3. The root canal systems are accessed; the intracanal medicament is removed by irrigating with 17% EDTA (20 mL/canal, 5 min).
4. The canals are dried with paper points. The clinician may infiltrate the apical region with 2% Lidocaine without vasoconstrictor to induce vasodilation and temporarily improve local anesthesia.
5. Bleeding is induced by rotating a pre-curved K-file size #25 at 2 mm past the apical foramen with the goal of having the whole canal filled with blood, possibly having it into the chamber above the level of the cemento-enamel junction.
6. Once a blood clot is formed, a premeasured piece of Collaplug™ (Zimmer Dental Inc, Warsaw, Indiana, U.S.A) is carefully placed on top of the blood clot to serve as an internal matrix for the placement of approximately 3 mm of white MTA (Dentsply, Tulsa, Oklahoma, U.S.A) or Biodentine (Septodont, France).
7. A (3–4 mm) layer of glass ionomer (e.g., Fuji IX ™, GC America, Alsip, Illinois, U.S.A.) is flowed gently over the MTA and light cured for 40 secs.
8. A bonded reinforced composite resin restoration (e.g., Z-100™, 3M, St. Paul, Minnesota, U.S.A) is placed over the glass ionomer.
9. The patient should be reviewed at three months, six months, and yearly after that for a total of four years.

REGENERATIVE ENDODONTIC OUTCOMES

The definition of clinical success has been a controversial topic in endodontics throughout the history of the specialty. Success has been typically evaluated by lack of symptoms and a strict radiographic criteria[197,198] and the absence of cultivable microorganisms.[199] Currently, the most widely accepted outcomes for conventional non-surgical root canal treatment include the absence of clinical and radiographic signs of pulpitis and apical periodontitis following treatment.[200,201]

Regenerative endodontic procedures are a significantly newer treatment modality than conventional root canals therapies, and their expected outcomes have not been clearly defined in the scientific literature. This is particularly troublesome when these procedures are directly compared to apexification procedures. These new procedures are providing unprecedented results that, in certain cases, go beyond the primary goal of healing of apical periodontitis. Common findings of continued radiographic root development, greater tooth survival and positive vitality testing prompt consideration of more ambitious clinical expectations for REP as compared to more traditional treatment approaches. In reality, a multilevel approach to evaluating outcomes is required for REPs. This approach should be focused on three levels of outcomes: patient-centered, clinician-centered and scientist-centered outcomes.

Patient-Centered Outcomes

Simply stated, the outcomes that directly matter to the wellbeing of our patients should be considered the first level of outcome, or the base of the outcomes pyramid (Figure 29-7). These outcomes are aligned with patient's expectations from any given clinical intervention. In 2010, the Patient-Centered Outcomes Research Institute (PCORI) was established in the United States of America though the Patient Protection and Affordable Care Act.[202,203] This initiative underscores the need to focus on patient outcomes when making any comparative analysis of the effectiveness of treatment that could bring a clinical meaningful benefit to patients treated by these interventions.

Traditional medical clinical research has focused on specific dependent measures, such as biological markers and other surrogate measures of treatment effectiveness. This approach of evaluating treatment interventions is very important since it focuses on a clinician-scientist established set of criteria and parameters, facilitating mechanistic

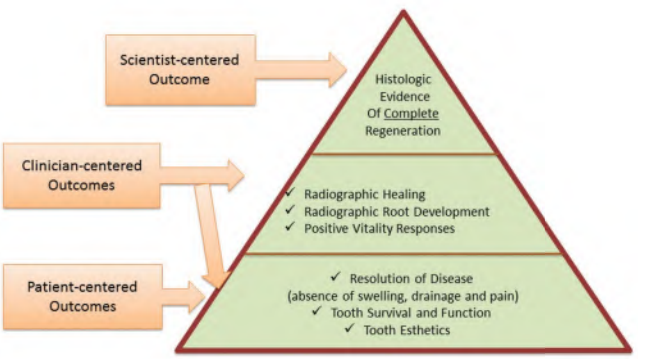

FIGURE 29-7 Regenerative endoodontic procedures must be assessed and evaluated in a systematic way, acknowledging that there are different levels of outcomes carrying different meanings for patients, clinicians, and scientists. However, potential benefit of improving patients' health and quality of life remains the goal and foundation of these procedures.

investigation. This approach, however, also tends to generalize findings, not necessarily addressing the impact on each individual patient treated. For example, c-reactive protein and vascular cell adhesion molecule-1 (VCAM-1) levels have been used as biological markers of atherosclerosis and angina pectoris.[204–206] The use of these markers as surrogate measures of treatment effectiveness allows for quantitative evaluation, but does not capture basic patient concerns, such as possible intense chest pain (angina) and possible myocardial infarction.

In endodontics, radiographic criteria were often applied as measure of clinical success.[207–209] This approach focuses on the resolution of symptoms and radiographic signs of "healing" as dependent measures. In this approach, a treatment that resolved moderate to severe debilitating pain, but resulted in a residual radiolucency, may have been considered a failure. This traditional approach largely ignores the overall benefit that the treatment brought to the patient. From the patient's perspective, the treatment resolved the symptoms and allowed normal function and survival of the tooth. Thus, a disconnect exists between the expectations of patient, clinicians and scientist. These expectations are not mutually exclusive but synergistic as they pertain to different aspects of the treatment, and their pursuit is a major driver of developments in the field. Lastly, patients should be empowered to make decisions about treatment effectiveness, reporting back to clinicians and researchers what has been beneficial or not beneficial. This approach places patients as stakeholders of their health, and of the development of new therapies.

Regenerative endodontic procedures, as a new treatment modality, must be compared to the longer established, more traditional endodontic treatment procedures for immature teeth, namely apexification procedures.[125,133] The primary concern for a practicing clinician must be to promote healing of the diseased tissues and patient well-being (patient-centered outcomes). Thus, the primary therapeutic goal must be resolution of apical periodontitis while promoting the survival and function of the tooth. Simply put, patients and guardians (in the case of young patients undergoing treatment) value the fact that the tooth is rendered pain free, and that it remains functional in the long term (survival).

Regenerative endodontic procedures have been proposed as an alternative treatment modality for teeth with immature roots and pulp necrosis.[9] Therefore, the direct comparison of REPs and apexification procedures is warranted. In 2012, a retrospective study aimed to directly compare the clinical outcomes for these two treatment modalities.[141] This is an important study because it was the first to establish standardized protocols for each treatment arm. Also, it included calcium hydroxide-mediated apexification (n = 22) and MTA-mediated apexification (n = 19) groups as variations of the apexification technique while comparing these to REPs (n = 22).[141] Resolution of the disease process (no pain, swelling or sinus tracts) was found in 100% of the REPs, 95% of the MTA apexification and 77% of calcium hydroxide apexification cases. On the other hand, another retrospective study that did not include standardization of treatment protocols found REPs to promote healing in 79% of patients treated, whereas apexification procedures promoted healing in 100% of the patients; this difference was found not to be significant.[210] In a prospective study, both MTA apexification and REPs were found to promote healing in 100% of all patients.[211] Further evidence of successful outcomes can be found in case series and retrospective patient cohort studies. Despite significant variations in etiology, inclusion and exclusion criteria, these studies demonstrate that in average both procedures successfully resolve the signs and symptoms of disease in approximately 90% of patients.

Survival of the tooth is another important patient-centered outcome. An ideal treatment, from the patient's perspective, is one that prolongs the functional life of an asymptomatic tooth. The survival of an immature tooth is of crucial importance to the patient since the tooth required an intervention at an early developmental stage, requiring the tooth to remain functional throughout the patient's life. In a retrospective study including more than 1.4 million patients, conventional root canal therapy was found to promote the eight-year survival in 97% of the cases.[212] Unfortunately, far less is known regarding the long term survival of immature teeth treated with either apexification or REPs. A retrospective study compared the survival of teeth treated with either REPs or apexification procedures with calcium hydroxide or placement of an MTA apical plug.[141] The survival of teeth treated with REPs (100% of teeth survived) during the follow-up period of the study (18 months) was significantly greater than that of teeth treated with calcium hydroxide (77%), but not different from teeth treated with an MTA apical plug (95%). These findings are in agreement with previous reports that prolonged use of calcium hydroxide can significantly weaken teeth, increasing their susceptibility to fracture.[138,140] Regenerative endodontic procedures have been shown to arrest the disease process and allow for retention of teeth with otherwise very poor prognosis (Figure 29-8) in patients still undergoing craniofacial development. Factors affecting the long-term survival of these teeth require further investigation with studies employing appropriate sample sizes and follow-up.

Clinician-Centered Outcomes

In addition to assessing patient's satisfaction with the treatment, clinicians further assess treatment outcome by evaluating whether the treatment provided the added benefit of continued radiographic root development and responses to vitality testing. There are numerous published cases that demonstrate continued root development post-treatment.[125] These reports provide subjective evidence that REPs promote root development. However, a retrospective study was the first to directly compare continued root development between apexification procedures (n = 40) and REPs (n = 48).[213] This

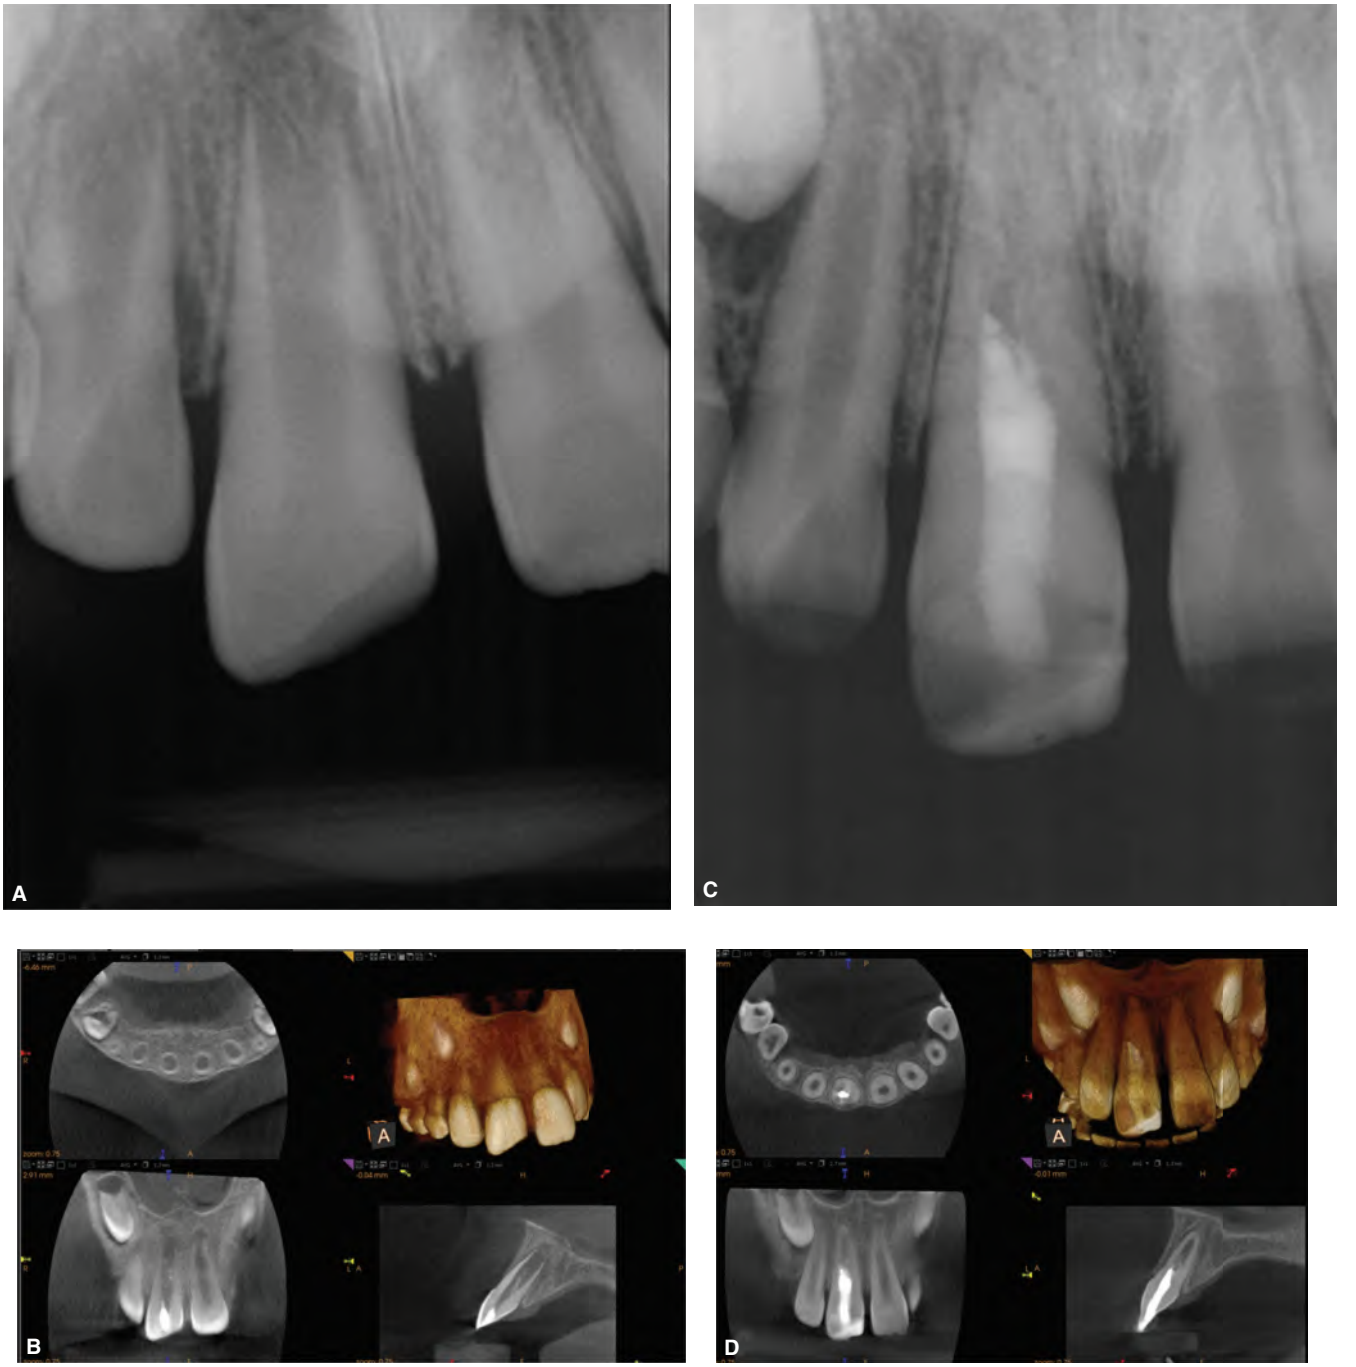

FIGURE 29-8 A 9-year-old boy suffered lateral luxation of the maxillary lateral and central incisors and an incomplete crown fracture of the right central incisor. ***A.*** The patient developed an acute apical abscess associated the right central incisor diagnosed with pulpal necrosis. The immature central incisor presented with fragile dentinal walls and open "blunderbuss" apex in the pre-operative radiograph. ***B.*** A regenerative endodontic procedure(revascularization/revitalization) was initiated with the use of double antibiotic paste as intracanal medicament in conjunction with an incision and drainage of the intraoral swelling resulting copious purulent exudate removal. At the final visit, patient was asymptomatic and intraoral swelling had resolved a limited-volume cone beam computer tomography (LV-CBCT) was taken providing a three-dimensional view of the immature root. The intracanal medicament was removed and the canal irrigated with 17% EDTA, dried and followed by intracanal bleeding evoked by over-instrumentation of apical tissues. An MTA coronal barrier was placed below the CEJ, followed by a glass ionomer barrier and composite restoration. ***C.*** At the one-year follow-up visit, the tooth responded to EPT and significant radiographic root development was evident on the periapical radiograp and on ***D.*** limited-volume cone beam computer tomography (LV-CBCT). (Courtesy of Dr. Julie Berkhoff, Colorado Springs, Colorado, U.S.A.)

study used a mathematical image-correction approach that permitted the comparison of non-standardized radiographs, revealing that regenerative procedures performed with either calcium hydroxide or triple antibiotic paste as intracanal medicaments produced significantly greater increases in root wall thickness and length. Importantly, this study established a methodology, later revised,[214] allowing unbiased and objective quantification of changes in root growth. These findings have been confirmed by Jeeruphan et al.[141] using a similar quantitative technique, reporting that teeth treated with revascularization showed a significantly greater percentage increase in root length (14.9%) compared with teeth treated by either MTA apexification (6.1%) or calcium hydroxide apexification (0.4%). They also reported that the revascularization protocol produced significantly greater percentage increases in root width (28.2%) compared with teeth treated by either MTA apexification (0.0%) or calcium hydroxide apexification (1.52%).[141]

Further evidence of continued root development can be found in a prospective randomized clinical trial that compared two different protocols of REPs to MTA apexification procedures.[211] Regenerative procedures promoted an average increase of 12% in root thickness and a 50% decrease in apical diameter (apical closure), whereas apexification procedures demonstrated no change during the 18-month observation period.[211] Interestingly, a recent retrospective study reported that changes in radiographic root development were highly variable and unpredictable, being not statistically different from those seen in MTA-apexification cases.[210] This discrepancy is likely due to the greater number of included cases with trauma as the etiology for pulpal necrosis, and the relatively small sample size. Collectively, studies using quantitative analysis have provided evidence that REPs promote increases in radiographic root development in most cases, but not all. The factors that influence this lack of response in certain cases are largely unknown, but could include the persistence of bacterial biofilms or antigens, the nature of the etiology, delay in treatment, and the impact of disinfection agents on the creation of a microenvironment conducive to regeneration.

Reestablishment of normal nociception must also be one of the goals of REPs. The role of innervation in the defense and homeostasis of the dental pulp has been highlighted in many elegant studies.[215–218] Primary afferents in the dental pulp are equipped to sense microbial antigens, participating in the inflammatory process evoked by invading microorganisms.[219,220] They modulate the immune reaction by the release of neuropeptides with vasoactive properties that increase immune cell recruitment and vascularity, localizing areas of insult to microabcesses within the dental pulp.[221] Also, trigeminal neurons have been reported to increase odontoblastic differentiation and dentinogenesis.[222] Furthermore, there has been recent evidence that glial cells normally present surrounding pulpal primary afferent fibers, participate in the process of odontogenesis by stimulating differentiation of cells of the pulp dentin complex, including odontoblasts.[223] Therefore, pulpal innervation is a crucial component of the pulp-dentin complex with many functions in addition to nociception. Reestablishment of "normal" nociception is one of the important criteria for the functional regeneration of the pulp-dentin complex.

Positive pulpal responses are observed and reported in approximately 50% of all published REP case reports.[125] The presence of functional nociceptors following REPS suggests that free nerve endings of primary afferents found in the periradicular area grow and sprout into the newly formed tissue, a process called axonal targeting. The nociceptive pulpal innervation depends largely on the targeting of axons from sensory neurons located in the trigeminal ganglia into newly developed tissues during organogenesis.[224,225] Specific chemical signals are required to mediate the directed growth of axons into a newly formed tissue. Several elegant studies have directly implicated nerve growth factor (NGF), glial-derived neurotrophic factor and brain-derived neurotrophic factor (BDNF) in the process of pulpal innervation.[226–231] A recent study demonstrated that stem cells of the apical papilla (SCAP) release neurotrophins that promote axonal growth and axonal targeting.[116] This process was completely blocked by a monoclonal antibody against BDNF revealing that this neurotrophic factor is crucial to the recruitment of adjacent free nerve endings.[116] Interestingly, complete pulpal regeneration, including innervation, was achieved in dogs with the use of autologous transplantation of DPSCs.[122] These cells were found to express high levels of BDNF compared to adipose and bone marrow MSCs.[232] Collectively, these findings support the hypothesis that MSCs transferred into the root canal space during REPs are likely important in the recruitment of apical primary afferent fibers through a specific mechanism of post-natal axonal targeting.

The presence of innervation alone does not explain the observed responses to either electric or cold tests. Likewise, the hydrodynamic theory does not explain responses to cold stimuli since it is not expected to be operative in regenerative cases that lack innervated coronal dentin (pulp chamber roof). Instead, the innervated tissue is likely to be in intimate contact with the coronal plug (MTA or other materials) layered with other restorative materials (e.g., glass ionomer and composite restoration). The explanation for this clinical phenomenon probably lies in the expression of cold-sensing channels in trigeminal ganglial neurons, such as the Transient Receptor Potential Ankyrin type 1 (TRPA1) and Transient Receptor Potential cation channel, subfamily M member 8 (TRPM8).[233–236] These cation-permeable channels are expressed in the free nerve endings of trigeminal neurons, including those present within the dental pulp, and undergo a conformational change at temperatures below 17°C and 26°C, respectively, allowing the influx of cations and membrane depolarization.[237] Their function as cold sensors may underlie the mechanisms by which pulp-like tissue can detect cold stimuli. On the other hand, the electric pulp test bypasses activation of specific channels in the free nerve endings and nonselectively activates voltage gated sodium channels expressed throughout the length of the peripheral fibers.[238,239]

In summary, clinicians often rely on the pre-established criteria of radiographic continued root development and pulpal testing responses to further evaluate the "success" of a regenerative procedure. The meaning of these criteria

for the patient in not clear since most patients and guardians simply expect the tooth to be pain free and functional. Nonetheless, it adds valuable information that clinicians can use to determine whether further interventions are necessary. Importantly, the clinician-centered criteria, that are often used to evaluates REPs, are not directly applicable to apexification procedures since root development and vitality responses are not expected following these apexification procedures.

Scientist-Centered Outcomes

Histological evaluation of teeth, which were previously treated with REPs but later extracted due to recurring trauma and fractures, suggests that the newly-formed tissue does not resemble the lost dental pulp.[240–242] This is the best example of a scientist-based outcome since it has strong scientific merit, but it does not necessarily interfere with consideration of rate of healing and continued root development seen in cases treated with REPs. Scientist-based outcomes can be some of the strongest drivers of advances in the field as researchers focus on the complex interplay between stem cells, scaffolds, growth factors and inflammation in order to achieve all desired outcomes, including complete histologic regeneration, or *de novo* formation of the pulp-dentin complex.

A 9-year-old male patient with an immature mandibular right first molar diagnosed with pulpal necrosis was treated with a "revitalization" procedure that included disinfection, use of triple antibiotic paste as intracanal medicament, intracanal bleeding in the distal canal and placement of PRP in the mesial canals.[242] The patient was asymptomatic for two years with both clinical and radiographic evidence of success. Unfortunately, the tooth was later diagnosed with an oblique fracture, perhaps due to the lack of adequate cuspal coverage. Histological examination of the extracted tooth revealed that the canals were filled with a vital connective tissue containing several foci of ectopic mineralization and the canal walls were covered by a mineralized tissue that resembled cellular and acellular cementum (Figure 29-9 and 29-10).

This case report highlights that the clinical success, seen until the time of fracture, was not significantly influenced by the nature of the tissue formed. Also, it demonstrated that regeneration, in its strict sense (formation of new dentin and odontoblast-like cells), was not accomplished. Instead, the histological outcome of this case suggests that a "guided

tissue repair" took place. Therefore, in this case, both patient and clinician-centered outcomes were met, but not the scientist-centered outcome of histologic regeneration.

The significance of the nature of the tissue formed for the clinical success of these cases remains largely unknown. Regenerative procedures are successfully performed on vital pulps, namely direct pulp capping procedures. Advances in biomaterials (e.g., MTA and Biodentine) that induce greater proliferation and differentiation of progenitor and stem cells have greatly improved the clinical outcomes of the procedures. In a large randomized clinical trial involving 35 dental practices, patients were randomized into direct pulp capping procedures with either calcium hydroxide (n = 181) or MTA (n = 195).[243] This study revealed that the use of MTA resulted in significantly greater clinical success (81.3%) than calcium hydroxide (69.5%). It is now established that newer generation biomaterials such as MTA or Biodentine, induce both direct and indirect effects on stem and progenitor cells of the dental pulp driving their recruitment and differentiation into odontoblast-like cells.[8,108,172] However, histological examination of the mineralized bridge suggests that the tissue formed does not resemble tubular dentin.

Tertiary dentin formed in response to an insult by surviving odontoblasts (reactionary dentinogenesis) is typically tubular, similar to primary and secondary dentins. Conversely, tertiary dentin formed by recruited "odontoblast-like" cells typically shows a range of tubularity from a regular tubular structure through to an atubular morphology, and when formed rapidly can present cellular inclusions (entrapment) of the mineralizing cells, being named osteodentin.[244] It is important to note that these cells do not have the morphological appearance of odontoblasts, but have been shown to express several of the recognized odontoblastic markers (such as DSP, DMP-1 and NeuN).[245,246] Thus, the desired formation of a biological seal (calcific barrier or mineralized bridge) in direct pulp capping procedures may not be considered true regeneration but "guided tissue repair." Nonetheless, the formation of this tissue allows for the maintenance of pulp vitality and normal physiology with high success rates.[247]

In summary, there is increasing evidence that the currently employed regenerative endodontic procedures (e.g., revascularization and revitalization procedures) are not allowing the formation of intracanal tissues that completely recapitulate the dental pulp. Histological studies have demonstrated the presence of connective tissues that are vascularized and innervated, that show some of the features of a pulp-like tissue. However, the presence of ectopic calcifications within the canal lumen and mineralized tissues resembling cementum along the dentinal walls suggest that clinicians and scientists are not yet able to achieve spatial, temporal, and lineage-specific control of stem cell differentiation. The ideal formation of dentin lined with odontoblast-like cells still remains elusive clinically. Nonetheless, these shortcomings largely ignore the benefits that these procedures bring to patients. Instead, the pursuit of true histological regeneration of physiological-like tissues as the pinnacle of sophistication for these biologically-based procedures is promoting substantial growth in our knowledge of the processes involved in repair and regeneration. Importantly, these advances are already being translated into clinical practice generating variations on the originally proposed clinical protocols and new treatment modalities, such as cell homing strategies and cell-based therapies.

FUTURE DIRECTIONS

It has become clear that greater effort should be made to preserve pulp vitality. Ideally, clinicians should be able to determine how much, if any, of the inflamed pulp to remove, before placing a bioactive coronal barrier and final restoration. However, clinicians still use subjective sensibility tests, and direct visualization of bleeding pulp stumps to establish pulp status, and to make decisions on whether to perform a pulpotomy (pulp capping) or pulpectomy (root canal therapy). Furthermore, these procedures have been offered mainly to young patients with a developing dentition. The impressive reparative and regenerative potential of dental pulp tissue makes these procedures a possibility, not only in deciduous or permanent immature teeth, but also in permanent fully mature teeth.[248]

A randomized multicenter clinical trial evaluated clinical outcomes of 407 patients with teeth diagnosed with irreversible pulpitis.[249] Approximately half of the patients received non-surgical root canal therapy, while the remaining patients were treated with a vital pulp therapy, consisting of pulp chamber pulpotomy and direct pulp capping with a calcium-enriched mixture (CEM). In this trial, patients experienced more post-operative discomfort following non-surgical root canal therapy and showed similar equivalent high clinical and radiographic success rates at the six months follow-up period.[249] In another randomized clinical trial, patients with molars diagnosed with symptomatic irreversible pulpitis (n = 413), were randomized into pulpotomy treatment arms, receiving either MTA or calcium-enriched mixture as a direct pulp capping material. At one-year follow-up, success rates were 95% for the MTA group and 92% for the calcium-enriched mixture.[250] These results are encouraging since these procedures promote the maintenance of a viable, functional pulp dentin complex while resolving the patients' chief complaint. Ideally, biomarkers should be identified as a chairside diagnostic indicator, of whether the remaining pulp is in an "irreversible" state or still harbors its inherent regenerative potential. The development of such technologies would provide powerful guidance, allowing clinicians to predictably preserve uninfected healthy dental pulp, even in cases presenting with spontaneous pain and lingering responses to cold stimuli.

In the treatment of immature teeth with pulpal necrosis using revascularization or revitalization procedures, a substantial number of undifferentiated stem cells are delivered into disinfected root canals.[100] Unfortunately, these cells are transferred to an environment that lacks adequate blood supply. It has been shown that they have the capacity to thrive in hypoxic environments, where they release various growth factors and neurotrophins that are crucial to the recruitment of blood vessels[251] and neurons.[252] However, the prolonged exposure of these cells to an environment of low oxygen tension, limited nutrients and gaseous exchange, can lead to cell death and impairment of differentiation for the surviving cells.[253,254] This disconnect between cellular demands and vascular supply could be avoided if cells were recruited progressively into the root canal space as blood vessels are formed.

Mesenchymal stem cells are highly mobile and have been shown to migrate towards concentration gradients of many known chemotactic factors, a process called stem cell homing.[38,44,52,255] The periapical tissues of immature teeth have rich sources of stem cells present in the apical lesions (i.e., inflamed periapical progenitor cells), apical papilla (SCAP), bone (bone marrow stem cells) and periodontal ligament. Therefore, these cells could be recruited into the root canal system if appropriate chemical signals and a suitable scaffold were provided. This strategy has been successfully demonstrated in many elegant studies.[38,256–260] A novel, cell homing system for endodontics, might be composed of an injectable scaffold with embedded chemotactic and angiogenic factors, released in a time-delayed fashion allowing for the progressive recruitment of stem cells concomitantly with supportive blood vessels. Alternatively, endogenous chemotactic and angiogenic factors sequestered within the dentin matrix might be progressively released from the walls of the pulp chamber by a slow-action demineralizing agent, possibly contained within a hydrogel.

CONCLUDING REMARKS

The field of regenerative endodontics has witnessed tremendous advances in the past decade, with knowledge gained on stem cell biology and the effects of endogenous and exogenous growth factors and morphogens, on the reparative and regenerative potential of the dental pulp. Also, the relatively young field of regenerative endodontics brings together basic scientists and clinicians, who in a multidisciplinary approach are making significant strides in endodontic tissue engineering.

Currently employed regenerative procedures are valuable adjuvants to the treatment of immature teeth with pulp necrosis and to retention of a functional pulp in cases of injured but vital teeth. Despite the clinical success of these procedures, they appear to promote a "guided tissue repair" process rather than a true regeneration of physiological-like tissues. Indeed, in order for the full regenerative potential to be met, significant more research and development needs to take place. A number of barriers to progress exist, including the absence of diagnostic markers correlating histological with clinical outcomes following treatment to facilitate case selection, insufficient knowledge of the molecular signaling interactions within pulp, in the context of the inflammatory environment and the consequences for regeneration, together with the need for better understanding and exploitation of the interplay between regeneration and low level cytokine stimulation during early stages of disease, and later stages of its resolution. Attention to all of these areas offers significant opportunities for progress in the evolution and clinical translation of regenerative endodontics. Future procedures may well incorporate the use of injectable scaffolds containing chemical cues to promote the orchestrated proliferation and differentiation of recruited stem cells to repopulate the root canal system, reestablishing a functional regenerated pulp-dentin complex. Endodontics is in an exciting phase from which many new developments, in regenerative therapies, will emerge to advance the specialty and patient-based treatment outcomes.

Chapter 30

Treatment of Endodontic Abscesses/Cellulitis, Cysts, and Flare-ups

J. Craig Baumgartner, Paul A. Rosenberg

Endodontic infections are caused by communities of microbes that invade tissue and produce an inflammatory disease. Molecular studies have revealed a diversity of microbiota involved in endodontic infections.[1–3] Microbes that have been detected include bacteria, spirochetes, fungi, and viruses.[4–7] These communities of microbes differ from individual to individual. Many of the organisms have not been cultivated and have not been tested for susceptibility to the antimicrobials available for treatment. Understanding the nature and diversity of endodontic infections is required to provide the best clinical treatment and adjunctive pharmacotherapeutics for a successful outcome.[8,9]

Periradicular abscesses and cellulitis occur when microbes invade periradicular tissues. The severity of the periradicular infections is related to the virulence of the organisms and host resistance. An abscess is a localized collection of pus within a tissue or confined space.[10] Pus is an accumulation of purulent exudate and consists of microbes, microbial by-products, neutrophils, cells undergoing autolysis, and cellular contents. Cellulitis is a symptomatic edematous inflammatory process that spreads diffusely through connective tissue and fascial planes; frequently associated with an infection by invasive microorganisms and subsequent breakdown of connective tissue.[10] Needle aspirates from inflamed tissue or incision for drainage often reveal pockets of purulence associated with cellulitis.[11] Clinically a cellulitis and an abscess should be considered a continuum of the infectious-inflammatory process. Once bacteria have invaded periradicular tissues an otherwise healthy patient will eventually exhibit clinical signs and symptoms. Locally the patient may experience swelling and mild to severe pain. As the infection and inflammatory response spreads to surrounding tissues the patient may experience systemic signs and symptoms such as chills, fever, lymphadenopathy, nausea, and headache. The tooth that is the reservoir of the endodontic infection will usually be sensitive to biting, percussion (touch), and eventually palpation. The tooth may or may not show radiographic evidence of periradicular disease. The pulp cavity of an infected tooth is the source of the infection spreading to periradicular tissues and for secondary (metastatic) infection that spread to fascial spaces of the head and neck. Appropriate treatment involves decreasing the bioburden by removing the reservoir of infection either by debridement of the infected root canal system or removal of the tooth along with drainage from swollen tissues. Adjunctive pharmacotherapeutics may also be indicated for cellulitis, progressive swellings, and where there are systemic signs and symptoms of infection.

The spread of infection into fascial spaces may be life threatening. There are potential spaces between anatomic structures of the head and neck, which may be involved in infection and inflammation. The fascial spaces of the head and neck have been placed into several anatomic groups.[12] An anatomic space that may be involved in mandibular infections is the ***mandibular buccal vestibule***. The swelling occurs between the cortical plate and the buccinator muscle in the posterior of the mandible and the mentalis muscle in the anterior. Mandibular anterior teeth may produce swelling of the ***mental or submental spaces*** (Figure 30-1). The ***mental space*** is located between the mentalis muscle and the platysma muscle. The ***submental space*** is between the mylohyoid muscle and the platysma muscle. Mandibular anterior teeth may also lead to swelling in the ***sublingual space*** located between the floor of the mouth and the inferiorly located mylohyoid muscle. The ***submandibular space*** (Figure 30-2) is between the mylohyoid and the platysma muscles. The source of infection in this space is usually a posterior tooth. ***Ludwig's angina*** is an infection that includes the submental, sublingual, and submandibular spaces. Cellulitis may extend to the pharyngeal and cervical spaces and produce airway obstruction.

Anatomic spaces involved in lateral face swelling include the ***maxillary buccal vestibule***. It is located between the cortical plate of the maxilla and the superior attachment of the buccinator muscle and associated with infections of maxillary posterior teeth. The ***buccal space*** (Figure 30-3) is between the lateral surface of the buccinator muscle and the overlying skin of the cheek. The source of the infection may be either a maxillary or mandibular posterior tooth. The ***submasseteric space*** lies between the lateral surface of the ramus of the mandible and the masseter muscle. The source of the infection is usually the mandibular third molar. The ***deep temporal space*** is between the lateral surface of the skull and the medial surface of the temporal muscle while the ***superficial temporal space*** lies between the temporal muscle and the overlying fascia.

Anatomic spaces involved in the pharyngeal and cervical areas include the ***pterygomandibular space*** (Figure 30-3). That space is usually associated with infection of the mandibular second or third molars. The pterygomandibular space is bounded by the lateral surface of the medial pterygoid muscle and the medial surface of the mandible. The bilateral ***parapharyngeal space*** is between the medial surface of the medial pterygoid muscle and the superior constrictor muscle.

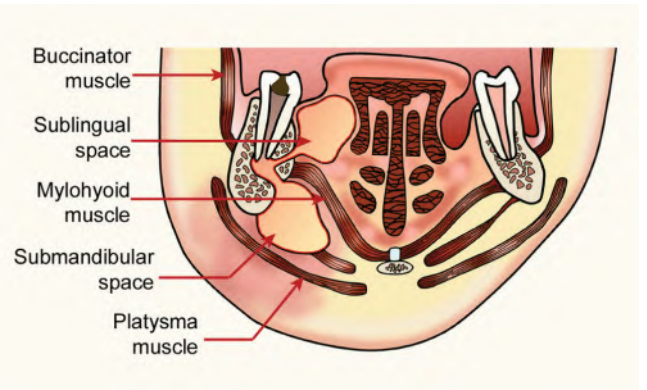

FIGURE 30-2 Submandibular and sublingual spaces. (Courtesy of William J. Girsch, Salem, OR.)

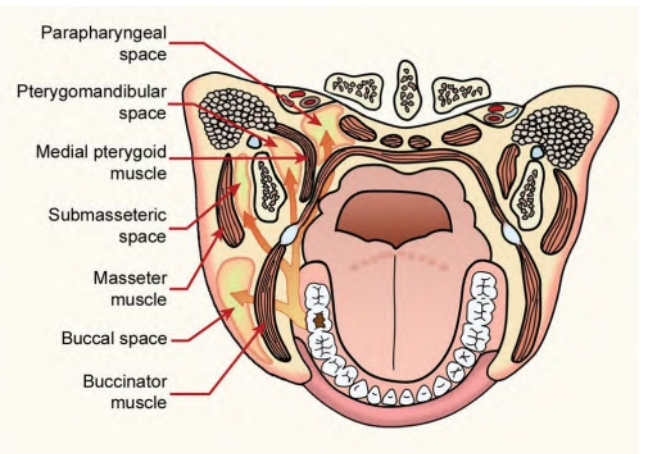

FIGURE 30-3 Buccal, submasseteric, pterygomandibular, and parapharyngeal spaces. (Courtesy of William J. Girsch, Salem, OR.)

The superior border is the base of the skull and the inferior border is the hyoid bone. The ***carotid space*** contains the carotid artery, internal jugular vein, and the vagus nerve. The ***retropharyngeal space*** (Figure 30-4) is posterior to the superior constrictor muscle and extends to the mediastinum. The ***pretracheal space*** surrounds the trachea and extends from the thyroid cartilage to the level of the aortic arch. The ***retrovisceral space*** extends from the base of the skull into the posterior mediastinum. The ***danger space*** (Figure 30-4) also extends from the base of the skull into the posterior mediastinum. The ***prevertebral space*** surrounds the vertebral column.

The anatomic spaces involved in midface swellings are the palate, the base of the upper lip, the infraorbital (canine) space, and the periorbital spaces. The source of infection for the ***palate*** is the maxillary teeth. Swelling of the ***base of the nose*** is typically caused by a maxillary central incisor with its root apex above the attachment of the orbicularis oris muscle. The ***infraorbital space*** (Figure 30-5) is between the levator anguli oris muscle and the levator labii superioris muscle. The source of the infection is usually the maxillary cuspid or first premolar. The ***periorbital space*** lies deep to the orbicularis

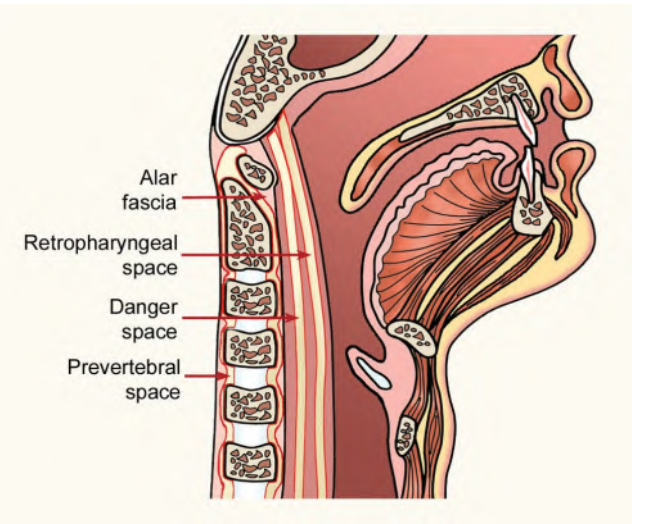

FIGURE 30-4 Pretracheal, prevertebral and danger spaces. (Courtesy of William J. Girsch, Salem, OR.)

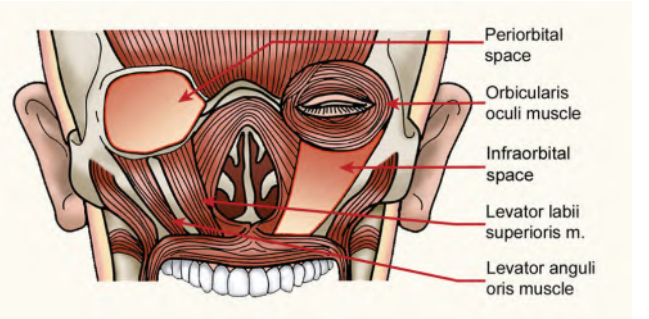

FIGURE 30-5 Periorbital and canine spaces. (Courtesy of William J. Girsch, Salem, OR.)

oculi muscle and becomes involved as a result of spread of infection from the buccal or infraorbital space. Infections of the midface are of special concern because of the possibility that they may result in cavernous sinus thrombosis. If the inflammation and resulting edema cause blood to back up into the cavernous sinus, the infected thrombi may escape into circulation and produce a life threatening event.

TREATMENT OF ENDODONTIC ABSCESSES/CELLULITIS

Prompt diagnosis and removal of the reservoir of infection are important for the successful treatment of endodontic infections. Drainage of infectious material and inflammatory mediators associated with endodontic infections may be established through the tooth, soft tissues, or alveolus. Surgical methods for drainage include incision for drainage, needle aspiration, and trephination. In otherwise healthy patients, chemomechanical debridement of the root canal system and drainage of an associated swelling will lead to rapid improvement of the patient's signs and symptoms. Tooth extraction is the alternative treatment to remove the reservoir of infection. After debridement of the root canal system, incision for drainage is indicated for periradicular swellings. Drainage from the access opening to the pulp cavity may not significantly reduce pain, percussion pain, swelling, or number of analgesics taken (Figure 30-6).[13]

Incision for Drainage

The importance of removing the source of the infection and drainage must be emphasized. Successful resolution of an infection requires removal of the source of infection and drainage of accumulated exudates. Drainage from a swelling caused by an abscess/cellulitis decreases the number of microbes, microbial by-products, and inflammatory mediators associated with the swelling. The removal of pockets of purulence and edematous fluid also improves circulation and allows delivery of prescribed antibiotics in a minimum inhibitory concentration. An incision for drainage or needle aspiration of a swelling associated with cellulitis will often reveal accumulations of purulence consistent with an abscess. An incision provides a pathway for drainage to prevent the further spread of the abscess/cellulitis. Nerve block anesthesia should be used and if necessary supplemented with local infiltration.

To achieve drainage from a swelling, a stab incision through the periosteum is made at the most dependant site of the swelling. A periosteal elevator or hemostat is then used for blunt dissection to allow drainage of any accumulated exudate and inflammatory mediators. Except for very small-localized swellings a drain should be sutured into place (Figure 30-7). Drains may be a piece of dental dam, a Penrose drain, or a capillary drain (Figure 30-8). The latter is ribbed and may stay under the tissues better than the

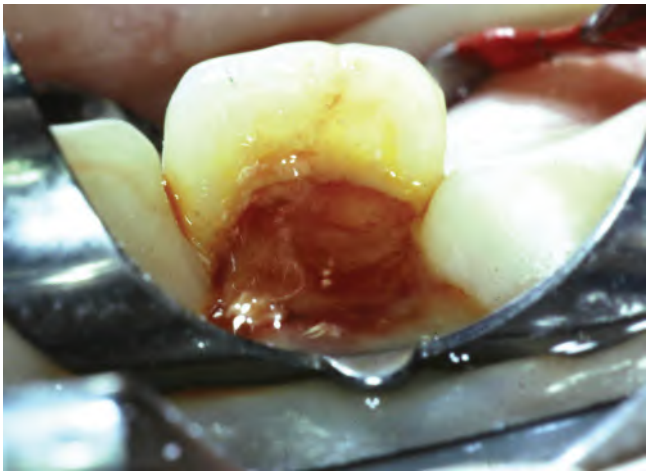

FIGURE 30-6 Purulent drainage upon access to the pulp cavity. (Courtesy of J. Craig Baumgartner, Kailua, HI, U.S.A.)

non-ribbed drains. Non-latex drains should be used for those allergic or sensitive to latex. A sutured drain keeps the incision open for continued drainage and encourages compliance by the patient to return for follow-up evaluations. The use of warm intraoral rinses may help promote drainage. The drain can usually be removed in 1 or 2 days when there is improvement of the patient's clinical signs and symptoms. Consultation and referral is indicated for severe infections or persistent infections.

Needle Aspiration

Needle aspiration may be described as the use of suction to remove fluids from a cavity or space. Needle aspiration is a surgical procedure that may provide information as to the presence and volume of exudate, cystic fluid, or blood. Aspirated samples may be used for microbial isolation and identification using either culturing or molecular methods (Figure 30-9).[3,14–16] In addition, the sample may be used for immunohistochemical analysis (Figure 30-9). In 1995, Simon et al.[17] described the clinical use of needle aspiration for intraoral swelling as an alternative technique to incision for drainage. Following regional and local anesthesia, the technique involves the use of a syringe with an 18 gauge needle to aspirate the contents of a swelling. Clinical advantages of needle aspiration over incision for drainage include reduced scarring, evaluation of volume and character of the aspirate, use of the aspirate for culture and sensitivity testing, and the lack of postoperative drain removal.

Antibiotics In Endodontics

The vast majority of infections of endodontic origin can be effectively managed without the use of antibiotics. Systemically administered antibiotics are not a substitute for proper endodontic treatment. Chemomechanical debridement of the infected root canal system with drainage through the root canal and by incision and drainage of swollen tissues will decrease the bioburden so that a normal healthy patient can begin the healing process. Antibiotics are not recommended for healthy patients with a symptomatic pulpitis, symptomatic apical periodontitis, a draining sinus tract, a localized swelling of endodontic origin, or following endodontic surgery (Table 30-1).[18–23] An antibiotic regimen should be prescribed in conjunction with proper endodontic therapy when there are systemic signs and symptoms of infection or a progressive/persistent spread of infection. The presence of a fever (>100°F), malaise, cellulitis, unexplained trismus, and progressive swelling are all signs and symptoms of systemic involvement and the spread of infection (Table 30-2).

Under these circumstances, an antibiotic is indicated in addition to debridement of the root canal harboring the infecting microbes and drainage of any accumulated purulence. Patients with serious endodontic infections should be closely followed on a daily basis. The patient's condition will usually rapidly improve once the source of the infection is removed. Because of the lack of circulation, systemically administered antibiotics are not effective against a reservoir of microorganisms within an infected root canal system. Likewise, a minimum inhibitory concentration of an antibiotic may not reach an anatomic space filled with purulence and edematous fluid because of poor circulation and the diffusion gradient that it must traverse. Pus consists mainly of neutrophils, cellular debris, bacteria, bacterial by-products, enzymes, and edematous fluid. An incision for drainage will allow drainage of the purulent material and improve circulation to the area. Drainage provides a pathway for removal of inflammatory mediators and helps prevent further spread of cellulitis in most cases.

Empirical selection of an antibiotic (antimicrobial agent) should be based on knowledge of which bacteria are most commonly associated with endodontic infections and their antibiotic susceptibility.[8,15,23–30] Many of the microbes in endodontic infections have yet to be cultivated for antimicrobial sensitivity. The clinician must be thoroughly familiar

Cellulitis
Osteomyelitis
Persistent Infections

with the antibiotic and inform the patient of the benefits, possible side effects, and possible sequelae of the patient's failure to take the proper dosage. A loading dose is important to provide an initial adequate therapeutic level of antibiotic. The antibiotic should generally be continued for 2 to 3 days following resolution of the major clinical signs and symptoms of the infection. Following removal of the source of the infection and adjunctive antibiotic therapy, significant improvement in the patient's status should be seen in 24 to 48 hours. A prescription written for a 7-day regimen of antibiotic therapy is usually adequate.

Penicillins are the antibiotics of choice for patients not allergic to them. However, up to 10% of the population may be allergic, so a careful history of drug hypersensitivity is important. Penicillin VK is effective against both facultative and anaerobic microorganisms commonly isolated and cultivated form endodontic infection. [8,15,25,27,28] A loading dose of 1,000 mg of penicillin VK should be orally administered, followed by 500 mg every 4 to 6 hours.

Amoxicillin is an antibiotic of choice for treating infections of endodontic origin.[8,15,23,25–28] Amoxicillin has an expanded spectrum of activity that may include bacteria involved in endodontic infections yet not cultivated in addition to bacteria not routinely associated with infections of endodontic origin. The clinician must decide if the expanded spectrum over penicillin VK is indicated. Amoxicillin is rapidly absorbed and provides sustained serum levels. Amoxicillin is recommended for medically compromised patients that require antibiotic prophylaxis. The usual oral dosage for amoxicillin to treat endodontic infections is 1,000 mg loading dose followed by 500 mg every 8 hours. An alternate dosage for amoxicillin is 875 mg every 12 hours. As stated above, a prescription written for a 7-day regimen of antibiotic therapy is usually adequate for endodontic infections once the reservoir of infection is removed by endodontic treatment or root extraction.

Clavulanate is a competitive inhibitor of beta-lactamase. Antibiotic susceptibility tests have shown excellent results against bacteria isolated form endodontic infections when clavulanate is used in combination with amoxicillin (Augmentin™).[8,15,23,25–28] This combination should be especially considered for patients that are immunocompromised. The usual oral dosage for amoxicillin with clavulanate is 1,000 mg loading dose followed by 500 mg every 8 hours. An alternate dosage is 875 mg every 12 hours.

Clindamycin is highly effective against both facultative and strict anaerobic bacteria associated with endodontic infections. It is well distributed throughout the body, especially to bone, where its concentration approaches that of plasma. Both penicillin and clindamycin have been shown to produce good results in treating odontogenic infections.[8,15,23,25,27] Clindamycin is rapidly absorbed even in the presence of food in the stomach. The oral adult dosage for serious endodontic infections is a 600 mg loading dose followed by 300 mg every 6 hours.

Erythromycin has traditionally been the alternative choice for patients allergic to penicillin, but it is not effective against anaerobes associated with endodontic infections. Clarithromycin and azithromycin are macrolides like erythromycin, with some advantages over the latter. They have a spectrum of antimicrobial activity that includes facultative bacteria and some anaerobic bacteria associated with infections of endodontic origin.[8,15] They also have less gastrointestinal upset than erythromycin. In a recent population-based Danish study, there was an increased risk of cardiac death with clarithromycin compared with those who were receiving penicillin V for similar infections.[31] The oral dosage for clarithromycin is a 500 mg loading dose followed by 250 mg every 12 hours. The oral dosage for azithromycin is a 500 mg loading dose followed by 250 mg once a day.

Metronidazole is a nitroimidazole that is active against parasites and anaerobic bacteria. However, it is ineffective against facultative bacteria.[8,15,32] It is a valuable antimicrobial agent in combination with penicillin when penicillin alone has been ineffective.[32] The usual oral dosage for metronidazole is a 1,000 mg loading dose followed by 500 mg every 6 hours. When patients fail to respond to treatment, consultation with a specialist is recommended.

Cephalosporins are usually not indicated for the treatment of endodontic infections. First generation cephalosporins do not have activity against the anaerobes usually involved in endodontic infections. Second generation cephalosporins have some efficacy for anaerobes; however, there is a possibility of cross-allergenicity of cephalosporins with penicillin.

Doxycycline occasionally may be indicated when the above antibiotics are contraindicated. However, many strains of bacteria have become resistant to tetracyclines.

Ciprofloxacin is a quinilone antibiotic that is not effective against the anaerobic bacteria usually isolated from endodontic infections. With a persistent infection it may be indicated to take culture and perform sensitivity tests to demonstrate the presence of susceptible organisms.

Prophylactic Antibiotics for Medically Compromised Patients

Prophylactic antibiotic coverage may be indicated for medically compromised patients requiring endodontic treatment. The American Heart Association (AHA) and the American Academy of Orthopaedic Surgeons have made guidelines for prophylactic antibiotic coverage.[33,34] The guidelines are meant to aid practitioners but are not intended as the standard of care or as a substitute for clinical judgment. The incidence of endocarditis following most procedures on patients with underlying cardiac disease is low. A reasonable approach for prescribing prophylactic antibiotics considers the degree to which the underlying disease creates a risk for endocarditis, the apparent risk for producing a bacteremia, adverse reactions to the prophylactic antibiotic, and the cost-benefit aspect of the regimen. Antibiotic prophylaxis is employed to prevent surgical infections or their postoperative sequelae, to prevent metastatic bacteremia, and to prevent accusation that "all was not done for the patient."[35] It is suspected that antibiotic prophylaxis is often prescribed to prevent malpractice claims.[35]

How antibiotics quickly kill bacteria in the blood is difficult to answer when many antibiotics are only effective with actively dividing bacteria. It is speculated that antibiotics may reduce metastatic infections by preventing adhesion of bacteria to tissues or inhibiting growth after attachment.[36] The principles of antibiotic prophylaxis state that the antibiotic must be in the system prior to an invasive procedure. If a patient has not taken the prescribed antibiotic, they should be rescheduled or wait an hour after administration of the antibiotic for treatment. However, there is data to support the use of an antibiotic up to 2 hours after the bacteremia.[35]

The incidence of bacteremia has been shown to be low during root canal therapy. A transient bacteremia can result from the extrusion of the microorganisms infecting the root canal beyond the apex of the tooth.[37–41] In addition, care must be taken when positioning dental dam clamps and accomplishing other dental procedures that may produce bleeding with an accompanying bacteremia. Medically compromised dental patients who are at risk of infection should receive a regimen of antibiotics that either follows the recommendations of the AHA or an alternate regimen determined in consultation with the patients' physicians.[35] It is believed that amoxicillin, ampicillin, and penicillin V are equally effective against alpha-hemolytic streptococci; however, amoxicillin is recommended because it is better absorbed from the gastrointestinal tract and provides higher and more sustained serum levels.[35] For cardiac conditions associated with endocarditis, prophylaxis is recommended for both non-surgical and surgical endodontics.[35] Antibiotic prophylaxis is recommended for cardiac conditions associated with endocarditis at a high or moderate risk category. Dental procedures for which antibiotic prophylaxis is recommended include endodontic instrumentation or surgery beyond the apex, but not intracanal endodontic treatment, post placement and buildup.[35] From a practical standpoint, it is difficult to determine with certainty that endodontic instruments did not pass beyond the apical foramen. Also included for prophylaxis antibiotics is intraligamentary (PDL) local anesthetics but not non-intraligamentary local anesthetic injections.[35]

A joint committee of the American Dental Association and American Academy of Orthopaedic Surgeons published their first advisory statement on antibiotic prophylaxis for patients with prosthetic joints.[33,34] Dental procedures of concern and the antibiotic regimens are the same as for endocarditis. Patients of potential increased risk of having a hematogenous total joint infection include all patients during the first 2 years following joint replacement, immunocompromised/immunosuppressed patients, and patients with comorbidities. For more details, see Chapter 31.

Collection Of A Microbial Sample

Adjunctive antibiotic therapy for endodontic infections is most often prescribed empirically based on our knowledge of the bacteria most often associated with endodontic infections. At times, culturing may provide valuable information to better select the appropriate antibiotic regimen. For example, an immunocompromised/immunosuppressed patient (not immunocompetent) or patients at high risk of developing an infection (e.g., history of infective endocarditis) following a bacteremia require close monitoring. These patients may have an infection caused by bacteria usually not associated with the oral cavity. Other examples include a seemingly healthy patient who has persistent or progressive symptoms following surgical or nonsurgical endodontic treatment. An aseptic microbial sample from a root canal is accomplished by first isolating the tooth with a dental dam and disinfecting the tooth surface and dental dam with sodium hypochlorite or other disinfectant. Sterile burs and instruments must be used to gain access to the root canal system. Intra-canal irrigation should not be used until after the microbial sample has been taken. If there is drainage from the canal, it may be sampled with a sterile paper point or aspirated into a syringe with a sterile 18–25-gauge needle depending on the viscosity of the exudates. The aspirate should be either taken immediately to a microbiology laboratory in the syringe or injected into pre-reduced transport media. To sample a dry root canal, a sterile syringe should be used to place some pre-reduced transport medium into the canal. A sterile endodontic

instrument is then used to scrape the walls of the canal to suspend microorganisms in the medium.

To prevent contamination by "normal oral flora," a microbial sample from a soft tissue swelling should be obtained using needle aspiration before making an incision for drainage (Figure 30-8). Once profound anesthesia is achieved, the surface of the mucosa should be dried and disinfected with an iodophor swab (The Purdue Frederick Company, Norwalk, Conn.) or a similar product. A sterile 16 to 20 gauge needle is then used to aspirate the exudate. The aspirate should be handled as described above (Figure 30-9). After collecting the specimen on a sterile swab, it should be quickly placed in pre-reduced medium for transport to the laboratory.

Good communication with the laboratory personnel is important. The sample should be Gram-stained to demonstrate which types of microorganisms predominate. The culture results should show the prominent isolated microorganisms and not just be identified as "normal oral flora." Antibiotics can usually be chosen to treat endodontic infections based on the identification of the prominent microorganisms in the culture. With persistent infections, susceptibility testing can be undertaken to establish which antibiotics are the most effective against resistant microbial isolates. At present, it may take 1 to 2 weeks to identify anaerobes using conventional methods. Some laboratories may have molecular methods available to rapidly detect and identify known opportunistic bacteria.

Cortical Trephination

Cortical trephination is defined as the surgical perforation of the alveolar cortical plate or apical foramen to release accumulated tissue exudates.[10] Cortical plate trephination is indicated for patients with severe pain of endodontic origin without intraoral or extraoral swelling and when drainage cannot be accomplished through the root canal (e.g., posts, filling material, ledging). Cortical trephination involves exposing the cortical bone, making an opening in the bone, and making a pathway through the cancellous bone to the root-end.[42–47] If the cortical plate is thin, a dental instrument such as a gutta-percha spreader may be used to penetrate the mucosa and cortical plate without an incision (Figure 30-10). Several studies have demonstrated that a patient with severe periapical pain without swelling will have significant relief following trephination.[43,44,48–50] Henry and Fraser[44] recommended trephination for the management of severe periapical pain of endodontic origin when drainage through the tooth is inadequate, impractical, or impossible. Their technique involved a submarginal horizontal full thickness flap to access the alveolar bone, the use of a surgical high speed round bur to access the involved root apex and abscessed area, and the placement of a sutured drain.

Other studies have not shown cortical trephination to be predictable in relieving periradicular pain.[45–47] One study found that the routine use of trephination for the reduction of pain or swelling in symptomatic necrotic teeth with periradicular radiolucencies was not predictable.[47] A systematic review of the literature concerning the emergency management of acute apical periodontitis in the permanent dentition also concluded that routine cortical trephination did not show significant benefit.[50] While there is no higher level of evidence justifying the routine use of surgical trephination, there are instances in which it is a reasonable treatment alternative. Patients with severe periradicular pain of endodontic origin without swelling may benefit from the procedure.

Decomprssion: Aspiration and Irrigation

The terms decompression and marsupialization are often used interchangeably. Decompression is the surgical exposure of a cyst wall and insertion of a tube or other type of drain to decompress the lesion during healing.[10] It is not uncommon for chronic periradicular pathosis to remain clinically asymptomatic and develop a bony defect of significant size. If left undiagnosed and untreated, periradicular pathosis may develop into self perpetuating entities that erode osseous supporting structures and encroach on multiple adjacent teeth, sinus cavities, neurovascular bundles, and even the nasal cavity. Bony lesions radiographically exceeding 200 square mm have a higher statistical chance of being cystic.[51] There are radicular cysts that may have matured to the extent that they are truly independent and nonsurgical endodontic treatment may no longer be enough to cause bony healing.[52,53] When nonsurgical endodontic does not resolve apical pathosis, surgical intervention is an alternative treatment recommendation.

Surgical treatment including the enucleation of extensive bony lesions may involve unintentional interruption of periradicular vascular and neural structures, development of soft tissue defects, and damage to adjacent anatomic structures. Decompression is a more conservative treatment option which allows the progressive reduction in lesion size and may eliminate the necessity of surgical enucleation. Decompression is intended to disrupt the integrity of the lesion wall, reduce the internal osmotic pressure, and permit osseous regeneration (Figures 30-11 and 30-12).

In 1982, Suzuki[54] suggested treating jaw cysts using an irrigational technique. In that study, the contents of 36 cysts were irrigated weekly for months and even years. This irrigation method involves the use of Ringer's solution, glucose, and antibiotics. The fluids aspirated from the cysts were quantitatively analyzed for electrolytes, inorganic substances, proteins, and lipids.[55] Irrigation of the lesions eventually resulted in the reduction in the volume and size of the cysts. The irrigation method is effective for the treatment of cysts in jaws.[54] Large cysts have been decompressed using acrylic stints, obturators, and tubing that extend into the lesion.[56–60] Acrylic stints or tubing was often left in for months with irrigation of the lesion. Neaverth and Berg described several cases of large lesion decompression that lasted from several weeks to more than a year.[59] The method used radioopaque tubing in conjunction with water irrigation by the patient. The tube was removed once there is evidence of elimination of the cystic lesion.

A surgical technique was described in case series format by Wong.[61] After flap reflection, a surgical fenestration was used to obtain some tissue for biopsy but the majority of bony defect was left intact. Copious drainage was accomplished and the defect irrigated with saline prior to suturing. This surgical treatment was effective in producing healing while avoiding potential complications. In 1997, Rees[62] reviewed and highlighted the treatment of large maxillary cysts by root canal treatment and subsequent decompression. The described technique used a drain made from surgical suction tubing. This seems to be the consensus treatment sequence currently in the dental literature. Figure 30-12 shows the radiographic and clinical appearance of decompression tube that was left in position for 1 week. At 1 week after placing the tube, the root canal was obturated. A 6-month follow-up radiograph shows bone filling in the apical lesion.

A 20-patient cohort study of decompression results by Enislidis and colleagues[63] is perhaps the best evidence of the technique's effectiveness. The authors describe the advantages as ease of treatment, confirmed diagnosis with biopsy, low morbidity, and low incidence of complications. Loushine[64] reported the removal of the decompression tube after only 2 days with follow-up examinations showing progressive osseous repair at 3, 6, and 12 months.[64] The use of decompression to treat odontogenic keratocyst (OKC) has also been reported by August et al.[65] A pediatric nasal airway was modified and placed in 14 OKCs for an average of 8.4 months. They were irrigated twice a day with chlorhexidine. At the time of cystectomy, 9 of 14 no longer showed histological features of OKCs. The epithelium had dedifferentiated and loss cytokeratin10 production in 64% of the patients.

Mejia et al.[66] reported in a case series format the use of a vacuum system within the root canal system. The technique produces a vacuum effect capable of removing copious amounts of exudate and inflammatory fluids. Perhaps the removal of the rather high osmolarity fluid and disruption of the bony defect lining is the impetus for subsequent healing.

The combination of aspiration and irrigation as an alternative to surgical endodontic treatment was reported by Hoen et al.[67] This case series demonstrated success using a single visit aspiration and saline irrigation of non-healing bony lesions associated with previously endodontically treated teeth. Following profound anesthesia, mucosa disinfection and aspiration of the cyst contents was accomplished using a 16 or 18 gauge needle attached to a syringe. Several milliliters of viscous aspirate were routinely obtained. The aspirates were submitted for aerobic and anaerobic culturing, Gram-staining, and immunoglobulin quantification. The level of IgG was significantly elevated in each specimen. Above normal levels of IgG have been shown to be consistent with cyst fluid.[55] It has also been shown that there is a high level of albumin and globulin in cysts compared to granulomas.[68] No bacteria were seen or cultured from any of the aspirates. At the 1 year follow-up appointments, the patients were asymptomatic and significant bony healing was seen on radiographs. It is important to develop a clear differential diagnosis and to have timely reevaluations of the patient's signs and symptoms to determine if further treatment is needed.[67]

An additional use of aspiration is to obtain a biopsy sample. August et al.[65] concluded that the use of needle aspiration for biopsy is a useful technique to distinguish between malignant and benign intraosseous jaw lesions. The described technique involved the use of a 10 ml syringe containing 1 or

2 mls of air attached to a 23 or 25 gauge needles. Once within the lesion, suction was applied and several quick passes were performed to obtain cellular material. The specimens were then placed on glass slides for smear preparation. The authors further suggested that aspiration may be the diagnostic tool of choice in a hospital setting due to its simplicity, suitability as an outpatient procedure, rapidity of interpretation, and minimal morbidity.[65] The accuracy of fine-needle aspiration biopsy of head and neck tumors has been reviewed in 218 patients.[69] The technique was determined to be a useful modality for the diagnosis of head and neck tumors. The use of such a technique requires coordination with a pathologist familiar with needle biopsy specimens.

ENDODONTIC FLARE-UPS

A flare-up is an acute exacerbation of an asymptomatic pulp/or periapical pathosis after the initiation or continuation of root canal treatment.[10] Treating similar teeth in patients with comparable medical and dental histories, and the same endodontic technique, is no assurance of a common outcome. While one patient may remain asymptomatic, another

may have a flare-up. The contrasting clinical outcomes may seem to occur in a random manner or lead to erroneous conclusions about the cause–effect relationship of endodontic procedures to the flare-up. While some flare-ups have an iatrogenic component, others do not. The development of moderate to severe inter-appointment pain, with or without swelling, is an infrequent but challenging problem. Severe pain and swelling associated with flare-ups represent the clinical manifestation of complex pathologic changes occurring at a cellular level. There is increasing evidence pointing to multiple complex factors involved in producing a flare-up. These factors include mechanical, microbial, chemical, immunological, gender, and psychological components. The regulation of periapical inflammation is highly complex and represents another factor in patients' response to endodontic procedures.[70–75]

Incidence of Flare-ups

Meta-analysis is a statistical procedure that integrates the results of several independent studies considered to be combinable. Pooled data from multiple studies increases the sample size and power, thus providing a more precise estimate of a treatment's effect. The decision about whether or not results of individual studies are similar enough to be included in a meta-analysis is a critical issue.[76]

A meta-analysis of the results of previous studies concerning the incidence of endodontic flare-ups reviewed all relevant articles published in dental journals in English from 1966 to May 2007. Only six studies met all inclusion criteria. Prospective case series and clinical trials were included in the meta-analysis.

The average percentage of incidence of flare-ups for 982 patients was found to be 8.4%.[74] Differences in experimental design do not allow for a direct comparison of studies; however, the presence of pre-operative pain or mechanical allodynia (defined as a reduced mechanical pain threshold, or percussion sensitivity) was a positive predictor of post-operative pain in more than 15 studies involving more than 6,600 patients.[77]

Predisposing Conditions

When symptomatic pretreatment patients have been included in the study cohort, predisposing conditions include periapical abscess, acute apical periodontitis, pre-operative pain, and swelling.[74,78] Studies have found that the lowest incidence of flare-ups occurred in patients without periapical pathosis and when a sinus tract is present.[78] It is reasonable to hypothesize that a sinus tract allows drainage and prevents an increase in periapical tissue pressure.

A recent prospective clinical study evaluated 500 one-visit root canal treatments referred to an endodontist.[79] A predictive model of pain following treatment was developed. The study determined the probability of the incidence, intensity, duration and triggering of post-endodontic pain. Factors considered included the patient's age, gender, medical status, location of the tooth, number of canals, pulp vitality, preoperative pain, periapical radiolucencies, previous emergency access, and presence of occlusal contacts with opposing teeth.

The predictive models showed that the incidence of post-endodontic pain was significantly lower when the treated tooth was not a molar (P = 0.003), demonstrated periapical radiolucencies (P = 0.003), had no history of previous pain (P = 0.006), or emergency endodontic treatment (P = 0.045), and had no occlusal contact. The probability of experiencing moderate or severe pain was higher with increasing age (P = 0.09) and in mandibular teeth (P = 0.045). The probability of pain lasting more than 2 days was increased with age (P = 0.1) and decreased in males (P = 0.007) and when a radiolucent lesion was seen on radiographs (P = 0.1). Results indicated that the most important factor in predicting the incidence of post-endodontic pain is the absence of occlusal contacts. It was predicted that the patient with the highest probability of developing post-endodontic pain had previously experienced pain in a molar with prior endodontic treatment, no apical radiolucency and occlusal contacts. In contrast, a hypothetical patient with no previous pain in an incisor, a cuspid or a bicuspid with an apical radiolucency and free from occlusion will have a 0.07 probability of developing post-endodontic pain. Those odds would be a very good bet.[79]

The etiology of an exacerbation should be seen as multifactorial, and dependent on interactions between the host's immunological response, infection, and physical damage.

Studies evaluated factors related to post-operative endodontic pain and flare-up. The presence of pre-operative pain or mechanical allodynia (reduced mechanical pain threshold, or percussion sensitivity) was a significant predictor of post-operative pain in more than 15 studies with a large number of patients.[80] The etiology of a flare-up is multifactorial, and dependent on interactions between the host's immunological response, infection, and physical damage. The major causative factor has been described as microbial in origin.[76]

There are additional factors that may also predispose a patient to pain. They include genetics, gender, and anxiety. These non-dental factors are being evaluated, and at this time it seems likely that in the future their significance will be more fully understood. Although no single factor completely predicts the occurrence and severity of post-operative pain, an astute clinician should recognize that the presence of pre-operative pain or mechanical allodynia (sensitivity to percussion) is a warning sign that post-operative pain is likely. That warning sign is an indication that pain-preventive steps should be taken. They include pain-preventive post-operative analgesics and occlusal reduction when there is evidence of mechanical allodynia.

Occlusal Adjustment

A number of clinical studies have evaluated the pain-preventive value of occlusal adjustment. It is difficult to compare their results of the trials due to different methodologies, inclusion and exclusion requirements, and specific purposes of the study. A clinical study investigated the answers to

the following questions: "Are there specific clinical conditions that may indicate a need for occlusal reduction? Can a reliable clinical profile be developed of patients most likely to benefit from occlusal reduction?"[81] The research hypothesized that there may be specific pre-operative conditions that are statistically significant indicators for occlusal reduction following instrumentation. This approach varied from previous research that placed all endodontic cases together in a single group without accounting for the importance of clinical variables. Among the conditions evaluated was the presence or absence of pulp vitality, pre-operative pain, and percussion sensitivity, presence of a periapical radiolucency, a stoma, swelling, and a history of bruxism. The purpose of the study was to evaluate specific clinical factors as indicators for occlusal reduction following endodontic instrumentation. A statistically valid profile of patients most likely to benefit from occlusal reduction was developed. In that study of 117 patients, approximately twice as many patients (80%) with a diagnosis of irreversible pulpitis, who underwent occlusal reduction, reported no post-treatment pain when compared to control subjects with no occlusal reduction.[81]

Research Findings

Occlusal reduction was found to result in the prevention of post operative pain when any or all of the following indicators were present:

- Sensitivity to percussion
- Vital Tooth
- History of pain
- Absence of a periapical radiographic lesion

Even when all of those pain predictors were present, occlusal reduction resulted in the complete absence of post-operative pain. That remarkable result seems to be due to relieving occlusal stress from the periodontal ligament (Figure 30-13).[81]

Other studies concerning occlusal reduction have reached different conclusions.[82–84] Significant differences in exclusion and inclusion criteria and methodologies may account for the varied findings. For example, one study examined only teeth with "mild" sensitivity to occlusion, and excluded those with more severe sensitivity.[84]

Genetics

The role of genetics is an entirely new and exciting variable for dentists to consider. Genetics may play a role in predisposing some patients to a variety of complications including pain, poor healing, and abscess formation. Considering the role of genetics in endodontics is complex and at an early stage of development. Increasingly, endodontic literature provides examples of how genetics may influence endodontic symptoms and outcomes. Genetic variants may play an important role in the healing of apical lesions, abscess formation, and pain. Findings suggest that specific markers associated with the pro-inflammatory regulator Il-1B, a key regulator of host response, may contribute to increased susceptibility to periapical pathosis.[85] It has also been suggested that genetic factors are associated with a susceptibility to develop symptomatic dental abscesses.[86,87] These preliminary findings point to a complex mix of factors associated with patient's pain and treatment outcomes. It is possible that as more information is collected we will be better able to identify those patients predisposed to pain and have a diminished capacity for healing.[88]

Pain Responses: Male And Female

Although a person's biological sex exerts a major influence on their gender identity, "sex" and "gender" are not interchangeable terms. The term "sex" refers to biologically based differences, while the term "gender" refers to socially based phenomena. If research subjects are to be categorized by anatomical features (chromosomes, reproductive organs), it is appropriate to describe the study as one of "sex differences." In contrast, if additional measures of masculinity/femininity or gender identity are used to describe subjects, then the term "gender differences" is appropriate.[89]

During the last 10 to 15 years, there has been a growing body of evidence indicating that there are substantial sex differences in clinical and experimental pain responses for women and men. It seems that women are at a substantially greater risk for many clinical pain conditions. An extensive review reported that a survey of the currently available epidemiological and laboratory data indicates that there is overwhelming evidence for clinical and experimental sex differences in pain. Numerous reasons for these findings have been given, including hormonal and genetically driven sex differences in brain neurochemistry. Furthermore, some highly prevalent chronic pain syndromes that are found in both sexes (including chronic fatigue syndrome, fibromyalgia, interstitial cystitis and temporo mandibular disorder) occur overwhelmingly more often (in more than 80% of cases in which treatment is sought) in women.[89]

Vital and Nonvital Pulps

A clinician may categorize flare-ups as occurring in vital or nonvital cases. The vital case can be defined as a case in which the pulp is still capable of conducting an impulse to higher centers. It does not imply that the pulp is healthy. In fact, although a tooth may test vital it may contain areas of acute

inflammation, chronic inflammation, and necrotic tissue in a dynamic mix. However, as long as sensibility tests (thermal or electricity) provoke a response, the tooth should be considered vital. The challenge for the clinician, while treating a vital case, is to completely extirpate well-innervated tissue without shredding it or instrumenting through the apical foramina, causing additional inflammation to periapical tissues.

The nonvital pulp poses a different problem. If we consider the vital case to be primarily a challenge of managing inflamed tissue, the nonvital case represents a challenge of managing infected tissue. Thus it poses a microbial challenge. The dentist must avoid pushing microbes and necrotic tissue debris through and beyond the apical foramen into the periapical tissues. The resulting inflammatory/immune response is the basic cause of the swelling and pain associated with nonvital case flare-ups. A chronic nonvital case may flare-up even with meticulous care by the clinician. Instrumentation of a canal or irrigation may inadvertently cause a severe reaction in the periapical tissues due to extrusion of bacteria and tissue debris. As stated earlier, this is not a simple case of extrusion of debris being the only factor involved. There is increasing evidence that genetic and other biological factors may play a role in predisposing some patients to exacerbations.

Retreatment Cases

Retreatment cases, in most studies, have had a significantly higher incidence of flare-ups than conventional cases (Figure 30-14).[74,75] One study found an extremely high incidence of flare-ups (13.6%) in retreatment teeth with apical periodontitis.[78] It can be hypothesized that retreatment cases are often technically difficult to treat, and there is a tendency to push remnants of gutta-percha, solvents, and other debris into the periapical tissues. Microbes may also be pushed apically during the retreatment process. Extrusion of infected debris or solvents into the periapical tissues during preparation of the canals is allegedly one of the principal causes of postoperative pain.[90–92] Retreatment cases are usually associated with a persistent or secondary root canal infection by therapy-resistant microorganisms that may be more difficult to eradicate when compared to primary infections.[72,92,93] In contrast, others have found no statistical significance in the relation of retreatment to flare-ups.[75]

Working Length

The apical portion of the root canal system has been considered the most critical anatomic area with regard to the need for cleaning, disinfection, and sealing.[72,94] Over extended instrumentation should be avoided as it can result in postoperative pain.[75] Nonvital teeth associated with a periapical lesion, as well as root-filled teeth with recalcitrant lesions, represent a different biological challenge.[75] In those cases, microorganisms may be at or near the apical foramen and accessory foramina that are in close contact with the periapical tissues.[72,95–97] Correct working length in infected teeth is essential.[72,98] Inaccurate working length or inadvertent over- or under-instrumentation can result in negative outcomes for the patient. Over-instrumentation may force infected debris into the periapical tissues eliciting a severe inflammatory response and pain. Under-instrumentation will leave microorganisms in close proximity to the apical foramina where they or their virulence factors can gain access to the periapical tissues.[72,99] Incomplete instrumentation can disrupt the balance within the microbial flora and allow previously inhibited species to overgrow.[100] If those strains of bacteria are virulent and/or reach sufficient numbers, damage to the periapical tissues may be intensified and result in an exacerbation of the lesion. Furthermore, environmental changes, induced by incomplete debridement, have the potential to activate virulence genes.[73] A change in host resistance or microbial virulence may allow a previously

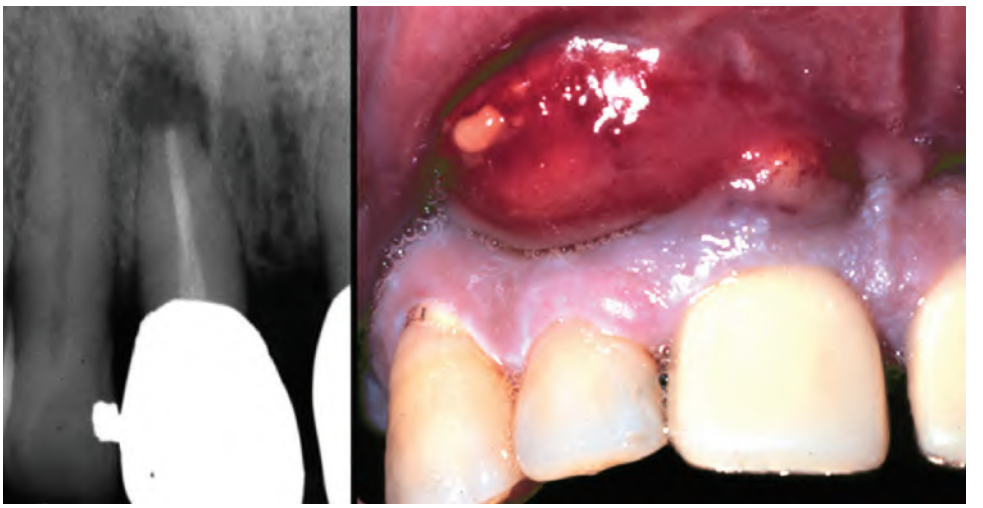

FIGURE 30-14 Swelling associated with flare-up following revision of previous endodontic treatment. (Courtesy of Paul A. Rosenberg, NY, U.S.A.)

asymptomatic situation to become symptomatic.[73] Clinical studies, however, have not linked incomplete canal preparation to flare-ups.[75,101,102]

Obturation

Overfilling can cause postoperative pain particularly when a substantial amount of filling material extrudes through the apical foramen. Gross overfilling involves the introduction of excess sealer (and its cytotoxic components) into the periapical tissues causing tissue damage and inflammation.[72]

A study found that overfilling was associated with significantly increased rate of pain and percussion sensitivity in 1-week follow-up examinations as compared with teeth not overfilled.[103] Scheduling of the obturation visit in relation to instrumentation may be another important factor. Obturation in the presence of acute apical periodontitis can be considered to be a predictor of postoperative pain. In order to avoid increased postoperative pain, patients who present for obturation but have significant acute apical periodontitis should have the procedure postponed until the tooth is more comfortable. Relief of pain can be achieved by treatment directed at reducing tissue levels of factors that stimulate peripheral terminals of nociceptors or by reducing mechanical stimulation of sensitized nociceptors (e.g., occlusal adjustment). Thus by deferring obturation of a tooth with pericementitis, further stimulation of sensitized nociceptors is avoided.[104]

Strategies to Prevent Flare-Ups

Variability in patients' pain sensitivity, perception, and tolerance may explain why they may react differently to endodontic treatment. Additional factors that may dispose patients to pain include genetics, level of anxiety, and their sex. Because there are a numerous factors associated with endodontic flare-ups an effective pain-preventive strategy must be multifaceted.[105–108]

Anxiety Reduction

High levels of stress, anxiety, or pessimism predict poor outcomes in measures that range from speed of wound healing to duration of hospital stay. Over 200 studies indicate that preemptive behavioral intervention, to decrease anxiety before and after surgery, reduces postoperative pain intensity and intake of analgesics improves treatment compliance, cardiovascular and respiratory indices, and accelerates recovery.[109] In a landmark study,[110] it was found that preoperative discussion of likely postsurgical treatments and associated discomfort halved the requirement for postoperative morphine and reduced time to discharge. Patients in that study also received instructions in a relaxation technique. Providing information about the procedure is an important step in preparing patients for endodontic treatment. Information about profound dental anesthesia and preventive pain strategies is an important anxiety reduction technique. Perhaps most importantly, the dentist should assure the patient that pain prevention is a primary concern. It was determined that patients given a running commentary concerning procedures and associated sensations rated themselves as less anxious and experiencing less pain than a normal control group.[111] Information about sensations experienced during treatment as well as a description of procedures appears to have a significant impact in reducing patient anxiety.[111]

Pharmacologic Strategies for Flare-Ups

Antibiotics

Antibiotics are frequently recommended to endodontic patients without a rational biologic basis.[112,113] An evidence-based review determined that the use of systemic antibiotics for the prevention of post-treatment endodontic pain should be discouraged.[114] As previously stated, antibiotic treatment is generally not recommended for healthy patients with localized endodontic infections. Systemic antibiotics should be considered if there is a spreading infection that indicates failure of local host responses to control bacterial irritants or the patient has a medical condition that compromises defense mechanisms and could expose the patient to higher systemic risks.[114]

NSAIDs and Acetaminophen

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been shown to be effective for managing pulpal and periapical pain.[104,115] However, due to the renal effects of NSAIDs as well as interactions with many anti-hypertensive drugs, acetaminophen should be considered for post-treatment pain in patients with known sensitivity to NSAIDs or aspirin. Acetaminophen should also be considered for those with the following disorders: ulcers, ulcerative colitis, asthma, or hypertension. Pretreatment with NSAIDs or acetaminophen has also been shown to be effective for reducing postoperative pain.[73,116] Pretreatment with NSAIDs for irreversible pulpitis should have the effect of reducing pulpal levels of the inflammatory mediator prostaglandin E2 (PGE2).[73,117]

Recently, the combination of ibuprofen/acetaminophen (paracetamol) has been advocated for use in an effort to avoid unpleasant side effects associated with opioids. There is good evidence that supports the use of this drug combination for the treatment of moderate to severe pain. A powerful clinical study used a double blind design that was placebo controlled randomized, single dose, and utilized three sites.[118] The study was designed to compare the efficacy and tolerability of different analgesic combinations, including a novel-single tablet combination of ibuprofen/paracetamol (acetaminophen). It investigated moderate to severe post-operative dental pain following extraction of at least three impacted molars, two of which were mandibular molars.

The study compared the efficacy of the following analgesics:

- Placebo
- Acetaminophen 500 mg/codeine 15 mg
- Ibuprofen 200 mg/codeine 12.8 mg
- Ibuprofen 200 mg/acetaminophen 500 mg
- Ibuprofen 400 mg/acetaminophen 500 mg

The results ranked the five treatments from best to worst:

- Two tablets of ibuprofen 200 mg/acetaminophen 500 mg
- One tablet of ibuprofen 200 mg/acetaminophen 500 mg
- Two tablets of ibuprofen 200 mg/codeine 12.8 mg
- Two tablets of acetaminophen 500 mg/codeine 15 mg
- Placebo

This study found that one or two tablets of the single-tablet combination of ibuprofen 200 mg/acetaminophen 500 mg was statistically significantly more effective than two tablets of acetaminophen/codeine or one tablet of the ibuprofen/acetaminophen combination. The peak pain relief was found to be higher and more sustained in patients taking two tablets of the single-tablet combination of ibuprofen/acetaminophen (*p* values compared with all other treatments). The proportion of subjects reporting adverse effects was significantly less with either one or two tablets of the single tablet combination of ibuprofen/acetaminophen compared with the codeine analgesic combinations. Codeine is known to be associated with several side effects, including nausea and vomiting.[118]

Combining ibuprofen with acetaminophen (APAP) provides dentists with an additional therapeutic strategy for managing moderate-acute postoperative dental pain. This combination has been reported to provide greater analgesia without significantly increasing the adverse effects that often are associated with opioid-containing analgesic combinations. The strategy of combining two analgesic agents having distinct mechanisms or sites of action, such as combining a peripherally acting analgesic with a centrally acting analgesic, has been advocated for many years. Analgesic formulations containing an opioid and a peripherally acting analgesic consistently provide greater pain relief than do the component agents when administered alone.

It is advisable to have endodontic patients take their analgesics "by the clock" rather than on an "as needed basis.[116] Patients should take an NSAID or acetaminophen just prior to, or immediately after, treatment. If they wait to take medication until after the onset of pain, there is usually a delay of up to 1 hour before they experience pain relief. It has been suggested that instructing patients to take their analgesics by the clock for the first few days provides a more consistent blood level of the drug and may contribute to more consistent pain relief.[117] The combination of ibuprofen and acetaminophen taken together has been shown to produce additive analgesia when treating dental pain.[104,116,119–121] Opioids may be added when indicated.

Long-acting Local Anesthetics

Long-acting local anesthetics (e.g., bupivicaine) can provide an increased period of post-treatment analgesia beyond the usual duration of anesthesia.[122,123] By blocking the activation of unmyelinated C-fiber nociceptors, the anesthetic decreases the potential for central sensitization.[104] Long-acting local anesthetics can provide a period of analgesia for up to 8 to 10 hours following block injections and may reduce pain even 48 hours later.[104,123] Use of long-acting local anesthetics is a valuable biologically based strategy that provides analgesia during the immediate postoperative period.[104] Endodontic treatment by itself can be expected to provide significant pain relief.

Treatment of Endodontic Flare-Ups

Selecting the appropriate treatment after an endodontic flare-up is dependent upon understanding its biological cause. For example, the clinician must determine if a flare-up is primarily iatrogenic in nature, as in the case of inaccurate canal measurement control, gross overfilling or microbiologically based, as in a necrotic case.

Diagnosis and Definitive Treatment

Treatment is always directed at the cause of the problem. If a nonvital tooth has not been fully instrumented, the canal must be instrumented and irrigated in order to eliminate the microbiological cause of the problem. Pain relief in the over-instrumented case is often dependent on an analgesic strategy. The under-instrumented case may require further instrumentation to the correct measurement, as well as the use of analgesics. Supplementary antibiotics are usually not necessary unless there is a significant swelling that appears to be spreading. History of the onset of pain is important in determining if the pain is spontaneous or provoked by a specific stimulus. For example, if a tooth had a history of acute apical periodontitis and its occlusion had not been reduced, that could be identified as a probable cause of postoperative pain.[81] In contrast, a complaint of swelling, pressure, and throbbing in the interproximal area might suggest a periodontal component of the problem that should be explored. If inaccurate measurement control was used or proper measurement not maintained, the clinician must determine if the canal was under- or over-instrumented. Working length should be reconfirmed, patency to the apical foramen obtained, and thorough debridement with copious irrigation completed. Remaining tissue, microorganisms and their products, and extrusion beyond the apex are major factors responsible for post-treatment symptoms.[124] Abscesse/cellulitis associated with a flare-up should be treated as previously described.

Chapter 31

Management Considerations for the Medically Complex Endodontic Patient

Bradford R. Johnson, Joel B. Epstein

One of the challenges facing dental specialists today is the assessment and management of patients with increasingly complex medical conditions. Not only has the average life expectancy increased dramatically over the past 50 years, but our elderly patients are much more likely to be at least partially dentulous and may have a complex medical history with multiple medical problems and use of numerous medications.[1] Approximately 25% of patients ages 65 to 74 and 35% of patients age 75 and older have a medical condition that would place them in ASA* category III or IV.[2] An aging population with both the desire and resources to preserve their natural dentition will drive the demand for root canal therapy for patients with complex medical conditions. Even in a typical population of younger and presumably healthier patients, approximately 50% of patients referred to a dental specialty practice may be expected to report at least one medical finding on their health history questionnaire.[1,3] Since medical complexity is often an indication for referral to a dental specialist,[4,5] endodontists should be prepared to accurately evaluate medically complex patients and identify situations that require a modification of normal treatment procedures and identify oral and systemic conditions requiring diagnosis and management.

This chapter provides an overview of well-known medical conditions requiring modification of treatment protocol ensuring safe endodontic treatment in an ambulatory dental setting. It is not intended as a substitute for case specific clinical judgment or consultation with medical experts. For purposes of this chapter, a medically complex patient will be defined as any patient requiring modification of the usual treatment procedure.

MEDICAL HISTORY AND PATIENT INTERVIEW

"Never Treat a Stranger" (Attributed to Sir William Osler)

The value of a thorough medical history and patient interview cannot be overemphasized. Recognition of a medical condition that requires treatment modification *prior* to treatment can avert significant treatment complications. Approximately 25% to 30% of patients seeking treatment in a dental office can be expected to report at least one medical condition that has potential relevance to dental treatment, although not all of these conditions will require treatment modification.[6,7] An adverse outcome, due to failure to recognize a known risk factor and modify treatment accordingly, is a major predictor of a successful liability claim.[8] Cardiovascular disease, drug allergies, diabetes, and concerns about the safety of vasoconstrictor use are some of the most common medical reasons for referral to a specialist.[1,9,10] This is consistent with an analysis of the most common medical emergencies in the dental office: angina, hypoglycemia, adverse reaction to local anesthetics, and seizures.[11]

A standard health history questionnaire should cover all common medical conditions (both treated and untreated), surgeries, hospitalizations, medications, and allergies. Although many standard forms are readily available and are usually convenient and easy to complete, most of these forms do not clearly lead to a specific determination of risk for dental treatment. More useful medical risk assessment models are under development and will be briefly discussed later in this chapter. The written health history questionnaire should always be supplemented with a patient interview to help decrease false positive and false negative findings and to further explore positive findings.[12] The clinician should review any positive findings with the patient and determine the patient's level of compliance with medical treatment recommendations. For example, a compliant patient, with well-managed hypertension, presents a relatively low risk, compared to a patient who refuses to take prescribed medications, or does so erratically. Unfortunately, for a variety of reasons, the reliability of self reported information in the health history may be less than ideal. Patients may simply forget to report important medical information, but it has also been shown that some patients will intentionally omit relevant information due to concerns over privacy or failure to understand how the information could be relevant to dental practice.[13,14]

Medications and Allergies

The list of medications and allergies should be consistent with disclosed medical conditions, and can alert the clinician to unlisted medical conditions as well as potential drug interactions. Relevant medical conditions and severity of systemic disease can often be determined by a careful analysis of the patient's list of medications.[15]

Herbs, dietary supplements, vitamins, and other over-the-counter (OTC) medications can contribute to complications in the dental setting although patients often fail to report

use of these substances in the initial evaluation.[16] In a recent survey of surgical patients, approximately one-third reported use of a non-prescription medication that could potentially inhibit coagulation or interact with anesthetics.[17] In particular, *Ginkgo biloba*, ginger, garlic, ginseng, feverfew, and vitamin E all inhibit platelet aggregation and can increase the risk of bleeding.[18] Ingredients in some OTC weight loss products can potentiate the effect of epinephrine and increase cardiac stress. The most obvious example of this phenomenon, ephedra, has been removed from the U.S. market by FDA order.

Previous Dental Treatment

A standard screening question for all patients should enquire about any problems with previous dental treatment. This line of questioning serves several important functions. First, it allows the patient to discuss any previous negative dental experiences as well as express possible anxiety related to the proposed treatment. A report of difficulty in achieving profound local anesthesia is a common finding, especially for root canal therapy. This provides an opportunity to demonstrate concern for one's patient and discuss how one plans to avoid a repeat of the previous experience. Second, potential adverse reactions to dental materials or drugs may emerge in response to this question. Finally, since this question is designed at least in part to help develop rapport with your patient, it can serve as a good lead into other important but potentially more sensitive questions (e.g., use of oral contraceptives, history of HIV).

Physical Exam—Vital Signs

In addition to the mandatory health history questionnaire and patient interview, vital signs (blood pressure, heart rate, respiratory rate, temperature, height, and weight) should be recorded prior to dental treatment whenever possible. In particular, blood pressure, heart rate, and respiratory rate provide essential risk assessment baseline information for all patients. Temperature may be routinely recorded but is specifically indicated in the presence of infection or signs of generalized malaise or toxicity. Height and weight can usually be obtained from the patient or guardian, and this information is particularly important in determining appropriate drug dosages in pediatric and geriatric patients and assessing unexplained changes in weight.

Although routine medical lab screening tests are not currently standard practice in the majority of dental offices, a recent multi-center study conducted in an academic dental school environment found that 83% of study participants had one or more abnormal test results and did not report a relevant explanatory disease in their medical history.[19] This finding suggests that many patients may be unaware of existing medical condition(s).

Relative Stress of the Planned Procedure and Behavioral Considerations

A patient's ability to tolerate the stress of dental treatment depends on the procedure planned, time required to complete the procedure, physical health status, and psychological factors. Anticipation of a stressful dental procedure can increase the heart rate and endogenous secretion of epinephrine in otherwise healthy adults.[20,21] In fact, even anticipation of a routine dental checkup can result in increased blood pressure in some patients.[22] Most changes in heart rate and blood pressure are within the normal physiologic range although more significant changes have been observed before administration of local anesthetic, during subgingival scaling and during extractions.[23] Since there are no specific guidelines for assigning stress levels to various dental procedures, clinical judgment is essential in determining whether or not stress reducing treatment modifications should be employed. Dental specialists, by virtue of additional training and experience, should be expected to provide treatment in a shorter time period and should be better prepared to manage complications than a general practitioner.

Endodontic treatment in general is often considered a high stress dental visit, especially among patients with no prior endodontic treatment experience, or patients who have had a previous negative experience with endodontic treatment. For many, the perception of the treatment often differs from the reality, that most current endodontic treatment is minimally invasive, relatively comfortable, efficient, and very well tolerated by the majority of patients when skillfully performed. In a study that measured salivary cortisol levels in patients undergoing a variety of dental procedures, root canal treatment was no different than a routine dental exam, prophylaxis, or restorative treatment and only tooth extraction resulted in a significant increase in salivary cortisol.[24] Surgical endodontic procedures, the presence of acute pain, self reported dental anxiety or difficulty with previous treatment, and lengthy procedures would all be expected to increase the level of stress.[23,25,26] If any of these conditions are present in addition to significant systemic disease, treatment modification including a stress reduction protocol should be considered.

Physical Health Status

The American Society of Anesthesiologists' (ASA) Health Classification System is the most widely used system for assessing physical health status, and helps determine the potential need for medical consultation and treatment modifications prior to dental and/or medical procedures (Table 31-1).

In general, ASA I status represents a healthy patient who does not require any treatment modification. An ASA II patient presents with well-controlled systemic disease and usually will not require significant treatment modification although stress reduction may be indicated. Patients in the ASA III category or above will almost always require medical consultation and possible treatment modifications. On the other hand, the ASA classification system has several significant limitations and should be used only as a general guide for determining pre- and post-operative risk. Even experienced anesthesiologists exhibit differences of opinion

TABLE 31-1 American Society of Anesthesiologists (ASA) Health Classification System and Treatment Modifications*

ASA physical classification	Description	Therapy modifications (McCarthy and Malamed, 1979)
ASA 1	Normal healthy patient	None (stress reduction as indicated)
ASA 2	Patient with mild systemic disease	Possible stress reduction and other modifications as needed
ASA 3	Patient with severe systemic disease that limits activity, but is not incapacitating	Possible strict modifications, stress reduction, and medical consultation are priorities
ASA 4	Patient with incapacitating systemic disease that is a constant threat to life	Minimal emergency care in office (may consist of pharmacologic management only); hospitalize for stressful elective treatment; medical consultation urged
ASA 5	Moribund patient who is not expected to survive the operation	Treatment in the hospital is limited to life support only, for example, airway and hemorrhage management
ASA 6	Declared brain-dead patient whose organs are being removed for donor purposes	Not applicable

*Adapted from Tables 1 and 2, Goodchild J, Glick M [29]

in the classification of cases.[27,28] In addition, when used alone, the ASA system is not a good predictor of operative risk.[29] Various authors have proposed a medical risk assessment process that focuses more clearly on medical conditions specifically relevant to dental practice.[2,6,29,30] Clinicians may want to consider health history questionnaires and verbal questions that focus primarily on medical conditions that would, when present, elevate the patient to ASA II status or above. That is, any positive response to one of the health history questions would automatically classify the patient, as at least ASA II and further exploration would be necessary to determine the extent of systemic disease. de Jong et al.[12,30,31] have developed and validated a patient questionnaire consisting of approximately 30 questions for use in assessing risk for dental treatment.

Medical Consultations

Approximately one-third of patients referred for a medical consultation result in recommendations for some modification of treatment procedures.[9] A request for consultation may occur by phone or letter and each approach has certain advantages and disadvantages. A phone conversation is immediate and may allow for the discovery of additional useful information. However, the lack of a written letter from the physician increases the risk for potential misunderstanding and provides a lower level of documentation from a medico-legal standpoint. The substance of all medical consultation conversations should be documented in the patient's record and, whenever possible, a letter detailing the physician's recommendations should be requested. A letter provides more formal documentation of the communication between health care providers. An additional consideration is current security standards for protecting certain health information that is transferred in electronic form (e.g., email) established by the HIPPA Security Rule. Encryption of email is now required if patient health information is exchanged via this format.

When requesting a medical consultation, the clinician should be specific and concise. The medical condition in question should be identified and the nature of dental procedure planned should be described (e.g., brief description of the procedure, type of anesthetic planned, potential for bleeding, expected length of procedure). The clinician should specifically ask the physician if the patient's medical condition requires any modification in the usual treatment protocol and, if so, what modifications are recommended. Since the ultimate responsibility for providing safe treatment rests with the dentist, any concerns about recommended treatment modifications should be resolved with the physician prior to treatment. Consultation may also be obtained from dental specialists with expertise and experience in a specific oral or medical condition, such as immunosuppressed or in cancer patients. In such a case, documentation as above is suggested.

ASSESSING THE NEED FOR TREATMENT MODIFICATIONS

Multi-Dimension Risk Assessment Model (MD-RAM)

Systemic disease can result in the loss of reserve capacity to handle stress.[15] A patient's ability to handle stress decreases in direct relation to the extent of systemic disease. The primary components of risk assessment for dental treatment are: physical health status, emotional or psychological status, and type of dental procedure planned.[32] Lapointe et al.[15] proposed a two-dimensional risk assessment model that correlated severity of disease and procedural stress. However, this model presented only two specific medical conditions as examples (ischemic heart disease and chronic obstructive pulmonary disease) and did not explicitly consider patient anxiety as a variable. Dental anxiety can increase sympathetic activity and can for some patients potentially precipitate a medical emergency.[33]

We propose a new model, the Multi-Dimension Risk Assessment Model (Figure 31-1 and Table 31-2) that incorporates the three primary aspects of risk assessment into a unified approach for evaluating perioperative risk related to treatment for the ambulatory dental patient. In this model, the dental patient is assigned a score ranging from 1 to 4 in each of three domains: physical health status (using the ASA classification system); procedural stress (type of procedure, length of time to complete the procedure, and clinician expertise) (Table 31-3); and psychological status (self-reported dental anxiety) (Table 31-4).

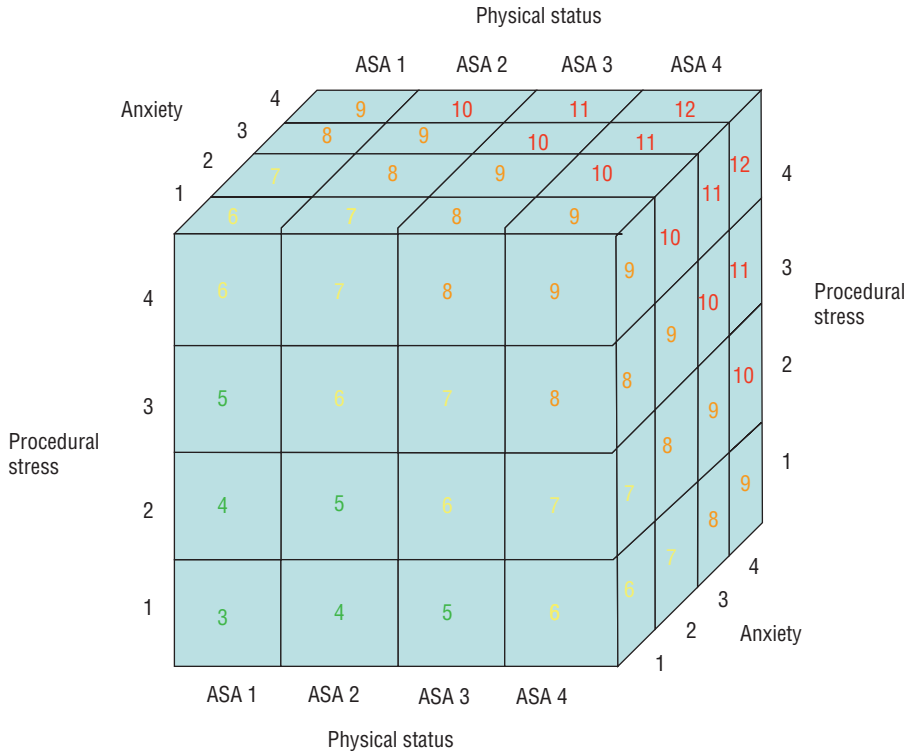

FIGURE 31-1 Multi-Dimension Risk Assessment Model (MD-RAM) (January 2015).

TABLE 31-2 Interpretation of Multi-Dimension Risk Assessment Model (MD-RAM) Scores

MID-RAM score	Interpretation
3-5	No treatment modification usually indicated
6-7	Possible medical consultation and treatment modification
8-9	Medical consultation often indicated and probable treatment modification
10-12	Medical consultation strongly advised; may require treatment in a hospital or specially equipped outpatient facility

TABLE 31-3 Estimates of Procedural Stress

Procedural stress scale	Examples*
1	Denture adjustment; noninvasive oral exam; radiographs
2	Procedures requiring local anesthesia; prophylaxis with subgingival scaling; simple restorative procedures; uncomplicated nonsurgical root canal treatment
3	Patients with acute pain and/or significant infection; extractions; surgical root canal; periodontal surgery
4	Bony impactions; trauma surgery

*Clinician should consider possible upgrading if procedure is lengthy and move either up or down depending on clinician's experience. (Adapted in part from Lapoint et al. [15])

TABLE 31-4 Behavioral Scale: Patient's Self-Report of Dental Anxiety

Dental anxiety scale	Verbal descriptor
1	No anxiety
2	Mild anxiety
3	Moderate anxiety
4	Severe anxiety

As with any model, the output is only as good as the information input. This model may provide a general guide for patient assessment and is not intended to be all-inclusive or substitute for case-specific clinical judgment. The primary purpose of this model is to assist clinicians in determining if treatment modification, often a stress reduction protocol, may be indicated prior to dental treatment. Disease-specific recommendations will be discussed later in this chapter.

Cardiovascular Disease

Heart disease is the leading cause of death in the United States[34] and can present challenges for safe patient management in the dental office. A possible association between apical periodontitis and coronary artery disease has been suggested, although it is very important to note that a cause and effect relationship has not been established.[35,36] An association between periodontal disease and atherosclerotic vascular disease has also been discussed but, again, causation has not been established.[37]

An interesting positive relationship between the use of systemic statins (one of the most commonly prescribed classes of drugs) and pulp chamber calcification was recently described.[38]

Hypertension

Hypertension is one of the most common medical conditions likely to be encountered in a dental office. Hypertensive patients are commonly defined as those receiving treatment for hypertension or those with a mean systolic blood pressure (SBP) of 140 mm Hg or greater and/or a mean diastolic pressure (DBP) of 90 mm Hg or greater. By this definition, approximately 31% of the adult population of the United States is hypertensive with about half of this group untreated and only one quarter receiving successful treatment for hypertension.[39] Since hypertension is typically asymptomatic, approximately one-third of patients with high blood pressure are unaware of their condition.[40] Even patients with normal blood pressure at ages 55 to 65 years have an almost 90% risk of developing hypertension by ages 80 to 85 years.[41] Patients with untreated or inadequately treated hypertension are at significantly increased risk for acute complications such as myocardial infarction and stroke and chronic complications of hypertension.

The clinical significance to the dental practitioner is clear since at least 15% of all adult dental patients have either untreated or inadequately treated hypertension; initial blood pressure measurement is an essential screening tool prior to dental treatment. In addition, it is appropriate to measure blood pressure at least annually during recall visits for all patients and at every visit for patients when an invasive dental procedure is planned.

Guidelines for the management of blood pressure were recently revised in the eighth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 8, 2013)[42] (Table 31-5). From a practical standpoint, patients with well-controlled hypertension or SBP below 160 and DBP below 100 should tolerate all routine dental procedures,[43] although referral for evaluation by the patient's physician is appropriate due to the well-documented benefits of maintaining blood pressure in the normal range. Patients with SBP between 160 and 180 or DBP between 100 and 110 should also be able to tolerate most dental procedures without significantly increased risk of perioperative cardiovascular complications, however complexity and stress of the planned treatment should be carefully considered with attention given to stress reduction strategies prior to treatment.[44] Although clear guidelines for establishing a cut-off point for dental treatment (emergency or routine) are lacking, it is generally accepted that patients with SBP greater than 180 and/or DBP greater than 110 should be referred for medical consultation and treatment prior to dental treatment and only emergency management of pain or acute infection should be considered.[44] Patients with SBP above 210 and/or DBP above 120 should be referred for emergent medical evaluation.

TABLE 31-5 Current 2014 Guidelines for Management of Hypertension Eighth Joint National Committee Report

Age	Blood pressure goal
≥ 60 years old	SBP < 150 mm Hg DBP < 90 mm Hg
< 60 years old (or any age with DM or CKD)	SBP < 140 mm Hg DBP < 90 mm Hg

(Adapted from James PA, et al. [42])

Vasoconstrictor Use in Patients with Cardiovascular Disease

Vasoconstrictors are used routinely in dental therapy including endodontics, as a component of local anesthetics and often as a hemostatic agent during periapical surgery. Local anesthetic with a vasoconstrictor, most commonly lidocaine with 1:100,000 epinephrine, is the usual anesthetic of choice for root canal therapy although many non-surgical procedures can be performed using local anesthetic without vasoconstrictor.[45] When a vasoconstrictor is indicated, epinephrine is preferred over levonordefrin due to a decreased potential for alpha-1 receptor stimulation.[46] Surgical procedures typically require greater quantities of local anesthetic with a vasoconstrictor than nonsurgical root canal treatment. In particular, patients with advanced cardiovascular disease, geriatric patients, and patients taking certain medications (e.g., MAO inhibitors and non-selective beta blockers) may have a reduced tolerance for vasoconstrictor containing local anesthetics. Since local anesthetic with a vasoconstrictor is very helpful in obtaining adequate hemostasis and visibility during periapical surgery, it may be difficult to perform the procedure using anesthetics without vasoconstrictors.[47]

Use of local anesthetics with vasoconstrictors in patients with cardiovascular disease has been somewhat controversial and was addressed by the previous JNC 7 report, but not discussed in the current JNC 8 guidelines. While the general goal should be to minimize the use of vasoconstrictors in patients with cardiovascular disease, the benefit of greater depth and duration of anesthesia when local anesthetics with a vasoconstrictor are used is a significant argument in favor of their use. Adequate pain control is an essential component of endodontic therapy since pain related stress could stimulate the release of significant quantities of endogenous catecholamines.

Different kinds of stress can increase the release of endogenous epinephrine by as much as 20 to 40 times over baseline values.[48] Pooled results from six studies of patients undergoing extraction or other minor oral surgery procedure demonstrated an average increase in SBP and DBP of 11.7 mm Hg and 3.3 mm Hg respectively as well as an increase in heart rate of 4.7 beats per minute. The use of local anesthetic containing epinephrine for these procedures resulted in an additional relatively minor increase in SBP of 4 mm Hg and six beats per minute.[49] Careful aspiration and use of adequate gauge needle to facilitate aspiration during injection is required to minimize the chance

of intravascular injection. Most authors feel that 0.036 mg of epinephrine (approximately two cartridges of local anesthetic with 1:100,000 epinephrine) should be safe for patients with cardiovascular disease except those with severe disease or other specific risk factors, and those with SBP requiring urgent medical attention.[44,49,50] Local anesthetics with vasoconstrictors should be avoided or used with extreme caution in patients with the following cardiovascular conditions: severe or poorly controlled hypertension, arrhythmias that are refractory to treatment, myocardial infarction within the past month, stroke within the past 6 months, coronary artery bypass graft within the past 3 months, and uncontrolled congestive heart failure.

