging from 4 to 10 mm in diameter may be harvested with a trephine bur for use in alveolar augmentation.[103] Trephine burs of varying diameters can remove bone cores of different lengths down to the lingual cortex of the mandible. A Molt curette or other instrument is then used to recover the bone core. It is critical that the bone cores be fixated and immobilized during the healing phase to avoid nonunion of the bone core to the native host mandible. After 4 to 6 months of bone healing, dental implants can usually be surgically placed into the grafted bone. After an additional 3-month healing period, the implants may be prosthetically restored.

Mandibular Ramus Donor Site

A second intraoral autogenous donor graft site that may be used is the mandibular ramus. The mandibular ramus has many advantages as a potential donor site. This area allows sufficient amounts of bone to be harvested for graft reconstruction and provides easy access to the ascending ramus, patient discomfort is less compared with the symphysis graft, and there is reduced risk for neurosensory disturbances from injury to the inferior alveolar neurovascular bundle. The primary disadvantage with the use of ramus grafts is that access may be difficult in some cases and the quantity of bone is limited (i.e., mainly in width).

Anatomy

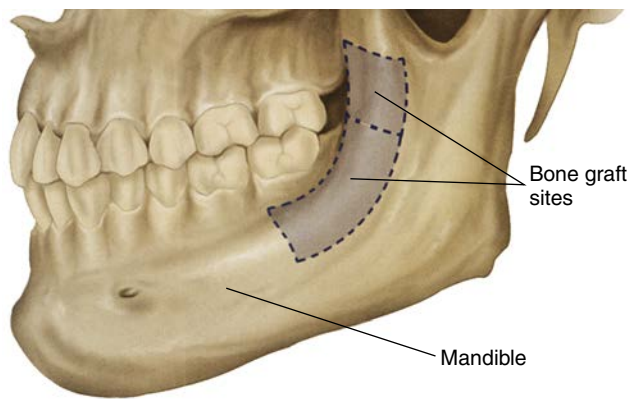
The mandibular ramus is the second largest part of the mandible (i.e., mandibular body is the largest), and it extends cranially from the angle of the mandible and away from the body at approximately 110 degrees. The ramus is quadrilaterally shaped and is made up of two surfaces, four borders, and two processes.

Anatomic Surfaces:
1. Lateral surface: It is relatively flat and is defined by the internal and external oblique ridges, and the Masseter muscle attachment encompasses much of the surface.
2. Medial surface: The medial surface includes the entrance to the mandibular foramen and the inferior alveolar vessels and nerve. The lingula is the surrounding prominent ridge that gives attachment to the sphenomandibular ligament. The mylohyoid groove runs obliquely downward and forward, and is the location for mylohyoid vessels and nerve. The internal pterygoid inserts behind the mylohyoid groove.


• **Fig. 38.19** Vestibular Closure. (A) Use of a "two layer" closure in a chin graft site limits excess tension on the healing wound as the mentalis muscle is flexed. The mentalis can be sutured to its remnants if they are visible or it can be anchored with sutures that pass from the muscle, through the interproximal tissue, around an incisor, and back through the adjacent interproximal papilla to then draw the muscle to its proper level. This is completed on both sides of the symphysis. (B) A second suture line is used to approximate the mucosal layer of the vestibule. Assuring that there is not any tension on the sutured wound. (C) Post operative photo showing a matured vestibular block graft donor site.

Anatomic Borders:
1. Inferior border: The lower border is a thicker part of the mandible, which is continuous with the inferior border of the mandible. The lower border junctions with the posterior

border at the angle of the mandible (gonial angle). The masseter muscle attaches laterally, and the internal pterygoid attaches medially.
2. Anterior border: It is continuous with the oblique line and is thin at the crest.

3. Posterior border: It is thicker and is covered by the parotid gland.
4. Superior border: This is a thin bone that makes up two processes, the coronoid and condylar. The mandibular notch is a deep concavity that separates the two processes.
• **Fig. 38.20** (A) The inferior osteotomy is planned and is usually 5 mm above the inferior border of the mandible when a harvest is primarily for an increased width of bone. (B) A fissure bur may be used to connect the dots of the planned bone block. (C) The block is usually designed to be harvested in two pieces. (D) After an osteotome is used to ensure the osteotomy is made up to the lingual plate, the chisel is angled to shear the one block from this landmark. (E) The second bone block is easier to harvest because the bone chisel can slide along the lingual plate with direct access. (F) The bone blocks are positioned in key implant regions, with at least two fixation screws.
● **Fig. 38.20, cont'd** (G) The bone blocks are recontoured in situ to smooth the edges, which might perforate the soft tissue flaps. (H) Additional particulate bone may be harvested from the symphysis with a rongeur or trephine bur. (I) The particulate bone is placed between the blocks and in any voids between the host bone and blocks. (J) A reentry into the host site after 5 months. (K) The block grafts usually exhibit less resorption compared with the particulate graft (in the center). (L) A drill guide is used to position the implants into the graft site. (M) Four implants are positioned in the grafted site. (N) After 4 months of healing the abutments are inserted and the prosthesis may be fabricated.


● **Fig. 38.21** The ramus and posterior body may be used as a bone block harvest site.

Anatomic Processes:

1. Coronoid process: This is a thin, triangular eminence that allows attachment to the masseter and temporalis muscle.
2. Condylar process: The condylar process ends with the condyle, which is the articular surface for articulation with the *articular disk* of the *temporomandibular joint* (Fig. 38.21).

Radiographic Evaluation

Clinical evaluation of the ascending ramus is ideally evaluated via CBCT technology. With the various CBCT views available to evaluate the ramus area, the amount of bone available for grafting, along with the location of the inferior alveolar nerve canal, may be determined. The anteroposterior length of the external oblique and prosthetic "buccal shelf" ranges from no presence from the third to first molar, to a dominant projection lateral to the body of the mandible. An index finger may be placed on the external oblique ridge of the ascending ramus and lateral aspect of the mandible. Often a ledge is palpable lateral to the second molar region and begins to disappear at the medial of the first molar. The wider the "ledge" lateral to the molars or body of an edentulous mandible, the wider the ramus block bone that can be harvested. Some mandibles have almost no "buccal shelf," whereas others are very significant (i.e., ~7 mm). Most often the buccal shelf disappears at the mid-first molar region to the anterior and to the third molar region on the posterior aspect. The ramus length is variable, with the most common vertical limit below the coronoid process, because this structure is so very thin that a block section would remove the entire segment. When determining the location of the graft site, there exist three anatomic variables that require clinical and radiographic evaluation.

1. The first variable includes the buccal-lingual mandibular canal position. Although the buccolingual position of the mandibular canal is variable within the body of the mandible, the distance from the canal to the medial aspect of the buccal cortical plate (medullary bone thickness) has been found to be greatest at the distal half of the first molar.[104] Therefore when larger grafts are planned, the anterior vertical bone cut may be made in this area. The vertical bone cuts are progressively deepened until bleeding from the underlying cancellous bone is visible, which will allow for a safe distance from the mandibular canal.[105,106]
2. The second variable is the distance from the external oblique and ramus to the inferior alveolar canal. The mean anteroposterior

width of the ramus is 30.5 mm, with the mandibular foramen located about two-thirds of the distance from the anterior border.[105] A CBCT scan is ideally used to assess and evaluate these bony dimensions. The lingula on the medial ramus is the entry point of the inferior alveolar nerve, and its location is variable. It may be at the occlusal plane (most often), above the occlusal plane, or below the occlusal plane. The lingula may be in the anterior third of the ramus, the middle third, or the distal third of the width of the ramus. As a general rule the higher and farther forward the lingula, the closer the inferior alveolar canal is adjacent to the external oblique ridge. As a result the ramus block harvest must be located lateral to the inferior alveolar canal and is usually less than 3 mm thick. The lower and more distal the lingual is in the ramus on the CBCT, the lower the inferior alveolar canal is to the external oblique. As a result the ramus block may be as much as 6 mm in width.

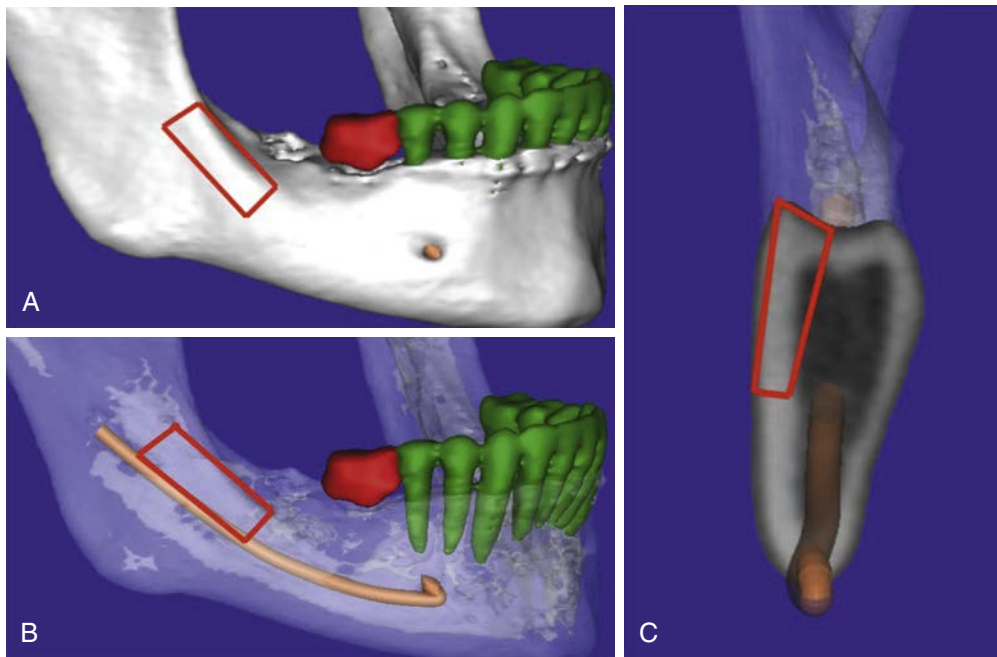
3. The third variable is the width of the posterior ramus. In general, females have a thinner ramus body and width compared with males. Because of these anatomic variables, a rectangular block of cortical bone 3 to 6 mm in thickness may be harvested from the ramus.[106] The length of the rectangular graft may range from 1 to 3.5 cm, and the height approximately 1 cm.[20,44,107] Such anatomic dimensions may correct width deficiencies involving a span of three to four teeth.

Although use of the coronoid process as an autologous graft has been reported,[108-110] the amount of bone for ridge augmentation is negligible considering the potential postoperative disability of a coronoidectomy.[111,112] However, such anatomic size and shape may be used as a veneer graft to gain additional ridge width. The anatomic proximity makes the ramus well suited for augmentation to the posterior mandible inadequate in width (Fig. 38.22).[42]

Incision and Reflection

The surgical procedure to harvest a block bone graft from the ramus is similar to performing a sagittal split ramus osteotomy.[106,113-119] With a scalpel, an incision is initiated on the midcrest of the ridge in the posterior edentulous patient, beginning at the base of the retromolar pad. Caution should always be exercised to avoid the retromolar pad in the incision design because this may result in neurosensory impairment issues (i.e., paresthesia, anesthesia, or dysphasia caused by injury of the lingual nerve, the chorda tympani nerve, and a sympathetic branch of the parasympathetic nerve to the submandibular gland with the lingual nerve).

Initiating the incision on the ascending ramus no higher than the level of the occlusal plane minimizes the possibility of severing the buccal artery or exposing the buccal fat pad.[106] The incision continues anteriorly into the buccal sulcus of the molar teeth or posterior ridge area. When making the incision in this area, often a minor bleeding issue may result. At the height of the occlusal plane, the buccal artery crosses the ascending ramus of the mandible. The maxillary artery traverses anteriorly and laterally to the retromolar pad. If severed, profuse bleeding is observed, which is usually treated with hemostats to clamp the vessel on the lingual aspect of the incision.

A mucoperiosteal flap is reflected from the mandibular body, exposing the lateral aspect of the ramus. The attachment of the buccinator muscle is observed first. A periosteal elevator is placed medial to this structure and directly on the bone of the external oblique and along the ramus. The flap is elevated


● **Fig. 38.22** Ramus Bone Graft. (A) Outline of four major osteotomy cuts. (B) Translucent outline of donor site and its relationship to the inferior alveolar canal. (C) Cross-sectional view of graft site.

superiorly along the external oblique ridge. After the facial flap is reflected the incision in the midramus may be extended to the attachment of the temporalis muscle. The periosteal elevator slides along the ramus 15 mm deep, down the ramus toward the first premolar region, and identifies the mental foramen. The host site is reflected and prepared for receiving the block graft (Fig. 38.23).

Donor Site Osteotomy Harvest

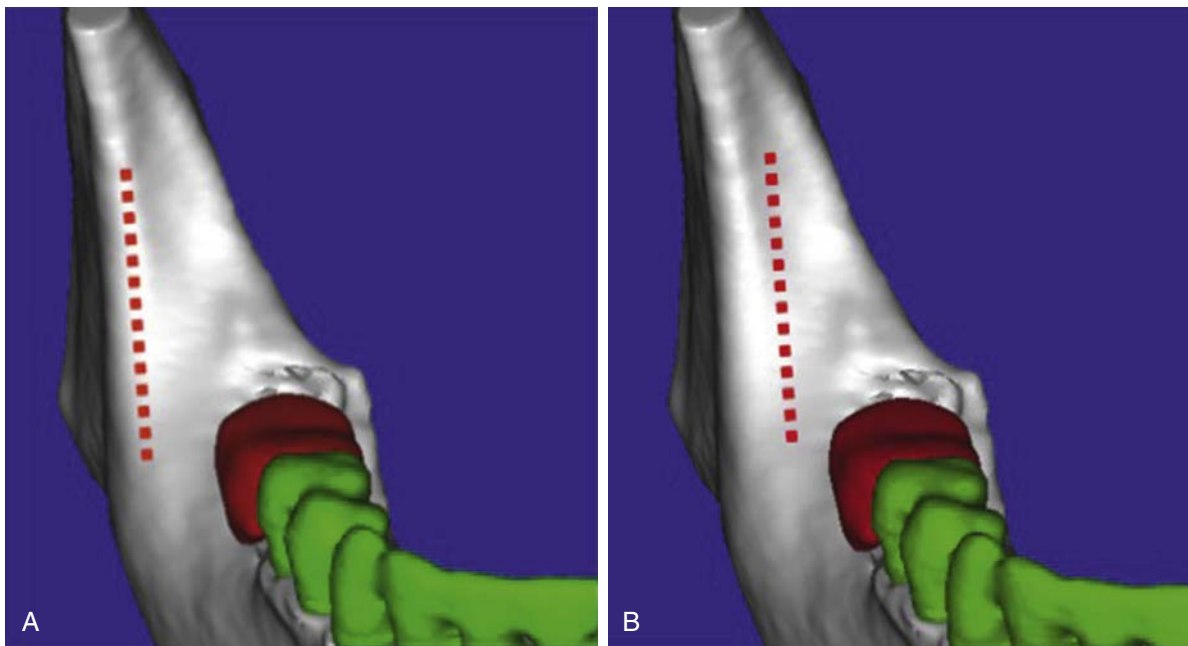
Superior Cut. The width of the ramus and the external oblique lateral of the mandibular body are identified. A straight handpiece and a small, round drill (No. 2–4) or a thin flat insert on a Piezosurgery unit punctures the bone 3 to 6 mm (i.e., dependent on the bony thickness as per the CBCT survey) from the lateral aspect of the ramus and external oblique for the superior cut. The holes should allow at least 3 mm of bone on the lingual of the ramus and 2 mm of bone adjacent to the molar teeth (when present). The length of the graft is determined, as dictated by the host site (previously reflected and prepared). The penetrating holes, just through the cortical bone, are then connected with a fissure bur (No. 557 surgical length) or Piezosurgery unit. The depth of the osteotomy should ideally be greater than 2 mm above the mandibular canal (Fig. 38.24).

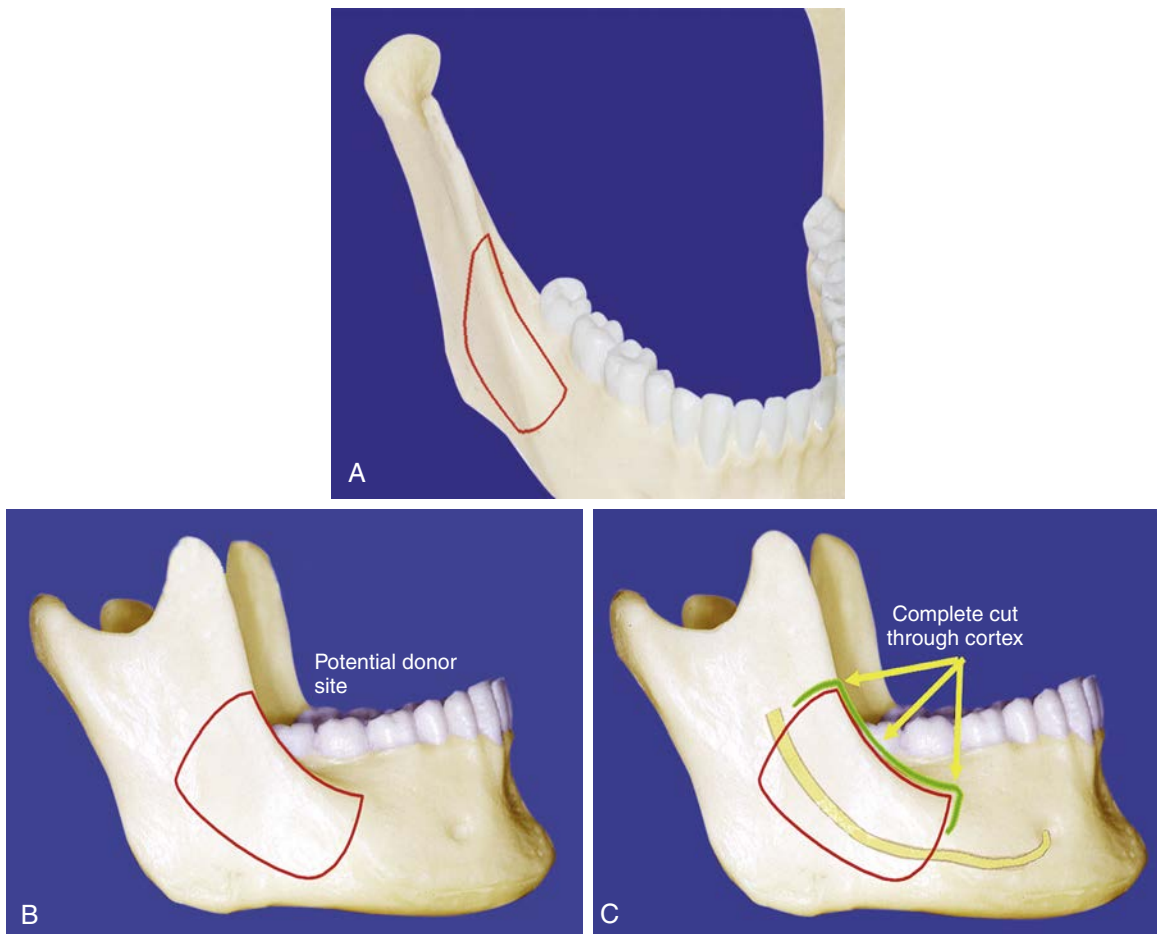
Vertical Cuts. The anterior vertical cut may then be made and begins in relation to the existence and width of the buccal shelf (extend oblique ridge) of the mandible. Usually the mid-first molar is in the position of the anterior vertical cut. After the vertical osteotomy approximates the position of the inferior alveolar nerve, the osteotomy is limited to the thickness of the buccal cortical plate, usually 2 to 3 mm in thickness. The osteotomy is progressively deepened until bleeding bone from the osteotomy is observed. The anterior osteotomy is usually 10 to 12 mm in length. The posterior osteotomy is then completed, which is usually above and lateral to the inferior alveolar nerve (in front of the lingula on the lingual of the ramus). The posterior osteotomy may be full thickness through the cortical plate to the horizontal osteotomy. Because the mandibular canal in this region is usually inferior or posterior, the osteotomy is made through the entire depth of the cortex (Figs. 38.25 and 38.26).

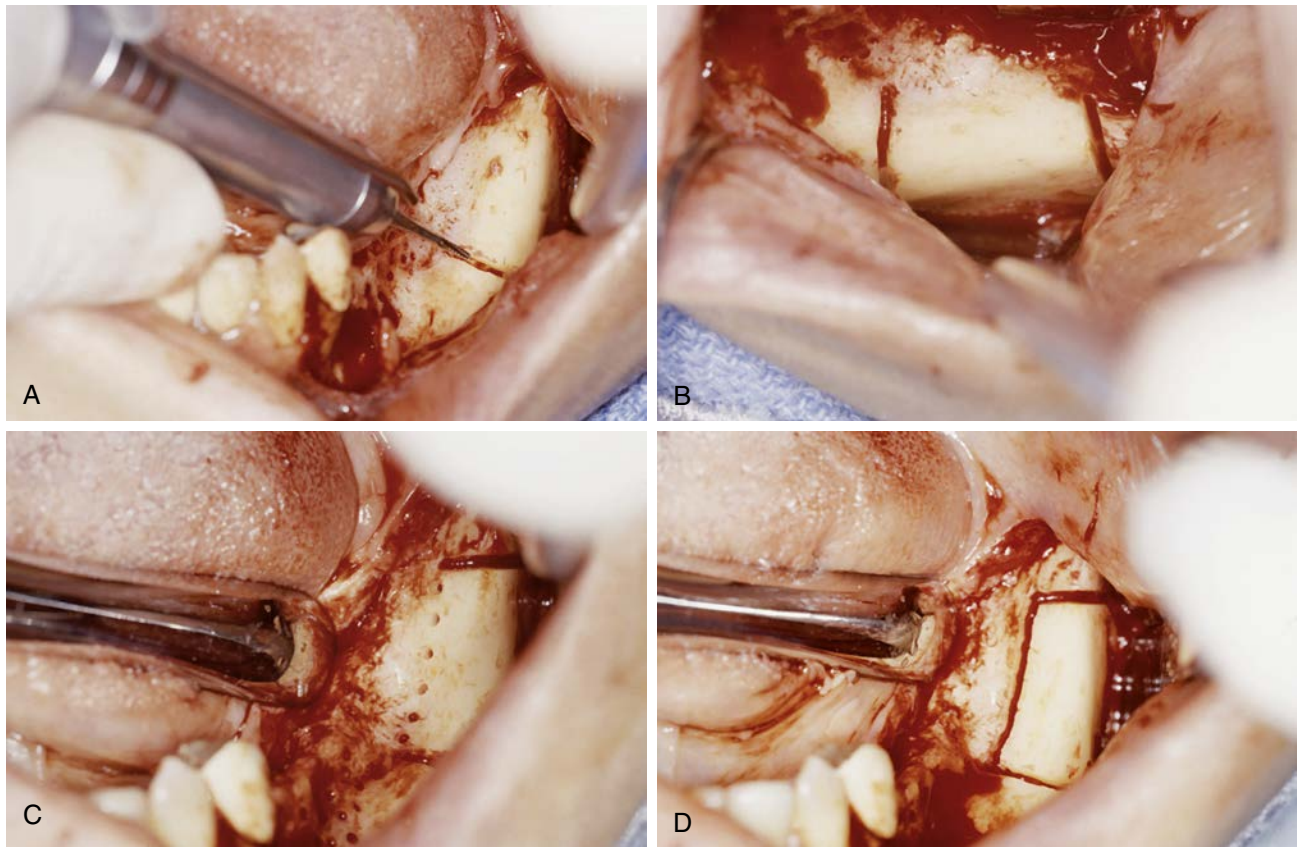
Inferior Cuts. The inferior osteotomy will connect the posterior, and anterior vertical cuts may be performed with an oscillating saw, large, round bur (No. 8) in a straight handpiece, or a right angled insert with a Piezosurgery unit. This cut is usually the most difficult because access and visibility are limited. With the inferior cut a shallower cut is made into the cortex to create a line of fracture. This inferior cut with a drill should not be made completely through the cortex, because it may be located in close proximity to the mandibular canal. The piezosurgery tip allows preparation of a more defined cut and it does not have the danger of damaging the nerve if it happens to come in contact with any vital structure.

Ideally the superior, anterior, and posterior vertical, and inferior cuts should be made continuous so ease of harvesting is accomplished. A thin chisel is gently tapped along the entire length of the external oblique osteotomy, taking care to parallel the lateral surface of the ramus to avoid inadvertent injury to the inferior alveolar nerve. A wider wedge chisel or Potts elevator may then be inserted and levered to pry the bone block segment free and complete the greenstick fracture of the graft from the ramus. After removal of the block, any sharp edges around the ramus are smoothed with a bur or file. A hemostatic dressing (collagen, gelatin sponge, oxidized cellulose) may be placed into the donor area, and closure of the site may be completed after fixation of the graft to the receptor site (Boxes 38.3 and 38.4).

Alternative Ramus Procedures

An alternative option from obtaining a ramus block is the harvesting of bone cores with trephine burs. The cores can be fixated if large enough or ground down to small particulate pieces that can
● **Fig. 38.23** (A) The ramus site is the first option for a block graft, especially when the posterior mandible requires augmentation. The incision in an edentulous posterior mandible starts at the retromolar pad and continues to the first premolar. (B) After the full-thickness posterior mucoperiosteal flap is reflected, the incision is extended lateral to the retromolar pad and directly over the bone of the ascending ramus to the height of the occlusal plane. (C) The facial flap is reflected, and the attachment of the buccinator muscle is identified. (D) A periosteal elevator slides along the lateral aspect of the ramus, under the masseter muscle, for a depth of 15 mm. The incision is extended along the ascending ramus when the donor block requires additional length. (E) Ramus retractors are shaped to retract the masseter and curved to allow the preparation of the block at the inferior margin. (F) The facial flap is advanced. Metzenbaum tissue scissors are used in a blunt dissection to create the submucosal space. (G) The host site is prepared for the graft with small holes through the cortical plate, 3 to 5 mm apart. (H) The host site is prepared with a round bur to create a wall of bone at the apical region of the graft.


• **Fig. 38.24** Superior Osteotomy Cuts. (A) Too close to the lateral border, which would result in too thin of a graft. (B) Ideal position that allows for a wider graft.


• **Fig. 38.25** (A) The ramus donor site is lateral to the molars (buccal shelf region) and extends up the ascending ramus. (B) The ramus donor site uses the outer cortical bone of the ramus and posterior body of the mandible. (C) The top portion of the ramus donor block (green line) is usually above and lateral to the position of the inferior alveolar nerve complex.


• **Fig. 38.26** (A) The anterior vertical cut is made with a straight handpiece and a fissure bur or oscillating saw. The position is often at the mid-first molar region. The cuts 5 mm above the inferior alveolar nerve (IAN) complex are full thickness. (B) The posterior vertical cut is often above and lateral to the lingual and IAN, and therefore may be made full thickness along the lateral ramus to the superior block margin. The width of the bone block on the superior margin is designed with a small, round bur and ranges from 3 to 6 mm in width from the lateral border. (C) The superior osteotomy is made through the cortical bone and may extend to within 5 mm of the posterior IAN. The horizontal dimension of the ramus block determines the width of the donor site and is related to the amount of bone needed and the anatomy of the donor site. (D) A fissure bur connects the pilot holes of the horizontal cut. This cut is through the cortical plate and may proceed to 2 mm above the IAN.

• BOX **38.3**   Ramus Graft

Indications
- Horizontal and vertical ridge augmentation
- Three to four tooth edentulous sites (maximum size = 3 × 5 cm)

Advantages
- Allows for largest average surface area of intraoral grafts
- No esthetic concerns
- Decreased pain and discomfort
- Decreased chance of incision dehiscence

Disadvantages
- Inferior alveolar and lingual nerve injury
- Access may be difficult
- Trismus

---

be used with a membrane graft. Small bone chisels can be used to remove the bone cores. It is hard to collect large volumes of bone using a trephine and harvesting of blocks is probably better suited for most involved graft sites (Figs. 38.27 and 38.28).

• BOX **38.4**   Ramus Graft Osteotomy Technique

Incision:
   Initiates at the level of the occlusal plane in the ascending ramus
      (medial to the external oblique ridge)
   Extends anteriorly, avoiding the retromolar pad
Superior: on external oblique ridge along anterior border of the mandibular
   ramus (approximately one-third width of the mandible)
Anterior: distal half of the first molar
Posterior: superior aspect of the external oblique ridge (level of occlusal
   plane)
Inferior: ~10 mm in height

Tuberosity Donor Site

The maxillary tuberosity has been shown to be a viable intraoral donor source for autogenous bone and a source of osteoprogenitor cells.[77,120] The tuberosity bone, although variable in the amount of bone that can be harvested, has been shown to be advantageous in maxillary sinus grafting and ridge augmentation procedures. The cancellous nature of this bone allows it to be shaped and molded.

Tuberosity grafts may be used as a particulate graft, or in some cases a block graft (Fig. 38.29).

Anatomy

The maxillary tuberosity is defined as the bone at the lower part of the infratemporal surface of the maxilla. It is a rounded eminence that is especially prominent after growth of the third molars. The quality of bone in the maxillary tuberosity is usually considered a very poor type of bone, usually a D4 bone with fine trabeculae and minimal to no cortical bone. The thicker soft tissue in the tuberosity area can be extremely misleading, which frequently results in a misrepresentation of the amount of available bone. The anatomic limitations of this area include the maxillary sinus, pterygoid plates, adjacent teeth when present, and the greater palatine canal.
• **Fig. 38.27** The ramus is exposed and bone cores are obtained via trephine burs.
• **Fig. 38.29** Cone beam computed tomographic panoramic view depicting a significant amount of tuberosity bone available for grafting.

In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

Radiographic Analysis

Ideally a CBCT examination will reveal the quantity of bone present below the sinus. It is imperative to make an accurate assessment of the bone quantity because exposing the maxillary sinus after graft removal may lead to increased complications (Fig. 38.30).

Incision and Reflection

The incision to expose the maxillary tuberosity consists of a crestal incision and a posterior vertical release (45 degrees) from the posterior part of the tuberosity. The incision should never extend onto the lingual contour of the posterior tuberosity or into the hamular notch area because this area is associated with an increased possibility of bleeding episodes. It is important to incise to the bone because in some cases the tissue can be very thick.

Donor Site Osteotomy Harvest

After reflection of a mucoperiosteal flap the bone may be harvested from the tuberosity with a double-action rongeur or chisel. Removing the graft with a chisel will allow the harvesting of a larger piece of bone; however, a greater chance of perforation into the maxillary sinus is possible (Fig. 38.31; Boxes 38.5 and 38.6).
• **Fig. 38.30** Cone Beam Computed Tomographic Cross Section. (A) Significant amount of bone for grafting. (B) Minimal amount of bone present that would likely result in a communication with the maxillary sinus.
• **Fig. 38.31** Tuberosity Harvest. (A) Bone removed from tuberosity with a double-action rongeur. (B) Tuberosity bone cores after harvest.

Indications
- Socket grafting, sinus augmentation, small bony defects
- Approximately 1–3 mL

Advantages
- Allows for largest average surface area of intraoral grafts
- No esthetic concerns
- Decreased pain and discomfort
- Decreased chance of incision dehiscence

Disadvantages
- Entry into maxillary sinus
- Oral-antral fistula
- Bleeding (posterior-superior alveolar, pterygoid plexus)
- Hematoma

Incision: midcrestal incision from first molar to posterior extent of ridge (short of hamular notch)
Bone harvest: double-action rongeur, chisel and mallet, Piezosurgery

Block Graft Preparation

Fixation of the Block Graft

Once the monocortical block of bone has been harvested, the recipient site is ready to receive the graft. It cannot be overstressed that for successful graft survival at the recipient site, complete soft tissue coverage must be present that is passive and tension free. If the soft tissue flap has extensive tension, the incision lines will open, resulting in graft exposure and eventual infection of the graft that will result in loss of the bone graft.

Soft Tissue Preparation

The soft tissue dissection beyond the graft recipient site will help to avoid soft tissue incision line opening and graft exposure. With most bone grafts, soft tissue closure may be challenging. Misch developed a submucosal space technique that helps in overcoming this potential complication. The technique reflects a full-thickness flap over the graft site and at least 5 mm above the height of the MGJ. The periosteum and soft tissues 5 mm above the MGJ remain on the bone and are not reflected. The facial flap is then lifted 3 to 5 mm above the depth of the MGJ and using a scalpel, an incision through the periosteum 1 to 2 mm deep and parallel to the crestal incision extends over and beyond the vertical releasing incision. After the incision is made through the periosteum, pointed tissue scissors (i.e., Metzenbaum scissors) may be introduced into the periosteal incision for 10 to 15 mm or more, parallel to the surface mucosa, with the blades of the scissors closed, so the facial flap thickness is 3 to 5 mm. The tissue scissors are then opened with blunt dissection, which allows the muscles to be separated from the flap and creates a submucosal space. With the periosteum, tissues and muscles attached to the bone are on one side, and a 3- to 5-mm-thick facial flap is on the other side.

With this technique the facial flap may now advance the depth of the submucosal space 10 mm or more. This technique greatly increases the ability to advance the soft tissue flap over a large block graft. The advantage of the submucosal space technique is that a split-thickness flap is created and maintains the muscles on the periosteum, which is attached to the bone above the contours of the host site. Because the muscle attachments are the primary source of vascularization to the periosteum and host bone, vascularity remains undisturbed. Muscle healing is a primary cause of flap retraction and incision line opening. Because the muscles are no longer attached to the facial flap and the flap may be advanced more than 10 mm, there is no tension on the incision line, which reduces the risk for incision line opening. One complication of the soft tissue procedures to improve graft coverage is the loss of vestibular depth. The reduced vestibular depth is rarely an esthetic concern, and when the restoration is implant retained, the prosthesis does not rely on a valve seal for primary retention (as in a complete denture). Advancement of the facial flap for graft coverage may also result in a reduction in keratinized mucosa over the facial aspect of the gingival crest. In some cases, soft tissue or acellular dermis grafts may be necessary, or the attached mucosa may be repositioned facially at the stage II implant uncovery surgery (Fig. 38.32).

Preparation of the Recipient Site

The next step in graft reconstruction is preparation of the lateral and crestal surfaces of the host and grafted bone using a small-diameter drill equal to or smaller than the drill size of bone screws used to fixate the donor bone (i.e., ~1.4-mm diameter). The rationale for this procedure is to facilitate angiogenesis at the graft site.

Drill perforations are 3 to 5 mm apart in the entire area of the graft and host site. Perforations are created under copious amounts of saline and penetrate both the facial and lingual plates of bone in the region of the graft, especially when augmentation is desired on both sides of the residual ridge. This procedure increases the availability of osteogenic cells, accelerates revascularization, increases the regional acceleratory phenomenon, and improves graft union[96,121,122] (Figs. 38.33 and 38.34).

Fixation of the Block Graft

After the block of bone has been harvested, it can be stored in sterile saline solution or immediately fixated to the host bone. Minimal time should elapse before placement of the block on the host bone.[123,124] When placing the bone graft onto the host bone, the cancellous portion of the graft should be in contact with the host bone.[81,125,126] Because the graft should passively rest on the host bone, the host bone and harvested block of bone need to be contoured before graft fixation.[127,128] The edges of the block of bone can be smoothed with a small, round bur to create a fine, smooth surface that blends in with the surface of the host bone when fixated with rigid fixation screws. Particulate cancellous bone can then be used to fill in any voids between the host bone and harvested block of bone.

When preparing the harvested block of bone, the drill holes on the surface of the block graft are slightly larger than the diameter of the rigid fixation screws. This permits the rigid fixation screws to compress the block graft directly up against the host bone while the screw is threaded completely through both cortices (Fig. 38.35). The outer thread of the fixation screw is usually 1.4 to 2.0 mm in diameter, with a V-shaped thread design. This allows the screw to thread into the host bone during fixation of the graft to the host bone, and removal of the screw at the time of implant placement 4 to 6 months after the graft has remodeled to
• **Fig. 38.32** Tissue Preparation for Tension-Free Closure.(A and B) Periosteal release technique with a scalpel. (C and D) Blunt dissection that stretches the periosteum with the use of blunted scissors.

the jaw. The head of the fixation screw should be 2.2 mm or more in diameter and flat so that it can compress the donor block graft against the host bone.

A lag fixation screw design should not be used. A lag screw design has smooth metal for 5 to 10 mm below the screw head, and the apical half of the screw has threads. When the screw is placed through the block of bone and host bone, the technique is effective in rigidly fixating the block of bone to the host bone (Fig. 38.36). However, when the screw is removed before implant placement, it has been observed that newly regenerated osseous tissue has formed around the smooth portion of the lag screw. This may present problems in removal of the lag screw. While removing the lag screw, the surgeon may have to tap the graft while the screw is being removed. This could lead to loosening of the bone graft from the host bone.

There are many rigid fixation screw kits that can be used in bone graft procedures available to the clinician. It is recommended that the clinician use self-tapping threaded screws with the tip of the screw pointed and not blunt, to allow penetration into bone. Screw kits come in a variety of screw diameter sizes. The two most commonly used to rigidly fixate the block of bone to the host bone are 2.0- and 1.6-mm-diameter screws. After the bone graft has been harvested the next step is stabilizing the graft passively to the host bone and rigidly fixating the graft with the use of rigid fixation screws, plates, or stainless-steel wires. If using rigid fixation screws, two or more screws are required to fixate the graft to the host bone that avoids movement. When using only a single rigid fixation screw, the block of bone may not be rigidly fixated to the host bone. If the graft is not rigidly

fixated to the host bone, the graft may rotate and move, which will lead to a fibrous union.

The screws are ideally secured to both the facial and the lingual cortical plates. Therefore with bicortical stabilization the osteotomy screw holes must penetrate both facial and lingual cortices. In most cases the host site will need to be altered to allow a passive fit for the graft. This is easily accomplished with a small, round carbide (No. 6, No. 8). In addition, the block may be altered with a pear-shaped carbide because the block should have no sharp edges. After recontouring, the donor block of bone is slightly recessed into the host bone 1 to 2 mm, and there should exist no micromovement. With completion of the bone graft procedure, the soft tissues are reapproximated and closed with sutures. After a graft healing period of 4 to 6 months, dental implants may be placed into the graft site.

Membranes and Block Grafts

The use of membranes over autogenous block grafts is controversial in the literature. Chaushu et al.[129] reported soft tissue complications, including membrane exposure (42 [30.7%] of 137), incision line opening (41 [30%] of 137), and perforation of the mucosa over the grafted bone (19 [14%] of 137). Infection of the grafted site occurred in 18 (13%) of 137 bone grafts. Gielkens et al.[130] conducted a metaanalysis to investigate the effects of barrier membranes on onlay autogenous grafts. They concluded after a vast systemic review that the available studies are too weak to support the use of membranes. Therefore at this time there are insufficient data to support the use or nonuse of barrier membranes with respect to bone resorption.
● **Fig. 38.33** Soft Tissue Removal. (A) Soft tissue removed with a sharp periosteal elevator. (B) Course carbide in a 1:1 straight handpiece.

Maturation and Integration of Block Grafts

In most cases, a radiographic survey (e.g. periapical, bite-wings, CBCT) is obtained to evaluate healing approximately 3–4 months after the initial surgery. In conjunction with the radiographic assessment, a clinical examination should be used to evaluate the changes in the grafted ridge contour as well as the tiassue health. Once healing is complete, tissue reflection access is obtained to remove any bone screws and allow for ideal implant placement. The autogenous graft should be evaluated for any mobility, which usually is indicative of bone graft failure. (Fig. 38.37, Fig. 38.38).

Comparison of Intraoral Bone-Grafting Donor Sites

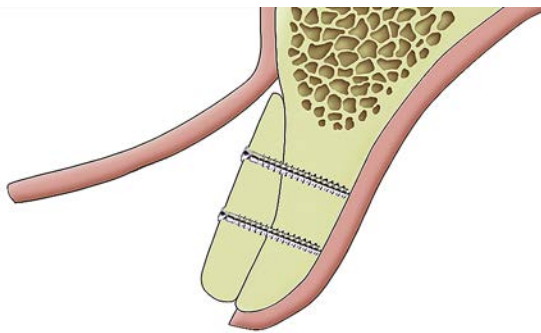
A comparison of intraoral donor sites for onlay grafting before implant placement was reported by Misch.[44] The volume of the symphyseal donor grafts was almost twice as great as ramus sites (1.74
● **Fig. 38.34** Recipient Site Decortication. (A) Decortication holes that initiate angiogenesis to heal the graft. (B) Must have bleeding through the decortication holes for the growth factor release.

● **Fig. 38.35** A lag screw approach is used to fixate the block. The screw slides through the block, and the screw head is larger than the hole in the block.

versus 0.9 cm³). The ramus was primarily a cortical graft, whereas the symphysis block was cortical/trabecular. However, the ramus and symphysis donor sites have similar success rates. Aloy-Prósper et al.[131] in a systemic review showed the success and survival rates of implants placed into vertical and horizontal defect ridges treated with intraoral block grafts. They concluded that placing implants into block grafts versus native bone had similar success rates.

Clavero et al.[120] compared the morbidity and amount of complications with ramus and symphysis donor sites. They determined although the symphysis has better accessibility, the ramus donor site allows for a greater amount of harvested bone, with higher bone density and more cortical content, together with fewer complications.

Gultekin et al.[132] studied the difference in bone loss between autogenous block grafts and guided bone regeneration (GBR). They concluded that both the block graft group and GBR group provided sufficient volume of bone for implant placement. However, the GBR group did show greater bone resorption in comparison with the autografts.

Yates et al.[133] compared the harvested volume of the ramus versus the symphysis and also the associated morbidity. They determined that the ramus can provide the greatest volume of bone and significantly less morbidity in comparison with symphysis bone grafting (Table 38.1).


● **Fig. 38.36** The screw should fixate each bone block. The screws should engage the lingual plate of the host site.

Postoperative Care and Instructions

An increase in incision line opening has been associated with postoperative smoking and diabetes in patients with autografts.[26,134] Patients should stop smoking at least 3 days before surgery and at a minimum until the incision line has healed. It is imperative that the graft be immobilized during healing and there exists no external pressure on the graft. Removable soft tissue–borne prostheses should not be worn or should be adjusted to prevent graft loading. The flange area of a removable prosthesis should be completely removed, and the edentulous ridge area is generously relieved, which requires the patient to use denture adhesive for prosthesis retention. However, the denture adhesive should not be placed over the incision line. The patient is instructed to use the provisional removable prosthesis for cosmetic appearance only rather than function.

Careful postoperative follow-up is necessary to inspect the bone graft region and eliminate pressure areas from an overlying prosthesis. More favorable provisional solutions are tooth-borne fixed or removable partial dentures, resin-bonded bridges, or denture teeth bonded to the adjacent dentition.[135] The use of transitional implants to support a fixed-interim prosthesis during the healing phase may be considered for patients less tolerant of removable provisional restorations.[136,137]

Complications

Symphysis Graft Complications

Incision Line Opening

Many factors predispose the symphysis donor site to incision line opening. If a vestibular incision is used, a two-layered suture technique is recommended. A suture with a high tensile strength should be used (e.g., Vicryl, PTFE) to maintain the integrity of the incision line. The patient should be instructed not to pull on the lower lip to evaluate the surgical site because this will increase the chances of incision dehiscence. Misch[138] determined that

TABLE 38.1	Comparison of Intraoral Donor Sites			
Criteria	**Symphysis**	**Ramus**	**Tuberosity**
Surgical access	Good	Fair to good	Fair to good
Patient cosmetic concern	High	Low	Low
Graft shape	Thick	Thin veneer	Thin to thick
Graft morphology	Cortico-cancellous	Cortical	Cancellous
Graft size (cm)	5–15	5–10	~5

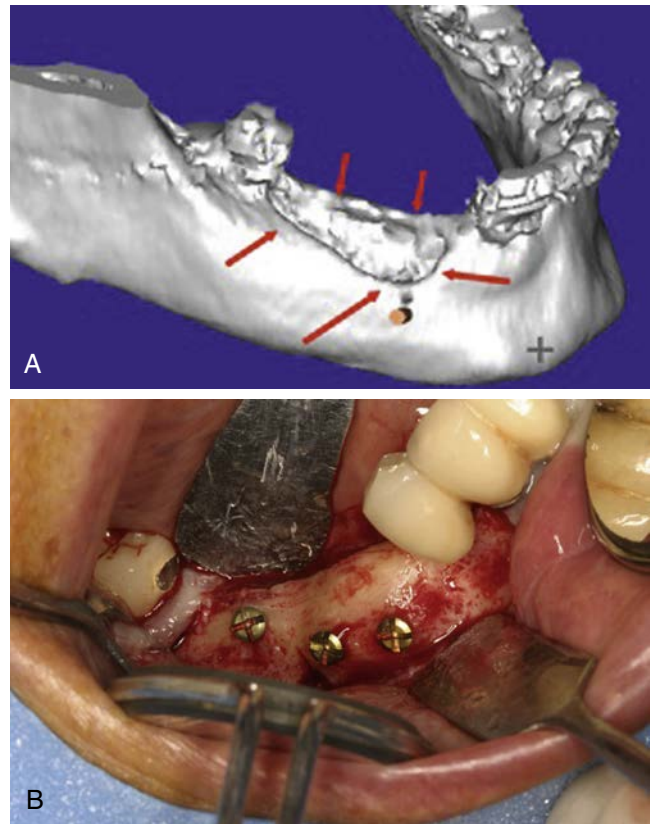
Neurosensory: tissue	Uncommon (temporary)	Uncommon	Uncommon
Incision dehiscence	Occasional (vestibular)	Uncommon	Uncommon

● **Fig. 38.37** (A). Two blocks of cortical bone have been fixated on the lateral aspect of the posterior mandibular ridge with fixation screws. Medullary particulate has been used to fill the voids around the block grafts. (B). The mineralized block grafts after five months of healing. Note the smooth surface of the final graft and the nature of the intertwined recipient site and the grafted blocks.

dehiscence of the donor site occurred in 10.7% of anterior mandibles because of function of the mentalis muscle, and no incision line opening was found in the posterior mandible or ramus donor sites.

