The term *internal derangement* applies to all joints and encompasses those disorders causing mechanical interference to normal joint functions. In the TMJs, this primarily involves displacement and distortion of the articular disk, as well as remodeling of the articular surfaces. Many of the articular disorders affecting the TMJs involve an abnormal or restricted range of motion and noise but are *relatively painless*. These include the congenital or developmental disorders, disk derangement disorders, osteoarthritis, and ankylosis listed in Table 17-6. Any pain associated with these disorders is usually momentary and associated with pulling or stretching of ligaments. In the case of *ankylosis*, pain ensues if the mandible is forcibly opened beyond adhesive restrictions. Forcible opening can cause acute inflammation. Primary or secondary *osteoarthritis*, unless accompanied by synovitis, is also associated with minimal pain or dysfunction,[50,59] although crepitus and limited range of motion may be present.

Inflammatory Disorders of the Joint

It is the inflammatory joint disorders that cause pain. Included in this group are *capsulitis and synovitis* and various *polyarthritides.*

Symptoms. Capsulitis and synovitis are inflammatory disorders of the joint that present with similar signs and symptoms and can only be differentiated with direct visualization of the tissues through arthroscopy or open joint surgery. Capsulitis or synovitis may occur alone or in combination with an internal derangement. The chief symptom is continuous pain over the joint, aggravated by function. Swelling may be evident, and the patient may complain of restricted jaw opening, ear pain, and an acute malocclusion (the back teeth on the same side do not touch). There is usually a history of trauma, infection, polyarthralgia, or chronic, nonpainful degenerative arthritis that is now in an acute stage.[59] Because the pain is fairly constant, the clinical picture is often complicated by central excitatory effects including myalgia or referred pain or myofascial TrPs. The pain tends to wax and wane with the course of the inflammation.

Symptoms in patients with a *polyarthritis* are similar to a capsulitis or synovitis and include pain at rest and with mandibular function, crepitus, and a limited range of motion.

Etiology. Inflammation of the capsule or synovium may occur secondary to localized trauma or infection, through overuse of the joint, or secondary to other joint disorders. Synovitis may also occur secondary to primary osteoarthritis.

The *polyarthridites* are due to systemic rheumatological illnesses that affect multiple joints. These most commonly include rheumatoid arthritis, juvenile rheumatoid arthritis, psoriatic arthritis, and gout. The autoimmune disorders and mixed connective tissue diseases such as scleroderma, Sjögren's syndrome, and lupus erythematosus may also affect the TMJ.[59]

Examination. For *capsulitis and synovitis*, palpation over the joint itself is painful. Posterior or superior joint loading and any movement that stretches the capsule may also increase the pain. Range of motion is not usually restricted except due to pain in the joint. Initiation of mandibular movement after a period of rest may be slow and "sticky." Inflammatory effusion in the joint may cause acute malocclusion with slight disclusion of the ipsilateral posterior teeth. Clenching may be painful, but biting on a tongue depressor ipsilateral to the affected joint may reduce the pain by preventing intercuspation and full closure.

In the *polyarthritides*, palpation of the joint is also painful. Range of motion is not affected except due to pain and

may be accompanied by crepitus; malocclusion is related to inflammatory effusion or lateral pterygoid muscle spasm secondary to the primary pain. In severe cases of rheumatoid arthritis, rapid resorption of the condyles causes an acute anterior open bite. Ankylosis may also occur.

Diagnostic Tests. Plain radiographs and tomography will show a few, if any, bony changes in the joint with *capsulitis or synovitis* unless these are secondary to osteoarthritis.MRI, on the other hand, will show a bright T^2-weighted signal in the presence of fluid.[59]

The *polyarthritides* will show extensive TMJ changes on radiographic examination. Radiographic changes include more gross deformities than are seen in osteoarthritis, including erosions, marginal proliferations, and flattening (Figure 17-8). Of particular diagnostic value in the polyarthritides are various serologic tests screening for evidence of rheumatoid disease such as antinuclear antibodies, elevated erythrocyte sedimentation rate, rheumatoid factor, or anemia, although not all rheumatologic diseases are seropositive. Definitive diagnosis and management of the polyarthritides are left to the rheumatologist. The dentist's role is to manage concomitant TMJ symptoms should they occur.

Treatment. In treating inflammatory TMJ disorders, palliative care is an appropriate first step. This includes jaw rest, a soft diet, and 7–14 days of *nonsteroidal anti-inflammatory drug* (NSAID) use. Intermittent application of ice or moist heat

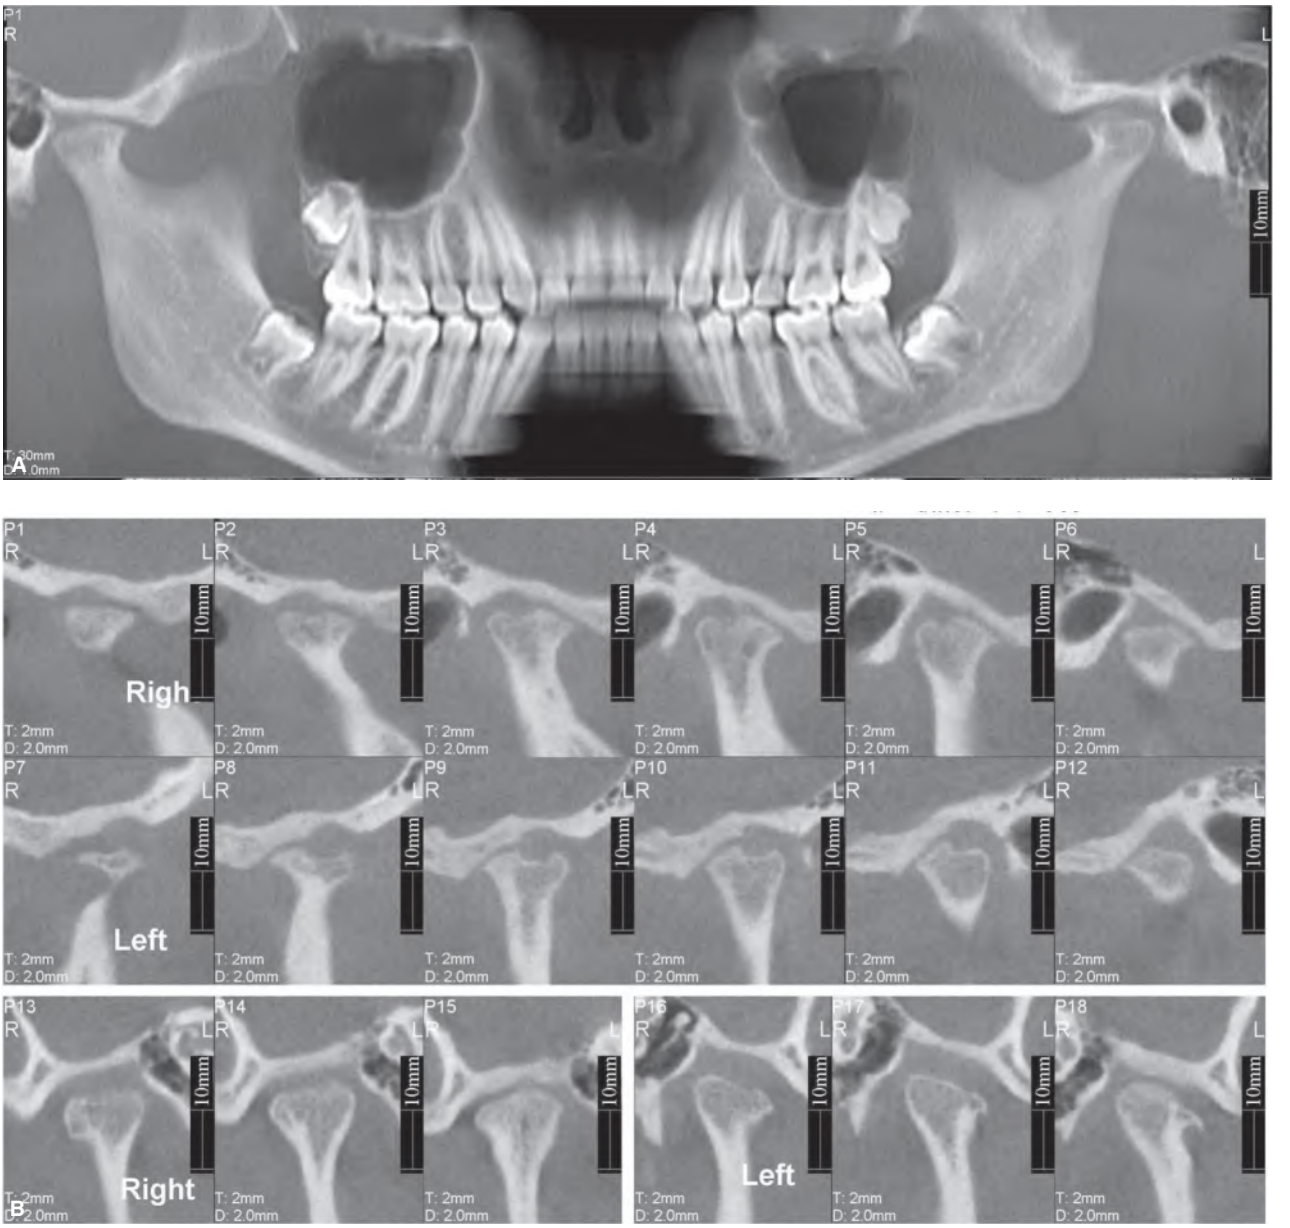

FIGURE 17-8 Tomography of a juvenile rheumatoid arthritic temporomandibular joint (TMJ). ***A.*** Observe the flattened surface of both TMJ condyles. ***B.*** Note the resorption of both articular surfaces of the TMJ and in particular, the significant resorption of the left condyle. may also be helpful. Office physical therapy, including ultrasonography, may be indicated in some patients. Single supracapsular or intra-articular injections of corticosteroids may be effective in reducing inflammation and pain if simpler methods prove ineffective. Pain relief from steroid injection can be expected to last 18–24 months provided that the patient limits joint use appropriately. It is generally accepted that steroid injections into the TMJ should be limited: no more than two in 12 months, and two or three in a lifetime. This is because there is currently insufficient evidence about the long-term effects, efficacy, and safety of intra-articular steroid injection,[60,61] so erring on the conservative side is advised.

Definitive therapy is aimed at reducing the causative or contributing factors. This must involve the patient who controls the functional demands placed on the joint and must be motivated to limit joint use and eliminate abusive habits. Home exercises, application of heat and ice, and massage are also important. In addition to the self-help program, construction of a *stabilization splint* may help reduce symptoms. If necessary, a psychological approach to decrease emotional stress and/or daytime clenching may also be instituted. Surgery is seldom, if ever, indicated.

If the condition is due to polyarthritis, management is similar to treating the systemic disease itself. It includes analgesics and anti-inflammatory agents such as aspirin, indomethacin, and ibuprofen, corticosteroids such as prednisone, gold salts, and penicillamine, as well as the same palliative and supportive therapies mentioned previously. Surgical intervention is limited to severe cases with marked dysfunction.

Referred Pain from Remote Pathological Sites

Angina Pectoris and Myocardial Infarction

Severe pain of cardiac origin can be referred to the mandible and the maxillary region and, surprisingly, pain from a pulpalgia may refer down the ipsilateral neck, shoulder, and arm.[62] These unusual patterns of pain referral may be explained by the fact that dorsal root ganglion cells have been shown to branch in the periphery[33,34] and that, in the rat at least, the dorsal root ganglion cell supplying the heart also supplies the arm[33] (Figure 17-9). Potential convergence of nerve fibers from different sensory dermatomes in the dorsal horn of the spinal cord provides a basis for a "convergence-projection" phenomenon for the pain referral (Figure 17-5).

Symptoms. Angina pectoris is typically characterized by heaviness, tightness, or aching pain in the mid or the upper sternum. These symptoms may radiate upward from the epigastrium to the mandible—the left more frequently than the right. This pattern is similar to that seen with myocardial infarction (Figure 17-10A). Precipitating factors include exertion and emotional excitement or ingestion of food.[63] Angina attacks are usually short-lasting, rarely longer than 15 minutes. Anginal pain referred to the teeth may be experienced with or without concomitant chest pain.[64]

Myocardial infarction is characterized by a symptom complex that includes a sudden, gradually increasing precordial pain, with an overwhelming feeling of suffocation. The pain

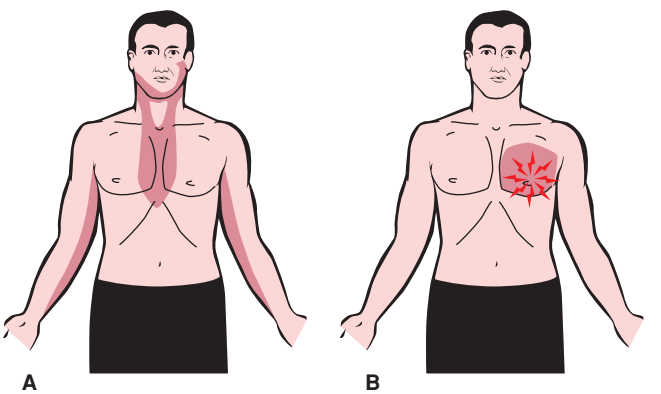

FIGURE 17-10 ***A.*** Pattern of pain and referred pain emanating from myocardial infarction. Central necktie pattern and greater left jaw and arm pain than on the right side are typical. ***B.*** Harmless noncardiac pain in the left chest. FIGURE 17-9 Branched primary afferent hypothesis of referred pain. According to this theory, a single primary afferent branches to supply both the deep structure stimulated and the structure(s) in which the pain is perceived. (Reproduced with permission from Fields HL, McGraw-Hill; 1987.[3])

of myocardial infarction is similar to angina but is more pronounced, long-lasting, and does not resolve with rest.

Severe pain in the left maxilla and mandible related to angina pectoris or myocardial infarction *may occur without any other symptoms*. Bonica reported an incidence as high as 18% for the presentation of cardiac pain as jaw or tooth pain alone.[65]

Examination. A careful history is important in diagnosing the referred oral pain of cardiac origin. The dentist must rule out dental disease quickly and efficiently.

Treatment. If previously undiagnosed cardiac pain is suspected, the patient must be referred to an emergency room immediately. The patient should be transported by emergency services personnel and not allowed to drive. It is wise to call the hospital and have them ready to receive the patient.

If the patient loses consciousness, basic cardiopulmonary resuscitation should be applied until help arrives. This may be lifesaving. Every dental office should be equipped with a defibrillator.

Thyroid

Disorders of the thyroid gland are prevalent in medical practice, second only to diabetes as an endocrine disorder.[47] *Subacute thyroiditis* (viral inflammation of the thyroid gland) is of interest to the dentist because it may refer *pain to the jaws and ears*.

Symptoms. The typical symptom picture includes a sore throat with pain over at least one lobe of the thyroid gland or pain radiating up the sides of the neck and into the *lower jaw, ears*, or occiput. *Swallowing may aggravate the symptoms*. This is usually associated with a feeling of pressure or fullness in the throat. There may be mild fever, asthenia, and malaise.[47] Symptoms may wax and wane over a period of months and then finally resolve with return of normal thyroid function.

Etiology. Subacute thyroiditis is reported to occur 2–3 weeks after an upper respiratory infection and is viral in origin.

Examination. The thyroid gland may be visibly enlarged and will be exquisitely tender to palpation with nodularity (Figure 17-11). If thyroiditis or other thyroid disease is suspected, referral to the patient's physician should be made.

FIGURE 17-11 Benign thyroid tumor that recurred following thyroidectomy was referring pain into the mandibular first molar on the homolateral side.

Treatment. Subacute thyroiditis may resolve spontaneously. Large doses of aspirin and occasionally steroids are used to control the pain and inflammation. Thyroid supplements are sometimes indicated.[47]

Carotid Artery

Carotidynia is a nonspecific symptom of unilateral vascular neck tenderness that was first described by Temple Fay in 1927.[66] Stimulation of various parts of the carotid artery in the region of the bifurcation was shown to cause pain in the *ipsilateral jaw, maxilla, teeth, gums*, scalp, eyes, or nose. Long thought to be a benign complaint, frequently associated with migraine, and often responding to migraine therapy,[67] carotidynia was removed from International Headache Society (IHS) classification in 2004 due to an apparent lack of radiological or pathological findings.[45] More recently, various systematic MRI and ultrasound and PET-CT studies have found evidence of abnormal soft tissue infiltration surrounding the symptomatic carotid arteries, renewing the interest in carotidynia as a potential distinct disease entity.[68]

Symptoms. Continuous or intermittent dull aching, rarely pulsing, jaw and neck pain, with occasional spread to the *masseter muscle, temple and TMJ region*. Aggravating factors may include *chewing, swallowing*, bending over, or straining at stool. Precipitating factors may include an inflammatory response secondary to physical trauma or bacterial or viral infection, drugs, or alcohol.

Etiology. Recent studies support the idea that there may be inflammation or abnormal soft tissue infiltration surrounding the symptomatic tender carotid bulb.[69]

Examination. Palpation may reveal tenderness and swelling over the ipsilateral carotid artery and aggravate the pain. The thyroid is nontender. All other tests and examinations are normal. Carotidynia has an extensive *differential diagnosis*, including such conditions as carotid artery dissection, aneurysm, fibromuscular dysplasia, elongated stylohyoid process, and temporal arteritis.

Treatment. Treatment recommendations range from reassurance and local heat to NSAIDs, steroids, or migraine medications.

Cervical Spine

There is a close functional connection between the cervical spine and the cranium and mandible. Many of the ligaments and muscles of the neck attach to both the head and the jaw, and all movements of the head and the neck affect the muscle activity in the masticatory muscles and the position of the mandible.[70] Because of these connections and the fact that disorders of the cervical spine and neck area may refer pain into the *facial region* due to the convergence of cervical and trigeminal primary afferent nociceptors in the nucleus caudalis of the spinal trigeminal tract, the cervical spine and musculature must be included in the assessment of orofacial pain complaints.

The normal cervical spine has 37 individual joints, making it the most complicated articular system in the body.[71] Most

of the structures in the neck have been shown to produce pain when stimulated.[72] Pain may be elicited through several different pathological processes including trauma; inflammation or misalignment of the vertebral bodies; inflammation or herniation of the intervertebral disks; trauma or strain in the spinal ligaments; and strains, spasms, or tears of the cervical muscles, and cervical dysfunction (lack of normal anatomical relationship or restricted functional movement of individual cervical vertebral joint segments).

Non-musculoskeletal pain-producing structures of the neck include the cervical nerve roots and nerves and the vertebral arteries.[72] Trauma, inflammation, and compression are implicated in the etiology of pain from these structures as well.

Acute cervical trauma and primary pathological processes of the neck are obviously not in the realm of the dentist to diagnose and treat; therefore, these will not be discussed. However, the cervical spine must be recognized as a potential source of dermatomal and referred pain into the head and the *orofacial* region.

Neck pain is very common. The pain is usually felt in the suboccipital region, may originate in any cervical structure, and is often referred to the frontal, orbital, temporal, parietal, and vertex regions.[72] Vertebral artery involvement or convergence of cervical neural input onto the spinal accessory and vagus nerves may induce visceral symptoms such as nausea, dizziness, or visual disturbance.[73] Recognizing the cervical contribution to these symptoms, along with prompt referral to an experienced physical therapist, may prevent the development of joint restrictions, cervical dysfunction, and progressive cervical disease such as bulging discs or spondylosis.

The tactile and painful dermatomes of the upper cervical nerves, C2 and C3, include the lower border of the mandible and the area surrounding the TMJs, a good portion of the external ears, posterior temporal and parietal regions of the head (Figure 17-12). Pain or dysfunction of these upper cervical areas may present as *mandibular or TMJ pain, lower molar toothache, throat tightness or difficulty swallowing*. Entrapment or chronic irritation of the nerve roots in the C4 to C7 area generally produces pain in the respective dermatomes in the shoulder and arm regions.[74] *Dermatomal pains* may have an aching or neuritic quality and typically follow the distribution of the cervical nerve root involved. Greater and lesser occipital nerves are often implicated as contributing to various headache presentations and nerve blocks are sometimes part of the treatment.[75] *Referred pains* on the other hand, are usually deep and aching and may present as headache that is not consistent with the dermatomal distribution of any of the cervical nerves. Referred symptoms from the neck may include *ipsilateral masticatory muscle tenderness* and *pain in the preauricular area*, *body of the mandible* and mastoid.

Examination. Postural evaluation is essential for all facial pain patients. Of particular importance is anterior head position. One simple quick test is to view the standing patient from the side. The ear should be in line with the acromioclavicular joint. If the ear is anterior to this landmark, the posterior cervical muscles, upper trapezius, levator scapula, and

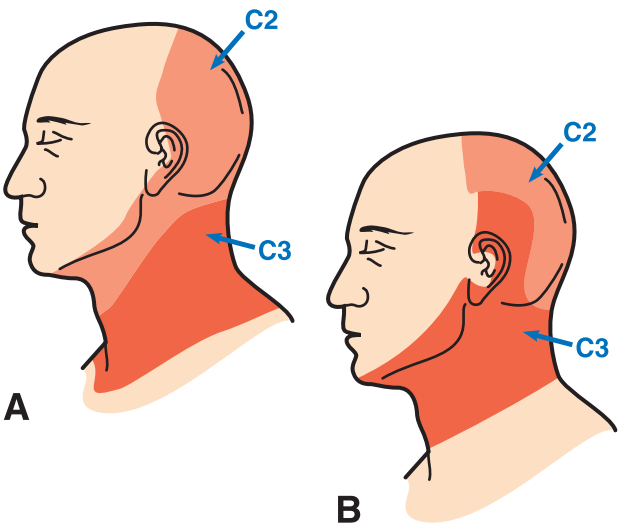

FIGURE 17-12 A study by Poletti revealed a slightly different distribution of C2-C3 dermatomes for pain than those previously defined by using tactile criteria. ***A.*** Upper image depicts the C2 and C3 tactile dermatomes previously defined by Foerster. SCM muscles are activated to keep the head rotated up and the eyes looking forward. This results in flexion of the lower cervical spine and extension of the upper cervical spine with potential for compression of neural and vascular elements between the occiput and C1 and C1 and C2. With anterior head positioning, the jaw elevator muscles are also activated as they counteract the gentle downward forces on the mandible from the supra and infra hyoid muscles that are now on the stretch. Changes in head position have been shown to affect occlusion and maximum mandibular opening.[76]

The examination of the cervical spine should include range of motion in flexion, extension, lateral flexion, and rotation. Additionally, the movement of the individual upper cervical segments (occiput-C1 and C1-C2) should be evaluated.[48] Cervical range of motion is often restricted with cervical dysfunction. Upper cervical dysfunction may be unilateral or bilateral.

Treatment. Physical therapy, including cervical joint mobilization along with a comprehensive home exercise program and postural retraining, is required to treat pain of cervical origin.

Local treatment of referred symptoms does not provide long-lasting, if any, relief. If the patient has a true dental or temporomandibular disorder *and* dysfunction of the cervical spine, both problems must be addressed.

INTRACRANIAL DISEASE

Although rare, intracranial lesions can cause pain referral to all areas of the head, face, and neck, including the oral cavity. Neurological or neurosurgical evaluation is critical to rule

out space-occupying lesions, intracranial infections, or neurological syndromes.

Intracranial causes of head and neck pain include those caused by *traction on pain-sensitive structures* (the venous sinuses, dural and cerebral arteries, the dura mater, and the cranial nerves) and those caused by *specific CNS syndromes*, such as neurofibromatosis or thalamic pain[77] (Table 17-7). Different types of cerebrovascular accidents and venous thrombosis may also cause painful CNS lesions.

Intracranial lesions are usually associated with different focal neurological signs or deficits such as weakness, dizziness, difficulty in speaking or swallowing, ptosis, areas of numbness, memory loss, or mental confusion. When painful, the quality of pain may vary from a generalized throbbing or aching to a more specific paroxysmal sharp pain. Systemic symptoms such as weight loss or fever, sudden onset of pain, or a pattern change of existing pain should all be cause for concern and raise red flags that the cause may be intracranial.

NEUROVASCULAR PAINS

This category of pain encompasses several of the primary headache disorders (headaches not of pathological origin) such as migraines and the trigeminal autonomic cephalalgias (TACs), as well as some headaches associated with pathological vascular disorders, such as temporal arteritis (Table 17-8).

Adapted from Headache Classification Committee of the International Headache Society, 2013.[45]

The list includes only those headaches that have a higher likelihood of presenting in the dental office due to the documented likelihood of occasionally presenting in an intraoral site.[78,79]

Benoliel et al[78] and Sharav[80] proposed creating an additional diagnostic subcategory in the IHS criteria[45], namely that of *neurovascular orofacial pain* in order to encompass those migraines and TAC type of pains that occur in the lower two-thirds of the face.

In general, these headache types share the following features. They all have primarily a deep, throbbing or pulsating quality, occasionally with superimposed sharp pain, and occasionally with an aching or burning background. The pain is exclusively or *predominantly unilateral* with pain-free or almost pain-free periods between attacks. The main difference between the different headache types lies in their temporal patterns (Figure 17-13) and their associated symptoms.

Migraine

Migraine is a debilitating, inherited, episodic disorder and a form of sensory processing disturbance in the CNS.[81] Migraine without aura and migraine with aura are the two most common forms. Migraine headaches are more common in females and 50% begin before the age of 20.[82]

Symptoms. The migraine headaches typically start on one side but can spread to involve both sides. There is often a premonitory period before the headache emerges that lasts hours and up to 2 days. This consists of combinations of vague symptoms such as fatigue, difficulty concentrating, neck stiffness, nausea, blurred vision, food cravings, and/or depression. These symptoms are part of the migraine process and are not considered to be triggers.

Some migraine patients do report having specific triggers to their headaches. These may include foods such as chocolate, cheese, fruit and alcohol (especially red wine), menstruation, weather changes, lack of sleep, histamines, and vasodilators.

The headache itself is predominantly unilateral in the frontal, temporal, or retrobulbar areas, although about 3% of migraine patients will complain of intraoral pain,[83] increasing the likelihood that an undiagnosed migraine patient will seek consultation with a dentist or endodontist before seeing their physician or an orofacial pain specialist.

The pain may begin as an ache but usually develops into a pain of throbbing, pulsating, or beating nature and, if untreated, will last 4–72 hours with variable pain-free periods (days to years) between attacks. Aggravating factors include exertion; patients will avoid activities such as walking, climbing stairs, coughing or moving the head. Associated symptoms may include photo~ and phonophobia, nausea, and/or vomiting. Sleep helps the headache to abate.