An important exception to this general rule regarding vasoconstrictors is choice of local anesthetic for intraosseous (IO) injections in patients with cardiovascular disease. IO injections are most commonly used as a supplemental anesthetic technique for teeth that are otherwise difficult to anesthetize. A transient increase in heart rate can be expected in about two-thirds of patients receiving an IO injection using lidocaine with 1:100,000 epinephrine although heart rate returns to near baseline within 4 minutes after injection.[51] No increase in heart rate was found in patients receiving an IO injection with a 3% mepivacaine solution. Although in this study no significant change in blood pressure was found in either group, the authors recommend 3% mepivacaine without vasoconstrictor for IO injection in patients with any medical condition that could reduce their tolerance for epinephrine.

Although most experts agree that use of gingival retraction cord containing epinephrine should be avoided in patients with significant cardiovascular disease,[44,49] some uncertainty exists over the use of racemic epinephrine impregnated pellets as recently advocated for improved hemostasis during periapical surgery.[47,52] In two clinical studies, no significant changes were observed in blood pressure or heart rate when epinephrine pellets (either cotton or collagen) were placed in the bony crypt to improve hemostasis during periapical surgery.[53,54] It is unlikely that a patient healthy enough to tolerate two or three cartridges of local anesthetic with 1:100,000 epinephrine would experience any untoward effects from the proper use of epinephrine impregnated pellets during periapical surgery. Regardless, other alternative topical hemostatic agents are available and should be considered for patients with significant cardiovascular disease.

Ischemic Heart Disease

When coronary atherosclerotic heart disease becomes sufficiently advanced to produce symptoms, it is referred to as ischemic heart disease. Ischemic heart disease is relatively common in the general population, especially with increasing age, and typically presents as angina or heart failure.[55] In most cases, diminished blood perfusion of the myocardium due to coronary artery disease (atherosclerosis) is the underlying cause with hypertension as a common contributing factor in heart failure. Congestive heart failure and enlargement of the heart result from weakening of the damaged heart muscle.

Chest pain, secondary to ischemic heart disease, develops when the oxygen demand of the myocardium exceeds the oxygen supply. Transient pain, referred to as angina pectoris, is often described as an aching, squeezing sensation or tightness in the middle of the chest. Angina is often precipitated by physical activity or stress and may radiate to the arm or jaw and may present as facial or dental pain. Fear and anxiety associated with dental treatment may be a precipitating factor for angina in some patients.[55] Of particular significance to dentists is the finding that orofacial pain may be the sole symptom of cardiac ischemia in approximately 6% of patients presenting with myocardial infarction. The ratio of bilateral to unilateral orofacial pain in this group of patients was 6:1.[56,57]

Sublingual or other forms of nitrates are the standard treatment for angina and should result in rapid reversal of symptoms. Patients should always be instructed to bring their anti-anginal medicine with them for dental appointments. If symptoms are not relieved with oral nitrates and suspension of stress inducing activity, then myocardial infarction (MI) should be suspected and immediate emergency treatment should be initiated. Since angina is usually a transient event, patients with progressive pain or pain at rest are considered to have unstable angina and present a significant perioperative risk for MI.[58] These patients are usually categorized as ASA IV. Chest pain that is manageable with rest or medication and relatively unchanged in duration, frequency, or severity over time is termed stable angina and represents a better prognosis and a somewhat lower risk level than unstable angina and typically classified as ASA II or ASA III.

Compared to other surgical procedures, most dental and oral surgery procedures are considered relatively low risk.[59,60] However, a history of significant cardiac disease can be a major predictor of perioperative risk, even for procedures with relatively low procedural stress. Recent MI (less than 1 month), unstable angina, past MI with significant residual damage, decompensated congestive heart failure, significant arrhythmias, and severe valvular disease are all considered major predictors of increased preoperative cardiovascular risk and these patients would usually be classified as ASA IV. Patients with stable angina, past history of MI (greater than 1 month) with minimal residual myocardial damage, compensated congestive heart failure, or diabetes mellitus should be considered intermediate risk and would usually be classified ASA II or ASA III.[59] The presence of multiple risk factors creates an additive increase in overall perioperative risk.[61] Even patients with a history of recent MI or unstable angina should be able to tolerate routine dental procedures with local anesthesia although medical consultation is required and conscious sedation with monitoring is often recommended.[60,62]

Treatment modification considerations for patients with ischemic heart disease should include: morning appointments, short appointments, oral pre-medication with an anxiolytic drug and/or nitrous oxide/oxygen sedation, limited use of vasoconstrictors (as previously discussed),

adequate pain management (during and after the dental appointment), treatment in a semi-sitting position and possible cardiac monitoring.[63] Sedation with a short acting oral benzodiazepine (e.g., triazolam or ativan) and/or nitrous oxide can reduce the stress of a dental procedure and increase the effectiveness of local anesthesia.[33] Clinicians must be aware of the medical need and legal requirements that include special training, permits, and monitoring when anxiolysis crosses over into conscious sedation. If conscious sedation is required, it is best performed by a trained provider of anesthesia/sedation and with another operator providing the dental care.

Heart Murmurs and Valvular Disease

Patients with valvular disease present two primary considerations for dental treatment: potential risk for infective endocarditis and risk of excessive bleeding in patients on anticoagulant therapy.[55] Management considerations for patients on anticoagulant therapy are discussed later in this chapter. Most heart valve abnormalities affect either the aortic or mitral valve and may cause turbulent blood flow or partial obstruction of blood flow (stenosis) or valve incompetence (regurgitation). Heart murmurs are common and may be benign or signify major underlying disease such as degenerative valve disorders (e.g., aortic stenosis), rheumatic heart disease, congenital valve lesions, prosthetic valves, atrial fibrillation, or congestive heart failure.[64] Other conditions that place patients at increased risk for infective endocarditis are systemic lupus erythematosus (SLE) and certain medications used for weight reduction (dexfenfluramine and fenfluramine-phentermine).[64,65] Dental management requires evaluation of the type of heart condition, risk of valve infection, and the risk of bacteremia from the planned dental procedure.

Current guidelines for prevention of infective endocarditis were published in 2007 and represent a significant change from previous American Heart Association guidelines.[66] For example, antibiotic prophylaxis is no longer recommended for patients with a history of mitral valve prolapse (with or without regurgitation), rheumatic heart disease, bicuspid valve disease, aortic stenosis, and certain congenital heart conditions. Antibiotic prophylaxis is now only recommended for patients with valvular disease associated with the highest risk of adverse outcomes from infective endocarditis. For patients in the highest risk category, antibiotic prophylaxis is recommended for dental procedures that involve manipulation of gingival tissues or the periapical region of teeth or perforation of the oral mucosa. For all other patients with valvular disease, the risks associated with routine antibiotic prophylaxis are greater than potential benefits.[66]

Figures 31-2 and 31-3 list the specific heart valve abnormalities and dental procedures that are considered highest risk for infective endocarditis. In general, procedures associated with non-surgical root canal treatment such as local anesthetic injection, placement of the dental dam, and instrumentation when contained within the canal system do not

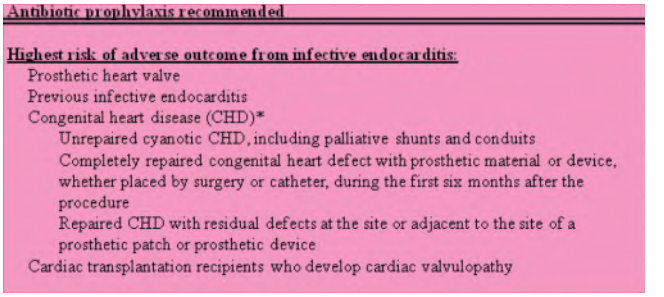

FIGURE 31-2 Recommendations for antibiotic prophylaxis based on risk stratification for infective endocarditis. (Adapted from: Wilson W, et al.[66])

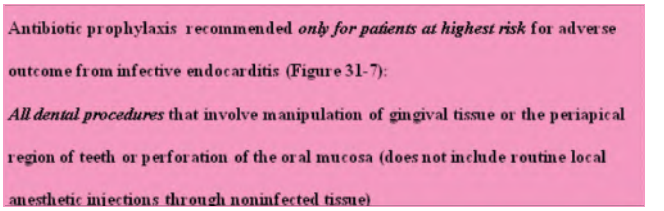

FIGURE 31-3 Risk of Dental Procedures. (Adapted from: Wilson W, et al.[66])

place the patient at significant risk for infective endocarditis.[67] The incidence and magnitude of bacteremia when canal instrumentation does not extend into the periapical tissues is very low, and almost all bacteria are eliminated from the blood within 10 minutes.[68,69] Canal instrumentation beyond the apex, intraligamentary and intraosseous injections, and periapical surgery can all be expected to result in a higher risk for transient bacteremia. In these situations, antibiotic pre-medication is recommended for patients in the highest risk disease categories. Infective endocarditis is only rarely directly linked to dental procedures and the efficacy of the recommended antibiotic regimen is questionable.[66,70–74] The current regimen and drugs of choice for antibiotic prophylaxis are presented in Table 31-6. These guidelines should be considered the current best evidence to guide clinical practice decisions; however, it is interesting to note that a recent study in England demonstrated an increase in cases of infective endocarditis following the widespread adoption of the new standards in 2008.[75] The increase in cases was found in both individuals at high risk and lower risk of infective endocarditis. Although the increase was statistically significant, the absolute number of cases was still very low and the authors caution that a causal relationship has not been established.

According to Lessard et al.,[64] some patients with significant heart murmurs may have dyspnea, fatigue, and difficulty breathing when reclined in the dental chair. Therefore the dental procedure may need to be performed with the chair in a more upright position.[64] These authors also suggest that use of a dental dam may be contraindicated for some of these patients due to restriction of air flow; however, this may be overcome with careful application of the dental dam, allowing the patient continuous

TABLE 31-6 Antibiotic Prophylaxis for Dental Procedures—All Regimens Are a Single Dose Given 30 to 60 Minutes Before Procedure

Standard oral regimen	**Adults: 20 g amoxicillin** **Children: 50 mg/kg**
Alternative oral regimen for patients allergic to penicillin or patients who are currently taking a penicillin class antibiotic	Adults: 2.0 g cephalexin or other 1st or 2nd generation cephalosporin in equivalent dosage* OR 600 mg clindamycin OR 500 mg azithromycin or clarithromycin Children: 50 mg/kg cephalexin or other 1st or 2nd generation cephalosporin in equivalent dosage* OR 20 mg/kg clindamycin OR 15 mg/kg azithromycin or clarithromycin
Patients unable to take oral medications	Adults: 2.0 g IM or IV ampicillin OR 1.0 g IM or IV cefazolin or ceftriaxone* Children: 50 mg/kg IM or IV ampicillin OR 50 mg/kg IM or IV cefazolin or ceftriaxone*
Alternative IM/IV regimen for patients allergic to penicillin and unable to take oral medications.	Adults: 1.0 g IM or IV cefazolin or ceftriaxone* OR Children: 50 mg/kg IM or IV cefazolin or ceftriaxone* OR 20 mg/kg IM or IV clindamycin within 30 minutes before the procedure.

*Cephalosporins should be used with caution in patients reporting an allergy to penicillin since approximately 5%–15% of patients who are allergic to penicillin will demonstrate cross reactivity with cephalosporins, especially first and second generation cephalosporins. (Adapted from: Wilson W, et al. [66])

air flow. Failure to use the dental dam is considered below the standard of care for root canal therapy and extraction may be the only option for these patients if a dental dam cannot be used.

Anticoagulant Therapy and Bleeding Disorders

Management of patients on anticoagulant therapy depends on the type of anticoagulant, reason for anticoagulant therapy, and type of planned procedure. Warfarin (Coumadin-DuPont Pharmaceuticals, Wilmington, DE, U.S.A.) anticoagulants are commonly prescribed for the treatment or prevention of thromboembolic events. This category of anticoagulant works by blocking the formation of prothrombin and other clotting factors. The international normalized ratio (INR) value is the accepted standard for measuring prothrombin time (PT). The desired therapeutic range for INR is usually between 2.0 and 3.5, depending on the underlying medical indication for anticoagulant therapy.

Limited oral surgery procedures, defined as simple forceps extraction of one to three teeth, may be safely performed on patients with INR values within the normal therapeutic range.[76–78] Non-surgical root canal treatment does not usually require modification of anticoagulant therapy although it is important to ascertain that the patient's INR is within the therapeutic range, especially if a nerve block injection is required. Periapical surgery may present a greater challenge for hemostasis even for patients well maintained within the therapeutic range. The clear field visibility normally required for proper surgical management of the root-end may not be possible in patients on anticoagulant therapy. Consultation with the patient's physician is required to assist in developing an appropriate treatment plan. Some patients may be able to tolerate discontinuation of warfarin therapy 2 days prior to a planned surgical procedure to allow for the INR to "drift" downward. In a prospective cohort study, Russo et al.[79] report that suspension of warfarin 2 days prior to a surgical procedure was associated with no bleeding problems and no thromboembolic events. They found that the average time spent at an INR less than 2.0 (critical value) was 28 hours and that 90% of the patients returned to the desired therapeutic INR value within 7 days. However, this strategy may place certain patients at greater risk for a thromboembolic event and in these cases discontinuation of anticoagulant therapy would not be recommended.

In general, patients on warfarin anticoagulant therapy should present minimal risk for significant bleeding during or after oral surgery and local measures to control bleeding should be adequate.[80,81] Jeske and Suchko,[82] in a review prepared for the American Dental Association Council on Scientific Affairs and Division of Science, recommend against routine discontinuation of anticoagulant therapy prior to dental procedures, including surgical procedures. Regardless of the management approach selected, consultation with the patient's physician and an INR test on the day of surgery is strongly recommended. Hospitalization and conversion to heparin therapy may be considered in special cases but the patient, physician, and surgeon must carefully weigh the potential risks against the expected outcome and benefits. One possible alternative is the use of low-molecular-weight heparins (LMWHs), which allows for patient self-administration and may present a viable alternative for some patients who need to remain at a high level of anticoagulation but wish to reduce the cost and time associated with traditional heparin conversion therapy.

A new category of novel oral anticoagulant (NOAC) medications is gaining acceptance as an alternative to warfarin for most anticoagulant indications except prosthetic heart valves.[83] Examples of drugs in this category include: apixaban (Eliquis™), dabigratan (Pradaxa™), edoxaban (Lixiana™), and rivaroxaban (Xarelto™). Compared to warfarin, NOACs have fewer interactions with foods and other drugs, and there is no need for routine blood chemistry monitoring. An example of this drug category, rivaroxaban prolongs PT by inhibiting factor X to Xa conversion and has a half-life of 8 to 12 hours. Unfortunately, the PT test is not a reliable measure of the level of anticoagulation and risk for bleeding during surgical procedures. Although it appears likely that patients who require minor dental procedures such as extraction or root canal treatment will not require discontinuation of NOAC therapy, evidence to support this decision is currently not available. Therefore, medical consultation is advised and the patient's physician may recommend discontinuing the NOAC drug for 1 to 2 days prior to a surgical procedure.[84]

Low dose aspirin therapy is known to increase bleeding time by irreversibly inhibiting platelet aggregation. No treatment modifications should be necessary for non-surgical root canal procedures. However, surgical procedures require evaluation of the reason for and necessity of aspirin therapy. It has been common practice to advise patients to discontinue aspirin therapy for 7 to 10 days prior to an oral surgical procedure.[85] At low dose therapeutic levels (<100 mg/day), aspirin may increase bleeding time and potentially complicate surgical procedures. However, Ardekian et al.[85] concluded that low dose aspirin therapy (<100 mg/day) should ***not*** be discontinued prior to oral surgery procedures and that bleeding could be controlled by local measures. Higher dose therapy may present a greater risk for bleeding either during or after surgery. Even though a patient on aspirin therapy may not be at high risk for significant intra or postoperative bleeding, a concern for periapical surgery is the visibility problems created by oozing blood. Consultation with the patient's physician or experienced dental specialist is advised to determine the medical reason for aspirin therapy and weigh the risks and benefits of discontinuing aspirin prior to the proposed surgery. It should be possible to perform periapical surgery without discontinuing aspirin therapy if necessary, but visibility during the procedure may be compromised and the prognosis may decrease accordingly.[47]

Nonsteroidal anti-inflammatory drugs (NSAIDs) also have an antiplatelet effect but, unlike aspirin, the effect is reversible when discontinued and platelet activity should be expected to return to normal within approximately three half-lives of the drug. Other commonly prescribed antiplatelet drugs include dipyridamole, ticlopidine, clopidogrel, abciximab, integrelin, tyrafiban, lamifiban. Heavy alcohol consumption, liver disease, and certain medications can increase the risk of perioperative bleeding in patients taking antiplatelet medications. Medical consultation is advised prior to surgical procedures and lab tests to determine platelet count and function (PFA-100 and Ivy BT) may be indicated. Some herbs and dietary supplements may also affect bleeding risk.

COX-2 selective inhibitors are known to increase the risk of venous thromboembolism and major coronary events.[86,87] Even ibuprofen, which is primarily a COX-1 inhibitor, probably the most commonly prescribed NSAID for dental pain, appears to increase the risk of major coronary events, but not major vascular events.[87]

Patients with inherited or acquired bleeding disorders are also at risk for excessive bleeding during and after periapical surgery procedures and may be at risk from local anesthetic injections particularly when using nerve block injections. Impaired liver function secondary to past or current alcohol or drug abuse may also predispose a patient to excessive bleeding during surgery. A medical consultation, usually with a hematologist, is required prior to dental treatment for patients with serious bleeding disorders such as thrombocytopenia, hemophilia, and von Willebrand's disease. Replacement of deficient coagulation factors or platelet transfusion may be required prior to dental treatment,[88] particularly if an inferior alveolar nerve block is required or surgical treatment is planned. If non-surgical root canal treatment can be performed with only infiltration local anesthesia, replacement may not be necessary.[89] However, this decision must be reached in consultation with the patient's hematologist.

Arrhythmias and Cardiac Pacemakers

Cardiac arrhythmias are a heterogeneous group of conditions defined as any disturbance in the normal rate or rhythm of the heartbeat. Arrhythmias are the result of abnormal impulse generation, impulse conduction, or both and can range from harmless to life threatening.[55] The overall prevalence of cardiac arrhythmias in the general dental patient population is about 17 % and more than 4% of those represented

serious, potentially life threatening arrhythmias.[90] Although arrhythmias are not uncommon in normal, healthy adults, the possibility of underlying cardiovascular disease, systemic disease, or medication-induced arrhythmia should be carefully evaluated prior to dental treatment. Anxiety associated with dental treatment may induce arrhythmias in susceptible patients. In addition, patients with cardiovascular disease are more prone to arrhythmias during oral surgery procedures with local anesthesia.[91] Patients taking digoxin for atrial fibrillation or congestive heart failure are especially at risk for arrhythmias during oral surgery procedures.[92]

Medications are usually the first line of treatment for cardiac arrhythmias although many of these have a narrow therapeutic safety range (e.g., digoxin) and must be carefully monitored. Surgery, cardioversion, and pacemakers are also used to treat arrhythmias. It is common for atrial fibrillation patients to be treated with an anticoagulant (typically warfarin or a NOAC drug- management discussed previously in this chapter). A history of cardiac arrhythmia is often disclosed in the medical history. In addition to the medical history, patients with an irregular pulse, unusually rapid or slow pulse, reports of syncope, palpitations, dizziness, angina, or dyspnea, should be referred to a physician for evaluation prior to dental treatment. Once the nature of the arrhythmia and stability of the condition has been determined, most dental treatment can be safely performed using the same stress reduction treatment modifications listed in the discussion of ischemic heart disease. As always, the clinician and staff should be prepared to manage a medical emergency if necessary.

Electrical interference from certain dental devices is a potential concern for patients with implanted cardiac pacemakers or cardioverter/defibrillators. In particular, electronic apex locators (EAL) and electric pulp testers (EPT) are commonly used in root canal therapy. Manufacturers of EAL and EPT devices warn against the use of these devices in patients with cardiac pacemakers. However, current cardiac pacemakers are well shielded from external electrical fields and the possibility for electrical interference seems to be very low.[93–97] Recent clinical studies support previous *in vitro* research and a case report in concluding that EAL and EPT devices should be safe to use in patients with cardiac pacemakers and cardioverter/defibrillators.[98,99] One caveat is that a mucosal lip clip was used in one study to complete the circuit with the EPT device instead of the common clinical practice of having the patient hold the EPT wand in his or her hand.[98] This lip clip technique is recommended if one elects to use an EPT device on a patient with a cardiac pacemaker since the practice of using the patient's hand to complete the circuit may allow for electrical current to pass through an area of the body in closer proximity to the pacemaker. The safety of this variation of the EPT technique has not yet been tested.

Heart Failure

Heart failure (HF), also known as congestive heart failure (CHF), is an increasingly common diagnosis in an aging population and represents the end-stage of other common cardiovascular diseases such as coronary artery disease, hypertension, cardiomyopathy, valvular heart disease, and MI.[100] HF results in an inability of the heart to efficiently pump blood that can involve one or both ventricles. Patients with HF typically present with significantly diminished reserve capacity for handling stress (including dental treatment) and are often taking multiple medications with the potential for drug interactions.

Patients with well-managed HF should tolerate routine dental treatment with possible minor treatment modifications, similar to those recommended for patients with ischemic heart disease. In addition, the underlying causes (coronary artery disease, hypertension, valve disease, etc.) and medications should be considered and managed appropriately. Patients with moderate to advanced HF may require a more upright chair position due to the presence of pulmonary edema. In these settings, poorly controlled HF may present with shortness of breath and peripheral edema. The clinician should be alert for orthostatic hypotension when making adjustments in chair position. Uncompensated, advanced HF requires medical consultation prior to dental treatment and vasoconstrictors should be avoided. These patients may require treatment in special care facilities or hospital based clinics. The New York Heart Association (NYHA) has developed a classification system for HF that can be adapted to assist in assessing risk for dental treatment (Table 31-7).

TABLE 31-7 New York Heart Association Classification System for Patients with Congestive Heart Failure and Dental Management Considerations

Heart Association CHF classification	Signs and symptoms	Dental management considerations
Class I	No limitations or physical activity; no dyspnea, fatigue, or palpitations with ordinary physical activity	Should be able to tolerate routine dental treatment; stress reduction protocol as needed
Class II	Slight limitation on physical activity; comfortable at rest but may experience fatigue, palpitations, and dyspnea with ordinary physical activity	Should be able to tolerate routine dental treatment; *stress* reduction protocol as needed; possible medical consultation
Class III	Significant limitation of activity; comfortable at rest but minor activity results in symptoms	Medical consultation; consider treatment in hospital dental clinic or similar facility; avoid vasoconstrictors
Class IV	Symptoms present at rest; symptoms exacerbated by any physical activity	Medical consultation; conservative treatment only; treatment in hospital dental clinic; avoid vasoconstrictors

Diabetes

Diabetes mellitus (DM) is a complex metabolic disorder characterized by abnormalities in carbohydrate, fat, and protein metabolism resulting either from a deficiency of insulin (type 1) or from target tissue resistance to its cellular metabolic effects (type 2). Hyperglycemia is the most clinically important metabolic aberration in DM and the basis for its diagnosis. Chronic hyperglycemia is associated with ophthalmic, renal, cardiovascular, cerebrovascular, and peripheral neurological complications. DM is defined as a fasting blood glucose level greater than 125 mg/dl and normal fasting blood glucose level is considered to be less than 110 mg/dl. Patients with fasting plasma glucose levels greater than 110 mg/dl but less than 126 mg/dl represent a transitional condition between normal and DM and are considered to have impaired glucose tolerance.[101] Identification of patients at this stage can allow for earlier preventive interventions and possibly delay or prevent progression to DM.

Gylcated hemoglobin (HbA1c) is considered to be a more accurate test for diabetes since it measures the average level of blood glucose over the previous 3 months. Normal HbA1c is less than 5.7%; pre-diabetes is 5.7 to 6.4%; and diabetes is defined as 6.5% or greater. The HbA1c goal for most diabetic patients is less than 7%.

Approximately 26 million children and adults in the United States, or 8.3% of the population, have DM and over one-third are unaware that they have the disease.[102] The epidemic of obesity in the United States is anticipated to result in an increase in the prevalence of diabetes.

When reviewing medical histories, the clinician should be aware of cardinal symptoms of DM, such as polydipsia, polyuria, polyphagia, weight loss, and weakness, and should be referred to a physician for diagnosis and treatment.[102] In diabetic patients, the clinician should ascertain how well-controlled the condition may be. Dental appointment scheduling should take into account the importance of nutritional consistency and the avoidance of appointments that will overlap with or prevent scheduled meals.

Symptoms of hypoglycemia may range from mild, such as anxiety, sweating, tachycardia, to severe, such as mental status changes, seizure, and coma. Severe hypoglycemic episodes are a medical emergency and should promptly be treated with 15 g of oral carbohydrate, such as 6 oz orange juice, three to four teaspoons of table sugar, five Life Savers, or three glucose or dextrose tablets. If a patient is unable to cooperate or swallow, 1 mg glucagon may be administered by subcutaneous or intramuscular injection. Side effects of glucagon include nausea, vomiting, and headache.

It has been well-established that hyposalivation, gingivitis, periodontitis, and periodontal bone loss are associated with DM, especially when poorly controlled.[103,104] The well-controlled diabetic may not be at increased risk of postoperative infection than the nondiabetic.[105] Therefore, surgical procedures in well-controlled diabetics do not require prophylactic antibiotics. However, when surgery is necessary in the poorly controlled diabetic, prophylactic antibiotics should be considered due to altered function of neutrophils in diabetics. Surgery may also increase insulin resistance such that a diabetic may become hyperglycemic in the postoperative period. Pre-operative antibiotics should be considered in these instances.[106] Furthermore, delayed alveolar healing following dentoalveolar surgery should raise the suspicion of osteomyelitis, for which prompt surgical consultation should be arranged. Oral complications may include dry mouth, and increased risk of candidiasis, particularly if an antibiotic is prescribed. The potential of diabetic neuropathy to cause oral symptoms should be considered in the diagnosis of orofacial and dental pain. Finally, patients with DM may present with systemic complications, each of which should be taken into account prior to dental procedures.

Pulmonary Disorders

Asthma

Asthma is a chronic inflammatory respiratory disease with recurrent episodes of chest tightness, coughing, dyspnea, and wheezing resulting from hyper-responsiveness and inflammation of bronchiole tissue. Overt attacks may be provoked by allergens, upper respiratory tract infections, genetic and environmental factors, certain medications, and highly emotional states such as anxiety, stress, and nervousness.

The endodontist should obtain a good history to determine the severity and stability of disease. Patients should be instructed to bring their inhalers (bronchodilators) to each appointment and inform the endodontist at the earliest sign or symptom of an asthma attack. During dental treatment, the most likely times for an acute exacerbation of asthma are during and immediately after local anesthetic administration and with stimulating procedures such as pulp extirpation.[107] Because stress is implicated as a precipitating factor in asthma attacks sedation may be beneficial. While nitrous oxide may be used in patients with mild-to-moderate asthma, its use is contraindicated in patients with severe asthma due to its potential to cause airway irritation.[108] Alternatively, oral premedication may be accomplished with small doses of a short-acting benzodiazepine. In patients taking theophylline, macrolide antibiotics should be avoided, as they have the potential to develop toxic levels of theophylline. In addition, it is important to note that aspirin and other NSAIDs may trigger asthma attacks in a proportion of patients.[109]

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a term for pulmonary disorders characterized by chronic irreversible obstruction of airflow from the lungs and represents the fourth most common cause of death in the United States.[110] The three most common forms of COPD are chronic bronchitis, emphysema, and bronchial asthma. Patients with pulmonary diseases typically present with one or more of the

following symptoms: cough, dyspnea, sputum, hemoptysis, wheezing, or chest pain.[111] Patients should be placed in a semi-supine position. Since use of a dental dam may induce a feeling of airway constriction, careful application of the dental dam and administration of humidified low-flow oxygen, generally between two and three liters per minute, may be considered. Nitrous oxide should not be used in patients with severe COPD.

Tuberculosis

Tuberculosis (TB) is an infectious disease that is spread by way of bacilli-containing airborne droplets, typically by coughing, sneezing, or talking. The signature lesion of TB is the tubercle, a granuloma formed by the continuing ingress of macrophages and lymphocytes to the site of the infection.[112] In the lung, tuberculous granulomas are frequently associated with regions of tissue necrosis, termed *caseous necrosis* due to its gross appearance. After the infection is established, symptomatic individuals will show pulmonary manifestations of the disease, often limited to the periphery of the middle and lower regions of the lung,[112] though reactivated disease is most commonly found in the lung apices.[113] Oral tubercular infections are rare, occurring in 0.05% to 5% of patients with TB, though when lesions are present, they typically consist of ulcers, fissures, or swellings on the dorsum of the tongue.[114] Despite the declining incidence of TB in the United States, health care workers including endodontists and their staff remain at elevated risk for contracting the disease.

It is imperative for the endodontist to educate office staff about TB prevention and recognition of symptoms and oral manifestations of the disease to protect the staff and other patients from becoming infected. A thorough medical history should be obtained, and any dental procedures on a patient with established or suspected active TB should be delayed until the individual can be treated and subsequently proved noninfectious.

Routine dental treatment is appropriate after it has been established that the patient has been adequately treated and there are no signs or symptoms of active disease. The clinician should be aware of potential drug interactions when managing dental patients undergoing antitubercular treatment. In patients taking medications such as rifampin and isoniazid, acetominophen should be avoided due to the potential for liver damage. The use of aspirin is discouraged in those individuals taking streptomycin due to a heightened risk of ototoxicity and vestibular disturbances.[115] Streptomycin is also known to cause facial paresthesia and pancytopenia.

Cerebrovascular Accident

Stroke

A cerebrovascular accident (CVA), or stroke, is subclassified into ischemic insults, occurring secondary to thrombosis or embolization, or hemorrhagic that usually indicate an arterial process. The lack of blood flow leads to deprivation of oxygen and glucose in a localized area of the brain. The endodontist should be aware of how to identify a patient having a stroke in his/her office. A useful mnemonic for early identification of a possible stroke is: F.A.S.T.:

F = Face: Ask the patient to smile. Does one side of the face droop?
A = Arms: Ask the patient to lift both arms. Does one arm drift downward?
S = Speech: Ask the patient to repeat a simple phrase. Is their speech slurred or strange?
T = Time: If you observe any of these signs, call your emergency operator (in the U.S.A. it is 911) (www.stroke.org).

Regardless of the procedure, a patient's blood pressure should be checked before treatment to identify a patient whose blood pressure is elevated and who might be at risk for a stroke if subjected to stress. Slurred speech, loss of motor control over a portion of the body, unilateral facial droop, unilateral visual changes, and unilateral severe headache are all potential signs of a stroke or transient ischemic attack (TIA). Should any of these events occur, the patient should have his/her vital signs checked, be placed in a supine position, have vital signs monitored, and be transported to an emergency facility immediately, as treatment must be activated in a timely manner. Patients with a history of stroke may be at risk for aspiration due to swallowing abnormalities, so they should be positioned in a semi-supine position, and dental dams should be carefully applied and should always be used. Post-stroke patients may be on oral anticoagulants, so if surgical intervention is planned, the endodontist should contact the physician to determine whether or not the risk of a thromboembolic event outweighs the benefits of postoperative hemostasis (please refer to subsection on *anticoagulant therapy and bleeding disorders*). The endodontist should also be aware that the post-stroke patient may experience emotional problems, including anger and depression and behavior inappropriate to the situation.

Seizures Disorders

Seizures are one of the most commonly encountered neurological disorders and can manifest as an isolated incident with unknown etiology or as a symptom of a condition that requires long-term treatment. A seizure is a temporary involuntary disturbance of brain function that results in synchronous, excessive, abnormal electrical discharges of the neurons in the central nervous system.[116] This manifestation can take the form of motor disturbances, altered feelings, or changes in the patient's level of consciousness. The two main categories of seizure classification are partial and generalized. Most people who have seizures have good control and are capable of receiving routine dental care.

The endodontist should be aware of the patient's seizure medications, since many antibiotics are contraindicated. Should a seizure occur in the dental office, the procedure should be stopped immediately and all instruments should be removed from the oral cavity. The patient should be placed

in a supine position and low to the ground. Basic life support should begin immediately, including opening the airway, obtaining vital signs such as heart rate and blood pressure, and contacting emergency medical services.

The risk of shunt infection following invasive dental treatment for patients with hydrocephalic shunts (ventriculoperitoneal and ventriculoatrial) is believed to be very low,[117] and because of this there is a lack of consensus regarding the need for antibiotic prophylaxis. An expert panel of the American Heart Association stated that antibiotic prophylaxis prior to dental treatment in patients with nonvalvular cardiovascular devices (including hydrocephalic shunts) was generally not recommended.[118] However, antibiotic prophylaxis was recommended if treatment involved incision and drainage of an abscess. One study found that pediatric dentists were more likely to be concerned about streptococcal microorganisms and neurosurgeons were more concerned about staphylococcal microorganisms in shunt infection.[119] The majority of both groups recommended penicillin prophylaxis although there are more appropriate antibiotics since staphylococcal microorganisms are responsible for most shunt infections.[118,119] (Refer to the discussion in the *Prosthetic joints and other prosthetic devices* section of this chapter.) Consultation with the patient's neurosurgeon is advised and close attention to any changes in prophylaxis guidelines is important.

Renal Disease and Dialysis

Chronic renal failure is a slowly progressive condition characterized by irreversible reduction in glomerular filtration rate (GFR). The progression of this disease begins with an asymptomatic decrease in kidney function and eventually results in end-stage renal disease (ESRD). Throughout the decline in function, multiple systems are affected, directly related to the kidney dysfunction. ESRD is potentially fatal unless the patient undergoes dialysis or kidney transplantation (please see the section: *solid organ transplantation* regarding kidney transplantation). Dialysis may take the form of hemodialysis that represents 90% of dialysis treatment,[120] or peritoneal dialysis. This treatment removes fluid and wastes and equilibrates electrolytes and acid-bases via diffusion and osmosis across a semi-permeable membrane.

The clinician must be aware of the ESRD patient's type and days of dialysis treatment as well as co-morbid conditions such as hypertension and/or diabetes. Mechanical trauma to platelets and anticoagulants such as heparin used during hemodialysis may increase the renal patient's tendency for bleeding. While it is recommended that dental procedures be performed on non-dialysis days, typically the day after dialysis,[121] the endodontist should be aware that abnormal platelet function may cause a greater risk of bleeding during surgical procedures. In addition, patients with ESRD require aggressive treatment of odontogenic infections. Antibiotic premedication has been recommended by some authors for hemodialysis patients with shunts who undergo invasive dental procedures,[122–124] and other authors have recommended antibiotic prophylaxis for all hemodialysis patients undergoing procedures that cause mucosal bleeding to prevent vascular access infections, bacteremia, and infective endocarditis.[123] However, an expert panel scientific statement from the American Heart Association does *not* recommend routine antibiotic prophylaxis for this group of patients prior to dental treatment, except in cases that involve incision and drainage of an abscess.[118] The majority of vascular grafts infections are associated with *Staph aureus*.[118]

Renal osteodystrophy and secondary hyperparathyroidism may occur in late-stage disease due to disorders in calcium, phosphorous, and abnormal vitamin D metabolism. Such a manifestation may increase a risk of jaw fracture during surgical procedures.

Because many drugs are metabolized via the kidney, renal dosing should account for the drug's extended half-life by lengthening the interval between medication doses and/or altering the dose of required medications. In particular, antibiotic medications should be adjusted for renal dosing. Nonsteroidal anti-inflammatory drugs should be avoided in patients with renal insufficiency due to their nephrotoxic effects, but no longer need to be avoided when the patient has ESRD.

Oral Cancer

Oropharyngeal cancer encompasses a variety of malignant diseases. More than 90% of oral cancers are squamous cell cancers, 9% are salivary gland tumors, sarcomas and lymphomas, and the remaining 1% are metastatic cancers originating in other parts of the body.[125] In the year 2015, the American Cancer Society projected 39,500 new cases of oral and oropharyngeal cancers and 7800 deaths from this disease.[126] Numerous risk factors have been implicated in the etiology of oropharyngeal cancer, including tobacco, excessive alcohol, ultraviolet light exposure, immunosuppression and viruses, specifically human papilloma virus (type 16).

Oral cancer has a variable appearance, including white or red patches, an exophytic mass, an ulceration, a granular raised lesion, a submucosal mass, or a combination thereof. Treatment of oropharyngeal cancer is composed of surgical intervention, radiation treatment, and chemotherapy, targeted therapy and immunotherapy is being investigated.[127] Multimodality therapy is now more commonly used for oropharyngeal cancer in order to obtain increased survival rates.

Cancers that are amenable to surgery, and that do not affect the oral cavity, require few treatment plan modifications. On the other hand, oropharyngeal cancer treatments and complications may cause significant changes in the oral cavity. Preceding cancer treatment, all sources of inflammation and potential infection must be eliminated. Whenever possible, nonrestorable teeth and teeth with a poor long-term periodontal prognosis (i.e., not expected to be retained for the patient's lifetime) within the field of high dose radiation, should be extracted preferably more than 2 weeks prior to radiation therapy. Symptomatic nonvital teeth can be endodontically treated at least one week before initiation of head and neck radiation or chemotherapy. Dental treatment

of asymptomatic teeth, even with periapical involvement, can be delayed, particularly if treatment can be limited to intracanal therapy. Within a high dose radiation field, teeth may be considered for extraction or definitive management. Many cancer patients have indwelling catheters that may be susceptible to infection. While controversial, the CDC does not recommend routine antibiotic prophylaxis before invasive dental procedures.[128] If an individual is receiving chemotherapy, the endodontist should be familiar with the patient's white blood count (WBC) and platelet status and may consult the physician and/or experienced oral care specialists. Endodontic procedures may be performed if the neutrophil count is greater than 1,000 cells/mm3 and platelets are greater than 50,000 cells/mm^3. Post-radiation osteonecrosis (PRON) results from radiation-induced changes in the jaws, may arise in bone exposed to high dose radiation, and is characterized by asymptomatic or painful bone exposure. Protocols to reduce the risk of osteonecrosis include endodontic therapy over extractions. Expert atraumatic surgical procedures, under local anesthetics that contain no or low concentration of epinephrine, plus prophylactic antibiotics and antibiotics during the week of healing are in order.[129]

Antiresorptive Agent-Induced Osteonecrosis of the Jaw (ARONJ)

Bisphosphonates are bone resorption inhibiting medications that are commonly used in cancer therapy and may be used in conjunction with cancer chemotherapy (e.g., multiple myeloma and metastatic bone, breast and prostate cancer) and management of hyperkalemia in cancer. They may also be used in the prevention and treatment of osteopenia, osteoporosis, and Paget's disease of the bone. Recent reports have suggested that bisphosphonates (e.g., pamidronate, zoledronic acid) increase the risk of osteonecrosis of the maxillary and mandibular bones, either spontaneously or following dental surgical procedures or oral trauma.[130–134]

The new name (ARONJ) for the condition previously known as bisphosphonate associated osteonecrosis (BON) reflects current knowledge that some non-bisphosphonate antiresportive medications also increase the risk of osteonecrotis of the jaw (e.g., denosumab).[135] Although the mechanism of action is not completely understood, it has been suggested that inhibition of osteoclastic bone resorption and remodeling, inhibition of angiogenesis, and the presence of infection and/or inflammation could contribute to the development of ARONJ.[132,136] There appears to be a dose-response relationship in that patients taking IV formulations appear to be at a greater risk for ARONJ.[137] The highest estimated risk for developing ARONJ in a patient who is taking an antiresorptive drug for a non-cancer related indication is about 0.10%.[135,136] The risk for developing ARONJ following an invasive dental procedure such as extraction is estimated to be about 0.5%.[136,138] The risk of ARONJ is significantly higher for patients with a history of IV bisphosphonate use and cancer. Although no data exists to objectively assess the relative risk of various invasive dental procedures, it is reasonable to assume that any procedure that requires exposure and manipulation of bone (e.g., implant placement, endodontic and periodontal surgery) has an increased risk of necrosis, although more extensive procedures are expected to have higher risk.[133,136] Unfortunately, previous suggestions that serum levels of C-terminal cross-linking telopeptide of Type I collagen (CTX) might be a useful predictor of which patients would be at higher risk for ARONJ has not been confirmed or supported by recent research.[135,136]

There are currently no scientific data to support any specific treatment protocol for the management of patients at risk for ARONJ, though minimally invasive procedures have been recommended.[133] Discontinuation of bisphosphonate therapy for several months before and after invasive dental treatment may be reasonable, but research to support this approach is currently absent and the agent has a multi-year presence in bone once administered; however the potential of reversible effects of denosumab in bone is possible and is being investigated. Before initiation of antiresporptive agents, aggressive preventive treatment should be performed including oral hygiene, caries control, and extraction of teeth with a poor long-term prognosis. For patients who have been taking bisphosphonates or denosumab, preventive care for high-risk patients is important to reduce the risk of developing ARONJ.

Nonsurgical endodontic treatment of teeth that would otherwise be extracted should be considered. Teeth with extensive carious lesions might be treated by nonsurgical endodontic therapy possibly followed by crown resection and restoration similar to preparing an overdenture abutment.[139] Another possible approach for management of non-restorable endodontically involved teeth is slow (four to six weeks) orthodontic extrusion of the root(s) (Figure 31-4 A–E). For patients at higher risk of developing ARONJ, surgical procedures including surgical endodontic procedures should be avoided if possible. Teriparatide, an osteoanabolic drug approved by the FDA for management of osteoporosis, has been suggested as a possible treatment for ARONJ, but this is only at the case report level of evidence and needs to be validated with larger scale controlled studies.[140] A case series has suggested the use of pentoxifylline and vitamin E for treatment of necrosis.[141] Informed consent for endodontic procedures should involve a discussion of risks, benefits, and alternative treatments with the patient.

Bone Marrow and Solid Organ Transplantation

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation (HSCT) may be indicated in patients with hematologic malignancy, nonhematologic malignancy, and some nonmalignant disorders. Patients may undergo an autologous (self) or allogeneic (non-self) transplantation, each of which has its own pros and cons. The goal is to treat bone marrow disease or to intensify therapy that would destroy bone marrow, following which the patient

FIGURE 31-4 Orthodontic extrusion (extraction) of a symptomatic, non-restorable tooth in a patient with recent history of IV bisphosphonate use ***A.*** Pre-operative bitewing radiograph of tooth #3. ***B.*** Working length radiograph. ***C.*** Immediate postoperative radiograph. ***D.*** Three months after atraumatic extrusion. The tooth has been atraumatically extracted. (Case courtesy of Dr. Robert Lee.)

is "rescued" by infusion of previously stored autologous hematopoietic stem cells or related or unrelated hematopoietic stem cells from a matched donor. Prior to transplantation, patients should undergo a thorough dental examination and treatment to permit adequate healing before the HSCT.[127] Pretreatment endodontic therapy should be completed at least 10 days prior to initiation of cancer therapy. Teeth with poor prognoses should be extracted, utilizing the 10-day window as a guide. Prophylactic antibiotics are also recommended in patients who are neutropenic (< 1,000 neutrophils/mm^3).

During and following high-dose chemotherapy/HSCT, aggressive oral hygiene measures should be instituted.

Numerous oral complications may develop, including mucositis, graft-versus-host-disease, infection, taste changes, and bleeding. Patients should not resume routine dental treatment, including dental scaling and polishing, until adequate immunologic reconstitution has taken place; this typically occurs no less than 1 year post-transplant. The aerosolization of debris and bacteria during the use of high-speed rotary cutting instruments can put the patient at risk for aspiration pneumonia; additionally, bacteremias occur as a result of dental treatment and can cause serious outcomes. Should treatment be deemed necessary within 1 year post-transplant, the endodontist must consult with the oncologist and/or expert/experienced dental provider to determine appropriate treatment.

Solid Organ Transplantation

It is important to reduce the risk of infection in the immunosuppressed recipient of a transplant.[142] Pre-transplant, patients should undergo eradication of dental disease, including endodontic procedures as warranted to remove any potential sources of infection, and deferral of any elective treatments. Of course, the endodontist should take into account the underlying condition for which the transplant is required. In the immediate post-transplant period, emergency dental procedures may be necessary. At this stage, patients are highly immunosuppressed to prevent organ rejection, so the AHA regimen of antibiotic prophylaxis with possible post-operative antibiotics may be recommended for invasive procedures.

Should a patient experience transplant rejection, dental care should be limited to emergency care only until stabilization is again achieved. After the post-transplantation patient has stabilized, indicated dental procedures may be performed after consultation with the patient's transplant team. Postoperative guidelines regarding prophylactic antibiotics have not been established but, if recommended, AHA guidelines may be used.[142] Finally, the endodontist should be aware that post-transplant recipients will likely be on immunosuppressant therapy and should determine the dose and potential impact upon the planned dental care.

Prosthetic Joints and Other Prosthetic Devices

The long-standing practice of recommending antibiotic prophylaxis prior to dental treatment for patients with prosthetic joints has been questioned and based upon high-quality evidence-based reviews is no longer recommended.[143,144] The current best evidence supports the following recommendation: "In general, for patients with prosthetic joint implants, prophylactic antibiotics are not recommended prior to dental procedures to prevent prosthetic joint infection."[144]

Several risk factors for developing prosthetic joint infection were identified and were also determined to be independent of dental treatment. The risk factors included: postoperative wound drainage, hematoma, or urinary tract infection, and previous surgery on the index joint, diabetes, or immunocompromised status. The potential risks of routine antibiotic prophylaxis, including risk of anaphylaxis, development of antibiotic resistance, and opportunistic infections, were judged to be greater than the potential benefits. As always, clinical judgment and informed patient preferences should be considered as part of the clinical decision making process. If consultation with the patient's orthopedic surgeon is warranted, discussion should be based upon up-to-date evidence-based guidelines. Antibiotic prophylaxis is not indicated for dental patients with pins, plates, screws, and penile or breast implants. A patient with a total joint replacement or other surgically placed prosthesis with acute orofacial infection should be aggressively treated as any other patient to eliminate the source of infection, and appropriate antibiotics should be administered as warranted for the dental infection but this is not related to risk of prosthesis infection.

Pregnancy

Few procedures are contraindicated during pregnancy, however medication use should be carefully considered. There is no contraindication to using necessary diagnostic procedures, such as appropriate radiographs, as long as normal safety precautions are followed. If dental caries is the source of pain or infection, invasive care such as endodontic therapy should be provided regardless of the patient's phase of pregnancy.[145] Elective dental procedures may, often, be performed in the second trimester, when the pregnancy is mostly devoted to maturation. While some medications may be harmful to the fetus, safe alternatives are often available.

Lidocaine and prilocaine local anesthetics have an FDA category B rating and consequently should be first-line choices for use with pregnant women. A common misconception is concern over the use of local anesthetics containing epinephrine. Local anesthetics containing epinephrine should be relatively safe for use during pregnancy[146] and allow for greater depth and duration of anesthesia as well as reduction of any potential systemic effect of lidocaine. In addition, the only commonly available alternative to local anesthetics with a vasoconstrictor is 3% mepivicaine, an FDA category C drug. If antibiotics are warranted, many commonly used first line choices are rated by the FDA as category B for pregnancy risk (e.g., amoxicillin, azithromycin, cephalexin, clindamycin, and penicillin).[146] Pregnant women may be more susceptible to infection[147] that may be partly due to physiologic changes as well as alterations in pharmacokinetics.

Human Immunodeficiency Virus (HIV)

HIV is a blood-borne retrovirus infection transmitted primarily by blood and bodily fluids by intimate sexual contact and parenteral means. Upon infection, a viral enzyme reverse transcriptase allows the virus to integrate viral DNA into the genome of an infected cell and replicate using the infected cell's ribosomes and protein synthesis. Initially, immune seroconversion with antiviral antibody

production occurs followed by a significant decrease in CD4+ lymphocytes.

The most effective management in the progression of HIV infection and AIDS is a combination of antiviral agents known as highly active antiretroviral therapies (HAART) that has significantly increased the lifespan and quality of life of individuals infected with HIV. Upon initial assessment of an HIV-infected individual, the patient's physician should be contacted to determine CD4+ counts and viral load, as well as baseline kidney and liver function. It is safe and desirable to assure that comprehensive dental care is available to HIV-positive patients. No modification of irreversible procedures or surgical treatment is recommended unless patients have reduced platelet count (<50,000 cells/ml) or neutrophil counts <1,000 cells/ml, at which time a patient may require antibiotic prophylaxis. Routine antibiotic use is contraindicated.

The prognosis for successful healing of necrotic teeth with chronic apical periodontitis following root canal treatment is essentially the same for HIV-positive patients as non-infected patients.[148,149] The endodontist should examine oral tissues, as oral conditions associated with HIV may identify a person who is unknowingly infected with HIV, may be used in staging and classification, and/or may denote progression to AIDS. Surgically treated teeth do not show delayed healing. Antibiotics are only used if warranted by the clinical infection, and in a neutropenic patient.

Sickle Cell Anemia

Sickle cell anemia (SCA) affects approximately 1 in 400 African-Americans and as much as 30% of the population of some Central and West African countries. Clinical concerns in endodontic practice include the propensity for painful vaso-occlusive episodes and bacterial infections.[150] Since patients with SCA may be considered immunocompromised and infections can trigger a sickle cell crisis, these patients usually require aggressive treatment of infections, including the use of systemic antibiotics.[150]

The vaso-occlusive aspects of the disease can result in tissue and bone necrosis and pulpal necrosis in an otherwise intact and healthy tooth.[151] A recent clinical study found that pulpal necrosis in clinically intact permanent teeth was 8.33 times higher in patients with SCA compared to non-SCA controls.[152] Since teeth with asymptomatic necrotic pulps can become infected, patients with SCA require careful pulpal evaluation. Nonsurgical root canal treatment of asymptomatic necrotic teeth prior to the development of acute symptoms and infection is indicated.

There is a lack of consensus regarding the value of prophylactic antibiotics for patients with SCA although the majority of pediatric dentistry program directors and pediatric hematologists recommend antibiotic coverage for invasive procedures such as extraction or other surgical procedures.[153]

Use of a local anesthetic with no or minimal vasoconstrictor may be advisable for nonsurgical procedures since the microvasculature is often already compromised by SCA.

Osteomyelitis is much more common in patients with SCA[150] and the risk/benefit ratio for surgical endodontic procedures should be carefully considered for patients with SCA.

Liver Disease

End-stage chronic liver disease (cirrhosis) is the result of hepatocellular injury and necrosis that leads to fibrosis and nodular regeneration. Cirrhosis may be asymptomatic for long periods of time and may be undiagnosed until systemic signs are apparent. Ultimately, chronic liver disease affects multiple body systems. For more information on the pre-liver transplant patient, please see the subsection *solid organ transplantation* earlier in this chapter.

Performing any surgery in the pre-liver transplant patient involves the risk of severe hemorrhage due to thrombocytopenia or reduced hepatic synthesis of coagulation factors. Preoperative evaluation should include a complete blood count with platelet count, prothrombin time (PT) or international normalized ratio (INR), and partial thromboplastin time (PTT) to ensure an intact coagulation system.

Patients with cirrhosis have an increased susceptibility to infection. Odontogenic infections should be treated aggressively that may require the addition of appropriate antibiotic treatment. Antibiotic prophylaxis prior to dental procedures is only recommended if the patient has a history of spontaneous bacterial peritonitis (SBP), ascites (accumulation of excess fluid in the abdomen), another medical indication for antibiotic prophylaxis, or whose medical condition would drastically deteriorate should SBP develop. When antibiotic prophylaxis is indicated in the patient with end-stage liver disease, a recommended oral regimen is 2.0 grams of Amoxicillin plus 500 mg of metronidazole 1 hour before the dental procedure, or patients may be given 2.0 grams of ampicillin plus 500 mg metronidazole intravenously 1 hour before the procedure.[154] Finally, the pharmacokinetics of drugs commonly used in dentistry can be altered in patients with end-stage liver disease. Alteration of medication dosage based upon hepatic compromise, additional medications, and site of metabolism of the medication may require consultation with the patient's physician or experienced dental specialist or referral to hospital environment.

Adrenal Suppression and Long-Term Steroid Use

The adrenal cortex produces mineralocorticoids, such as aldosterone, and glucocorticoids, such as cortisol, which are important in maintaining fluid volume. Adrenocortical insufficiency may result primarily from Addison's disease, an autoimmune condition, or secondarily from hypothalamic or pituitary disease or from the administration of exogenous corticosteroids (30 mg/day or more of cortisol equivalent for more than five days [about 5 mg prednisone]). Supplemental steroids are often recommended before and possibly following surgery to prevent adrenal crisis in patients who receive chronic daily steroid therapy; however, adrenal crisis

during or after dental treatment is very uncommon and most patients probably do not require steroid supplementation.[155] If supplementation is indicated for a minor surgical procedure (such as routine endodontic surgery), the glucocorticoid target is about 25 milligrams of hydrocortisone equivalent (5 mg of prednisone) on the day of surgery. If a moderate risk surgery is to be performed, the glucocorticoid target is about 50 to 75 mg per day of hydrocortisone equivalent on the day of surgery and for 1 postoperative day.

Nonsurgical dental procedures, including nonsurgical root canal treatment, generally require no supplementation; however, this should be reviewed on a case-by-case basis and consideration given to the anticipated procedural stress and patient tolerance for dental treatment.[155] As a rule of thumb, a patient who recently discontinued use of exogenous corticosteroids for more than five days should wait 2 weeks before undergoing surgical procedures. Patients on alternate day steroids do not likely require steroid supplementation, and is often a goal of therapy for those requiring chronic steroid use. Efforts to control pain and infection can decrease the risk of an adrenal crisis.

Allergies

The prevalence of allergies and allergy-related diseases has increased significantly in recent years.[156] Approximately 15 to 20% of dental patients report some form of allergy on their medical history questionnaire and approximately 5% report allergy to one or more drugs.[157] In fact, allergy is the single most common positive finding on the medical history questionnaire.[2] Fortunately, with the exceptions of latex and certain antibiotics, the majority of reported allergies are to substances not typically used in dental treatment. Even so, many materials used in root canal therapy have the potential for eliciting an allergic reaction. The medical history questionnaire serves as the first stage in screening for allergies but should always be supplemented with direct patient questioning about history of allergic reactions to any drugs or substances. True allergic reactions are characterized by one, or more, of the following: skin rash, swelling, urticaria, throat/chest tightness, shortness of breath, rhinorrhea, and conjunctivitis.

Type I (immediate or anaphylactic, IgE-mediated) and Type IV (delayed, cell-mediated) are the two types of allergic reactions most likely to be encountered as a result of exposure to a substance used in endodontic treatment. Type I hypersensitivity requires previous exposure to the antigen and can occur after a single prior exposure or multiple prior exposures to the allergen. The reaction occurs shortly after exposure and can rapidly progress to life threatening anaphylaxis. Type IV hypersensitivity typically appears 48 to 72 hours after exposure and is mediated by T lymphocytes in contrast to the humoral immune system (antibody) mediated Type I reaction. Contact dermatitis is a classic Type IV reaction. When materials used in endodontic treatment come in contact with the periapical tissues (either intentionally or inadvertently), there is the potential for a delayed Type IV hypersensitivity reaction. The allergic potential of various materials commonly used in endodontic treatment is summarized in Table 31-8.

TABLE 31-8 Allergic Potential of Materials Commonly Used in Endodontic Treatment

Category	Material	Allergic potential
Barriers	Natural rubber latex	+
	Vinyl (polyvinyl chloride)	–*
	Nitrile (acrylonitrile and butadiene)	–*
	Polycholoroprene (Neoprene)	–*
Irrigating solutions	Sodium hypochlorite (0.5%–5.25%)	+
	Hydrogen peroxide (3%–30%)	–
	Chlorhexidine (0.2%–2%)	+
	Iodine potassium iodide (2%–5%)	+
	Ethylenediamine tetra acetic acid (EDTA) (10%–17%)	–
	Citric acid (10%–50%)	–
	MTAD (mixture of tetracycline, citric acid, and detergent)	?
Intracanal medications	Phenols	+
	Aldehydes	+
	Calcium hydroxide	–
	Iodine containing pastes	+
Sealers and filling Materials	ZnOE materials (various sealers and temporary filling materials)	+
	Epoxy resins	+
	Glass ionomers	–
	Composite resins	?
	Mineral trioxide aggregate (MTA)	–
	Calcium chelate/polyvinyl resin	–
	Gutta percha (trans 1, 4-isoprene polymer)	?

Allergy to Local Anesthetics

True Type I allergy to an amide local anesthetic is extremely rare. Nevertheless, patients reporting a history of allergic reaction to a local anesthetic require thorough evaluation prior to proceeding with treatment (assuming a local anesthetic is needed for root canal treatment) since true allergic reactions have been reported.[158–167] Perhaps the most common response elicited upon exploration of the presumed allergic reaction is a report of tachycardia, syncope or general uneasiness following local anesthetic injection. Such a response almost certainly represents a psychogenic reaction rather than true allergy.[166,168] Careful aspiration during injection can help prevent an inadvertent intravascular injection and subsequent increased toxicity and potential for adverse reaction.

In a prospective study of 5,018 dental patients who received a local anesthetic, 25 (0.5%) adverse reactions were recorded. Twenty-two of the reactions were mild, quickly reversible, and considered to be psychogenic in nature. Only two of the reactions were initially viewed as possible allergic reactions and both of these were excluded as true allergic reactions after provocative challenge tests. In another study of 236 patients who experienced an adverse reaction after

injection of local anesthetic, all tested negative following intradermal injection of local anesthetic containing epinephrine and preservative.[169]

Sulfite preservatives used in local anesthetics containing epinephrine and latex allergen released into the anesthetic solution from the vial stopper are both potential causes of allergic reactions. Although reaction to the sulfite preservative is also believed to be rare,[169] allergic reactions to preservatives used in local anesthetics have been reported.[170–172] Since preservatives are only used in local anesthetics containing a vasoconstrictor, the risk of allergic reaction from this potential source can be eliminated by using an anesthetic without vasoconstrictor and preservative (e.g., 3% mepivicaine). Local anesthetic cartridges contain two potential sources of latex allergen that could possibly leach into the anesthetic solution—the rubber stopper and the diaphragm. A review of the literature found no case reports or controlled studies demonstrating that the latex present in a dental local anesthetic cartridge could cause an allergic reaction.[173] However, this same review found several case reports of allergic reactions attributed to trace amounts of latex found in other medication vial stoppers and intravenous tubing. Even though there is no strong evidence to support avoidance of local anesthetic cartridges in patients with a known latex allergy, experts in the area have recommended using local anesthetic from glass enclosed vials to avoid any potential risk of exposure to latex allergens.[167] If it can be determined that the local anesthetic cartridge contains non-latex materials for the diaphragm and stopper, then there is no need for concern.

It should also be noted that a documented allergy to one type of amide local anesthetic does not necessarily imply allergy to all amide local anesthetics and often a readily available alternative can be found after testing.[162,166] As a practical matter, patients referred for allergy testing should be given sample cartridges of at least two different local anesthetics so the allergist can test with the same solution that will be used for dental treatment. Options for patients with a documented allergy to all commonly used local anesthetics include sedation, general anesthesia, electronic anesthesia[166,175] and injectable diphenhydramine. A solution of 1% diphenhydramine with 1:100,000 epinephrine can be compounded by a local pharmacist and used for infiltration or mandibular block injections. The dosage should be limited to a maximum of 50 mg at each appointment.

Allergy to Latex

Of the many materials used in the dental office with the potential for initiating an allergic reaction, natural rubber latex (NRL) is the most common.[176] Reports of allergic reactions to NRL began in 1987 coincident with the widespread adoption of universal precautions, including the use of latex gloves for practically all medical and dental procedures.[177,178] Type IV sensitivity is the most common type and is related to the various chemicals used in processing NRL. The potentially much more serious Type I sensitivity to NRL is a reaction to proteins found in NRL. Approximately 6% of the general population is believed to have Type I sensitivity to NRL and this number increases to as much as 17% for health care workers.[179] Urticaria is the most common initial finding in Type I sensitivity reaction to NRL.[177]

Patients with a history of multiple surgeries (especially spina bifida) or atopy (multiple allergies) and health care workers all have an increased risk of sensitivity to NRL. Some food allergies (e.g., avocado and banana) are associated with an increased risk of latex allergy. Considering the multiple potential sources of exposure to NRL in the dental office (e.g., dental dam material, gloves, local anesthetic cartridges, rubber mouth props, rubber tubing, and even some blood pressure cuffs), history of allergy to NRL requires special treatment modifications. In addition, clinicians who treat patients with known or suspected sensitivity to NRL should be prepared to provide initial management of an acute allergic reaction if necessary.

Consultation with the patient's primary care physician or allergist is advised to help assess the degree of risk, previous reactions and treatment, and possible premedication with a corticosteroid. All potential sources of NRL exposure in the dental office should be considered. Non-latex gloves and dental dam material are now readily available from commercial sources and these items may be easily substituted for NRL containing products. Since latex allergens can be transferred by contact with powder from latex gloves and other sources, it may be prudent to schedule the patient as the first of the day to decrease the chance of contact with residual latex allergens on environmental surfaces, clothing, and room air.[180] The potential for cross-reaction with gutta-percha in NRL sensitive patients has not been demonstrated although caution should be exercised to avoid extrusion of any filling material beyond the confines of the root canal space. Also, as previously discussed, the potential for reaction to latex allergens present in the local anesthetic cartridge stopper or diaphragm should be considered.

Antibiotics and Analgesics

Allergy to penicillin is one of the most common drug allergies and affects approximately 5% to 10% of the population.[157] Although many reported allergic reactions cannot be confirmed, unless the patient is willing to undergo testing to rule out allergy to penicillin, it is safest to assume to the allergy is real and select an alternative antibiotic. In the case of allergy to penicillin, it should be presumed that the patient is also allergic to the synthetic penicillins. In addition, cephalosporins show cross-reactivity but only in approximately 5 to 10% of penicillin allergic patients.[157] Clindamycin is an appropriate alternative to penicillin for treatment of endodontic infections and bacterial endocarditis prophylaxis.[67,181]

Nonsteroidal anti-inflammatory drugs are the usual drugs of first choice for management of endodontic related pain and are tolerated well by most patients. However, caution should be used in prescribing NSAIDs in patients with asthma and/or known allergy or sensitivity to aspirin.

Reports of allergy to codeine are most commonly related to gastrointestinal side effects rather than true allergy, although allergy to opioid analgesics does occur. If the patient's history suggests an adverse reaction related to gastrointestinal distress (including nausea, emesis or constipation), an alternative synthetic narcotic or combination pain medicine may be considered.

Irrigating Solutions

Sodium hypochlorite, in concentrations varying from 0.5% to 6.0%, is currently the most commonly used canal disinfectant and irrigating solution in endodontics.[182–184] Sodium hypochlorite possesses excellent tissue solvent and antimicrobial properties but also demonstrates concentration related tissue toxicity. Although an allergic reaction and/or hypersensitivity to sodium hypochlorite when used as an endodontic irrigating solution is rare, several cases have been reported.[183,185,186] It has been suggested that some patients may be sensitized by exposure to household bleaching products.[183] Alternatives to sodium hypochlorite include: sterile saline or water, chlorhexidine (0.2 – 2%), iodine potassium iodide (2 – 5%), hydrogen peroxide (3%), ethylenediamine tetraacetic acid (EDTA – 10 – 17%), citric acid (10%), and a recently introduced material, MTAD.[184,187–190] Of these alternatives, iodine potassium iodide and chlorhexidine also possess the potential for stimulating an allergic reaction. A recent review article provides an excellent overview of the relative advantages and disadvantages of these selected irrigating solutions.[184]

Intracanal Medications, Cements and Filling Materials

Intracanal medications such as formocreosol, formaldehyde, eugenol, camphorated phenols, and cresatin are all known to be potential allergens.[191,192] Fortunately, these canal medications are not frequently used in current endodontic therapy. Calcium hydroxide paste, a commonly used intra-appointment medication, is not allergenic. Temporary filling materials containing zinc oxide and eugenol (ZnOE) have the potential for allergic reactions and, unlike materials contained exclusively within the confines of the root canal space, are likely to have contact with mucosal tissues.[193]

ZnOE, a potential allergen, is a common component of many root canal sealers and two common root-end filling materials (IRM® and Super EBA®). Sealers containing formaldehyde or paraformaldehyde (such as N2 paste and Endometazone), especially when extruded beyond the apex, have been demonstrated to stimulate often severe allergic reactions.[194–197] Resin-based sealers such as AH26® and AHPlus® also have the potential to stimulate an allergic response[191] although this is believed to be rare. Calcium hydroxide-based sealers such as Sealapex® or glass ionomer sealers such as Ketac-Endo® could be reasonable alternatives for patients with known allergy to any of the components of ZnOE or resin based sealers. As always, one should carefully read the list of ingredients since at least one sealer marketed as a calcium hydroxide based sealer contains a significant ZnOE component.

Dentin-bonded resin-type root-end filling materials have demonstrated excellent biocompatibility in long-term clinical studies with no evidence of allergic reactions in treatment failures.[198–200] However, the choice of resin filling material is important since some resins are known to release formaldehyde when setting. Mineral trioxide aggregate (MTA) and newer bioceramic materials used for root-end fillings, apexification, perforation repair, and pulp capping have demonstrated excellent biocompatibility and no suspected allergic potential.[201–203]

Although there have been case reports of suspected allergic reactions to gutta-percha in patients who were allergic to natural rubber latex (NRL),[204,205] the possibility that the reactions were due to another material used in root canal treatment could not be ruled out. In fact, cross-reactivity between commercially available gutta-percha and NRL has not been demonstrated.[206,207] In addition, gutta-percha is normally well contained within the confines of the root canal space and therefore should not have the potential to elicit an immune response. Gutta-percha manufactured for root canal treatment contains other ingredients such as barium sulfate, zinc oxide, waxes and coloring agents so potential allergy to any of these materials should be considered, especially if there is potential for extrusion of filling material. In patients with multiple allergies (atopy) and suspected allergy to any of the components of gutta-percha, consultation with the patient's physician is advised.

If safe use of the standard obturating material cannot be confirmed, one alternative is to fill the root canal space with MTA or a bioceramic material. This technique presents some technical challenges, especially in smaller canals, but should be manageable by an experienced clinician. MTA has a relatively long setting time (about four hours) but once final hardening has occurred, removal of the filling material through an orthograde approach is difficult and only possible in large, straight canals.

Chapter 32

Drug Interactions and Laboratory Tests

S. Craig Rhodes, Paul D. Eleazer

Drug-drug interactions, as well as some food-drug, herbal/diet medicine-drug, and vitamin-mineral/drug interactions, are discussed in this chapter. While dentists are not obliged to treat every patient, they cannot deny treatment based upon a patient's disability, such as a medical condition. For more details, see Chapter 31. Therefore, it is important to be prepared to treat patients taking multiple drugs by becoming aware of dangerous drug interactions.

The drug interaction information in this chapter is derived from the work of a panel of pharmacologists who factor the likelihood of an interaction, with the severity of a possible reaction to arrive at a level of clinical significance.[1] Some less-likely reactions, with serious potential adverse results, are also included. Certainly new reactions, some serious, will be discovered as more knowledge accumulates. On-line resources are available for updated information.[2,3]

Principles of pharmacology and history taking can help clinicians determine probable risk for individual patients. Drug interactions can be classed as pharmacokinetic or pharmacodynamic. Pharmacokinetic reactions include changes of rate or extent of absorption, distribution, metabolism, or excretion. Pharmacodynamic drug interactions involve a change in the patient's response without a change in drug plasma level.

An example of a pharmacokinetic absorption is the antidiarrheal Kao-Pectate (kaolin and pectin) that decreases the absorption of tetracycline antibiotics. An example of pharmacokinetic drug interaction of distribution is epinephrine and the beta-blocker drugs competing for the same binding site on albumin. Metabolism-type pharmacokinetic interactions include the macrolide family of antimicrobials, competing for the breakdown liver enzyme pathway with drugs such as Tagamet (cimetidine). Elimination drug reactions include the competition of methotrexate and non-steroidal anti-inflammatory drugs (NSAIDs) for removal by the kidney.

An example of a pharmacodynamics reaction is ethanol and a benzodiazepine combining to increase central nervous system (CNS) sedation without a detectable difference in plasma levels in either of the drugs from their levels if administered alone.

Interviewing the patient may provide valuable clues about possible drug reactions or interactions. When drug action is plotted against response in a large patient population, the graph is almost always a bell-shaped curve, meaning that a few patients develop an exaggerated response and some show very little effect. Most people have the expected response. If a patient has a history of over- or under- response to a drug, the clinician should be alert for a similar response. Drug interactions for members of the same drug class are likely to be analogous, but there can be exceptions. A second major consideration in history taking is the possibility of inaccurate reporting by the patient. Such may be the case with a patient who denies a medical problem, based on a sense of bravado, or one who vainly wants to postpone admission of the encroachment of age. Furthermore, patients may simply forget important details of their drugs or specific dosages. In addition, many lay persons not well versed in medical conditions may not grasp the importance of reporting all of their specific conditions or chronic medications.

Some authors have suggested that generic medications may not be as effective as brand name drugs, especially for certain categories of drugs. An example is illustrated by the discovery of imperfections with enteric coatings that would subsequently not protect the medication from the adverse effects of acid stomach contents.[4] A more recent study demonstrated a lack of bioequivalence between brand name and generic levothyroxine for use in children with severe congenital hypothyroidism. There appears to have been an insensitive FDA pharmacokinetic standard in the production of the generic version of the drug, as compared to the brand name version.[5]

The prudent practitioner should observe drug interaction reports for newly introduced drugs, and be cautious about prescribing these drugs until sufficient time has elapsed to elucidate all reactions. Often, drug interactions are discovered after a drug has been introduced to the market, even though many lab tests, animal tests, and human trials were performed before release of the drug for sale. An example of such a situation is the non-opiate drug ketorolac (Toradol). It was found to be very effective in controlling postoperative dental pain and was widely prescribed before being associated, through post-market surveillance, with stomach bleeding and kidney problems. This eventually led to a brief withdrawal of the oral form from the market, except for brief follow-up to parenteral use.[6] Ketorolac is currently indicated for short-term (≤ 5 days in adult patients) management of moderately-severe acute pain requiring analgesia at an opiate level.

Dentists are fortunate that they seldom need to prescribe drugs for chronic use. Taking medications for relatively shorter periods of time minimizes the potential for drug interactions and side effects that can potentially occur more often when these medications are taken for extended periods of time. Even so, some important drug interactions occur rapidly.

For many drug interactions, the net result is simply a change in reaction to one or both drugs. This change can be an increased response or a decreased effect. Sometimes, a combination of drugs results in an unexpected interaction. An example of a surprising increased drug effect occurs when administering benzodiazepine drugs to patients taking the calcium channel blocker diltiazem (Cardizem). The combination causes little change to diltiazem action, but results, however, in a rapid increase in benzodiazepine sedation, apparently because the calcium channel blocker decreases the metabolic breakdown of the benzodiazepine. In one study, the area under the curve of benzodiazepine over time nearly tripled.[7]

Individual variation plays an important role in much of what we know about drug interactions. Generally, those affected more are the elderly, whose metabolic systems are less robust. Often, those with chronic systemic disease, and those taking multiple medicines, are more likely to have drug interactions. Unknown reactions may also be at work. Patients taking herbal medicines and those on atypical diets may also be more likely to have an unexpected drug reaction.

Some patients may not be greatly affected by a drug interaction and might not report it to their prescribing doctor. Even among observant patients, the number of dramatic drug interactions that affect every patient every time is probably very low. This inconsistency of effect may allow the practitioner to gain confidence in prescribing drugs if they see their patients having no problems. Even for a specific individual, past experience with combining drugs is no guarantee of safety.

The most serious reactions of concern to dentists are listed in Tables 32-1 to 32-12. With theophylline, the margin between therapeutic dose and toxic level is narrow. With international travel now commonplace, drugs removed from the market in one country may be brought in from another. One needs to know overseas trade names as well as the generic labels. Such is the case with the non-sedating antihistamines astemizole (Hismanal) and terfenadine (Seldane), which can cause life-threatening *torsade de pointes* cardiac arrhythmias if combined with macrolide antibiotics.

Systemic epinephrine can adversely affect a patient without drug interaction by increasing anxiety and causing a frightening tachycardia. Keeping the local anesthetic in the local area minimizes the possibility of drug interaction. However, Lipp et al.[8] experimented with labeled epinephrine. They found a 22% incidence of intravascular injection without a positive aspiration. That means that clinicians should not derive a false sense of security, from a lack of aspiration of blood, during an anesthetic injection. Avoidance of systemic interaction can best be assured by a slow injection. Observation of the patient, for signs of systemic injection of epinephrine, such as pallor, tachycardia, and anxiety, are essential. For more details, see Chapter 18.

The concept of decreased drug effect from orally administered antibiotics has received attention in the lay press. Careful research has led to the belief that antibacterial drugs, commonly used by dentists, are quite unlikely to cause failure in oral contraceptives. Research suggests that azole antifungal drugs, such as ketoconazole, may reduce the therapeutic efficacy of hormonal contraceptives. The anti-tuberculosis drug rifampin may also reduce the therapeutic efficacy of hormonal contraceptives. Yet it is prudent for clinicians to suggest alternative methods of contraception to female patients of childbearing age prescribed antibiotics. Birth control pills are not 100% effective along with certain antibiotics.

Over-the-counter drugs can cause interactions of concern to the dentist. Herbals as well as vitamin and mineral supplements can also cause drug interaction problems. Many patients consider these non-prescription drugs to be innocuous dietary supplements, and fail to report taking them in their histories. Recent studies have elucidated many drug interactions with herbal medications and supplements (addressed later in this chapter).

Dentists commonly use antimicrobial drugs, pain relievers, and local anesthetics. Antimicrobial drugs have eliminated many risks of life. The first true antibiotic, penicillin, came into common use among dentists following World War II. Because so many patients have subsequently taken antibiotics, it is of little wonder that many drug interactions with these drugs have been identified.

Tetracyclines were developed after penicillin. As they were gaining in popular usage, penicillin drugs were undergoing structural modifications to afford different forms, in order to counter the emerging antibiotic resistance issues. Erythromycin, the original macrolide antibiotic, was introduced after the tetracyclines. For a time, erythromycin was widely popular among dentists, who chose it primarily because it eliminated the risk of anaphylaxis to penicillin and because antibiotic resistance to this drug originally seemed to be relatively limited. While severe allergic problems have not arisen, bacterial resistance and serious drug interactions have limited the use of erythromycin and its congeners, clarithromycin (Biaxin) and azithromycin (Zithromax).

The many drugs now known to interact with macrolides do so because of shared metabolic pathways that delay metabolism. Higher levels of one or both drugs can commonly result in severe cardiac rhythm problems, some life threatening. Surprisingly, even anti-arrhythmic drugs may cause such arrhythmias when administered with macrolides. One should note that combinations do not always cause a predictable reaction, meaning that prescribing a certain dose for a particular individual without an untoward reaction does not guarantee a similar result for subsequent prescriptions.

Serious reactions of severe muscle wasting may occur with macrolides when combined with "statin" drugs, very commonly used for lowering cholesterol. These drugs inhibit HMG-CoA reductase, a key enzyme in the production pathway of the "bad" or low-density cholesterol. Muscle aches are among the first symptoms that can occur with the drug alone, but occur much more often when the macrolide antibiotic effectively increases its concentration, by impeding

metabolism through their common liver pathway. The symptoms may take a few days to appear. Damaged muscle leads to increased creatinine phosphokinase enzyme levels that are typically used to confirm a clinician's suspicion of this potentially very serious drug interaction.

Ergot derivatives, such as Migranal, mitigate vascular headaches and may interact with macrolide antibiotics, inducing peripheral ischemia secondary to vasospasm. Not all patients respond to reversal therapy for this drug interaction, making this a very serious potential problem.

Yet another category of classic interaction, with drugs slowing metabolic pathways, occurs with macrolides. To reach therapeutic levels, theophylline is often administered in doses close to the toxic threshold. When paired with erythromycin, the decreased elimination may push the concentration of the bronchodilator into a danger zone. Obviously, the higher the patient's therapeutic dose, the greater the risk. Early studies indicate azithromycin probably acts similarly, while clarithromycin (in a study of five patients) did not affect theophylline pharmacotherapeutics.[9,10]

Table 32-1 contains more serious and more probable reactions of drugs with macrolide antibiotics. Dentists who prescribe macrolides should maintain vigilance for signs of any interaction.

Table 32-2 ranks potential reactions to metronidazole (Flagyl), a drug many dentists prescribe. This drug's antibacterial spectrum covers obligate anaerobes, however, some of these microorganisms demonstrate resistance to the drug. Clinicians often use this DNA-impeding agent along with a penicillin or cephalosporin bactericidal drug. Research has shown that most endodontic infections contain multiple organisms, with many facultative microbes.[11] Outcome analysis of microbial susceptibilities of cultures from endodontic infections shows that metronidazole alone is not effective for these infections.[12]

Metronidazole shares the adverse interaction of anticoagulant drugs with all antibiotics. By killing normal gut flora, the production of vitamin K decreases, thus altering the balance between the normal clot-promoting vitamin and the clot-preventing anticoagulant. The result is that a clinical bleeding problem is more likely to occur. Metronidazole has an additional interaction of importance to the overall clotting balance. It further increases bleeding proclivity by a direct inhibition of the metabolism of warfarin (Coumadin).[13]

Also of note, metronidazole shows interaction with ethanol, just as with disulfiram (Antabuse), resulting in nausea and vomiting in many patients. The clinician should caution patients to avoid ethanol while taking metronidazole and for 1 full day thereafter to ensure no untoward drug interaction. Another drug interaction of metronidazole is, when combined with Antabuse, patients taking metronidazole have experienced acute psychotic reactions.

TABLE 32-1 Potential Reactions between Macrolide* Antibiotics and All Drugs

Rapid Reactions	Delayed Reactions
Very significant reaction	
Established reaction	*Established reactions*
▲ Carbamazepine (Tegretol) (→ toxicity) (468)	▲ Cisapride (Propulcid) (increased arrhythmia) (522) ▲ Digoxin (→ toxicity) (792)
Possible reaction	*Probable reaction*
Ergot derivatives (→ peripheral ischemia (884)	▲ Anticoagulants (→ bleed) (187) ▲ "HMG-COA Reductase Inhibitors"(→ myopathy) (rhabdomyolysis) (1070) ▲ Pimozide (Orap) antipsychotic (→ cardiotoxicity) (1642)
	Suspected reactions ▲ Antiarrhythmics (→ arrhythmia) (112) ▲ Eplerenone (Inspira) (hyperkalemia) (→ arrhythmia (875) Grapefruit = ▲ absorption (→ toxicity) (1339) Some quinonolones = (→ arrhythmia) (1341) Verapamil, ▲ macrolide (→ cardiotoxicity) (2286)
Somewhat less significant reaction	*Established reactions* ▲ Theophylline (→ toxicity) (2119) ▲ Corticosteroid (→ possible toxicity) (627) ▲ Cyclosporine = (→ nephrotoxicity amp; neurotoxicity) (676)
	Probable reaction Rifampin (→ ▼ antibacterial/▲ gut effects) (1342)
Suspected reaction	*Suspected reaction*
▲ Benzodiazepines (→ sedation) (328)	Tacrolimus (Prograf) (→▲ tacrolimus toxicity) (2039) Repag (Prandin) (→▲ Repag = ▼ blood glucose (1811)

Numbers indicate page number in Facts and Comparisons, Drug Interactions.[1]

*Macrolides share liver metabolic pathways with many other drugs, generally resulting in delayed metabolism of both drugs, which increases drug levels.

▼ Drug action is probably diminished.

▲ Drug action is probably increased.

TABLE 32-2 Metronidazole* (Flagyl) and All Drugs

Rapid Reactions	Delayed Reactions
Very significant reaction	▲ Anticoagulants (bleeding) (194)
Somewhat less significant reaction	*Suspected reaction*
Suspected reaction	Barbiturates speed metabolism of metronidazole (→ ▼ antibacterial) (1434)
Ethanol (→ disulfiram reaction) (830)	Disulfiram (→ acute psychosis) (830)

Numbers indicate page number in Facts and Comparisons, Drug Interactions.[1]

*This antibiotic decreases metabolism of warfarin. It also may cause nausea if combined with ethanol or disulfiram (Antabuse), but reaction is inconsistent.

▼ Drug action is probably diminished.

▲ Drug action is probably increased.

TABLE 32-3 Penicillins/Cephalosporins and All Drugs

Delayed Reactions
Suspected reaction
Tetracyclines (→ bactericidal drug) (1604)
Methotrexate (→ toxicity) (1411)
Somewhat less significant
Suspected reactions
Allopurinol (Zyloprim) (→ absorption) (1597)
Food → decreases absorption (1602)
Beta-blockers (▼ antihypertensive + antianginal effects) (155)
Warfarin, ▲ bleeding (208)
Aminoglycosides are inactivated by parenteral Penicillin (PCN) (85)
Aminoglycosides + cephalosporin (increased nephrotoxicity) (81)

Numbers indicate page number in Facts and Comparisons, Drug Interactions.[1]

▼ Drug action is probably diminished.

▲ Drug action is probably increased.

Except for potentially fatal allergic reactions (anaphylaxis), the penicillin families of antibiotics, and the cephalosporins, have remained relatively free of serious drug interactions (Table 32-3). The penicillins are very effective against common endodontic pathogens.[12] Most cephalosporins are not effective against the strict anaerobes found in endodontic infections. There are varying levels of cross-allergenicity seen between penicillins and cephalosporins, depending upon the specific chemical structure of the latter.

Methotrexate, a powerful anti-metabolite for some types of cancer and for refractory arthritis patients, when combined with penicillins, vancomycin, trimethoprim, tetracyclines, or sulfonamides has resulted in severe toxicity, including renal failure, myelosuppression, neutropenia, thrombocytopenia, and skin ulcerations. Cephalosporins have not been reported to cause this drug interaction. Metronidazole can also interact with NSAIDs to effect severe toxic reactions resulting from the reduced clearance of methotrexate.

Quinolone antibiotics have potential to cause severe interactions with several drugs (Table 32-4). As with macrolides, quinolones can cause serious cardiac rhythm problems in the presence of many other drugs. The macrolide-quinolone combination is one of the drug interactions that can cause fatal arrhythmias. Macrolides or quinolones plus cisapride (Propulcid) may interrupt normal nerve impulse conduction within the heart that may threaten life. Yet another problem that quinolones have is the drug interaction with theophylline. The shared metabolic pathway similarly causes theophylline concentrations to increase to toxic levels. These similarities occur even though the molecular structures of the two drug classes are quite different.

Coumadin plus quinolone may produce a cardiac rhythm problem.[14] All antibiotics can cause bleeding problems for patients taking anticoagulants because the antibiotic kills gut flora that produce vitamin K, a natural substance that enhances clotting. Lack of this balance means the patient can take longer for his or her blood to clot. When healthy patients take an antibiotic, the reduction in vitamin K causes no clinically apparent change in clotting parameters.

TABLE 32-4 Quinolone Antibiotics and All Drugs

Rapid Reactions	Delayed Reactions
Very significant reaction	*Probable reaction*

The well-informed dentist should be able to order and evaluate blood-clotting tests such as bleeding time and International Normalized Ratio (INR) with the patient's physician.

Tetracyclines have seen resurgence in popularity among dentists because of their actions against collagenase and their effectiveness against periodontal pathogens, many shared with endodontic diseases. Both of these advantages carry over into endodontics. While there is a long list of drugs that interact with tetracycline, the reactions tend to be inconsistent and rarely life threatening (Table 32-5). The digoxin-tetracycline interaction arguably has the most serious potential. In a small portion of the population, the gut flora metabolizes a significant percentage of their digoxin dose, meaning that they require a fairly high dose to achieve the proper steady-state digoxin level. Tetracyclines can induce significant microflora changes, such that greater digoxin absorption leads to toxic levels. As noted above, macrolides interact with digoxin in a different way, inhibiting renal excretion of digoxin, also reaching potentially toxic levels, and this change can last for many days after the macrolide is stopped.

While it may be nice to contemplate treating endodontic patients without antibiotics, such is an unrealistic dream. The rapid discovery of new interactions mandates that those who treat infected patients keep abreast of contemporary information. No antibiotic is without the potential for interaction with other drugs.

Pain control drugs fall into a similar situation. Certainly, modern endodontic techniques and better appreciation of the value of "not" harming tissues adjacent to root canals have helped reduce the need for pain-relieving drugs. Yet, postoperative pain will remain a factor in treating some endodontic maladies. Clinical experience of many dentists reinforces the experimental observations that NSAIDs are effective pain relievers. Most practitioners find NSAIDs as effective as codeine or hydrocodone. Chronic NSAID use has resulted in stomach and kidney problems, especially among the elderly, but only a few problems have been associated with short-term use.

▼ Drug action is probably diminished.
▲ Drug action is probably increased.

Serious drug interactions with NSAIDs are relatively rare (Table 32-6). The effect of Coumadin is potentiated by NSAIDs. The prescription of NSAIDs for only a few doses limits the clinical appearance of this interaction. On the other hand, a very serious NSAID reaction is with methotrexate, resulting in kidney failure. This reaction is more likely with high-dose methotrexate, typically used for anti-neoplastic therapy, as opposed to the lower doses used for rheumatoid arthritis refractory to less powerful drugs.

Patients taking beta-blockers may experience hypertension breakthrough when taking NSAIDs. Sulindac (Clinoril) apparently does not have the propensity to cause this reaction.[15]

Lithium toxicity induced by concurrent NSAID use has occurred. The decrease of lithium metabolism has not resulted in clinical problems in healthy patients.[16]

NSAIDs and the very popular antidepressants that work by selective serotonin re-uptake inhibition (SSRI) drugs within brain synapses can interact adversely, as can similar drugs that act at synapses. Increased gastrointestinal (GI) bleeding has been reported, although the problem has also occurred when an SSRI drug was used alone.[17]

Narcotic pain relievers will continue to play a useful role for dentists, albeit less necessary because of improved understanding and better instruments and techniques. Demerol (Meperidine) is the most troublesome for potential interactions. The most serious, sometimes resulting in death, is less likely now because mono-amine oxidase inhibitors are rarely prescribed. Other reactions are also listed in Table 32-7.

Control of intra-operative pain is a standard by which patients judge their endodontic caregiver. Pilots are judged by how smoothly they can land a plane even though this is

*Most reactions are due to additive central nervous system effects.

but a small part of a pilot's overall skill set. Similarly, patients will judge us by our skill at giving an "easy shot."

There are two separate drug interaction considerations with local anesthetics, the anesthetic itself and the vasoconstrictor. Epinephrine is very rapidly metabolized, so any new drug interaction becomes rapidly apparent to the clinician (Table 32-8). Tolerance of the vasoconstrictor in one dose means that an additional dose after about 5 minutes can be given with similar result, given that neither is injected intravascularly. Toxicity of the antibiotic drug is another matter.

Hypertensive events have been documented in patients taking beta-blockers, furazolidone (Furoxone), tricyclic antidepressants, Methyldopa, and the anti-hypertensive drugs guanethedine (Ismelin) and Rauwolfia alkaloids. Beta-blocker interactions are potentially the most serious. It is advisable to take a preoperative blood pressure reading to establish a baseline for that patient. Furthermore, intravascular injection can occur without a positive aspiration of blood.[8]

The anesthetic itself does not cause any serious drug interactions (Table 32-9). The problem with anesthetics is that repeated injections can build to overdose levels because, unlike the very rapidly metabolized vasoconstrictor, the anesthetic agent is metabolized over hours. This is especially important to note for pediatric patients whose body mass cannot tolerate as much anesthetic as an adult.

Beta-blockers may interact with lidocaine, lowering the number of doses to reach the toxic range. This drug interaction is believed to occur via inhibition of hepatic metabolic enzymes.[18]

Cimetidine (Tagamet) increases lidocaine levels too, probably by the same general effect on liver enzymes. Yet, the reaction does not occur every time the drugs are combined.[19] Research on the other histamine H2 antagonists failed to show this interaction.

Benzodiazepine reactions are typically one of the increased drug-drug effects. This can be accounted for by beginning with a lower dose, perhaps half a pill, until the patient's own reaction is defined. The protease inhibitor reactions, however, have been reported to induce severe sedation and respiratory depression. As noted in Table 32-10, no drug

▲ Drug action is probably increased.

interactions with benzodiazepines have been ranked in the very significant category.

Table 32-11 lists drugs that may be used by dentists that can interact with Coumadin (Warfarin). This extensive list calls for careful consideration by the dentist and alerting the patient to watch for signs of bleeding. Notably, the rapid reaction category is empty, indicating that short-term use carries with it less potential for harm.

DRUG INTERACTIONS WITH DIETARY SUPPLEMENTS

The U.S. Food and Drug Administration (FDA) defines a dietary supplement as a product intended for ingestion that contains a "dietary ingredient" intended to add further nutritional value to (supplement) the diet. Such "dietary ingredients" may include but are not limited to vitamins, minerals, and herbs or other botanicals. Such supplements may be obtained in various forms such as tablets, capsules, softgels, gelcaps, liquids, or powders.[20]

As consumers live longer, take an increasing number of medications, and more commonly experience medical conditions such as diabetes and obesity, it is likely that the use of dietary supplements will likewise increase. Many patients are hesitant to disclose and/or discuss their use of dietary supplements with their dentist, unless specifically asked to provide such information. Many of these supplements have the potential to adversely interact with some of the prescribed medications patients ingest. One study found that 45% of herbal supplement users were exposed to at least one potential drug–herb interaction.[21] It behooves all dental practitioners to query patients about their use of dietary supplements. What specific supplements, in what dosages, by what regimens, and in what forms are appropriate questions. It is also helpful to note if the patient's physician has recommended the supplements and for what specific medical conditions the supplements are being taken.

DRUG INTERACTIONS WITH FOOD AND HERBALS

Licorice is the root of *Glycyrrhiza glabra*, a legume native to India, Southern Europe, and parts of Asia. It is commonly used as a flavoring agent in tobacco and confectionary foods. The purported medicinal uses of it include anti-inflammatory, antiviral, antimicrobial, and blood-pressure

increasing effects. The principal active ingredient in licorice is glycyrrhizin that has been shown to alter levels of corticosteroids, either increasing or decreasing the drug.[22] The mechanism is thought to be an inhibition of the conversion of cortisol to cortisone, by interfering with the enzyme 11-betahydroxysteroid dehydrogenase. The overall effect can be one similar to hyperaldosteronism.[23] The interaction could be more serious in patients on a high-dose steroid.

Grapefruit juice mediated drug interactions have been shown to occur due to an irreversible inhibition of cytochrome P450 enzymes (specifically CYP3A4) involved in phase I drug metabolism. The result may be damaging to high levels of the drug, even in the absence of other drugs. This action contradicts the typical finding, that food binds with drugs to decrease absorption, or at least slows drug absorption.

Orange juice, particularly when calcium-fortified, lowers the levels of the fluoroquinones Cipro (ciprofloxacin) and Levaquin (levofloxacin). Both orange and apple juices have been shown to inhibit organic anion transporting polypeptide 2B1 (OATP2B1), an uptake transporter that is associated with the oral absorption of drugs, notably fexofenadine (Allegra).[24]

Dairy products all contain the heavy metal ion calcium that can hinder the absorption of tetracyclines (demeclocycline, tetracycline, doxycycline, and minocycline). Doxycycline is the least affected of the tetracycline family to bind with heavy metal ions in a process called chelation.[25] Calcium in dairy products and supplements may also impair the absorption of fluoride. Therefore, patients should be advised to avoid intake of dairy products for at least 1 hour before, or 2 after, the administration of these drugs.

Ethyl alcohol was discussed previously in this chapter, but there is a brief review here.[26] Perhaps, because it is so often used or abused among patients, alcohol is sometimes considered a food. Generally, its interactions serve to increase the effect of drugs that act on the CNS. It delays gastric emptying, so can delay absorption of almost any drug taken by mouth. It specifically interacts with metronidazole in a disulfiram class reaction, inducing nausea and vomiting. All the above reactions are dose-related, so the astute clinician should caution patients accordingly. The interaction with Tylenol (acetaminophen) is different and potentially lethal. The chronic abuse of ethyl alcohol induces the CYP P450 enzymes that metabolize acetaminophen, resulting in the rapid metabolism of acetaminophen, with consequent high levels of a hepatotoxic acetaminophen metabolite, known as NAPQI, N-acetyl-p-benzoquinone.

Khat (*Catha edulis*) is a stimulant plant from East Africa and Southern Arabia that is usually chewed to reduce fatigue and appetite. It has been imported into the United States and other countries as a recreational euphoric agent. The euphoric effect is attributed to cathinone, a sympathomimetic amine similar to amphetamine.[27] It is sometimes smoked to achieve higher concentrations that may induce hallucinations.

Khat has been shown to decrease the absorption of amoxicillin and its close congener, ampicillin. This may lead to persistence of an infection. A small study demonstrated the maximum decrease to occur 2 hours after chewing khat.[28] Chronic khat use can result in arrhythmias, hypertension, and ischemic cardiomyopathy. As such, it has been recommended to use minimal amounts of sympathomimetic drugs for such patients.[29]

Ginkgo biloba, commonly used as a memory enhancer, interacts with salicylates and NSAIDS to increase bleeding. The apparent mechanism is by lowered platelet aggregation that decreases blood coagulation.

Kava (*Piper methysticum*), a perennial shrub native to regions of the South Pacific, is drunk as a tea and also can be obtained in pill or liquid forms. It is used to relieve stress and produce a sense of well-being. A single, but serious drug interaction-induced coma has been reported. While the reaction occurred when combined with alprazolam (Xanax), experts anticipate that the danger likely extends to the entire benzodiazepine family.[30] Based upon concerns regarding hepatotoxicity, Kava has been either restricted or withdrawn from several countries since 2002.[31]

St. John's wort (SJW) (*Hypericum perforatum*), a herbaceous perennial plant native to Europe, is the leading complementary and alternative medicine (CAM) treatment for depression and related psychiatric disorders in the United States.[32] It has the potential for causing several drug interactions. Chief among them are the drugs that are cytochrome P450 (3A4, 2C19, 2E1) and/or intestinal P-glycoprotein substrates. The metabolism of such drugs as erythromycin, prednisone, tetracycline, several benzodiazepines, clarithromycin, warfarin, cyclosporine, statins, and clindamycin is induced by SJW, leading to a potentially reduced overall effectiveness of these drugs.[33] Also, serotonin syndrome may result when SJW is taken along with the anti-depression selective serotonin reuptake inhibitors (SSRIs), or with 5-HT receptor agonists within the brain.[34]

Evening primrose (*Oenothera biennis*) is an herbaceous flowering plant native to the Americas. It is commonly marketed in an oil form as a purported remedy for rheumatoid arthritis, premenstrual syndrome, and eczema although these claims are lacking in scientific evidence. Its seed extract contains polyphenols that are attributed with having antioxidant properties. It has been reported to have cariostatic effects by inhibiting the growth of *Streptococcus mutans* and glucosyltransferase activities.[35] It has also been demonstrated to have anti-inflammatory activity.[36] Evening primrose oil interacts with salicylates and NSAIDs, potentially resulting in an additive anticoagulant effect.

Valerian (*Valeriana officinalis*) is a perennial flowering plant native to Europe and portions of Asia and has been introduced into North America. It is commonly provided in a capsule form and is advocated for use as a sedative or anxiolytic. As with the drug interactions seen with SJW, valerian has influence on the activity of the cytochrome P450 enzymes involved in phase I drug metabolism. Interactions

of valerian with drugs such as benzodiazepines, opiates, antihistamines, and other sedative hypnotics such as zaleplon and zolpidem can lead to additive therapeutic and adverse effects (increased sedation).[33]

DRUG INTERACTIONS WITH VITAMIN AND MINERAL SUPPLEMENTS

An adequate diet should provide all the necessary vitamins and minerals required by a healthy adult. Yet vitamins and minerals continue to be purchased in ever-greater numbers. In 2010, Amercian Association of Retired Persons (AARP) and the National Center for Complementary and Alternative Medicine (NCCAM) conducted a telephone survey aimed at assessing the discussion of complementary and alternative medicines (CAM) with their healthcare providers.[37] The survey indicated 47% of adults over age 50 reported using CAM in the previous 12 months and 53% reported using them at some time in their lives. Of CAM users, nearly 70% admitted not discussing their supplement use with their healthcare providers. It is important for dentists to ask their patients about their use of CAMs in order to be able to accurately assess the potential for drug interactions.

The excessive use of zinc-containing denture adhesives can lead to a deficiency of copper that in turn can cause symptoms such as paresthesias, gait and balance problems, and anemia.[38] Cipro (ciprofloxacin) absorption is also diminished in the presence of zinc, as are tetracycline concentrations. This essential heavy metal additive is common in multivitamin preparations. The net result of the interactions is lowering of antibiotic levels in the 25% to 40% range.[39,40]

Vitamin D may induce cytochrome P450 (CYP3A4) that could result in reduced availability of its substrate drugs (midazolam, erythromycin, ketoconazole, itraconazole, triazolam, clarithromycin, and erythromycin).

Vitamin E can interact with anticoagulant and antiplatelet medications (salicylates, clopidogrel, heparin, low-molecular-weight heparins, warfarin, and NSAIDs) to increase bleeding via the inhibition of platelet aggregation. It also has the potential to antagonize the effects of vitamin K-dependent clotting factors with 800 units/day or more. Vitamin E also poses the theoretical risk of increasing the metabolism of substrate drugs for CYP3A4, as already mentioned for vitamin D.[41]

Excessive intake of vitamin K can lower the anticoagulant effect of warfarin.[41]

DRUG INTERACTIONS WITH WEIGHT-LOSS MEDICATIONS

As the incidence of obesity continues to escalate among children and adults, many people turn to weight-loss medicines, as their efforts toward lifestyle modification prove insufficient. Medications used to treat obesity have the potential to interact with drugs commonly used in dentistry.

Orlistat inhibits the absorption of dietary fats by up to 30%. It has the potential to enhance the anticoagulant effect of warfarin. Careful monitoring of the patient's INR should be done to make sure it is within an acceptable range (2.0–3.5).[42]

Phentermine, as an amphetamine derivative, has the potential to enhance the sympathomimetic response to epinephrine and levonordefrin in dental local anesthetics, leading to increased blood pressure and cardiotoxicity, especially in existing cardiac patients.[43] The same caveat applies to patients taking the phentermine-topiramate combination pill (Qysmia). This combination medication also has the potential to impact with sympathomimetics or benzodiazepines.[44]

Phendimetrazine, diethylpropion, and benzphetamine are also sympathomimetic amines with properties similar to those of the amphetamines. They have the same potential to modify the CNS effects of dopamine, serotonin, or norepinephrine. The same cardiac and blood pressure precautions should be employed when these drugs are reported by patients, and especially so for those with existing cardiovascular conditions.[42]

LAB TESTS OF POTENTIAL IMPORTANCE IN ENDODONTICS

Laboratory tests are commonly helpful to dentists. The list of such lab tests is not exhaustive, and dentists should not be limited to those tests listed below. Dentists may be uncomfortable in ordering laboratory tests due to unfamiliarity or perceived patient resistance.

A recent survey was conducted to assess patient attitudes towards chair side medical screening in a dental setting.[45] The survey results indicated the majority of respondents were willing to have a dentist conduct screening for heart disease, hypertension, diabetes, HIV, and hepatitis infection. Referral to a physician is always appropriate, but there is no reason for a dentist to be intimidated by the process of ordering lab tests for their patients.

Dentists are often the first healthcare provider to identify systemic disease. Oral tissues are often the first to be affected. Moreover, many patients do not regularly visit their physician, or many receive only cursory information on subtleties of oral changes from disease. Leukemia, bacterial endocarditis, various cancers, and many other diseases are first suspected in the dental office. Ordering a laboratory test to confirm or rule-out suspicions is perfectly appropriate for any dentist. Culture and sensitivity testing, for identification of a cause of infection and the most likely effective antimicrobial, should be included in every dentist's armamentarium.

Typically, dentists will ask patients to complete a medical history questionnaire. Prior to providing consultations, examinations, and treatment, results should be reviewed during a dialogue between the dentist and patient prior to the physical examination. In order to obtain all the necessary

information for the formulation of an adequate risk assessment,[46] patients are then assigned to a physical status category, commonly the one based on the classification system developed by the American Society of Anesthesiologists (ASA).[47] Medical consultations with the patient's personal physician(s) are often necessary when the dentist is uncertain of the accurate assignment of physical status category and/or the anticipated degree of risk to the patient.

Problems with this recommended protocol can arise when patients are either unaware of their health status, are hesitant to provide this information within the dental office setting, or are less than truthful regarding medical conditions they may have for concerns of privacy and/or fees. It is this first group of patients, the ones who may be unaware of their health status, who may benefit the most from medical screenings involving lab tests within the dental office setting. One recent study provided medical screening tests to patients within a dental setting in order to examine the relationships between the laboratory test results and the patient's self-reported medical health status.[48] The authors found 83% of the participants had one or more abnormal test results and did not disclose a relevant medical condition in their history. The results suggest that many patients would benefit from screening within the dental office.

The dental profession has always taken a leading role promoting prevention. As healthcare reform has rapidly evolved within the United States over the past decade, a renewed emphasis has been placed on prevention, along with the integration of healthcare practitioners involved in primary care across professions and disciplines. The Affordable Care Act (ACA) includes recommendations designed to shift the focus of healthcare away from the traditional treatment of illness toward a system more aligned with overall patient wellness. The expansion of the dental profession, to incorporate the medical screening of patients for undiagnosed conditions, is a logical extension of our historical emphasis on preventive health care. In time, this may prove to play an important role in attempts to control the epidemic rates of incidence of such chronic maladies as cardiovascular disease and diabetes mellitus.

Cardiovascular disease (CVD) and diabetes mellitus (DM) are important public health concerns, and assessing disease risks for these conditions can readily be accomplished within a dental setting. For CVD the Framingham-based risk score is widely used.[49] Use of this algorithm can assess the patient's risk of experiencing coronary heart disease within the next 10 years. In assessing the risk for coronary heart disease, screening tests such as blood pressure, high- and low-density lipoproteins, triglycerides, and body mass index, over a 1-year period, could be utilized. DM-appropriate screening tests could include hemoglobin A1c (HbA1c), random plasma glucose, body mass index, urine glucose, and glucose challenge testing.

Other screening tests, including liver function tests such as aspartate aminotransferase (AST), hematocrit, hemoglobin, herpes simplex virus (HSV), complete blood cell count (CBC), urinalysis, and a standard blood chemistry panel, have also been utilized in previous studies conducted in a dental setting.[48,50]

Disorders of inflammation, perhaps related to a chronic dental infection, may cause an increased erythrocyte sedimentation rate (ESR). Blood tests may be helpful identifying blood dyscrasias, from cellular imbalances to inflammatory system evaluation, to clotting factors. Most classic hemophiliacs are diagnosed early in life and can provide the dentist with historically important information. Every dentist should be aware of the risks associated with altered blood clotting profiles of their patients. Newly identified risk assessment studies have shown the mortality and morbidity of decreasing anti-clotting parameters. The dentist should be comfortable interpreting these tests, to determine if a patient is a candidate for a surgical procedure.

The prothrombin time (PT) test has been largely replaced by the INR that uses a standardized control and expresses the result in a percent of normal clotting time. This test evaluates the extrinsic clotting mechanism. With an INR of 1 being the normal level, minor dental alveolar surgery can be carried out to an INR level, <3.5 with local methods of hemostasis sufficing. For other than minor surgery, consultation should be obtained with consideration for modification of the anticoagulation or hospitalization.

The partial thromboplastin time (PTT) test remains valuable to determine function of the intrinsic clotting pathway that includes the clotting factors in blood plasma.

Bleeding time, the number of minutes required for a standard wound to clot, may help diagnose later onset problems of importance to the dentist such as von Willebrand's disease, where the intrinsic factor VIII is diminished by this hereditary defect. Also, bleeding time identified disorders of the platelet system, including those induced by salicylates or NSAIDs.

The CBC test enumerates platelets, RBC and WBC counts, and can confirm or rule out many suspicious findings. An increased number of red blood cells, polycythemia vera, can reveal itself clinically as darker gingiva, due to the engorgement of the vascular system. An increase in the number of white blood cells can manifest as bleeding gingival that is seen in many forms of leukemia. Petechiae due to sickle cell anemia can be diagnosed by the occasional characteristic shaped red blood cells clogging oral capillaries.

While it is easier to direct patients and staff, who are accidentally exposed to blood-borne pathogens, to someone trained in counseling for such risks, tests for such infectious agents may be ordered by the dentist who suspects a disease.

Patients with unexplained radiolucencies of their jaws may need testing for certain disorders. For example, a multiple myeloma patient will have elevated abnormal antibod-ies known as Bence-Jones protein in his or her urine. A patient with hyperparathyroidism-caused bone radiolucencies will have elevated blood calcium and decreased blood phosphorous level. Urinary levels of calcium may

be lower, with increased phosphorous found in the urine. Serum alkaline phosphatase (ALP) is elevated in hyperparathyroidism, although not as markedly as with Paget's disease.

Allergies can make life unpleasant for many. They may stem from food allergies that can cause nutritional imbalances and may be suggested by changes in the appearance of oral tissues. This may include commonly used dental materials, such as nickel or eugenol, making the patient less likely to have a favorable treatment outcome. The dentist who suspects such a problem will probably refer the patient to an allergist for skin or other tests and then help manage the dental aspects of the patient's care.

SUMMARY

There is a limited understanding of drug interaction incidence because of under-reporting. Also, animal studies may not directly transfer to the human. Animals cannot express mood changes effectively, and there are some metabolic differences between animals and man.

The astute clinician should explain possible adverse or undesirable reactions with patients so that they may watch for an adverse outcome. This chapter emphasizes drug reactions that are potentially very serious and/or are very likely to occur. Some practitioners will see interactions of drugs beyond those covered here. It is important to report suspected drug interactions to the FDA for evaluation through their Medwatch program.[51] The FDA periodically sends information about newly discovered, serious drug interactions, to practitioners registered by state license to practice dentistry. The dentist should report suspected drug interactions to the appropriate administrations in their countries. Furthermore, the reader should remember that information about drug interactions is constantly changing, mostly with newly discovered interaction reports.

Chapter 33

Outcomes of Endodontic Therapy

Kishor Gulabivala, Yuan-Ling Ng

HISTORICAL CONTEXT OF EVALUATING ENDODONTIC OUTCOMES

The development of medical and dental practices has been guided by prevailing philosophies and consensus of expert opinions. Fears of fatal oral sepsis from deficient root canal treatments at the beginning of the last century led to widespread extraction of pulpless teeth. Endodontics virtually disappeared from many dental schools as the focal infection theory reigned for about 50 years[1] until around 1940.

Rescue of the Endodontic discipline was attributed to individual diligent dental practitioners in Europe and United States, who meticulously recorded their treatments, as well as their outcomes to demonstrate their effectiveness in controlling root canal infection. Such individual endeavors of merit restored the discipline of endodontics that was granted its specialist status in 1952 in the United States.

The costs of health care have risen alarmingly as improvements in general health have driven the survival of western populations, as well as their teeth, much later into life, prompting a host of re-evaluations of the altered economic burdens on society. The *cost-effectiveness of treatment procedures* for management of diseases, therefore, came under close scrutiny and thus began the era of evidence-based medicine and dentistry, with its emphasis on costs, benefits, and outcomes of treatment. Individual studies proved too small to provide confident estimates of intervention outcomes in the wider population. Attempts to pool outcome data for greater power brought the realization that the collective pool of data originating from different centers was heterogeneous and precluded definitive conclusions. Characterization of data types and their quality naturally led to the realization of the need for standardization of approaches in measuring outcomes to enable more meaningful pooling.

A modern re-visitation of the "focal infection era" in the last 20 years, rather than threaten the endodontic discipline, as in the past, prompted the urgency for establishing a better evidence-base for judging the impact on systemic health. Ironically, the modern threat to the endodontic discipline was posed by the cost-economic pressures exerted on treatment planning decisions centering on the question of whether to "save the tooth" or extract it with replacement by an implant-supported crown. Once again, the science of evidence-based practice has helped to avert irrational options-appraisals that lean towards extraction of savable teeth.[2,3]

By the time of writing, the pendulum had swung firmly back in favor of maintaining predictably restorable teeth rather than to extracting and replacing them with implant-retained crowns. The clinician must, therefore, be ready to play a critical and influential role in restorative treatment planning decisions. Endodontists must not be relegated to the subordinate role of "root canal therapists" providing technical execution of the procedure on prescription. It follows, therefore, that the endodontist must have a sound knowledge of the basic science underpinning the clinical discipline, as well as a rounded clinician with good general treatment planning skills.