Neurosensory Impairment

Neurosensory deficits of the third branch of the trigeminal nerve are rare in association with symphysis grafts. However, it is a common sequela to have neurosensory changes in the mandibular anterior teeth. Because the second terminal branch of the inferior alveolar nerve (incisive branch) terminates in the anterior mandibular area, it is not uncommon to sever this section of the nerve during osteotomy preparation. However, because the incisive nerve is only a sensory nerve to the incisor teeth, this usually results in only a "dullness" in sensation. Hoppenreijs et al.[139,140] showed a negative pulpal response in 16% of patients after a symphysis graft, with total resolution in 6 to 12 months.

Usually a neurosensory impairment of the mandibular anterior teeth does not result in a painful sensation, but it is disruptive, causing patients to generally describe the incisors as having a "woody feeling." This series of complications can usually be avoided by refraining from aggressive harvesting of medullary bone surrounding the donor site.


● **Fig. 38.38** (A). This 3 D image shows the severe bony defect resulting from removal of a blade implant. This vertical defect extends to the level of the mandibular canal. (B). Five month postop matured block graft site that was supplemented with particulate around the remaining defects. Note the density of the final bony structure.

Studies have shown the incidence of neuropraxia after the harvesting of block grafts from the ramus versus the symphysis. After 18 months, more than 50% of the patients with harvest sites in the symphysis still had altered sensation. None of the patients in the ramus donor group reported any symptoms at 18 months.[141]

The superior portion of the harvest site should be prepared at least 5 mm below the level of the incisor root tips to prevent a neurosensory impairment. Care must be taken to avoid the longer roots of the cuspids as each end of the harvest pattern is prepared. Aggressive harvesting of the medullary portion of the symphysis should be minimized in the superior aspects if possible to limit damage to neural pathways through the region. Most importantly, complete patient education must be conducted "before" the surgery informing the patient about potential sensory changes that could occur. The patient should be aware that he or she could feel a dullness or "woody" feeling of the mandibular anterior teeth after surgery. This can be temporary or a permanent condition, but it has never been described as a particularly annoying feeling. Rarely is there an indication for endodontic therapy, as the vitality of the teeth returns to normal.

Bleeding Episodes

When a cortical graft and the surrounding medullary bone are harvested in the symphyseal region, the underlying neurovascular components are often compromised. These disruptions to the nerves and blood vessels may be accompanied by possible significant bleeding immediately after the graft harvest.

● **Fig. 38.39** (A) Cross-sectional image depicts fractured symphyseal plate from poor patient selection of a symphysis graft. (B) Axial view. (*From Cordaro L, Rossini C, Mijiritsky E. Fracture and displacement of lingual cortical plate of mandibular symphysis following bone harvesting: case report.* Implant Dent. *2004;13:202-206.*)

The incisive nerve is the second terminal branch of the inferior alveolar nerve that provides innervation to the mandibular teeth. The incisive nerve path between the mental foramina has been known to be a safe zone for bone harvesting because of the lack of vital structures that can be affected by grafts taken from this region. A thorough understanding of the neurologic and vascular anatomy in this region is critical for the prevention of complications during and after surgery in the symphyseal region. Aggressive graft harvesting in this area may give rise to a lingual plate perforation, which leads to possible significant bleeding issues and airway management complications.

The sublingual arteries may also cause significant bleeding if the lingual plate is perforated. The incisive neurovascular bundle is found to join other vascular structures in the midsymphyseal region. The genioglossus muscle attaches to the genial tubercle in the midline, and the sublingual artery courses through the lingual foramen at the genial tubercle. The lingual artery is approximately 1 to 2 mm in diameter, and cross-sectional views clearly show its anastomosis with the incisive canal at this point.

The preparation of a grafting osteotomy in the midline can potentially resect these blood vessels if they fall in the path of the vertical preparation. If this occurs, the sectioned extension of the lingual artery can prolapse back into the floor of the mouth. The severed vessel may release arterial blood flow in the sublingual space, potentially raising the tongue to a point that compromises the airway. Immediate emergency intervention to maintain the airway is critical, and in some cases this requires use of a tracheostomy until the blood flow has been controlled (Fig. 38.39).

Ptosis

One of the main patient concerns when confronted with the prospect of symphysis grafting is a change in facial or soft tissue appearance. The idea of having a permanent bony chin defect or ptosis contributes to a patient's apprehension regarding this procedure.

The main concern of patients after a symphysis graft is a postoperative change in the soft tissue contour of the chin. In the literature there exists no evidence of a statistically significant incidence of dehiscence or chin ptosis after a symphysis graft. To minimize the possibility of ptosis, avoid degloving the mentalis muscle by maintaining the facial and inferior aspects of the mandible and the lingual aspect of the inferior border of the mandible during flap refection. In addition, to prevent lower lip height reduction and vermilion zone inversion, the integrity of the periosteum to the inferior reflection should not be deeper than one-third of the total distance from the vermilion border to the MGJ. An extraoral bandage or pressure dressing may be used postoperatively for support and to help with compression of the wound.

Ramus Graft Complications

Neurosensory Deficit

Patients have also shown less concern with bone removal from the ramus area, and augmentation of this donor site is unnecessary. Although vestibular incision dehiscence has occurred with symphysis grafts, it is usually not a common occurrence in the ramus donor site. Patients are less able to discern neurosensory disturbances in the posterior buccal soft tissues compared with the lower lip and chin. Although the incision along the external oblique ridge may injure the long buccal nerve, reports of postoperative neurosensory deficit in the buccal mucosa are less frequent and will most likely go unnoticed by the patient.[142,143] In contrast with the teeth superior to the symphysis donor site, patients have reported minimal altered sensation in their molar teeth.[44,144]

Damage to the inferior alveolar neurovascular bundle could also occur during harvesting of the graft in the ramus area of the mandible. When using bone chisels or elevators, the instruments must parallel the lateral surface of the ramus to avoid a nerve impairment. If the inferior ramus cut is below the level of the inferior alveolar canal, graft separation should not be completed until it can be verified that the neurovascular bundle is not trapped within the graft. Although nerve injury to the inferior alveolar nerve is low, patients should be aware of this risk during the consultation before surgery.

On occasion the inferior alveolar nerve is identified and directly observed when the block graft is removed from the ramus. When this occurs, dexamethasone (Decadron) 4 mg (1 cc) may be placed
● **Fig. 38.40** (A) On occasion the inferior alveolar nerve complex can be identified after the block is removed. (B) When this occurs, dexamethasone (Decadron) 4 mg (1 cc) may be used directly on the nerve to reduce inflammation.
● **Fig. 38.41** Large donor graft site leading to exposure of the inferior alveolar nerve (arrow) with associated neurosensory impairment. *(From Caldwell CS. Bone grafting complications. directly on the nerve for 30 seconds to reduce inflammation and edema. A second dose of 4 mg (1 cc) then is applied for an additional 30 seconds. A collagen sponge may be placed over the site, but hydroxyapatite or graft material is not indicated (Figs. 38.40 and 38.41).

Bone Graft Complications

Incision Line Opening in Bone-Grafting Sites

Maintenance of complete soft tissue coverage over healing bone-grafting sites is one of the most important principles that must be observed for predictable grafting success.

Anytime that the healing graft site is exposed to the oral flora during the healing process, there will be some type of compromised change in the final graft site volume and in its overall integrity. Incision line opening with compromised graft results can often be a major limiting factor in successful implant placement.

Incision line opening can compromise even the most carefully planned regeneration site, and most of these graft sites will require additional grafting at a later time if an actual complication develops. An open incision line introduces numerous potential complications into the healing process. First, the introduction of microorganisms into a graft site through an open incision leads to an infection in the healing graft site. Exposure of the block graft and accompanied graft particles accompanied by the presence of purulence is an indication of impending failure of the graft. The infection reduces the pH in the graft site, causing a breakdown of the graft and eventually compromising the resulting ridge volume. Second, an open incision line may allow exposure and breakdown of any barrier membranes, contributing to fibrous tissue ingrowth into the graft site. Lastly, there exists a potential for particulate graft materials that have been packed around the circumference of the block to escape the graft site, resulting in an inadequate bone volume in the final proposed implant site.[145]

Tension-free tissue coverage is the most critical variable in preventing incision line opening. A clinician's experience in manipulation of soft tissue affects this aspect of bone regeneration more than any other part of bone regeneration surgery. As the clinician gains more experience in delicate tissue management and begins to understand the maintenance of a tension-free flap closure, problems with graft and membrane exposure will become an uncommon occurrence.

The inner surface of a reflected flap is lined with the periosteum: a thin, dense layer of tissue that cannot be stretched. It is impossible to stretch the soft tissue flap over a graft site without first severing this layer of tissue. This "tissue release" is accomplished by preparing a clear and continuous releasing incision through the periosteum, exposing the underlying elastic layers of tissue that can then be released for expansion of the flap over the enlarged graft site. As this incision perforates the periosteal layer, the two edges clearly separate, allowing the elastic tissue below the periosteum to stretch. A sharp pair of Metzenbaum scissors is then placed into the space below the periosteum, and as the scissor tips are opened, the tissue easily releases and the edges separate farther. This is repeated until the complete flap is stretched over the graft site and 5 mm beyond the opposite flap margin.

In the event of an incision line opening, the patient should be placed on a frequent monitoring protocol to observe the status
• **Fig. 38.42** (A) Incision line opening or block dehiscence is a complication of block bone grafts. (B) The soft tissue should not be resutured over the graft that dehisces during the first few months. Instead, the block is recontoured so the bone above the tissue margins is removed. The area is left to heal by secondary intention.

of the graft material and any grafting hardware present. The oral microflora must be managed with the use of daily chlorhexidine rinses. The clinician must not attempt to suture the site again because healing margins along incision lines feature tissue that cannot, at that time, support the pressure of another suture under tension.

If graft dehiscence occurs, the wound should be allowed to heal by secondary intention. Resuturing an incision line opening is rarely successful and will usually result in a larger dehiscence. The block graft may be recontoured with a diamond bur to reduce the bulk of exposed bone. The bone above the margins of the surrounding tissue is ground off, which also removes the biofilm. This procedure is repeated every 2 to 4 weeks until the site is closed (Figs. 38.42 and 38.43).

Mobility of the Block

Mobility of an autogenous graft during the healing process will almost always result in a graft failure. Mobility of the block prevents proper integration of the newly forming bone, and eventually it will lead to soft tissue invasion between the block and the recipient site. Rigid fixation of the block graft to the recipient bone site is critical for success in the regenerative process. Although regeneration with block grafting is related to the concept of "barrier by bulk," micromovement will often contribute to a weak bond between the cortical graft and the recipient site. This will potentially cause the block to separate from the ridge as pressure is placed on the interface between the native bone and the integrated block as a result of the implant being inserted into the osteotomy. The most common cause for graft mobility is insufficient fixation or pressure from a prosthesis postoperatively.

Initial fixation of a block graft must be attained when the block is originally placed in the recipient site. Any movement of the block during the healing process will disrupt the formation of a stable clot around the migrating cells, and a loose block will not integrate into the host bone. Ideally two fixation screws should be used in every block graft, eliminating any micromovement of the block during the healing process.

The recipient site should be prepared for close approximation of the surface of the block graft to the recipient site. The block should be inlaid into the recipient site, and particles of medullary bone or allograft should be packed around the circumference,
• **Fig. 38.43** Consequences of Resuturing an Incision Line Opening. (A) Incision line opening 2 weeks after surgery and treated with resuturing. (B) Six weeks postresuturing showing significant incision line opening.

filling any discrepancies. The temporary prosthesis should be adjusted to prevent any contact with the graft site, and the buccal flange should be removed on any removable appliance to limit micromovement.

Fixation screws should be engaged into the underlying bone enough to provide rigid support of the graft. A longer shaft on

the supporting screw may be necessary to obtain ridge fixation in soft bone. The screws should have a self-threading tip, and the preparation hole should be prepared deep enough to prevent the shaft of the screw from bottoming out in dense cortical bone. Excess insertion pressure on a screw passing into very dense bone without adequate depth preparation can contribute to the head of the screw snapping off during its insertion. Most updated fixation screws have a pointed self-threading screw tip that helps with screw insertion.

If micromovement of the block graft occurs during surgery, the block should be removed and the screws should be replaced with longer or wider fixation screws. If the movement occurs during the healing phase, the block should be monitored carefully; however, most likely it will need to be removed (Fig. 38.44).

Soft Tissue Irritation From an Overextended Fixation Screw

Bone fixation screws are routinely placed in the bony ridge for various reasons during implant-related surgery. It is not uncommon to discover the end of a screw extending beyond the lingual or palatal cortical plate. When this occurs, there is a potential for the overextended screw to cause discomfort. Overextended screws can be a source of irritation to the thin soft tissue on the lingual aspect of the mandible. The movement of the thin mucosa and tongue against the sharp point of the screw can cause quite a bit of discomfort. This is not usually an issue in the maxilla, where the thicker nature of the palatal tissue acts as a protective buffer.

To prevent this complication, screw placement should be followed by both a visual inspection of the opposing surface of cortical bone and a digital review of any potential problems areas that will need correction. The only way to treat an overextended screw involves reflection of a flap to provide access for removal of the overextension or removal of the complete screw. Screw removal is not usually a reasonable solution because that would require reflection of the tissue overlying the maturing graft site and disruption of the graft as the screw is removed (Fig. 38.45).

Implant Placement

Because mandibular donor grafts exhibit minimal resorption, predictable gains in bone volume allow implant placement in most planned sites. A staged treatment plan with implant placement after graft healing is the preferred method of reconstruction. Reports on simultaneous implant insertion during bone graft placement have revealed complications, such as block graft fracture, wound dehiscence with exposure of implants and graft, and a higher implant failure rate compared with a staged approach.[38-40,46,55,146] In addition, diminished bone contact has been found around titanium implants placed simultaneously with autologous grafts.[12,30,85,147] A staged surgery permits implant placement for ideal prosthetic alignment without the concern of graft fixation or remodeling. Staging the implant placement also provides an improved vascularity of the transplanted bone as the exposed surface area is increased and unimpeded by an inert biomaterial.[53,148] It also allows for any unanticipated increase in graft resorption and should provide a more stable foundation. The implant-bone interface should be improved, because the implant surface is in close contact with the already incorporated bone graft. Autologous bone grafts offer an improved quality
• **Fig. 38.44** Prevention of Graft Mobility. (A) Two screws need to be placed to prevent micromovement during healing. (B) The donor site needs to be prepared to minimize "rocking" of the graft when fixated. (C) Block graft securely fits into host site. (*From Caldwell CS. Bone grafting complications. of bone at earlier healing times compared with allogeneic bone grafts or guided bone regeneration techniques.[38,58,87,149-151] The density of healed block mandibular bone grafts has been found to be D1 to D2 regardless of the original quality of the recipient site.[38,44,58] An appropriate drilling sequence for dense bone and
• **Fig. 38.45** Screw Overextension. (A) When screw extends through the lingual plate (arrow), this will often result in pain and discomfort for the patient. (B) Preoperative evaluation for fixation screw. (C) Ideally the fixation screw should exhibit bicortical stabilization, and the length measurements may be determined via cone beam computed tomographic measurements. (D) The protruding tip of this fixation screw has been visualized. (*From Caldwell CS. Bone grafting complications. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

tapping may be necessary for atraumatic implant placement. The implant surgery activates bone formation and induces interfacial remodeling with bone maintenance, even in unloaded conditions.[152,153] After integration a progressive bone loading of the implants is recommended.[154] Additional graft resorption after implant insertion has not been noted radiographically on loaded cases.[155-158]

Summary

Autologous bone grafts are the only type of graft material that heals via osteogenesis, osteoinduction, and osteoconduction. Bone harvested from the maxillofacial region offers several advantages in the reconstruction of the residual ridge for implant placement. Intraoral donor sites require only one operational field, which decreases

the surgical and anesthetic time. Larger block bone grafts may be harvested from the mandibular symphysis, body, or ramus area. Particulate autograft may be harvested from the maxillary tuberosity, extraosseous tori, ridge osteoplasty, extraction sites, implant osteotomy, and bone collection devices. These grafts require a short healing period and exhibit minimal resorption, while maintaining their dense quality. The morbidity of graft harvest is low, and complications usually result in only temporary debilitation. The use of these techniques allows the placement of implants in ideal positions for optimal esthetics and functional support.

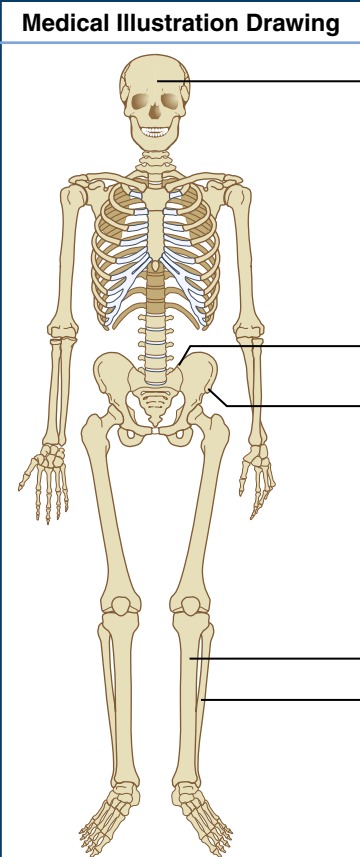
Extraoral Bone Grafting for Implant Reconstruction

DAVID J. DATTILO

Introduction

The pool of patients that are eligible for dental implant reconstruction has expanded widely since Brånemark's research first hit the world of dentistry in the early 1980's. Extensive research in bone biology, coupled with newer and proven bone grafting techniques, leaves almost no patient outside the boundaries of eligible recipients. This includes patients with large bony defects resulting from trauma, resection from pathologic lesions, and congenital deformities, which would be classified as division E in the Misch-Judy classification of available bone and prosthetic options.[1,2] Procedures designed to provide large quantities of bone harvested from outside of the facial region that were previously used to only restore continuity and primitive function now are expected to reproduce vertical and horizontal dimensions for ideal placement of implant fixtures for the support of multiple prosthetic designs.

These new demands on the implant surgeon make the evaluation of the recipient defect, both dimensions and biologic environment, as well as the appropriateness of the potential donor site bone quality, of paramount importance. For instance, loss of bone from treatment of neoplastic or other pathologic processes represents far greater reconstructive challenges than loss of bone from trauma or infection. Other factors important to deciding the type and quantity of bone graft required to be harvested for larger defects is the presence of systemic diseases and the possible exposure to therapeutic doses of ionizing radiation. Success rates of bone grafts in irradiated jaws have been found to be lower by significant amounts, as well as complication rates of 81.3%.[3] The rich cellular components that make autogenous grafts the "gold standard" of implant-supported bone grafts, along with techniques such as hyperbaric oxygen treatment, platelet-rich plasma, and the use of engineered growth factors such as bone morphogenetic protein (BMP), all act to combat and hopefully overcome any hostile environment to provide a healthy osseous base for the placement of dental implants.


The four major anatomic areas for harvesting of free autogenous bone that will be discussed in this chapter include the cranium, the anterior and posterior iliac crest, and the tibial plateau. The necessity required for the proverbial Mother of these inventive techniques was primarily provided by the multiple facial injuries sustained by American and German soldiers during World War I and II. Surgeons from both countries, when faced with such large deformities caused by the latest in wartime ballistics, searched the body for the largest reservoirs of bone that could be used to fill these functional and cosmetic defects. Surgical researchers Wolff, Moss, Tessier, Boyne, and Marx then took these procedures and investigated the details of bone graft healing and the interaction between the bone and the recipient soft tissue bed.[7,8] These initial autogenous bone grafts, however, were characterized by rapid and advanced bone resorption, which sometimes reached 30% to 90% in the best of conditions.[9,10] With the advent of endosteal implants used in conjunction with autogenous grafts, research began reporting the maintenance of the grafted bone and the prevention of this rapid bone resorption.[11,12] Surgeons placing extraoral autogenous bone grafts, when used in conjunction with endosteal implants, can now expect to maintain better than 90% of the initial grafted segment.

Autogenous free bone grafts harvested from these four donor sites and their subsequent recipient sites have other unique biologic qualities that contribute to their appropriate use for dental implant support. Calvarium and mandibular bone are of intramembranous origin formed through the progressive differentiation from primordial mesenchymal cells to stem cells to osteocytes, while the maxilla, anterior and posterior iliac crest and the tibia are formed through endochondral ossification through the transformation and replacement of already formed cartilage.

Early studies comparing these two types of grafts on animal models revealed superiority of intramembranous bone grafts taken from the skull to endochondral bone grafts taken from the ilium or the rib.[4,5] At one year, the intramembranous grafts appeared to maintain the original grafted volume, whereas the endochondral grafts were decreased in volume by 75%. These findings appeared to be counterintuitive because the higher cancellous bone content of the endochondral grafts would seem to welcome a much faster revascularization than the more cortical intramembranous bone. Follow up studies actually showed a more rapid revascularization of these membranous grafts with complete ingrowth of vessels from the host bone and periosteum at 14 days whereas the endochondral bone still showed significant areas of necrotic bone and areas of resorption.[6]

Ironically, it appears the mechanism of revascularization of both the intramembranous and endochondral grafts proceeds along the same pathway borrowing similarities from both mechanisms with the grafted bone acting as the matrix (osteoconduction) that

Medical Illustration Drawing	Source	Cortical	Cancellous
	Cranium	Large area on bilateral parietal regions	Minimal
	Posterior iliac crest	5x5 cm Cortico-cancellous blocks	100−125cc's Morcilized bone
	Anterior iliac crest	3x5 cm Cortico-cancellous blocks	50cc's Morcilized bone
	Tibia	None	24−40cc's Cancellous bone
	Fibula	Maximum of 26cm in length and 3cm in width of vascularized bicortical bone	

• **Fig. 39.1** Extraoral autogenous donor sites with the resultant quantity of cortical and cancellous bone.

is subsequently replaced by osteoid generated by viable osteogenic cells (osteogenesis) with regulation from grafted growth factors (osteoinduction).

Each of the four major donor sites for free autogenous grafts are unique in their ability to provide one or both of the essential structural elements of bone, which include the strong and rigid cortical or the softer but more cellular and regenerative cancellous. These two bone types also differ in the process in which they regenerate new bone. The calvarial graft is predominantly cortical bone and used in areas in which maintenance of a particular dimension is essential for a longer term, bone grafts from the iliac crest provide both cortical and cancellous bone in different quantities, and the tibial plateau is useful for obtaining quantities of cancellous bone only (Fig. 39.1).

All of these grafts can be augmented with a number of different supplemental materials, regenerated blood products, and exogenous growth factors, which may assist in turning these grafted sites into the ideal bone quality to support future implant placement.

Finally, in spite of all of the positive science and technology supporting the potential regenerative capacity of free autogenous grafts, there will always be instances in which the size of the defect, or the lack of sufficient soft tissue cover and blood supply, or both, prevent the use of this technique. For the sake of completeness, the end of this chapter will discuss the use of the vascularized composite bone grafts. Originally used to augment the largest of facial defects with less than optimum cosmetic and functional results, this procedure also has progressed and improved along with the rise in dental implant technology to refine the technique

and provide more than an acceptable osseous base for an implant-supported prosthesis.

Extraoral Donor Bone Graft Sites

Calvarial Graft

The prospect of having bone harvested from the skull (calvarial), which is an area so close to one of the most vital structures of the human body, makes most patients cringe at the possibilities of such a dangerous procedure. The reality is quite the opposite. Of all of the extraoral bone grafting procedures discussed in this chapter, the split-thickness calvarial graft offers a very convenient option of unlimited bone with the least amount of postoperative morbidity. Access incisions are hidden inside the hairline and postoperative pain is minimal. For implant-guided reconstruction, the donor site lies close to the recipient site, therefore the procedure is not prolonged significantly more than an intraoral grafting procedure. The cortical nature and volume of the outside table with the intervening diploe of cancellous bone provide wide possibilities of shape, contour, and stability for reconstruction of any potential dental implant site. This bone is particularly useful for onlay grafting to augment the atrophic mandible and maxilla (Fig. 39.2).

Tessier, in his landmark publication in 1982, first championed the use of full- and split-thickness cranial grafts for the reconstruction of congenital deformities in children and young adults.[13] For the purposes of site preparation for the placement of dental implants, the use of the split-thickness graft will more than suffice.
● **Fig. 39.2** Cranial bone harvest graft. Ideal location of graft harvest with underlying anatomic landmarks. (From Kademani D, Tiwana P, eds. *Atlas of Oral & Maxillofacial Surgery.* Philadelphia, PA: Elsevier; 2015.)

The parietal bone, just above the insertion of the temporalis muscle, is the ideal spot for harvesting because of its thickness and its relative isolation from vital structures both above and below the cranial vault. The thickness of the parietal bone can vary from 3 to 12 mm, and any site less than 6 mm is a contraindication because of the possibility of dura exposure and possible tear. This procedure is also contraindicated in children less than 9 years of age because of the underdevelopment of the diploic space.[14] It is also recommended that surgeons choose the nondominant hemisphere side of the cranium, although postharvest magnetic resonance imaging (MRI) studies of the underlying brain did not detect any abnormalities, even in cases when there was a full-thickness breach.[15]

Anatomy and Technique

Incision design and placement is dependent on the amount of graft required for the reconstruction. For a large graft, a bicoronal incision is marked off in the hair bearing the scalp 4.0 cm posterior to the anterior hairline to hide the resultant scar and to expose as much of the parietal surface as possible. For smaller grafts, incisions may be made directly over the donor sight (Fig. 39.3).

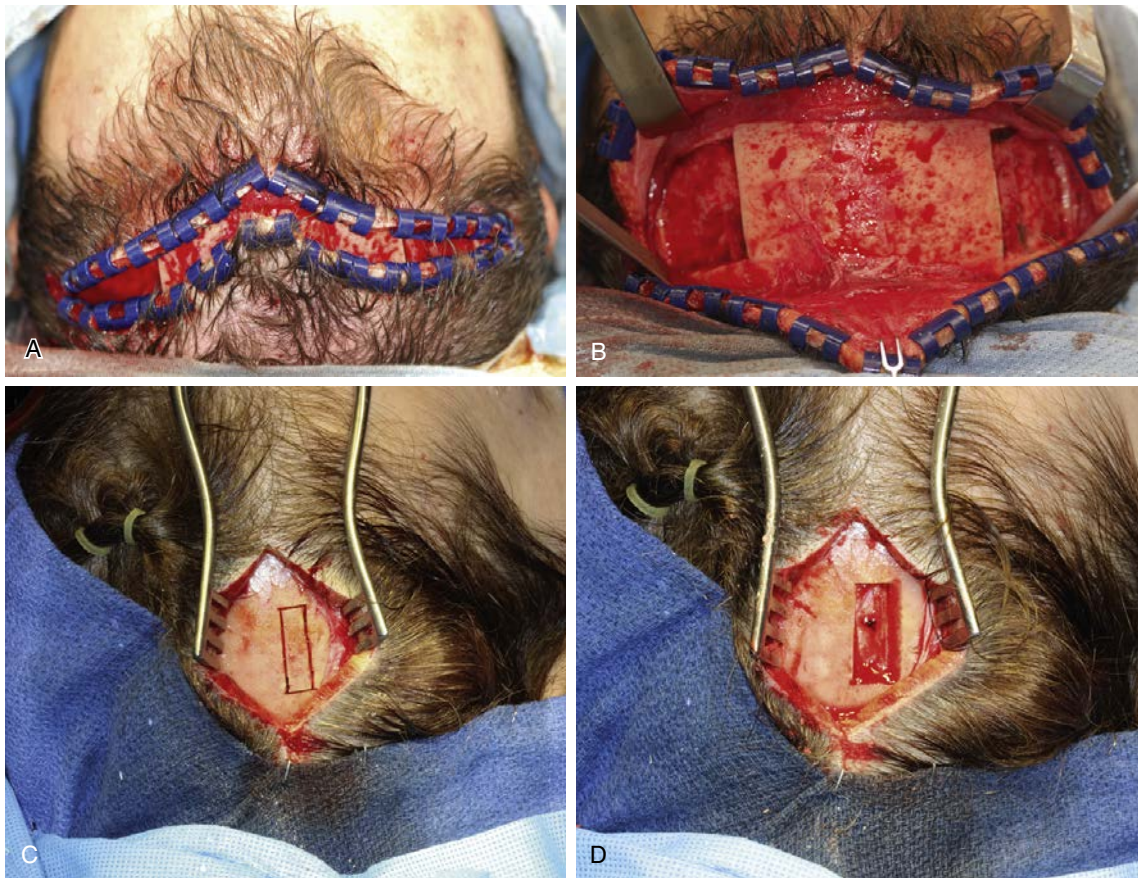
The hair is washed and prepped, however, it is not shaved. Local anesthetic with vasoconstrictor is injected along the planned incision site. It is imperative to wait the mandatory time (5–7 minutes) to allow the anesthetic vasoconstriction in this very vascular area to be effective. Electrocautery may be used from the dermis layer down to the bone so as to not disturb the hair follicles. Raney clips are then placed on both sides of the incision to help control further bleeding. Bone incisions are then outlined with a surgical marker or electrocautery, making sure all boundaries are behind the coronal suture and well away from the midline to avoid the superior sagittal sinus. The superior incision should be placed 2.0 cm lateral to the superior sagittal sinus, and the inferior extent of the incision should be 2.0 cm above the squamoparietal suture to avoid the middle meningeal artery. This area, the middle to posterior region of the parietal bone, has been shown to exhibit the thickest bone with the most developed diploic space.[16] For the

purposes of grafting for implant site preparation, ideal graft measurements can be separated into 1 to 1.5 × 3 to 4 cm to prevent fracture of the graft during harvesting.

With presurgical data from computerized tomography (CT) or cone beam CT (CBCT) scans indicating the approximate thickness of the skull, the initial osteotomies are initiated with a small Steiger bur or a Piezo saw down to the underlying diploe. Copious irrigation during the osteotomy is important so that the temperature of the bone is not increased this close to the cranial contents and to maintain the cellular vitality of the bone graft as best as possible. The outer edge of the initial osteotomy is then beveled down with an egg-shaped bur to provide a better access angle to allow a curved osteotome into the appropriate plane of the underlying diploe (Fig. 39.4). Beveling around additional sides of the initial graft may be necessary to avoid breaching the internal table. Once the initial graft of a multiple graft donor site is elevated cleanly, the remaining segments can be lifted much easier having already established the appropriate plane and angle between the outer and inner table.

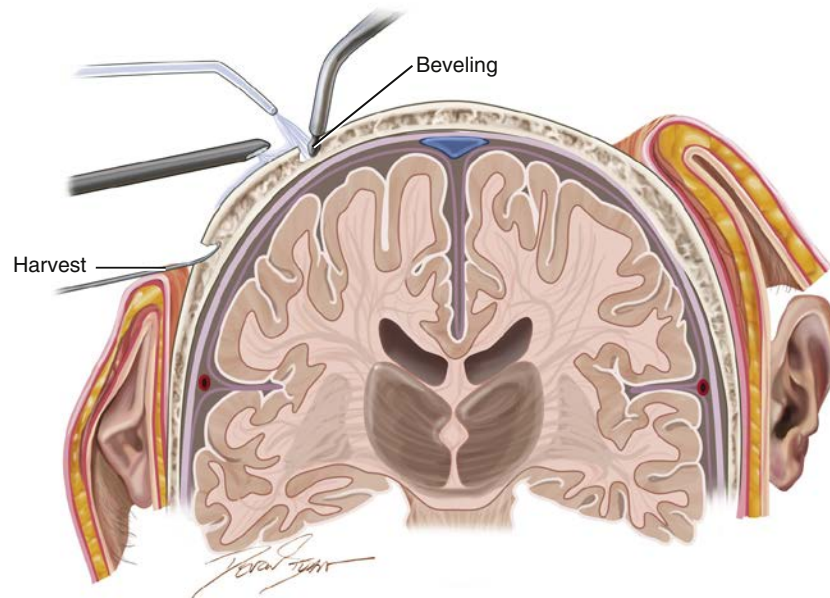
After the grafts have been removed and placed in saline, hemostasis is obtained and the wound is closed in layers. Various cements, putties, and bone substitutes are available to reestablish the contour of the cranium and obtain hemostasis from the cut edges of the bone. Closure of the periosteum and galea are performed with resorbable sutures, and the skin can be closed with staples as long as attention is paid to eversion of the scalp margins. Drains are rarely necessary.

Complications

1. *Alopecia along the incision line.* This is caused by the use of electrocautery and prolonged use of Raney clips, causing ischemic hair follicle injury. Scars caused by this can be minimized by using a zigzag incision design.
2. *Bleeding from the harvest site.* This can be controlled by the use of surgical hemostatic agents such as topical microfibrillar collagen (Avitine) and the use of bone wax or bone cement packed


• **Fig. 39.3** Calvarian graft incision. (A) Bicoronal incision design for large grafts. (B) access for harvesting grafts from both sides of the parietal cranium. (C) Smaller incision design. (D) Bone graft harvest for single site.

Beveling

Harvest


• **Fig. 39.4** Calvarian osteotomy. Beveling the osteotomy to prevent perforation of inner table while raising outer table graft. (From Kademani D, Tiwana P, eds. *Atlas of Oral & Maxillofacial Surgery.* Philadelphia, PA: Elsevier; 2015.)

into the diploic spaces and along the base of the bed. If bone cement is used, make sure that the exogenic heat caused by the chemical setup of the material does not come into contact with the bed until it has dissipated.

3. *Inner table perforations.* Small inner table perforations with no evidence of a dural tear are of no consequence and can be covered with any selection of softer fillers. If a small tear exists, then the tear will need to be sutured closed to prevent a cerebrospinal fluid leak. If the tear is large and no immediate means of closure is at hand, then a neurosurgical consult is necessary.

4. *Bleeding from major vessels.* These are very rare occasions, however, if a misadventure would result in copious bleeding from the central sagittal sinus and continuous pressure with surgical packing is indicated. Because this is venous blood, the hemostatic control should not result in any brain or scalp ischemia. If the middle meningeal artery on the inferior border of the temporal border is cut, then an immediate neurosurgical consult is necessary because this could result in an epidural hematoma.

Case Study

A 32-year-old male with a history of congenital absence of multiple maxillary and mandibular teeth presents for implant reconstruction. The patient had previous orthognathic surgery to correct a class III maxillary atrophic deformity. CT scans revealed severe alveolar bone atrophy of all four quadrants (Fig. 39.5).

Through a bicoronal approach, split-thickness outer table grafts were harvested from the parietal bone from the right and the left cranium. The grafts were placed with two-point fixation in an onlay fashion throughout the maxilla and mandible. Additional particulate bone pulverized from the unused grafts was used to fill in areas between the fixated grafts (Fig. 39.6).

At 6 months the grafted sites were exposed for removal of fixation screws and placement of implant fixtures. Note the minimal change and resorption of the original grafts that is emblematic of the high-density cortical grafts of the cranium. Surgical guide splints were fabricated before the uncovering for implant placement (Figs. 39.7 and 39.8; Boxes 39.1 and 39.2).

Iliac Crest Bone Graft

The ilium is historically the most popular donor site for facial bone grafting because of the high volume of cancellous and cortical bone. The corticocancellous block harvested from the ilium provides the "best of both worlds" in bone grafting by combining the high cellular transfer of the cancellous matrix with the BMP-rich structural support of the cortical bone (Fig. 39.9).

The anterior ilium may yield up to 50 cc of bone for augmentation. This amount can reconstruct a 5.0-cm segmental defect of the mandible using the following equation: 1.0 cm requires 10.0 cc of bone. For the purposes of implant site preparation, this is usually sufficient; however, if larger division E deformities exist, then the posterior ilium may be used. The posterior iliac crest can be harvested for donor bone when more significant volumes are necessary for the grafting of a facial defect. The posterior iliac crest provides the same quality and ratio of cancellous and cortical bone but in quantities approaching 100 ml of cancellous bone and a maximum of a 5 × 5-cm cortical block.[17]

The success of endosseous implants placed in iliac crest grafted sites is well documented. In a retrospective study by Misch published in 1994 and updated in 1999, a total of 1364 implants

placed in iliac crest bone grafts (940 maxillary and 424 mandibular) in either an immediate or delayed fashion revealed an overall survival rate of 96.7%[18] (Table 39.1).

The diversity of the iliac crest bone makes it useful not just in large segmental defects but also in routine C–w and C–h defects, which may benefit from the presence of the greater osteogenic potential of the autogenous bone, such as larger unilateral or bilateral sinus lift procedures. As with any bone graft, the success depends on adherence to basic surgical principles that call for rigid immobilization with screw fixation of the blocks and a rigid basket-type containment membrane (space maintenance) for all cancellous-only grafts, with minimal external pressure throughout the healing period (Box 39.3).

The disadvantages of both the anterior and the posterior iliac crest grafts include the use of a distant site from the oral cavity. This may require the use of two surgical teams or an increased surgical time for a single team with meticulous attention to maintaining separate fields to prevent cross-contamination from the oral cavity. In the case of the posterior iliac crest the surgical time can be doubled because the patient needs to be turned to the prone position for harvest. Contraindications to the use of the anterior or posterior ilium would be the presence of a hip prosthesis to reduce any risk of hardware failure or infection (Box 39.4).

Anatomy and Technique

The surgeon needs to first palpate the anatomic landmarks of the iliac crest, which can be difficult in obese patients, but it is absolutely necessary to prevent damage to local sensory nerves that overlay the anterior ilium. From posterior to anterior the landmarks include the iliohypogastric, the subcostal, and the lateral femoral cutaneous nerves. The iliohypogastric nerve arises from the dorsal rami of L1 and L2 (lumbar vertebrae) and passes directly over the midcrest and is in most cases unavoidable. The subcostal nerve arises from the dorsal ramus of T12 over the edge of the anterior superior spine to innervate the skin of the groin. The lateral femoral cutaneous nerve will also sometimes deviate from its usual course under the inguinal ligament in 2.5% of the population and also pass over the same area of the anterior ilium.[19] Therefore the anterior superior iliac spine (ASIS) is first marked and the crest is then palpated to the widest

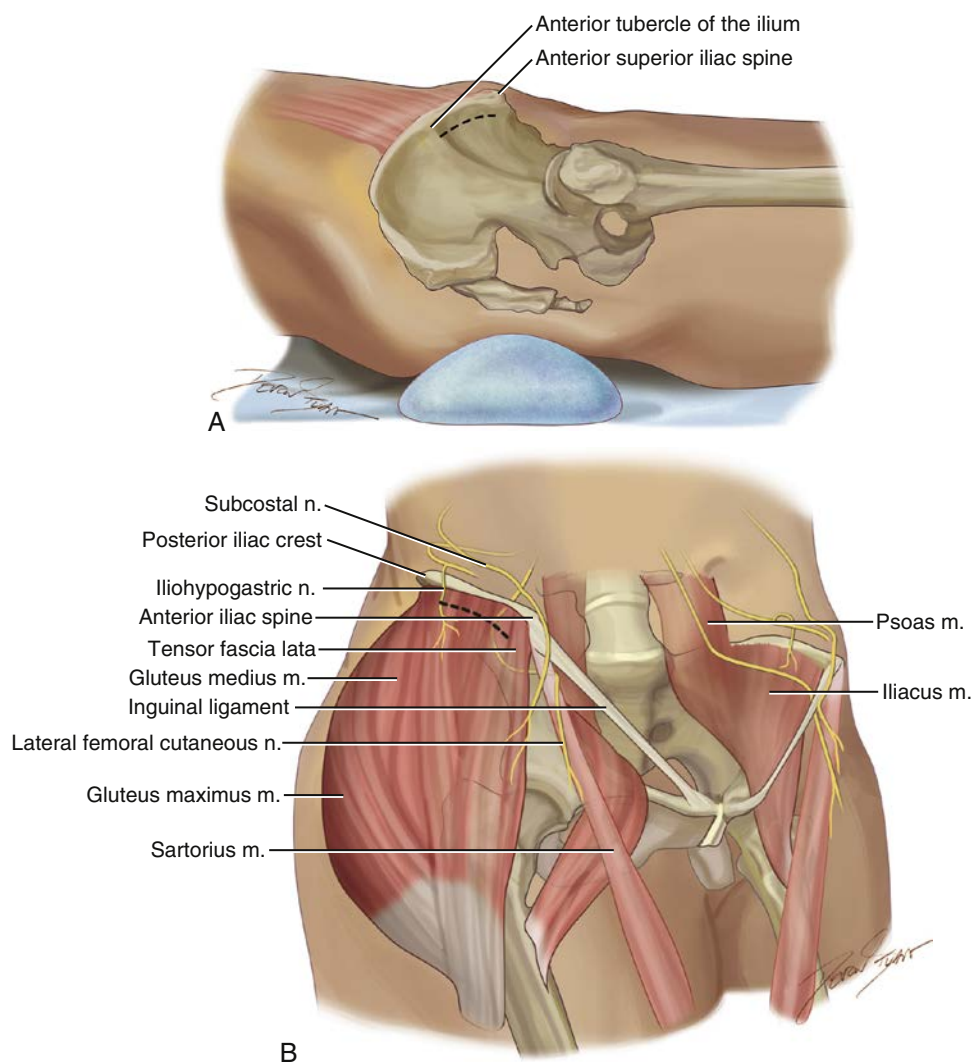
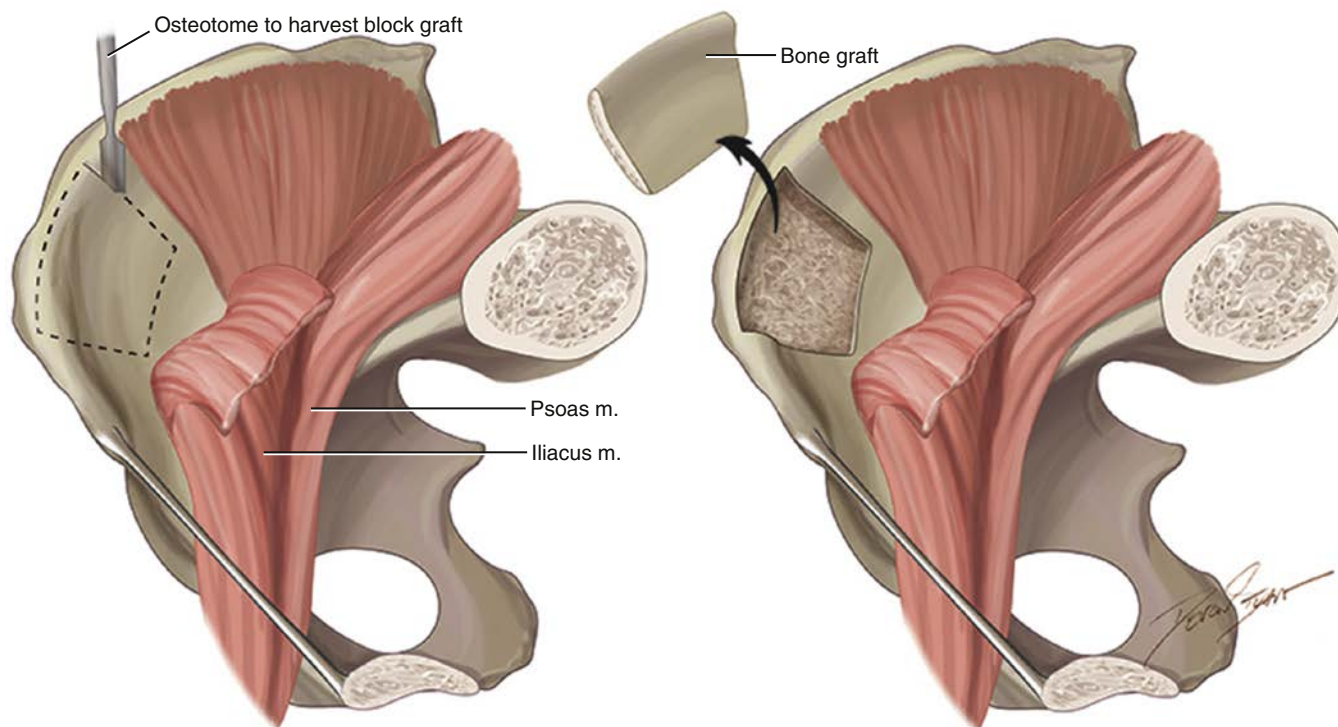
2. Contraindicated in metabolic bone disease, previous fracture site or osteomyelitis, or previous hip prosthesis

portion to the iliac tubercle. The incision is then marked 2 cm lateral to the iliac crest and 2 cm posterior to the ASIS to reduce injury to these two important sensory nerves[19,20] (Fig. 39.10).