"Facial migraines" or *neurovascular orofacial pains* is pain with many similarities to migraine that occurs in the lower two thirds of the face, most frequently in the *alveolus* occasionally with an *associated mucosal site*. There may be referred *pain to the lips or chin, or to the infraorbital or preauricular*

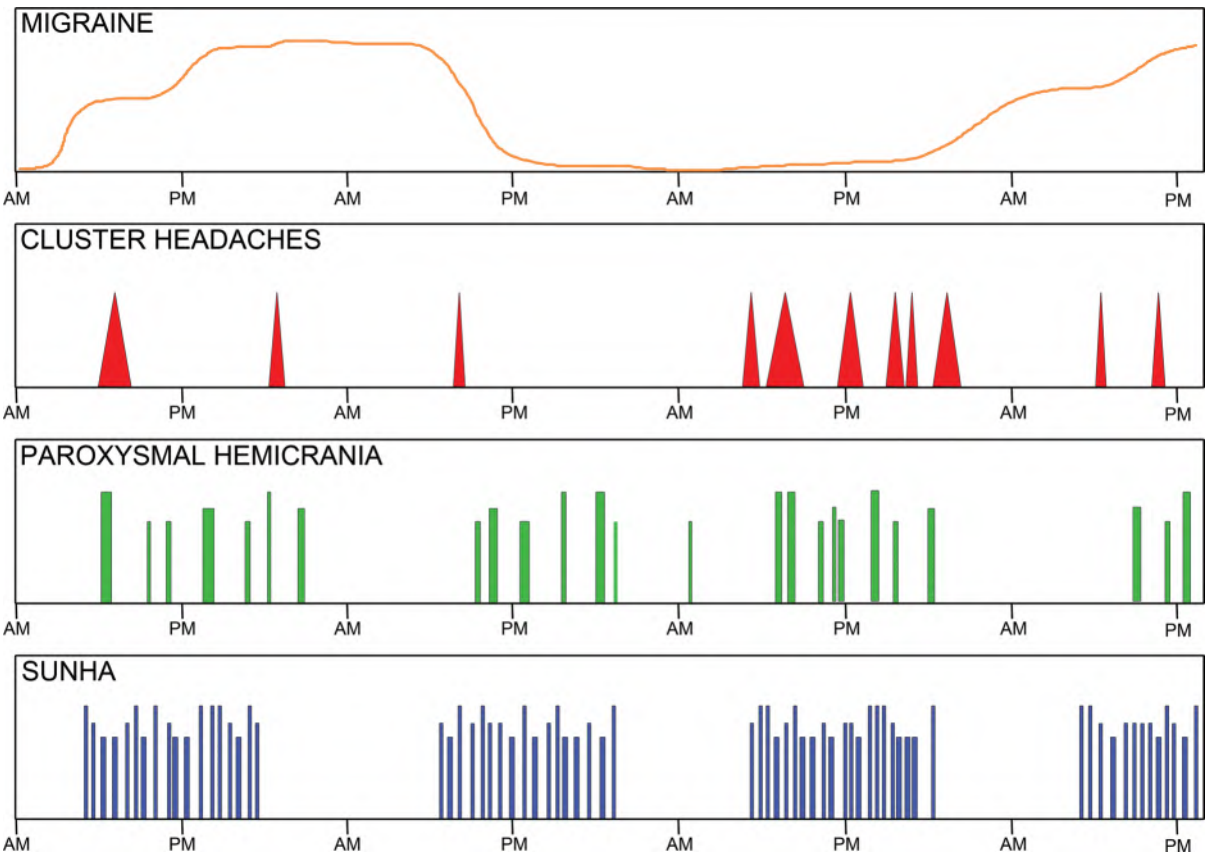

FIGURE 17-13 Comparison of temporal pattern of four main "neurovascular" headache types. (Reproduced with permission and courtesy of Drs. Bernadette Jaeger and Austin Skootsky, Los Angeles, CA, U.S.A.)

regions.[78] Neurovascular orofacial pain, similar to migraine, is also more common in women, primarily unilateral in location, and throbbing in quality. The pain may last minutes to hours, some patients reporting that the pain lasts over 24 hours. Over 36% of patients have associated autonomic symptoms[79] such as tearing, nasal congestion, photo~ or phonophobia, and nausea.[78] A potentially misleading sign is that some of these patients also report *dental sensitivity to cold*.[84] Often patients will present having had one or more root canal treatments in the teeth in the painful region without relief of their pain.

Migraine with aura is distinguished from *migraine without aura* by the occurrence of transient, reversible, focal neurological symptoms (the aura), 5–20 minutes prior to the onset of headache pain. Visual auras are most common and may present as flashing lights, halos, or loss of part of the visual field. Somatosensory auras are also common and consist of dysesthesias that start in one hand and spread up to involve the ipsilateral side of the face, nose, and mouth.[45,85,]

Often patients with migraine, especially migraine without aura, have *overlying MFP*, causing additional dull, aching headache pain.[86,87] The prevalence of temporomandibular disorders (TMDs) and various orofacial pain disorders in relation to headaches has been reported.[87]

Etiology. The exact etiology and pathogenesis of *migraine with aura* headaches remain controversial, the past attribution to intra and extracranial vascular changes having been disproven through magnetic resonance angiography studies.[89]

Current evidence suggests that migraine arises from a "brain state of altered excitability" that leads to activation and sensitization of the trigeminovascular system in genetically susceptible people."[4] The trigeminovascular system consists of the trigeminal neurons and the blood vessels they innervate. In migraine, this consists largely of the ophthalmic division of the trigeminal nerve and the large pain producing cerebral blood vessels.

The migraine aura is associated with a brief hyperaemia in the brain that correlates with visual changes, followed by a pathognomonic spreading oligemia (decrease in blood flow) that starts in the visual cortex and spreads forward and persists throughout the headache phase.[90] These regional cerebral blood flow changes have not been found in migraine without aura, although blood flow changes in the brain stem may occur.[45] The cortical spreading depression has been shown in animals to cause sustained activation of the meningeal nociceptors and central trigeminovascular neurons and is thereby thought to activate headache mechanisms.[4]

The pain of migraine is thought to be *referred* from a sterile neurogenic inflammation, caused by the release of vasoactive neuropeptides from nerves surrounding the affected intracranial vasculature, to the more superficial cranial structures through convergence of vascular and somatic nerve fibers on single second-order pain transmission neurons in the trigeminal nucleus caudalis.[91] While the mechanism of pain

generation in migraine is still controversial, evidence suggests that central sensitization in the trigeminocervical complex (the trigeminal nucleus caudalis and the dorsal horns of C1 and C2), together with the reflex connections of the trigeminal system with the cranial parasympathetic neuronal flow mediated through the pterygopalatine, otic and carotid ganglia, results in headache and cutaneous allodynia.[92–95]

Examination. The diagnosis of migraine can usually be made by history, but in the case of neurovascular orofacial pain, examination of the patient complaining of undiagnosed intermittent toothache or facial pain should include a thorough dental, TMJ, and muscle evaluation. Once obvious dental and joint pathology have been ruled out, and the qualitative and temporal pattern of the pain raises the possibility of dental or facial migraine, referral to an orofacial pain dentist should be made. Dental heroics should be avoided.

Diagnostic Tests. There are no diagnostic tests that will confirm the diagnosis of migraine headache. If the headache is of recent onset or the pattern of a preexisting headache has changed, a neurological evaluation including a CT scan or an MRI may be indicated.

Treatment. Long-term management of migraine headache typically requires identification and control of any obvious contributing factors such as diet, sleep, and stress. Restriction of alcohol intake, regular meals, exercise, relaxation therapy, and good sleep hygiene may help prevent the onset of migraine. If myofascial TrPs or musculoskeletal dysfunction is present, competent treatment of these will significantly reduce the frequency of vascular headache symptoms and reduce the need for migraine medications. For those patients in whom stress, depression, or anxiety play a role, psychological interventions such as stress management and relaxation training, biofeedback, or cognitive behavioral therapy may be indicated.

Medications used in the treatment of migraine include abortive and prophylactic drugs, the choice of which depends on the frequency of migraine attacks. Individuals who suffer less than three or four migraines per month may do well with abortive drugs that are taken during the onset of the headache or migrainous facial pain.

Abortive drugs are particularly useful in migraine with aura for which the aura warns the patient that a headache is pending. The serotonin 5-HT(1B/1D) agonists or "triptans" are highly effective. They improve headache as well as nausea, photo~ and phonophobia, and cutaneous allodynia.[95]

Prophylactic medications are used when headache frequency exceeds 3 or 4 per month since the triptans may cause coronary vasospasm or ischemia. Prophylactic medications include β-blockers, tricyclic antidepressants, calcium channel blockers, 5-HT antagonists, and antiepileptic drugs such as valproic acid, gabapentin, and topiramate.

Despite a plethora of migraine specific medications, up to half of migraineurs do not seek medical advice and self-medicate. The most common remedy is bed rest and over 50% of patients use over the counter analgesics. This is despite the fact that studies have shown that there is an improved quality of life when patients use triptans.[96]

The use of botulinum toxin has been approved by the US Food and Drug Association for use in chronic migraine headaches, cases in which a person has more than 15 days of headache per month.[97] The protocol consists of injection of 5 units of Botox in 31 sites along the corrugator, procerus, frontalis, temporalis, occipital, cervical paraspinals and upper trapezius muscles bilaterally for a total of 155 units.

Trigeminal Autonomic Cephalalgias

Cluster headaches, paroxysmal hemicranias, short-lasting neuralgiform headaches (SUNCT and SUNA), and hemicrania continua (HC) belong to the TACs. Because the *pain quality is similar to dental pulpitis*, any of these headache types may present first in the dental office.[78,98] All three share several clinical characteristics: unilateral, pulsatile or sharp, severe trigeminal pain with significant autonomic features such as tearing, rhinorrhea, and conjunctival injection and often cause awakening from sleep. They may share similar etiological or pathophysiological mechanisms. Nonetheless, they are easily distinguishable clinically and clearly differ from migraine.

Symptoms. Cluster headaches are probably one of the most painful conditions known to man and derive their name from their temporal pattern. They tend to occur in "clusters," a series of once every other day to eight 15- to 180-minute attacks per day lasting for several weeks or months, followed by remissions of months or years[45] (Figure 17-13). These headaches are found four to five times more frequently in men than in women, particularly in men aged 20–50 years *who smoke*.[99] The pain is a severe, unilateral, continuous, intense ache or burning that often occurs at night. The most common site is around or behind the eye radiating to the forehead and temple or around and behind the eye radiating infraorbitally *into the maxilla and occasionally into the teeth*, rarely to the lower jaw and neck.[100] Because of the oral symptoms, *serious diagnostic errors are committed by dentists*. Researchers from the University of California, Los Angeles reported that 42% of 33 patients suffering cluster headache had been seen by dentists and that 50% of these patients *had received inappropriate dental treatment*.[101]

Visual or sensory auras are absent with cluster headaches, but nasal stuffiness, lacrimation, rhinorrhea, conjunctival injection, perspiration of the forehead and face, and Horner's syndrome (ptosis of upper lid and miosis) are characteristic. Precipitating factors may include alcohol or other vasodilating substances, such as nitroglycerine. Cluster headache patients typically pace the floor during their headaches due to the intensity of pain. This is in contrast to migraine patients who typically retreat to a dark room to sleep.

Cluster headaches may progress from the more classic episodic form, occurring in periods lasting 1 week to 1 year, with at least a 2-week pain-free period in between, to a chronic form in which remissions are absent or last less than 2 weeks.[45] Rarely is the chronic form present from the onset.

Paroxysmal Hemicrania has similar characteristics to cluster headache, including *pain in dental structures*, but the attacks are shorter lasting (2–30 minutes), more frequent (5 per day for more than half the time),[45] and occur almost equally in men and women,[102] with a mean age of onset between 30–40 years. Most attacks are spontaneous, but certain triggers have been identified including neck movement, stress, alcohol, and exercise.

The quality of pain is throbbing, stabbing, sharp, or boring with an intensity that parallels that of cluster headaches, the patient often choosing to pace the floor during an attack. Pain location is predominantly oculotemporal, frontal and maxillary, always on the same side, and can spread to involve the entire side of the head and the neck, shoulder, and arm.[102,103] Cases involving paroxysmal hemicrania presenting as *intermittent toothache* have been reported.[104]

As with cluster headache associated symptoms include cranial autonomic symptoms and while they are predominantly unilateral, both sides may be affected. As with cluster, paroxysmal hemicrania may wake the patient from sleep, although this is not considered characteristic.[105] The awakenings with both headache types is considered to be REM sleep related.[106] Nausea and vomiting are usually absent, as are visual or somatosensory auras. Paroxysmal hemicrania is completely responsive to indomethacin.

The *short-lasting, unilateral, neuralgiform headache attacks (SUNHA)* are characterized by moderate to severe, extremely short-lasting attacks (from 5 seconds to 3 minutes) of unilateral, stabbing, sometimes electrical or burning, rarely pulsatile[106] ocular or periocular pain that *may radiate into the teeth*. Attacks occur 3–200 times per day, and there is prominent redness and tearing of the ipsilateral eye.[45]

There are two subtypes of SUNHA, short-lasting, unilateral, neuralgiform headache attacks *with conjunctival injection and tearing (SUNCT)* and short-lasting, unilateral, neuralgiform headache attacks *with cranial autonomic symptoms (SUNA).*[45] These two subtypes are differentiated primarily by the presence of both conjunctival injection and tearing in SUNCT and only one or none in SUNA. SUNCT may be a variation of SUNA.[4]

Because of the electrical, stabbing, short-lasting characteristics, SUNCT and SUNA may be difficult to distinguish from first division trigeminal neuralgia, although the pain is reported to be less intense. Triggering factors include light mechanical stimuli but, in contrast to trigeminal neuralgia, there is a short latency between the stimulus and the onset of pain.[107] Neck movements may also set off an attack. Also in contrast to trigeminal neuralgia, SUNCT/SUNA has no refractory period after an attack.[108] Trigeminal neuralgia and SUNCT/SUNA may occur together in the same patient. Because the signs and symptoms overlap, the differentiation may be clinically quite difficult and in those cases, patients should receive both diagnoses.[45]

Hemicrania Continua. This headache is strictly unilateral and completely responsive to indomethacin.[45] The pain is a continuous throbbing, sometimes dull and pressure-like, with mild autonomic symptoms, and daily or every other day exacerbations that last from 30 minutes to 10 hours, rarely several days. When severe, it resembles migraine and even has similar associated symptoms such as nausea, photo~ and phonophobia. Because of the similarity of symptoms to other chronic daily headaches (chronic or transformed migraine, chronic tension-type headache, new daily persistent headache) HC is often misdiagnosed. Up to *33% of patients consulted a dentist first* and *20% were given a dental diagnosis.*[109] HC, similar to paroxysmal hemicrania, is completely responsive to indomethacin, the headache abating within hours of being given an adequate dose of the medication.

Etiology of TACs. Headache presentations consistent with any of the TACs may be secondary to head trauma, or other pathologic phenomena such as malignancy, benign tumors, carotid artery dissection, vertebral artery injury, brain stem infarction, or arteriovenous malformations to name a few.[4] Thus, careful history taking and thorough evaluations are very important in all cases of unusual pain presentations, especially in the absence of obvious dental pathology.

The exact etiology or pathophysiology of TACs is as yet unknown; however, the similarity of the symptoms, the rhythmicity and autonomic features suggest a common pathophysiology. Because of the rhythmicity and predilection for attacks to occur at night, involvement of the posterior hypothalamus was suspected and confirmed by various neuroimaging techniques.[110,111] The location of the pain and the accompanying autonomic symptoms, implicates activity in the first and second divisions of the trigeminal nerve. Vasodilation, once considered an important element in the pathogenesis of cluster, is now thought to be secondary to trigeminovascular activation.[112] This is because the pain of cluster headache typically precedes any extracranial blood flow changes, and intracranial blood flow studies have shown inconsistent results.[112] Instead, trigeminal activation is implicated in causing neurogenic inflammation in the peripheral sites subserved by V1 and V2, resulting in clinical redness, swelling and pain. The parasympathetic nervous system is activated through connections in the salivary nucleus in the brain stem resulting in the autonomic phenomena (the trigemino-parasympathetic reflex).[113]

Examination. The diagnosis of all of the TACs is based on signs and symptoms. There are no diagnostic tests to confirm a diagnosis of TAC. Either the patient presents with a typical history and no abnormalities on physical and neurological examination or the examination causes suspicion of organic lesions with an ultimately normal neuroimaging scan.[45] Mild ptosis and miosis with or without periorbital swelling and conjunctival congestion may be present on the side of the headache if the patient is seen during or shortly after an attack. Dental pathology, part of the differential in the presentation of many TACs, must be carefully ruled out.

Treatment. Definitive treatment of TACs is best left to the orofacial pain dentist or other health care providers with a specific interest in headache management.

Cluster Headaches. Many of the treatments used for migraine therapy are also useful in cluster headaches, including symptomatic use of subcutaneous or intranasal triptans.[4] In general, however, prophylactic medications are more appropriate in cluster headache because of the frequency of attacks and because prodromal warning symptoms are rare. Cluster headache patients are often wakened from sleep, and the pain reaches its high intensity very quickly. Once the cluster period subsides, patients are weaned from their prophylactic medications until the headaches recur.

Oxygen inhalation (100% 7–8 L/min with a nonrebreathing mask), given at the very beginning of an attack for 15 minutes, may be successful in aborting an attack. In rare cases of resistant chronic cluster headache, microvascular decompression or lysis of the trigeminal ganglion, deep brain stimulation, gamma knife treatment, or stimulation of the posterior inferior hypothalamus may be considered.[4]

Paroxysmal Hemicrania and HC. Indomethacin is the medication of choice for paroxysmal hemicrania. If the pain does not resolve with this medication, it is unlikely to be paroxysmal hemicranias or HC. Aspirin and naproxen have a partial effect, but the relief is not as dramatic as with indomethacin.[114]

SUNHA. SUNCT and SUNA appear to be quite resistant to most of the usual first line medication choices for neurovascular headaches and also those medications used for neuropathic pains such as trigeminal neuralgia. The medication that has shown the most promise is lamotrigine and this drug is now considered the first line of treatment, followed by gabapentin and topiramate.[107] Neurovascular decompression of the trigeminal nerve has been shown to have high efficacy in resistant cases,[115] further supporting a potential connection between SUNCT, SUNA, and trigeminal neuralgia.

Headaches Associated With Vascular Disorders

This category includes headaches that are attributable to demonstrable disease, such as *giant cell arteritis*. Other pathological vascular causes of headache include vertebral or carotid artery dissection, subarachnoid hemorrhage, arteriovenous malformations, or venous thrombosis. Headaches due to such intracranial disease are unlikely to appear in the dental office and are therefore not further described. *Giant cell arteritis*, however, does on occasion present with *dental symptoms*, and may produce serious, irreversible consequences, such as blindness, if left unrecognized and untreated.

Giant Cell Arteritis (Temporal Arteritis)

Symptoms. The patient with giant cell arteritis is usually over 50 years old and may have other rheumatic symptoms, such as muscle aches, morning stiffness and polymyalgia rheumatica. Most have head, face, or neck pain, and involvement of the temporal artery may cause pain or tiredness with mastication ("jaw claudication"), inefficient chewing and perhaps even temporomandibular joint arthralgia, that may be the first or only complaints.[116] *Burning tongue or dental pain* has also been reported and missing the correct diagnosis has resulted in *inappropriate, ineffective endodontic surgery*.[117]

The pain is usually unilateral and in the anatomic area of the artery. However, it may radiate down to the ear, *teeth*, and occiput with generalized scalp tenderness and arthralgia.[118] Temporal arteritis may resemble a migraine attack because it, too, has a persistent throbbing quality that may last hours to days and the location is unilateral, over the temple area. *Temporal arteritis*, however, has an *additional burning, ache-like quality*. The pain increases with lowering of the head, *mastication*, and movements that create increased blood flow to that artery.

The patient may present with complaints of malaise, fatigue, anorexia, and weight loss if the arteritis occurs as a febrile illness. In advanced cases, patients may complain of transient visual loss on the side of the headache. This is a particularly severe symptom and requires immediate, aggressive treatment since thrombosis of the ophthalmic artery may result in partial or complete blindness. In up to 38% of patients, visual symptoms may be the only presenting symptom.[119]

Etiology. Arterial inflammation or chronic vasculitis, that may often be associated with immunological disorders, is the causative factor in this headache. Arterial biopsy often reveals frayed elastic tissues and giant cells in the vessel walls on histological examination.[118]

Examination. Dental examination is negative. The temporal artery may be tender to palpation, thickened, and enlarged and may lack a normal pulse.

Digital pressure with occlusion of the common carotid artery on the same side will frequently alleviate the symptoms. Ophthalmological examination or evaluation of optic ischemia is mandatory.

Diagnostic Tests. In giant cell arteritis, erythrocyte sedimentation rate, although a nonspecific test, will be significantly elevated. Definitive diagnosis is based on arterial biopsy. The entire temporal artery is typically removed to ensure sampling of diseased sections; skip lesions are common. Treatment is never delayed if visual disturbance is present.

Treatment. The dentist who suspects temporal arteritis should immediately refer the patient to a rheumatologist or an internist for complete workup. If optic symptoms are present, emergency ophthalmological examination is essential without delay.

Treatment of the condition consists of emergency dosages of steroids. When the elevated sedimentation rate has been reduced, maintenance doses of *prednisone* are administered as clinically determined.

Carotid or Vertebral Artery Pain. The dissection of the carotid or vertebral arteries, sometimes secondary to trauma such as whiplash and sometimes completely spontaneous, causes headache and cervical pain on the same side as the dissection. This serious, life-threatening condition is typically acute and accompanied by symptoms of transient ischemic attack or stroke and patients will seek medical

evaluation. However, sometimes patients with carotid dissection have symptoms consistent with one of the TACs and, due to *referral of pain into the jaws and teeth*, may, on occasion first seek dental care. Careful history and awareness of unusual symptoms and signs will help the clinician realize that this is not a dental problem and make appropriate and urgent referrals.

NEUROPATHIC PAINS

Neuropathic pain is pain that is due to some form of lesion or disease of the somatosensory system. This is in contrast to the normal transmission of noxious signals along nerves and to the central nervous system and cortex.

Neuropathic pain may occur after trauma, infection, or other disease process that affects the nerves or central nervous system directly such as mechanical damage from compression (such as with intraosseous dental implants), trauma, entrapment, traction or scarring; metabolic disorders such as diabetes; alcoholism or nutritional deficiencies; neoplastic disorders such as multiple myeloma; toxic reactions to drugs, metals, or certain organic substances; infectious or inflammatory processes such as herpes, hepatitis, leprosy; immune diseases such as multiple sclerosis; or genetic disorders such as porphyria.

It may also be due to changes that occur after an insult that leaves the normal sensory processing in the peripheral or central nervous systems in disarray, such as is seen in posttraumatic or postherpetic neuropathies.

Not all neuropathies are painful. When they are, they may be dramatically so. The distinguishing feature of peripheral neuropathic pains in the head and neck region is the quality of pain, that is burning, sharp, shooting, lancinating, or electric-like. The distribution of the pain is limited to the anatomical pathways of the nerve involved and is almost always unilateral. Sensory abnormalities may include diminished pain sensation in the presence of hypersensitivity to typically nonpainful stimuli.

In general, *neuropathic pains* in the head and neck can be divided into two main groups based on their temporal pattern, the *paroxysmal neuralgias* or *continuous neuropathies*

Some neuropathic pains are stimulus dependent, some occur spontaneously and are stimulus independent or both. Some neuropathic pains are accompanied by hyperalgesia and/or areas of numbness.

Paroxysmal Neuralgias

Symptoms. Paroxysmal, lancinating, sharp, unilateral pain that follows a distinct dermatomal pattern is common to all paroxysmal neuralgias. The pain is often described as electric-like, shooting, cutting, or stabbing. The attacks may last only a few seconds to minutes, with virtually no discomfort between attacks. Sometimes patients notice a vague prodrome of tingling and occasionally ache or burn after an attack. The attacks may occur intermittently, with days to months between a series of attacks. Usually, patients complain of "trigger areas" that, when stimulated, precipitate an attack. These are frequently located within the distribution of the nerve affected, usually on the skin or the oral mucosa. Neural blockade of the trigger area almost always relieves the pain for the duration of action of the local anesthetic. Should neural blockade fail to relieve the symptoms, either the diagnosis or the nerve block technique must be questioned. Each type of paroxysmal neuralgia has its own distinct characteristics.

Trigeminal Neuralgia and Pretrigeminal Neuralgia

Trigeminal neuralgia usually affects one or at most two divisions of the fifth cranial nerve, the maxillary and mandibular divisions being most common.[45] The maxillary or mandibular divisions alone are the next most frequently affected, with ophthalmic division neuralgias being the least common. The pain is unilateral 96% of the time. Touching and washing the face, tooth brushing, shaving, chewing, talking, or even cold wind against the face may set off the trigger and result in pain. Deep pressure or painful stimuli are usually tolerated without a painful episode. Patients go to extraordinary lengths, such as not shaving, washing, or brushing their teeth, to avoid stimulating the trigger area. Between attacks, patients are completely pain-free. Long remissions for months or years are not uncommon but tend to decrease with increasing age. Because the vast majority of trigeminal neuralgia cases involve the jaws, *dentists are commonly the first ones to see these patients*.

Trigeminal neuralgia is almost twice as common in women as in men and usually starts after the age of 50 and increases with age.[120] Anyone under the age of 40 with this disorder should be referred to a neurologist to be worked up for a structural lesion or multiple sclerosis.

Trigeminal neuralgia may rarely present comorbidly with any of the TACs, in which case the pain condition may be called cluster-tic or paroxysmal hemicranias-tic.[4] Certainly, SUNCT has several features that make it difficult to distinguish from trigeminal neuralgia and the two disorders do occasionally occur together.[45]

A syndrome of pain preceding the onset of true paroxysmal trigeminal neuralgia, known as *pretrigeminal neuralgia* (PTN), has been described.[121,122] Patients may present themselves up to 2 years before developing trigeminal neuralgia, with pain usually *localized to one alveolar quadrant* and sometimes a sinus. They may describe this pain as dull, aching, and/or burning, or as a sharp (burning) toothache, not unlike pain arising from the dental pulp. Some patients may also report a "pins and needles" sensation. The duration of PTN pain may be 2 hours to several months, with variable periods of remission. Movement, usually opening of the mouth, may trigger the pain.

Dental disease may be minimal or absent. Retained root tips are the most common finding, and their removal has been

associated with remission of pain. Obvious dental disease should be treated, but dental heroics in the absence of clinical or radiographic findings should be avoided. It was reported that 61% of the cases with PTN or trigeminal neuralgia were incorrectly diagnosed and treated for dental conditions.[123] Onset of classic trigeminal neuralgia may be quite sudden and occurs in the same division affected by the PTN symptoms. The onset may follow remission produced by previous dental treatment.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is 70–100 times **less** common than trigeminal neuralgia.[120] The symptoms include unilateral and 25% of the time nonconcurrent bilateral stabbing pain in the distribution of both the glossopharyngeal nerve (lateral posterior pharyngeal and tonsillar areas, the base of the tongue, down into the throat), and also the auricular and pharyngeal branches of the vagus nerve (the eustachian tube or ear, and down the neck).[45] Sometimes pain radiates into the vagal region and *may be associated with salivation or unilateral oral dryness*, flushing, sweating, tinnitus, cardiac arrhythmias, hypertension, vertigo, or syncope. *Throat movements*, pressure on the tragus of the ear, *yawning*, or *swallowing* may trigger the pain. Again, local anesthesia of the trigger area temporarily prevents precipitation of attacks. This can be accomplished by spraying the posterior pharynx with a topical anesthetic.

Eagle's syndrome may be the cause of symptoms similar to those of glossopharyngeal neuralgia,[124] although some believe that this syndrome is not sufficiently validated.[45] The symptoms that include a "sore throat" and *posterior tongue and pharyngeal pain* are thought to be related to the compression of the area of the glossopharyngeal nerve by a calcified elongation of the *styloid process* of the temporal bone. Precipitating factors include fast rotation of the head, swallowing, and pharyngeal motion from talking and chewing. Blurring of vision and vertigo are rarely seen.

Nervus Intermedius Neuralgia

Nervus intermedius neuralgia is extremely rare. The pain is often described as a lancinating "hot poker" in the ear. It may occur anterior to, posterior to, or on the pinna; in the auditory canal; or, occasionally, in *the soft palate*. A duller background pain may persist between attacks. Attacks may be accompanied by *salivation, tinnitus*, vertigo, or *dysgeusia*.[45,125] The trigger area is usually in the external auditory canal. This neuralgia has also been termed *Ramsay Hunt syndrome* or geniculate neuralgia, and is often associated with *herpes zoster* (or shingles). It may in some patients be due to a variant of glossopharyngeal neuralgia with pain in the ear.[45]

Superior Laryngeal Neuralgia

Superior laryngeal neuralgia is also a rare neuralgia with paroxysmal neuralgic pains of varying duration, minutes to hours, *located in the throat, submandibular region, or under the ear*. Triggering factors include *swallowing*, turning the head, loud vocalizations, or stimulating the site overlying the hypothyroid membrane where the nerve enters the laryngeal structures.

Occipital Neuralgia

Occipital neuralgia occurs in the distribution of the greater or lesser occipital nerves to the back of the head and mastoid process. The *ear and the underside of the mandible* may be involved because of the dermatomal patterns of C2 and C3 (Figure 17-12). The pain often radiates into the *frontal and temporal regions*, occasionally with the same sharp, electric-like character of the other neuralgias, but may last hours instead of seconds. Sometimes the pain takes on a more continuous burning, aching nature. A case of maxillary right posterior quadrant dental pain due to occipital neuralgia has been reported.[126] Trauma, especially rotational injuries to the neck, may precede the onset. Trigger zones, such as those seen with trigeminal neuralgia, are rare. The pain may be associated with neck and back pain, and emotional stress is a common aggravating factor.