Types of Disease and Its Treatment

Endodontic treatment is aimed at treating pulpal disease caused by inflammation and/or infection that generally commence in the pulp tissue and progress to the periradicular tissues *via* portals of communication conveying the neuro-vascular supply. Direct spread of disease across the cementum is precluded by its nature.

Incipient or established-but-limited pulpitis may be managed by vital pulp therapy when it is believed that a sufficient body of pulp tissue remains healthy and unaffected. The direct and uncontrolled spread of pulp inflammation is buffered by specific neuro-vascular mechanisms, distinct from those in the remainder of the body to prevent the pulp from self-strangulation. More advanced pulpitis judged to be on the verge of involving the apical tissues, may require root canal treatment. Where pulpal necrosis and infection have already ensued with consequent apical inflammation, root canal treatment is required to manage the resident intra-radicular infection, unless some natural or iatrogenic obstruction precludes access to the apical anatomy, in which case periradicular surgery may be required for such access. Persistent apical periodontitis following technically inadequate root canal treatment may require root canal retreatment. Persistent apical periodontitis following technically adequate root canal treatment may require root canal retreatment or periradicular surgery to manage the source of the persistent disease.

Recently, a new treatment modality, the "regenerative endodontic procedure" (also called pulp regeneration or revascularization) has been introduced for "*de novo* synthesis" of pulp or connective tissue inside the immature teeth with pulp necrosis and apical periodontitis leading to arrested root development. "Endodontic therapy" is therefore a collective and non-specific term for a range of different procedures

directed at managing disease of different degrees of severity and extent within the pulp tissue or extending beyond the apical confines of the root(s).

Endodontic treatment encompasses the following distinct procedures:

1. Vital pulp therapy (indirect pulp therapy, direct pulp capping, pulpotomy);
2. Nonsurgical root canal treatment;
3. Surgical root canal treatment;
4. Nonsurgical root canal retreatment;
5. Surgical retreatment;
6. Regenerative endodontic procedure.

The ideal outcome for endodontic treatment consists of controlled reduction of infection and inflammation, accompanied by healing through regeneration; although sometimes repair may follow instead. Unfortunately, none of the involved tissues are within the direct sight of the clinician, hidden as they are by their housings of hard tooth structure or alveolar bone and their gingival/mucosal coverings. Consequently, surrogate measures have to be employed to evaluate the presence or absence of inflammation or its resolution. This process is further complicated by the lack of direct correlation between measures of chronic inflammation and its clinical manifestation, as well as the sensitivity of methods to image such tissues.

TYPES OF OUTCOME MEASURES

Chronic inflammation is typically clinically asymptomatic, unless superimposed by acute exacerbation. Clinical detection of chronic inflammation of pulpal and periradicular tissues, that are hidden from direct view, is consequently challenging and requires indirect or associated (proxy) measures. The process calls upon the clinician to triangulate various sources of information to form a judgment about the presence or absence of disease.

In its broadest sense, an outcome measure for a treatment intervention may constitute any consistently anticipated and measurable consequence of the treatment. The prepared shape of the root canal system, microbial load reduction, and technical quality of root filling may all be regarded as outcome measures by this definition. The ultimate *clinical* measures, however, assess the prevention or resolution of disease (or inflammation).

The outcome of endodontic treatment may be assessed in four dimensions as in other medical disciplines. The first dimension is physical/physiological and related to presence or absence of pulpal or periapical health/disease, pain, and function. The second dimension assesses longevity or tooth survival; the third dimension relates to economics and assesses direct and indirect costs; whilst the fourth dimension examines psychological aspects involving perceptions of Oral Health Related Quality of Life (OHRQoL) and esthetics.

PURPOSE OF EVALUATING OUTCOMES

Evaluation of treatment outcomes enables the effectiveness of interventions to be determined. In association with the characterization of the properties of the intervention protocol, the specific factors affecting the outcome may be determined, that in turn may help to estimate the prognosis of impending treatments.

Effectiveness of Procedures

Treatment procedures must be effective for them to be recommended to patients as an option. This must form part of the informed consent process, wherein the risks, benefits, and potential outcomes are articulated to the patient. The availability of pooled outcome data and consensus guidelines offers both patients and endodontists reassurance and confidence in the validity and predictability of the offered procedure. Pooled average outcome data may not, however, always placate patients that the particular endodontist offering the treatment does indeed have the requisite experience, skills, and personal outcomes matching at least the average figures of performance. It behooves individual practitioners to observe and develop their own personal outcome data; a growing practice in modern surgery.

Personal outcome data offers the patient more precise measures for comparison and expectation. It also aids the practitioner in refining their technique and knowledge to further improve their outcomes, ultimately to help improve the overall pooled data.[4]

Factors Affecting Outcomes

Pooling homogenous data offers the potential to evaluate and prioritize the factors that exert a dominant influence on outcomes. In this way, protocols for treatment may be refined in a progressive fashion so as to reach for the perfect meld of technical performance, clinical outcome, and biological effect necessary for the most predictable and favourable result. Evaluation of factors (microbiota, immune and healing response, intervention, host, operator) affecting treatment outcomes arguably provides the strongest driver and hub for generation of translational *hypotheses* to improve outcomes. Weighing the relative importance of individual factors should help to pinpoint the key biological and clinical factors at play and how best to manage them technically and clinically.

Value for Prognostication

The science of prognostication (predicting, projecting, prophesising, or foretelling the likely outcome of treatment) for an individual tooth is not well advanced in endodontics as it is at least partly based on factors affecting outcomes of endodontic treatment. The latter knowledge and its biologic correlates are still in the process of elucidation. Furthermore, the overall prognosis of a tooth is dependent

upon three individual prognoses and their summative effect. These include the endodontic, periodontal, and restorative prognoses. Each subsumes a set of subsidiary factors that will influence the overall prognosis. Finally, the tooth in question must be considered from a strategic perspective, relative to its position in the dental arch, and the contribution it makes in the dynamic occlusion and overall dental function.

The complexity of the problem of analyzing the factors affecting outcomes of endodontic treatment is highlighted by comparison with the randomized controlled trial of a drug as a treatment intervention. Drugs have a clearly prescribed and standardized dose delivered by specified timings to affect an anticipated blood or target tissue concentration for a defined duration. Treatment data recording is confined to compliance with the prescription, possible checking of blood or tissue levels and the final outcome measure.

In stark contrast, a surgical intervention, regardless of standardisation of treatment protocol, is subject to great variation in its delivery, dependent upon interpretation and execution of the protocol by each operator. To add to the levels of complexity and variation, surgical protocols are often multi-step, sequential procedures, each prospective step dependent upon the previous for its efficacy. Even characterizing and accurately recording any variations in a putatively standardized protocol, therefore, becomes a challenge, since many aspects and steps must be recorded. This leads to the next challenge, that of demonstrating compliance with the accuracy of such complex data gathering. Furthermore, it becomes important from an analytical perspective to not only consider the effect of individual steps (factors) alone but also the effect of any interaction between the multiple steps inherent in the procedure. Although these issues could theoretically be controlled in well-designed and executed randomized controlled trials (RCTs), the potential bias related to recruitment and drop-out is inevitable, in particular within small scale trials. The use of strict participant selection criteria may limit the generalization of findings. In addition, the effects of pre-operative factors and some treatment steps cannot be randomized and can only be investigated in observational studies. Well-designed RCTs and population-based observational studies can therefore serve as complementary forms of research to ensure that the results of clinical trials translate into tangible benefits in the general population. Even when such comprehensive observational prospective outcome data is available, its utilization to individually calculate the prognosis in a particular scenario may be challenging.

Clinically, there may be two distinct ways to estimate prognosis: (1) to apply heuristic principles and intuitively gauge the effect of dominant factors; or at the other end of the extreme; (2) to mathematically input comprehensive data into an algorithmic model to calculate the estimated outcome. An even more sophisticated approach may be to use mathematical modeling to calculate iterations on the effect of variations within the system. At present, the evidence-base is insufficient to allow such a sophisticated approach.

Value for Future Development of Treatment Protocols

Evaluation of outcomes and the factors that affect them are fundamental to the creation of a suitable data foundation for future application to endodontic prognostication. Endodontic treatment options compete with alternative dental therapies and, consequently, the survival of the discipline demands a suitable blend of efficacy, efficiency, utility, predictability, and cost-effectiveness of its principal procedures. Evidence-based practice, in turn, demands relevant data to support these outcomes. Achievement of this goal will require diligence and conscientious application by multiple centres of teams. Analyses of such powerful datasets will ultimately yield proper insight into the procedures used. Coupled with an evolving biological insight of the problem, it will become possible to derive new therapeutic solutions from first principles, as well as the technical and clinical skills necessary to deliver them through a broad spectrum of clinicians.

OUTCOME MEASURES FOR ENDODONTIC TREATMENT

Vital Pulp Therapy Outcome Measures

The techniques used to maintain the vitality and health of pulps in teeth with extensive caries or those with traumatic/mechanical exposures include: (1) Indirect pulp capping with one-step or two-step (stepwise) caries excavation; (2) direct pulp capping of exposed pulps; or (3) partial/full pulpotomy procedures for more extensively involved pulps. For more details, see Chapter 27.

The surrogate outcome measures adopted in studies have included: (1) clinical success (positive response to pulp tests; and absence of pain, soft-tissue swelling, sinus tract, periradicular radiolucency, or pathologic root resorption); (2) patient satisfaction; and/or (3) adverse events (pain, swelling, tooth fracture); or (4) tooth extraction. Although not providing a specific follow-up strategy, the 2006 European Society of Endodontology quality guidelines suggested "initial review at no longer than 6 months and thereafter at further regular intervals." They did, however, provide the criteria for judging the favorable outcome of vital pulp therapy: (1) normal response to pulp sensitivity tests (when feasible); (2) absence of pain and other symptoms; (3) radiological evidence of dentinal bridge formation; (4) radiological evidence of continued root formation in immature teeth; (5) absence of clinical and radiographic signs of internal root resorption and apical periodontitis. Guidelines on pulp therapy for primary and immature permanent teeth provided by the American Academy of Paediatric Dentistry in 2009 suggested the following criteria: (1) tooth vitality maintained; (2) absence of

post-treatment signs or symptoms such as sensitivity; pain or swelling; (3) occurrence of pulp healing and reparative dentin formation; (4) absence of radiographic evidence of internal or external root resorption, periapical radiolucency, abnormal calcification, or other pathologic changes; and (5) teeth with immature roots should show continued root development and apexogenesis. There are substantial differences in the criteria adopted in published clinical studies on outcomes of vital pulp therapy with few studies adopting all of the criteria. The duration and frequency of radiological review varies substantially from first review at one month followed by three-monthly reviews to an initial assessment at 6–12 weeks, followed by six and twelve-monthly reviews. The latter is more widely accepted because of the relative benefit of information yield *against* unnecessary radiation to patients from early and short interval radiological reviews. Follow-up over 10 years suggests declining success rates inferring probable slow spread of pulpal inflammation and latent disease in some cases, presumably because it is difficult to accurately judge the initial state of the pulp. The conclusion is that longer follow-up periods are merited.

Nonsurgical Root Canal (Re)Treatment Outcome Measures

Root canal treatment may be employed either to prevent or resolve periapical disease. Given that periapical lesions result from *interaction between* microbiota (and their products) and the host defenses, their prevention or resolution depends upon preventing or terminating such *interaction*.

Prior absence of apical periodontitis implies (in most instances) an absence of apical microbial colonization coupled with vital, healthy pulp tissue in the apical part of the root. The purpose of chemo-mechanical debridement would then be to extirpate the pulp (necrotic, inflamed or healthy) to prevent apical infection; thus, asepsis is the prime requirement. The precise technical details of the protocol may not matter as long as it is effective in aseptic removal of the pulp tissue. This is validated by the high chance of *retaining periapical health* (90%-99% judged by conventional radiography), regardless of the clinical protocol used.[5]

In the case of teeth with established periapical lesions, the challenge is different; the prime purpose in such cases would be to remove the established microbial biofilm to switch off the periapical host response. The challenge is greater still when the periapical lesion is larger as it is associated with a more diverse infection,[6] that is more difficult to eradicate.[7] A number of approaches (protocols) have been used to achieve this general aim.

The healing process after root canal treatment has not been deeply researched. Nevertheless, ideal healing should eventually result in regeneration and formation of cementum over the apical termini, isolating the root canal system from the periapex but this is not an inevitable end-result. Incomplete removal of the apical infection would reduce but not eliminate the inflammatory area and in fact this is generally what does happen.[8] This implies that residual infection in the apical area of the canal is the norm following completion of root canal treatment with ongoing microbial-host interaction beyond the end of treatment, influenced to varying degrees by the prior root canal treatment procedure and now resident root filling material.[9]

The culture test has been used during root canal treatment as an interim measure of the efficacy of the chemo-mechanical procedure, however, it has fallen out of favor in contemporary practice for a variety of reasons. The *immediate* outcome measures at the end of the root canal treatment procedure are the technical quality of root-filling and absence of clinical signs and symptoms of persistent periapical disease.[10,11] The *definitive* outcome measure (in conjunction with absence of signs and symptoms), however, is periapical healing, since the treatment is aimed at resolution of periapical disease.[12] Clinical judgment of periapical healing is based on the absence of signs of infection and inflammation, such as pain, tenderness to pressure/percussion of the tooth, tenderness to palpation of the related soft tissues, absence of swelling and sinus and radiographic demonstration of reduction in the size of the periapical lesion (if sufficient time has lapsed), with a completely normal periodontal ligament space as the end-point. Although the majority of periapical lesions show radiographic evidence of healing within one year,[13,14] healing can actually take anything up to four years or longer.[15] On the other hand, the longitudinal follow-up[16] of 14 cases presenting with widened apical periodontal ligament for 10 years revealed unfavorable future healing in a small proportion of the cases (28%, 4/14).

Absence of signs and symptoms of periapical disease with persistence of radiographic evidence of periapical radiolucency may indicate either fibrous repair or persistent chronic inflammation. Only time or acute exacerbation would identify the latter, whereas the former should remain asymptomatic. Although some patients do anecdotally report discomfort in cold, damp weather, that is consistent with discomfort from scars in other parts of the body, commonly joints.

Longevity measures include survival of the root canal fillings or treatment and tooth retention or survival. The term *functional retention* was coined by Friedman and Mor[17] to mean retention of the tooth in the absence of signs and symptoms, regardless of the radiographic presence of a lesion. The term *functionality* should further and more specifically cover the functional utility of the tooth, that is, some patients may complain that despite absence of specific signs and symptoms of infection or inflammation, they find it impossible to use the tooth because it "feels" weak or vulnerable.

Modern definitions of health embrace a broader spectrum of measures including psychological well-being. Instruments to assess these aspects have been developed in general medicine and adapted for application to dentistry, such as the Oral Health Related Quality of Life instrument. There is no definitive instrument for measuring these aspects

in endodontics as yet. Studies published so far have mainly adapted versions of Oral Health Impact Profile (OHIP).

The periapical status of root-treated teeth has traditionally been assessed using two-dimensional conventional radiographic imaging. Such imaging suffers from low sensitivity, particularly in the posterior parts of the mouth due to anatomical superimposition. Digital imaging technology enables image manipulation, including digital subtraction, densitometric analysis, correction of grey values and the manipulation of brightness and contrast but these do not address the main deficiencies. For more details, see Chapter 9B.

A three-dimensional imaging technique, cone-beam computed tomography (CBCT), requiring only 8% of the effective dose of conventional computed tomography, has been proposed as a means of overcoming the problem of superimposition of tissue layers and structures. For more details, see Chapters 9C and 10. CBCT has been found to be significantly more accurate in detecting small bone lesions in an animal model. Other evidence to support the superior sensitivity of CBCT is available from studies using a variety (size, shape) of simulated defects created in bone as gold standards by chemical or mechanical means in pig or human jaws. Although the validity of clinical outcome data derived using conventional radiographic technique has been questioned, the *routine use* of CBCT is not recommendedowing to its higher radiation dosage (×2-3). The use of CBCT that may be more sensitive for detecting periapical healing may give lower healing rates and longer durations to complete healing.

Many studies adopt a threshold for judging successful periapical healing that is passed only when *both* radiographic and clinical criteria are satisfied. Comparison of success rates estimated with or without clinical examination revealed no[18] or only a very small difference (1%),[13] although crucially, a small proportion of cases present with persistent symptoms despite complete radiographic resolution of the periapical lesion.[19]

The definition for success/failure by Strindberg[15] embracing both radiographic and clinical findings have been widely adopted or adapted. Success was defined by absence of symptoms and radiographic evidence of normal periodontal ligament structure, accepting some widening around excess filling material. Failure was conversely defined by presence of symptoms and radiographic evidence of decrease, stasis, increase in the periradicular rarefaction; or appearance of a new rarefaction. Friedman & Mor,[17] preferred the terms "healed," "healing," and "diseased" instead of "success/failure" because of the potential of the latter to confuse patients. The "healed" category corresponds to "success" as defined by Strindberg,[15] whilst "healing" corresponds to "success" as defined by Bender et al.[10,11]

The long duration of the periapical healing process coupled with the reduced recall rates at longer follow-up periods has prompted setting of the thresholds for success at partial healing (reduced lesion size) rather than complete healing. Setting the threshold of success at "*reduced periapical radiolucency size*" has been described as either a "*loose*" or a "*lenient*" measure[17]; whilst, setting the threshold at "complete resolution" has been described either as a "*strict*"[12] or "*stringent*" measure.[17] The frequency of adoption of these two thresholds has been similar in previous studies; the expected success rates using "strict" criteria would be expected to be lower than those based on "loose" criteria; the difference varies from 4% to 48%[5,12].

A five-point periapical index (PAI) for measuring the periapical status has been used in some studies.[20,21] The studies though only reported the increase or decrease in mean scores for the clinical factors under investigation coupled with the proportion of successful cases. This approach unfortunately precludes direct comparison of their data with studies reporting conventional dichotomised outcomes. Other studies using the index dichotomized the scores into "healthy" (PAI 1 or 2) or "diseased" (PAI 3–5) categories[22] to overcome this problem. This system of designation is debatable, given that the PAI score 2 represents periodontal ligament widening or in fact a persistent lesion, albeit incipient.

Periapical Surgery Outcome Measures

Non-surgical root canal treatment alone may fail to resolve apical periodontitis in a small proportion of cases because of lack of access to the infection or non-microbial etiology. Microbial persistence may be localized intra-radicularly to the apical canal anatomy or the apical dentinal tubules; or extra-radicularly on the root surface or in the periapical lesion. In these instances, a surgical approach to the periapex may be required, *in addition* to the non-surgical approach.

The outcome of root-end management *via* a periapical surgical approach has been assessed by clinical and radiographic criteria as for non-surgical root canal treatment. However, the radiographic criteria for successful periapical healing are different from those for non-surgical root canal treatment.[23,24] Complete healing was defined by: (1) reformation of a periodontal ligament space with normal width & lamina dura around the apex, or a slight increase in the width of the apical periodontal space (less than twice the width of non-involved parts of the root), or a tiny defect in the lamina dura (maximum 1 mm^2) adjacent to the root filling; or (2) complete bone repair with the deficiency that either the bone bordering the apical area lacks the density of the surrounding non-involved bone, or that there is an absence of apical periodontal space. Incomplete healing (scar tissue) was defined by: (1) a decreased or static rarefaction; or (2) an isolated scar tissue in the bone. Either of these conditions may be found with: (1) bone structure within the rarefaction; (2) a well demarcated but irregular periphery to the rarefaction; (3) asymmetrical distribution of the rarefaction around the apex; or (4) angular connection between the rarefaction and the periodontal ligament space. Periodontal

attachment loss, in the form of marginal gingival recession, is an additional consideration for measuring the outcome of periapical surgery.

OUTCOME DATA FOR VITAL PULP THERAPY PROCEDURES

The vital pulp therapy procedures discussed in this chapter include those for managing extensive caries with a high risk of pulpal exposure or pulps exposed through caries or traumatic injuries.

Indirect Pulp Capping (One-step Versus Step-wise Excavation)

The most conservative management for extensive caries is indirect pulp capping using either the one-step or the two-step (step-wise) excavation approach. The step-wise excavation approach with initial partial caries removal was advocated to reduce the risk of pulpal exposure; the latter putatively being associated with poorer outcomes. The clinical outcomes of the "one-step" or "step-wise" approaches have been compared in three randomized controlled trials on permanent teeth with deep caries.[25-28] Step-wise excavation gave a lower rate of pulp exposure coupled with higher chance of long-term clinical success than the one-step excavation approach[25,26] (Table 33-1). Maltz et al.[27,28] however, found the contrary; they attributed the low long-term clinical success rate of the step-wise approach to patients not returning for scheduled completion of treatment. Interestingly, comparison of the cost-effectiveness of the "one-step" versus the "step-wise" excavation techniques, using health-economic modeling involving simulated treatment of a molar tooth with deep caries in a 15-year-old patient, revealed the former procedure to accrue lower long-term costs as well as longer tooth retention and pulp vitality.[29]

Meta-analyses of data from studies listed in Table 33-1 gave a weighted pooled success rate of 81.7% for indirect pulp capping using the one-step approach (95% confidence interval [CI]: 72.7%, 90.6%) that was similar to the weighted pooled success rate for the step-wise approach (81.9%; 95% CI: 72.1%, 91.7%).

Calcium hydroxide cement was the preferred lining material for the pulpal surface, whilst zinc oxide/eugenol based cement was the preferred base material in most studies. Recently, resin-modified-glass-ionomer liner has also been used but the type of lining material did not influence the outcome (Table 33-1). The age of patients, presence of pre-operative pain, and pulpal exposure during excavation proved to be significant prognostic factors.

Direct Pulp Capping

Direct pulp capping is performed on teeth with pulp exposures caused by caries, caries excavation, traumatic injuries, or root resorption. Most studies investigating the clinical outcome of direct pulp capping on permanent teeth had excluded teeth with signs and symptoms of irreversible pulpitis and apical pathosis (Table 33-2). Saline, sodium hypochlorite, and chlorhexidine have been reportedly used to irrigate the exposed pulp and to achieve hemostasis, whilst calcium hydroxide paste and mineral trioxide aggregate (MTA) were the commonly used capping materials (Table 33-2).

Meta-analysis of data from studies listed in Table 33-2 gave a weighted pooled success rate of 70.1% (95% CI: 59.9%, 80.2%). The patient's age and sex; tooth location and type; pulp exposure type, size, and its location; and the restoration type, size, and quality did not have a significant influence on success. Although the outcome of direct pulp capping of teeth with immature *versus* mature apices has not been systematically compared in individual studies, indirect comparison of pooled data from different studies[30] revealed the former was associated with significantly more successful outcomes.

The type of capping material was another significant prognostic factor, with MTA performing superiorly to calcium hydroxide in a randomized controlled trial[31] and in a systematic review.[30]

Pulpotomy

Earlier studies on the outcome of *partial pulpotomy* (specifying varying definitions of pulpal extent) had only included teeth with vital traumatic pulp exposures but recent studies have also included teeth with carious exposures (Table 33-3). Teeth with spontaneous or severe pain as well as signs and symptoms of apical pathosis were excluded (Table 33-3). On the other hand, the outcomes of *full pulptomies* (removing the coronal pulp and retaining the radicular pulp) had only been investigated in teeth with carious exposures (Table 33-4). Saline irrigation has been preferred for achieving hemostasis, whilst calcium hydroxide or more recently MTA, were the preferred pulp capping materials (Table 33-3).

Meta-analysis of data from studies listed in Table 33-3 and Table 33-4 gave a weighted pooled success rate of 79.3% (95% CI: 66.7%, 91.8%) for partial pulpotomies and 82.4% (95% CI: 69.3%, 95.4%) for full pulpotomies.

The effects of potential prognostic factors for pulpotomy have not been explored systematically except for the pulp capping material. Randomized controlled trials revealed MTA achieved similar outcomes in partial[32] or full[33] pulpotomies when compared with calcium hydroxide.

Summary of Prognostic Factors for Vital Pulp Therapy

In summary, vital pulp therapy performed under guideline standards with optimal coronal seal achieved promising long-term success in teeth with carious, mechanical, or traumatic exposures of healthy pulps.

The most important factors affecting the outcome of vital pulp therapy are: pre-existing health of the pulp; adequate removal of infected hard or soft tissues; careful operative technique to avoid damage to residual tissues; and exclusion of microbial leakage around the final restoration. It can be

difficult to gauge the health of the residual pulp as it is a matter of subjective assessment and relies on experience in pulp diagnosis. The degree of pulp bleeding upon exposure is a more reliable tool to judge the status of the pulp than the pre-operative clinical signs and symptoms. Continued bleeding after 10 minutes, even after rinsing with sodium hypochlorite solution may suggest that the residual pulp was still heavily inflamed and a complete pulpectomy may be a more effective treatment modality. Removal of infected tissue is a matter of subjective experience but may be aided by various dyes. The final factor is reliant upon the correct choice of restorative material and its adequate manipulation to prevent leakage.

Factors such as age and health of the patient, size and nature (carious or traumatic) of pulp exposure, and its duration of exposure to the oral environment (up to 48 hours) do not, in themselves, appear to compromise outcomes of vital pulp therapy.

OUTCOMES OF NON-SURGICAL ROOT CANAL TREATMENT

In contrast to other areas of endodontics, the number of studies and extent of investigation of non-surgical root canal treatment is more comprehensive, yielding a much greater breadth and depth of insight, even though the quality and scope of the research does not always reach the highest levels. The following summary is therefore more elaborate than preceding sections.

A systematic review and meta-analysis of the factors affecting primary root canal treatment outcome conducted by the authors revealed the following: the mean success rate (complete healing) measured by radiographic evidence of periapical health was 83% when vital pulpectomy was performed (Figure 33-1); it reduced to 72% when root canal treatment was performed to eradicate the established infection associated with a periapical lesion (Figure 33-2).

Factors Affecting Periapical Health or Healing Following Root Canal Treatment

The factors influencing the maintenance of periapical health or periapical healing of pre-existing lesions following root canal treatment may be broadly classified into *patient-related* factors (age, sex, general health, tooth anatomy, pre-operative pulpal and periapical status), *treatment-related* factors (operator characteristics, canal shaping/enlargement, irrigation, medication, culture test and obturation), and *restorative-related* factors. Some factors had a profound impact on success rates, whilst others showed a negligible effect. Patient-related factors characterizing the nature of the disease showed the most potent effect (periapical status), whilst most of the treatment-related factors, individually, were found to exert a weak effect; the exceptions were the apical extent of root canal treatment relative to the root canal terminus that showed a strong effect. In addition, the quality of the post-operative restorative care also exerted a profound influence on outcome of treatment.

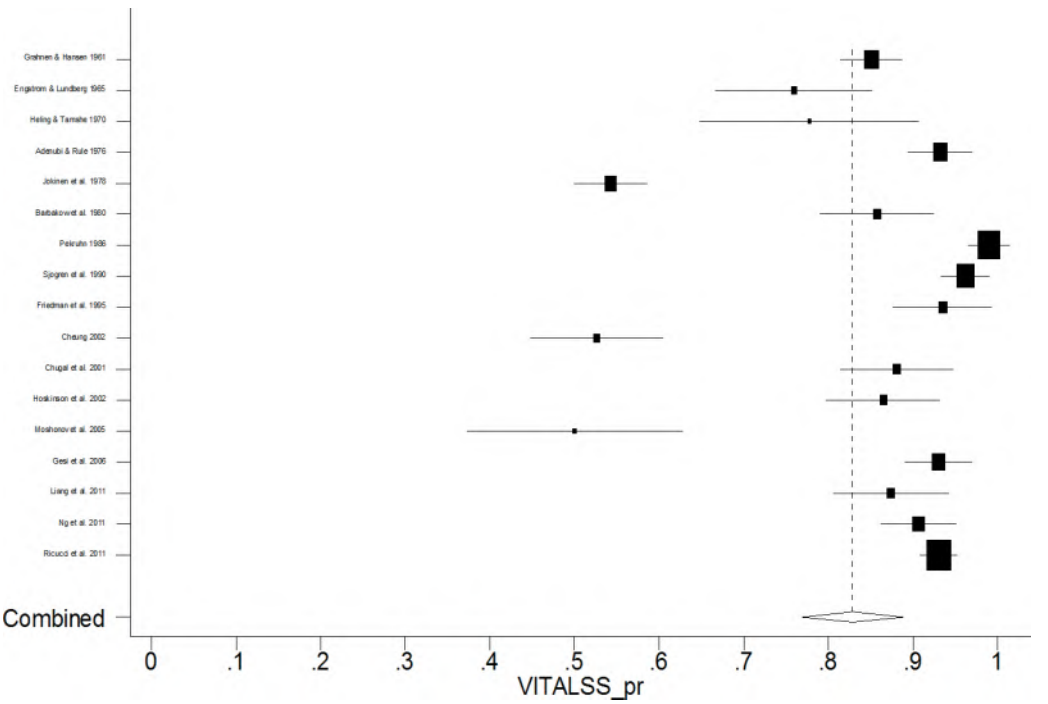

FIGURE 33-1 Forest plot showing results of pooled and individual study's probability of maintained periapical health for pre-operatively vital teeth undergoing root canal treatment. (Pooled probability = 0.83; 95% confidence interval: 0.77, 0.89.)

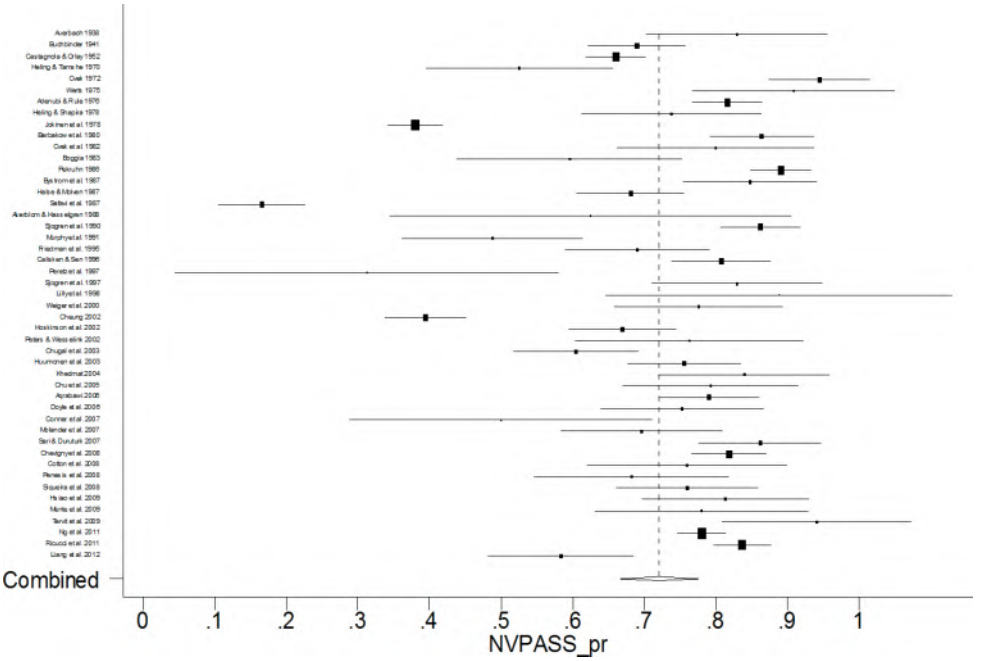

FIGURE 33-2 Forest plot showing results of pooled and individual study's probability of periapical health for teeth associated with non-vital pulps and periapical radiolucencies undergoing root canal treatment. (Pooled probability = 0.72; 95% confidence interval: 0.67, 0.78.)

Patient-related Factors

Patient's age and sex consistently had no significant influence on outcome, whilst some specific health conditions (diabetes, compromised innate immune response) apparently had a significant influence. The evidence for the effect of host immune response, characterized by the general health of the patient, is, however, weak. Recent emerging evidence suggests that the host response, characterized by polymorphisms of various genes involved in periapical healing, may have an effect on outcomes. The importance of the host response to maintenance of periapical health or periapical healing was also supported by the statistically significant clustering effect of multiple teeth within the same patient in a prospective study.[13]

The perception that single-rooted teeth exhibit simpler canal anatomy and should accrue better and more predictable outcomes proved to be untrue. Having accounted for the potential confounding effect of periapical disease, it is found that tooth type did not exert a strong influence on success rates. This would appear to be counter-intuitive but may be explained by the logical inference that canal complexities in the apical anatomy probably play a more dominant role than canal system complexities more coronally.[14]

The most dominant factor influencing the success of root canal treatment negatively is the presence (Figure 33-3) and size of a periapical lesion (Pooled OR comparing pre-operative large [> 5mm] versus small [< 5 mm] periapical radiolucencies = 2.2; 95% CI: 1.3, 3.7)[5,13]; these factors must be accounted for when analyzing the influence of any other factor. The profound change in success rates once a periapical lesion becomes established is telling, since it is correlated with the establishment of infection in the apical canal anatomy. This suggests that once the apical canal complexities become infected, it may be much more difficult to eradicate the infection.

The negative influence of large periapical lesions has a ready and acceptable biological explanation, in that the diversity of microorganisms (by number of species and their relative abundance) is greater in teeth with larger periapical lesions.[6] The infection was more likely to persist in those canals with a higher number of microorganisms pre-operatively.[7] Larger lesions may represent longer-standing root canal infections that may have penetrated deeper into dentinal tubules and accessory anatomy in the complex canal system[34] where mechanical and chemical decontamination procedures may not readily reach. Larger lesions may also represent cystic transformation.[35] Finally, the host response may also play a part as patients with larger lesions probably respond less favorably to residual infection.[8]

Most of the other investigated pre-operative factors (pain, tooth tenderness to percussion, soft tissue tenderness to palpation, swellings, sinus tracts, periodontal probing defect of endodontic origin, root resorption) are in fact different clinical manifestations of periapical disease. They may, therefore, act as surrogate measures or complement "presence and size of periapical lesion" in measuring the effect of "severity" of periapical disease within a broad continuous spectrum. Of these, only presence of pre-operative pain, sinus tract, swelling and apical resorption have been found to be prognostic factors significantly reducing the success of root canal treatment.

The negative impact of sinus tract and swelling, either in the acute or chronic form, on periapical healing would

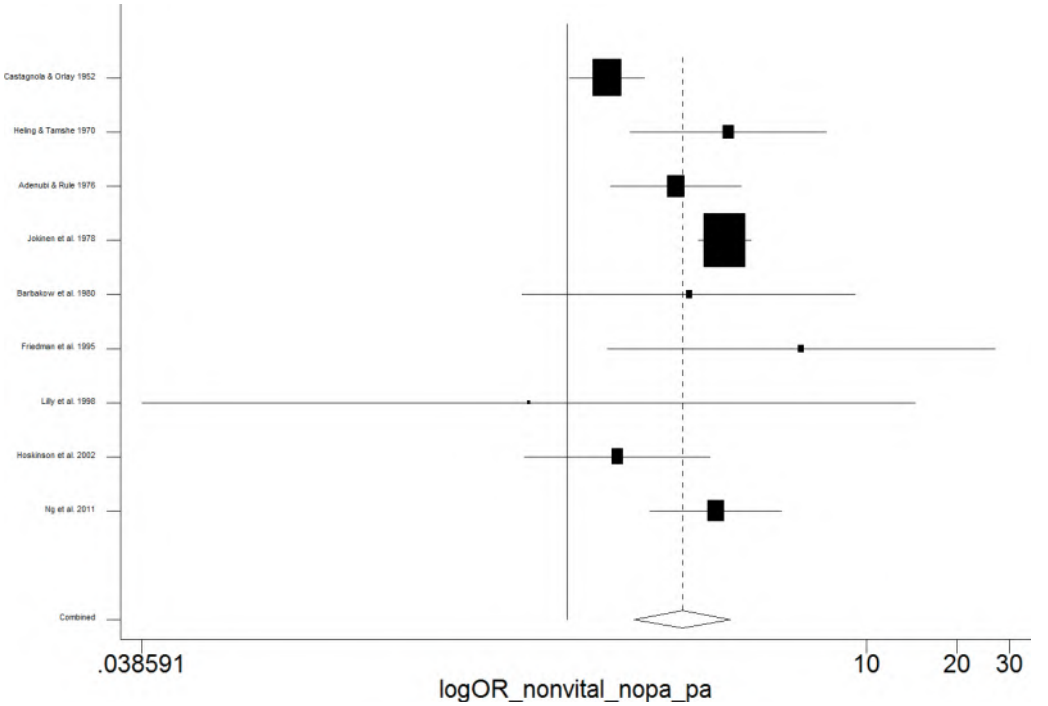

FIGURE 33-3 Forest plot showing pooled and individual study's odds ratio (OR) for periapical health of teeth undergoing root canal treatment with pre-operative non-vital pulps and absence of periapical radiolucencies versus teeth with non-vital pulps and presence of periapical radiolucencies. (Pooled OR = 2.4; 95% CI: 1.7, 3.5.)

seem to be related to suppuration and proliferation of microbiota into the periapical tissues; that is, the host tissues being overwhelmed by the microbiota. The precise mechanisms for reduced success rates remain unclear but must reflect the nature of host-microbial interaction. Clinically, however, endodontically-related sinus tracts (intra-oral and extra-oral) can demonstrate dramatic healing following adequate endodontic treatment.

Treatment-Related Factors

The impact of operator qualification and skill has not been specifically investigated but systematic review demonstrates the involvement of clinicians with different educational and training backgrounds (undergraduate students, general dental practitioners, postgraduate students and specialists).[12] This has allowed partitioning of outcome data to reveal clear trends with superior outcomes associated with greater experience and training. Technical skills would appear to play an important role in the outcome. However, the lack of appropriate tools or methodology to objectively quantify operator skills precludes segregation of the complex constellation of cognitive, technical, and clinical skills. The role of technical refinement must be balanced against the overall understanding of the biological problem by the operator, and crucially, the motivation and integrity with which the procedure is performed.

The use of dental dam in modern root canal treatment is so widely accepted that the absence of systematic data on its influence on root canal treatment outcome is a surprise. One study on retreatment[36] had analyzed the influence of dental dam compared to cotton roll isolation and found significantly higher success rates with the former approach. Another observational study reported a significantly higher success rate of root canal-treated teeth,[37] when dental dam was employed during post placement, compared to when it was not. The principal justification for dental dam use is based on patient safety and the medico-legal implications of root canal instrument inhalation by the patient.

The virtues of magnification and illumination during root canal treatment are universally extolled by endodontists but a systematic review failed to locate objective evidence for the view.[38] A prospective study[13] investigating this factor found an insignificant influence on the outcome. Use of a microscope may sometimes assist location of the second mesio-buccal canal in maxillary molars (64%), but this only made a small difference to the success rates associated with mesio-buccal roots, when a periapical lesion was present.[13] The true benefit of a microscope can only be verified through a randomized controlled trial but current evidence precludes a significant impact on the critical step of apical infection control.

Mechanical preparation

A variety of instruments of different cutting designs, tips, tapers, and materials of construction may be employed to mechanically prepare the root canal system to a defined size and taper. Numerous laboratory studies testify to their properties, efficacy, and utility but investigation of their influence in clinical canal

enlargement appears only in two non-randomized prospective studies.[13,39] In the former study,[13] the better success rates for NiTi instruments (hand or rotary) compared with stainless steel instruments were attributable to the fact that tactile skills training was achieved through a preliminary focus on the use of stainless steel files to develop tactile sensitivity and consistency. Only on demonstration of this competency did the trainees progress to NiTi instruments. More importantly, such senior trainees were more likely to have already established a better understanding of the biological rationale for root canal treatment. The ability to gain and maintain apical patency as well as to avoid procedural errors was better instilled in the senior students, whilst in selected cases, NiTi instruments appear capable of achieving the same in primary root canal treatment undertaken by undergraduates.[40] The importance of biological insight over technical skill development alone in the performance of root canal treatment appears to be reinforced by the observation that improvements in the technical quality of root fillings through training in NiTi instrumentation and single-cone root filling did not accrue a parallel improvement in periapical status.[39]

A key tenet of the European Society of Endodontology (ESE) guidelines is that root canal debridement must be extended to the terminus of the canal system; that is expressed variously as extension to the "apical constriction," or to "0.5 to 2 mm from the radiographic apex,", or to the "cemento-dentinal junction." This guideline is broadly supported by the fact that outcome of treatment is compromised by canal obstruction or failure to achieve patency to the canal terminus.[13,15,41] Ng et al.[13] reported a two-fold reduction in periapical healing when patency to the canal terminus was not achieved. It could be speculated that the lack of mechanical negotiability of canals may be due to the presence of obstructions caused by "denticles," tertiary dentine, acute branching or a fine plexus of apical canals, or dentin/organic debris.

The debate on the optimal size of apical canal preparation remains topical in the absence of definitive evidence; the findings from relevant *in vitro* and clinical studies have been reviewed before.[42] So far, six clinical outcome studies have considered the issue or have systematically investigated the effect of apical size of canal preparation on treatment outcome.[13,15,18,43-45] One randomized controlled trial revealed that enlargement of the canal to three sizes larger than the first apical binding file was adequate,[45] the mean final size was ISO 30. Observational studies,[13,15,18] although not designed to investigate the effect of apical canal size as their principal focus, did not find a statistically significant influence attributable to this factor. Nevertheless, they all reported the same inverse trend of decreasing success rates with an increase in size of apical preparation.

It was speculated that canal preparation to larger apical sizes might compromise treatment success by generation of more apical dentine debris, that in the absence of an adequate irrigation regimen may serve to block infected apical canal exits. Continued generation of dentin debris, in the absence of sufficient irrigation may lead to what is termed "dentin mud," that may ultimately create a blockage. The impatient or neophyte dentist/endodontist may fail to resist the temptation to force the instrument back to length resulting in the classically described procedural errors of apical transportation, canal straightening, and perforation. An alternative mechanism is required to explain the higher failures in initially large canals; it is hypothesized that immature roots present a different debridement challenge, where the canal shape is not amenable to cleaning of the main portions of the canal by conventional instruments. Perhaps an intracanal brush may be a more suitable cleaning device in such teeth. The findings from the above studies, therefore, do not concur with views that more effective microbial elimination may be achieved with larger apical preparations.[46-48]

The issue of apical preparation size should be considered alongside that of the taper of the rest of the canal preparation. Again, there is a paucity of sufficient direct evidence for the influence of degree of canal taper on root canal treatment outcome. The ESE guidelines recommend only that canal preparation should be tapered from crown to apex without stipulating any particular degree of taper. Three studies have analyzed the influence of canal preparation taper on primary treatment and retreatment outcome, although again, none had focused their investigation on this factor.[13,18,49] Smith et al.[49] using loose criteria for determination of success, found that a "flared" preparation (wide taper) resulted in a significantly higher success rate compared with a "conical" preparation (narrow taper); the exact degree of taper was not reported and the effects of confounders were not controlled. In contrast, Hoskinson et al.[18] and Ng et al.[13] using strict criteria did not find any significant difference in treatment outcome between narrow (.05) and wide (.10) canal tapers. The controlled use of stainless steel instruments in a step-back technique may create .05 (1 mm step back) or .10 (0.5 mm step back) tapers, although, of course, uncontrolled use of such instruments may generate a variety of shapes. Ng et al.[13] also compared these (.05 and .10) preparation tapers with .02, .04, .06, and .08, tapers (generally achieved by using non-ISO, greater taper, nickel-titanium instruments) and found no significant effect on treatment outcome. They cautioned that their investigation of the influence of canal preparation taper without randomization could be confounded by the initial size of canal, type of instrument, and operator experience.

Triangulation of the available data on the effects of canal preparation taper on treatment outcome intuitively suggests that, according to current best evidence, it is not necessary to over-enlarge the canal to achieve periapical healing. An apical preparation size of ISO 30 with a .05 taper for stainless steel instrumentation or .06 taper for NiTi instrumentation may be sufficient for many canals, subject to adequate irrigation. Precisely what biological and hydrodynamic mechanisms underpin such sufficiency is more difficult to define based on available evidence. Although a number of laboratory studies[50] have investigated the interaction between canal dimensions and irrigation or obturation dynamics, the precise physical, chemical, or biological mechanisms that ultimately enable periapical healing remain unknown, although

collaborations with fluid dynamics specialists[50] and (micro) biologists[51] may ultimately yield a clearer picture.

Procedural errors during root canal preparation include canal blockage, ledge formation, apical zipping and transportation, straightening of canal curvature, tooth or root perforation at the pulp chamber or radicular level, and separation of instruments. Of these, the effects of changes in canal shape (ledge formation, apical zipping and transportation) have not been specifically investigated and reported, whilst the effect of canal blockage was explored previously.

Iatrogenic perforations during treatment were found to result in significantly lower chance of periapical healing.[13,41,52-55] These studies did not analyze further the specific prognostic factors for teeth with perforation, such as time lapse before defect repair, location and size of perforation, and adequacy of perforation seal. An observational study[56] that had specifically evaluated the outcome of MTA® repair of root perforations revealed substantially lower success rates amongst cases with perforation of larger size or those present in the furcation region. The use of MTA® as perforation repair material may improve the treatment outcome of these cases, attributable to its biocompatible and effective seal.

Instrument separation during treatment has been found to reduce the success rate significantly,[13,15] however, the prevalence of instrument separation was low (0.5% - 0.9%) in these studies, precluding an analysis of causative factors. A case-control study[57] revealed a small but not statistically significant difference in success rates between periapically-involved teeth (with or without retained separated instruments) managed by endodontists. The stage of canal debridement at which instrument separation occurred may have implications on the outcome. The corono-apical location of a separated instrument and whether the instrument was successfully bypassed were found to have no effect on treatment outcome. The positive influence of separated instrument removal on treatment outcome was, however, found in cases managed by undergraduate students.[58]

Irrigation

Different chemical agents have been used as irrigants for root canal treatment, singly or in various combinations, both in clinical practice and in the studies reviewed. They have included water, saline, local anaesthetic, sodium hypochlorite, iodine, chloramine, sulphuric acid, EDTA, hydrogen peroxide, organic acid, Savlon®, urea peroxide and Biosept® (a quaternary ammonium compound).[5] Most of the studies had used sodium hypochlorite as an irrigant,[5] regardless of whether it was primary treatment or retreatment. For more details, see Chapter 21.

A prospective study[13] systematically investigated the effect of the irrigant on the success rates of root canal retreatment. Although not a randomized controlled trial, it revealed interesting new findings on the effects of irrigants. Whilst a higher concentration of sodium hypochlorite (5% vs 2.5%) made negligible difference to treatment outcome, the additional use of other specific irrigants had a significant influence on success rates.[13] The use of higher concentration NaOCl solutions did not yield improved periapical healing, that is an observation consistent with previous clinical/microbiological findings.[59,60] Comparing 0.5% to 5.0% NaOCl solution for irrigation, it was found that concentration of solution, *per se*, did not appear to increase the proportion of teeth, either rendered culture-negative[59] or associated with periapical healing.[60] As iodine and sodium hypochlorite are both halogen-releasing agents and attack common key protein groups, the finding that the additional use of 10% povidone-iodine for irrigation had no additional influence on treatment success was as expected. Surprisingly, however, the additional use of 0.2% chlorhexidine solution for irrigation was found to *reduce* the success of treatment significantly.[13] This finding was in complete contrast to previous reports[61,62] on its equivalent or superior *in vivo* antibacterial efficacy when compared with sodium hypochlorite solution.

The use of chlorhexidine as a final irrigant following sodium hypochlorite irrigation had been recommended some years ago[63] and was justified on several grounds, including its substantivity in root dentine, relative lack of toxicity, and broad-spectrum efficacy. Not until recently has alternate irrigation with sodium hypochlorite and chlorhexidine solution raised serious concerns because of their interaction product, an insoluble precipitate containing para-chloro-aniline, that is cytotoxic and carcinogenic. Apart from mutually depleting the active moiety in the two solutions for microbial inactivation, the precipitate may cause persistent irritation to the periapical tissue, and block dentinal tubules and accessory anatomy, possibly explaining the observed lower success rate when chlorhexidine was used as an additional irrigant.

Ng et al.[13] also found that the additional use of EDTA had a profound effect on improving radiographically observed periapical healing associated with root canal treatment (OR = 1.6 [1.1, 2.1]). The observed synergistic effect of sodium hypochlorite and EDTA had been previously demonstrated in terms of bacterial load reduction[64] but not periapical healing. The long-term (≥ two years) outcome of their cases stratified by canal disinfection protocols of Sunqvist's group[65] did not support their microbiological findings. Given the complexity of their study design (clinical and microbiologic), their sample size was restricted to 11–15 teeth per group, limiting their outcome data. The synergistic effect of the two disinfectants has been attributed to the chelating properties of the sodium salts of EDTA and their roles have been reviewed by Zehnder.[66] EDTA solution assists negotiation of narrow or sclerosed canals by demineralization of canal surface dentine and helps removal of compacted debris from non-instrumented canal anatomy. It may also facilitate deeper penetration of sodium hypochlorite solution into dentin by opening dentinal tubules and removing the smear layer from the instrumented surface, and lastly may help detach or breakup biofilms adhering to root canal walls.[67]

Although the beneficial effects of irrigant agitation (manually or automatically) on irrigant penetration and flushing action have been repeatedly demonstrated in *in-vitro* studies,

a recent randomized controlled trial[68] failed to confirm a significant influence of ultrasonic agitation of NaOCl irrigant on periapical healing. However, their sample size was small (n = 41-43 per group), and the duration of follow-up was less than two years post-treatment.

Medicament

Previous treatment outcome studies have used a variety of root canal medicaments in the inter-appointment period instead of standardizing this variable. These mainly included calcium hydroxide, creosote, and iodine solutions. However, there is an absence of studies investigating the influence of this factor alone on treatment outcome.

The use of a mixture of calcium hydroxide and chlorhexidine has been tested based on the speculation that the mixture would be more effective against *E. faecalis*.

Root canal bacterial culture results prior to obturation

In the distant past, completion of root canal treatment by obturation would only be done after a negative culture test result, interpreted as confirmation of absence of bacteria in the root canal system. This practice has, unfortunately, fallen out of clinical favor because of the perceived predictability and good prognosis of root canal treatment without microbiological sampling. Sampling procedures are considered lengthy, difficult, inaccurate, requiring laboratory support, and having low benefit/cost ratio. However, a preobturation negative culture result can increase treatment success two-fold (Pooled OR = 2.1; 95% CI: 1.5, 2.9). One large study[69] in particular contributed to the demise of the culture test. Nevertheless, even their study showed a 10% difference in success in favor of the negative culture test when periapical disease was present. The outcome is even worse when a positive culture test result combines with the presence of a periapical lesion.

Numerous studies have evaluated the effect of different stages of root canal treatment on the intra-radicular microbiota, both qualitatively and quantitatively (Table 33-5). Some studies merely report positive culture tests, whereas others have identified and quantified intraradicular microbiota before and after various stages of treatment.

The effect of the steps up to and including the "mechanical preparation" of the canal(s) on the microbiota has been tested using only water or saline as the irrigant. Taken collectively, the studies show that negative cultures were achieved on a weighted pooled average in 31% of the cases (range 0–79%). When sodium hypochlorite (concentration range 0.5%-5.0%) irrigation supplemented the steps up to "mechanical preparation," the frequency of negative cultures immediately after debridement increased to a weighted pooled average of 52% (range 13%-95%) (Table 33-5).

Most studies report culture reversals during the inter-appointment period when active antimicrobial dressing is not used in the root canal system between appointments. The reversals may be due to regrowth of residual microorganisms or recontamination by microbial leakage around the access cavity dressing. When active inter-appointment antimicrobial intra-canal dressing is used, the frequency of negative cultures in the subsequent visit were achieved on average in 71% of cases (range 25%-100%) (Table 33-5).

Type of Persistent Microorganisms

Microorganisms in preobturation cultures have included: *Enterococcus*, *Streptococcus*, *Staphylococcus*, *Lactobacillus*, *Veillonella*, *Pseudomonas*, *Fusobacterium* species and yeasts.

Key; NaOCl = Sodium hypochlorite; CH = Calcium hydroxide; CP = Camphorated phenol; CMCP = Camphorated monochlorophenol; PP = paper point sample; r culture = culture test before obturation

Some studies have found no relationship between individual species and treatment failure but others have. While the overall failure rate for cases with positive cultures was 31%, that for teeth with *Enterococcus* species was 55% and for teeth with *Streptococcus* species was 90%.[70] In another study, good quality root canal treatment on 54 teeth with asymptomatic periapical disease gave an overall success rate of 74%, but teeth with *Enterococcus faecalis* only achieved a success rate of 66%.[71] These associations cannot be regarded as cause-effect and a relationship should also be sought between microbial diversity and treatment outcome. The success rate for teeth with no detected microorganisms was 80%, whereas for teeth with detected microorganisms in the canal before obturation was 33%.

A monkey-model study[72] used a 4- or 5-strain infection to test the effect of debridement and obturation procedures on outcome. When bacteria remained after chemo-mechanical debridement, 79% of the root canals were associated with non-healed periapical lesions, compared with 28% when no bacteria were found to remain. Combinations of several residual bacterial species were more frequently related to non-healed lesions than were single strains. When no bacteria were detected at the end of chemo-mechanical debridement, healing occurred independently of the quality of the root filling. In contrast, when bacteria were detected in the canal system, there was a greater correlation with non-healing associated with poor-quality root fillings than with technically well-performed fillings. In root canals where bacteria were found after removal of the root filling, 97% had not healed, compared with 18% for those root canal systems with no bacteria detected upon removal of root filling. The study emphasizes the importance of reducing bacteria below detection limits before permanent root filling in order to achieve optimal healing conditions for the periapical tissues. It also reinforces the view that obturation does indeed play a role when residual infection is present.

Regardless of the technique for obtaining a sample for culture, the use of a negative culture result to inform progress of treatment has a positive impact on treatment outcome. The association of specific species with treatment failure is not well established but the identity of the small group of species isolated from positive cultures is relatively constant and may hold answers to treatment resistance and failure. It would be advantageous if future technology could render quick, reliable, and affordable chair-side detection of residual microorganisms. It is, however, important to account for the other factors that influence root canal treatment outcome.

Root filling material and technique

The inter-relationship between the core root filling material, sealer, and technique for their placement complicates the investigation of the effect of root filling material and technique on treatment outcome. In previous studies on treatment outcome, the most commonly used core root filling material was gutta-percha with various types of sealer or gutta-percha softened in chloroform (chloropercha).[5] The sealers used may be classified into zinc oxide eugenol-based, glass ionomer-based and resin-based types.[5] Recently introduced materials such as Resilon®, SmartSeal®, and MTA have been adopted but not penetrated the market significantly, except for the use of MTA in apical surgery, immature apices, and perforation repair prior to obturation. In any case, there is no evidence to show that the nature of root filling material and the technique used for placement have any significant influence on treatment outcome.

Apical extent of root filling

Of the many intra-operative factors, this has been the most frequently and thoroughly investigated, presumably because it retrospectively offers a readily measurable outcome. In these previous studies, the apical extent of root fillings has been classified into three categories for statistical analyses. These are: (1) more than 2 mm short of radiographic apex (short); (2) 0-2 mm within the radiographic apex (flush); and (3) extended beyond the radiographic apex (long).[5] The apical extent of root filling was found to have a significant influence on the success rates of treatment, regardless of the periapical status.[5,13] Flush root fillings were associated with the highest success rates (Pooled success rate = 0.81; 95% CI: 0.76, 0.86), followed by short root fillings (Pooled success rate = 0.76; 95% CI: 0.71, 0.82), whilst long root fillings were associated with the lowest success rates (Pooled success rate = 0.66; 95% CI: 0.56, 0.75).

Most previous retrospective studies could not distinguish between the effects of apical extent of instrumentation *versus* the apical extent of obturation; however, the London Eastman study[13] was able to separate the effect of these two factors and found them both to independently and significantly affect periapical healing. The factors though did correlate with each other, consistent with the fact that canals are normally filled to the same extent as canal preparation. A single measure "apical extent of root filling," therefore, conveys information about both the extent of canal cleaning and obturation. The exception is when instruments or cleaning agents are overextended during canal preparation, without root filling extrusion.

Extrusion of cleaning, medication, or filling materials beyond the apical terminus into the surrounding tissues may result in delayed healing or even treatment failure, due to a foreign body reaction. Magnesium and silicon from the talc-contaminated extruded gutta-percha were found to induce a foreign body reaction, resulting in treatment failure.[73] An animal study has shown that large pieces of subcutaneously implanted gutta-percha in guinea pigs were well encapsulated in collagenous capsules, but fine particles of gutta-percha induced an intense, localized tissue response.[74] The inference that perhaps extrusion of large pieces of gutta-percha may not impact on periapical healing was not supported by data from previous studies.[5,13] The discrepancy may possibly be attributable to microbial contamination of the extruded gutta-percha in the clinical scenario.

Radiographic evidence of "sealer puffs" extruding through the main apical foramina and lateral/accessory canals has been pursued with vigor in the belief of its value as "good practice" by some endodontists. Their perception is that

this sign is a surrogate measure of root canal system cleanliness and ardently argue that healing would follow, albeit with some delay. The published evidence on the effects of sealer extrusion into the periapical tissues has been contradictory. Friedman et al.[75] found that extrusion of a glass ionomer-based sealer significantly reduced success rates. In contrast, Ng et al.[13] reported that extrusion of a zinc oxide eugenol-based sealer had no significant effect on periapical healing. The discrepancy may be attributed to the difference in sealer type and the duration of treatment follow-up. The radiographic assessment of the presence or resorption of sealer may be complicated by the radiolucent property of its basic components and the insufficient sensitivity of the radiographic method to detect small traces of it.[13] It is theoretically possible that, in some cases, the radiographic disappearance of extruded sealer may simply be due to resorption of the radio-opaque additive, barium sulphate, or its uptake by macrophages still resident in the vicinity.[73]

Extruded glass ionomer-based,[75] zinc oxide eugenol-based,[76] silicone-based[76] sealers or Endomethasone®[77] were not found to be resorbed/absorbed by periapical tissues after one year. Traces of calcium hydroxide-based sealer (Sealapex®) could still be detected after three years.[78] In the latter study, treatments were carried out on primary molar teeth and the canals were obturated with Sealapex® without gutta-percha. With longer duration of follow-up, complete resorption of extruded zinc-oxide eugenol-based sealers (Procosol®, Roth Elite®)[79] and a resin-based sealer (AH Plus, Dentsply/DeTrey, Konstanz, Germany)[78] was demonstrated in 69% and 45% of the cases after four and five years, respectively. Ng et al.[13] advanced two explanations for the difference between the effect of extruded core gutta-percha and zinc oxide/eugenol sealer; the latter is antibacterial and may kill residual microorganisms, whilst it is also more soluble and readily removed by host cells compared to gutta-percha.

Quality of root filling

Another much investigated parameter of obturation in retrospective studies has been the radiographic measure of "quality of root filling." The rationale for complete obturation of the root canal system is to prevent re-contamination by colonization from the residual infection or newly invading microorganisms. Both are putatively prevented by a "tight" seal with the canal wall and an absence of voids within the body of the material. Quality of root filling may, therefore, be regarded either as poor root filling technique or as a surrogate measure of the quality of the entire root canal treatment, since good obturation is reliant upon properly executed preliminary steps in canal preparation.

A recent systematic review[5] reported that the criteria for judging the quality of root fillings have not been well defined in previous studies.[18,41,55] An unsatisfactory root filling has been defined as "inadequate seal," "poor apical seal" or "radiographic presence of voids." Despite inadequacies in the criteria for judging root filling quality, satisfactory root fillings, judged by radiographs, were found to be associated with significantly higher success rates than unsatisfactory root fillings (Pooled OR = 3.9; 95% CI: 2.5, 6.2).[5]

Acute exacerbation during treatment

The aetio-pathogenesis of the inter-appointment "flare-up" or pain has not been precisely determined and several hypothetical mechanisms involving chemical, mechanical, or microbial injury to the periradicular tissues, as well as psychological influences, have been suggested as contributory to post-preparation pain and swelling. Although this factor has not been specifically studied in the context of periapical healing, acute "flare-ups" during treatment were found to have no significant association with periapical healing in two studies.[41,43] In contrast, the London Eastman study[13] found that pain or swelling occurred in 15% of cases after chemo-mechanical debridement, and significantly reduced success as measured by periapical healing. This interesting finding may be explained by the hypothesis that "flare-ups" were caused by extrusion of contaminated material during canal preparation. Such material may elicit a foreign body reaction or transient extra-radicular infection, resulting in treatment failure in some of these cases. Alternatively, acute symptoms may have been the result of incomplete chemo-mechanical debridement at the first appointment, leading to a shift in canal microbial ecology, favoring the growth of more virulent microorganisms and hence leading to post-preparation pain, as well as subsequent treatment failure. The exact biological mechanisms of failure in these cases remain obscure and warrant further investigation.

Number of treatment visits

The effect of number of treatment visits on periapical healing remains an on-going controversy, fuelled by debate between specialists and dentists arguing for single visit treatment on the basis of cost-effectiveness and business-sense against academics and some specialists arguing for multiple visit treatments, based on biological rationale. The main thread of argument for multiple visit treatments has been that primary debridement is not completely effective in eliminating all the adherent microbial biofilm[8] and the residual microorganisms may multiply and recolonize the canal system.[59,65] It is therefore considered desirable to use the inter-appointment period to dress the canal with a long-lasting or slow-release antimicrobial agent capable of destroying or incapacitating residual microorganisms, as well as to take the opportunity to gauge the initial periapical response before root filling. Calcium hydroxide has served in this capacity for many years because of its ability to dissolve organic tissue, kill microorganisms, detoxify antigenic material, and act as a slow release agent because of its low solubility-product in an aqueous environment. However, its antimicrobial ability has come under close scrutiny recently, with advocates suggesting that the material is not suitable for this purpose.[80] A final resolution to this debate is awaited based on robust clinical evidence. All the published randomized controlled trials found no significant influence attributable to number of visits, but they all lacked statistical power.[81-84]

The debate about the merits of single or multiple visit treatments will continue unabated given the respective strengths of the motivational drivers amongst the opposing groups. The issue may only be resolved by properly documented, large randomized controlled trials (currently unavailable) because unrecorded confounders (operator skill, biological or technical case complexity, and patient compliance) underlying the factor "number of treatment visits" would continue to play out their biasing effect in non-randomized studies. In any case, regardless of these debates, the long-standing clinical cornerstones for proceeding to obturation, that of absence of exudate, pus, odor and symptoms, should be followed.

Post Root Canal Treatment Restorative-related Factors

Effect of quality and type of restoration

The placement of a coronal restoration after root canal filling is the final step in the management of teeth undergoing root canal treatment and is shown to have a major impact on outcomes. Teeth with satisfactory coronal restorations were found to have significantly better periapical healing compared with those with unsatisfactory restorations (OR = 3.3; 95% CI: 1.1, 10.3).[5] The term "satisfactory restorations" has been defined variously as: (1) a restoration with no evidence of marginal discrepancy; (2) no evidence of marginal discoloration; (3) no evidence of recurrent caries; and (4) absence of a history of decementation.[18,85]

Given that one of the roles of coronal restorations is to prevent post-operative root canal re-infection, the criteria for unsatisfactory restoration given by Hoskinson et al.[18] and Ricucci et al.[85] could not infer coronal leakage when the inner core was still intact. Consequently, the London Eastman study[13] adopted a different classification and definition for unsatisfactory restorations in order to depict obvious and potential coronal leakage more effectively. The two groups of unsatisfactory restorations were defined as those with: (1) obvious signs of exposed root filling; and (2) potential leakage indicated by marginal defects and history of de-cementation. It is perhaps this strategy that contributed to the finding of an extremely profound effect (OR = 10.7; 95% CI: 3.7, 31.5) of this factor on the outcome.

A number of investigations have been performed based on comparisons between the types of post-root canal treatment restorations, including: permanent *versus* temporary restorations;[13,55,75] crown *versus* plastic restorations;[13,41,55,75] presence *versus* absence of posts;[13,75] and non-abutment *versus* abutment.[13,41] Teeth that had been permanently restored were associated with significantly higher success rates than their temporarily restored counterparts in some studies[55,75] but not in others.[13,86] The type of permanent restoration[13,41,55,75] was found to have no significant influence on the outcome of treatment.

It has often been recommended that it would be wise to provide a sub-seal over the root filling in case of loss of a permanent or temporary restoration; the sub-seal would be glass ionomer (GIC) or zinc oxide eugenol cement. The placement of a GIC or zinc oxide eugenol (IRM®) cement lining coronal to the gutta-percha filling and underneath the permanent core in order to provide additional antibacterial coronal seal was found to have no beneficial effect on treatment success in a prospective study.[13] However, this may simply reflect a good definitive coronal seal.

In summary, it is advantageous that an adequate restoration should be placed after root canal treatment to prevent subsequent microbial recontamination. Therefore, the provision of a good quality coronal restoration, regardless of type, should be considered the final part of the root canal treatment procedure following obturation.

Use of root treated teeth as abutments for prostheses and occlusal contacts

Mechanical stress on the restoration/tooth complex is a function of the role of individual teeth in the occlusal scheme. The pattern of occlusal loading, both in static and dynamic occlusion, is dictated by whether the teeth are involved as single units or abutments (bridge/denture) and whether they have holding or guiding contacts. It is reasonable to expect that bridge and denture abutments may be placed under unfavorable loads, as may last-standing teeth in the dental arch. Such teeth may, therefore, be expected to have lower success rates through development of cracks and fractures due to fatigue. This observation has been confirmed for teeth functioning as bridge abutments compared with those restored as individual units following root canal treatment.[41]

Summary of Factors Influencing Periapical Healing Following Non-surgical Root Canal Treatment

The factors having a major impact on periapical health following root canal treatment were:

- presence and size of periapical lesion;
- patency at the canal terminus (achieving patency significantly increased the odds of success by 2-fold)[13];
- apical extent of chemomechanical preparation in relation to the radiographic apex;
- outcome of intra-operative microbial sample and culture test;
- iatrogenic perforation (if present, the odds of success was reduced by 30%)[13]
- quality of root canal treatment judged by the radiographic appearance of the root filling;
- quality of the final coronal restoration.

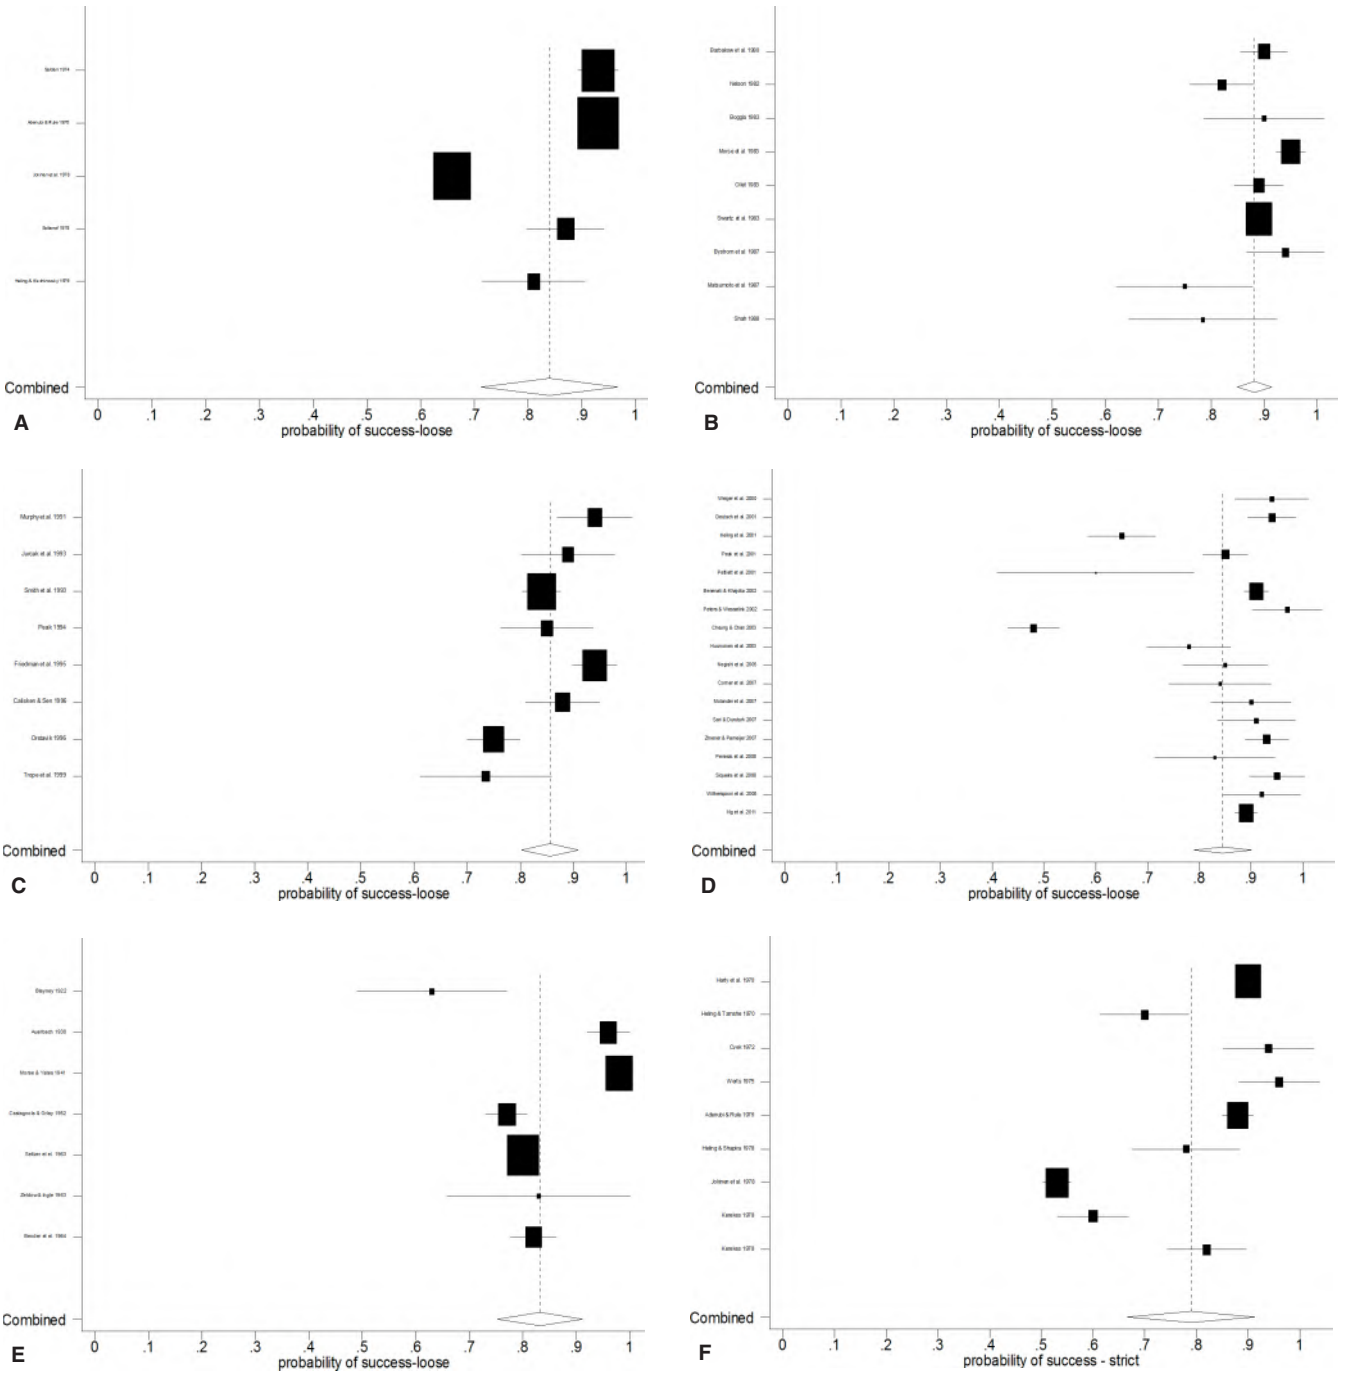
The factors having minimal effect on root canal treatment outcome were:

- age of patient;
- gender of patient;
- tooth morphological type; and

- specific root canal treatment protocol/technique (preparation, irrigation and obturation material and technique).

The improvements in techniques of mechanical and chemical canal preparation have not resulted in increases in success rates for both primary root canal treatment and secondary root canal retreatment over the last century (Figure 33-4). This fact may be explained by the observation that currently available techniques may be ineffective in eliminating the infection in the apical canal anatomy, resulting in ongoing interaction between the residual infection, root filling material and host defense. Such continued interaction probably plays a definitive role in determining the final outcome.

It is notable that all the factors having a strong influence on periapical health after root canal treatment are associated in some way with root canal infection. Further improvements in root canal treatment outcomes may therefore be achieved by understanding the nature of the root canal infection (especially apically), the manner in which the microbiota is altered by treatment and the nature of its interaction with the host.



Conitnued

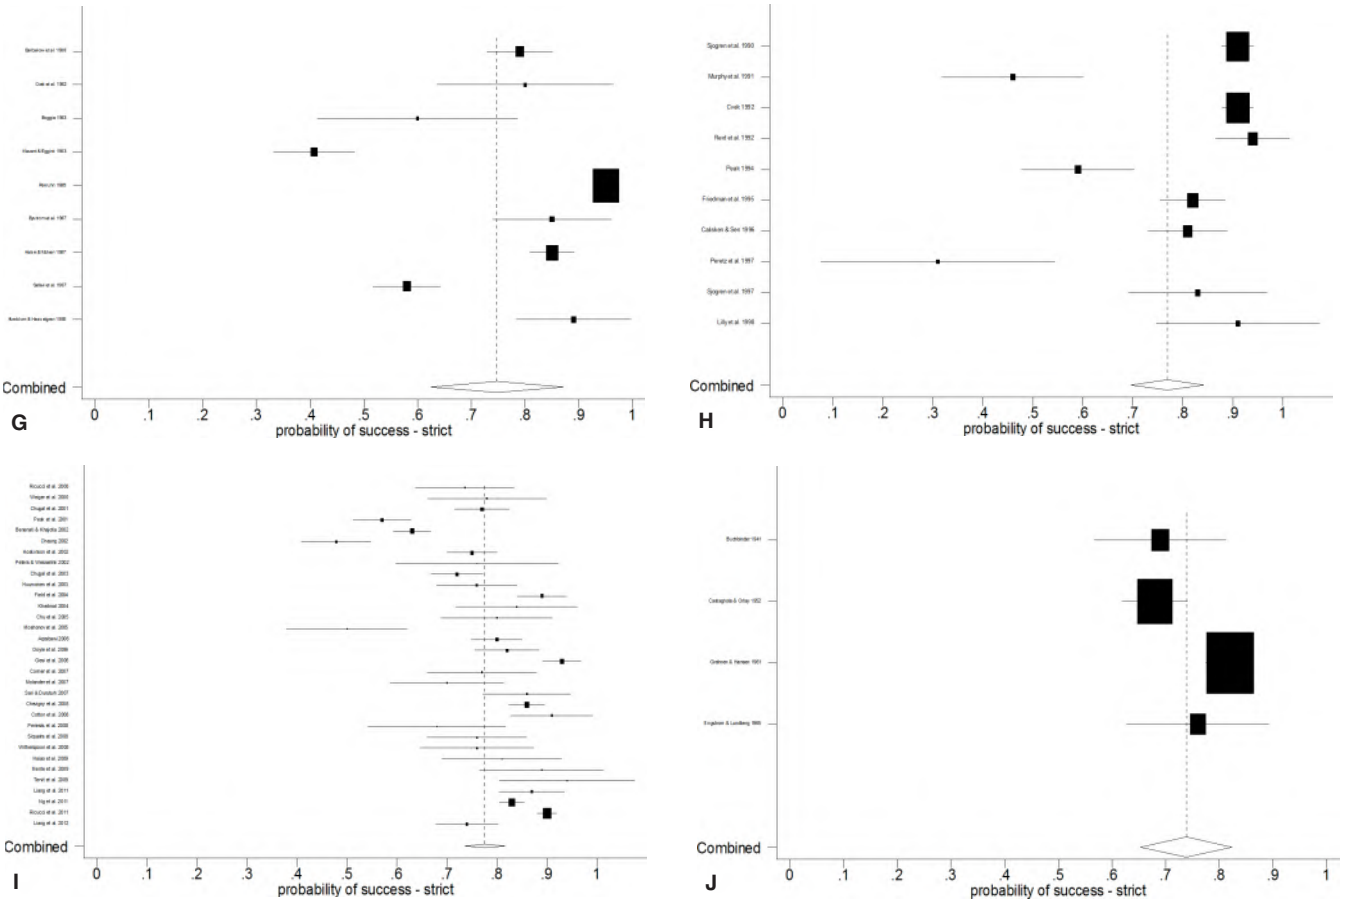


FIGURE 33-4 (Continued) ***A-J.*** Forest plots showing pooled and individual study's probability of periapical health for teeth undergoing root canal treatment by "decade of publication" and "criteria for success."

Factors Affecting Tooth Survival Following Root Canal Treatment

A systematic review and meta-analysis has shown that 93% of root-treated teeth survive at two years post-operatively; but this survival reduced to 88% at 10 years following treatment (Figure 33-5). The common reasons for such tooth loss were due to extractions precipitated by problems of endodontic origin; tooth/root fracture; or restoration failure.[87,88] Consistent with the studies on periapical healing, the prognostic factors for survival of teeth as the outcome measure may be divided into patient-related, intraoperative-related and restorative-related factors.

Patient-related Factors

Medical conditions

Ng et al.[88] found that teeth in patients suffering from diabetes or receiving systemic steroid therapy had a higher chance of being extracted after treatment. The negative influence of diabetes on tooth survival is consistent with the report by Mindiola et al.,[89] whilst the influence of steroid therapy had never been reported previously. It may be argued that patients suffering from diabetes were more susceptible to periodontal disease[90] or had a lower success rate of root canal treatment,[91] that in turn could be the reason for tooth extraction. They, however, reported that over 50% of such teeth were extracted due to persistent pain. Some of these observations may be explained by the presence of neuropathy, a debilitating painful complication of diabetes.[92] It was further interesting to note that systemic steroid therapy is often prescribed to control such chronic pain.[93-95]

Tooth morphological type and location

Tooth types may vary in susceptibility to tooth fracture, a common reason for tooth loss after treatment. Ng et al.[87] found that tooth type had significant influence on survival, with non-molar teeth associated with significantly higher chance of survival than molar teeth (Pooled OR = 1.4; 95% CI: 1.1, 1.6). Maxillary premolars and mandibular molars were found to have the highest frequency of extraction, with tooth fracture being the most common reason. The observation is consistent with previous reports on fracture incidence of maxillary premolars and mandibular molars. These data do not confer any insight on the timing of crack origin or its propagation, merely that it was the decisive factor in failure; the cracks/fractures are likely to have pre-dated the root canal treatment.

The factors "proximal contacts" (Pooled OR = 2.6; 95% CI: 1.8, 3.7) and "terminal (last standing) teeth" were found to affect tooth survival significantly,[87,88] but were significantly

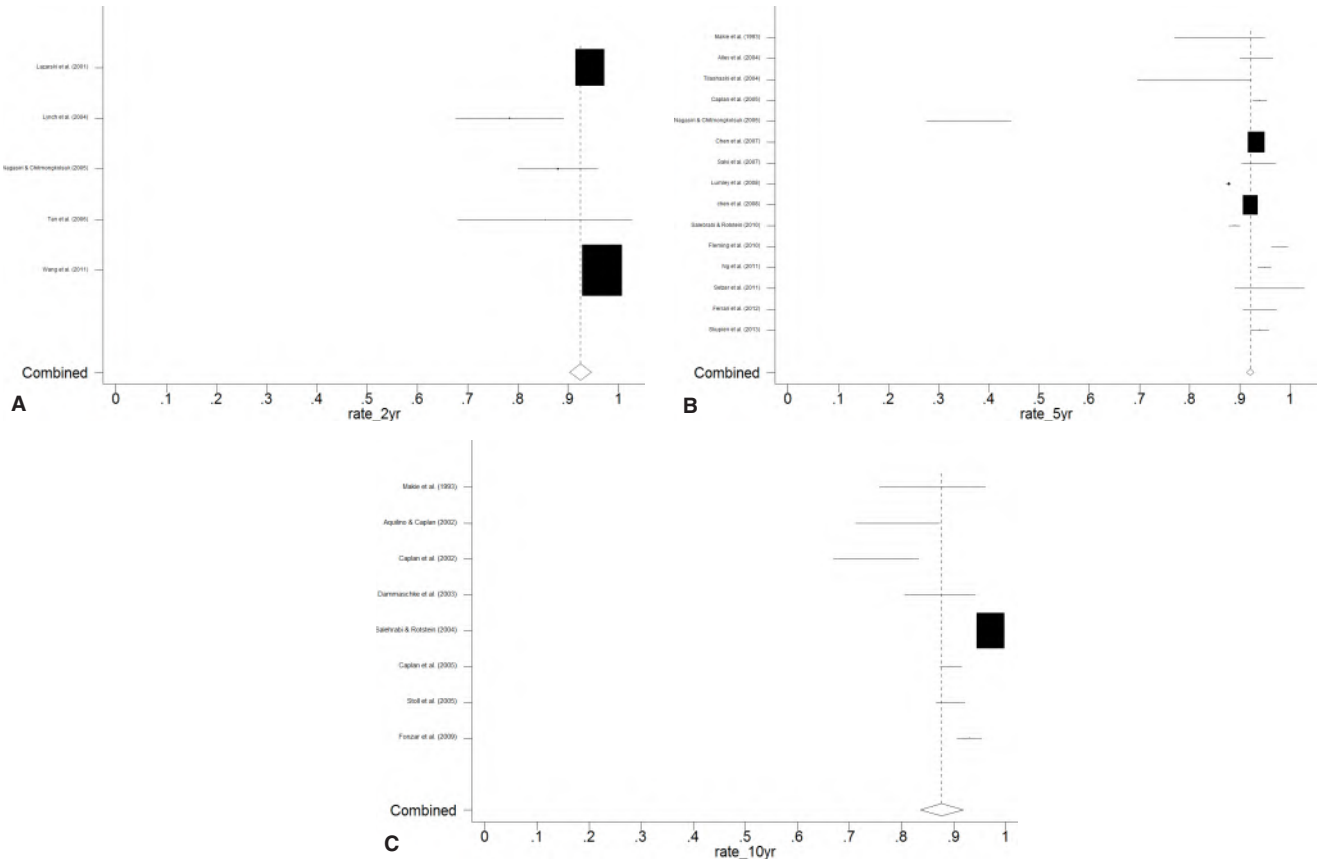

FIGURE 33-5 Forest plots showing pooled and individual study's probability of ***A.*** Two-year (Pooled probability = 0.93; 95% CI: 0.90, 0.95); ***B.*** Five-year (Pooled probability = 0.92; 95% CI: 0.91, 0.93); and ***C.*** 10-year (Pooled probability = 0.88; 95% CI: 0.84, 0.92) survival of teeth undergoing root canal treatment.

correlated to "molar teeth." Most of the extractions of terminal teeth, or teeth with one or less proximal contact, were due to tooth fracture.[88]

The observation may be explained by the unfavorable distribution of occlusal forces and higher non-axial stress on terminal teeth and those with less than two proximal contacts. Other possible reasons explaining their higher rate of loss are that: (1) failure of root canal treatment in a terminal tooth may be accepted more willingly because of little perceived esthetic value; and (2) clinicians may be less likely to offer further treatment on terminal molar teeth due to difficult access. It therefore seems important to ensure favorable distribution of occlusal forces when designing restorations for molar teeth, teeth with one or less adjacent teeth, and terminal teeth following retreatment.

Pre-operative conditions of teeth

The presence of pre-operative periapical lesions (the most significant prognostic factor for endodontic success) was found to have no significant influence on tooth survival.[88] On the other hand, pre-operative periodontal probing defects of endodontic origin, pre-operative pain, and pre-operative sinus tracts were found to reduce tooth survival.[88] These observations are consistent with a previous report that the mere presence of a periapical radiolucency was not a sufficient reason for dentists and patients to seek active treatment.[96] The negative impact of pre-operative pain on survival outcome highlights the importance of accurate pain diagnosis. In some instances, the pain may have been of non-endodontic origin, and therefore would persist after treatment.[19] In other instances, pre-operative pain of endodontic origin may persist following treatment, as a result of peripheral or central sensitization. Therefore effective pain diagnosis and management for patients presenting with pre-operative pain are crucial.

The presence of pre-operative cervical resorption and perforation were also found to significantly reduce tooth survival.[88] This was as expected because tooth fracture and re-infection due to leakage are likely sequelae in such cases. In the presence of re-infection, clinicians are more inclined to suggest extraction due to the intuitive perception of poor long-term prognosis of such teeth.

Treatment-related Factors

Amongst all the intra-operative factors, "failed to use dental dam,"[97] "lack of patency at apical foramen,"[88] and "extrusion of gutta-percha root filling"[88] were found to reduce tooth survival. It was found that extraction of teeth with the latter two conditions was more likely to be due to persistent endodontic problems as both of them were also prognostic

factors for treatment success based on periapical healing. In the presence of persistent problems and knowing that the treatment objective of cleaning to the canal terminus could not be achieved, patients and dentists may be more likely to opt for extraction sooner than later.

Restorative-related Factors

Protection of teeth with crowns or cast restorations had not been found to influence treatment success based on periapical healing although placement of good cores had. In contrast, placement of crowns or cast restorations was found to improve significantly tooth survival (Pooled OR = 3.5; 95% CI: 2.6, 4.7).[87,88,98] This suggests that crowns and cast restorations help prevent tooth fracture, whilst the mere placement of a satisfactory core would be sufficient to prevent re-infection after treatment. Unfortunately, these studies were not able to investigate the inter-relationship between tooth morphological type, the extent of tooth tissue loss after treatment and the type of final restoration.

On the basis of laboratory[99] and clinical findings,[100] posterior teeth with compromised marginal ridges (mesial or distal), together with evidence of heavy occusal loading evidenced by faceting, may benefit from cast cuspal coverage restorations. The restoration design should attempt to preserve as much remaining tooth tissue as possible; the implication is that the so-called non-esthetic but technically demanding partial veneer onlays and partial coverage crowns would be the restorations of choice for root-treated teeth. In anterior teeth, the missing tooth tissue may often be replaced with adhesive restorative material. A crown is only indicated when the remaining tooth structure is compromised. With the advancement of adhesive dentistry, full crowns will probably be fabricated to replace existing old deficient crowns while more conservative cuspal protecting restorations will be used to restore endodontically treated teeth.

The use of cast post and cores for retention of restorations was also found to reduce tooth survival.[87,88] It may be speculated that the presence of posts has different effects on anterior and posterior teeth as they are subjected to different directions and amount of occlusal force. It was reported that only 12% of the extracted teeth with cast post and cores were incisors or canines.[88] Therefore, the inference is that the use of such retention should be particularly avoided in premolar and molar teeth. Alternative treatment options should therefore be considered for molar or premolar teeth lacking sufficient tooth structure. In contrast, a randomized controlled trial[101] revealed that fiber-post retention significantly improved survival of root-treated premolars restored with single-unit metal-ceramic crowns, regardless of the extent of residual coronal dentin with the exception of those teeth with four coronal walls remaining.

Ng et al.[88] observed that teeth functioning as prosthetic abutments had poorer survival but the number of teeth (n = 94) functioning as abutments was too small in their sample to demonstrate a statistically significant effect. As before, the explanation may reside in the excessive and unfavorable distribution of occlusal stresses on abutment teeth.

Summary of Factors Influencing the Survival of Teeth Following Root Canal Treatment

The conditions found to significantly improve tooth survival following root canal treatment were:

- non-molar teeth;
- teeth with both mesial and distal adjacent teeth;
- teeth not located distal-most in the arch;
- teeth (molar) with cast restorations after treatment;
- teeth not requiring cast post and core for support and retention of restoration;
- teeth not functioning as abutments for fixed prostheses;
- absence of pre-operative deep periodontal probing defects, pain, sinus tract, or perforation; and finally,
- achievement of patency at canal terminus and absence of root filling extrusion during treatment.

Impact of Root Canal Treatment on Quality of Life

The impact of root canal treatment on oral health-related quality of life of patients has been evaluated using the short form (OHIP-14) or modified version (OHIP-17) of Oral Health Impact Profile (OHIP-14). The distinctly positive impact of root canal treatment was apparent, regardless of cultural background of the patient group and the measure used. As expected, physical pain, psychological discomfort (feeling tense), and disability (difficulty in relaxing) were the most improved domains following treatment.

OUTCOME OF NON-SURGICAL RETREATMENT

When root canal treatment fails to resolve periapical disease, it is often considered appropriate to retreat the tooth using conventional approaches first, especially when the previous treatment is technically deficient. This requires removal of the previous root-filling material and any other material placed for restorative reasons. Correction of any iatrogenic procedural errors may also be required, if possible. All material must be removed in their entirety to ensure delivery of antimicrobial agents to all surfaces of the root canal dentin. The periapical healing rates of root canal retreatment are generally perceived to be lower, compared to primary treatment because of:

1. obstructed access to the apical infection; and/or
2. a potentially more resistant microbiota.

The outcomes from a range of studies show that the mean weighted success (healed) rate is 66%, about 6% lower than in the case of primary treatment on teeth with apical periodontitis (Figure 33-6).[13,102] On the other hand, the survival rate of

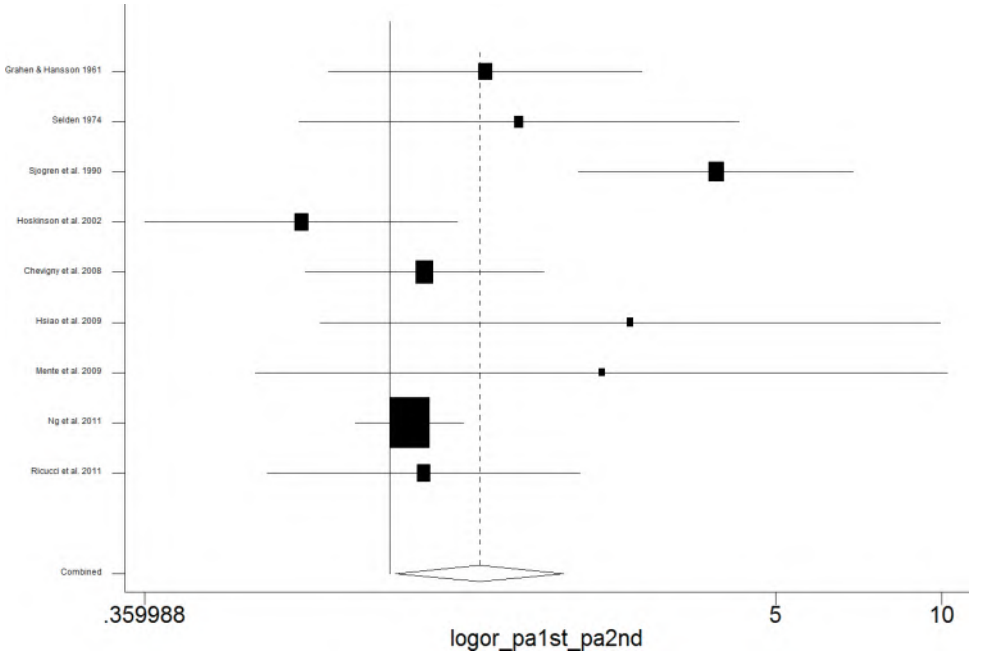

FIGURE 33-6 Forest plot showing pooled and individual study's odds ratio of periapical health for teeth with pre-operative periapical radiolucency undergoing primary root canal treatment versus root canal retreatment. (Pooled OR = 1.5; 95% CI: 1.0, 2.1.)

treatment. The differences between the microsurgical and traditional approaches may therefore have been exaggerated in their review.[107]

The authors' unpublished meta-analyses,[112] stratified by duration, following treatment revealed the pooled probability of success based on complete healing plateaued after two years post-operatively: being 51% (95% CI: 42%, 60%) after six months; 68% (95% CI: 63%, 73%) after 12 months; 76% (95% CI: 67%, 84%) after 24 months; 74% (95% CI: 52%, 95%) after 48 months; and 74% (95% CI: 66%, 82%) after more than 48 months. It is therefore advisable to follow-up periapical surgery cases for a minimum of two years; and better still for up to four years.

The potential prognostic factors for surgical endodontics may be classified into patient-related factors, surgical treatment-related factors, and restorative-related factors.

Patient-related Factors

Previous reports on the influence of patient's age and sex on root-end surgery outcome have been inconsistent. Meta-analysis of pooled data and the authors' data revealed minimal influence attributable to this factor.[112] As expected, most studies restricted their surgical cases to healthy patients. Only two studies had included both healthy, as well as patients with systemic medical conditions, and found no significant influence attributable to this status.[112,113] Tobacco smoking habits, that have a negative impact on the regenerative potential of human adult stem cells,[114] has been found to have no significant influence on root-end surgery outcome.[113,115,116]

The majority of the root-end surgery outcome studies published up to early 1990s had restricted their cases to single-rooted anterior teeth. Outcome data on posterior teeth had only become available to a greater extent within this millennium. The reported higher success rates associated with anterior (compared to posterior) teeth[115,117,118] or maxillary (compared to mandibular) teeth[119] could be attributed to better surgical access. As an exception, maxillary lateral incisors were often associated with scar tissue healing.[23,120] This healing outcome has been attributed to the palatal curvature of the root apex, that may allow the disease process to perforate the palatal cortical plate more readily, ultimately resulting in a "through and through" defect after surgical access. However, these observations have not been consistently reported. Meta-analyses of pooled published data revealed tooth type had minimal effect on root-end surgery outcome.[112]

The extent and nature of the pre-operative periapical disease may have a profound influence on periapical surgery outcome, and may be characterized by the clinical (swelling, sinus, pain) and radiographic (size of radiolucency) presentation, extent of bone defect, and histopathological diagnosis of the biopsied tissue. The extent of pre-operative periapical radiolucency (or bone defect) has a strong negative impact on root-end surgery outcome. A number of reasons may be advanced to explain this observation. The diseased tissues in larger periapical lesions may be more difficult to remove in their entirety, and require longer duration for complete bone repair; there may also be a greater likelihood of healing by secondary intention (fibrous tissue repair) when both buccal and palatal cortical plates are perforated. In contrast,

teeth having undergone root canal retreatment has been found to be similar to that for primary root canal treatment.[88]

The factors affecting outcomes of periapical health and tooth survival, following root canal retreatment, were otherwise identical to those affecting primary root canal treatment. Of the potential prognostic factors unique to retreatment cases, the main one showing significant influence on outcome after treatment was the ability to remove or bypass preexisting root filling material or separated instrument during retreatment. This is understandable because it would have a direct impact on the ability to achieve canal patency at the terminus.[13] For more details, see Chapter 23.

OUTOME OF SURGICAL ENDODONTICS

Factors Affecting Periapical Health or Healing Following Periapical Surgery and Root-end Filling

There are a number of published systematic reviews on the prognostic factors for periapical surgery involving apical filling.[38,103-111] The major limitations of these pooled data sets are the uncontrolled duration of follow-up after treatment and that "loose" radiographic criteria had been adopted. An (as yet) unpublished meta-analysis, by the authors,[112] using data from the studies listed in Table 33-6 revealed that the weighted pooled probability of success defined by complete radiographic healing was 67.5% (95% CI: 62.9%, 72.0%) following periapical surgery with root-e FIGURE 33-7 nd cavity filling (Figure 33-7). The forest plot trend in Figure 33-7 shows higher success rates in more recent studies. This observation is consistent with the much higher pooled success rate of 92% (95% CI: 86%, 95%) revealed in the meta-analysis of prospective outcome data of surgical endodontic treatments performed by a so-called "modern" technique (*using magnification, root-end resection with minimal or no bevel, root-end cavity preparation with ultrasonic tips, and modern root-end root canal filling*).[109,110] In congruence with the above finding, Setzer et al.[107] reported that the pooled success rate of treatment using a microsurgical approach (94%; 95% CI: 89%, 98%) was more favorable than traditional root-end surgery (59%; 95% CI: 55%, 63%). However, the studies included in the latter meta-analysis differed in design, case selection, duration of follow-up, and the provision of pre-operative non-surgical

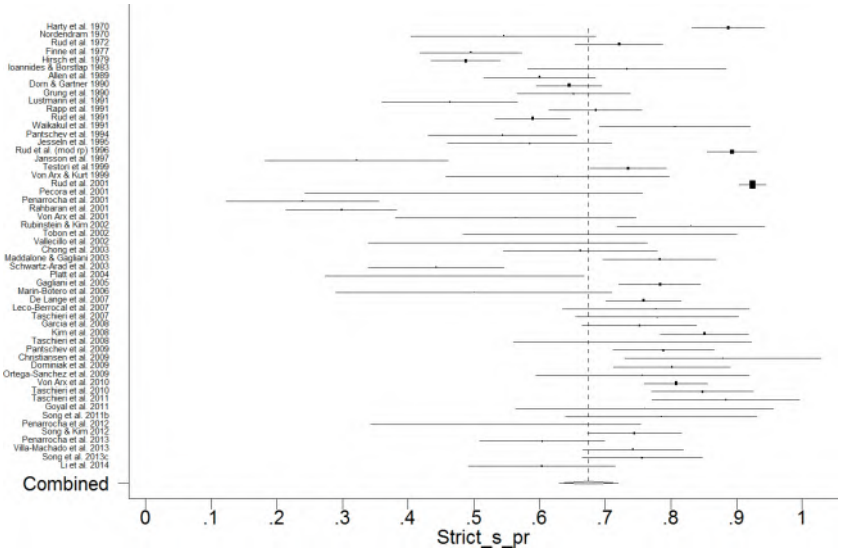

FIGURE 33-7 Forest plot showing pooled and individual study's probability of complete periapical healing following apical surgery.

removal of diseased tissue from a small apical lesion may lead to enlargement of the bony crypt to gain access, resulting in more complete eradication of such tissue.

A further problem of the extent of bone defect manifests when bone absence extends along the root face as a root dehiscence, called an apical-marginal defect; under normal circumstances, the root is expected to have connective tissue attachment to the overlying mucosa. If these soft tissues are detached during flap reflection, healing may be accompanied by apical migration of the junctional epithelium along the bone-denuded root surface and into the periapical bony crypt,[121] this would present radiographically as incomplete, or scar tissue, healing. Such types of healing outcomes have been reported often in teeth with apical marginal defects.[116,122] It has been proposed that such an attachment may be more susceptible to dissemination of marginal inflammation to the apical area,[108] although the periodontal literature does not accord with this view.[123]

The presence of swelling, sinus tract, or symptoms at the time of surgery has been found to be a significant outcome predictor.[116,124] It has been speculated that these presentations signify a (sub)acute phase of disease with possible "extra-radicular" infection, complete eradication of which may be difficult.[111]

The taking of a routine biopsy during root-end surgery to establish a definitive diagnosis has become an accepted standard of care in modern endodontic surgery. The histopathological diagnosis of the biopsied periapical lesion is frequently found to be a "granuloma" or "cyst."[125] Both pathological entities involve inflammatory responses to intra- or extra-radicular infection. Once the pathological tissues have been enucleated and the source of infection controlled, the nature of the pre-existing diseased tissue is unlikely to influence the healing process after its enucleation and root-end surgery.[112,125-127]

The quality of previous treatment, including the coronal restoration and root filling, as well as history of non-surgical retreatment or periapical surgery have been reported to influence surgical outcome. An adequate coronal restoration is considered a prerequisite for teeth undergoing periapical surgery. Only 26% (n=21/81) of the studies, reviewed by the authors, provided information about the restorative status.[112] The significant impact of the pre-operative quality of coronal restoration was reported in one study.[128]

A satisfactorily disinfected and obturated root canal system has also been considered to be a prerequisite for periapical surgery.[129] However, one of the key indicators for surgery includes the scenario where the root canal system could not be accessed to its apical terminus. Therefore, investigation of the effect of this factor may be limited by potential confounders. A number of studies that used multi-variable regression models to control confounding revealed no significant influence of the density[112,128] or extent[112,113,130] of pre-existing root filling. In contrast, the Toronto study[131,132] reported that a pre-operative root-filling of adequate length was associated with an increased odds of disease-persistence after surgery compared with those teeth with short or over-extended pre-operative root fillings, even after adjusting for potential confounding. It is, however, worth noting that in this study a root-end filling was *not* placed in 14% of the cases. It may be speculated that the apical extent of the pre-existing root filling may have no prognostic value as long as a retro-cavity is prepared and filled. Taking the argument further, it is technically even possible, circumstances allowing, to perform root canal treatment from the root-end using files or ultrasonic instruments of adequate length, coupled with a suitable gutta-percha obturation technique.[133] (See Chapter 34 and Figures 34-14 and 34-15)

Root-end surgery performed to an optimal standard may still be associated with persistent periapical disease because of residual intra-radicular infection, new intra-radicular infection, established through coronal leakage or root fracture, or residual extra-radicular infection. Repeat surgery adopting a different strategy or approach is therefore liable to succumb to the same failure, explaining the consistently reported poorer prognosis in such cases.[111,112,134]

Surgical Treatment Factors

The influence of adopting technical advances on surgical outcomes has been extensively investigated since 1990s, including the effect of using enhanced magnification and illumination, micro-surgical instruments and techniques, as well as the root-end filling materials.

Magnification and illumination of the surgical site, using an operating microscope, may allow better appreciation of the periapical tissues, bony crypt and root surface, facilitating more effective management of the crypt and root end. Meta-analysis[112] of data available from two observational studies[113,118] showed that magnification was associated with a significantly higher success rate. Meta-analyses[38,103,110] comparing the type of magnification (magnifying loupes, surgical microscope, or endoscope) showed no significant impact on root-end surgery outcome except an updated meta-analysis by Tsesis et al.[109] The latter suggested that using a surgical microscope, or endoscope, achieved significantly better outcomes than using loupes. However, the observation did not hold true when the analyses were stratified by root-end filling material.

Other contemporary procedures in root-end surgery include the use of back-exhausted air-rotor handpiece for osteotomy and apicectomy, minimal bevel root-end resection, root-end cavity preparation with ultrasonic retro-tips, and modern root-end filling material.

The effect of osteotomy technique on root-end surgery outcome has not been reported previously. The authors' meta-analysis[112] revealed no obvious difference in success rates using the air-rotor or air-motor handpiece. Investigation of the effect of surgical crypt size has been limited by its significant correlation with the pre-osteotomy extent of the lesion.[112,132,135] Therefore, the influence of the amount of bone removal cannot be determined.

Contemporary root-end management with minimal bevel resection and ultrasonic retro-tip cavity preparation (*conventionally with 3mm in depth*) has consistently been associated with higher success rates when compared with the traditional approach (*high respective angle, root-end cavity preparation with bur*).[107,112,113,118,119,136] The better outcome is attributed to more predictable and effective root-end management (capturing apical canal complexities, root-end preparation, and root-end filling).

Other contemporary root-end management techniques include retrograde root canal treatment and the "through and through" surgical approach (orthograde root canal treatment combined with a surgical approach in the same procedure). The latter approach is indicated when exudation into the root canal system cannot be controlled by non-surgical means. Recent unpublished study[112] revealed that the retrograde root canal treatment was associated with the highest success rates (59%, 88%), followed by the conventional ultrasonic retro-preparation approach (53%, 80%), and then the through and through approach (48%, 74%), based on both strict or loose criteria, respectively.

Exploration of the literature on retro-cavity and retro-filling techniques reveals the interesting observation that periapical surgery prior to the mid-1990s only involved root resection without any form of retro-preparation or filling. Periapical surgery adopting a traditional root-end filling technique conferred no advantage to healing when the orthograde root-filling was judged to be satisfactory.[120,135,137-140] In contrast, a randomized controlled trial revealed that teeth treated with "smoothing" of the orthograde gutta-percha root filling after apicectomy (52%) were associated with a significantly lower 1-year healing rate (loose criteria) than those teeth treated with root-end cavity and filled with MTA (97%).[141] The absence of a root-end filling has also been implicated as one of the most common possible causes of failure in periapical surgery.[142]

The types of retro-filling materials used in the studies reviewed by the authors [112] included: amalgam, super ethoxybenzoic acid (super-EBA®), zinc oxide eugenol based intermediate restorative material (IRM®), gutta-percha, composite resin, glass ionomer cement (GIC), and Cavit®. Investigation of the influence of root-end filling material may be confounded by the root-end management approach in observational studies. For example, amalgam had mostly been used in studies adopting a traditional (class 1) root-end cavity. On the other hand, flowable composite (Retroplast™), in combination with a dentin bonding agent,[143] exclusively used a saucer-shaped retro-cavity, designed to increase the surface area for adhesion, that would be enhanced by polymerization shrinkage towards the dentin surface rather than away from a canal wall. The Retroplast™ approach yielded significantly better periapical healing (73%) in a randomized controlled trial compared with GIC (31%).[144] Other randomized controlled trials have found no significant difference in the success rates of periapical surgery when contemporary root-end filling materials were compared: MTA (92%, 92%)[145,146] *vs* IRM (86%, 87%)[145,146], respectively; MTA (96%) *vs* super-EBA (93%)[147]; IRM (91%) *vs* super-EBA (82%)[148]; and IRM (85%) *vs* gutta-percha with AH plus sealer (90%)[149]. Of note, all the above trials had only followed up their cases for one year (with one exception)[145] and also adopted loose criteria for determination of periapical healing outcome. The authors' meta-analyses[112] pooling data from both observational studies and randomized controlled trials concurred with the above findings. Use of amalgam as a root-end filling material was associated with a significantly lower success rate than using IRM or super-EBA, whilst no significant difference was found in the success rate when MTA, super-EBA, IRM or composite resin were used.

The use of hemostatic agents has been reported in the majority of previous studies, including adrenalin-impregnated cotton pellets, epinephrine-containing local anesthetic saturated pellets, ferric sulfate, bone wax, thrombin, calcium sulfate, gelatin-based foam, oxidized cellulose, or bovine-derived collagen. Wang et al.[131] found their use did not have significant influence on periapical healing outcomes, while the effect of type of hemostatic agent had not been investigated.

The use of guided tissue regeneration techniques, such as membranes and/or grafting material, has been advocated

for cases with "through and through" defects (missing buccal and palatal cortical plates) but there are inconsistent reports on their benefits. The authors' meta-analyses[112] did not reveal a significant influence of such approaches on the periapical healing outcome.

Post-operative Factors

The influence of post-operative factors such as the presence of signs and symptoms post-surgery had only been investigated in two studies.[112,135] Rud et al.[135] reported that sero-hemorrhagic exudate under the flap, or an abscess present post-surgery, was not significantly associated with periapical healing. However, another study[112] revealed the presence of tooth tenderness to percussion at the suture removal appointment was associated with a significantly reduced chance of ultimate periapical healing.

Antibiotics had been prophylactically prescribed post-surgery to prevent wound infection but both a randomized controlled trial[146] and a meta-analysis[111] of observational data concluded that there was no beneficial effect.

The influence of the quality of coronal restoration at review has only been investigated by a few studies, a contrast to the literature on non-surgical root canal treatment outcome. Nevertheless, placement of a permanent restoration post-surgery or teeth with satisfactory coronal restoration at recall was associated with better outcome.

Summary of Factors Influencing Periapical Healing Following Root-end Surgery

The factors having a major impact on the outcome of periapical surgery with root-end cavities and fillings in teeth with pre-operative periapical radiolucencies based on the authors' meta-analyses[112] are:

- small (≤ 5 mm) *versus* large (> 5 mm) periapical lesion (risk ratio = 1.2; 95% CI: 1.1, 1.3);
- periapical lesion involving one *versus* both cortical plates (risk ratio = 1.2; 95% CI: 1.0, 1.5);
- absence *versus* presence of previous surgery (risk ratio = 1.2; 95% CI: 1.1, 1.3);
- with *versus* without the use of magnification during surgery (risk ratio = 1.5; 95% CI: 1.3, 1.8);
- root-end resection with minimum *versus* obvious bevel (risk ratio = 1.3; 95% CI: 1.2, 1.4);
- use of ultrasonic tip versus bur for retro-cavity preparation (risk ratio = 1.3; 95% CI: 1.2, 1.4); and
- use of retro-filling material with mineral trioxide aggregate cement (MTA), super ethoxybenzoic acid cement (EBA), or intermediate restorative material (IRM) *versus* amalgam. The use of MTA resulted in a similar outcome to SuperEBA™ (risk ratio = 1.0; 95% CI: 0.99, 1.1) or IRM® (risk ratio = 1.1; 95% CI: 0.98, 1.1), whereas SuperEBA™ and IRM® were associated with significantly higher chances of success than amalgam (risk ratio = 1.2; 95% CI: 1.1, 1.3) as the retro-filling material.