The subcutaneous tissue and the subperiosteal plane is then infiltrated with local anesthesia and vasoconstrictor. After appropriate prepping and draping, the incision is made through skin down to the superficial abdominal facia or Camper and Scarpa fascia. Once through this fascial layer, the crest is easily palpated and the fibers from the medial external oblique and the lateral tensor fascia lata muscle are separated. A periosteal incision can now be made with electrocautery between these two muscles. Continuing to stay at least 1.5 cm posterior to the ASIS, subperiosteal dissection is performed to obtain access to the crest, as well as the medial wall under the iliacus muscle. Free cancellous bone can then be harvested through cortical windows created through the crest and corticocancellous blocks obtained by further exposure down the medial wall elevating the iliacus muscle. Blocks can be harvested via osteotomies


• **Fig. 39.10** (A) Lateral view demonstrating placement of a soft roll to elevate the anterior iliac crest. The incision *(dashed line)* is placed lateral to the crest and posterior to the anterior iliac spine. (B) Anterior view of the anterior iliac crest shows the relationships of the muscular and neural structures as they relate to the proposed incision *(dashed line).* Although not typically visualized during harvest, the iliohypogastric nerve may be encountered with posterior extension of the incision. (From Kademani D, Tiwana P, eds. *Atlas of Oral & Maxillofacial Surgery.* Philadelphia, PA: Elsevier; 2015.)


● **Fig. 39.11** Harvesting of a corticocancellous block from the medial aspect of the anterior ilium after reflection of the iliacus muscle. An osteotome or saw can be used for the corticotomies in the suggested design. After retrieval of the block, the exposed underlying cancellous bone can be harvested using bone curettes and gouges. (From Kademani D, Tiwana P, eds. *Atlas of Oral & Maxillofacial Surgery.* Philadelphia, PA: Elsevier; 2015.)

through the medial wall down to the cancellous layer. A parallel incision is then made to the first cut at a desired distance no more than 4 to 5 cm from the first cuts. Ninety-degree incisions are then made to connect these cuts on the inferior and superior margins. With the use of an osteotome the cortical cancellous blocks are lifted away carefully to not penetrate the posterior wall (Fig. 39.11).

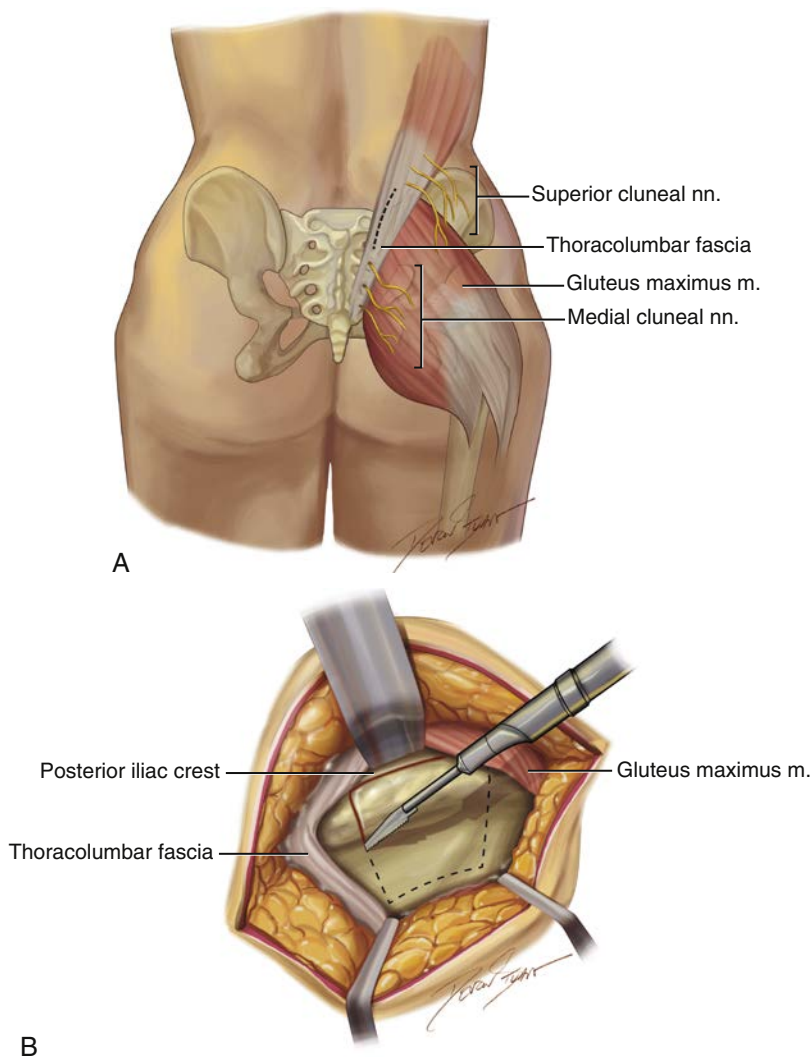
After the block graft has been elevated, additional cancellous bone for augmentation of the graft can be curettaged from the sides and the base of the graft bed. Closure of the periosteum and fascial layers is performed after hemostasis of the bone edges and any soft tissue adjacent to the donor site. Drains are not usually necessary. The use of long-acting local anesthetics can be used to help in postoperative pain control and to encourage early ambulation.

The technique for posterior iliac harvest differs from the anterior iliac in many ways; however, the most obvious way is the prone positioning of the patient. Either before or after exposure of the recipient site, all extraoral or intraoral wounds need to be packed and isolated from contamination while the patient is turned and the graft harvested. Incisions should be first marked beginning at least 1 cm lateral to the posterior superior iliac spine to avoid the sacroiliac ligament and then extended 5 to 6 cm laterally. After local and hemostatic infiltration, an incision is made through skin and taken down to the superior iliac spine. Unlike the anterior technique, grafts are harvested from the lateral cortex

by elevating the gluteal musculature with the superior cut being just below the crest of the ridge to avoid ilium fractures caused by weakening (Fig. 39.12).

In children both the anterior and posterior iliac crests act as ossification sites and not true growth centers. The cartilaginous crest should be kept intact, and any grafts, cortical or cancellous, should be harvested from below this border.

Complications

1. *Seroma.* A common complication surrounding the incision site usually caused by over activity in the early postoperative course. Initial aspiration and placement of drain if it continues to recur.
2. *Bleeding and hematoma.* A stable hematoma can arise from persistent oozing from the harvest bone beds. Hematomas can be prevented with fibrillary collagen packing or bone wax at the bone edges. Normally they will reabsorb. An expanding hematoma caused by an active bleeder is a much more serious situation and, as in pelvic fractures, could result in a large amount of blood loss before its presence is identified. The patient should be treated for any signs of hypovolemic shock, and the wound should be reexplored to identify and control the bleed.
3. *Postoperative paresthesia of the thigh.* Also known as meralgia paresthetica, this is a temporary paresthesia of the distribution of the lateral femoral cutaneous nerve, which could be caused


- **Fig. 39.12** (A) Outline demonstrating incision design of posterior iliac crest harvest in relation to superior cluneal and medial cluneal nerves. (B) Outline of osteotomies. (From Kademani D, Tiwana P, eds. *Atlas of Oral & Maxillofacial Surgery.* Philadelphia, PA: Elsevier; 2015.)

by pressure on the nerve from a hematoma of the iliacus muscle at the harvest site of the anterior table or pressure from retraction of the anterior flap. Permanent anesthesia could be the result of a poorly placed incision.

4. *Postoperative pain.* This is helped by long-acting local anesthetics with intravenous (IV) and analgesics by mouth (PO), and aggressive physical therapy to get the patient up and walking.

5. *Abdominal perforation.* This is a very rare occurrence of an anterior table harvest caused by the protection from surrounding musculature. Overweight patients may be at higher risk because anatomy is unclear, and over aggressive use of rotary instruments for bone harvest may exist. An immediate general surgery consult is indicated (see Table 39.1).

Case Study 1: Corticocancellous Morcellized Graft

A 28-year-old female with a history of basal cell nevus syndrome presented with right-sided swelling of her face. CT scan and Panorex revealed a multilocular radiolucent lesion encompassing the body and ascending ramus of the left mandible. Biopsy confirmed the presence of a diffuse spread of an odontogenic keratocyst (Fig. 39.13).

The patient was taken to the operating room for resection of the lesion, which required disarticulation of the condyle and was immediately reconstructed with an anterior iliac crest bone graft through an external facial incision. The corticocancellous blocks were placed in a bone mill and collagen-soaked sponges of BMP were placed into the rigidly fixated bone crib (Fig. 39.14).

At 20 weeks with the CT scan showing good consolidation of bone, the implant fixtures were placed. At 4 months the dental implants (Fig. 39.15) were uncovered and restored. At 5 years the grafted area continued to show good consolidation, continued support for the implant fixtures, and no recurrence of the cystic tumor (Fig. 39.16).

Case Study 2: Corticocancellous Block Grafts

A 53-year-old female with an atrophic maxilla prefers a fixed prosthesis to articulate against a partially dentate mandible, very
• **Fig. 39.13** (A) Large keratocyst of left mandible. (B) Preresection occlusion.

narrow bone in the anterior, and low-lying sinus floors on the posterior bilaterally (Fig. 39.17).

Corticocancellous strips were then harvested from the inner table of the anterior iliac crest. Bilateral sinus lifts were performed using cancellous bone from the residual harvest bed. The harvested blocks were then cut appropriately and then rigidly fixated as onlay grafts (Fig. 39.18). Additional cancellous bone was used to augment the rigidly fixated grafts, and the surgical site was closed in a tension-free fashion. The bone grafts were allowed to heal and consolidate for 6 months. A full denture prosthesis was fabricated for the patient for the interim period. The site was reopened, the fixating screw removed, and eight implant fixtures were placed (Fig. 39.19). After integration of the implants a fixed hybrid prosthesis was fabricated.
• **Fig. 39.16** (A) Final restored occlusion. (B) Final Panorex of restored segment showing consolidated graft with implants.

Tibial Bone Graft

The proximal tibial metaphysis provides an excellent source of cancellous bone. The quantity that may be harvested is close to or equal to that of the anterior ilium. The tibial graft has a low complication rate and is technically easy to perform. Comparison of tibial versus iliac crest grafts in secondary alveolar cleft reconstruction showed similar bone densities at 6 months.[21] Tibial bone grafts are most commonly used for maxillary sinus lift procedures and augmentation of existing bone for the placement of implant fixtures.[22] The rather low morbidity and easy surgical access allows skeletally mature adults to have the surgery completed on an outpatient basis. Because of possible damage to developing epiphyseal growth plates, this procedure is not recommended for children or adolescents; however, several authors have reported the safe and successful use of these grafts for alveolar cleft grafting in children.[23]

As with the ilium grafting sites, it is recommended to avoid sites that have had previous surgery with orthopedic hardware or prosthetic joint replacements. It is also prudent to avoid using this procedure on patients that apply large amounts of force to the tibia on a repetitive basis, such as runners and other active athletes.

Anatomy and Technique

After placing support under the leg and rotating it to provide better access, the surgeon marks out a 2- to 3-cm incision site over the skin of the anterolateral aspect of the leg directly over the Gerdy tubercle, which is lateral to the tuberosity. Catone and colleagues[24] described the incision as angled, with its cephalic limit superior and medial to the tibialis anterior muscle origin and extending lateral to the patellar ligament. After incising through the subcutaneous and fascial layers of the iliotibial tract, the periosteum is reflected to expose the cortex of the tibial metaphysis. With the use of an end-cutting bur, a window is cut into the cortex approximately the size of a dime. This cortical layer is very thin and usually is of little use to the graft and is not replaced. Bone curettes are then used to remove the cancellous bone in all directions and down the shaft of the tibia. Careful attention in harvesting in the superior direction is taken so that the joint space is not entered. A thrombin-soaked collagen sponge can then be placed in the donor site for hemostasis, and the wound is closed in layers with the iliotibial tract closed, followed by the skin and subcutaneous tissue (Fig. 39.20).

• **Fig. 39.17** (A) Preoperative panoramic image. (B) Clinical photo of atrophic maxillary ridge.

An alternative medial approach has been described[25] with similar soft tissue and bony osteotomies to harvest the donor graft. This approach, however, does not transect the iliotibial tract, resulting in less soft tissue covering the bony donor site and creating the potential for wound breakdown after closure (Box 39.5).

Postoperatively the patient can bear weight as tolerated with no vigorous physical activity for 6 weeks. Local wound care with periodic elevation of the site to prevent swelling is recommended. Routine analgesia of hydrocodone or acetaminophen is usually adequate.

Complications

1. *Ankle swelling.* Swelling and ecchymosis is caused by the natural lymphatic drainage system of the lower leg. In most cases, this will spontaneously resolve.
2. *Knee joint entrance or tibia fracture.* This is caused by over aggressive harvesting of bone in a superior direction. Initial treatment would be splinting of the leg with staphylococcal antibiotic coverage, followed by orthopedic surgical consult (Box 39.6).

Case Study

A 56-year-old female presented with large edentulous maxillary posterior space for implant reconstruction. A low-lying sinus floor precluded implant placement without sinus grafting. The patient was given an IV deep sedation, and the intraoral and right knee sites were prepped and draped and kept isolated from each other throughout the procedure. A 4-cm incision was designed and infiltrated with local anesthesia just blow the Gerdy tubercle on the right leg (Fig. 39.21).

• **Fig. 39.22** (A) Outline of donor site. (B) Bone harvested from donor site. (C) Preparation of with platelet-rich plasma (PRP). (D) Donor bone mixed with PRP.

The anterior wall of the tibial plateau was exposed and hemostasis obtained. With the use of a small round bur a circular bone incision was made and the thin cortical cap removed. Then, 24 cc of cancellous bone was curetted out of the site and mixed with strips of platelet-rich fibrin and packed into the sinus floor bed. Enough supportive bone was available to place immediate implants at the time of surgery (Figs. 39.22 and 39.23).

Vascularized Composite Graft: The Fibula

As mentioned previously, when the bed for a bone graft is compromised by radiation therapy, lack of blood supply, extensive length of the defect, or just the compromised medical condition of the patient, a vascularized composite graft may be indicated. These grafts differ from the free autogenous grafts because they do not depend on the recipient's local environment to aid in the regeneration and consolidation of new bone. These composite grafts bring their own blood supply with them and maintain normal physiologic function within all of the transferred tissues. This will include a certain amount of soft tissue that helps to cover and protect these bone grafts in compromised receptor sites. The downside of these grafts is the increased procedure time and the sometimes unavailable expertise of a microvascular surgeon. Technical complications include larger defects at the donor sites and the inability of the surgeon to construct a bony bed that is any different from the anatomic dimensions of the grafted bone. In the past, this bone stock, while providing excellent reconstruction of the continuity defect, did not always provide the best base for an implant-supported prosthesis. As the reconstructive surgeon and implantologist worked together over the years and realized the limitations of both, most of these problems have been resolved. These advances in cooperation between the surgeon and the implantologist is no better evidenced than in the emergence of the computer-aided design (CAD)/computer-aided manufacturing (CAM) technology, producing three-dimensional models for both the harvest and the implant placement, which has decreased treatment time from months to days.

Since the composite bone grafts were introduced in the late 1970s many donor sites have been recommended. In 1989 Hidalgo introduced the osteocutaneous fibula free flap for use in mandibular reconstruction, with 12 cases measuring defects averaging 13.5 cm.[26] Since then the fibula free flap has become the gold standard for reconstruction of large mandibular defects because of its consistency in size, its vascular pedicle length, and its ability to provide a reliable skin paddle with the bone flap. Its segmental blood supply also allows for in situ osteotomies, which aids in better anatomic reconstruction (Box 39.7).

Regarding quality of bone for osseointegration, Frodel and Moscoso, in two separate studies, compared the bone stock and thickness as it relates to the placement of endosseous implants in the four commonly used vascularized donor sites: the iliac crest, scapula, fibula, and radius. Although the iliac crest was found to have greater amount of bone stock, the results did not achieve statistical significance and the testing relied mostly on clinical observation.[27,28]
• **Fig. 39.23** (A) Maxillary sinus prepared for graft. (B) Lateral wall sinus augmentation. (C) Final wound closure.

• **BOX 39.7** **Vascularized Composite Graft: Advantages and Indications**

1. Reconstruction defects with poor tissue vascularity and questionable soft tissue coverage
2. Reconstruction of defects larger than 6 cm
3. Postcancer reconstruction with provision of protective skin paddle
4. Can withstand postsurgical radiation
5. Failed large free bone grafted segments
6. Can withstand immediate placement of dental implants

The first histologic study of the bone implant interface in a human vascularized graft was reported by Dattilo and colleagues in 1995.[29] This study showed that although the implant had successfully integrated into the iliac crest grafted bone and was clinically stable, the surrounding bone resembled the fine trabecular pattern of D4 density most commonly found in areas of the posterior maxilla (Fig. 39.24A). Sumi and coworkers in 2001 published a similar study using fibula graft and found the interface and surrounding bone to be more dense and cortical,

resembling the D1 and D2 of the anterior native mandible[30] (see Fig. 39.24B–C). This amount of bone density that has been shown to increase the stability and longevity of implants gives the fibula another distinct advantage over the other composite grafts (Box 39.8).

Anatomy and Technique

A detailed description of the surgical approach and harvest of this graft is beyond the scope of this chapter. However, a basic knowledge of the anatomic contents and its harvest is important for the implant surgeon to know, as well as the limitations and benefits of its use. The graft is harvested via a lateral approach through the intermuscular septum of the peroneus longus and peroneus brevis muscles. Dissection is taken to the anterior compartment for dissection of the vascular pedicle. The composite graft is based off the peroneal artery, which is a branch of the popliteal artery Fig. 39.26. During this dissection of the feeding vasculature, the anterior tibial artery and the deep peroneal nerve need to be identified and retracted medially to prevent injury. The diameter of the peroneal artery is 1 to 2.5 mm and matches well with the facial artery and vein, which are the most common vessels used for anastomosis in the receptive bed
• **Fig. 39.24** (A) Implant interface with iliac crest composite graft with the fine trabecular pattern of pre-dominantly cancellous bone. (B) Implant interface with fibula graft with dense cortical bone on left cortex side and fine cortical interface on marrow side. region. Of maximum importance is the careful dissection of the eight perforating vessels along the fibula, which are most commonly located along the junction of the middle third and distal third of the fibula. The vascularized bone is accompanied by portions of the peroneus longus, peroneus brevis, and the tibialis posterior muscle. The composition of the graft can change, however, depending on the position of perforating vessels to the skin and musculature (Fig. 39.25). Dissection down to the fibula and subsequent resection is performed while the vascular pedicle is still intact. The available fibula can have a width between 1.0 and 3.0 cm and a length of up to 26 cm; however, at least 5.0 to 8.0 cm is needed to be left on the superior and inferior portion to maintain stability to the ankle and knee joint. It is at this point that CAD/CAM-generated cutting guides can be used to perform the initial resection and subsequent segmental osteotomies using the rich blood supply to this graft.[31] Custom-generated plates also can be placed at this time, as well as placement of endosseous dental implants, before separating the blood supply (Fig. 39.26).

Only after all of this is completed will the microvascular surgeon resect the peroneal artery and venous complex and reapproximate it up to the receptor bed in the upper or lower jaw. A prefabricated plate, also generated from the custom CAD/CAM models, can now rigidly fixate the composite graft in place.

Complications

1. *Thrombosis of the arterial (pale flap) and venous (blue flap).* This will result in necrosis of the flap if local measures or the reanastomosis procedure fails.
2. *Wound Infection.* Treat this with antibiotics and local wound care.
3. *Compartment syndrome.* This is rare but serious. It is caused by internal pressure on donor site tissue. Immediate surgical intervention is indicated.

Case Study 1: Fibula Reconstruction with Immediate Placement and Loading of Implants

A 34-year-old male with a multiloculated lesion of the anterior mandible extending from #18 to #29 with tissue diagnosis of ameloblastoma (Fig. 39.27). Virtual surgical planning (VSP) using CAD/CAM images to fabricate surgical cutting guides, custom rigid fixation plates, and custom models were used to determine implant placement and positioning for immediate placement of interim prosthesis. At surgery, custom cutting guides were used for resection of the tumor at predetermined positions (Fig. 39.28). At surgery the pedicle flap was exposed through the lateral approach and the fibula was osteotomized at the specific length needed using cutting cones provided by virtual planning models. Guides also were provided by the virtual planning models (Fig. 39.29). Because of the unique segmental blood supply of the fibula, separate osteotomies could be made to form the necessary curvature as dictated by the presurgical models. The implants are placed and the custom plate is fastened to the graft before the in situ graft is released from the peroneal vascular blood supply. The peroneal vein and artery is then released and reanastomosed to the facial artery and vein near the reception site of the graft after the anterior segment is rigidly fixated to the right and left proximal segments of the mandible. The interim denture is then fixated to the
• **Fig. 39.25** Cross-sectional anatomy of the leg showing two possible sizes of osteocutaneous grafts. The upper smaller graft has septocutaneous vascular perforators running through the crural septum between the peroneus longus and brevis muscles and gastrocnemius muscles. The larger graft is necessitated when the perforators are identified partially through the flexor hallucis longus muscle requiring harvesting of parts of this muscle. (From Kademani D, Tiwana P, eds. *Atlas of Oral & Maxillofacial Surgery.* Philadelphia, PA: Elsevier; 2015.)

transoral implants. Implants placed in the bicortical vascularized graft routinely measure greater than 35 ncm of torque to allow placement of immediate prostheses (Figs. 39.30–39.33).

Case Study 2: Double-Barrel Fibula Graft with Immediate Placement of Implants

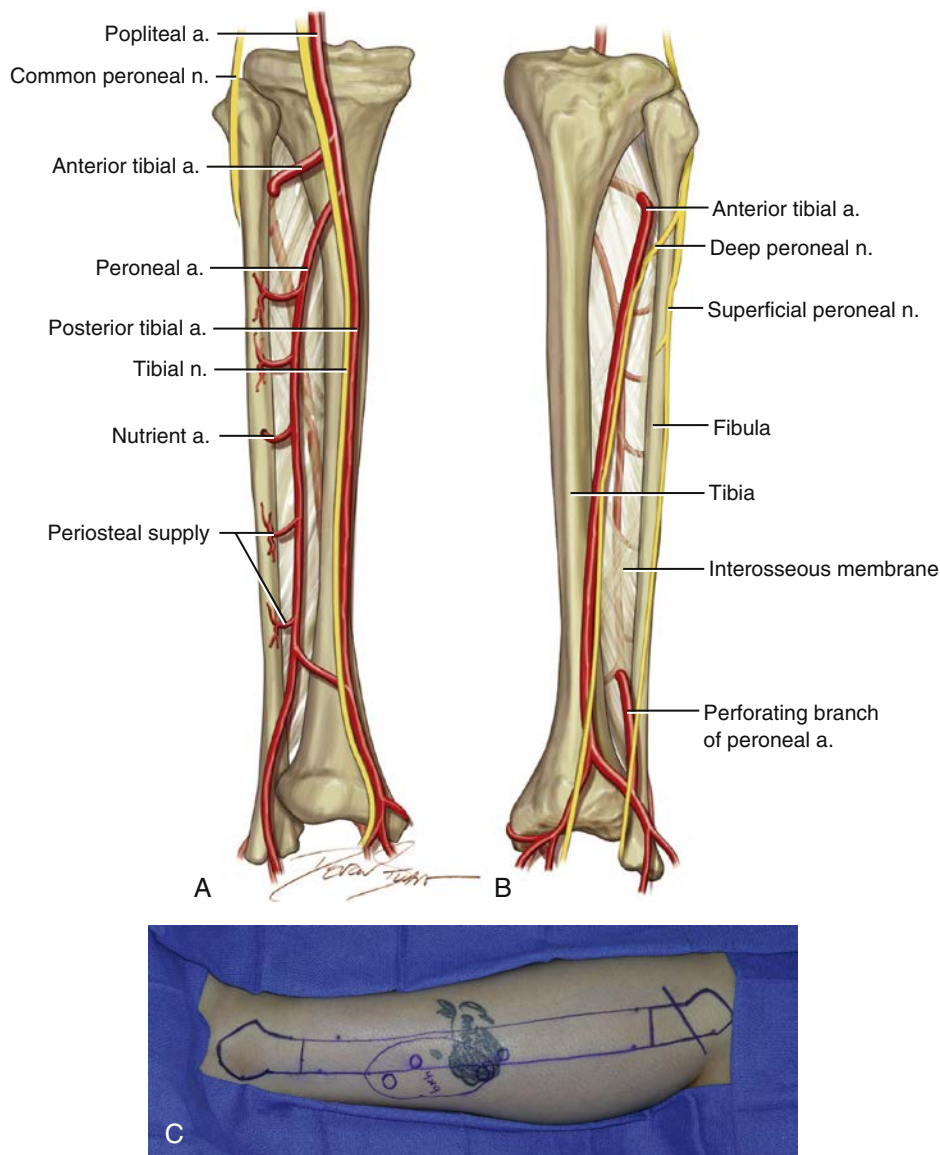
The double-barrel technique is used to increase the height of the reconstructed mandible. This is a 52-year-old male with a pathologic fracture of the mandible caused by osteoradionecrosis (Fig. 39.34). The wide excision of the necrotic bone was planned and the guides were fabricated to complete the graft and the implants in one surgery.

The custom plate and the fibula models were used to first resect the bone at the proper dimension and also to osteotomize the fibula in situ at the proper length. The dental implants were placed with guides into the upper segment before detaching the graft from the peroneal blood supply (Fig. 39.35). The graft is brought up to the jaw and folded on itself, maintaining the blood supply to double the height. The inferior segment is secured to the custom plate to reapproximate the natural contour of the jaw, and the upper segment has more freedom to be rotated and secured in a position that is best suited for a good functional occlusion (Fig. 39.36).

Finally both segments are secured and covered with portions of the soft tissue pedicle to secure its survival. The implants are uncovered in 4 months and restored. Sometimes it is necessary to debulk thick intraoral soft tissue pedicles and perform grafted vestibuloplasties to create a more healthy, soft tissue environment around the implants (Fig. 39.37).

Summary

The revolution in oral reconstruction brought about by the introduction of dental implants has revived the art and science of bone regeneration and grafting in dentistry. From the reconstruction of major jaw deformities to the augmentation of the smallest defect around a single tooth a bone graft is almost always considered to improve the environment of an implant fixture and help ensure its longevity.

The autogenous bone from the donor sites described in this chapter provide the three major qualities of a successful graft: osteoconduction, osteoinduction, and osteogenesis. The transfer of viable primitive mesenchymal and osteoblastic cells, as well as the growth factors (BMP) place the autogenous bone graft well above any of the allografts yet developed. Pain, deformity, and complications at the harvesting site are the


• **Fig. 39.26** (A) Anterior view of left leg. The common peroneal nerve crosses the fibular neck, dividing into the superficial and deep peroneal nerves. The anterior tibial vessel descends with the deep peroneal nerve along the anterior medial aspect of the interosseous membrane. The distal aspect of the peroneal artery passes through the interosseous membrane into the anterior compartment. (B) Posterior view of left leg. The popliteal artery branches into the anterior tibial artery, which branches into the anterior tibial artery and the posterior tibial artery, which branches into the peroneal artery, which provides the blood supply to the fibula through a nutrient artery and numerous periosteal vessels. (C) Fibula illustrated with 6 cm marked from the fibular head and lateral malleolus. Peroneal nerve illustrated inferior to the fibular head. Perforators marked in circles and a 4 × 9-cm skin paddle is drawn out (Courtesy of Fayette Williams DDS, MD.). (From Kademani D, Tiwana P, eds. *Atlas of Oral & Maxillofacial Surgery.* Philadelphia, PA: Elsevier; 2015.)

usual arguments for using alloplastic or nonautogenous substances as replacements. In a report published in 2005 a group of renowned craniofacial surgeons presented a survey of their combined 25-year experience with cranial, tibial, crest, and rib grafts. In 20,000 cases reviewed, less than 1% of complications were noted in any one area of bone harvest. The authors' conclusions were that the often heard statement that an alloplastic material was used to "spare the patient the added time and complications of harvesting and autogenous graft" is, in fact, not a reasonable argument for a well-trained surgeon and may

actually cause a failure or a compromised result at the reconstructed site.[32]

VSP will no doubt be a strong influence in the future of extraoral autogenous grafting for the implant patient. From the fabrication of custom cutting guides for resection, harvesting, and placement of larger grafts to the fabrication of immediate implant-borne prosthesis, these new computerized technologies will continue to promote and maintain the extraoral autogenous bone graft as the gold standard of dental implant reconstruction.

The Use of Botox and Dermal Fillers in Oral Implantology

RANDOLPH R. RESNIK AND AMANDA M. SHEEHAN

The field of oral implantology is constantly changing because of the advances in technology and science. With a better understanding of the dynamic relationships of the soft tissues surrounding the orofacial complex, the use of injectable botulinum toxins (BTXs) and dermal fillers has become an integral part of dentistry. With respect to oral implantology, dental implant clinicians are in a unique position to evaluate and treat patients with these products. These pharmacologic agents may be used to control parafunctional habits, help restore function, relieve pain, and supplement facial esthetics in conjunction with implant prosthetic procedures. Currently, the two most popular treatments used in conjunction with oral implantology procedures include the use of injectable neurotoxins (BTX) and injectable dermal fillers (hyaluronic acid).

Injectable Neurotoxin (Botulinum Toxin)

Botulinum toxin, first used in humans in the 1970s, has become very popular in dentistry. In 2002 Botox was approved in the United States for cosmetic treatment and for the treatment of excessive forces from hyperfunctional muscle activity. There exist eight different serotypes of BTX (i.e., designated as A to H), with some being purified for therapeutic injections into hyperactive muscles. Today, botulinum toxin type A (BTX-A; purified isolate from fermentation of the bacterium *Clostridium botulinum*) is the most potent and widely used serotype in clinical practice. BTX-A is a stable compound that is present in a vacuum-dried powder that currently is marketed under three different brand names: Botox, Dysport, and Xeomin. They all contain the same active ingredient of BTX-A; however, they differ in their formulation: onabotulinum toxin A (Botox), abobotulinum toxin A (Dysport), and incobotulinumtoxin A (Xeomin).

Mechanism of Action

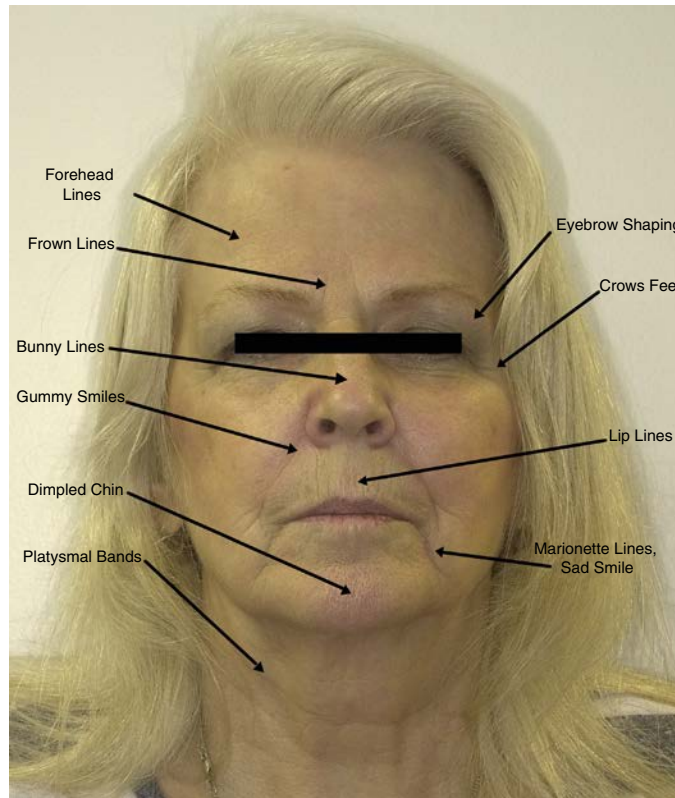
In general, BTX-A blocks the neuromuscular transmission by inhibiting the release of acetylcholine from motor nerve terminals, which results in a reduction of muscle contractions. Acetylcholine is a neurotransmitter that is responsible for muscle contractions. The muscle inhibition occurs in multiple steps (binding, internalization, translocation, and cleavage) by BTX-A cleaving to a protein (SNAP-25), which is an integral part of acetylcholine docking and release from vesicles in the nerve endings. When injected intramuscularly, BTX-A produces a chemical denervation of the muscle, which results in a reduction of muscle activity (Fig. 40.1).[1]

The effects of the botulinum neurotoxins are temporary because the nerve terminals will recover back to their normal function. Initially axonal sprouts arise from the affected nerve in response to growth factors from the inactive muscle. The axonal sprouts form new immature synapses to the injected muscle, which allows neuromuscular transmission to return to normal.

How Supplied and Preparation

In the United States BTX-A is manufactured as a purified neurotoxin complex supplied as a white powder in sterile glass vials. Each vial contains either 50, 100, and 200 units (U) of BTX-A, with an expiration date of 2 years when stored properly at –5°C to –20°C. The BTX-A vial should always be refrigerated until use. Because of its powder form, the BTX-A must be reconstituted with 0.9% NaCl sterile saline solution. Most commonly, BTX-A is supplied in a 100-U vial that is usually diluted with 2 or 4 mL of saline, which results in a 5.0/2.5-U BTX-A per 0.1 mL solution. Commonly the dilution is dictated by the muscle or region being treated, or by the clinician's preference. Usually a 1.0-mL tuberculin syringe with a 26- to 30-gauge needle is used to draw up the required solution for administration.[2] Once opened and reconstituted, the solution must be used within 24 hours because the BTX-A and diluent contain no preservatives. The solution should be stored in a refrigerator at 2°C to 8°C (36°F–46°F). If preservatives are used, the shelf-life is significantly increased. Hexsel et al.[3] have shown that refrigerated, reconstituted BXT-A can be used for up to 6 weeks without loss of efficacy (Table 40.1 and Fig. 40.2).

Generalized Botulinum Toxin Type A Injection Technique/Dose

In general, injections should be made perpendicular to the skin surface and intramuscularly into the belly of the muscle. However, in some situations a more customized injection pattern may be required.


• **Fig. 40.1** (A and B) Diagram depicting the action of botulinum toxin at the neuromuscular junction. (A) Normal acetylcholine release. Synaptobrevin and VAMP-2 (not shown) on the surface of the vesicle containing acetylcholine joins with SNAP-25 and syntaxin on the internal axonal surface. This forms a complex that allows fusion of the vesicle with the membrane to release acetylcholine into the synaptic cleft. Acetylcholine binds to its receptor on the surface of the muscle cell, opening voltage-gated sodium channels that result in membrane depolarization. (B) Action of botulinum toxin. Botulinum toxin type A (BTA) is internalized by the axon when bound by its receptor on the cell surface. The light chain of the toxin is taken up and cleaves the SNARE proteins before the acetylcholine vesicles can bind. The result is a lack of acetylcholine release into the synaptic cleft and subsequent paralysis of the muscle. (C) Common facial anatomic areas for Botox injections. (A and B: From Miller J, Clarkson E. Botulinum toxin type a: review and its role in the dental office. Dent Clin North Am. 2016;60:509-521.)

TABLE 40.1	Dilution Table for Botulinum Toxin Type A	
BTX-A VIAL	Diluent Added (0.9% NaCl)	Resulting Dose (Units/0.1mL)
50 units	1.25 mL 1.0 mL	4.0 units 5.0 units
100 units	2.50 mL 2.0 mL	4.0 units 5.0 units
200 units	5.0 mL 4.0 mL	4.0 units 5.0 units

For muscle injections in the orofacial region, skin preparation should always be completed using aseptic alcohol wipes and dry sterile gauze sponges. In most clinical situations the muscles should be injected bilaterally to minimize complications from asymmetry or unequal nerve involvement (i.e., number of units will vary depending on the target muscle). When considering the ideal dosing amount, the total number of units will depend on the area of interest, muscle mass, and strength and gender of the patient. In general, men will require more units than women. Care should be taken when choosing the dilution being used because higher dilution may result in further migration of the BTX-A and may result in unwanted effects.

Duration of Action

The U.S. Drug Administration recommends an injection frequency of once every 3 months with the lowest effective dose. In some patients multiple injections may over time result in the development of antibodies to BTX-A, which results in effect reduction and inactivating the toxin activity. However, in general the length of efficacy varies among individuals and is dependent on the patient's metabolism of the toxin and the use or activity of the muscle being treated.

Botulinum Toxin Type A Uses in Implant Dentistry

1. Parafunctional habits
2. Temporomandibular joint syndrome/temporomandibular dysfunction (TMJ/TMD)
3. Excessive tissue display (gummy smile)

Parafunctional Habits

Masseter Muscle Hyperactivity

A common sequela of patients with parafunction is masseter hypertrophy. The masseter muscle is one of the primary muscles of mastication. When the masseter muscle is hyperactive or overused, the facial appearance often enlarges and results in a negative cosmetic impact with altered facial lines. Muscle function is also altered, which results in excessive force being placed on the teeth/implants. Studies have shown a significant reduction in masseter muscle volume with an average reduction in mass of 22% and up to approximately 35% reduction after the continued use of BTX-A[4] (Figs. 40.3 and 40.4).

Anatomy. The masseter muscle is a thick quadrilateral muscle that consists of two heads: (1) superficial and (2) deep.

Superficial: The larger superficial head arises by a thick aponeurosis from the maxillary process to the zygomatic bone and from the anterior two-thirds of the inferior border of the zygomatic arch. The fibers pass inferior and posterior, and are inserted in the angle of the mandible and inferior half of the lateral surface of the mandibular ramus.

Deep: The smaller deep head arises from the posterior third of the lower border and the medial surface of the zygomatic arch. Its fibers pass in a downward and forward direction to be inserted into the upper half of the ramus as high as the coronoid process of the mandible. Anteriorly the superficial head conceals the deep head and posteriorly is covered by the parotid gland.

Innervation and Blood Supply. The masseter is innervated by the anterior division of the mandibular division (V3) of the trigeminal nerve. The pathway of innervation is gyrus precentralis > genu capsula interna > nucleus motorius nervi trigemini > nervus trigeminus > nervus mandibularis > musculus masseter. The blood supply to the masseter muscle is derived from three blood vessels: the masseteric branch of the maxillary artery, the facial artery, and the transverse facial branch of the superficial temporal artery.

Function. The primary function of the masseter muscle is elevation of the mandible. The masseter muscle parallels the medial pterygoid muscle; however, it is significantly stronger and its superficial fibers can be responsible for protrusive movements.[5]

Botox Technique. Injection into the masseter muscle for the treatment of masseter hypertrophy was first discussed by von Lindern et al.[6] They suggested injections into the zygomatic arch and mandibular angle. However, this method revealed a higher risk for injection into the parotid gland, which led to significant complications. Hu et al.[7] determined a safe zone for injection sites into the masseter muscle. They recommended the safest entry point to be in the central compartment of the masseter muscle as to avoid injections into the parotid gland and the mandibular branch of the facial nerve. The parotid gland is located superficial and at the posterior margin of the muscle. Branches of the facial nerve also run superficial to the muscle. The delineation of the "safe zone" is a line drawn from the lower ear to the angle of the mouth (superior margin). The anterior extent is determined by palpation and the posterior extent is the posterior angle of the mandible (Fig. 40.4). The inferior border is delineated by the inferior border of the mandible.

Mapping Injection Sites. An outline of the muscle needs to be completed to determine the maximum areas of contraction and tension points of the masseter muscle. Initially a line is drawn with a removable skin marker from the lateral commissure (corner of the mouth) to the bottom of earlobe (small pointed eminence of the external ear that projects over the meatus). The inferior border of the mandible is outlined, and the anterior and posterior borders of the muscle are marked. The patient is asked to clench his or her teeth, and the maximum contraction points are documented and marked. Skin markings can easily be removed with alcohol swabs.

Injection Technique. Two syringes of reconstituted 25 U of BTX-A are drawn up in into syringes and approximately 5 U is injected deep into the belly of the muscle at each tension point. In most cases the needle is inserted perpendicular to the skin surface (Fig. 40.5).

Studies. Many studies have shown the successful reduction in masseter hypertrophy via BTX-A injections.[7-10] With multiple injections, concomitant reduction in gross masseter size has been shown to be up to 40%.[8] Rafferty et al.[11] showed masseter-induced bite force reduction of up to 85% at week 3 after injections and 65% less at week 7. However, clenching returned to

• **Fig. 40.2** Reconstitution of Botulinum Toxin Type A (BTX-A). (A) 0.9% Sodium Chloride Vial (B) Using an appropriate-size needle and syringe, draw up 1, 1.25 or 2.5 mL of 0.9% preservative sterile saline. (C) Invert needle and tap side to expel any air bubbles. (D) Insert the needle and slowly inject the saline into the BTX-A. Vacuum must be present in the vial, which demonstrates that sterility of the vial is intact. (E) Remove the syringe, then gently mix the vial with the saline by rotating the vial. Record the date and time of reconstitution on the label. (F) Using a small tuberculin syringe draw up the required amount of solution; angle the needle into the bottom corner of the vial to allow for full extraction of solution. Do not completely invert the vial and expel any air bubbles in the syringe barrel. (G and H) Final syringes with BTX-A solution are ready for injection.

baseline values faster as the result of other muscles compensating. Van Zandijcke and Marchau[12] described in 1990 the use of 100 U of BTX-A injections to the temporalis and masseter muscles in patients with brain injuries. The mean duration of response was approximately 19 weeks and mean peak effect (abolishment of grinding) was approximately 3.5 weeks. In general the targeted musculature usually adapts to the injections, and frequency of injections usually decreases because of the atrophy of the muscles.

Complications. Injections in the masseter muscle area are relatively safe with minimal side effects. Inaccurate injection location

• **Fig. 40.5** Masseter Mapping and Injection Technique. (A) Skin Marker, (B) Commissure—ear lobe line drawn. (C) Inferior border of mandible trajectory evaluated. (D) Inferior border points marked. (E) Inferior border and posterior border points connected. (F) Anterior masseter muscle border marked.

or too high injection volume may lead to excessive swelling, bruising, facial muscle weakness, and xerostomia. Postoperatively, patients may report a "thicker" saliva and usually this is related to higher doses and injections into the parotid gland. Injections made too far anteriorly may lead to BTX-A diffusion into adjacent muscles, leading to smile alteration (Fig. 40.6).

Temporalis Muscle

The temporalis muscle (also called the *temporal muscle*) is considered a muscle of mastication and arises from the temporal fossa.

Anatomy. The temporalis muscle is a broad, fan-shaped muscle of mastication on the lateral aspect of the skull. It arises from the temporal fossa, which is a large depression on the lateral aspect of the skull. A temporal fascia completely covers the surface of the muscle. The muscle fibers converge as they descend through a space between the zygomatic arch and end with the temporalis tendon. The temporalis tendon is considered a very thick tendon that inserts at the coronoid process of the mandible (Fig. 40.7).

Innervation and Blood Supply. The third division of the mandibular branch of the trigeminal nerve innervates the temporalis muscle by the deep temporal nerves. The deep temporal branches of the maxillary artery, along with the middle temporal artery, contribute to the blood supply of the muscle.

Function. The temporalis muscle is considered the strongest muscle of mastication. It can be divided into two functional parts, the anterior and posterior. The anterior temporalis runs vertically and is responsible for elevation of the mandible. The posterior temporalis runs horizontally, and contraction results in retrusive movements of the mandible.[13]

Botox Technique

Mapping Injection Sites. The anterior, posterior, and superior extent of the temporalis muscle is marked with a skin marker. As the patient clenches his or her teeth, the maximum areas of contraction and/or tension points are marked within the boundaries.