Etiology. The paroxysmal neuralgias are considered *symptomatic* if a specific pathological process affecting the involved nerve can be identified and *classical* if not.[45] Paroxysmal neuralgias rarely occur in young people unless there is a distinct compression of the nerve by a tumor or other structural lesion. Compression of the nerve either peripherally or centrally by bone, scar tissue, tumors, aberrant arteries, or arteriovenous malformations causes *axonal loss and focal demyelination*, which is postulated to result in ectopic firing and reduced segmental inhibition of the low-threshold mechanoreceptors and wide-dynamic-range relay neurons.[127] The net effect is a *lowered threshold* of neuronal firing for which ordinary orofacial maneuvers such as chewing, swallowing, talking, or smiling may precipitate a neuralgic attack.

Trigeminal neuralgia, along with other paroxysmal cranial neuralgias, is typically considered idiopathic, although nerve compression by intracranial arteries that have become slack and tortuous with age is thought to be the likely culprit.[45] The *demyelinating* lesions associated with *multiple sclerosis* may also precipitate trigeminal neuralgia in younger individuals. The symptoms of trigeminal neuralgia associated with diabetic polyradiculopathy have also been reported.[128]

Glossopharyngeal neuralgia is more commonly, secondary to another pathologic disorder. For example tumors are found in 25% of cases. Local infection, neck trauma, elongation of the styloid process (Eagle's syndrome), and compression of the nerve root by a tortuous vertebral or posterior inferior cerebellar artery are other symptomatic causes of this ninth nerve neuralgia.[129] Unlike trigeminal neuralgia, glossopharyngeal neuralgia is almost never associated with multiple sclerosis,[130] and has been reported to be associated with an anomaly of the nerve itself.[131]

Occipital neuralgia may be secondary to hypertrophic fibrosis of subcutaneous tissue around the occipital nerve following trauma, irritation of the nerve by the atlantoaxial ligament, spondylosis of the upper cervical spine, spinal

cord tumors, or tubercular granulomas.[132] Myofascial TrPs in the semispinalis capitis and splenius cervicus muscles may mimic this type of pain or may cause neuralgia-like symptoms due to the entrapment of the greater occipital nerve as it passes through the tense semispinalis muscle fibers.[49] Since treatment of myofascial TrPs is noninvasive, with very low morbidity and no mortality, they must be carefully ruled out before neurectomy or other neuroablative techniques are considered.[133]

Examination. A patient presenting with symptoms of *trigeminal neuralgia* must be worked up for dental disorders, sinus disease, and head and neck infections or neoplasms. Since nerve compressions from intracranial tumors, aneurysms or vascular malformations, or central lesions from multiple sclerosis may also cause symptomatic trigeminal neuralgia, all patients with trigeminal neuralgia-like symptoms should be worked up with an *imaging study* of the head, either *contrast-enhanced CT or MRI or magnetic resonance tomographic angiography*, in addition to routine films.

Diagnosis of *PTN* is based on the clinical presentation of constant *dull toothache pain* in the absence of dental or neurological findings and normal radiographic, CT, or MRI examinations.

Since *glossopharyngeal neuralgia* is more often associated with nasopharyngeal, tonsillar, or posterior fossa tumors or other disease than is trigeminal neuralgia, imaging studies including skull films, panoramic films, and MRI are essential.

In *Eagle's syndrome*, the diagnosis is usually established on the basis of radiographs, as well as intraoral finger palpation of the posterior pharyngeal area. Panoramic films should reveal a *styloid process that is so long* that its image projects beyond the ramus of the mandible. Anything shorter is not significant, and other causes for the patient's pain should be sought. Pain is alleviated temporarily by neural block of the suspected compressive area. Treatment is primarily surgical shortening of the styloid process either through an intraoral or an extraoral approach.[124]

Occipital neuralgia requires a thorough musculoskeletal evaluation in addition to a cervical spine radiographic series to rule out neoplasms or other local destructive lesions. Digital palpation of the greater occipital nerve along the nuchal line may be painful. Caudal pressure to the vertex of the head while it is flexed and rotated toward the side of the pain may reproduce cervical compression symptoms.[132] Sensory loss is rare. Because myofascial TrPs may mimic or accompany this disorder, careful palpation of the posterior cervical muscles for the tight bands and focal tenderness with referred pain, characteristic of myofascial TrPs, is essential.[45,133]

Treatment. Obviously, if a neuralgia is "symptomatic" or the result of identifiable pathologic entity or structural lesion, treatment is directed at correction of the cause. However, for classical paroxysmal neuralgias, the first treatment of choice is the drug *carbamazepine (Tegretol)*. Carbamazepine and oxcarbazepine are most efficacious in trigeminal neuralgia and remain the first line of therapy.[134] These drugs have some success in glossopharyngeal or nervus intermedius neuralgias as well. Lamotrigine and baclofen (Lioresal) are the next most efficacious. Other medications such as topiramate, gabapentin (Neurontin), pregabalin (Lyrica), and Botox are also used, alone or in combination. All of these medications may cause varying degrees of dizziness, drowsiness, and mental confusion. In addition, carbamazepine may cause hematopoietic changes and baclofen may affect liver enzymes. Although such side effects are not as common as once thought and are less common with gabapentin and pregabalin, patients taking any of these medications must be monitored very closely initially.

Certainly, when medications become ineffective, or the patient cannot tolerate them, either due to severe drowsiness or frank allergy, neurosurgical intervention remains an option. As the success rates with neurosurgical interventions such as gamma knife, radiosurgery, percutaneous rhizotomies, and microvascular decompression improve and the morbidity goes down, surgical interventions are recommended earlier as more patients may benefit with fewer side effects.[135]

Therapies, especially medications, used to treat true trigeminal neuralgia have been reported to work for *PTN* as well.[136]

Classical *glossopharyngeal neuralgia* can be managed with the same medications and surgical techniques used for trigeminal neuralgia.[4]

Because of its predominantly musculoskeletal etiology, *occipital neuralgia* lends itself best to non-pharmacological and nonsurgical treatments. Consequently, physical therapy, postural reeducation, corrected ergonomics, home neck-stretching exercises, TrP injections, and even C2 nerve blocks are the first line of approach.[137]

Surgical section of the nervus intermedius or the chorda tympani has been reported to relieve the pain of *nervus intermedius neuralgia*[138] if management with anticonvulsants fails.

Neuromas

Neuromas are nonneoplastic, nonencapsulated, tangled masses of axons, Schwann cells, endoneurial cells, and perineurial cells in a dense collagenous matrix (Figure 17-14).

Etiology. Neuromas tend to develop when a nerve axon is transected, as might occur with a dental extraction, surgery, or trauma. The proximal stump of a transected nerve is still connected to its cell body and, in a few days postinjury, starts to sprout axons, in an attempt to reestablish continuity with its distal segment. Usually, this process is unsuccessful, especially in soft tissue; therefore, a tangled mass of tissue results.[139] In the orofacial region, neuromas most commonly develop in the area of the mental foramen, followed by the lower lip, tongue, and buccal mucosa, all easily traumatized sites. Neuromas are least likely to occur in the inferior alveolar canal because the bone guides the tissue growth.

Symptoms. A neuroma may be completely asymptomatic, and, in fact, approximately 25% of them are. However, neuromas are capable of generating very prolonged electrical impulses in response to a variety of stimuli, including touch.[139] The nerves in the trigeminal system have been

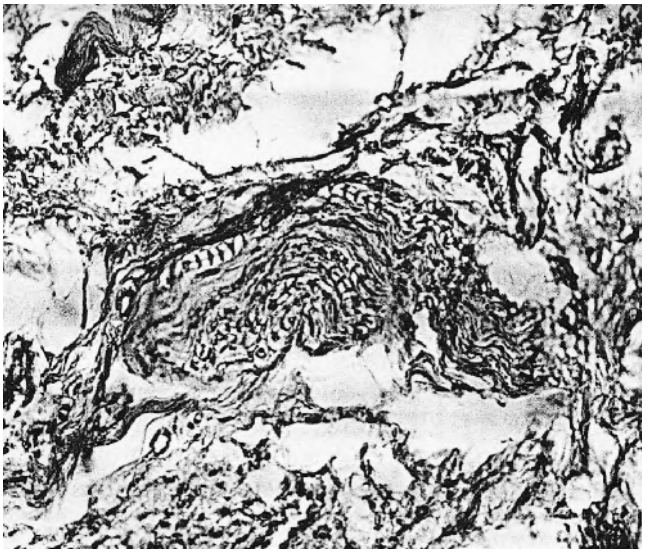

FIGURE 17-14 Amputation neuroma revealed by biopsy. Strikingly clear-cut, tangled, and well-myelinated fibers, cut at various angles, are massed with irregular sheath and perineural connective tissues into an abnormal aggragate of varying size and surrounded by well-vascularized fibrous tissue. Biopsy was occasioned by sharp, intermittent pricking "nerve pain" 6 months in duration, becoming more diffuse and steady. (Courtesy of Dr. Gordon Agnew, U.S.A.)

shown to be less sensitive to spontaneous or touch stimulated discharge than neuromas in other parts of the body.[139]

The diagnostic features of a neuroma include a history of prior surgery or a lacerating injury at the site of the pain, along with precipitation of the pain with local pressure or traction. The pain is short-lasting, with a burning, tingling, radiating quality. A drop of local anesthetic will abolish the response. If the neuroma has developed on the inferior alveolar nerve, it may be visible radiographically as a widening of the mandibular canal.

Neuromas may also occur in the *TMJ postsurgically* or postlacerating trauma.[140] Symptoms include restricted joint movement due to adhesions and pain with neuropathic qualities (sharp, shooting, itching, burning) on stretching of the adhesions. The deep aching pain of musculoskeletal disorders is lacking.

Examination. In the oral cavity, neuromas may appear as nodules of normal surface color but usually are not visible or palpable. Of greater interest is the presence of a scar, indicating previous injury or surgery. In the TMJ, movement against adhesive restrictions, as with jaw opening, should elicit short-lasting neuropathic pain.

Treatment. A one-time excision of a sensitive neuroma located in the accessible scar tissue is worth trying provided that the pain is localized and can be relieved by infiltration with a local anesthetic.[141] Unfortunately, neuroma excision and other peripheral neuroablative procedures provide significant relief in very few patients.[141] *Neuromas often re-form*, and the pain may return. Medications such as carbamazepine (Tegretol) or amitriptyline (Elavil) may be helpful but should be used only if the patient feels that the pain is severe enough to warrant tolerating the side effects that may accompany these medications.

Neck Tongue Syndrome. This is a very rare condition where rotation of the head causes occipital and cervical pain along with *paresthesias, dysesthesias, or anesthesia of the tongue or even a sensation of movement* on the same side as the neck pain.[45,142] The pain lasts seconds to 2 minutes.[142] Patients may have restricted range of motion of the neck and radicular symptoms into the arm.[142]

The proprioceptive fibers of the tongue run from the ansa hypoglossi to the C2 ventral ramus. During sudden rotation of the neck, especially when there is subluxation of the atlanto axial joint, stretching and/or compression of the second cervical root is thought to cause these symptoms.[143]

Continuous Neuropathies

Continuous trigeminal neuropathies typically occur after some kind of peripheral nerve damage or "deafferentation." This category includes postherpetic, posttraumatic, and postsurgical neuropathies, as well as anesthesia dolorosa. As with paroxysmal neuralgias, the continuous neuropathies follow the distribution of the damaged nerve but differ in that the pain is more or less continuous, with some fluctuation over time. Patients report altered sensations, dysesthesias, or pain in the distribution of the nerve that varies from tingling, numbness, and twitching to prickling or burning. They may also report "formication," which is a sensation of worms under the skin or ants crawling over the skin. The dysesthesias are generally discomforting to the patient because they are continuous and exacerbated by movement or touching of the area. As with paroxysmal neuralgias, local anesthetic blocks of the nerve eliminate all paresthesias except numbness.

Painful Trigeminal Neuropathy Due to Acute Herpes Zoster

Herpes zoster is a painful acute viral infection produced by the varicella zoster virus. Varicella zoster causes chickenpox in the young and afterward remains in the ganglia of sensory nerve endings in a dormant "provirus" form. Periodically, the virus reverts to its infectious state and is held in check by circulating antibodies. If an individual is immune-compromised or is older and has a low antibody titer, the infectious virus is able to retrace its path down the sensory nerve and escape into the skin, where it causes the typical skin eruptions and vesicles of zoster. Acute hemorrhagic inflammation with demyelination and axonal degeneration of dorsal root ganglion cells has been demonstrated in early[144] and more recent[145] pathological studies.

The incidence of acute herpes zoster outbreaks has diminished dramatically since the varicella vaccine became available in 1995, reducing the acute disease by 75%.[146] Without the vaccine, acute herpes zoster affected individuals over 70 years of age 12 times more frequently than persons under 10 presumably because their antibody titer decreased as their exposure to children with chickenpox diminished. The older the individual, the more severe the rash and the acute pain,

and, the more severe the prodromal pain, the higher the likelihood that that person will develop postherpetic neuropathy (PHN).[147]

Symptoms. Continuous pain in the distribution of the affected nerve and malaise commonly precedes the eruption of *acute herpes zoster* by up to 7 days,[45] sometimes along with paresthesia and shooting pains. Vesicles form, become infected, scab over, and heal. Small and sometimes severe scars are left behind. The scars are usually anesthetic, the skin between being hyperesthetic.

Ten percent to 15% of patients with herpes zoster develop unilateral lesions in the head and neck region, and 80% of these are in the ophthalmic division of the trigeminal nerve (Figure 17-15). C1-3 are also sometimes affected. When the first division of cranial nerve V is affected, vesicles may appear on the cornea, and the risk of impaired vision is high. If the infection affects the *maxillary division of the trigeminal nerve*, intraoral eruptions may develop concomitantly with those on the skin. Involvement of the oral mucosa without cutaneous involvement may occur and must be differentiated from aphthous stomatitis. Multiple devitalized teeth, isolated in a single quadrant, have been reported as a rare complication of herpes zoster infection.[148]

If the *facial nerve (cranial nerve VII)* is involved, facial palsy may occur due to pressure on the nerve from inflammatory swelling in the bony canal. The pupil may become permanently paralyzed, and the upper eyelid may droop. Involvement of the geniculate ganglion causes lesions to erupt in the external auditory canal, may cause acoustic symptoms, and is known as Ramsey Hunt syndrome.[45]

FIGURE 17-15 Herpes zoster infection of the first division of the trigeminal cranial nerve. (Courtesy of Faculty of Medicine, University of Toronto, Canada.)

Treatment. Treatment of herpes zoster is primarily focused on pain relief, reducing the rash, and reducing the risk of complications such as local infection, spread to other areas, and development of postherpeticneuropathy. The medications of choice are the antiviral drugs valaciclovir and famciclovir, which both performed equally for resolution of the lesions and pain control.[149] Newer medications are being tested and appear to offer improvements such as reduced dosing, fewer side effects, and improved effectiveness.[150] Systemic steroids help reduce the clinical symptoms significantly if started within 3 days of eruption of vesicles, but have little impact on the development of PHN.[151]

Most important is the control of pain. This can be achieved with over the counter analgesics such as acetaminophen. Amitriptyline has been shown to provide pain relief and shorten the duration of the illness. The problem is that older individuals may have difficulty taking amitryptiline due to the cardiac effects. Nortriptyline or desipramine may be better choices.

Postherpetic Neuropathy (PHN)

PHN may follow an acute attack within 3 months of *herpes zoster* ("shingles") in up to 22% of people who get the acute disease.

PHN results when the pain of acute zoster does not subside as the acute eruption clears. Risk factors include increased age, the severity of the prodromal pain of the acute zoster, the severity of the pain with the acute zoster, and the severity of the rash.[152]

The pain of PHN often has several distinct components. Patients complain of a steady, deep, aching, burning pain along with superimposed sharp, stabbing pains similar to trigeminal neuralgia. In addition, many complain of *allodynia*, pain in response to light brushing of the skin, an innocuous event under normal circumstances. "Postherpetic itch" occurs in 30–50% of patients and, despite a mild to moderate intensity, it rated as more bothersome than pain.[153] The pain is limited to the distribution of the affected nerve, and there is usually cutaneous scarring and sensory loss.[148] Complaints of *formication* are common. Since this pain is severe and unrelenting, it places a large emotional burden on the elderly patients who suffer from it causing interruption of sleep, drug reliance, depression, and even contemplation of suicide.

Examination. The history of acute zoster infection and the obvious scars it leaves behind, including pale, red or purplish skin discoloration, make diagnosis relatively simple in most cases. PHN, on the other hand, may occur up to 3 months after the vesicular stage of herpes zoster has healed. If the patient knows he has had herpes zoster infection, the diagnosis will be self-evident. The dentist, however, should carefully check the mouth to ascertain that a concomitant severe pulpitis is not superimposed on the condition and perform temperature and pinprick evaluations.

Difficulty in diagnosis arises when the severe vesicular herpetic attack is not manifested but rather one or two small

aphthous ulcers appear in the oral cavity or on the lips or face. This mild attack is often forgotten by the patient, and a careful history is essential.[154]

Treatment. Although age is the most important risk factor for the development of this painful chronic disorder, early treatment during the *acute phase of herpes zoster* with antiviral agents or certain tricyclic antidepressants such as amitriptyline combined with psychosocial support, may be effective in preventing the development of PHN.[155] Tricyclic antidepressants, gabapentin, and opioids are the only medications that have shown efficacy in randomized clinical trials.[153,156] Although sympathetic nerve blocks do tend to reduce acute herpetic pain, they have not been proven to be effective in preventing PHN.[148,157]

The treatment of PHN is often difficult and unrewarding. The longer the infection continues and the longer the patient has PHN, the more difficult pain management becomes. *Amelioration of the depression* that invariably accompanies this condition is as significant in therapy as reduction of the primary pain.

Painful Traumatic Trigeminal Neuropathies (PTTNs)

Traumatic injury to or disease of the peripheral nerves often results in sensory changes qualitatively different from PHN that are sometimes accompanied by pain. The most common dental causes of painful traumatic trigeminal neuropathy (PTTN) are dental implants, third molar extractions, nerve blocks and root canal therapy.

Anesthesia dolorosa is an extreme form of PTTN that occurs after a deliberate or iatrogenic lesion of one of the branches the trigeminal nerve or the occipital nerve. There is "persistent and painful anesthesia or dysesthesia within the area of the distribution of [the damaged nerve]," accompanied by diminished sensation to pinprick and sometimes other sensory loss.[45]

Dental implants may cause direct trauma to a major nerve (usually the mandibular nerve) or irritation of smaller nerve fibers (in the maxilla) immediately upon placement. Sometimes dental implants cause no pain until the crown is cemented and they are loaded.[158] The pain after crown placement may be due to extensive peri-implant innervation.[159]

Third molar extractions may be followed by short-term hypoesthesia, which improves in most patients.[160] Unless there is iatrogenic damage to the mandibular nerve during surgery, there appears to be little risk of neuropathic pain.[161] However with iatrogenic damage, pain occurred in 70% of cases.[162]

Root canal treatment is accompanied by about a 3–13% incidence of persistent pain.[163] Surgical endodontic procedures were associated with painful trigeminal neuropathy in 5% of cases.[164]

Symptoms of PTTN. The pain is described as a continuous tingling, numb, twitching, or prickly sensation, sometimes with burning or shooting triggered by touch or movement. The pain occurs unilaterally along the injured nerve and rarely spreads to another dermatome. Patients may describe sensations of hot, cold, swelling, local redness, or flushing. There is significant allodynia and electric pains may be precipitated with percussion over the nerve.

Pathophysiology of PTTN can be explained in part by several of the pain phenomena described at the beginning of this chapter, namely peripheral sensitization from tissue injury and inflammation, central sensitization, glial cell activation, and ectopic activity from nerve injury.

Treatment. The best treatment for traumatic trigeminal neuropathies is prevention. To this end, preventive analgesia, the use of preventive interventions such as preoperative opioids, perioperative gabapentin and/or pregabalin, or local anesthetic blocks during surgery have been studied and while they seem to reduce postoperative pain, there is no solid data to indicate that they prevent the emergence of persistent pain.[4] There is interest in developing screening tools to identify patients at higher risk of developing neuropathy after surgery as there is evidence that environmental, psychosocial, and genetic factors play a role.[165]

Treatment of established PTTN may be met with varying success and can include any of the pharmacological therapies used for the other neuralgias as well as acupuncture, transcutaneous electrical nerve stimulation. Cognitive behavioral therapy to combat comorbid anxiety and depression and address quality of life issues was not shown to be effective.[166]

Surgical therapies to repair damaged nerves do improve the level of sensation,[167] and the success has been good for painful neuropathies where nerve repair was aimed at clear sources for the neuropathy such as scar tissue removal or relief of compression (dental implant removal) or neuroma excision.[168] Central procedures have not been systematically studied but may be useful in intractable cases.[4]

"CAUSALGIC PAIN" AKA CHRONIC REGIONAL PAIN SYNDROME (CRPS)

Causalgia is a word derived from the Greek words *kausos*, meaning "heat," and *algia*, meaning "pain." Causalgia was first described by Mitchell in 1864 as a syndrome of burning pain that appeared in the extremities following partial injury to a major peripheral nerve by a high-velocity missile trauma.[169] In 1947, Evans[170] used the term reflex sympathetic dystrophy (RSD) to describe the same burning pain. Evans noted that the pain had many features of sympathetic stimulation such as redness, swelling, sweating, and atrophic changes in the skin, muscles, and bones. He also found that minor injuries, such as fractures or sprains, could precipitate this pain, not just major nerve trauma. That same year, Bingham published the first report of RSD of the face.[171] Since then additional publications, but relatively few, have documented this pain syndrome in the face.[172–176]

In the early 1990s, this pain disorder was renamed "*complex regional pain syndrome (CRPS)*" *type I and type II*: Type 1 for those pains after minor injuries (RSD) and Type II for pain after major injuries (causalgia), although the distinction seems to be unnecessary.

In 1994, the IASP came up with research diagnostic criteria that had excellent sensitivity but low specificity.[177,178] Additional clinical diagnostic criteria were added to the IASP diagnostic criteria ("the Budapest Criteria") in order to improve specificity for research purposes.[179] An additional subtype was added CRPS- not otherwise specified (NOS) in order to account for cases that did not meet all of the typical criteria.

Symptoms. The characteristic pain is a *continuous, deep, hot, burning ache* with painful cutaneous hypersensitivity (allodynia) and hyperalgesia that is disproportionate to the inciting injury and *spreads nondermatomally beyond the injury site*. The pain is present at rest and aggravated by light touch, heat, cold, movement, or emotional stress.

Typically, *CRPS* begins a few days to several weeks after an injury. In the head and neck region, CRPS/RSD has been reported to develop after maxillofacial surgery for cancer, head injury, *molar extraction*, and sinus surgery.[172]

In the limbs, undiagnosed or untreated CRPS passes through an initial or "traumatic" stage characterized by a burning ache, edema, and hyperthermia to a second or "dystrophic" stage, with cool, cyanotic skin, spreading pain, and edema. The third or "atrophic" stage is evidenced by muscle atrophy, osteopenia or osteoporosis, smooth, glossy, mottled-appearing skin, and intractable pain. However, because of the abundant collateral blood circulation in the head and neck region, the bony, vascular, and trophic changes so typical in the extremities are less common in the face.[172] This is also probably why CRPS is recognized so infrequently in the head and neck region. In the absence of sympathetic changes, CRPS of the face resembles PTTN, except that the pain spreads beyond the expected dermatome based on the site of the insult or trauma.

Etiology. Similar to PTTN, CRPS may be due to sensitization of the primary afferent nociceptors and spinal tract neurons. In addition, disinhibition of central nociceptive neurons and reorganization of thalamocortical somatosensory maps seem to play a role.[4,180]

Clinically, the sympathetic nervous system is implicated in these pains[181] but while sympathetic blockade provides profound relief in some cases, it does not in others.[182]

Examination. The patient with CRPS complains of pain at the slightest touch and is difficult to examine. The skin may be flushed and dry or cold and sweaty, and a temperature difference may be discernible.

Diagnostic tests. Definitive diagnosis of the condition in the head and neck may be accomplished through immediate reduction of pain and hyperesthesia with a successful local anesthetic block of the stellate ganglion, although systematic review of the literature has shown some mixed results.[182] This procedure requires a trained anesthesiologist since the stellate ganglion is located in close proximity to several vital structures, including the vertebral artery and the apex of the lung.

Treatment. If the stellate ganglion block was successful in eliminating or significantly reducing the pain, repeated sympathetic blocks are the treatment of choice.[172] Early intervention is best. Oral medications such as steroids, low-dose tricyclic antidepressants with or without an anticonvulsant may be a useful adjunct or alternative.[183] Biofeedback and relaxation techniques may help reduce generalized sympathetic activity. Transcutaneous electrical nerve stimulation or acupuncture in combination with physical therapy may be helpful in providing relief and increasing function.

When dealing with any neuropathic or sympathetically maintained pain, referral to a neurologist should be considered if there are any subjective complaints or objective findings of cranial nerve deficits such as areas of facial hypesthesia, persistent motor weakness or paralysis, or a depressed corneal reflex.

MUSCLE PAINS

Pain of muscular origin is generally described as a continuous, deep, dull ache or as tightness or pressure. Once dental pathology has been ruled out, it is undoubtedly the most prevalent cause of pain in the head and neck region.[50,184] The most common muscle disorder to be familiar with is myofascial pain (MFP).

Local muscle soreness or "*noninflammatory myalgia*" is usually an acute process seen in the dental office from protective co-contraction of muscles secondary to an inflammatory or infectious process such as pericoronitis or other source of deep pain or a heavy occlusal contact after crown placement, that responds well to correction of the inciting factor.[185]

Myospasm, an involuntary CNS induced continuous contraction of a muscle or group of muscles, is less common in the jaws than previously thought.[185] When encountered, it is also usually associated with deep pain input from other sources such as joint inflammation, or dental infection, although fatigue or overuse of the muscle or idiopathic mechanisms may also be involved.[186,187] Treatment involves reducing the pain with massage, vapocoolant spray, ice, or local anesthetic injection (plain, NO vasoconstrictor!) and gently stretching passively to achieve full muscle length. Elimination of the causative factor, if present, will prevent recurrence.

Myofascial Pain (MFP)

MFP, a regional referred pain syndrome associated with focally tender TrPs in muscle, is a prevalent cause of pain in all parts of the body and has been reported as a common source of pain in numerous medical specialties.[49] For example, almost 30% of patients presenting themselves with a complaint of pain in an internal medicine practice[51] and over 80% of patients in a chronic pain center[188] had MFP as a primary diagnosis. It is also the most prevalent cause of painful symptoms in TMDs.[50]

Symptoms. In *MFP*, the presenting pain complaint is usually a *referred symptom* with a *deep, dull aching quality* located in or about normal muscular or, importantly, nonmuscular structures. In the head and neck region, the patient may complain of such things as *toothache*, sinus pain, *TMJ pain*, or

headache, yet evaluation of these areas or structures does not reveal any pathological change. In fact, *any undiagnosed deep, dull, aching pain may be myofascial in origin*. The intensity of MFP should not be underestimated: the pain intensity has been documented to be equal or slightly greater than pain from other causes.[51]

Associated symptoms, thought to be due to the physiological sensory, motor, and autonomic effects seen with prolonged pain, are common and may confuse the clinical picture.[49,189] Associated sensory complaints may include tenderness in the referred pain site, such as scalp pain on brushing the hair, or *abnormal sensitivity of the teeth*.[190,191] Motor effects include increased electromyographic (EMG) activity in the pain reference zone, although patients rarely complain about this specifically.[189,190] Autonomic changes such as localized vasoconstriction (pallor), sweating, lacrimation, coryza, increased salivation, and nausea and vomiting have also been reported.[49,190,192]

Patients note worsening of symptoms with increased psychological stress, cold weather, immobility, and overuse of involved muscles. Hot baths, rest, warm weather, and massage are typical alleviating factors.

Etiology. Myofascial TrPs tend to develop with protective muscle splinting after acute trauma, with chronic muscle overload, secondary to other chronically painful conditions, and secondary to referred pain from other TrPs. They can be activated by additional acute muscle overload, and also through psychological stress.

Acute trauma is easily identified and includes injuries such as those caused by falls, blows, sports injuries, motor vehicle accidents, excessive or unusual exercise, or even *prolonged jaw opening* at the dental office.