The pre-operative presence of signs and/or symptoms (risk ratio = 1.2; 95% CI: 1.1, 1.3)[113], periodontal status (risk ratio= 2.1; 95% CI: 1.1, 3.8)[130] and quality of the coronal restoration (risk ratio= 1.6; 95% CI: 1.2, 2.1)[113] have also been revealed as significant prognostic factors by individual studies.

The factors having minimal effect on surgical re-treatment outcome[112] were:

- age of patient;
- gender of patient;
- general health of patient;
- tooth type;
- quality of the pre-existing root canal filling judged radiographically, and
- histological diagnosis of the biopsied periapical lesion (cyst or granuloma).

The periodontal attachment levels after periapical surgery is an additional soft tissue outcome measure. Studies have compared the effect of different soft tissue incision techniques (intrasulcular with or without involving interproximal papilla, submarginal, papilla-base).[150-153] As expected, all concluded that negligible marginal recession could be achieved by adopting a flap design that avoided reflection of the interproximal papilla.

The improvement in outcomes of periapical surgery has been attributed to modern surgical techniques plus a greater biological awareness of clinicians.[107,111] In addition, and perhaps even more importantly, case selection may be more critical in excluding potential failures, inferring that prognostication may have improved.

Factors Affecting Tooth Survival Following Periapical Surgery and Root-end Filling

Unlike non-surgical root canal treatment, the outcome measure of tooth survival of surgical cases was investigated in one study[154] at the time of writing. The reported median survival time for first-time surgery was 92 months (95% CI: 41, 143) and that for re-surgery was 39 months (95% CI: 6, 72).[154] The failure events, however, included tooth extraction and clinical and radiographic signs of periapical disease after treatment.

Impact of Periapical Surgery on Quality of Life

The impact of periapical surgery on the patient's quality of life has only been evaluated using a questionnaire including three domains: physical function (chewing, talking, sleeping, daily routine and work), physical pain, and other physical symptoms (swelling, bleeding, nausea, bad taste/breath).[155] It was concluded that the papilla-base incision flap design resulted in a lower impact on physical pain and other symptoms within the first week post-operation. The impact on physical pain has also been explored by two other studies;[156,157] both reported the post-operative pain was of

relatively short duration, with the intensity peaking at three to five hours post-operatively and progressively decreasing with time, with no significant influencing factors identified.

CONCLUSIONS

The procedures used to maintain pulp vitality and for prevention and treatment of periapical disease are able to achieve excellent outcomes. The outcome data and potential prognostic factors should be considered during treatment options appraisal and planning. Despite the fact that most important prognostic factors are beyond the control of clinicians, optimal outcomes for individual cases may still be achieved by performing the procedure to guideline standards.

From a health economic perspective, conventional root canal treatment is a very cost-effective treatment as a first line intervention to extend the life of the tooth with a pre-operative periapical lesion.[2,3] If root canal treatment subsequently fails, non-surgical and surgical retreatments are also more cost-effective than replacement with a prosthesis.[2,3] Ultimately, all sources of evidence must be assessed for biasing influences based on the local cultures, expertise, treatment predilection, and funding sources.

Chapter 34

Achieving Long-Term Success with Endodontic Therapy

Fernando Goldberg

This chapter highlights the important role of endodontic treatment in retaining the natural tooth in the dental arch and thereby preserving or restoring oral health.

General Aspects

To achieve a successful endodontic outcome, previous chapters describe procedures to perform adequate endodontic treatment. In addition to other procedures, forms of therapy used in endodontic treatment include pulpectomy, treatment of pulp necrosis, retreatment, and periradicular surgery. Success attributed to these treatments varies from 80% to 95%. This rate changes according to the anatomical and pathological variables of each clinical case as well as the practitioner's skills performing the indicated procedures. Given this success rate, endodontic treatment is always preferable to extraction and implant placement.[1] Saving the tooth means that periodontal tissue can be preserved and therefore ensures that normal periradicular bone is maintained (Figure 34-1).

Because an implant is a foreign structure, devoid of periodontium, the most it can do is maintain surrounding bone but not produce new crestal bone. For this reason, the amount of annual bone loss considered normal is used as one of the criteria for assessing implant success. This premise does not exist in endodontics. Our aim is to remove the entire diseased content of the root canal system so one can perform a three-dimensional obturation and thus return the tooth to periodontal health.

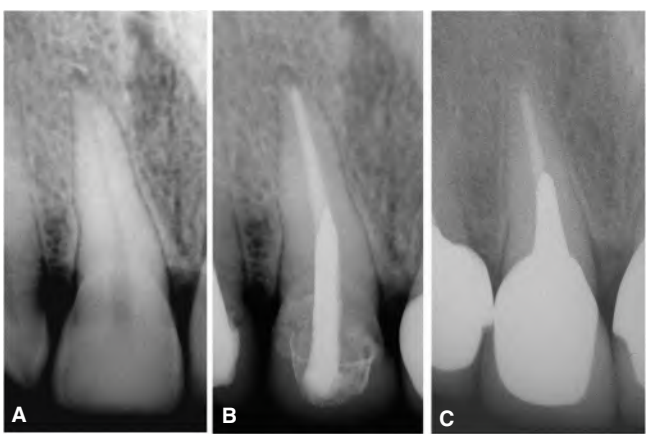

FIGURE 34-1 Long-term follow-up of nonsurgical endodontic treatment in a maxillary central incisor of a 32-year old female. ***A.*** Preoperative radiograph showing evidence of periapical radiolucency. Pulp vitality tests were negative. ***B.*** Postoperative radiograph. ***C.*** 31-year follow-up radiograph showing normal appearance of periapical area and crestal bone.

Efficient Endodontic Treatment → Healthy Periodontium → Normal Periradicular Bone

In general, and except for very specific cases, when endodontic treatment meets all the requirements for successful root canal treatment, the end result will be to maintain or restore the health of the periodontal tissues: cementum, periodontal ligament, compact bone or *lamina dura* and alveolar bone.

It is necessary to re-sensitize the dental profession to the importance of saving the natural tooth. A distressing survey among dentists in the United States in 2011 showed that dentists currently may have less confidence in endodontic treatment versus dental implants.[2]

Concept of Long-Term Success in Endodontics

Success in endodontics is determined by various aspects, for example, clinical, radiographic and patient conditions.

Clinical: Subjective–absence of any type of pain. Objective—absence of local or widespread swelling, mobility, and gingival or cutaneous sinus tract.

Radiographic: Normal thickness of the periodontal ligament space, continuity of the alveolar compact bone, recovery of alveolar cancellous bone, and absence of root resorption.

For calibration purposes, Ørstavik et al.[3] recommended the use of an ordinal scale (PAI, periapical index) of five categories for radiographic assessment of endodontic treatment results. Scores 1 and 2 correspond to a sound or normal periapical status, whereas scores of 3, 4, and 5 reflect changes in this area.

Currently, advanced imaging techniques, such as Cone Beam Computerized Tomography (CBCT), are important diagnostic aids. For more details, see Chapter 9C. In many cases, CBCT allows a more accurate interpretation of periradicular status, than conventional periapical radiography.[4–8]

*Patient Condition*s: The aim is to return the patient's oral health, function, and esthetics. Friedman and Mor[9] consider the terms *success* and *failure* to be ambiguous, and instead suggest using the terms *healed*, *healing* (in progress), or disease. Healed means clinical and radiographic normalcy, whereas ***healing*** means a normal clinical presentation combined with reduced periradicular radiolucency.

The authors identify *disease* as the emergence or persistence of periradicular radiolucency with clinical normalcy, or the presence of clinical signs or symptoms despite normal radiographic appearance. They also define *functional retention* as the presence of clinical normalcy with either the absence or presence of periradicular radiolucency.

According to the American Association of Endodontists' recommendations[10] the long-term results of endodontic treatment may be categorized as:

Healed—Functional, asymptomatic tooth with minimal or no radiographic periradicular pathosis.

Non-healed—Nonfunctional, symptomatic tooth with or without radiographic periradicular pathosis.

Healing—Tooth, asymptomatic and functional, with periradicular radiographic pathosis, or symptomatic tooth with or without radiographic periradicular pathosis but with unaffected function. In this regard, a functional tooth is a treated tooth or root that is serving its intended purpose in the dentition.

Gutmann et al.[11] have suggested the use of three categories when assessing long-term postoperative clinical and radiographic follow-ups: *Acceptable, Uncertain and Unacceptable*, with a fourth category corresponding to *acceptable clinical function.* After carrying out endodontic treatment, a prudent observation period of four years is generally applied for assessing the state of periradicular health, clinically and radiographically, and deciding the best approach.[11]

Conventional radiography offers an incomplete picture, since it represents a two-dimensional image of a three-dimensional reality. This often hinders accurate diagnosis, both preoperatively and postoperatively. This includes superimposition of neighboring anatomical features. Additionally, formation of non-calcified fibrous scar tissue, without an inflammatory reaction, may be associated with the repair mechanism of large periradicular lesions.[12,13]

It must be remembered that radiographic interpretation merely provides supporting data that should always be backed by a thorough clinical assessment. The patient must be made aware of the importance of long-term observation of the endodontic procedure and periodical follow-up appointments should be scheduled.

Suggested Clinical Approaches

Clinical approaches can be implemented in each of the following scenarios:

Healed: When there are no clinical symptoms and/or radiographic signs indicating recovery of periradicular tissues. One is also advised to monitor coronal restorations periodically. (Figure 34-2).

Healing: In such cases, the patient must be made aware of the need for regular clinical and radiographic check-ups (every 6 months to 1 year) (Figure 34-3). During this period, it is imperative to monitor the coronal restoration to ensure coronal seal and prevent possible fractures.

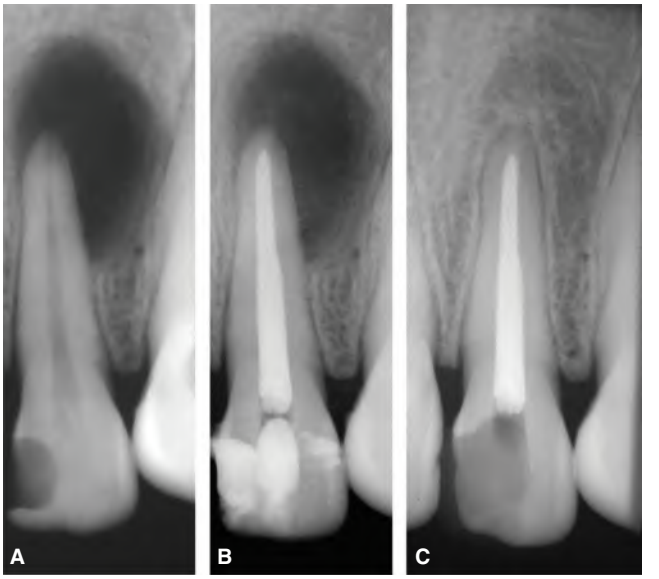

FIGURE 34-2 Healing of large periapical lesion in a maxillary lateral incisor of a 43-year-old female. ***A.*** Preoperative radiograph showing a large periapical radiolucency. Pulp vitality tests were negative. ***B.*** Immediate postoperative radiograph. ***C.*** Four-year follow-up radiograph showing resolution of the periapical radiolucency.

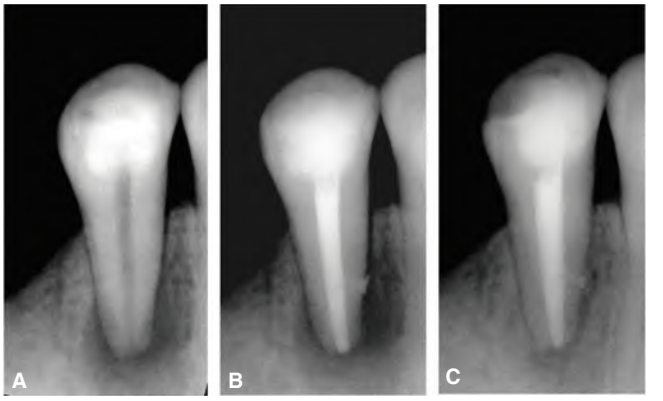

FIGURE 34-3 Healing of periapical lesion in a mandibular premolar of a 55-year-old male. ***A.*** Preoperative radiograph showing a large periapical radiolucency. Pulp vitality tests were negative. ***B.*** Immediate postoperative radiograph. Extrusion of sealer through a lateral portal of exit is evident (arrow). ***C.*** One-year follow-up radiograph showing active resolution of the periapical radiolucency.

Not healed: If a persisting or progressing periradicular radiolucency is diagnosed radiographically, in conjunction with subjective clinical symptoms (induced or spontaneous pain) or objective symptoms (localized or diffuse swelling, gingival or a cutaneous fistula), the patient must be advised to undergo non-surgical or surgical retreatment or extraction. The decision is based on local and general factors (Figure 34-4).

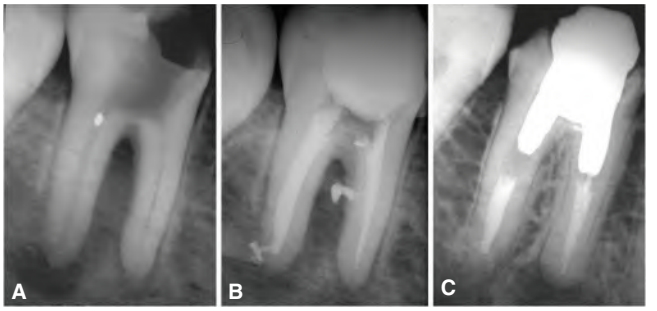

FIGURE 34-4 Treatment of a periradicular pathosis in a mandibular first molar of a 28-year-old male considered a failure. ***A.*** Preoperative radiograph showing periradicular radiolucencies associated with the mesial and distal roots as well as the furcation area. Root canal space exposed to the oral cavity. ***B.*** Immediate postoperative radiograph. Remnants of sealer extruding through a lateral portal of exit toward the furcation area. ***C.*** Five-year follow up radiograph showing marked reduction in size of the radiolucency associated with the furcation and the distal root. However, the periapical radiolucency in the mesial root has not been resolved.

Functional Retention: After a detailed clinical and radiographic examination, the patient should be made aware of the tooth in question, and given proper advice about the desirability of checking the tooth regularly. For example, patients with possible post-extraction complications, elderly patients, patients with anatomical or functional disadvantages for prosthetic and implant replacement or alternatively suggest extraction. When in doubt, and when merited, a computed tomography scan may contribute to a more thorough assessment thereby making it possible to pronosticate the outcome with greater certainty.

In all cases, a differential diagnosis should be done to clarify whether the cause of the detected disease is endodontic (e.g., intracanal infection), non-endodontic (e.g., neighboring conditions of non-endodontic origin) or mixed (e.g., combined endodontic-periodontal lesions). For more details, see Chapters 3, 8, 17, and 36.

Factors Involved in Achieving Endodontic Success

These factors can be divided into those that are derived from the endodontic process itself, general patient-dependent factors, and even factors involving the practitioner. Regarding endodontic treatment factors, all stages of treatment must be considered, beginning with a correct diagnosis and treatment plan, followed by efficient implementation of all procedures—including cosmetic and functional restoration of the treated tooth—and ending with confirmation of the repair by long-term postoperative observation.

During treatment, the practitioner will have to overcome challenges presented by anatomical complexities of the tooth being treated, which may affect a successful outcome (Figure 34-5). For more details, see Chapter 26. Similarly, the severity

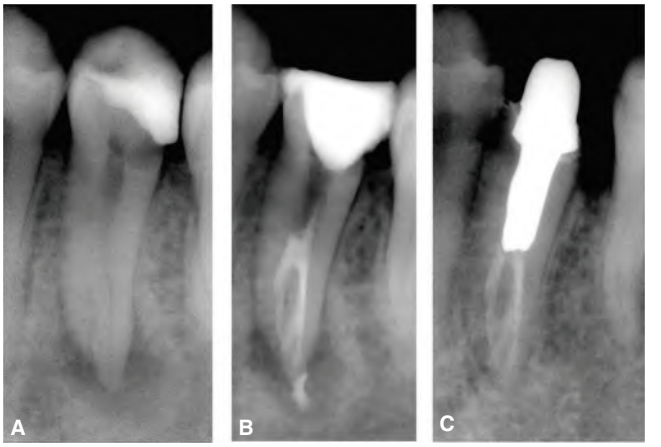

FIGURE 34-5 Endodontic treatment in a symptomatic mandibular premolar with complex radicular anatomy. ***A.*** Preoperative radiograph showing periapical radiolucency associated with necrotic pulp. ***B.*** Immediate postoperative radiograph showing endodontic filling of a trifurcated root canal system. ***C.*** 3-year follow-up radiograph showing resolution of the periapical radiolucency.

of the disease present will be a crucial factor when making a prognosis and deciding on the action to be taken. Among general factors, it is essential to consider those concerning the biological response of the patient (host). With regard to the dentist, the practitioner's experience in endodontic practice is of importance when analyzing the prognosis.

Long-Term Observation

In medical surgery, a successful surgical operation does not always guarantee healing of the treated disease. The same is true of endodontics; proper treatment does not always mean long-term success. For this reason, just taking an immediate postoperative radiograph does not mark the end of treatment. Treatment success is established by long-term postoperative observation.

Radiographs may reveal three different situations: failure of the treatment performed, resolution of the periradicular lesion (bone restored to its original condition), or "scarring" of the periradicular radiolucency (presence of some remnants of periradicular radiolucency) (Figures 34-4, 34-6, & 34-7). Regarding the latter, in some situations, where periradicular radiolucencies are extensive, their radiographic size diminishes after endodontic treatment. However, asymptomatic radiolucent area may persist.[12,13] More prolonged clinical and radiographic observation is needed in such cases.

Relationship Between Immediate Postoperative Pain and Long-Term Success

Once endodontic treatment has been completed, the clinician should monitor the patient during the days following treatment since spontaneous painful symptoms may be present for a few days. Sensitivity to chewing and percussion is common and may last for several days.[14] Administration of analgesics and anti-inflammatory agents is prescribed. When

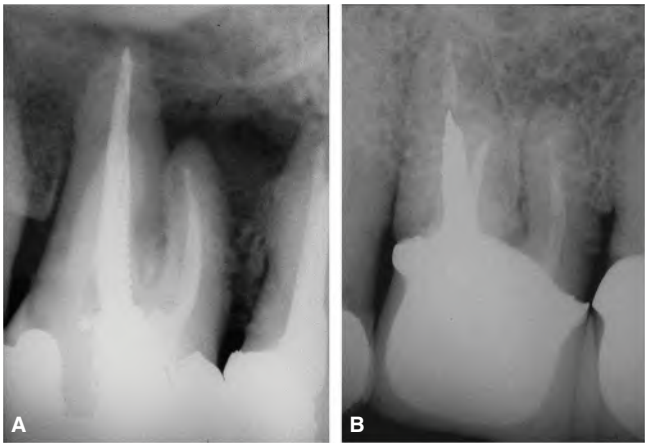

FIGURE 34-6 Long-term follow-up of nonsurgical endodontic treatment in a maxillary first molar of a 28-year-old male. ***A.*** Immediate postoperative radiograph showing a periapical radiolucency associated with the mesiobucal root. ***B.*** 35-year follow-up radiograph showing marked reduction in size of the radiolucency. This may indicate a possible formation of apical scar.

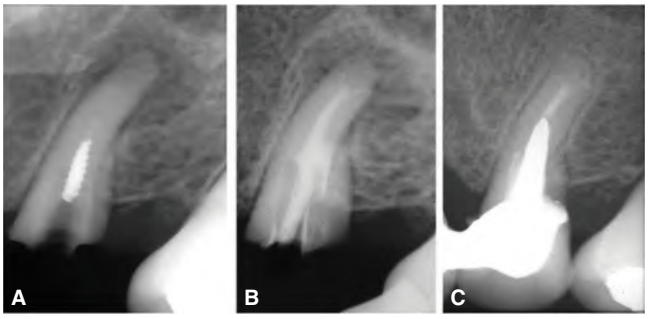

FIGURE 34-7 Resolution of a periradicular lesion. Long-term follow-up of nonsurgical endodontic retreatment in a maxillary second premolar of a 30-year-old female. Patient sought treatment after the prosthetic restoration on the tooth fractured. ***A.*** Preoperative radiograph showing a large periapical radiolucency associated with the tooth. Deficient endodontic treatment and a separated screw post is observed. ***B.*** Immediate postoperative radiograph. Complex apical anatomy is demonstrated by sealer extrusion (arrows). ***C.*** 11-year follow-up radiograph showing resolution of the periapical radiolucency. The tooth is asymptomatic and serves as abutment for fixed prosthesis.

the pulp tissue is necrotic, with or without a periradicular lesion, the painful reaction can be more intense and may be accompanied by localized or diffuse swelling. If systemic signs and symptoms are present (flare-up), it is advisable to prescribe an appropriate antibiotic in addition to analgesics and anti-inflammatory agents.[15,16] For more details, see Chapter 30.

If the endodontic treatment has been properly carried out, the symptoms are bound to clear up in a few days. In very few cases, despite having carried out successful treatment, painful symptoms may persist for a longer period without any visible radiographic changes.[17] In general, it is desirable to avoid an immediate postoperative reaction, since it has no bearing on the long-term prognosis of the treatment. Since endodontic treatment is a surgical procedure by nature, it may give rise to a postoperative inflammatory reaction expressed with a range of symptoms.

Long-Term Assessment of Root Canal Treatment

Teeth With Vital Pulps

When a tooth must undergo pulpectomy, the inflammatory process generally affects only the pulp without radiographic evidence of periradicular involvement. In such cases, endodontic therapy will involve removal of the pulp, cleaning and shaping the root canal system, followed by obturation. Proper endodontic procedure sets out to maintain the health of the periradicular tissues and the long-term radiographic periradicular image should therefore be similar to the immediate postoperative image. Many practitioners carry out this treatment in a single visit. Vital pulpectomy success rate is greater than 94% (Figure 34-8).[18–20]

Teeth With Necrotic Pulps

In endodontic treatments involving necrotic pulps, disinfection is the most important additional step prior to obturation. In such cases, microorganisms are present in the root canal system and may penetrate deeply into the dentin through the dentinal tubules. Therefore the therapeutic process must be more thorough. Endodontic treatment may require more than one visit as well as intracanal dressings with medication between visits.

Radiographically, the periradicular area may or may not be involved. Treatment of this condition can be based on whether the tooth has periradicular periodontitis or not.

a. Teeth with necrotic pulps without periradicular periodontitis

   Several publications indicate that long-term success rates of such cases ranges between 86% and 95%.[18–22] Results depend on various factors: anatomical difficulty, skill of the practitioner (students, graduates and specialists), intraoperative challenges, and long-term observation time. (Figure 34-9).

b. Teeth with necrotic pulps and periradicular periodontitis

   Periradicular periodontitis is considered to be present when a radiograph shows a circumscribed or diffuse radiolucency surrounding, or at the side of, the tooth apex. This means the inflammatory process has developed in the periradicular tissues, connected to the root canal system through the apical foramen or lateral foramina. In such cases, the success rate of endodontic treatment ranges between 80% to 86% (Figure 34-10).[18,20–23]

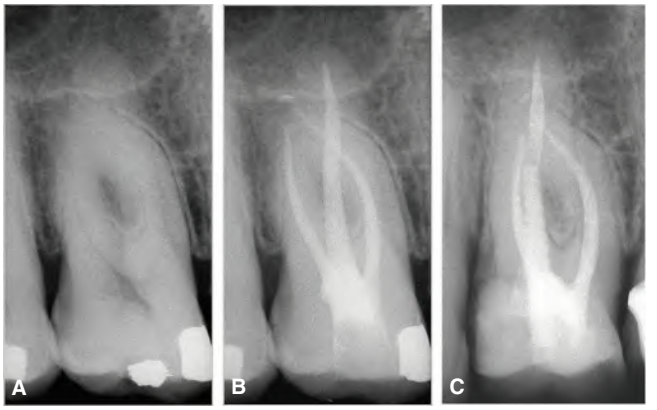

FIGURE 34-8 Nonsurgical endodontic treatment in a maxillary first molar. Patient presented with acute clinical symptoms of pulpitis. ***A.*** Preoperative radiograph. ***B.*** Immediate postoperative radiograph. ***C.*** Five-year follow-up radiograph. The tooth is asymptomatic and has been restored to function.

FIGURE 34-9 Nonsurgical endodontic treatment following pulp necrosis in a mandibular second molar of a 32-year-old male. ***A.*** Preoperative radiograph showing occlusal and distal coronal restorations. ***B.*** Immediate postoperative radiograph. ***C.*** Five-year follow-up radiograph showing normal appearance of the periradicular tissues.

There is some disagreement over the relationship between long-term success rate and the number of treatment sessions.[24–27] In general, it may be assumed that if the treatment was properly done, there is no significant difference between both procedures.[28–34] Practitioners who perform endodontic treatment in more than one visit do so to increase disinfection by using an intracanal antimicrobial dressing between visits. In specific cases such as intracanal bleeding, persistent canal exudate, severe preoperative pain and acute clinical symptoms, the use of an intracanal dressing is indicated and multiple-visit treatment is preferred.

When patients of different age and sex were compared, the success rates were similar.[23,35] However, in cases of very young patients presenting with immature apices with pulp necrosis, with or without periradicular involvement, current therapeutic procedures can vary. These range from apexification to endodontic regeneration. Long-term outcome assessment of such cases requires frequent monitoring and follow-up over longer periods of time.

To summarize, the prognosis of endodontic therapy in teeth with vital pulps is similar to that of teeth with necrotic pulps without periradicular periodontitis. Both conditions offer a better prognosis than treatment of teeth with necrotic pulps and periradicular periodontitis.

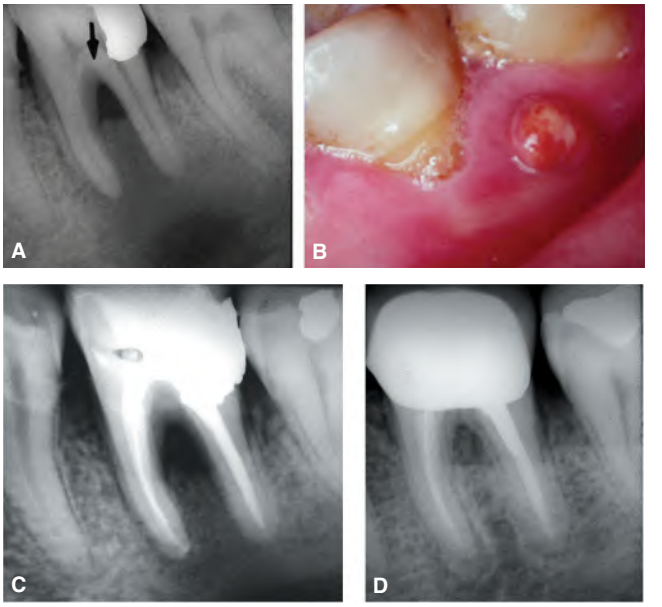

FIGURE 34-10 Nonsurgical endodontic treatment in a mandibular first molar of a 56-year-old male. ***A.*** Preoperative radiograph showing a large periradicular radiolucency extending to the furcation region (arrow). Pulp vitality tests were negative. ***B.*** Clinical photograph showing a sinus tract associated with the affected tooth. ***C.*** Immediate postoperative radiograph. ***D.*** 10-year follow-up radiograph showing resolution of the periradicular radiolucency. The patient was asymptomatic and the tooth restored to function.

Non-Surgical Retreatment (Reintervention)

During orthograde endodontic retreatment, complete removal of previous filling material is crucial, in order to enable new cleaning, shaping, disinfection, and filling of the root canal system.

Several studies indicated a rise in retreatments in endodontic practice.[36,37] Unfortunately, many general practitioners now prefer extraction and implant placement to endodontic retreatment.[2] Numerous publications on procedures performed in different countries indicate that the reason for failure of endodontic therapy is often the low quality of endodontic treatments rendered by general practitioners.[38–43]

The reported success rate obtained with endodontic retreatment varied from 62% to 95% (Figure 34-11).[9,18,20,23,44–48] This wide range is generally due to factors related to the anatomical difficulty of each clinical case, size and type of periradicular lesions, therapeutic procedure performed during primary treatment, postoperative observation periods used in each case, skill of the operator, and the lack of calibration in the studies.

Retreatment in teeth with periradicular radiolucency showed a 13% to 20% lower success rate than those teeth without periradicular pathosis.[18,23,47,48] Gorni and Gagliani[49] reported a success rate of 86.8% when the morphology of treated teeth was not altered as a result of previous treatment, and 47% in cases where the tooth anatomy had been changed. This clearly shows that the prognosis of

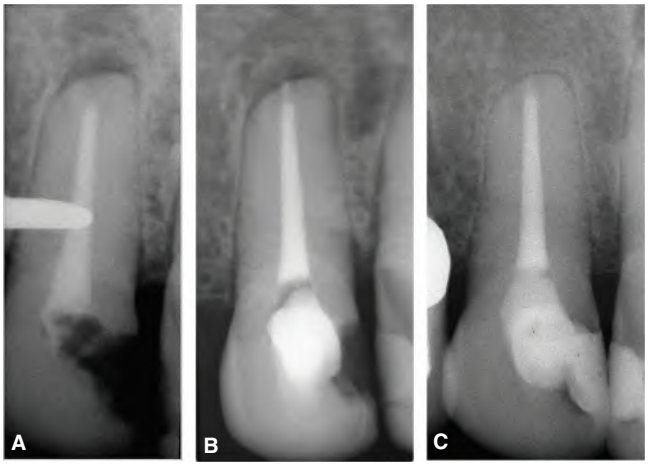

FIGURE 34-11 Nonsurgical endodontic retreatment in a maxillary lateral incisor of a 28-year-old female. The tooth was symptomatic on percussion. ***A.*** Preoperative radiograph showing periradicular radiolucency associated with the affected tooth. The coronal obturation is missing and the pulp chamber is open to the oral cavity. ***B.*** Immediate postoperative radiograph. ***C.*** 17-year follow-up radiograph showing resolution of the periradicular radiolucency. The tooth was asymptomatic throughout the entire follow-up period.

retreatment is linked not only to the presence of disease but also to changes induced in the root canal due to the previous practitioner's actions (blockages, broken instruments, perforations, transportations and other mishaps).

In general, if it is possible, in retreatment, to reach the apical foramen and remove the primary obturation so that proper cleaning, shaping and refilling of the root canal can be achieved, the outcome is no different from that achieved in cases of initial endodontic treatment of teeth with pulp necrosis.

Root Integrity

Prior to endodontic treatment, it is important to observe root integrity of teeth to be treated following radiographic diagnosis. This step is particularly important in teeth that have suffered traumatic injuries. The existence of internal resorptions communicating with the periodontal tissue as well as external resorptions can have an impact on the prognosis (Figure 34-12). In some cases, root resorptions are not radiographically visible, either because they are too small or because they are located on either the buccal, lingual, or palatal root surfaces superimposed over the root on the radiographic image.[50] In both situations, depending on the location, extent and rate of resorption, prognosis is uncertain, and occasionally additional surgery is required. For more details, see Chapter 15.

When considering root integrity, root perforation is another clinical challenge. The use of enhanced illumination and magnification, as well as appropriate materials with efficient sealing capacity such as Mineral Trioxide Aggregate (MTA), are positive factors that considerably increase the likelihood of a favorable prognosis (Figure 34-13).[51,52]

Perforation location, size, origin, and the time between occurrence and treatment must be considered when evaluating

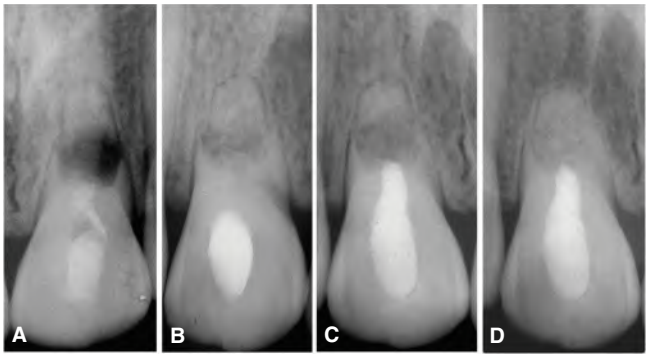

FIGURE 34-12 Nonsurgical endodontic retreatment in a traumatized maxillary central incisor of an 18-year-old male. On examination, the tooth was mobile and symptomatic on biting. ***A.*** Preoperative radiograph showing a large middle root radiolucency. Extensive root defect associated with the affected tooth is observed. ***B.*** Radiograph showing calcium hydroxide intracanal medication in place. ***C.*** Immediate postoperative radiograph. The root canal was obturated with gutta-percha and sealer. ***D.*** Three-year follow-up radiograph showing resolution of the radiolucency. The tooth is asymptomatic and mobility restored to normal.

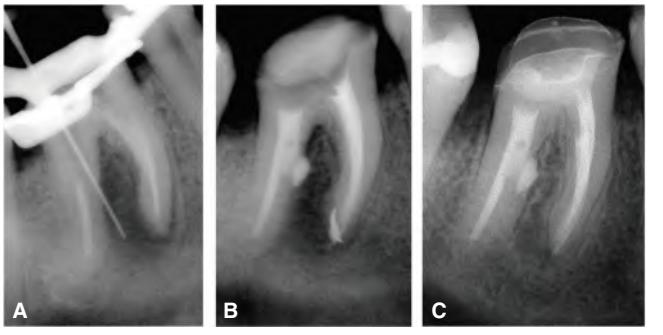

FIGURE 34-13 Nonsurgical endodontic retreatment in a perforated mandibular first molar of a 38-year-old female. ***A.*** Preoperative radiograph showing a large interradicular radiolucency. An endodontic instrument demonstrates the area of perforation in the distal root caused by inadequate post placement. ***B.*** Immediate postoperative radiograph. Endodontic retreatment was done and the perforation sealed with Mineral Trioxide Aggregate (MTA). ***C.*** Three-year follow-up radiograph showing resolution of the radiolucency. The tooth is asymptomatic.

prognosis. Large perforations with a high degree of contamination will yield unfavorable prognosis and often surgical treatment is required.

Endodontic Surgery

Endodontic surgery is not oral surgery in the traditional sense. Rather, it is endodontic treatment through a surgical flap.[53] In some clinical situations, periradicular surgery is the treatment of choice. Possible indications include failed retreatments, cystic lesions, perforations in the middle or apical third of the root, separated instruments that are difficult or unfeasible to remove, and canals that are inaccessible due to calcifications or obstructions (Figure 34-14).

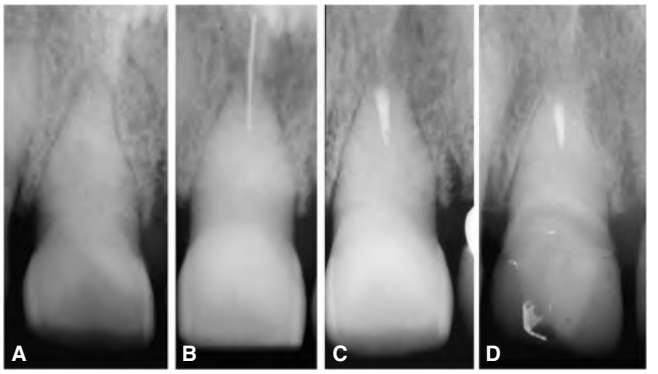

FIGURE 34-14 Surgical endodontic treatment in a maxillary central incisor of a 42-year-old female. The patient reported spontaneous pain in this tooth. ***A.*** Preoperative radiograph showing evidence of a calcified root canal system. ***B.*** Intraoperative radiograph during retro-instrumentation of the accessible portion of the root canal. ***C.*** Immediate postoperative radiograph showing the retro-obturation of the root canal with thermoplasticized gutta-percha and sealer. ***D.*** 18-year follow-up. Periradicular normalcy can be observed.

In recent years, advances in materials and technology contributed to the high success rate of endodontic surgery.[54–58] For more details, see Chapter 24. In this sense, retrograde instrumentation and obturation of the entire untreated root canal increases the chance of success insofar as it meets requirements for cleaning and complete filling of the contaminated endodontic space and closing off communications between the root canal and the periodontal ligament[59,60] (Figure 34-15).

FUNCTIONAL RETENTION

As mentioned earlier, the percentage success rate of nonsurgical and surgical endodontic treatment and retreatment is around 85%. If we now consider the concept of success in terms of functional retention or survival, this average rises to more than 90%.[35,42,48,60–63]

TIME FACTOR IN LONG-TERM OBSERVATION

There is considerable disagreement over the long-term postoperative observation time necessary to consider the outcome of endodontic treatment. The minimum acceptable time is generally considered to be at least 4 to 5 years.[22,28,45,60,64]

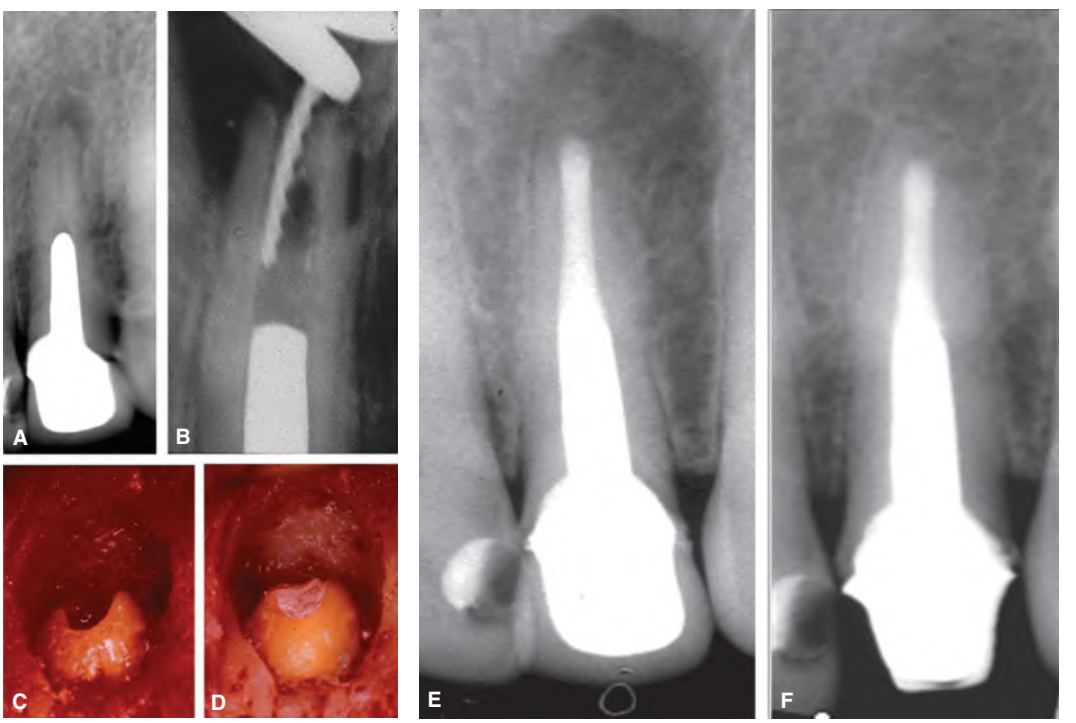

FIGURE 34-15 Surgical endodontic retreatment in a maxillary lateral incisor of a 38-year-old female. ***A.*** Preoperative radiograph showing a periapical radiolucency associated with the tooth. A large post and a crown are present. There is no evidence that the remaining root canal space was treated. The patient reported intermittent symptoms associated with this tooth. A decision was made to keep the post in place, reflect a buccal flap, and approach the remainder of the root canal space from the apical end. ***B.*** Radiograph showing endodontic instrument inserted from the apex. ***C.*** Clinical photograph following instrumentation of the root canal space. ***D.*** Clinical photograph following retro-obturation of the root canal space with thermoplasticized gutta-percha and sealer. ***E.*** Immediate postoperative radiograph. The root canal space was retro-obturated to the post level. ***F.*** 17-year follow-up radiograph. The periapical radiolucency has resolved and the patient is asymptomatic.

Increasing postoperative monitoring time increased the success rate observed in cases of initial endodontic treatment as well as in cases of non-surgical endodontic retreatment (Figure 34-16).[46,60,65] If, during the observation period following endodontic treatment, the tooth is asymptomatic and periradicular radiolucency decreases, it is appropriate to continue monitoring it for a longer period.

Effect of Overfills on Long-Term Prognosis

Overfilling may occur during obturation of non-surgical endodontic treatment or retreatment. In such cases, sealer may extrude laterally (via a lateral portal of exit) or apically (via the apical foramina) (Figures 34-17 & 34-18). The overfill may also result in tiny particles of sealer difficult to identify on the radiograph, that can be mistaken with normal periradicular bone.[23,66–68]

During instrumentation and obturation, contaminated dentin particles may sometimes be projected through the apical foramen together with necrotic organic debris. These are not visible on the radiograph and compose part of the overfilling along with the extruded sealer. Many reactions attributed to overfilled sealer may actually be caused by extruded contaminated material not detectable on the radiograph.

The relationship between overfilling and long-term prognosis of endodontic treatment is controversial. While some believe it reduces the long-term success rate, others claim that it has no effect.[18,21,23,46,47,65,67–70]

The quantity of overfilled material, the type of material, its consistency, and the host's reaction to the material are important considerations. In situations where the overfills are small and involve conventional sealers, the healing may be delayed but not impaired (Figures 34-19).[46,65,70] Under certain circumstances, the overfilled material is fully reabsorbed over time, while in other situations it remains embedded in the tissues without compromising the long-term treatment success. Likewise, during retreatment, fragments of gutta-percha can extrude to periapical tissues via the apical foramen. In some cases, the material may provoke a foreign body reaction, while in others, the material doesn't cause any adverse reaction and is reabsorbed after a period of time (Figure 34-20). In these cases, clinical and radiographic

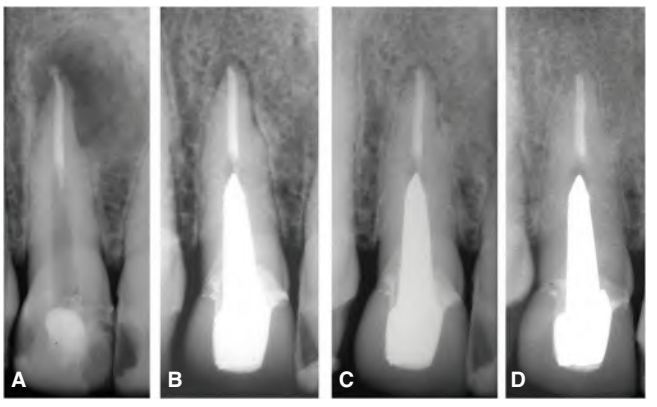

FIGURE 34-16 Endodontic treatment in a maxillary lateral incisor of a 32-year-old female. The patient presented with severe irradiating pain. ***A.*** Immediate postoperative radiograph showing periapical radiolucency associated with the affected tooth. ***B.*** Six-year follow-up radiograph showing marked reduction of periapical radiolucency, however, without complete resolution. The patient is asymptomatic. ***C.*** 10-year follow-up radiograph showing further reduction in size of the periapical radiolucency. The patient is still asymptomatic. ***D.*** 25-year follow-up radiograph. The periapical radiolucency has completely resolved.

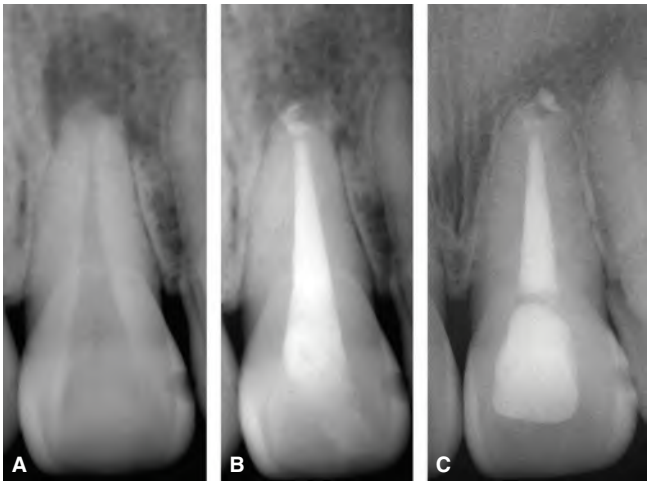

FIGURE 34-17 Endodontic treatment in a maxillary central incisor of a 25-year-old female. The patient reported to have suffered a traumatic injury to the tooth several years earlier. ***A.*** Preoperative radiograph showing periapical radiolucency and apical root resorption. ***B.*** Immediate postoperative radiograph. ***C.*** 17-year follow-up radiograph. Evidence of sealer remnants can still be observed. The periapical radiolucency has resolved and the tooth restored to function.

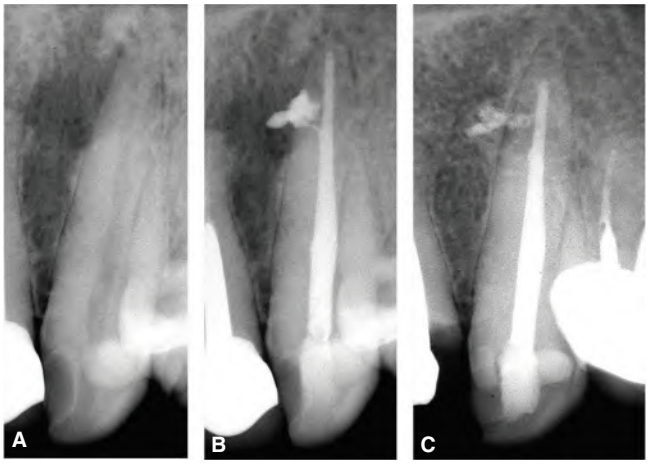

FIGURE 34-18 Endodontic treatment in a maxillary canine of a 42-year-old male. ***A.*** Preoperative radiograph showing a lateral radiolucency between the middle and apical third of the root. Vitality tests were negative. ***B.*** Immediate postoperative radiograph. Sealer extruding through a lateral portal of exit is evident. ***C.*** 12-year follow-up radiograph. The lateral radiolucency has resolved. Evidence of sealer remnants is still observed. The patient is asymptomatic and the tooth restored to function.

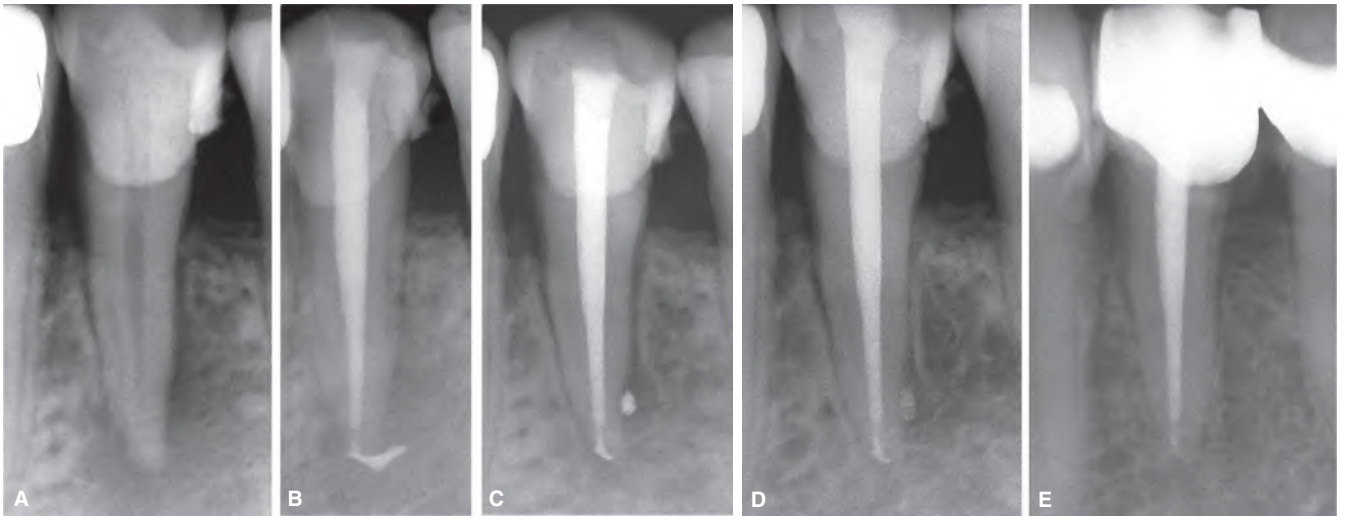

FIGURE 34-19 Endodontic treatment in a mandibular first premolar of a 41-year-old male. The patient reported severe pain associated with the tooth. ***A.*** Preoperative radiograph showing large periradicular radiolucency associated with the affected tooth. Vitality tests were negative. ***B.*** Immediate postoperative radiograph. ***C.*** Six-month follow-up showing marked reduction in size of periapical radiolucency. Persistent radiolucency surrounding sealer remnants still noticeable. ***D.*** Two-year follow-up radiograph. Further reduction in size of the periapical radiolucency is evident. The extruded sealer is less apparent. ***E.*** 11-year follow-up radiograph. The periapical radiolucency has resolved and the extruded sealer has disintegrated. The patient is asymptomatic and the tooth restored to function.

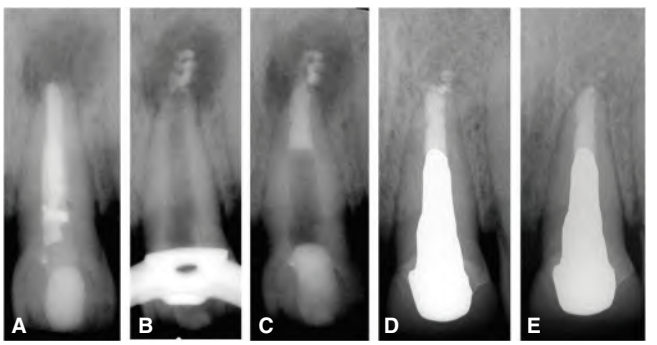

FIGURE 34-20 Endodontic retreatment in a maxillary central incisor of a 28-year-old male. The patient reported to have suffered traumatic injury to the tooth in childhood. ***A.*** Preoperative radiograph showing periapical radiolucency associated with the affected tooth. The patient was asymptomatic. ***B.*** Radiograph taken after removal of the previous root canal filling. Remnants of old filling material can be detected in the periapical area. ***C.*** Immediate postoperative radiograph. The apical part of the root canal was filled with MTA. ***D.*** Six-year follow-up radiograph showing marked reduction in size of the periapical radiolucency and in the amount of the extruded material. ***E.*** 10-year follow-up radiograph. Periapical radiolucency has resolved and extruded material almost completely reabsorbed.

observation must be extended for a longer period of time to assess of the final clinical approach to be taken. For gross overfills, the final outcome is less certain and surgical removal of the extruded material may be necessary.

Reasons for Failure of Endodontic Treatment

In some cases, in spite of correct diagnosis and treatment procedures, a non-surgical endodontic treatment or re-treatment may still fail. Persistence of periradicular periodontitis can be due to microbial or non-microbial reasons. The former includes inadequate removal of intraradicular infection during operating procedures, extracanal endodontic infection, and possible coronal leakage from an inadequate restoration.[13,21,40,41,43,68,70–79] The latter includes deposits of cholesterol crystals in periradicular lesions, true cysts, and reactions to foreign bodies due to the extrusion of various materials into the periradicular area.[13,70,79–82] Likewise, the presence of radicular cracks or fractures not visible on the radiograph, extensive root resorption, and severe endodontic-periodontic disease can also be the cause of failure.

Deficient elimination of the septic contents of the root canal system is generally due to the presence of anatomical complexities not readily accessible, inadequate canal cleaning, disinfection and filling procedures, intraoperative accidents, and missed canals. In such situations, non-surgical or surgical retreatment will be the preferred treatment once the cause of failure has been identified.

Deciding on tooth extraction after endodontic treatment is more likely to occur for periodontal or prosthetic causes rather than failure of root canal treatment.[83]

Differential diagnosis is important since some anatomical structures and pathologic conditions may appear on the radiograph to be associated with the radicular area and therefore be improperly diagnosed as endodontic in origin.[84] Under such circumstances, computed tomography is a useful diagnostic tool. For more details, see Chapters 9C & 10.

During endodontic therapy, unnecessary removal of tooth structure must be avoided to prevent potential fracture of the treated tooth. Endodontic success would then become a dental failure. An important factor to consider when assessing the prognosis of endodontic treatment is coronal reconstruction. Coronal leakage, over time, constitutes a reason for endodontic failure. Although the role of coronal filtration is debatable, a satisfactory restoration is undoubtedly necessary to guarantee functional and esthetic success.[21,23,41,85,86] A permanent restoration must therefore be placed as soon as possible in order to reinforce the tooth and prevent microbial invasion.

Lastly, when considering reasons for endodontic treatment failure, one cannot ignore the role of systemic conditions of the patient. The prognosis must be considered doubtful in patients with uncontrolled diabetes or severe immuno-compromised diseases.[60]

CHAPTER 35

Contemporary Restoration of Endodontically Treated Teeth

NADIM Z. BABA, CHARLES J. GOODACRE

Various methods of restoring pulpless teeth have been reported for more than 200 years. In 1747 Pierre Fauchard[1] described the process by which roots of maxillary anterior teeth were used for the restoration of single teeth and the replacement of multiple teeth (Figure 35-1). Posts were fabricated of gold or silver and held in the root canal space with a heat-softened adhesive called "mastic."[1,2] The longevity of restorations made using this technique was attested to by Fauchard: "Teeth and artificial dentures, fastened with posts and gold wire, hold better than all others. They sometimes last fifteen to twenty years and even more without displacement. Common thread and silk, used ordinarily to attach all kinds of teeth or artificial pieces, do not last long."[1]

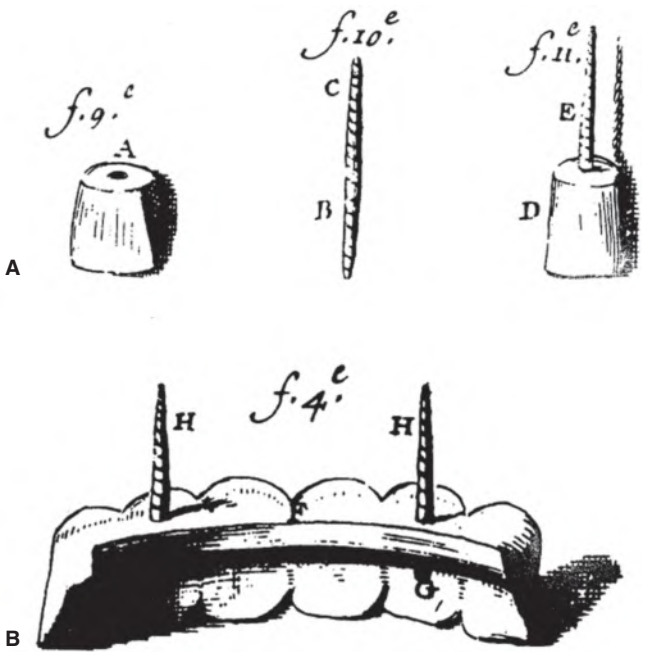

FIGURE 35-1 Early attempts to restore single or multiple units. ***A.*** "Pivottooth" consisting of crown, post, and assembled unit. ***B.*** Six-unit anterior fixed partial dental prosthesis "pivoted" in lateral incisors with canines cantilevered. Crowns were fashioned from a diversity of materials. Human, hippopotamus, sea horse, and ox teeth were used, as well as ivory and oxen leg bones. Posts were usually made from precious metals and fastened to the crown and root by using a heated sticky "mastic" prepared by gum, lac, turpentine, and white coral powder.

The replacement crowns were made from bone, ivory, animal teeth, and sound natural tooth crowns. Gradually the use of these natural substances declined, to be slowly replaced by porcelain. A pivot (what is today termed a post) was used to retain the artificial porcelain crown into a root canal and the crown-post combination was termed a "pivot crown." Porcelain pivot crowns were described in the early 1800's by a well-known dentist of Paris, Dubois de Chemant.[2] Pivoting (posting) of artificial crowns to natural roots became the most common method of replacing artificial teeth, and was reported as the "best that can be employed" by Chapin Harris in *The Dental Art* in 1839.[3]

Early pivot crowns in the United States used seasoned wood (white hickory) pivots.[4] The pivot was adapted to the inside of an all-ceramic crown and also into the root canal space. Moisture would swell the wood and retain the pivot in place.[2] Surprisingly, Prothero[2] reported removing two central incisor crowns with wooden pivots that had been successfully used for 18 years. Subsequently, pivot crowns were fabricated using wood/metal combinations and then more durable all-metal pivots were used. Metal pivot retention was achieved by various means such as threads, pins, surface roughening, and split designs that provided mechanical spring retention.[2]

Unfortunately, adequate cements were not available to these early practitioners, cements that would have enhanced post retention and decreased abrasion of the root caused by movement of metal posts within the canal. One of the best representations of a pivoted tooth appears in *Dental Physiology and Surgery*, written by Sir John Tomes in 1849 (Figure 35-2).[5] Tomes's post length and diameter conformed closely to today's principles in fabricating posts.

Endodontic therapy by these dental pioneers embraced only minimal efforts to clean, shape, and obturate the canal. Frequent use of the wood posts in empty canals led to repeated episodes of swelling and pain. Wood posts, however, did allow the escape of the so-called "morbid humors." A groove in the post or root canal provided a pathway for continual suppuration from the periradicular tissues.[1]

Although many of the restorative techniques used today had their inception in the 1800's and early 1900's, **proper**

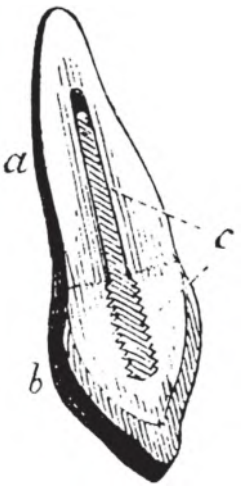

FIGURE 35-2 Principles used today in selecting post length and diameter were understood and taught by early practitioners during mid-1800s.

endodontic treatment was neglected until years later. Today, both the endodontic and prosthodontic aspects of treatment have advanced significantly, new materials and techniques have been developed, and a substantial body of scientific knowledge is available upon which to base clinical treatment decisions.

This chapter describes the techniques commonly employed when restoring endodontically treated teeth and answers frequently associated questions. Whenever possible, the answers and discussion will be supported by scientific evidence. Conflicting results will be presented to provide a comprehensive understanding of the available evidence.

SHOULD CROWNS BE PLACED ON ENDODONTICALLY TREATED TEETH?

A retrospective study[6] of 1,273 teeth endodontically treated 1 to 25 years previously compared the clinical success of anterior and posterior teeth. Endodontically treated teeth with restorations that encompassed the tooth (onlays, partial or complete coverage metal crowns, and metal ceramic crowns) were compared with endodontically treated teeth with no coronal coverage restorations. It was determined that in **anterior teeth**, **coronal coverage crowns did not significantly improve the success of endodontically treated teeth**. This finding supports the use of a conservative restoration such as an etched resin restoration in the access opening of otherwise intact or minimally restored anterior teeth. Crowns are only indicated on endodontically treated anterior teeth when they are structurally weakened by the presence of large and/or multiple coronal restorations or they require significant form/color changes that cannot be effected by bleaching, resin bonding, or porcelain laminate veneers. Scurria and colleagues[7] collected data from 30 insurance carriers in 45 states regarding the procedures 654 general dentists performed on endodontically treated teeth. The data indicated that 67% of endodontically treated anterior teeth were restored without a crown, supporting the concept that many anterior teeth are being satisfactorily restored without the use of a crown.

When endodontically treated **posterior teeth** (with and without coronal coverage restorations) were compared, **a significant increase in the clinical success** was noted when **cuspal coverage crowns** were placed on maxillary and mandibular molars and premolars.[6] In a study of 116 failed and extracted endodontically treated teeth, Vire[8] reported that teeth restored with crowns had greater longevity than uncrowned teeth. A strong association was found between crown placement and the survival of endodontically treated teeth. Endodontically treated teeth (ETT) with crowns were lost after an average of 87 months whereas ETT without crowns were lost after an average of 50 months. If long-term tooth survival is the primary goal, placing a crown on an endodontically treated posterior tooth enhances survival (Figure 35-3).[9] Aquilino and colleagues[9] reported that ETT with cuspal coverage had six times greater rate of survival than those without cuspal coverage. Therefore, restorations that encompass the cusps should be used on posterior teeth that have intercuspation with opposing teeth and thereby receive occlusal forces that push the cusps apart.

Salehrabi and colleagues[10] performed an epidemiological study in a large patient population and reported that 85% of the teeth that were extracted (3%) after initial non-surgical endodontic treatment, had no full coronal coverage. A prospective study by Ng and colleagues[11] evaluated the factors affecting outcomes of non-surgical RCT. They found that ETT that were not restored with a crown had a worse survival rate than those that were. In a systematic review, Stavropolou and colleagues[12] concluded that ETT restored with crowns had a higher long-term survival rate compared to those not restored with crowns. The previously discussed insurance data[7] indicated that 37% to 40% of posterior endodontically treated teeth were restored by practitioners without a crown, a method of treatment not supported by the long-term clinical prognosis of posterior endodontically treated teeth that do not have cusp-encompassing crowns.

There are, however, certain posterior teeth (not as high as 40%) that do not have substantive occlusal intercuspation or have an occlusal form that precludes intercuspation of a nature that attempts to separate the cusps (such as mandibular first premolars with small, poorly developed lingual cusps). When these teeth are intact or minimally restored (small MO or DO restorations), they would be reasonable candidates for restoration of only the access opening without use of a coronal coverage crown.[13] However, the survival rate of ETT will likely be lower when ETT have lost excessive amounts of tooth structure. In a recent systematic review, Federowicz and colleagues[14] looked at the effects of the restoration of ETT by crowns versus conventional filling materials. They concluded that there is no evidence to support or refute the effectiveness of crowns over filling materials for the restoration of ETT. However, more clinical data are required to determine the long-term survival of these teeth when large composite resin restorations are present in conjunction of heavy wear, heavy forces, or parafunctional habits. ETT that have been previously restored and weakened by

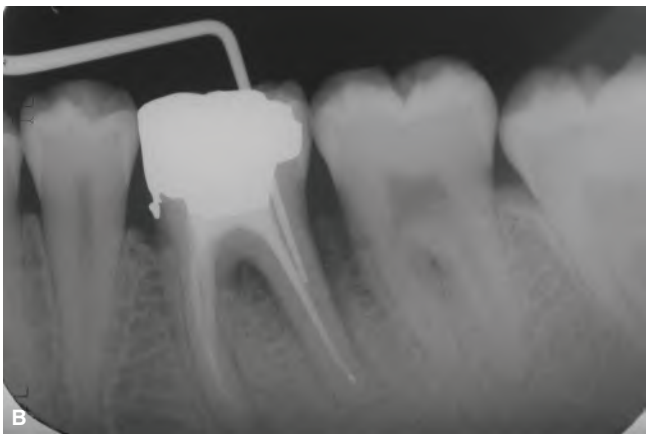

FIGURE 35-3 ***A.*** Buccal view of an endodontically treated mandibular left first molar without cuspal coverage reveals a dental fistula. ***B.*** Pre-operative radiograph showing a deep, isolated, and narrow periodontal pocket. ***C.*** Extracted tooth showing the fracture extending down both roots. (Reprinted with permission from Baba NZ.[331])

prior removal of tooth structure should be restored with a crown that encompasses the cusps.

In contrast to the above recommendations, a 3-year clinical study by Manocci and colleagues[15] evaluated the clinical success rate of endodontically treated premolars restored with a post and direct composite resin restorations with and without complete crown coverage. They found that both had a similar success rate. Nagasiri and colleagues,[16] in a retrospective cohort study, indicated that when endodontically treated molars are completely intact except for a conservative access opening, they could be restored successfully by using composite resin restorations. They found that the 5-year survival rate of teeth without cuspal coverage was 36%.

Multiple clinical studies of fixed partial dentures, many with long spans and cantilevers, have determined that endodontically treated abutments failed more often than vital teeth due to tooth fracture,[17–21] supporting the greater fragility of endodontically treated teeth and the need to design restorations that reduce the potential for both crown and root fractures when extensive fixed prosthodontic treatment is required.

The high demand for esthetic restorations, the desire for conservative treatment and the benefit of covering the cusps caused some clinicians to use endocrowns.[22–24] This restoration consist of an onlay or crown with core material in a single unit. The core material engages in the cavity prepared into the pulp chamber. Endocrown fabricated of nanoceramic was found to have a favorable mode of failure when ETT, with no Build-up material, are used.[25,26] The authors found the endocrowns to be more resistant than teeth restored with a post, composite resin core, and a ceramic crown.

Gutmann[27] reviewed the literature and presented an overview of several articles that identify what happens when teeth are endodontically treated. These articles provide background information important to an understanding of why **coronal coverage crowns help prevent fractures of posterior teeth**. Endodontically treated dog teeth were found to have 9% less moisture than vital teeth.[28] In addition, it was found that dehydration increases stiffness and decreases the flexibility in teeth. However, dehydration by itself does not account for the physical property changes in dentin.[29] Yet in another investigation of 23 matched pairs of human ETT and their vital contralateral teeth, the moisture levels were not statistically significantly different.[30] In some teeth that had undergone root canal therapy as many as 15 to 20 years earlier, the moisture content was not necessarily reduced, even after extended periods of time. It has been stated that dehydration alone does not account for changes in physical properties of dentin.[29] Also, with aging, greater amounts of peritubular dentin are formed, which decreases the amount of organic materials that may contain moisture.

It has been shown that endodontic procedures reduce tooth stiffness by 5%, attributed primarily to the access opening.[31] Tidmarsh[32] described the structure of an intact tooth that permits deformation when loaded occlusally and elastic recovery after removal of the load. The direct relationship between tooth structure removed during tooth preparation and tooth deformation under load has been described.[33] Dentin from endodontically treated teeth has been shown to exhibit significantly lower shear strength and toughness than vital dentin.[34] Rivera and colleagues[35] stated that the effort required to fracture dentin may be less when teeth are endodontically treated because of more immature (potentially weaker) collagen intermolecular cross-links. In a recent study, it was found that collagen fibrils degraded over time

FIGURE 35-4 Traumatized tooth before endodontic procedure. Placement of a bonded resin restoration in the access opening after root canal treatment and whitening is the only treatment required since crowns do not enhance the longevity of anterior endodontically treated teeth. A crown will be indicated only when esthetic and functional needs cannot be achieved through more conservative treatments.

in teeth with zinc phosphate-cemented posts. Acid demineralization can also occur from bacteria and acid etching.[36]

CONCLUSIONS

Restorations that encompass the cusps of endodontically treated posterior teeth have been found to increase the clinical longevity of these teeth. Therefore, **crowns should be placed on endodontically treated posterior teeth that have occlusal intercuspation with opposing teeth** of the nature that places expansive forces on the cusps. Since **crowns do not enhance the clinical success of anterior endodontically treated teeth**, their use on relatively sound teeth should be limited to situations where esthetic and functional requirements cannot be adequately achieved by other more conservative restorations (Figure 35-4).

WITH PULPLESS TEETH, DO POSTS IMPROVE LONG-TERM CLINICAL PROGNOSIS OR ENHANCE STRENGTH?

Historically, the use of posts was based on the concept that a post reinforces the tooth.

Laboratory Data

Virtually all laboratory studies[37–47] have shown that placement of a post and core either fails to increase the fracture resistance of endodontically treated teeth or decreases the fracture resistance of the tooth when a force is applied via a mechanical testing machine. Lovdahl and Nicholls[37] found that endodontically treated maxillary central incisors were stronger when the natural crown was intact, except for the access opening, than when they were restored with cast posts and cores or pin-retained amalgams. Lu[38] found that posts placed in intact endodontically treated central incisors did not lead to an increase in the force required to fracture the tooth or in the position and angulation of the fracture line. Pontius[39] found that maxillary incisors, without posts, resisted higher failure loads than the other groups with posts and crowns. Gluskin[40] found that mandibular incisors with intact natural crowns exhibited greater resistance to transverse loads than teeth with posts and cores. McDonald[41] found no difference in the impact fracture resistance of mandibular incisors with or without posts. Eshelman and Sayegh[42] reported similar results when posts were placed in extracted dog lateral incisors. Guzy and Nicholls[43] determined that there was no significant reinforcement achieved by cementing a post into an endodontically treated tooth that was intact except for the access opening. Leary and colleagues[44] measured the root deflection of endodontically treated teeth before and after posts of various lengths were cemented into prepared root canals. They found no significant differences in strength between the teeth with or without a post. Trope and colleagues[45] determined that preparing a post space weakened endodontically treated teeth compared with ones in which only an access opening was made, but no post space.

A potential situation where a post and core could strengthen a tooth was identified by Hunter and colleagues[46] using photoelastic stress analysis. They determined that removal of internal tooth structure during endodontic therapy is accompanied by a proportional increase in stress. They also determined that minimal root canal enlargement for a post does not substantially weaken a tooth but when excessive root canal enlargement has occurred, a post strengthens the tooth. Therefore, **if the walls of a root canal are thin** due to removal of internal root caries or overinstrumentation during post preparation, then **a post may potentially strengthen the tooth**.

Two-dimensional finite element analysis was used in one study[47] to determine the effect of posts on dentin stress in pulpless teeth. When loaded vertically along the long axis, a post reduced maximal dentin stress by as much as 20%. However, only a small (3% to 8%) decrease in dentin stress was found when a tooth with a post was subjected to masticatory and traumatic loadings at 45° to the incisal edge. The authors proposed that the reinforcement effect of posts is doubtful for anterior teeth because they are subjected to angular forces.

Clinical Data

Sorenson and Martinoff[48] evaluated endodontically treated teeth with and without posts and cores. Some of the teeth were restored with single crowns while others served as fixed partial denture abutments or removable partial denture abutments. Posts and cores significantly decreased the clinical success rate of teeth with single crowns, improved

the clinical success of removable partial denture abutment teeth, and had little influence on the clinical success of fixed partial denture abutments. Eckerbom and colleagues[49] examined the radiographs of 200 consecutive patients and reexamined the patients radiographically 5 to 7 years later to determine the prevalence of apical periodontitis. Of the 636 endodontically treated teeth evaluated, 378 had posts and 258 did not have posts. At both examinations, **apical periodontitis was significantly more common in teeth with posts** than in endodontically treated teeth without posts. Morfis[50] evaluated the incidence of vertical root fracture in 460 endodontically treated teeth, 266 of which had posts. There were 17 teeth with root fracture after a time period of at least 3 years. Nine of the 17 fractured teeth had posts and eight root fractures occurred in teeth without posts. Morfis[50] concluded that the endodontic technique may cause vertical root fracture. In an analysis of data from multiple clinical studies, Goodacre[51] found that 3% of teeth with posts fractured. **None of these clinical data provides definitive support for the concept that post and cores strengthen endodontically treated teeth or improve their long-term prognosis**.

The Purpose of Posts

Since clinical and laboratory data indicate teeth are not strengthened by posts, their purpose is for retention of a core that will provide appropriate support for the definitive crown or prosthesis. Unfortunately, this primary purpose has not been completely recognized. Hussey[52] noted that 24% of general dental practitioners felt that a post strengthens teeth. A 1994 survey (with responses from 1066 practitioners and educators) revealed some interesting facts. Ten percent of the dentist respondents felt that every endodontically treated tooth should receive a post. It was determined that 62% of dentists over age 50 believed a post reinforces the tooth whereas only 41% of the dentists under age 41 believed in that concept. Thirty-nine percent of part-time faculty, 41% of full-time faculty, and 56% of non-faculty practitioners felt that posts reinforce teeth.[53]

CONCLUSIONS

Both laboratory and clinical data fail to provide definitive support for the concept that posts strengthen endodontically treated teeth. Therefore, **the purpose of a post is to provide retention for a core**.

WHAT IS THE CLINICAL FAILURE RATE OF POSTS AND CORES?

Several studies provide clinical data regarding the number of posts and cores that failed over certain time periods[54–66] (Table 35-1). When this number is divided by the total number of posts and cores placed, a failure percentage is determined. A 9% overall average for failure was calculated by averaging the failure percentages from 10 studies (an average study length of six years). In these studies, the percent failure ranged from 7% to 14%.

A review of more specific details from the 11 studies provides insight into the length of each study and the number of posts and cores evaluated. The findings of a 5-year retrospective study of 66 posts and cores indicate there were six failures and a 9% failure rate.[54] Another study found that 17 of 154 posts failed after 3 years for an 11% failure rate.[45] A failure rate of 9% was found in three studies.[56–58] Two studies reported a 7% post and core failure rate after 9 years or more.[59,65] An 8% failure rate (39 of 516 posts and cores) was published when 516 posts and cores placed by senior dental students were retrospectively evaluated,[60] whereas another study recorded a 14% failure rate (eight failures in 56 posts and cores) from posts and cores placed by dental students.[61] A study of 397 posts followed for 25 years reported a 10% post and core failure rate after 25 years (40 of 397 posts failed).[64] A more recent study recorded a 6% failure rate (19 of 308 posts) for posts placed in a specialist practice setting.[66]

Kaplan-Meier survival statistics (percentage of survival over certain time periods) were presented or could be calculated from the data in nine studies[62] (Table 35-2). The survival rates ranged from a high of 99% after 10 years or more

of follow-up to a 78% survival rate after a mean time of 5.2 years. The failure percentage per year has also been calculated and ranged from 1.56% per year[47] to 4.3% per year.[63]

CONCLUSIONS

Posts and cores had an average clinical failure rate of 9% (6% to 14% range) when the data from 11 studies were combined (average study length of 8 years).

WHAT ARE THE MOST COMMON TYPES OF POST AND CORE FAILURES?

Eight studies[54,55,57,58,60,65–68] indicate that **post loosening is the most common cause of post and core failure** (Figure 35-5). Turner[54] reported on 100 failures of post-retained crowns and indicated that post loosening was the most common type of failure. Of the 100 failures, 59 were caused by post loosening. The next most common occurrences were 42 apical abscesses followed by 19 carious lesions. There were 10 root fractures and six post fractures. In another paper by Turner,[67] he reported the findings of a 5-year retrospective study of 52 post-retained crowns. Six posts had come loose which was the most common failure. Lewis and Smith[68] presented data regarding 67 post and core failures after 4 years. Forty-seven of the failures resulted from posts loosening, eight from root fractures, seven from caries, and four from bent or fractured posts. Bergman and colleagues[57] found eight failures in 96 posts after 5 years. Six posts had come loose and two roots fractured. Hatzikyriakos and colleagues[55] reported on 154 posts and cores after 3 years. Five posts had come loose, five crowns had come loose, four roots fractured, and caries caused three failures. Mentink[60] identified 30 post loosenings and 9 tooth fractures when evaluating 516 posts and cores over a 1- to 10-year time period (4.8 years mean study length). Torbjörner and colleagues[58] reported on the frequency of three technical failures (loss of retention, root fracture, and post fracture). They did not report biologic failures. Loss of retention was the most frequent post failure, accounting for 45 of the 72 post and core failures. Root fracture (Figure 35-6) was the second most common failure cause followed by post fracture. Balkenhol and colleagues[65] reported on 802 posts and cores over a 10-year period. Thirty-nine posts had loosened, eight had longitudinal root fracture, and six had transverse root fracture.

In two studies, factors other than loss of retention were listed as the most common cause of failure.[56,59] Sorenson and Martinoff[56] evaluated 420 posts and cores and recorded 36 failures. Of the 36 failures, eight were related to restorable tooth fractures, 12 to nonrestorable tooth fractures, 13 to loss of retention, and three were caused by root perforations. Weine and colleagues[59] found nine failures in 138 cast posts and cores after 10 years or more. Three failures were caused by restorative procedures, two by endodontic treatment, two by periodontal problems, and two by root fractures. No posts failed due to loss of retention.

Four studies have provided data on the incidence of tooth fracture but no information regarding post loosening. Linde[69] reported that three of 42 teeth fractured, Ross[70] found no fractures with 86 posts, Morfis[50] found that 10 of 266 teeth fractured, and Wallerstedt[61] identified two fractures with 56 posts.

Loss of retention and tooth fracture (in that order of occurrence) are the two most common causes of failure

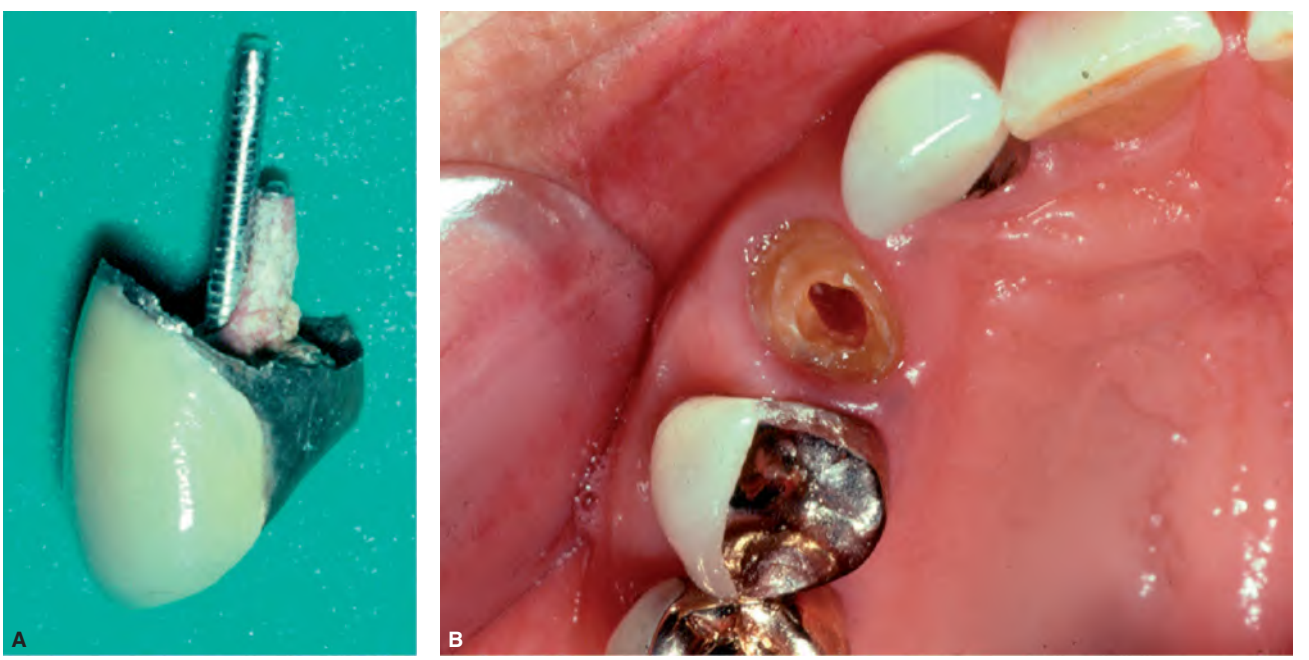

FIGURE 35-5 Post and crown loosened from maxillary canine a few years after placement. ***A.*** Both the post/core and the crown came off. ***B.*** Clinical photo shows very little cervical tooth structure for retention of the crown.

FIGURE 35-6 Radiograph of a fractured maxillary first premolar with a post with excessive diameter and insufficient length, two problems frequently seen in conjunction with fractured roots.

when these studies are collectively analyzed by averaging the numerical data from all the studies. Five percent of the posts placed (144 of 2,980 posts) experienced loss of retention (Table 35-3). Two percent of the posts placed (82 of 3,827 posts) failed via tooth fracture (Table 35-4).

CONCLUSIONS

Loss of retention and tooth fracture are the two most common causes of post and core failure.

WHICH POST DESIGN PRODUCES THE GREATEST RETENTION?

Laboratory Data

There have been many laboratory studies comparing the retention of various post designs. Threaded posts provide the greatest retention, followed by cemented, parallel-sided posts. Tapered cemented posts are the least retentive. Cemented, parallel-sided posts with serrations are more retentive than cemented, smooth-sided parallel posts. These laboratory data are discussed below.

Clinical Data

There is clinical support for these laboratory studies. Torbjörner and colleagues[58] reported significantly greater loss of retention with tapered posts (7%) compared to parallel posts (4%). Sorenson and Martinoff[56] determined that 4% of tapered posts failed by loss of retention whereas 1% of parallel posts failed in that manner. Turner[67] indicated that tapered posts loosened clinically more frequently than parallel-sided posts. Lewis and Smith[68] also found a higher loss of retention with smooth-walled tapered posts than parallel posts. Bergman and colleagues[57] and Mentink and colleagues[60] evaluated only tapered posts, and both studies reported that 6% of tapered posts failed via loss of retention, values higher than those recorded by Torbjörner and colleagues[58] and Sorenson and Martinoff[56] for parallel posts.

Contrasting results were reported by Weine and colleagues.[59] They found no clinical failures from loss of retention with cast tapered posts. Hatzikyriakos and colleagues[55] studied tapered threaded posts, parallel cemented posts, and tapered cemented posts. The only posts that loosened from the root were parallel cemented posts.

CONCLUSIONS

Tapered posts are the least retentive and threaded posts the most retentive in laboratory studies. Most of the clinical data supports the laboratory findings.

IS THERE A RELATIONSHIP BETWEEN POST FORM AND THE POTENTIAL FOR ROOT FRACTURE?

Laboratory Data

Using photoelastic stress analysis, Henry[71] determined that threaded posts produced undesirable levels of stress. Another study used strain gauges attached to the root and compared four parallel-sided threaded posts with one parallel-sided nonthreaded post.[70] Two of the threaded posts produced the highest strains, whereas two other threaded posts caused strains comparable to the nonthreaded post. Standlee and coleagues,[72] using photoelastic methods, indicated that tapered, threaded posts were the worst stress producers. When three types of threaded posts were compared in extracted teeth, Deutsch and colleagues[73] found that **tapered, threaded posts increased root fracture by 20 times that of the parallel threaded posts** (Figure 35-7).

Laboratory testing of **split threaded posts** has provided varying results, but more research groups have concluded

FIGURE 35-7 Radiograph showing a threaded post that may have caused root fracture in the second premolar.

they **do not reduce the stress associated with threaded posts.** Thorsteinsson and colleagues[74] determined that split threaded posts did not reduce stress concentration during loading. In another study, split threaded posts were found to produce installation stresses comparable to other threaded posts.[75] Greater stress concentrations than those of some other threaded posts were reported under simulated functional loading.[76–78] Rolf and colleagues[79] found that a split threaded post produced comparable stress to one type of threaded post and less stress than a third threaded post design. Ross and colleagues[70] determined a split threaded post produced less root strain than two other threaded posts and comparable strain to a third threaded post and a nonthreaded post. Another research group[80] concluded the split threaded design reduced the stresses caused during cementation compared to a rigid threaded post design. Multiple photoelastic stress studies have concluded that **posts designed for cementation produced less stress than threaded posts.**[71,72,79]

When parallel-sided cemented posts were compared with tapered cemented posts, photoelastic stress testing results have generally favored parallel-sided posts. Using this methodology, Henry[71] found that parallel-sided posts distribute stress more evenly to the root. Finite element analysis studies produced similar results.[81,82] Two additional photoelastic studies[74,77] concluded that parallel posts concentrate stress apically and tapered posts concentrate stress at the post-core junction. Also using photoelastic testing, Assif and colleagues[83] found that tapered posts showed equal stress distribution between the cementoenamel junction and the

apex compared with parallel posts that concentrated the stress apically.

When fracture patterns in extracted teeth were used to compare parallel and tapered posts, the evidence favoring parallel posts is less favorable. Sorenson and Engelman[84] determined that tapered posts caused more extensive fractures than parallel-sided posts did, but the load required to create fracture was significantly higher with tapered posts. Lu,[38] also using extracted teeth, found no difference in the fracture location between prefabricated parallel posts and cast posts and cores. Assif and colleagues[85] tested the resistance of extracted teeth to fracture when the teeth were restored with either parallel or tapered posts and complete crowns. No significant differences were noted, and post design did not influence fracture resistance.

In analyzing the stress distribution of posts, it was noted that tapered posts generate the least cementation stress and should be considered for teeth that have thin root walls, are nearly perforated or have perforation repairs.[77]

Clinical Data

There are several clinical studies that provide data related to the incidence of root fracture associated with different post forms. Some of these studies provide a comparison of multiple post forms, whereas other studies evaluated only one type of post. Combining all the root fracture data for each post form from both types of studies reveals some interesting trends (Table 35-5). Five studies present data regarding root fractures and threaded posts,[50,56,61,69,86] four regarding fractures associated with parallel-sided cemented posts[50,56,58,86] and nine related to tapered cemented posts.[50,56–59,60,64,65,86] If the total number of threaded posts evaluated in the five studies is divided into the total number of fractures found with threaded posts, a percent value can be determined that represents the average incidence of tooth fracture associated with threaded posts in the five studies. The same data can be calculated for parallel cemented and tapered cemented posts, permitting a comparison of the root fracture incidences associated with these three post forms.

Combining the five studies that reported data relative to **threaded posts** produced a mean **fracture rate of 7%** (11 fractures from 169 posts). The four clinical studies that contain fracture data from **parallel-sided cemented posts** produced a mean **fracture incidence of 1%** (9 fractures from 687 posts). From the seven studies reporting root fracture with **tapered posts**, there is a mean **fracture rate of 2%** (66 root fractures from 2,752 posts). This combined study data support the previously cited photoelastic laboratory stress tests, indicating that the greatest incidence of root fractures occurred with threaded posts and that the lowest incidence of root fracture was associated with parallel cemented posts. In a meta-analysis of selected clinical studies, Creugers and colleagues[62] calculated a 91% tooth survival rate for cemented cast posts and cores and an 81% survival rate for threaded posts with resin cores.

While the combined data from all the studies for each type of post revealed certain trends, analysis of individual studies (where multiple post forms were compared in the same study) produced less conclusive results. One study of threaded posts and cemented posts determined that teeth with threaded posts were lost more frequently than teeth with cast posts.[49] In three other clinical comparisons of threaded and cemented posts, no tooth fracture differences were noted.[50,55,86] In addition to the comparisons of threaded and cemented posts, four clinical studies provide data comparing the tooth fracture incidences associated with parallel-sided and tapered posts. In comparing parallel and tapered posts by reviewing dental charting records, a higher failure rate was reported with tapered posts than with parallel posts in two studies, and the failures were judged to be more severe with tapered posts.[56,58] Two other clinical studies determined there were no differences between tapered and parallel-sided posts.[58,86] Hatzikynakos and colleagues[55] found no significant differences between 47 parallel cemented posts and 44 tapered cemented posts after 3 years of service. Ross[86] evaluated 86 teeth with posts and cores that had been restored at least 5 years previously. No fracture differences were found between 38 tapered cemented posts and 39 parallel cemented posts.

Unfortunately, the total number of clinical studies that compared multiple post forms in the same study is limited. Also, several factors may have affected the findings of available studies. Two of the papers that contained a comparison of multiple post forms covered sufficiently long time periods (10 to 25 years) that the tapered cemented posts may have been in place for much longer time periods than the parallel-sided cemented posts (due to the later

introduction of parallel posts into the dental market).[56,58] The mean time since the placement of each post form was not identified in these studies. Also, both of these studies were based on reviews of patient records (rather than clinical examinations) and depended on the accuracy of dental charts in determining if and when posts failed as well as the cause of the failure. Another factor that affected the results of many of the referenced clinical studies was the length of the posts. For instance, in Sorenson and Martinoff's study,[56] 44% of the tapered cemented posts had a length that was half (or less than half) the incisocervical/occlusocervical dimension of the crown whereas only 4% of the parallel cemented posts were that short. Since short posts have been associated with higher root stresses in laboratory studies, the difference in post length may have affected their findings where tooth fractures occurred with 18 of 245 tapered posts compared with no fractures with 170 parallel posts.

CONCLUSIONS

When evaluating the relationship between post form and root fracture, **laboratory tests** generally indicate all types of **threaded posts produce the greatest potential for root fracture**. When comparing tapered and parallel cemented posts using photoelastic stress analysis, the results generally favor the parallel cemented posts. However, the evidence is mixed when the comparison between tapered and parallel posts is based on fracture patterns in extracted teeth created by applying a force via a mechanical testing machine.

When evaluating the combined data from multiple **clinical studies, threaded posts generally produced the highest root fracture incidence** (7%) compared with tapered cemented posts (2%) and parallel cemented posts (1%). Analysis of individual clinical studies as opposed to the combined data produces less conclusive results. Additional comparative clinical studies would be beneficial, including designs that have not yet been evaluated in comparative studies.

WHAT IS THE PROPER LENGTH FOR A POST?

A wide range of recommendations has been made regarding post length, which includes the following:

1. The post length should equal the incisocervical or occlusocervical dimension of the crown.[87–94]
2. The post should be longer than the crown.[95]
3. The post should be one-third of the crown length.[96]
4. The post should be half of the root length.[97,98]
5. The post should be two-thirds of the root length.[99–103]
6. The post should be four-fifths of the root length.[104]
7. The post should be terminated halfway between the crestal bone and root apex.[105–107]
8. The post should be as long as possible without disturbing the apical seal.[71]

A review of scientific data provides the basis for differentiating between these varied guidelines. While short posts have never been advocated, they have been frequently observed during radiographic examinations (Figures 35-8 and 35-9). Grieve and McAndrew[108] found that only 34% of 327 posts were as long as the incisocervical length of the crown. In a clinical study of 200 endodontically treated teeth, Ross[86] determined that only 14% of posts were two-thirds or more of the root length and 49% of the posts were one-third or less of the root length. A radiographic study of 217 posts determined that only 5% of the posts were two-thirds to three-fourths of the root length.[109] In a retrospective clinical study of 52 posts, Turner[54] radiographically compared the length of the post with the maximal length available if 3 mm of gutta-percha were retained. Posts that came loose used only 59% of the ideal length and only 37% of the posts were longer than the proposed minimal length. Nine millimeters was proposed as the ideal length. Short posts have been associated with higher root stresses[46,75,77,81,82] and a greater tendency for root fracture to occur.

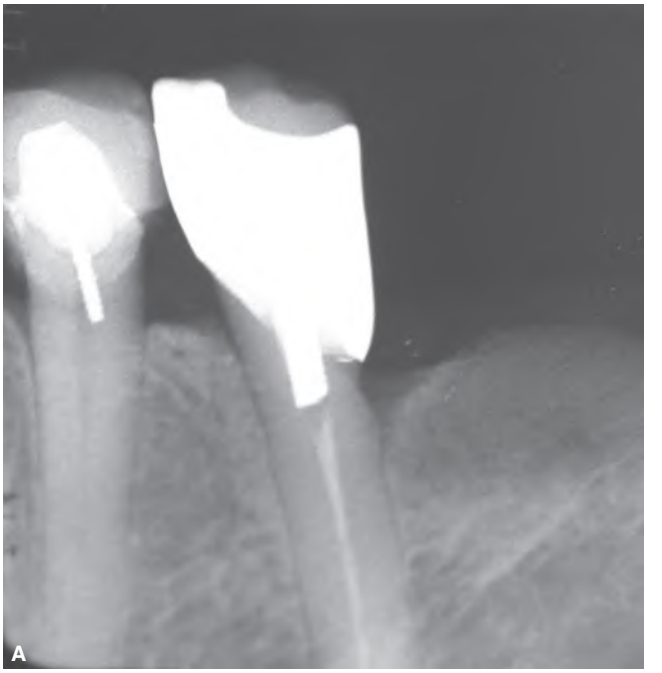
Sorensen and Martinoff[56] determined that the clinical success was markedly improved when the post was equal to or greater than the crown length. According to Johnson and Sakumura[110] posts that were three-fourths or more of the root length were up to 30% more retentive than posts that were half of the root length or equal to the crown length. Leary and colleagues[111] indicated that posts with a length at least three-fourths of the root offered the greatest rigidity and least root bending.

This data indicates post length would appropriately be three-fourths that of root length. However, some interesting results occur when post length guidelines of two-thirds to three-fourths of the root length are applied to teeth with average, long, and short root lengths. It was determined that a post approaching this recommended length range is not possible without compromising the apical seal by retaining less than 5 mm of gutta-percha.[112] When post length was half that of the root, the apical seal was rarely compromised on average length roots. However, when posts were two-thirds of the root length, many of the average and short length roots would have less than the optimal gutta-percha seal. Shillingburg and colleagues[113] also indicated making the post length equal the clinical crown length can cause the post to encroach on the 4-mm "safety zone" required for an apical seal.

Abou-Rass and calleagues[114] proposed a post length guideline for maxillary and mandibular molars based on the incidence of lateral root perforations when post preparations were made in 150 extracted teeth. They determined molar posts should not be extended more than 7 mm apical to the root canal orifice.

When teeth have diminished bone support, stresses increase dramatically and are concentrated in the dentin near the post apex.[115] A recent finite element model study established a relationship between post length and alveolar bone level.[116] To minimize stress in the dentin and in the post, the post should extend more than 4 mm apical to the bone.

FIGURE 35-8 ***A.*** Diminished bone support of a maxillary central incisor. ***B.*** Root fracture caused by stresses on the tooth. ***C.*** Broken crown showing the fracture line at the apex of the post. (Reprinted with permission from Baba NZ.[331])



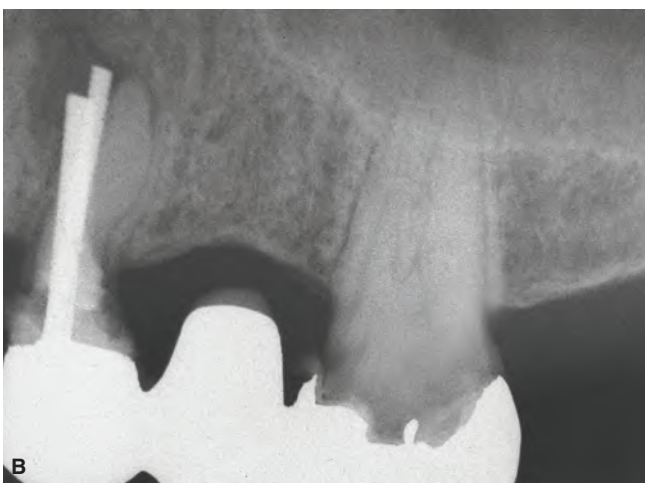


FIGURE 35-9 ***A.*** Radiograph of a second premolar with a very short post; the lack of adequate retention for the core can result in the prosthesis loosening. ***B.*** Radiograph of first maxillary left premolar with a very long post; the inadequate size of the post caused the perforation of the roots. (Figure 9B reprinted with permission from Baba NZ.[331])

CONCLUSIONS

Reasonable clinical guidelines for length include the following:

1. Make the post approximately three-fourths of the length of the root when treating long rooted teeth.
2. When average root length is encountered, post length is dictated by **retaining 5 mm of apical gutta-percha** and extending the post to the gutta-percha (Figure 35-10).
3. Whenever possible, posts should extend at least 4 mm apical to the bone crest to decrease dentin stress.

4. Molar posts should not be extended more than 7 mm into the root canal apical to the base of the pulp chamber (Figure 35-11).

HOW MUCH GUTTA-PERCHA SHOULD BE RETAINED TO PRESERVE THE APICAL SEAL?

It has been determined that when 4 mm of gutta-percha is retained, only one of 89 specimens showed leakage, whereas 32 of 88 specimens leaked when only 2 mm of gutta-percha was retained.[117] Two studies found no leakage at 4 mm,[118,119] and two additional studies found little leakage at 4 mm.[117,120] Portell and colleagues[121] found that most specimens with only 3 mm of apical gutta-percha had some leakage. When the leakage associated with 3, 5, and 7 mm of gutta-percha was compared, Mattison and colleagues[122] found significant leakage differences between each of the dimensions. They proposed that at least 5 mm of gutta-percha is required for an adequate apical seal. Nixon and colleagues[123] compared the sealing capabilities of 3, 4, 5, 6, and 7 mm of apical gutta-percha using dye penetration. The greatest leakage occurred when only 3 mm was retained, and it was significantly different from the other groups. They also noted a significant decrease in leakage occurred when 6 mm of gutta-percha remained. Raiden and Gendelman[124] cemented stainless steel posts with zinc phosphate cement in teeth with residual root canal fillings of 1, 2, 3, and 4 mm. They tested apical leakage using a passive dye system and concluded that 4 mm of apical seal provided a leakage value of zero. Kvist and colleagues[125] examined radiographs from 852 clinical endodontic treatments. Posts were present in 424 of the teeth. Roots with posts in which the remaining root filling material was shorter than 3 mm showed a significantly higher frequency of periapical radiolucencies. Using a pressure-driven tracer assay, Wu and colleagues[126] and Abramovitz and colleagues[127] found that 4 or 5 mm of apical seal were inferior in their ability to prevent leakage, compared with an original full-length root canal filling. Similarly, Metzger and colleagues[128] compared the sealing capabilities of 3, 5, 7, and 9 mm of apical gutta-percha using a pressure-driven radioactive tracer assay. They concluded that the sealing is proportional to the length of the remaining filling and that original full-length root canal fillings have a superior seal compared to 3, 5, and 7 mm of apical gutta-percha.

FIGURE 35-10 Five millimeters of gutta-percha was retained in the maxillary premolar and the post extended to that point.

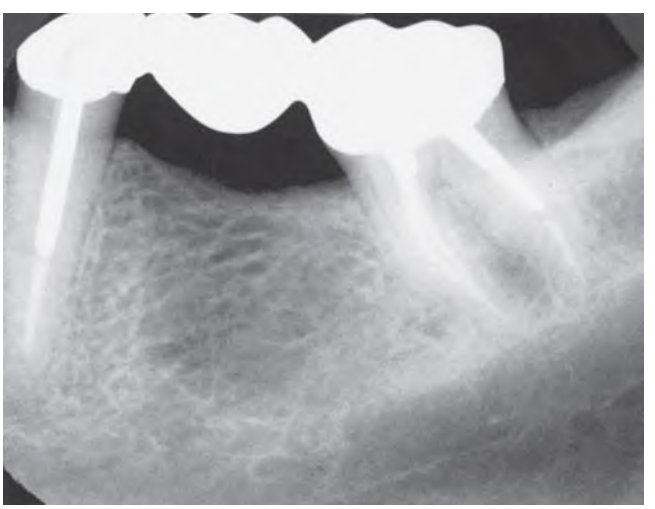

FIGURE 35-11 The post in the distal canal of the mandibular molar extends to a maximal length of 7 mm.

CONCLUSIONS

Since there is greater leakage when only 2 to 3 mm of gutta-percha is present (Figure 35-12), 4 to 5 millimeters should be retained apically to ensure an adequate seal. Although studies indicate 4 mm produces an adequate seal, stopping at 4 mm is difficult and radiographic angulation errors could lead to retention of less than 4 mm. **Therefore, at least 5 mm of gutta-percha should be retained apically. This seal**

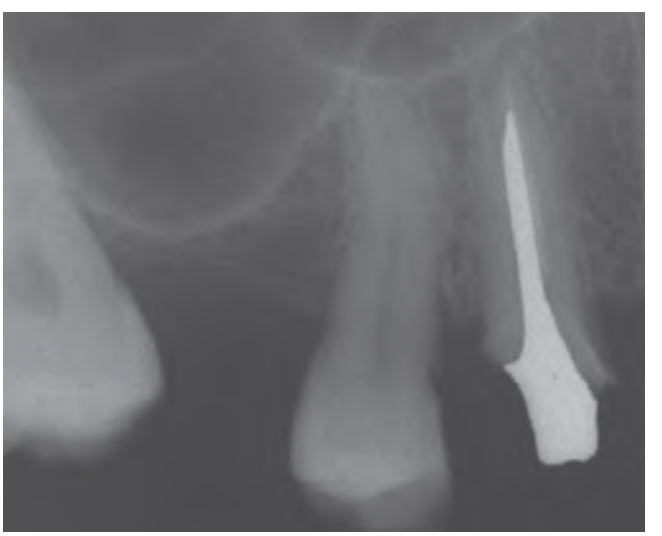

FIGURE 35-12 Less than 2 mm of gutta-percha remains in the maxillary first premola rapical to the cast post and core, increasing the risk of failure.

is complemented by a seal provided by the post and core, and the overlying crown. (Figure 35-11).

DOES POST DIAMETER AFFECT RETENTION AND THE POTENTIAL FOR TOOTH FRACTURE?

Studies relating post diameter to post retention have failed to establish a definitive relationship. Two studies determined there was an increase in post retention as the diameter increased,[113,129] whereas three studies found no significant retention changes with diameter variations.[130,121,131] Krupp and colleagues[132] indicated that post length was the most important factor affecting retention and post diameter was a secondary factor.

A more definitive relationship has been established between post diameter and stress in the tooth. Mattison[133] found that as the post diameter increased, **stress increased in the tooth**. Trabert and colleagues[134] measured the impact resistance of extracted maxillary central incisors as post diameter increased and found that increasing the post diameter decreased the tooth's resistance to fracture. Deutsch and colleagues[73] determined there was a six-fold increase in the potential for root fracture with every millimeter decrease in tooth diameter. However, two finite element studies failed to find higher tooth stresses with larger-diameter posts.[80,82]

CONCLUSIONS

Laboratory studies relating retention to post diameter have produced mixed results, whereas a more definitive relationship has been established between root fracture and large-diameter posts (Figure 35-13).

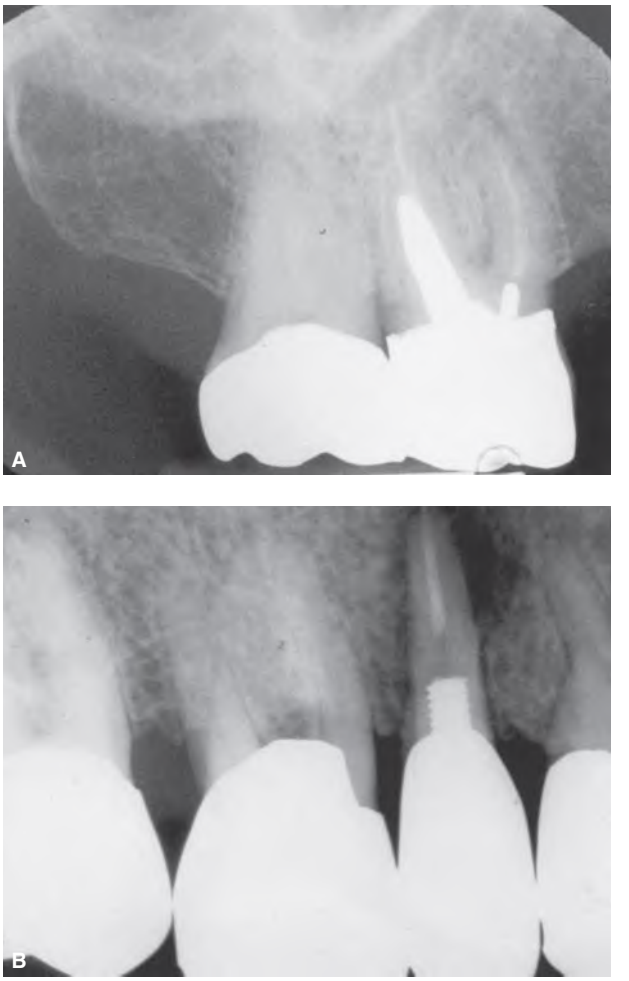

FIGURE 35-13 Excessive post diameters. ***A.*** Large-diameter post placed in the palatal root of the maxillary molar. ***B.*** Large-diameter threaded post caused fracture of the maxillary second premolar. The radiographic appearance of the bone is typical of a fractured root—a teardrop-shaped lesion with diffuse border.

WHAT IS THE RELATIONSHIP BETWEEN POST DIAMETER AND THE POTENTIAL FOR ROOT PERFORATIONS?

In a literature review of guidelines associated with post diameter, Lloyd and Palik[135] indicate there are three distinct philosophies of post space preparation. One group advocates the narrowest diameter for fabrication of a certain post length (the conservationists). Another group proposes a space with a diameter that does not exceed one-third the root diameter (the proportionists). The third group advised leaving at least 1 mm of sound dentin surrounding the entire post (the preservationists).

Based on the proportional concept of one-third the root diameter, three studies measured the root diameters of extracted teeth and proposed post diameters that would not exceed that proportion.[113,114,136] Tilk and colleagues[136] examined 1,500 roots. They measured the narrowest mesiodistal dimension at the apical, middle, and cervical one-thirds of the teeth except the palatal root of the maxillary first molar that was measured faciolingually. Based on the 95% confidence level that post width would not exceed one-third of the apical width of the root, they proposed the following post widths: small teeth such as mandibular incisors (0.6 to 0.7 mm); large-diameter roots such as maxillary central incisors and the palatal root of the maxillary first molar (1.0 mm); and for the remaining teeth (0.8 to 0.9 mm).

Shillingburg and colleagues[113] measured 700 root dimensions to determine the post diameters that would minimize the risk of perforation. Also based on not exceeding one-third the mesiodistal root width, they recommended the following post diameters: mandibular incisors (0.7 mm); maxillary central incisors or other large roots (1.7 mm - which was the maximal recommended dimension); post tip diameter (at least 1.5 mm less than the root diameter at that point); and post diameter at the middle of the root length (2.0 mm less than the root diameter).

Post spaces were prepared in 150 extracted maxillary and mandibular molars by using different instrument diameters and the resulting incidences of perforations were recorded.[114] The authors determined that the mesial roots of mandibular

molars and the buccal roots of maxillary molars should not be used for posts due to the higher risk of perforation on the furcation side of the root. For the principal roots (mandibular distal and maxillary palatal), they determined that posts should not be extended more than 7 mm into the root canal (apical to the pulp chamber) due to the risk of perforation. Regarding instrument size, they concluded that post preparations can be safely completed using a No. 2 Peeso instrument, but perforations are more likely when the larger No. 3 and 4 Peeso instruments were used.

Raiden and colleagues[137] evaluated several instrument diameters (0.7, 0.9, 1.1, 1.3, 1.5 and 1.7 millimeters) to determine which one(s) would preserve at least 1 mm of root wall thickness following post preparation in maxillary first premolars. They determined that instrument diameter must be small (0.7 mm or less) for maxillary first premolars with single canals because the mesial and distal developmental root depressions restrict the amount of available tooth structure in the centrally located single root canal. However, when there are dual canals, the instrument can be as large as 1.1 millimeters because the canals are located buccally and lingually into thicker areas of the roots.

CONCLUSIONS

Instruments used to prepare posts should be related in size to root dimensions to avoid excessive post diameters that lead to root perforation (Figure 35-14). Safe instrument diameters to use are 0.6 to 0.7 mm for small teeth such as mandibular incisors and 1 to 1.2 mm for large-diameter roots such as the maxillary central incisor. Molar posts longer than 7 mm have an increased chance of perforations and therefore should be avoided even when using instruments of an appropriate diameter.

CAN GUTTA-PERCHA BE REMOVED IMMEDIATELY AFTER ENDODONTIC TREATMENT AND A POST SPACE PREPARED?

Several studies indicate there is no difference in the leakage of the root canal filling material when the post space is prepared immediately after completing endodontic therapy.[118,138,120,139] Bourgeois and Lemon[138] found no difference between immediate preparation of a post space and preparation 1 week later when 4 mm of gutta-percha was retained. Zmener[120] found no difference in dye penetration between gutta-percha removal after 5 minutes and 48 hours. Two sealers were tested and 4 mm of gutta-percha was retained apically. When lateral condensation of gutta-percha was used, Madison and Zakariasen[118] found no difference in the dye penetration between immediate removal and 48-hour removal. Using the chloropercha filling technique, Schnell[139] found no difference between immediate removal of gutta-percha and no removal of gutta-percha. By contrast, Dickey and colleagues[140] found significantly greater leakage with immediate gutta-percha removal.