Injection Technique. The injection technique for the temporalis muscle usually consists of two injections, superficial and deep, according to the location of the areas of maximum contraction. The superficial injections are positioned into the thinner upper portions of the temporalis muscle in a fan shape. The deeper injection involves the split of the superficial temporalis fascia, which is located approximately 1.5 mm superior to the zygomatic arch[15] (Figs. 40.8 and 40.9).

Duration. When BTX-A is injected for parafunctional habits in temporalis muscles, patients appear to require repeated injections at approximately 5 months. Other studies have shown injections to be repeated every 6 months.[14]

● **Fig. 40.6** Smile Alteration Complication: (A) Normal smile, (B) Smile alteration resulting from injection on the right side which was too medial, which inadvertently diffused and affected the Risorius muscle. Note the constricted smile on the right side.

● **Fig. 40.8** Temporalis Muscle Boundaries.

Temporomandibular Joint Syndrome (TMJ)/ Temporomandibular Dysfunction (TMD) Pain

The use of BTX-A has been shown to treat TMJ or TMD complications, with the injection of the masseter and temporalis muscles. Guarda-Nardini et al.[16] demonstrated the use of Botox in the treatment of decreasing myofascial pain symptoms in bruxers, compared with saline injections. Baker et al.[17] evaluated the use of masseter and temporalis injections for patients exhibiting chronic masticatory myofascial pain dysfunction. Results showed a decrease in overall pain and overall maximum voluntary opening.

Success rates are variable in the treatment of patients with TMJ. Studies have reported that BTXs used for the treatment of TMD disorders may cause dysphagia[18] or temporal drooling.[19] However, in both of these reports greater than 100 U was administered.

Temporomandibular Dysfunction/Temporomandibular Joint Technique

The TMD/TMJ BTX-A technique is very similar to the traditional masseter and temporalis muscle techniques, with the only difference being dictated by myofascial trigger points. To determine the location of injections for TMD/TMJ technique, myofascial trigger points must be located. Trigger points are hyperirritable areas within the fascia surrounding the muscle, which may differ from areas of maximum contraction. Usually in TMD/TMJ cases, one or more trigger points are generally present, which on palpation will cause transmission of pain along the muscle or neuronal tracks. Disruption of the trigger points have been reported to bring short- and long-term pain relief.[20]

1. Palpate for two trigger points in the masseter and mark with a skin marker.
2. Palpate for three trigger points in the temporalis and mark with tissue pen.

• **Fig. 40.9** Temporalis Technique. (A) Maximum areas of contraction and/or trigger points evaluated while the patient clenches his teeth. (B) Trigger points are marked with skin marker. (C) Final tension points. (D) Anterior and superior borders are marked. (E) Final boundary outline and tension points. (F and G) Five units of botulinum toxin type A per injection point.

3. Clean injection areas with alcohol wipes.
4. Using four tuberculin syringes, draw up (2) 20-U syringes and (2) 25-U syringes.
5. Inject 10 U into each trigger point in the masseter.
6. Inject 12.5 U into temporalis anterior fan, 7.5 U into the middle, and 5 U into the temporalis posterior fan. (Fig. 40.10).

Excessive Tissue Display (Gummy Smile)

In the rehabilitation of the dental implant patient, clinicians are often confronted with excessive display of maxillary gingival tissue on smiling. The "gummy smile" results in difficulty in restoring patients because of nonideal esthetics and displeasure

● **Fig. 40.10** Temporomandibular Dysfunction/Temporomandibular Joint Technique: Clean Injection Areas With Alcohol Wipes. (A and B) Palpate for (A) two trigger points in the masseter and (B) three trigger points in the temporalis, and mark with tissue pen. (C) Using four tuberculin syringes, draw up (2) 20-U syringes and (2) 25-U syringes. (D) Inject 10 U into each trigger point in the masseter. (E) Inject 12.5 U into anterior fan, 7.5 U into the middle, and 5 U into the posterior fan of the temporalis muscle.

in the prosthesis-tissue junction. Caution should be exercised with the treatment of gummy smiles because vertical maxillary excess is historically treated surgically by means of maxillary impaction via a Le Fort 1 osteotomy procedure. For patients exhibiting delayed passive eruption, gingivectomies are the ideal treatment. Botox can be used for correction of hyperfunctional upper lip elevator muscles. Therefore, before treatment, it is crucial that the etiology of the gummy smile be ascertained.

Kokich et al.[21] described an excessive gingival-to-lip distance of 4 mm or more, which they classified as "unattractive" by laypeople and dental professionals. Excessive gingival display has been shown to have a prevalence rate of approximately 11% of the population, with more women displaying excessive gingiva than men, with a 2:1 female:male ratio.[22,23,24]

There exist two types of smiles in the literature, the "social" and the "enjoyment" smile. The social smile is a voluntary, unstrained and static facial expression that is usually used as a greeting. The lip component is due to the muscular contraction of the elevator muscles of the lip. In contrast, the enjoyment smile is involuntary and usually results from laughter or pleasure. The upper and lower lip elevator and depressor muscles are responsible for the full expansion of the lips, which show maximum anterior tooth display.[25] A cosmetic smile has been defined as displaying less than 2 mm of the gum tissue. Any smile showing more than 2 mm is classified as a gummy smile or excessive gingival display.[26] When treating these patients, it is imperative to have a

preoperative photo of their enjoyment smile showing their maximum lip movement, to properly assess the needs and outcome of the BTX-A treatment. In summary, a thorough intraoral and extraoral examination is imperative because the excessive gingival display may be treated with BTX-A only when it caused by hypermobility of the lip, not when the excessive gingival display is the result of the position of the maxilla (skeletal position) or a short upper lip (Fig. 40.11).

Etiology

In the production of a smile, many muscles are involved, including orbicularis oris, levator labii superioris alaeque nasi (LLSAN), levator labii superioris (LLS), zygomaticus major (ZM), and depressor septi nasi muscle. In cases of true hyperfunctional upper lips, the primary muscle responsible for the hyperactivity with resultant excess display of gingiva is the LLSAN. The LLSAN is translated from the Latin as the "lifter of the upper lip and wing of the nose." This muscle originates from the upper frontal process of the maxilla and inserts into the skin of the lateral nostril and upper lip. Its main action involves elevation of the upper lip and is also involved in dilation of the nostrils and creation of associated deep nasolabial folds (Fig. 40.12 and Box 40.1).

Injection Technique

Hwang et al.,[27] at Yonsei University College of Dentistry, have proposed an injection point for the treatment of a gummy smile,

• BOX 40.1 **Facial Muscles Anatomy and Function**

Orbicularis Oris Muscle
Origin: maxilla and mandible
Insertion: skin around the lip
Function: muscle encircling the mouth is a sphincter muscle and is
    responsible for closing the mouth; it is known as the "kissing muscle,"
    because it is used to pucker the lips

Levator Anguli Oris Muscle
Origin: maxilla inferior to the infraorbital foramen
Insertion: modiolus
Function: lifts the upper lip

Zygomaticus Major Muscles
Origin: zygomatic bone
Insertion: orbicularis at modiolus
Function: works with the risorius muscle to assist in laughing and smiling by
    lifting the corners of the mouth

Zygomaticus Minor Muscles
Origin: malar surface of the zygomatic bone
Insertion: orbicularis oris
Function: draws the upper lip backward, upward, and outward and is used
    in smiling

Levator Labii Superior Muscle
Origin: medial infraorbital margin
Insertion: skin and muscle of the upper lip
Function: elevates the lip

Levator Anguli Muscle
Origin: maxilla
Insertion: modiolus
Function: elevates the angle of the mouth medially

Levator Labii Superior Alaeque Nasi Muscle
Origin: nasal bone
Insertion: nostril and upper lip
Function: dilates the nostril and elevates the upper lip and nose

Depressor Anguli Oris Muscle
Origin: tubercle of mandible
Insertion: modiolus of mouth
Function: depresses angle of mouth

Depressor Labii Inferior Muscle
Origin: oblique line of mandible between symphysis and mental foramen
Insertion: integument of the lower lip, orbicularis oris, modiolus
Function: depression of the lower lip

Risorius Muscle
Origin: parotid fascia
Insertion: modiolus
Function: retracts the angle of the mouth to produce a smile

Buccinator Muscle
Origin: alveolar processes of maxilla and mandible
Insertion: fibers of orbicularis oris
Function: compresses the cheeks against the teeth

---

which is named the Yonsei point. The Yonsei point is located at the center of a triangle formed by LLS, LLSAN, and zygomaticus minor muscles. The merger of these muscles can be felt by palpating lateral to the nose while smiling and is roughly 1 cm lateral to the ala of the nose and 3 cm superior from the lateral oral commissure. Hwang et al.[27] have recommended a dose of 3 U at each injection site (bilaterally).

Achieving ideal outcomes for the treatment of excessive tissue display is extremely technique sensitive, with excess treatment often occurring in transverse elongation and dysfunctional animation of the maxillary lip. Therefore clinicians early on their learning curve should treat these areas cautiously and gradually, with multiple low-dose treatments over a longer time period in lieu of a single bolus in one appointment.[28] Ideally the lip at rest and high lip line should be documented with photographs by measuring from the gingival zenith to the inferior border of the upper lip. Patients with natural asymmetry to their smile may need different amounts of BTX-A on each side to achieve an ideal smile level. The asymmetry should be reevaluated at a 2-week interval, and more BTX-A can be added to the hyperactive side (Figs. 40.13 to 40.15).

Facial asymmetry corrected with Botox should be over a 4-week period, with approximately 2 U administered bilaterally at the initial visit and 1 U administered 2 weeks later. This technique usually will result in a more symmetric smile.

Duration. The duration of action of BTX-A is not permanent, lasting on average for 6 months with a range of 4 to 8 months.[29] In most cases, BTX-A needs to be administered approximately two to three times a year, depending on how much muscle activity

• **Fig. 40.13** Yonsei Point. Is located 1 cm lateral to the ala of the nose and 3 cm superior to the oral commissure.

is present. The therapeutic effects will usually appear in 24 to 72 hours and peak in 1 to 4 weeks, with a decline after 3 to 4 months.[30]

Studies. Polo[22] showed favorable results with a mean gingival exposure reduction of 5.2 mm. Although the amount of

• **Fig. 40.14** Gummy Smile Injection Points (Yonsei). (A) Gummy smile, (B) Yonsei injection points.

gingival display increased from 2 weeks to 24 weeks, the amount of original display had not returned at 24 weeks. Park et al.[31] showed a mean reduction in masseter thickness of up to 2.9 mm, measured at 3 months postoperatively. With multiple injections, eventual atrophy of the masseter muscle resulted in requiring less frequent doses, with a recommended recall of 4 to 6 months.

Complications. In the treatment of the gummy smile, many complications may arise consisting of asymmetries, lip sagging, lip protrusion, exaggerated lip elongation, and interference with speech. As stated, the clinician must be able to distinguish hyperfunctional upper lips from other causes of gummy smiles. For instance, attempts to treat maxillary excess conditions with BTX-A may lead to unnatural results from the excessive loss of function needed to prevent gingival display. When short clinical crowns are present, tissue alteration in the form of a gingivoplasty should be completed to obtain esthetic crown lengthening. In general, vertical maxillary excess cases are usually treated with a maxillary impaction via Le Fort I osteotomy.

Generalized Botulinum Toxin Type A Postoperative Instructions

Postoperative care is very important with BTX-A patients because deviation from the following instructions may lead to increased complications:

1. Patients should be instructed not to touch or massage the injected areas for a minimum of 4 hours. This will prevent the dispersion of BTX-A into adjacent sites and allow the BTX-A to penetrate the targeted area for ideal effect.
2. Patients should restrict physical activity for a minimum of 24 to 48 hours because this will minimize inflammation.
3. Patients should avoid alcohol and smoking. Excessive perspiration (e.g., exercise, sauna) should be avoided because tissue healing may be affected.
4. Patients should be instructed to refrain from lying down for at least 4 hours after injections in the face because this may alter the dispersion of the BTX-A.
5. Patients should be educated on potential bruising, redness, and swelling, which are common after the injections. These side effects usually will resolve within 7 to 10 days.
6. Patient education is important on expectations because results may not be immediate. Usually changes will be seen as early as 3 to 7 days, with maximum results after 14 days.

Generalized Contraindications to Botox

Generalized contraindications to Botox include[32]:

- Psychologically unstable patients or patients who have questionable motives and unrealistic expectations
- Individuals who are dependent on intact facial movements and expressions for their livelihood (e.g., actors, singers, musicians, and other media personalities)
- Patients afflicted with a neuromuscular disorder (e.g., myasthenia gravis, Eaton-Lambert syndrome, tardive dyskinesia, stroke)
- Individuals who are allergic to any of the components of BTX-A or BTX-B (i.e., BTX, human albumin, saline, lactose, and sodium succinate) or eggs
- Patients who are currently taking specific medications that may interfere with neuromuscular impulse transmission and may potentiate the side effects of BTX (e.g., aminoglycosides, penicillamine, quinine, and calcium blockers); drug classes that have been shown to affect BTX-A include anticholinergic drugs, muscle relaxants, other botulinum neurotoxin products, dopamine-blocking drugs, and some over-the-counter vitamins such as vitamin E, fish oils, Omega 3 fatty acids, and coenzyme Q_{10}
- Pregnant or lactating individuals (BTXs are classified as pregnancy category C drugs)
- Patients with presence of infection at the proposed injection site

Generalized Complications to Botox

Generalized complications to Botox include:

- Migration of BTX-A into associated muscles near the injection site
- Headache or flu-like symptoms
- Discomfort or pain at injection site

● **Fig. 40.15 Gummy Smile Technique.** (A and B) Have patient smile as large as possible and document with photos. (C) Injection site is cleaned with alcohol wipe. (D) Palpate for the levator labii superioris alaeque nasi muscle and mark with tissue pen bilaterally. (E) Have patient smile and verify vertical movement of marked areas. (F) Draw up two separate tuberculin syringes with 1 to 2 U of BTX-A.

- Spread of BTX-A toxin effects, which spread to unwanted muscle or anatomic areas; this is most likely a result of the incorrect injection site or too great a volume administered
- Breathing or swallowing complications that may occur immediately or weeks after injections
- Swelling, rash, headache, local numbness, pain at injection site, bruising, respiratory problems, or allergic reactions
- Antibiotics have been shown to shorten the length of duration of BTX-A

Injectable Fillers

Another pharmacologic agent that is becoming increasingly popular in implant dentistry is dermal fillers. In the past, injectable fillers such as liquid silicone and bovine collagen were used to replace or enhance the volume of subcutaneous tissue. However, these products exhibited a high incidence of allergic and foreign body reactions. Today, many fillers without the side effects that were associated with the earlier agents are on the market. These

Fig. 40.15, cont'd (G) Inject 1 to 2 units into levator labii superioris alaeque nasi muscle bilaterally by inserting needle halfway the depth of the needle. (H and I) After 2 weeks the patient should be evaluated for symmetry and adjusted if needed.

newer filler products are classified as either "permanent" (e.g., polymethylmethacrylate [PMMA], calcium hydroxyl appetite, and expanded polytetrafluoroethylene) or "nonpermanent" (e.g., collagen or hyaluronic acid). Currently, the most commonly used fillers in dentistry are hyaluronic acid products such as Juvéderm (Allergan) and Restylane (Medicis).[33] These filler products have the advantage of being supplied in various viscosities, are easy to handle, have safe antigenicity, and effects can be reversed or dissolved using hyaluronidase (reversal agent) (Table 40.2).

Significant advances in the injectable dermal filler markets have led to a growing interest and increased usage. These minimally invasive injectable procedures have been geared toward the treatment of facial aging and facial enhancement; however, they are becoming more popular in dental implant-related areas. Approximately 3 million soft tissue procedures were performed in the United States in 2016, of which the majority were of hyaluronic acid–based fillers.[34]

With respect to dental implant patients, many patients are at an advanced age, with associated facial aging symptoms. Therefore the implant clinician must consider the benefits of rejuvenation techniques for maximizing the cosmetic outcomes in association with the implant procedures. In today's implant practice, the standard is for the implant dentist to consider the benefits of facial volume restoration when performing implant surgery on patients who may benefit from these products.

Hyaluronic acid fillers have become popular in the United States and global markets because they are user friendly, are stable at room temperature, are available in single preloaded syringes that require no preparation, are relatively inexpensive, and have the ability to be reversed with hyaluronidase. Additional advantages include they exhibit longer duration of action in comparison with collagen preparations and require no allergy testing.

Hyaluronic acid is an anionic, simple nonsulfated glycosaminoglycan widely found throughout connective, epithelial, and neural tissues. The natural hyaluronic acid contributes to tissue repair via cell hydration and lubrication. With age, the hyaluronic acid in the skin decreases, which results in decreased dermal hydration. If the skin is exposed to excessive ultraviolet B rays, cells within the dermis will induce the loss of hyaluronic acid from dermal tissue, resulting in photoaging.

Hyaluronic acid has a large particle size that leads to its inherent hydrophilic nature, thus allowing it to retain large amounts of water (can absorb up to 1000 times its molecular weight). When injected under the skin the hyaluronic acid fillers attract and bind water, thus providing volume to the skin. Because of its nonimmunogenic nature, it is devoid of many of the allergenic collagen fillers that were prevalent in the past.

The modern hyaluronic acid–based fillers are created by crosslinking the hyaluronic acid chains by conjugation with butanediol

TABLE 40.2	**Available Dermal Fillers**	
Material	**Brand Name**	**Duration and Biodegradability**
Autologous fat		Temporary and biodegradable
Hyaluronic acid	*Restylane®, Restylane Perlane®, Restylane Lipp®, Restylane Touch®, Restylane Vital®* Macrolane® 20, 30

• **Fig. 40.16** Available Dermal Fillers (Allergan, Irvine, Calif.).

diglycidyl ether. The cross-linked hyaluronic acid may be processed in various ways that yield homogeneous gels (the Juvéderm family) or suspensions of particles in gel carriers (NASHA Restylane). Therefore, each type of hyaluronic acid filler contains varying amounts of hyaluronic acid and through the various cross-linking processes, different properties of gels and varying degradation rates result (Fig. 40.16).

Mechanism of Action

The use of hyaluronic acid stimulates cell proliferation, migration, angiogenesis, and reepithelialization, and reduces collagen and scar formation.[35] In comparison with collagen injections, hyaluronic acid products do not require preinjection testing and produce relatively reproducible, longer-lasting results.[36]

How Supplied and Preparation

Currently, there are three major companies, Allergan, Medicis, and Merz, that have multiple hyaluronic acid fillers on the market. There is no universal filler that is appropriate for every application or for every patient. It is important to understand the physical properties of the fillers and how they interact for predictable clinical outcomes. Each of the major brands have multiple hyaluronic acid options in their lines that are specifically designed for different treatment sites. It is important to properly understand and follow the indications for usage for each hyaluronic acid filler being used. Some of the more common dermal fillers include:

Restylane (Sub-Q, Uppsala, Sweden) was the first hyaluronic acid product sold in the United States. Restylane is supplied as a gel with a particle size of 400 μm. This product is most commonly used to treat nasolabial folds, the lips, and the oral commissures. It can also be used for cheek augmentation and to improve deformities of the chin and prejowl sulcus. However, it is not generally used for the treatment of fine lines.

Perlane (Sub-Q, Uppsala, Sweden) is a hyaluronic acid product of nonanimal origin. It has a large particle size (1000 μm) and is used to treat moderate-to-severe wrinkles and folds. This product contains 0.3% lidocaine to decrease injection discomfort.

Juvéderm (Allergan Inc., Santa Barbara, Calif.) has many advantages over Restylane. It is usually softer and produces fewer lumps in the skin when injected close to the surface. Juvéderm is popular in correcting slight or moderate nasolabial folds in patients with fine skin. It is also used for lip enhancement and to treat minor defects in facial contours. Juvéderm has multiple
• **Fig. 40.17** Photo of general indications for dermal fillers. (*From Aicken M. Dermal filler doses.* Aesthetics. *2017;4:41.* © Aesthetics Media Ltd)

sublines of products with different viscosities. One of their recent products is Juvéderm Volbella, which is a soft, smooth gel used to increase lip fullness and correct perioral lines. Another popular Juvéderm product is Juvéderm Voluma, which is used for the cheek area and for midfacial volume loss. Juvéderm Vollure is commonly used in nasolabial folds and perioral restoration.

Restylane Lipp (Allergan Inc., Santa Barbara, Calif.) is a specific hyaluronic acid gel that is designed for lip augmentation. The benefit of this material is that it lasts approximately 12 months; however, it must be homogenously distributed. Injecting excessive volume may lead to the inability of massage to redistribute the material.

BELOTERO® (Merz) is a high-quality hyaluronic acid dermal fillers with patented CPM® (Cohesive Polydensi ed Matrix) technology that integrates easily to smooth various tissues. It is mainly used for wrinkles or fine lines as well as restoring facial volume.

Versa (Revanesse) hyaluronic acid is for nasolabial folds in mid to deep dermis.

Indications

The main indication for the use of dermal fillers is for facial rejuvenation. Another popular area to use Dermal fillers are used to correct volume deficiencies to enhance facial contours. One of the most common areas is the nasolabial fold, which forms a pronounced furrow as patients age. Specifically, in implant dentistry the use of dermal fillers for black triangles is becoming increasingly popular. In addition, with respect to implant prosthetics, because of hard and soft tissue loss, dermal fillers are being used for lip augmentation, facial augmentation, and commissures for the treatment of angular cheilitis or a downturned smile (Fig. 40.17).

General Technique

A definite learning curve exists when injecting dermal fillers. It is imperative the clinician obtain adequate training and practice in performing these procedures. Depending on the anatomic area, there exists a variation in the amount of injected material, along with the depth and angle of injection. In addition, the clinician must understand the ideal dermal filling agent specific to the area of treatment. The viscosity of the material selected will dictate the gauge of needle used to deliver the dermal filler, with 30 gauge being the most commonly used. Lighter body materials often used in the lips may use a 32 gauge, while heavier bodied materials may require a 27 gauge. Microcannulas have grown increasingly

popular because they yield advantages such as fewer injection points, leading to less trauma to the tissue and blood vessels.

Injection Technique

There exist two general techniques for injecting dermal fillers into tissue:

Retrograde technique: Needle is advanced and syringe plunger is depressed as the needle is withdrawn.

Anterograde technique: Plunger is depressed as soon as needle is placed subdermally so the filler elevates the subcutaneous tissues, which reduces the incidence of vascular perforation.

Specifically, there are a number of detailed injecting techniques that have been developed over the years. Each of the following techniques allow for a tailored approach which is specific for the anatomic location and clinical outcome expected. Some of the more common techniques include linear threading, fanning, serial puncturing, or cross-hatching. A combination of multiple techniques is often used.

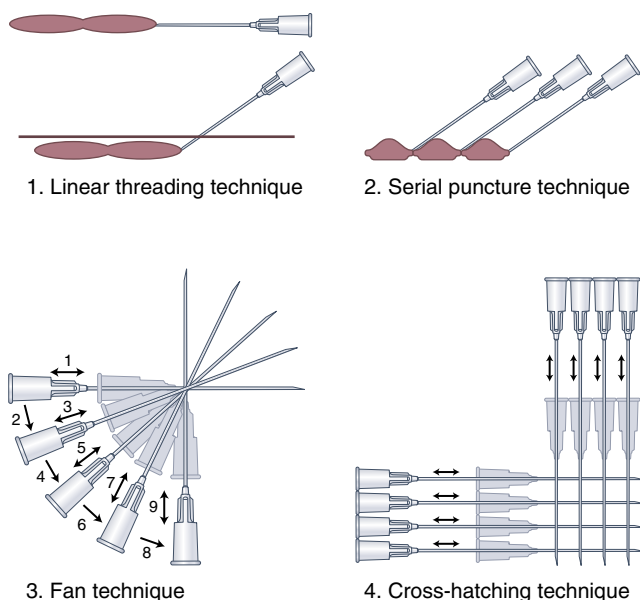
1. *Linear threading:* The full length of the needle is inserted into the tissue and the filler is injected as the syringe is slowly retracted. This technique results in the filler remaining in the location of the injection, therefore not spreading or dissipating throughout the tissue. The linear threading or "tunneling" technique is ideal for straight, narrow lines and wrinkles.

2. *Serial puncture:* Multiple injections are placed serially along the length of the treatment so the filler will merge in a continuous line. This technique is usually indicated for small, fine lines and wrinkles.

3. *Fan technique:* One line of the filler material is injected by the linear threading technique; then the direction is changed and injected along a new line.

4. *Cross-hatching:* The linear threading technique is used at the periphery of the treatment area; the needle is withdrawn and is inserted adjacent to the first site and the procedure is repeated. This method is carried out continuously at right angles to the original line (Fig. 40.18).

Duration of Action

In general, temporary dermal fillers usually last from 6 to 12 months; however much variation exists depending on the treatment location, patient's anatomy, and muscle use. Newer temporary fillers are coming onto the market that have longer durations, ranging from 18 months to 24 months.


● **Fig. 40.18** Dermal Filler Techniques. (1) Linear threading; (2) serial puncture; (3) fan; and (4) cross-hatching.

1. Linear threading technique
2. Serial puncture technique
3. Fan technique
4. Cross-hatching technique

Permanent Fillers

With the scope of procedures increasing with soft tissue augmentation, an increasing demand for permanent fillers is becoming more prevalent. The U.S. Food and Drug Administration defines permanent fillers as materials that are composed of nonabsorbable or permanent materials.[9] Permanent fillers are advantageous in providing long-term results; however, they carry the potential for irreversible complications. Therefore these agents require clinicians with experience and a higher level of expertise. Currently, in the United States, the available permanent fillers are PMMA and liquid injectable silicone. The use of liquid injectable silicone and PMMA is advantageous because they require no maintenance procedures that result in increased inconvenience, cost, and pain. The main disadvantage of permanent fillers is that they cannot be reversed or removed easily. The postoperative side effects associated with permanent fillers tend to be far greater than temporary fillers. A second disadvantage of permanent fillers is their lack of adaptability or modification as facial tissues change shape.[37]

Dermal Filler Use in Implant Dentistry

1. Black triangle
2. Lips
3. Face/cheek augmentation because of midfacial volume loss
4. Commissure (downturned smile and angular cheilitis)

Black Triangles

The soft tissues adjacent to a dental implant ideally need to be in harmony with adjacent teeth and/or implants. Unfortunately, especially in the maxillary anterior region, it is not uncommon for there to be a lack of papilla tissue (black triangle), resulting in non-ideal esthetic and functional issues. Papilla tissue may be lost from trauma, tooth loss, lack of adjacent contact area, or associated bone loss. The reconstruction of interdental papilla is a complicated and difficult periodontal treatment. There exist very limited options in the surgical treatment of this problem. To

● **Fig. 40.19** Black Triangle. Maxillary anterior between #8 and #9 resulting in an unesthetic result.

further complicate the situation, food particles often accumulate in the space and create esthetic issues (Fig. 40.19).

Etiology

In anterior regions of the dentition, the interdental papilla is usually of a pyramidal form, whereas in the posterior regions the papillae are more flattened in the buccolingual direction. Tarnow et al.[38] have shown that the level of the bony crest to the contact area has a direct correlation between the presence or absence of interproximal papillae. Their results showed when there was 5 mm or less from the contact area to the crestal bone, 100% of the time papillae were present. When the distance was 6 mm or greater than 7 mm, respectively, 56% or 27% of the time papillae were present. Other studies have shown papillae decrease with increasing distance between adjacent roots and have become more prominent with increasing distance from the contact area to the alveolar crest.[39]

Tarnow, in a second study, showed increased crestal bone loss when the interimplant distance was less than 3 mm.[40] Therefore papilla loss would occur when implants adjacent to each other are placed too close. However, many additional factors are significant in determining whether papillae are present, which include tooth size and shape, implant/tooth position, periodontal status, tissue biotype, and possible prosthesis overhang/misfit.

Nordland and Tarnow[41] have proposed a classification using three reference points that include the contact point, facial and apical extent of cement-enamel junction (CEJ), and interproximal extent of CEJ. From these criteria a classification was reported with four descriptions of papilla:

Normal: interdental papilla occupies embrasure space to the apical part of the interdental contact point
Class I: tip of interdental papilla occupies space between the interdental contact point and the most coronal part of the CEJ
Class II: tip of interdental papilla lies at or apical to the CEJ but coronal to the apicalmost part of the CEJ on facial aspect
Class III: tip of interdental papilla lies at level with or apical to the facial CEJ

Injection Technique. A hyaluronic gel is injected 2 to 3 mm apical to the tip of the papilla. The tissue is entered with the needle until bone is contacted. The needle is slightly pulled back and material is deposited to plump up the papilla. A gentle massage and molding of the filler is completed, ideally with a cotton swab. Approximately 0.1 to 0.15 ml of product is used routinely per papilla treated (Fig. 40.20). Usually, papillary injected need to be repeated every 6 months.

● **Fig. 40.20** Black Triangles Technique. (A) Obtain a photo of the black triangle area as a baseline. Anesthetize area to be treated via local infiltration. (B) Inject hyaluronic acid dermal filler into papilla with the bevel of the needle down and angled in the direction that the papilla needs to be bulked. (C) Shape papilla using cotton-tip applicators. Often multiple appointments are needed to achieve ideal outcome. (D) Immediate post-operative view. (E) 2-week post-operative view after two treatments.

Lips

When evaluating patients for comprehensive dental care involving dental implants, the lips are an often overlooked anatomic area. Lips are an essential part of the facial symmetry of the patient and esthetics. In society today patients are more esthetically conscious and view lips as needing to be fuller and more pronounced. When the vermilion lip is thin, facial harmony may be disrupted. With the aging process, there becomes a less exposed vermilion, consisting of increased loss of vermilion bulk and length.

Anatomy

The lips are referred to as the "Labium superius oris" (upper) and "Labium inferius oris" (lower). The anatomy of the upper lip extends from the base of the nose superiorly to the nasolabial folds laterally and inferiorly to the free edge of the vermilion border.
- **Fig. 40.21** Lip Anatomy.

The vermilion border is defined as the junction of the lips and the skin, and the area with the borders is termed the *vermilion zone*.

The vermilion border of the upper lip is known as the "Cupid's bow." Along the upper vermilion/skin border, two elevations of the vermilion form the Cupid's bow, which are raised vertical columns of tissue that form a midline depression called the *philtrum*.[42] The fleshy protuberance in the center of the upper lip is the tubercle, which is also known as the procheilon (Fig. 40.21).

Most Common Lip Issues

The most common patient complaint concerning the lips is a deflating vermilion, mainly from insufficient volume. Usually female lips are fuller and bulge forward in comparison with male lips. The most ideal approach to lip augmentation depends on the deficiency and the patient's esthetic expectations. Most commonly the upper lip is treated more often than the lower. In general, genetically thin lips are treated with a deeper-placed filler, followed by volume correction with a superficial filler arch. When cosmetic enhancement is required, a superficially placed filler for expansion of the vermilion is ideal.[42]

Injection Technique

Jacono[43] has postulated a classification of 15 anatomic lip zones that is used to direct fillers for lip augmentation and to customize lip contour and size. This intended technique allows for better direction of the filler placement to create more fullness and maintain shape. He maintains five major zones within the lip region: vermilion/white roll, subvermilion, peristomal, philtral column, and commissural. The subvermilion corresponds to the dry mucosal lip, and the peristomal at the junction of dry and wet mucosal lip. The vermilion/white roll can be further subdivided in the upper lip to include lateral, Cupid's bow apical, and central philtral zones, whereas the lower lip vermilion is divided into medial and lateral zones. The subvermilion is subdivided into medial and lateral zones, and the peristomal into medial and lateral zones (Fig. 40.22).

1. Anesthesia is completed with an infraorbital block on the maxilla and a mental or inferior alveolar on the mandibular arch.
2. Different techniques are advocated for lip filler placement. The serial puncture and linear threading are usually used when applying the antegrade or retrograde method. The choice of one technique over another is usually personal preference of the clinician.
- **Fig. 40.22** Lip Injection Anesthesia. (A) Maxillary infraorbital injection. (B) Mandibular mental nerve block.

3. Medium-depth fillers are usually used for lip augmentation, such as: (1) Restylane, (2) Juvéderm Ultra, and (3) Esthélis Basic with the use of a 30-gauge needle or a 27-gauge cannula (Fig. 40.23).

Lip Injection Complications Complications

The most common complications from lip filler injections include post-injection lumps and nodules. Improper technique or over-aggressive injection may lead to irregularity or lumpiness, which usually occurs when overcorrection is completed. If the filler product is placed too superficial, beading can occur, leaving an unesthetic result. If large nodules or lumps are present, hyaluronidase injections may be used to dissolve the product. Herpetic labialis reactivation may be prevented with oral antivirals (acyclovir, famciclovir, or valaciclovir) (Fig. 40.24).

Face

There are two common areas in the face that directly impact esthetics with dental implant patients. These include the nasolabial folds and marionette lines, which become more prominent
• **Fig. 40.23** Lip Technique. The lip augmentation is initiated by anesthetizing the upper and lower lips with bilateral Gordon Modified infraorbital blocks, mental blocks, (A) infiltration lateral to commissure of the mouth. (B, C, and D) Generally, begin by outlining the lips by injecting the subvermilion border starting at the commissure by placing retrograde threads. (E) Massage the outline using Vaseline to smooth.

Fig. 40.23, cont'd (F). After the outline is completed, place two linear threads through the philtrum columns. Massage to smooth using cotton-tip applicator. (G- H) Assess for asymmetries and correct with threading or serial punctures. (I and J) Fill the lower and upper body of the lips to your liking. Massage well to smooth any irregularities.

• **Fig. 40.24** Lip Complications: Edema and Ecchymosis.

• **Fig. 40.25** (A and B) Dermal filler sites within the facial area.

with the aging process and loss of teeth/bone. The problem with these areas is the loss of volume and that they develop folds that become unesthetic. The darks lines associated with these areas are from a "shadow," which results from an elevated lateral component and less elevated medial area (i.e., a step is present between the two tissue areas)[44] (Fig. 40.25).

Goal of Facial Fillers

Basically, the goal of facial fillers is reduction of the "steps," which will reduce the loss of the shadow and the appearance of the lines.

Nasolabial Folds/Nasolabial Crease

As patients age, the vertical lines at the corner of the mouth become more evident. The zygomatic retaining ligaments become lax and the malar soft tissue migrates downward along the direction of the Zygomaticus Muscles (ZM), which results in bulging against the nasolabial crease. The skin lateral to the crease will stretch and become redundant, which results in the formation of a prominent nasolabial fold.[45]

Anatomic Area. The nasolabial folds include two skin folds that are located from the side of the nose to the corners of the mouth, which is made up of bulging fat pads. Basically this is the area that separates the cheek from the upper lip. The extent of the fold is at the junction of the nasal alar, the cheek, and the upper lip. As the fold progresses inferiorly, it will be in either a straight, convex, or concave shape and ends below and lateral to the corner of the mouth.[46] This anatomic area has been termed "smile" or "laugh" lines.[47] When patients smile, multiple muscles are responsible for the accentuation of the fold. The ZM muscle will pull the cheeks superior and laterally, and the orbicularis oris muscle pulls the upper lip inferiorly and medially. The levator anguli oris will contract, which results in the skin fold crease deepening and becoming more prevalent. The nasolabial crease, or sulcus, is the facial line between the upper lip and cheek, extending from the alae nasi to the lip commissure.

Injection Technique. In the treatment of nasolabial folds, volume of material is paramount to restoring contour. Usually a thicker dermal filler material is utilized deeper into the tissue space. If superficial placement of a thinner dermal filler is used, lack of contour will result with minimal longevity. Most commonly, the retrograde linear threading technique is used along
the nasolabial fold. Caution should always be exercised in staying medial to the fold while depositing the product. If filler is injected laterally, deepening of the fold will occur resulting in esthetic issues.

Complication. Caution should be exercised in injecting in the subcutaneous layer lateral to the ala because the angular artery is most commonly located and the risk for vascular occlusion is higher (Fig. 40.26).

Marionette Lines

Marionette lines are associated with advancing age and are dependent on facial structure and anatomy. They are bilateral extensions of the nasolabial crease, which are directed inferiorly.

Anatomic Area. The marionette lines are formed mainly from the depressor anguli oris muscle and platysma muscle.

Injection Technique. The filler is ideally placed inferiorly in the subcutaneous layer and dermis in the oral commissure. To achieve a tissue eversion, inject in a fanning direction, which forms a tent pole effect. The use of the filler in the depressor anguli oris and mentalis and platysma below the mandibular margin allows the lateral oral commissure to elevate, restoring a more harmonious expression.

Complications. Injecting above or lateral to the lines will increase the shadowing effect by increasing the step (Fig. 40.27).
● **Fig. 40.26** Nasolabial Fold. (A) Nasolabial fold marked with skin marker. (B) Using the anterograde linear threading technique, dermal fillers are extruded along the nasolabial fold. (C and D) Be sure to stay medial to the fold while depositing product because extending laterally will result in deepening the fold. (E and F) Final medial injections.

Angular Cheilitis

Angular cheilitis is diagnosed by the presence of redness, inflammation, maceration, and fissuring of the oral commissures. Patients usually describe a painful, burning area at the corners of the mouth. In many cases mastication is impacted and range of opening is compromised.

Etiology. The etiology of angular cheilitis is multifactorial and involves many conditions that promote a moist environment within the oral commissure area. Deficiencies in iron, riboflavin (B_2), folate (B_9), cobalamin (B_{12}), or zinc have been associated with this disorder. In addition, a decrease in vertical dimension from tooth loss, bone resorption, or inability to wear prostheses leads to the development of angular cheilitis. In almost all cases *Candida albicans* contributes to the pathophysiology of angular cheilitis.

Injection Technique. Therapeutic use of dermal fillers in the lips and perioral structures has become increasingly popular in implant dentistry (Fig. 40.28). Treatment of the lips and perioral structures
• **Fig. 40.27** Marionette lines follow the line down from the nasal labial fold, ensuring that you stay medial to the fold again. (A) Fan across in an upward vector to lighten the marionette lines (B–D). Follow with fanning or cross-hatching above the marionette lines in an upward direction (E and F). Massage well to eliminate any bumps from the product.

yields various practical dental improvements in orthognathic soft tissue profile, retention of removable prosthetics, proper phonetics, asymmetric smiles, and loss of soft tissue profile due to missing teeth. In treating the oral commissures a significant decrease in angular cheilitis has been noted. Injection of dermal fillers has been shown to restore the commissure anatomy and decrease the sulcus area to minimize recurrence. However, the clinician must investigate all possible etiologies of the angular cheilitis and treat accordingly. Nutritional deficiencies and a collapsed vertical dimension of occlusion have been associated with angular cheilitis. Anticandidal treatment may be used alone or in conjunction with dermal filler treatment. The injection technique for angular cheilitis includes having the patient opening wide, and injection of dermal filler directly into the commissure with a linear thread technique. The threading or fanning technique may be used also under the lower lip in an upward vector to increase elevation of the tissue.

Reversals for Dermal Fillers

Dermal fillers are advantageous because they exhibit reversibility with an enzyme, hyaluronidase. Hyaluronidase is a naturally occurring protein in the body and will catabolize hyaluronic acid usually within 24 hours through hydrolysis. This reversal agent is mainly used when overcorrection or misplacement of the dermal filler occurs.

Complications With Dermal Fillers

Dermal fillers are associated with complications, some that can be quite severe. A through medical history is advised before injecting dermal fillers. A history of hypertrophic scars or keloids may contraindicate the procedure. A history of herpes simplex infections may require premedication with valacyclovir

• **Fig. 40.28** Angular Cheilitis. (A) With the patient opening wide, inject directly into the commissure with a linear thread. (B) Follow with linear thread in the lower lip line. Massage lip to smooth. (C) Optional fanning below to fill any depressions. (D) Often this treatment is done in combination with injecting the depressor anguli oris with botulinum toxin type A.

or other antivirals before lip injections. Patients who take anti-coagulant therapy or certain vitamins should be treated with caution because of increased risks associated with bleeding and bruising.

The most common complication of dermal fillers includes an asymmetric appearance caused by too much material being injected into a particular site. Clinicians should always attempt to undertreat specific areas because overtreatment is extremely difficult to remedy.

More common local complications appear as redness, inflammation, and bruising. This often occurs secondarily from trauma caused by the injections. Erythema usually resolves within hours; however, edema may last for multiple days. Edema may be reduced by minimizing the number of injection sites, using epinephrine-containing anesthetics, and applying ice/cold compresses after the procedure. It has been suggested that using a product such as arnica (homeopathic herb) may reduce the effects of the trauma from the injections.

Injection to the proper angle and depth is of utmost importance; being too superficial may result in the "Tyndall effect," where the skin appears bluish at the injection site. Tissue necrosis may also occur if the filler occludes a blood vessel. In the event of suspected tissue necrosis, immediate reversal with hyaluronidase is advised and close postoperative care is imperative.

Complications[48]

Early Onset (Immediate > 15 Days)
Due to the procedure, not filler related
   Erythema
   Pain bruising
   Swelling at injection site
   Infection (viral or bacterial) can be related to filler due to biofilm
Due to filler behavior and placement technique
   Overcorrection
   Misplacement
   Hypersensitivity (type IV reaction)
   Vascular occlusion
   Granuloma

Late Onset (> 15 days)
Due to the procedure, not filler related
   Chronic infection
   Itching
Due to filler behavior and placement technique
   Skin discoloration
   Nodules (product accumulation)
   Hypertropic scarring
   Hypersensitivity (type IV reaction)

Conclusion

The use of Botox and dermal fillers have been shown through the literature to be valuable adjuncts in implant dentistry. These pharmacologic agents are successful in treating many facial and maxillofacial musculature dysfunctions as they provide an overall conservative, minimally invasive treatment approach. Most notably, Botox may be indicated for the treatment of parafunctional habits that may be detrimental to the overall dental implant success. In addition, the use of Botox in the treatment of various temporomandibular joint syndrome/temporomandibular dysfunction (TMJ/TMD) disorders and excessive tissue display (gummy smiles) have been shown to successful. The use of dermal fillers have become popular for facial and cheek soft tissue augmentation as well as for the treatment of angular cheilitis. With respect to dental implants, papilla loss leading to the formation of black triangles may be treated with dermal fillers leading to the reversal of the open spaces. Therefore, with the advances of technology and science, the use of Botox products as well as dermal fillers are becoming more popular and have become a mainstay in implant dentistry.

Dental Implant Maintenance

41

Peri-Mucositis and Peri-Implantitis Diagnosis, Classification, Etiologies, and Therapies

JON B. SUZUKI AND KEVIN R. SUZUKI

Implant dentistry has evolved into an evidence-based, clinical science with well-documented research to validate previously unsupported clinical practice procedures. Significant efforts that focus on the biology and biomechanics of implant dentistry have helped to develop and refine clinical techniques based on peer-reviewed findings. However, despite improved and predictable clinical successes in implantology, peri-implant diseases have been diagnosed with increasing incidence. The evolution of research and understanding of biologic concepts in implant dentistry and implant rescue has caused many areas of debate and controversy. Innovative theories have been developed that have resulted in technique modifications. Science has spurred implant dentistry to new pinnacles of success, which is highly based upon essential principles of periodontal regeneration.

The tremendous expansion of knowledge in implant dentistry has created new ideas and terminology that is redefined based on new applications to implant dentistry. In many instances new research may contradict established paradigms. It may be challenging for clinicians to select correct protocols, procedures, armamentarium, and techniques. As materials and techniques are further investigated, dogma may undergo criticism and controversy. Experienced clinicians consistently introduce and refine techniques and instruments to maintain clinical excellence as technology and research advance.

One area of expansion of knowledge and views relates to the maintenance of dental implants. Early research explored techniques and instruments that were current for the methods and materials of that era. Although many of those implants are still in function in patients today, research and advances in technology have given us newer materials, implant design, and protocols to maintain dental implant health.

An understanding of the mucoepithelial implant attachment is essential before commencing maintenance procedures. Controversies and parameters for probing and crestal bone loss are important for clinicians to recognize. There are anatomic and histologic differences between the attachment apparatus of teeth compared with implants that are osseointegrated. The bacterial plaque biofilm on these implant-tissue attachments may be significant to clinical success.

When the clinician understands the parameters of implants and teeth, specific maintenance plans may be established for the patient to minimize the possibility of developing peri-implant disease. Clinicians should inform patients of expectations and outcomes during treatment, and demonstrate oral hygiene options appropriate during each stage. Patients need to recognize the importance of maintenance protocols, and clinicians should assess compliance to home care routines. Patients also should be competent to perform home maintenance. These strategies would certainly minimize risks for peri-implant disease and implant failures.

As the acceptance of and demand for dental implants increase, the need to understand the importance of maintenance as it relates to long-term implant success also increases. The role of the dental hygienist in implant maintenance and care as well as diagnosing peri-implant disease is increasing and becoming more defined.