Chronic muscle overload is more insidious and includes long-term muscle overuse due to poor posture and body mechanics, abnormal strain, and repetitive motion-type injuries.

Secondary myofascial TrPs develop in response to prolonged underlying disease, especially if painful (migraine, persistent pulpalgia, post herpetic neuropathy) since any process that activates nociceptors may induce motor effects and TrP development. Secondary MFP may prolong and complicate pain due to other causes. MFP needs to be identified and treated to reduce pain and improve response to other therapies. Patients with what appears to be primary MFP, in whom TrPs and pain recur despite appropriate initial response to TrP therapies and compliance to home exercise, must be reevaluated for occult underlying disease or other perpetuating factors.

Secondary or *"satellite" TrPs* develop in muscles in the site of referred pain from referred motor activity.[189] These satellite TrPs are extremely common and may cause their own referred pain pattern, further confusing the clinical picture. For example, upper anterior toothache may be due to referred pain from a temporalis muscle TrP but if treatment of that TrPs only provides temporary relief, there may be a "key" TrP in the upper trapezius muscle and definitive resolution of the myofascial referred toothache will require inactivation of the trapezius trigger point.

In MFP, the presenting pain complaint is always associated with a TrP located in a taut band of skeletal muscle that is often distant from the site of pain. TrPs are focally tender, firm, nodular areas in muscle that, with appropriate palpation, produce spontaneous referred pain or intensify existing pain in local or distant locations.[193–195] Patients are typically unaware of the existence of these TrPs. TrPs are considered active when the referred pain pattern and associated symptoms are clinically present and latent when they are not. TrPs will vacillate between active and latent states depending on the amount of psychological stress the individual is under and the amount of muscle overload placed on the affected muscle.

The location of TrPs and their associated referred pain patterns are predictable and reproducible from patient to patient[49] (Figures 17-16 to 17-19). A meticulous discussion of MFP, as well as a complete compendium of the pain referral patterns for most muscles of the body, has been brilliantly detailed by Travell and Simons.[49,196]

Pathophysiology. With some training, myofascial TrPs are relatively easy to palpate. Despite the comparative ease of clinical identification of TrPs, controversy still exists about their structure, exact pathophysiology and the role of the central nervous system. Suffice it to say that research over the last 25 years has led to the conclusion that MFP may be

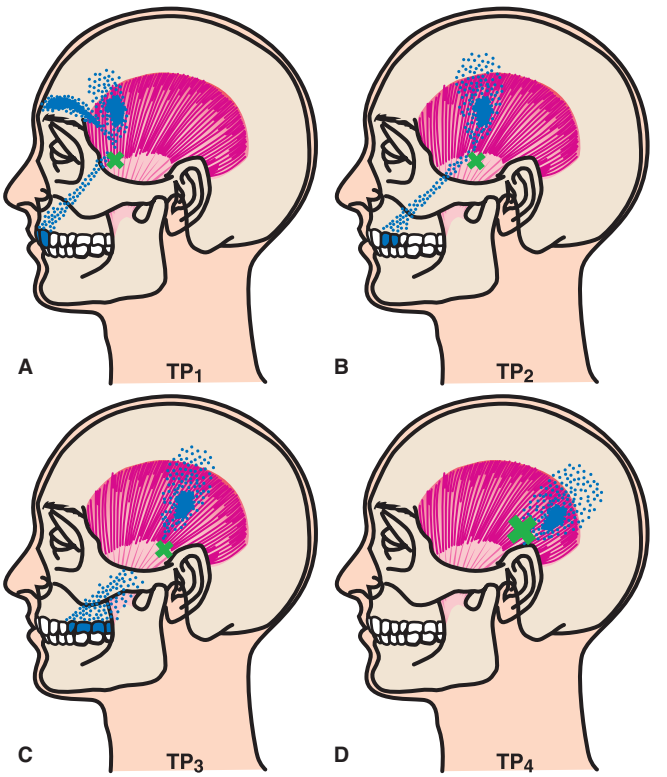

FIGURE 17-16 Referred pain patterns from trigger points (green "x"s) in the temporalis muscle (main referral zone, blue, spillover zone, stippled blue). ***A.*** Note referral to anterior teeth from anterior TrP labeled TP1. ***B,C.*** TP2 and TP3 refer to the maxillary posterior teeth, sinus, and zygomatic area. ***D.*** Posterior TrP, TP4, refers to the supra-auricular area. a complex form of neuromuscular dysfunction where neurogenic inflammation, wide dynamic range neurons, and limbic system structures contribute to muscle sensitization, somatovisceral interactions, the development of chronic pain and the objective physical findings of allodynia, hyperalgesia, and referred pain.[128,197–199]

Simons' integrated trigger point hypothesis, namely that the myofascial TrP represents an area of isolated sustained muscle contraction due to excess acetylcholine release, is still considered the most credible theory to date.[197] Isolated sustained muscle contraction would result in uncontrolled metabolism, and localized ischemia that is initiated by acute muscle injury or strain.[190] This theory does provide a credible explanation for the palpable nodules and taut muscle bands associated with TrPs. The TrP nodule is described as a group of "contraction knots" in which a number of individual muscle fibers are maximally contracted at the end-plate zone, making them shorter and wider at that point than the noncontracted neighboring fibers. If enough fibers are so activated, a *palpable nodule* could result. As for the taut band, both ends of these affected muscle fibers would be maximally stretched out and "taut," producing the palpable taut band (Figure 17-20). This theory overlaps with the "Cinderella hypothesis" proposed by Hagg[186] where the idea is that TrPs could develop in response to muscle recruitment patterns during submaximal level exertions with moderate or low physical load, not unlike those encountered with computer work or typing.[187]

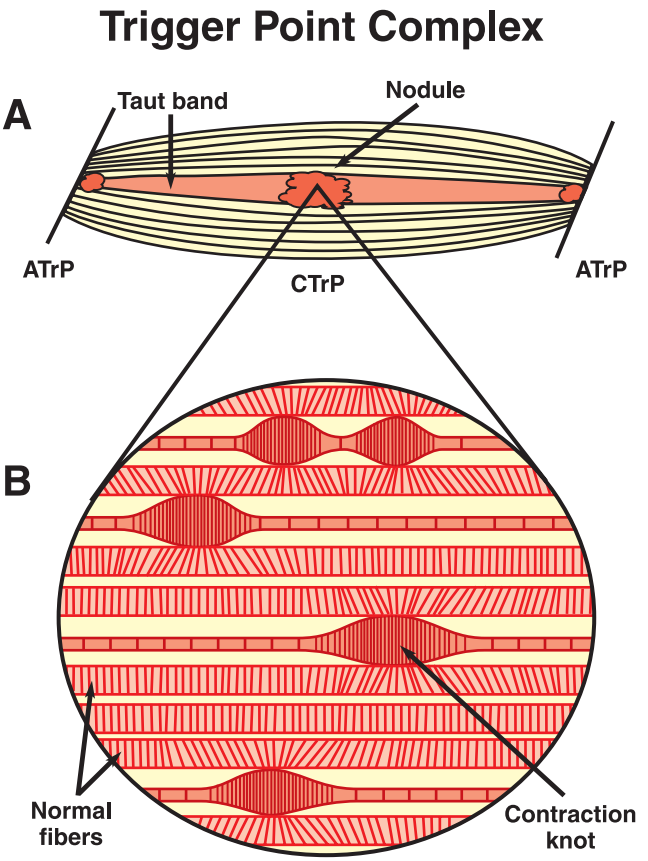

FIGURE 17-20 Schematic conceptualization of a trigger point (TrP) in a longitudinal section of muscle. ***A.*** The central TrP (CTrP), which is found in the muscle where the motor nerve axons enter (end-plate zone), is clinically tender to palpation. This area contains numerous "contraction knots," maximally contracted individual muscle fibers that are shorter and wider at the motor end plate than the noncontracted neighboring fibers. ***B.*** Enlarged view of the central TrP showing the distribution of five contraction knots. The vertical lines in each muscle fiber identify the relative spacing of its sarcomeres, the sarcomeres within the contraction knots experiencing maximal contracture and being markedly shorter and wider than the sarcomere of the neighboring normal muscle fibers. In fibers with these contraction knots (note the lower three individual knots), the sarcomeres on the part of the muscle fiber that extends beyond both ends of the contraction knot are elongated and narrow compared with normal sarcomeres. In patients, the central TrP would feel nodular as compared to the adjacent muscle tissue because it contains numerous "swollen" contraction knots that take up additional space and are much more firm and tense than uninvolved muscle fibers. If enough fibers are so activated, a palpable nodule could result. As for the taut band, both ends of these affected muscle fibers would be maximally stretched out and "taut," producing the palpable taut band. (Reproduced with permission from Travell JG, Simons DG, et al, 1999.[49])

The mechanism of referred pain from myofascial TrPs is also under speculation. According to Mense[200] and Vecchiet et al.,[201] the convergence-projection and convergence-facilitation models of referred pain (described earlier under section "Referred Pain") do not directly apply to muscle pain because there is little convergence of neurons from deep tissues in the dorsal horn.[200] These authors propose that convergent connections from other spinal cord segments are "unmasked" or opened by nociceptive input from skeletal muscle and that referral to other myotomes is due to the release and spread of substance P to adjacent spinal segments[200] (Figure 17-21A). Simons[190] has expanded on this theory to specifically explain the referred pain from TrPs (Figure 17-21B).

Examination. Because the patient's pain complaint is typically a referred symptom, it is usually distant from the muscle containing the guilty TrP,[49] although some TrPs also cause more localized pain symptoms. Multiple TrPs can produce overlapping areas of referred pain (Figure 17-22). The pattern of pain can be used in reverse to identify possible etiological TrPs.

Systematic fingertip or pincer type examination of suspected muscles and their contralateral counterparts, looking for taut bands and focal tenderness, is *essential* (Figure 17-23A–C). Effective TrP palpation is a skill that must be learned and practiced. Depending on the muscle, the tip of the index finger should be used for flat palpation or the index finger and the thumb for pincer-type palpation.[49] Once a TrP is found, algometry studies support the application of 2 to 3 kg/cm^2 of pressure to elicit pain.[193–195] The recent DC/TMD diagnostic criteria recommend 1-1.5kg/cm^2 of pressure.[195] The pressure should be applied for at least 5-10 seconds to elicit the referred pain pattern, if any. The examination may replicate the patient's pain so precisely that there is no doubt about the diagnosis. If uncertainty exists, specific TrP therapies, such as "spray and stretch" or TrP injections, described in the following, may be used diagnostically.

All head and neck muscles should be routinely examined in patients with a persistent pain complaint. This will help identify both primary and secondary MFP in addition to help identify TrPs in key muscles (e.g., upper trapezius or sternocleidomastoid) that may be inducing or perpetuating satellite TrPs in muscles located in the pain referral sites (e.g., temporalis).[49,189]

Treatment. Recommended treatment of MFP involves most importantly identification and control of causal and perpetuating factors, patient education, and specific home stretching exercises. Therapeutic techniques such as "spray and stretch," (Figure 17-24), voluntary contract release, TrP pressure release, and TrP injections are useful adjunctive techniques that usually facilitate the patient's recovery

Perpetuating factors most commonly include mechanical factors that place an increased load on the muscles. Teaching patients good posture and body mechanics will go a long way in reducing referred pain from myofascial TrPs, especially in the head and neck region.[187,202] An *intraoral stabilization appliance* may be indicated if the patient clenches or bruxes their teeth at night.[4,59,185]

Psychological factors, such as *stress* that has been shown to cause TrP activation,[203] or *depression* that lowers pain thresholds, will contribute to MFP. Sleep disturbance and general inactivity are also common perpetuating factors. Simple stress management and relaxation skills are invaluable in

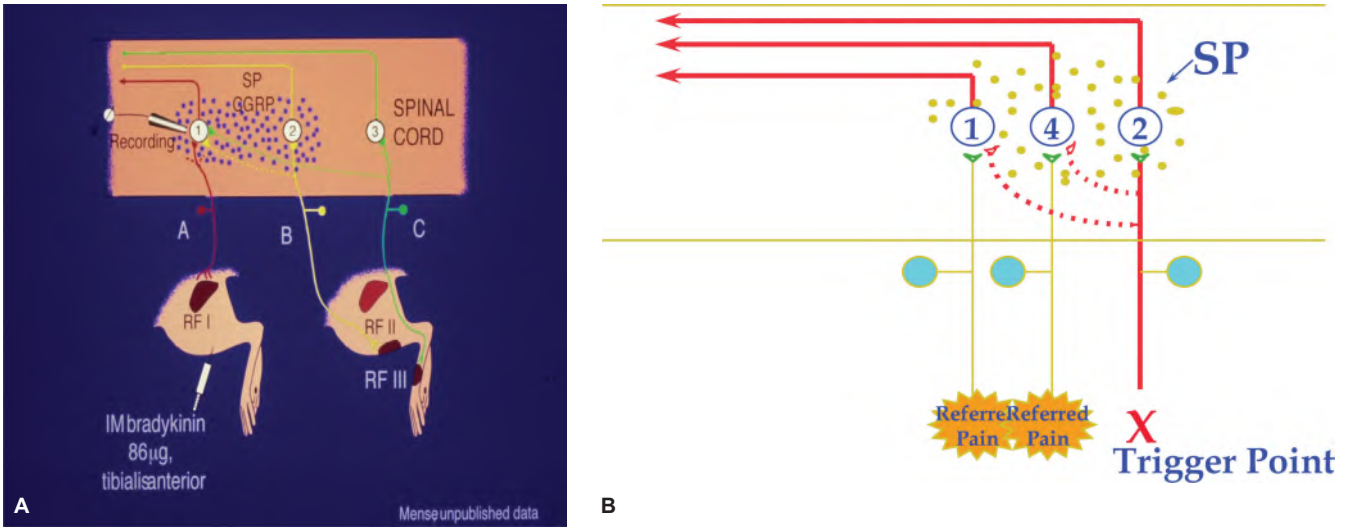

FIGURE 17-21 ***A.*** Neuroanatomic model explaining the appearance of new receptive fields (RFs) by unmasking latent connections in the dorsal horn. The activity of the second order pain transmission neuron #1 was recorded with a microelectrode introduced into the spinal cord. This neuron was connected by pathway A to its original RF I in the biceps femoris muscle. Solid lines represent synaptically effective connections, dashed lines ineffective or latent connections. The injection of pain inducing bradykinin was made outside RF I into the RF of neuron 2 (RF II). The bradykinin-induced excitation of nociceptive fibers of pathway B is assumed to release substance P (SP) and calcitonin gene-related peptide (CGRP) in the dorsal horn, which diffuse to neuron #1 (denoted by stippling) and increase the efficacy of latent connections from pathways B and C to this cell. Within 5–15 minutes neuron #1 could also be activated by stimulation of RF II and RF III. ***B.*** Extension of Mense's model of deep referred pain to explain some TrP characteristics not accounted for by his model. No direct experimental evidence substantiates this modification. Second order pain transmission neurons #1 and #2 correspond to neurons #1 and #2 in the Mense model. Neurons #1 and #4 are connected by yellow lines to their respective RFs. These RFs are the areas that would be identified as the source of nociception when neurons #1 and #4 are activated. Nociceptive input from the TrP would activate second order pain transmission neuron #2 and could account for the initial localized pain in response to pressure applied to the TrP. This activity is assumed to release SP and CGRP in the dorsal horn that diffuses (stippling) to neurons #1 and #4. This increases the efficacy of latent connections (dashed red lines) to these cells. Now neurons #1 and #4 can be activated by nociceptive activity originating in the TrP and would be perceived as referred pain. (Figure 17-21A reproduced with permission from Mense S, 1993.[201] Figure 17-21B reproduced with permission from Simons DG, 1993.[191, 201])

controlling involuntary muscle tension if this is a problem.[204] Mild depression and associated sleep disturbance can be treated with low doses of *tricyclic antidepressant drugs* and a structured exercise/ activation program.

Other perpetuating factors include metabolic, endocrine, or nutritional inadequacies that affect muscle metabolism.[49,205] Patients should be screened for general good health and referred to their physician for management of any systemic abnormalities. In secondary MFP, the primary causative painful disorder, such as TMJ capsulitis, pulpitis, or chronic neuropathy, must also be treated or managed.

Spray and stretch is a highly successful adjunct for the management of myofascial TrPs that uses a vapocoolant spray (Gebauer, Co., Cleveland, OH) to facilitate muscle stretching. Muscle stretching has been shown to reduce the intensity of referred pain and TrP sensitivity in patients with MFP.[206] The vapocoolant is applied slowly in a systematic pattern over the muscle being stretched and into the pain reference zone (Figure 17-24). This technique and alternatives not using a vapocoolant are described in detail elsewhere.[49] Long-term improvement is dependent on **control of the perpetuating factors** that overload the affected muscles.

Needling of TrPs with or without injection of solution has also been shown to be helpful in reducing the TrP activity to allow stretching.[207,208] Impaling the TrP and eliciting a twitch response are critical for a superior clinical effect.[208] Dry needling or injection of "key" myofascial TrPs has been shown to reduce the activity and tenderness in related satellite TrPs.[189] Although dry needling is effective, the use of a local anesthetic reduces postinjection soreness.[208] If a local anesthetic is to be injected, 0.5% procaine or 0.5% lidocaine is recommended. Longer-acting amide local anesthetics or local anesthetics containing epinephrine cause permanent muscle damage.[209] Injection must always be followed by stretch.[49] Trigger point injection in the absence of a home program that addresses relevant perpetuating factors will provide only temporary relief. Randomized controlled studies, looking at the efficacy of botulinum toxin in comparison to dry needling, saline or other placebo solutions in TrP injections, have shown that overall Botox is no more effective than dry needling or other solutions.[210,211]

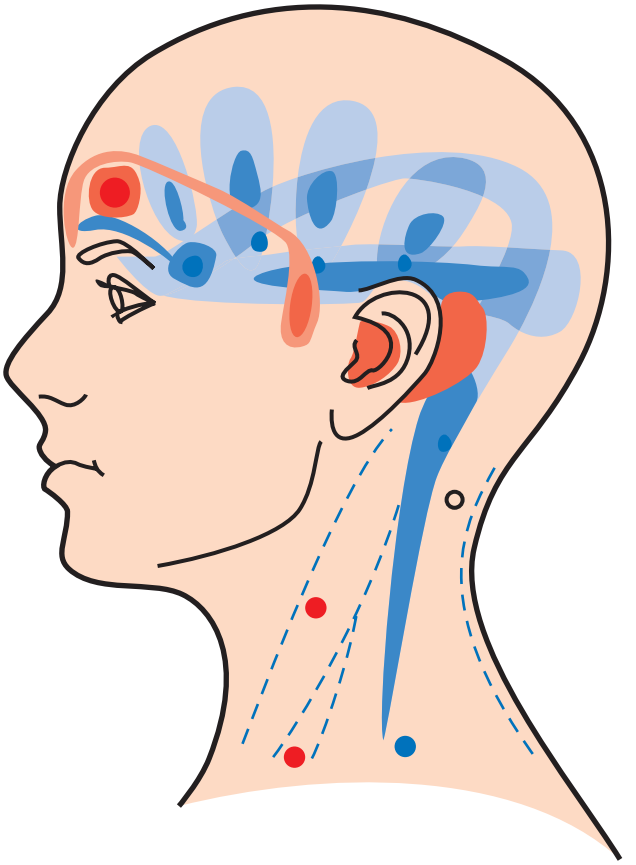

FIGURE 17-22 Overlapping pain referral patterns from the temporalis, sternocleidomastoid, upper trapezius, and suboccipital muscles produce a clinical picture of "tension-type headache." Unilateral symptoms may mimic migraine without aura. (Reproduced with permission and courtesy of Dr. Bernadette Jaeger, Los Angeles, CA, U.S.A.)

Tension-type headaches. *Tension-type headaches* are usually bilateral, with a pressing, non-pulsating quality. They last 20 minutes to 7 days when episodic and may be daily without remission when chronic.[45] Overlapping referred pain patterns from myofascial TrPs can produce a typical tension-type headache (see Figure 17-22). Studies have documented the presence of focally tender points and referred pain in this type of headache[212–214] Others have postulated that MFP and tension-type headaches may share a common underlying pathophysiology.[4] Thus, the same treatment strategies used for MFP also work well for the reduction of tension-type headache.[213,215]

PERSISTENT IDIOPATHIC FACIAL PAIN

Phantom tooth pain, atypical odontalgia, and atypical facial pain are terms used in the literature that fall under the current IHS category of *Persistent idiopathic facial pain*, dull, aching, mostly unilateral burning or throbbing pain that recurs daily for 2 or more hours for more than 3 months, may have sharp or stabbing exacerbations, is aggravated by stress and may radiate to a wider region.[45] There are rarely any sensory changes and no apparent pathologic processes. The onset may be related to an injury or invasive procedure but the pain persists without any demonstrable local cause.[45] However, based on the retrospective analysis of data collected on 493 consecutive patients, 35 who met the inclusion criteria for atypical facial pain, all but one had diagnosable physical problems and sometimes multiple overlapping physical diagnoses causing the pain.[216] Over half (19 of 35) were found to have MFP due to TrPs as a primary cause or a significant contributing factor to the pain. This data, underscores the importance of a careful diagnostic evaluation in the evaluation of patients with unusual pain presentations.

Two types of persistent idiopathic facial pain that commonly appear in the dental office are *atypical odontalgia* (idiopathic or phantom toothache, trigeminal dysesthesia) and *burning mouth syndrome*. Although deafferentation (neuropathic pain) is believed to play a role in both of these pain syndromes, the mechanism and the etiology are still largely speculative.

Atypical Odontalgia—Persistent Dentoalveolar Pain

IHS defines atypical odontalgia as a continuous dental or tooth site pain without any identifiable dental cause.[45] This pain may be a PTTN, but its throbbing nature along with the tendency for the painful site to move around implicates a potential neurovascular source for the pain as well.[4]

It is extremely important for dentists to be aware of the existence of this disorder to avoid performing unnecessary dental procedures and extractions. It has been postulated that as many as 3% to >7% of endodontic patients may suffer from this type of tooth pain, especially if they had pain prior to pulp extirpation.[217]

Symptoms. The chief complaint is a *deep, dull, aching, sometimes burning pain in a tooth or tooth site* that is unchanging over weeks or months. The pain is fairly continuous with some diurnal fluctuation, and usually worsens as the day progresses. The vast majority of patients present themselves with unilateral pain, although other quadrants may become involved and other oral and facial sites may hurt.

Most patients are *female* and *over 40 years* of age. The onset of the pain may coincide with or develop within 1 month or so after dental treatment (especially endodontic therapy or extraction) or trauma or medical procedures related to the face, increasing the impression that the pain is neuropathic.[218,219] There is evidence to support the diagnosis of PTTN in many of these cases and neurovascular pain in others, again emphasizing the importance of careful evaluation and diagnosis of unusual pain presentations.[220]

Examination. Intraoral and radiographic examinations are typically unrevealing. If the pain is in a tooth as opposed to an extraction site, responses to percussion, thermal testing, and electric pulp stimulation are variable. The majority of patients report little or no relief with diagnostic local anesthetic blocks.

Treatment. Invasive, irreversible treatments, such as endodontic therapy, exploratory surgery, extraction, or even

FIGURE 17-23 Muscle palpation for myofascial trigger points. ***A.*** "Flat" fingertip palpation of the masseter muscle looking for taut bands and focal tenderness characteristic of myofascial TrPs. The flat palpation technique is also useful for temporalis, suboccipital, medial pterygoid, and upper back muscles. ***B.*** "Pincer" palpation of the deep clavicular head of the sternocleidomastoid muscle. ***C.*** "Pincer" palpation of the superficial sternal head. Heads should be palpated separately. The upper border of the trapezius also lends itself to pincer palpation. (Reproduced with permission and courtesy of Dr. Bernadette Jaeger, Los Angeles, CA.)

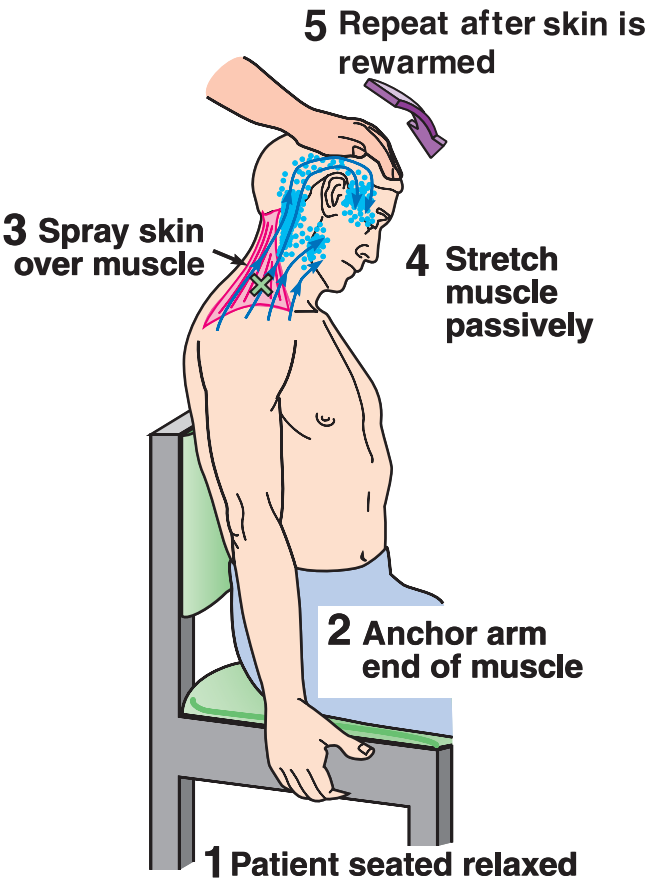

FIGURE 17-24 Sequence of steps when spraying and stretching any muscle to treat MF TrPs, here applied to the upper trapezius. **1.** Patient supported in a comfortable relaxed position. **2.** One end of the muscle is anchored. **3.** Skin sprayed with three to four parallel sweeps of vapocoolant over the length of the muscle and into the referred pain site. (arrows). **4.** Immediately after completing the spray pattern, the patient is asked to inhale deeply, then exhale as gentle pressure is applied to stretch the muscle during exhalation. **5.** Steps 3 and 4 should be repeated only after the skin is rewarmed. Hot packs and several cycles of full active range of motion follow. (Reproduced with permission from Travell JG, Simon DG, et al, 1999.[49])

occlusal adjustments, *are contraindicated*.[218] This is because, despite possible transient relief, the pain is likely to recur with equal or greater intensity.

The current treatment of choice is the use of *tricyclic antidepressant agents* such as *amitriptyline or imipramine* alone or, if there is a burning quality to the pain, in combination with a *phenothiazine*. Patients may need reassurance that *the pain is real and not psychogenic* but that invasive procedures will not help.

If a patient complains of associated gingival hyperesthesia, the use of topical agents such as topical anesthetic or capsaicin has been shown to be beneficial.[219] Unwanted stimulation of the area can be reduced by construction of an acrylic stent that can also be used to help apply any topical medication.

Burning Mouth Syndrome

Burning mouth syndrome (BMS) is an intraoral pain disorder that most commonly affects postmenopausal women. When it primarily affects the tongue, it is referred to as burning tongue or glossodynia.

Symptoms. Patients complain of intraoral burning, the tip and sides of the tongue being the most common sites, followed by the palate. Dry mouth, thirst, taste and sleep disturbances, headaches, and other pain complaints are frequently associated symptoms. Onset is often related to a dental procedure. The intensity of pain is quantitatively similar to that of toothache, although the quality is burning rather than pulsing, aching, or throbbing. The pain increases as the day progresses and tends to peak in the early evening. Patients with BMS may complain of spontaneous tastes or "taste phantoms" (dysgeusia).[224]

Etiology. There are many obvious oral and systemic conditions that are associated with mucogingival and glossal pains. These include candidiasis, geographic tongue, allergies to dental materials, denture dysfunction, xerostomia, various anemias and vitamin deficiencies (iron, vitamin B_{12}, or folic acid), diabetes mellitus, several dermatological disorders (lupus, lichen planus, erythema multiforme), human immunodeficiency virus, or systemic medications (either directly or indirectly through resultant xerostomia). However, in BMS, controlled studies have documented that the oral mucosa appears normal, and no obvious organic cause can be identified.[222]

Research supports a theory that damage to or dysfunction of the chorda tympani branch of CN VII contributes to the dysguesia and pain of burning mouth.[223] The special sense of taste from the tongue is mediated by the chorda tympani (anterior two thirds) and CN IX (posterior one-third). The chorda tympani innervates the fungiform papillae of the tongue, which, in turn, are surrounded by pain fibers from cranial nerve V. The chorda tympani normally inhibits both cranial nerve V (pain fibers) and cranial nerve IX (taste). Damage or partial deafferentation of the chorda tympani appears to release inhibition of both cranial nerves V and IX, producing both pain and taste phantoms, respectively.[224]

BMS is not to be confused with postmenopausal oral discomfort that has a burning component. In the latter condition, estrogen replacement therapy is effective about half of the time.[225] Psychological factors, although present in some of this population, do not appear to be etiological.[226]

Examination. The patient with BMS generally has a negative intraoral examination.[222] Obvious tissue irritating causes such as denture soreness, rough crowns or teeth, and other causes of tissue irritation such as candidiasis or true vitamin deficiencies must, of course, be ruled out.