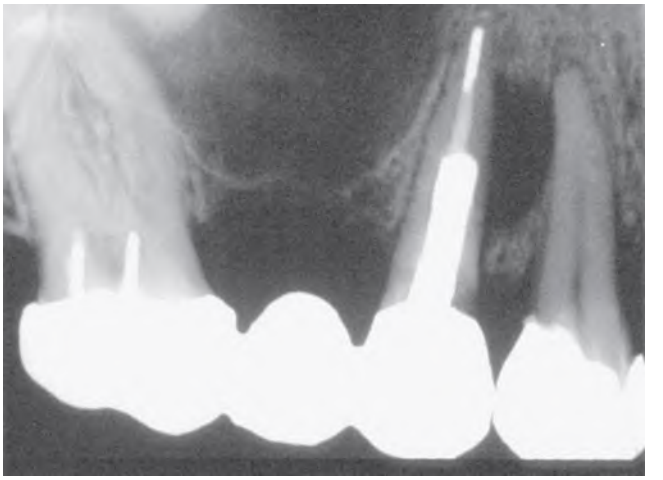

FIGURE 35-14 Excessive post diameter in the maxillary second premolar created a perforation in the mesial root concavity. Note the distinct border and round form of the radiolucent lesion, characteristics indicative of a root perforation.

Kwan and Harrington[141] tested the effect of immediate gutta-percha removal using both warm instruments and rotary instruments. There was no significant difference between the controls and immediate removal using warm pluggers and files.

Karapanou and colleagues[142] compared immediate and delayed removal of two sealers (a zinc oxide-eugenol-based sealer and a resin-based sealer). No difference between immediate and delayed removed was noted with the resin-based sealer, but delayed removal of the zinc oxide-eugenol-based sealer produced significantly greater leakage. Abramovitz and colleagues[127] compared immediate gutta-percha removal using hot pluggers and delayed gutta-percha removal (after two weeks) using Gates Glidden drills. They found no difference between the two methods.

Portell and colleagues[143] found that delayed gutta-percha removal (after two weeks) caused significantly more leakage than immediate removal when only 3 mm of gutta-percha was retained apically. Fan and colleagues[144] found more leakage from delayed removal of gutta-percha. Solano and colleagues[145] found a less significant difference in apical leakage between teeth whose post spaces were prepared at the time of the obturation and 1 week later using warm gutta-percha condensation and AH Plus sealer.

CONCLUSIONS

Adequately condensed gutta-percha can be safely removed immediately after endodontic treatment.

WHAT INSTRUMENTS REMOVE GUTTA-PERCHA WITHOUT DISTURBING THE APICAL SEAL?

Three methods have been advocated for the removal of gutta-percha during preparation of a post space: chemical (oil of eucalyptus, oil of turpentine and chloroform),

thermal (electrical or heated instruments), and mechanical (Gates Glidden drills, Peeso reamers, etc.). The chemical removal of gutta-percha for post space preparation is not utilized for specific reasons (microleakage, inability to control removal).[122,138] However, thermal and mechanical techniques or a combination of both are routinely used.

Multiple studies have determined there is no difference in leakage between removing gutta-percha with hot instruments and removing it with rotary instruments.[117,122,146] Suchina and Ludington[146] and Mattison and colleagues[122] found no difference between hot instrument removal and removal with Gates Glidden burs. Camp and Todd[117] found no difference between Peeso reamers, Gates Glidden burs, and hot instruments. Hiltner and colleagues[147] compared warm plugger removal with two types of rotary instruments (GPX burs and Peeso reamers). There were no significant differences in dye leakage between any of the groups. Contrasting results were found by Haddix and colleagues.[148] They measured significantly less leakage when the gutta-percha was removed with a heated plugger than when either a GPX instrument or Gates Glidden drills were used. DeCleen[149] found that it is desirable to remove gutta-percha using a heated instrument first, and then a small Gates Glidden drill. Using a pressure-driven radioactive tracer assay, Abramovitz and colleagues[127] found no difference in apical leakage between hot pluggers and Gates Glidden drills. Balto and colleagues[150] compared two methods of gutta-percha removal and their impact on apical leakage. They found that removing gutta-percha with Peeso reamers showed less leakage compared with using a hot plugger.

CONCLUSIONS

Both rotary instruments and hot hand instruments can be safely used to remove adequately condensed gutta-percha when 5 mm is retained apically.

CAN A SEPERATED INSTRUMENT BE REMOVED DURING POST SPACE PREPARATION AND STILL MAINTAIN THE APICAL SEAL?

Following root canal therapy, the endodontically treated tooth could present with a separated instrument (files, rotary instruments, etc.) in any part of the canal. Attempts to remove these fragments prior to post space preparation could lead to loss of apical seal, perforations, ledge formation, and/or over enlargement of the canal. A decision to bypass or remove the fragment will depend on the type and position of the broken instrument, the canal anatomy, the position of the fractured instrument, and should be determined by an endodontist with the use of an operating microscope. For more details, see Chapter 23.

Bypassing fractured instruments seems to be the best approach. Hülsmann and Schinkel[151] reported an overall success rate of 68% when bypassing broken instruments from canals in vivo. Ward and colleagues[152] reported an overall success rate of 73%. Suter and colleagues[153] with the use of an operating microscope were able to achieve an overall success rate of 87% when removing broken instruments.

CONCLUSIONS

If a separated fragment of any instrument cannot be removed from the canal during post space preparation, it should be bypassed or left in the canal.

CAN A PORTION OF SILVER POINT BE REMOVED AND STILL MAINTAIN THE APICAL SEAL?

In one study, all the specimens leaked when 1 mm of a 5-mm long silver point was removed by using a round bur.[120] Neagley[119] found that removal of the filling material coronal to the silver point with a Peeso reamer caused no leakage. However, when all the filling material was removed and 1 mm of the silver point removed, complete dye penetration occurred in eight of nine specimens.

CONCLUSIONS

The removal of a portion of a silver point during post preparation causes apical leakage.

HOW SOON SHOULD THE DEFINITIVE RESTORATION BE PLACED AFTER POST SPACE PREPARATION?

One-Piece Provisional Restoration

It is well established that a deficient root canal obturation and a poor coronal restoration will potentially allow saliva and microorganisms to penetrate the root canal causing periapical disease.[154–160]

Provisional restorations are mainly used to provide the patient with a functional and esthetic restoration.[150,161–164] Demarchi and colleagues[161] found that a tooth restored with a temporary post-crown combination had significantly greater leakage than definitively cemented prefabricated posts and separate crowns. Similar results were found by Fox and colleagues[162] when they compared cast post and cores cemented with zinc phosphate cement, prefabricated posts and composite resin cores cemented with resin cement, and provisional post-crowns cemented with zinc oxide-eugenol cement. In a 3-year retrospective clinical study, Lynch and colleagues[163] evaluated 176 endodontically treated teeth. They found that the loss of endodontically treated teeth occurred more often with those teeth restored with provisional restorations. Following these results, several studies[150,162] suggested that the definitive post and restoration

should be cemented as soon as possible in order to prevent recontamination of the root canal. However, to minimize leakage and enhance long-term success, the definitive coronal restoration should be of superior quality.[158,165–168]

Temporary Coronal Access Filling

Balto and colleagues[150] compared the leakage of different provisional materials used in post-prepared root canals. They found that none of the provisional restorations tested (Cavit, IRM, and Temp Bond) prevented coronal leakage when left for a long period of time (30 days). Safavi and colleagues[164] evaluated the prognosis of endodontically treated teeth following delayed placement of the definitive coronal restoration. A total of 464 endodontically treated teeth were followed radiographically. They found a higher success rate when the definitive restorations (silver amalgam, composite resin, or definitive restoration with or without post and cores) were placed as compared with teeth restored with provisional coronal access restorations (IRM or Cavit).

Torabinejad and colleagues[158] found that defective restorations could cause root canal system reinfection within 19 days. Ray and Trope[165] found that a combination of a poor coronal restoration and poor endodontic treatment resulted in a high failure rate of endodontically treated teeth. In a retrospective study, Iqbal and colleagues[166] found that a combination of good quality endodontic treatment and coronal restoration leads to a high success rate of endodontically treated teeth. Tronstad and colleagues[167] indicated that the quality of the endodontic treatment was more important than that of the coronal restoration.

CONCLUSIONS

Following endodontic treatment, post-space preparation should be performed and a post definitively cemented as soon as possible: the same day for a prefabricated post, and as soon as possible for a custom-fabricated post and core. The prepared tooth should then be restored with a well-fitting provisional restoration (good marginal seal and occlusion) followed by cementation of the definitive crown in as short a time as possible.

DOES THE USE OF A CERVICAL FERRULE (CIRCUMFERENTIAL BAND OF METAL) THAT ENGAGES TOOTH STRUCTURE HELP PREVENT TOOTH FRACTURE?

Survey data have been published that indicates the percentage of respondents who felt a ferrule (circumferential band of metal) increased a tooth's resistance to fracture.[53] Fifty-six percent of general dentists, 67% of prosthodontists, and 73% of board-certified prosthodontists felt that core ferrules increased a tooth's fracture resistance. To investigate this concept, several research studies have been performed. Some of the articles indicate ferrules are beneficial whereas others found no increase in fracture resistance.

The results appear indecisive until differences between study designs are analyzed. First, some of the studies tested ferrules that were part of a cast metal core (core ferrules),[169–173] whereas other studies evaluated the effectiveness of ferrules created by the overlying crown engaging tooth structure.[174–187] One study evaluated both core ferrules and crown ferrules.[188] Second, there were differences in the form of the ferrule, and therefore, the manner by which the metal engaged tooth structure (beveled sloping surface versus extension over relatively parallel prepared tooth structure). Third, there were variations in the amount of tooth structure encompassed by the ferrules.

The data generally indicates that ferrules formed as part of the core are less effective than ferrules created when the overlying crown engages tooth structure. In four of the six core ferrule studies, they were found to be ineffective.[170,171,173,188] Also, in one of the two studies where the core ferrule was effective, the ferrule form was a 2-mm parallel extension of the core over tooth structure as opposed to a bevel.[169] In the other study where core ferrules were found to be effective, a torsional force was used as opposed to an angular lingual force.[172] In the crown ferrule studies, most of the ferrules effectively increased a tooth's resistance to fracture. Only when the crown ferrule was of minimal dimension or a sloping form, it was found to be ineffective.[174,188] In support of these studies, Rosen and Partida-Rivera[189] found that a 2-mm cast gold collar (not part of the post and core) was very effective in preventing root fracture when a tapered screw post was intentionally threaded into roots so as to induce fracture. Assif and colleagues[190] found no difference in the tooth fracture patterns of parallel posts, tapered posts and parallel posts with a tapered end when they were covered by a crown that grasped 2 mm of tooth structure. Akkayan and colleagues[181] found no significant difference between fiber-reinforced and zirconia dowels when the ferrule length was 2 mm.

The data also supports the concept that ferrules that grasp larger amounts of tooth structure are more effective than those engaging only a small amount of tooth structure. In both the core and crown ferrule studies the tooth's resistance to fracture was increased when a substantive amount of tooth structure was engaged (2 mm in the core ferrule studies and 1 to 2 mm in the crown ferrule studies). Libman and Nicholls[174] found the 0.5- to 1.0-mm crown ferrule to be ineffective whereas a 1.5- to 2.0-mm crown ferrule to be effective. Isidor and colleagues[176] determined that increasing crown ferrule length significantly increased the number of cyclic cycles required to cause specimen failure. They compared no ferrule with 1.25 and 2.55 mm crown ferrules. They concluded that ferrule length was more important than post length in increasing a tooth's resistance to fracture under cyclic loading. Zhi-Yue and Yu-Xing[180] found that a 2-mm crown ferrule effectively enhanced the fracture strength of endodontically treated teeth when a cast post and core was used. Pereira and colleagues[187] compared the effect of no crown ferrule with 1-, 2-, and 3-mm crown ferrules. They found that a 3-mm crown ferrule

significantly increased the fracture resistance of endodontically treated teeth compared to a 2-mm crown ferrule.

The form of the prepared ferrule also appears to affect a tooth's fracture resistance in the previously cited studies. Only one beveled/sloping ferrule was effective in enhancing a tooth's fracture resistance and that was when a torsional force was applied to the tooth. Tan and colleagues[183] compared a 2-mm uniform crown ferrule that extended around the entire crown circumference with a 2-mm nonuniform crown ferrule where the ferrule was only 0.5 mm on the proximal surfaces. The uniform ferrule produced significantly greater fracture resistance than a nonuniform ferrule. In an *in vitro* study, Naumann and colleagues[184] evaluated the effect of chewing simulation on the fracture resistance of maxillary endodontically treated teeth with incomplete crown ferrules. The greatest variation of failure load was associated with the absence of portions (facial, palatal, or interproximal) of the crown ferrule. Ng and colleagues[185] investigated the effect of limited residual axial tooth structure on the fracture resistance of maxillary anterior endodontically treated teeth. They found that in the absence of 360° of circumferential coronal tooth structure, the location of the remaining coronal tooth structure may be an important factor for determining the fracture resistance of endodontically treated teeth. The palatal axial wall was as effective as a 360° circumference in providing fracture resistance.

CONCLUSIONS

Differences of opinion exist regarding the effectiveness of ferrules in preventing tooth fracture. Ferrules have been tested when they are part of the core and also when the ferrule is created by the overlying crown engaging tooth structure. Most data indicates **a ferrule created by the crown** encompassing tooth structure **is more effective** than a ferrule that is part of the post and core (Figure 35-15). Ferrule effectiveness is enhanced by grasping larger amounts of tooth structure. The amount of tooth structure engaged by the overlying crown appears to be more important than the length of the post in increasing a tooth's resistance to fracture. **Ferrules are more effective** when the crown encompasses relatively **parallel prepared tooth structure** than when it engages beveled/sloping tooth surfaces. Ferrules that encompass 2 mm of tooth structure around the entire circumference of a tooth are more effective than nonuniform ferrules.

POST AND CORE PLACEMENT TECHNIQUES

Pretreatment Data Review

When it has been determined that a post and core is required to properly retain a definitive single crown or fixed partial denture of an endodontically treated tooth, the following characteristics should be determined prior to beginning the clinical procedures associated with the fabrication of a post and core.

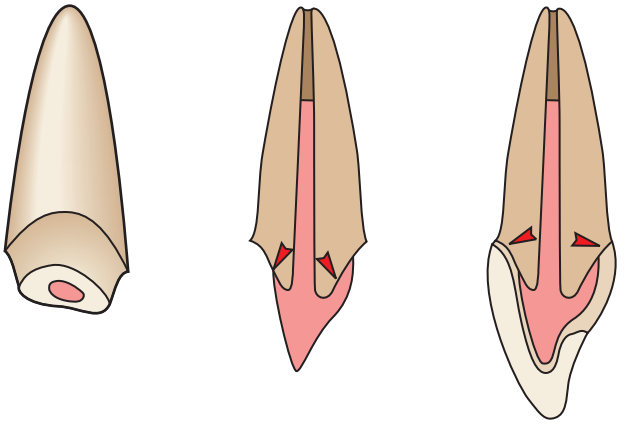

FIGURE 35-15 Types of ferrules. ***A.*** Tooth prepared for a post and core. ***B.*** Post and core has been cemented into the tooth. The arrows note how the core has created a ferrule around the tooth (note the reduction in the width of remaining coronal tooth structure to develop this core ferrule). ***C.*** A metal ceramic crown has been cemented over the core. The arrows show how the crown encompasses the tooth cervically, establishing a crown ferrule.

Post Length

Since 5 mm of gutta-percha should be retained apically to assure a good seal (as measured radiographically), posts should be extended to that length in all teeth except molars. With molars, posts should be placed in the primary roots (palatal root of maxillary molars and distal roots of mandibular molars) and should not be extended more than 7 mm apical to the origin of the root canal in the base of the pulp chamber (Figure 35-11). Extension beyond this length can lead to root perforation or only very thin areas of remaining tooth structure.

Post Diameter

A frequently used and clinically appropriate guideline for post diameter is not to exceed one-third the root canal diameter. It has been determined that when a root canal is prepared for a post and the diameter is increased beyond one-third of the root diameter, the tooth becomes exponentially weaker. Each millimeter of increase (beyond one-third the root diameter) causes a six-fold increase in the potential for root fracture.[73] Based on measuring the root dimensions of 1,500 teeth (125 of each tooth) and using the guideline that the post should be one-third the root diameter, optimal post diameter measurements have been determined to be approximately 0.6 mm for mandibular incisors, 1.0 mm for maxillary central incisors, maxillary and mandibular canines and the palatal root of the maxillary first molar.[135] The recommended post diameter for the other teeth was 0.8 mm.[135] Another study of 700 teeth recommended that post diameter should range from 0.7 mm for mandibular incisors to a maximum of 1.7 mmm for maxillary central incisors.[113]

Anatomic and Structural Limitations

The practitioner who completed the endodontic treatment is ideally suited to identify characteristics of the pulp chamber,

rooted canal(s) anatomy, and completed endodontic filling that should be reviewed before placing a post and core. These characteristics include the presence and extent of dentinal craze lines, identification of teeth where further root preparation (beyond that needed to complete endodontic instrumentation) will result in less than 1 mm of remaining dentin or a post diameter greater than one-third of the root diameter area, information regarding areas where the remaining tooth structure is thin, and the point at which significant root curvature begins.

Craze Lines

Craze lines in dentin are areas of weakness where further crack propagation may result in root fracture and tooth loss. The patient should be informed of their presence with appropriate chart documentation of crack location. It is prudent to avoid post placement, if possible, in favor of a restorative material core. If a post is required, it should passively fit the canal and the definitive restoration should entirely encompass the cracked area, whenever possible, by forming a ferrule.

Dentin Thickness After Endodontic Treatment

Following normal and appropriate endodontic instrumentation, teeth can possess less than 1 mm of dentin, indicating there should be no further root preparation for the post. When these teeth are encountered, it is best to fabricate a post that fits into the existing morphologic form and diameter rather than additionally preparing the root to accept a prefabricated type of post. This characteristic is one of the primary indications for the use of a custom cast post and core. One study determined that canines (maxillary and mandibular), maxillary central and lateral incisors, and the palatal root of maxillary first molars possessed more than 1 mm of dentin after endodontic cleaning and shaping.[192] All other teeth had roots with less than 1 mm of remaining dentin following endodontic treatment. With the goal of preserving 1 mm of remaining dentin lateral to posts, it has been determined that single-canal maxillary first premolars should have posts that are 0.7 mm in diameter or less.[137] Mandibular premolars with oval/ribbon-shaped canals should not be subjected to any preparation of the root canal for a post since it will result in less than 1 mm of dentin.[192] Preparation of the mesial root canals in mandibular molars and the facial root canals in maxillary molars can result in perforation or only thin areas of remaining dentin. Based on the measurements of residual dentin thickness, it is recommended that posts not be placed in these roots if possible.

Root Curvature

When root curvature is present, post length must be limited so as to preserve remaining dentin, thereby helping to prevent root fracture or perforation. Root curvature occurs most frequently in the apical 5 mm of the root. Therefore, if 5 mm of gutta-percha is retained apically, curved portions of the root are usually avoided. As discussed previously under post length, molar posts should not exceed 7 mm in the roots because of the potential for perforation due to root curvature and the presence of developmental root depressions. Molar roots are frequently curved and the post should terminate at the point where substantive curvature begins.

Type of Post and Core

Custom Cast Post

For many years, custom cast post and cores have been considered to be the standard of care when restoring endodontically treated teeth and have historically been made of metal. Gold, silver-palladium, and base metal alloys are the most commonly used metals. For economic reasons, base metal alloys were introduced as an alternative metal to high-noble alloys. The major disadvantages of base metal alloys are their manipulation (laboratory and clinical), their hardness, and their unstable chemical structure.[193] The degradation of base metal alloys releases substances that could be harmful to the patient.[193–195] Silver-palladium alloys were introduced as a replacement for gold and base metal alloys. They are relatively easy to manipulate and have many properties similar to those of gold casting alloys.[196] However, the castability of silver-palladium alloys was shown to be inferior to that of gold-based alloys.[193,197,198]

Cast posts and cores can be fabricated by using either a direct or an indirect technique, and several methods have been described for the intraoral fabrication of an acrylic resin pattern for a direct post and core.[199–203] Prefabricated plastic patterns are commonly used, and they are relined to fit the post space with an autopolymerizing acrylic resin (Figure 35-16). The coronal adaptation of the tooth is usually completed using the same resin, and the core contoured intraorally to the desired form. The only disadvantage of this direct technique is the amount of chairside time required to perform the procedure.

As an alternative, indirect techniques for the fabrication of cast post and cores have been proposed.[204–206] However, this procedure requires meticulous attention to a defined protocol to insure success. One technique uses a lentulo spiral instrument to carry impression material to the apical aspect of the prepared post space. Since a thin projection of polymerized impression material can be distorted or torn upon removal from the mouth, reinforcement of the impression material is required. This reinforcement can be accomplished by using several materials such as a plastic pin or metal wire. Care must be taken when using plastic pins to ensure that they are not slightly flexed by placement into a curved canal or through contact with the impression tray, thereby allowing a return to their original form upon impression removal with some resulting distortion. The use of a portion of a safety pin is an excellent material as long as it is made of spring steel, thereby preventing flexion. A bendable metal pin can be distorted upon impression removal. Complete seating of a section from a safety pin until it contacts the gutta-percha is recommended. Upon removal of the impression from the mouth, the presence of the metal pin at the apical extension of the impression material indicates there was no elongation of the impression material upon removal.

(Figure 35-16B to I reprinted with permission from Baba NZ.[331])

To make the impression technique easier, prefabricated precision plastic dowels were introduced.[207,208] After the selection of the desired diameter for the dowel, a corresponding drill is used to prepare the post space at the appropriate length. The dowel is then inserted into the prepared canal, picked up in an impression, and transferred to the dental laboratory for fabrication.

A proposed advantage of cast post and cores is their purported ease of removal in case of an endodontic retreatement.[209–211] In addition, several long-term clinical studies have reported high success rates with cast post and cores.[60,212]

Prefabricated Post

Prefabricated posts have become quite popular and a wide variety of systems are available: parallel-sided or tapered, smooth or serrated, passive (cement/bonded) or active (threaded) or combinations of these.[213–215] Threaded posts depend primarily on engaging the tooth—either through threads formed in the dentin as the post is screwed into the root or through threads previously "tapped" into the dentin. The majority of these posts are metallic. Recently, in response to a need for tooth-colored posts, several nonmetallic posts such as carbon fiber epoxy resin, zirconia, glass fiber-reinforced (GFR) epoxy resin, and ultra high strength polyethelene fiber-reinforced (PFR) posts are available and early data indicates they can be acceptable alternatives to metallic posts.

The carbon fiber-reinforced (CFR) epoxy resin post system was developed in France in 1988 by Duret and Renaud[216–218] and first introduced in Europe in the early 1990s.[219–221] The matrix for this post is an epoxy resin reinforced with unidirectional carbon fibers parallel to the long axis of the post. The fibers are 8 μm in diameter and uniformly embedded in the epoxy resin matrix. By weight, the fibers comprise 64% of the post and are stretched before injection of the resin matrix to maximize the physical properties of the post (Figure 35-17).[216,222,223] The post is reported to absorb applied stresses and distribute these stresses along the entire post channel.[224] The bulk of the carbon fibers is made from polyacrylonitrile by heating it in air at 200°C to 250°C and then in an inert atmosphere at 1200°C. This process removes hydrogen, nitrogen and oxygen, leaving a chain of carbon atoms and forming carbon fibers.[225]

The CFR post has been reported to exhibit high fatigue strength, high tensile strength, and a modulus of elasticity similar to dentin.[219,222,226–229] The post was originally radiolucent; however, a radiopaque post is now available. Radiopacity is produced by placing traces of barium sulfate and/or silicate inside the post. Mannocci and colleagues[230] examined radiographically five different types of fiber posts. They found that only Composiposts and Snowposts had uniform radiopacity. Finger and colleagues[231] examined the radiopacity of seven fiber-reinforced resin posts compared to a titanium post. Compared to other posts, they found CFR posts had an acceptable radiopacity.

The posts are available in different shapes: double cylindrical with conical stabilization ledges or conical shapes (Figure 35-18). The surface texture of the post may be smooth or serrated. Studies have indicated that serrations increased mechanical retention although the smooth post also bonded well to adhesive dental resin.[228,232] The post has a surface roughness of 5 to 10 μm to enhance mechanical adhesion of the autopolymerizing luting material, and the post appears to be biocompatible based on cytotoxicity tests.[227,233]

Several studies indicate that CFR posts exhibit adequate physical properties compared to metal posts.[223,226,234,235] In a retrospective study over 4 years, Ferrari and colleagues[234] indicated that the Cosmopost system was superior to the

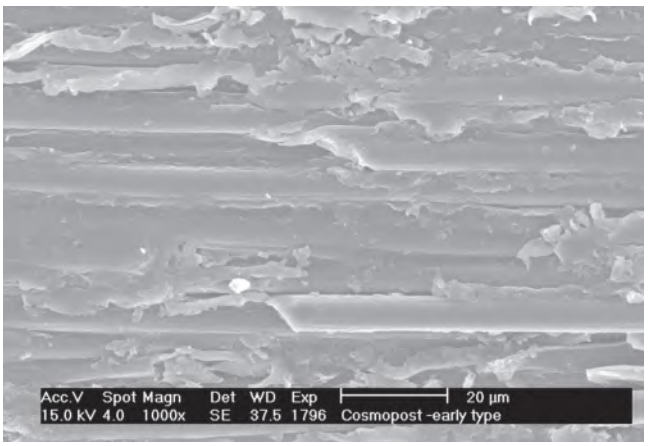

FIGURE 35-17 Surface texture of a carbon fiber-reinforced epoxy resin dowel (SEM magnification: ×1000).

FIGURE 35-18 Available shapes of carbon fiber-reinforced epoxy resin posts.

conventional cast post and core system. King and Setchell [226] and Duret and colleagues[223] evaluated the physical properties (fracture resistance and modulus of elasticity) of CFR posts and both reported that these posts are stronger than prefabricated metal posts.

Contrasting results were reported by Sidoli and colleagues[236] in an *in vitro* study. They found that CFR posts exhibited inferior strength when compared with metallic posts. Similar results were also obtained by Purton and Love[237] and Asmussen and colleagues.[238]

Martinez-Insua and colleagues[239] studied the fracture resistance of teeth restored with CFR posts and cast posts. They reported a significantly higher fracture threshold for cast post and cores. A clinical evaluation of CFR posts suggested that these posts did not perform as well as conventional cast post and cores.[240] However, the results of this study must be interpreted with caution because of the relatively small sample size (27 teeth) used in this study.

Multiple studies indicate a decrease in the strength of CFR posts after thermocycling and cyclic loading.[241–244] In addition, contact of the post with oral fluids reduced their flexural strength values.[233–245] In two studies, results showed no significant difference among a CFR posts, cast post and cores, and metal posts when restoring mandibular incisor teeth. No differences were noted in the mode or state of fracture observed.[246,247]

Multiple *in-vitro* studies have reported that CFR posts are less likely to cause fracture of the root at failure. The mode of failure of teeth restored with CFR posts in these studies was more favorable to the remaining tooth structure.[181,226,236,239,248–252] However, despite all these advantageous properties, one should question certain *in vivo* applications of the CFR post. When the ferrule is small or absent in an endodontically treated tooth restored with a CFR post, loads may cause the post to flex causing a micromovement of the entire core. The cement seal at the margin of the crown can be compromised, accompanied by microleakage of oral bacteria and fluids. As a result, secondary caries may develop in the space and may not be easily detected.[252]

The short-term clinical studies of CFR posts appear promising but some of the long-term studies report higher failure rates. Wennström[210] restored 173 teeth with CFR posts and reported two failures after a period of 3 to 4 years. A short-term retrospective study of 236 teeth treated 2 to 3 years previously reported no failures of the posts.[253] Ferrari and colleagues[234] studied 100 CFR posts and reported a failure rate of 3.2% after a mean time of 3.8 years of clinical service. In a prospective study of 59 CFR posts, Glazer and colleagues[254] indicated that these posts did not fracture but there was a 7.7% absolute failure rate. Another retrospective study[255] of 1,304 CFR posts followed from 1 to 6 years found that a 3.2% failure rate that was attributed to debonding during removal of temporary crowns and periapical lesions. Hedlund and colleagues[256] studied the clinical performance of 65 CFR posts for an average of 2.3 years of clinical service and found a 3% failure rate. In a retrospective study of 64 CFR posts, Segerström and colleagues[257] found that nearly 50% of the CFR posts were lost after a mean time of 6.7 years.

Should fracture of CFR posts occur, a potential advantage is the relative ease of removal from the post space compared to metal posts. A removal kit has been suggested for this procedure and the latter is recommended as a single use only item.[258–262]

Glass fiber-reinforced (GFR) epoxy resin posts The high demand for esthetic restorations and all-ceramic crowns led to the development of a variety of tooth-colored post systems as an alternative to metal and CFR posts. The GFR epoxy resin post is made of glass or silica fibers (white or translucent). Glass fiber posts can be made of different types of glasses: electrical glass, high-strength glass, or quartz fibers (Figure 35-19).[244,263] The commonly used fibers are silica-based (50 to 70% SiO_2), in addition to other oxides.[264]

The GFR post is available in different shapes: cylindrical, cylindroconical, or conical shape (Figure 35-20). An *in vitro* assessment of several GFR post systems indicated that parallel-sided GFR posts are more retentive than tapered GFR posts.[265]

The composition of the glass fibers in the matrix tends to play an important role in the strength of the post. Newman and colleagues[243] compared the fracture resistance of two GFR posts containing different weight percentages of glass fibers. They found that the higher content of glass fibers in

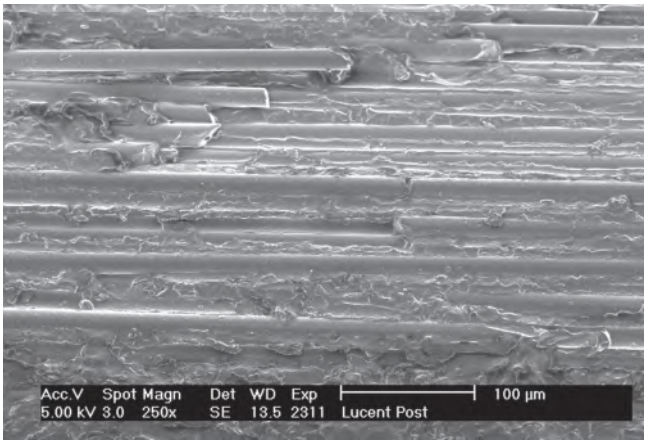

FIGURE 35-19 Surface texture of a glass fiber-reinforced epoxy resin post (SEM magnification: ×250).

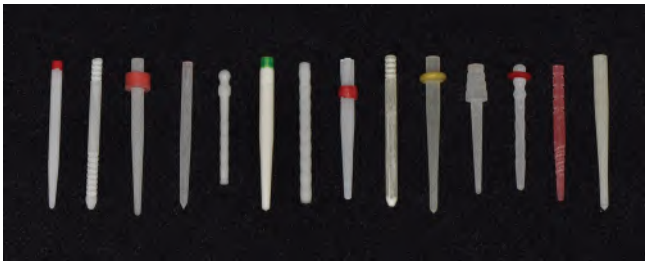

FIGURE 35-20 Available shapes and designs for glass fiber-reinforced epoxy resin posts. (Reprinted with permission from Baba NZ.[331])

the post contributed to the greater strength displayed by the tested post.

The GFR post has been reported to exhibit high fatigue strength, high tensile strength, and a modulus of elasticity closer to dentin than that of CFR posts.[229,238,266] The GFR post is as strong as the CFR post and approximately twice as rigid.[267]

The flexural strength of GFR posts is not related to the type of glass fiber used. Galhano and colleagues[229] evaluated the flexural strength of carbon fiber, quartz fiber, and glass fiber posts. They found that the posts behaved similarly because of the same concentration and type of the epoxy resin used to join the fibers together. Pfeiffer and colleagues[268] evaluated, *in vitro*, the yield strength of GFR post, titanium, and zirconia posts. They found that the yield strength was significantly higher for the zirconia and titanium posts when compared with GFR posts.

Several studies have determined that there is a decrease in the strength (about 40%) of GFR posts after thermocycling and cyclic loading. In addition, contact of the post with oral fluids (short- and long-term) reduced their flexural strength.[241,244,269–271]

Two studies indicate that the tensile bond strength between the composite resin core material and the GFR post is less than that developed with a titanium post.[272,273] Other studies indicated that there was a good adhesive bond between the GFR post and composite resin cements.[272,274,275] The bonding of the core to the post can be improved by treating the post with airborne-particle abrasion.[276] Similar results were obtained by treating the surface of the post with hydrogen peroxide and silane or hydrofluoric acid and silane.[277,278] During fatigue loading, a composite resin core bonded to a GFR post provided significantly stronger crown retention than cast gold posts and cores and titanium posts with composite resin cores.[182]

Similarly to CFR posts, multiple studies have shown that GFR posts are less likely to cause fracture of the root at failure.[243,279–281] The mode of failure of teeth restored with CFR posts in these studies was more favorable to the remaining tooth structure. However, studies have discussed the importance of the presence of a ferrule effect in achieving a high success rate.[181,184,185,282] Malferrari and colleagues[281] restored 180 teeth with GFR posts and reported no post, core, or root fracture after 30 months of service. Naumann and colleagues[283] found that the survival rate of parallel-sided and tapered GFR posts was similar.

Polyethylene fiber-reinforced posts (PFR) are made of ultra high molecular weight polyethylene woven-fiber ribbon (Ribbond, Ribbond Inc, Seattle, Washington). They are not post and cores in the traditional sense. It is a polyethylene-woven fiber ribbon that is coated with a dentin bonding agent and packed into the canal, where it is then light polymerized in position.[284–286] The Ribbond material has a three-dimensional structure due to either a leno weave or a triaxial architectural design (Figure 35-21). These designs are composed of a great number of nodal intersections that prevent crack propagation and provide a mechanical retention for the composite resin cement. When PFR posts were compared with metal posts in the laboratory, the fiber-reinforced posts reduced the incidence of vertical root fracture. The addition of a small-size prefabricated post to the PFR post increased the strength of the post-and-core complex. However, the strength of the PFR post did not approach that of a cast metal post and core.[284]

FIGURE 35-21 Close-up of polyethelene fiber-reinforced post material in its original package. (Reprinted with permission from Baba NZ.[331])

When compared to other fiber-reinforced composite post systems the PFR posts were also found to protect the remaining tooth structure.[243] These results may be attributed to the manufacturer's recommendations not to enlarging the root canals, not to removing undercuts present in the root canal, and forming a 1.5 to 2 mm crown ferrule. The presence of a large volume of core material, and a sufficient dentin bonding area coronally seems to greatly affect the mean load-to-failure value of PFR posts.[243] Eskitascioglu and colleagues[287] evaluated two post and core systems using a fracture strength test and a finite element analysis. They found that stress accumulated along the cervical region of the tooth and along the buccal bone. Minimum stress was recorded within the PFR post system. They suggested that the PFR post could be advantageous for the restoration of teeth with apical resection.

Newman and colleagues[243] compared the effect of three fiber-reinforced composite post systems on the fracture resistance of endodontically treated teeth. They found that when PFR posts were placed in narrow canals, they performed better than GFR posts. They suggested the PFR post be formed to the shape of the canal.

The use of PFR posts to restore endodontically treated teeth appears to be a promising alternative to the stainless steel and zirconia dowel posts with respect to microleakage.[288] Usumez and colleagues[288] compared in vitro the microleakage of three esthetic, adhesively luted dowel systems with a conventional dowel system. They found that the PFR posts and the GFR posts exhibited less microleakage compared to zirconia posts.

Zirconia posts The trend toward the use of all-ceramic crowns has encouraged manufacturers to explore the development of all-ceramic posts.[289–292] A metal-free post avoids the

discoloration of tooth structure that can occur with metal posts and produces optical properties comparable to all-ceramic crowns.[293–296] One type of all-ceramic post is the zirconia post, composed of zirconium oxide (ZrO_2), an inert material used for a range of applications. Its high fracture toughness, high flexural strength and excellent resistance to corrosion encouraged orthopedists to use it at articulation surfaces.[297] Studies have suggested that zirconia specimens transplanted in animals were very stable after long-term aging, and there was no apparent degradation of the specimens.[297–301]

Zirconia (Tetragonal Zirconium Polycrystals, TZP) exhibits phase transformation. Low-temperature degradation of TZP is known to occur as a result of spontaneous phase transformation of tetragonal zirconia to monoclinic phase during ageing at 130 to 300°C possibly within a water environment. It has been reported that this degradation leads to a decrease in strength due to the formation of microcracks accompanying the phase transformation. To inhibit this phase transformation, certain oxides (magnesium, yttrium or calcium oxide) are added to fully or partially stabilize the tetragonal phase of zirconia at room temperature. This mechanism is known as transformation toughening.[292,298,302–304]

The type of zirconia used for dental posts is composed of TZP with 3% mol yttrium oxide (Y_2O_3) and is called YTZP (Yttria-stabilized tetragonal polycrystalline zirconia).[292,305] YTZP is composed of a dense fine-grained structure (0.5 μm average diameter) that provides the post with toughness and a smooth surface.[303,305,306] The zirconia post is extremely radiopaque, biocompatible, possesses high flexural strength and fracture toughness, and may act similar to steel.[298–302,307–315] In addition, the post has a low solubility[312] and is not affected by thermocycling.[241] The post is available in a cylindroconical shape (Figure 35–22).

The Zirconia post has a smooth surface configuration with no grooves, serrations or roughness to enhance mechanical retention (Figure 35-23). As a result the zirconia post does not bond well to composite resins and may not provide the best support for a brittle all-ceramic crown. [272,317–319] Dietshi and colleagues[318] found that these posts also have poor resin-bonding capabilities to dentin after dynamic loading and thermocycling due to the rigidity of the post. In a cyclic loading test performed in a wet environment, Mannoci and colleagues[250] found that the survival rate of zirconia posts compared to fiber posts was significantly lower.

In vitro studies[272,275,319,320] indicated that the smooth surface configuration of untreated zirconia posts leads to failure at the cement/post interface. The vast majority of the cement remained in the root and was not attached to the zirconia dowels. Wegner and Kern[321] evaluated the bond strength of composite resin cement to zirconia posts. They found that the long-term bond strength of the composite resin cement to zirconia posts is weak. Several studies found that acid etching and silanization of zirconia posts does not improve the strength of the resin bond to the zirconia-based material because of the lack of or no silica content in the post.[321–324] However, tribochemical silica coating was found to increase the bond strength of composite resin to the zirconia post.[325,326]

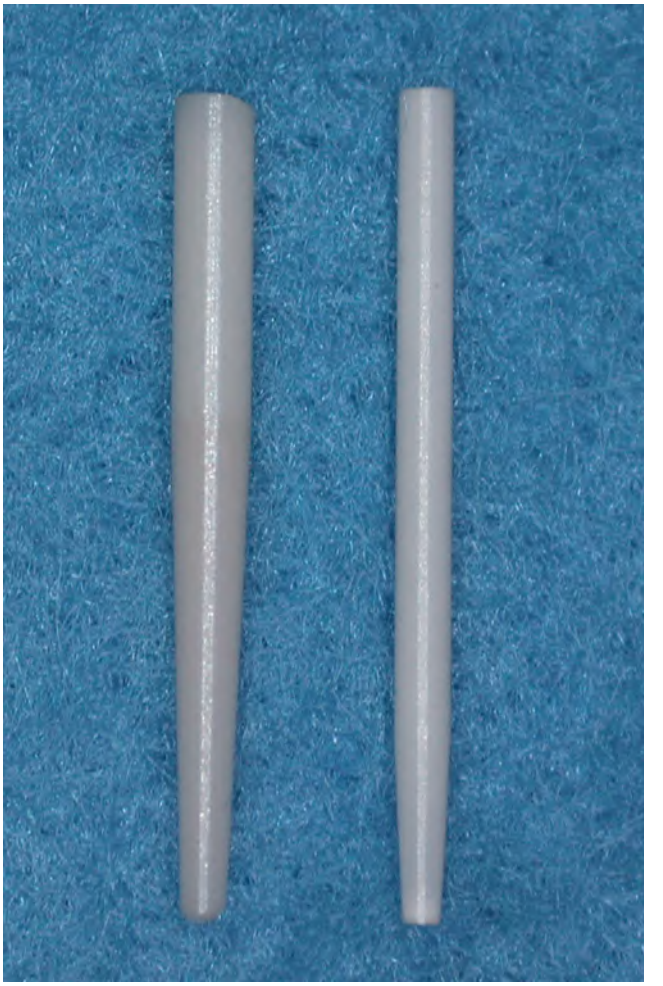

FIGURE 35-22 Available shapes and designs for zirconia posts.

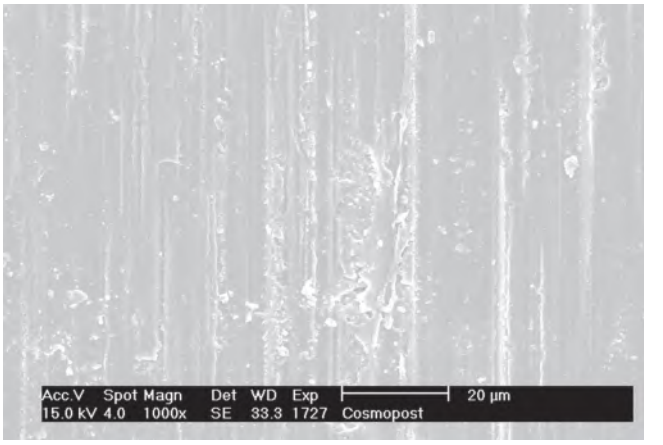

FIGURE 35-23 Surface texture of zirconia post (SEM magnification: ×1000).

Oblak and colleagues[327] compared the fracture resistance of prefabricated zirconia posts after different surface treatments. They found that airborne particle-abraded posts exhibited significantly higher resistance to fracture than posts that have been ground with a diamond instrument.

The use of heat-pressed glass to form the core instead of composite resin has been suggested.[212,310,311] This approach

may improve the physical properties of the all-ceramic post and core.

When the mechanical properties of zirconia posts were evaluated it was reported that these posts are very stiff and strong, with no plastic behavior.[238,309,310] Pfeiffer and colleagues[268] found that the zirconia post had a significantly higher yield strength compared with titanium and GFR posts.

Several studies indicated that many commonly used posts exhibit higher fracture resistance than zirconia posts.[249,308,328,329] In addition, once they fracture, the irretrievable posts will leave unrestorable roots.[181,329] Nothdurft and colleagues[330] evaluated the clinical performance of 30 zirconia posts in a short-term retrospective study. They found no signs of failure of these posts. However, these results should be analyzed with caution because of the small sample size and a short follow-up time.

Root Selection for Multirooted Teeth

Premolars

When post and cores are needed in prelomars, posts are best placed in the palatal root of maxillary premolar and the straightest root for the mandibular canal. The buccal root could be prepared to a depth of 1 to 2 mm and to serve as an antirotational lock, if needed.

Molars

When posts and cores are needed in molars, posts are best placed in roots that have the greatest dentin thickness and the smallest developmental root depressions. The most appropriate roots (the primary roots) in maxillary molars are the palatal roots and in mandibular molars are the distal roots (Figure 35-24). The facial roots of maxillary molars and the mesial root of mandibular molars should be avoided if at all possible. If these roots must be used in addition to the primary roots, then the post length should be short (3 to 4 mm) and a small-diameter instrument should be used (no larger than a No. 2 Peeso instrument that is 1.0 mm in diameter). When 7-mm long posts were placed in the mesial root of mandibular molars, 20 of the 75 tested teeth had only a thin layer of remaining dentin or were perforated.[101]

Type of Definitive Restoration

It is important to know the type of single crown or retainer (all-metal, all-ceramic, metal ceramic) that will be used as the definitive restoration for each endodontically treated tooth that requires a post and core. This knowledge permits the tooth to be reduced in accordance with the reduction depths and form recommended for each type of crown/retainer.

Coronal Tooth Preparation

Restoration of endodontically treated teeth must be a team effort between the endodontist and the dentist responsible for the coronal restoration, requiring two-way communication. If it can be co-coordinated, the first step in the fabrication of a post and core should ideally be preparation of the coronal tooth (Figure 35-25) for the type of definitive restoration that will be placed (all-metal crown, metal ceramic crown, all-ceramic crown). This procedure will help in determining the structure of the post-core fabrication. Each type of restoration requires different amounts of tooth reduction, and the form of the tooth preparation varies considerably. By preparing the coronal tooth structure first, the structural integrity of remaining dentin and enamel can be assessed. When the remaining peripheral tooth structure is very thin and would likely not possess sufficient strength to resist occlusal forces transmitted through the crown to the tooth, the thin structure is removed and replaced as part of the core.

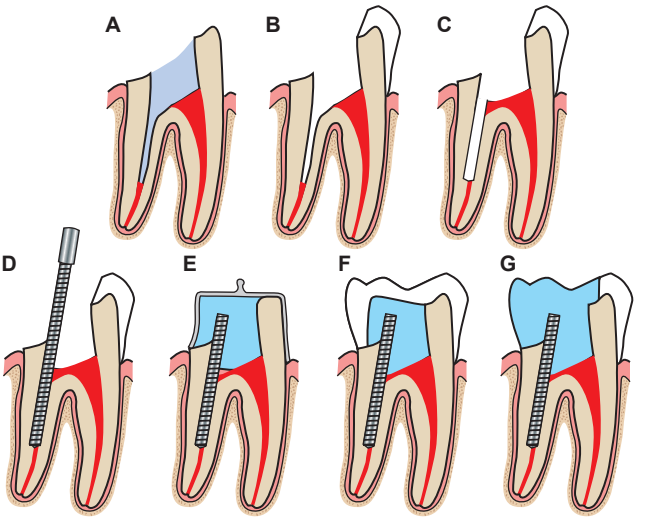

FIGURE 35-24 Placement of Para Post and restorative material core in a molar. ***A.*** Endodontic treatment completed. ***B.*** Provisional restorative material in the pulpal chamber has been removed and gutta-percha removed from the distal root canal. ***C.*** Post space formed with a drill. ***D.*** Trial placement of the post. ***E.*** The post has been shortened and cemented. A restorative material core has been formed. ***F.*** The tooth with core has been prepared, an impression made, and the definitive crown cemented. ***G.*** If there is an extended time delay between placement of the core and preparation of the tooth for a crown, the core can be built to full tooth contour to serve as the interim restoration.

FIGURE 35-25 Coronal tooth preparation. The existing crown has been removed on an endodontically treated tooth. Initial reduction of the tooth has been completed to permit assessment of integrity of remaining coronal tooth structure.

This order of procedure also establishes morphologic borders that can be used to guide core fabrication so it is confluent with surrounding tooth structure and possesses the desired tooth preparation form.

Pulp Chamber Preparation

Treatment materials present in the pulp chamber following endodontic treatment (restorative materials sealing the coronal access and gutta-percha) are removed using rotary instruments (Figure 35-26). If a prefabricated post will be cemented into a root canal and a restorative material core built around the post, morphologic undercuts present in the pulp chamber should be retained for core retention. If a custom cast post and core is fabricated, then pulp chamber undercuts should be either blocked out with a definitive cement or a restorative material that is bonded to the tooth or the undercut eliminated by removing tooth structure. If removing the undercut through tooth preparation would result in substantive tooth structure removal that weakens the tooth, then blocking out the undercut is the treatment of choice.

Root Canal Preparation

The individual who completed the root canal is ideally suited to prepare the root canal, being the one that is most knowledgeable regarding root curvatures and areas where no further root preparation should be performed because it will result in areas of thin residual dentin. For this reason, it may be prudent to prepare the root canal for a post as a continuation of the endodontic treatment.

If the canal has not been prepared for a post as part of the endodontic treatment process, it will be necessary to remove the filling material using either a warm endodontic hand instrument or a slow-speed rotary instrument such as a Gates Glidden drill (Dentsply Maillefer North America, Tulsa, OK) or Peeso instrument (Dentsply Maillefer North America, Tulsa, OK). If a warm hand instrument is used, it is advisable to place a dental dam so as to prevent aspiration or swallowing of the hand instrument should it be dropped.

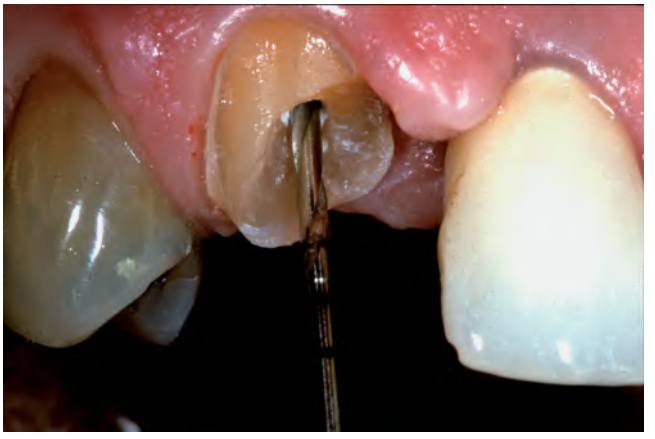

FIGURE 35-26 Pulp chamber preparation. Rotary instrument being used to remove provisional material.

Successful use of rotary instruments is related to initially using a small-diameter instrument (one that only removes the filling material without dentin removal). This small-diameter instrument is used to remove small vertical increments (1 to 2 mm) of the root canal filling material. After each vertical increment is removed, a visual inspection should be made to verify that the endodontic filling material is centered in the post preparation. The incremental root canal filling removal is continued until the appropriate length is established (Figure 35-27). Post preparation length is determined

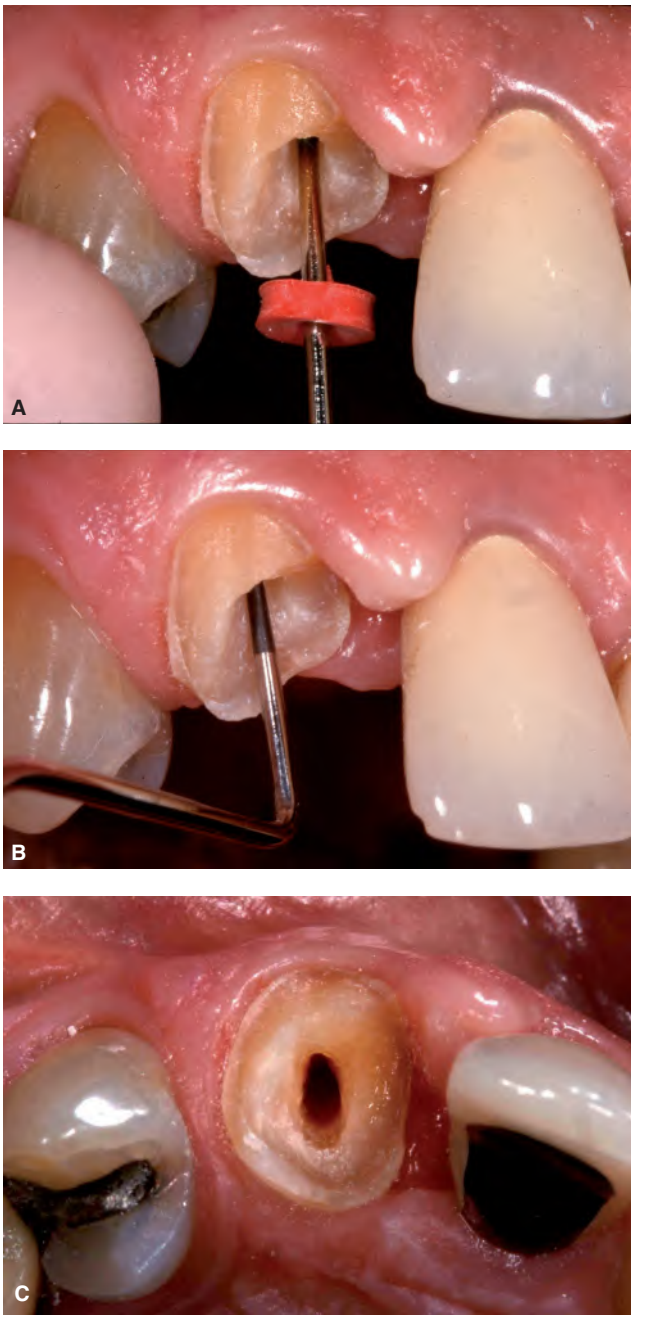

FIGURE 35-27 Root canal preparation. ***A.*** Rotary instrument being used to prepare post space in the root canal. Note the rubber ring around the instrument to identify the appropriate apical extension of the post preparation. ***B.*** Periodontal probe being used to measure post space depth. ***C.*** Post space preparation completed.

using a periodontal probe. Remaining gutta-percha length is evaluated by comparing periodontal probing depths with landmarks on the postendodontic radiograph and by making a radiograph of the prepared post space. After the length is established then any required increases to the post diameter are performed using incrementally larger rotary instruments or hand files.

Chapter 36

Endodontic–Periodontal Interrelationships

Ilan Rotstein, Borja Zabalegui, Khalid Al-Hezaimi

ENDODONTIC–PERIODONTAL COMMUNICATION

Understanding the interrelationships between endodontic and periodontal diseases is crucial for correct diagnosis, prognosis, and treatment decision making. The dental pulp and periodontium are closely related, and pathways of communications between these structures often determine the progress of disease in these tissues.[1–4] The main pathways for communication between the dental pulp and the periodontium are (1) dentinal tubules, (2) lateral and accessory canals, and (3) the apical foramen.

Dentinal Tubules

Direct communication between the pulp and the periodontium may occur via patent dentinal tubules if the cementum layer is interrupted. This is usually attributed to developmental defects, disease processes, or surgical procedures involving root surfaces. Exposed dentinal tubules, in areas devoid of cementum, may serve as communication pathways between the pulp and the periodontal ligament (Figure 36-1).

Radicular dentin tubules extending from the pulp to the cemento-dentinal junction run a relatively straight course.[4] Their diameter ranges from 1 mm at the periphery to 3 mm near the pulp.[5] The tubular lumen decreases with age or as a response to chronic low grade stimuli causing apposition of highly mineralized peritubular dentin. The density of dentin tubules varies from approximately 15,000/mm^2 in the cervical portion of the root down to 8,000/mm^2 near the apex. At the pulpal end, however, tubular numbers increase to 57,000/mm^2.[5] When the cementum and enamel do not meet at the cemento-enamel junction (CEJ), these tubules remain exposed, thus creating pathways of communication between the pulp and the periodontal ligament. Cervical dentin hypersensitivity is a classic example of such tubular exposure.

Scanning electron microscopic studies have demonstrated that dentin exposure at the CEJ occurs in about 18% of teeth.[6] This incidence is even higher in anterior teeth reaching up to 25%.[6] The same tooth may also have several different CEJ characteristics, presenting dentin covered with cementum on one side whereas the other sides have dentin exposure.[7] Dentin exposure plays an important role in the progression of endodontic or periodontal pathogens, as well as cementum root scaling and planing, trauma, and chemically induced pathosis.[8–10]

Lateral and Accessory Canals

Lateral and accessory canals may be found anywhere along the root[11–16] (Figure 36-2). It is estimated that 30 to 40% of all teeth have lateral or accessory canals, mostly found in the apical third of the root.[14] De Deus[14] found that 17% of the teeth examined presented lateral canals in the apical third of the root, about 9% in the middle third, and less than 2% in the coronal third. Kirkham,[15] however, reported that only 2% of lateral canals were associated with periodontal pockets.

Accessory canals in the furcation of molars may also be pathways of communication between the pulp and periodontium.[12,16] The reported incidence of furcal accessory canals varies from 23% to 76%.[13,14,16] In vital pulps, these accessory canals contain connective tissue and blood vessels that connect the circulatory system of the pulp with the periodontium. However, not all these canals extend the full length from the pulp chamber to the floor of the furcation.[17] Seltzer et al.[18] suggested that pulpal inflammation or necrosis may cause inflammatory reaction in the inter-radicular periodontal tissues. Patent lateral and accessory canals are a potential pathway for the spread of microorganisms and their toxic by-products, as well as other irritants, from the pulp to the periodontal ligament and vice versa, resulting in an inflammatory process in the involved tissues (Figure 36-3).

Clinically, lateral and accessory canals are very difficult to detect. Pineda and Kuttler[19] reported that about 30% of lateral canals could be identified through use of two-view radiographs, whereas standard radiographs identified only about 8%. Moreover, using this method, the identification of any accessory canals in the furcation area of molar teeth was also possible. Clinically, predictable identification of lateral and accessory canals, on the basis of radiographic interpretation alone, may be achieved in a very small number of cases. Several clinical aids, however, may be helpful for their identification: (1) a radiographic image of a discrete lateral lesion associated with a necrotic pulp; (2) radiographic identification of a "notch" on the lateral root surface suggesting the presence of an orifice; (3) demonstration of root canal filling material, or sealer, extruding through the patent orifices; and (4) advanced imaging techniques.

Apical Foramen

The apical foramen is the main pathway of communication between the pulp and periodontium. Irritants from a diseased pulp may permeate readily through the apical foramen resulting in periapical pathosis. The apical foramen may also be a portal of entry of irritants from deep periodontal pockets

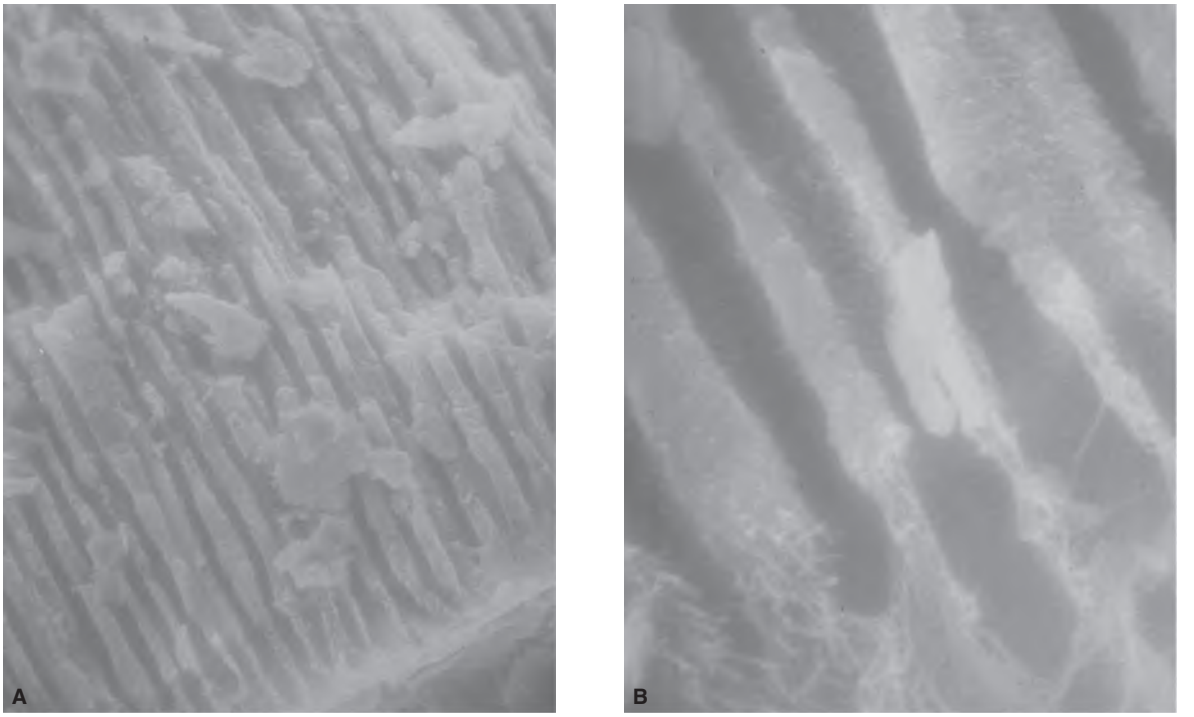

FIGURE 36-1 ***A.*** Scanning electron micrograph of open dentinal tubules. ***B.*** Higher magnification demonstrates absence of odontoblastic processes.

into the pulp. Often, such irritants cause a local inflammatory response associated with bone and root resorption. Elimination of the etiologic irritants from the root canal, as well as from the periodontal tissues, is therefore essential to promote healing.[1,2,20,21]

PULPAL–PERIODONTAL INTERRELATIONSHIP

When the pulp becomes infected, it elicits an inflammatory response of the periodontal ligament at the apical foramen and/or openings of lateral and accessory canals. Inflammatory by-products of pulpal origin may permeate through the apex, lateral and accessory canals, and dentinal tubules to trigger an inflammatory vascular response in the periodontium. Among those products are living pathogens such as certain bacterial strains, fungi, and viruses[22–30] as well as several non-living pathogens.[31–34] In certain cases, pulpal disease may stimulate epithelial growth that will affect the integrity of the periradicular tissues.[35,36]

The result of pulp inflammation can range in extent from minimal inflammation, confined to the periodontal ligament to extensive destruction of the periodontal ligament, tooth socket, and surrounding bone. Such a lesion may result in a localized or diffuse swelling that occasionally involves the gingival attachment. A lesion related to pulpal necrosis may result in a sinus tract that drains through the alveolar mucosa or attached gingiva. Occasionally, it may also drain through the gingival sulcus of the involved tooth or the gingival sulcus of an adjacent tooth. In most instances, after adequate root canal treatment, lesions resulting from pulpal necrosis resolve uneventfully, and the integrity of the periodontal tissues are re-established.[2,20,37]

Certain procedures involved in root canal treatment as well as irrigants, intra-canal medicaments, sealers, and filling materials have the potential to cause an inflammatory response in the periodontium. These inflammatory responses, however, are usually transient in nature and quickly resolved if the materials are confined within the canal space. Periodontal defects, resulting from attachment breakdown, may occur after procedural mishaps, such as perforations of the floor of a pulp chamber or the root surface apical to the gingival attachment, strip perforations, or root perforations from cleaning and shaping procedures. Periodontal defects may also be caused by vertical root fractures associated with excessive force used during canal obturation or restorative procedures.

PERIODONTAL–PULPAL INTERRELATIONSHIP

The effect of periodontal inflammation on the pulp is more controversial.[18,38–52] It appears that, clinically, the pulp is usually not affected by periodontal disease until the defect has exposed a pathway of communication between the root canal and the oral environment.[11] At this stage, pathogens

that pass from the oral cavity through the accessory canal into the pulp may cause a localized inflammatory reaction that could be followed by pulp necrosis. On the other hand, if the microvasculature of the apical foramen remains intact, the pulp may test positive to pulp vitality tests. The effect on the pulp from periodontal treatment is similar during scaling, curettage, or periodontal surgery if accessory canals are severed and/or opened to the oral environment. In such cases, pathogenic invasion and secondary inflammation and necrosis of the pulp may result.[47] It has been suggested that endodontic infection in molars, involved with periodontal disease, might enhance progression of periodontitis by spreading pathogens through accessory canals and dentinal tubules.[50,51]

ETIOLOGICAL FACTORS

Among the living pathogens from a diseased pulp, that can cause lesions in the apical tissues and periodontium, are bacteria (Figure 36-4), fungi (Figure 36-5), and viruses (Figure 36-6). These pathogens and their by-products must be eliminated during endodontic treatment. For more details see Chapter 3.

Bacteria

Bacteria play a critical role in both endodontic and periodontal diseases.[28,53–60] Periapical tissues become involved following bacterial invasion of the pulp, leading to partial or total pulp necrosis. Kakehashi et al.[53] demonstrated the relationship between the presence of microorganisms in the pulp and periapical disease. Pulps of normal rats were exposed and left open to the oral environment. Pulp necrosis ensued followed by periapical inflammation, lesion formation, and furcal inflammation. On the other hand, when the same procedure was performed in germ-free rats, the pulps remained vital and relatively non-inflamed and the exposure sites were repaired by dentin. The study demonstrated that without microorganisms and their products, periapical lesions would not occur from exposed pulps. Möller et al.[55] confirmed these findings in monkeys.

Proteolytic bacteria predominate in the root canal flora, which changes over time to a more anaerobic microbiota.[61,62] Specific profiles of periodontal pathogens in pulpal and periodontal diseases associated with the same tooth were also studied.[63] It appears that periodontal pathogens and endodontic pathogens are similar and that endodontic–periodontal interrelationships are a critical pathway for both diseases.

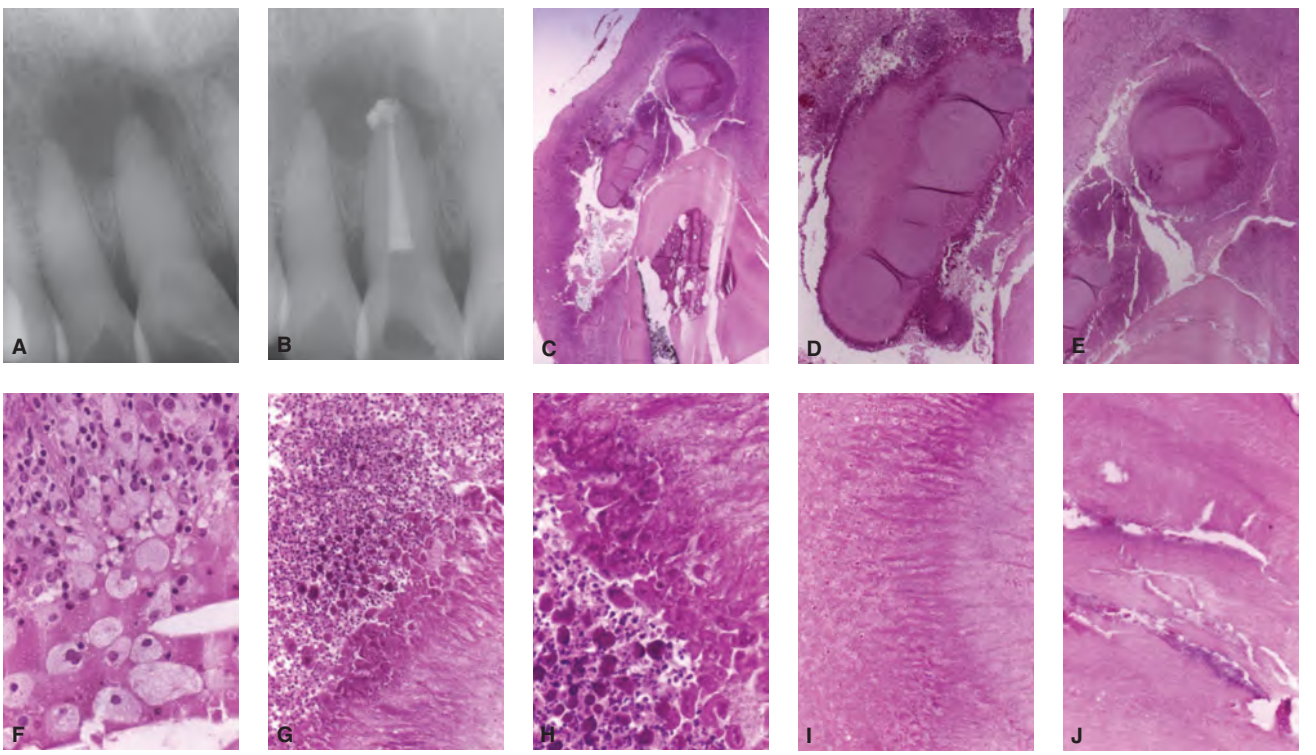

FIGURE 36-4 Periapical *Actinomyces* infection. This case demonstrates the growth of bacteria past the apical foramen and their invasion of apical cementum and periapical tissues. ***A.*** Radiograph of a maxillary central incisor with a necrotic pulp showing a large periapical lesion. ***B.*** Non-surgical endodontic treatment was done but symptoms persisted. ***C.*** Apical surgery was then performed. (Courtesy of Dr. James H.S. Simon, Los Angeles, CA, U.S.A.)

Spirochetes are associated with both endodontic and periodontal diseases. Spirochetes are found more frequently in subgingival plaque than in root canals. As several studies have shown a large diversity of oral treponemes present in subgingival biofilms of periodontal pockets,[64–66] it has been assumed that the presence or absence of oral spirochetes can be used to differentiate between endodontic and periodontal abscesses.[23] However, today, the presence of spirochetes in the root canal system is well documented and has been demonstrated by different identification techniques.[25,26,67,68] The spirochete species most frequently found in root canals are *Treponema denticola*[69,70] and *Treponema maltophilium*.[71]

L-form bacteria may also have a role in endodontic disease.[72] Some bacteria strains can undergo morphological transition to their L-form after exposure to certain agents, particularly penicillin. L-form bacteria may transform with several intermediate L-form transitional stages. This may occur either spontaneously or by induction in a cyclic manner. Under certain conditions, depending on host resistance factors and bacterial virulence, the L-forms revert to their original pathogenic bacterial form and may then be responsible for acute exacerbation of chronic apical lesions.[72]

Fungi

The presence and prevalence of fungi associated with endodontic infections is well documented.[29,73–83] The majority of these fungi are *Candida albicans*.[82,83] Fungi may also colonize canal walls and invade dentinal tubules. Other species such as *Candida glabrata*, *Candida guillermondii*, *Candida incospicia*, and *Rodotorula mucilaginosa* have also been detected.[82]

Factors affecting the colonization of the root canal by fungi are not fully understood. It has been suggested that the reduction of specific strains of bacteria in the root canal during endodontic treatment may allow fungal overgrowth

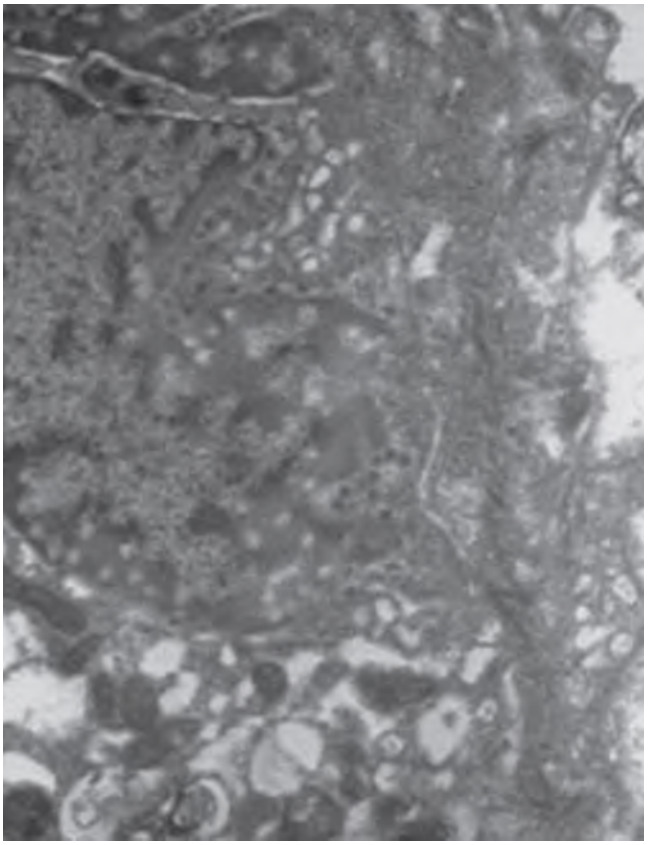

FIGURE 36-6 Transmission electron micrograph of the nucleus of a macrophage in a periapical lesion suggesting a possible viral infection. (Courtesy of Dr. James H.S. Simon, Los Angeles, CA, U.S.A.)

in the remaining low nutrient environment.[78,84] Another possibility is that fungi may gain access to the root canal from the oral cavity as a result of poor asepsis during endodontic treatment or post-preparation procedures. It has been found that approximately 20% of adult periodontitis patients also harbor subgingival fungi.[85,86] As in endodontic infections, *C. albicans* was the most common species isolated.[87]

It has also been demonstrated that the presence of fungi in root canals is directly associated with their presence in saliva.[27] These findings further stress the importance of using aseptic endodontic and periodontal techniques, maintaining the integrity of dental hard tissues, and restoring the tooth crown as soon as practical with a well-sealed permanent restoration in order to prevent re-infection.

Viruses

Viruses may also play a role in the pathogenesis of both endodontic and periodontal diseases. In patients with periodontal disease, herpes simplex virus was frequently detected in gingival crevicular fluid and in gingival biopsies of periodontal lesions.[88] Human cytomegalovirus was observed in about 65% of periodontal pocket samples and in about 85% of gingival tissue samples. Epstein–Barr virus type I was observed in more than 40% of pocket samples and in about 80% of the gingival tissue samples.[88] Gingival herpesviruses were found to be associated with increased occurrence of subgingival *Porphyromonas gingivalis, Bacteroides forsythus, Prevotella intermedia, Prevotella nigrescens, T. denticola*, and *Actinobacillus actinomyce-temcomitans*, thus suggesting a role in overgrowth of periodontal pathogenic bacteria.[89]

Certain viruses may also be involved in pulpal disease and associated periapical pathoses such as human cytomegalovirus and Epstein–Barr virus.[90] It appears that active virus infection may give rise to production of an array of cytokines and chemokines with the potential to induce immunosuppression and tissue destruction.[91] Herpesvirus activation in periapical inflammatory cells may impair the host defense mechanisms and give rise to overgrowth of bacteria, as seen in periodontal lesions. Herpesvirus-mediated immune suppression may also be detrimental in periapical infections due to already compromised host resistant factors and affected connective tissues in situ.[92] Alterations between prolonged periods of herpesvirus latency interrupted by periods of activation may explain some burst-like symptomatic episodes of periapical disease. Absence of herpesvirus infection or viral reactivation may be the reason that some periapical lesions remain clinically stable and asymptomatic for extended periods of time.[90] However, more research is needed to further clarify the relationship between viral infections and pulpal and/or periodontal diseases.

CONTRIBUTING FACTORS

Periapical disease may also be associated with non-microbial factors.[31–34,93–94] For more details see Chapter 3. Clinically, the following factors may play an important roll in the initiation and progression of endodontic disease:

Inadequate Endodontic Treatment

It is essential to clean, shape, and obturate the canal system well in order to enhance successful outcomes.[20,95–97] Poor endodontic treatment often results in treatment failure.[98] Endodontic failures can be treated either by orthograde retreatment or by endodontic surgery with good success rates. In recent years, retreatment techniques have improved dramatically due to use of the operating microscope and development of new armamentarium.

Coronal Leakage

The term "coronal leakage" refers to leakage of microbes and other irritants to and through the root canal filling. Coronal leakage is a major cause of endodontic treatment failure.[99,100] Root canals may also become contaminated by microorganisms due to delay in placement of a coronal restoration and fracture of the coronal

restoration and/or the tooth.[99] Defective restorations and adequate root canal fillings will have a higher incidence of failures than teeth with inadequate root canal fillings and adequate restorations.[98] In an in vitro study, it was found that packing excess gutta-percha and sealer over the floor of the pulp chamber, after completion of root canal filling, did not provide a better seal of the root canals.[100] It is therefore recommended that excess of gutta-percha filling should be removed to the level of the canal orifices and the floor of the pulp chamber be protected with a well-sealed restorative material. An adequate coronal restoration is the primary barrier against coronal leakage and microbial contamination of the root canal treatment.[98] It is essential that the root canal system be protected by good endodontic obturation and a well-sealed coronal restoration.

Traumatic Injuries

Traumatic injuries to teeth may involve the pulp and the surrounding periodontal attachment apparatus. Dental injuries may vary but generally can be classified as enamel fractures, crown fractures without pulp involvement, crown fractures with pulp involvement, crown-root fracture, root fracture, luxation, and avulsion.[101] Treatment and prognosis will depend on the type of injury.[101] Surgical exposure of the remaining tooth structure is one option. For more details see Chapters 12 and 13.

Root Perforations

Root perforations may often cause clinical complications that lead to periodontal lesions. Root perforations may result from extensive carious lesions, resorption, or from operator error during root canal instrumentation or post preparation.[102] Treatment prognosis of root perforations depends on the size, location, time of diagnosis and treatment, degree of periodontal damage as well as the sealing ability and biocompatibility of the repair material. It has been recognized that treatment success depends mainly on immediate sealing of the perforation and appropriate infection control. When the root perforation is situated close to the alveolar crest, it may be possible to raise a flap and repair the defect with an appropriate filling material. In deeper perforations, or in a furcation, immediate repair of the perforation has a better prognosis than management of an infected one. Many materials have been used to seal root perforations. Mineral Trioxide Aggregate is widely used to seal root perforations.[102–104] For more details see Chapter 23.

Another treatment modality for perforations, root resorptions, and certain root fractures in the cervical third region is orthodontic root extrusion.[105–108] The procedure has very good prognosis and a low risk of relapse. It can be performed either immediately or over a few weeks period depending on each individual case. The goal of controlled root extrusion is to modify the soft tissues and bone and is therefore used to correct gingival discrepancies and osseous defects of periodontally involved teeth.[106] It is also used in the management of non-restorable teeth and as a non-surgical alternative to crown lengthening.[107]

Developmental Malformations

Radicular invaginations or radicular grooves can lead to an untreatable periodontal condition[108] (Figure 36-7). These grooves usually begin in the central fossa of maxillary central and lateral incisors crossing over the cingulum and continuing apically down the root for varying distances. Such a groove is probably the result of an attempt of the tooth germ to form another root. As long as the epithelial attachment remains intact, the periodontium remains healthy. However, once this attachment is breached and the groove becomes contaminated, a self-sustaining infrabony pocket can be formed along its entire length. This fissure-like defect provides a nidus for accumulation of microorganisms and an avenue for the progression of periodontal

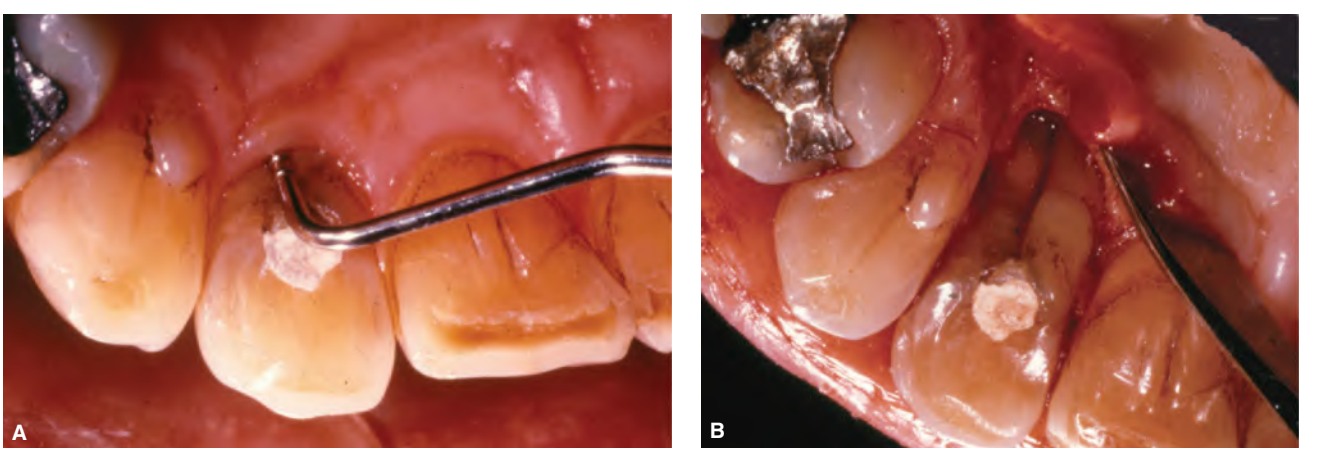

FIGURE 36-7 ***A.*** Probing deep lingual pocket associated with radicular invagination. ***B.*** Raised flap reveals the depth and length of deep lingual groove.

disease that can also affect the pulp. Radiographically, the area of bone destruction follows the course of the groove.

Clinically, the patient may present symptoms of a periodontal abscess or a variety of asymptomatic endodontic conditions. If the condition is purely periodontal, it can be diagnosed by visually following the groove to the gingival margin and by probing the depth of the pocket, which is usually tubular in form and localized to this one area, as opposed to a more generalized periodontal problem. The tooth will also respond to pulp testing procedures. If this condition is also associated with an endodontic disease, the patient may present clinically with any of the spectrum of endodontic symptoms. While performing clinical examination, the clinician must look for the groove as it may have been altered by a previous access opening or restoration placed in the access cavity. The appearance of a teardrop-shaped area on the radiograph should immediately arouse suspicion. The developmental groove may be visible on the radiograph as a dark vertical line. This condition must be differentiated from a vertical fracture, which may give a similar radiographic appearance.

The prognosis of root canal treatment in such cases is guarded, depending on the apical extent of the groove. Radicular grooves are self-sustaining infra-bony pockets and therefore scaling and root planing will not suffice. Although the acute nature of the problem may be alleviated initially, the source of the chronic or acute inflammation must be eradicated by a surgical approach. Treatment consists of burring out the groove, placing bone substitutes, and surgical management of the soft tissues and underlying bone.[109–111] If unsuccessful, the tooth needs to be extracted due to poor prognosis.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis for treatment and prognosis of endodontic-periodontal diseases can be achieved by using the following classification: (1) primary endodontic diseases, (2) primary periodontal diseases, and (3) combined diseases.[1,2] The combined diseases include (1) primary endodontic disease with secondary periodontal involvement, (2) primary periodontal disease with secondary endodontic involvement, and (3) true combined diseases. This classification is based on how these lesions are formed. By understanding the pathogenesis, the clinician can then offer an appropriate course of treatment and better assess the prognosis.

Primary Endodontic Disease

A chronic apical abscess may drain coronally through the periodontal ligament into the gingival sulcus. This condition may clinically mimic the presence of a periodontal abscess draining through a pseudo-pocket. In reality, the pocket is a sinus tract from pulpal origin that opens through the periodontal ligament area. A deep solitary pocket in the absence of periodontal disease may indicate the presence of a lesion of endodontic origin. For diagnostic purposes, a gutta-percha cone, or another tracking instrument, should be inserted into the sinus tract and radiographs taken. This will determine the origin of the lesion.

A sulcular pocket of endodontic origin is typically very narrow compared to a pocket of periodontal origin. A similar condition occurs where drainage from the apex of a molar extends coronally into the furcation area. This may also occur in the presence of accessory canals extending from a necrotic pulp into the furcation area. A vertical root fracture or a radicular crack should always be ruled out as they may give initially similar periodontal clinical findings. Primary endodontic lesions usually heal following root canal treatment. The sinus tract extending into the gingival sulcus or furcation area quickly heals once the affected pulp has been removed and the root canals cleaned, shaped, and obturated (Figures 36-8 to 36-10).

Primary Periodontal Disease

These types of conditions are caused primarily by periodontal pathogens. In this process, chronic marginal periodontitis progresses apically along the root surface. In most cases, pulp tests indicate a clinically normal pulpal reaction (Figures 36-11 & 36-12). There is frequently an accumulation of plaque and calculus and the pockets are wider. The prognosis depends upon the stage of periodontal disease and the efficacy of periodontal treatment. The clinician must also be aware of the radiographic appearance of periodontal disease associated with developmental radicular anomalies (Figure 36-13).

Combined Diseaes

Primary Endodontic Disease with Secondary Priodontal Involvement

Untreated suppurating primary endodontic disease may sometimes become secondarily involved with marginal periodontal breakdown. In such cases, marginal periodontitis is developed as a result of plaque formation at the gingival margin of the sinus tract. When plaque or calculus is present, the treatment and prognosis of the tooth are different than those of teeth involved with only primary endodontic disease. The tooth now requires both endodontic and periodontal treatments. If the endodontic treatment is adequate, the prognosis depends on the severity of the marginal periodontal damage and the efficacy of periodontal treatment. With endodontic treatment alone, only part of the lesion will heal to the level of the secondary periodontal lesion (Figures 36-14).

A similar clinical picture may also occur as a result of root perforation during root canal treatment, or where pins or posts have been misplaced during coronal restoration. Sometimes, symptoms may be acute, with periodontal abscess formation associated with pain, swelling, purulent exudate, and pocket formation and tooth mobility. A more chronic response may also occur without pain and involves the sudden appearance of a pocket with bleeding on probing or exudation of pus.

Root fractures may also mimic the appearance of primary endodontic lesions with secondary periodontal involvement

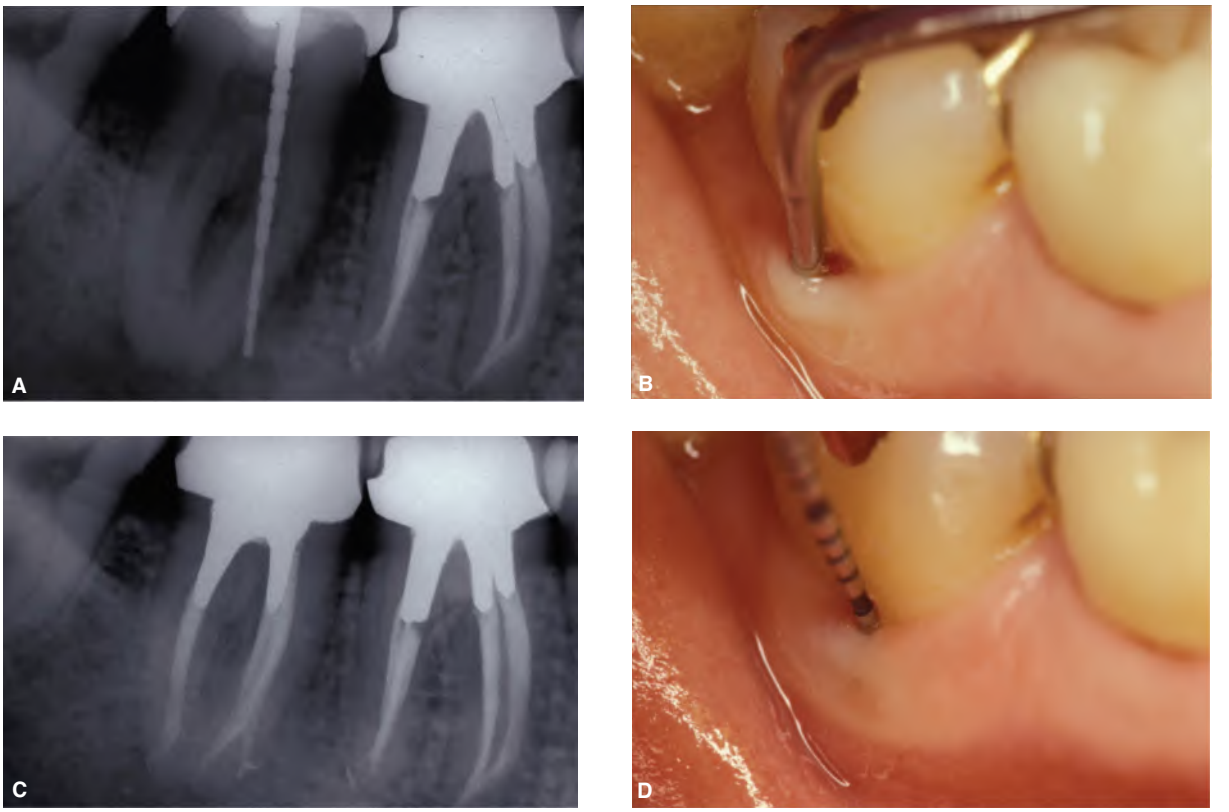

FIGURE 36-8 Primary endodontic disease in a mandibular second molar with necrotic pulp. ***A.*** Preoperative radiograph showing periradicular radiolucency associated with the affected tooth. ***B.*** Clinically, a deep narrow buccal periodontal defect can be probed. ***C.*** One year after root canal treatment, resolution of the periradicular bony radiolucency is evident. ***D.*** Clinically, the buccal defect healed and probing is normal. (Courtesy of Dr. Jean-Yves Cochet, Paris, France.)

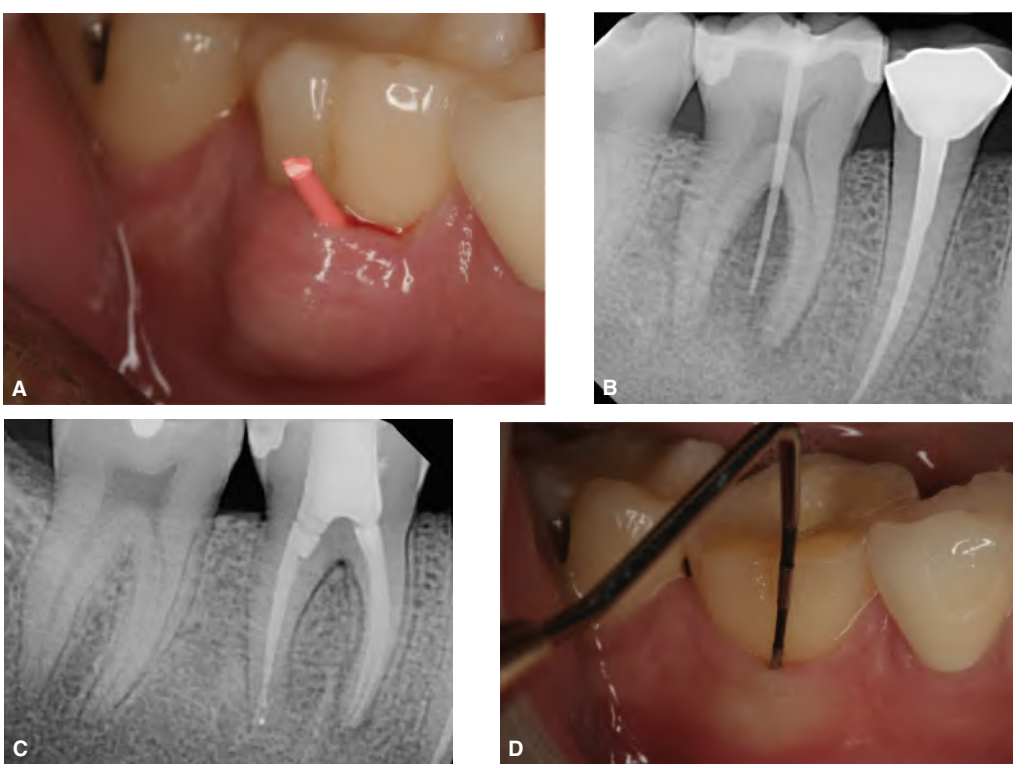

FIGURE 36-9 Primary endodontic disease in a mandibular first molar with a necrotic pulp. ***A.*** Abscess on the buccal aspect of the tooth is traced with a gutta-percha cone. ***B.*** Periapical radiograph showing radiolucency associated with the mesial and distal roots as well as the furcation area. ***C.*** Radiograph taken 4 months after root canal therapy showing active bony healing. ***D.*** Clinically, the buccal periodontal defect healed and probing is normal. (Courtesy of Dr. Ziv Simon, Beverly Hills, CA, U.S.A.)

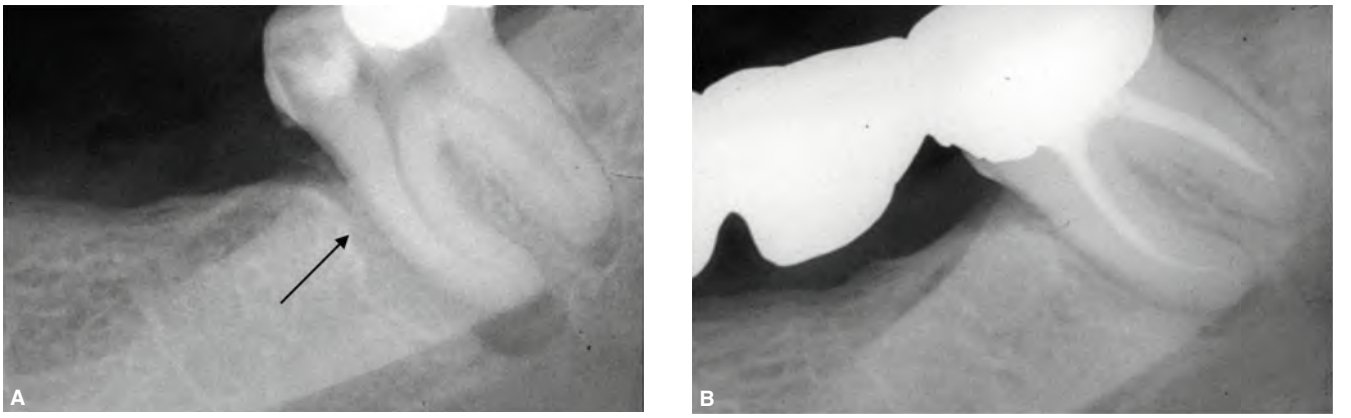

FIGURE 36-10 Primary endodontic disease in a mandibular second molar of a 45-year-old male. ***A.*** Preoperative radiograph showing evidence of coronal caries and periradicular radiolucencies associated with the affected tooth. Note, localized, narrow and elongated radiolucency alongside the mesial root (arrow). The tooth was symptomatic and pulp sensibility tests were negative. Endodontic treatment was done. ***B.*** Two-year follow-up radiograph showing resolution of the periradicular radiolucencies. The patient was comfortable and the tooth has been serving as a distal abutment for a prosthetic reconstruction. (Courtesy of Dr. Borja Zabalegui, Bilbao, Spain.)

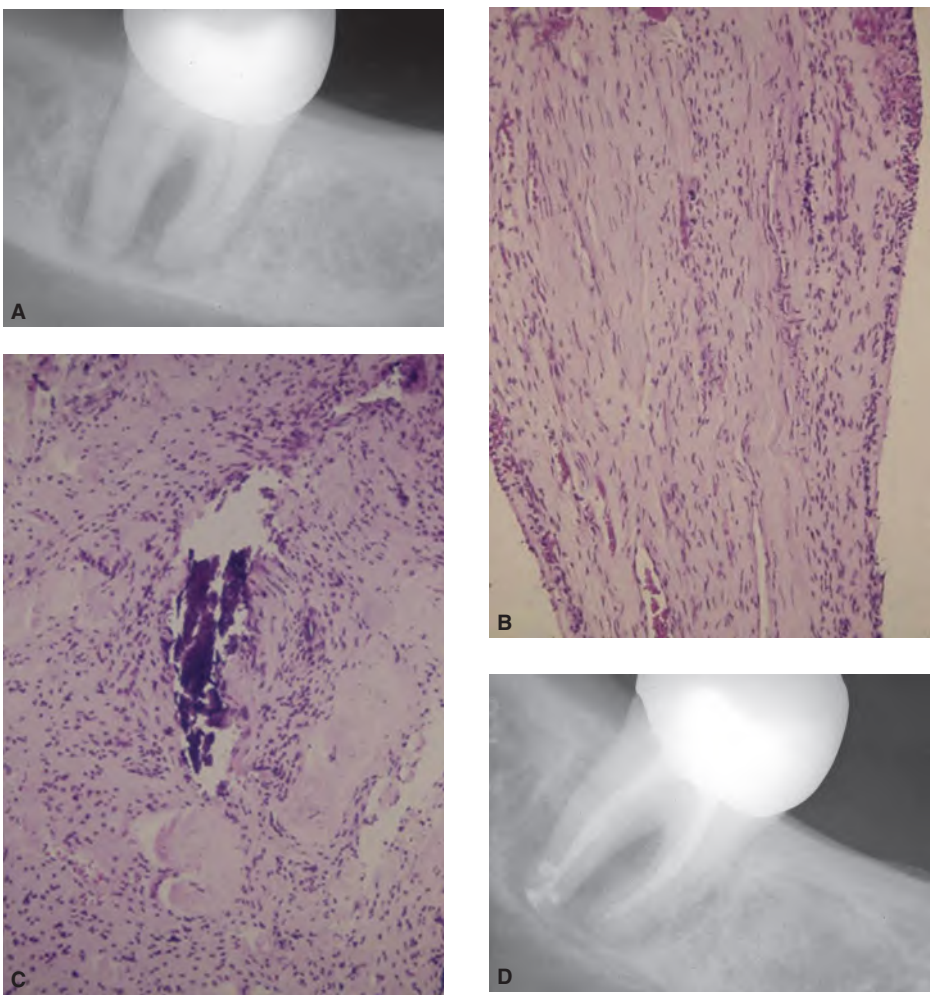

FIGURE 36-11 Primary periodontal disease in a mandibular second molar simulating endodontic lesion. Patient was referred for endodontic treatment. ***A.*** Preoperative radiograph showing periradicular radiolucency; however, the tooth responded to pulp sensibility tests. The referring dentist insisted that endodontic treatment should be done. ***B.*** Photomicrograph of the pulp tissue removed during treatment. Note normal appearance of the pulp. ***C.*** Higher magnification shows normal cellular components as well as blood microvasculature. ***D.*** Post-operative radiograph. The tooth was subsequently lost due to the periodontal disease. (Courtesy of Dr. James H.S. Simon, Los Angeles, CA, U.S.A.)

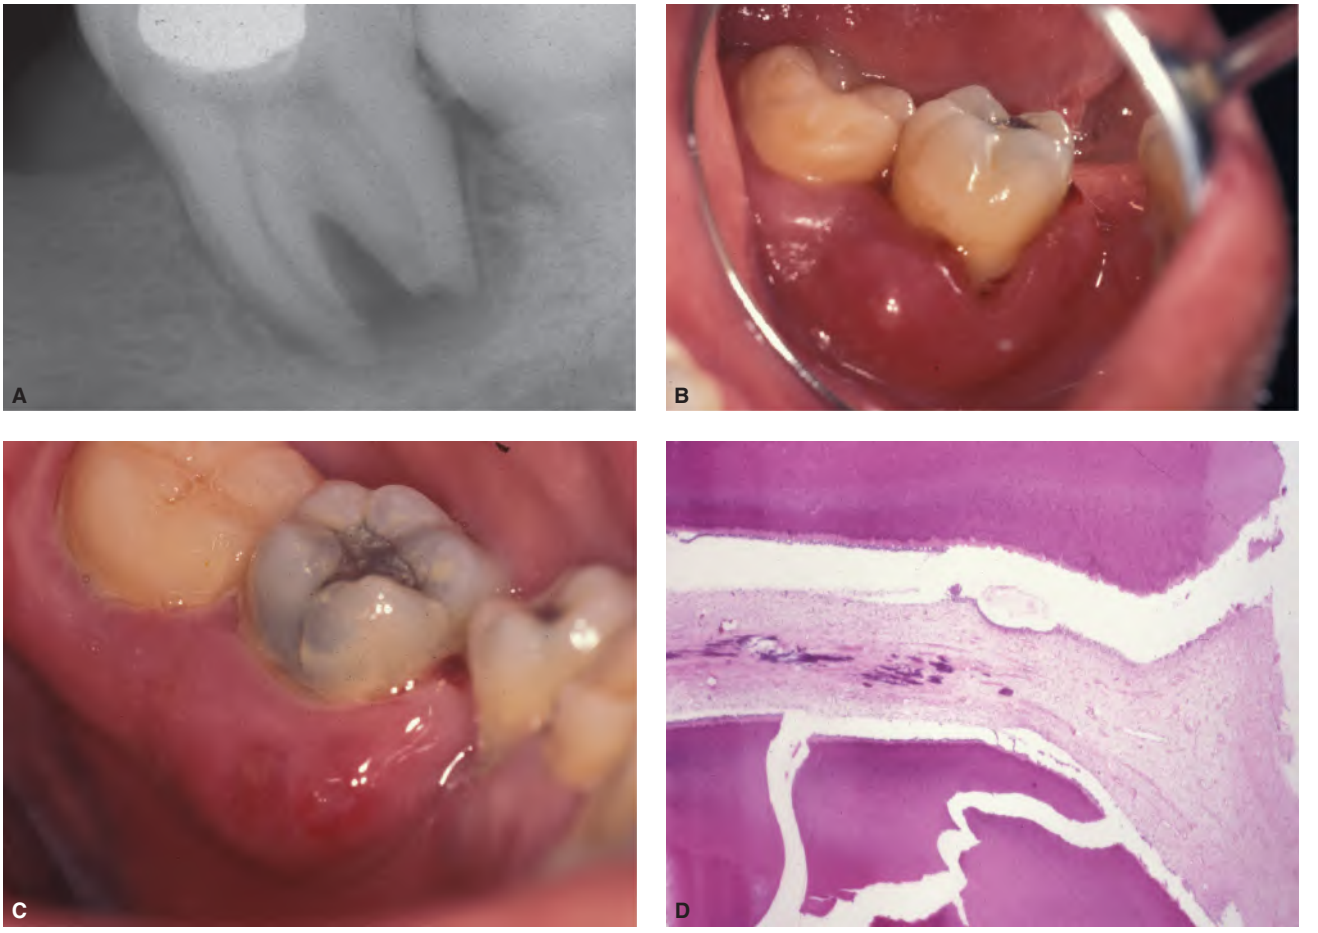

FIGURE 36-12 Primary periodontal disease in a mandibular first molar simulating endodontic lesion. ***A.*** Radiograph showing periradicular radiolucency and periapical resorption associated with the affected tooth. ***B, C.*** Buccal and lingual views. Note, gingival swelling and evidence of periodontal disease. In addition, an occulsal filling is present close to the pulp chamber. In spite of the clinical and radiographic picture, the pulp responded normal to sensibility tests indicating the radiolucency, resorption and gingival swelling are of periodontal origin. ***D.*** Microphotograph stained with H&E showing floor of the pulp chamber and entrance to the mesial canal containing normal pulp tissue (original magnification × 40).

(Figure 36-15). These may occur following traumatic injury, damaging chewing habits, excessive occlusal forces or in endodontically treated teeth restored with large post (Figure 36-16). In such cases, a local deepening of a periodontal pocket and more acute periodontal abscess symptoms can be found.

Primary Periodontal Disease with Secondary Endodontic Involvement

A periodontal pocket may continue and progress until the apical tissues are involved. In this case, the pulp may become infected due to irritants entering via lateral canals or the apical foramen and subsequently become necrotic. (Figures 36-17 to 36-19).

In single-rooted teeth, the prognosis is usually poor. In molar teeth, the prognosis may be better because not all the roots may suffer the same loss of supporting tissues. In some of these cases, root resection can be considered as a treatment alternative.

Microorganisms originating from the periodontal pocket can be a source of root canal infection. A strong correlation between the presence of microorganisms in root canals and their presence in periodontal pockets of advanced periodontitis has been demonstrated indicating that similar pathogens may be involved in both diseases.[112,113] As long as the neurovascular supply of the pulp remains intact, prospects for survival are good. If the neurovascular supply is lost to periodontal disease, pulpal necrosis will ensue.[45]

Treatment complications of periodontal disease can also lead to secondary endodontic involvement. Lateral canals and dentinal tubules may be opened to the oral environment by curettage, scaling, or surgical flap procedures. In such cases, blood vessels within a lateral canal can be severed by a curette and microorganisms introduced into the area during treatment. This may often result in pulp inflammation and necrosis.

TRUE COMBINED DISEASES

True combined diseases occur less often. They are usually formed when an endodontic disease progressing coronally joins with an infected periodontal pocket progressing

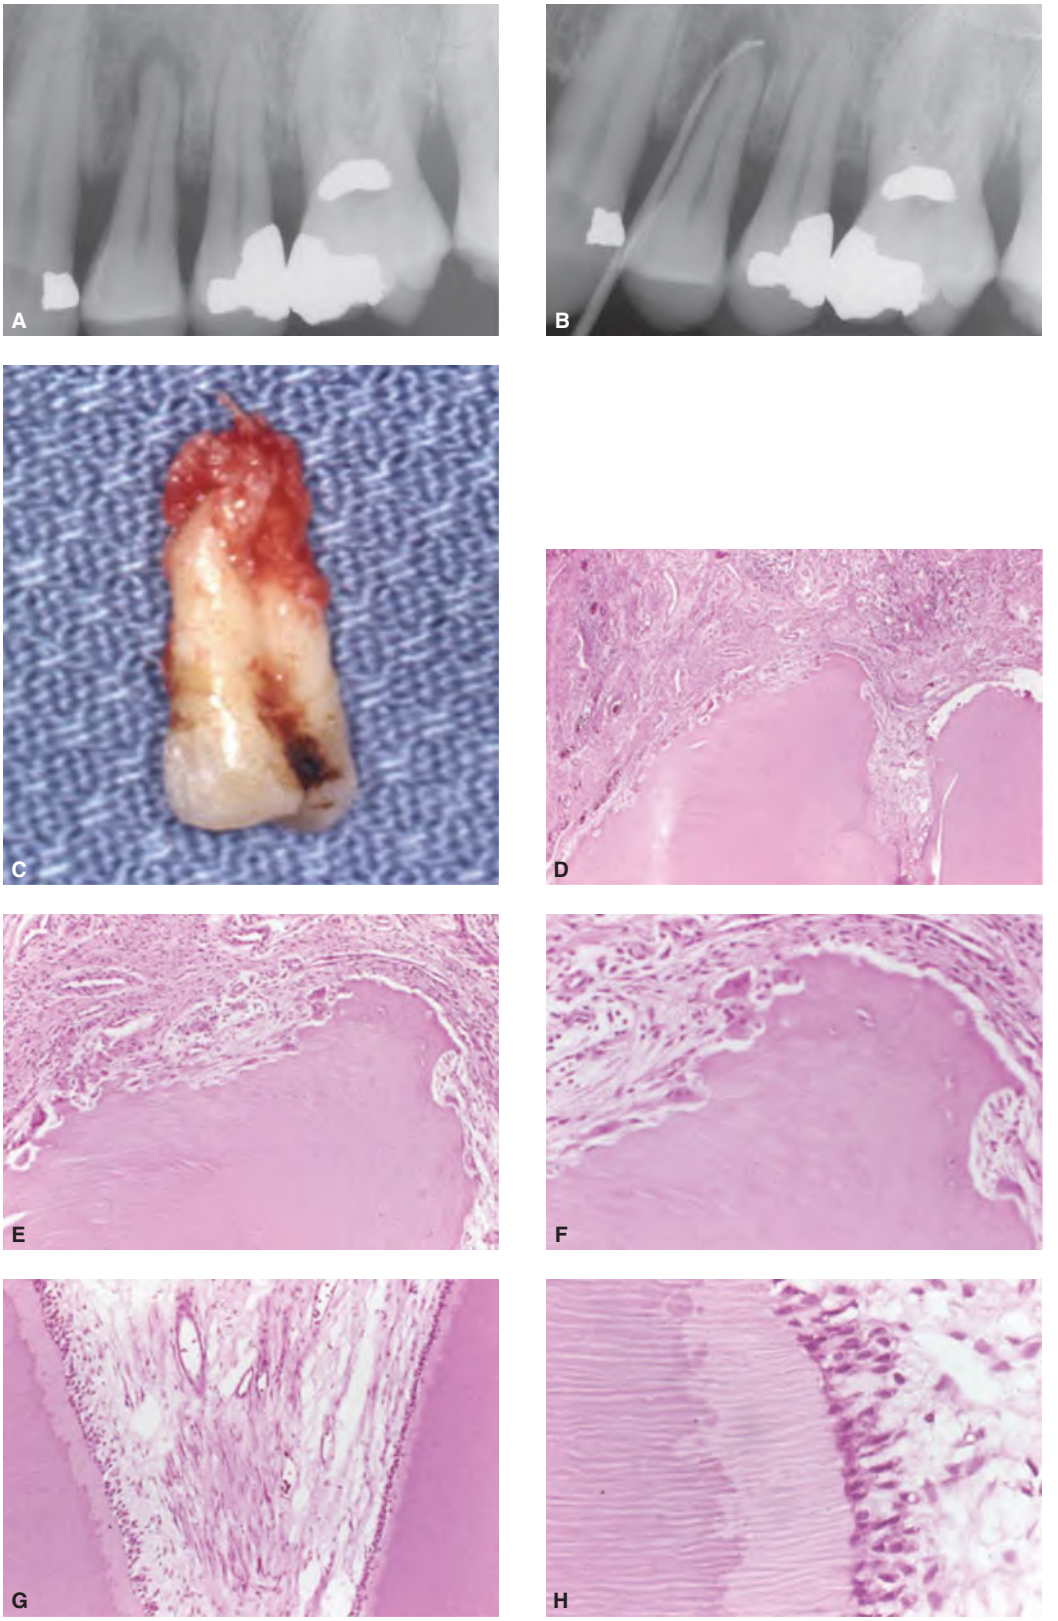

FIGURE 36-13 Primary periodontal disease in a maxillary first premolar. ***A.*** Radiograph showing alveolar bone loss and a periapical lesion. Clinically, a deep narrow pocket was found on the mesial aspect of the root. There was no evidence of caries, and the tooth responded normally to pulp sensibility tests. ***B.*** Radiograph showing pocket tracking with gutta-percha cone to the apical area. It was decided to extract the tooth. ***C.*** Clinical view of the extracted tooth with the attached lesion. Note a deep mesial radicular development groove. ***D.*** Photomicrograph of the apex of the tooth with the attached lesion. ***E, F.*** Higher magnification shows the inflammatory lesion, cementum and dentin resorption, and osteoclasts. ***G, H.*** Histologic sections of the pulp chamber shows uninflammed pulp, odontoblastic layer, and intact predentin. (Courtesy of Dr. James H.S. Simon, Los Angeles, CA, U.S.A.)