Implants and associated prostheses are much different from natural teeth and may require adjunctive procedures and instruments for professional and patient care. Complications may arise when clinicians fail to comprehend these differences, because they may adversely impact the implant's outcome, increasing the morbidity of treatment. The techniques and protocols used must be effective at removing biofilms and accretions, and procedures performed by patients and clinicians should avoid damage to the components of the implant, abutment, restoration, and associated tissue.

Establishment and maintenance of the soft tissue seal around the transmucosal portion of the implant enhances the success of an implant. This barrier is fundamentally a result of appropriate wound healing and connection of epithelial attachments. The maintenance of healthy peri-implant tissues contributes to implant success and minimizes peri-implant disease. In addition, tissues free of inflammation and a biofilm-controlled implant sulcus will support the patient's general and oral health.

Peri-implant Disease

One important, but often neglected, component of comprehensive dental implant treatment is the postprosthetic evaluation and treatment of peri-implant issues. There are many conflicting opinions and controversies on the diagnosis and treatment of these complications. Failure to effectively and promptly diagnose and treat peri-implant disease with dental implants leads to an increase in implant and prosthetic failure.

Dental professionals are initially trained to have a firm understanding of the disease processes associated with the natural dentition. A variety of tests, indices, and radiographic signs are used to determine the health of a natural tooth. Dental implants and their related prostheses have fundamentally different relationships to the oral environment than teeth, and these differences necessitate a change in diagnostic protocol for the determination of health. Failure to understand these processes may lead to undiagnosed disease states and potential morbidity of the implant system.

The implant clinician must have a strong understanding of the anatomic and histologic differences between natural dentition and the dental implant as they pertain to periodontal structures. By having this foundation, the clinician may appreciate these necessary differences and will be better equipped to effectively diagnose peri-implant disease processes. With the increase in the number of dental implants being placed each year, a resultant increase in the incidence of peri-implant disease has been seen. Two conditions of peri-implant disease are ***peri-implant mucositis*** and ***peri-implantitis***.[1] The 6th European Workshop on Periodontology in 2008 concluded that peri-implant diseases are infectious in nature and are defined by "changes in the level of crestal bone, presence of bleeding on probing, and/or suppuration; with or without deepening of the peri-implant pockets."[2]

In differentiation between these two peri-implant conditions, both have been shown to be localized around implants and demonstrate features similar to adult chronic periodontal disease.[3] These conditions may be analogous to gingivitis (peri-mucositis) and periodontitis (peri-implantitis). However, biologic differences exist between the natural teeth and implants. Basically, peri-implant tissues are more susceptible to infections, due to differences in soft tissue attachment and biofilms that may advance to the alveolar-implant complex (see discussion in Chapter 42).[4]

Gingivitis is a bacteria-induced inflammation involving the region of the marginal gingiva above the crest of bone and adjacent to a natural tooth. The most common forms are associated with plaque and may be classified as: (1) acute necrotizing, (2) ulcerative, (3) hormonal, (4) drug induced, or (5) spontaneously occurring.[5] These categories may also relate to the gingival tissues around an implant.[6,7] The classification of gingivitis and periodontitis has currently been updated by the American Academy of Periodontology.[8]

The bacteria responsible for gingivitis around a tooth may affect the epithelial attachment, without loss of connective tissue attachment. Because the connective tissue attachment of a tooth extends an average of 1.07 mm above the crestal bone, at least 1 mm of protective barrier above the bone is present. In contrast, no connective tissue attachment zone exists around an implant because there is an absence of connective fibers that extend into the implant surface. Therefore no connective tissue barrier exists to protect the crestal bone around an implant.[9]

Periodontitis around teeth is characterized by apical movement of junctional epithelium and periodontal attachment, coupled with loss of alveolar bone. Bacteria are thought to be responsible by stimulating the body's immune response, which results in an overall resorptive effect on the periodontal attachment apparatus. The American Academy of Periodontology (2018) recognizes stages of periodontitis: stage 1, stage 2, stage 3, and stage 4. Former specific subtypes[10] for each category such as adult chronic periodontitis, rapidly progressive periodontitis, localized juvenile, and prepubertal periodontitis are now encompassed within stage 1, stage 2, and stage 3 of periodontitis.

In contrast with teeth, early crestal bone loss around an implant body prosthetically may not always be caused by pathogens. In many cases, the associated bone loss may result from stress factors too great for the immature, incompletely mineralized bone-implant interface or an extension of the biologic width onto a smooth metal crest module.[11] Therefore, an implant may exhibit early crestal bone loss with a different mechanism or cause, compared with natural teeth. However, bacteria in some cases may be the primary factor, because anaerobic bacteria have been observed in the microgap between the implant and the abutment or in the sulcus of implants. This is especially evident when sulcus depths are greater than 5 mm (Box 41.1).[12] A systematic review[13] highlights potential etiologies of early crestal bone loss around recently osseointegrated implants.

In summary, periodontal disease that develops around dental implants has been classified into two separate entities: peri-implant mucositis and peri-implantitis. Peri-implant mucositis is defined as a reversible inflammatory reaction in the peri-implant tissues surrounding an implant. Peri-implantitis is defined as an inflammatory reaction, with loss of supporting bone around an implant (Fig. 41.1).

The Role of Biofilm in Peri-Implant Disease

The oral biofilm originates from bacteria and saliva, which result in sticky masses of bacteria with a polysaccharide matrix that accumulate on hard and soft surfaces in the oral cavity. The bacterial and biofilm formation may adhere to any implant surfaces in the oral cavity and have been reported to result in pocket formation and loss of the supporting bone.[14-16] Di Giulio et al.[17] determined that biofilm is one of the major causes of implant failure. The Consensus of the 7th European Workshop on Periodontology stated that peri-implant infections are always caused by plaque and its by-products (i.e., biofilm).[18]

The role of biofilms has been heavily studied and has been reported to be responsible for approximately 65% of peri-implant diseases.[19] After exposure of the implant surface to the oral cavity, a pellicle is formed in less than 30 minutes.[20] The pellicle is derived from the saliva, various bacteria present in the oral cavity, and also host tissue products. After formation of the pellicle, bacterial attachment occurs by cell-to-cell adhesion on the implant surface.[21] Most bacteria use biofilm as the primary method of

growth, because they facilitate nutrient exchange and prevent competing microorganisms.[22] Studies have shown the process of biofilm colonization is the same on teeth as with dental implants.[23]

Therefore the most ideal solution to prevent microbial infections is to decrease the colonization of bacteria on implant surfaces. Unfortunately, many characteristics (e.g., material, surface roughness) of prosthetic and implant surfaces directly affect the bacterial adhesion and biofilm formation.[24]

For reversal of the peri-implant disease process, the biofilm must be removed with mechanical debridement or chemical obliteration. If not removed, mature plaque will form. It has been shown that bacteria will migrate from teeth to implants and from implant to implant. Similar to teeth, clinical findings of failing implants include inflammation, pocket formation, and progressive bone loss.[25]

The microorganisms may initiate an inflammatory release of cytokines that will enhance accumulation of neutrophils to the implant lesion. This process will continue to attract more leukocytes and continue to facilitate more peri-implant tissue damage and inflammation.[26,27] If the inflammation progresses, it will lead to peri-implantitis, with the characteristic feature of bone loss around the implant. If left untreated, stromal tissue cells may also propagate, leading to an increase in infiltrates of proinflammatory cells that promotes further tissue breakdown,[28-30] which may eventually lead to loss of osseointegration, implant mobility, and ultimately implant failure.[31-33] In addition to the results of a

systematic review, there is evidence that the pathogens *Prevotella intermedia*, *Campylobacter rectus*, *Aggregatibacter actinomycetemcomitans*, and *Treponema denticola* have been implicated in the pathogenesis of peri-implantitis.[34,35]

Current chemotherapeutics cannot penetrate thick biofilm, because rough surfaces have been found to hold more biofilm than smooth surfaces.[36] Bacterial deposits produce exotoxins and lipopolysaccharides (endotoxins) that inhibit fibroblast and osteoblastic growth, and thus prevent proximal regeneration onto the implant surface. Although it is impossible to guarantee 100% sterility of exposed implant surfaces, the body is capable of removing small amounts of bacterial deposit via host defense mechanisms.[37]

Carefully removing macrodeposits of plaque biofilm and irrigating with antimicrobial solution is generally sufficient to allow a favorable environment for new attachment formation. It is recommended that patients complete a full-mouth debridement to reduce bacterial colonies, including plaque biofilms on exposed implant surfaces (Box 41.2).

Peri-implant Mucositis

Peri-implant mucositis is an inflammatory condition of the soft tissue surrounding an implant, which is similar to gingivitis around natural teeth. In both animal and human studies, peri-implant mucositis has been shown clinically and histologically to be comparable to gingivitis around natural teeth.[184] This has been defined

• **Fig. 41.1** (A) Spongiotic gingivitis exhibiting erythematous marginal tissue with cyanotic tissue. (B) Periodontitis: mandibular anterior exhibiting severe horizontal bone loss. (C) Peri-mucositis: erythematous buccal gingiva with associated bleeding around implant crown. (D) Peri-implantitis: significant bone loss with erythematous tissue with significant plaque accumulation. (*From Suzuki JB, Misch CE. Periodontal and maintenance complications. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

as a reversible condition with no loss of attachment or bone loss. The prevalence rate of peri-implant mucositis (bleeding on probing and no loss of bone) in systemic reviews has been shown to be approximately 30% of implants and 47 % of patients.[38] However, other studies have reported the incidence to be as high as 80% of patients and 50 % of implants observed. Ferreira et al. reported a prevalence of 64.6% at the patient level and 62.6% at

implant level.[39] Clinically, bleeding on peri-implant probing with mucositis may be present without suppuration. If peri-mucositis is allowed to progress, peri-implantitis may result, which includes loss of bone and possible loss of osseointegration, similar to loss of attachment and bone with periodontitis. The relationship between plaque accumulation and peri-implant mucosal inflammation has been proven through numerous studies (Fig. 41.2).[40-42]

Etiology

Most cases of peri-implant mucositis are due to poor oral hygiene, inability to clean the implant or prosthesis, nonideal implant position, poor fit of the prosthesis, and retained cement. Poorly placed implants or overcontoured prostheses may lead to difficulty or inability to properly clean the implants (Fig. 41.3). In addition, peri-implant mucositis may also be caused by titanium alloy hypersensitivity. Most dental implants today are covered by a titanium dioxide layer that gives the implant a high surface energy that facilitates the interaction between the host tissues and the dental implant. When the implant becomes exposed to the oral environment, a lower surface energy may provoke a type IV hypersensitivity reaction that may contribute to peri-implant mucositis.[43]

Prevention

Because of the high prevalence of peri-implant mucositis, it is imperative that the clinician be able to assess the risk profile of each patient and integrate these considerations when treatment

planning is initiated. A consensus report by the Academy of Periodontology has shown risk factors to include poor oral hygiene, history of periodontal disease, smoking, retained cement, and occlusal disharmonies. Therefore, a comprehensive medical history should be evaluated for any risk factors and the patient should be informed of possible associated complications.

Tobacco smoking leads to the end product of nicotine and nornicotine that increases cytokine levels and reactive oxygen species. Increased smoking has been shown to result in increased levels of alveolar bone loss with dental implants.[44] Diabetes mellitus has also been shown to increase the risk for peri-implant disease compared with healthy individuals.[45] This is due to elevated blood sugar levels that compromise wound healing and the host immune system.

Management

Peri-implant mucositis is a reversible inflammatory process. However, if not treated properly, the persistent inflammatory condition may progress to peri-implantitis that results in irreversible bone loss. In most cases peri-implant mucositis is a precursor for the development of peri-implantitis.[46]

Nonsurgical (closed debridement) mechanical debridement to remove plaque and calculus from the implant surface using mechanical instruments such as scalers and curettes coupled with antimicrobial rinse therapies is the primary therapeutic approach for peri-implant mucositis.[47]

In a systematic review, nonsurgical mechanical debridement is effective in the management of peri-implant mucositis. Use of antiseptics increased the observed outcomes.[48] It is crucial to implement a comprehensive patient and professional oral hygiene program to manage peri-implant mucositis. Power brushes, interproximal and irrigation power devices, dentifrices, and antimicrobials have been shown to be highly effective in the management of peri-implant mucositis.

Professional Mechanical Debridement

For the removal of supragingival and subgingival biofilm and bacteria, debridement of the exposed implant surface and implant abutment must be completed. There exist many different debridement systems.

Curettes. The selection of scalers for titanium implant debridement is important to minimize surface changes after treatment. Various types of curettes are available for debridement procedures (Fig. 41.4):
• **Fig. 41.5** Peri-mucositis Treatment. (A,B) Scaling technique around an implant with peri-implant inflammation.

- Titanium-coated curettes are specifically made for dental implant debridement because they have a similar hardness to the titanium surface and will not scratch or mar the surface.
- Carbon-fiber curettes are softer than the implant surfaces and will not damage the implant surface. These types of curettes are prone to fracture.
- Teflon curettes are similar to carbon-reinforced curettes and will not scratch the surface of the implant.
- Plastic curettes have been advocated as the instrument of choice to prevent damage from the implant surface.
- Stainless-steel curettes are much harder than titanium alloy and are not recommended for use around dental implants because they may alter the implant surface.[49]
- Amorphous resin scalers come with unfilled or filled resin. Unfilled resin scalers have no reinforcements for shape or stiffness, whereas filled resin fillers may use materials such as silica, graphite, or glass. These scalers have replacement tips on stainless-steel handles.
- Titanium brush burs insert into implant motors. They have a variety of shapes, allowing them to adapt around the implant or prosthesis surface circumferentially, around a single surface, and for groove cleaning. Brushes are used at 600 rpm and adapted against the implant surface to remove debris.

Hasturk et al. evaluated six different types of scaler materials to scratch surfaces of different brands of implants abutments, and they were compared with scanning electron microscopy. The results showed glass-filled resin curettes caused the most scratches, whereas the unfilled resin scalers had the least surface alteration. However, these studies are on smooth titanium abutments and not on the rough implant surface.[50]

There may not be clinical relevance regarding whether curettes scratch implant surfaces. Anastassiadis et al. reported that metal scalers do not readily scratch cementum; it is questionable that a titanium implant surface, which has a higher Mohs hardness, should be of any concern.[51]

Furthermore, scalers as a whole may be effective in removing large calculus particles or granulation tissues but are rather ineffective trying to navigate the perimeter and grooves of an exposed implant surface. For that reason, curette material may not be a significant concern, but rather the activity of curetting may be (Fig. 41.5).

Ultrasonic Devices

Ultrasonic devices with special polyetheretherketone-coated tips have been used to debride the implant surface. This tip is made of a plastic material with a stainless-steel core. This ultrasonic device allows the debridement of plaque and calculus, while leaving a smooth and clean surface.

Although metal tips are not recommended, plastic tips may be at an increased risk of shredding when cleaning around implant

grooves and threads. Tips made of PEEK material (Hu-Friedy, Chicago, Ill.) have been shown to be resistant to shredding and may be considered (Fig. 41.6).

Antimicrobials

Antiseptics are defined as antimicrobial substances that are non-damaging to living tissue/skin while reducing the possibility of infection, sepsis, or putrefaction. Several types of antiseptics are ready for dental use: chlorhexidine 0.12% or 0.2%, cetylpyridinium chloride, sodium hypochlorite 1.0%, hydrogen peroxide 3.0%, citric acid 40.0%, Ethylenediamine tetraacetic acid (EDTA) 24%, povidone-iodine 10%, and phenols/essential oils.[52,53]

For management of peri-mucositis, several qualities are needed for antiseptics to be effective: biofilm penetration, long substantivity, tissue biocompatibility, and low resistance. Removal of macrodeposits should be performed with scalers first.

Chlorhexidine applied on a cotton pellet and burnished against a machined surface has shown a 92.9% *Porphyromonas gingivalis* endotoxin reduction.[54] Povidone-iodine has high antiseptic capability but has a highly irritating effect if any residue comes in contact with an osseous structure. Several of the antiseptics and their effectiveness on *Staphylococcus epidermidis*, *Candida albicans*, and *S. sanguinis* have been investigated. Although sodium hypochlorite was most effective in the reduction of all three bacterial biofilms, it has the highest tissue toxicity. Hydrogen peroxide was active against only *C. albicans*, whereas chlorhexidine gluconate and phenols/essential oils had activity against only *Streptococcus sanguinis* and *C. albicans*[55] (Fig. 41.7).

Patient At-Home Mechanical Debridement

Implant patients must understand their role in maintaining their dental implants and implant prosthesis. An individualized home care assessment and protocol must be developed for each patient, and it must be customized according to the tissue condition, implant position, and type of prosthesis. Home care devices that have been shown to be safe around implant surfaces include toothbrushes (manual or powered), floss (e.g., plastic, braided nylon, coated, stiffened ends to clean under pontic areas, and dental tape). In addition, oral irrigators, interdental brushes, and end-tuft brushes may be used. (See Chapter 42 for a complete list of home care aids.) A strong home care regimen may significantly reduce the amount and composition of subgingival microbiota around teeth. This reduction most likely will translate to a decreased risk for periodontal disease initiation or recurrence. Furthermore, the decreased prevalence of periodontal pathogens in supragingival plaque decreases potential reservoirs of these species.[63]

Peri-implantitis

The American Academy of Periodontology has defined peri-implantitis as an "inflammatory reaction associated with the loss of supporting bone beyond initial biologic bone remodeling

• **Fig. 41.6** Ultrasonic scalers may be used to treat peri-mucositis.

• **Fig. 41.7** (A) Chlorhexidine: used as a rinse or locally applied (Peridex; 3M ESPE Dental Products, St. Paul, Minn.). (B) Local application of chlorhexidine to implant surface.

around an implant in function."[64] Peri-implantitis has been shown to exhibit similar microbial flora as chronic periodontitis. Although there is no consensus regarding microorganisms, Perez-Chaparro et al.[65] identified three commonly occurring pathogens associated with peri-implantitis: *Porphyromonas gingivalis*, *Treponema denticola*, and *Tannerella forsythia*. The dental implant may exhibit all the signs of peri-implant diseases, including exudate, increased pocket depths, and crater-like osseous defects, which are strictly localized around the implant. If left untreated, significant bone loss, infection, and mobility could result, leading to loss of implant osseointegration. Additional clinical signs include radiographic vertical bone loss greater than 2 mm, bleeding on probing (with or without exudate), mucosal swelling and erythema, and an absence of pain (Box 41.4). The crestal bone loss may be induced by stress, bacteria, or a combination of both. A systematic review on peri-implantitis[66] identifies acknowledged etiologies and related causes of peri-implantitis.

After bone loss from stress or bacteria occurs, the sulcular crevice deepens and a decrease in oxygen tension is present. Anaerobic pathogenic bacteria may become the primary promoters of the continued bone loss. An exudate or abscess indicates exacerbation of the peri-implant disease and possible accelerated bone loss. Studies have shown the prevalence rate of peri-implantitis has been found in 28% to 56% of subjects and 12% to 43% of implant sites (Fig. 41.9).[67]

Etiology

Peri-implantitis has been associated with a gram-negative anaerobic microbiota, similar to that found in severe periodontitis around natural teeth.[68] Peri-implantitis encompasses similar clinical signs of peri-implant mucositis, but loss of bone and attachment is observed. A stabilized implant that continues to exhibit loss of bone levels is indicative of peri-implantitis.

Biofilm

Although bacterial biofilm insult is identified as the main cause of peri-implant mucositis, peri-implantitis is considered to be initiated by stress factors caused by poor biomechanical forces. In addition, several other etiologic factors exist, such as poor implant placement, poor oral hygiene, residual cement, host response, poor implant surface, unfavorable osseous density, untreated periodontitis, alcohol excess, smoking, untreated endodontic lesions, diabetes, among others. Monje et al.,[69] in a systemic review, confirmed that peri-implantitis may be prevented with a strong peri-implant maintenance program, along with a comprehensive patient, clinical, and implant-related evaluation. They concluded a minimum recall and hygiene program be tailored to the patient's risk profiling and at a minimum of a 5- to 6-month interval.

Occlusal Stress

Unfavorable stress factors can initiate crestal bone loss, and bacterial biofilm challenges may further enhance the rate of osseous destruction. In recent studies, bacterial biofilms attached onto the surface of implants were shown to create a highly acidic environment that causes corrosion, pitting, cracking, etc.[70] Furthermore, recent studies have shed light on the release of titanium ions from the implant surface, which results in a significant increase in a local inflammatory response[71] (Table 41.1).

History of Periodontitis

Most long-term studies and systemic reviews have concluded that patients with a history of periodontitis had a higher incidence of peri-implantitis in comparison with periodontally healthy patients.[72,73] Papantonopoulos et al.[74] have reported on two implant phenotypes that are directly related to peri-implantitis. A peri-implantitis-susceptible phenotype was associated with fewer teeth and younger age, and was predominantly in the mandible. A peri-implantitis-resistant phenotype was mainly found in the maxilla.[74]

Smoking/Tobacco Use

Although many conflicting studies exist on the relationship between smoking and peri-implantitis, most reports have shown statistically significant differences between smokers and non-smokers. Rinke et al.[75] reported that smokers had an approximate odds ratio of 31.58 in development of peri-implantitis. The overall peri-implantitis rate in their study population was 11.2% and as high as 53% for patients who smoked and had a history of periodontitis.

Diabetes

The relationship between diabetes and periodontal disease is well established. Poorly controlled diabetes has also been associated with peri-implantitis.[76,77] Venza et al.[78] reported that the long-term prognosis for dental implants is more favorable when the patient's glycosylated hemoglobin (HbA_{1c}) is less than 7%.

Canullo et al.[79] proposed an evidence-based classification for different clinical subtypes of peri-implantitis, including: (1) surgically triggered peri-implantitis, (2) prosthetically driven peri-implantitis, and (3) plaque-induced peri-implantitis. They state that these three subtypes of peri-implantitis are separate, different entities that may be distinguished with predictive profiles. In addition, various risk factors can act synergistically with a clinical scenario, which make the causative factors more difficult (Table 41.2).[79]

Prevention

Home Care

An effective oral hygiene program is paramount to minimize peri-implant disease. This has been shown through various studies. Direct correlations between poor oral hygiene and peri-implant bone loss in a 10-year follow-up study were reported.[80] Other studies have shown a correlation with poor oral hygiene and a higher plaque score.[81] In addition, patients who have lost their teeth to periodontal disease are more susceptible to peri-implantitis.[82]

Professional Care

Thorough periodontal charting and review is essential. Patients with periodontitis must have this pathologic condition controlled before implant placement. Patients who do not demonstrate the
• **Fig. 41.9** **Peri-Implantitis.** (A and B) Clinical images depicting bone loss. (C) Radiograph showing significant bone loss around implant. (D) Cratering bone loss. (E) Implant failure caused by calculus formation.

ability to maintain oral hygiene need to be educated and put on stringent professional care regimens.

Prosthetic Design

A thoroughly evaluated cone beam computed tomography scan study with favorable biomechanical design for prosthetics is mandatory. Ideal implant position is paramount to allow for a properly designed prosthesis that is cleansable.

Cementation Technique

The meticulous use of cements when delivering a prosthesis is imperative, or the clinician can choose to use a screw-retained prostheses. If a cementable prosthesis is utilized, the clinician must take precautions to prevent retainment of cement. Conventional cementable techniques that are normally used for natural teeth are not recommended (See Fig. 41.5).

TABLE 41.1 Human Studies on Peri-Implantitis Treatment

Author	Procedure	Number of Patients and Implants and Time of Follow Up	Treatment	Outcome
Leonhardt et al 2003	Access surgery	9 patients 26 implants 60 months	Systemic antibiotics (according to micro-biologic analysis) + access surgery + decontamination of the implant surface using 10% hydrogen peroxide 0.2% CHX 2× a day rinse	Healing: 58% of the implants 7 implants lost 4/19 ongoing bone loss 6/19 bone gain Mean gingival bleeding was reduced from 100%–5% Disease progression at 2 other implants
Romeo et al 2007	Apically repositioned flap surgery + implant surface modification Resective surgery	19 patients 38 implants (11 hollow screw and 7 solid screw) 12–24–36 months	Systemic antibiotics (amoxicillin for 8 days) + full mouth disinfection 9 patients with resective surgery and 10 with resective surgery and modification of surface topography Implant surface decontamination with metronidazole gel, tetracycline hydrochloride, and saline	Radiographic assessment: Implantoplasty is an effective treatment procedure Significantly better results w/apical reposition flap surgery + implant surface modification
Behneke et al 1997	Bone grafts and bone graft substitutes surgery • Nonsubmerged	10 patients 14 implants 6 months–2 years	Irrigation with iodine + systemic antibiotics (Ornidazole 500 mg × 2 for 7 days) Implant surface treated with air powder and irrigation with saline 7 implants with 2–3 wall defects got bone chips and 7 implants with 1 wall defect got bone blocks	Clinical: (6 months/14 implants) BI: 2.4–0.3 PD: 5.9–2.3 mm Clinical: (2 years/5 implants) BI: 2.4–0.4 PD: 5.9–2.5 mm Radiographic: (3–12 months/14 implants) Average bone fill: 3 mm
Behneke et al 2000	Bone grafts and bone graft substitutes surgery • Nonsubmerged	25 implants 6 months to 3 years	Irrigation with iodine for 1 month + debridement with mucoperiosteal flap surgery Implant surface decontamination with air abrasive instruments for 30 seconds + saline irrigation + 7 bone chips and 18 bone blocks (Metronidazole 400 × 2 for 7 days)	Clinical: (1 year/18 implants) PD: 5.3–2.2 mm Clinical: (3 year/10 implants) PD: 5.3–1.6 mm Radiographic: (1 year/18 implants) Mean bone fill: 3.9 mm Radiographic: (3 year/10 implants) Mean bone fill: 4.2 mm
Aughtun et al 1992	Barrier membranes • Nonsubmerged	12 patients 15 implants 6–12 months	ePTFE membrane + systemic antibiotics (tetracycline 200 mg × 1 for 12 days) + implant detoxification (air powder) + irrigation with saline	Clinical: PI: 1.9–1.0 BI: 1.1–1.1 PD: 5.2–4.1 mm Radiographic Mean bone loss: 0.8 mm Minor improvements on soft tissue conditions Membrane exposure
Jovanovic et al 1992	Barrier membranes • Nonsubmerged	7 patients 10 implants 6 months to 3 years	ePTFE membrane + systemic antibiotics (Tetracycline 250 mg × 4 for 7 days) + implant detoxification (air-powder + chloramine T + saline irrigation)	Clinical: PI: 1.7–0.6 GI: 2.1–0.3 PD: 6.8–4.1 mm All clinical signs improved Radiographically: 7 defects showed bone fill 3 defects: no bone fill

TABLE 41.1	Human Studies on Peri-implantitis Treatment—cont'd			
Author	Procedure	Number of Patients and Implants and Time of Follow Up	Treatment	Outcome

Khoury and Buchmann 2001	Grafting materials + barrier membranes	25 patients 41 implants 36 months	Systemic antibiotics
			Group 1 (12 implants): detoxification with chlorhexidine irrigation + citric acid + hydrogen peroxide + saline + bone blocks and particulate bone
			Group 2 (20 implants): treatments as group 1 + ePTFE
			Group 3 (9 implants): treatments as group 1 + collagen membrane (submerged)
				Clinical:
				    1: PD reductions: 5.1 mm
				    2. PD reductions: 5.4 mm
				    3. PD reductions: 2.61 mm
				Radiographic:
				    2.4 mm bone fill
				    2.8 mm bone fill
				    1.9 mm bone fill
				58.6% of the barrier treated implant sites were compromised by early post therapy complications
				The additional application of barriers does not improve the overall treatment outcomes 3 years following therapy

Mattout et al 1995	With and without grafting material	19 patients	23 defects: ePTFE alone 11 defects: ePTFE + DFDBA + hydrated tetracycline Postoperative: 0.1% CHX + amoxicillin 500 mg (2× for 8 days)	Mean success rate 68% for the membrane group and 90% for the membrane + bone allograft

Schwarz et al 2006	Grafting materials + barrier membranes
	• Nonsubmerged
		22 patients 22 implants 6 months	Granulation tissue removed + implant surface debridement with plastic curettes + irrigation with saline
			Group 1: Nanocrystalline HA
			Group 2: Bovine xenograft + resorbable collagen membrane
				Clinical:
				    1: PD: reductions: 2.1 mm
				    2. PD: reductions: 2.6 mm
				"In both groups, radiologic observation revealed a decreased translucency within the intrabony component of the respective peri-implant bone defect."
				Additionally, both treatments resulted in clinically reductions in PD and gains of CAL at 6 months after surgery

Schwarz et al 2008	Grafting materials + barrier membranes
	• Nonsubmerged
		22 patients 2 years	Group 1: Access flap surgery + nanocrystalline hydroxyapatite
			Group 2: Access flap surgery + natural bone mineral + collagen membrane
				2 patients in NHA: severe pus formation at 12 months
				Clinically:
				PD:
				    Group 1: 1.5 ± 0.6 mm
				    Group 2: 2.4 ± 0.8 mm
				CAL gains:
				    Group 1: 1.0 ± 0.4 mm
				    Group 2: 2.0 ± 0.8 mm
				Both treatments showed efficacy over 2 years. Natural bone mineral + collagen membrane showed better clinical improvements

Roos-Jansaker et al 2007a	Grafting materials + barrier membranes
	• Nonsubmerged
		36 patients 65 implants 12 months	Systemic antibiotic (amoxicillin 375 × 3 + metronidazole 400 mg × 2) for 10 days starting 1 day before surgery
			Debridement of the granulation tissue, implant surface decontamination with hydrogen peroxide and irrigated with saline
			Group I: Bone substitute + resorbable membrane
			Group 2: Bone substitute but no membrane
				Group 1:
				    PD reduction: 2.9 mm
				    Mean bone fill: 1.5 mm
				Group 2:
				    PD reduction: 3.4 mm
				    Mean bone fill: 1.4 mm

Control of Parafunctional Forces

An occlusal guard is crucial in preventing unfavorable occlusal stress. The night guard is adjusted to be on a flat plane occlusion to disperse stress. Careful discussion should be conducted with the dental laboratory to convey the desired design for successful clinical outcomes.

Management

The objective of treatment for peri-implantitis is for osseous regeneration of the implant-bone defect. However, such treatment has been challenging because the implant surface needs to be detoxified, along with modifying the soft and hard tissues. This may involve nonsurgical and surgical treatment.

TABLE 41.2	Predictive Profiles Associated With Peri-Implantitis[223,224]	
Risk Factor	**Predictive Profiles**
Type 1: surgical factors	• Presence of plaque associated with orovestibular and mesiodistal implant malpositioning • Failed bone reconstruction
Type 2: prosthetic factors	• Plaque associated with retained cement remnants • Nonideal finish line margin (≥2 mm below soft tissue margin) • Occlusal overloading • Prosthesis material fracture • Abutment screw loosening • Implant fracture
Type 3: plaque-induced	Generalized bone-level recession associated with plaque accumulation, without any surgical/prosthetic complication

Nonsurgical Management of Peri-Implantitis

Nonsurgical treatment of peri-implant mucositis is often successful. In contrast, the nonsurgical treatment for peri-implantitis is not as predictable. This is most likely due to the inability to remove the bacterial biofilm from the exposed implant surface. Such difficulty has been especially observed with rough surface dental implants.[83] A systematic review illustrated that implant surfaces and diameter are potential risk factors for bone loss and peri-implantitis.[84]

The nonsurgical treatment of peri-implantitis usually involves the debridement and detoxification of implant surfaces, similar to the treatment of peri-implant mucositis. However, the issue that arises is that these exposed surfaces usually have concurrent subgingival pockets.

Low-Abrasive Amino Acid Glycine Powder. Low-abrasive amino acid glycine powder has been shown to be an effective treatment for removing biofilm without damaging the implant surface, and hard and soft tissues of the periodontium. This technique uses a special handpiece with a plastic tube nozzle with three orthogonally oriented holes. An air-powder mixture with reduced pressure is expelled through the nozzle, which prevents the formation of air emphysema complications. The nozzle is moved in a circumferential movement around the implant surface.[85]

Although more extensive studies need to be conducted as to technique efficacy, glycine powder can be incorporated into a treatment regimen. The clinician should be careful to use the powder only in areas where access is available, including a posttreatment rinse to remove any residue. This modality is best used in cases with a buccal dehiscence and/or horizontal bone loss without crater or infrabony pocketing. An air-powder unit (Hu-Friedy, Chicago, Ill.) that adapts to a slow-speed handpiece is available and may be used effectively (Fig. 41.10).

Ultrasonic Devices. For treatment of peri-implantitis, tip modifications (i.e., carbon fiber, silicone, or plastic) must be used. Care must be exercised not to use metal tips as they may alter the implant surface. Ultrasonic devices should be used only when plastic tips are available. Irrigation and meticulous cleaning are recommended in treatment for either open flap debridement or closed flap irrigation.

Lasers. One of the newer and least invasive methodologies to treat peri-implant mucositis and peri-implantitis involves the use of laser photonic energy, a coherent form of infrared or visible light, usually of a single wavelength. Lasers have been used effectively for decades in oral implantology in second-stage recovery of implants through the ablation and vaporization of overlying soft tissue.[86]

Laser Protocols. Similar to their use in treating periodontal disease, lasers provide different treatment approaches for peri-implantitis: nonsurgical, surgical, antimicrobial photodynamic therapy, and photobiomodulation.

- *Nonsurgical:* In the nonsurgical modality, lasers are used adjunctively to help remove calculus, reduce inflammation and remove diseased soft tissue, and reduce subgingival pathogens. Using different types of lasers, such as the diode, Nd:YAG (neodymium-doped yttrium aluminum garnet), erbium, or carbon dioxide laser, the laser beam is directed at the inflamed soft tissue within the sulcus, using noncontact overlapping strokes to disrupt the biofilm, reduce the microbial population, and decontaminate the pocket epithelium. Erbium lasers have also been shown to remove calculus from the implant surface.[87-95]

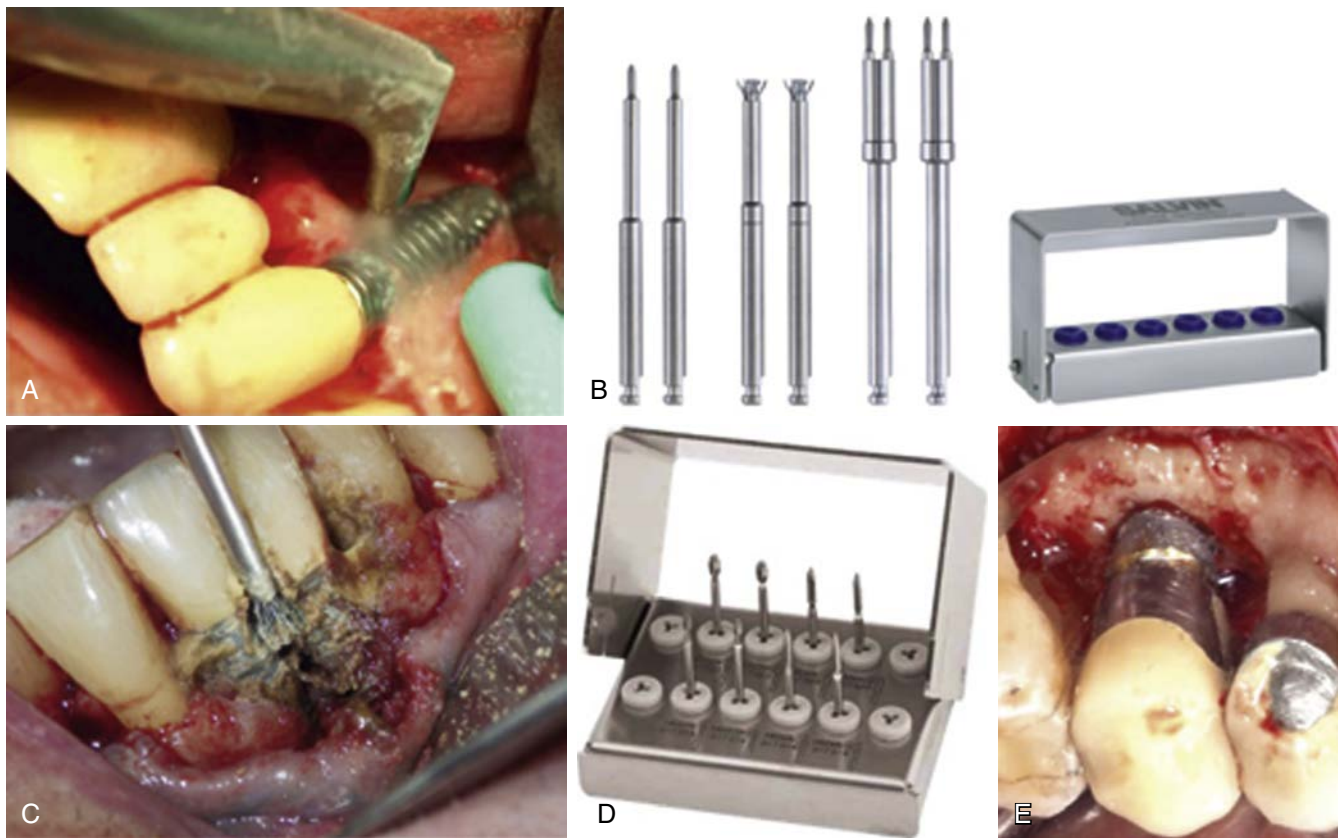
- *Surgical:* Minimally invasive laser-assisted surgical techniques involve removal of diseased epithelial lining. More invasive surgical procedures involve conventional elevation of a full-thickness flap for surgical access, followed by laser-assisted degranulation, surface debridement and decontamination, and osseous tissue removal or recontouring. As indicated, bone augmentation may be performed through placement of bone-grafting material.[96-103]

- *Antimicrobial Photodynamic Therapy:* Antimicrobial photodynamic therapy in periodontology is a light-based approach to terminating bacteria. A photoactivatable substance (photosensitizer) is applied to the targeted area (i.e., within the sulcus) and then activated by laser light. Singlet oxygen and other cytotoxic reactive agents are produced to reduce periodontopathogens.[104-109]

- *Photobiomodulation:* is a form of light therapy that uses nonionizing forms of light, including lasers in the visible and infrared spectrum. The nonthermal technique is used to elicit photophysical and photochemical events. In implantology, it is used to promote wound healing and tissue regeneration. It has also been shown to increase osteoblastic proliferation, collagen deposition, and bone neoformation.[110-115]

Although laser-based peri-implantitis treatment techniques are generally positive, some studies indicate adjunctive use of lasers have limited or no extra beneficial effect compared with conventional treatment methodologies. Additional well-designed, long-term, randomized controlled trials are needed to verify the clinical and microbiologic outcomes of laser use.[116-118]

Assurance of positive therapeutic outcomes is facilitated by an informed clinical technique, prudent use of proper laser operating parameters, and awareness of all laser wavelengths. However, when used inappropriately, laser energy can adversely alter implant surfaces and/or induce undesirable temperature increases, which may be detrimental to implant health[119-122] (Fig. 41.11).

In 2014 a human clinical study consisting of 16 patients was published, using a pulsed 1064-nm Nd:YAG laser (PerioLase MVP-7; Millennium Dental Technologies, Cerritos, Calif.). The technique introduced is known as the Laser-Assisted Peri-Implantitis Protocol (LAPIP) to manage patients with peri-implantitis[123] without the use of bone augmentation (Fig. 41.12). (LAPIP is


• **Fig. 41.10** (A) **Low-Abrasive Powder.** Hu-Friedy glycine powder jet used to debride titanium implant surfaces, (B) Titanium Brushes, (C) Clinical image of titanium brushes applying detioxification agent, (D) Implantplasty Kit for removal of implant threads, (E) Implant with threads removed.

a registered trademark of Millennium Dental Technologies, Inc., Cerritos, Calif.)

The clinicians used a modification of a well-defined surgical procedure, the Laser-Assisted New Attachment Protocol (LANAP), used for treating periodontitis. This technique was defined as a minimally invasive surgical therapy that may be appropriate for multiple periodontal defects and possibly as a first line of management of periodontal disease.[124] In two recent histologic studies, the LANAP has shown evidence of new attachment and tissue regeneration.[125,126] Based on this evidence, in 2016 the U.S. Food and Drug Administration granted marketing clearance for the PerioLase MVP-7 Laser for a first-of-its-kind clinical indication for use: periodontal regeneration, that is, true regeneration of the attachment apparatus (new cementum, new periodontal ligament, and new alveolar bone) on a previously diseased root surface when used specifically in the LANAP.

For the treatment of peri-implantitis, the LAPIP follows the step-by-step sequence defined in the LANAP procedure, but with a reduced light dose (energy) around implants.

1. Surgical probings are performed under local anesthesia to record the depths of all bony defects around the implant. Pocket depth and phenotype help to determine the amount of laser energy to be delivered during the ablation and hemostasis applications.
2. The laser fiber is then inserted into the periodontal pocket, oriented in a prescribed fashion, and the laser is activated at particular settings to ablate (remove) the diseased epithelial lining and granulomatous tissue, to denature pathologic proteins, and to create bacteria antisepsis.

3. Ultrasonic scalers are used to remove foreign substances (including calculus and cement) from the implant surfaces.
4. Bone is modified, removed, reshaped, and decorticated in a prescribed manner to stimulate the release of blood, stem cells, and growth factors from the bone.
5. The laser is then used again at specifically adjusted settings in hemostasis mode to form a thick, stable fibrin clot, activate growth factors, and upregulate gene expression.
6. Coronal soft tissue is approximated against the implant using finger pressure to achieve adhesion. No sutures are used because this is a flapless procedure.
7. Removal of occlusal interference is performed to reduce traumatic forces and mobility.

The technique has been shown to produce healing in an environment conducive to true regeneration of new alveolar bone. Reosseointegration of the implant is anticipated.

The study analyzed 16 cases, 9 females and 7 males, with an average age of 54 years and a range of 32 to 79 years. Median time that had elapsed between the date of implant placement and the date of LAPIP treatment was 4 years (3 months to 16 years). Follow-up data ranged from 8 to 36 months after LAPIP treatment. All clinicians reported control of the peri-implantitis infection, reversal of bone loss, and rescue of the incumbent implant.

Radiographic evidence combined with three-dimensional geometric modeling was used to estimate the rate of addition of new bone to the alveolar crest. The rate of bone deposition was determined to be 14.9 mm^2 in cross-sectional area per year. In two cases, new bone deposition was observed at rates of 0.62 and 1.6 mm^3 per month, respectively. Complete recovery (resolution of

peri-implantitis) averaged 1 to 3 years, depending on the size of the initial lesion. Analysis of collected data revealed that bone deposition is not linear. Large defects healed more rapidly at first, but the rate slowed as the defect diminished. A modest trend was shown for larger lesions to heal more rapidly.

Although the results of this clinical study appear promising, further study of the predictability and effectiveness of the LAPIP technique is warranted. The effectiveness of the 1064-nm Nd:YAG laser wavelength in achieving its successful clinical outcomes with the LAPIP protocol may be attributed to a variety of factors.[127] These include the Nd:YAG laser's ability to:

- selectively remove inflamed pocket epithelium, with no significant damage to underlying connective tissue,[128-131]
- reduce pathogenic microorganisms in the periodontal pocket,[132-136]
- produce an antiinflammatory effect,[137-140] and
- stimulate alveolar bone growth at the cellular level.[141-144]

Whether used adjunctively or as the primary instrument, lasers offer the field of oral implantology a number of safe and effective clinical applications for the treatment of peri-implant mucositis and peri-implantitis. Techniques range from nonsurgical and surgical uses, to antimicrobial photodynamic therapy and photo biostimulation. Additional investigations will further determine the underlying mechanisms of their action. Proper training and scrupulous adherence to specific laser-based protocols will help assure favorable therapeutic patient outcomes.

Laser settings are specific to each individual laser according to manufacturers' protocols. Care should be exercised to cover all exposed surfaces (i.e., each exposed thread) for the detoxification process. Use of regenerative material (allografts and extended resorbable membranes) is highly recommended. Tissues are modified and sutured to reapproximate tissue for tension-free primary closure.

It is critical to limit time exposure of the implant surface with the laser application to avoid overheating or charring. This may increase implant morbidity and possibly lead to premature loss of the implant because of bone disintegration.

Locally Applied Antibiotics. The recommended locally applied antibiotic (LDA) during surgical implant rescue is tetracycline at 50 mg/mL solution. Tetracycline capsules can be opened and mixed with small amounts of saline solution to create a paste. This paste is burnished onto implant surfaces for 60 seconds, then thoroughly rinsed with saline. Tetracycline is bacteriostatic, as it targets the 30s ribosomal subunit in the messenger RNA translation complex of bacterial protein synthesis. Because tetracycline has an inhibitory effect on matrix metalloproteinases, the tetracycline paste needs to be completely removed. A study with pure tetracycline application showed reosseointegration after 4 months.[56] It is highly recommended to incorporate tetracycline in surgical rescue therapy for peri-implantitis.