Tests. Candidiasis should be tested for, even if the mucosa looks normal. *Local anesthetic rinse* will decrease the pain of other conditions such as geographical tongue or candidiasis but increase the pain of burning mouth. This increase in pain

is thought to be due to further loss of **A**β fiber inhibition. Sedimentation rate may be mildly elevated, and, in view of the higher incidence of immunological abnormalities, rheumatological evaluation should be considered.

Treatment. The management of BMS is still not satisfactory. Topical clonazepam (sucking on clonazeoam lozenges), benzodiazepines and low dose tricyclic antidepressants have some success.[222]

CONCLUSION

In conclusion, it is a time-consuming and difficult task to understand and manage people suffering unusual or chronic pain. Many multidisciplinary pain clinics employ orofacial pain dentists; physicians; psychologists; nurses; physical, occupational, and myotherapists; and other health professionals to coordinate patient care and to provide a comprehensive healthy environment for rehabilitation. Chronic pain management, including orofacial pain, is a growing specialty in health care. It takes years of training and experience to gain adequate insight into these complex cases.

Several dental schools across the United States now offer CODA accredited 2-year postgraduate orofacial pain programs to train interested dentists in the field of orofacial pain. Dentists with competence in this field and who have passed a certifying examination can be identified by contacting the American Board of Orofacial Pain or the equivalent Board or certifying agency in other countries. Orofacial pain dentists, armed with knowledge, interest, curiosity, and patience, and, finally, the instruments of diagnosis, enjoy the most rewarding experience—identifying the source of pain and relieving the suffering of a fellow human being. The orofacial pain dentist, oriented toward looking at the patient as a whole person, can gain much satisfaction from arriving at a correct diagnosis and saving teeth or preventing unnecessary surgery.

The complex and personal nature of good diagnosis cannot be overemphasized. This is the area in which the dentist is most likely, on a professional basis, to earn the respect and friendship of colleagues, both dental and medical, as well as patients.

ACKNOWLEDGMENT

The author would like to thank Jennifer Bassiur, DDS for her contributions to the neurophysiology section of this chapter and Austin Skootsky for production and update of two figures, as well as for putting the references into order.

Chapter 18

Management of Pain, Fear, and Anxiety in the Endodontic Patient

Stanley F. Malamed

Pain, fear, and anxiety are not uniquely endodontic problems; they are, however, far more significant in endodontics because of the commonplace nature of the patients' underlying problem: pain. "Fear of dentists" consistently appears in surveys of common fears, along with fear of heights, flying, mice, and public speaking.[1] Common dental fears include fear of the unknown, fear of pain, and, perhaps the most common, fear of the "shot."

Numerous studies have assessed the incidence of dental fear (odontophobia, dentophobia) in the general population, determining that between 10% and 30% of the adult population suffers from moderately severe to extreme odontophobia.[2–4] Chanpong and colleagues,[4] in a survey of Canadian adults (n = 1101), found 7.6% stating they had "missed, cancelled, or avoided a dental appointment because of fear or anxiety." In response to the question "How would you assess your feelings toward having dental treatment done?" 5.5% assessed themselves as either "very afraid" (2.0%) or "terrified" (3.5%). In this "high fear" group, 49.2% had missed, cancelled, or avoided a dental appointment because of fear or anxiety compared with only 5.2% of the "low or no fear" group. Enkling and colleagues[5] reported that in 67% of odontophobic patients a prior painful dental or medical experience was the primary cause of their fear, followed by fear of needles (33%).

Dental fear is real and it hurts. For the patient, it is palpable. For the doctor and office staff, it stands as a barrier to the delivery of quality dental care. Within the realm of endodontics, many patients requiring root canal treatment do so as an end result of their extreme odontophobia. The first endodontic appointment, during which access will be gained and pulpal tissues removed, provides the greatest challenge to the endodontist, confronted with a patient who is in acute pain and having possibly been in chronic pain for several months, and who is fearful, not just of the local anesthetic injection but of the idea of "root canal work" itself.

Pain and fear are a potent combination, capable of provoking some of the most catastrophic situations imaginable in the dental office environment. Surveying the incidence of medical emergencies in the dental environment, Malamed[6] found that 54.9% occurred during the administration of the local anesthetic with an additional 22.0% occurring during dental treatment. When a medical emergency arose during dental treatment, 65.8% occurred during pulpal extirpation (26.9%) or tooth extraction (38.9%).[7] Over three-quarters of medical emergencies seen in dentistry are stress-related. Potentially stress-related medical emergencies include syncope, hyperventilation, the "epinephrine reaction," bronchospasm, seizures, angina pectoris, myocardial infarction, and cardiac arrest.

RECOGNITION OF FEAR

Recognition of dental fear should not be left until the patient is seated in the dental chair. Quite often the receptionist is asked revealing questions by patients, such as "Is the doctor gentle?" "Does the doctor give good shots?" Patients in the reception area may converse amongst themselves, discussing their upcoming treatment, perhaps in lurid ways. This invaluable information must be relayed to chair-side personnel who can now act to prevent a "problem" from developing.

Once seated in the dental chair, the patient's fears usually become more obvious. Fearful patients simply do not "look" comfortable. Legs remain crossed and fingers clutch the armrest of the dental chair, the so-called "white-knuckle syndrome." The patient closely watches everything, not wanting to be "snuck up on" by the doctor. Responses to questions are unusually prompt; speech is rapid. Perspiration may be observed on the patient's forehead, upper lip, and perhaps underarms.

If any of the previous is noted, it is important for the doctor to confront the patients, asking them "if anything about the upcoming procedure bothers them" Once the patient admits to having fears and once the fears are out in the open, the "problem" should be manageable.

Management problems occurring during the local anesthetic administration can be almost entirely prevented by taking a patient's "feelings" about receiving "shots" into consideration. Most people do not relish the thought of receiving intraoral local anesthetic injections as demonstrated by the high incidence of adverse reactions occurring at this time. Fifty-five percent of all medical emergencies reported by Malamed[6] were fainting, and over 54% of all emergencies occurred during administration of the local anesthetic.[7] Syncope accounted for 61.1% of dental office medical emergencies reported during a 1-year period in New Zealand.[8]

Fainting during injection is preventable by following a few simple steps aimed at making all local anesthetic injections as comfortable (atraumatic) as possible: (1) placing the patient about to receive an intraoral injection into a supine position *prior* to injection, (2) slow administration of the local anesthetic solution, and (3) use of sedation, if warranted, prior to the administration of the local anesthetic.

MANAGEMENT OF FEAR OF DENTISTRY

The concept behind the successful use of sedation is that fearful patients are overly focused on everything that happens around them, and to them, in the dental office environment. Sedation is about distraction—taking the patients mind away from what is happening in their mouth during the dental appointment. Distraction may occur with or without the use of drugs. Music, dark glasses, movies are nondrug means of distracting the fearful patient. Administration of a central nervous system (CNS)-depressant drug lessens the patients' awareness, taking their mind away from thinking about the dental treatment. They no longer over-respond to stimulation. They no longer care about the procedure and, in effect, become more "usual" patients.

Definitions

Pharmacosedation occurs as a result of depression of the CNS. Although various levels of CNS depression will be discussed, one is in fact dealing with a continuum, from the earliest manifestations of a drug's action—*minimal sedation*, through the controlled loss of consciousness—*general anesthesia*. Most jurisdictions in the United States require a licensed dentist to obtain a permit before being allowed to administer CNS-depressant drugs via various routes and to varying levels of CNS depression. A number of dental (and medical) organizations have published guidelines for the safe and effective use of these drugs.[9–11]

When describing, and defining, the various levels of CNS depression, the precise wording of the definition may vary slightly from country to country, state to state, province to province, and organization to organization, but the essence of the definitions is the same. The reader is strongly advised to adhere to those definitions that have been established in the jurisdiction in which he or she is licensed. Definitions, proposed by the American Society of Anesthesiologists, describe the degree of CNS depression ultimately achieved (Table 18-1).[12] The definitions that follow are taken from the American Dental Association's (ADA's) Guidelines for the Use of Sedation and General Anesthesia by Dentists.[11]

Minimal Sedation

Minimal sedation is defined as "a minimally depressed level of consciousness that retains the patient's ability to independently and continuously maintain an airway and respond appropriately to physical stimulation or verbal command, and that is produced by a pharmacologic or nonpharmacologic method or a combination thereof. Although cognitive function and coordination may be modestly impaired, ventilatory and cardiovascular functions are unaffected."[11–12] "In accord with this particular definition, the drug(s) and/or techniques used should carry a margin of safety wide enough to render unintended loss of consciousness unlikely. Furthermore, patients whose only response is a reflexive withdrawal from repeated painful stimuli would not be considered to be in a state of minimal sedation."[11–12]

"When the intent is minimal sedation for adults, the appropriate dosing of enteral drugs is no more than the maximum recommended dose of a single drug that can be prescribed for unmonitored home use."[11–12]

Nitrous oxide/oxygen (N_2O–O_2) inhalation sedation, when used in combination with other CNS-depressant drugs may produce minimal, moderate, or deep sedation or general anesthesia.

The following definitions apply to administration of ***minimal sedation***:

Maximum recommended therapeutic dose (MRTD): maximum FDA-recommended dose of a drug approved for unmonitored home use.

Incremental dosing: administration of multiple doses of a drug until a desired effect is reached, but not to exceed the MRTD.

Titration: administration of incremental doses of a drug until a desired effect is reached. Knowledge of each drug's time of onset, peak response, and duration of action is essential. Although the concept of titration of a drug to effect is critical, when the intent is minimal sedation, one must know whether the previous dose has taken full effect before administering an additional drug dose.

Moderate Sedation

Moderate sedation is "a drug-induced depression of consciousness during which patients respond purposefully to verbal

TABLE 18-1 ASA Chart of Categories

	Minimal Sedation (Anxiolysis)	Moderate Sedation/ Analgesia (Conscious Sedation)	Deep Sedation/Analgesia	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful* response to verbal or tactile stimulation	Purposeful* response after repeated or painful stimulation	Unarousable, even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

*Source: American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists.[12]

commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained."[11–12] "In accord with this particular definition, the drugs and/or techniques used should carry a margin of safety wide enough to render unintended loss of consciousness unlikely. Repeated dosing of an agent before the effects of previous dosing can be fully appreciated may result in a greater alteration of the state of consciousness than is the intent of the dentist."[11–12] "Furthermore, a patient whose only response is a reflexive withdrawal from a painful stimulus is not considered to be in a state of moderate sedation."[11–12]

Deep Sedation

Deep sedation is "a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained."[11–12]

General Anesthesia

General anesthesia is "a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired."[11–12]

"Because sedation and general anesthesia are a continuum, it is not always possible to predict how an individual patient will respond. Hence, practitioners intending to produce a given level of sedation should be able to diagnose and manage the physiologic consequences (rescue) for patients whose level of sedation becomes deeper than initially intended."[12]

"For all levels of sedation, the practitioner must have the training, skills, and equipment to identify and manage such an occurrence until either assistance arrives (emergency medical service) or the patient returns to the intended level of sedation without airway or cardiovascular complications."[12]

REGULATION

Through the 1960s, upon receiving a dental degree and a license to practice dentistry, dentists in the United States were allowed to administer any form of anesthesia (from local anesthesia to sedation to general anesthesia). No prohibitions, except for common sense, existed. As no formal training had been received in these techniques (aside from local anesthesia) in dental school, most new doctors prudently avoided their use, managing fearful patients as best they could. Some, however, felt that they could easily administer anesthesia (in the broad sense) to their patients. Although some were successful, a large enough number became involved in serious untoward events, leading to death or severe neurologic damage, that governmental agencies (state dental boards and/or legislatures) began to seriously question whether dentists should be allowed to perform these techniques.

In the early 1970s, an Alaskan dentist had several deaths occur under halothane general anesthesia. As this dentist had little or no formal training in general anesthesia, Alaska became the first state to ban the administration of general anesthesia in the dental office. In 1974, in response to four patient deaths under general anesthesia in a short span of time in the office of an untrained dentist, Ohio became the first state to limit the use of general anesthesia to dentists who could prove adequate training, either through an oral surgery program or a 1-year anesthesiology residency.[13,14]

As of April 2015, all 50 states in the United States have enacted regulation governing the administration of general anesthesia and deep sedation in dental offices.[15] Deep sedation, by virtue of the fact that the patient's ventilatory status and ability to maintain an airway may be impaired, requires a level of training equal to that of general anesthesia. Education and training in general anesthesia in the United States requires a minimum of a 3-year residency in anesthesiology.[16]

Some dentists, untrained and now unable to administer general anesthesia, began administering CNS-depressant drugs parenterally, either intramuscularly or intravenously, as these techniques had not yet been regulated. Not surprisingly, a number of deaths occurred, as well as other serious morbidities over the ensuing years. And also, not surprisingly, legislative bodies began to regulate parenteral sedation. All 50 states in the United States now regulate the administration of parenteral moderate sedation.[17] (Intranasal [IN] sedation, a relatively new approach to CNS-depressant drug administration used primarily in pediatric dentistry, is classified as a parenteral route of drug administration.)

The oral route, the least effective and least controllable common mode of drug delivery, had always enjoyed a somewhat limited use in dentistry. As other routes of drug delivery and levels of sedation encountered increased scrutiny and regulation, interest burgeoned in this, as yet, unregulated mode of drug administration.

Orally administered drugs had always been an important management technique within the specialty practice of pediatric dentistry, with chloral hydrate, hydroxyzine, and promethazine forming a triad of oft-used drugs. In 1985, the American Academy of Pediatric Dentistry developed guidelines for the use of sedation by pediatric dentists who received adequate clinical and didactic experience in this technique during their residencies. These guidelines have been reevaluated several times with the most recent version accepted and published in 2008.[18]

Unfortunately, some untrained nonpediatric dentists (e.g., general dentists), now unable to administer drugs parenterally, began using oral sedative drugs to achieve more profound levels of CNS depression, with predictable results: death and severe morbidity (e.g., brain damage). Legislation to require permits for oral moderate sedation (OMS) in children appeared in the late 1990s. Enacted in 2000, California's legislation requires a

permit for OMS in patients less than 13 years of age.[19] At present, 11 states in the United States require advanced education and awarding of a permit for a licensed dentist to administer oral conscious sedation (OCS) to a pediatric patient.[17]

OMS for adult dental patients had an increase in popularity in the mid-1990s, that continues today. Although many oral drugs are available, one drug, triazolam (Halcion®), has proven the most popular.[20,21]

Now, for the first time, state dental boards have acted proactively rather than reactively as in the past, enacting legislation mandating continuing dental education (CDE) and a permit to administer OMS to the adult or pediatric dental patient. As of April 2015, 19 states in the United States have requirements for CDE and a permit for adult OCS.[17]

One route of drug administration has yet to be mentioned: inhalation. In contrast to the oral route, the inhalation route represents *the* most controllable technique of drug administration. In dentistry in the United States, the combination of N_2O and O_2 is available and used, with varying frequency, in approximately 35% of dental offices.[22] The ADA, in concert with manufacturers of inhalation sedation units, mandated the inclusion of safety features into these machines. The goal of these safety features is to make it close to impossible the administration of levels of O_2 less than 21% (ambient air) to a patient.[23] Deaths and serious morbidity associated with N_2O–O_2 inhalation sedation in dentistry have not occurred in recent years due primarily to the addition of these safety features and the requirement of the ADA's Commission on Dental Accreditation that all graduating dental students be trained to proficiency in inhalation sedation.[24] As of April 2015, only a handful of states require a permit for the use of inhalation sedation.

Sedation: Nondrug Techniques (Iatrosedation)

Management of a patient's dental fear should begin as soon as the patient enters the dental office. The environment, the ambiance of the office, establishes a mood either of quiet relaxation or of a hurried, frenetic pace. The dental staff should be alert to any telltale signs of dental fear and, if noted, report it to the dentist immediately. "Forewarned is forearmed." Relaxation of a patient by the doctor's behavior has been termed *iatrosedation*, a term formulated by Dr. Nathan Friedman.[25] The word is derived from the Greek prefix *iatro*, "pertaining to the doctor," and *sedation*, "the relief of anxiety."

The concept on which iatrosedation is based is rather basic: that the behavior of the doctor and staff has a profound influence on the behavior of the patient. Other terms applied to this concept include suggestion, chairside/bedside manner, and the "laying on of hands." The underlying premise of all these techniques is similar: that one can use nonchemical means to aid in relaxing the patient. For a more in-depth discussion of nondrug techniques of sedation, the reader is referred to *Sedation: a guide to patient management*.[26] Examples of iatrosedative techniques include hypnosis, acupuncture, audioanalgesia, and biofeedback.

Iatrosedation forms the building block for all sedation techniques requiring drug administration. Simply put, a patient who remains fearful, perhaps with distrust of the doctor, is less likely to "allow" their CNS-depressant drug to work. Although true for all routes of drug administration, it is especially relevant with the oral and inhalation routes.

The doctor who establishes a bond of trust with their patients will have them sit back in the dental chair and "let the drug work." Conversely, where the doctor–patient relationship is strained or uncomfortable, patients are much less likely to surrender to the clinical effects of the drug, not wanting to "lose control" of the situation. The level defined as minimal sedation is highly unlikely to succeed in this situation. Moderate sedation would have a somewhat greater success rate but still with a significant, perhaps unacceptably high, failure rate (Table 18-2).

Sedation: Drug Techniques (Pharamacosedation)

In dentistry, CNS-depressant drugs are administered by four routes: commonly by oral and inhalation, and less commonly by intravenous (IV) and intramuscular (IM). IN drug administration is a relatively recent addition to this armamentarium, primarily employed to provide moderate sedation in children.[27]

The following is a brief overview of these routes of CNS-depressant drug administration in dentistry. It is not meant to substitute for a complete course in pharmacology or in the safe and effective technique of drug administration. The doctor wishing to administer drugs by any of these routes should check with their regulatory boards for specific education and permit requirements for each technique or level of sedation.

Inhalation Sedation (N_2O–O_2)

Inhalation sedation with N_2O–O_2 represents the most controllable technique of sedation available and should represent, in this author's opinion, the "starter technique" for sedation in dentistry. Inhalation sedation possesses a number of compelling clinical properties that serve to increase its success rate and its safety, including (1) rapid onset of action (~20–30 s); (2) a level

TABLE 18-2 Efficacy of Sedation By Routes of Drug Administration

Technique route	Titrate to effect	Rapid reversal	Expected success rate (%)
Intravenous	Yes	Yes*	90
Inhalation	Yes	Yes	80
Intramuscular	No	No	67
Intranasal	No	No	67
Oral (adult)	No	No	50–60

†General anesthesia is *not* a sedation technique. It is included for comparative purposes only.
#Dependent on route of administration and drug.

of CNS depression that can rapidly be increased, if necessary; (3) the level of CNS depression that can be rapidly decreased, if needed—a significant factor in increasing the safety of inhalation sedation; (4) complete recovery following the delivery of 100% O_2 at the conclusion of the procedure, permitting almost all N_2O–O_2 patients to be discharged from the dental office unescorted, and with no prohibitions on their postinhalation sedation activities. No other route of drug administration offers this significant advantage. Because of its rapid onset, inhalation sedation with N_2O–O_2 may be titrated. The ability to titrate increases both the success and safety of the technique.

In order for the dose of any drug to be titrated, it must enter into the cardiovascular system rapidly. When possible, titration allows the doctor to individualize the dosage of the drug for each patient, negating the so-called "bell-shaped" or "normal distribution" curve. Approximately 68% of persons respond "normally" to the "usual" dose of a drug (normoresponders). Fourteen percent will under-react to this usual dose (hyporesponders), while 14% will overreact to the same dose (hyperresponders).

The technique of inhalation sedation with N_2O–O_2 possesses very few significant disadvantages. One factor, common to it and several other techniques, is that of patient cooperation. The patient breathes the gasses through a small mask placed on the nose, the nasal hood. Uncooperative patients, usually odontophobic younger children, or any patient who is claustrophobic, might not allow the nasal hood to be placed, condemning the inhalation route to failure. Persons unable to breathe through their nose, for whatever reason, will be unable to receive inhalation sedation in a dental office. A recommended technique of administration of N_2O–O_2 is outlined in (Table 18-3).

Inhalation sedation with N_2O–O_2 may be employed to provide minimum to moderate sedation. It may also be administered, where permitted by state regulation, in conjunction with drugs administered by other routes, to supplement the CNS depression they provide. N_2O–O_2 when used in combination with sedative agents may produce minimal, moderate, or deep sedation or general anesthesia.[11]

The use of N_2O–O_2 inhalation sedation in endodontics should become more common given the positive attributes of the technique. A common complaint from endodontists is that the nasal hood "is in the way" (Figure 18-1). Once experience is gained in the technique, this ceases to be a concern. Inhalation sedation with N_2O–O_2 has a success rate of approximately 80% in adult patients.

TABLE 18-3 Technique of Inhalation Sedation–A Review

1. Prior to placing nasal hood, start a flow of 5–6 LPM (liters per minute) of O_2.
2. Have patient assist in proper placement and securing of the nasal hood.
3. Determine if patient can "breathe comfortably" with 100% oxygen. ("Is the flow volume adequate?"). Increase the flow, if necessary.
4. Start titration of N_2O by increasing its flow to 1 LPM, decreasing the O_2 flow by 1 LPM.
5. After 1 min, determine what, if any, signs and symptoms the patient may be experiencing.
6. If needed, increase N_2O by 0.5 LPM, decreasing O_2, 0.5 LPM.
7. Repeat steps 5 and 6 until the patient reaches the desired level of sedation.
8. Administer local anesthesia as would be done if the patient were not receiving N_2O–O_2.
9. At the conclusion of the procedure, increase the O_2 flow to the level determined in step 3 and return the N_2O to O LPM.
10. Permit the patient to breathe 100% O_2, for not less than 3–5 min before considering removal of the nasal hood.
11. Assess recovery from sedation. If considered recovered, remove nasal hood before terminating the flow of O_2.
12. Permit the patient to leave dental chair. Have a staff person close to the patient so as to prevent any possible injury when standing, due to postural hypotension.
13. Document treatment in the patient's chart.

Oral Moderate Sedation

The oral route is the least controllable route of drug administration. A number of factors work against an orally administered drug being effective, including a slow onset of action (~1 h for most drugs); erratic absorption of the drug from the gastrointestinal (GI) tract; and, for some drugs, a significant hepatic first-pass effect. For these reasons, titration of the drug to clinical effect is not possible, eliminating the most important safety factor in drug administration. Once administered, the level of CNS depression reached by oral drugs is not easily increased (providing deeper sedation) or decreased (lighter sedation).

The duration of CNS depression from orally administered drugs greatly exceeds the typical length of the dental visit so these patients will always require an escort on being discharged from the office. This escort need be a responsible adult who has a vested interest in the health and safety of the patient.

The only advantages associated with the oral route of drug administration are that it is easier for both the doctor and the patient.

Having just described a technique that seems quite mediocre compared with other routes of administration, it must be stated that there is a legitimate place for orally administered CNS depressants in dentistry.

FIGURE 18-1 N_2O–O_2 nasal hood—Porter Silhouette Mask (Courtesy of Porter Instrument, Philadelphia, PA, www.porterinstrument.com/silhouette).

Odontophobic patients, especially when faced with the fear of root canal treatment, frequently require management with CNS depressants (1) the night prior to the planned appointment, in order for the patient to experience a restful night's sleep, and (2) in the morning, 1 h prior to the scheduled dental visit, to assist them in overcoming any last minute increase in their anxiety.

In the absence of other sedation techniques in a dental office, the oral route may also be used for intraoperative sedation. However, owing to the lack of control maintained over this technique by the doctor, the goal in administering oral CNS depressants should be limited to minimal to moderate CNS depression.

A number of excellent oral preparations are currently available. Table 18-4 presents some commonly used drugs and their recommended dosages.[28,29] When used alone, and in recommended dosages, orally administered drugs will have a success rate of approximately 50%–60% in adult patients. This success rate is even lower in younger children.

Intravenous Moderate Sedation

CNS-depressant drugs administered intravenously in the dorsum of the hand reach the brain in approximately 20–30 s. With this rapid onset, IV drug administration allows patients to be titrated to a desired level of CNS depression, thereby increasing control over the effect of the administered drug and, ultimately, the safety of the technique. Other advantages of IV drug administration include the ability to rapidly increase the level of sedation, if needed, and the reversibility of the most commonly administered IV drugs (benzodiazepines and opioids).

Disadvantages associated with intravenously administered CNS depressants include the requirement of fasting prior to the procedure, Nil Per Os (NPO status); an inability to quickly lessen the level of CNS depression; an inability to reverse the clinical actions of some drugs; and prolonged clinical recovery with an attendant need for an adult escort for the patient when discharged from the dental office.

Venipuncture is a learned skill and, though normally quite easy to achieve, represents the most difficult part of the entire IV sedation procedure. Once venous access is obtained, titration to the desired level of CNS depression is normally accomplished easily.

Many CNS-depressant drugs are available for IV administration, but those most often employed are the benzodiazepines, midazolam (formerly Versed®), and diazepam (formerly Valium®).

State requirements for a permit to employ IV moderate sedation (also termed "parenteral sedation") most often mandate 60 h of didactics and approximately 20 cases of IV sedation administered by the doctor in a supervised environment.[17] Variation may exist from jurisdiction to jurisdiction, so it is strongly advised that specific state or provincial dental board regulations be consulted.

Basic IV sedation technique has evolved over the past four decades. The combination of pentobarbital (Nembutal), meperidine (Demerol), and scopolamine represented the original IV technique introduced in the 1950s by Dr. Neils Björn Jörgensen.[30] As described by Jörgensen, the drugs were injected directly into the vein via the syringe that was then removed.[31] The Jörgensen technique provided a duration of CNS depression of approximately 2 h, a function of the barbiturate, a pentobarbital. With the introduction in the early 1960s of the benzodiazepine diazepam, a shorter duration of CNS depression became possible.[32] An additional benefit of diazepam was a brief period (approximately 10 min) of retrograde amnesia, permitting potentially traumatic procedures to be done with a likelihood of the patient not having any recall. For the patient this meant, in essence, that the fearful event (e.g., local anesthetic injection) never happened.

TABLE 18-4 Oral CNS-Depressants Used in Dentistry

Generic Name	Proprietary Name Availability (mg)		Usual Dental Dosage
Benzodiazepines			
Alprazolam	Niravam, Xanax	Tab: 0.25, 0.5, 1.0, 2.0	0.25–0.5 (max 4 mg/day)
Diazepam		Tab: 2, 5, 10	2–10 mg bid-qid
Flurazepam	Dalmane	Cap: 15, 30	15–30 mg at bedtime
Lorazepam	Ativan	05, 1.0, 70	2–3 mg/day given bid-tid
Midazaolam		Syr: 2 mg/mL	Pediatrics: 0.25–1.0 mg/kg single dose
Oxazepam	Serax	Cap: 10, 15, 30 Tab: 15	Adults (anxiety): mild to moderate: severe: 15–30 tid-qid
Triazolam	Halcion	Tab: 0.125, 0.15	0.25 qhs, max 0.5
Miscellaneous, nonbenzodiazepine anxiolytics, sedatives			
Eszopiclone	Lunesta	Tab: 1.0, 2.0, 3.0	Initial: 2 mg qhs

IV moderate sedation with a benzodiazepine has become the most popular technique in dentistry. IV benzodiazepine sedation meets the needs of contemporary dental practice, that is, sedation for approximately 1 h. Introduced in the United States in 1986, midazolam (Versed®) has now supplanted diazepam (Valium®) as the most used IV benzodiazepine in the area of 1-h IV moderate sedation. (As an aside, neither proprietary name, Versed or Valium exists any longer. The drugs are available solely as generics, midazolam and diazepam) Midazolam, unlike diazepam, is water soluble, thus capable of being administered intramuscularly and intranasally (see following discussions of these techniques). The amnestic properties of midazolam are considerably greater than diazepam's, providing lack of recall for most, if not all, of the dental appointment. Either drug, with one titrating dose, will provide the doctor with approximately 1 h of working time.