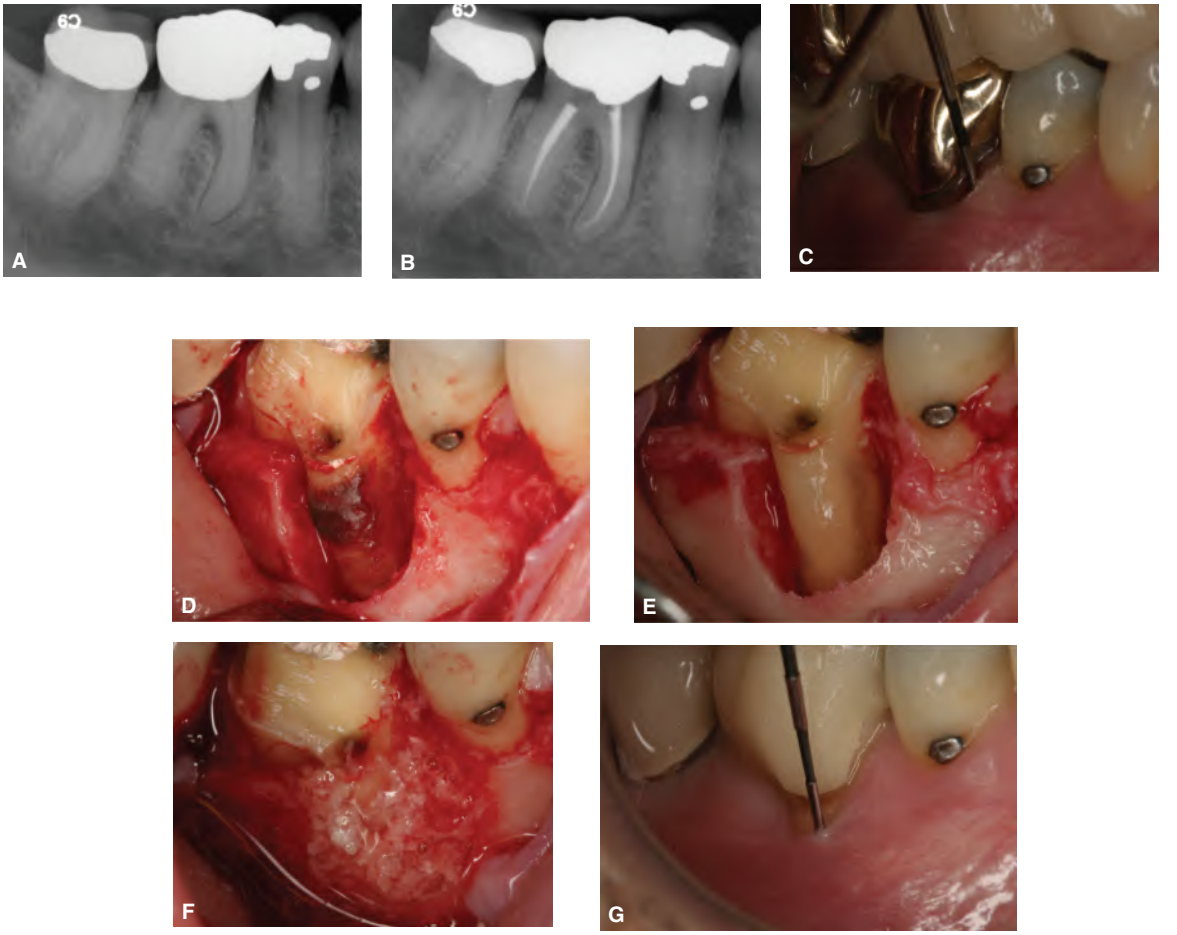

FIGURE 36-14 Primary endodontic disease with secondary periodontal involvement. ***A.*** Pre-operative radiograph of a symptomatic lower right first molar. Pulp sensibility tests were negative. Initial diagnosis of periapical periodontitis caused by a necrotic pulp was established. ***B.*** Endodontic treatment was done, however, residual deep pocket (7-9 mm) on the mesial root remained. ***C.*** Examination reveals a large mucogingival defect with minimal keratinization and absence of attached gingiva. ***D.*** Upon exploration, severe bone loss and abundant calculus on the mesial root were observed. ***E.*** The root surface was then debrided and the bony defect cleaned. ***F.*** Bony defect is repaired with bone graft material and a resorbable membrane. ***G.*** Two-month follow-up shows active healing of the defect. (Courtesy of Dr. Ziv Simon, Beverly Hills, CA, U.S.A.)

apically.[1,2] The degree of attachment loss in this type of lesions is large and the prognosis guarded in single-rooted teeth (Figures 36-20 to 36-22). In most cases, periapical healing may be anticipated following successful endodontic treatment. However, the periodontal tissues may not always respond well to treatment, and healing will depend on the severity of the condition and the efficacy of periodontal therapy. In such cases, regeneration procedures may prove beneficial.[114,115]

The radiographic appearance of combined endodontic-periodontal disease may be similar to that of a vertically fractured tooth. A fracture that has invaded the pulp space causing pulp necrosis may also be considered a true combined lesion and yet not be amenable to successful treatment. Often, it is necessary to perform surgical exploration of the affected site to confirm the diagnosis.

PROGNOSIS

Correct diagnosis of the etiology of the disease process, whether endodontic, periodontal, or combined, will determine the treatment and long-term prognosis. The main factors to consider are pulp vitality and type and extent of the periodontal condition. For example, the prognosis for a tooth with a necrotic pulp, with or without a sinus track, is excellent following adequate root canal treatment. However, the prognosis of root canal treatment in a tooth with severe periodontal disease is dependent on the success of the periodontal treatment.

Primary endodontic disease need only be treated by endodontic therapy. Good prognosis is to be expected if appropriate endodontic treatment is carried out. Primary periodontal disease should only be treated by periodontal treatment. In this case, the prognosis depends on severity of the periodontal disease and the patient's tissues response.

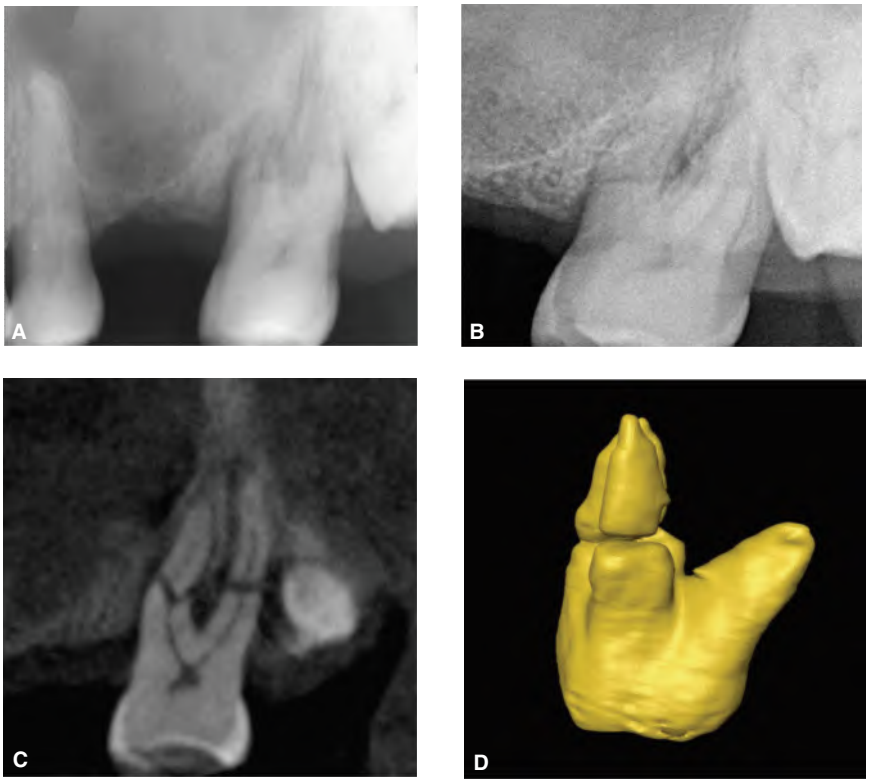

FIGURE 36-15 Primary endodontic disease with secondary periodontal involvement in a maxillary left second molar of a 48-year-old male. ***A.*** Preoperative radiograph showing periradicular radiolucency associated mainly with the mesiobuccal root. The tooth was sensitive to percussion and pulp sensibility tests were negative. The patient didn't recall any significant traumatic injury to the area. ***B.*** Additional preoperative radiograph, from a different angulation, shows possible horizontal fracture in the mesial root (arrow). ***C.*** Cone Beam Computerized Tomography (100 voxel; sagital view) indicates presence of horizontal root fractures in both buccal roots. ***D.*** Segmentation analysis (Amira Visage software) demonstrates root fractures in both buccal roots while the palatal root appears intact. (Courtesy of Dr. Borja Zabalequi, Bilbao, Spain.)

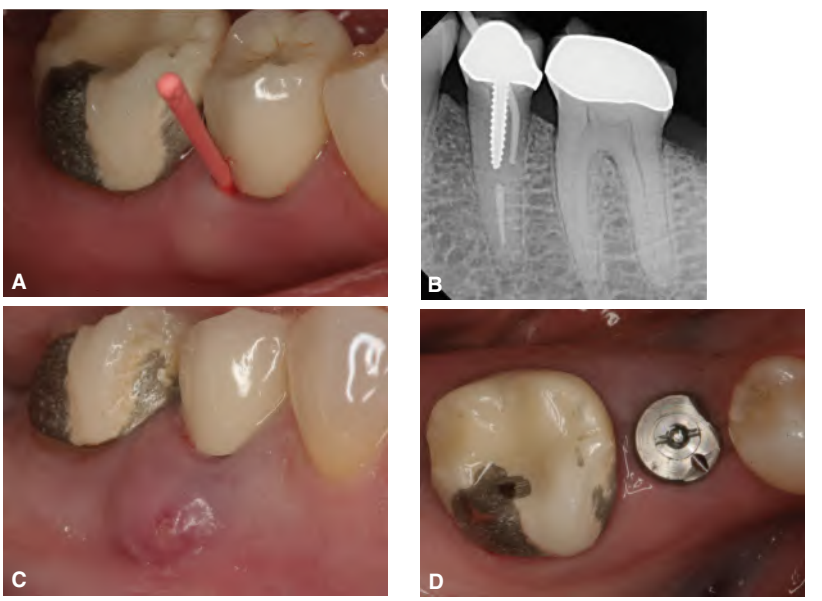

FIGURE 36-16 Complications of certain defects along the root may have similar clinical appearance of primary endodontic disease with secondary periodontal involvement. ***A.*** Patient presented with a localized deep pocket (traced with a gutta-percha cone) associated with an endodontically treated mandibular second premolar. ***B.*** Periapical radiograph showing the gutta-percha cone pointing to an area of the root associated with a screw post. ***C.*** Subsequent abscess formation on the buccal aspect of the tooth caused loss of the buccal plate. ***D.*** Surgical exploration confirmed the presence of a vertical root fracture and the tooth was extracted and replaced by an implant. (Courtesy of Dr. Ziv Simon, Beverly Hills, CA, U.S.A.)

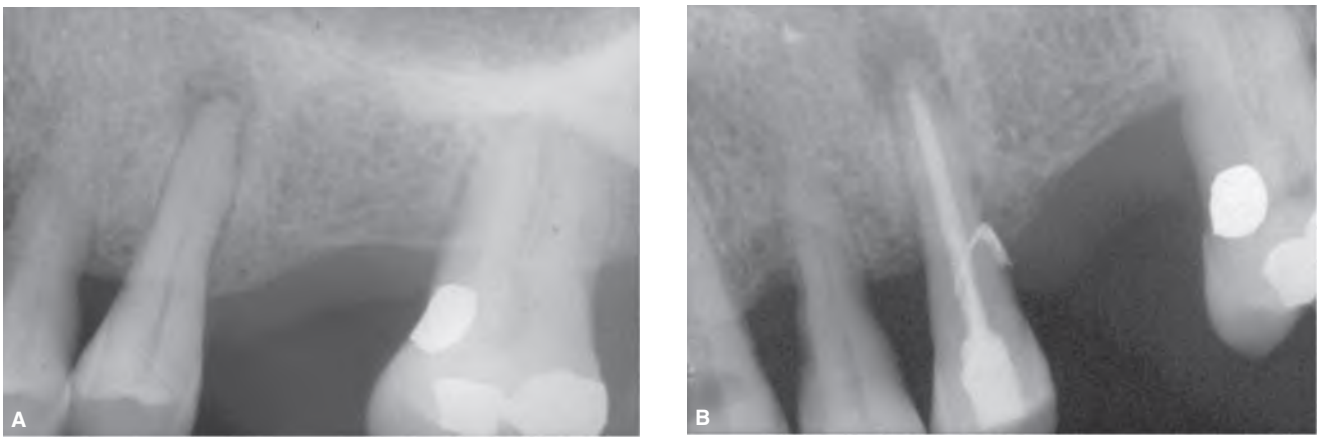

FIGURE 36-17 Primary periodontal disease with secondary endodontic involvement in a maxillary premolar. ***A.*** Radiograph showing bone loss in one-third of the root and separate periapical radiolucency. The crown was intact, but pulp sensibility tests were negative. ***B.*** Radiograph taken immediately after root canal treatment showing sealer in lateral canal that was exposed due to bone loss.

FIGURE 36-18 Primary periodontal disease with secondary endodontic involvement in a mandibular canine of a 35-year-old male. ***A.*** Preoperative radiograph showing extensive periradicular radiolucency associated with the affected tooth. The tooth was mobile and pulp sensibility tests were negative. ***B.*** Clinical view showing purulent discharge from a mesial periodontal defect associated with the canine. Endodontic treatment was done followed by periodontal therapy. ***C.*** Seven-year follow-up radiograph. The radiolucency associated with the endodontic component has resolved. The tooth was not mobile and the patient was comfortable. However, a controlled periodontal defect still remains due to the primary periodontal nature of the disease. ***D.*** Clinical view showing resolution of the purulent discharge. (Courtesy of Dr. Borja Zabalequi, Bilbao, Spain.)

FIGURE 36-19 Primary periodontal disease with secondary endodontic involvement in a mandibular lateral incisor of a 47-year-old male. ***A.*** Preoperative radiograph showing extensive periradicular radiolucency associated with the affected tooth. The tooth was mobile and pulp sensibility tests were negative. ***B.*** Clinical exploration revealed an extensive distal bony defect. Endodontic treatment was done that was later followed by regenerative periodontal therapy. ***C.*** 18-month follow-up radiograph. The size of the bony radiolucency has been reduced significantly. The tooth was not mobile and the patient was comfortable. (Courtesy of Dr. Borja Zabalequi, Bilbao, Spain.)

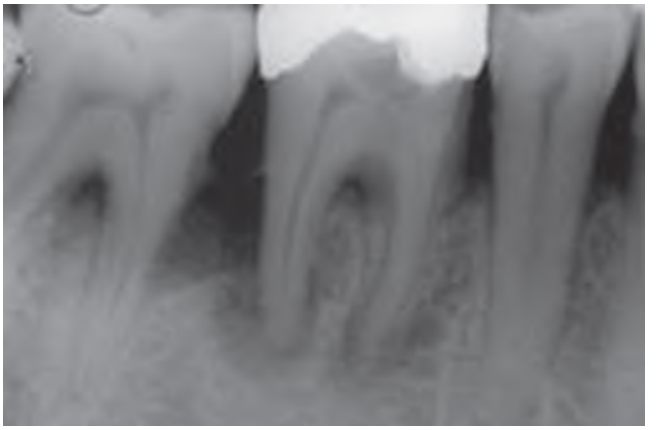

FIGURE 36-20 True combined endodontic–periodontal disease in a mandibular first molar. Radiograph showing separate progression of endodontic disease and periodontal disease. The tooth remained untreated and consequently the two lesions joined together.

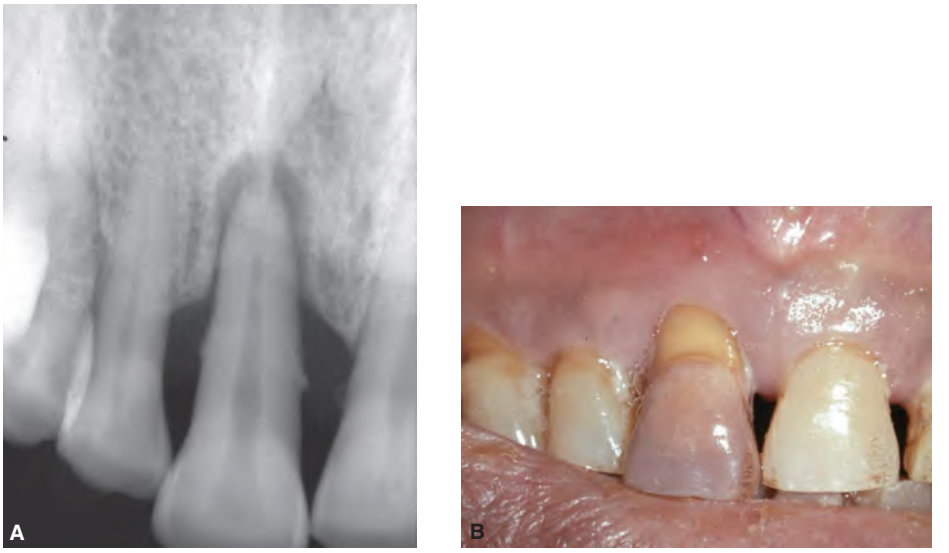

FIGURE 36-21 True combined endodontic–periodontal disease in a maxillary central incisor. ***A.*** Radiograph showing bone loss in two-thirds of the root with calculus present and separate periapical radiolucency. ***B.*** Clinical examination revealed coronal color change of the tooth involved and pus draining from the gingival crevis. Pulp sensibility tests were negative.

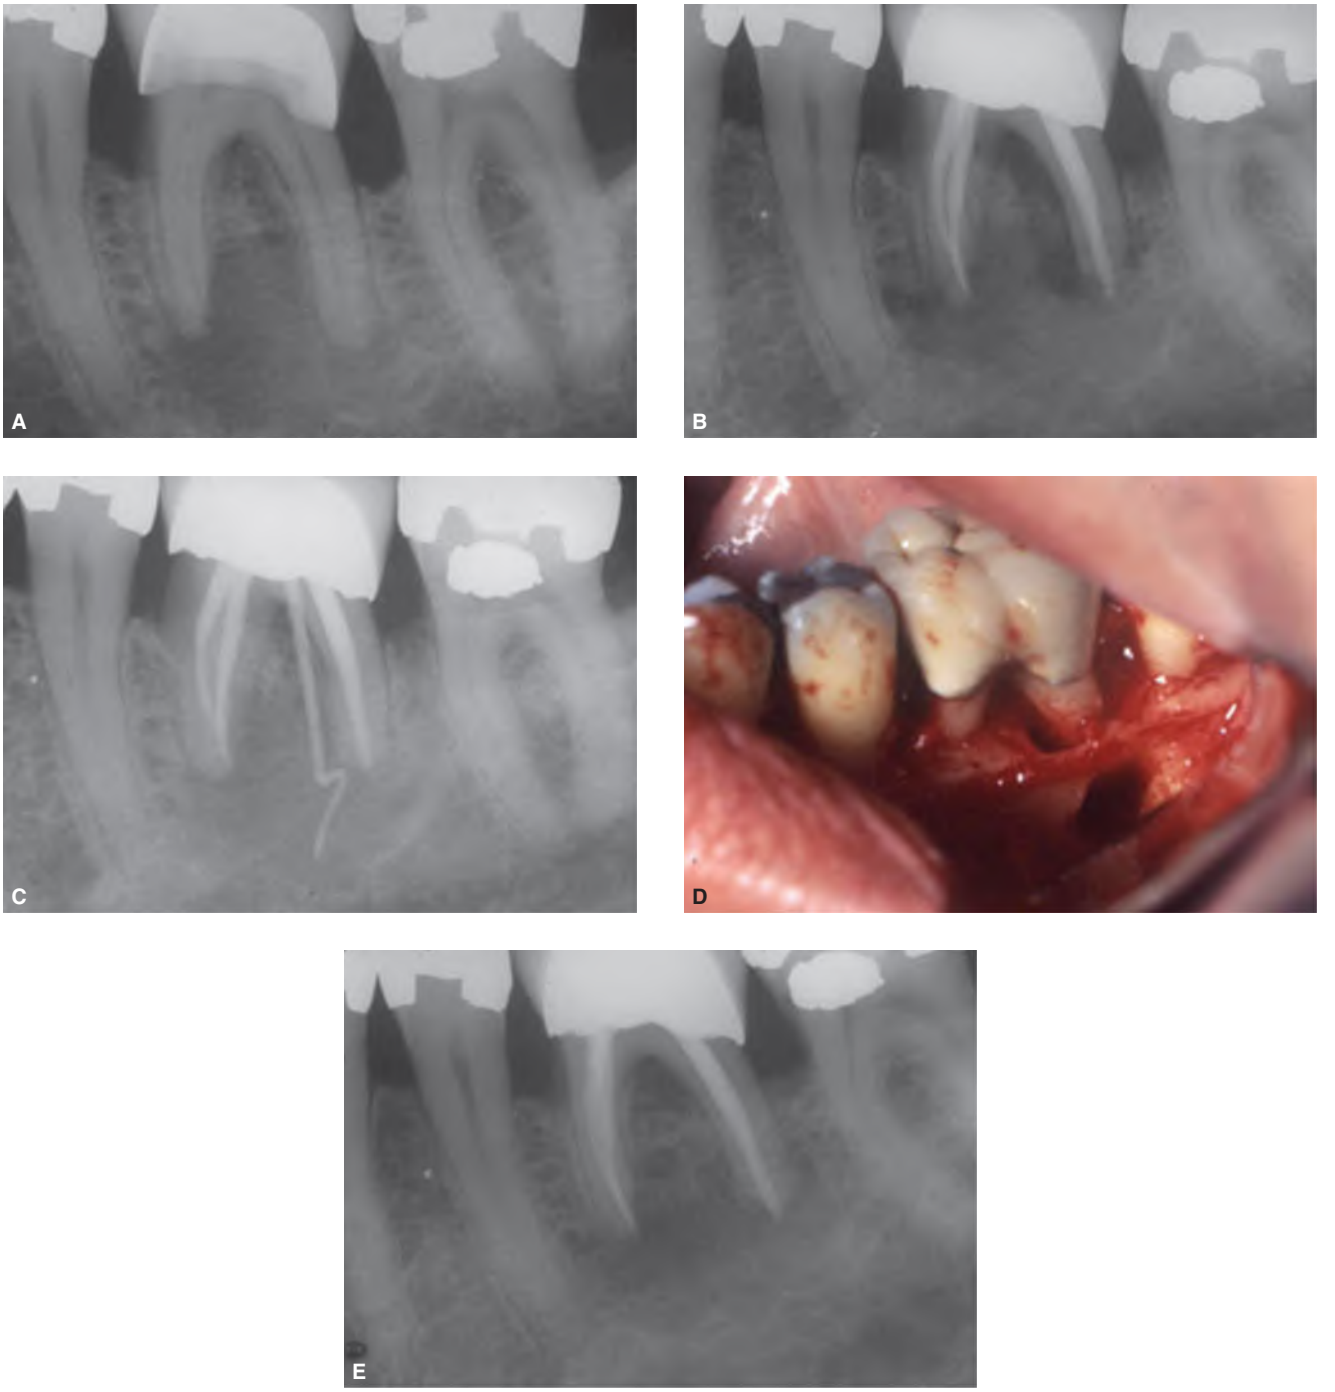

FIGURE 36-22 True combined endodontic–periodontal diseases in a mandibular first molar. ***A.*** Preoperative radiograph showing periradicular radiolucencies. Pulp sensibility tests were negative. ***B.*** Immediate post-operative radiograph of non-surgical endodontic treatment. ***C.*** Six-month follow-up radiograph showing no evidence of healing. Gutta-percha cone is inserted in the buccal gingival sulcus. ***D.*** Clinical photograph showing treatment of the root surfaces and removal of the periradicular lesion. ***E.*** One-year follow-up radiograph demonstrates evidence of active healing.

Primary endodontic disease with secondary periodontal involvement should first be treated endodontically. Treatment results should be evaluated in 2 to 3 months and only then periodontal treatment should be considered. This sequence of treatment allows sufficient time for initial tissue healing and better assessment of the periodontal condition.[116] It also reduces the potential risk of introducing microorganisms and their by-products during the initial phase of healing. Aggressive removal of the periodontal ligament and underlying cementum during interim endodontic treatment might adversely affect periodontal healing.[117] Lesions of endodontic etiology will heal, in most cases, following adequate endodontic treatment, leaving the periodontal component to be treated.

Primary periodontal disease with secondary endodontic involvement and true combined endodontic-periodontal

diseases require both endodontic and periodontal considerations. The prognosis of primary periodontal disease with secondary endodontic involvement and true combined diseases depends primarily upon severity of the periodontal disease and periodontal tissues response to treatment. True combined diseases usually have a more guarded prognosis. The prognosis of combined diseases depends mainly on the success of periodontal therapy.

Chapter 37

Endodontic Therapy in the Elderly Patient

Thomas A. Levy, Jaydeep S. Talim, Ilan Rotstein

You can't help getting older but you don't have to get old

—George Burns

In the last decade, the number of aging patients has been constantly growing, and in the coming years, an even more rapid growth is expected (Figure 37-1). Aging population is a global phenomenon having profound implications on human life, society, and economics. In 2009, the elderly population (65 years or older) in the United States reached 40 million, approximately 15% of the population for that year.[1] By 2030, it is estimated that the number will reach about 72 million individuals.[1] In the United States, the average life expectancy also increased between the years 2000 and 2010. For women it increased by 1.7 years (to 80.6 years) and for men by 2.1 years (to 78.6 years).[2]

In other highly populated countries, such as China and India, a similar pattern occurs. China already has 180 million people over 60 years of age, and it is estimated that the number will reach 240 million by 2020, and 360 million by 2030.[3] In India the number of citizens over 60 years of age is estimated to increase from 100 million to more than 170 million by 2026[4] (Figure 37-2). A sevenfold increase in population over age 80 is also expected.[5]

As the population ages, elderly patients become a more heterogeneous social and economic group. Cognitive status, multiple chronic diseases, and medications add to the heterogeneity of this population. Consequently, physical, emotional, and psychological conditions of the elderly patient must be considered for proper and successful oral healthcare, including endodontic therapy. It is thus important to provide a practical evidence-based endodontic approach that enables appropriate patient management and maintains and/or improves oral health as part of total healthcare services.[6,7]

Elderly patients also constitute a growing share of dentistry's economy. A simple projection for the next 20 years shows the importance these patients will have on dental finances (Figure 37-3). Based on today's visit rates and average expenditures, patients age 61 and older will increase their contribution from 23% of total dental expenditures in 2006 to 28% in 2018 and to 32% in 2030. The number of endodontic procedures in the elderly population in the United States has also been growing steadily.[8] Estimates suggest that as many as 62% of people over age of 60 have at least one tooth with apical periodontitis of pulpal origin.[9] It is therefore expected that clinicians performing endodontic therapy will see more patients with increasing complexity of medical conditions. This is highlighted by a shift of disease from infectious and acute illnesses to more chronic and degenerative diseases.[2] Issues related to barriers in access to endodontic care of elderly patients will become increasingly significant.

This chapter discusses the physiological and pathological changes in the aging dentition as well as clinical considerations and expected endodontic treatment outcomes for the elderly endodontic patient.

PHYSIOLOGICAL CHANGES

Dental Tissues

With age, several physiological and degenerative changes occur in the enamel, dentin, cementum, and pulp.

Enamel

Enamel is the hardest biological substance in the human body, comprising of 92% hydroxyapatite, 6% water, and 2% organic matter.[10,11] A broad spectrum of physical and chemical changes occurs in aging enamel. These changes are caused by caries, oral habits, attrition, abrasion, erosion, trauma, and dental treatment. The enamel surface becomes more susceptible to insults due to reduction in the inter-prismatic organic matrix.[12] Also, the hardness of its outer surface is decreased by almost 12%.[13] These molecular changes cause the enamel to become more brittle and may also contribute to formation of cracks and micro-fractures in elderly patients.[14]

Clinically, these changes may lead to tooth fracture by propagation and possible endodontic treatment failure due to coronal leakage from cracks harboring microorganisms.

Dentin

Dentin consists of 47% hydroxyapaptite, 30% organic matter, and 23% water.[10,11,15] It is the most voluminous structural component of the human tooth. Formation of primary dentin occurs before apex closure, while secondary dentin formation occurs after root formation and is observed throughout the patient's life.

In maxillary incisors, secondary dentin formation occurs primarily on the lingual wall of the pulp chamber while in molars it mainly occurs on the floor of the pulp chamber.[16] Tertiary dentin is formed in response to trauma of microbial, physical, or chemical origin. It can be either reactionary, formed by original surviving odontoblast cells, or reparative, formed by new odontoblast-like cells following the death of primary odontoblasts.[17] Tertiary dentin is less tubular and thus more permeable. Sclerotic dentin, on the other hand, is hyper-mineralized and less permeable resulting in a decreased sensation to cold, hot, sweet, and pain.[18]

Dentin deposition is often more marked in the coronal area of the root canal system, with deeper areas of the root canals remaining patent even into very old age. However, apical dentin contains fewer tubules and thus has potentially fewer areas for remaining microbes to reside in the post-obturation phase.[19] Therefore, a well prepared, irrigated, and obturated root canal system will have very good prognosis.

With age, several structural changes in dentin occur. Dentin of older teeth contains less water than that of younger teeth and is more likely to have cracks develop within its structures.[20] With age, the dentin undergoes reduction in fracture resistance, contributing to mechanical changes and possible structural failures.[20]

Calcifications or calcific metamorphosis in the pulp lumen can result from aging, caries, trauma, or dental treatment such as pulp capping.[21] Calcifications can be found in form of free, attached, or embedded denticles (dentin-like pulp stones) or diffuse (linear) calcifications that are atubular or less tubular.[22] Pulp stones are more prevalent in the coronal pulp, whereas diffuse calcifications tend to be found in radicular pulp. Pulp stones are usually translucent and, upon removal, reveal a darker pulpal floor with developmental fissure lines. As part of endodontic treatment, it is essential to remove pulp stones and calcific tissue, since necrotic or degenerated pulp tissue and microorganisms may be harbored in crevices between the calcific tissue and the dentin.

Certain medications, taken for systemic conditions, may cause dentin hyper-calcification and loss of vertical height of the pulp chamber. It was reported that patients taking statins to treat high blood cholesterol levels had a higher prevalence of root canal obliterations.[23] Another study reported that patients using Prostacyclin (PGI2), prescribed for Raynaud's syndrome, showed an increase in tertiary dentin formation.[24] In such cases, the teeth may appear darker.

Cementum

Cementum thickness increases threefold between the ages of 10 and 75 years.[14] The thickest layer is found at the apex. Along the root, varying degrees of thickness are found, depending on recession and wear of the root surface.[14] Cementum width ranges from 100 microns to 200 microns in young teeth and from 400 microns to 500 microns in older teeth.[25] This cementum thickening causes an increase in the distance between the anatomic apex and the apical foramen,[26] as well as the radiographic apex and cemento-dentinal junction (CDJ).[17] This may affect correct assessment of working length as it can give a radiographic appearance of the working length being short. Electronic apex locators prove very beneficial in avoiding such errors. For more details, see Chapter 19.

In addition, the number and size of portals of exit, apical, and accessory foramina, may decrease with age and become less permeable due to calcification.[27] The effect of this phenomenon on the outcome of endodontic treatment is not completely clear.

Pulp

With age, the volume of the pulp decreases and a reduction in the neurovascular components occurs.[28–30] These changes decrease cell density of the pulp tissue (fewer fibroblasts, odontoblasts, and antigen presenting cells), causing fibrosis and altering the dentinogenesis.[31,32] These events lead to increased dentin thickness, with continuing reduction of the lumen in the pulp chamber and root canal system. Such changes, depending on past history of caries, restorations and other stimuli, may be either physiologic or pathologic in nature. Generally, the number of cells in the dental pulp diminishes with age as proliferative activity peaks early in life and then decreases.[33] However, cell proliferation may be maintained well into adulthood and continue into old age.

Odontoblastic activity and continued deposition of secondary and tertiary dentin occurs throughout life. However, this activity is reduced with age. A decrease in pulp cell density may reduce the reparative capacity of the pulp after restorative treatment, but the increase in dentin thickness may aid in pulp protection.

In a study of pulp cell functional viability in Wister rats of different ages 1 to 18 months, odontoblasts and sub-odontoblast density decreased significantly with age. This reduction in density may help explain the slower secondary dentin secretion and decreased capacity of pulpal repair. This should be taken into consideration during treatment planning decisions, for example in procedures such as pulp capping.[34]

Studies on histochemical distribution in the aging dental pulp show decrease in the metabolic activity. Capillaries in the sub-odontoblastic layer decrease and there is a thinning of the odontoblast layer.[35] Also the pulp tissue endothelium becomes thinner.[36] Ikawa,[37] using laser Doppler flowmetry, found that pulpal blood flow significantly decreased with age. Interestingly, using RNA microarray technique, genetic changes have been shown to take place, whereby the genes involved in apoptosis are more highly expressed as the dental pulp ages.[38]

Much like pulp vascularity, the number of pulpal neurons is reduced as an individual ages. Bernick[28,29] showed that 90% of teeth of individuals older than 40 years have some degree of calcification of the pulp space that leads to obliteration of nerves. In a later study, Bernick[30] determined that in the aging process there is also progressive deposition of calcified mass originating in the root pulpal space leading to a decrease in the number of nerves in the coronal pulp tissue.

Studies have found that the total number of myelinated fibers decreased with age, particularly at the expense of A-delta fibers. The A-beta fibers, however, remained constant.[39] The decrease in A-delta fibers might be related to reduced sensitivity to perception of pain, as these fibers are fast conducting.[40] In addition, it was found that older patients had reduced pulpal volume that affected both myelinated and unmyelinated fibers, leading to misdiagnosis and improper treatment.[41] Also immune-histochemical findings in mice have shown marked age-related decrease in pulpal Calcitonin Gene Related Protein (CGRP) and Substance-P (SP),[42] and reduction in sensitivity to pulpal stimulation.[43] These changes in the neurovasculature and cellular content are probably the reason why pulp breakdown in the elderly often occurs without the classic symptoms of irreversible pulpitis.[43]

A degenerative pulp tissue may serve as nidus for growth of calcific inclusions. It has been found that 93% of all older teeth have caries, fractures, or defective restoration margins.[44] The majority were found on clinical and radiographic examinations prior to restoration removal.[44] Thus these factors should be taken into consideration during diagnosis, repair of structurally damaged teeth, and addressing pulpal response to restorative procedures.

Pulpal atherosclerosis has been speculated to affect pulpal blood vessels and pulpal response to injury. Interestingly, atherosclerosis could not be demonstrated to occur in the pulp.[45,46] Also, head and neck radiation therapy does not seem to affect the microvasculature of the pulp.[47]

Related Oral Tissues

Periradicular Bone

There is not sufficient data in the literature regarding unique age-related changes in periradicular bone and its response to endodontic treatment. In general, bone formation steadily declines with age leading to a significant reduction in bone mass.[48] The alveolar bone has high plasticity and under physiological conditions, it is preserved by the equilibrium between osteoblastic and osteoclastic activity influenced by parathyroid hormone (PTH), vitamin metabolites, calcitonin, estrogen, plasmatic concentration of calcium and phosphate, neurotransmitters, growth factors and local cytokines.[49] The reduction in bone formation might be due to a decrease in osteoblast-proliferating precursors or to decreased synthesis and secretion of essential bone matrix proteins. The extracellular matrix surrounding osteoblasts has been shown to play an important role in bone metabolism. A possible dysfunction of this matrix might occur concomitantly with the aging process.[49]

Osteoporosis, a multifactorial metabolic disorder, is a major disorder afflicting men and women in old age. The most common structural changes are reduction in size and number of bony trabeculae and thinning of the cortical region, particularly in the anterior region of the maxilla and the posterior region of the mandible. However, it is inconclusive whether this bone heals differently after non-surgical and surgical endodontic treatment. Also there are no documented differences between the radiographic interpretation of pre-treatment and post-treatment evaluation.[50]

Periodontal Ligament

The fiber and cellular content of the periodontal ligament (PDL) decrease with age and its structure becomes more irregular.[51] PDL cells of elderly individuals show lower rates of chemotaxy and proliferation than those of young individuals.[49] Thus the PDL is not an ideal source to obtain undifferentiated stem cells.

Clinically, progressive changes in gingival tissue, due to recession, periodontal disease or periodontal treatment, may expose lateral or accessory canals, that may act as a portal of entry for microorganisms to the dental pulp.[52]

Salivary Glands

Structural changes in both parenchymal and stromal tissues of salivary glands also occur with age. There is a reduction in the volume of acini and an increase in ductal volume, fatty and fibrous tissues, and callus formation in the salivary gland.[53] Salivary IgA, mucins, immunologic, and non-immunologic systems are also reduced in the elderly, making them more susceptible to caries and oral lesions.

Xerostomia, hypo-salivary function or dry mouth is a frequent complaint of elderly individuals and it constitutes a major clinical problem. More than 25% of patients over 65 complain of xerostomia.[54] In one-third of cases, xerostomia does not reflect a real reduction in salivary flow rate but rather the subjective feeling of a dry mouth. Only a relatively small number of patients suffering from xerostomia exhibits known etiology such as radiation therapy or Sjogren's syndrome. In the majority of cases, the etiology may be related to age, disease, and certain medications.[55] Dry mouth oral Rinse (Biotene) has proved effective in controlling xerostomia for a number of elderly patients. Radiation therapy for cancer causes a significant reduction in salivary flow predisposing patients to xerostomia, radiation-related caries, and oral fungal infections.[56]

Xerostomia-related side effects of various medications coupled with gingival recession, root exposure, hypersensitivity, leaking restorations, poor oral hygiene, and root caries may lead to an increased demand for endodontic treatment in the elderly.[57]

Temporomandibular Joint

The temporomandibular joint (TMJ) has unique anatomical and functional features that makes it different from other joints in the human body. Condylar remodeling is a physiologic process that aims to adapt the structure of the TMJ to meet the functional demands. Although structural changes are thought to be related to TMJ dysfunction, the mechanism of these changes, affected by reactive processes such as

remodeling, aging, and osteoarthritis, has not yet been completely clarified. Temporomandibular dysfunction (TMJD) caused by a compromised occlusion from multiple missing teeth, drifted teeth, bruxism, and loss of vertical dimension or arthritic disease may cause acute or chronic pain and affect the inter-incisal opening and duration of time the patient can keep the mouth open during endodontic treatment.[58] This may affect the endodontic appointment duration and limit the access for endodontic instrumentation, especially in posterior teeth.

Although most dental pain appears to be due to intraoral causes such caries, trauma, and periodontal disease,[59] atypical fascial neuralgia may be a cause for referred pain from the muscles of mastication. The accumulation of inflammatory mediators such as cytokines, eicosanoids, and neuropeptides in these muscles evoke chronic pain that may mimic endodontic pain.[60] Each affected muscle can refer pain signals to specific teeth. Diagnosis is aided, especially in elderly patients, by palpating each of the muscles of mastication individually. Pain increases as palpation is performed, however it subsides after repeated palpation or massage. For more details, see Chapter 17.

PATHOLOGICAL CHANGES

Systemic Diseases

Elderly patients may be susceptible to infections due to immunosuppression from a cumulative effect of aging, systemic diseases, and prolonged consumption of prescription drugs. Disease modifiers such as diabetes mellitus, high blood pressure, cardiovascular disease, cancer, and viral infections may alter the progression, severity, and host response to treatment and prognosis.

Diabetes: The documented effects of diabetes on apical periodontitis are characterized by higher prevalence of apical periodontitis, larger lesions,[61] twice the number of flare-ups (4.8%) as compared to non-diabetics (2.3%) and lower success rates.[62] Also preoperative presence of apical periodontitis in root canal treated teeth in diabetic patients showed lower success rate than in non-diabetics.[62]

Elevated blood glucose may have severe pathological consequences. In patients with sustained hyperglycemia, proteins, including collagen, become irreversible glycated to form advanced glycation end-products (AGEs). Altered host response to infection occurs in diabetics and may be related to accumulation of AGEs and their interaction with their receptors RAGEs in tissue, mediating chronic cellular perturbations, dysfunction, and alteration in tissues ability to respond to infection. Histologically, there is increased vascular permeability and enhanced expression of adhesion molecules onto endothelial cells and macrophages.

Different cells are affected as result of the AGE-RAGE interaction. Macrophages release pro-inflammatory cytokines and matrix metalloproteinases. Neutrophils show impaired adherence, chemotaxis and phagocytosis, whereas fibroblast exhibit increased activity of matrix metalloproteinases and impaired collagen synthesis. These events may lead to an exaggerated and sustained response to infection and diminished reparative response.[63] Recall procedures for immunologically suppressed patients may need to be extended due to delayed healing patterns.

Hypertension: It is estimated that more than 50 million people in the United States have high blood pressure or are taking antihypertensive medications. Lack of compliance is a major issue in medical treatment of hypertensive patients. Therefore, it is prudent for the clinician to measure blood pressure along with other vital signs at every visit.

The decision, whether to administer a local anesthetic agent containing vasoconstrictor to a patient with hypertension or other cardiovascular disease, is a common concern amongst clinicians. One of the primary advantages of vasoconstrictors in dental local anesthetics is to delay the absorption of the anesthetic into the blood stream. It increases the depth and the duration of anesthesia while decreasing the risk of toxic reaction. Additionally, the vasoconstrictor provides local hemostasis. Epinephrine and levonordefrin are the two vasoconstrictor agents commonly used in dental local anesthetic formulations. Although they do have slightly differing cardiac effects, they carry the same precautions for their use. For more details, see Chapters 18 and 31.

If a patient is suffering from severe uncontrolled hypertension, elective dental treatment should be delayed until the blood pressure is under control. However if emergency dental treatment is required, the clinician may elect to use one to two cartridges of local anesthetic with a vasoconstrictor. This dose will have minimal physiologic effect and will provide prolonged anesthesia. If the anesthesia wears off too soon, endogenous epinephrine produced by the patient, resulting from painful experience, will be greater than the amount of epinephrine from the dental anesthetic cartridge.[64]

Another concern is the possibility of adverse interaction between the local anesthetic agent and a patient's antihypertensive medication, particularly the adrenergic blocking agents. The nonselective beta-adrenergic drugs, such as propranolol (Inderal), pose the greatest risk of adverse interaction.[64] In these patients, an injection of vasoconstrictor-containing local anesthetic may produce marked peripheral vasoconstriction that could potentially result in a dangerous increase in blood pressure, due to the pre-existing medication-induced inhibition of the compensatory skeletal muscle vasodilation. This compensatory skeletal muscle vasodilation normally acts to balance the peripheral vasoconstriction effects in non-medicated patients. The cardio-selective beta-blockers (Lopressor, Tenormin) carry less risk of adverse reactions. For more details, see Chapters 18 and 31.

Cardiovascular disease: Cardiovascular diseases (CVDs) are known to originate from endothelial inflammatory dysfunction and are influenced by risk factors such as smoking, diabetes, hypertension, and dyslipidemia. The pathogenesis of atherosclerosis involves the formation of an atheromatous plaque on the inner walls of major blood vessels leading to myocardial infection, stroke and even death. Mature plaques are composed of lymphocytes, macrophages, and bacteria.[65]

Chronic inflammation plays a crucial role in the pathogenesis and progression of atherosclerosis and at the same time promotes acute CVD events such as plaque rupture and coronary thrombosis. Both long-standing inflammation and acute-phase response characterized by increased systemic levels of C-reactive protein (CRP),[66,67] that is associated with many systemic effects of inflammation, have been implicated with increased risk of CVD. However, well-controlled peer-reviewed studies failed to provide any direct causal relationship between endodontic infection and increased risk of CVD.[68,69]

Pacemakers and implantable cardioverter defibrillators (ICDs) are devices that regulate cardiac rate and rhythm. Both are susceptible to electromagnetic interferences. Piezoelectric instruments and electronic apex locators have shown to have no effect on these devices.[70]

Viral infections: The incidence of herpes zoster (shingles) caused by varicella-zoster virus (VZV), is higher in elderly individuals.[71] After causing chicken pox in childhood, the virus remains latent in dorsal root ganglion cells for possibly future reactivation. The herpetic lesions are self-limiting and typically follow the innervation pathway of the nerve. Patients with herpes zoster in the trigeminal nerve may present symptoms of pulpal pain without showing any pulpal disease. Sometimes the viral infection may also be followed by neuropathic pain along the pathway of the affected nerve, causing post-herpetic neuralgia that can mimic odontogenic pain.[72] A few case reports have shown pulpal pathosis (pulpitis, necrosis, or internal resorption and apical periodontitis) following the appearance of herpetic lesions.[73] Therefore, herpes zoster should always be ruled out as a potential etiology when no local irritants are present. Accurate diagnosis and management of the underlying condition rather than endodontic treatment should be the appropriate course of action.[74]

Cancer: Ignoring oral healthcare in aging patients undergoing cancer radiation and chemotherapy can predispose them to serious oral infections due to immunosuppression. Medical consultation for pre-medication and treatment and laboratory values for absolute neutrophil count must be obtained prior to any surgical procedures. In patients with a post-radiation total dose greater than 6500 cGy, endodontic treatment with de-coronation is preferred over extraction due to increased risk of osteonecrosis.[75] Preventive treatment using fluoride and artificial saliva rinses will minimize radiation-associated caries and opportunistic fungi.

Dementia and Parkinson's Disease: Movement disorders (dyskinesia), such as Parkinson's disease,[76] Dystonia, Gilles de la Tourette's syndrome, and Huntington's disease, are characterized by involuntary body movements. Some generalized dyskinesia have focal manifestations in the orofacial region. However, the available information in the literature is limited.[77]

Clinically, patients' involuntary movements while taking radiographs, performing CBCT scans, or during other diagnostic procedures may make interpretation difficult. Thus preoperative radiographic assessment of anatomy and pathology, assessment of working length, and post-treatment assessment of obturation and healing patterns may be challenging (Figure 37-4).

The clinician should accommodate the procedure for involuntary patient movements during use of any rotary instrumentation or working with the enhanced magnification. Constant patient movements may reduce the efficacy of the operating microscope.

For more detailed discussion on the medically complex patient, see Chapter 31.

Medications

Elderly patients suffering from systemic disease are usually consuming a variety of medications. Twenty five percent of all hospitalized patients are taking six or more prescribed medications.[78] Ninety percent of the general population over 70 years of age takes medications on a regular basis.[79] One-third of this population takes more than three medications.[79] Care must be taken to avoid complications and possible unwarranted interactions. Often, patients will not mention their medical condition and medications (prescription or non-prescription) since some do not see its relevance to dentistry. Therefore, patients or their family members should be thoroughly questioned regarding all prescription and non-prescription medications.

Several medications may cause osteonecrosis of the jaw. Methotrexate, an immunosuppressant used in treatment of chronic diseases such as rheumatoid arthritis, Crohn's disease, and ulcerative colitis as well as bisphosphonate, used in the treatment of multiple myeloma, Paget's disease, metastatic cancer, or osteoporosis, can cause the patient to be more susceptible to osteonecrosis of the jaw.[80] As stated earlier in this chapter, in these patients non-surgical endodontic treatment (sometimes followed by de-coronation) is the treatment of choice until extraction or surgical procedure is permitted.

Trauma

According the Centers for Disease Control and Prevention, each year millions of individuals aged 65 and older fall.[81] Falls are usually due to frailness, postural imbalance, exhaustion, or fainting. Falls can cause moderate to severe injuries, such as limb fractures and head and neck trauma. One in three individuals 65 or older fall each year but less than half inform their healthcare provider.[82] In 2013, 2.5 million non-fatal falls of older adults were treated in emergency departments and more than 734,000 of these patients were hospitalized.[83] If the patient is referred for endodontic treatment directly after trauma, it is essential to rule out any underlying cranial injury that would require urgent hospital care. The management of dental injuries is the same in the elderly patient as in the younger patient. Routine follow-up appointments, to monitor pulp status and to provide endodontic treatment before the root canal system undergoes excessive calcification, will be beneficial to both the patient and the clinician.

Sometimes, elderly patients may present in the dental office with pulp necrosis or a discolored tooth and not report any history of trauma. Careful medical history often reveals a history of general anesthesia and intubation performed a few years earlier.

Dental trauma is the second most common complication of intubation.[84] This type of trauma has been termed *silent trauma*[85] (Figure 37-5). Following silent trauma, teeth heal by laying down secondary dentin with pulp canal obliteration

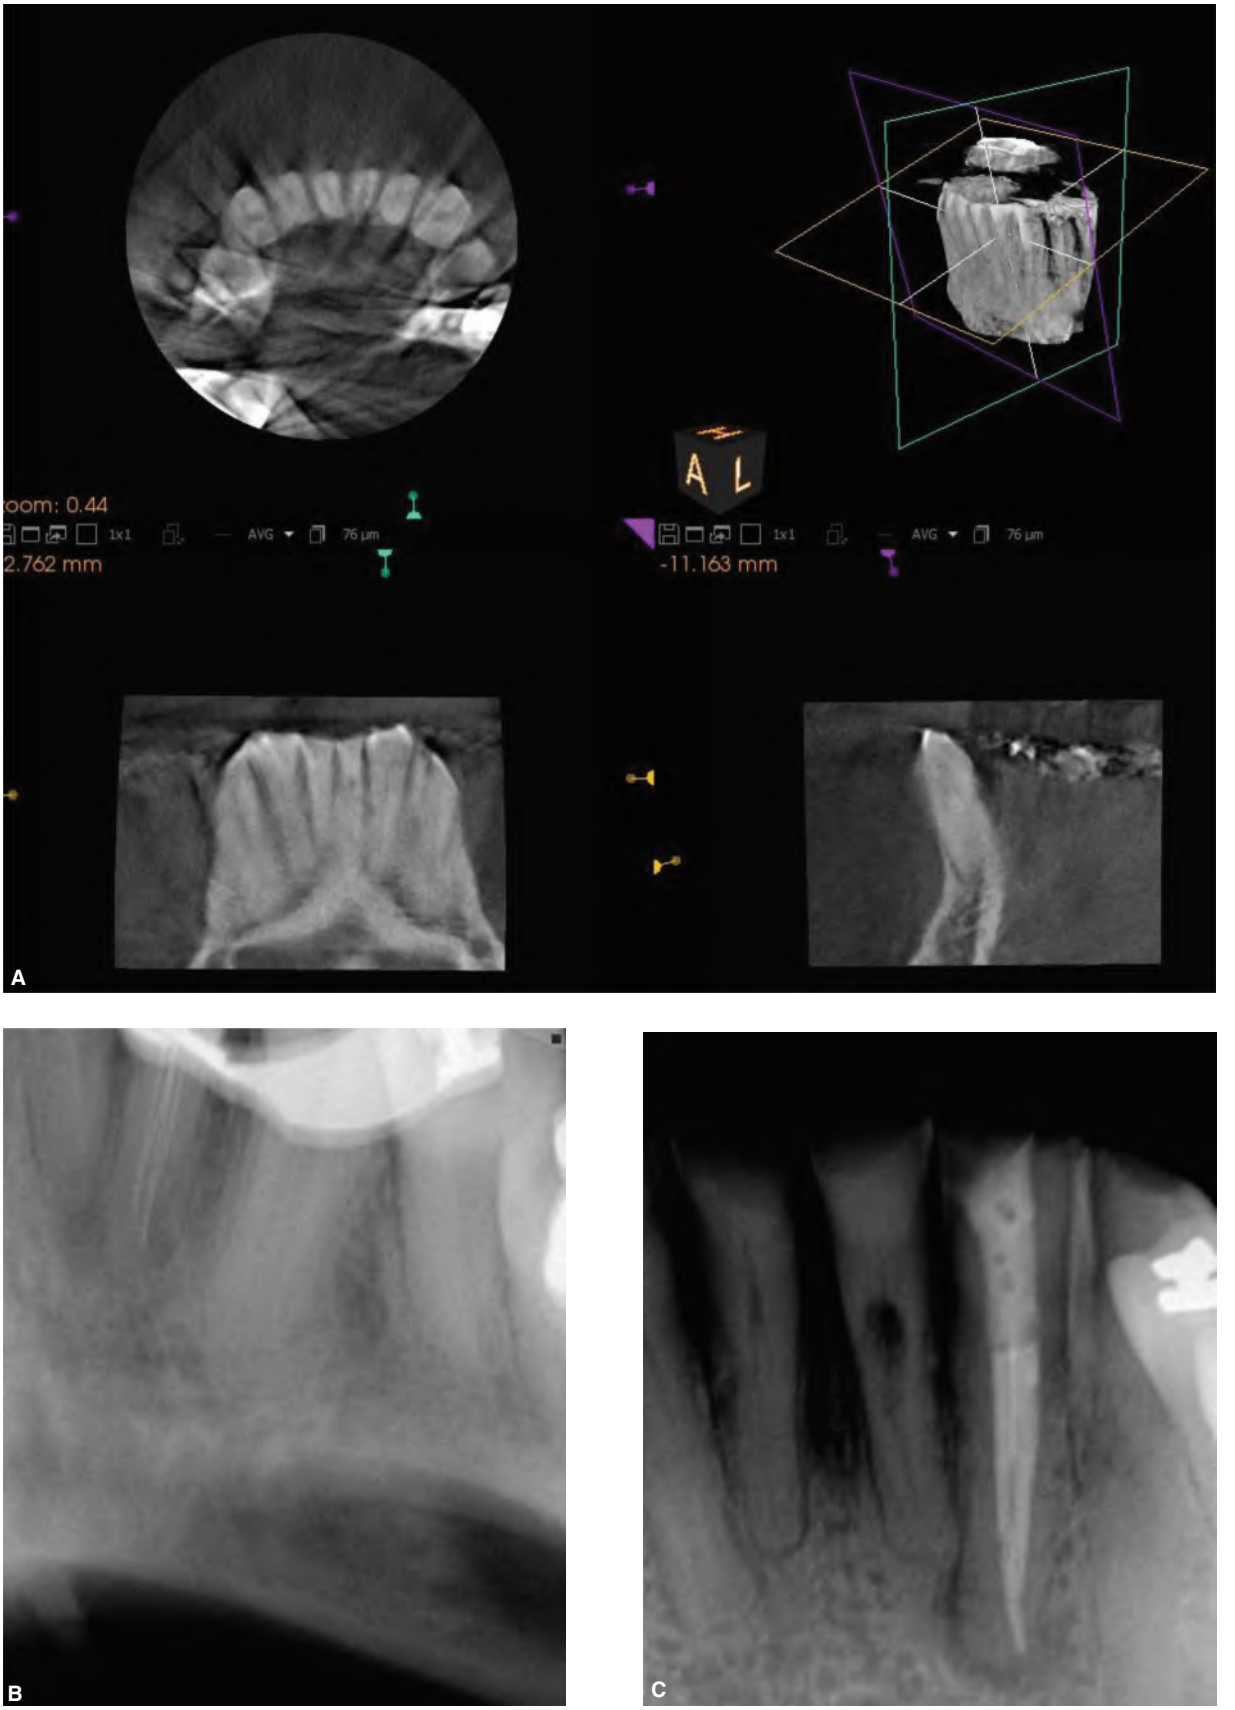

FIGURE 37-4 Radiographic distortions associated with patient's involuntary movements. ***A.*** Cone beam computed tomography (CBCT) taken on an 81-year-old male patient with Dystonia. Note the motion artifacts in the CBCT image analysis. ***B.*** Distortion of length assessment radiograph. ***C.*** Postoperative periapical radiograph of a mandibular canine showing voids in obturation, restorative material due to patient movement.

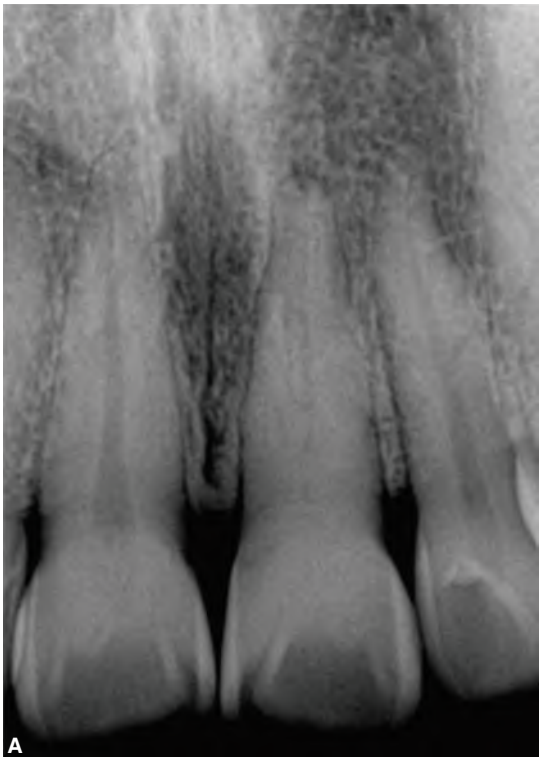

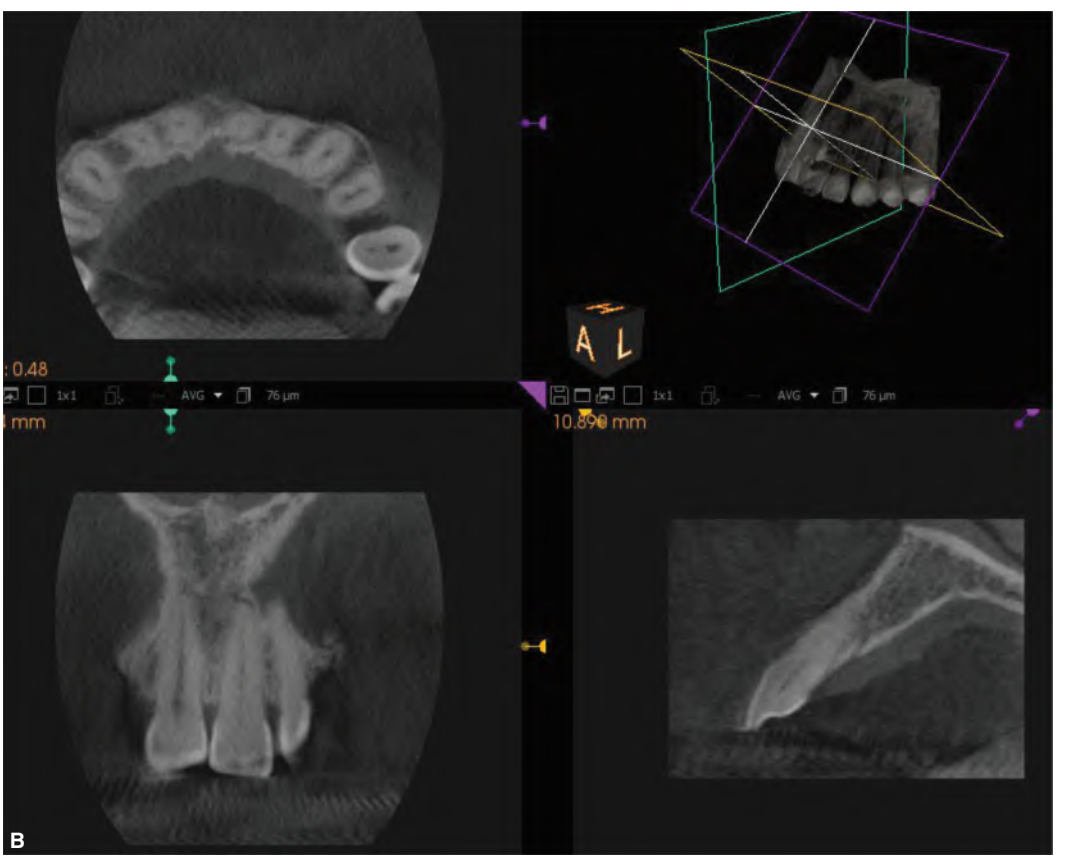

FIGURE 37-5 (*Continued on facing page*)

FIGURE 37-5 Patient with etiology of silent trauma. ***A.*** Radiograph of a symptomatic non-vital maxillary left central incisor in a 71-year-old female. The pulp space appears obliterated. Initially, the patient did not report of any history of traumatic injury to the tooth. After further inquiry, the patient recalled that she underwent surgery under general anesthesia 2 years previously. ***B.*** Cone Beam Computed Tomography (CBCT) views (coronal, axial, and sagittal) showing presence of patent root canal. ***C.*** Postoperative radiograph. The root canal system was prepared and obturated. Following treatment, the patient was asymptomatic.

and calcific metamorphosis, or undergo pulp necrosis, along with inflammatory resorption and/or replacement resorption.[86] Although a root canal system may appear obliterated on a periapical radiograph, histologically it may not be completely calcified and can be treated endodontically.[87]

In crown fractures with pulpal involvement, root canal treatment may be the treatment of choice, as prognosis of pulp cap procedure will be poor, due to diminished capacity of the pulp for healing.[88] In cases of crown-root fractures extending subgingivally, elderly patients may not agree to extensive treatment such as crown lengthening or orthodontic-surgical extrusion procedures to establish ferrule.

In root fracture cases treatment may include repositioning of the coronal segment and stabilization by a flexible splint for 12 weeks to help pulpal and periodontal repair. However, in root fractures associated with a persistent sinus tract or periodontal defect, the teeth will need to be extracted due to poor prognosis.

CLINICAL CONSIDERATIONS

Endodontic Treatment Outcomes

Based on epidemiological studies there is no correlation between age and outcome of endodontic treatment. Endodontic treatment can be as predictable in the elderly patient as in younger patients.[89] Also, studies have shown similar healing pattern of oral tissue in the young and the old, with a delay in healing response in older teeth.[90] Healing is primarily affected by vascularity in the damaged tissue and not age *per se*.[91]

There are no medical contraindications to endodontic therapy in the elderly except for the American Society of Anesthesiologist (ASA) type IV or type V patient, needing urgent medical attention. Age *per se* does not seem to affect the outcome or healing of endodontic treatment.[91–96] Outcomes studies have shown that treatment outcome is mainly affected by the preoperative presence of apical periodontitis, the quality and extent of the root canal filling, and quality and type of restoration following root canal treatment. However, patients with diminished healing capacity caused by conditions such as diabetes,[62] immunosuppression, or use of certain medications may influence the duration for periradicular healing.

Endodontic outcome studies have consistently shown a survival and retention rate higher than 90% in teeth treated with non-surgical root canal therapy.[97,98] Therefore, when indicated, endodontic treatment is a good alternative to extraction and tooth replacement.[99,100] The decision to perform endodontic treatment should be based upon medical health of the patient, prognosis, and cost-benefit of treatment.

Treatment prognosis in the elderly patient may sometimes depend on other factors than just long-term outcomes. Occasionally, a tooth with esthetic consideration but questionable restorability might be a candidate to be retained,[101] or a non-functional tooth may need to be retained where extraction might cause health complications (Figure 37-6).

Accessibility to Care

Elderly patients may need easy access to the dental office and operatory. Some may use accessories such as a cane, wheelchair, or a motorized cart. If the patient is ambulatory, access to the office requires a ramp and/or elevator. Waiting rooms, operatories, and restrooms need to be handicap accessible. Elderly patients should be monitored by the office staff from the moment they enter the dental operatory until discharge upon completion of the treatment. In tandem, as more elderly patients find it difficult to visit a dental office, dental care services at senior citizen community centers and mobile dental clinics should also be available.

Appointment Time and Duration

Appointments should be scheduled according to the patient's preference. Usually, morning appointments are better,[102,103] however, they should be synchronized with the patient's medication, meals, or other medical treatment regimens. Appointments should preferably be of short duration

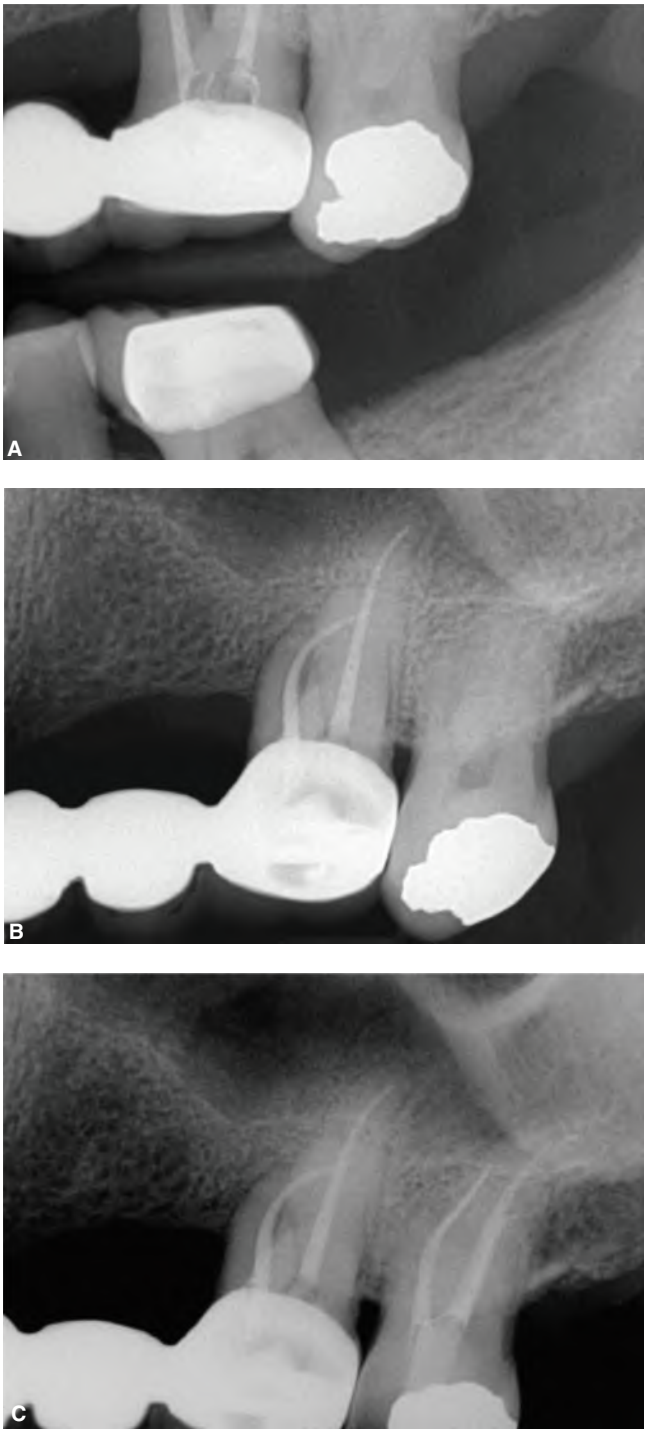

FIGURE 37-6 Medical contra-indication to extraction. ***A.*** Preoperative bitewing radiograph of a symptomatic supra-erupted maxillary left second molar in a 83-year-old male with a history of a recent open heart surgery. Although non-functional, the tooth was treated endodontically. ***B.*** Preoperative periapical radiograph. ***C.*** Postoperative radiograph. Following treatment, the patient was asymptomatic.

based on the patient's physical and medical conditions. Also, whenever possible and indicated, the number of treatment visits should be reduced since many elderly patients rely on being accompanied by others during dental visits.

Medical History

Due to visual, auditory, and cognitive impairment, the Health Insurance Portability and Accountability Act (HIPAA) of 1996 mandates a family, friend, or caregiver may need to assist in completing the medical and dental history and in describing the chief complaint. The clinician should thoroughly review the medical history, need for medical consultation, premedication, and drug interactions before initiation any dental treatment. Over the counter non-prescription medications, natural, herbal or homeopathic supplements may affect and alter the clotting mechanism especial during endodontic surgery and should be identified. For more details, see Chapter 8.

Dental History

Details of dental history of aging patients are rarely complete and may show treatment by several dentists at different locations. The clinician should make all attempts to research and review old dental records and gather as much information as possible. The number of times the tooth has been restored, the addition of restorative surfaces on a tooth over time, history of falls, and surgery under general anesthesia may be pertinent to the diagnosis. Exposure to factors that contribute to oral cancers accumulates with age and many systemic diseases may initially manifest prodromal oral signs or symptoms.[104]

Diagnostic Tests

The positioning of intraoral radiographic films and inflexible digital sensors may be difficult due to decrease in muscle tonicity, limited intra-oral opening, and presence of exostoses. Use of soft foam padding around the edges of the digital sensor or smaller pediatric sensors should be considered. A careful preoperative assessment of the bitewing and multiple angled periapical radiographs will help plan access preparation, and alert the clinician if the axial inclination of the crown does not coincide with the long axis of the root. Poorly contoured crowns or over contoured crowns made to compensate for spacing and to close interproximal contacts must be identified. Sometimes, if the tooth undergoing endodontic treatment is heavily restored and calcified, a periapical radiograph of the contralateral tooth may be beneficial in determining the anatomy of the root canal system. The clinician can also assess previous radiographs if available, to determine position and deposition of tertiary dentin over time.

Often it may be prudent to obtain prior permission from the patient and referring dentist to remove a prosthetic crown if access becomes difficult. The clinician may consider and prescribe a CBCT analysis in severe cases of calcification and retreatment after determining the benefit to risk ratio to the patient.[105]

Differential Diagnosis

Differential diagnosis, mainly of pain and its origin, is key for successful treatment planning. The occurrence of arthritic diseases such as TMJD, in either chronic or acute episodes, atypical facial pain, neuritis and neuralgia, maxillary

sinusitis, osteonecrosis of the jaw and tumors may mask or mimic odontogenic pain in elderly patients (Figure 37-7). In many instances these diseases impact quality of physical and psychological function, therefore, these complaints must be acknowledged and addressed.

There is limited evidence of age related changes in the physiological functioning of peripheral and CNS nociceptive pathways from young to older populations. Studies indicate that the aging dental pulp showed alterations in its ability to respond to pain stimuli.[28–30] There are fewer cells, blood vessels, and nerve bundles in the pulp and a marked decrease in the density of nerves is evident. As mentioned earlier, with age there is a subsequent decrease in neuropeptides such as CGRP and Substance P in the pulp. Also calcification and reduction in pulp volume cause a decrease in response to environmental stimulation or induced stimulation of diagnostic tests. Thus, following an insult, the pulp in the elderly patient may undergo necrosis without intermediate symptoms. For more details, see Chapters 8 and 17.

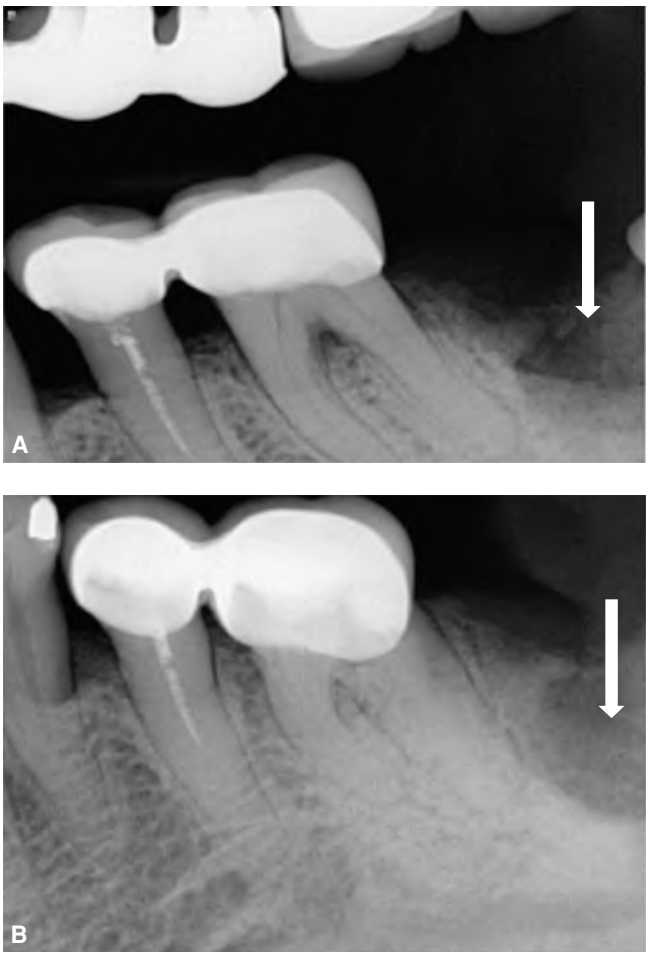

FIGURE 37-7 Pain mimicking endodontic symptoms in a 83-year-old female with osteonecrosis of the jaw (ONJ). The patient was referred for root canal treatment in the mandibular left first molar. Both the mandibular left first molar and second premolar were asymptomatic and responded normally to pulp testing. The patient has been receiving medical treatment for ONJ that developed after extraction of the mandibular left second molar. ***A.*** Preoperative bitewing radiograph and ***B.*** Preoperative periapical radiograph showing area of osteonecrosis in the lower left mandible.

Additionally, a significant number of elderly patients may have multiple restorations on the same tooth over a period of time with reduced pulpal healing capacity and greater tendency to undergo pulpal necrosis.[106] Establishing the culprit tooth in a patient with multiple tooth restorations can be challenging due to decreased response to stimuli.

Case Selection

In most cases, there are no contraindications to endodontic treatment. However, in some cases, case selection should be done cautiously taking into consideration the physical limitations of the patient. On the other hand, in certain medically compromising situations, endodontic treatment should be selected as the treatment of choice. For example, patients presenting with osteoradionecrosis during radiation therapy or those with bisphosphonate-related osteonecrosis of the jaw (BRONJ).

Prophylactic root canal treatment may be indicated in asymptomatic healthy pulps when restorative considerations such as overdenture abutments or in cases of root amputation in teeth with localized periodontal involvement.

Patient Positioning and Comfort

Elderly patients may require special positioning during treatment. They should be seated comfortably in the dental chair equipped with an adjustable headrest and pillows. Some patients may have difficulty reclining in an extreme supine position due to conditions such as osteoarthritis or neck and back problems (Figure 37-8). At the end of the endodontic procedure bring back the patient from supine position in a gradual manner in order to avoid orthostatic hypotension. Bite blocks should be used to stabilize the jaw especially in patients with conditions affecting muscle tonicity such as Parkinson's disease or dystonia. Bright operatory and surgical

FIGURE 37-8 81-year-old patient undergoing endodontic treatment in a minimally reclined position.

operating microscope lights may be shielded from the elderly patient's eyes by using dark glasses. Also, blankets may be necessary if the temperature in the operatory is too low for the patient.

Prior to discharging the patient, allow them time to recover both mentally and physically. Verbal and written instructions should be given to the patient and to the accompanying individual. Reemphasize the importance of maintaining good oral hygiene and regular recall appointments.

Anesthesia

Older patients tend to be less anxious, have a higher threshold of pain tolerance, and are more likely to prefer less anesthetic, especially if the tooth is asymptomatic. There are no contraindications to use vasoconstrictors in dental local anesthetics in routine endodontic procedures in elderly patients.

Supplemental anesthesia such as intra-osseous or intra-ligamentary injections should only be administered as the last option, after informing and educating the patient of anticipated heart rate increase. It may be advisable to use non-vasoconstrictor local anesthetics such as 3% mepivacaine for such procedures. For more details, see Chapters 18 and 31.

Tooth Isolation

All root caries and defective restorations should be removed to evaluate tooth restorability and to determine if the tooth is salvageable. Placing a clamp may be challenging in patients with decreased muscle tonicity, or with limited oral opening. Often the dental dam may need to be placed after access and location of canal orifices. Avoid clasping teeth that appear weak from extensive caries or restorations especially in the anterior dentition.

Elderly patients may need to be given frequent breaks during the appointment to facilitate breathing or use of restroom. The dental dam may need to be taken off during this time. The tooth should ideally be temporized with cotton and temporary restorative material during this phase. For more details on tooth isolation, see Chapter 19.

Access Cavity

Enhanced illumination and magnification will greatly enhance visibility and aid in access. The clinician needs to be aware, that due to modified patient positioning in the dental chair, the orientation of the crown or the root may change during visualization and access. "Walking" a periodontal probe along the cemento-enamel junction (CEJ) and using the "Laws of Access Preparation."[107] will provide a systematic approach to locating root canal orifices.

Initial access into a calcified pulp chamber may be gained without a dental dam to aid in visualization of the pulp chamber and to avoid iatrogenic procedural errors (Figure 37-9). Orientation should be verified and confirmed visually and radiographically. The traditional "drop into the pulp chamber" may not be felt, making careful exploration with an endodontic explorer and the measurements from occlusal surface to the roof of the pulp chamber more relevant. A radiopaque marker such as gutta-percha from a down-pack gun or calcium hydroxide paste at the depth of the exploration can reveal critical information on a bitewing radiograph (Figure 37-10).

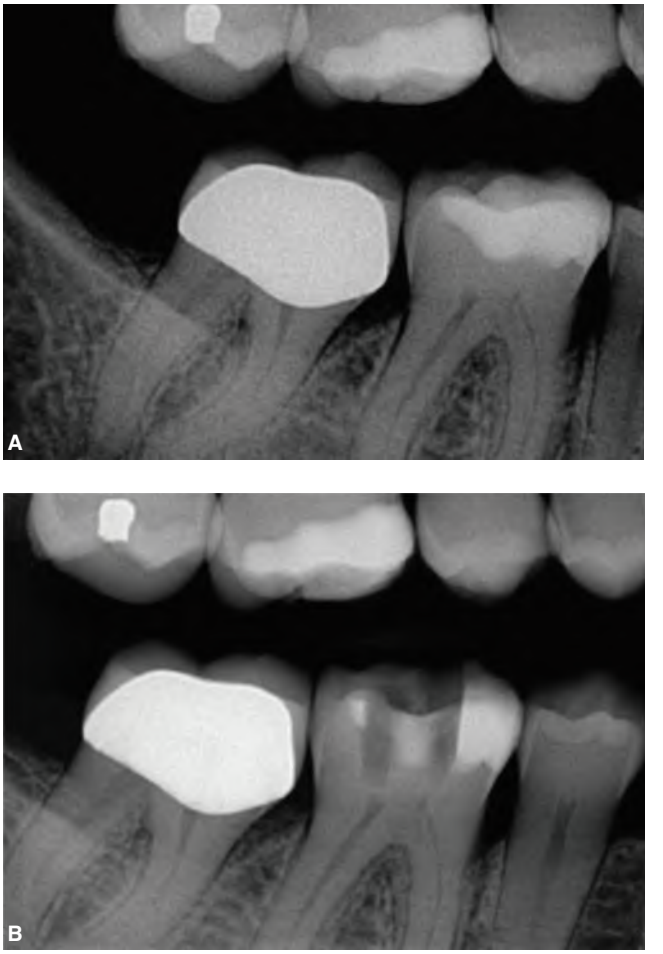

FIGURE 37-9 Access preparation assessment prior to placement of the dental dam in a 69-year-old patient. ***A.*** Preoperative bitewing radiograph of the mandibular right first molar. The pulp chamber appeared partially obliterated. ***B.*** Intraoperative bitewing radiograph taken without the dental dam for orientation purposes.

Often the access preparation may need to be modified or enlarged in order to locate the canals orifices. As soon as the canals are located it is important to place the dental dam. As stated earlier even if the canals appear calcified on a radiograph, histologically a root canal space is always present[87] (Figure 37-11). If the canals cannot be located, it may be wise to schedule for the patient to return or consider other treatment options.

Canal Length Determination

As described earlier, age-related cementum thickening may alter the original locations of apical foramen.[17,27] Electronic apex locator readings, together with good radiographic assessment, tactile sensation, and wet-dry paper point test to

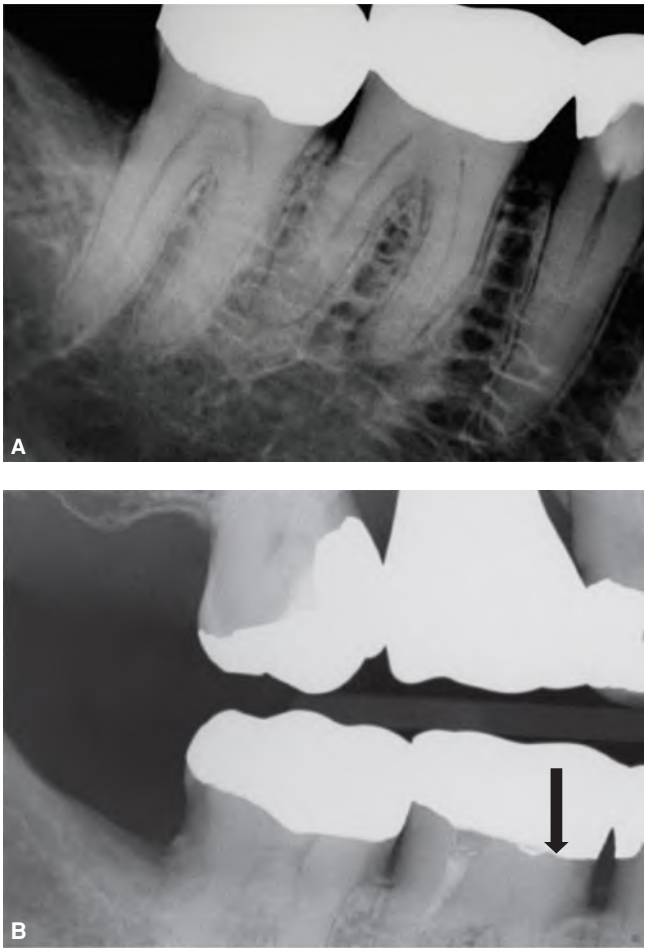

FIGURE 37-10 Use of radiopaque tracer for assessment of access preparation in a tooth with a calcified pulp chamber. ***A.*** Preoperative radiograph of the mandibular right first molar in a 73-year-old male showing a full coverage restoration and apparent obliteration of the pulp chamber. ***B.*** Intra-operative bite-wing radiograph showing access orientation with aid of radiopaque calcium hydroxide.

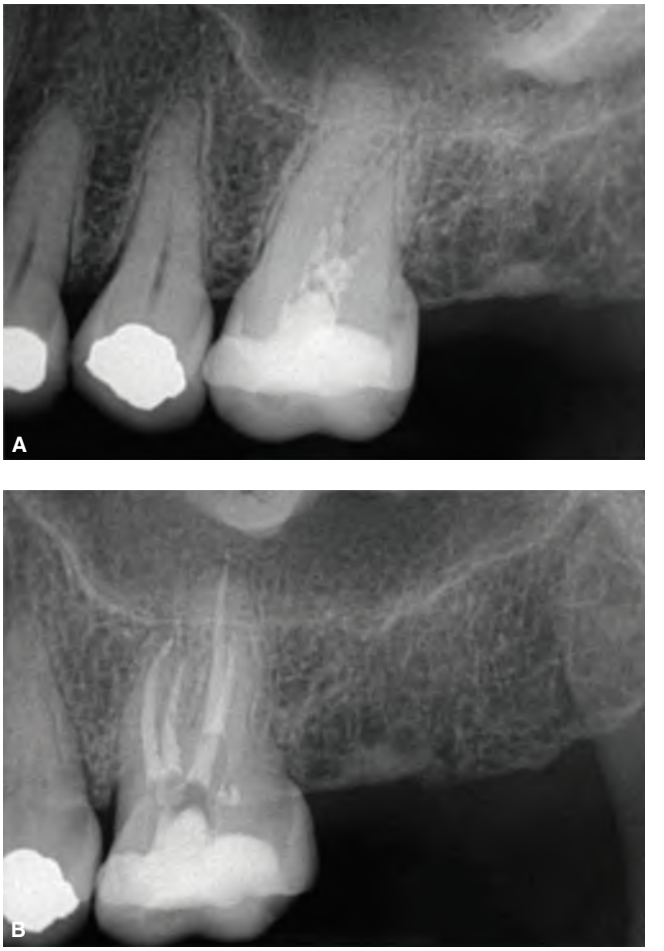

FIGURE 37-11 ***A.*** Preoperative radiograph of the maxillary left first molar in an 82-year-old female. The root canals appear partially obliterated. The patient was referred to the endodontist after an attempt to fully access and negotiate the canals was unsuccessful. ***B.*** Postoperative radiograph showing complete obturation of the root canal system.

determine the working length, are important. Patency may not be achievable in all cases.

Cleaning and Shaping

There are no specific considerations for cleaning and shaping procedures in the elderly patient. After establishing a glide-path and working length, the clean and shaping can be completed using standard protocol. It should be noted that the root canal lumen is expected to be smaller and the dentin tissue more sclerotic. Copious use of chelating agent such as Ethylene Diamine Tetra Acetic acid (EDTA) with specific files such as "Stiff files" (Brasseler), C (Dentsply), and C-plus files (Dentsply/Maillefer) to help negotiation and establish a glide path may be helpful. Some rotary files such as ProGliders (variable taper) and PathFiles (0.02 taper) (Dentsply) may help expedite this initial enlargement of the canal, but are to be used only after establishing a safe glide path for the rotary file. Frequent irrigation with sodium hypochlorite will help soften and dissolve the fibrous pulp tissue greatly facilitating the shaping and cleaning procedure.

Obturation

No special treatment modifications are needed for cold or warm obturation techniques. For more details, see Chapter 22. When using the down-pack and backfill for the warm vertical obturation techniques, the clinician should be conscious of the fact that the elderly patient may not have an adequate intra-oral opening and may move during the procedure. Sometimes a different obturation system such as carrier-based or a single cone technique may have to be considered as an alternative.

Tooth Restoration

Elderly patients may present with teeth that have had multiple restorations or insults over time. At this point, these teeth often need extensive restorations such as full coverage

or onlays. Due care needs to be given to avoid aggressive preparations since these cumulative factors can tilt the balance in favor of pulpal pathosis.

It is essential to place a coronal seal immediately after root canal therapy to prevent failure of treatment due to coronal leakage.[108–110] Older patients are more likely to have previous cervical or sub-gingival root caries. Often, the final restoration may not extend to cover the pre-existing sub-gingival restoration. Ease of application and potential fluoride releasing properties of glass-ionomer or glass-ionomer resin-modified restorative materials makes them preferable over the more technique-sensitive composite restorations. For more details, see Chapter 35.

Retreatment

With age, the incidence of endodontic retreatments may increase, due to coronal leakage from loss of seal, recurrent caries or fracture of teeth, and restorations.[111] Also, overlooked or missed canals are a more common cause of failure in older patients. An isolated symptom, heat sensitivity is usually indicative of a missed canal.[112] Retreatment indications and considerations are the same as in younger patients. For more details, see Chapter 23.

Apical Surgery

Often, with age, the position of anatomic structures such as the maxillary sinus, the inferior alveolar nerve canal, mental foramen, and incisive foramen may change as a result of multiple missing teeth and residual ridge resorption over time. The changes in position of these anatomical entities should be observed and considered during the treatment planning.

Elderly patients may be taking prescription anti-coagulants or self-prescribed low-dose aspirin. A thorough medical history evaluation and questioning will provide key information on allopathic, homeopathic or herbal anti-coagulant agents. Studies have shown that anti-coagulant therapy should preferably not be stopped and hemorrhage during endodontic surgery should be controlled by local hemostatic agents.[113] Post-operatively, patients must be informed about the possibility of ecchymosis. This sub-epithelial hemorrhaging presents itself as purple-red discoloration and is self-limiting. Tissues regain normal color in few weeks.

Sometimes, due to periodontal disease, root resorption or crown attrition, periodontal and endodontic surgery may need to be combined to get adequate crown root ratio and tissue attachment.

Chapter 38

Endodontic Therapy in the Pediatric Patient

Enrique Bimstein, Yaara Y. Berdan

JUSTIFICATION FOR ENDODONTIC THERAPY IN THE PRIMARY DENTITION

Dental caries is the most common chronic disease of children in the United States, and has been described as a silent epidemic that restricts activities in school, home, parent's work, and often diminishing the quality of life (Figure 38-1).[1–3] Although there has been a reduction in dental caries in permanent teeth over the past few decades, caries prevalence in the primary dentition has only stabilized and may have even increased slightly in some population groups.[1]

Early childhood caries can begin soon after eruption (Figure 38-2) and, if neglected, may rapidly deteriorate to virulent forms of caries, leading to unrestorable teeth, pulp inflammation, and ultimately pulp necrosis and a lasting detrimental impact on the dentition (Figure 38-3).[4]

The American Academy of Pediatric Dentistry (AAPD) states that dental care is medically necessary to prevent and eliminate orofacial disease, infection, and pain, to restore the form and function of the dentition, and to correct facial disfiguration or dysfunction.[5] Dental neglect is defined as dental caries, periodontal diseases and other oral conditions that, if left untreated, can lead to pain, infection, loss of function (Figure 38-3),[2] and in extreme situations may endanger the child's life (Figure 38-4). This represents a most relevant problem in the United States of America as reflected in a recent manuscript that provided representative estimates of hospital-based emergency department (ED) visits during the year 2008 for dental caries, pulp and periapical lesions, gingival/periodontal lesions, and mouth cellulitis in patients who were ≤21-years-old.[6] A total of 215,073 ED visits with dental conditions occurred among children; 41% of them included the diagnosis of pulpal and periapical conditions; while 3% were diagnosed with oral abscess/cellulitis. An additional study done with the purpose of determining the prevalence, types, and treatment of dental emergencies that presented to a tertiary care pediatric ED indicated that, among 247 non-traumatic dental complaints, 59% were in children younger than 5 years old, 8% required hospitalization for intravenous antibiotics, and 82% were discharged from the ED with oral antibiotics.[7] Prevalence of oral disease in children, as well as available data, may vary from continent to continent and from country to country. Readers should check the available publications pertaining to their individual countries.

Primary teeth are more susceptible to the carious process than permanent teeth, due to their smaller size, thinner enamel and dentin, and larger pulp horns (Figure 38-5).[8–10] Additionally, this higher susceptibility is related to the fact that primary teeth show a lower calcium content, slightly

FIGURE 38-1 A child in pain from dental origin.

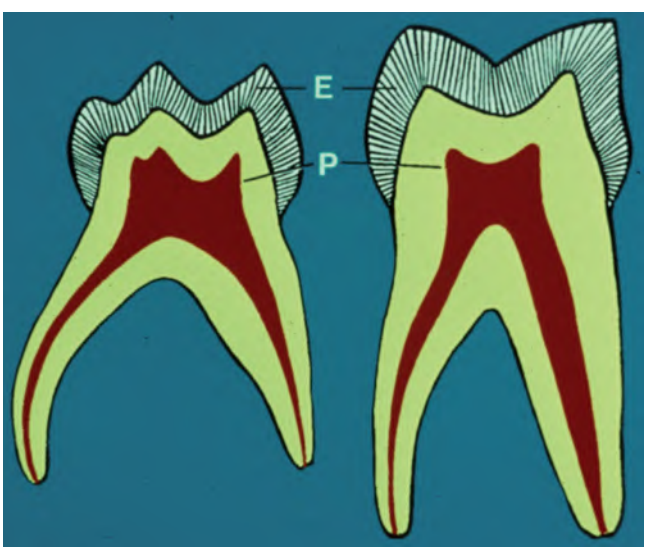

FIGURE 38-5 Contrasting primary and permanent molars. Note large pulp space and thin dentin in the primary molar (E- enamel; P- pulp).

lower calcium-to-phosphate ratio, higher water content, and higher organic content than permanent teeth. Consequently, early childhood caries progresses rapidly owing to the lower degree of mineralization, higher carbonate content, and higher porosity of the mineralized tissues of the primary teeth.[11–13] Clearly, prevention or the early restoration of primary teeth ensuring the omission of pulpal inflammation and infections are fundamental components of the practice of pediatric dentistry.

The assumption that primary teeth are not important since they exfoliate, and that attempts to maintain them with pulpal therapy are unnecessary, fails to take into account the important functions of deciduous teeth. Primary teeth enable children to eat solid foods, aid in speech development, and maintain space for the permanent dentition (Figure 38-6A&B).[8,14] Children's confidence

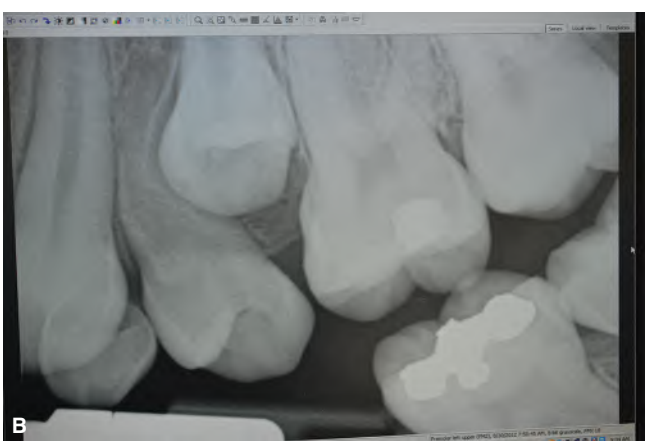

FIGURE 38-6 ***A.*** Clinical picture of a child in the mixed dentition period after early extraction of the primary maxillary right second molar, and mesial drift of the permanent first molar. ***B.*** Periapical radiograph of an adolescent after early extraction of the primary maxillary left second molar and impaction of the succedaneous tooth due to mesial drift of the permanent first and second molars and distal drift of the first premolar. (38-6A, courtesy of Dr. Shaul Yehezkel, Los Angeles, CA, U.S.A.)

and self-esteem are enhanced by the appearance of their teeth. Keeping primary teeth healthy is important not only to prevent a child from experiencing pain and disease, but to enhance their social development, esthetics, quality of life, development and eruption of the permanent successors, and the prevention of the development of detrimental oral habits.[8,14–17] Although space maintainers can be used successfully to reduce the prevalence and severity of malocclusion following premature loss of primary teeth, they are not without complications. Adverse effects associated with space maintainers include: 1) dislodged, broken, and lost appliances; 2) plaque accumulation; 3) caries; 4) damage or interference with the successor tooth eruption (Figure 38-7); 5) undesirable tooth movement; 6) inhibition of alveolar growth; 7) soft tissue impingement; and 8) pain.[18] Therefore, pulpally involved primary teeth should be retained when possible with appropriate endodontic treatments.[19]

Because of the significant value of primary molars and the potential harm of early extraction, it may even be justified to treat a primary molar with a poor prognosis with the intent to maintain the tooth until it is no longer needed as a space maintainer. However, this decision needs to be balanced with the maintenance or creation of a favorable environment that does not interfere with the normal exfoliation of the primary tooth, and the development and eruption of the succedaneous tooth. While alternative strategies for posterior space maintenance and occlusal guidance are frequently required in cases when it becomes imperative to extract primary molars, the loss of a primary incisor after the eruption of the primary canines does not result in space loss, but may be an esthetic concern.[15,16]

According to the AAPD Guideline on Pulp Therapy for Primary and Immature Permanent Teeth, the primary objective of pulp therapy in the primary dentition is to maintain the health and integrity of the teeth and their supporting structures.[18] Several vital (e.g., pulp cap or pulpotomy) or non-vital pulp (e.g., pulpectomy) therapies are possible for primary teeth.[18] Accurate assessment of pulp condition that indicates which treatment is the most appropriate in each individual case may be the most challenging aspect of treatment. This chapter presents updated information on pulp diagnosis, and on selection of the matching pulp treatment for primary teeth, emphasizing the need to take into consideration the individual characteristics of each case, in the best interest of the child.

FIGURE 38-7 Ectopic eruption of the permanent mandibular left lateral incisor behind a lingual arch that is preventing its physiological alignment.

RATIONALE FOR SELECTION OF ADEQUATE PULP THERAPY IN THE PRIMARY DENTITION

The treatment of endodontic conditions in primary teeth should take into consideration the child's medical and dental histories, subjective evaluation of the area associated with the current symptoms/chief complaint (as informed by the child and the parent), objective clinical and radiographic findings, value of each tooth in relation to the child's overall oral development and occlusion, potential of inflamed pulp tissues to recover, restorability of the tooth, as well as the child's physical and mental development and behavior, and alternatives to pulp treatments.[18,19] Recognition of the healing potential of the inflamed dental pulp, and awareness of the improvements in dental materials and techniques, has contributed to the development of endodontic primary teeth treatments that have high success rates. Sound relationship between the extent of the carious lesion, the degree of pulp involvement, and the type of treatment are important factors.[18,19]

In order to deliver the most adequate dental care to pediatric patients, the following dynamic variables should be considered:

a. *Growth and development of the dentition*:
The "life cycle" of the primary tooth involves its intra-alveolar development, eruption, completion of root development, and root resorption that eventually facilitates the natural exfoliation of the tooth, harmonizing with the development and eruption of the permanent successor, or in some cases acquiring developmental disturbances.[8,10,20–22] Therefore, it is essential for the pulp therapy of the primary tooth not to interfere with the proper development of the primary tooth and its permanent successor, or with the transition from the primary to the permanent dentition. Furthermore, the selection of the type of therapy must take into consideration the stage of development of the primary tooth and its successor.
Table 38-1 summarizes the average ages for the various stages of dental development. However, the clinician must be aware that these data represent only mean values and significant variations from the timing of the normal developmental stages, requiring that each case be evaluated

TABLE 38-1 Developmental Stages of the Primary and Permanent Dentition[8,21]

Dentition	Arch	Tooth	Enamel completed	Eruption	Root completed	Exfoliation
Primary	Maxillary	Central incisor	1 ½ mo	7 ½ mo	1 ½ yrs	7 yrs
		Lateral incisor	2 ½ mo	9 mo	2 yrs	8 yrs
		Cuspid	9 mo	18 m	3 ¼ yrs	11 yrs
		1st Molar	6 mo	14 mo	2 ½ yrs	9 yrs
		2nd molar	11 mo	24 mo	3 yrs	11 yrs
	Mandible	Central incisor	2 ½ mo	6 mo	1 ½ yrs	6 yrs
		Lateral incisor	3 mo	7 mo	1 ½ yrs	7 yrs
		Cuspid	9 mo	16 mo	3 ¼ yrs	10 yrs
		1st Molar	5 ½ mo	12 mo	2 ¼ yrs	9 yrs
		2nd molar	10 mo	20 mo	3 yrs	10 yrs
Permanent	Maxilla	Central incisor	4–5 yrs	7–8 yrs	10 yrs	
		Lateral incisor	4–5 yrs	8–9 yrs	11 yrs	
		Cuspid	6–7 yrs	11–12 yrs	13–15 yrs	
		1st Premolar	5–6 yrs	10–11 yrs	12–13 yrs	
		2nd Premolar	6–7 yrs	10–12 yrs	12–14 yrs	
		1st Molar	2 ½–3 yrs	6–7 yrs	9–10 yrs	
		2nd Molar	7–8 yrs	12–13 yrs	14–16 yrs	NA
	Mandible	Central incisor	4–5 yrs	6–7 yrs	9 yrs	
		Lateral incisor	4–5 yrs	7–8 yrs	10 yrs	
		Cuspid	6–7 yrs	9–10 yrs	12–14 yrs	
		1st Premolar	5–6 yrs	10–12 yrs	12–13 yrs	
		2nd Premolar	6–7 yrs	11–12 yrs	13–14 yrs	
		1st Molar	2 ½–3 yrs	6–7 yrs	9–10 yrs	
		2nd Molar	7–8 yrs	11–13 yrs	14–15 yrs	

mos = months, yrs = years.

individually.[8,10,21] The dental age, rather than the chronologic age, must be carefully evaluated for teeth present in the mouth, amount of root resorption of the primary tooth, amount of bone between the primary tooth and its permanent successor, and the degree of development of the permanent tooth.

b. *Child's ability to cooperate with dental treatment and/or extent of treatment*:
The risks and benefits involved in advanced behavior guidance techniques, such as pharmacologic sedation or general anesthesia, should be considered in favor of a less conservative approach, diminishing the possibility of failure, and the need for re-treatment. For example, performing an extraction instead of a pulpotomy or a pulpectomy on a tooth with a doubtful prognosis. On the other hand, it is up to the clinician's judgment to evaluate the risk and benefit of an "extra effort" to maintain a pulpally involved primary tooth in specific situations. For example, preventing space loss caused by extraction of a second primary molar before the eruption of the first permanent molars (Figure 38-6A&B), or when a primary molar has no permanent successor.

c. *Anatomy and morphology of the primary teeth*:
Due to the fact that in primary teeth the enamel and dentin are much thinner and the pulp horns much larger than in the permanent teeth, dental caries, restorations and traumatic crown fractures often come close to, or involve, the pulp (Figures 38-5 and 38-8).[8–10] The clinician must be familiar with the root anatomy of primary teeth. While

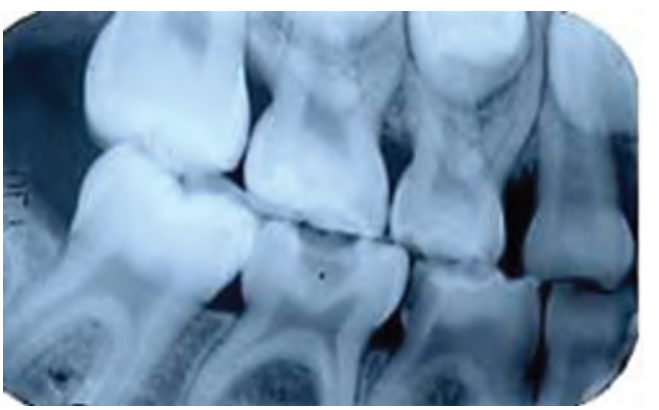

FIGURE 38-8 Bite-wing radiograph showing deep caries in proximity to the pulp in both primary mandibular right molars.

the root canal of anterior primary teeth is normally a large single canal, the molars usually have three root canals; two canals in the mesial root and one in the distal root of mandibular molars, and one canal in each of the three roots in maxillary molars. Two canals have also been found in the mesio-buccal and disto-buccal roots, and some reports have indicated a relatively high incidence of fusion of the distobuccal and palatal root canals.[8–10,23]

The canals are the least complex when the teeth are newly erupted. Narrowing of the canal system takes place with the formation of secondary dentin, and the apical root canal system is modified by the physiological resorption

that has been reported to start immediately after the completion of primary root formation.[8,23] Roots of primary molars have a greater flare than those of permanent teeth, since the primary teeth accommodate the developing succedaneous premolars (Figure 38-9A&B).[8–10,23]

d. *Comprehensive medical history*:
The patient's systemic evaluation is an indispensable component of the oral evaluation and treatment of children, since a systemic condition may, in some cases, be the main factor for choosing the most adequate treatment of pulpally involved primary teeth.[18] In every case, but more emphatically in children with systemic diseases, endodontically treated teeth should be clinically and radiographically monitored periodically for signs of internal resorption (in the case of pulp capping or pulpotomy), or failure due to pulpal, periapical, and/or furcal infections.

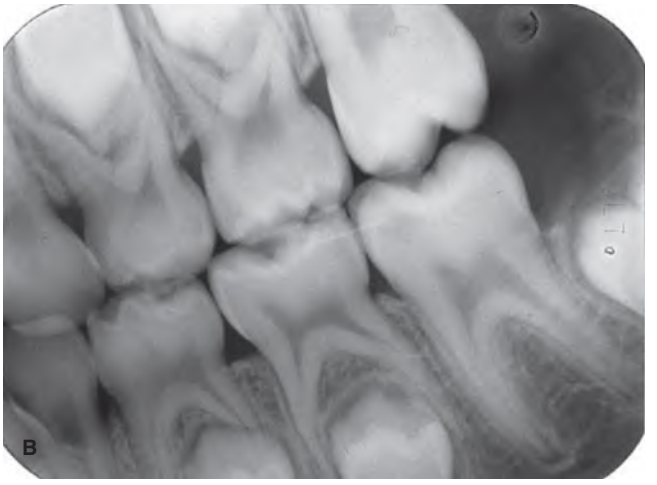

FIGURE 38-9 ***A.*** Transparent model showing the close relationship between the erupted primary teeth and their developing permanent successors. ***B.*** Bite-wing radiograph of the mixed dentition in which the close relationship between the primary teeth and their permanent successors is evident.

The presence and treatment of the following systemic conditions, among others, must be taken in consideration when deciding the adequate treatment of a particular tooth:

1. Cancer disease and therapy
Pediatric patients at all stages of chemotherapy, bone marrow transplantation, and/or radiation therapy require a specially tailored oral/dental treatment program that takes into consideration the systemic impact of the disease and its therapies, and the impact an odontogenic infection would have on their overall health. Immunosuppressed children are at high risk for septicemia that may be caused by oral infections, and require a more radical treatment such as tooth extractions.[24–27]

   Consistent with this rationale, the AAPD guidelines indicate that although there were no studies that address the safety of performing pulp therapy in primary teeth prior to the initiation of chemotherapy and/or radiotherapy, many clinicians choose to provide a more definitive treatment in the form of extraction in order to prevent any residue of oral infection in immune suppressed children, that may lead to pulpal/periapical/furcal infections during immune suppression periods and be life threatening.[25] On the other hand, a recent study by Halperson et al.[24] suggested that pulpotomy treatments in children undergoing therapy for cancer did not increase the risk of these children to develop bacteremia or systemic complications from an oral origin, that there was no significant difference between the success rates of pulpotomy treatments between children receiving therapy for cancer and healthy children and therefore, recommended the re-evaluation of the AAPD guidelines for treating carious teeth involving the pulp in the pediatric oncological patient.[24] Nevertheless, the clinician should be aware that the blood supply may be compromised in patients undergoing radiotherapy, resulting in an impaired repair mechanism following infection and extraction and a significant risk of osteonecrosis.[24] Space maintainers have not been recommended for immunosuppressed patients, increasing their risk of space loss and permanent tooth eruption problems.[24,27] In patients with hemophilia, pulp treatments may be considered more desirable than extractions since it prevents an increased risk for bleeding.[25] Pulp therapy in all chronically ill children may be done only after taking into consideration the systemic treatment, the prognosis of each child's general health, the prognosis of the pulp therapy, and the relevance of the affected tooth.[24–27]

2. Immunosuppression
In addition to children with cancer, those with conditions that increase the possibility of subacute bacterial endocarditis like nephritis, cyclic or chronic neutropenia, or conditions that depress the granulocye and polymorphonuclear counts should not be subjected to the possible development of an acute infection.[26]

3. Congenital heart disease
   There are no recommendations from the AAPD with respect to pulp therapy in a patient with congenital heart disease (CHD) of any severity, but the Guidelines of the Australasian Academy of Pediatric Dentistry state that a vital pulpotomy is contraindicated in these patients.[28] However, this recommendation is empirical and is only based on the rationale to avoid any potential negative sequel from an unsuccessful pulp treatment in a patient with CHD. It is notable that a survey done in 2013 indicated that AAPD members preferred extraction over pulp treatment for patients with irreversible pulpitis suffering from CHD.[29]
4. Diabetes
   A case report indicates that odontogenic infections may be very dangerous in children with diabetes or in those patients with immune diseases since they may lead to ketoacidosis.[30]

e. *Chief complaint and history of pain*:
Subjective evaluation of the affected oral area of the child is based on the current symptoms/chief complaint and by questioning the child and the parent on the location, intensity, duration, stimulus, relief, and spontaneity of the complaint.[18] Subjective symptoms are important factors when establishing a diagnosis, but since young children may be unable to communicate their symptoms, or have a limited ability to recall their pain history, there is a need to rely on the parents to get a more accurate history. In addition, the clinician must take into account that it is not uncommon for a pulp to degenerate to the point of abscess, or developing a pulp polyp, without the child's recalling any discomfort (Figure 38-10A&B).[26]

The information regarding a correlation between histological inflammatory changes within the pulp and reported pain history is inconsistent.[31–36] While several reports have failed to prove a strong correlation between the two,[31–35] most clinicians agree with the concept that when pain is stimulated by an external irritant and resolves when the noxious stimulus is removed, it indicates that the pulp is reversibly inflamed, and that spontaneous pain, throbbing pain, or pain that continues long after the causative factor has been removed, or that keeps the patient awake at night usually signifies an irreversible pulpal inflammation.[26,36] In an interesting study, Guthrie et al.[36] showed an association between a spontaneous toothache and extensive degenerative changes extending into the root canals, as reflected in an hemogram of the exposed pulp.[36] It is also of general belief that pain upon biting and the need for analgesics are indicative of an irreversibly inflamed pulp.[18,36] However, pain upon biting may also be elicited by food impaction into a chronic periodontal defect adjacent to proximal caries; the periodontal defect may heal after tooth restoration with no need for pulp treatment.[37]

f. *Extraoral clinical examination*:
Extraoral patient evaluation should begin by observing the patient when entering the room, and his/her demeanor and extent of discomfort can be evaluated while reviewing the medical information with the parents. A visual examination and palpation of the head and neck are important in helping to determine whether swelling is present and if there is any lymphadenopathy. Odontogenic infections rarely spread beyond the periapical space, however, on some occasions the infection may spread into contiguous anatomic areas through bone, fascial, or muscular barriers.[38]

FIGURE 38-10 ***A.*** Clinical (mirror) picture of a primary maxillary left second molar with deep caries and pulp exposure. The child did not report any pain. ***B.*** Clinical (mirror) picture of a primary maxillary right first molar with deep caries and a pulp polip. The child did not report any pain.