Tetracycline capsules (two 500-mg capsules) may be mixed with a few drops of saline to form a viscous consistency. It should stay gelled when applied to exposed implant surfaces during surgery. The mixture is allowed to sit on the implant surface for 1 minute, then is thoroughly rinsed off. It allows proximal contact of antibiotics to implant surface colonies and may assist in success in treatment of peri-implantitis.

Another option of local antibiotic administration is with minocycline, which is a tetracycline derivative. Minocycline is manufactured in an encapsulated microsphere of poly(lactic-coglycolic acid), a biodegradable polymer called Arestin (OraPharma, Warminster, Pa.).[57] The subgingival application of minocycline microspheres has been shown to maintain therapeutic levels for 14 days. Williams et al.[58] reported on a 9-month study that showed the

• **Fig. 41.8** Locally Applied Antibiotic. Arestin placed into the sulcus area for the treatment of peri-mucositis.

• **BOX 41.3** Antibiotic Prescription Formulation

Amoxicillin 500 mg tid (three times per day), total of 21 capsules
Metronidazole 250 mg, 21 tablets tid, until all consumed by the patient
Minocycline (Arestin) applied subgingivally around implants with pockets

---

therapeutic efficacy of minocycline microspheres in significantly reducing probing depth in conjunction with scaling. Oringer et al.[59] concluded that minocycline microspheres induce a potent short-term reduction in the gingival crevicular fluid molecular markers of bone resorption (Fig. 41.8).

Systemic Antibiotics. The use of systemic antibiotics has been established for management of periodontitis.[60] However, peri-mucositis treatment studies with use of systemic antibiotics are lacking. It is known that patients with periodontitis are three times more likely to experience peri-implantitis, but the bacterial colonies found in peri-implantitis and periodontitis share few characteristics. Still, many studies have demonstrated the most effective antibiotic combination is amoxicillin and metronidazole.

Metronidazole is bactericidal to anaerobic organisms and disrupts DNA synthesis. It has been shown to be especially effective against *A. actinomycetemcomitans, P. gingivalis,* and *P. intermedia.*[61] The combination of amoxicillin and metronidazole has also been shown to have long-term effects against *A. actinomycetemcomitans*[62] (Box 41.3).

For patients who are allergic to amoxicillin, alternative systemic antibiotics are clindamycin, ciprofloxacin, metronidazole, or azithromycin. Local drug delivery systems such as minocycline (Arestin, off U.S. Food and Drug Administration label) may be considered.

Surgical Management of Peri-Implantitis

Although nonsurgical treatment of peri-implantitis may be effective in some cases, the majority of cases require a more invasive approach to ensure an effective treatment outcome. There are various surgical techniques (see later) to treat peri-implantitis, depending on the final objective.[145] Surgical management is completed with curettes, specialized titanium brushes with an implant handpiece, and/or a glycine polishing handpiece. Along with mechanical decontamination, a chemical decontamination process should be followed, using compounds such as doxycycline/tetracycline or citric acid. The flaps are then

• **Fig. 41.13** Peri-implantitis Treatment. (A) Clinical view of localized edematous tissue. (B) Radiograph depicting circumferential bone loss. (C) Three months post-LANAP treatment. (D and E) Nine months post-LANAP treatment. (*Courtesy Allen Honigman, DDS*)

reapproximated in their original position, using horizontal mattress sutures, which adapt tissue around the implant while creating a ferrule effect. Interrupted sutures will also serve this purpose (Fig. 41.13).

It is possible to also complete a subepithelial tissue augmentation while performing the access flap debridement. Simultaneous tissue grafting with debridement had a significant reduction of bleeding on probing, pocket depth, and clinical attachment loss at a 6-month postoperative evaluation.[146]

1. Sulcular incision around desired dentition being careful to extend at least one tooth mesial and one tooth distal in anticipation to the area of treatment
2. Full-thickness flap reflection is complete past the mucogingival junction on both buccal and palatal/lingual if necessary
3. Implants are detoxified with tetracycline paste, EDTA, or citric acid, cleaned with curettes and titanium brushes
4. Air powder glycine to further clean implant threads previously exposed
• **Fig. 41.14** Regenerative Procedures. (A) Radiograph depicting significant bone loss surrounding implant in the first molar position. (B) Full-thickness reflection showing extent of defect with retained cement. (C) Detoxification with tetracycline hydrochloride, after removal of cement. (D) Augmentation with allograft. (E) Postoperative radiograph 2 years postoperatively. (*Courtesy Dr. Nolen Levine.*)

5. Flaps are readapted over osseous structure and should be in relatively similar position
6. Horizontal mattress sutures or interrupted sutures may be used, being cautious not to exert excess tension, which causes bunching of tissues; tissue does not have to be completely approximated; new tissue will form and granulate in the wound site

Heitz-Mayeld et al.[147] reported on a 12-month prospective study with antiinfective surgical therapy outcomes for peri-implant disease. Thirty-six patients with moderate to advanced peri-implantitis had access flap disinfection, followed with a combination of systemic antibiotics (amoxicillin and metronidazole). At 1 year, 92% of patients had stable crestal bone height, and all had a marked reduction of probing depth. On probing, 47% had complete resolution of bleeding.[147]

Regenerative Procedures. For peri-implantitis cases where a crater-like defect is present, regeneration is recommended (Fig. 41.14). Even though regeneration is an ideal treatment modality for all peri-implantitis cases, there are criteria that must be fulfilled to allow successful treatment. In a similar principle to bone

regeneration for natural teeth, the greater number of osseous walls remaining in a defect, the better the anticipated clinical outcomes.

Also, the prosthesis must be free from any premature contacts that may introduce excessive force to the implant interface. Ideally, especially in single-tooth implant cases, removal of the crown would be performed to ensure proper healing. A sulcular incision is performed from one tooth mesial to one tooth distal of the implant. A full-thickness mucoperiosteal flap is reflected to gain adequate access to defect. Thorough removal of granulation tissue is vital. Mechanical debridement is then initiated. A titanium brush with a small tip may be needed to access the implant surface if the osseous crater around the implant has little access.

After thorough mechanical debridement, freeze-dried bone allograft may be packed in with a resorbable membrane. Soft tissue augmentation may also be included, which will enhance healing. Flap advancement is usually indicated to achieve soft tissue primary closure around implants. A high tensile suture material suture is recommended to ensure the flap does not open prematurely. Implants should be free from any pressure or premature contacts that may introduce excessive force to the implant interface. Ideally, especially in single-tooth implant cases, any occlusal prematurities should be removed.

In addition to the steps listed earlier, enamel matrix protein, platelet-derived growth factor, and human allograft or bovine xenograft in conjunction with a collagen membrane or subepithelial tissue graft was suggested to enhance regeneration. Systematic reviews on the merits of clinical regeneration, of platelet concentrates[148] and bone marrow aspirates have been published recently.[149]

Regenerative Technique

1. Sulcular incision is made around the clinical site with one tooth mesial and one tooth distal.
2. Full-thickness mucoperiosteal flap is reflected past the mucogingival junction to ensure enough tension release from flap tissue. It is essential to produce adequate release so there is minimal tension when closing the flap. Inadequate reflection will result in incision line opening, which will increase morbidity of the graft.
3. The bone surface is curetted to clean and remove all soft tissue remnants. Bone surface is curetted, being careful to remove all remnants of soft tissue. Detoxification:
   a. Tetracycline paste, EDTA, or citric acid is applied to the exposed surface for 30 to 60 seconds.
   b. Rinse with sterile saline for 30 seconds.
4. A full-thickness flap is reflected to gain adequate access to the defect and implant threads. Thorough removal of granulation tissue is critical. Bone graft of choice (i.e., ideally an autograft or allograft) is placed on defect.
5. A resorbable membrane (extended resorbable collagen membrane: 4–6 months) is then draped over bone graft, being careful to cover 3 mm past all edges of bone graft.
6. Tissue tension is reduced via tissue-stretching techniques. Flaps are sutured (i.e., high-tensile strength suture material [polyglycolic acid (PGA) sutures, 4–0]), being careful to provide tension-free closure to produce maximal contact between tissue edges (primary closure) (Fig. 41.15).

Apically Repositioned Surgical Technique. This surgical technique is used for implants that have generalized horizontal bone loss greater than one to two threads. An internal bevel incision or sulcular incisions circumscribing buccal and lingual contours of the implant are made. Two vertical incisions are added on the mesial and distal of the implant, creating a pyramidal flap. The clinician should recognize the importance of the blood supply of the flap, and a wide base is necessary to ensure the sulcular

margin of the flap does not slough. On the lingual/palatal a gingivectomy may be performed at the level of the anticipated final gingival height. Submarginal incisions may be performed in cases where keratinized gingival tissue is adequate (e.g., palate). Ideally a partial-thickness flap is recommended because it will improve apical flap adaptation. Full-thickness flaps elevation technique may be easier in difficult-to-access clinical sites.

Once reflected, similar treatment as the access flap may be vital. Granulation tissue needs to be completely removed, followed by thorough cleaning of implant surfaces. A chemical detoxification can similarly be performed. A decision may be made to remove implant threads with a handpiece if significant loss of osseous support is present and regeneration is unlikely. The final flap is sutured to the underlying periosteal tissue if a split-thickness flap was used. If a full-thickness flap was performed, it can be adapted apically via individual interrupted sutures. The goal is to readapt tissue back onto remaining osseous support to minimize thickness of a soft tissue collar, thereby minimizing probing depth.

Steps of Flap Access, Debridement, and Resective Surgery are described below:

1. Sulcular incision is made around desired dentition, being careful to extend at least one tooth mesial and one tooth distal in anticipation to the area of treatment.
2. Full-thickness flap reflection is complete past the mucogingival junction on both buccal and palatal/lingual if necessary.
3. Osseous recontouring is complete at this time to create a positive architecture.
4. Implants are detoxified with tetracycline paste, EDTA, or citric acid, cleaned with curettes and titanium brushes.
5. Air-powder glycine treatment of exposed implant threads is performed.
6. Flaps are readapted over remaining osseous structure and should be apical in comparison with the original flap position.
7. Horizontal mattress sutures or interrupted sutures can be used, being careful not to exert too much tension that causes bunching of tissues. Tissues do not have to be completely approximated. New tissue will form and granulate in the wound site (Table 41.3).

Platelet Concentrate Growth Factors. In implant dentistry the two most common platelet concentrates are termed under the general acronyms of PRP (platelet-rich plasma) or PRF (platelet-rich fibrin). These products are often considered growth factors and used in regenerative medicine. Although protocols vary, most platelet concentrates are blood extracts from a whole blood sample that is processed via centrifugation. The processing technique separates the blood components into usable (e.g., fibrinogen/fibrin, platelets, growth factors, and leukocytes in liquid plasma) or unusable (e.g., red blood cells).[150]

The use of platelet concentrates (e.g., PRP and PRF) for the treatment of peri-implant defects has been widely researched, with varying results. Unfortunately, the literature on this topic is controversial and conclusions are extremely variable.

Platelet-Rich Plasma. PRP with and without bone substitutes has been studied with the treatment of peri-implant defects. In various dog research models, most researchers have not found beneficial results with PRP alone,[151] in combination with xenograft bone,[152-154] and with guided bone regeneration procedures.[155] In general the literature as a whole has not shown a significant benefit in the treatment of peri-implant defects. Simonpieri et al.,[156] in a comprehensive review, stated that PRP does not show conclusive results. A possible reason for this is that natural bleeding from the surgery site is sufficient to saturate the area with blood growth factors and allow for increased healing ability.
• **Fig. 41.15** Treatment of Peri-implantitis. (A) Maxillary right canine exhibiting bone loss and peri-implantitis. (B) Clinical view. Platelet-Rich Fibrin. In contrast, PRF is used as a "generic" name for the second-generation platelet concentrates, which are derivatives of PRP. The original protocol by Dohan, Choukroun, et al.[157] used no anticoagulants and was termed L-PRF (leukocyte- and platelet-rich fibrin). Later, they have been modified to include advanced-PRF (A-PRF) and injectable-PRF (i-PRF), as well as several other groups of products.

The L-PRF fibrin matrix contains mostly platelets and leukocytes (e.g., lymphocytes). The L-PRF clot is created without blood modification (i.e., no anticoagulants) and is the result of the natural coagulation process during centrifugation.[158] Because of its strong fibrin network and bone growth cell factors (leukocytes, platelet aggregates, circulating stem cells), the L-PRF clot has been shown to have beneficial results, with bone substitutes in the filling of peri-implant defects.

With respect to bone regeneration and treatment of defects, L-PRF has been shown to be beneficial when added to bone substitute material.[159] Also, when L-PRF is used as a regenerated membrane, increase soft tissue healing is seen. Numerous studies have confirmed increased benefits of soft tissue stimulation and promotion of gingival remodeling.[160,161] The L-PRF has also been shown to regulate the interactions between the bone and soft tissue, thereby promoting healing and remodeling of the tissue.[162]

Because peri-implantitis involves an inflammatory and bacteria-laden defect, the exposed implant surface is contaminated with a bacterial biofilm and altered surface characteristics. The titanium oxide surface is destroyed with peri-implant disease,

new bone growth can be initiated only after complete decontamination of the implant surface. Therefore, if the contaminated surface is not restored, bone grafting will most likely not be successful. Multiple protocols have been suggested to clean (i.e., detoxify) the implant surface. Although dependent on the type of implant surface, the use of PRF in the bone regeneration technique has been shown to heal compromised peri-implant defects.[163]

Protocol.

1. A full-thickness reflection is completed to expose the osseous and mucogingival defect. Debridement is completed to remove nonvital hard tissue, together with granulation tissue.
2. The implant surface is then detoxified with citric acid, EDTA, and/or tetracycline paste. A titanium brush may be used with a latch-type handpiece to aid in the decontamination process.
3. A whole blood sample is collected in a 10-mL tube without an anticoagulant.
4. The blood sample is immediately centrifuged for 12 minutes at approximately 2700 rpm. Because there is no anticoagulant, the platelets are activated and trigger the coagulation cascade when they contact the tube walls. There will exist three distinct layers: (1) top layer—platelet-poor plasma (PPP); (2) middle layer—PRF; and (3) bottom layer—red blood cells.
5. The fibrinogen is transformed into a fibrin network via the circulating thrombin. The resultant fibrin clot is located in the center of the tube, which is concentrated with acellular plasma and platelets.

TABLE 41.3	Treatment of Peri-mucositis and Peri-implantitis

Peri-Mucositis

Patient Self-Administered

Plaque Control
- Toothbrushes (manual or powered)
- Toothpastes
- Antimicrobial rinses
- Flossing/oral irrigators
- Topical application of gel
- Systemic antibiotics
- Probiotic *Lactobacillus reuteri*–containing tablets

Professional

Mechanical plaque control
- Hand instruments
- Powered instruments

Chemical plaque control
- Local delivery of antibiotics
- Chlorhexidine (antimicrobials)
- Phosphoric acid
- Ozone, oxygen, and saline solution

Mucogingival debridement
Prosthesis alteration

Peri-Implantitis

Non-Surgical

Mechanical instruments
- Nonmetal instruments
- Rubber cups
- Air abrasive
- Metal instruments
- Burs

Adjunctive treatments
- Microbiologic test
- Local antimicrobials
- Systemic antimicrobials

Disinfect titanium surfaces
- Antiseptics
- Chemical
- Air polishing
- Laser

Mucogingival debridement
Prosthesis alteration

Surgical
- Open flap debridement
- Surface decontamination
- Regenerative approaches
- Biologics
- Guided tissue regeneration
- Guided bone regeneration
- Systemic antibiotics

Retrograde Peri-implantitis (Maintenance and Prevention)

Patient self-administered preventive regimens
Supportive periodontal therapy/maintenance (professionally)
- Mechanical nonsurgical therapy
- Mucogingival Debridement
- Prosthesis Alteration

Adapted from Suzuki JB, Misch CE. Periodontal and maintenance complications. In: Resnik RR, Misch CE, eds. *Misch's Avoiding Complications in Oral Implantology.* St. Louis, MO: Elsevier; 2018.

6. The acellular plasma (PPP), which is the top layer, may be removed with a pipette into a syringe. The PRF fibrin clot is then placed into a PRF box and processed into a membrane. The liquid part (PRF) of the PRF box is then collected and placed in with the graft material. If additional liquid is indicated for the graft material, the acellular plasma (PPP) may be added, as a small number of platelets are present in this concentrate.

7. After grafting the defect, the PRF membrane is placed over the defect. If a second membrane is used (e.g., collagen), then the membrane may be moistened with acellular plasma.

8. The soft tissue flaps are approximated and closed with a high-tensile-strength suture material (e.g., Vicryl, polytetrafluoroethylene [PTFE]).

In conclusion, the L-PRF technique is a simple, effective, and nonexpensive technique to enhance the soft and hard tissues around peri-implant defects. When added to the bone substitute material, there exist immune and antibacterial properties that benefit the healing process.[164,165] The use of L-PRF as a membrane allows the peri-implant defect to create a healthy, thick, and stable soft tissue interface for increased soft tissue health.

Suzuki-Resnik Peri-Implant Disease Protocol

To simplify the treatment of peri-implant disease and maintenance protocols, Suzuki and Resnik have formulated a comprehensive treatment regimen. This consists of four protocols with associated detailed step-by-step regimen.

PROTOCOL 1:

< 3mm probing depths
No Plaque or No Bleeding on Probing (BOP)

Treatment
- Maintain Regular Home Care
- 3 - 6 month hygiene recall

PROTOCOL 2: (Peri-Implant Mucositis)

< 3mm probing depths
Plaque presence / Bleeding on Probing (BOP)
    Or

3 – 5 mm probing depths
Plaque presence / Bleeding on Probing (BOP)

Treatment
- Follow **Treatment Regimen A**
- Increase Hygiene Recall Frequency (~ 3 months)
- Increase Home Care Education
- If no resolution, proceed to Protocol 3

PROTOCOL 3: (Peri-Implantitis)

> 5 mm probing depths
Plaque presence / Bleeding on Probing
Crestal Bone Loss > 2 mm

Treatment

- Follow **Treatment Regimen A, B, C, & D**
- Increase Hygiene Recall Frequency (~ 3 months)
- Increase Home Care Education
- Rx

PROTOCOL 4: Implant Mobility

Pain upon function
Bone loss > 50% of implant length
Uncontrolled exudate

Treatment

- Follow **Treatment Regimen E**

Peri-Implant Disease Treatment Regimen

Treatment Regimen A: Mechanical Closed Debridement (Acceptable Instrumentation)

- Resin, Titanium, Graphite, Carbon-Fiber, and Gold-tipped instruments can be used to remove deposits
- Prophy Cup/Brush
- Air-Polisher with Glycine Powder (Hu-Friedy), Prophy Jet (Dentsply)
- Cavitron (use blue implant tip)
- Rx: Chlorhexidine (0.12%, 0.2%) or cetylpyridinium chloride
- Check Occlusion

Treatment Regimen B: Antiseptic Therapy

- Subgingival antiseptic irrigation (0.12%, 0.2% Chlorhexidine) is added to the mechanical therapy
  - Irrigate intracrevicularly to disrupt and dislodge the biofilm, then thoroughly debride the implant surface with a curette. Irrigate a 2nd time to rinse out the debris and further detoxify the subgingival area. Pressure is then applied for one minute to obtain intimate soft tissue/restoration contact.
- Alternative Antiseptic; diluted sodium hypochlorite (NAOCl).
  - Diluted (.25%) NAOCl solution = one teaspoon (5ml) of standard 6% household bleach (Clorox) and diluting it with 4 oz (125ml) of water.
- Check Occlusion, possible occlusal guard

Treatment Regimen C: ANTIBIOTICS

- Add systemic and/or local antibiotic treatment

Systemic : **Amoxicillin, Metronidazole (500 mg, 3 times/daily for 8 days)**

  Alternative: Clindamycin, Augmentin, Tetracycline, Bactrim, Ciprofloxacin

Local : **Tetracycline**

  Alternative: , Doxycycline, Minocycline spheres (Arestin®)

Treatment Regimen D: SURGERY (Access, Open Debridement, Bone Graft, Closure)

Step 1: Access Flap, Open Debridement with Hand Instruments, Implantoplasty (Salvin Bur Kit)

Step 2: Detoxify With:

- 1. Apply **0.12% or 0.2% Chlorhexidine** with cotton pellet for 60 sec. (rinse with saline)
  +
- 2a. Apply **20-40% Citric Acid** with cotton pellet or spatula or titanium brushes (Salvin) for 60 sec.(rinse with saline)
  OR
- 2b. Apply **Tetracycline Paste** with titanium brushes (Salvin) for 60 sec. (rinse with saline)
  - Other Detoxification Agents: EDTA, Hydrogen Peroxide, 0.25% NAOCl
  - Er:YAG laser

  (diode laser alone results in an unacceptable increase in implant body temperature)

Step 3: Bone Graft with Mineralized/Demineralized (70/30) + Autograft (if indicated)

Step 4: Cross-Linked Collagen (Extended Collagen)

Step 5: Tension-Free Closure with Vicryl (PGA) or PTFE sutures

Treatment Regimen E: IMPLANT REMOVAL

Lack of Keratinized Tissues

Lack of a zone of keratinized gingiva around teeth and oral implants is now recognized as serving an important clinical function for implant health. Direct clinical evidence confirms the need for nonmobile keratinized tissue next to natural teeth. However, the tooth with the least amount of keratinized tissue is often the mandibular first premolar.[166] Yet this tooth is rarely the first tooth lost from periodontal disease. If all other periodontal indices are normal, the amount or absence of keratinized gingiva has little to do with the expected longevity of the tooth. In longitudinal studies, the lack of adequate keratinized and attached tissue does not compromise the long-term health of soft and hard tissue, as long as patients maintain good oral hygiene.[167,168]

Many clinicians consider keratinized attached gingiva important to maintaining gingival health.[169] Mucogingival considerations in restorative dentistry have been considered.[170] They concluded that if subgingival restorations were to be placed in areas of minimal keratinized gingiva with less than optimal plaque control, augmentation to widen the zone of keratinized tissue may be warranted.

Although keratinized tissue around a tooth may not be mandatory for long-term health, a number of benefits are present with keratinized mucosa. The color, contour, and texture of the soft tissue drape should be similar around implants and teeth when in the esthetic zone. The interdental papillae should ideally fill the interproximal spaces. A high smile line often exposes the free gingival margin and interdental papillae zones. The keratinized tissue is more resistant to abrasion. As a result, hygiene aids are more comfortable to use, and mastication is less likely to cause discomfort.

The degree of gingival recession appears related to the absence of keratinized gingiva. Root sensitivity and esthetic concerns may be associated with gingival recession. From a restorative dental aspect, keratinized mucosa is more manageable during the retraction and impression-making process. Subgingival margin placement is improved, as is long-term stability in the presence of

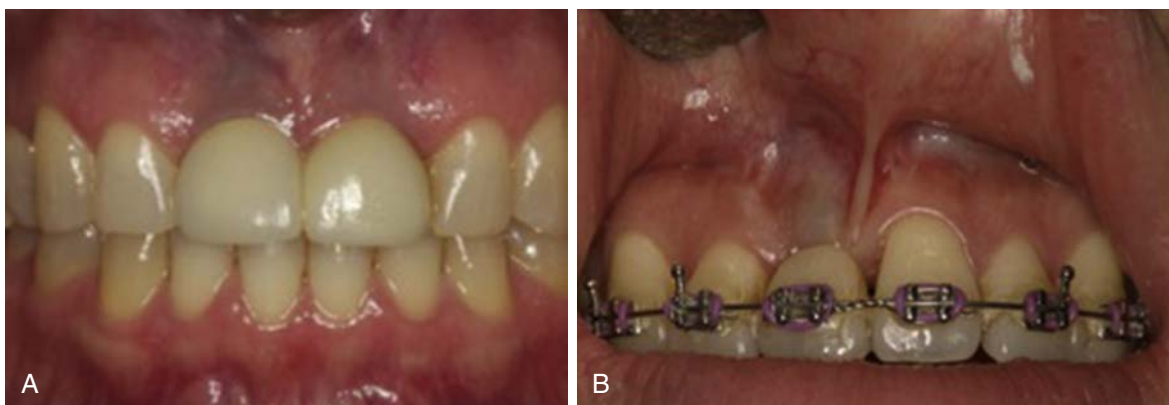
keratinized tissue. Many of these benefits directly apply to the soft tissue around an implant.

Natural teeth have two primary types of tissue: attached, keratinized gingiva and unattached, nonkeratinized mucosa. The type of tissue around a dental implant is more varied than natural teeth. After bone loss in the maxilla, excess tissue is often found, and the tissue is usually keratinized, unattached gingiva. An implant
- **Fig. 41.16** Ideal Keratinized Tissue. (A) Healthy tissue surrounding implant. (B) Preoperative evaluation measuring the amount of attached tissue.

placed in the region may also have keratinized, unattached tissue. The tissues around the implant may also be similar to most natural teeth, surrounded by keratinized, attached gingiva (Fig. 41.16). The tissues may be nonkeratinized, unattached mucosa, more often in the mandible after bone height loss or after a bone graft and flap advancement to approximate the gingiva (Fig. 41.17). The nonkeratinized tissue may also be attached when acellular dermal matrix tissue (Oracell; Salvin Dental Specialities) is positioned under the periosteum and bounds the overlying tissues to the bone. In theory, structural differences in implants compared with teeth make them more susceptible to the development of inflammation and bone loss when exposed to plaque accumulation or microbial invasion (e.g., less vascular supply, fewer fibroblasts, lack of connective tissue attachment, cementation).[171]

Some reports indicate that the lack of keratinized tissue may contribute to implant failure. Kircsch et al. reported the most important criterion for implant health in the posterior mandible was related to the absence or presence of keratinized gingiva.[172] In this report mobile, nonkeratinized mucosa exhibited greater probing depths, which was histologically confirmed. A study in monkeys found that an absence of keratinized mucosa increases the susceptibility of peri-implant regions to plaque-induced destruction.[173]

The presence of keratinized tissue next to an implant presents some unique benefits, compared with natural teeth. Keratinized gingiva has more hemidesmosomes; the junctional epithelial attachment zone may be of benefit when in keratinized tissue. Whereas the orientation of collagen fibers in the connective tissue zone of an implant may appear perpendicular to the implant surface, these fibers in mobile nonkeratinized tissue run parallel to the surface of the implant.

Mobile mucosa may disrupt the implant-epithelial attachment zone and contribute to an increased risk for inflammation from plaque (Fig. 41.18).[174] In addition to the general advantages of keratinized tissue stated for teeth, keratinized tissue around implants may also be beneficial in several other ways. In a two-stage protocol the implant is less likely to become exposed during the healing process. The formation of an interdental/implant papillae is completely unpredictable with mobile nonkeratinized tissues. When the nonkeratinized tissue is mobile, several reports state that this is unsatisfactory.
- **Fig. 41.17** (A and B) Implants placed to retain a lower overdenture that are malpositioned with minimal attached tissue present. In these type of cases, the tissue will usually remain irritated, inflamed, and painful.


● **Fig. 41.18** (A and B) Maxillary implants with inadequate attached tissue.

A classification of attached gingiva and surgical alternatives to improve soft tissue types in edentulous sites for implant placement is critical for long-term implant survival.[175] Ideal adequate keratinized tissue should be established clinically before implant placement, especially in the posterior regions.

Interestingly, the studies that have advocated for the need for keratinized mucosa around dental implants have primarily investigated implants with rough surfaces. Failure of rough-surface implants (e.g., hydroxyapatite-coated and plasma-sprayed cylinder-shaped implants) has been related to a lack of keratinized mucosa.[176]

A meta-analysis reported 20% fewer instances of peri-implantitis in smooth-surface implants compared with rough-surface implants.[177] Another benefit of keratinized tissue is the clinical ease of treatment to reduce pocket depths if crestal bone loss occurs. Probing depths of 6 mm or more are more often associated with anaerobic bacteria. If the implant is out of the esthetic zone, a gingivectomy to reduce pocket depth is predictable. An apically positioned flap with nonkeratinized mucosa is less predictable and is more difficult to perform.

The significance of keratinized mucosa in the maintenance of dental implants with different surface conditions cannot be underestimated. All 69 patients and 339 implants in the study had implant restorations for at least 3 years, and as long as 24 years, with an average of 8.1 years. Bleeding index, modified plaque index, gingival index, probing depth, width of attached keratinized mucosa, and amount of attached mucosa were recorded. In addition, average annual bone loss was calculated, using past and present radiographs. Gingival inflammation and plaque accumulation were significantly higher in patients with less than 2 mm of keratinized mucosa or 1 mm of attached mucosa. The surface condition of the implant was not statistically significant in this study, although the smooth implants with less than 2 mm of keratinized mucosa were less stable than other groups relative to the soft tissue profile.

In this study the average annual bone loss was not influenced by the amount of keratinized or attached mucosa or the type of implant surface configuration (smooth versus rough). The greatest amount of bone loss was observed with rough implants in keratinized mucosa of less than 1 mm, but the difference was not statistically significant. The presence of keratinized mucosa was most significantly advantageous in the soft tissue health of posterior implants, as indicated by the gingival index. Posterior implants, even in the presence of keratinized tissue, had a 3.5-fold higher annual bone loss than anterior implants in this study (0.14 versus 0.04 mm). Implant location appears to be more important than the presence or absence of keratinized mucosa.

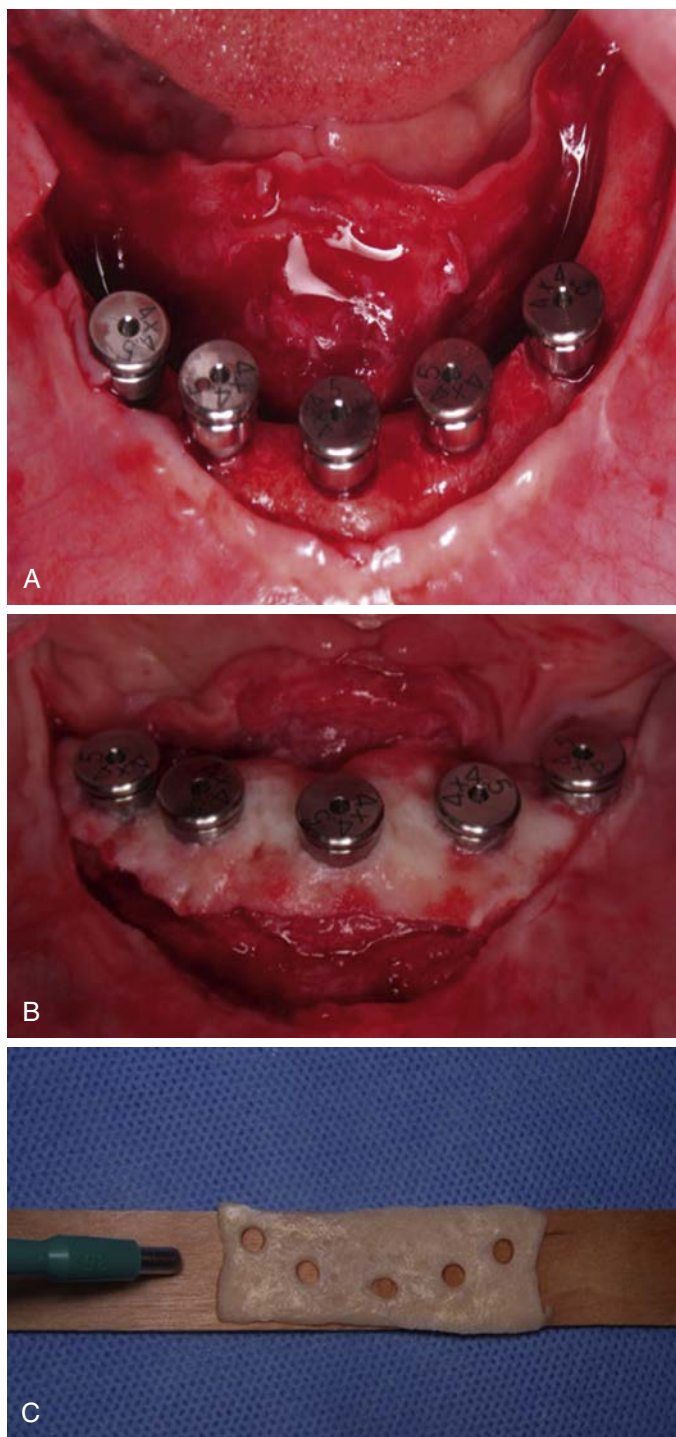
In most clinical situations attached keratinized gingiva is more desirable. A fixed prosthesis (FP-1) in the esthetic zone requires keratinized mucosa to develop the soft tissue drape around the implant restorations. Mandibular overdentures also benefit from a vestibule and zone of nonmobile keratinized tissue around the implant abutments to minimize the possibility of painful tissue.

Management of Lack of Keratinized Tissue

Several surgical techniques to increase the amount of keratinized tissue around dental implants have been described in the literature:
1. Autogenous free gingival graft
2. Autogenous subepithelial connective tissue graft
3. Allogenic soft tissue grafts from human cadavers (e.g., Oracell; Salvin Dental)
4. Xenogenic soft tissue grafts from animals

Augmentation can be completed before surgery, concurrent with surgery, or after implant surgery. The most ideal time to graft is before surgery.

Presurgical Augmentations
1. A trapezoidal flap is reflected from the desired areas of grafting.
2. Full-thickness mucoperiosteal flap is the design of choice.
3. Autogenous or acellular dermal matrix (Oracell; Salvin Dental) is modified to the desired dimensions.
4. PGA or chromic suture is used (5–0 recommended) to secure allogenic dermal matrix (AlloDerm) to the recipient site.
5. Flap is modified to be tension free and pulled over to cover acellular dermal matrix and sutured with 4–0 or 5–0 with PGA or PTFE sutures (Fig. 41.19).

Concurrent Augmentation
The steps for concurrent augmentation are as follows:
1. The full-thickness flap is reflected at the site of desired implant position (one tooth mesial and one tooth distal).
2. After implant placement and/or bone augmentation, autogenous or acellular dermal matrix is layered over the augmentation site.
3. It is critical to have abundant tissue release (i.e., tension-free closure) to allow coverage of soft tissue over bone graft.
4. The flap is sutured with no tension and secured for primary intention healing with 4–0 or 5–0 with PGA or PTFE sutures (Figs. 41.20 and 41.21).
• **Fig. 41.19** Free Gingival Graft. (A) Mandibular left first molar with compromised attached tissue. (B) Recipient site modified. (C) Palatal graft removed. (D) Palatal tissue graft. (E) Tissue graft sutured in place.
• **Fig. 41.20** Acellular Dermis. (A) Bone graft with inadequate attached tissue. (B) Acellular dermis placed around implant healing abutments.


- **Fig. 41.21** Acellular Dermis. (A) Five implants placed in the anterior mandible. (B) Dermis modified to fit over healing abutments. (C) Dermis placed over implants and healing abutments.

Post-implant Tissue Augmentation

After the soft tissue flap has healed, the soft tissue augmentation can be performed during the abutment change appointment or uncovery appointment (3 months of healing). The steps are as follows:

1. A full-thickness flap is reflected, being wide enough to cover the size of the autogenous or acellular dermal matrix membrane.

2. Dermal matrix is ideally positioned and sutured to neighboring attached tissue (chromic 5–0).
3. The flap is advanced over the matrix, being careful to cover the entire allograft tissue (5–0 sutures are preferred).

Retained Cement Peri-implant Disease

Cemented implant prostheses are used in implant dentistry because of the lower cost, relative simplicity, more passive fit, improved esthetics, and similarity to traditional prosthetics. However, with all of these advantages comes a significant disadvantage, the retention of postoperative cement. The retained cement has been shown to harbor bacteria (similar to calculus with a natural tooth), which leads to peri-implant disease (Fig. 41.22).

During implant restoration cementation, it is possible that excess cement can become extruded into the gingival sulcus around the implant. The presence of cement in the sulcus has been shown to cause complications such as discomfort, inflammation, soft tissue swelling, and bleeding or exudate on probing.[178] It has been reported that cement can extrude at the implant abutment-interface when subgingival margins are present. Subgingival cement associated with an implant is more difficult to remove compared with a natural tooth, and various instruments used for this purpose have been shown to result in damage to implant abutments.[179] It has been proposed that any mass of foreign material present adjacent to a dental implant has the potential to negatively impact health and survival of the implant. The specific material itself may determine how a disease process can manifest. Further, the use of cements intended for natural teeth may not be appropriate for use with implant restorations.[180]

Studies suggest that excess cement has been shown to be a possible cause of implant failure.[181] Incidence of excess cement extrusion into peri-implant soft tissues and its adverse effects are well documented in the literature.[182,183] Cement retains microbial flora similar to organisms responsible for inflammatory periodontal diseases. The surface of retained cement has a rough topography, making removal of these microbes difficult, and can also result in accumulation significant enough to form a peri-implant biofilm similar to natural teeth.[185,186] Clinical studies that have analyzed retained methacrylate-based cement samples from patients for bacterial colonization have shown a strong tendency for bacterial invasion by pathogens and opportunistic species.[187] Remnant cement from implant restorations has been associated with consequences of increased bleeding on probing, suppuration, and peri-implant attachment loss.[188] It is the formation of a peri-implant biofilm that can cause the initiation and progression of peri-implant mucositis and peri-implantitis diseases.[189-191] Peri-Implantitis has been documented in several studies with a prevalence rate that ranges from 6% to as high as 47% of patients who have implants and have been followed over periods of 9 to 14 years.[192-194]

The problem of excess cement has been associated with greater than 80% of cases of peri-implant disease. No particular difference or correlation could be associated with the type of cement used to lute the restoration in regard to either the presence of disease or treatment response (when comparing resin cement, resin-modified glass ionomer, zinc polycarboxylate, and glass ionomer). Further, the presence of cement retention and inflammation was not dependent on the type of implant surface; titanium plasma–sprayed or sand-blasted large-grit acid-etched surfaces and titanium dioxide–blasted surfaces were
• **Fig. 41.22** Retained Cement. (A) Radiograph depicting retained subgingival cement. (B) Six months postoperatively. (C) Cement retention leading to failure of implant.

compared.[195] In cases where cement is inadvertently left as an overhang or expressed into the peri-implant tissues, it should be detected and removed.

Etiology

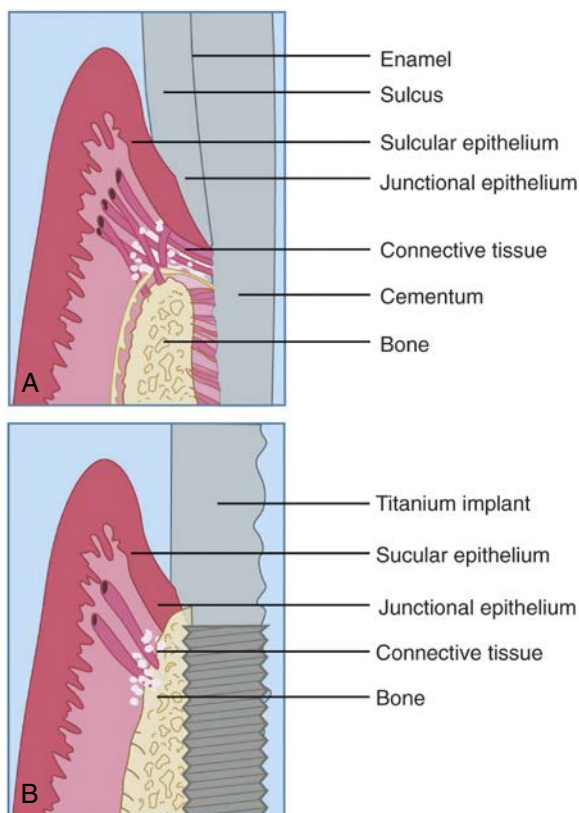
The etiology of cement-retained peri-implantitis is as follows:

Cement: The retained cement acts as a nidus for bacterial accumulation and proliferation. The roughened surface of the cement inhibits the hygienic removal of the bacteria, which leads to peri-implant disease. Cement acts the same way as the etiologic factor in periodontal disease.

Sulcus-Teeth Versus Implant: Around natural teeth the junctional epithelium and connective tissue attachment insert perpendicularly into the cementum, which tends to prevent the flow of excess cement into the sulcus. In contrast, the connective tissue around dental implants runs parallel, with no attachment into the implant surface. The flow of cement is not restricted, and it easily migrates apically (Fig. 41.23).

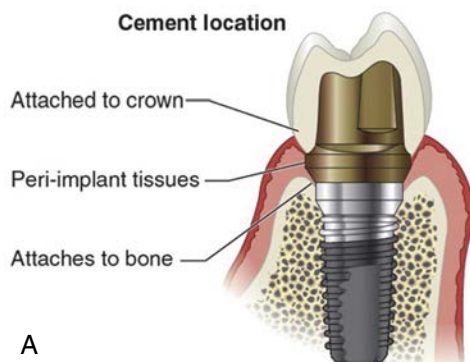
Submucosal Margins: Margins of implant restorations are often placed more than 2 mm subgingivally for a better emergence profile and esthetics. However, studies have shown the deeper the margins, the more difficult the removal of cement. In margins that are greater than 1.5 mm subgingivally, it is almost impossible to remove the cement totally.[197]

Location: Retained cement may attach to the following: (1) crown, (2) abutment, and (3) bone. If the cement is pushed into the sulcular area and reaches the bone, significant chronic issues will arise (Fig. 41.24).

Timing: Perhaps one of the most interesting, yet troubling aspects of cement-associated peri-implant disease is the range of time that can and has historically passed before obvious signs of an inflammatory disease response is evident during clinical detection. Wilson and Thomas[196] have shown that the time it takes for retained cement to become problematic and to eventually be diagnosed is in a range of 4 months to 9.3 years, with an average of 3 years. Another group showed detection ranging from several weeks to 4 years postcementation. This documented that delayed detection in inflammatory signs of peri-implant disease indicates a premise that cemented implant restorations should be examined periodically for disease.[199]


• **Fig. 41.23** Different Attachment Systems for Implant Versus Tooth. (A) Circular fibers attach into the cementum, minimizing the possibility of cement retention. (B) Because an endosseous implant does not contain an attachment system with the tissue, retained cement can be easily extruded into the sulcular area. (*From Resnik RR. Fixed prosthodontics complications. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018; adapted from LeBeau J. Maintaining the long-term health of the dental implant and the implant-borne restoration.* Compend Contin Educ Oral Hyg. *1997;3:3–10.*)

Radiographic Evaluation: Several techniques are described in the literature to locate excess cement around implant restorations. These include use of a dental endoscope and an invasive method of open flap debridement for direct observation.[200,201] Radiographic examination has been shown to be effective at detecting excess cement overhangs in tooth-supported restorations and can serve as a less invasive method of detection for cement-retained implant-supported restorations.[202,203] Radiographic examination is valuable in cement detection only if the luting agent has a high-enough radiodensity level.[204]

It is significant to note that with respect to restoration luting cements and radiopacity, there is no currently established minimum radiopacity standard (however, there is currently a national standard radiopaque value mandated for all endodontic sealer cements; American National Standards Institute/ADA specification No. 57). Therefore there is a broad range of radiographic visibility for restorative luting cements from having a highly radiopaque appearance to being completely undetectable.[205] Ideally, the luting agent should be more radiographically dense than the titanium alloys. Cements that are zinc based (i.e., Fleck's, Temp-Bond, Tempbond NE) have been shown to be most readily detectable radiographically with the higher gray level values. Studies have shown that many non-zinc-based cements are not detected radiographically, such as self-adhesive resin cement (RelyX Unicem), resin cement (Improv and Premier Implant Cement), glass ionomer (RelyX), and calcium hydroxide (Dycal). Being able to evaluate the presence of excess cement and then determining whether removal is indicated is crucial to facilitate appropriate restorative protocols.[206] After restoration cementation, residual excess cement has the highest likelihood of detection at the interproximal aspects. It is at these sites where the accumulation of the bulk of excess cement produces the effect of an enhanced radiopacity described by one group as the "peripheral egg shell effect."[207]


• **Fig. 41.24** Cement Attachment Location. (A) Retained cement may adhere to the crown/abutment, peri-implant tissues, or the bone. (B) Implant with deep pathologic pocket associated with retained cement.