Direct injection of a drug into a vein, followed by removal of the syringe at the start of the dental procedure, gave way to the continuous IV infusion, in which venous access is maintained for the duration of the procedure. Initially, winged needles, also known as "scalp vein" and "butterfly needles," were used (Figure 18-2). Easy to insert, the winged needle has the disturbing propensity to perforate the vein during the dental procedure, leading to loss of venous access and formation of a hematoma. In recent years, the indwelling catheter has replaced the 'butterfly needle' as the preferred device. Once inserted and secured in a vein, the 3" plastic catheter is unlikely to accidentally become dislodged (Figure 18-3).

Opioids, specifically the short-acting fentanyl, have also been used in IV moderate sedation. When the primary goal of IV drug administration is management of fear, there is usually little or no need for opioid administration. Indeed, in the vast majority of successful IV sedation cases, the only drug(s) administered are either midazolam and/or diazepam. However, in situations in which surgery or other dental procedures that may prove painful are planned, or in which successful pain control may not be easily achieved with local anesthesia alone, opioid administration may be justified.

FIGURE 18-2 Intravenous needles.

FIGURE 18-3 Indwelling catheter.

IV moderate sedation, administered carefully titrated to clinical effect, has a success rate of 90%. The IV route can be used to achieve moderate and deep sedation, as well as general anesthesia.

Intramuscular

IM, like IV, is a parenteral route of administration, in which the drug bypasses the GI tract, being absorbed directly into the systemic (venous) circulation. The hepatic first-pass effect is negated, leading to more reliable absorption and more rapid onset of action (~10–20 min) than with enterally administered drugs. However, titration is not possible, as the onset is not rapid enough, thus denying the IM route a major safety benefit and thereby limiting its indications for use in sedation in dentistry.

Doses of IM drugs are primarily determined on a weight (e.g. mg/kg) basis. Given the appropriate dosage, approximately 70% of patients should be CNS depressed to the desired level of sedation. However, another 15% will likely be under-sedated with that same dose, whereas the remaining 15% are CNS depressed to a level beyond that which is being sought. This latter group, hyperresponders to the drug, may be CNS depressed to a level beyond which the doctor is able to safely manage them. For example, an IM drug is administered to a patient to achieve a level of moderate sedation. However, the resultant level of CNS depression is deep sedation. At this level, patients are unable to adequately maintain their airway without assistance (e.g., head-tilt, chin-lift). Dental care would, of course, need to be delayed, as the doctor is required to "rescue" patients from this unintended level of CNS depression. Airway management and, possibly, ventilatory assistance are continued until the level of CNS depression lightens, a process that could require several hours.

Along with the inability to titrate IM drugs, it is also not possible to rapidly lessen or deepen the level of sedation. Reversal of intramuscularly administered drugs, if possible, by intravenously administered flumazenil or naloxone, would be

somewhat successful for a period of time. However, as a reservoir of the IM drug exists within the muscle into which it was injected previously, the drug will continue to be absorbed over several hours leading to the likelihood of a rebound sedation effect occurring as the action of the intravenously administered reversal agent diminishes. IM administration of the reversal agent is generally not recommended as its onset, 10–20 min, is too slow to provide any immediate relief in the event of over-sedation. Additionally, the degree of the intramuscularly administered reversal agent's effectiveness would be less than that seen following its administration IV.

IM drugs are not as controllable as intravenously administered drugs. Sedation should, therefore, be limited to a moderate level, with the doctor trained to recognize and manage (e.g., rescue) the patients should they inadvertently enter deep sedation. Patients receiving IM drugs for sedation must also maintain NPO status prior to sedation.

Recovery from IM drugs is prolonged; thus, the patient must have an adult escort when being discharged from the office. This being said, it would seem that IM drugs have few indications in dentistry. However, used judiciously by the doctor trained in parenteral moderate sedation (IV, IM, IN), the technique can be employed with a likelihood of success of about 67%. Midazolam is the most commonly employed IM CNS-depressant drug in moderate sedation.

Intranasal

The IN administration of CNS-depressant drugs is relatively new within medicine and dentistry, though it has been used for many years by drug abusers (e.g., cocaine) and for the administration of nasal decongestants.

Nasal mucosa is highly vascular; therefore, absorption of drugs instilled into the nares is more rapid than for other routes of administration. Lam and colleagues[27] compared the efficacy, in children, of IN midazolam with that of its IM administration, finding the level of sedation to be comparable. IN midazolam has also been adopted in emergency medicine in the management of acute seizures in pediatric patients.[33] Primosch[34] compared nasal drops versus nasal spray as a technique of IN drug administration and found that although the effectiveness of moderate sedation was not influenced by the method of nasal administration, spray administration produced significantly less aversive behavior than administering drops in 2- to 3-year-old dental patients of similar behavioral characteristics.

Most studies and clinical usage of the IN route of drug administration appear in pediatrics, there being few reports of the use of this technique, and of its effectiveness, in adults, thereby limiting its utility in most endodontic cases.

The advantages of IN drug administration include its more rapid onset of action (compared with enteral routes) and the lack of need for injection and the accompanying trauma, both psychological and physical, associated with it.

Disadvantages of IN drug administration are similar to those of IM. IN drugs cannot be titrated. Dosages are based on weight (mg/kg). Along with the inability to titrate IN drugs, it is also not possible to rapidly lessen or deepen the level of the resultant CNS depression. Reversal of intranasally administered drugs, if possible, by intravenously administered flumazenil or naloxone, would be somewhat successful. IM or IN administration of a reversal agent is generally not recommended as its onset, 10–20 min, is too slow to provide any immediate relief in the event of over-sedation. Additionally, the efficacy of an IM or IN reversal agent would be less than that seen with its IV administration.

IN drugs are not as controllable as intravenously administered drugs. The level of CNS depression sought should, therefore, be limited to moderate, with the doctor trained to recognize and manage (e.g., rescue) the patients should they enter into deep sedation. Patients receiving IN drugs for sedation must also maintain NPO status prior to sedation.

Recovery from IN drugs is prolonged, thus the requirement for an adult escort for the patient when discharged from the office.

Utilization of the techniques of moderate sedation enable the endodontist to manage the dental fears of the overwhelming majority of odontophobic patients. Table 18-5 illustrates the possible uses of the techniques of moderate sedation in endodontic practice. Unfortunately, not all fears can be successfully managed with moderate sedation techniques. For these few patients, general anesthesia is required.

General Anesthesia

General anesthesia is the controlled loss of consciousness, the final step in our continuum of CNS depression that started with minimal sedation. The success rates of the sedation

TABLE 18-5 Techniques of Moderate Sedation–Summary

	Preoperative		Perioperative	Ability to titrate	CNS depression level when used alone	CNS depression level used in combination
	Night prior to treatment	Morning of treatment				
Oral sedation	Yes	Yes	Yes	No	Min, mod	Min, mod, deep, GA
Inhalation			Yes	Yes	Mod	Mod, deep, GA
IV			Yes	Yes	Mod, deep, GA	Mod, deep, GA
IM/IN			Yes	No	Mod, deep, GA	Mod, deep, GA

Abbreviations: Deep, deep sedation; GA, general anesthesia, Min, minimal sedation; Mod, moderate sedation.

techniques described previously, along with the amnestic properties of some of the drugs employed, specifically the benzodiazepines midazolam and triazolam, has decreased the need for general anesthesia as a method of managing significant numbers of odontophobic patients.

All 50 states in the United States regulate the use of general anesthesia in dentistry.[15] A residency in anesthesiology of 3-years duration represents the current educational requirement. As of April 2015, 10 residency programs in anesthesiology for dentists were accredited by the American Dental Board of Anesthesiology.[35]

Doctors who have completed accredited residencies becoming dentist anesthesiologists provide anesthesia services for other dentists either (1) by establishing a free-standing outpatient surgical center, in which the endodontist (or any other dentist) brings the odontophobic patient to the surgical center to carry out the scheduled procedures while the patient receives general anesthesia provided by the dentist anesthesiologist, or (2) by traveling to the office of the dentist who will be managing the dental needs of the fearful patient, wherein dentist anesthesiologists bring along all of their anesthesia drugs, equipment, and expertise.

Once the dentist anesthesiologist has induced general anesthesia, the dentist can then proceed with the endodontic procedure on a now more nearly "ideal" patient.

Management of Perioperative Pain in the Endodontic Patient

Peter Milgrom wrote, "Deal with the fear first, then pain will be a minor problem."[36] The prevention of treatment-related pain occurring during the extirpation of pulpal tissues is a not uncommon problem. In a survey of 121 dentists, 31% stated they had encountered a problem "often" or "sometimes" when treating mandibular premolars, while 55% had the same difficulties with mandibular molars in all clinical situations.[37] Molars were the only maxillary teeth proving difficult to anesthetize (16%).[37]

Asked about difficulties obtaining adequate anesthesia with various types of dental disease, the majority indicated frequent difficulty when treating exacerbated chronic pulpitis (69%) and acute pulpitis (74%).[37]

When fear of dentistry is added to this clinical situation, the likelihood of obtaining the level of clinical anesthesia required to painlessly enter into the pulp chamber and extirpate pulpal tissues is markedly diminished.

Ignoring a patient's fear only exacerbates this situation as the patient will, remain overly alert throughout the procedure, responding to even the most usually innocuous of stimuli (e.g., sound, vibration, pressure) as though they were painful.

Pain Control in Endodontics the Local Anesthetic Drugs

Local anesthetics are the safest and most effective drugs in medicine for the prevention and management of pain. Local anesthetics are also the only drugs that actually prevent nociceptive impulses from reaching the brain where they are interpreted as pain.

Five local anesthetics are employed by the dental profession: articaine HCl, bupivacaine HCl, lidocaine HCl, mepivacaine HCl, and prilocaine HCl.*

Table 18-1 lists local anesthetic formulations currently available in North America (April 2015) based on their expected duration of pulpal anesthesia (in the nonpulpally-involved tooth). In dentistry in the United States, lidocaine (49%) and articaine (35%) represent approximately 85% of local anesthetic usage (December 2014).[38]

"Plain" local anesthetic formulations, mepivacaine 3% or prilocaine 4%, are unlikely to provide either the depth or duration of pulpal anesthesia necessary to successfully (e.g., painlessly) extirpate the pulp of an infected tooth, especially the mandibular molar.[39] As all injectable local anesthetics are inherently vasodilators (arterioles, capillaries), nonvasoconstrictor-containing formulations produce an increase in blood flow at the site of drug deposition. Increased blood flow leads to three potentially negative outcomes: (1) less profound anesthesia, a result of a smaller volume of local anesthetic entering into the nerve; (2) a shorter duration of action, as the local anesthetic diffuses out of the nerve more quickly; and (3) a higher local anesthetic blood level, potentially increasing the risk of overdose when large doses are administered.

Inclusion of a vasoconstrictor, epinephrine, or levonordefrin (in the United States), in the anesthetic solution negates these actions by decreasing blood flow at the site of drug administration. This allows a greater amount of local anesthetic to diffuse into the nerve where it remains for a longer time, resulting in an increased depth of anesthesia; longer duration of pulpal anesthesia; and a decreased local anesthetic blood level (e.g., decreased risk of overdose).

Concentrations of epinephrine required to provide these beneficial effects are minimal, usually 1:100,000 (articaine, lidocaine), or 1:200,000 (articaine, bupivacaine, prilocaine). Use of epinephrine 1:50,000 (lidocaine) should be limited solely to the provision of localized areas of hemostasis during surgical procedures involving soft tissue. Only a few drops of the solution need be infiltrated directly into the surgical site to produce this action.

Lidocaine 2% with Epinephrine 1:100,000 or 1:50,000

This drug will provide duration of pulpal anesthesia of approximately 60 min in the nonpulpally involved tooth, with duration of soft tissue anesthesia ranging from 3 to 5 h. Onset of pulpal anesthesia is usually listed as developing in from 3 to 5 min following injection. As there is no clinical difference in the quality (depth, duration) of anesthesia between the two concentrations of epinephrine,

*All local anesthetics are used in their water-soluble acid salt form. Therefore the correct designation for all LAs should be: lidocaine HCl, mepivacaine HCl, and so on. For the sake of brevity they will be referred to simply by their name, for example, lidocaine, mepivacaine.

use of the 1:100,000 is recommended for pain control purposes. The only recommended use of 1:50,000 epinephrine is hemostasis. Both lidocaine formulations are appropriate for pulpal anesthesia when extirpating the pulp of an infected tooth, though the 1:100,000 formulation is still recommended.

Articaine 4% with Epinephrine 1:200,000 or 1:100,000

This drug is similar to lidocaine in both the onset and duration of (soft and pulpal) anesthesia. As there is no clinical difference in anesthetic onset, depth, or duration between the two articaine formulations, it is suggested that the 1:200,000 formulation be used for pain control purposes, though the author of this chapter has no qualms employing the 1:100,000 formulation of articaine for pain control. Both articaine formulations are appropriate for pulpal anesthesia when extirpating the pulp of an infected tooth.

Though scientific evidence of a superiority of articaine over the other commonly used local anesthetics is lacking,[40,41] anecdotal reports from endodontists indicate a perceived increased rate of successful pulpal anesthesia. However, there is evidence that administration of articaine by mandibular infiltration in adult patients results in more successful anesthesia used either as a sole injection or as a supplement to inferior alveolar nerve block (IANB) when compared with lidocaine.[42,43] The use of articaine by buccal infiltration in the mandible is discussed in the following technique section.

Mepivacaine 3% ("Plain") or Mepivacaine 2% with Levonordefrin 1:20,000

Mepivacaine 2% with levonordefrin is quite similar in its clinical characteristics to both lidocaine and articaine with epinephrine. Levonordefrin is used as a 1:20,000 concentration, providing clinical actions similar to epinephrine 1:100,000, though its cardiovascular effects are not as pronounced.[44] Mepivacaine 2% with levonordefrin is an appropriate local anesthetic when extirpating the pulp of an infected tooth.

Mepivacaine 3% ("plain") is a short-acting local anesthetic providing between 20 and 40 min of pulpal anesthesia. Infiltration of mepivacaine 3% will provide approximately 20 min of pulpal anesthesia but up to about 40 min when administered by nerve block. The depth of pulpal anesthesia is not as profound as the levonordefrin-containing solution and therefore is not commonly selected for administration when extirpating the pulp of an infected tooth.[39] However, the pH of 3% mepivacaine is higher (~6.5) than vasoconstrictor-containing formulations and many dentists take advantage of this by administering a fraction of a cartridge (e.g., about 1/4–1/3) prior to the administration of a vasoconstrictor-containing solution to make the injection more comfortable. The pH of a local anesthetic containing a vasoconstrictor is approximately 3.5.

Prilocaine 4% ("Plain") or Prilocaine 4% with Epinephrine 1:200,000

Prilocaine is available as both 4% "plain" formulation and 4% with 1:200,000 epinephrine. The epinephrine-containing formulation provides approximately 60 min of pulpal and from 3 to 5 h of soft tissue anesthesia. Prilocaine was the first local anesthetic formulation to have 1:200,000 epinephrine—still the least concentrated epinephrine solution available in dentistry in the United States. It is an appropriate formulation for pulpal anesthesia when extirpating the pulp of an infected tooth.

Prilocaine 4% "plain," like mepivacaine "plain' provides a relatively short duration of not as profound pulpal anesthesia. It is, therefore, less likely to provide pulpal anesthesia profound enough to permit painless access to, and extirpation of, an infected pulp. Also like mepivacaine "plain," the duration of pulpal anesthesia observed with prilocaine 4% plain differs significantly when administered by infiltration (~10–20 min) or nerve block (NB) (up to 60 min).

Both formulations of prilocaine 4% have been associated with a perceived increased risk of paresthesia when administered by IANB.[45]

Bupivacaine 0.5% with Epinephrine 1:200,000

Bupivacaine 0.5% with epinephrine 1:200,000 is a long-duration formulation when administered by nerve block. Though providing a longer duration of pulpal anesthesia by infiltration than any of the other local anesthetic formulations, it is following NB where bupivacaine stands out. Pulpal anesthesia of up to 6 h duration has been seen in some clinical trials following IANB.[46] One negative to the use of the drug as a primary agent for pain control is its prolonged time of onset of anesthesia (6–10 min). However, the primary use of bupivacaine in dentistry has been as an integral part of the protocol for the prevention of postsurgical pain[47] (Table 18-2).

Table 18-3 summarizes the currently available local anesthetic formulations as related to their onset, duration of soft tissue and pulpal anesthesia, and recommended maximum dosage.

BUFFERED LOCAL ANESTHETIC SOLUTIONS

A vasoconstrictor is added to injectable local anesthetics to increase both the depth and duration of pain control as well to increase their safety (by retarding their diffusion into the cardiovascular system, resulting in lower anesthetic blood levels thereby minimizing the risk of local anesthetic overdose). Vasoconstrictor-containing local anesthetic solutions are highly acidic, with a pH of approximately 3.5. "Plain" local anesthetic solutions have a pH of approximately 6.5.

More acidic local anesthetic solutions have a slower onset of action compared to "plain" drugs as a result of a smaller percentage of the un-ionized form (RN) of the local

anesthetic present in the solution. The RN form of the local anesthetic is lipid-soluble—able to diffuse through the lipid-rich nerve membrane into the nerve to then block sodium (Na^+) channels, producing anesthesia. In acidic solutions hydrogen ions (H^+) are present. The more acidic the solution the greater the number of H^+ present. Some H^+ attach to RN forming RNH^+ an ionic form that is unable to cross the nerve membrane. With lidocaine, at a pH of 3.5, 0.004% of the ions present in solution are RN. (Table 18-4). Once injected, the body slowly buffers the local anesthesia (LA) solution toward the physiologic pH of 7.35–7.45, a process that may require up to 45 min following IANB.[48] At a pH of 7.4, 24.03% of lidocaine is present in the RN-form, able to penetrate the nerve membrane.

This process can now be accelerated through buffering (e.g., alkalinizing) the dental local anesthetic solution immediately before its administration with a stabilized sodium bicarbonate solution.[48] The process of buffering a dental local anesthetic cartridge takes between 3 and 5 s.[49]

Time for onset of pulpal anesthesia was compared between lidocaine 2% with epinephrine 1:100,000 (pH 3.5) and buffered lidocaine 2% with epinephrine 1:100,000 in a prospective, randomized, double-blinded trial. Onset of pulpal anesthesia (assessed by electric pulp tester) was 6 min 37 s for the "traditional" local anesthetic solution and 1 min 51 s for the buffered lidocaine solution.[50] Seventy-one percent of the buffered local anesthetics achieved pulpal anesthesia in less than 2 min, only 12% of the traditional anesthetics achieved this.

The injections of buffered lidocaine were more comfortable (VAS† of 0.6) compared to the unbuffered lidocaine injections (VAS = 2.3). Anecdotal reports from dentists, particularly endodontists, indicate that there is an increased efficacy of buffered lidocaine when anesthetizing "hot" mandibular molars, compared with unbuffered LA solutions.

The United States Food and Drug Administration has approved local anesthetic buffering only for lidocaine, (as of April 2015), however all other dental local anesthetics have been buffered with success comparable to that found with lidocaine.

Buffered local anesthetic solutions appear to have an important place in the pain management armamentarium of endodontists.

Pain Control in Endodontics-Maxillary Technique

The basic injection technique employed for maxillary anesthesia, by most dentists, is the ***infiltration*** (supraperiosteal). The buccal cortical plate of bone in most adult patients is thin and porous enough for local anesthetic solution deposited at the apex of a tooth to diffuse through it and block nerve conduction. Infiltration anesthesia requires deposition of approximately 0.6 mL of solution at, or above, the apex of the tooth to be treated. A 27-gauge short dental needle is recommended.

The most difficult teeth to anesthetize in the maxilla are molars, especially following infiltration anesthesia. If the palatal root of the first or second maxillary molar extends ("flares") more toward the palate than "normal," infiltration of a solution of lidocaine, mepivacaine, prilocaine, or bupivacaine may not diffuse far enough medially, failing to anesthetize the palatal root, causing the patient to experience pain when that area of the tooth is treated. Infiltration of articaine will, in most cases, provide anesthesia of the flared palatal root, evidence of its greater lipid-solubility and ability to diffuse through soft and hard tissues better than other local anesthetics.

Where maxillary infiltration is unsuccessful (e.g., thicker than normal cortical bone; presence of apical infection, flared palatal root of molar), NB anesthesia is suggested. Maxillary nerve blocks include the anterior superior alveolar (ASA) NB; posterior superior alveolar (PSA) NB; anterior middle superior alveolar (AMSA) NB; and the second division (V_2) NB.

Anterior Superior Alveolar (ASA) NB

This technique is often (mistakenly) termed the "infraorbital" NB. (The infraorbital nerve is a terminal branch of the maxillary division of the trigeminal nerve, and provides anesthesia only to the soft tissues of the lower eyelid, lateral border of the nose, and upper lip). The ASA nerve provides anesthesia to the maxillary incisors, canine and, in most patients, the premolars.

Following negative aspiration, a volume of 0.9–1.2 mL of anesthetic solution is deposited outside the infraorbital foramen (completing the infraorbital NB). The most significant part of the technique is as follows: the application of digital pressure over the infraorbital foramen for 1–2 min, forcing the local anesthetic into the foramen, blocking the ASA nerve. A 27-gauge short needle is recommended.

Posterior Superior Alveolar (PSA) NB

A 27-gauge short needle is inserted into the buccal fold adjacent to the second maxillary molar. The syringe is oriented in an "inward, upward, and backward" direction and the needle advanced 16 mm. The needle tip should now be located just posterior and medial to the maxillary tuberosity, in the pterygomaxillary space, where the PSA nerves are found. Following negative aspiration a volume of 0.9 mL of anesthetic is administered.

Anterior Middle Superior Alveolar (AMSA) NB

Computer-controlled local anesthetic delivery systems have enabled local anesthetic injections to be delivered more comfortably.[51] As a result of their studies, the AMSA NB was developed. The AMSA NB provides pulpal anesthesia to the maxillary incisors, canine, and premolars; their supporting buccal soft tissues and bone; as well as soft tissue anesthesia of the entire palate on the side of injection. No extraoral anesthesia occurs (e.g., lip, anterior face).[52,53]

†VAS—visual analog scale. "0" "I felt nothing"; "10" "the worst pain ever experienced." VAS readings of 3 or lower are considered "comfortable."

A 27-gauge short needle is recommended. Needle insertion is on the hard palate about halfway along an imaginary line connecting the midpalatal suture to the free gingival margin between the first and second maxillary premolars.[54] A volume of 1.4–1.8 mL is slowly administered following negative aspiration.

The AMSA NB would be indicated for use when soft tissues in the maxillary buccal fold of the tooth to be treated show evidence of infection.

Maxillary (V_2) NB

The V_2 NB is indicated primarily when anesthesia of the entire hemimaxilla is required—a rare event in endodontics. However, when other techniques—infiltration, nerve block, intraosseous (IO)—have failed or are contraindicated, the V_2 block should be considered. Two approaches are described—a "high tuberosity' approach and the "greater palatine canal" approach. The "high tuberosity" approach is easier to administer but is associated with a higher positive aspiration rate and risk of hematoma, while the "greater palatine canal" is more difficult to master but is associated with fewer complications.[55] Both approaches to the V_2 NB are described in detail in dental local anesthesia texts.[55] Table 18-6 summarizes drug administration techniques.

Pain Control in Endodontics—Mandibular Technique

It is in the mandible where most significant problems in achieving effective pain control arise. Thirty-one percent of doctors (37 of 121 doctors surveyed) stated they had difficulty achieving pain control "often" or "sometimes" treating mandibular premolars while 55% (67 of 121) mentioned the

TABLE 18-6 Comparison of Routes of Drug Administration

Route of Drug Administration	Onset of Action	Titrate Yes–No	Advantages	Disadvantages
Inhalation	Rapid (~20 s)	Yes	Patient need not be NPO; rapid onset; titration; rapidly increase or decrease level of CNS depression; full recovery in most patients; no prohibitions of postoperative functions	Patient cooperation required; ineffective if unable to breathe through nose
Oral	Slow (~1 h for maximal clinical effect)	No	Easy for patient; easy for doctor	Patient cooperation needed; slow onset; inability to titrate; erratic absorption from GI tract; significant hepatic 1st-pass effect for some drugs; no control over ultimate level of CNS depression; inability to quickly increase or decrease level of CNS depression; inability to reverse CNS depression; prolonged recovery; requirement for escort for patient on leaving dental office
Parenteral: Intramuscular	Intermediate (10–20 min)	No	More reliable absorption than oral; minimal patient cooperation required	Patient must be NPO; potential needle injury; relatively slow onset; inability to titrate; no control over ultimate level of CNS depression; inability to quickly increase or decrease level of CNS depression; inability to reverse CNS depression; prolonged recovery; requirement for escort for patient on leaving dental office
Parenteral: Intravenous	Rapid (~20 s)	Yes	Rapid onset; titration; rapidly increase level of CNS depression; most drugs reversible	Venipuncture is learned technique; patient must be NPO; inability to quickly decrease level of CNS depression; prolonged recovery; requirement for escort for patient on leaving dental office
Parenteral: Intranasal	Intermediate (10–20 min)	No	More reliable absorption than oral; minimal patient cooperation required	Unpleasant (bitter) taste if liquid enters oral cavity; may irritate nasal mucosa; inability to titrate; no control over ultimate level of CNS depression; inability to quickly increase or decrease level of CNS depression; inability to reverse CNS depression; prolonged recovery; requirement for escort for patient on leaving dental office

same for mandibular molars, in all treatment circumstances, not solely endodontically-involved teeth.[37]

Incisive NB

Anesthesia of the premolars, canine, and incisors can easily be achieved in most clinical situations using the incisive NB(often incorrectly termed the "mental" nerve block).

A 27-gauge short needle is recommended. The mental foramen is located based on a well angulated radiograph or by palpation in the buccal fold. It is most often located at or below the apex of the second mandibular premolar. The needle is inserted into the lowest portion of the buccal fold at about the first premolar and then advanced until the needle tip lies outside the mental foramen (the syringe should be kept below the patient's line-of-sight for psychological reasons). Following negative aspiration 0.6–0.9 mL of local anesthetic is deposited slowly. This completes the mental NB. As is the case with the previously discussed ASA NB, the most important aspect of this technique is the application of finger pressure over the site of local anesthetic deposition for minimally 1 min, preferably 2, forcing local anesthetic into the mental foramen, blocking the incisive nerve at that location. All teeth anterior to this location will be pulpally anesthetized.

The incisive NB will provide clinically adequate pulpal anesthesia in essentially all clinical situations, leaving us to consider those "darned" mandibular molars.

Inferior Alveolar NB

The IANB is the traditional technique employed by dentists worldwide when seeking to achieve mandibular anesthesia. Yet this technique has a relatively low success rate overall, and even more so in pulpally involved teeth. In situations of exacerbated chronic pulpitis, 69% (84 of 121) had anesthetic difficulties (almost always, often or sometimes) with 74% mentioning similar problems with acute pulpitis.[37]

There are many approaches to the IANB; the most commonly used involving placing the barrel of the syringe in the corner of the patient's mouth on the contralateral side. The appropriate intraoral landmark is located and the needle (a 25- or 27-gauge long needle is strongly recommended‡) is advanced until bone is gently contacted on the lingual aspect of the mandibular ramus. Following two negative aspirations, a volume of 1.5 mL of local anesthetic is deposited slowly. The syringe is withdrawn and the needle reinserted into the soft tissue in the buccal fold just distal to the last mandibular molar to anesthetize the buccal nerve. Following negative aspiration the remaining 0.3 mL of anesthetic solution is deposited. This buccal NB provides anesthesia to the buccal soft tissues distal to the mental foramen.