Cellulitis is associated with significant morbidity in children. Oral health providers may encounter children with odontogenic infections that may progress and develop systemic signs and symptoms including fever, malaise, tachycardia, dehydration, periorbital and orbital cellulitis (Figure 38-4), Ludwig's angina, and intracranial abscesses.[39–42] These maladies have the potential to lead to death as in the tragic case of Deamonte Driver (reported in The Washington Post, February 28, 2007), a 12-year-old boy who died from a brain infection of odontogenic origin. These signs and symptoms are even more

dangerous in children with chronic or acute systemic diseases and therefore, extraction of the involved tooth after proper medication with antibiotics, rather than pulp therapy, should be the treatment of choice.[26]

g. *Intraoral clinical examination*:
Intraoral clinical examination may begin with the child pointing with his/her finger to the tooth/area where he/she feels the pain and by that leads the clinician to the offending oral lesion. Accordingly, one should avoid misdiagnosis since the offending tooth may not always be the one with the largest carious lesion, or the pain may not be from dental origin as in the case of an aphthous ulcer. Signs that may be associated with pulp pathology include swelling of the vestibulum, parulis, and sinus tract (Figures 38-3 and 38-11).

The intraoral clinical examination should include inspection for the presence of carious lesions, tooth discoloration, palpation of the tissues surrounding the tooth to evaluate sensitivity to touch, tissue fluctuation, abnormal mobility (normal or increased accompanied by pain when tested), swelling and presence of an exudate from the marginal sulcus or from a sinus tract, and/or swelling of the attached gingiva or oral mucosa.[26] Sensitivity to percussion or pressure in a primary tooth with a deep caries lesion may suggest some degree of pulpal disease, however, the possibility of chronic or acute periodontal disease should also be taken in consideration.[18,37,43,44]

Accounting for the behavioral aspects involved in pediatric dentistry, it is possible to perform a "kind" percussion test in primary teeth by tapping on the tooth with a finger instead of with the back of a dental mirror.[44] Most importantly, during the intraoral clinical examination, comparison of both sides of the mouth should always be done.

Although infrequent, periodontal abscesses in the primary dentition are possible and should be differentiated from pulp originated abscesses by the clinical and radiographic signs. A periodontal abscess may manifest with pus draining from the gingival sulcus rather than producing pronounced buccal swelling, and a periodontal abscess may not produce an interadicular radiolucency (Figure 38-12A&B).[43]

h. *Radiographic examination*:
Intra-oral radiographs are essential for the overall evaluation of the condition of the primary dentition. These provide unique information about the extent of the carious lesion, the proximity of large restorations to the pulp, presence of periapical or interadicular radiolucencies, degree of pathological or physiological root resorption, amount of bone between the primary and its permanent successor, and the presence and degree of development of the permanent successor.

Pulp inflammation and necrosis in primary teeth may lead to periapical radiolucencies in the anterior teeth (Figure 38-13), interadicular, or interadicular and periapical radiolucencies in the primary molars (Figures 38-14, 38-15 and 38-16A&B),[18,26,44,45] atypical root resorption (Figure 38-13), and in some cases, damage to the permanent successor (Figures 38-15 and 38-16A&B). The finding that pulp necrosis in primary molars usually manifests in the radiograph at the interadicular area (Figure 38-14) and not

at the periapical area is related to the common presence of furcal canals in primary molars.[45]

Pulp inflammation may lead to internal dentin resorption at the pulp chamber or root canal (Figures 38-16A&B and 38-17).[36] Due to the thinness of the roots of primary teeth, internal resorption may easily result in root perforation and subsequent alveolar bone resorption necessitating extraction to prevent damage to the alveolar bone and the permanent successor (Figure 38-16A&B).[45,46] Evidence of pulp inflammation in primary teeth may also include obliteration of the pulp cavity with dentin (Figure 38-17).

i. *Pulp testing:*
Thermal and electrical pulp testing are seldom used in the primary dentition because of unreliable results. For these tests to be effective, the pulp must have a sufficient number of mature neurons. Primary teeth are not fully innervated with A-type myelinated axons, the neural components that are responsible for the sensation of pulpal pain, as physiologic resorption begins shortly after

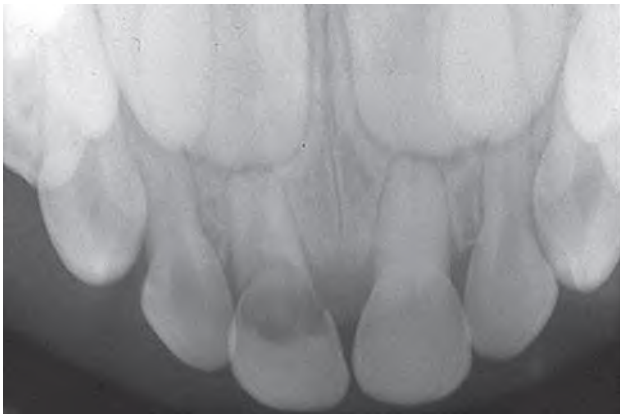

FIGURE 38-17 Periapical radiograph of primary maxillary incisor area after trauma in the past. While the primary left central incisor shows obliteration of the pulp cavity, the primary right central incisor shows a large area of internal resorption.

the root is fully developed.[47] This can be compared to the finding that immature bicuspids are less responsive to stimuli due to a reduced number of pain receptors and therefore, more likely to produce a false negative response from electric and thermal tests.[47]

Thermal and electric pulp testing in primary teeth may only indicate the presence of necrosis, and do not reflect the degree of inflammation of the pulp. It is also possible to get a positive response from a necrotic pulp in which the content of the pulp canal is liquid.[18] In addition, the child's apprehension or inability to comprehend the test may lead to erroneous evaluation.[18] It may, therefore, be summarized that despite a study that reported that electric pulp testing may be reliable for the diagnosis of the pulp status in primary teeth,[48] pulp testing is mostly not recommended in primary teeth and eliciting pain in a small child may trigger compliance problems.

In attempts to eliminate the problem of low reliability of children in the subjective evaluation of pain caused by electric or thermal pulp testing, the objective evaluation of the pulp condition of primary teeth has been tested with pulse oximetry or laser Doppler flowmeter.[49–52] Pulse oximetry estimates the arterial hemoglobin saturation indicating the presence of blood flow in the pulp.[49] A study on primary and immature permanent teeth concluded that pulse oximetry is applicable to primary and immature permanent teeth where patient cooperation and the incomplete innervation reduces the effectiveness and reliability of thermal and electric pulp testing methods.[50] Munshi et al.[49] reported zero pulse oximeter measurements of 10 known non-vital teeth, immature vital permanent teeth recorded average values of 98% and vital primary teeth recorded average values of 93%. They concluded that pulse oximeter has the ability to differentiate between vital and non-vital teeth.[49] Still, the lack of probes that are optimized for dentistry and the insulation of the pulp by the surrounding hard tissues are obstacles to the pulse detection and the use of pulse oximetry in clinical dentistry.[49]

A study of laser Doppler flowmetry, designed to measure the velocity of red blood cells in capillaries, in 119 primary incisor teeth of 32 children between the ages 4 and 10 years old concluded that laser Doppler flowmeter may be considered a noninvasive, nonpainful, direct, objective, and acceptable method of intrapulpal blood flow in primary incisors.[51] It is important to consider that this study was done on primary incisors with at least two thirds of their root, in children under general anesthesia, before and after extraction or before and after a pulpectomy, and was based on the comparison between the dental flowmeter output and the electrocardiogram signal.[51] However, the reliability and the price of the laser Doppler flowmeter have impeded its routine use.[52]

j. *Operative diagnosis:*

In addition to the initial clinical and radiographic examination, the diagnosis of the pulp condition is defined during treatment by direct evaluation of the exposed pulp tissue. For example, the need for a pulpectomy, or extraction, is indicated by the finding of a necrotic pulp or by a dark color and/or profuse bleeding and the inability to obtain hemostasis during a pulpotomy.[26]

The key to successful pulp therapy is accurate diagnosis. The clinician must be mindful to the fact that the patient's systemic and oral histories, clinical evaluation, and radiographic findings must be integrated in order to be able to achieve a precise pulpal diagnosis and hence the most appropriate treatment. Pulpal and periapical diagnosis should not rely solely on a single diagnostic test or one piece of information. Inaccurate diagnosis of pulpal status may result in inappropriate treatment, questionable prognosis, and in the case of the primary dentition, potential damage to the developing dentition (Figures 38-15, 38-16B, and 38-18).

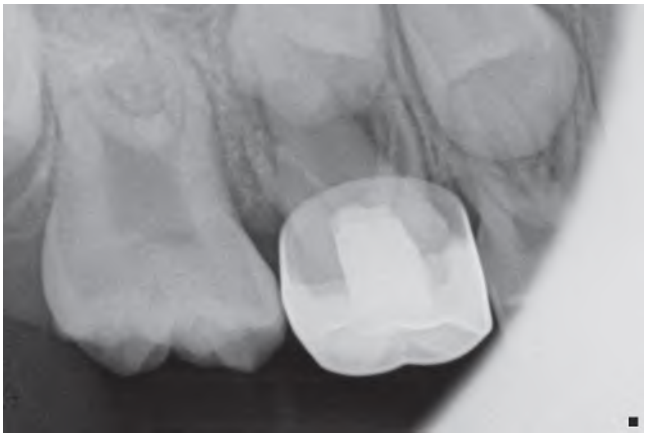

FIGURE 38-18 Periapical radiograph of a primary maxillary right second molar in which internal resorption and an interadicular radiolucent area developed after a pulpotomy. Note that the bone compacta surrounding the crown of the permanent successor has been lost.

PULP THERAPY FOR PRIMARY TEETH

A primary objective of pulp therapy is to maintain the integrity and health of teeth and their supporting tissues, and in the case of the primary dentition allow for the normal exfoliation of the primary teeth and eruption of the succedaneous teeth.[18,26,44] The dentin-pulp complex of the primary teeth has a similar response to dental caries as the permanent teeth, and pulpally involved primary teeth are amenable to comparable pulp therapy modalities as permanent teeth, with procedures such as direct or indirect pulp capping, pulpotomy and pulpectomy, depending on the extent of the caries, the pulp condition, and tooth restorability.[18,26,44] The indications, objectives, and type of pulpal therapy depend on whether the pulp is normal, reversibly inflamed (reversible pulpitis) and thus capable of healing, irreversibly inflamed (irreversible pulpitis) and thus incapable of healing, or necrotic.[18,26,44]

Dental caries involving more than half the dentine thickness in primary teeth is associated with variable degrees of reversible pulpal inflammation. The objective of pulp treatment should be to maintain the vitality of the pulp of a tooth affected by caries, or other causes affecting the pulp, such as traumatic injuries.[53–55] Therefore, a non-aggressive approach of caries removal in primary teeth should be taken in consideration with the aim of avoiding pulp exposures, maintaining the vitality of the pulp, and allowing pulp healing.[53–57] Invasion of the dentinal tubules by caries pathogens triggers defense and repair mechanisms within the dentin-pulp complex to contain pathogen spread and reduce dental pulp tissue damage. Odontoblasts situated beneath infected dentinal tubules secrete reactionary dentin, accompanied by neuronal sprouting and immune cell invasion into the reactory collagen matrix.[58] As the result of this process, the pulp may recede and a pulp exposure may be prevented (Figure 38-19). However, this is not always the case and the dental pulp may eventually become exposed by caries (Figures 38-10A&B, 38-11, 38-15, and 38-20).

Vital pulp therapies are those procedures that allow the affected pulp to heal, maintain the vitality of the pulp, and protect the pulp from an exposure. It can be defined as any restorative dental treatment that is focused on minimizing trauma to the dental pulp.[18,59] The objectives of vital pulp therapy are to eradicate the potential for infection, maintain the tooth in a quiescent state, preserve space for underlying permanent teeth, and retain the primary tooth when the permanent tooth is congenitally absent.[18,59] These conservative procedures, aimed at preserving pulp vitality, can only be effective when the status of the pulp is accurately assessed as normal or reversibly inflamed.[60] Non-vital pulp therapy for the primary dentition are performed when the radicular pulp tissue is diagnosed with irreversible pulpitis or necrotic.[18,59]

Dental Materials Commonly Used in Vital Pulp Therapies in Primary Teeth

Dental materials used for vital pulp therapy ideally should have the following properties: a) inhibit bacterial growth, b) induce mineralization, c) establish a tight bacterial seal, d) resist long-term bacterial leakage, and e) stimulate the remaining pulp tissue to return to a healthy state while promoting the formation of dentin.[61] While some materials, or techniques, are limited to one specific pulp treatment (e.g., formocresol and ferric sulfate are limited to be used in pulpotomies), some materials may be used for various treatments such as indirect or direct pulp capping, and pulpotomy. These include calcium hydroxide ($Ca(OH)_2$), mineral trioxide aggregate (MTA) and Biodentine™. These materials are used in vital pulp therapy procedures that aim to maintain the vitality of the pulp.

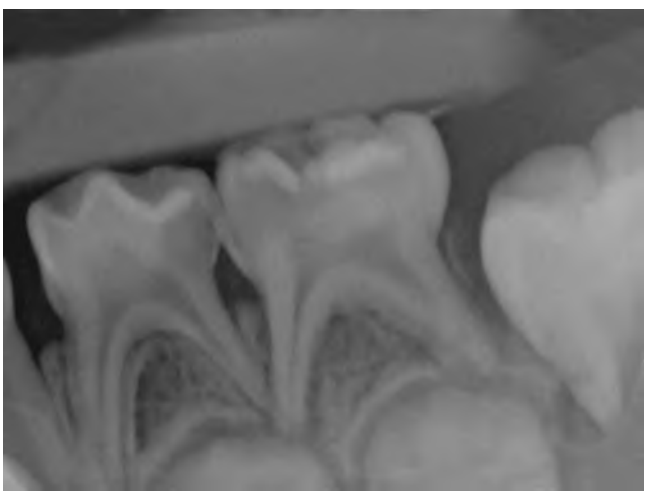

FIGURE 38-19 Periapical radiograph of primary mandibular left molars with deep caries. Note the recession of the distal portion of the pulp in the primary first molar as a defensive process from the carious injury.

FIGURE 38-20 Primary second molar in which a carious pulp exposure became evident during removal of carious dentine.

Calcium Hydroxide

$Ca(OH)_2$ was introduced to the dental profession in 1921 and was considered the "gold standard" of pulp capping materials for several decades.[62] It is a white odorless powder classified as a strong base, its main actions come from the ionic dissociation of Ca^{2+} and OH^- ions and their effect on vital tissues. The high pH of calcium hydroxide provides antimicrobial activity and encourages tissue repair by promoting tertiary dentin secretion.[63] The therapeutic effect of calcium hydroxide may also be due to its extraction of growth factors from the dentin matrix. Once released, these growth factors may play a key role in tertiary dentinogenesis.[64]

Although $Ca(OH)_2$ has been considered the gold standard for pulp capping with the advent of new research and materials, the disadvantages of calcium hydroxide are becoming evident. Calcium hydroxide degrades over time, has a low compressive strength, and has poor sealing properties.[65] Multiple tunnel defects were found in 89% of dentin bridges after calcium hydroxide pulp capping, and 41% of these bridges were associated with recurring pulpal inflammation or necrosis, and with the presence of inflammatory cells and stained bacterial profiles.[66] Tunnel defects in dentinal bridges under calcium hydroxide can act as pathways for bacterial microleakage.[67] Microbial microleakage can impede the formation of the dentinal bridge by odontoblast-like cells.

Glass Ionomer Cements

Glass ionomer cements (GICs) were introduced to dentistry in the early 1970s. Glass ionomer consist primarily of alumina, silica, and polyalkenoic acid and are self-curing materials. GICs form chemical bonds to tooth structure, are biocompatible, and release fluoride ions for uptake by enamel and dentin.[68] Because of glass ionomer's ability to chemically bond to tooth structure, it can prevent the diffusion of potentially toxic materials through dentin to the pulp. GIC provides an excellent seal against microorganisms and shows good biocompatibility when used in close approximation but not in direct contact with the pulp.[69]

Resin-modified glass ionomer cement (RMGIC) materials such as Vitremer (3M ESPE) and Fuji II LC cement contain glass-ionomer powder, to which a light-cure resin is added. RMGIC not only have improved physical characteristics, but the photopolymerizable resin component reduces initial hardening time substantially. Conversely, RMGICs are more cytotoxic to the pulp cells than conventional GICs due to the presence of unpolymerized monomers, and should not be applied directly to the pulp tissue.[70] Clinical evidence of RMGI promoting reparative dentin has not been reported. However, Farooq et al.[71] reported 93% success of indirect pulp therapy IPT over an average of four years with the use of a RMGI as a liner or base without the use of $Ca(OH)_2$.[71]

Mineral Trioxide Aggregate

Mineral trioxide aggregate (MTA) is a fine hydrophilic powder. It consists of tricalcium silicate, tricalicum aluminate, tricalcium oxide, silicate oxide, and bismuth oxide.[72] Studies analyzing the constituents of both gray and white ProRoot® MTA have conclusively shown that both materials are similar to Portland cement but with bismuth oxide added, presumably to make the material radiopaque.[73] Each pack of ProRoot® MTA comes with a pre-measured unit dose of water for convenience in mixing. In the presence of moisture, MTA sets into a hard mass by forming $Ca(OH)_2$ and silicate hydrate gel.[72]

MTA was originally developed to seal communications between the dental root and the surrounding surfaces.[74] Over the years, further research of the material resulted in its application in various clinical situations,[73] and MTA has been used as a material for vital pulp therapy in both primary and permanent teeth due to its favorable properties.[75] The rationale behind the use of MTA is that it prevents micro-leakage, is biocompatible, promotes regeneration of original tissues when it is placed in contact with the dental pulp or peri-radicular tissues, and has not been found to induce internal resorption that has been observed in teeth treated with some other medicaments.[73] MTA has a pH of 10.2 immediately after mixing that increases to 12.5 after 3 hours of setting. It is similar to the pH of calcium hydroxide. MTA does not show signs of solubility contributing to the good seal achieved with MTA and prevention of bacterial contamination of the pulp.[76,77] MTA induces a dentin bridge formation that is faster and with better integrity than that formed by calcium hydroxide. This is achieved with more favorable pulpal tissue reaction as there is less pulpal inflammation, hyperemia, and necrosis of the pulp than has been associated with the use of calcium hydroxide.[78]

Since the set time for MTA is several hours, the manufacturer recommends the placement of the final restoration at a second appointment to assure the set of the material. In the first visit, a wet cotton pellet is applied over the MTA, and the tooth is temporized. In the second visit, the cotton pellet is removed, and the permanent restoration applied after the MTA has sufficiently hardened. However, it would be beneficial for patients and dentists alike if the final adhesive restoration could be placed over MTA during the same visit, especially in pediatric dentistry. Eid et al.[79] concluded that resin-modified GIC can be successfully applied on freshly mixed MTA in a single visit with no expected adverse reactions between the two materials.

Interestingly, an in vivo study comparing the clinical and microbiological outcomes of MTA, medical Portland cement, and calcium hydroxide as a liner for protecting the dentin–pulp complex of permanent and primary teeth, subjected to two-step indirect pulp therapy found no difference in outcome.[80] This finding demonstrates the potential of indirect pulp treatment and that a well-sealed restoration is fundamental for treatment success. Incidentally, MTA was intended for direct capping of pulp exposures and the manufacturer does not advocate its use for indirect pulp capping.

The original MTA was gray in color but in 2002, a white MTA (WMTA) was marketed due to esthetic concerns of

gray MTA (GMTA) staining tooth structure. The WMTA contains less iron, aluminum, and magnesium oxides than its GMTA counterpart. GMTA has been investigated more than the white MTA, and while some reports suggest that GMTA may invoke a more desirable biologic response than WMTA, existing reports as a whole are insufficient.[81] WMTA, however, may still cause tooth discoloration, most likely due to reaction of MTA with blood.[82]

Biodentine™

Biodentine™ is a tricalcium silicate-based cement that was introduced to the market in 2009 as a dentine replacement material and has gained popularity in recent years as a biocompatible and bioactive dentin substitute.[83] Biodentine™ is similar to MTA, formulated using MTA-based cement technology while improving some of the properties of MTA, such as physical properties and handling.[83] Biodentine™ is a powder and liquid system that, when combined, forms a gel structure with an initial set time of 9-12 minutes but with a longer final setting time.[83,84] Biodentine™ is utilized for pulp capping, repair of endodontic root perforations, apexification and retrograde fillings, and has also been suggested for use in pulpotomy treatments of primary teeth.[59,83,85]

Numerous studies have shown Biodentine to have favorable properties, including biocompatibility, ease of handling, negative solubility, and high compressive strength, while providing a good seal without any dentin conditioning.[84,85] When Biodentine™ was used for direct pulp capping, the tertiary dentin was well formed without tunnel defects, and without evidence of adjacent pulpal inflammation.[86] Biodentine™ has been shown to form hydroxyapatite on its surface as a result of contact with tissue fluids.[84] This property produces a material that is not soluble and is dimensionally stable. Although more studies are needed, Biodentine™ holds promise for use in clinical procedures as a biocompatible and easily handled product with a short setting time.[83]

VITAL PULP THERAPY FOR THE PRIMARY DENTITION

Protective Liner

A protective liner (PL) is a thinly applied flowable material, placed on the pulpal surface of a deep cavity preparation to cover the exposed dentin tubules after complete caries removal (Figure 38-21). Its purpose is to act as a defensive barrier between the restorative material and the pulp, minimize postoperative sensitivity, preserve the tooth's vitality in teeth with a normal pulp, promote tissue healing and tertiary dentin formation, and minimize microbial microleakage.[18,59] Though the materials used as cavity liners have no direct contact with the pulp tissue, these materials should possess the same qualities as those used for direct pulp caps and promote healing, be biocompatible, induce dentin formation, minimize bacterial leakage, and inhibit bacterial growth.[61] The PL should therefore seal the dentin and prevent microorganisms and their by-products from contaminating the pulp.[18] At the discretion of the clinician, the

FIGURE 38-21 Primary mandibular left second molar after complete deep carious removal and cavity preparation for a stainless steel crown, prior to placement of a protective liner.

PL may be $Ca(OH)_2$, a dentin bonding agent, or a glass ionomer cement.[18,59,62,87] Adverse post-treatment clinical signs or symptoms such as sensitivity, pain, or swelling should not occur.[18,59]

A recent review of current restorative concepts of pulp protection revealed that the main function of liners is to protect the pulp from microbial penetration along the tooth restoration interface, as opposed to the commonly held belief that the liners protected the pulp from the restorative materials.[87] Other studies have also found that the presence, or absence, of liners has no effect on postoperative sensitivity or pulpal complications.[88,89] While the use of a PL is similar to indirect pulp capping, PL includes the complete removal of caries, while the indirect pulp capping does not involve removing the deepest part of the carious lesion.[18,59]

Indirect Pulp Capping

Bjørndal[19] quoted Dr. GV Black: "it is better to expose the pulp of a tooth than to leave it covered only with softened dentin." Indeed, for many years the complete removal of caries and subsequent restoration of the tooth was the standard method of treating carious lesions in the primary dentition.[19] However, this approach may easily result in pulp exposures in primary teeth due to their anatomical characteristics.[8–10] Yet, in the same publication, Bjørndal indicated that a different interpretation of the very same clinical situation may result in a completely different treatment approach, based on the fact that it is desirable to avoid pulp exposures and facilitate pulp healing.[19]

Indirect pulp capping (IPC), also named indirect pulp therapy, is the intentional incomplete removal of carious dentin in order to avoid a pulp tissue exposure, and treatment of the decay process with a biocompatible material and adhesive restorations that provide a good seal (Figure 38-22).[18,56,57,59] IPC is based on the following assumptions:[18,56–59,90–92]

FIGURE 38-22 Primary maxillary right second molar after removal of the softened and infected dentin. The remaining partially demineralized stained carious dentin will be covered with an indirect pulp capping biocompatible material to prevent pulp exposure.

a) the presence of microorganisms in dentin itself is not a determining factor of caries progression but dependent on the metabolic activity of the biofilm present on the dental surface. The demineralization of enamel and dentin reflects this metabolic activity; b) changes in the biofilm caused by the IPC tend to arrest the sealed carious lesion and stimulate pulp healing and repair. Lin and Langeland[93] showed that when no pulp exposure occurred, the pulp's repair capacity was excellent, but after exposure, it was questionable and unpredictable. In addition, the risk of displacing infected dentin chips into the pulp with total pulp excavation increases the risk of pulpal inflammatory breakdown.[94]

Clinical procedures involving incomplete caries removal are also based on the concept that carious dentine lesions are composed of two distinct layers.[95] The outer layer is highly infected with cariogenic bacteria, structurally disarranged, and presents no mechanical properties. It is considered irreversibly damaged and its complete removal is recommended. The inner layer, or affected dentin, is only partially demineralized, is able to remineralize under a well-placed and sealed restoration, and should be maintained to avoid exposure of the pulp.[95–99] The caries close to the pulp is then covered with a biocompatible liner material such as a dentin bonding agent, RMGIC, $Ca(OH)_2$, zinc oxide eugenol (ZOE), GIC, MTA or Biodentine™.[18,56,57,90–92] In any case, it is most important to completely remove the decay from the dentin-enamel junction, along the axial walls of the cavity, as this has shown to improve the integrity and marginal seal of the restoration.[99]

A systematic review of pulp preservation studies through 2008 found that most investigations used calcium hydroxide for indirect pulp capping, yet, other materials were also found to reduce cariogenic microorganisms and promote remineralization as effectively as calcium hydroxide.[91] When $Ca(OH)_2$ is utilized, a GIC or reinforced zinc oxide/eugenol material should be placed over it to provide a seal against microleakage, since $Ca(OH)_2$ has a high solubility, poor seal, and low comprehensive strength.[18] Currently, it appears that the use of GIC for IPC is more popular than $Ca(OH)_2$ since GIC has the additional advantage of inhibitory activity against cariogenic microorganisms,[18] and the ability to reduce permeability and sensitivity.[100] Other studies have indicated that the presence or absence of protective liners has no effect on postoperative sensitivity or pulpal complications.[88,89]

GIC has the ability to infiltrate the smear layer with resin, during placement, and to penetrate dentin tubules by forming resin tags in acid etched dentin. The IPC pulp healing effect promotes remineralization of the demineralized remaining dentin.[101,102] Particularly in pediatric dentistry, the use of RMGIC is advantageous since these materials may act as a base and restorative material. This is due to their ease of handling, advantageous mechanical characteristics, compared to conventional glass ionomer cements, and their high success rate when used as IPC materials.[101] The question of whether different materials used for IPC produce different degrees of remineralization on the remaining dentin under an IPC has been addressed by comparing the dentin under IPC treatments in primary molars accomplished with Ca(OH)2, RMGIC, gutta-percha, or a self-etching primer. Regardless of the protective material used, there was mineral gain by the affected dentin after IPC.[101–103]

As our knowledge of caries pathogenesis and pulpal response improves, it is becoming possible to plan the treatment of carious primary molars with a more evidence-based approach. A recent systematic review concluded that incomplete caries removal was advantageous, particularly in teeth with caries close to the pulp. This treatment was found to significantly reduce the risks of pulpal exposure and postoperative pulpal symptoms, compared with complete caries excavation.[104] A 2013 update of a 2006 systematic review of complete or ultraconservative removal of decayed tissue concluded that "the current evidence demonstrates that in symptomless, vital, carious primary or permanent teeth, stepwise and partial excavation, reduced the risk of pulp exposure".[105]

It has been considered that there is insufficient evidence to determine whether it is necessary to re-enter and excavate further in the stepwise excavation technique, however, the studies on teeth in which the cavity was not re-entered, reported no adverse consequences.[105] Furthermore, the findings that there is remineralization of the remaining dentin, based on an increase of calcium and phosphorous, that few viable microorganisms remain in the deep dentinal layers after the tooth has been properly sealed, and that RMGICs can simultaneously serve as a base and restorative material with high clinical, radiographic, ultrastructural and microbiological success rates, suggest that there is no need for cavity reopening with the purpose of removing the remaining carious dentin after an IPC.[56,100–102] Recognition of the success of IPC[71,105–108] is reflected in a 2007 survey of primary tooth pulp therapy that found that 83% of American dental schools use, or teach indirect pulp capping as opposed to 70% that used or taught that procedure in 1997.[109] Furthermore, IPC

has been shown to have a higher success rate than pulpotomy in long-term studies. Therefore, it has been suggested that IPC is preferable to pulpotomy when the pulp is normal or has a diagnosis of reversible pulpitis.[7,18,106,108]

Atraumatic Restorative Technique and Interim Therapeutic Restoration

Variations of IPC are the atraumatic restorative technique (ART) and the interim therapeutic restoration (ITR) as defined by the World Health Organization (WHO) and the AAPD respectively. ART and IRT involve the partial removal of caries without anesthetizing the tooth and placing a glass ionomer restoration.[110,111] ART has been endorsed by the WHO, as a means of restoring and preventing caries in populations with little access to traditional dental care.[110] ITR has been recommended by the AAPD when circumstances do not permit traditional cavity preparation or placement of traditional dental restorations, or when caries control is necessary prior to placement of definitive restorations, as part of the comprehensive dental care in the dental home.[111] The reported success rates of ATR depend on the material used for restoration, length of the follow-up studies, and on the location and extent of the glass ionomer restorations; some studies indicate success rates from 57.1% to 100%.[112–114]

The success of the ART is also dependent on the antimicrobial properties of freshly prepared restorative materials, since restorative materials used in ART have a potent effect against cariogenic microorganisms and the prevention of secondary caries.[115] It has been demonstrated that the microhardness of dentin under ART increases over time, but does not reach the degree of hardness of healthy dentin.[116,117] A recent study investigated the effect of a GIC as a liner, over infected unexcavated dentin, after 60 days, and at 10 to 15 months. After 60 days, the dentin already exhibited a better organization, fewer bacteria, and signs of remineralization.[118] The study concluded that: a) the lining material to be placed on infected dentin is not fundamental for caries arrestment; b) when the cavity is properly sealed, carious dentin tends to reorganize within 60 days, and the remineralization process still continues for a longer period of time. Moreover, it has been considered that with ITR there is no conclusive evidence indicating that it is necessary to re-enter the tooth to remove the residual caries, as long as the tooth remains sealed from additional microbial contamination. Evidence of the success of ITR should include no radiographic evidence of pathological internal or external resorption or other pathologic changes, and there should be no harm to the permanent successor.[111,112]

The Hall technique, developed by Dr. Nora Hall in the 1980's, is a conservative treatment alternative for carious primary molars.[119] This controversial non-invasive technique involves the use of SSCs with glass ionomer cement to seal over caries lesions in primary molars without administration of local anesthetic, no caries removal, and no crown preparation. This technique showed a similar success rate for SSCs placed using the traditional technique that includes administering local anesthetic, caries removal, and crown preparation.[119]

Direct Pulp Capping

Direct pulp capping (DPC) is the treatment of an exposed vital pulp by sealing the pulpal wound with a material placed directly on the pulp to facilitate the formation of reparative dentin and maintenance of pulp vitality.[120] In primary teeth, DPC is indicated for small mechanical or traumatic exposures.[18] The clinical intra-operative judgment is most important since proper evaluation of the size of the exposure, the appearance of the pulp, and the amount of bleeding are valuable observations in the diagnosis of the condition of the pulp and treatment decision-making. DPC is not recommended for carious pulp exposures (Figure 38-20),[18] as teeth with carious pulp exposures are unlikely to be completely vital and have compromised healing potential due to infection of the pulp that causes irreversible pulpal inflammation.[121,122]

Biocompatibility of dental materials used for direct pulp capping is a major factor since the material is in direct contact with the connective tissue and has the potential to damage the viability of pulpal cells. The creation of the dentin bridge is beneficial as it provides natural protection to the pulp and is also a sign of biological recovery represented by odontoblast or odontoblast-like cell activity.[123] Calcium hydroxide has been the standard against which all other pulp capping materials have been compared, due to its induction of mineralization and inhibition of bacterial growth.[123–125] However, cells in contact with calcium hydroxide are killed due to its alkaline pH, forming a necrotic zone that causes a mild irritation to the adjacent vital pulp tissue, initiating an inflammatory response. In the absence of infection, the pulp will heal with a hard tissue barrier.[125]

Although the research on the biocompatibility of MTA and Biodentine™ is rather limited, existing information suggests these materials to be less toxic compared to glass ionomer cement and calcium hydroxide.[83] Biodentine™ has been found to promote healing when placed directly in contact with the pulp by enhancing the proliferation, migration, and adhesion of human dental pulp stem cells, confirming the biocompatible and bioactive characteristics of the material.[126] In addition, clinical and histological evidence from a study performed on molars indicated that MTA and Biodentine™ have similar efficacy in pulp capping, inducing complete dentinal bridge formation with minimal or no inflammation.[86]

A 12-month follow-up study, in which hemostasis was attained with various solutions prior to the DPC in primary molars, indicated a radiographic success rate of 100% when hemostasis was attained with octenidine dihydrochloride, 94.7% with sodium hypochlorite, 93.3% with chlorhexidine digluconate, and 84.2% with a saline solution.[127] A recent study indicated that the success rates of DPC in primary teeth after a 12-month follow-up was about 75% when the pulp was capped with calcium sulfate or $Ca(OH)_2$.[128] Yet, it has recently been stated that no good quality long-term studies are available on the success rates of DPC in primary

teeth, and the recommendations for DPC in primary teeth are based on clinical experience and expert opinions that assume that DPC may have a low success rate in primary teeth.[129] Therefore, the use of DPC in primary teeth is considered to have limited application for teeth with a small, iatrogenic, non-carious pulpal exposure and within 1 or 2 years prior to exfoliation.[129]

Clinical, radiographic, and histological analysis of the effects of MTA used in direct pulp capping and pulpotomies of primary teeth showed favorable clinical and radiographic pulp response.[130] It can be concluded that the success rate of DPC in primary teeth is dependent on contamination before, during and after the clinical procedure, and the success rate is increased by limiting treatment to non-carious exposures, use of an antiseptic to obtain hemostasis, and an hermetic restoration that prevents leakage. By the same token, DPC in cariously exposed primary molars is contraindicated due to a high incidence of internal resorption.[129] The vital pulp treatments alternatives that the clinician may consider for a carious pulp exposure are either an indirect pulp capping or a pulpotomy.

Vital Pulpotomy

The treatment of choice for carious or mechanical pulp exposures in primary teeth, larger than pinpoint, is cervical pulpotomy. This rationale is based on the notion that iatrogenic exposures larger than a pinpoint and infected pulps may have very limited potential for recovery and need to be removed.[18,59,129] A pulpotomy is preferred to a pulpectomy in primary teeth since a pulpectomy in primary molars is complicated by unpredictable and tortuous root canals that may be difficult, or impossible, to clean, shape, and properly obturate (Figure 38-23). It is also beneficial to keep the length of children's appointments as short as possible without compromising the quality of the treatment.[18,59,129] A pulpotomy is contraindicated when the radicular pulp is diagnosed with irreversible pulpitis or necrosis. In such cases, a pulpectomy or extraction should be considered.[18,59,129]

A pulpotomy in a primary tooth should allow the maintenance of the tooth in a symptomless state (no sensitivity, pain, or swelling), with healthy supporting tissues, and without eliciting any damage to the permanent succedaneous tooth, or interfering with the transition from the primary to the permanent tooth.[18,129] Internal resorption may sometimes lead to root perforation and it may be an indication for extraction.[46] However, internal resorption may also be self-limiting and stable, its advancement depending on microbial stimulation of the clastic cells involved in hard tissue resorption; without this stimulation, the resorption will not advance.[131] Therefore, clinical decision for treatment should be based on longitudinal monitoring of the internal resorption and removing the affected tooth if perforation causes loss of supportive bone or clinical signs of infection and inflammation.

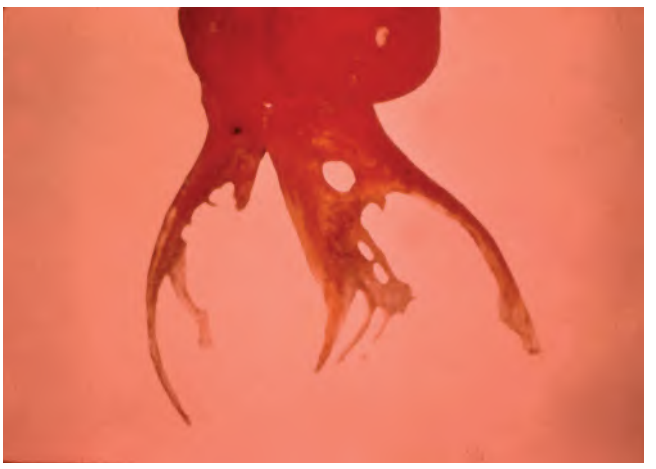

FIGURE 38-23 Root canal system of a primary molar.

Many options for pulpotomy treatment of primary teeth have been reported in the literature, among them calcium hydroxide, formocresol, glutarhaldehyde, electrosurgery, collagen, MTA, Biodentine, sodium hypochloride, and laser and electro-fulguration.[18,26,44,59,129] After any of these methods is applied to the radicular pulp stumps, the pulp chamber is filled with reinforced, or non-reinforced, zinc/oxide eugenol, or other suitable base, and the tooth is restored with a well-sealed restoration.[18,26,59,130,132,133] Reports on the influence of the final restoration on success rates of pulpotomy treatment in primary teeth indicate that a higher success rate is obtained with stainless steel crowns than with amalgams. Therefore, it has been recommended that pulpotomized primary teeth should be restored with one surface amalgam only if their natural exfoliation is expected within less than two years.[18,132,133]

Pulpotomy Technique

Pulpotomies in primary teeth are mostly performed in molars but may also be carried out in anterior teeth. While permanent teeth may be treated with partial coronal pulpotomy, or cervical pulpotomies,[134–136] a pulpotomy in primary teeth involves the complete amputation of the coronal pulp.[18,59,132,133] The pulpotomy technique in primary molars includes (after proper anesthesia and dental dam isolation) the complete removal of carious tissue, using a large round bur, at low speed, and/or with a sharp spoon excavator, starting from the dentin-enamel junction, and finalizing at the center of the cavity. This is done in order to minimize the contamination of the pulp chamber with infected carious dentin (Figure 38-24).

When the carious pulp is exposed, the pulp chamber is unroofed with a 330-tungsten bur, mounted in a water-cooled high-speed turbine, producing a funnel-shaped access to the entrance of the root canals (Figure 38-25). The opening of the pulp chamber must be wide enough to allow proper access and complete removal of the pulp tissue from the pulp chamber, and complete amputation of the coronal pulp (Figure 38-25). Tags of pulp tissue under ledges of dentin may bleed profusely and lead to an erroneous diagnosis of irreversible pulp inflammation of a normal pulp.[26] The complete removal of the pulp tissue is done with either a sharp excavator, or a clean large round bur, with care not to cause a perforation of the pulp chamber floor (Figure 38-26).

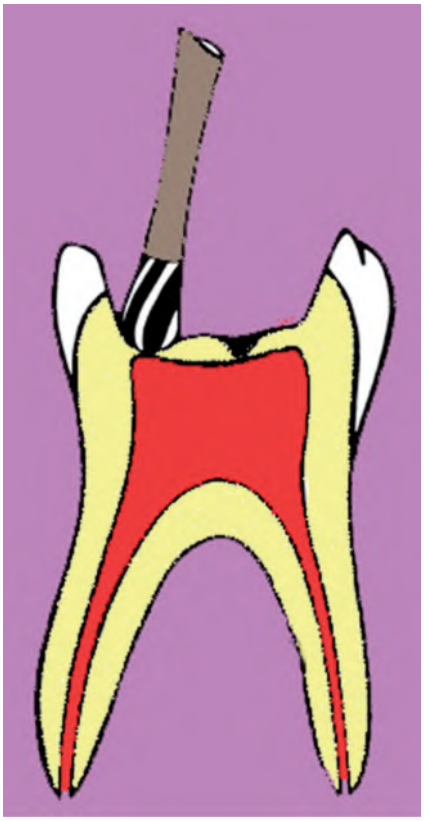

FIGURE 38-24 Caries removal.

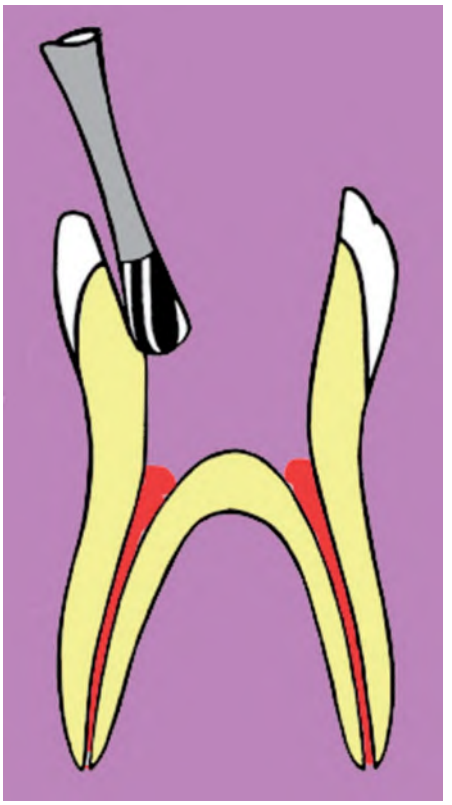

FIGURE 38-25 Removal of the roof of the pulp chamber.

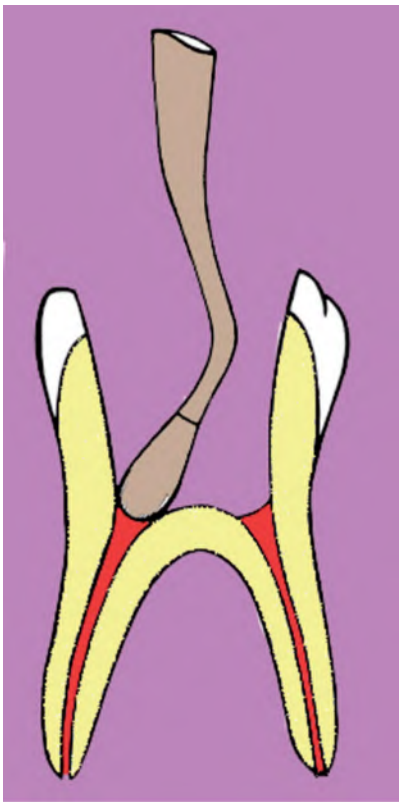

FIGURE 38-26 Removal of the coronal pulp with a spoon excavator.

The pulp chamber in primary molars is comparatively shallow and can be easily perforated.[26,137]

During the opening of the pulp chamber, and after the removal of the pulp tissue, the clinician must assess the condition of the pulp based on the appearance and consistency of the pulp tissue and bleeding amount. Lack of bleeding is usually indicative of necrosis; profuse bleeding, or a dark blood color, is usually indicative of irreversible pulpal inflammation.[36] In addition, bleeding from the pulp stumps at the entrance of the pulp canals should stop with the help of a dry or wet (with water, saline, sodium hypochlorite or chlorhexidine), cotton pellet applied with pressure for a few minutes (Figure 38-27). If the hemorrhage is readily controlled and the pulp stumps appear normal, it can be assumed that the pulp tissue in the canals is normal or capable of healing.[26]

Pharmacologic Pulpotomies

Ideally, the pharmacologic pulp dressing materials that are applied to the radicular pulp stumps for primary teeth pulpotomies should be biocompatible.[26,59]

a. *Calcium hydroxide*
The rationale of using calcium hydroxide as a pulp dressing material for vital pulpotomy in primary teeth is that it is expected to facilitate the formation of a dentine bridge and promote healing of the radicular pulp tissue.[137] However, studies indicate that this is not the case. It appears that about two-thirds of primary teeth treated with this technique fail as the result of pathologic internal resorption, which has been

FIGURE 38-27 View of the floor of the pulp chamber and the pulp stumps of a primary mandibular left second molar after removal of the coronal pulp. Note the reddish appearance of the pulp stumps after achieving hemostasis with a cotton pellet.

related to the calcium hydroxide having no beneficial effect on the inflamed pulp and the creation of an extravascular blood clot.[138–140] This was confirmed by a recent review and network meta-analysis indicating that after 18–24 months, formocresol, ferric sulfate, and MTA showed significantly better clinical and radiographic outcomes than calcium hydroxide and laser therapies in primary molar pulpotomies.[141]

b. *Formocresol*

The initial use of formocresol (FC) as a pulp medicament is attributed to J. P. Buckley, who from 1904 to 1906 outlined the use of a mixture of formalin and cresol to treat necrotic pulps.[137] Subsequently, Dr. Sweet developed a multi-appointment pulpotomy procedure that eventually led to the current single-appointment pulpotomy for primary teeth.[137] The original Buckley's solution was composed of 19% formaldehyde, 35% tricresol, 15% glycerin, and 31% water.[137]

The treatment of primary teeth with FC pulpotomy has a history of excellent clinical success despite its inability to promote healing, and the release of formaldehyde that may diffuse through the pulp and fixate (mummify/fixate) adjacent pulp tissue.[137] Berger,[142] using a one appointment FC pulpotomy, covered pulp stumps of cariously exposed primary molars with a zinc oxide-eugenol cement in which formocresol had been added to the eugenol liquid (equal parts). This treatment was 97% successful on the basis of radiographic examination and 82% on the basis of histologic examination.[142] At the amputation site, a layer of superficial debris was observed. Below this is a zone of fixation, consisting of a darker staining area and compressed tissue with good cellular detail. Below the zone of fixation, the pulp appears to be more cellular with the odontoblastic layer well preserved. At the apical region, there is minimal cellular change, with a tendency for ingrowth of fibrous connective tissue.[142] It has also been claimed that, subsequent to formocresol application, fixation occurs in the coronal third of the radicular pulp, chronic inflammation in the middle third, and vital tissue in the apical third. The rationale and success of fixation is the creation of a tolerable irritation that replaces an intolerable infection.[137,142]

Despite the reported high clinical success rates of FC pulpotomies in primary teeth (70% to 97%), histologic studies have suggested that FC may be cytotoxic, devitalize the pulp, and cause chronic inflammation and tissue necrosis. Additional concerns include the possible diffusion of formaldehyde from the pulpal site into the systemic circulation and potential mutagenic and carcinogenic effect in humans.[143–146] Therefore, the need for finding a replacement for FC pulpotomies has been repeatedly advocated.[144–148] With the recognition of the high clinical success achieved with FC, whilst attempting to reduce its deleterious effects, several studies have investigated the use of diluted FC, or shorter applications of FC, on the pulp stumps.[149–156] The use of a one-fifth diluted FC has been recommended since it is expected to achieve the desired cellular response of the full strength FC, allow a faster recovery of the affected cells, is a safer medication with less systemic toxic potential, and has similar success rates than the full strength FC.[149–153] The one-fifth concentration is prepared by mixing three parts of glycerin with one part of distilled water, then adding four parts of this mixture to one part of the original Buckley's formocresol.[151–153] However, a survey by King et al.[154] on the concentration of formocresol used by pediatric dentists in primary tooth pulpotomy, found that 84% of 422 pediatric dentists used formocresol for pulpotomies, and that among those, only 27% used the diluted formocresol.[154]

Research on one-minute application of FC has indicated that its success rates are comparable to five-minute diluted or full-strength solutions; however, the one-minute technique showed a tendency toward early exfoliation, no effect on clinical management, and no increase in incidence of defects on succedaneous teeth.[155,156] Even so, due to FC potential for cytotoxic, mutagenic, and carcinogenic effects in humans, a continuous quest for a replacement of FC pulpotomies has taken place, resulting in various pharmacologic and non-pharmacologic alternatives, some of which are described below.

c. *Glutaraldehyde*

Glutaraldehyde (GA) is an excellent disinfectant that is active against vegetative and spore forms of bacteria and is considered superior to formaldehyde preparations.[18,148,157–161] This is due to: a) links to protein instantaneously allowing the presence of normal pulp tissue beneath the pulpotomy site; b) less volatility than formocresol; c) less apical damage and less necrosis; d) no evidence of ingrowth of granulation tissue into the apex; e) less dystrophic calcification; f) less antigenicity; and g) lower toxicity. Similar to FC, a 2% GA solution is applied to the radicular pulp stumps for four to five minutes. Although GA seems to compare favorably with formocresol, it has not substituted FC.[18,148,157–161]

d. *Ferric sulfate*
Fei et al.[140] indicated that ferric sulfate (FS) was first utilized as a hemostatic agent before the placement of $Ca(OH)_2$ in monkey teeth pulpotomies, with promising results. Later, FS was used as a pulpotomy dressing agent by itself.[140] When FS comes in contact with blood, a ferric ion-protein complex is formed and the membrane of this complex seals the severed blood vessels producing hemostasis thereby preventing pulpal hemorrhage. FS precludes the problems previously encountered due to clot formation when using $Ca(OH)_2$ and minimizes inflammation and internal resorption. However, its ability to induce a favorable histological result in the form of secondary dentin and dentinal bridging is questionable.[140,159–163] Papagiannoulis[163] reported that the internal resorption present in some ferric sulfate treated teeth did not progress or even remineralize. After removal of the coronal pulp tissue, the technique of ferric sulfate pulpotomy includes the application of FS to the pulp stumps, for 15 seconds, with a felted tip (or a small cotton pellet) (Figure 38-28A). The FS is then rinsed with water and after the water is removed, the pulp stumps are evaluated for hemostasis (Figure 38-28B). The pulp chamber is then sealed with zinc oxide eugenol, and the tooth restored, preferably with a stainless steel crown.[26,59,160,162–164]

e. *Mineral Trioxide Aggregate (MTA)*
In the MTA pulpotomy technique, after amputation of the pulp from the pulp chamber, the pulp stumps are covered with a paste obtained by mixing MTA powder (ProRoot® MTA, Dentsply, Tulsa, OK, U.S.A.) with sterile water at a 3:1 powder to water ratio according to manufacturer's instruction. It is followed by filling of the pulp chamber with a zinc oxide eugenol paste. The tooth is then restored, preferably with a stainless steel crown.[164] Previously, the clinical guidelines for use of MTA required the placement of a wet cotton pellet to allow the material to set.[165,166] Current instructions specify the placement of a light-cured resin or glass-ionomer liner to cover the ProRoot® MTA material, prior to tooth restoration. Although one study showed no detriment to placing glass ionomer on MTA prior to it setting,[79] another study showed MTA breakdown under glass ionomer cement placed for 15 minutes after MTA application.[166]

MTA pulpotomies have been found to provide similar, or better, results than pulpotomy dressed with other materials, and has been suggested to be a suitable replacement for formocresol.[73,86,164,165,167–169] The results from a meta-analysis showed that after 9–12 months, MTA had significantly better clinical and radiographic outcomes than formocresol and calcium hydroxide, and that calcium hydroxide had more failures than formocresol and ferric sulfate.[141] After 18–24 months, formocresol, ferric sulfate, and MTA had significantly better clinical and radiographic outcomes than calcium hydroxide and laser therapies in primary molar pulpotomies.[141]

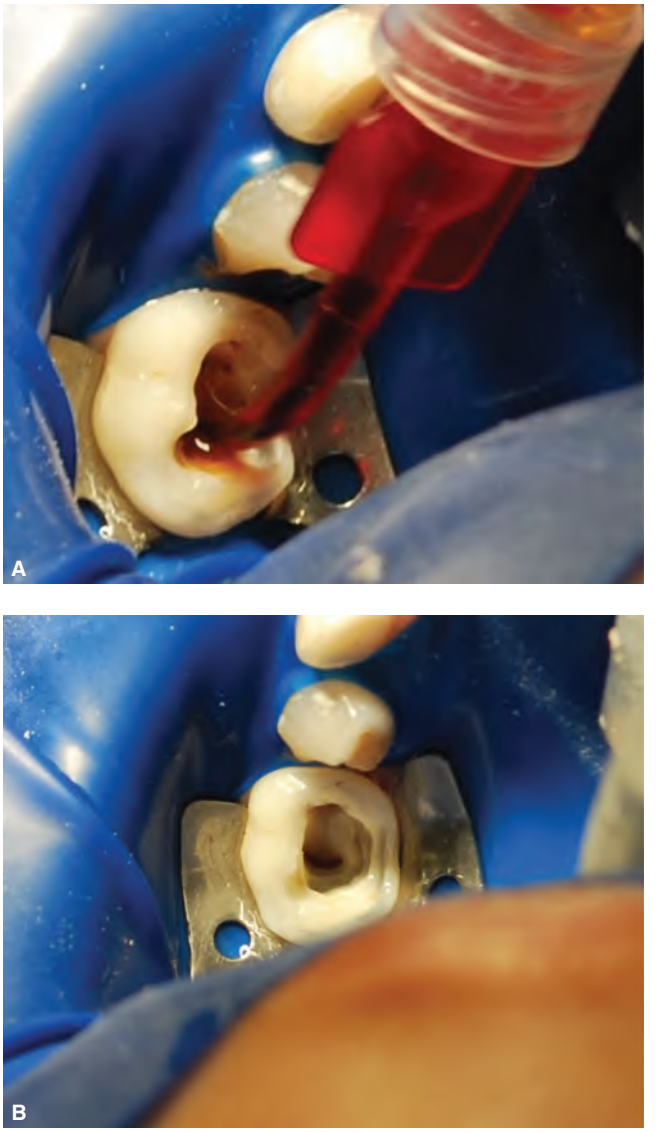

FIGURE 38-28 ***A.*** Application of ferric sulfate with a felted tip on the pulp stumps. ***B.*** After application of ferric sulfate, pulp stumps appear brown instead of red.

Challenges with ProRoot® MTA are the prolonged setting time and cost. Since Portland cement (PC) has a similar composition to MTA (PC differs from MTA by the absence of bismuth ions and the presence of potassium ions, but both have comparable antibacterial activity), PC has been considered as a possible substitute for MTA in endodontic treatments, after being sterilized with ethylene oxide and mixed with sterile water.[170,171]

At least two publications reported the use of PC as a pulpotomy dressing material in children. Conti et al.[171] reported success of PC pulpotomies in a 7-year-old boy and in a 6-year-old girl. A clinical research study by Sakai et al.[170] compared the use of MTA and PC as pulp dressing material in 30 carious human primary teeth of children aged 5–9 years old. Clinical and radiographic results after 6, 12, 18 and 24 months lead to the conclusion that all the pulpotomy treatments were successful. The only

statistically significant difference ($p<0.05$) between MTA and PC was that the beginning of mineralized material deposition could be radiographically detected after six months in 100% and 57.14% of the teeth treated with PC or MTA pulpotomies, respectively.[170]

A concern has been expressed about the possible arsenic content in PC and MTA. A review of the literature, however, suggested that the arsenic level in PC and MTA is low and therefore, unlikely to cause toxic effects.[172,173] A recent comparison of the metal contents in Type V gray and structural white PC, ProRoot® MTA, and MTA showed increased levels of calcium, nickel, and zinc in structural white PC.[174] Type V PC presented the highest levels of arsenic, chromium, copper, iron, lead, and manganese ($P < 0.05$). Bismuth was found in all cements, and the lowest concentration levels were observed in Portland cements, while the highest were observed in ProRoot® MTA.[174] Despite the potential use of PC in primary tooth pulpotomies, additional studies and approval of government regulatory offices are required before PC can be considered for use in human.

A study of pulp capping in dogs' teeth showed that a calcified bridge could be seen 1 week after treatment with white or gray MTA.[175] While there are no significant differences between the treatments, white MTA has not been found to have a significant higher toxicity than gray MTA, and both products were considered to be biocompatible.[176] Gray and white MTA presented high levels of clinical and radiographic success, but gray MTA showed significantly higher number of dentine bridge formations than white MTA.[175–177]

f. *Biodentine™*

Concerns regarding toxicity and mutagenicity of FC and the cost of MTA have led to research on the use of Biodentine™ as a pulp capping and pulpotomy dressing material in primary teeth,[83,86,178,179] An histologic study in pigs' teeth, where the pulpal response to Biodentine™ and MTA was evaluated, concluded that both materials have bioactive properties, encouraged hard tissue regeneration, and provoked no signs of moderate or severe pulp inflammation response.[179] An additional study on pulp capping of mechanically exposed pulps of permanent intact human molars indicated that Biodentine had similar efficacy as MTA.[86] The clinical use of Biodentine™ and MTA pulpotomies is the same.

g. *Sodium hypochlorite*

Sodium hypochlorite (NaOCl) has been successfully used for many years in endodontic therapy as an irrigant for permanent teeth. At low concentrations it has been found to be biocompatible, non-irritating, and hemostatic to exposed pulpal tissue. It has the ability to eliminate bacteria, superficial inflamed tissue, and dentine debris from exposure sites, while leaving the deeper healthy pulp tissue unharmed.[143,159,180–184]

The technique of NaOCl pulpotomy includes removal of the coronal pulp, achieving hemostasis, placing a cotton pellet saturated with 3% NaOCl for 30 seconds, rinsing with sterile saline and filling the pulp chamber with ZOE. The success rate for this treatment is similar to that of formocresol.[143,185,186]

The use of sodium hypochlorite as a disinfectant material of the pulp chamber, before application of calcium hydroxide, or mineral trioxide aggregate, on top of the pulp stumps in primary teeth, has also been examined in at least three studies.[187–189] The first study concluded that the use of NaOCl does not affect the success of calcium hydroxide or MTA pulpotomies.[187] Additionally, regardless of the cleansing agent, MTA was found to be superior to calcium hydroxide and it, therefore, appears that the selection of the proper medicament is more important than the choice of the cleaning agent in primary teeth pulpotomies.[187]

The second study indicated that NaOCl pulpotomy results are comparable to those with FC.[188] The third study concluded that the use of sodium hypochlorite, as an antimicrobial agent, prior to application of the pulpotomy dressing, improved the success rate of calcium hydroxide pulpotomies, to equal the success of MTA pulpotomies for observation periods of up to 12 months.[189]

h. *Collagen*

The use of collagen as a pulp dressing material, over pulp stumps of pulpotomized teeth, is based on the following facts:[190–194] a) collagen has a potent hemostatic property and ability to aggregate platelets, facilitating wound maturation by enhancing initial blood clot and fibrin linkage formation; b) collagen functions as a chemotactic agent for fibroblasts and improves their migration and attachment through its fibrillar structure, thus enhancing cell migration into the space between the collagen membrane and the pulp wound; c) collagen fibers are able to induce mineral formation and orient hydroxyapatite crystals; d) collagen has a proven rate of success in dentistry when used for guided tissue regeneration, root conditioning, hemostatic, and wound dressing agent; e) collagen has a low immune response and toxicity, the ability to promote cellular growth and attachment, homeostasis, and the added advantage of antibiotic incorporation, making it a prospective product for vital pulp therapy.

Formation of a dentinal bridge has been demonstrated in animal teeth after application of an enriched collagen solution (that contained some vitamins, amino acids, and other nutritive factors) on the pulp amputation site.[190–191] Yet, another study, using plain collagen, showed that human osteogenic protein had good characteristics as a direct pulp capping material. On the other hand, collagen matrix itself did not initiate mineralization nor created dentinal bridge, thus indicating that some kind of a stimulative chemical factor is necessary for the development of protective reaction of traumatized dental pulp, and that the mere contact with biocompatible non-stimulative matter is not sufficient.[193] More recently, a randomized, controlled, prospective two-year clinical study was done on 40 teeth of 20 children in the age group of 7–10 years.[194] Collagen particles were mixed with saline into paste-like consistency, then carried into

the pulp chamber and compressed using a damp cotton pellet. It concluded that collagen, used for covering the radicular pulp remnants after pulpotomy, was proven to be a promising alternative as a pulp medicament.[194] The use of collagen as a pulp dressing material in children's pulpotomies requires additional scientific evidence, and the process and expense involved still presents a hindrance.

NONPHARMACOLOGIC PULPOTOMY TECHNIQUES

The characteristics of non-pharmacologic pulpotomy techniques (that do not involve the placement of a pulp dressing material over the radicular pulp stumps) for primary teeth should be inexpensive, simple to use, bactericidal, completed efficiently in one appointment, and produce a high clinical and radiographic success rate. These techniques include electrosurgery/electrofulguration and laser applied to the radicular pulp stumps.

a. *Electrofulguration*
Electrofulguration, or the controlled surgical destruction of tissue with an electric current, has been reported as a nonpharmacological pulpotomy technique, with clinical and radiographic success rates that range from 54.6% to 100%.[195–200] In this technique, after removal of the pulp from the pulp chamber and hemostasis, the electrosurgery dental electrode (i.e., HyfrecatorR 705A, Birtcher Medical Systems, Irvine CA, U.S.A.) is placed 1–2 mm above the radicular pulp stumps and allowed to produce an electrical pulse to each pulp stump for 1 second, in a rotational sequence to avoid heat build-up in any one area of the tooth. After the electrofulguration of each pulp stump, a sterile cotton pellet is placed, with pressure, on the next pulp orifice to be electrosurgically treated, to absorb any blood or tissue fluids before the next current application.[195,197] The electrofulguration of all the pulp stumps can be repeated up to three times with cool down periods of five seconds between each application of the current. When properly completed, the pulpal stumps appear dry and completely blackened.[195,197]

Two studies that evaluated the histological effect of electrosurgery in dog teeth presented conflicting results; while one study indicated that the conventional formocresol pulpotomy technique is histopathologically superior to the electrosurgery pulpotomy technique,[199] the second study indicated that mechanical or electrosurgical coronal pulp removal exhibited less histopathological reaction than the teeth treated by formocresol pulpotomy.[200] Clinical research studies on electrosurgery pulpotomies, performed in children, have compared pulpotomies done with $Ca(OH)_2$, formocresol, ferric sulfate or diode laser pulpotomies and indicated inconsistent results. Nevertheless, they suggested a general trend that electrosurgery has a similar success rates to the other techniques, and that placing ZOE or $Ca(OH)_2$ over the pulp stumps following electrofulguration doesn't cause significant differences in the success rates.[196–198]

b. *Laser*
The application of lasers as a non-pharmacologic hemostatic procedure for the pulpotomy technique has a potential to increase healing, stimulate odontogenesis, and preserve vitality of the dental pulp.[201–208] In fact, an Nd:Yag laser has been evaluated in several studies, with excellent results. Low-level laser therapy (LLLT) has shown a potential for hemorrhage control, absence of mechanical contact, healing of dental tissue by the stimulation of regenerative cells, pain reduction, and edema regression with consequent anti-inflammatory effects.[207,208] From a biological point of view, LLLT offers low energy density for the target cell, and stimulates membranes, or organelles, leading to positive biomodulation and biostimulation.[207,208] After the initial removal of the pulp tissue from the pulp chamber, the technique achieves complete hemostasis by direct multiple applications of the laser beam, until the pulp is ablated at, or in, the canal orifice. Subsequently, the pulp chamber is filled with an intermediate restorative material (IRM), zinc oxide eugenol,[204,205] or a layer of MTA (laser-MTA technique). The MTA is covered with Vitrebond to achieve a firm foundation that prevents disturbance of the unset MTA.[203]

SUCCESS RATES OF THE VARIOUS PULPOTOMY DRESSING MATERIALS AND TECHNIQUES

The determination of a successful clinical and radiographic outcome with a pulpotomy in primary teeth includes: no spontaneous pain and/or sensitivity to pressure/percussion, no swelling, no sinus tract, or pathologic mobility, no furcation or periapical radiolucencies, no widening of the periodontal ligament, no internal or external pathologic internal or external resorption, and normal exfoliation of the primary tooth and eruption of the permanent successor.[18,26,59]

Formocresol (FC) and ferric sulfate (FS) have shown in retrospective and prospective studies that they have equivalent clinical and radiographic success rates; the clinical success rates ranging between 84% to 100% and 89% to 100% respectively, and their radiographic success being 73% to 96% and 74% to 97% respectively. The success rate of NaOCl pulpotomies is similar.[143] The two most common pathologic findings reported in the literature for pulpotomized primary teeth treated with FS and FC are internal resorption and furcation bone destruction. In the case of NaOCl, internal resorption, furcation bone destruction, and external root resorption were found, with many of the failures demonstrating more than one pathological outcome (Figures 38-18, 38-29, and 38-30).[143]

Many studies have attempted to evaluate the success rates of the various pulpotomy techniques, producing inconsistent results. A systematic review and network meta-analysis of 37 research studies (22 of them included in the final meta

FIGURE 38-29 Bite-wing radiograph taken several months after pulpotomies were performed in the primary maxillary and mandibular left second molars. Note the obliteration of the root canals in both molars, and internal resorption, partially calcified, at the distal root of the mandibular second molar.

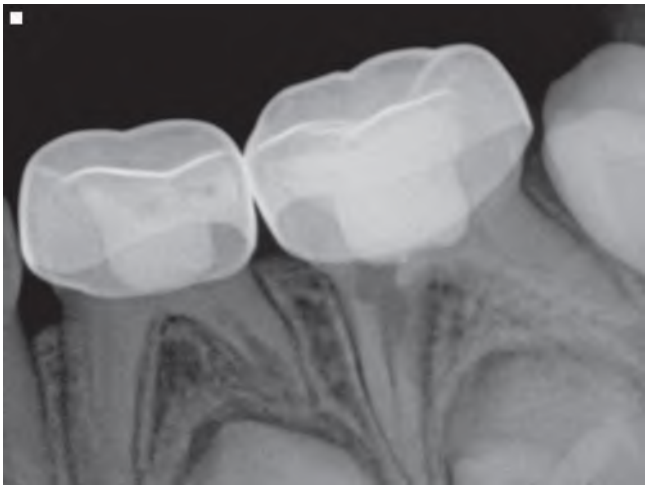

FIGURE 38-30 Follow-up periapical radiograph of pulpotomized primary mandibular left molars. The mesial root of the second molar shows internal resorption. The distal root of the first molar shows atypical internal resorption that may be related to physiologic resorption process and/or pulp inflammation.

analysis) on success rates of vital pulpotomies in primary teeth using formocresol, ferric sulfate, calcium hydroxide, and MTA indicated that: a) the success rates of the vital pulpotomy technique depend on the properties of the material itself and on the biocompatibility to the remaining radicular tissue; b) after 18–24 months teeth treated with laser therapy were two to three times more likely to fail compared to formocresol, ferric sulfate, and MTA; c) MTA has higher success rates than calcium hydroxide and laser therapies after 18–24 months and better success rates than formocresol, calcium hydroxide and laser therapies after 9–12 months.[141] Sonmez et al.[209] compared four pulpotomy techniques in primary teeth and found that after a two-year period, the success rates were 76% for formocresol, 73.3% or ferric sulfate, 46.1% for Ca(OH)2, and 66.6% for MTA.

Biodentine™ is a relatively new material and therefore, the research on its clinical, radiographic and histologic success in the pulpotomy treatment of primary teeth is limited. Nevertheless, the available information shows promising results. A study on 28 caries-free maxillary and mandibular permanent intact human molars were mechanically exposed and a pulp capping was performed with either Biodentine™ or MTA. The teeth were extracted after six weeks and examined with light microscopy. The majority of the specimens showed complete bridge formation and the absence of an inflammatory cell response.[86] A study that compared NaOCl and FC pulpotomies indicated a 100% clinical success rate for both medicaments after three months and at six months, and after 12 months NaOCl showed 95% and 87.5% clinical and radiographic success rate respectively, while FC showed 95% clinical and radiographic success rates.[210] A study by Durmus & Tanboga[211] comparing FC, FS, and diode laser pulpotomies found that after 12 months, the clinical success rates were 97%, 95%, and 100% respectively, and the radiographic success rates were 87%, 79%, and 75% respectively.

They concluded that when considering the radiographic success rates, laser pulpotomies may not replace formocresol or ferric sulfate pulpotomies in primary molars.[211] On the other hand, the opposite conclusion was reached in a nine-month follow-up study by Yadav et al.[198] in which an 86.6% clinical success rate was found for FS whereas 100% clinical success rate was found in electrosurgical and diode laser groups. Radiographically, an 80% success rate was found in all the three groups with internal resorption being the most common cause of failure.[198] A systematic review of pulp therapy has suggested that ferric sulfate, electrocautery, and formocresol pulpotomies have similar success, and that MTA pulpotomies have a very high success rates with the gray and white formulations having success rates of 90% and 100% respectively.[129]

It can therefore be concluded that there is no clear and sufficient evidence to identify one superior pulpotomy medicament and technique. Nevertheless, two medicaments may be preferable: MTA or FS. The cost of MTA may preclude its clinical use in some countries and therefore, FS could be used in most situations.[129,212] Another point that needs to be noted is that FC is no longer used in Canada and the Netherlands mainly due to safety concerns.[212]

DEEP PULPOTOMY TECHNIQUE

The clinician may face situations in which, after complete removal of the coronal pulp tissue, it is difficult to control bleeding from the pulp stumps, indicating the possibility that the radicular pulp (at least in its most coronal portion) has irreversible inflammation. In these cases, the clinician has several options: perform a deep pulpotomy (or partial pulpectomy), pulpectomy, or extraction.[18,26,59] A deep pulpotomy is accomplished by penetrating the root canals with

a small round bur to a depth of about 2–3 mmm, rinsing with water, or saline, and if hemostasis is achieved a regular pulpotomy is carried out. If hemostasis is not achieved, a pulpectomy or extraction should be performed.[18,26,59]

NON-VITAL PULP THERAPY FOR PRIMARY TEETH

Pulpectomy

A pulpectomy in a primary tooth is indicated when the tooth is diagnosed with irreversible pulpitis and/or pulp necrosis, as indicated by the child's symptoms, clinical or radiographic findings, or when clinical signs of irreversible pulpitis are present.[18] Knowledge of the pulp system morphology of the primary teeth facilitates optimal pulpal treatment. Although the pulp of a primary tooth is histologically similar to the pulp of a permanent tooth, the morphology of deciduous teeth is different in many respects from that of the succedaneous teeth, with the primary molar roots being relatively longer and more slender, that is, mandibular molar roots are narrower mesio-distally, the maxillary mesio-bucal and disto-buccal roots are narrower mesio-distally, maxillary palatal roots are narrower buccolingually, and the primary molars are characterized by a high incidence of accessory canals.[8,10,213]

Pulpectomy Technique

After administration of local anesthesia and dental dam isolation, the pulp chamber is accessed. The major objectives of the access opening are to remove the roof of the pulp chamber, all coronal pulp tissue, and locate all canals. This requires a thorough knowledge of the location, size, morphology, and variations of the root canals. Studies that analyzed the difficulties encountered with root canal treatment of primary teeth found that most difficulties were attributed to deficiencies in access; small access cavity size impedes access to the root canal system, resulting in missed canals and inadequate instrumentation.[213,214] Primary first molars presented with more difficulties in access and canal location than primary second molars in both arches.[214]

The objective of cleaning and shaping of the root canals is to remove all pulp tissue and microorganisms and their by-products from the root canal system. Traditionally, this has been accomplished with hand files but experimental and clinical evidence shows that NiTi rotaries promote improved preparation quality.[215] Although the use of rotary instruments in primary molars was initially not advised,[213] recent research has found that this instrumentation technique is advantageous and can be utilized in the shaping of primary teeth. Rotary instrumentation of deciduous teeth was first described by Barr et al.[216,217] One of the advantages of using rotary instrumentation when treating primary teeth is a decreased work time that may help to prevent behavior difficulties.[218,219] Due to the built-in taper in the rotary instrument design, their use results in a smooth funnel-form preparation that easily accepts pulpectomy filling material and may increase clinical success.[220] The clinician must also keep in mind the morphology of the primary molar roots that are widely divergent and curved.[8–10] Care must also be taken not to over-instrument as perforations can readily occur in the thin dentinal walls of the root canals.

Correct working length determination is necessary for successful treatment as this ensures a more thorough chemomechanical disinfection of the root canal system without harming the succedaneous tooth (Figure 38-31). Overextension of files can also over-enlarge the apical foramen and result in overfilling of the root filling material. The challenge with establishing working length in primary teeth is that the apical area changes as a result of the physiologic root resorption. Radiographic determination of working length and electronic apex locators are both acceptable methods that are currently used.[221,222] The advantages for the use of electronic apex locator is the avoidance of radiation, bypassing of radiographs in children that cannot tolerate them, and less reliance on subjective interpretation, especially with the complexity of resorption.

When using radiographs, the endodontic working length should ideally be 1–2 mm short of the radiographic apex and, if obvious signs of root resorption are present, it may be necessary to further shorten the working length by an additional 1–2 mm. If hemorrhage is encountered after the pulp tissue has been removed, this is an indication that root resorption has likely occurred and the working length should be shortened 2–3 mm from the radiographic apex.[213] Interestingly, an in-vivo study by Kielbassa et al.[223] concluded that the Root ZX apex locator can be recommended for clinical implementation of endodontics in primary teeth, and that the accuracy was higher when there was no resorption, while in the presence of resorption, the working length was slightly underestimated as is intentionally done with radiographs.[223]

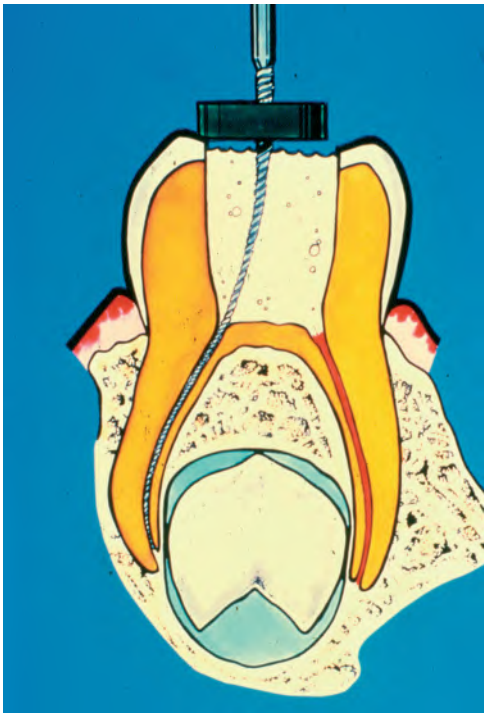

FIGURE 38-31 Pulpectomy treatment. File inserted into the canal. (Courtesy of Dr. Albert C. Goerig, Olympia, WA, U.S.A.)

Root canal treatment in primary molars requires profuse irrigation since it is difficult to completely remove the inflamed and necrotic tissue from the intricate anatomy of the pulp canals by instrumentation alone. As in permanent teeth, the endodontic infection in primary teeth is usually multimicrobial, including aerobic, facultative, and anaerobic microorganisms.[224] Root canal irrigation of a primary tooth with an inert solution cannot adequately reduce the microbial population in the root canal system, and disinfection with irrigants such as sodium hypochlorite or chlorhexidine, significantly increases the possibility of optimal decontamination of the canals.

Sodium hypochlorite is the most commonly used endodontic irrigant. It is safe to use it in primary teeth but since it is a potent tissue irritant it must not be extruded beyond the apex.[18] While Goerig and Camp[213] recommend the use of a 5.25% NaOCl (the percentage of full strength NaOCl in 1983), the AAPD recommends the use of a diluted concentration of 1% NaOCl.[18] Sodium hypochlorie has the capability of dissolving both vital and non-vital tissue. For more details, see Chapter 21.

Chlorhexidine is another antimicrobial that is used for root canal irrigation. It has a broad-spectrum antimicrobial action, lower toxicity than sodium hypochlorite and substantivity (the ability to bind to proteins and thus have prolonged activity). However, chlorhexidine is unable to dissolve pulp tissue.[225]

Ethylenediamine tetraacetic acid (EDTA) has been recommended as an adjuvant in root canal therapy for permanent teeth as it removes the smear layer.[225] However, a study by Tannure et al.[226] did not show any difference in primary teeth pulpectomy outcomes when the smear layer was removed, or allowed to remain.[226]

An ideal root filling material for primary teeth (Figures 38-32A-C) should be antiseptic, resorb concomitantly to the physiologic root resorbing process, harmless to the adjacent tooth germ, radiopaque, easily inserted, easily removed when required, biocompatible, not a cause of gross overextension or under filling, and should not induce pathologic root resorption or furcation/apical radiolucencies.[18,26,59] The root canal filling materials that have been considered resorbable and suitable for primary teeth pulpectomies include $Ca(OH)_2$, non-reinforced ZOE, iodoform paste, and combinations of iodoform with other materials (Table 38-2).[18,26,59] In addition, the use of Ledermix (Lederle Laboratories, Wolfathausen, Germany) that is composed of dimethylchlorotetracycline and triamcinolone has been mentioned as a possible root canal medicament for primary teeth.[59]

The use of ZOE as a root canal obturation material for primary teeth was first described by Sweet in 1930. When in a dense mass, it may resist resorption, irritate the periapical tissues, trigger foreign body reactions, possibly relate to enamel defects in the permanent teeth, and may remain in the alveolar bone for years.[227,228] Several research studies and case reports indicate the success percentages of the use of various root canal filling materials for primary teeth (Table 38-3). Generally; [226,229–246] a) the success rates of primary teeth pulpectomies are between 65% to 100%; b) the degree of pre-operative root resorption has an inverted relationship with the success rate of the treatment; c) since

Note the root filing material that has extruded through a sinus track. ***B.*** Postoperative periapical radiograph of a root canal treatment in a primary mandibular left second molar. Note the interadicular radiolucency distal to the mesial root. Also, the end point of the root filling material is at the anatomic apex. ***C.*** Radiograph after 6 months of root canal treatment in the mandibular second molar. Note that the radiolucency distal to the mesial root is no longer present. (38-32A&B, courtesy of Dr. Moti Moskovitz, Jerusalem, Israel.)

TABLE 38-2 Main Components of Root Canal Pastes for Primary Teeth

Paste	Composition
Maisto	Iodoform, camphor, menthol, parachlorophenol, zinc oxide, lanolin and thymol
Kri paste	Iodoform, camphor, menthol, and parachlorophenol
Endoflas	Iodoform, zinc oxide, calcium hydroxide, barium sulfate, eugenol, and parachlorophenol
Vitapex	Iodoform and calcium hydroxide
Metapex	Iodoform and calcium hydroxide

TABLE 38-3 Success Rates for Pulpectomies in the Primary Dentition Using Various Root Canal Filling Materials

Manuscript	Material	Follow up	Type of teeth	Sample size	Success rate (%)
Holan et al. (1993)[235]	Kri	12->48 mos	Molars	44	84.0
	ZOE*			34	65.0
Fuks et al. (2002)[237]	Endoflas	6–52 mos	Incisors and molars	47	70.0
Mortazavi (2004)[233]	ZOE*	10–16 mos	Molars and anterior	32	78.5
	Vitapex			26	100
Moskovitz et al. (2005)[238]	Endoflas	6–77	Molars	139	82.0
Sari et al. (2008)[240]	Sealapex	3 yrs	Incisors, cuspids & molars	52	92.3
Moskovitz et al. (2010)[242]	Endoflas	6–113 mos	Molars	242	90.9
Subramaniam et al. (2011)[241]	Endoflas	18 mos	Molars	45	93.3
	ZOE*				93.3
	Metapex				100.0
Rewal et al. (2014)[232]	Endoflas	9 mos	Molars	50	83.0
	ZOE*				100.0

Abbreviations: mos = months; yrs = years.
*Zinc oxide eugenol.

the radiographic apex does not coincide with the anatomical apex, the operator should intentionally underfill the root canals; d) there is a trend for a higher success rates with under-filled or flush-filled root canal fillings than with overfilled root canals; e) even with an adequate ZOE root canal filling, there is a chance for altering the path of eruption of the succedaneous tooth (e.g., anterior cross-bite or premolar ectopic eruption) since ZOE may resist resorption; f) pulpectomies with ZOE have a similar success rate in molars and anterior teeth; g) iodoform pastes may resorb within the canals but still the clinical and radiographic outcome is excellent; h) the success rate of iodoform pastes is higher than with ZOE; i) pulpectomies after trauma have a reduced success rate compared to pulpectomies related to caries; j) there is no statistically significant difference between the success rates of the different filling materials, but KRI paste, Endoflas or Metapex are considered better than ZOE; k) the success rates are higher in teeth restored with SSCs (with the exception of one study in which a success rate of 100% was reported for teeth restored with GIC against 90.9% of teeth restored with SSC); l) teeth that had a radiolucent area before treatment have a lower success rate than teeth that did not have it (98% and 90.1% respectively); m) there is no general relationship between the root canal therapy and ectopic eruption or premolar hypoplasia; n) periodic follow-up should include radiographic examination of the interadicular and periapical areas of primary teeth with root canal treatment.

Studies on the methodology for placement of the root canal obturation material inside the roots have indicated that, with ZOE pulpectomies, there was no statistically significant difference between using a lentulo spiral mounted on a slow-speed handpiece, or rotated by hand, as evaluated by the quality of the root canal filling or success rate.[234] Vitapex® is provided in a syringe with disposable tips that are introduced into the root canal while filling the canals. If any of the root canal filling material for primary teeth is expressed beyond the apex, it should be resorbable and non-toxic to the periapical tissues and the permanent tooth germ.[227,229]

While ZOE root fillings may resist resorption, iodoform pastes resorb within 1 or 2 weeks, without evidence of causing any disturbance to the permanent successor.[227,229] Holan et al.[235] compared ZOE and an iodoform paste (KRI paste) and found that the success rate for KRI paste was 84% versus 65% for ZOE, ($P < 0.05$). Overfilling with ZOE led to a failure rate of 59% as opposed to 21% for KRI ($P < 0.02$) and underfilling led to similar results, with a failure rate of 17% for ZOE and 14% for KRI.[235] These findings are consistent with previous studies indicating that iodoform-based pastes have a superior clinical efficacy when compared to ZOE. The search for a better root canal obturation paste for primary teeth led to the comparison of the success of primary teeth root canal therapies utilizing a triple antibiotic mix (metronidazole, ciprofloxacin, and minocycline) and Vitapex®, an iodoform paste. The results indicated that both groups showed 100% and 96% clinical success at 6 and

12 months, and a radiographic success at 6 months of 84% and 80% respectively, and 76% and 56% after 12 months respectively.[236]

A two-visit pulpectomy technique has been reported in the literature;[233] in the first visit, the necrotic tissue is removed from the pulp chamber, a formocresol-moistened cotton pellet is placed in the pulp chamber and the tooth is sealed with a temporary restoration; after 1 or 2 weeks the root canals are treated. The clinician however, must keep in mind that due to behavior considerations in pediatric patients, it is desired to diminish the circumstances where there is a need to re-enter a tooth for the same treatment.

LESION STERILIZATION

Lesion Sterilization and Tissue Repair Therapy (LSTR) is a relatively new biologic approach that uses a mixture of three antibacterial drugs, namely, metronidazole, ciprofloxacin, and minocycline (3Mix) for disinfecting root canal systems.[247] This technique is indicated for teeth that show presence of external or internal root resorption and may have guarded prognosis.[248–250] This is a non-instrumentation endodontics treatment, and since this procedure depends on the elimination of microorganisms through chemical and not mechanical means, it is much simpler than the traditional pulpectomy and requires shorter chair time.[248–250] It is also suitable for teeth with physiological resorption as these are more challenging to instrument and fill to the correct length. Repair of damaged tissues can be expected if lesions are disinfected.[250]

To prepare the antibiotic powder, each drug is removed from its enteric coating, pulverized in a porcelain mortar, and stored separately in tightly capped porcelain containers in a refrigerator. On the day of treatment, the antibiotic paste is prepared by combining the three antibiotic powders (3-Mix) with propylene glycol and macrogol immediately, prior to placement into the tooth.[248] Propylene glycol allows for penetration of the antibiotics into dentin.[251] Since minocycline may cause black discoloration of the tooth and gingival, it has been replaced with clindamycin. Some clinicians also add iodoform to the paste in order to make it radiopaque.[249]

The clinical procedure includes proper anesthesia, dental dam isolation, pulp access, and removal of necrotic tissue from the pulp chamber (not from the root canals). The canal orifices are enlarged with a round bur (1 mm diameter and 2 mm depth) to create medicament receptacles. If canal bleeding exists, it is controlled with 10% NaOCl. The walls of the pulp chamber are cleaned with 35% phosphoric acid, rinsed, dried, and the antibiotic mix is then placed in the medicine receptacles created with the round bur and the floor of the pulp chamber. The access opening is sealed with glass ionomer cement and the tooth is restored with a stainless steel crown.[249,250] The success of the technique is manifested by a lack of pain, resolution of swelling/parulis/sinus tract (if present), and bone healing. Burrus et al.[249] recently published three successful cases with LSTR.

PHOTODYNAMIC THERAPY

Root canal sanitizers with a high capacity to eliminate microorganisms are considered a key factor to treatment success of pulpectomies in primary teeth. In this context, antimicrobial photodynamic therapy (PAT) has been considered a very promising approach to disinfect dentinal walls of primary teeth.[252–254] PAT is used as an adjunct to chemo-mechanical methods in an attempt to eliminate persistent microorganisms by using a laser to create free oxygen radicals; these reactive oxygen species damage cellular components, leading to cell death, in this case, microbial disinfection.[252,253] The advantage of PAT is its effectiveness on bacteria resistant to antibiotics and low likelihood of development of bacterial resistance to these treatments.[254] Limited clinical information is currently available on the use and outcome of PAT in root canal disinfection.[255] There have been two case reports on the use of PAT in deciduous teeth,[252,253] but further clinical research is required to establish its efficacy for root canal disinfection, especially when treating teeth with resistant bacterial strains. Once the canals have been obturated, the chamber and access opening are filled with reinforced ZOE, and the tooth is permanently restored. As with permanent teeth, treatment success of endodontically treated primary teeth also depends on the placement of a well-sealed restoration.

TOOTH RESTORATION AFTER PULP THERAPY IN THE PRIMARY DENTITION

The placement of leakage free margins that prevent microbial penetration is of utmost importance. Accordingly, in the case of emergency pulpotomies, a high failure rate was demonstrated for teeth restored with temporary restorations as opposed to those restored with permanent ones.[256] Traditionally, stainless steel crowns (SSCs) have been used for restoring primary teeth that had undergone pulpotomy, or pulpectomy, since SSCs demonstrate greater longevity and reduced need for retreatment, compared to multi-surface amalgam (that would be the case in most primary teeth with carious pulp exposures).[213,257,258] Although a recent Cochrane review could not find any randomized controlled trials to compare the effectiveness of restoring badly broken down primary molars with stainless steel crowns as compared with filling materials, lower levels of evidence have consistently shown stainless steel restorations to be more successful.[259] The authors of the Cochrane systematic review concluded that the absence of evidence for preformed metal crowns should not be misinterpreted as evidence for their lack of efficacy.[259] The clinician may confront situations in which SSC may be esthetically unpleasing to parents, or children. For these cases, GIC that chemically bond to the tooth and release fluoride, and resin restorations, are good options for restoring endodontically treated primary teeth.[260–263]

RELEVANCE OF FOLLOW-UP AFTER PULP THERAPY IN PRIMARY TEETH

Despite the high success rate for most properly selected pulp therapies in the primary dentition, the clinician must not ignore the possibility for complications and failures, some of which may have the potential for serious consequences on the primary and the developing permanent dentitions (Figures 38-18, & 38-33 to 38-35). Potential complications are: malposition, or delay in eruption of the succedaneous tooth, enamel defects, discoloration, and inflammatory or radicular cyst formation.[264] While no significant difference has been found between the life-span of primary teeth with, or without, a formocresol pulpotomy,[265] one study reported that pulpotomized primary teeth may have an early exfoliation.[152] However, this relationship is not clear.

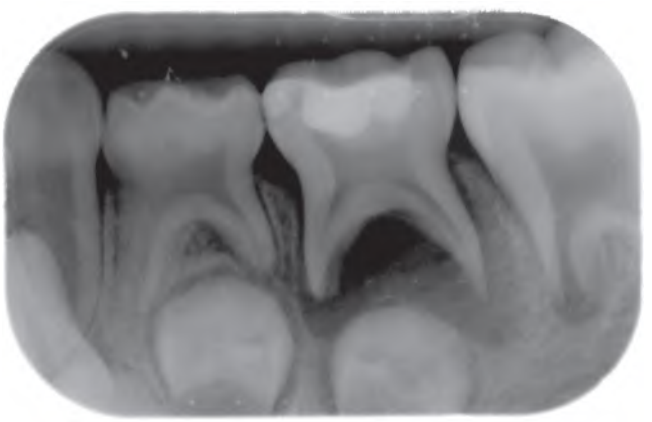

FIGURE 38-33 Periapical radiograph of a primary mandibular left second molar after an unsuccessful indirect pulp capping. Note the large interadicular and periapical area that has already affected the bone compacta surrounding the tooth bud of the permanent successor.

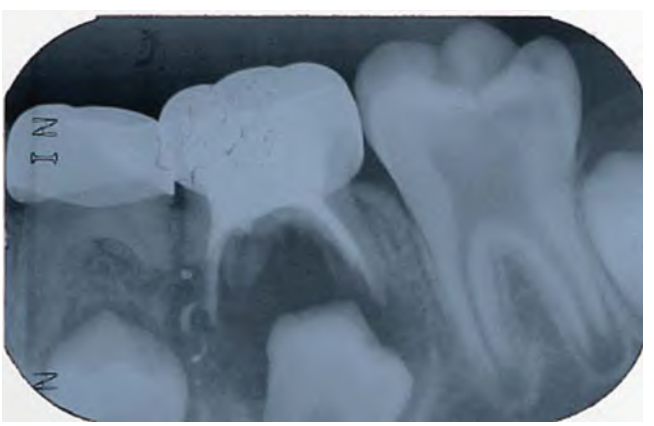

FIGURE 38-34 Follow-up periapical radiograph of an unsuccessful root canal in a primary mandibular left second molar. Note the interadicular and periapical radiolucency, and displacement of the permanent premolar successor. (Courtesy of Dr. Moti Moskovitz, Jerusalem, Israel.)

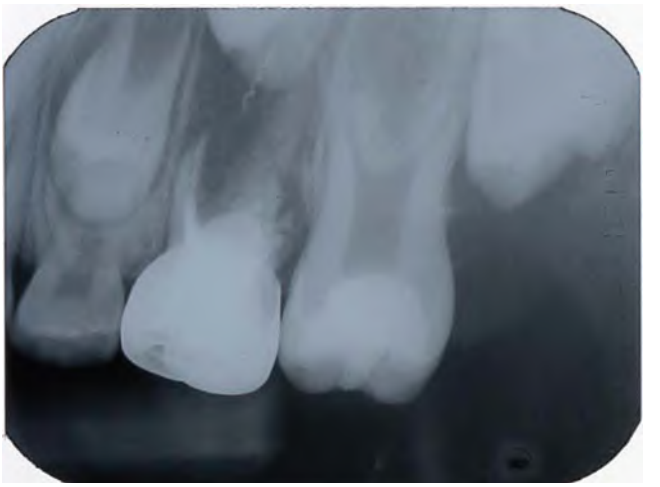

FIGURE 38-35 Follow-up periapical radiograph of an unsuccessful endodontic treatment in the primary maxillary left second molar. Note the separated segment of lentulo spiral associated with a large periapical radiolucency coronally to the permanent successor that shows delayed eruption. (Courtesy of Dr. Moti Moskovitz, Jerusalem, Israel.)

Human and animal reports suggest that primary molar interadicular or periapical pathology may affect the coronal development of the succedaneous premolars, causing hypoplastic areas.[266–268] Another study showed no significant differences in the presence of enamel hypoplasia in premolars under pulpotomized primary molars, even when considering the age at which the pulpotomy was performed.[269]

A serious complication related to pulpotomies is the development of dentigerous cysts that have been related to formocresol pulpotomies.[264,270] Radicular cysts, considered to be associated with pulpotomized primary molars, have been described as large, rapidly growing, causing buccal expansion, facial swelling, pain, pyrexia, pus discharge, and displacement of the succedaneous tooth that in most cases would require adjunctive orthodontics to facilitate their eruption to their adequate position in the arch. Furthermore, the inflammatory exudate may spread into the dental follicle of immature succedaneous teeth arresting their normal development.[271,272] Most of the cysts associated with pulpotomized primary teeth appear in the mandible and under the second primary molar.[264] Cysts under pulpotomized primary teeth may develop at any given time. One study reported a range of five months to three years with an average of 20 months.[271] Another study reported a range of 1.5 to 6 years with an average of 3.5 years.[264] These wide ranges strongly emphasize the need for long-term clinical and radiographic evaluation of pulpotomized primary teeth, and the need to extract as soon as a radiolucent pathological area is discovered.

BLEACHING OF PRIMARY TEETH

Tooth discoloration is common after trauma to the primary dentition. Among other causes, it may be related to calcific metamorphosis, a pulp hematoma, or pulp necrosis.[273,274]

Primary teeth with dark crown discoloration are kept in the mouth without the need of pulp therapy as long as there are no additional clinical and radiographic signs that indicate the need for pulpectomy,[275] or the clinician is requested by children and/or parents who are esthetically concerned to do some treatment that will improve the child's appearance.[276] Available options to treat this problem are facing of the primary teeth with composite materials, strip crowns, prefabricated esthetic crowns, or bleaching.

Dental whitening may be accomplished by using either professional or at-home bleaching modalities with combinations of hydrogen peroxide, carbamide peroxide, and sodium perborate in conjunction with different heat and light sources, or lasers.[277–281] The advantages of in-office whitening or whitening products dispensed and monitored by a dental professional include: a) an initial professional examination to help identify causes of discoloration and clinical concerns with treatment (e.g., existing restorations and side effects); b) professional control and soft-tissue protection; c) rapid results.[281] While internal bleaching requires a high level of patient compliance, dental skill and may be expensive, external bleaching represents an easier and cheaper treatment.[277]

Brantley et al.[277] described a clinical procedure for bleaching traumatized primary teeth that stained after trauma: an alginate impression of the affected teeth is taken for the fabrication of a custom no-reservoir bleaching tray from a soft thermoplastic material (Sof-tray, Ultradent Products Inc., South Jordon, UT). Next, an American Dental Association-approved 10% carbamide peroxide gel that is water-soluble and pleasant-tasting (Platinum Overnight, Colgate Oral Pharmaceuticals, Canton, MA) is placed in the tray. The length and frequency of application of the bleaching material is based on the degree of discoloration and the ongoing results of the treatment. Brantley et al.[277] started with a small amount of bleaching material (10% carbamide peroxide) in a tray for 1 hour per day for two weeks, continued with overnight use every third night for two more weeks, achieving removal of most of the discoloration with no deleterious effects such as sensitivity or abnormal exfoliation.

The most common cause for tooth discoloration is pulpal hemorrhage due to trauma.[282] The process of treatment and irrigation with sodium hypochlorite often resolves the discoloration, however, on occasions the tooth remains discolored. If this is an esthetic concern, the discoloration can be treated effectively with intra-coronal bleaching. Hydrogen peroxide is a popular active ingredient in currently used tooth bleaching materials. It acts on the pigments present in enamel and dentin by transforming complex molecules into simpler (less colored) ones.[283] Sodium perborate is a stable white powder that is also used as a bleaching agent, it was originally used as an interim appointment bleaching agent since it is significantly less caustic than hydrogen peroxide. Current literature and clinical studies support the use of sodium perborate mixed with water for bleaching nonvital teeth.[282,284,285] Studies have shown higher incidences of root resorption when hydrogen peroxide is mixed with sodium perborate,[286] or any mixture of sodium perborate is heated.[284] Therefore, the use of hydrogen peroxide and heating any mixture of sodium perborate are not recommended.[281]

As primary teeth are filled with resorbable pastes, these pastes cannot prevent leakage of the bleaching material into the canal. Leakage of bleaching material into the periradicular area may result in external root resorption.[280] A good sealing plug (of MTA, GIC, RMGI) of at least 2 mm should therefore be placed apically to the cemento-enamel junction to prevent leakage.[278] This plug should allow the sodium perborate to be placed at least 1 mm below the cervical margin. This ensures adequate bleaching of the cervical portion of the crown.[287] Although there are not that many studies of nonvital tooth bleaching in primary teeth it has been shown to be safe and effective.[281] Primary teeth are good candidates for nonvital bleaching as they are highly permeable due to the large diameter of the dentinal tubules. Nonvital bleaching offers a good option to improve esthetics of discolored teeth.

ANTIBIOTICS

Antibiotics are beneficial for the treatment of oral infections when indicated. Drug resistance of common bacteria is prevalent due to over-prescription practices and uninformed demands of patients. To diminish the incidence of drug resistance and the risk of antibiotics overprescription, healthcare providers must exercise caution when prescribing antibiotics to children.[288,289] Antibiotic therapy is usually not indicated when the dental infection is limited to the pulp, or the immediate surrounding tissue. However, when a child presents with systemic signs of infection, a fever or facial swelling, secondary to an odontogenic infection, antibiotics are usually indicated along with emergency dental treatment. Penicillin remains the drug of choice, with the occasional need to add metronidazole for anaerobic coverage.[288,289]

Chapter 39

Interrelationships of Endodontics and Orthodontics in Treatment Planning and Patient Treatment

James L. Gutmann, Vivian Manjarrés

Only since the turn of the last century has there been a significant focus on the interactive relationships that exist between the disciplines of Endodontics and Orthodontics.[1] These relationships focus heavily on tooth trauma, resorptive defects, and alterations or damage to the dental pulp during orthodontic tooth movement (OTM). Ironically, while the literature provides great support for these relationships during the past 100 years,[2–4] articles are still being published that claim there is no interaction, especially following trauma,[5,6] similar to reports that surfaced in the 1930s.[7] This chapter addresses this interaction, using both literature and clinical experiences and outcomes, along with examples of the types of interactions that may occur, and often do occur, to the tooth and pulpal-periodontal complex during OTM.

Initially, the reader is referred to two extensively documented papers that have addressed the challenges of treatment planning in the presence of endodontic-orthodontic interrelationships[1] and the interactive role of tooth trauma, pulpal status, and orthodontic tooth movement.[8] The information contained within these publications provides a sound literature basis for the claimed relationships that do exist and question those that may not occur. However, unfortunately, there is a paucity of high-level evidence-based studies that have examined the intricacies of the interactions that do occur during OTM.[8,9] Key issues identified in the tooth and pulpal-periodontal complex during OTM that impact treatment planning and clinical outcomes are discussed, and supportive literature identified. These issues have been modified from the literature identified immediately above.[8] Where controversy exists or greater explanations are necessary, an in-depth assessment of current findings and clinical trends are presented.

The prevalence of traumatic tooth injuries in young patients is rapidly being identified globally and the management of these injuries, along with societal concerns is receiving mixed attention based on the surrounding circumstances and knowledge of the treating professionals.[10–44]

There are a significant number of studies being published globally that have addressed the incidence of traumatic injuries in young patients. However, follow-up documentation as to how many of these undergo OTM and the sequelae encountered in this process is not available. This finding demands that in anticipation of any OTM a thorough dental history is mandatory, with leading questions if necessary to secure information regarding a history of tooth trauma, no matter how slight. This concern is especially imperative when child abuse is suspected, as parents would be reluctant to convey this to the treating dentist and the young patient is only too often afraid to share these adverse experiences. The same is true for those subjected to physical spousal abuse, as the potential damage to the teeth may often be overlooked when planning for OTM.[17–19,43,44]

While the prevalence of tooth injuries in young patients is being identified, the incidence and prevalence in adult populations has received little attention.[8]

Studies are essential to ascertain the incidence and prevalence of traumatic tooth injuries in adult patients. Data on this issue is minimal within this population[45] and virtually non-existent relative to how many of these patients seek or ultimately have teeth that are subjected to OTM.

OTM in both the young patient and adult patient has increased substantially in the past 3 to 4 decades. Unfortunately little is known about the prevalence of OTM in adult populations compared to adolescents. There is some documentation that adults seek OTM to alter esthetic appearances, manage tooth crowding or malposition[46] or concomitant isolated periodontal disease, to enhance the quality of life, their self-esteem and self-confidence.[47,48] However, there is also documentation that indicates that some types of OTM in adults may not be as successful as that in younger patients, such as repositioning of impacted canines, retaining crestal bone and preventing open gingival embrasures following OTM.[49] However, these outcomes have not been correlated with tooth trauma, nor have they correlated with previous challenges to the teeth involved, such as extensive restorations, alterations in pulpal viability, previous endodontic procedures, or periodontal disease.[50]

It is common to have a different set of historical and clinical circumstances surrounding OTM with adult teeth due to the fact that most of the teeth involved will have been subjected to multiple insults or challenges to their pulps prior to OTM. Whether or not the impact of these challenges is being addressed prior to OTM is unknown.

Therefore, the incidence of deleterious sequelae over time is unknown.

There is a tremendous void in the literature with regards to this issue. Important questions can be raised in this realm, such as: do all teeth that are planned for OTM subjected to sensibility testing? Are more than just panoramic radiographs taken of teeth, with previous and possibly questionable outcomes, that encompass other treatment modalities? Are other specialists consulted prior to initiating OTM? With specific reference to endodontic concerns, Meeran[51] summarized the issues succinctly: "A complete and detailed history of the dentition should be taken, with specific attention to history of dental trauma. Radiographic examination of the teeth for evidence of pulpal obliteration is highly important, as these teeth are at a higher risk of irreversible pulpal changes during orthodontic treatment. Patients who have risk factors for pulpal necrosis with orthodontic treatment (impacted teeth, teeth with a history of trauma, caries or restorations, teeth with evidence of pulpal obliteration) should be informed about the risk of pulpal damage during treatment and informed consent taken before treatment. Light continuous orthodontic forces must be applied to move teeth, respecting physiologic boundaries. Extreme care should be taken to ensure that the intended orthodontic tooth movement does not challenge the apical blood supply (e.g., compressing the root apex against the cortical plate). Pulpal symptoms that arise during orthodontic treatment should be recognized early and treated appropriately without delay." In line with the previous statement, many authors have addressed the changes that occur in permanent teeth.[52–60]

In teeth that have been traumatized, resorptive activity may be especially enhanced during OTM. Therefore an extensive evaluation of teeth that have been traumatized prior to OTM is essential, as teeth with signs of root resorption before orthodontic movement, whether root treated or not, may be more prone to root resorption during movement.[1,5,61–65]

The importance of securing a good dental history from the patient cannot be over-emphasized. When orthodontic tooth movement is being planned on traumatized teeth there may be an accentuated resorptive response, especially if the trauma was severe.[64,66] Traumatized teeth often display signs of root resorption prior to orthodontic OTM.[67] Resorption of previously avulsed or luxated teeth has also been noted to be greater during OTM.[1] However, if a tooth presents with immature root development and has suffered an intrusive luxation, then it will be difficult to assess the pulpal status; careful orthodontic extrusion over a period of 3 to 4 weeks is advisable as is radiographic monitoring for signs or symptoms of resorption or pulpal demise, respectively. Surgical repositioning can also be considered.[61] It is in this realm of decision making and evaluation that CBCT evaluations may play an additional important role in patient communications and treatment choices, especially in light of potential changes in bone and root density due to OTM.[68]

Patients, both young and adult who have a history of tooth trauma may be at risk for additional trauma. Likewise, OTM may pose an increased risk for resorptive activities, especially should trauma occur during tooth movement.

Very few prospective, or for that matter retrospective, studies exist to provide even best-evidence directives under these circumstances. Clinical experience will usually guide the treatment rendered if any, depending on the signs and symptoms and degree of trauma. However, those patients, particularly the young and those involved in sporting activities who have suffered dental trauma are often at risk for additional trauma[17] and, therefore, during any OTM there may be an increased risk of resorption.

Teeth suffering trauma during orthodontic treatment, especially when periodontal injury occurs, often exhibit a high level of pulpal changes, from vascular alterations and fibrosis and calcifications,[59] to total canal obliteration (radiographically),[60] to a significantly high level of pulpal necrosis.[69–72] This is especially true with teeth that were orthodontically intruded first and then received trauma.[70] Also, teeth that have had trauma with severe periodontal injuries are highly susceptible to pulpal necrosis during orthodontic intrusion and extrusion.[71,72] These circumstances require careful assessment when there is a planned use of temporary anchorage devices, referred to as TADs or miniscrews, for tooth repositioning. Care must be taken not to provoke further trauma during placement of the TADs.

The use of Cone Beam Computerized Tomography (CBCT) scans in patients with a higher risk of root resorption may be of benefit during treatment planning and ongoing OTM.

In this realm of decision making and evaluation, CBCT evaluations may play an additional important role in patient communications and treatment choices, especially in light of the variabilities in bone and root density and the potential changes that may occur in the dental pulp during OTM (Figure 39-1).[63,68,69] However, concern has been expressed about the use of CBCTs in orthodontics, considering it as unacceptable as a substitute for conventional radiography.[73] An alternative may be to use quantitative digital subtraction radiography.[74]

The literature supports both the healing of root fractures and the ability to move these teeth orthodontically, provided there is no obvious evidence of replacement resorption or ankylosis. The use of the CBCT in these cases is essential.

The use of CBCT will be highly effective in determining the exact location and path of the fracture (Figure 39-2).[63,75,76] Significant evidence exists that indicates apical and mid-root fractures can heal, some with and some without endodontic intervention.[77–80] However, whether healed or not, their presence is certainly becoming more common, especially in adult patients for whom teeth can be moved orthodontically. There is a paucity of extensive, detailed evidence to support treatment planning options in this clinical situation. However, based on studies with small sample sizes or case reports,[81] orthodontic movement of teeth with repaired fractures is possible, even if the fractures at the time of the accident were extensive with marked fragment dislocation.[82] Application of light OTM forces would be indicated[83] and case monitoring would be appropriate to ensure positive outcomes.[84–86] In this regard the use of CBCT technology is warranted for both the initial diagnosis and subsequent follow-up evaluation.[68,87] These cases should be evaluated for up to 2 years subsequent to OTM, assessing pulpal responses, and tooth mobility.[1] Should ankylosis occur, movement will not be possible. Issues surrounding the orthodontic movement of teeth that have experienced fractures will be addressed in subsequent sections. Needless to say, the pulps in these teeth will have suffered some challenge to their viability, with some retaining variable responses to sensibility testing, some undergoing complete necrosis or calcification, and a small number experiencing an internal resorptive phenomenon.[88]

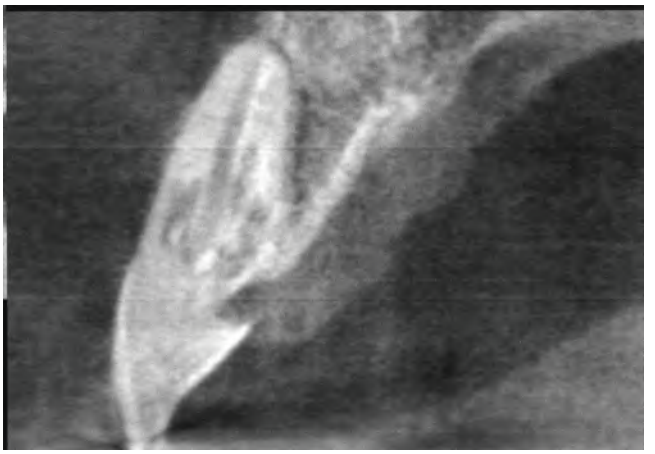

FIGURE 39-1 Details of alterations in root integrity that can be provided using a CBCT image, the full impact of which may not be evident on periapical radiographs. Note the external invasive resorption along the pulpal space coupled with defect on the palatal aspect of the crown at the level of the cingulum.