Type of cement: Many types of cement are used today in implant dentistry to retain implant-supported crowns. Agar et al.[208] have shown that cement with resin components is the most difficult to remove from the abutment surface after cementation. Cements containing zinc have been shown to be ideal for cementing implant crowns because they are the easiest to see radiographically. Zinc phosphate is a well-known popular cement choice, which makes retrievability difficult. In addition, because of its solubility in the oral environment, a dry field is definitely needed. Provisional cements are also popular in cementing implant crowns because they allow for retrieval. However, because provisional cements exhibit weaker retentive strengths, uncementation of the implant prosthesis may be problematic.

Cememt Thickness: There is a large variation in the radiographic detection ability of cements. Some cements have a very high radiographic density, which allows for detection on radiographs. However, many cannot be detected, even at greater thickness ($\approx$2 mm).

Cementation technique: A common reason for retained cement is the cervical cementation technique, which usually parallels the technique for cementation on natural teeth.

Most clinicians place an excessive amount of cement within the internal surface of the crown, which leads to extrusion in the sulcular area.

Prevention

Supragingival Margins. Excess retained cement may be minimized by designing the abutment margins supragingivally. However, dentists are reluctant to place the margins at this level, especially if the crowns are in the esthetic zone. Studies have shown margins placed 1 mm supragingival or at the gingival margins allow for ease of cement removal without a decreased chance of retention.[209]

Ideal Application of Cement. Controlling the amount of cement that is placed in the implant crown will allow for a decreased possibility of cement retention. Clinicians are reluctant to use a small amount of cement because this translates into the possibility of leakage and loss of retention.

Excess cement may lead to improper seating, alteration of occlusion, and difficulty in cement removal. Ideally a uniform thickness of 40 µm over the intaglio surface is ideal; however, in a clinical setting, this is very difficult. The internal surface of the crown may sometimes be irregular, and unequal flow patterns may exist between parallel and nonparallel surfaces.

Additional factors that complicate ideal cementation are the cement's flow properties, viscosity, dimensional stability, and wettability of the surfaces.

Screw-Retained Prostheses. Although screw-retained implant prostheses have the disadvantages of higher cost and compromised esthetics in some cases, the lack of cement is a significant advantage.

Implant Abutment Modification. To reduce the amount of excess cement, studies have shown that modification of the abutment leads to less pressure and extruded cement. Ideally the abutment should be vented with two 0.75-mm radius vent holes, placed 3 mm apical to the occlusal area of the abutment and 180 degrees apart. This technique by Wadhwani et al.[210] has been shown to limit the amount of cement extruded into the gingival sulcus of implant-retained crowns.

Techniques

Various techniques to reduce retained cement have been discussed in the literature. A popular technique is the abutment copy technique, which uses Teflon tape inside the intaglio surface before copying the abutment with a polyvinyl siloxane material. The cement-filled final implant crown is seated on the copied abutment for excess cement removal before it is quickly transferred intraorally to be fully seated. This technique minimizes the possibility of retained cement; however, it has limitations when cementing a multiple splinted implant prosthesis[211] (Fig. 41.25).

The Resnik technique (lubrication technique) uses water-soluble petroleum jelly placed on the outer surfaces of the crown or prosthesis and below the implant margin (i.e., sulcular area). A controlled cementation technique is utilized which controls the amount of cement used and also allows for the removal of excess cement prior to final cementation. The advantage of this technique allows for the prevention of cement from adhering to the crown, sulcus, or underlying bone (Box 41.5 and Fig. 41.26).

Removal of Retained Implant Cement

Even the most diligent and skilled implant clinician may leave residual cement in the sulcular area of implant crowns. The importance of postoperative appointments for implant patients after cementation of the restoration cannot be overemphasized. Regular maintenance is extremely crucial for cement-retained crowns. Possible symptoms that may warrant an evaluation for retained cement are localized inflammation, bleeding on probing, exudate, progressively increased probing depths, and radiographic bone loss.

Nonsurgical

Nonsurgical treatment includes regular curettage with hand instruments. It should be noted it is very difficult to remove all cement non-surgically.

Surgical

In many cases, surgical access is necessary for complete cement removal, which includes flap, curettage, and detoxification with possible grafting. In cases of peri-implant disease the detection and removal of excess cement have frequently (76% of afflicted patients) resulted in resolution of clinical inflammatory signs in as little as a month posttreatment. This was possibly due to removal of cement irritants causing both bacterial and mechanical insult. Some authors advocate hand scalers, piezoelectric, and magnetostrictive mechanical devices (along with the benefit of a dental endoscope instrument for direct visualization of cement deposits)[212] (Fig. 41.27).

Peri-implant Mucosal Hyperplasia

The gingival overgrowth results in extreme difficulty for the patient to maintain adequate hygiene and for the clinician in performing debridement. When gingival overgrowth is associated with radiographic bone loss, the resultant periodontal pockets are expressed as "true" periodontal pockets. If there is no associated bone loss, the pockets are termed "pseudo" pockets or gingival pockets.[213]

Gingival hyperplasia may also result in an esthetic issue for the patient. This will require surgical intervention to reduce the tissue. In addition, gingival hyperplasia may make it impossible for a prosthesis to be completely seated (i.e., bar overdenture) or give rise to chronic tissue soreness.
• **Fig. 41.25** Cementation Technique. (A) Polytetrafluoroethylene tape placed over abutment. (B) Crown inserted onto abutment. (C) Polyvinyl impression material added to the internal surface of the crown to make an abutment duplicate. (D) Internal surface of crown: abutment inserted onto implant in the mouth. (E) Cement added to crown and placed on polyvinyl abutment duplicate. (F) Excess cement removed, then inserted onto abutment in mouth.

• BOX 41.5 | **Cementation Technique (Resnik Technique)**

Step 1: Apply water-soluble petroleum jelly to the outer margin of the crown with a 1-mL tuberculin syringe.
Step 2: Seal the abutment screw (cotton ball, Teflon tape) without sealing the entire access.
Step 3: Place a thin layer of petroleum jelly 360 degrees with a 1 mL tuberculin syringe within the sulcus and around the implant.
Step 4: Apply a thin layer (≈40 μm) of cement to the intaglio surface of the crown abutment.
Step 5: Seat crown, remove crown, remove excess cement adhered to the outer margin surface, and remove any sulcular excess cement and petroelum jelly with a brush.
Step 6: Reseat crown, evaluate for any excess cement.

• **Fig. 41.26** Alternative Cementation Technique. (A) Outside of the crown is lubricated with water-soluble petroleum jelly. (D) Peri-implant tissues immediately after instrumentation. (E) Radiograph demonstrating excess cement has been removed. (F) Condition of peri-implant tissues at 6-week reevaluation appointment.

Etiology

After clinical diagnosis of implant-related gingival overgrowth, potential etiologies must be identified, such as hormonal, medication induced, allergy induced, or patient-related habits. Various hormonal factors (e.g., related to pregnancy or puberty) and medications have been associated with the gingival overgrowth. Medications such as phenytoin (i.e., Dilantin), immunosuppressants (e.g., cyclosporine), calcium channel blockers, and amphetamines have been associated with gingival hyperplasia.

Gingival overgrowth has also been associated with patient habits such as mouth breathing. Allergy-induced hyperplasia is also becoming more prevalent in implant dentistry. With the use of titanium alloys for the fabrication of the dental implants and abutments, exacerbated allergic reactions are becoming a more common problem. Nickel (Ni), combined with titanium or in the final prosthesis, may exacerbate and cause an acute allergic reaction. Aluminum (Al) and beryllium (Be) have been associated with eczema and soft tissue reactions that result in gingival overgrowth.

Prevention

If a patient is considered to be at high risk for implant-related gingival hyperplasia (e.g., because of medications), he or she should be instructed to maintain meticulous oral hygiene. In addition, a more frequent recall protocol (four times per year) should be implemented that includes debridement. The prosthesis should be evaluated and maintained with a minimum of 1 mm of space between the tissue and the prosthesis, for ease of cleaning and prevention of prosthesis-induced irritation.

Management

The treatment of peri-implant hyperplasia should begin with conventional periodontal therapies to reduce plaque biofilm and inflammation. The surgical management of implant gingival overgrowth may require gingivectomy (if adequate keratinized gingiva is present) or apically positioned flaps (without adequate keratinized gingiva).

The use of 0.12% or 0.2% chlorhexidine twice per day has been shown to be successful in reducing tissue overgrowth and bacteria counts. When gingival hyperplasia is present around implants associated with overdentures, care should be exercised to minimize further enlargement (Fig. 41.28).

Commonly, practitioners will relieve the denture so the path of insertion does not cause irritation or mucosal injury. This may lead to inadequate thickness of acrylic, predisposing the prosthesis to fracture. Ideally the tissue enlargement should be reduced and the causative agent identified and treated accordingly. It is important to note that even with meticulous care and removal of etiology, gingival overgrowth may recur. Communication with the patient is key to avoid misunderstanding (Box 41.6).

Implant Quality Scale

The criteria for success in implant dentistry remain complex. Most clinical studies reporting success and failure do not qualify the type of success achieved. Instead, the term *success* primarily has been used interchangeably with survival of the implant. The term *failure* has been used to indicate the implant is no longer present in the mouth. Nearly all reports in the prosthetic literature also report survival as success.

What is success for a natural tooth? In the periodontal literature a quality of health is presented, and well-established guidelines

based on clinical criteria describe the ideal health of natural teeth. The general term *success* in implant dentistry should be replaced with the concept of quality of health, with a health-disease continuum describing the status of implants.

TABLE 41.4 Implant Quality Scale

Implant Quality Scales	Clinical Conditions	Suzuki-Resnik Protocol
Success (optimal health) Osseointegration/Stage 0 osseoseparation	No pain or tenderness upon function 0 mobility <2 mm radiographic bone loss from initial surgery PD < 4 mm No suppuration No BOP	Protocol 1
Survival (satisfactory health) Stage I osseoseparation Peri-mucositis	No pain 0 mobility <2 mm radiographic bone loss from initial surgery Peri-mucosal inflammation PD ± 4 mm (bleeding and/or suppuration on probing)	Protocol 2
Survival (potentially compromised) Stage II osseoseparation Early peri-implantitis	No pain 0 mobility 2–4 mm radiographic bone loss PD ± 4 mm (bleeding and/or suppuration on probing) Peri-mucosal inflammation Bone loss <25% of the implant length	Protocol 2 or Protocol 3
Survival (compromised health) Stage III osseoseparation Moderate peri-implantitis	Variable pain 0 mobility Peri-mucosal inflammation PD ≥6 mm (bleeding and/or suppuration on probing) Bone loss 25%–50% of the implant length	Protocol 3
Failure (clinical failure) Stage IV osseoseparation Advanced peri-implantitis	Peri-mucosal inflammation Pain upon function PD >8 mm (bleeding and/or suppuration on probing) Bone loss >50% of the implant length Mobility Uncontrolled exudate Maybe no longer in mouth	Protocol 4
Others (such as retrograde peri-implantitis)	Variable peri-mucosal inflammation Radiographically: periapical lesion around implant Clinical: pain, tenderness, fistula formation or swelling	Surgical reentry and revision or removal of implant

BOP, bleeding on probing; *PD*, probing depth; *SPT*, supportive periodontal therapy.

From Suzuki JB, Misch CE. Periodontal and maintenance complications. In: Resnik RR, Misch CE, eds. *Misch's Avoiding Complications in Oral Implantology*. St. Louis, MO: Elsevier; 2018. Data from Suzuki JB, Hsiao YJ, Misch CE. Personal communication, 2017.

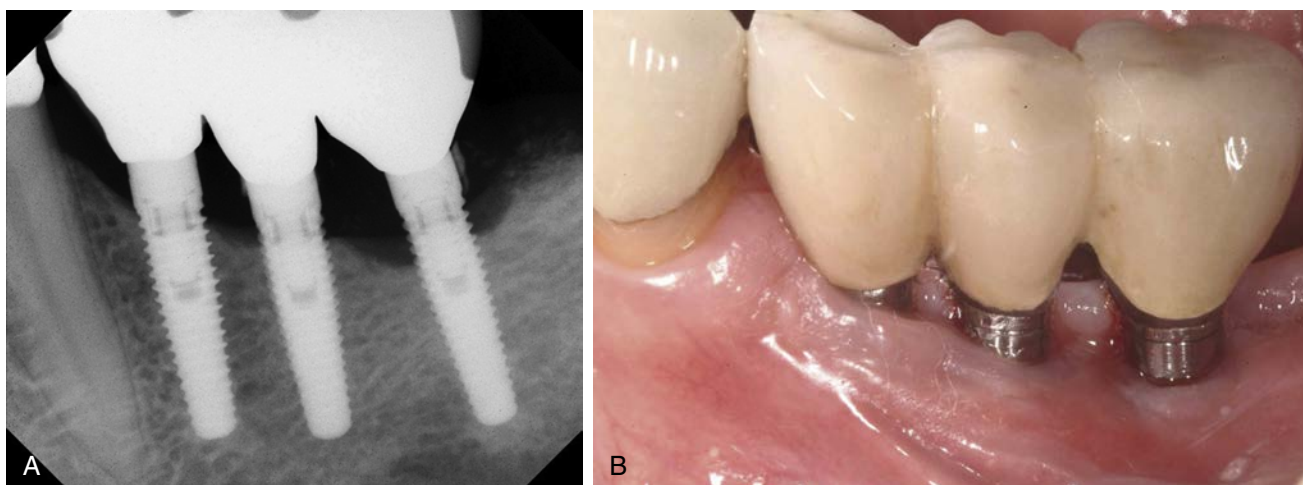
Success criteria for endosteal implants have been proposed previously.[214-218] The Misch scale proposes management modalities corresponding to different treatment levels.[219]

The most recent Suzuki-Misch-Hsiao implant health scale was published in Resnik and Misch's *Avoiding Implant Complications* (2017).[220] The Suzuki-Misch-Hsaio scale presented implant quality of health based on clinical evaluation (Table 41.4). This quality of health scale allows the implant dentist to evaluate an implant using the listed criteria, place it in the appropriate category, and then treat the implant accordingly. The prognosis also is related to the quality scale.

Ideal clinical conditions for natural teeth include absence of pain, less than 0.1 mm of initial horizontal mobility under lateral forces of less than 100 g, less than 0.15 mm of secondary mobility with lateral forces of 500 g, absence of observed vertical mobility, periodontal probing depths of less than 2.5 mm, radiographic crestal bone height 1.5 to 2.0 mm below the cementoenamel junction, intact lamina dura, no bleeding on probing, no exudate, and absence of recession or furcation involvement on multirooted teeth.

The American Dental Association CDT (2018) has defined five periodontal types for diagnosis and treatment of natural teeth.[221,222] The American Dental Association's categories of disease do not simply indicate success or failure but rather a range from health to disease. This classification allows a clinical approach to treatment in each category. A similar scale for implants has been established as an aid to diagnosis and treatment that also proposes management approaches according to the signs and symptoms.

Group I: Optimum Health

Group I represents implant success with optimum health conditions. No pain is observed with palpation, percussion, or function. No mobility is noted in any direction with loads less than 500 g of implant movement (IM). Less than 2.0 mm of crestal
• **Fig. 41.29** Group I: Optimum Health. (A and B) Ideal implants with no associated bone loss.


• **Fig. 41.30** Group II: Satisfactory Health. (A and B) Implants exhibit satisfactory health and are stable, but tenderness is observed on palpation, percussion, or function.

bone has been lost since the placement of the implant. This bone loss is typically a result of the implant biologic width below the abutment connection and surface of the implant. The implant has no history of exudate, and no radiolucency is present around the implant body. The probing depth is equal to or less than 5 mm and is stable after the first year. Ideally the bleeding index is 0 to 1. Group I implants follow a normal maintenance program every 6 months. The prognosis is very good to excellent (Fig. 41.29).

Group II: Satisfactory Health

Group II implants exhibit satisfactory health and are stable. No tenderness is observed on palpation, percussion, or function. No observable implant mobility was present in the horizontal or vertical direction with loads less than 500 g. Crestal radiographic bone loss is observed between 2 and 4 mm from implant placement. The most common cause is the early loading bone loss related to the amount of occlusal force and the density of the bone. No pain is observed. Probing depths may be as much as 5 to 6 mm because of the original tissue thickness and marginal bone loss, but are stable. Bleeding on probing index is often 1 or even 2. These implants may be considered to have peri-implant mucositis. The treatment indicated for group II implants consists of a stress reduction protocol for the implant system, shorter intervals between hygiene appointments (e.g., 3 months), reinforcement of oral hygiene instructions, annual radiographs until the crestal bone has stabilized, and gingivoplasty or sulcus reduction procedures where indicated. The prognosis is good to very good depending on the depth of the implant sulcus.

For pockets less than 6 mm in depth, the following can be concluded:
1. Mechanical therapy alone or combined with chlorhexidine results in the clinical resolution of peri-implant mucositis lesions.
2. Histologically both treatments result in minimal inflammation compatible with health.
3. The mechanical effect alone is sufficient to attain clinical and histologic resolution of mucositis lesions (Fig. 41.30).

Group III: Compromised Survival

Group III implants are classified as compromised survival and exhibit a slight-to-moderate peri-implantitis and compromised health status. Peri-implantitis is defined as an inflammatory process affecting the tissue around an implant that results in loss of supporting bone.

Group III implants are characterized by radiographically evident vertical bone loss, peri-implant pocket, bleeding on probing (plus occasional suppuration), and mucosal swelling and redness but no pain on function.

These implants warrant more aggressive clinical therapy. No pain is apparent in function, but tenderness may be slight on percussion or function. No vertical or initial horizontal mobility (IM-0) is evident. Greater than 4 mm of crestal bone loss has occurred since implant insertion but less than half the length of the implant. Greater than 7 mm and increasing probing depths are also present, usually accompanied by bleeding when probing. Exudate episodes may have lasted more than 1 to 2 weeks and may be accompanied by a slight radiolucency evident around a crestal region of the implant.

Group III implants warrant aggressive surgical and prosthetic intervention. Stress factors are also addressed. The prosthesis may be removed in nonesthetic regions. If a bar (used to support and retain an overdenture) is present, it may be removed during the surgical therapy. Modification of the occlusal scheme and methods to decrease the forces in the afflicted regions after hard and soft tissue surgical treatment include decreasing cantilever length, occlusal adjustment, and occlusal splint therapy.

In cases of rapid bone changes, the prosthesis design may be modified completely from a fixed to a removable restoration to stress relief and soft tissue support. Additional implants to support the restoration may be indicated, especially if the patient is unwilling to wear a removable prosthesis.

Systemic and topical antibiotics and local chemical agents such as chlorhexidine are indicated in the presence of exudate.

However, this method is usually of short-term benefit if the causative agents of implant failure are not eliminated.

Surgical management most often consists of soft tissue removal or exposure of a portion of the implant. Bone grafts may be used together with these approaches around the implant. A three-step approach is implemented for this category in the following order: (1) antimicrobial therapy (local or systemic), (2) stress reduction, and (3) surgical intervention.

The prognosis is good to guarded, depending on the ability to reduce and control stress after the surgical corrections have improved the soft and hard tissue health (Fig. 41.31).

Group IV: Clinical Failure

Group IV of implant health is clinical or absolute failure. The implant should be removed under any of these conditions: (1) pain on palpation, percussion, or function; (2) greater than 0.5 mm of horizontal mobility; (3) any vertical mobility; (4) uncontrolled progressive bone loss; (5) uncontrolled exudate; (6) more than 50% bone loss around the implant; (7) generalized radiolucency; or (8) implants surgically placed but unable to be restored (sleepers). Implants that are surgically removed or exfoliated are also in the category of failure.

This category also includes implants surgically removed or exfoliated and no longer in the mouth. The remaining edentulous area often is treated with autogenous, synthetic, or other substitute bone graft materials to replace the missing bone. After the favorable bony conditions are augmented, implants may be inserted again with a good prognosis.

The terminology for implant failure often is confusing, with different terms describing similar situations. Terminology for implant failure using the time period of failure has been suggested as a primary criterion. Many implant failures are not described ideally by the time of the complication and are not addressed in this nomenclature.
• **Fig. 41.31** Group III: Compromised Survival. (A and B) Implants are classified as compromised survival and exhibit a slight-to-moderate peri-implantitis and compromised health status.

Occasionally the patient will not permit removal of the implant. Regardless of whether the patient returns for implant removal, the implant is recorded as a failure in all statistical data. The patient should be warned against the irreversible damage to the surrounding bone with implants retained in this condition. Consideration should be given to their removal because future treatment may be compromised (Fig. 41.32).

Conclusion

Once the surgical and prosthetic phases of implant therapy have been completed, the work of the clinician is not over. Patients must be educated regarding proper maintenance of their implant-supported restorations, and routine examinations should be performed to monitor overall health. Many differences exist in the biology of natural teeth compared with implant-supported restorations as they pertain to periodontal status. It is critically important that the implant clinician recognize these differences, properly diagnose disease states, and effectively manage these problems should they arise. By understanding the etiologies of the various peri-implant disease states, a clinician can work with the patient to build an effective protocol of prevention (Figs. 41.33 and 41.34).

Implant Maintenance: Long-Term Implant Success

JON B. SUZUKI AND DIANA BRONSTEIN

The maintenance of endosseous implants has evolved over many decades, from trial and error of various anecdotal supportive therapy methods to evidence-based protocols. These newer maintenance protocols allow for the implant clinician to implement individualized patient care of the peri-implant tissues.[1,2] With patients understanding the benefits of dental implants, the dental profession is moving away from traditional prosthetics and integrating the latest dental implant technologic advances into treatment plans. Therefore in the future, a greater need will be required by the implant clinician to integrate a comprehensive systemic and supportive protocol to maintain the success and longevity of the implant prosthesis.[3]

Prevention of peri-implant disease is now an accepted fundamental cornerstone of effective and predictable treatment strategies. The preventive approach commences with ideal and realistic case selection, preoperative patient education, and control of risk factors associated with increased implant complication incidence.[4] The lifelong professional implant maintenance protocol must be communicated to and acknowledged by the patient as part of his or her presurgical educational process. Patients at a higher risk for the development of peri-implantitis need to be identified and monitored with a stricter maintenance protocol. In addition, because of the inherent differences between implants and teeth, patient education is crucial on the specifics of hygiene with respect to the dental implants and the type of prosthesis.[5]

Anatomy of Peri-implant Hard and Soft Tissues

The implant clinician must have a strong foundation for the relationship between the peri-implant tissues and the signs of disease so that early detection and definitive treatment may be rendered. If a disease process goes undiagnosed, hard and soft tissues complications may lead to an increased morbidity of the implants or associated prosthesis. When evaluating the hard and soft tissues surrounding a dental implant, many differences exist between the natural teeth and dental implants. The support system of natural teeth is much better designed to reduce biomechanical forces to the crestal bone region, thereby reducing the possibility of peri-implant disease. Because of the periodontal membrane, nerve and blood vessel complex, and occlusal material (enamel), occlusal overload is far less in comparison with dental implants.[6]

Soft Tissue Differences

For a natural tooth the surrounding soft tissue has an average biological width of 2.04 mm between the depth of the sulcus and the crest of the alveolar bone.[7] It should be noted that the biological "width" is actually a height dimension with a greater range in the posterior region compared with the anterior and may be greater than 4 mm in height.[8] With natural teeth the biologic width is composed of a connective tissue attachment (1.07 mm average) above the bone and a junctional epithelial attachment (0.97 mm average) at the sulcus base, with the most consistent value among individuals being the connective tissue attachment.

The connective tissue attachment zone of the "biological width" around a tooth will prevent penetration into the sulcus and allows gingival fibers of the connective tissue attachment zone to establish direct connection with the cementum of the natural tooth. It acts as a physical barrier to the bacteria in the sulcus to the underlining periodontal tissues. Eleven different gingival fiber groups comprise the connective tissue attachment zone observed around a natural tooth and tissue: dentogingival (coronal, horizontal, and apical), alveologingival, intercapillary, transgingival, circular, semicircular, dentoperiosteal, transseptal, periosteogingival, intercircular, and intergingival.[9] At least six of these gingival fiber groups insert into the cementum of the natural tooth: the dentogingival (coronal, horizontal, and apical), dentoperiosteal, transseptal, circular, semicircular, and transgingival fibers. In addition, some crestal fibers from the periodontal fiber bundles also insert into the cementum above the alveolar bone, forming a true attachment to the tooth. Clinically this attachment will prevent a periodontal probe from invading the periodontal ligament (PDL) space and minimize the ingress of bacteria (Fig. 42.1).

In comparison, the sulcular regions around an implant are very similar in many respects. The rete peg formation within the attached gingiva and the histologic lining of the gingiva within the sulcus are similar in implants and teeth.[10] A free gingival margin forms around a tooth or implant, with nonkeratinized sulcular epithelium and the epithelial cells. At the base, junctional epithelial cells are present for both. However, a fundamental difference characterizes the base of the gingival complex around teeth. Whereas a tooth has two primary regions that make up the biological width, an implant has only one (Fig. 42.2).

The biological seal for an implant, which is analogous to the epithelial attachment of the tooth, is needed to protect

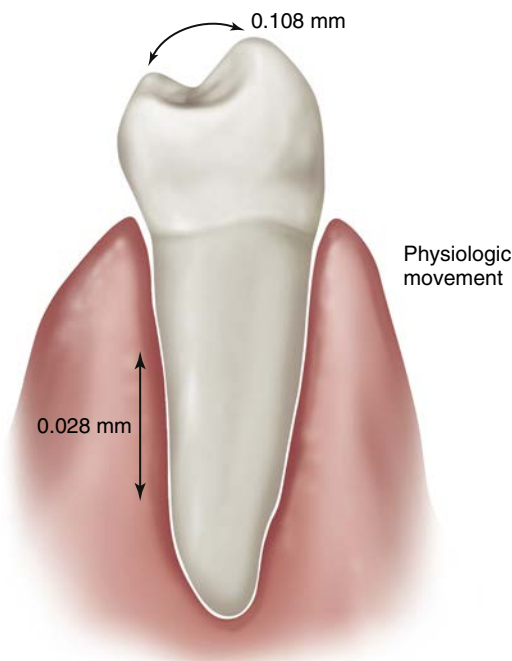
1192

● **Fig. 42.1** The biologic width for a natural tooth is approximately 1 mm of connective tissue above the bone and 1 mm of epithelial attachment between the sulcus and the connective tissue. *(From Misch CE. An implant is not a tooth: a comparison of periodontal indices.* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.)*
● **Fig. 42.2** The soft tissue around an implant (I) has a sulcular region very similar to a tooth. A free gingival margin (F) with nonkeratinized sulcular epithelium and cells at the base (C) has junctional epithelial attachment above the bone (B). *CT,* Connective tissue.

the implant-bone interface against bacterial irritants, as well as mechanical trauma such as restorative materials, prosthesis design, and occlusal forces. Cochran et al.[11] has reported the biologic width to be 3.3 mm for dental implants, but unlike the biological width dimension for teeth, they also included the sulcus depth. In a typical implant gingival region, only two of the gingival fiber groups are found around a tooth (circular and periosteogingival fibers), and no periodontal fibers are present.[12] These fibers do not insert into the implant body below the abutment margin as they do into the cementum of natural teeth.[13] Instead, the collagen fibers around an implant run parallel to the implant surface, not perpendicular, as with natural teeth.[14] Hence the implant has only a junctional epithelial "attachment" system. The gingival and periosteal fiber groups are responsible for the connective tissue attachment component of the biological width around teeth, and these are not present around the transosteal region of an implant. The "biological width" around the abutment-implant connection should not be similarly compared with the connective tissue attachment of a tooth. The biological seal around dental implants may to some degree prevent the migration of bacteria and endotoxins into the underlying bone. However, an attachment component of the biological width similar to the one found with natural teeth is not present with dental implants (Fig. 42.3).

Tooth Versus Implant Movement

A natural tooth exhibits normal physiologic movements in vertical, horizontal, and rotational directions. The amount of movement of a natural tooth is related to its surface area and root design. Therefore the number and length of the roots; their diameter, shape, and position; and the health of the PDL primarily influence a tooth's mobility. A healthy tooth normally exhibits zero clinical mobility in a vertical direction. Studies have shown the actual initial vertical tooth movement to be approximately 28 μm and is the same for anterior and posterior teeth.[15] The vertical movement of a rigid implant (i.e., integrated) has been measured as 2 to 3 μm under a 10-lb force and is due mostly to the viscoelastic properties of the underlying bone (i.e., bone density at the bone-implant interface).[16]

Muhlemann[17] found that horizontal tooth movement may be divided into initial mobility and secondary movement. The initial mobility is observed with a light force, occurs immediately, and is a consequence of the PDL. Initial horizontal tooth mobility is greater than initial vertical movement. A very light force (500 g) horizontally moves the tooth. The initial horizontal mobility of a healthy, "nonmobile" posterior tooth is less than that of an anterior tooth and ranges from 56 to 75μm, which is two to nine times the vertical movement of the tooth.
● **Fig. 42.3** An implant has no connective tissue fibers in the connective tissue zone that insert into the implant. The peri-implant probe penetrates the sulcus, junctional epithelial attachment (JE), and most of the connective tissue zone. *CT,* Connective tissue; *FGM,* free gingival margin. *(From Misch CE. An implant is not a tooth: a comparison of periodontal indices.* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.)*


● **Fig. 42.4** The physiologic movement of a tooth has been measured as 28 μm in the apical direction and up to 108 μm in the horizontal direction. *(From Misch CE. An implant is not a tooth: a comparison of periodontal indices.* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.)*

Initial horizontal mobility is even greater in anterior teeth and ranges from 70 to 108 μm in health[18] (Fig. 42.4).

The secondary tooth movement described by Muhlemann[17] occurs after the initial movement, when greater forces are applied. When an additional force is applied to the tooth, a secondary movement is also observed, which is related directly to the amount of force. The secondary tooth movement is related to the viscoelasticity of the bone and measures as much as 40 μm under considerably greater force (Fig. 42.5).
● **Fig. 42.5** A secondary horizontal movement of a tooth occurs after the initial tooth movement when a greater force is applied and is related to the deformation of the alveolar bone. *(From Misch CE. An implant is not a tooth: a comparison of periodontal indices.* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.)*
● **Fig. 42.6** Osseointegration is a histologic term that describes a direct bone-implant contact at the level of magnification of a light microscope.

When evaluating implant movement, "rigid fixation" indicates the absence of clinical mobility of an implant tested with vertical or horizontal forces less than 500 g. Rigid fixation is a clinical term, and osseointegration is a histologic term. Osseointegration is defined as bone in direct contact with an implant surface at the magnification of a light microscope (Fig. 42.6). Over the years these two terms have been used interchangeably, and implant abutment support is most predictable with rigid fixation. Lack of implant mobility (IM) does not always coincide with a direct bone-implant interface. However, when observed clinically, rigid fixation usually means that at least a portion of the implant is in direct contact with bone, although the percentage of bone contact cannot be specified. A mobile implant indicates the presence of connective tissue between the implant and bone.

Increased tooth mobility may be caused by occlusal trauma or bone loss. Increased tooth mobility alone is not a criterion of periodontal health or pathology. Unlike a tooth, for which mobility is not a primary factor for longevity, mobility is a primary determining factor for implant health. Rigid fixation is also an excellent indicator of the implant health status because it is an easy,

objective test. As such, rigid fixation is usually the first clinical criterion and the most important when evaluating a dental implant.

Past techniques to evaluate primary stability and mobility of dental implants have included percussion and mobility tests with mirror handles. However, these techniques were very subjective and were associated with inaccurate results. In implant dentistry today, the most common technique to assess the stability of dental implants is the use of resonance frequency analysis (RFA). Resonance frequency analysis (RFA) is a non-invasive, reliable, and clinically acceptable technique developed by Meredith in 1996.[19] This technique includes magnetic pulses being sent to a small metal post that is temporarily attached to the implant. As the post vibrates, the probe reads the resonance frequency which is translated into a value termed implant stability quotient (ISQ). The ISQ value is evaluated via a scale that ranges from 1 to 100, with high values indicating increased stability. Usually, acceptable ranges of stability lie between 55 – 85 ISQ, with values below 55 indicating possible mobility of the implant.[20] This technology is advantageous as measurements may be taken at the time of implant placement and used as a baseline for future measurements in the evaluation of the health of the dental implant. The Penguin RFA® (Glidewell Direct; Irvine, Calif.) is commercially available which uses re-usable multi-pegs that are implant specific. In addition, this device is cordless which is very user friendly for the clinician. When evaluating mobility of the implant, ideally the prosthesis should be removed, which allows for the multi-pegs to be directly inserted into the implant body.

Evaluating the mobility of the prosthesis does not allow for an accurate assessment of dental implant health as the associated mobility is most commonly from a loose abutment screw (Box 42.1 and Fig. 42.7).

A natural tooth with primary occlusal trauma exhibits an increase in clinical mobility and radiographic PDL space. After the cause of trauma is eliminated, the tooth may return to zero clinical mobility and a normal radiographic appearance. This scenario is not predictable around an implant. The implant clinician should not restore an implant with any clinical mobility, because the risk for failure is great. However, after the prosthesis is completed and IM-1 develops, the risk is small to evaluate the implant for a few months and decrease almost all stress during this time frame. Implants with slight detectable mobility of approximately 0.1 mm of horizontal movement (IM-1), similar to the mobility of a healthy central incisor, on occasion may return to rigid fixation and zero mobility. However, to reachieve rigid fixation, the implant should be taken completely out of occlusion for several months and strictly monitored. The return of rigid fixation of an implant is far greater if no mobility is noted before the implant is placed into function.

An implant with horizontal movement greater than 0.5 mm (IM-3) is at much greater risk than a tooth. A root form implant with greater than 0.5 mm horizontal mobility (IM-3) or any vertical mobility (IM-4) should be removed to avoid continued bone loss and future compromise of the implant site or adjacent teeth (Table 42.1).

Maintenance Protocol

Medical and Dental Histories

The first step in the maintenance protocol is to update the patient's medical and dental histories. This is a mandatory component of the maintenance protocol and is crucial in determining whether there presently exist any concomitant conditions that would predispose the patient to peri-implant disease.

• **Fig. 42.7** (A, B) Penguin Resonance Frequency Analysis Unit (Aseptico) which measures the ISQ (Implant Stability Quotient) implant stability using reusable, calibrated MulTipegs.

• BOX **42.1** Mobility Measurements[97]	
Scale	**Description**
0	Absence of clinical mobility with 500 g in any direction
1	Slight detectable horizontal movement
2	Moderate visible horizontal mobility up to 0.5 mm
3	Severe horizontal movement greater than 0.5 mm
4	Moderate-to-severe horizontal and any visible vertical movement

Medical History

Medical conditions may change during the maintenance phase (i.e., after implant prosthesis completion) of treatment that have a direct impact on the morbidity and success of the implants or prosthesis. It is imperative the patient relates any updates to his or her medical history because many systemic conditions may affect the long-term prognosis of dental implants and the prosthesis.

1. Xerostomia: The lack of saliva (i.e., dry mouth) is caused by hypofunction of the salivary glands and may be caused by numerous medications and systemic conditions. Most commonly, autoimmune conditions may result in xerostomia, as well as many medications, especially if given concurrently.

TABLE 42.1	Comprehensive Differences Between Natural Teeth and Dental Implants	
	Natural Teeth	**Dental Implants**
Interface	Periodontal membrane	Direct bone
Junctional epithelium	Hemidesmosomes and basal lamina (lamina lucida and lamina densa zones)	Hemidesmosomes and basal lamina (lamina lucida and lamina densa, and sublamina lucida zones)
Connective tissue	12 groups: six insert perpendicular to tooth surfaces ↓ Collagen, ↑ fibroblasts	Only two groups: parallel and circular fibers; no attachment to the implant surface ↑ Collagen, ↓ fibroblasts
Vascularity	Greater; supraperiosteal and PDL	Less; mainly periosteal
Biologic width	2.04–2.91 mm	3.08 mm
Mobility	+	–
Pain	+/– (tooth may be hyperemic)	–
Attrition	+ Wear facets, abfraction, fremitus	– (~ porcelain fracture, possible screw loosening)
Radiographic changes	+ Increased radiopacity and thickness of cribriform plate	Crestal bone loss
Interference awareness	+ (Proprioception)	– (Osseoperception)
Nonvertical forces	Relatively tolerated	Results in bone loss
Force-related movement	Primary: movement of PDL Secondary: osseous movement	Primary: osseous movement
Lateral force	Apical third of root surface	Crestal bone
Lateral movement	56–108 μm	10–50 μm
Apical movement	25–100 μm	3–5 μm
Tactile sensitivity	High	Low
Signs of overloading	PDL thickening, fremitus, mobility, wear facets, pain	Screw loosening, screw fracture, abutment fracture, implant body fracture, bone loss

PDL, Periodontal ligament.

Xerostomia has been shown to affect the dental biofilm composition and intraoral healing of the soft tissues. Immune cells (e.g., neutrophils) and immune factors (e.g., lysozyme, secretory IgA) are normally delivered and distributed in the oral cavity through the saliva; therefore a lack of saliva may lead to lowered antimicrobial components in the oral cavity.[21-24] Prosthetically, patients who acquire xerostomia after completion of treatment may become compromised. For example, a patient with a soft tissue–borne implant prosthesis (i.e., RP-5 overdenture) may experience soft tissue irritation because of the lack of saliva.

2. Autoimmune diseases: Selected autoimmune diseases have been associated with peri-implantitis. For example, lichen planus causes the hemidesmosomal epithelial attachment to the implant surface to become disabled, leading to peri-implant mucositis and possibly progressing to peri-implantitis.[25] However, long-term implant survival, according to current research, does not seem to be affected.[26] With many autoimmune diseases, patients may lose their manual dexterity, thereby decreasing hygiene ability and also difficulty in removing an attachment-dependent overdenture prosthesis. Some of the more common autoimmune disorders and the associated symptoms that may affect the oral cavity are as follows:
   - Sjogren's syndrome: xerostomia
   - Systemic lupus erythematosus: corticosteroid treatment and immunosuppressive medications

   - Scleroderma: manual dexterity and immunosuppressive medications
   - Rheumatoid arthritis: manual dexterity and immunosuppressive medications
   - HIV: compromised lymphocytes and immunosuppressive medications
3. Bone diseases: Altered bone physiology in conditions such as osteoporosis/osteomalacia/osteopenia, Paget's disease, and fibrous dysplasia may significantly increase the risk for complications for implant patients.[27]
4. Diabetes: Poor diabetic control (i.e., > 7% A_{1c}) correlates the inflammatory markers closer to patients with chronic periodontitis when peri-implantitis is present. Patients with diabetes, especially if uncontrolled, are prone to acquire infections and vascular complications. The healing process is affected by the impairment of vascular function, chemotaxis, and neutrophil function, as well as an anaerobic milieu. Protein metabolism is decreased, and healing of soft and hard tissue is delayed, which may lead to the susceptibility of infection. Neuropathy and impaired nerve regeneration may be altered, as well as angiogenesis.[28]
5. Pregnancy: During the maintenance period, radiographs should be delayed until after birth with pregnant patients. Medical clearance should be obtained if radiographs or procedures need to be performed on an emergency basis.

6. Radiation treatment to the oral cavity: Patients who receive radiation to the oral cavity after implant treatment may suffer from many deficits including oral mucositis, xerostomia, compromised healing, and reduced angiogenesis. This is a direct result of changes in the vascularity and cellularity of hard and soft tissue, damage to the salivary glands, and increased collagen synthesis that results in fibrosis. Therefore patients exhibiting these complications should be treated symptomatically. Patients who presently wear a tissue-borne prosthesis (RP-5) may benefit from changing the final prosthesis to a fixed (non-tissue-bearing) prosthesis.

7. Sleep apnea: Patients who are diagnosed with sleep apnea are often treated with continuous positive airway pressure(CPAP). The CPAP machine uses a hose and mask that delivers constant steady air pressure. CPAP machines may place an increased force on the oral cavity. Therefore if patients are using a CPAP machine, the implant area should be monitored closely.

8. Elderly patients: Elderly patients have been shown to have many issues with adapting to the final implant prostheses. Postinsertion complications such as muscle control, hygiene difficulty, tissue inflammation, and overdenture seating are significant in the older population study. During maintenance visits, patient education should be continuously reenforced.

9. Smoking: The use of tobacco should be closely monitored with implant patients. Studies have shown the detrimental effects of the gases and chemicals (e.g., nitrogen, carbon monoxide, carbon dioxide, ammonia, hydrogen cyanide, benzene, nicotine) released in cigarette smoke. Multiple retrospective studies have shown that smokers experience almost twice as many implant failures compared with nonsmokers, and there exists a strong correlation with peri-implantitis.[29] The negative effects of smoking on the implants/prosthesis should be reenforced at each maintenance visit.

10. Phenytoin (Dilantin): The most common medication to cause peri-implant conditions is phenytoin (Dilantin). Dilantin is associated with a high incidence of gingival overgrowth (hyperplasia) of peri-implant soft tissue, *implant gingival hyperplasia*, *mucosal proliferation*, *proliferative gingivitis*, and *implant-related tissue hyperplasia*, and has been recognized as a significant clinical issue in implant dentistry today. If there is no associated bone loss, the pockets are termed *pseudopockets* or *gingival pockets.* These hyperplasia-induced pockets may harbor pathogenic anaerobic bacteria. The plaque biofilm colonization and maturation in implant pockets initiates inflammation. The resultant hyperplastic tissue is most commonly composed of compact collagenous fibers, fibroblasts, and inflammatory cells. Management of peri-implant gingival overgrowth should include the identification of the etiology (e.g., medication or humoral). If the etiology is determined to be medication induced, consultation with the patient's physician is recommended for possible alternative treatment.

11. Miscellaneous: Epidemiologic and longitudinal studies have found an association of peri-implantitis prevalence with hepatitis and cardiovascular disease.[30] Cardiovascular disease is associated with periodontitis and peri-implantitis through the systemic-inflammatory-mediator link and appears to be an indirect cofactor in patients whose profile identifies them as being predisposed to inflammatory diseases.[31]

Interestingly, genetics has been implicated with aggressive periodontal diseases, which appear to be correlated with peri-implantitis. Studies associate peri-implant disease with the *IL-1* gene polymorphism in smokers.[32]

• BOX 42.2 Loe and Silness Bleeding Index

Normal
0 = mild inflammation, slight color change and edema, no bleeding
1 = moderate inflammation, redness, edema, bleeds on probing
2 = severe inflammation, marked redness and edema ulceration, spontaneous bleeding

---

Dental History

The dental history update is crucial in determining any changes to the patient's oral condition. Changes in home care practices, along with recent dental treatment, should be documented and evaluated for any impact on the implant prostheses. Of special concern are parafunctional habits (e.g., clenching, bruxism), which if present or worsening may lead to peri-implant diseases or implant failure.

Clinical Evaluation of the Implant(s)/Prosthesis

Soft Tissue Assessment

An overview of the visual signs of gingival inflammation (e.g., redness, edema, alterations of tissue contour, fistula tracts) should be evaluated and documented. Poor tissue tone (i.e., thin, friable, flaccid) surrounding an implant may harbor food, plaque, and calculus, which increases the possibility of inflammation and infection. A gingival health index may be used to evaluate the soft tissue health. The most common bleeding gingival index used for implants is the Loe and Silness gingival index. When used on teeth, this index scores gingival inflammation from 0 to 3 on the facial, lingual, and mesial surfaces of all teeth. The symptom of bleeding comprises a score of at least 2 (Box 42.2). The facial and lingual are already being probed to evaluate bone loss that cannot be seen on a radiograph. Because the bleeding index evaluates inflammation, the Loe and Silness index is adequate for implants, and because fewer implants typically are used to restore a region compared with the presence of natural teeth, one also may evaluate the distal surface when bleeding is present[33] (Fig. 42.8).

Assessment of Home Care

Because the presence of microbial biofilm has been shown to be a leading factor in the pathogenesis of peri-implant disease, the routine assessment of plaque accumulation should be a priority of each maintenance visit. This objective form of plaque monitoring should ideally be performed and documented at each maintenance visit. Consistent use of the same plaque index is paramount because this will allow an easier determination of the presence of a disease process. High plaque scores have been shown to have a direct correlation with peri-implant mucositis and increased probing depths.[34] Mombelli et al.[35] and Lindquist et al.[36] have reported implant-specific plaque indices to be used at dental implant maintenance appointments. Mombelli et al.[35] suggested a numerical scale from 0 to 3, which is dependent on the amount of visible plaque present or by running a probe over the implant surface. Lindquist et al.[36] recommended a similar scale (i.e., 0–2) dependent on the amount of visible plaque (Fig. 42.9 and Box 42.3).

Probing

Probing around dental implants is a controversial topic even though it has been shown in the literature to be a reliable and important factor in determining peri-implant health. The safety of probing, once thought to be detrimental, has been well established

● **Fig. 42.8** Soft Tissue Assessment. (A) Edematous tissue surrounding dental implant. (B) Significant gingival recession leading to exposure of the implant bodies allowing for plaque accumulation. (C) Poor tissue quality resulting from facial bone loss. (D) Soft tissue recession resulting from apical positioned implant which leads to soft tissue loss and resultant black triangles.
● **Fig. 42.9** (A and B) Plaque accumulation as a result of recession and poor oral hygiene.

and does not jeopardize the integrity of the implant system.[37,38] Etter et al.[39] reported after probing of the implant system, healing of the epithelial attachment will occur approximately 5 days after clinical probing.