Given the significant failure rate of the IANB, other approaches to mandibular anesthesia have been developed including the Gow-Gates mandibular NB; the Akinosi-Vazirani (or Vazirani-Akinosi) closed-mouth mandibular NB, the periodontal ligament (PDL) injection, IO anesthesia; and the administration of articaine by buccal infiltration in the mandible either as a sole injection or as a supplement to a previously administered IANB.

Gow-Gates Mandibular NB

In 1973 an article describing a "high" technique of mandibular anesthesia was published.[58] The technique, using extraoral landmarks, described depositing local anesthetic solution at the lateral aspect of the neck of the mandibular condyle. This technique now known as the "Gow-Gates technique," has become popular. Simply put, the most common reason for an experienced dentist to miss the IANB is deposition of the local anesthetic *below* the mandibular foramen. The nerve is "gone," having disappeared into mandibular bone that is too thick to permit local anesthetic diffusion to occur. We have "missed." In most situations the doctor goes back and administers a second IANB at a site just slightly higher (5–10 mm) than the initial tissue puncture, and profound anesthesia develops. We have learned, through trial and error, that this patient's mandibular foramen is "higher" than the average patient's. "A higher injection is better."

Dr. Gow-Gates took this concept of "higher is better" to an extreme, depositing local anesthetic at the neck of the mandibular condyle. The mandibular division of the trigeminal nerve (V_3) has just exited foramen ovale and, with the patient's mouth opened wide, V_3 is lying close to the mandibular condyle. Using a 25- or 27-gauge long dental needle the depth of soft tissue penetration to bone is approximately 25 mm. The Gow-Gates mandibular NB is described more fully in textbooks of local anesthesia and videos.[59,60] If bone is not contacted, local anesthetic should not be administered. Once mastered, the Gow-Gates technique has a higher success rate than the IANB.[61]

Akinosi-Vazirani, or Vazirani-Akinosi, Closed Mouth Mandibular NB

In clinical situations where a patient has a unilateral trismus (spasm of the muscles of mastication) and is unable to open their mouth, neither the IANB nor Gow-Gates techniques can be administered. If this patient presents in pain, requiring endodontic treatment on a mandibular molar, this closed-mouth mandibular block technique can be employed with a rather high success rate for pain control, but with an even higher success rate at blocking the motor portion of V_3.[62,63] Blocking the motor portion of V_3 allows the patient to open their mouth. If pain control has not also occurred, then other techniques (IANB, Gow-Gates) can now be employed.

‡ All-too-often dentists will use a 30-gauge short needle for the IANB in adult patients. This author strongly recommends ***NOT*** doing so. Though rare, dental needles can break. If a needle is inserted into soft tissue to its entire length (to its hub), when it breaks (breaking *always* occurs at the hub) the needle fragment is "lost." Retrieval is usually difficult and is fraught with significant complications.[56,57] In a review of broken needle reports Malamed et al found all involved short needles with 95% being 30-gauge. Of 86 reports of broken needles, 92% occurred with IANB.[56]

A 25- or 27-gauge long dental needle is recommended. With the patient's teeth gently in contact, the barrel of the syringe is placed adjacent to the maxillary buccal fold. The needle is inserted into the soft tissue on the lingual aspect of the mandibular ramus at a site directly across from the maxillary tuberosity. The height of needle insertion is that of the mucogingival junction of the last maxillary molar. With the needle bevel facing ***away*** from bone the needle is advanced 25 mm. This should place it in the vicinity of V_3. As no bone is contacted (the needle is advanced parallel to the mandibular ramus) this depth of needle penetration is only an approximation. If unsuccessful, a second attempt is made with insertion being either at a greater depth or lesser depth, as determined by the doctor. The Akinosi-Vazirani technique deposits local anesthetic at a position midway between that of the IANB (lowest) and Gow-Gates (highest). Table 18-5 summarizes mandibular injection techniques.

Pain Control in Endodontics—Alternative Techniques

The injection techniques described previously will provide effective pain control in virtually all clinical situations. However there will be occasions when successful pain control remains elusive. This is particularly likely to occur with mandibular molars. The techniques described in the following may be used in either the maxillary or mandibular arches but have been most often used in the latter, as mandibular molars are the most difficult teeth to fully anesthetize.

Periodontal Ligament Injection

The PDL injection, also known as the PDL or intraligamentary injection, can be used as a sole injection or as a supplement to a partially successful NB or infiltration.[64] In endodontics, the PDL is most commonly used to supplement a partially successful IANB where a small, isolated area of the tooth remains sensitive during treatment, while the remainder of the tooth is insensitive. In this example, the mesial aspect of a mandibular first molar remains sensitive during treatment. A 27-gauge short needle is recommended. The bevel of the needle is placed into the periodontal space on the mesial aspect of the first molar, either the mesiobuccal or mesiolingual. With the bevel facing the root of the tooth the needle is advanced into the PDL space until firm resistance is encountered. A volume of 0.2 mL of local anesthetic is deposited slowly. Successful PDL injection is predicted on the following: (1) significant resistance to the drugs' deposition; (2) ischemia of the soft tissues in the area (this will occur whether or not the anesthetic solution contains a vasoconstrictor). The onset of anesthesia is virtually instantaneous. However the duration of pulpal anesthesia is impossible to determine because of the small volume of local anesthetic administered. If necessary, additional anesthetic may be administered during the procedure.

The PDL injection should not be administered into an area where clinical or radiographic evidence of infection is present. Additionally the PDL injection may not be as effective in the presence of periapical infection.

The PDL injection is a variation of IO anesthesia (see following discussion).

Intraosseous Injection

IO anesthesia has been demonstrated to be a valuable adjunct to achieving pain control in difficult clinical situations.[65–67] The thickness of the cortical plate of bone in the adult mandible, of most patients, precludes successful administration of infiltration anesthesia. The mental foramen, usually situated apical to the second premolar, permits local anesthetic access to the incisive nerve, blocking nerve impulses originating anterior to this location (e.g., incisive NB).

Creating a small perforation in the cortical plate of bone distal to the tooth to be treated permits a short 27-gauge dental needle to be painlessly inserted. Local anesthetic solution is slowly administered. For "hot" mandibular teeth it is recommended that one cartridge (1.8 mL) be administered.[68]

Because of the vascularity of this area it is not uncommon for patients to experience palpitations whenever a vasoconstrictor-containing local anesthetic is used. As vasoconstrictor-containing local anesthetics provide a longer duration and more profound anesthesia than "plain" local anesthetics, it is recommended that a 1:200,000 epinephrine concentration be selected.[69,70]

Using a local anesthetic containing epinephrine should provide pulpal anesthesia of approximately 30 min duration while a "plain" solution should provide approximately 15 min of not as profound anesthesia.

The IO procedure is relatively comfortable. Local infiltration of the soft tissue at the site of the injection is recommended. Perforation of the interproximal bone is almost always entirely atraumatic.

The technique is described in greater detail in local anesthesia textbooks.[71]

Intrapulpal Injection

Prior to the introduction of IO anesthesia, buffered local anesthetics and articaine (see the following), achieving anesthesia profound enough to permit entry into the pulp chamber of infected mandibular (and on rare occasion, maxillary) teeth was problematic. More specifically, this problem occurred with mandibular molars because few alternative techniques were available with which the doctor could obtain profound anesthesia.

Deposition of local anesthetic directly into the coronal portion of the pulp chamber of a pulpally involved tooth provides effective anesthesia for pulpal extirpation and instrumentation where other techniques have failed. The intrapulpal injection may be used on any tooth when difficulty in providing profound pain control exists, but from a practical view it is necessary most commonly on mandibular molars.[72,73] Intrapulpal injection produces pain control both by the pharmacological action of the local anesthetic and

applied pressure. This technique may be used once the pulp chamber is exposed, either surgically or pathologically.

The needle is placed into the perforation in the roof of the pulp chamber (preferably a small opening) and a volume of 0.2–0.3 mL of local anesthetic is injected. Unfortunately, there will be a brief moment of pain experienced by the patient as the drug is administered.

Fortunately, today, with the availability of multiple anesthetic options, the need for intrapulpal injection has significantly decreased.

Articaine by Buccal Infiltration

Articaine 4% with epinephrine 1:100,000 or 1:200,000 has become the second most used local anesthetic in dentistry in the United States despite having only been introduced in June 2000,[38] and the fact that most well-designed clinical trials have concluded that articaine is "as safe and effective as lidocaine" (the drug to which it is most often compared).[74,75]

Following its introduction, numerous anecdotal reports were received from dentists claiming they no longer needed to administer the IANB to work in the adult mandible painlessly. They stated that mandibular infiltration with articaine HCl was uniformly successful. These claims were initially met with skepticism. However over the past 9 years, a number of well-designed clinical trials comparing infiltration in the adult mandible of articaine HCl 4% with epinephrine 1:100,000 to lidocaine 2% with epinephrine 1:100,000 or 1:80,000 clearly demonstrated articaine's superiority when administered as a sole injection for pulpal anesthesia.[76–78]

Of greater clinical significance for endodontics is the buccal infiltration of articaine as a supplement to theIANB, and other block techniques, that may be less than fully effective in blocking nerve conduction in "hot" mandibular molars. Kanaa et al.[79] administered IANBs (lidocaine 2%, epinephrine 1:80,000) to subjects on two occasions. Subjects then received either a buccal infiltration of articaine 4% with epinephrine 1:100,000 (2.0 mL) by the first molar or a "dummy" injection at the same site. The first molar, first premolar, and lateral incisor were tested using electric pulp tester (EPT) for 45 min. Significant increases in success were noted with articaine infiltration for the first molar and lateral incisor ($p = <0.001$) (Table 18-7) At the conclusion of the study (45 min) there was no indication of decreasing anesthetic efficacy in any of the three teeth tested[79] (Figure 18-4).

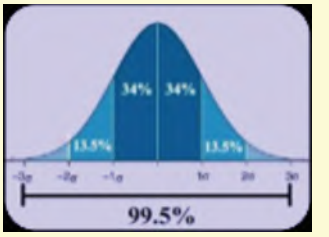
Greater success would be seen in "real life" clinical situations by supplementing an IANB with articaine buccal infiltration (0.9–1.2 mL) at the apex of the tooth to be treated. (In the clinical trial articaine was infiltrated by the first mandibular molar).

Suggested Local Anesthetic Technique Sequences for Maxillary and Mandibular Endodontically-Involved Teeth

It is this author's suggestion that the following sequences be considered when seeking painless entry into a "vital" pulp chamber. Both maxillary and mandibular sequences begin with the assumption that "all is good."(Tables 18-8–18-13).

TABLE 18-7 Local Anesthetics by Expected Duration of Pulpal Anesthesia

- Short-duration (~30 min)
- Lidocaine 2%, Mepivacaine 3%, Prilocaine 4%
- Intermediate-duration (~60 min)
- Articaine 4%, Lidocaine 2%, Mepivacaine 2%, Prilocaine or 4% (all with vasoconstrictor)
- Long-duration (>90 min)
- Bupivacaine 0.5% (with vasoconstrictor)



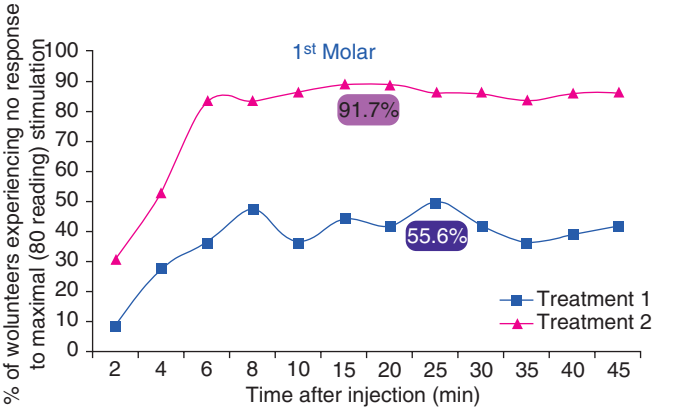


FIGURE 18-4 Duration of pulpal anesthesia for mandibular first molar following IANB with lidocaine 2% epinephrine 1:80,000 (blue line) versus IANB with lidocaine 2% epinephrine 1:80,000 with articaine 4% with epinephrine 1:100,000 buccal infiltration (pink line).[43]

TABLE 18-8 Suggested Pain Management Protocol

Pre-surgical NSAID po 1 h prior to appointment
- Ibuprofen 600 mg

LA of choice for surgery
- Articaine, Lidocaine, Mepivacaine, Prilocaine

Long-acting LA at end of surgery just prior to discharge of patient
- Bupivacaine

NSAID on timed basis (q4,6,8h) for xx days
- Ibuprofen 600 mg qid

Postsurgical telephone call early evening

Maxillary teeth:

1. Infiltration
   a. Preferably with buffered lidocaine or articaine
2. Appropriate NB (ASA, PSA, AMSA)
   a. Supplement NB with buffered articaine buccal infiltration (1.0 mL)
3. Consider sedation
   a. Inhalation sedation with N_2O–O_2 preferred

If necessary:

4. PDL injection

TABLE 18-9 Comparison of Available Local Anesthetic Formulations

Drug %	Vasoconstrictor	Mg LA/Cartridge	Onset (Pulpal)	Duration (Pulpal)	Duration (Soft Tissue)	MRD (FDA) mg/kg (Absolute Max)
Lidocaine 2%	Epi 1:50,000 Epi 1:100,000	36	3–5 min	60 min	3–5 h	7.0 (500)

3.5 (with epi)	0.004	0.005	0.008	0.003

TABLE 18-11 Summary of Maxillary Injection Techniques

Technique	Pulpal Anesthesia of …	Recommended Volume of Local Anesthetic (mL)
Infiltration (supraperiosteal)	Single maxillary tooth	0.6
Anterior superior alveolar NB	Incisors, canine, premolars	0.9–1.2
Posterior superior alveolar NB	Molars	0.9–1.8
Anterior middle superior alveolar NB	Incisors, canine, premolars	1.4–1.8
Maxillary (V_2) NB	Incisors, canine, premolars, molars	1.8

TABLE 18-12 Summary of Mandibular Injection Techniques

Technique	Pulpal Anesthesia of …	Recommended Volume of Local Anesthetic (mL)
Articaine infiltration	Single maxillary tooth	0.9–1.2
Incisive NB	Incisors, canine, premolars	0.6–0.9
Inferior alveolar NB	Incisors, canine, premolars, molars	1.5
Gow-Gates mandibular NB	Incisors, canine, premolars, molars	1.8
Akinosi-Vazirani (closed mouth) mandibular NB	Incisors, canine, premolars, molars	1.8

TABLE 18-13 Percentage of Successful IANB: Lidocaine Versus Lidocaine and Articaine Infiltration[43]

Anesthesia Success >2 Consecutive 80/80 Readings	IA + A-Caine Infiltration	IA + A-Caine Infiltration	IA + Dummy Infiltration	IA + Dummy Infiltration	McNemar Test *P*-Value
	Failure *n* (%)	Success *n* (%)	Failure *n* (%)	Success *n* (%)	
1st molar	3 (8.3)	33 (91.7)	16 (44.4)	20 (55.6)	<0.001
Premolars	4 (11.1)	32 (88.9)	12 (33.3)	24 (66.7)	0.021
Lateral incisors	8 (22.2)	28 (77.8)	29 (80.6)	7 (19.4)	<0.001

5. IO (rarely necessary in maxilla)
6. Intrapulpal (rarely necessary in maxilla)

Mandibular teeth:

1. Block technique: IANB, Gow-Gates NB, Akinosi-Vazirani NB
   a. Preferably with buffered lidocaine or articaine
2. Supplement NB with buffered articaine infiltration in buccal fold of tooth to be treated (1.0 mL)
3. Consider sedation
   a. Inhalation sedation with N_2O–O_2 preferred

If necessary:

4. PDL injection
5. Intraosseous
6. Intrapulpal

SUMMARY

Dental pain, anxiety, and fear exist and are a fact of life, especially in the specialty of endodontics. The primary obstacles to successful endodontic treatment are the presence of dual problems: pain and fear. To ignore fear, in the best of circumstances, will complicate dental treatment unnecessarily, as the patient remains an unwilling participant throughout the procedure. Fear lowers the pain reaction threshold, with odontophobic patients being unable to sit still during their treatment, adding to the frustration of the treating doctor. Fear increases catecholamine release into the cardiovascular system with a resultant rise in the incidence and severity of medical emergency situations.

The recognition of fear, and its management, removes a primary obstacle to the delivery of health care. Once fear is eliminated, clinically adequate pain control is normally accomplished quite readily through administration of local anesthetics, the safest and most effective drugs in medicine for preventing and managing pain.

The "hot" tooth, especially a mandibular molar, can also present a significant barrier to the delivery of painless dental care. Fortunately, today there are many options for the dentist to choose from. New local anesthetics (e.g., articaine); buffered local anesthetic solutions; newer techniques (e.g., Gow-Gates NB; Vazirani-Akinosi NB); and articaine administered by buccal infiltration in the mandible, all work to increase the likelihood of endodontic treatment being delivered painlessly.

Chapter 19

Preparation for Treatment

C. John Munce, Terrell F. Pannkuk, Adham A. Azim, Rajiv G. Patel, Ziv Simon

CASE PRESENTATION AND TREATMENT PLANNING

Proper dentist–patient communication is an important aspect of any dental treatment. Thorough case presentation and truthful, complete answers to all of a patient's questions, fosters a warm and trusting relationship. This results in better patient compliance and a lower level of anxiety during treatment.[1] Patients presenting for endodontic treatment usually have many questions involving the nature of the procedure, the amount of pain expected during and after treatment, as well as the success rate and long-term prognosis of treatment.

The determination as to whether or not a tooth requires endodontic treatment is established during the initial examination. With the aid of an intraoral camera, radiography, cone-beam computed tomography (CBCT), and other imaging tools (see Chapter 9), the case can be fully presented to the patient. These high-tech diagnostic devices allow the dentist to thoroughly explain the reasons for the patient's current discomfort or condition, the need for intervention and the expected treatment outcome. The examination should not be limited to endodontic evaluation alone, but should include periodontal and restorative considerations as well (see Chapter 8).

Once the necessity for endodontic treatment has been established, nonsurgical root canal treatment or retreatment will most often be the recommended procedures. Occasionally, surgical intervention, such as apicoectomy or intentional replantation, may be advised to address unresolved periapical pathosis, obstructed canals, or other conditions not able to be addressed nonsurgically. The clinician should also be able to determine if further treatment might be required to ensure a good, long-term prognosis. Procedures such as surgical crown lengthening or orthodontic extrusion might be necessary to facilitate tooth isolation and subsequent restoration. In conjunction with endodontic treatment, guided bone regeneration may be required to restore the periodontal attachment and contribute to the longevity of the tooth.[2]

The clinician should be familiar with advanced restorative and periodontal procedures. Many teeth previously determined to be nonrestorable or considered likely to have a poor treatment outcome, can currently be saved with a higher degree of predictability (Figure 19-1). Decision-making should involve the entire team of collaborating clinicians, including the endodontist, periodontist, orthodontist, and restorative dentist as well as the patient. In the absence of severe pain or swelling requiring emergency endodontic intervention, treatment planning should be completed prior to initiating treatment. It is essential to collect all relevant diagnostic information prior to starting a course of treatment (Figure 19-2). In some instances, no treatment is advised and extraction is recommended (Figure 19-3).

Teeth requiring nonsurgical endodontic intervention may often present with an existing full coverage restoration. In cases where poor margins exist, the restoration should be removed and the restorability should be determined. If the margins are adequate, the clinician may attempt to maintain the restoration providing it does not interfere with access and visibility. The decision to remove or maintain an adequate full coverage restoration rests largely with the clinician and should be determined on a case-by-case basis.

Patients are often concerned about the time and number of appointments required to complete root canal therapy. The current evidence suggests that endodontic treatment may be completed in single (when indicated) or multiple visits with similar success rates and post-operative complications.[3–5] With advancements in endodontic armamentarium, completion of endodontic treatment in a single visit has gained popularity. Multiple visits, on the other hand, may be advantageous for many case types, including retreatment, calcified canals, broken instruments, post removal, cases with tortuous canals, and patient management cases to name a few. Multiple visits, however, are indicated in cases of severe symptoms, persistent canal exudate, resorption or when further canal disinfection is required through intracanal medication.[6–9] Inexperienced clinicians should anticipate extra time requirements for root canal treatment. In all cases, the length of any given treatment visit should not extend beyond the tolerance level of either the patient nor the dentist. When limits have been reached, intracanal medication should be placed (when appropriate), the tooth temporized and another appointment scheduled to continue the treatment.

INFORMED CONSENT

Endodontic treatment, like all dental treatment, must be preceded by informed consent. The dentist must thoroughly explain the proposed treatment, the benefits, the risks, and alternative treatments, including the option of no treatment at all.[10,11] Informed consent is a legal concept developed via case law and is enforceable through judicial actions. The prudent clinician will be careful to "inform before he or she performs."[12]

Informed consent is the patient's agreement to a proposed course of treatment, based on having received clear and understandable information about the potential benefits and risks of the proposed treatment. The dentist should ensure that the

FIGURE 19-1 ***A–C***, Periapical radiograph of a maxillary central incisor with large periapical lesion and a sinus tract tracing to the apex that shows apical resorption. This tooth was associated with grade II mobility and probing to the apex on the palatal surface. ***D–F***, CBCT images showing loss of the buccal plate of bone and the interproximal bone support. In the sagittal view, the tooth appears to have a poor crown–root ratio. ***G,H***, Periapical radiographs following root canal treatment using MTA as an apical barrier. Patient then underwent surgical intervention to remove the periapical granuloma, and guided tissue regeneration (GTR) using allograft bone material and resorbable membrane was performed. ***I–K***, Six-month follow-up showing complete healing of the surgical site with no mobility and normal probing (3 mm) 360°. ***L,M***, Follow-up CBCT showing bone filling the entire osseous defect. (Courtesy of Dr. Adham A. Azim, Buffalo, NY.)

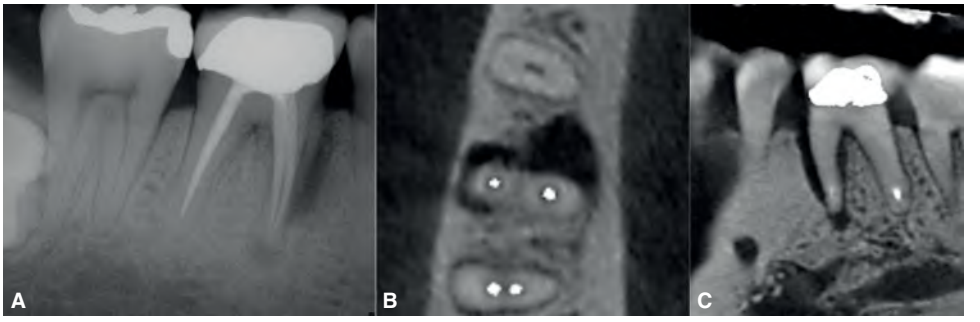

FIGURE 19-3 ***A***, Periapical radiograph of the mandibular right first molar showing prior endodontic treatment and a lateral lesion extending the full length of the mesial aspect of the mesial root, contiguous with the apical lesion on the mesial. ***B***, CBCT axial view shows the lesion extending from the buccal surface to the lingual surface of the mesial root. ***C***, CBCT sagittal view shows a bone loss pattern typical of vertical root fracture, extending the full length of both the mesial and furcal aspects of the mesial root. Extraction was advised. (Courtesy of Dr. Adham A. Azim, Buffalo, NY.)

information is provided to the patient in a language and terms that the patient understands. If necessary, an interpreter should be used or written information in the patient's native language is provided. While a statutory definition of "informed consent" may or may not exist in a particular state, there is extensive case law that defines the process, and it is well understood within the medical and legal communities to mean that a patient must "receive sufficient information to make a meaningful decision" regarding his or her own health care.[10]

Informed consent involves the process of the practitioner's explanation of the treatment, its potential benefits and risks, and the patient's understanding of that explanation. The informed consent discussion should be documented in the patient's treatment record. Although it is not required to use a written informed consent form, the American Association of Endodontists provides a sample form that can be used (Figure 19-4). Patient treatment refusal should be documented in the patient's record. Dentists should be aware of

SAMPLE STATEMENT OF CONSENT FOR ENDODONTIC TREATMENT

1. I hereby authorize Dr. _____ and any other agents or employees of _____ and such assistants as may be selected by any of them to treat the condition(s) described below:

   _____

   _____

2. The procedure(s) necessary to treat the condition(s) have been explained to me, and I understand the nature of the procedure(s) to be: _____

   _____

3. The prognosis for this(these) procedure(s) was described as: _____

   _____

4. I have been informed of possible alternative methods of treatment including no treatment at all.

5. The doctor has explained to me that there are certain inherent and potential risks in any treatment plan or procedure. I understand that the following may be inherent or potential risks for the treatment I will receive:
   swelling; sensitivity; bleeding; pain; infection; numbness and/or tingling sensation in the lip, tongue, chin, gums, cheeks, and teeth, which is transient but on infrequent occasions may be permanent; reactions to injections; changes in occlusion (biting); jaw muscle cramps and spasm; temporomandibular joint difficulty; loosening of teeth, crowns or bridges; referred pain to ear, neck and head; delayed healing; sinus perforations; treatment failure; complications resulting from the use of dental instruments (broken instruments—perforation of tooth, root, sinus), medications, anesthetics and injections; discoloration of the face; reactions to medications causing drowsiness and lack of coordination; and antibiotics may inhibit the effectiveness of birth control pills.

6. It has been explained to me and I understand that a perfect result is not guaranteed or warranted and cannot be guaranteed or warranted.

7. I have been given the opportunity to question the doctor concerning the nature of treatment, the inherent risks of the treatment, and the alternatives to this treatment.

8. This consent form does not encompass the entire discussion I had with the doctor regarding the proposed treatment.

country or state laws and whether informed refusals must be set forth in writing.

To ensure adequate disclosure, so the patient can be fully informed, the dentist should draw upon clinical judgment and experience, as well as current literature and research. The standard is whether a reasonable patient would be able to understand and whether a reasonable patient would have consented to the treatment if adequately informed of the significant risks.

TREATMENT TEAM COMMUNICATION

Computer technology has transformed the traditional "post-card" single tooth endodontic treatment report showing two radiographs taken before and after endodontic therapy into a comprehensive real-time information exchange of ongoing treatment planning and execution details. A digital charting system, with coordinated file storage, can simplify the

organization of patient's records containing text, image, and even video files. The data can then be conveniently retrieved and organized into an e-mail, containing multiple attachments providing all collaborating clinicians with the details of a planned and treated case. A networked computer system, with a main server, basic computer literacy, and technical support, are mandatory for a modern dental practice.

The advantage of digital communication is clear, with the patient receiving efficient interdisciplinary treatment unobstructed by delays. Comprehensive treatment planning is less prone to confusion, misinterpretation, and potential catastrophic errors.

Ideal technological tools, for ideal treatment team communication, include the following:

1. Networked computer system
2. Digital charting software that may include an integrated or separate image organizer
3. Digital radiography
4. Flatbed scanner (reflective and film capability)
5. Dental operating microscope with still and video camera attachment
6. Redundant backup systems in addition to the local network computer system (cloud, web-based, secondary external hard drives rotated off-site)
7. Online meeting and conferencing software

A strategically designed office may create a seamless gathering of data from chair-side to the front office, that is then converted and stored into organized electronic files, enabling efficient communication to the collaborating clinicians, oftentimes even before the patient walks out of the office (Figure 19-5).

FIGURE 19-5 With a convenient location of the computer screen and keyboard, the creation and storage of digital records can occur contemporaneously and photographic images can be easily captured via a camera mounted on the microscope. (Courtesy of Dr. Terrell F. Pannkuk, Santa Barbara, CA.)

The numerous technological advantages of modern data collection and communication come with many significant risks as well. Computer hacking, viruses, and identity theft are universal concerns that have alarmingly become common place. The Congressional Research Service reported that in 2012, 12.6 million Americans were victims of identity theft, and the average fraud victim incurred $365 in costs as a result.[13]

The risks of a security breach are not only a direct expense to the practitioner, but can also create liability should the patient's private information be stolen. Health Insurance Portability and Accountability Act (HIPAA) was created in the United States in 1996. A specific privacy rule was enacted in 2003 that dramatically changed health care practice and the release of patient information. The disclosure of Protected Health Information (PHI) has been strictly enforced and regulated such that reasonable steps to safeguard privacy are expected at all times.