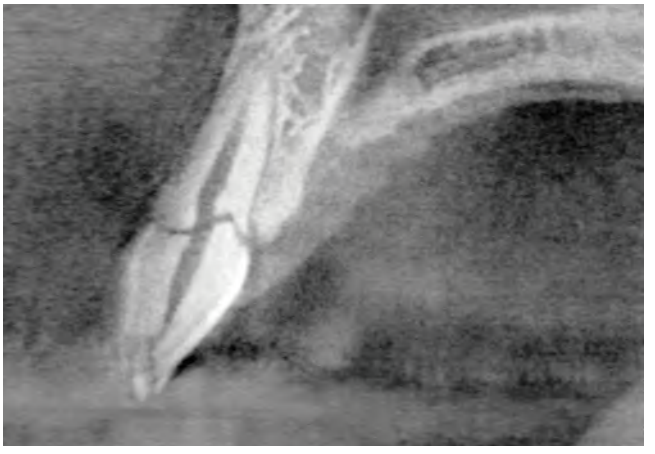

FIGURE 39-2 A coronal third fracture exhibiting a tortuous path through the coronal aspect of the tooth. The ability to determine the true nature of these fractures is enhanced with CBCT.

OTM should be considered in the treatment planning of teeth with subgingival coronal fractures based on the nature of the retained root structure, in particular its length and width, along with esthetic considerations.

Many deep, coronal subgingival fractures cannot be restored adequately and the tooth may develop periodontal complications (Figure 39-2). These cases are the most difficult to treat because of their location and the possibility for extreme mobility of the fractured coronal root segment.[65] Depending on the location of the fracture, immediate stabilization is indicated, and the need for a root canal procedure is necessary for tooth retention.[89] The use of CBCT will be highly effective in determining the exact location and path of the fracture, no matter its location in the root. Furthermore, if the clinician can probe periodontally to the fracture site, then the coronal segment should be removed and a treatment plan for the apical segment determined. Periodontal probings to the level of the fracture indicate that salivary contamination has occurred and the two segments will not heal properly; moreover, the pulp is most likely infected. Once the coronal segment is removed, the apical segment can be orthodontically moved coronally[90] and a post, core, and crown as needed can be fabricated to retain the apical segment.[91–94] Depending on the length and the shape of the root, this is not always feasible, in which case the apical segment must be extracted.

Surgical repositioning can also be considered.[61,95–99] Careful marginal extrusion, along with rotation if necessary, can result in minimal to no root resorption and allows for immediate restoration and stabilization during the healing process.[98] In teeth with immature apical formation, a more conservative approach of orthodontic extrusion is indicated and surgical repositioning is contraindicated.[41,100] Orthodontic intrusion of teeth with immature roots has been shown to have six times higher chance of presenting pulp canal obliteration than mature teeth and a lower risk of developing root resorption, that would tend to favor careful, slow OTM. The most frequent post-injury complications found in these teeth were pulp necrosis (73.3%), marginal bone loss (60%), inflammatory root resorption (40%), pulp canal obliteration (26.7%), and replacement root resorption (20%).[99] Moreover, in the young patient with these types of traumatic injuries, pulp tests cannot distinguish between a

"vital pulp" and an "unhealthy pulp," especially in the absence of signs or symptoms or if OTM is indicated, in the extrusion procedure, or subsequent to the repositioning. Secondly, the restoration of these teeth may not be the same as that planned for the adult patient, especially in the case of pulp space obliteration or other root/crown defects.[101]

The health of the dental pulp, following either traumatic tooth injuries, or a compromised tooth of an adult patient, is difficult to determine. This is especially true because the use of the terms vital and non-vital, along with reversible and irreversible, do not necessarily accurately characterize the status of the pulp.

Just because a tooth is symptom-free, no radiographic changes are evident and the tooth responds to sensibility testing does not mean that it has a healthy dental pulp. Vitality is one issue, while chronic inflammation and/or tissue degeneration lend a whole new perspective on establishing the normality of a dental pulp, before and during tooth movement, especially in the adult patient.[8]

Integrated diagnoses and treatment planning principles must take into account the status of the dental pulp (especially in adults), history of previous dental treatment or trauma, and physical appearance of the teeth. Pulp "sensibility" testing each tooth that will be involved in OTM should be done using both electric pulp testing and thermal tests. However there are no new clinical testing methods and a problem or disconnect actually exists with all presently used tests. While the clinician wishes to know the physiological condition or relative "health" of the pulp tissue, the tests only provide an indirect assessment by stimulation of the nerve tissue or possible blood flow.

The electric pulp test (EPT) provides the clinician with a response or no response that may help to differentiate normal from necrotic pulps. During usage, a medium, such as tooth paste or gel is used to insure the electrical contact between the tooth and the tip of the tester. Ideally the tip of the tester is placed at the incisal edge for the anterior teeth.[102] On posterior teeth, the favored location for placement of the tester is on the buccal cusp tip.[103] Many clinicians tend to favor the mid-facial or buccal surfaces, however false readings may occur.[104] The relative number or reading on the tester is not an indication of the relative health or disease of the pulp. Because EPTs apply an increasing power on a logarithmic, not linear scale, responses at the very highest power levels cannot be reasonably accepted as normal. EPTs can provide false-positives and false negatives up to 20% of the time. Further limitations of EPTs are the lack of response on teeth with immature root development, teeth traumatically injured, and teeth that exhibit significant coronal and/or linear calcification of the pulpal space.[8]

Thermal testing, primarily cold, is more beneficial in determining the responsiveness of any given pulp.[105] This test may be conducted with ice, crystals of ethyl chloride, or carbon dioxide spray or cold water.[106] Ice sticks or ice pencils can conveniently be made by filling and freezing the discarded plastic sheaths from disposable anesthetic needles. Testing is limited to one location on one tooth at time, placing the stimulus on the same position on each tooth. In cases where responses seem uncertain or vague, consider testing all exposed surfaces of each tooth. It will be seen with experience that responses will often vary on the same tooth.[106] An important aspect of using thermal testing actually lies in evaluation of teeth subsequent to OTM, where cold testing is considered much more reliable than EPT.[107,54]

Transillumination is used to determine tooth transparency and presence of crazes or cracks or opacities that would indicate possible previous pulpal changes of concern. All teeth with previous compromises, such as trauma, caries, restorations, etc., should be noted and color photos are recommended. The presence of discoloration,[1] such as a ***yellowish/brownish hue***, may indicate significant amounts of irritational (reparative) dentin may have formed in the crown of the tooth; whereas a ***pinkish hue*** may indicate that there is vascular damage in the pulp and or the presence of internal resorption;[1,108] while a ***grayish hue or gray-blue opacity*** may indicate that the pulp is necrotic.

In light of the compromised, yet symptom-free pulpal status often found in adult patients, the potential impact of heat that may be generated during bracket placement[109,110] and debonding procedures must be addressed.[111–114] Early studies that addressed the impact of heat on the dental pulp indicated that pulp temperatures that rose 5° – 17°C caused progressively severe pulpal necrosis.[115] Initial *in vivo* studies by Baldissara *et al.*[116] on young permanent premolars, demonstrated temperature increases in the pulp from 8.9° to 14.7°C without histologic damage. What appeared to be the determining factor was the rate of heat delivery as opposed to the absolute temperature. Furthermore, the results suggest a low susceptibility of cells to heat, which does not appear to be a major factor of injury, at least in the short term. Additional studies by Baldissara *et al.*[117] indicated that temperature rises from 39.5° to 50.4°C cause pain in patients. Studies that address light curing the brackets to the teeth indicate that temperature increases are below any critical values that might impact irreversibly on the dental pulp. With bracket debonding however, temperature values may rise close to critical values and efforts must be made to minimize these occurrences through the use of water cooling or fine burs. With both scenarios, data obtained does not reflect actual clinical findings that may impact negatively on adult teeth that may already have compromised pulps, due to trauma or to a number of other insults. This is an area that needs research to support clinical procedures.

During the clinical examination, all teeth that have deep composite restorations and/or pulp cappings evident or documented should be tested extensively. Key to this assessment is the depth of the restoration, the remaining dentin thickness, and the tooth's response to thermal testing. Ironically in this day and age of extensive, and sometimes irresponsible, replacement even of good amalgam restorations with composites, failure to understand and consider the fact that deep composite restorations are more prone to cause pulpal

breakdown over time often leads to an extensive challenge to the dental pulp.[118] While empirical, clinical experience tends to support the fact that these teeth often present with accentuated signs and symptoms of pulpal necrosis and acute apical periodontitis. Anticipation of this possibility when planning tooth movement should be a priority.

Histologic and molecular biologic changes in the dental pulp have been identified due to OTM, some of which may result in degenerative changes in the pulp.

Clinicians may not recognize that OTM may adversely impact on the physiology of the dental pulp. Research into this area does support this concept and must be considered during treatment planning.[199] Two factors appear to impact this relationship: (1) the degree of pulpal compromise or challenge before the orthodontic tooth movement; and (2) the degree and type of force being placed on the tooth over time. In the case of the former, this will mostly likely vary from adolescent to adult and from previous episodes of trauma to extent of restorative treatment or long-term presence of periodontal disease.

During rapid tooth movement, pulpal alterations or injury may occur.[59,60,199] This is due primarily to an alteration in the blood vessels in the apical periodontium and those entering the pulp. Clinically the teeth may have altered sensations to stimuli.[120] Effects of this nature may have a direct impact on the metabolism of the pulp tissue, in particular the odontoblasts in fully formed teeth, and Hertwig's Epithelial Root Sheath in incompletely formed teeth (subsequent sections on the impact of trauma on teeth undergoing apexification). A common clinical challenge that has been shown to impact on the dental pulp (and potentially the roots and the periodontium) is movement, both surgical and nonsurgical of impacted canines (Figure 39-3).[121,122] Pulpal changes and their consequences also appear to be proportionally more severe with greater orthodontic forces, particularly during intrusive forces.[59,123]

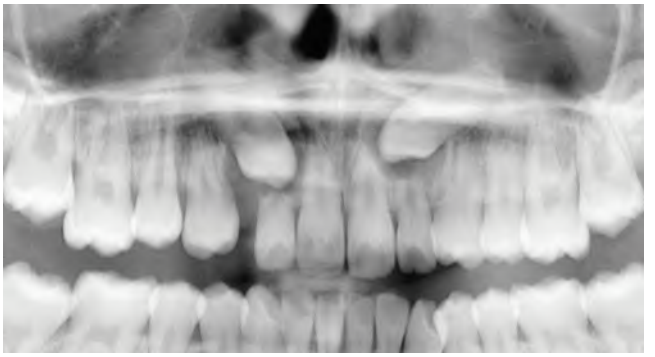

FIGURE 39-3 A panoramic dental radiograph showing extensive root damage to the maxillary lateral incisors due to impacted canines. Furthermore, if the lateral incisors can be maintained, there will be challenges within the scope of root canal procedures. Also, note that there are calcific alterations in the pulp space of the left maxillary incisor indicating pulpal degeneration. (Courtesy of Dr. Kathleen Valencia, Weston, Florida, U.S.A.)

Oppenheim[124,125] showed some signs of severe pulpal degeneration in all human cases using a labiolingual expansion appliance. The movement afforded by this technique resulted in a tipping motion in the apical third of the root. As a result, he recommended the use of light intermittent forces to reduce damage to the dental tissues and provide time for possible repair. Tşchamer noted that some of the odontoblasts will degenerate while other pulpal cells will undergo atrophy during appliance activation in late adolescent patients.[126] Historically, these findings have been supported by numerous studies.[127–131]

Investigative results indicate a relationship between the biologic effect of an orthodontic force and the maturity of the tooth, particularly the dentinogenic activity of the pulp.[132,133] This would imply that a greater dentinogenic activity coupled with a larger apical foramen would result in a reduction of detrimental effects from orthodontic forces. Ooshita noted that the surrounding tissues of bone and periodontal ligament that are linked to the tooth with an open or large foramen demonstrate accelerated activity during tooth movement.[134] Labart et al. reported an increased pulpal respiration as a result of orthodontic forces being applied to the continuously erupting rat incisor.[135] To further clarify these issues, and to address the ability of the pulp to recover following insult, Unterseher et al. assessed the pulpal respiration response after a 7-day rest period following tooth movement.[136] After initial respiratory depression, there was a return to normal respiratory rates within 1 week. Age was negatively correlated with the respiration rate, while apical opening size was positively correlated with the respiration rate.

Historically, specific angiogenic changes in the human dental pulp associated with orthodontic movement have received limited study. Angiogenesis is the formation of new capillary structures ultimately leading to the organization of larger structures by a process of neovascularization.[137] Kvinnsland and associates,[138] using fluorescent microspheres, showed a substantial increase in blood flow in the dental pulp of mesially tipped rat molars. Nixon et al.,[139] using the rat model, also found that there was a significant vascular change with an increased number of functional pulpal vessels as related to the specific forces applied. These findings contradicted those of Anstendig & Kronman who observed fewer blood vessels in tooth pulps subjected to orthodontic forces.[140]

McDonald & Pitt Ford[141] identified that blood flow changes within the pulp during tooth movement are not a mere reduction with no further response, but have dynamic changes that overcome potentially poor perfusion of the tissues. This finding further substantiated the studies by Vandevska-Radunovic et al.[142]

Derringer and co-workers identified a significantly greater number of new microvessels in orthodontically moved teeth within 5 days of treatment commencement.[143] These findings and more current studies[144] would support not only the presence of significant angiogenesis in the pulp, but also the presence of the necessary angiogenic growth factors for enhanced growth of the microvascular system.[145]

Alterations in the pulpal vasculature with subsequent alterations in the metabolism of the pulpal cells will usually

result in an increased deposition of reparative dentin in both the coronal and radicular portions of the pulp, along with a concurrent increase in dystrophic mineralization.[60,119] This response has been reported to result, in some cases, in complete obliteration of the pulpal space.[146] The incidence of this occurrence, however, does not appear to be clinically significant, at least in adolescents,[147] although a resultant pulpal necrosis can occur.[128,148,149] Most of the time related changes that occur in the pulp are considered reversible, unless the pulp has undergone previous insult or challenge. Nixon *et al.*[139] identified a force dependent increase in predentin width that was measured at the peak of the tooth movement cycle in the rat model. Pulps were considered to be normal prior to tooth movement. No differences were found with regard to location in the pulpal space that would indicate that the pulp couldn't distinguish the specific location of the applied force. What is of clinical importance appears to be the history of trauma to the tooth prior to the OTM,[150] and the radiographic observation that the pulpal space may have narrowed prior to or during the active tooth movement. In teeth that have undergone varying degrees of pulp space calcification, in particular those with extensive restorations or evidence of periodontal disease, responses, or lack thereof, to pulp testing with electrical devices may be of no value. Recent studies support the use of thermal testing, as opposed to electric pulp testing[107,54] or pulse oximetry.[151]

Neural responses and evidence for the release of specific neural transmitters have also been assessed during orthodontic tooth movement.[152] Specific intrapulpal axon response to orthodontic movement was explored using human teeth with open apices that were subjected to short-term movement and long-term movement.[153] Subsequently the teeth were extracted and evaluated under both light and electron microscopy. Although unmyelinated axons outnumbered myelinated axons, no significant differences in myelinated or unmyelinated axon numbers were observed between the experimental (orthodontic movement) and the control (no orthodontic movement) teeth. Therefore intrapulpal axon alterations appear minimal and not progressive with conservative tooth movement. This study infers that no irreversible insult is inflicted on healthy teeth undergoing conservative orthodontic treatment. This does not, however, account for the fact that the changes detected generally do not produce symptoms in teeth that already have a symptom-free degenerating pulp. Rather, symptoms of reversible or irreversible pulpitis may still be present and may be masked by the discomfort felt from changes in force that are made during appliance modifications. Furthermore, pulp tests cannot distinguish between a "vital pulp" and an "unhealthy pulp."

Precise metabolic events involved in neural transmission of nociceptive information during tooth movement have focused on the peptidergic pathways, that purportedly inhibit the firing of pain-conducting fibers,[154–157] the presence of calcitonin gene-related peptide immunoreactive nerve fibers (CGRP IR),[158,159] and the presence of substance P (SP).[156,160] These studies indicate that neuropeptides play an important role in the regulation of the blood flow to the pulp and the periodontium. In particular, there is a greater CGRP-IR fiber response in the pulp and periradicular tissues during tooth movement that is accentuated around the vascular system. The resultant increase in the blood flow to these tissues during tooth movement impacts on the availability of cells of hematopoetic origin (osteoclast precursors), that are capable under local stimulatory factors to differentiate into osteoclasts and influence the resorptive remodelling process of the teeth.[142,161]

While radiographic changes of pulp space obliteration during, or following, tooth movement are usually obvious, the lack of further dentin elaboration may not impress the clinician until other clinical or radiographic findings surface. This can occur following the introduction of orthodontic forces that are beyond the physiological tolerance of both the periodontal and pulpal vessels. Subsequent pulpal necrosis may result and may not be detected until clinically there is a darkening of the crown of the tooth. This indicates a liberation of hemoglobin that breaks down into hemosiderin (a dark yellow, iron-containing pigment), that ultimately penetrates the dentinal tubules. Also indicative of a pulp necrosis could be the presence of patient signs or symptoms, appearance of a radiolucency, or the failure of the pulp space to close with irritational dentin in a manner compatible with adjacent teeth.[119] Histological findings in the pulp that may support these possibilities have been described by Mostafa et al.[162] in response to orthodontic movement of teeth or rapid palatal expansion.[163] Specific pulp responses to tooth movement noted included circulatory disturbances with congested and dilated vessels, odontoblastic degeneration, altered gene expression and proliferation of fibroblasts, vacuolization and edema of the tissues and eventually fibrotic changes; to maxillary expansion with heavy orthopedic forces, reversible vascular changes were noted.[163] While some may consider these changes as temporary,[163–165] teeth with complete apical formation and teeth with pulps that have had previous compromises such as trauma, caries, and restorations or periodontal disease may be more susceptible to irreversible pulpal changes or necrosis under this type of orthodontic movement.[166]

During rapid tooth movement, pulpal injury may occur and changes are seen primarily in the apical vascular.[57,167,168] Clinically, patients may describe some altered sensations to various stimuli.[53,131,139,169,170] Depending on the degree and nature of the movement, pulpal degeneration can occur over the time of the orthodontic tooth movement or may be delayed in its appearance. This is often evident in a narrowing of the canal because of increased dentinogenesis.[53,149,158,162] Furthermore, the release of chemical mediators of inflammation from the pulp (especially if undergoing an inflammatory response or is in a degenerative state) during rapid tooth movement may enhance apical resorption.[171]

This potential for adverse responses should alert the clinician to do the following to prevent problems or identify problems that may have occurred with the dental pulp

during orthodontic tooth movement. Initially, baseline pulpal responses on all teeth that will be involved in orthodontic treatment should be obtained. This concept is not readily apparent to the clinician as, only too often, if the teeth look fine "clinically" there is a perceived need that there are no problems. The same is true if there do not appear to be any tooth problems on a panoramic-type radiograph. In this light, a full set of periapical and bitewing radiographs are essential prior to any treatment. In some cases if particular areas are in question, possibly a CBCT would be appropriate.[63,172–176] Moreover, a detailed history of what may have happened to the patient's dentition over time, especially with adults is also essential, *vis a vis* tooth trauma, whether severe or incidental.

During tooth movement, forces should be carefully monitored. Subsequent to orthodontic movement, all teeth should again be evaluated for any signs or symptoms of adverse sequelae, both clinically and radiographically, using the data gathered prior to treatment for comparison. This latter mandate should also be considered at least 1 year following the removal of all orthodontic appliances.

Due to the significant remodeling changes that occur during OTM that may alter the vasculature, as discussed, multiple other changes occur on a molecular biological level that alter the cellular and extracellular matrix reorganization leading to the synthesis and release of various neurotransmitters, cytokines, growth factors, colony-stimulating factors and metabolites, in addition to genetically driven or altered factors that are influenced by the mechanical forces being applied.[177–179] While the impact on the dentition of the child or adolescent patient may be minimal with reference to the teeth and bone, the impact on the adult, who has undergone changes in the dental pulp and supporting periodontium, may be significant. While there is a proliferation of isolated studies in this realm that have been identified, many of these factors during or subsequent to tooth movement,[143,144,180–186] little is known of the implications when integrating these findings in the clinical setting from a pulpal standpoint. Relative to the periodontium, however, matrix metalloproteinase-1 (MMP-1) and cathepsin K are important in root resorption during tooth movement because they degrade the collagenous bone matrix in a mode similar to bone resorption.[187,188]

The presence of root resorptive changes may be difficult to ascertain on two-dimensional radiographs. Sufficient mineral per unit volume must be lost from the tooth to make a judgment of a radiographic appearance of resorption. Hence the value of the CBCT is most important in these cases.

As previously discussed, the use of the CBCT, while potentially exposing the patient to greater amounts of radiation,[73] may be necessary in those cases where the patient is at greater risk for tooth resorption during OTM based on an overall assessment of case factors.[176] Severe incisor root resorption has been associated with impacted maxillary canines, especially in female patients, severely mesiodistally displaced and vertically positioned canines adjacent to the middle third of the adjacent incisor roots, dental follicles wider than 2 mm and normal lateral incisors.[189] The implications are obvious in this scenario as often endodontists are challenged with the management of severe incisor resorption in teeth both symptomatic and symptom-free (Figure 39-4). Moreover, and as discussed previously, the presence of root resorption before OTM, in addition to extractions, reduced root length, decreased crown/root ratio and thin alveolar bone represent risk factors for severe root resorption in maxillary incisors during orthodontic treatment.[190] Hence, the use of the CBCT may be warranted in cases suspected of having teeth with resorptive processes during treatment planning for OTM.

Both apical and lateral root resorption may be identified with OTM, especially in maxillary lateral incisors and premolars.

This outcome can easily present a problem for the clinician, during diagnosis and treatment planning (Figures 39- 5 to 39-7). Often the resorptive defect may not be limited to the mesial or distal surfaces and if present on the buccal or lingual/palatal tooth surfaces may not be discernable using periapical radiographs until >10% or more of the mineral per unit volume is lost.[171,191]

If a pulp is non-vital or degenerating, following trauma in the young patient or as may be found in the adult patient due to multiple long-term insults, and the tooth is undergoing OTM, there may be a greater chance for an active resorptive process.

If a pulp is non-vital or degenerating and undergoing tooth movement, then a greater chance for an active resorptive process exists.[171] ***Hence the dictate to evaluate all teeth prior to orthodontic movement, especially in the adult patient is imperative***. This is especially necessary in cases of planned intrusion[123] vs. extrusion,[192,193] where intrusive forces appear to have a more deleterious impact on the pulp. However, this complication may be minimized with the use of non-steroidal anti-inflammatory drugs.[193]

If necessary, all suspect teeth or teeth with a definite diagnosis that requires a root canal procedure should be treated before orthodontic tooth movement; or if the movement has commenced, it should be stopped and root treatment should be done before movement begins again. Additionally, the placement of a permanent restoration is advisable to ensure a coronal seal.[84]

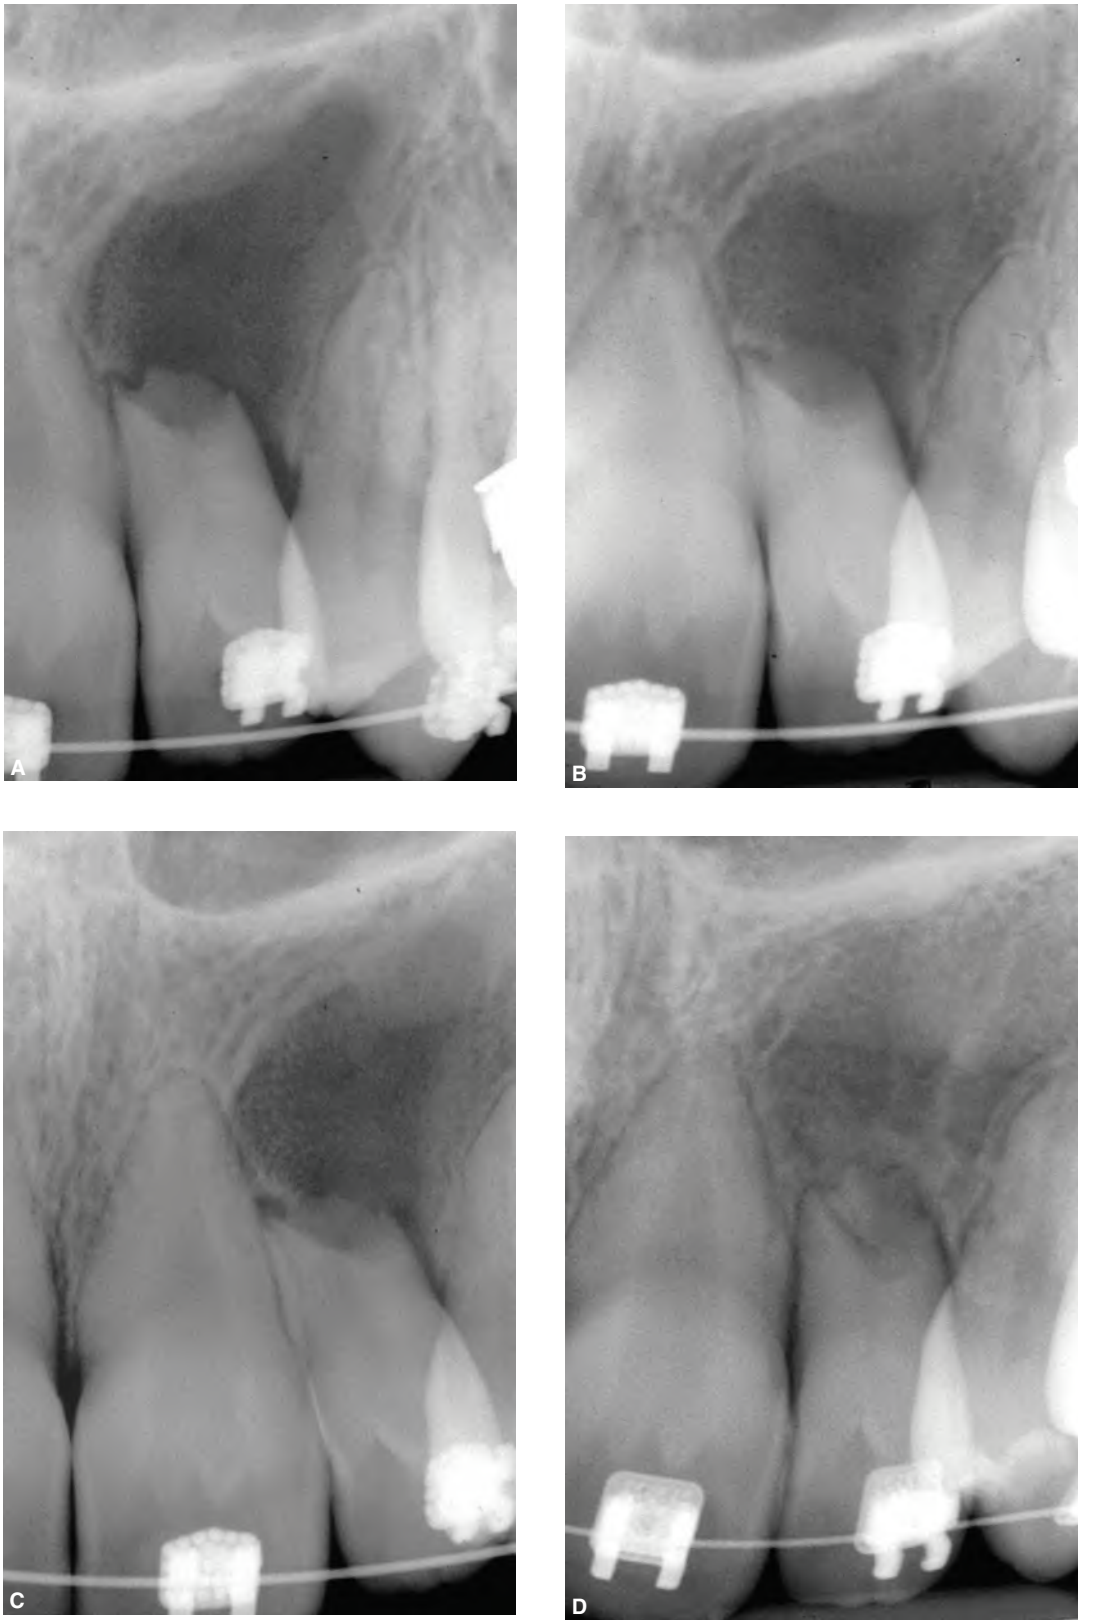

FIGURE 39-4 ***A.*** While resorbed lateral incisors can pose challenges to the endodontist, following the removal of impacted canines, often a "wait and watch" endodontic approach is indicated. ***B & C.*** represent a 3- and 6-month evaluation of the site; the patient is symptom-free and tooth discoloration is minimal. ***D.*** A one-year evaluation shows almost complete osseous repair with the only endodontic intervention being diagnosis, treatment plan and periodic evaluation. (Courtesy of Dr. Sonia Ferreyra, Cordobá, Argentina.)

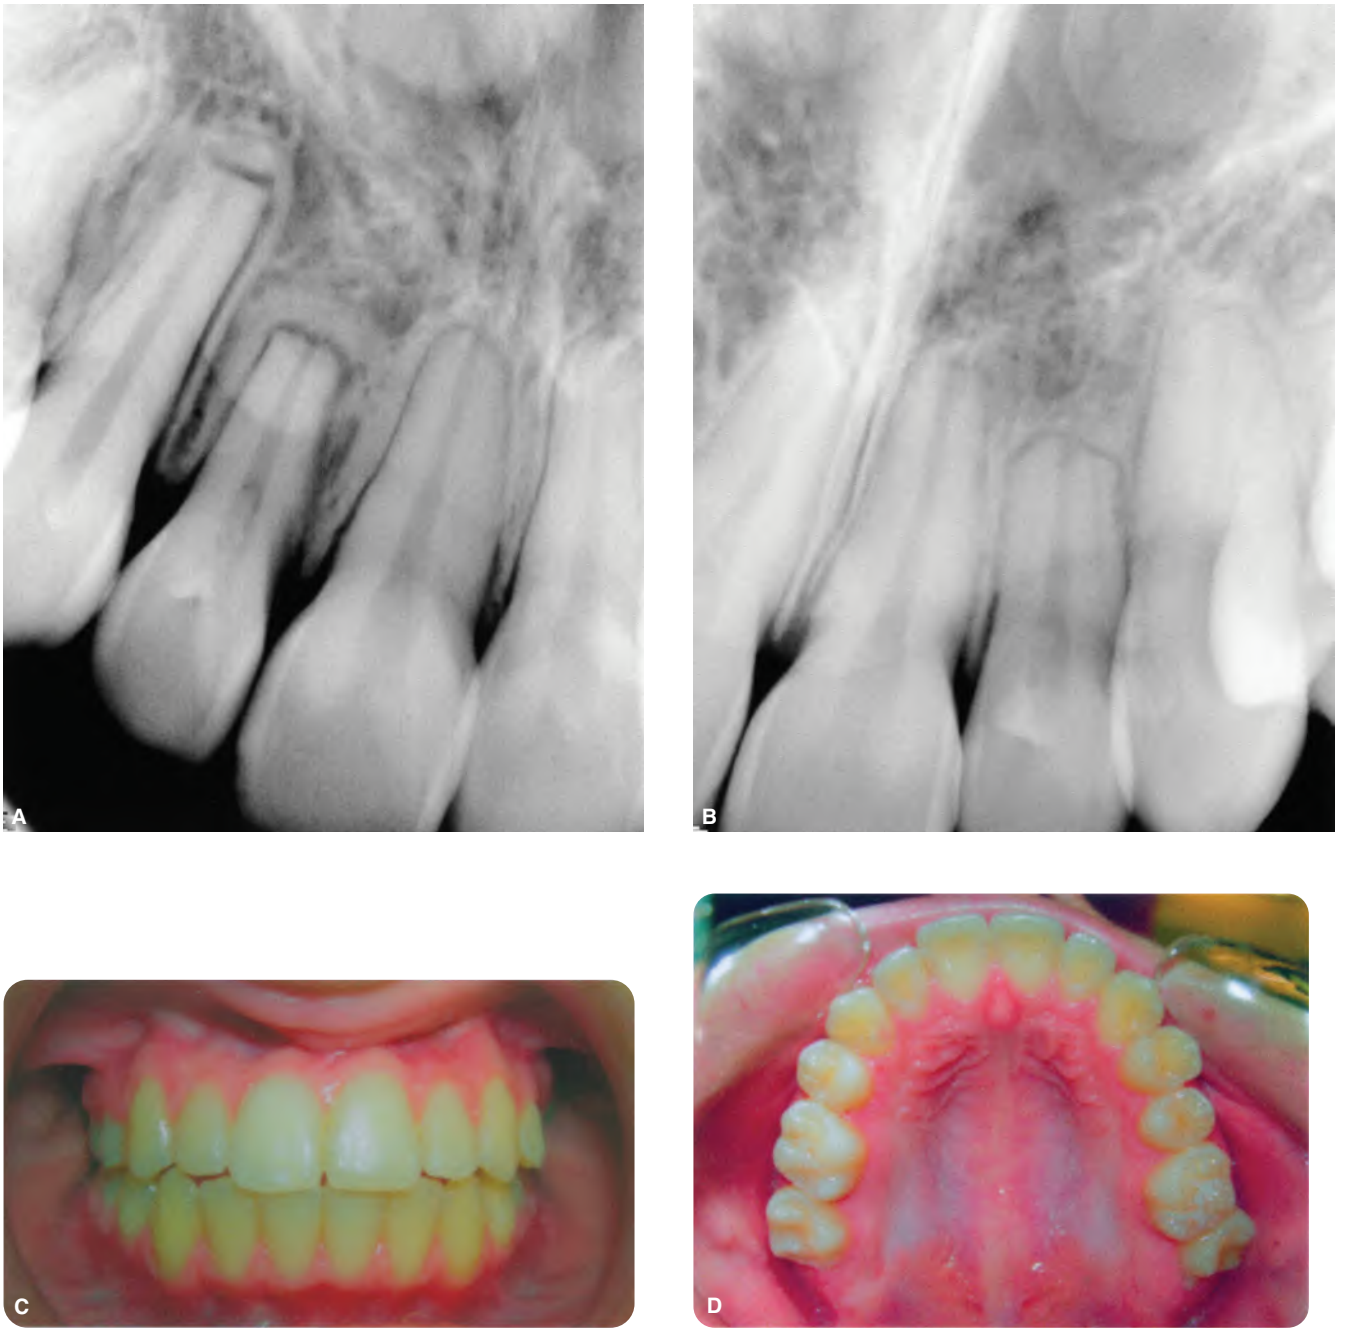

FIGURE 39-5 ***A & B.*** Right and left radiographic views of a 15-year-old female who had undergone OTM for 3 years. Significant resorption is evident on all maxillary incisors. Also of note is the increased bone density and width of the lamina dura around the blunted root apices along with the build of calcification in the coronal aspect of the two lateral incisors that may indicate pulpal degenerative changes. ***C & D.*** No discoloration of the crowns is present. (Courtesy of Dr. Kathleen M. Valencia, Weston, Florida, U.S.A. [Radiographs and photographs].)

Dental pulp tissue plays an important role in the inflammatory process involved with apical root resorption. Pulp extirpation, may be effective to alter progressive severe root resorption that may occur during OTM. The same is true in cases of a necrotic pulp or when there is failure of previous root canal procedures.

Studies indicate that orthodontic force affects dental pulps via the rupture of blood vessels and vacuolization of pulp tissues.[141,194] Further studies have hypothesized that injured pulp cells may express macrophage colony-stimulating factor (M-CSF) and the receptor activator of nuclear factor kappa-B ligand (RANKL), thereby stimulating the appearance of odontoclasts and their destructive activity.[195] Pulp removal

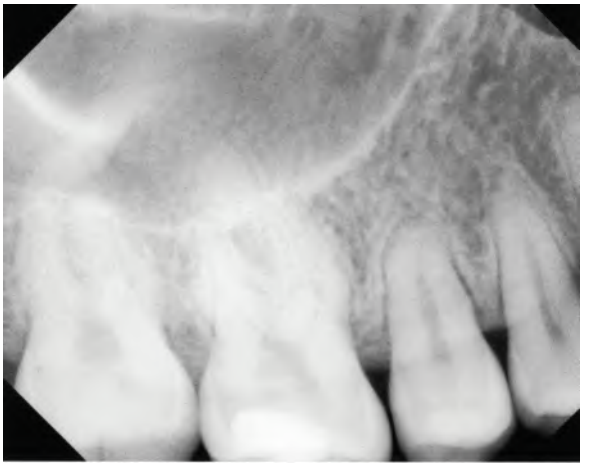

FIGURE 39-6 The maxillary premolars are often affected by apical root resorption during OTM.

FIGURE 39-7 Lateral root resorption may also occur during OTM.

in the presence of this type of resorptive activity during OTM is suggested as a primary treatment modality for the management of this process.[195] The same situation presents itself in the case of teeth requiring revision of previous root canal procedures prior to OTM (Figure 39-8)

Teeth with previous root canal procedures, without a history of trauma, can be moved the similar distances as teeth with presumably vital pulps; but what about teeth requiring root canal procedures during active OTM?

Root-treated teeth can be readily moved the same distances as teeth with vital pulps.[196,197] This presumes that there would be no other factors that may prevent tooth movement, such as the presence of replacement resorption (or ankylosis) that may occur after certain traumatic incidences, or be the result of injury to the apical periodontal ligament by the root canal filling material.[198] However, the risk of external apical root resorption exists during an OTM.

The clinical challenge is how to manage teeth requiring root canal procedures during OTM. Initially the root canal or canals can be enlarged, shaped, cleaned, and calcium hydroxide ($Ca[OH]_2$) placed as an interim dressing.[199] The coronal access opening must be sealed properly, preferably with a bonded composite material. Orthodontic movement can be resumed immediately. Canal obturation can occur subsequent to the termination of orthodontic treatment; or, the entire root canal treatment can be completed, and the coronal access opening sealed. Orthodontic treatment can resume in 10 days to 2 weeks, after any periradicular inflammation has resolved. A short-term use of non-steroidal anti-inflammatory drugs can be considered.[193]

If a failing root canal treatment is identified (signs, symptoms) during orthodontic tooth movement, then revision of treatment is indicated using $Ca(OH)_2$ and chlorhexidine[200,201] to disinfectant the root canal or to minimize microbial populations found commonly in root canals requiring treatment revision.[202–204]

In an early literature review by Steadman,[205] root canal treatment was criticized in that it was claimed that the devitalized root acts as a foreign body causing chronic irritation and root resorption. (This was more of a carry-over from the Focal Infection Era.) Histological sections of such resorptions showed cellular pictures typical of a foreign-body reaction. Steadman considered that the resorption could not be controlled and therefore the prognosis for these teeth was unfavorable. He even went to the point of suggesting, based on the literature, that because of the resorptions, the roots of these teeth would become ankylosed, thereby eliminating the possibility of OTM. Huettner & Young[206] challenged Steadman's theory and evaluated the root structure of monkey teeth with both vital and non-vital pulps (root canal treatment) following OTM. Maxillary teeth were treated and obturated with gutta-percha and Kerr's root canal sealer. The mandibular teeth were treated and obturated with silver cones and sealer. All teeth initially had vital pulps, were treated in an aseptic environment, and were allowed to "rest" for 3 weeks following the root canal procedures to give the apical periodontal ligament time to heal (not a contemporary dictate). The edgewise fixed appliance technique of orthodontic tooth movement was used and the experiment was performed 6 to 8 weeks prior to animal sacrifice. Histological examination showed no foreign-body reactions and the root resorption that was observed was similar in both teeth with vital pulps and no pulps. Similar findings of no difference in the amount of resorption

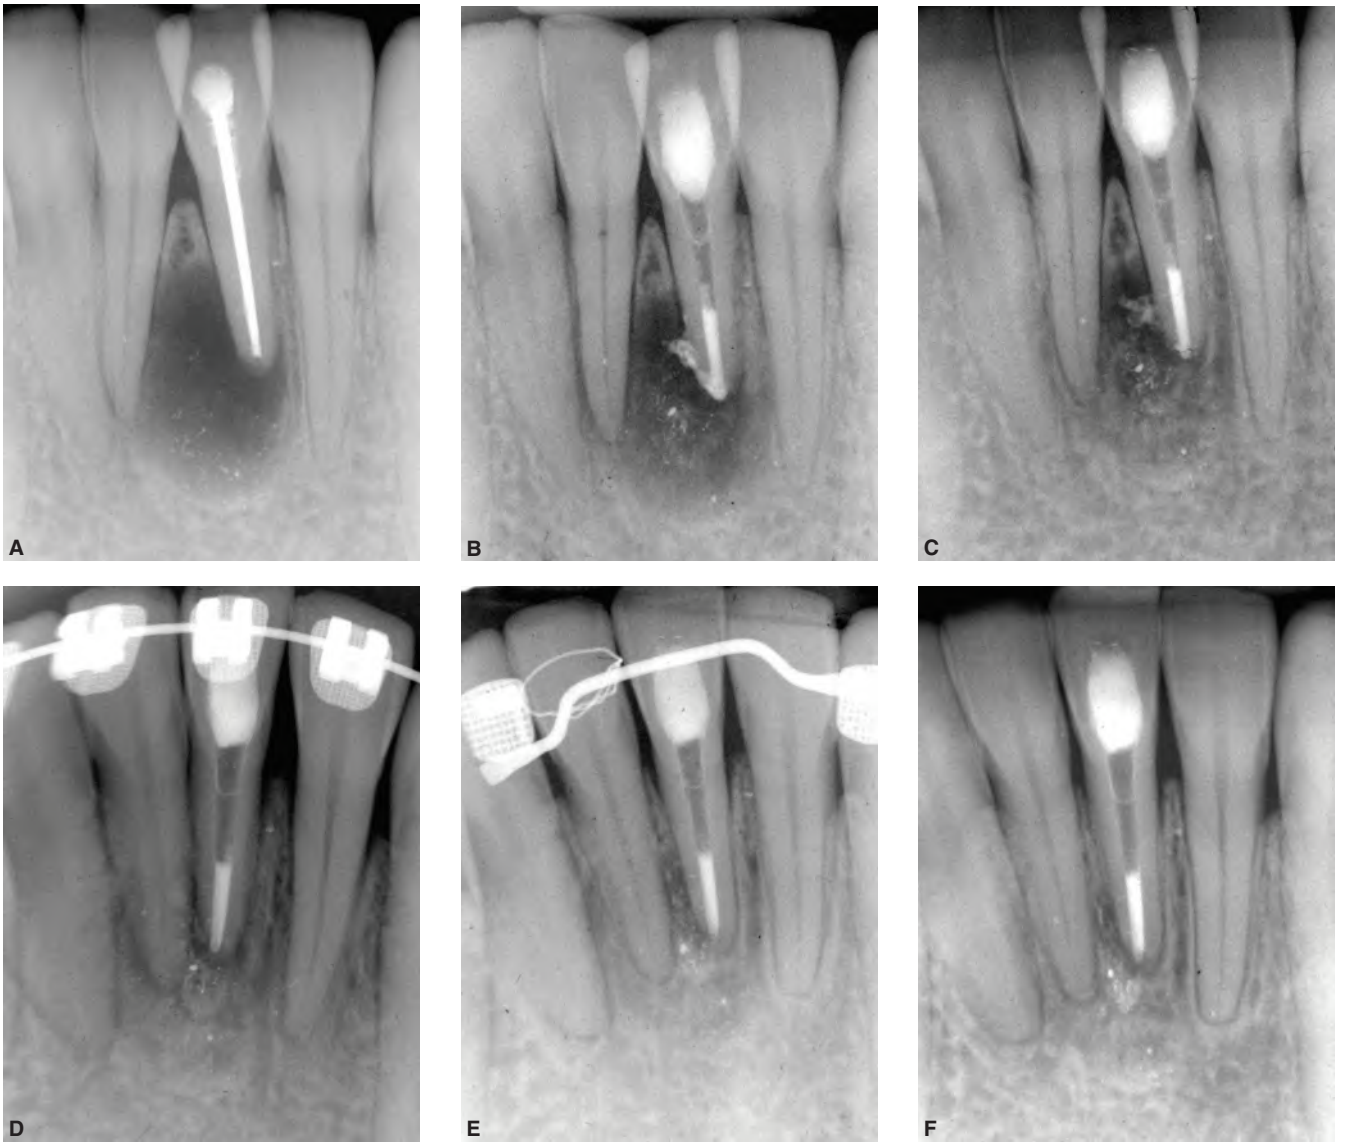

FIGURE 39-8 ***A.*** Mandibular incisor of a 26-year-old male scheduled for extraction prior to OTM due to misalignment and the presence of what was called an "apical cyst" following a root canal procedure. The patient preferred to retain the tooth, if possible. ***B.*** Revision of the previous root canal procedure. ***C.*** Six-month evaluation showing osseous repair. ***D.*** Nine-month evaluation showing repositioning of the tooth along with further osseous healing. ***E.*** Twelve-month evaluation with arch bar to stabilize the repositioned teeth. ***F.*** Eighteen-month evaluation; tooth is stable and patient is symptom-free, however, the tooth has not been restored properly.

with the two experimental groups was also reported by Weiss.[207] Wickwire et al. [208] reviewed 45 orthodontic patient case histories that contained 53 root-treated teeth from six practices that included the following orthodontic techniques: edgewise, Begg, and partial banding mechanotherapy. Historical data, lateral cephalograms, and appropriate radiographs were used to evaluate the teeth. Data revealed those teeth with root canal treatment moved as readily as teeth with vital pulps, but there *"appeared"* to be greater radiographic evidence of root resorption in the root-treated teeth when compared to the controls.

In an in vivo study on cats, Mattison et al. showed no significant difference between external root resorption of endodontically treated and teeth with vital pulps when both were subjected to orthodontic forces;[196] the same outcome was determined by Kindelan.[5]

The severity of external apical root resorption on teeth with vital pulps versus root treated teeth was determined by Spurrier and co-workers.[209] Forty-three patients who had one or more endodontically treated teeth before OTM that exhibited signs of apical root resorption after treatment were studied. Vital contralateral incisors served as controls. Incisors with vital pulps resorbed to

a significantly greater degree than incisors that had been root treated. Control teeth in males exhibited a statistically significant increase in resorption over control teeth in females. On the other hand, no differences were noted between genders with the treated teeth. Similar findings were recorded by Remington et al.,[210] although differences were not found in the incidence of resorption between teeth with vital pulps and root treated teeth, in a targeted population of British school children.[211]

Further studies evaluated the effectiveness of orthodontic forces in moving root-filled teeth and the degree of external apical root resorption that may occur in the ferret animal model.[197] Three months after root canal procedures and OTM with an orthodontic spring, tooth movement was assessed from pre- and post-treatment mandibular casts, and by fluorescence microscopy from labelled (procion red dye) bone deposition. Root-filled teeth and those with vital pulps moved similar distances when subjected to the same forces. Root-filled teeth showed greater loss of cementum after tooth movement than teeth with pulps, but without significant differences in radiographic root length. The root-filled teeth also showed more resorption lacunae than teeth with vital pulps, but the small difference in incidence between active (orthodontically) root-filled teeth and inactive root-filled teeth was not statistically significant. This suggests that the incidence of resorption lacunae may be related to non-vitality, and probably the presence of periradicular lesions, rather than orthodontic forces. These findings are in agreement with other studies.[196]

To the contrary, Bender and associates suggested that the loss of the release of neuropeptides from a pulp that has been removed would result in a decrease of the CGRP-IR fibers and a reduction in the amount of resorption seen in root treated teeth.[171] These suggestions supported the findings of other investigations,[212,213] especially when using attractive magnets for controlled tooth extrusion following deep coronal fractures.[214] In the former studies, the periodontal vascular network and axonal characteristics were within normal limits with no significant changes in blood flow or neuronal densities. In the latter study, no resorption was noted.

In a sample of 39 pairs of contralateral teeth with and without root canal treatment in 36 patients, Mirabella and Årtun found that there was significantly less resorption in root-treated teeth.[215] Here again, to the contrary, other studies found that there was no significant difference in the amount or severity of resorption during OTM between root-filled teeth and their contralateral teeth with vital pulps.[216] The study was done on adult patients (n = 77) with a mean age of 32.7 ± 10.7 years, using multiband/bracket orthodontic movement for at least 1 year. Further studies in this realm appear in conflict and quality evidence-based research is indicated.

Clinically, many important questions relative to this issue should be addressed during treatment planning.

Potential problem: Does the root canal treatment that has been provided appear to be at the highest level of technical excellence, that is, are there any concerns radiographically or clinically (signs or symptoms) about the quality of the treatment?
Outcome-solution: A thorough examination is essential of each tooth that has been root treated. If necessary, referral to a specialist should be considered. There should be no evidence of discomfort to function and no evidence of radiolucencies, apically or laterally on the specific teeth, or for that matter active resorption. The root canal filling should be dense (no voids especially in the apical 1/3) and positioned at the end of the root canal. Excessive extrusion of root filling materials may predispose to a greater inflammatory response during tooth movement.

Potential problem: Is there any reason to question the integrity of the coronal restoration *vis a vis* the potential for coronal leakage that might be contaminating the root canal system?
Outcome-solution: Good periapical and bitewing radiographs must be made and evaluated. If still in doubt, a CBCT may be indicated. Restorative–tooth margins must be evaluated as well as determining the presence or absence of periodontal disease. Restorations must be stable and exhibit no obvious clinical defects.

Potential problem: If root-filled teeth are subject to the resorptive phenomenon during tooth movement, what will happen to the root canal filing material?
Outcome-solution: The tooth may resorb, exfoliate, and the filling material may be removed with the tooth. Likewise, the tooth may resorb, exfoliate, and the filling material may be left in the bone. In these cases, if the material is gutta-percha, then a fibrous capsule will probably surround it. It is also possible that a sinus tract may form, and the material will require removal. With gutta-percha present, the extended material may undergo resorption after the tooth has undergone resorption and exfoliation. In some cases the root may begin to resorb, exposing the filling material; subsequently the resorption ceases with the filling material protruding beyond the new apical foramen. In this situation the root is often seen to develop a new periodontal ligament space and lamina dura around the root apex in close approximation to the filling material. In other cases, once the apical resorption begins a radiolucency develops around the root apex and the filling material. A sinus tract may be developing, or there may be incidences of localized swelling. Likewise, the tooth may remain symptom free and function normally.

Potential problem: Will the apical seal in the root canal system be altered, resulting in failure of the root canal treatment if resorption should occur?
Outcome-solution: If a root canal has been properly enlarged, shaped, cleaned, disinfected, and three-dimensionally obturated, then the apical seal would be sustained no matter what the extent of the apical resorption. Here too, however, multiple possibilities exist. Although the apical seal remains intact during the resorptive process, the complete seal of the canal may be challenged by coronal leakage. Exposure of the dentinal tubules that may harbor necrotic tissue, bacterial endotoxins, biofilms and bacteria may serve as sources that provide sufficient apical irritation to stimulate an extended or deleterious inflammatory resorptive process. Clinical evidence exists for apical root resorption on teeth with previous root canal treatment in which a portion of the root is missing, the filling material is visible in the surrounding periradicular tissues, no radiographic evidence of pathosis exists, and a normal periodontal ligament space and lamina dura are present.

While contemporarily popular for intruding or extruding teeth, mini-screws or temporary anchorage devices may result in pulpal problems or root resorption. Damage to the dental pulp or root structure could occur with the aberrant placement of these devices.

Orthodontic miniscrews have become quite popular due to their simplicity of both placement and removal, along with the need for minimal patient compliance.[217,218] Once placed, they generally remain stationary in the bone and provide increased anchorage capacity for tooth movement, with particularly good outcomes with palatal placement.[218] Details on their advantages on research activities evaluating their outcomes have been identified in the literature, along with several of the complications encountered in their use.[219,220] These complications include injury or damage to adjacent structures, such as periodontal ligament, tooth root, nerves, blood vessels, sinus, and mandibular canal. Animal studies have indicated that pulp and root damage from miniscrew placement rarely affects the prognosis of the tooth,[221] although inflammation and infection can occur around the miniscrew implant. When the damage from the placement of the anchorage device is limited to the cemental surface, healing occurred in time, with no adverse effects on the tooth.[222,223] However, when the miniscrews were place into the roots, close to 80% failed, but ultimately the defects healed with an osteoid or osteocementum tissue.[224,225] The actual failure of miniscrews is primarily due to their inability to remain anchored in the bone under the applied forces or when in advertently placed into a root.[220] With respect to the former, the thickness of the cortical plate appears to play a major role in retention and force distribution.[226]

From an endodontic standpoint, necrotic pulps have been identified due to damage caused by incorrect miniscrew placement[227] as well as extensive apical resorption during extensive intrusive movements using miniscrew anchorage;[228] to both pulpal damage and root damage requiring both nonsurgical and surgical root canal procedures;[229] and to root damage requiring surgical repair.[230]

Teeth undergoing normal apical root closure, or those that have been treated to allow for apexogenesis, can be moved orthodontically.

In teeth undergoing apexogenesis, there is minimal information at best as to the impact of orthodontic tooth movement. Apexogenesis is the continued and normal formation of the root and its apex[231] and is not really a treatment procedure. This term applies to teeth in which the coronal pulp has been compromised through trauma or caries, but clinically it is determined that the apical to middle portions of the pulp are sufficiently viable to allow root development to continue. Often these pulps, when exposed, have been capped with $Ca(OH)_2$ or MTA (either as a pulp cap or the material has been placed on the radicular pulp stump during a pulpotomy).[232–235] With the open apex and enhanced blood flow, normal root formation usually occurs; however, during movement, Hertwig's Sheath may be displaced resulting in an anatomically abnormal root shape, stunted root growth, or possibly even death of the sheath's cells. Clinical experience would tend to support the safe movement of these teeth, although each case will present with different circumstances and needs.

Teeth with non-vital pulps and open apices may also be considered for OTM provided there is no apparent infection present. If infection is present, root treatment using apexification or regenerative procedures must be considered.

With a significant amount of trauma occurring in younger patients who may have teeth in various stages of root development, this issue is of great importance; however, little detailed evidence is available regarding outcomes. Case reports[236] and anecdotal evidence[237] have indicated that teeth undergoing apexification may actually display the formation of a hard tissue barrier during orthodontic tooth movement as opposed to apical resorption.[238]These clinical findings would tend to support the theories of Ooshita[132] and Hamersky et al.[133] in which the accelerated biological activity of the periradicular tissues during tooth movement may have a beneficial effect on a tooth with an open or large apical foramen. In this regard the use of $Ca(OH)_2$ for the apexification procedure would tend to provide an environment conducive for a positive outcome. However, when considering the amount of apexification that is being done contemporarily in one visit using

mineral trioxide aggregate (MTA), no information is available on the outcome of this technique relative to hard tissue formation or apical resorption.[239,240] What is known however is that MTA stimulates the formation of calcium hydroxide, with subsequent formations of calcium phosphates and hydroxyapatite, that are conducive to hard tissue formation (Figure 39-9).[241–243] Moreover, the long-term use of calcium hydroxide may impact on the strength of the dentin.[244] Recent case reports have focused on the use of platelet-rich plasma as an internal matrix followed by the placement of MTA[245,246] or Biodentine (a calcium sulfate bioceramic).[247,248]

Often teeth with open apices are subjected to multiple, and at times, different types of trauma. Each particular set of circumstances must be carefully assessed and integrated treatment plans developed to achieve success.

REVITALIZATION/REGENERATION

The initiative of revitalization/regeneration of the dental pulp or mesenchymal tissues in the case of a seemingly necrotic pulp and open, immature apical formation has developed some of its own nomenclature in its claims, such as bioroot engineering, pulp revascularization, regenerative endodontic treatment or regenerative therapies, regenerative scaffolds and stem cells from the apical papilla (SCAP).[249–252]

While only supported by numerous diverse case reports or case series at this moment, there is a significant research initiative to pursue this model, calling it "the hidden treasure in apical papilla."[251,253] The treasure refers to the uniqueness of the SCAP relative to cellular types and their potential for differentiation and expression of their genetic potential, for example, cells that have the phenotypic capability of becoming new odontoblasts. If possible, this combination, along with the genetic capabilities of cells from the periodontal ligament, or periodontal ligament stem cells (PDLSCs) would be able to truly regenerate the lost or damaged tissues.[251] While the future of this approach to pulpal regeneration appears promising, not all studies have been positive. Chen and co-workers found, in a case series, that the outcome of continued root development was not as predictable as increased thickening of the canal walls in human immature permanent teeth with infected necrotic pulp tissue and apical periodontitis/abscess after revascularization procedures. Continued root development of revitalized immature permanent necrotic teeth depends on whether the Hertwig's epithelial root sheath survives in case of an apical periodontitis/abscess. Severe pulp canal calcification (obliteration) by hard tissue formation might be a complication of internal replacement resorption or union between the intracanal hard tissue and the apical bone (ankylosis) in revitalized immature permanent teeth with necrotic pulps.[254] Even in light of the variable outcomes of this proposed treatment modality, there is no information available relative to the OTM of any of the teeth that have undergone these procedures.

The potential impact of sequelae following OTM on non-surgical root canal procedures or surgical endodontics has received mixed attention and more definitive studies are indicated.

The major focus of any endodontic intervention appears to be in the prevention or management of post OTM root resorption. Many publications have addressed clinical perspectives and empirical approaches to this challenge and the reader is referred to them for a more complete assessment of the issues at hand.[255] However, some recent perspectives have been gleaned on the determination of root canal working length following root resorption as a sequelae to OTM.[256] Using electronic apex locators, the accuracy of working length determination was not affected by resorptive defects in a model that simulated apical root resorption.

The earliest report dealing with the orthodontic movement of teeth with previous endodontic nonsurgical and surgical treatment is attributed to Baranowskyj.[257] In this canine study the rate of healing of the hard and soft alveolar tissues was assessed on teeth that had root fillings and previous periapical surgeries, and that were subject to an early application of orthodontic intrusive forces. Histological assessment of 6-week specimens indicated that healing was completely delayed in the teeth with root fillings and root-end resections. There was no visible attempt at bone regeneration in the surgical defect or at formation of a new periodontal ligament or cementum. The surgical defects were filled with degenerating blood clots and there was evidence of attempts at organization and infiltration with endothelial buds (angiogenesis). The control group showed almost complete healing of all tissues. Histological assessment of both groups at 12 weeks indicated regeneration of bone and periodontal ligament was complete in the control and approximately two-thirds of the experimental group. The apical cementum in the experimental group was also only one-third as complete and a mild resorptive response was evident. The early application of orthodontic forces after surgical endodontic treatment markedly delayed the healing process and the specific cause was identified as tooth mobility and its impact on the ossifying media of the supporting apical tissues.

While not definitive, another report on the orthodontic movement of root-end resected teeth is attributed to Wickwire et al.[208] In their root-treated population of 53 teeth that were moved orthodontically, four had received root-end resections. Although there was a greater incidence of root resorption with the movement of root-treated teeth, no mention was made as to the status of the root-end resected teeth.

While successful movement of teeth following surgical endodontic procedures has been observed clinically, very little has been written addressing the ramifications of the approach to treatment. Considerations would include the propensity for a greater amount of apical resorption due to

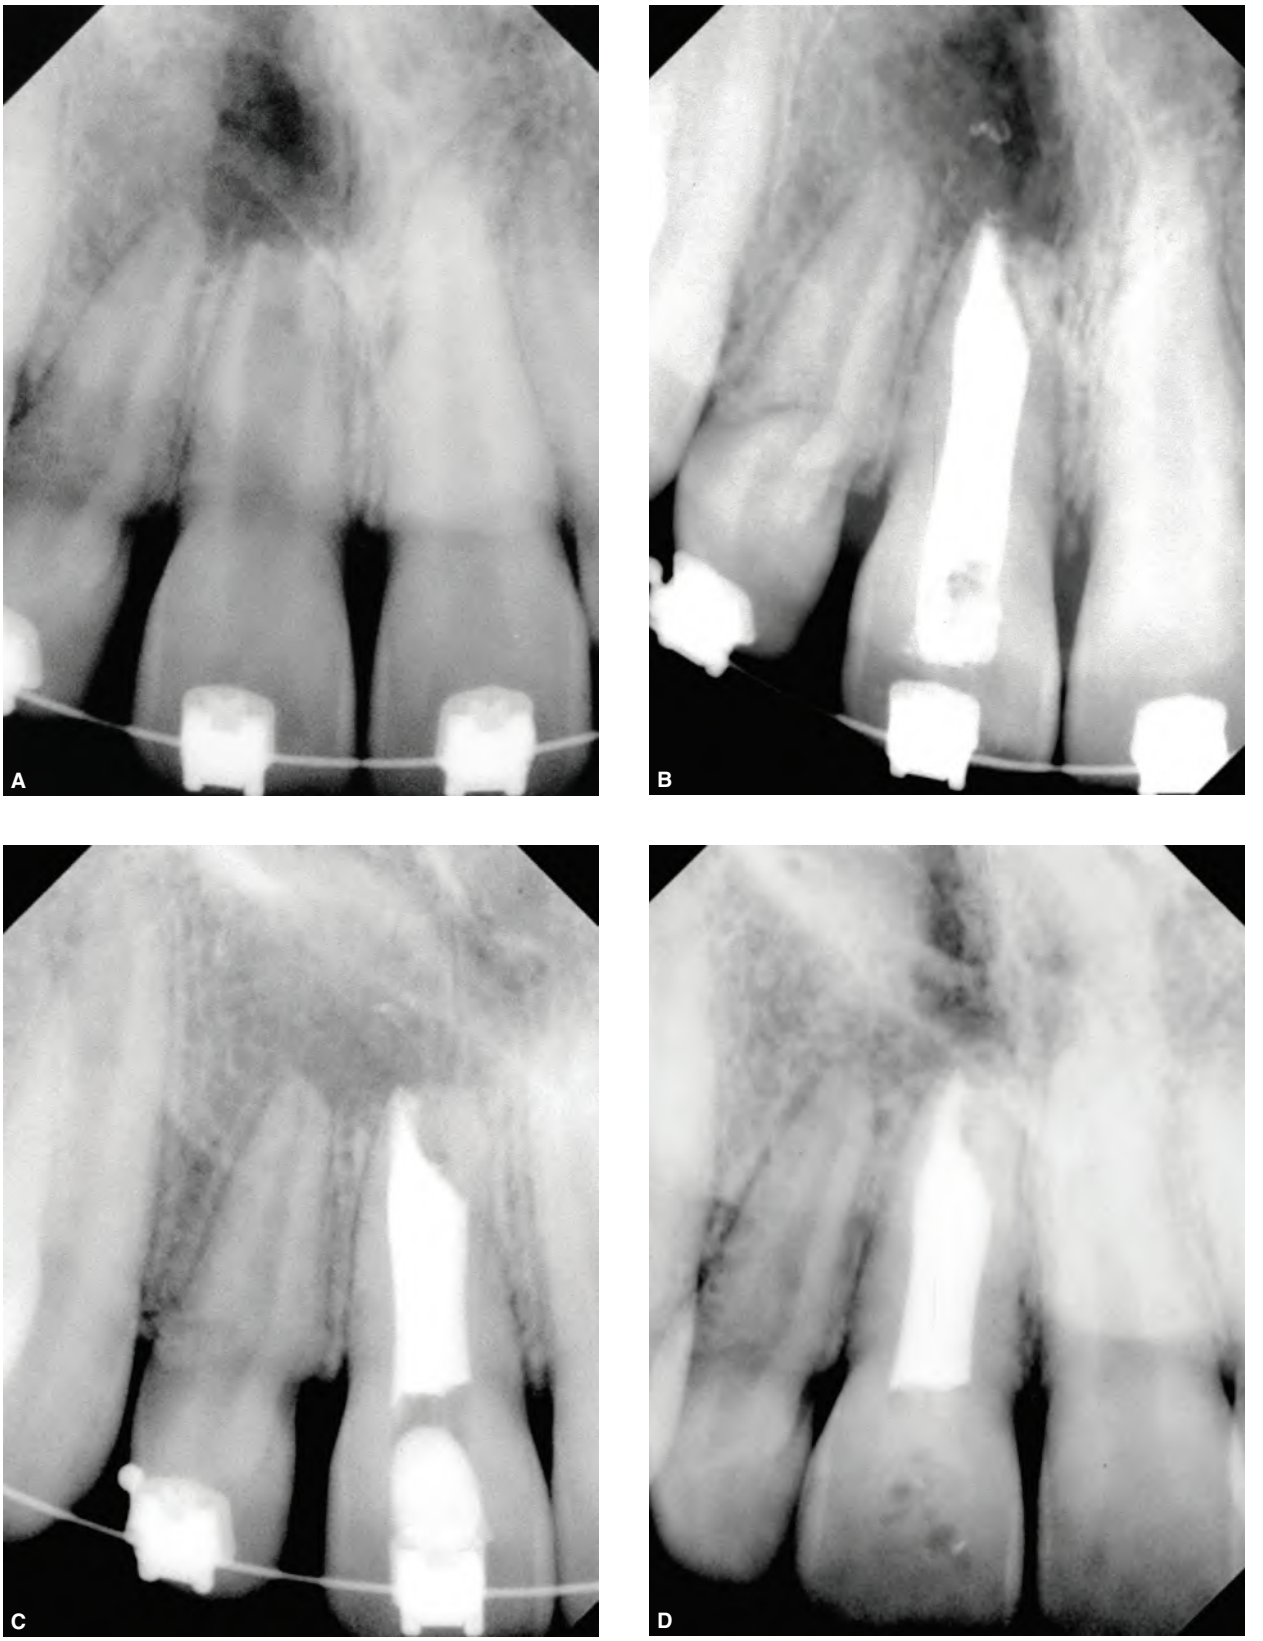

FIGURE 39-9 ***A.*** Radiograph of a maxillary right central incisor taken after OTM has begun. The 18- year-old female patient had suffered trauma at an earlier age, however no periapical radiograph was taken prior to OTM nor were the teeth tested. ***B.*** The tooth was accessed (pulp was necrotic), the canal shaped, cleaned and disinfected and filled entirely with MTA. Note, there was only a small opening apically, even though the original radiograph depicted immature root development. ***C.*** Six-month evaluation showing some osseous repair. ***D.*** Eighteen-month evaluation showing good healing. The patient is symptom-free.

the exposed dentin on the resected root face, irritation and persistent inflammation that may be caused by the root-end filling material, and the adequacy of the seal achieved with the root-end filling material. Other factors to consider are the quality of the nonsurgical root canal obturation at the level of resection, the potential for exposed, contaminated dentinal tubules at the point of resection with potential for harboring residual bacteria, endotoxins and biofilms,[202,203] and the potential for localized marginal periodontitis in those cases where a dehiscence or fenestration may be present. In this context the major causes for failure following surgical endodontic procedures have been identified as failure to debride and obturate thoroughly the root canal system, and the superimposition of periodontal disease in the surgical site.[258,259] Low levels of success with surgical endodontics have been reported also in the absence of a sound buccal cortical plate of bone.[260,261] Recently this scenario has prompted the use of guided tissue regenerative procedures to enhance surgical outcomes.[262–268] These issues must be considered in the treatment planning phase prior to tooth movement.

While there is a paucity of studies, a recent case report by Stefopoulos[269] identified a positive long-term outcome of root-end surgery combined with OTM. A 5-year recall indicated healing that could be classified as incomplete healing or scar tissue. Therefore, if surgical endodontic intervention is absolutely necessary during OTM, then the orthodontic component should be delayed for possibly up to 6 months to allow for tooth stability and significant healing of the periradicular tissues. Another consideration would be to use bone grafting material concomitant with the surgical procedure to stabilize the extracellular matrix and ossifying media forming in the surgical site.

In summary, the complete assessment of all teeth, whether in the young patient or adult, in which OTM is being considered, is essential. Thorough records, including radiographs and photographs before or during orthodontic diagnosis and treatment planning are indicated. Reassessment during the OTM and documentation of any new findings compared to the baseline information are necessary to determine if the dental pulp is undergoing adverse changes or if root resorption is present. This is especially important during OTM of previous traumatized teeth. Prevention in the endodontic-orthodontic relationships that exist, when possible, is paramount to tooth retention and distress-free function.

Chapter 40

Tooth Discoloration and Bleaching of Non-Vital Teeth

Ilan Rotstein

Tooth discoloration is a clinical esthetic problem. Often, patients seek corrective treatment modalities to improve the appearance of their teeth, mainly in the esthetic zone. In vital teeth, bleaching is usually done extracoronally. In non-vital teeth, it is often done intracoronally; variations may exist. This chapter focuses on bleaching of non-vital teeth.

ETIOLOGY OF TOOTH DISCOLORATION

Tooth discoloration can be induced by intrinsic stains incorporated in tooth structures and extrinsic stains deposited on tooth surfaces. This can be due to patient- or dentist-related causes[1] (Table 40-1). Correct diagnosis of the etiology of discoloration is essential for treatment decision-making and outcome assessment.

Patient-Related Causes

Pulp Necrosis

Microbial, mechanical, or chemical irritation to the pulp may result in tissue necrosis. Disintegration by-products penetrate the dentinal tubules and discolor the surrounding dentin. The degree of discoloration is directly related to how long the pulp has been necrotic. The longer the discoloring compounds are present in the pulp chamber, the greater is the discoloration. This type of discoloration can often be corrected successfully with intracoronal bleaching (Figures 40-1 and 40-2).

Intrapulpal Hemorrhage

Intrapulpal hemorrhage and lysis of erythrocytes are common results of traumatic injury to a tooth. Blood disintegration products, mainly iron sulfides, flow to the pulp lumen and permeate into the dentin tubules to discolor the surrounding tissue. If the pulp becomes necrotic, the discoloration persists and usually intesifies with time. If the pulp recovers, the discoloration may be reversed, with the tooth regaining its original shade. Intracoronal bleaching is usually effective for treating this type of discoloration with high level of patient satisfaction[2-5] (Figures 40-3 and 40-4)

TABLE 40-1 Etiology of Tooth Discoloration

Patient-related causes	Dentist-related causes
Pulp necrosis	Pulp tissue remnants
Intrapulpal hemorrhage	Intracanal medicaments
Calcific metamorphosis	Endodontic obturation materials
Age	Restorative materials
Developmental defects	
Medications	

Calcific Metamorphosis

Calcific metamorphosis is seen most frequently in the anterior teeth. It is a pulpal response to trauma that is characterized by rapid deposition of hard tissue within the root canal

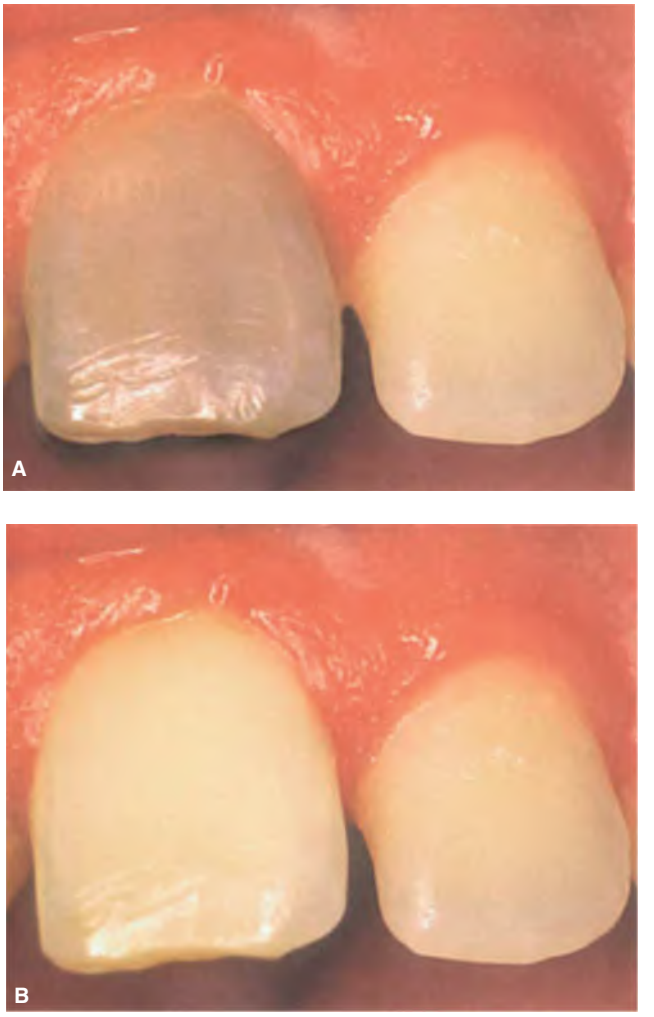

FIGURE 40-1 Discoloration of a maxillary central incisor caused by pulpal necrosis. ***A.*** Tooth shade prior to bleaching. ***B.*** A mixture of sodium perborate and distilled water, placed in the chamber two times for 3 weeks, achieved lightening of the tooth to its natural shade. (Reproduced with permission from Claisse-Crinquette A, Endo Contact, Paris, France, 1999;2:16-20.)

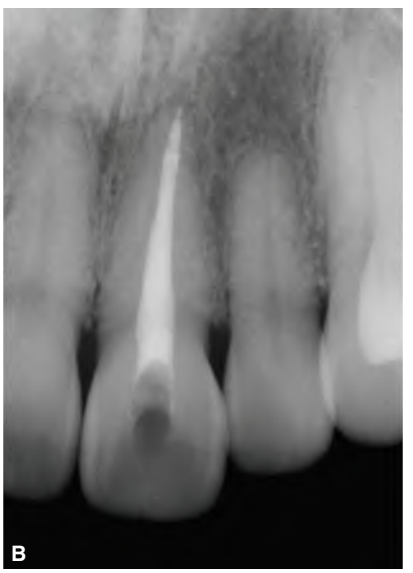

FIGURE 40-2 Intracoronal bleaching of tooth discoloration due to pulp necrosis in a maxillary left central incisor of a 40-year-old female. ***A.*** Pre-treatment photograph. ***B.*** Post endodontic treatment radiograph of the discolored tooth. ***C.*** After 4 weeks of *walking bleach* with sodium perborate, the tooth regained its original shade. (Courtesy of Dr. Abdi Sameni, Los Angeles, CA, U.S.A.)

FIGURE 40-3 Intracoronal bleaching of tooth discoloration following a traumatic injury in a maxillary left central incisor of a 25-year-old female. Part of the crown was fractured 13 years previously and was restored with a bonded composite restoration. Endodontic treatment was also done. ***A.*** Pre-treatment photograph showing discolored shade of the crown in contrast to the color of the bonded restoration. ***B.*** A shade guide is used for recording purposes and treatment planning. ***C.*** After 4 weeks of *walking bleach* with sodium perborate, the discolored part of the tooth has regained its original shade and is now matching the bonded restoration. In the long term, a bonded porcelain veneer will be beneficial. (Courtesy of Dr. Abdi Sameni, Los Angeles, CA, U.S.A.)

space. In certain traumatic injuries, a temporary disruption of blood supply occurs, followed by the destruction of odontoblasts. These are replaced by undifferentiated mesenchymal cells that rapidly form reparative dentin. As a result, the translucency of the crowns of such teeth gradually decreases, giving rise to a yellowish or a yellow-brown discoloration. Root canal therapy is often required, followed by intracoronal bleaching.

FIGURE 40-4 Intracoronal bleaching in a traumatized maxillary left central incisor of a 23-year-old female. ***A.*** Tooth discoloration is reflected through the porcelain veneer restoration. ***B.*** Periapical radiograph of the affected tooth. The patient suffered a traumatic injury 9 years previously. Endodontic treatment was done that included apexification. ***C.*** The affected tooth is prepared for a porcelain crown and the adjacent tooth for a veneer restoration. Note, dentin discoloration in the maxillary left central incisor as compared to the adjacent right central incisor. ***D.*** Intracoronal bleaching with sodium perborate significantly improved the discoloration. ***E.*** The tooth was restored to esthetics and function. ***F.*** Clinical view of the esthetic zone showing harmonious tooth shades. (Courtesy of Dr. Abdi Sameni, Los Angeles, CA, U.S.A.)

Age

Tooth color tends to become progressively darker with age, which is a physiological change resulting from dentin apposition, thinning of the enamel, and changes of optical properties in tooth structure. Cumulative extrinsic stains from food and beverages also contribute to this type of tooth discoloration that becomes more pronounced in the elderly, owing to the inevitable cracking, crazing, and incisal wear of the enamel and the underlying dentin. Unless pulp pathosis is noted, intracoronal bleaching is not indicated. In such cases, extracoronal approach should be the treatment of choice.

Developmental Defects in Tooth Structure

Discoloration may result from developmental defects occurring during enamel and dentin formation, either hypocalcific or hypoplastic. Enamel *hypocalcification*, a distinct brownish or whitish area, is commonly found on the buccal aspect of affected crowns. The enamel is well formed with an intact surface.

Enamel *hypoplasia* differs from hypocalcification in that the enamel is defective and porous. This condition may be hereditary, as in *amelogenesis imperfecta*, or *hereditary hypophosphatemia*, or a result of environmental factors such as infections, tumors, or trauma. Presumably, during enamel formation, the matrix is altered and does not mineralize properly. The defective enamel is porous and readily discolored by materials present in the oral cavity. In such cases, bleaching effect may not be permanent, depending on the severity and extent of hypoplasia and the nature of discoloration.

Dental fluorosis, or mottled tooth, is a type of enamel hypoplasia. It is caused by an excessive exposure to fluoride during tooth formation, resulting in defects in mineralized structures, particularly in the enamel matrix. The severity of subsequent staining generally depends on the degree of hypoplasia that is directly related to the amount of fluoride exposure during odontogenesis.[6] The affected teeth are not discolored on eruption, but their porous surface attracts extrinsic stains present in the oral cavity. Discoloration is usually bilaterally symmetric. It presents as various degrees of intermittent white spotting, chalky or opaque areas, yellow or brown discoloration, and, in severe cases, surface pitting of the enamel. Discoloration of mild to moderate dental fluorosis is usually bleached externally, however, restorative approaches should be considered for the cases of severe dental fluorosis.

Several systemic conditions may also cause tooth discoloration. *Erythroblastosis fetalis*, for example, may occur in the fetus or in a newborn because of Rh incompatibility factors, resulting in the lysis of erythrocytes and incorporation of hemosiderin pigment in the forming dentin.[7] However, such discoloration is now uncommon. High fever during tooth formation may result in chronologic enamel hypoplasia that gives rise to banding-type surface discoloration. *Porphyria*, a metabolic disease, may also cause reddish or brownish discoloration of deciduous and permanent teeth. *Thalassemia* and sickle cell anemia may cause intrinsic blue, brown, or green discolorations. *Amelogenesis imperfecta* may result in yellow or brown discolorations. *Dentinogenesis imperfecta* causes brownish violet, yellowish, or gray discoloration. These conditions are usually not amenable to bleaching and correction by restorative means is preferred.

Discoloration Caused by Medications

Administration or ingestion of certain medications during tooth formation may cause severe discoloration both in enamel and dentin.[8-10] Tetracycline is an antibiotic that was used extensively during the 1950s and 1960s for prophylactic protection and for the treatment of chronic obstructive pulmonary disease, mycoplasma, and rickettsial infections. It was sometimes prescribed for long periods of time, years in some cases, and therefore was a common cause of tooth discoloration in children. While tetracycline is no longer prescribed for prolonged periods, dentists still face the residue of damage to teeth appearance from such medications.

Tooth shades from discoloration can be yellow, yellow-brown, brown, dark gray, or blue depending on the type of tetracycline, dosage, duration of intake, and patient's age at the time of administration. Discoloration is usually bilateral, affecting multiple teeth in both arches. Deposition of tetracycline may be continuous or in stripes depending on whether the ingestion was continuous or interrupted (Figure 40-5).

The mechanism of tetracycline discoloration is not fully understood. Tetracycline bound to calcium is thought to be incorporated into the hydroxyapatite crystal of both enamel

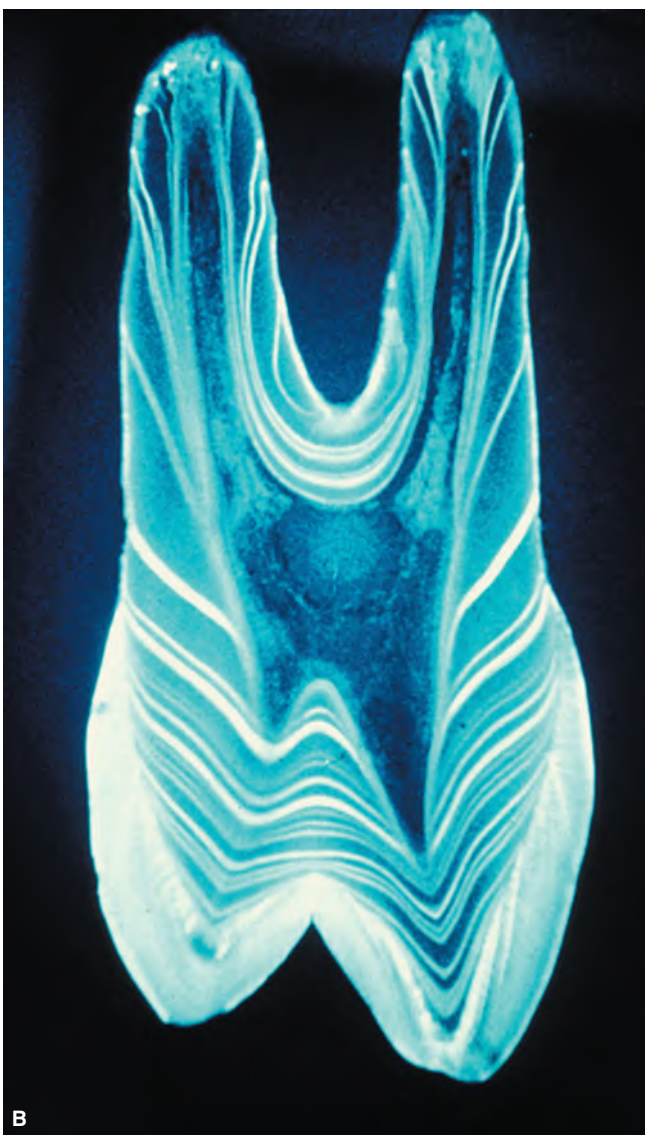

FIGURE 40-5 A AND B: Tetracycline-induced tooth discoloration. ***A.*** Clinical appearance. ***B.*** Fluorescent photomicrograph of an extracted tooth showing stripes of tetracycline deposition caused by start and stop of drug ingestion. (Image 5B, courtesy of Dr. D.L. Meyers., U.S.A.)

and dentin, but mostly found in dentin. The exposure of tetracycline-stained teeth to ultraviolet radiation leads to the formation of a reddish-purple oxidation by-product that discolors the teeth. In children, the anterior teeth often discolor first, whereas the less-exposed posterior teeth are discolored more slowly. In adults, natural photobleaching of the anterior teeth has been observed, particularly in individuals whose teeth are excessively exposed to sunlight owing to maxillary lip insufficiency.

Tetracycline discoloration has been classified into three groups according to severity.[11] First-degree discoloration is light yellow, light brown, or light gray and occurs uniformly throughout the crown, without banding. Second-degree discoloration is more intense and also without banding. Third-degree discoloration is very intense, and the clinical crown exhibits horizontal color banding. This type of discoloration usually predominates in the cervical regions. Correction of tetracycline-stained teeth may pose a clinical challenge. For mild to certain moderate cases, repeated external bleaching for an extended period can be effective.[12-14] However, severe cases, especially those of dark gray color, should be corrected by restorative means.

Dentist-Related Causes

Tooth discolorations caused by certain dental materials or inappropriate operating techniques can occur; such dentist-related discolorations are usually preventable and efforts should be made to avoid them.

Pulp Tissue Remnants

The tissue remaining in the pulp chamber disintegrates gradually and may cause discoloration. Therefore, pulp horns must always be included in the access cavity to ensure removal of pulpal remnants and to prevent retention of sealers at a later stage. Intracoronal bleaching in these cases is usually successful.

Intracanal Medicaments

Several intracanal medicaments can cause internal staining of dentin. Phenolics or iodoform-based medicaments sealed in the root canal and chamber are in direct contact with dentin, sometimes for long periods, allowing penetration and oxidation. These compounds have a tendency to discolor the dentin gradually. Intracoronal bleaching is often used to correct this problem.

Endodontic Obturation Materials

This is a frequent and severe cause of single tooth discoloration. Incomplete removal of obturating materials and sealer remnants from the pulp chamber, mainly those containing metallic components, often results in dark discoloration.[15-19] This can be easily prevented by removing all materials to a level just below the gingival margin (Figure 40-6). Intracoronal bleaching is the treatment of choice in addition to removing the obturating material. The prognosis, however, depends on the type of sealer and the duration of discoloration.

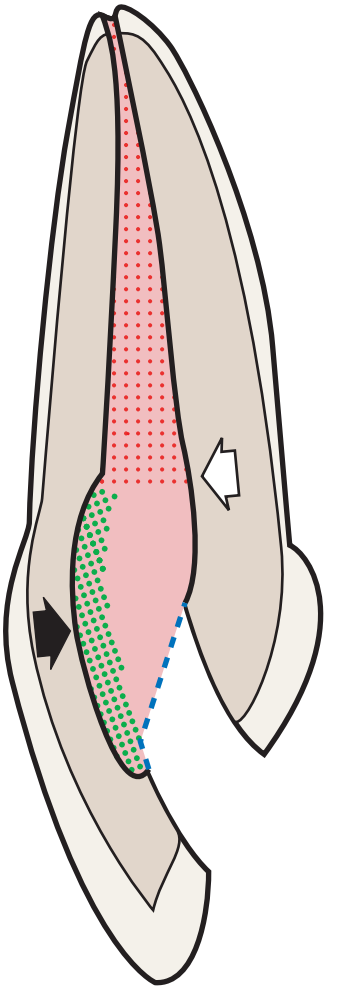

FIGURE 40-6 Gutta-percha, sealer, and dentin removal prior to bleaching. Green-dotted area represents gutta-percha filling that is removed to a level below the attached gingival (white arrow) along with the removal of dentin to eliminate heavy stain concentration and pulp horn material (black arrow).

Restorative Materials

Amalgams

Amalgams were frequently used in the past to restore lingual access preparations or developmental grooves in anterior teeth. In addition to the inherent dark, metallic color of an amalgam restoration, amalgams degrade over time and corrosion products can cause tooth discoloration. Such discolorations are difficult to bleach and tend to re-discolor with time. Amalgam restorations in premolar teeth may also be an esthetic concern in patients with wide smile line. Sometimes the dark appearance of the crown is caused by an amalgam restoration that can be seen through the tooth structure. In such cases, replacing the amalgam with an esthetic restoration usually corrects the problem.

Pins and Posts

Metal pins and prefabricated posts have sometimes been used to reinforce a composite restoration in the anterior dentition. Discoloration from inappropriately placed pins and

posts is caused by the metal seen through the composite or tooth structure. In such cases, coverage of the pins with a white cement or removal of the metal and replacement of the composite restoration is indicated.

Resin Composites

Microleakage around resin composite restorations attracts extrinsic stains. Open margins allow stains to enter the interface between the restoration and the tooth structure and discolor the underlying dentin. Resin composites may also become discolored with time, affecting the shade of the crown. These conditions are generally corrected by replacing the old composite restoration with a new, well-sealed one.

TOOTH BLEACHING

Bleaching is a treatment modality involving an oxidative chemical that alters the light-absorbing and/or light-reflecting nature of a material structure, thereby increasing its perception of whiteness. In-office tooth bleaching using peroxide compounds has been practiced in dentistry for more than a century.

Bleaching Materials

The active ingredients in tooth bleaching materials are peroxide compounds. While currently a variety of bleaching materials are available, the most commonly used peroxide compounds are sodium perborate, hydrogen peroxide, and carbamide peroxide. Bleaching materials for extracoronal bleaching mainly contain hydrogen peroxide and carbamide peroxide, whereas sodium perborate is primarily used for intracoronal bleaching.

Sodium Perborate

Sodium perborate ($NaBO_3$) is available in powdered form or as various commercial preparations. When fresh, it contains about 95% perborate, corresponding to 9.9% of the available oxygen. Sodium perborate is stable when dry. In the presence of acid, warm air, or water, however, it decomposes to form sodium metaborate, H_2O_2, and nascent oxygen. Three types of sodium perborate preparations are available: monohydrate, trihydrate, and tetrahydrate. They differ in oxygen content that determines their bleaching efficacy.[20] Commonly used sodium perborate preparations are alkaline, and their pH depends on the amount of H_2O_2 released and the residual sodium metaborate.[21] Sodium perborate is more easily controlled and is safer than concentrated H_2O_2. Therefore, it should be the material of choice in most intracoronal bleaching procedures (Figure 40-7).

Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) has been used at various concentrations ranging from 3% to35%. H_2O_2 at high concentration is caustic and burns tissues on contact. These materials must be handled with care to avoid their contact with tissues during the handling and bleaching treatment. H_2O_2 is not recommended for routine intracoronal use in non-vital teeth.

FIGURE 40-7 Sodium perborate powder and water are mixed to a thick consistency of wet sand.

Carbamide Peroxide

Carbamide peroxide ($CH_6N_2O_3$), also known as urea hydrogen peroxide, exists in the form of white crystals or as a crystallized powder containing approximately 35% H_2O_2. It forms H_2O_2 and urea in aqueous solution. Concentrations ranging from 10 to 30% (equivalent to approximately 3.5% to 8.6% H_2O_2) are often used. Occasionally, higher concentrations were used in selected cases.

Bleaching preparations containing carbamide peroxide usually also include glycerine or propylene glycol, sodium stannate, phosphoric or citric acid, and flavor additives. In some preparations, carbopol, a water-soluble polyacrylic acid polymer, is added as a thickening agent. Carbopol also prolongs the release of active peroxide and improves shelf life. Carbamide peroxide is mainly used for extracoronal bleaching. Nevertheless, it has been used successfully, either alone or in combination with another agent, for intracoronal bleaching of non-vital teeth.[19,22,23]

Bleaching Mechanisms

The exact mechanisms of tooth bleaching have not yet been fully elucidated; however, it is generally believed that free radicals produced by H_2O_2 may be responsible for bleaching effects, and they are similar to that in textile and paper bleaching. H_2O_2 diffuses through the enamel and dentin, producing free radicals that react with pigment molecules breaking

their double bonds. The change in pigment molecule configuration and/or size may result in changes in their optical properties, and consequently, the perception of a lighter color by human eyes. This assumption also helps to explain the common observation of shade rebounding shortly after the bleaching treatment, probably due to the reformation of double bonds. In addition to the chemical effect, other possible mechanisms include cleansing of tooth surface, temporary dehydration of enamel during the bleaching process, and change of enamel surface.

A number of factors, relating to both the patient (e.g., age, gender, and initial tooth color), the bleaching material used (e.g., type of peroxide compound, peroxide concentration, other ingredients), and application method (e.g., contact time, application frequency) may contribute to the bleaching efficacy and the subsequent stability of the esthetic results.

Intracoronal Bleaching of Endodontically Treated Teeth

Intracoronal bleaching of endodontically treated teeth may be successfully carried out with satisfying long-term esthetic results (Figure 40-8). A successful outcome depends mainly on the etiology, correct diagnosis, and proper selection of bleaching technique[1,24,25] (Table 40-2). The methods most commonly employed to bleach endodontically treated teeth are the "walking bleach" and the thermocatalytic techniques. *Walking bleach* is preferred since it is safer, more comfortable for the patient, and requires less chair time.[26-29]

Walking Bleach Technique

The term *walking bleach* was first coined by Nutting and Poe[30] referring to the bleaching action occurring between patients' visits. Since that time, the technique evolved and underwent few modifications, mainly by eliminating the use of Superoxol (30% H_2O_2) making it a very popular and safe technique.[29,31,32] The *walking bleach* technique should be attempted first in all cases requiring intracoronal bleaching. It involves the following steps:

1. Familiarize the patient with the possible causes of discoloration, the procedure to be followed, the expected outcome, and the possibility of future rediscoloration.

TABLE 40-2 Indications and Contraindications for Bleaching Endodontically Treated Teeth

Indications	Contraindications
• Discolorations of pulp chamber origin • Dentin discolorations • Discolorations not amenable to extracoronal bleaching	• Superficial enamel discolorations • Defective enamel formation • Severe dentin loss • Presence of caries • Discolored composites

FIGURE 40-8 Intracoronal bleaching of an endodontically treated maxillary left central incisor in a 30-year-old female. ***A.*** Discoloration is reflected through the porcelain veneer restoration. ***B.*** Periapical radiograph of the affected tooth. Intracoronal bleaching was done after completion of the endodontic treatment. A paste of sodium perborate mixed with water was sealed in the pulp chamber. ***C.*** *Walking bleach* improved the shade of the porcelain veneer. ***D.*** Three-year follow up photograph showing esthetic results. ***E.*** Three-year follow up radiograph. (Courtesy of Dr. Abdi. Sameni, Los Angeles, CA, U.S.A.)

2. Radiographically assess the status of the periapical tissues and the quality of endodontic obturation. Endodontic failure or questionable obturation should always be retreated prior to bleaching.
3. Assess the quality and shade of any restoration present and replace it if defective. Tooth discoloration is frequently the result of leaking or discolored restorations. In such cases, cleaning the pulp chamber and replacing the defective restorations will usually suffice.
4. Evaluate tooth color with a shade guide and, if possible, take clinical photographs at the beginning of and throughout the procedure. These provide a point of reference for future comparison.
5. Isolate the tooth with a dental dam. The dam must fit tightly at the cervical margin of the tooth to prevent possible leakage of the bleaching agent onto the gingival tissue. Interproximal wedges and ligatures may also be used for better isolation.
6. Remove all restorative materials from the access cavity, expose the dentin, and refine the access. Verify that the pulp horns and other areas containing the pulp tissue are clean.
7. Remove all materials to a level just below the labial–gingival margin. Orange solvent, chloroform, or xylene on a cotton pellet may be used to completely dissolve sealer remnants. Etching the dentin with phosphoric acid is unnecessary and may not improve the prognosis.[33]
8. To cover the endodontic obturation, apply a sufficiently thick layer, at least 2 mm, of a protective white cement barrier, such as polycarboxylate cement, zinc phosphate cement, glass ionomer, intermediate restorative material (IRM) (Dentsply/ Caulk, York, PA, U.S.A.), white colored MTA (Dentsply/Tulsa Dental, Tulsa, OK, U.S.A.), or Cavit (3M ESPE, St. Paul, MN, U.S.A.). The coronal height of the barrier should protect the dentinal tubules and conform to the external epithelial attachment.[34]
9. Prepare the *walking bleach* paste by mixing sodium perborate and an inert liquid, such as water, saline, or anesthetic solution, to a thick consistency of wet sand. Although sodium perborate plus 30% H_2O_2 mixture may bleach faster, in most cases, long-term results are similar to those with sodium perborate and water alone and therefore need not be used routinely.[3,4,31,32] With a plastic instrument, pack the pulp chamber with the paste. Remove excess liquid by tamping with a cotton pellet. This also compresses and pushes the paste into all areas of the pulp chamber.
10. Remove the excess bleaching paste from undercuts in the pulp horn and gingival area and apply a thick well-sealed temporary filling (preferably IRM) directly against the paste and into the undercuts. To ensure a good seal, carefully pack the temporary filling, at least 3 mm thick.
11. Remove the dental dam and inform the patient that bleaching agents work slowly and that significant lightening may not be evident for several days.
12. Evaluate the patient 2 weeks later and, if necessary, repeat the procedure several times.[29,31] Repeat treatments are similar to the first one.
13. As an optional procedure, if initial bleaching is not satisfactory, strengthen the walking bleach paste by mixing sodium perborate with gradually increasing concentrations of H_2O_2 (3% to 30%) instead of water. The more potent oxidizers may have an enhanced bleaching effect but are not used routinely because of the possibility of permeation into the tubules and damage to the cervical periodontium by these more caustic agents. In such cases, a protective cream, such as Orabase or Vaseline, must be applied to the surrounding gingival tissues prior to dam placement.
14. In most cases, discoloration will improve after one to two treatments. If after three attempts there is no significant improvement, reassess the case for correct diagnosis of the etiology of discoloration and treatment plan.

Thermocatalytic

This technique involves placement of the oxidizing chemical, generally H_2O_2, into the pulp chamber followed by heat application either by electric heating devices or specially designed lamps.[35] Care must be taken when using these heating devices to avoid overheating the teeth and the surrounding tissues. Intermittent treatment with cooling breaks is preferred over a continuous session. In addition, surrounding soft tissues should be protected with Vaseline, Orabase, or cocoa butter during treatment to avoid heat damage.

Potential damage by the thermocatalytic approach is external cervical root resorption caused by irritation to the cementum and the periodontal ligament (Figure 40-9). This is possibly attributable to the oxidizing agent combined with heating.[36,37] Therefore, application of highly concentrated H_2O_2 and heat during intracoronal bleaching is questionable and should not be carried out routinely.

Ultraviolet Photooxidation

This technique applies ultraviolet light (instead of a bleaching lamp) to the labial surface of the tooth to be bleached. A H_2O_2 solution is placed in the pulp chamber on a cotton pellet followed by a 2-minute exposure to ultraviolet light. Supposedly, this causes oxygen release, like the thermocatalytic bleaching technique.[38]

Potential Adverse Effects from Intracoronal Bleaching

Chemical Burns

High concentrations of H_2O_2 are caustic and cause chemical burns and sloughing of the gingiva. When using such solutions, the H_2O_2 concentration should be maintained as low as practical and the soft tissues should always be protected with Vaseline, Orabase, or cocoa butter. H_2O_2 at high concentration is not the agent of choice for routine intracoronal bleaching.

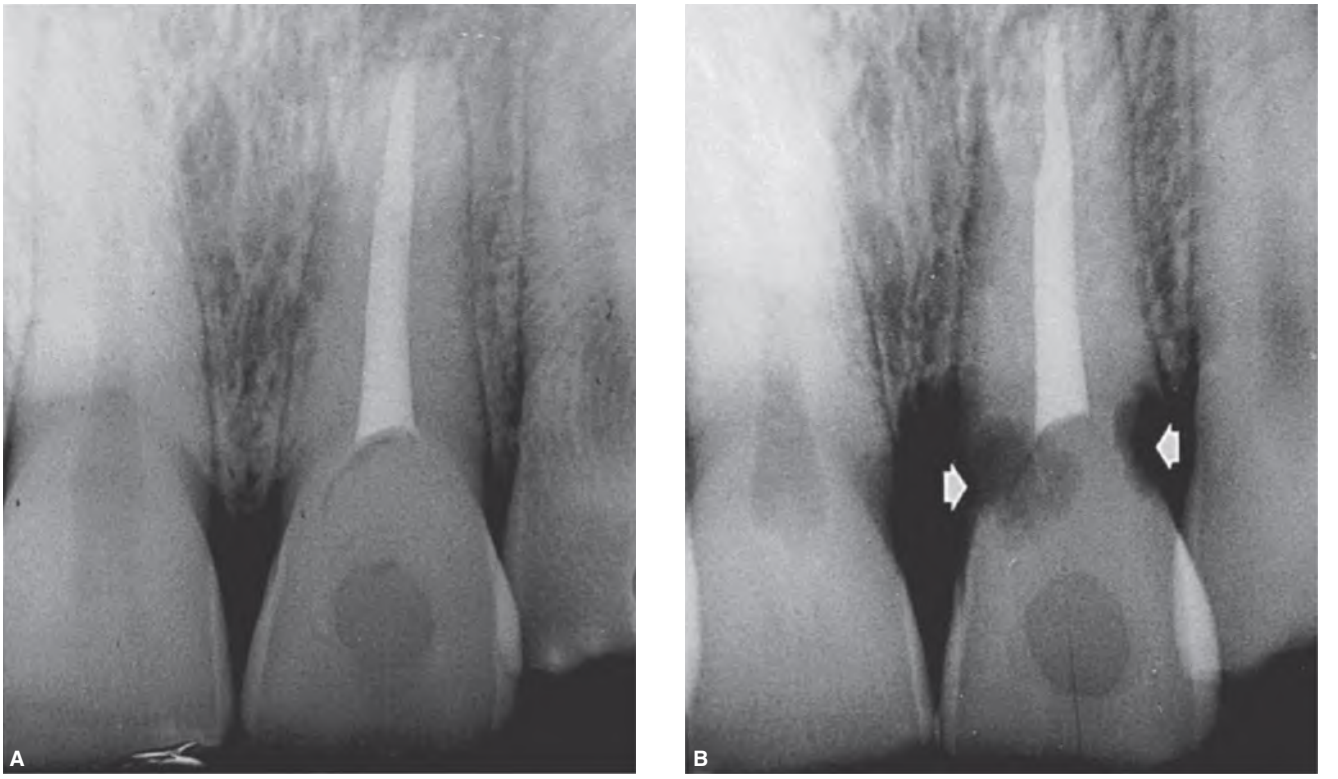

FIGURE 40-9 External root resorption following thermocatalytic bleaching. ***A.*** Nine-year recall radiograph of a maxillary central incisor devitalized by trauma and treated endodontically shortly thereafter. ***B.*** Radiograph taken 2 years following bleaching showing evidence of root resorption (arrows). Highly concentrated H_2O_2 and heat were used as part of the treatment. (Reproduced with permission from Harrington GW, Natkin E. *J Endod*. 1979;5:344-348.[44])

Inhibition on Resin Polymerization and Bonding Strength

Oxygen inhibits resin polymerization; consequently, residual H_2O_2 in tooth structure after bleaching adversely affects the bonding strength of resin composites to enamel and dentin.[39,40] Scanning electron microscopy (SEM) examination has shown an increase in resin porosity.[41] This presents a clinical problem when immediate esthetic restoration of the bleached tooth is required. It is therefore recommended that residual H_2O_2 be totally eliminated prior to composite placement. One study reported that 3 minutes of catalase treatment effectively removed all of the residual H_2O_2 from the pulp chamber of human teeth.[42]

External Root Resorption

Clinical reports[43-53] and histological studies[36,37,54] have shown that intracoronal bleaching may, under certain conditions, induce external cervical root resorption. This is probably caused by the highly concentrated oxidizing agent used in those cases, particularly 30 to 35% H_2O_2. The mechanism of bleaching-induced damage to the periodontium or the cementum is not fully clear. Presumably, the irritating chemical diffuses via unprotected dentinal tubules and cementum defects.[55-57] This causes necrosis of the cementum, inflammation of the periodontal ligament, and, subsequently, root resorption. The process may be enhanced if heat is applied[58] or in the presence of bacteria.[59] Previous traumatic injury and age may act as predisposing factors.[43] (Figure 40-9).

Potential complications can be prevented if safety precautions are carried out during bleaching treatment. Also, routine monitoring of bleaching cases allows early detection of any unwarranted results and reduces the risk of potential complications.

Suggestions for Safe Bleaching of Endodontically Treated Teeth

- Isolate the tooth effectively. Intracoronal bleaching should always be carried out under dental dam isolation. Interproximal wedges and ligatures may also be used for better protection.
- Protect the oral mucosa. Protective creams, such as Orabase, Vaseline, or cocoa butter, must be applied to the surrounding oral mucosa to prevent chemical burns by caustic oxidizers. Animal studies suggested that catalase applied to oral tissues prior to bleaching treatment totally prevents the associated tissue damage.[60]
- Verify adequate endodontic obturation. The quality of root canal obturation should always be assessed clinically and radiographically prior to bleaching. Adequate obturation ensures a better overall prognosis of the treated tooth. It also provides an additional barrier against damage by oxidizers to the periodontal ligament and periapical tissues.

- Use protective barriers over the coronal extent of the root canal filling. This is essential to prevent leakage of bleaching agents that may infiltrate between gutta-percha and root canal walls, reaching the periodontal ligament via dentinal tubules, lateral canals, or the root apex. In none of the clinical reports of postbleaching root resorption was a protective barrier used. Various materials can be used for this purpose.[61,62] Barrier thickness and its relationship to the cementoenamel junction are most important.[34,61] The ideal barrier should protect the dentinal tubules and conform to the external epithelial attachment (Figure 40-10).
- Avoid acid etching. It has been suggested that acid etching of dentin in the chamber to remove the smear layer and open the tubules would allow better penetration of the oxidizer. This procedure has not proved beneficial.[33] The use of caustic chemicals in the pulp chamber is undesirable as they may result in irritation to the periodontal ligament.

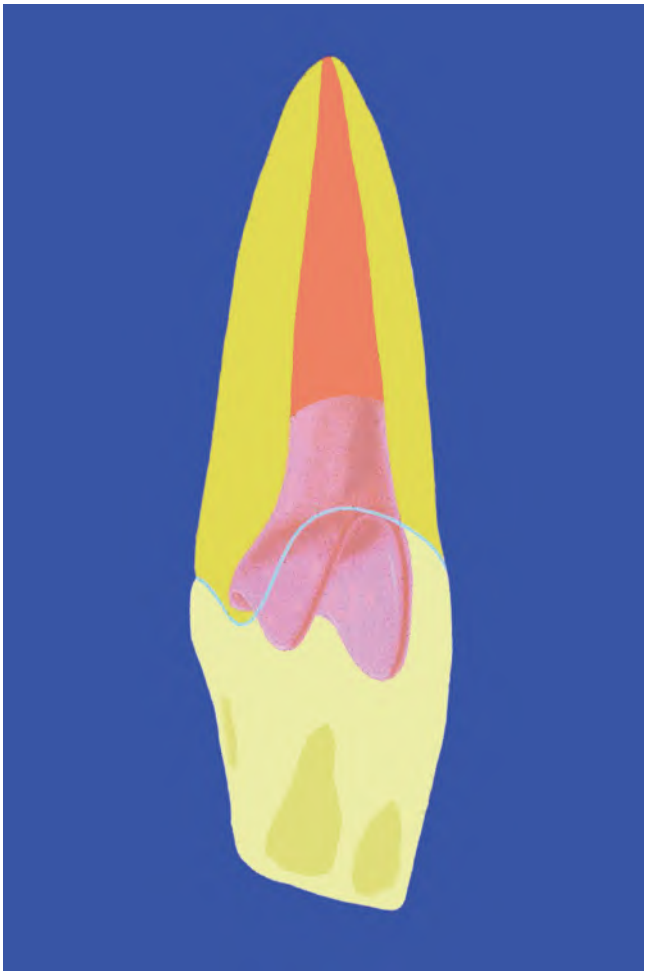

FIGURE 40-10 Schematic illustration of the intracoronal protective bleach barrier. The shape of the barrier matches the contour of the external epithelial attachment. (Reproduced with permission from Steiner DR, West JD. *J Endod*. 1994; 20:304–306.[35])

- Avoid strong oxidizers. Procedures and techniques applying strong oxidizers should be avoided if they are not essential for bleaching. Solutions of 30% to 35% H_2O_2, either alone or in combination with other agents, should not be used routinely for intracoronal bleaching. Sodium perborate is mild and quite safe, and usually no additional protection of the soft tissues is required.[63,64] Generally, however, oxidizing agents should not be exposed to more of the pulp space and dentin than absolutely necessary to obtain a satisfactory clinical result.
- Avoid heat. Excessive heat may damage the cementum and the periodontal ligament as well as dentin and enamel, especially when combined with strong oxidizers.[36,37] Although no direct correlation has been established between heat application and external cervical root resorption, it should be limited during bleaching procedures.
- Recall periodically. Bleached teeth should be frequently examined both clinically and radiographically. Early detection of an unusual occurrence can improve the prognosis since corrective therapy may still be applied.

Restoration of Intracoronally Bleached Teeth

Proper tooth restoration is essential for long-term successful bleaching results. Microleakage of lingual access restorations is a problem,[65] and a leaky restoration may again lead to contamination and tooth discoloration.

The pulp chamber and the access cavity should be carefully restored with a light shade, light-cured, acid-etched composite resin. The composite material should be placed at a depth that seals the cavity and provides some incisal support. Light curing from the labial surface, rather than the lingual surface, is recommended since this results in the shrinkage of the composite resin toward the axial walls, reducing the rate of microleakage.[66] Placing white cement beneath the composite access restoration is recommended. Filling the chamber completely with composite may cause loss of translucency and difficulty in distinguishing between composite and tooth structure during rebleaching.[67]

Discolored tooth structure may reflect through porcelain crowns and veneers thereby compromising the final esthetic result. Intracoronal bleaching, prior to placement of bonded porcelain crowns or veneers, is advantageous (Figure 40-4).

As stated previously, residual H_2O_2 from bleaching treatment may adversely affect the bonding strength of composites.[39] Therefore, waiting for at least 7 days after bleaching, prior to restoring the tooth with resin composites, has been recommended. Catalase treatment at the final visit may enhance the removal of residual peroxides from the access cavity; however, this requires further clinical investigation.[42] Packing calcium hydroxide paste in the pulp chamber for a few weeks prior to the placement of final restoration, to counteract acidity caused by bleaching agents and to prevent root resorption, has also been suggested; this procedure, however, is unnecessary with walking bleach.[21]