The connective tissue zone for an implant has only two fiber groups, and neither of them inserts into the implant. As a result, with an implant, the probe goes beyond the sulcus, through the junctional epithelium attachment, and through the type III collagen connective tissues and reaches closer to the bone.[40] Because the probe penetrates deeper next to an implant compared with a tooth, one should take

care not to contaminate the implant sulcus with bacteria from a diseased periodontal site. To prevent contamination, the dental probe tip may be placed in chlorhexidine after each reading, thereby reducing the possibility of inoculating the sulcular area of the next probed area. In most cases probing depths of 2 to 4 mm have been established as a healthy condition[41] (Figs. 42.10 and 42.11).

In addition, there exists controversy concerning the type of periodontal probe to use with dental implants. Many authors have advocated the use of plastic periodontal probes[42,43]; however, more recent articles have recommended conventional metal

• **Fig. 42.10** A probe placed into the sulcus of a tooth goes through the sulcus and the epithelial attachment. It is stopped by the connective tissue attachment. The biological width of a natural tooth has a connective tissue zone that inserts into the cementum of the tooth. A periodontal probe will penetrate the sulcus and the junctional epithelial (JE) attachment. *CT,* Connective tissue; *FGM,* free gingival margin. *(From Misch CE. An implant is not a tooth: a comparison of periodontal indices.* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.)*

probes because they do not appear to damage the mucosal attachment or mar the implant surface.[44,45]

Ideally there should be baseline clinical probing depths acquired after the initial insertion of the prosthesis. However, in some cases, because of malpositioned implants or an overcontoured prosthesis, obtaining true probing depths may be difficult. In these cases a more routine radiographic evaluation is indicated to help ascertain peri-implant health.

When bleeding on probing is present, usually this is indicative of positive peri-implant disease. Studies have shown that similar to natural teeth, the absence of bleeding on probing may be interpreted as highly predictive of stability of the peri-implant tissues.[46,47] However, a positive correlation exists with bleeding on probing and histologic signs of inflammation at peri-implant tissue levels.[48]

Care should be exercised to avoid false-positive readings for bleeding on probing depths. Gerber et al.[49] reported that a pressure of approximately 0.15 N should be used to minimize

incorrect readings. Probing around dental implants has been shown to be more sensitive to force variation in comparison with natural teeth.[50]

The thickness and the type of tissue may influence the mucosa/epithelium surrounding a dental implant. Van Steenberghe et al.[51] determined that shallow (minimal) probing depths are associated with keratinized tissue, and deeper probing depths are consistent with alveolar mucosa (i.e., movable tissue) surrounding the implant.

On probing the peri-implant tissues, if suppuration is present, the implant clinician should be conscious of the strong evidence of the presence of infection or peri-implant disease. Radiographic evaluation should be immediately completed to determine the etiology of the exudate and the infectious origin.

When evaluating probing depths, greater than 3 mm is not a definite sign of peri-implantitis; peri-implant tissue dimensions are influenced by the implant type and shape, the connections of the multiple components (material and retention mode), and the prosthetic restoration design and configuration. Coveted soft tissue conditioning in the esthetic zone to simulate an interdental papilla can lead to an increase in the distance from the implant shoulder to the mucosal margin of up to 5 mm.[52] Clinical presentations may be misdiagnosed as peri-implantitis when factors such as mucositis and marginal bone remodeling ensue from deep positioning of the implant for more acceptable esthetic outcomes. The diagnosis of peri-implantitis may also be caused by the local anatomic variations.[53]

Controversy surrounds the issue of using bleeding and gingival health as an implant health indicator. Unlike a natural tooth, implant success in the first few years is related more often to biomechanical equilibrium than to gingival health. Compared with a natural tooth, the soft tissue inflammation caused specifically by bacteria may be more restricted to above the crestal bone, because of the lack of a periodontal membrane or fibrous tissue between the implant and the bone interface. As a result the bleeding index may not be as significant when evaluating early implant health status.[54]

Presence of Keratinized Tissue

In recent literature, compelling clinical published reports have correlated peri-implantitis with keratinized gingiva and biotype thickness. A few studies have shown a minimal correlation between keratinized tissue and implant success. However, other reports have shown a lack of keratinized tissue is associated with bone loss,[55] increased plaque acculumlation,[56] increased gingival recession,[57] increased gingival inflammation,[58] and a higher frequency of bleeding on probing.[59]

The soft tissue at the implant site has been recognized as a crucial factor in long-term maintenance of healthy implant restorations. The soft tissue quality at the implant site, together with the gingival biotype, is a predisposing factor in a patient's resistance to plaque accumulation and inflammatory-mediated peri-implant disease.[60,61] Unattached, nonkeratinized mucosal tissue is more problematic because implants do not have inserting supracrestal gingival fibers, which serve as a barrier to bacterial insult; Sharpey's fibers run parallel to the implant, leaving only the hemidesmosomal seal of the junctional epithelium at the neck of the implant to protect underlying soft and hard peri-implant structures. During the mastication process, this seal may be broken when the vestibule is shallow and frenum attachment is high, causing excess pressure on the

● **Fig. 42.11** Controversies related to probing include the material of the probe and the difficulty in obtaining accurate measurements (A) probing around an implant retaining a bar overdenture; (B) if excessive probing pressure is used, probing depths will be inaccurate and traumatize the tissue; (C) if the prosthesis is overcontoured, difficulty in probing will result; (D) difficulty probing with a plastic probe around the contours of a fixed prosthesis.

tissue. Microbial colonization may then progress to the crestal and peri-implant tissue, which may result in the early stages of peri-implant disease. If plaque control is not adequate around the implants lacking keratinized gingiva, tissue may cause irritation and sensitivity, which may be uncomfortable for the patient.

For the existing soft tissue the quality may be classified as either a thin or a thick biotype. Thin gingival biotype is indicative of thin underlying supporting bone. Thin structures are less vascularized and more prone to recession and resorption in the presence of inflammation. Therefore patients with a thin biotype are more susceptible to peri-implant complications, especially if keratinized tissue is compromised (Box 42.4).

In conclusion, there is increasing literature to support the advantage of keratinized tissue over nonkeratinized tissue. Many authors recommend keratinized mucosa more intensely than others.

In specific clinical instances, attached, keratinized gingiva is more often desirable. For example, a fixed prosthesis (FP-1) in the esthetic zone (anterior maxilla) will require keratinized mucosa to

---

• BOX 42.4 Benefits of Keratinized Tissue Around an Implant

1. Similar to natural teeth tissue in color, contour, and texture of the soft tissue drape
2. More esthetic, especially when a high smile line exists
3. Keratinized tissue is more resistant to abrasion
4. Maintaining papillae is more predictable if keratinized tissue is present
4. Hygiene aids are more comfortable to use
5. Degree of gingival recession is proportional to the amount of keratinized gingiva
6. Keratinized mucosa is more manageable during the retraction and impression process
7. Long-term tissue stability is greater with keratinized tissue
8. With two-stage implant placement, wound dehiscence is less likely

develop a soft tissue drape around the implant prosthesis. Another prime example is with a mandibular overdenture, which benefits from a stable vestibule and a zone of nonmobile tissue around the
● **Fig. 42.12** Inadequate Keratinized Tissue. (A) Lack of quality attached tissue on facial aspect of the healing abutments. (B and C) Lack of keratinized tissue on facial of final prosthesis. (D) Bar overdenture exhibiting compromised attached tissue because of the facial placement of the implants.

implant abutments. When these conditions exist, it is less likely for patients to exhibit tissue sensitivity. Current recommendations based on clinical experience and current systematic reviews are to evaluate and, if possible, increase deficient sites of inadequate keratinized gingiva around implants prophylactically if peri-implant disease exists[62,63] (Fig. 42.12).

Mobility of Implant/Prosthesis

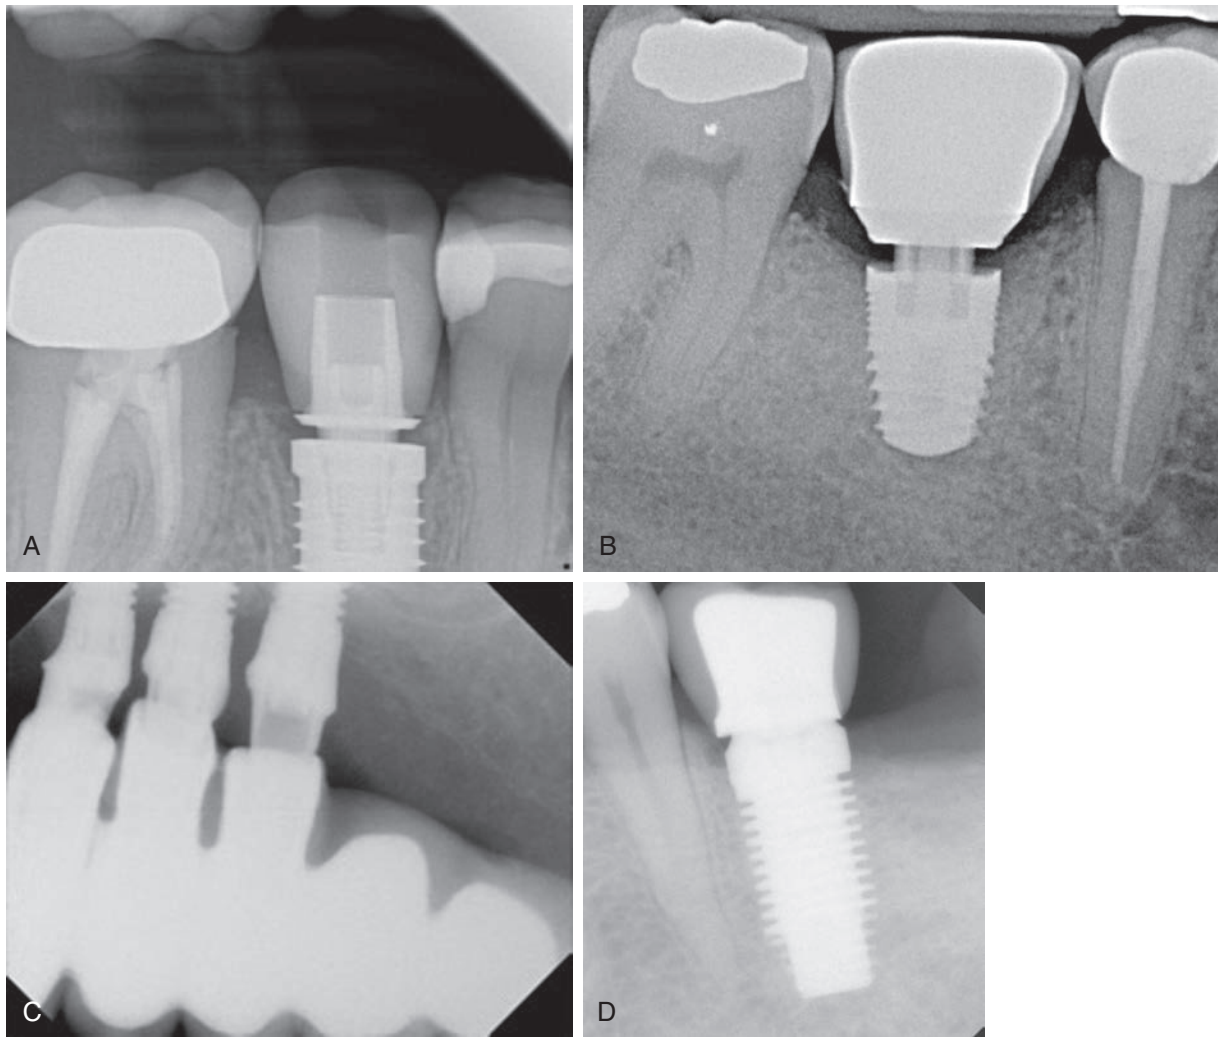
At each maintenance appointment the mobility of the prosthesis and implants should be evaluated. If mobility exists, the etiology should be ascertained, specifically if it is due to a loose screw or implant failure. Usually if pain is present when the prosthesis is moved in a buccal-lingual and apical direction, then it is most likely due to an implant failure (i.e., unless the tissue is impinging on the tissue, resulting in pain). When implant failure exists, pain will result because of the soft tissue interface. If no pain exists, then usually this is indicative of screw loosening (Fig. 42.13).

Pain/Sensitivity

A component of the maintenance protocol is the determination of any possible subjective findings of pain, tenderness, and sensitivity concerning the patient's peri-implant tissues, implant body, or implant prosthesis. Pain and tenderness are subjective criteria and depend on the patient's interpretation of the degree of discomfort.

Pain is defined as an unpleasant sensation ranging from mild discomfort to excruciating agony. Tenderness is more an unpleasant awareness of the region. An implant rarely is troubled by the subjective criteria of pain or sensitivity after initial healing. In contrast to a natural tooth an implant does not become hyperemic and is not temperature sensitive. If a traumatic occlusion situation is present, rarely will symptoms be present with an implant.

Implant-Related Pain. After the implant has achieved primary healing, absence of pain under vertical or horizontal forces is a primary subjective criterion. Usually, but not always, pain does not occur unless the implant is mobile and surrounded by inflamed tissue or has rigid fixation but impinges on a nerve. The most common condition that causes discomfort from an implant is when a loose implant abutment is entrapping some of the soft tissue in the abutment-implant connection. Usually, after the soft tissue in the region is removed and the abutment is repositioned, the discomfort or pain will subside.

When an implant is mobile, pain may occur early or late in treatment. In either case the condition rarely improves. Pain on loading of rigid implants has been observed more often on immediately loaded implants compared with those healing unloaded for an extended period. Implant sensitivity or mild tenderness rather than pain in a rigid implant is also most unusual and signals a more significant complication for an implant than for a tooth. Tenderness during function or percussion usually implies


• **Fig. 42.13** (A and B) Mobile implant prostheses diagnosed at the maintenance appointment. (C) Ill-fitting and loose full-arch fixed prosthesis. (D) Ill-fitting prosthesis which may result from loose abutment screw.

healing in the proximity of a nerve or, on rare occasions, bone stress beyond physiologic limits.

On occasion an implant body may fracture from fatigue. Fatigue is related to the amount of force, the number of cycles, the strength of the material, the diameter of the component, and the number of implants splinted together. This condition is similar to a fractured root. In any case, radiographic evidence of the fracture may be difficult to ascertain. Percussion and forces up to 500 g (1.2 psi) with a bite stick are used clinically to evaluate a tooth or implant for pain or discomfort. Percussion and heavy biting on a wood stick associated with pain are clinical indices. In these cases the implant is most often removed, which especially in the mandible (i.e., dense bone) may be difficult (Fig. 42.14).

Abutment-Related Pain. When the abutment-implant connection is not secure, pain may result because of tissue integration into the void. This pain is usually persistent and occurs most often during percussion or function. If this occurs, the prosthesis and abutment should be removed, soft tissue excised, and components repositioned (Fig. 42.15).

Infection-Related Pain. Especially in the early stages of peri-implantitis, pain usually does not present as a primary clinical symptom. Unless active infection with suppuration accompanies sufficient osseous destruction, patients do not experience pain.

Because dental implants do not have a PDL support and its sensory apparatus, low-grade infections and bone resorption are not detected by marginal gingiva. As the disease process begins around an implant, the patient may feel slight irritation, but normally not alarming pain.[64,65] It is recommended that the implant clinician be proactive in evaluating the status of dental implants with the incorporation of a routine maintenance protocol for implant patients.

Occlusion

Ideally, in most fixed implant cases an implant-protected occlusion should be present. Implant-protected occlusion (i.e., canine guidance) should be adhered to so the anterior teeth protect the posterior teeth (i.e., protrusive movements) and the posterior teeth protect the anterior (i.e., centric occlusion).

Traumatic occlusion has been shown to be an etiologic factor in the loss of bone around the peri-implant region. A timed occlusion should always be present, which includes the natural teeth contacting first before the contact of the implant (i.e., to compensate for the PDL compression during occlusal contacts). During light contact, extrathin articulating paper (e.g., shimstock) should be easily pulled through the occlusal contact with an implant. Then during heavy contact, minimal resistance should be present. Miyata et al.[66] reported with monkey studies that bone loss
● **Fig. 42.14** Implant Pain. (A and B) If pain is present with an implant, it is usually a failure because of a soft tissue encapsulation; radiographs reveal significant radiolucency surrounding the implant bodies. (C and D) If suppuration is present, usually the patient will be symptomatic.

may occur with an excess occlusal contact of 180 μm, even in the absence of peri-implant inflammation. Therefore it is imperative that the implant clinician evaluate and modify the existing occlusion if necessary, at each appointment (Fig. 42.16).

In addition, the presence of parafunctional habits (e.g., clenching, bruxism) should be documented and treated, most commonly with an occlusal guard. A hard acrylic centric is most commonly used.

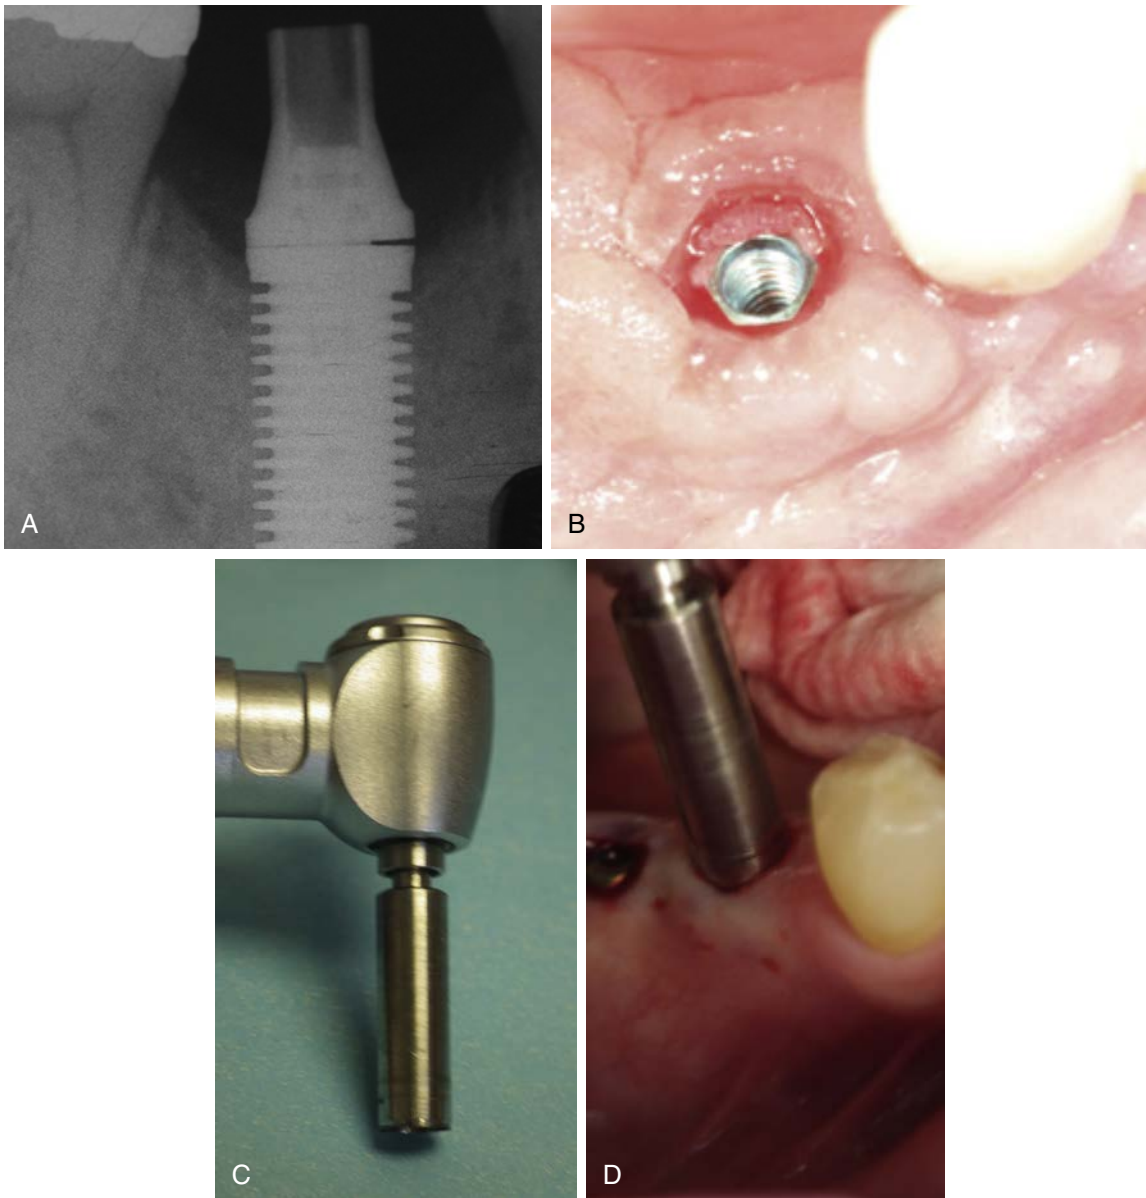
Prosthesis

At each maintenance appointment the prosthesis should be evaluated for not only mobility but also any fractures of the prosthesis material (e.g., porcelain, acrylic, zirconia). If material fracture is present, the occlusion should be immediately evaluated and the possibility of replacement is determined. For a removable prosthesis, all implant attachments should be evaluated for mobility and retention.

Radiographic Evaluation of the Implant and Prosthesis

An accurate and thorough radiographic examination should be performed as a routine adjunct to the clinical maintenance examination (Box 41.2). Ideally the radiographic modality used should be able to standardize the evaluation of the implant interface and bone level. The selection of the radiographic modality is dictated by the number and position of implants, along with the type of prosthesis.

Upon radiographic evaluation the crestal bone region is often the most diagnostic for the ranges of optimum, satisfactory, and compromised health conditions. Radiographic interpretation is one of the easiest clinical tools to use to assess implant crestal bone loss, but has many limitations. However, a two-dimensional radiograph will illustrate only the mesial and distal crestal levels of bone (Fig. 42.17).

When early bone loss occurs, it is most often present on the facial aspect of the implant. The absence of radiolucency around an implant does not indicate bone is present at the interface. Therefore two-dimensional radiographs (i.e., periapical, bitewings, panographic films) may often be misleading on revealing the amount of bone loss. In the mandibular anterior region, as much as a 40% decrease in density is necessary to produce a traditional radiographic difference in this region because of the dense cortical bone.[67] When abundant bone width is present, a V-shaped crestal defect around an implant may be surrounded by cortical bone and, as a result, the radiograph is less diagnostic for bone loss.


● **Fig. 42.15** Abutment-Related Pain. (A) An incomplete abutment seating will result in tissue growth with resultant pain. (B) After implant is removed, tissue impingement is evident. (C and D) The excess tissue is removed with a latch-type tissue punch.

Radiograph Type

The type of radiograph used in the evaluation of the implant and prosthesis is difficult to generalize. Standardized periapical radiographs are usually recommended as the most common type of radiographic modality in evaluation of dental implants. The long cone paralleling technique should be used to minimize image distortion.[68] Panoramic radiographs exhibit inherent disadvantages, including magnification, distortion, overlapping images, and poor resolution. Therefore panoramic radiographs are not the most ideal radiograph in evaluating bone loss (Fig. 42.18). However, in cases where periapical or bitewing radiographs cannot be obtained, panoramic films may be used.

Cone beam computed tomography (CBCT) scans, although superior to plain film radiographs in the diagnosis and treatment planning phases of implant dentistry, are usually not indicated for routine maintenance unless complications are present.

Studies evaluating the visibility of the buccal plate showed that if the amount of bone present is less than 0.6 mm in thickness, the bone will be invisible on a CBCT image.[69] In addition, CBCT images suffer from beam hardening, which leads to the formation of a radiolucency surrounding the implant. This occurs from a greater number of photons being absorbed (Fig. 42.19). In summary, the type of image modality should be specifically tailored to each individual patient, according to clinical and anatomic circumstances.

Radiograph Accuracy

It is often more difficult to obtain an accurate radiograph of the implant body in comparison with a natural tooth. Most commonly, implants are placed more apical to the apex of the preexisting natural teeth. As a result the apex of the implant often is located beyond muscle attachments or in regions almost impossible to capture with a parallel radiographic method. A foreshortened

image to encompass the apical portion of the implant results in poor display of the crestal bone. An accurate radiograph will show a clear depiction of the threads on the radiograph and a proper angulation. If the implant threads are clear on one side but blurry on the other, the angulation was incorrect by approximately 10%[70] (Fig. 42.20). If both sides of a threaded implant

are unclear, the radiograph is not diagnostic for crestal bone loss assessment because of angulation issues. Ideally the abutment-implant connection should appear as a clear line between the two components. When the top of the implant is placed at the crest of the regional bone, the amount of crestal bone loss is most easy to evaluate (Fig. 42.21).

In addition, the prosthesis should be evaluated for any radiographic changes from the baseline radiographs. Of utmost importance is the fit of the prosthesis because an ill-fitting or loose prosthesis may lead to peri-implant disease. If a space is present between the prosthesis and the abutment, the prosthesis should be immediately evaluated for passivity and mobility.

Radiograph Timing

The most important radiograph for use in the maintenance phase is the postprosthetic baseline radiograph. This radiograph is most often taken at the prosthesis insertion appointment. By this time the "biological width" most likely will have influenced the implant crest module bone level.

In general, implants with machined surfaces or external hex connections are usually subject to an initial remodeling of the bone level. Adell et al.[71] reported an average bone loss of 1.5 mm during the first year and 0.1 mm per year thereafter. However, recent implant design changes have reduced this bone loss with internal connections and platform switching.[72,73]

In most cases an individualized radiographic protocol should be developed based on the number and location of implants, type of prosthesis, and any associated complications. A comprehensive and generalized radiologic protocol was established by Resnik[74] in 2016 (Box 42.5).

Radiographic Crestal Bone Loss

The marginal bone around the implant crestal region is usually a significant indicator of implant health. The cause of crestal bone loss around an implant is multifactorial and may occur at different

● **Fig. 42.16** Occlusal Contacts. (A) The occlusion should be checked at each maintenance appointment to ensure lack of premature contacts. (B) Ideal occlusion consists of primary contact (i.e., light occlusion) on the natural teeth and light contact on implants during heavy occlusion.
● **Fig. 42.17** (A) Radiograph depicting significant bone loss surrounding the anterior implant; however, this may be misleading because it depicts only the mesial and distal bone levels. (B) Vertical bitewing exhibiting ideal angulation.

time periods: surgical bone loss, initial "biologic width" bone loss, early loading bone loss, intermediate-term bone loss, and long-term bone loss. Each period may be associated with a different cause for the bone loss. Most often the surgical trauma results in minimal bone loss, but on occasion, bone loss may reach several millimeters (Fig. 42.22).

When the abutment is attached to the implant body, approximately 0.5 to 1 mm of connective tissue forms apical to this connection.[75] This associated bone loss may be caused by an "implant biologic width." Initial bone loss during the surgical healing phase may vary for submerged and unsubmerged healing protocols.[76]

After the implant is connected with a permucosal element, the marginal bone may be lost during the first month from: (1) the position of the abutment-implant connection or (2) the crest

● **Fig. 42.18** Panoramic Image. The determination of the amount of bone loss on a panoramic image is misleading because of the magnification, distortion, overlapping images, and poor resolution.

module design of the implant. The abutment-implant connection may cause 0.5 to 1.0 mm of bone loss when it is at or below the bone. In addition, when smooth metal is present below the abutment-implant connection, additional bone loss will occur in direct relation to the smooth metal region. The bone levels will most often reside at the first thread or at a roughened surface after the first month after permucosal element placement (Fig. 42.23 and Box 42.6).

Diagnosis of Peri-implant Disease

After the clinical and radiographic maintenance examination is complete, a diagnosis of the current peri-implant condition is warranted. In the evaluation of the peri-implant tissues, three possible conditions may exist: (1) healthy condition, (2) peri-implant mucositis, and (3) peri-implantitis.

Healthy Condition

If there exist no signs of inflammation, bleeding, recession, bone loss, or implant/prosthesis mobility, then the patient's implants/prosthesis is determined to be in a "healthy" state (Fig. 42.24 and Box 42.7).

Treatment includes adherence to routine implant maintenance (i.e., usually 3–6 months).

Peri-implant Mucositis

Peri-implant mucositis is defined as a localized inflammation within the soft tissue surrounding the implant bodies. In addition, redness and bleeding on probing may be present. However, the bone level has not changed; therefore no hard tissue recession (i.e., bone loss) has occurred. Peri-implant mucositis is similar to gingivitis with respect to natural teeth (Fig. 42.25).

● **Fig. 42.19** Inherent Cone Beam Computed Tomography Disadvantages. (A) Beam hardening resulting in a radiolucency surrounding the implant. (B) Scatter that is caused by the presence metallic objects (e.g., crowns, implants).

Treatment includes remediation of the causative factors of peri-implant mucositis and associated follow-up care.

Peri-implantitis

Peri-implantitis is defined as localized inflammation with concomitant bone loss. In most peri-implantitis cases suppuration and clinical probing depths are present, together with bleeding on probing. On radiographic evaluation, marginal bone loss is present in comparison with the original baseline radiographs (Fig. 42.26).

● **Fig. 42.20** On this periapical radiograph the threads are clear. On the right side only, the central ray was not directed completely perpendicular to the implant body but was within 10 degrees. This film is not ideal to ascertain the amount of bone loss.

Treatment includes remediation of the causative factors and usually hard and soft tissue surgical intervention, followed by continued maintenance care.

Frequency of Maintenance Visits

Peri-implant disease may result from opportunistic infections that lead to soft and hard tissue complications; therefore it is mandatory to monitor the peri-implant tissues at regular intervals. If early signs of disease are diagnosed, aggressive intervention may prevent the loss of hard tissue. Zitzman et al.[77] reported that peri-implant mucositis may exhibit apical progression after only 3 months of plaque buildup around implants. Therefore a 3-month maintenance regimen is recommended within the first year of implant placement to evaluate the tissue health and the patient's home care. If after the first year the peri-implant tissues are healthy, then the maintenance interval may be extended to 6 months. However, a stricter recall protocol should be adhered to if the patient does exhibit risk factors or comorbidities.[78]

Patient Home Care

Ideally a home care assessment should be determined before the initiation of dental implant treatment. In partially or completely edentulous patients, usually compromised home care is already present. In addition, during the postsurgical phase of treatment, patients are often lax in their hygiene practices because of fear of causing damage to the surgery site. Therefore it is imperative that the patient be educated on the necessity and need for a comprehensive home care regimen.

When educating patients on home care, various techniques may be used, as long as they are safe and effective. Depending on the type of implant, implant position, location in the oral cavity, and type and size of the prosthesis, various devices along with the frequency may be recommended. No single hygiene device has been shown to be ideal in all situations. There exists a full array of
● **Fig. 42.21** (A) Poor angulation resulting in no threads of the implants being seen. (B) Ideal positioning as implant threads on mesial and distal are easily seen.

brushes, floss threading systems, and other devices available to aid patients in their hygiene protocols.

One common mistake often employed by clinicians is to add too many oral hygiene devices for patient home care. Studies have shown that when multiple devices are recommended, patients are more apt to become discouraged and less motivated. However, when a combination of toothbrushing devices, auxiliary aids, and antimicrobial mouthrinses are used, an increased plaque inhibition is seen.[79]

Specific Dentifrices

Manual and Electromechanical Devices

In general most exposed facial and lingual surfaces may be cleaned with a soft, multitufted nylon toothbrush. The implant clinician should recommend to each individual patient which brush angle would be ideal to access all areas within the mouth. The modified Bass technique should be used or a short, horizontal, back-and-forth movement may be incorporated into the hygiene regimen. The brush may be held at a 45-degree angle to the gingival tissue.[80]

Most commonly, patients often prefer electromechanical devices, which have been shown to be superior to manual brushing around dental implants.[81] When using electromechanical devices (i.e., sonic toothbrushes, oscillating-rotating power toothbrushes), especially in difficult-to-access areas, end-tufted brushes and tapered rotary brushes tend to be beneficial. Studies have confirmed the benefits of these devices.[82,83] Rasperini et al.[82] reported

• **BOX 42.5** | **Radiograph Timing Protocol**

Preoperative

Cone Beam Computed Tomography
• All vital structures identified
• Sinus-related procedures: must confirm patency of ostium and lack of pathology

Intraoperative
• Peri-apical radiograph (PA) after pilot drill during placement to confirm positioning and proximity to vital structures and adjacent teeth
• PA of final placement with cover screw or healing abutment
• PA before uncover surgery (stage 2 procedure)

Prosthetic
• PA to confirm implant is ready to restore
• PA to confirm abutment is seated properly
• PA to confirm proper seating of prosthesis/cement removal (will be baseline for future evaluation radiographs)

Postoperative
• PA once annually for the first 3 years after implant prosthetics to monitor bone level
• Normal (acceptable): <0.2 mm vertical bone loss per year for first 3 years
• After 3 years, PA should be taken every 2 years
  In addition to radiographic evaluation, the following should be evaluated:
• Presence of pain, suppuration
• Implant and/or prosthesis mobility
• Hyperocclusion
• Soft tissue changes (bleeding, recession, hyperplasia)
  In some cases a periapical radiograph cannot be accurately obtained because of positioning issues; therefore a panoramic radiograph may be used as an alternative radiographic modality.

---

a reduction in bleeding (~50% in the first year) and decrease in probing depths (~0.3 mm) with power toothbrushes.

Most manufactured power brushes have soft, interchangeable bristle heads (flattened, rubber cuplike, short and long pointed

---

in shape) that may be used. The short and long pointed tips are ideal for reaching proximal areas, wide embrasures, and pontic areas under a splinted prosthesis. The hollowed rubber cup may be used on the facial and lingual aspects of the implant and prosthesis (Fig. 42.27).

Toothpaste/Gel

The selection of a toothpaste should be low abrasive as to not scratch the surface of the exposed implant. Dentifrices should be avoided that contain harsh abrasive ingredients, including stain removers and smoker's toothpaste.[84] Selective fluorides may result in etching and roughness on implant surfaces.[85,86]

Interproximal Brushes

With some types of prostheses (e.g., full-arch fixed prosthesis), interproximal brushes with small brush heads may be indicated to gain easier access. Ideally these types of device should be plastic-coated because metal may damage the implant surface.[79] The interdental brush is used to massage the gingival tissue, which results in increased blood flow and healthier tissue. Patients should be instructed to insert the tip interproximally in an occlusal direction and use a gentle rotary motion against the gingiva[80] (Fig. 42.28).

Floss Aids

Flossing around dental implants is also a controversial topic. Most patients are resistant to flossing their natural teeth, especially if floss threaders are required. Therefore flossing has an inherent disadvantage in patient compliance and also dexterity issues. When flossing around implants, it is often difficult to manipulate and maneuver the floss around a malpositioned implant or an overcontoured/atypical prosthesis. Floss is ideally used interproximally, especially when a splinted prosthesis is present. Thicker floss is available (e.g., "yarnlike") that allows for cleaning around abutments and prostheses, and ease of penetrating hard to reach interproximal areas. Floss may be used in conjunction with chlorhexidine or other antimicrobials to decrease plaque accumulation.

It is imperative that the patient is instructed on the proper technique on flossing around dental implants. Improper or overaggressive flossing may lead to tissue trauma and resultant peri-implant soft tissue lesions (Fig. 42.29).

Oral Irrigator

The oral irrigator (e.g., Air Floss Pro, Philips) may be beneficial in removing supragingival debris, especially when difficult access exists because of the prosthesis type. Numerous studies have shown an oral irrigator to be superior in reducing gingival bleeding, inflammation, and plaque in comparison with string floss.[87-89] Magnuson et al.[90] found oral irrigators to reduce bleeding around implants by 81% in contrast with 33% for flossing. However, caution must be exercised in using an oral irrigator because excessive force (i.e., high pressure) may damage the junctional epithelium, which may lead to a bacteremia.[91] To minimize complications, patients should be instructed on the proper use of these devices, mainly using a low to medium speed and angulating the tip to be perpendicular to the long axis of the implant body.

Patients should be instructed to use a nonmetal tip once to twice daily.

An antimicrobial (e.g., chlorhexidine, cetylpyridinium chloride) may be used as an irrigant that decreases the bacterial count in the oral cavity.[92] Studies comparing rinsing with 0.12% chlorhexidine with irrigating with 0.06% chlorhexidine showed the irrigation group to be 87% more effective in reducing gingivitis in comparison with the rinsing group[93] (Fig. 42.30 and Box 42.8).

Antimicrobial Rinses

The regular use of chemotherapeutic agents such as antimicrobial rinses may be used as an adjunct in plaque control. Chlorhexidine gluconate is the most commonly used antimicrobial rinse in implant dentistry because it is safe, inexpensive, and nontoxic. It is very effective because of its substantivity, which is the binding of the medication to the soft tissues and implant surfaces. Studies have shown that a 30-second rinse of chlorhexidine inhibits 90% of oral bacteria for more than 5 hours.[92] Chlorhexidine or cetylpyridinium chloride may be locally applied with a cotton swab or may be used as a rinse twice daily (Fig. 42.31 (B)).

In-Office Debridement

In certain situations a maintenance visit will lead to the need for in-office debridement. When excessive dental plaque and calculus are present, the dental professional must use instruments for proper removal. However, care should be exercised in not damaging the implant or prosthesis. Older implant systems made of commercially pure titanium, which is a softer metal, are easily damaged with conventional instruments. If surface damage results, the titanium oxide surface layer will be altered, which may cause surface corrosion.[94] However, more recent implant designs use titanium alloy, which is far more resistant to surface alteration.

• BOX 42.8 Benefits of Oral Irrigator[3]

- May clean supragingival, subgingival, and interdental areas
- May remove supragingival and subgingival plaque (biofilm)
- Has been shown to be more effective than string floss for dental implants
- More effective than chlorhexidine with implant care
- Has been shown to be safe if used properly
- Easy to use

The use of ultrasonic instrumentation is not recommended with dental implants, unless the stainless steel tips are covered with a protective sleeve. Fig. 42.28 (B) these scalers may disrupt the titanium dioxide surface, which leads to plaque accumulation. These scratches and gouges may be detrimental to long-term health and hygiene practices.[95] Air polishers with bicarbonate particles (e.g., Prophy-Jet) may also be detrimental to the implant surface. Studies have shown alteration of the implant surface may result because random pitting and irregularities within the surface may occur. Therefore air polishers with bicarbonate particles should not be used around implants or the prosthesis.[96]

Low-abrasive amino acid glycine powder has been shown to be an effective treatment for removing biofilm without damaging the implant surface or hard and soft tissues. This piezo instrument (Hu-Friedy, Chicago, Ill.) uses a special handpiece with a plastic tube nozzle with three orthogonally oriented holes. An air-powder mixture with reduced pressure is expelled through the nozzle, which prevents the formation of air emphysema complications. The nozzle is moved in a circumferential movement around the implant surface Fig. 42.30 (A), (B), (C) and Fig. 42.31 (A).

Although more extensive studies need to be conducted as to technique efficacy, glycine powder can be incorporated into a treatment regimen. The clinician should be careful to use the powder only in areas where access is available and a posttreatment rinse can remove any residue. This modality is best used in cases with buccal dehiscence and/or horizontal bone loss without crater or infrabony pocketing.

After debridement procedures a follow-up visit should be scheduled approximately 1 month later. At this appointment the health of the peri-implant tissues should be evaluated together with home care reinforcement. Usually after the 1-month follow-up the patient should be seen on a 3-month recall. If peri-implant health is normal, patients can usually be placed on a 3- to 6-month recall system.

Conclusion

The ongoing maintenance of dental implants is one of the most important factors for long-term health. With increasing numbers of implants being placed each year, it is evident that the prevention of peri-implant disease is paramount to success. An individualized implant maintenance program needs to be implemented that is tailored to the specific patient, the implants, and the prosthesis. Successful implant maintenance depends on many factors, most importantly communication and collaboration between the dental professional and the patient. Peri-implant disease is a prevalent disease; therefore a comprehensive maintenance program is essential to decrease complications. The implant clinician must understand the factors and the need for a systematic maintenance protocol, along with informing his or her patients of the most updated information to ensure longevity of their implants and prosthesis.

Treatment Plan Options

Edentulous Maxilla

1. **No treatment**
   Disadvantage: Difficulty in eating/speaking, continued bone loss, maintain current prosthesis (ill-fitting)
2. **Complete upper denture**
   Advantage: Minimal treatment, fast
   Disadvantage: Removable prosthesis disadvantages, difficulty in eating/speaking, palate coverage, continued bone loss
3. **Implant-supported overdenture (Removable, RP5)**
   Advantage: Removable prosthesis that "clips" in, added retention, soft tissue support
   Disadvantage: Full denture with palate, needs to be removed sometime each day removable, clips need changed on a regular basis (additional cost), may have associated mobility of prosthesis
4. **Implant-supported overdenture (removable, RP4)**
   Advantage: Removable prosthesis that clips in, horseshoe shaped (no full palate), no soft tissue coverage, totally implant supported
   Disadvantage: needs to be removed sometime each day removable prosthesis, clips need changed on a regular basis (additional cost)
5. **Implant-supported fixed prosthesis (fixed)**
   Advantage: Fixed prosthesis (Non-Removable) increased biting force, Closest prosthesis to natural teeth
   Disadvantage: Usually will require extensive bone grafting and more implants, possible need for pink porcelain or acrylic because of the amount of bone loss, teeth will be larger (FP-2/FP-3), may not be able to increase soft tissue support, increased expense

Edentulous Mandible

1. **No treatment**
   Disadvantage: Difficulty in eating/speaking, continued bone loss, maintain current prosthesis (ill-fitting)
2. **Complete lower denture**
   Advantage: Minimal treatment, fast
   Disadvantage: Removable prosthesis, difficulty in eating/speaking, continued bone loss
3. **Implant-supported overdenture (Removable, RP5)**
   Advantage: Removable prosthesis that clips in, less implants required, soft tissue support
   Disadvantage: Full denture, needs to be removed sometime each day removable, clips need changed on a regular basis (additional cost),May have associated mobility
4. **Implant-supported overdenture (removable, RP4)**
   Advantage: Removable prosthesis that clips in, no soft tissue coverage
   Disadvantage: needs to be removed sometime each day, removable, clips need changed on a regular basis (additional cost)
5. **Implant-supported fixed prosthesis (fixed), Requires more implants than RP-5**
   Advantage: Fixed prosthesis (Non-Removable) increased biting force, Closest prosthesis to natural teeth

   Disadvantage: Usually will require more implants, increased expense, possible need for pink porcelain or acrylic because of the amount of bone loss, teeth will be larger (FP-2/FP-3), may not be able to increase soft tissue support

Single Tooth Missing

1. **No treatment**
   Disadvantage: Esthetics, adjacent teeth may move (tilting), supraeruption, decreased mastication, food impaction, continued bone loss, occlusal force
2. **Removable Partial denture**
   Advantage: Minimal treatment, fast
   Disadvantage: Removable prosthesis, difficulty in eating/speaking, extensive pressure on adjacent teeth/soft tissue which leads to additional tooth loss, poor long-term success rate, increased bone loss, tissue soreness
3. **Fixed partial denture**
   Advantage: Fast, esthetic, usually no need for hard/soft tissue grafting
   Disadvantage: Alteration of adjacent teeth, higher incidence of decay, increased endodontic treatment (~15%), hygiene difficulty
4. **Implant-supported crown**
   Advantage: No alteration of adjacent teeth, higher success rate than fixed partial denture (most studies >90% success rate)
   Disadvantage: Longer treatment time, requires bone quality and quantity, esthetic issues possible

Multiple Missing Teeth

1. **No treatment**
   Disadvantage: Esthetics, adjacent teeth will move (tilting), supraeruption, decreased mastication, continued bone loss, food impaction, occlusal force
2. **Removable Partial denture**
   Advantage: Minimal treatment, fast
   Disadvantage: Removable prosthesis, difficulty in eating/speaking, tissue soreness, places extensive pressure on adjacent teeth/soft tissue which leads to additional tooth loss, poor long-term success rate
3. **Fixed partial denture (if indicated)**
   Advantage: Fast, esthetic
   Disadvantage: Alteration of adjacent teeth, higher incidence of decay, increased endodontic treatment (~ 15%), hygiene difficulty
4. **Implant-supported prosthesis**
   Advantage: No alteration of adjacent teeth, higher success rate than fixed partial denture (most studies >90% success rate)
   Disadvantage: Longer treatment time, requires bone quality and quantity, esthetic issues possible