Patient information exchange via e-mail must be limited to the patient's approved treatment team, and it is prudent to include an e-mail tag such as the following to prevent the accidental dissemination of private information:

> Confidentiality Notice: The information contained in and transmitted with this communication is strictly confidential, is intended only for the use of the intended recipient, and is the property of [insert name of dentist]. If you are not the intended recipient, you are hereby notified that any use of the information contained in or transmitted with the communication or dissemination, distribution, or copying of this communication is strictly prohibited by law. If you have received this communication in error, please immediately return this communication to the sender and delete the original message and any copy of it in your possession.

In summary, a referred consultation with a specialist is a request for an advanced perspective of the diagnosis and an advanced treatment service. Treatment team communication should be an interdisciplinary educational interaction that provides enhanced patient-centered care. The majority of endodontic procedures are performed by nonspecialists. This has significantly increased the complexity of cases referred to endodontic specialists. Retreatment of iatrogenically compromised teeth, as well as treatment of patients having special management problems, has often become the typical case referred to an endodontist. The endodontic specialty, and the dental profession as a whole, will greatly benefit by the clinical practitioner having an interdisciplinary focus, and seeking to learn and share from each patient interaction.

PREMEDICATION WITH ANTIBIOTICS

In the past, patients presenting for endodontic treatment were often prescribed prophylactic antibiotics to prevent possible pain and swelling (flare-up). In a survey of the American Association of Endodontists in 2002, 85% of participants reported that they prescribed a pretreatment

loading dose of antibiotics.[14] However, subsequent studies have shown that prophylactic antibiotic prescription has no effect on endodontic flare-up.[15,16]

Patients with certain medical conditions may require antibiotic premedication prior to endodontic treatment. For example, patients with risk of developing infective endocarditis (IE) should receive antibiotic premedication to prevent blood borne microorganisms from flourishing in the blood stream and lodging on shunts or prostheses.[17,18] In 2007, the American Heart Association (AHA) established significant updates in the guidelines for prophylactic antibiotics regimens to their prior 1997 guidelines.[19] The reason for the revision was that endocarditis is much more likely to result from frequent exposure to random bacteremias associated with daily activities than from bacteremia caused by a dental procedure.[20] In addition, the revised AHA guidelines were based on evidence that the risks of antibiotic-associated adverse effects exceeded the benefits.[21,22] The AHA now recommends that prophylactic antibiotics be limited to only those patients with high risk of developing IE, such as patients with the following conditions[19]:

1. Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
2. A history of IE
3. A cardiac transplant that develops cardiac valvulopathy
4. Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
5. A completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
6. Any repaired congenital heart defect with residual defect at the site or adjacent to the site of a prosthetic patch or a prosthetic device (that inhibits endothelialization)

Except for the conditions listed previously, prophylactic antibiotics are no longer recommended for any other form of congenital heart disease.[19] For patients with the select conditions, prophylaxis is reasonable because endothelialization of a prosthetic material occurs within 6 months after the procedure.

The AHA has developed a standard antibiotic regimen for patients at high risk of developing IE, with alternative regimens for patients with allergies or when oral administration is not possible. The standard antibiotic regimen for all dental procedures is currently amoxicillin since it is better absorbed by the gastrointestinal tract and maintains a higher serum level than penicillin. The recommended regimens and dosages are listed in Table 19-1.[19]

For patients at high risk of developing IE, it is recommended that the patient take prophylactic antibiotics 1 h prior to dental treatment. This allows the antibiotics to reach adequate levels in the blood stream. If the patient forgets to take the prophylactic dose, the recommended dosage may be administered up to 2 h after the procedure. In cases where a patient is on an antibiotic regimen prior to treatment, the dentist may prescribe a different class of antibiotics than the class the patient is currently using. (For example, if the patient is currently on a regimen of clindamycin, the dentist should select amoxicillin for prophylaxis.)

In 2003, an advisory statement was drafted by the American Dental Association (ADA) and the American Academy of Orthopedic Surgeons (AAOS) stating that there was insufficient evidence supporting prophylactic antibiotic prescription for patients with total joint replacement.[23] Due to the lack of evidence, a regimen similar to patients with high risk of IE was recommended for patients with total joint replacement for the first 2 years after surgery. In 2014, the ADA Council on Scientific Affairs assembled an expert panel to update and clarify the clinical recommendations for premedications to patients with total joint replacement receiving dental treatment. No association between dental procedures and prosthetic joint infections was found in the updated systemic review and the panel concluded that there is no need to prescribe prophylactic antibiotics before dental procedures for patients with prosthetic joint replacements.[24] Since it is impossible to make recommendations for all patients, the ADA encourages dental professional to take this recommendation into account, consult with the patient's orthopedic surgeon when needed, and consider the patient's needs and preferences

TABLE 19-1 Recommended Antibiotic Regimen and Dosage for Patients Requiring Premedication before Dental Treatment

	Antibiotic regimen	Dosage 30–60 min prior to treatment		Administration
		Adults	Children	
Standard dosage	Amoxicillin,	2 g	50 mg/kg	Oral
	Cefazolin	1 g	50 mg/kg	
Allergy to penicillin	Clinadmicin	600 mg	20 mg/kg	Oral
	Azithromycin/clarithromycin	500 mg	15 mg/kg	
	Cephalexin	2 g	50 mg/kg	
Inability to administer orally	Cefazolin or ceftriaxone	1 g	50 mg/kg	IM or IV
	Ampicillin	2 g	50 mg/kg	
Allergy + inability to administer orally	Clinadmicin	600 mg	20 mg/kg	IM or IV
	Cefazolin/ceftriaxone	1 g	50 mg/kg	

Abbreviation: IM = intramuscular; IV = intravenous; kg = kilogram; mg = milligram.

when planning treatment. Clinicians should also exercise their clinical judgment in determining whether premedication for a patient is appropriate.

It is important to note that an antibiotic regimen should be prescribed in conjunction with proper endodontic treatment when there are systemic signs and symptoms of infection or a progressive/persistent spread of infection. For more details, see Chapter 30.

ANTI-ANXIETY REGIMEN

Patients presenting for endodontic treatment are often anxious about the procedure. There is often an unrealistic assumption that the procedure will be painful. Such misinformation can result in making it difficult for the patient to be relaxed during treatment. Although a majority of patients are able to control their fear, some fail to do so. Clinicians should attempt to fully explain the dental procedures prior to treatment and discuss possible minor discomforts during or after the treatment. Explanation of the treatment steps before initiating the procedure has been shown to reduce the patient's anxiety level.[1] In cases where patient's fear cannot be controlled, antianxiety protocol ranging from nitrous oxide to conscious sedation can be administered. For more details, see Chapter 18. The selection of the appropriate antianxiety medication should be based on each individual patient and his or her ability to control his or her behavior and anxiety during the treatment appointment.

PAIN MEDICATION

It can be challenging to completely anesthetize patients presenting for endodontic treatment with inflamed pulp or periapical tissue. The low pH environment resulting from the inflamed pulp or periapical tissue may affect the efficiency of local anesthetics and result in anesthetic failure.[25,26] Prescribing low dose of oral ketamine (10 mg) before endodontic treatment has been shown to enhance the effect of inferior alveolar nerve block in treatment of mandibular molars with irreversible pulpitis.[27] Other studies have shown that preoperative administration of ibuprofen or other nonsteroidal anti-inflammatory drugs (NSAID) 1 h prior to the local anesthesia injection is an effective method for achieving a profound anesthesia during endodontic treatment in teeth with inflamed pulp tissue.[28]

Postoperative pain may be anticipated following endodontic therapy.[29,30] Irritation of the periapical area may be expected due to extrusion of debris, irrigation, and root filling material during treatment. Studies have shown that prophylactic administration of pain medication may reduce postoperative pain.[31–33] Although postoperative pain may be mild or even absent following endodontic therapy,[34] clinicians often prescribe prophylactic pain medication to avoid possible moderate or severe pain after endodontic treatment.

THE DENTAL OPERATING MICROSCOPE

The Romans, in the first century, noted that objects viewed through glass appeared larger. Thus began the historical timeline of discoveries and inventions that significantly enhanced human vision. In 1609 Galileo Galilei mounted a convex and concave lens and created the compound microscope.[35] A new world of health science was revealed by Anton van Leeuwenhoek "largely due not only to his method of grinding, but also to the skill with which he mounted his lense."[36] In his letters to the Royal Society, his controversial claim to have documented single-celled organisms in 1674 which he called *animalcules* put him at odds for a period with the intelligentsia of his day. In 1922, Nylen performed a surgical procedure on the eye, that marked the beginning of modern microsurgery.[37,38] A few decades later the microscope became the standard protocol for additional medical specialties including neurology as well as ophthalmology,[39,40] coinciding with the Carl Zeiss Company (Germany) introducing the first commercial binocular microscope in 1953.[41]

A physician and dentist introduced the first dental operating microscope in 1978.[42,43] This team of Apotheker and Jako worked with Chayes-Virginia to develop the "dentiscope" and offered the first clinical hands-on microscope courses at Harvard Dental School in 1982.[41,44] Interest in the first generation dental microscope was minimal and Chayes-Virginia discontinued production and sales by 1986.

The Commission on Dental Accreditation (CODA) of the ADA received a formal recommendation by the American Association of Endodontists (AAE) in 1995 to include microscope training in the Accreditation Standards for Advanced Specialty Education Programs in Endodontics that was agreed upon in 1996, and microscope training became mandatory in these programs in 1997. In spite of the mandatory microscope training for the endodontic specialty, a significant number of endodontic specialists in practice and great number of general dentists performing endodontic procedures do not use this important tool. Figure 19-5 demonstrates the use of a dental operating microscope during four-handed dentistry.

Benefits of the microscope used for endodontic procedures include:

1. Improved treatment of calcified canals[45,46]
2. Refinement of endodontic surgical procedures such as apicoectomy with root-end filling where the micropreparation includes microgrooves and allows a smaller discrete access plan[47]
3. Improved management of complex root anatomy during nonsurgical endodontic treatment[48–52]
4. Improvement of postsurgical healing due to less traumatic flap management and approximation of tissues during microsuturing to favor healing by primary intention.[39,53,54]
5. Elimination of obstructions from root canals[55–58]
6. Diagnosis of root fractures[59]
7. Internal repair of root perforations[60]

Endodontic treatment performed prior to the introduction of the microscope was limited to tactile awareness without a clear view of the operating field. Dental instruments were larger with a cumbersome design. These same larger instruments used with the modern dental operating microscope are ill-suited for the finer perspective offered with 10×–20× magnification and enhanced lighting allowing direct visualization and preparation of anatomical features existing deeper in the root. Microsurgical ultrasonic instruments, microburs, and microsurgical hand instruments have been introduced to accommodate the new "micro perspective." A reduction in the frequency of surgical endodontic procedures has occurred as use of the microscope allows meticulous dismantling of posts and materials cemented and placed deep in the root. In one study, clinicians under and over the age of 40 were compared for visual acuity.[61] Visual acuity is measured as the angle between the eye and two distinct points or the identifying dimension of a recognized structure, which in the study was the E-optotype used in routine eye examinations. Dentists over 40 years of age were dependent on the microscope to inspect any location inside the root canal. It was found that dentists over the age of 40 could rarely detect the 0.06 mm width of a canal orifice without the orthograde illumination and magnification provided by a dental operating microscope.

The advent of the dental operating microscope has been described as a revolutionary advancement in diagnosis and execution of endodontic therapy.[62] The AAE has stated that microsurgery offers distinct advantages over traditional endodontic surgery.[63]

The following are common microscope options:

Microscope mountings:

1. Floor stand
2. Lateral wall mount
3. Ceiling mount

Lighting options:

1. Halide
2. Xenon
3. LED

Documentation accessories:

1. Still camera
   a. Video capture
   b. Digital "Point and shoot"
   c. SLR (Figure 19-6)
2. Video

The position of the patient and microscope can be adjusted to facilitate treatment in different areas of the mouth and the following guidelines determine position:

1. Vertical posture of the dentist and assistant in their respective chairs set to match positioning parameters.
2. The clinician's arms should hang relaxed and straight.

FIGURE 19-6 A beam splitter on the microscope allows the addition of adapters to accommodate video and SLR photography. (Courtesy of Dr. Terrell F. Pannkuk, Santa Barbara, CA.)

3. The head of the patient requires a sufficient angle and arching of the neck to accommodate visibility and access to posterior teeth when working in the 11–12-o'clock position. Occasional operator rotation to the 9-o'clock position is required for oral examination and use of hand files without contortion of the shoulders and arms.
4. Lower to middle magnification steps are used during most treatment procedures and the highest step magnification setting is used primarily for photography.
5. Indirect vision with a mirror is required for maxillary teeth and is often more comfortable than treating mandibular teeth in patients having limited jaw opening.

In summary, the complexities of the root canal system are illuminated, magnified, and better treated by a dentist utilizing the advantage of a dental operating microscope. The AAE published information highlighting the specific advantages of practicing endodontics with the microscope.[47] The advent of numerous microscope choices and features adapted to dental practice have shown microscopic dental technique to prolong a dentist's practice career and provide higher quality treatment.

LOUPES

Although the dental operating microscope is the preferred method for enhanced visualization during endodontic procedures, many practitioners report effective use of loupes. Some practitioners use the microscope for some aspects of a procedure and loupes for other aspects depending upon the desired amount of magnification. When utilizing loupes, high-intensity illumination is critical in order to elaborate the field and to reduce shadowing.

Innovations are being made for loupes as well as attached headlamps. There are adjustable magnification levels ranging from 3× to 5× (Orascoptic, Middleton, WI, U.S.A.). Higher levels of magnification with expanded field are available, including 4.5×, 6×, and 8× (Designs for Vision,

Ronkonkoma, NY, U.S.A.) and 5.5×, 6.5×, and 8× (SurgiTel, Ann Arbor, MI, U.S.A.). The higher the magnification, the smaller the depth and width of the field of vision. However, because endodontic procedures are generally performed within a confined space, the higher powers are recommended in order to visualize fine detail and deep canal morphology. Headlamps may be attached to the frames or on a separate headband and may consist of xenon or LED lights.

The visual acuity of loupes decreases as the working distance increases. Therefore, tall practitioners may need higher magnification. The loupes should feel comfortable, the neck should not be strained, and the visual field angulation should be adjusted to the operator's specific circumstance and preference. Many manufacturers also provide prescription within the lens portion surrounding in-the-lens telescopes.

For educational purposes and communication among collaborating clinicians, sophisticated high-magnification loupes (up to 8× or greater by special order) with power-matched video camera and coaxial high-intensity illumination offer not only excellent intraoral procedural capture, but also the unique ability for the clinician to capture at will, by a simple turn of the head, steps of a technique distant from the oral cavity such as custom fabrication or modification of clinical implements or instruments and procedures performed by the endodontic assistant. There are a number of loupe-mounted video systems available, including NanoCam (Designs for Vision, Ronkonkoma, NY, U.S.A.), HD LoupeCam (VizVOCUS, Scottsdale, AZ, U.S.A.), Surgicam Pro (SurgiTel, Ann Arbor, MI, U.S.A.) and through-the-lens Alos camera (High Q, Lexington, KY, U.S.A.).

ENDODONTIC SETUP

All instruments necessary for endodontic treatment should be conveniently available in the operatory to both the assistant and the dentist, and they should be neatly arranged for procedural efficiency. Various specialized instrument holders and setups are available (Figure 19-7), and each office should develop the setup that is most efficient and convenient. Typically, the endodontic tray setup will include the following:

- Injection syringe and anesthetic
- Mirror, periodontal probe and endodontic explorer
- Dental dam, dental dam frame, clamp forceps and dental dam punch
- Clamp(s)
- Floss for passing the dam through proximal contacts and for ligating the clamp
- High-speed and slow-speed handpieces and burs
- Locking cotton plier for general purposes and for bur and rotary instrument insertion (Figure 19-8)
- Canal-irrigation syringes
- Endodontic spoon excavator
- Mixing spatula and mixing pad or glass slab
- Obturation instruments

FIGURE 19-7 Endodontic instrument kit. (Courtesy of HuFriedy, Chicago, IL.)

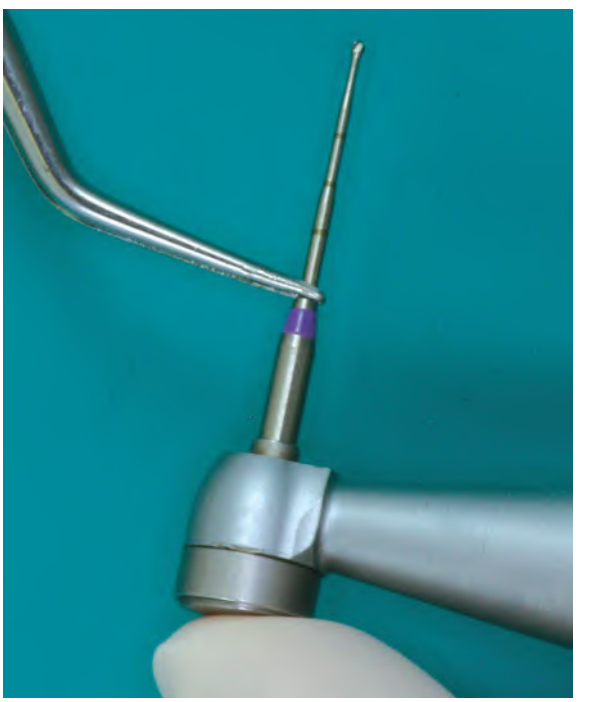

FIGURE 19-8 Various endodontic rotary instruments, including the Munce Discovery Burs as demonstrated here, Gates Glidden burs and rotary files, can be conveniently "dropped" into a latch-type slow-speed handpiece with a locking cotton plier while spinning the rotor via the foot control.

- Canal cleaning and shaping instruments that can be arranged on a disposable sponge (or another disposable setting) in a carrier such as the Endoring (Jordco, Beaverton, OR, U.S.A.) (Figure 19-9)

FIGURE 19-9 The Endoring allows for efficient setup and access to hand and rotary files. (Courtesy of Jordco, Beaverton, OR.)

FIGURE 19-10 Views of the front and back of the ASI Advanced Endodontic System® Designer Series Ergo iTech. (Courtesy of ASI, Englewood, CO.)

Conveniently located and readily accessible should be various broken instrument retrieval devices, crown removal devices, mineral trioxide aggregate (MTA) (or alternative), various irrigants, sealer, gutta-percha, Dycal, Cavit, posts, and build-up materials as well as supporting instrumentaria.

A delivery cart system, specifically configured for endodontics, can contribute to proper ergonomics and efficiency in the operatory. The Ergo iTech™ (Figure 19-10) provides a unique solution for diverse endodontic instrumentation. Dentists can designate their specific choice of instruments and instrument locations on the cart, each with operation from a single foot control. Accessories can be integrated such as instrument trays, a monitor mount, and an internal CPU shelf.

TOOTH ISOLATION

Dental dam isolation has been used for over 150 years, developed by Dr. Stanford C. Barnum in 1864.[64] Since then it has evolved to include multiple shapes and types, all with a common aim, to isolate the tooth structure during dental procedures. Dental dam isolation is the optimal method of endodontic isolation. Numerous advantages include[65–69]:

1. Protection of the patient from swallowing or aspiration of endodontic instruments, irrigants or medicaments.
2. Creation of an aseptic operating field and elimination of salivary contamination of the root canal system and instruments.
3. Reduction in the microbial content of air turbine aerosols produced during dental procedures and thus a reduction of cross-contamination risk in the dental practice.
4. Creation of a more efficient and favorable working environment by minimizing rinsing and patient conversations.
5. Improved visibility by providing a dry field and minimizing mirror fogging.
6. Retraction and protection of the tongue, lip and other soft tissues.

Recent studies have shown a significant improvement in the survival and outcome of endodontically treated teeth when dental dam was used during root canal therapy and post placement.[70,71] Although it may be inconvenient for a clinician to use with certain patients (mouth breathers, patients with exaggerated gag reflex, severely anxious patients), inconvenience is not an acceptable excuse for avoiding dental dam placement. Root canal treatment without dental dam isolation may place doctors under litigation risks if the patient swallows or aspirates an endodontic instrument (Figure 19-11).[65,72] Previous publications state that "routine placement of dental dam is the standard of care,"[73] and it is a mandatory procedure for limiting cross-contamination, infection of the root canal system, and potential systemic infection.[65–69,74] In some clinical situations (calcified pulp chambers, calcified canals, crowned teeth), locating the canal(s) is challenging and may require orientation of the external root surface using a periodontal probe. In such cases, and depending on the tooth location, placement of dental dam can be delayed until canals are located to avoid excessive damage to the remaining tooth structure or possible root perforation and its consequent complications. Once the canals are located, the dental dam should be placed immediately. No endodontic file should be inserted into a canal without dental dam isolation.

Dental Dam Components

The dental dam system consists of three main components: a dental dam sheet, frame, and a clamp. The dental dam sheets are autoclavable and come in different thicknesses (thin, medium, heavy, extra heavy, and special heavy), colors (ranging from light yellow to gray), sizes (5 x 5 and 6 x 6 in) and

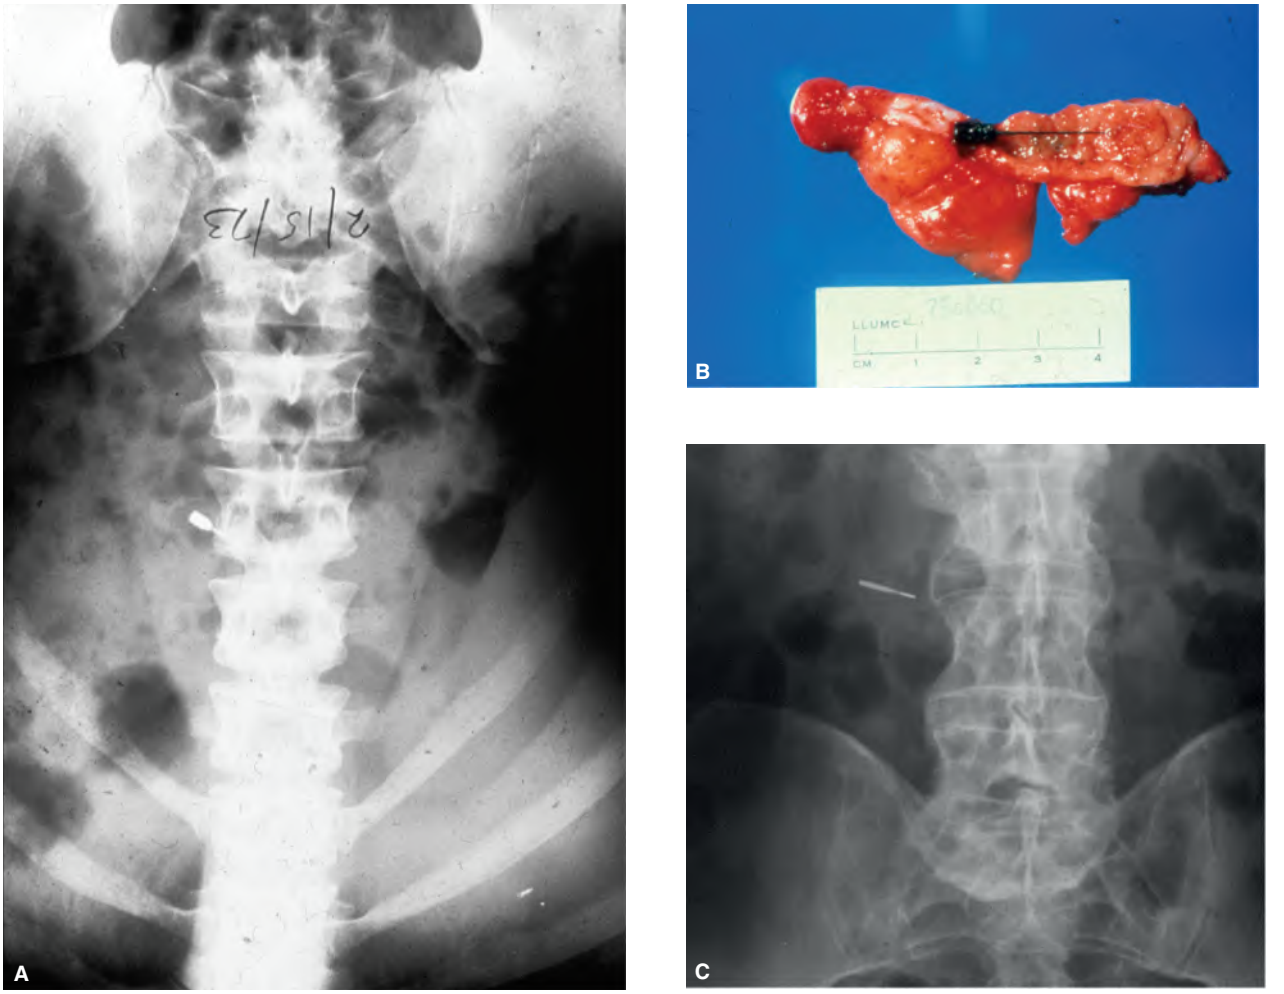

FIGURE 19-11 ***A***, Swallowed endodontic file ended up in the appendix resulting in acute appendicitis. ***B***, Specimen shows file in the appendix removed by appendectomy. Use of dental dam would have prevented this complication. ***C***, Dental burs can sometimes disengage from headpieces and be swallowed, as shown here. This is also preventable with dental dam. (***A*** and ***B*** reproduced with permission from Thomsen LC, Appleton SS, Engstrom HI. Appendicitis induced by an endodontic file. *Gen Dent* 1989:37–50.)

materials (latex and nonlatex). The commonly used dental dam sheet in endodontics is the medium thickness due to its higher resistance to tear compared to the thin sheets and its easier manipulation compared to the heavier variants. The selection of the dental dam color depends primarily on the clinician's preference. Darker color sheets will provide better contrast, improved visibility, and higher quality images and videos during photographing and recording. Lighter colors, on the other hand, create a brighter field, which may be useful if the illumination is compromised. The sheet also comes in a nonlatex form for patients with latex allergy. The nonlatex dental dam, however, comes in only one size- 6" × 6", and one thickness—medium.

The function of the dental dam frame (Figure 19-12) is to retract the sheet during procedures and to allow visibility and access to the tooth. Frames are available in either metal or plastic. Although metal frames are more durable, they require removal before taking radiographs. This may affect the stability of the dam and can compromise isolation. Plastic frames, on the other hand, offer certain advantages during endodontic procedures. They are radiolucent and thus do not require removal prior to taking radiographs. Plastic frames are available in different shapes and forms including fixed and hinged. They are also available as disposable frames. The plastic hinged frame allows the dam to be folded to one side for taking radiographs necessary during endodontic treatment.

The function of the clamp is to retain the dental dam and frame on to the target tooth. In case of multiple tooth isolation, the clamp is always placed on the most posterior tooth to be isolated. The clamp is formed of two beaks with a connecting bow (Figure 19-13). The beaks can be apically inclined or serrated (tiger clamps) to allow better engagement of teeth with compromised structure. The beaks of the clamp are positioned

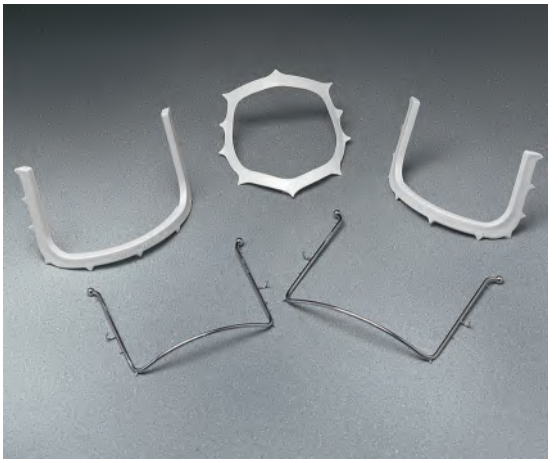

FIGURE 19-12 Images of different shapes of metal and plastic dental dam frames.

FIGURE 19-13 Image of a Hu-Friedy tiger clamp. 1. Central wing; 2. anterior wing; 3. bow; 4. beaks; 5.tines; 6. forceps hole; 7. anterior notch; 8. posterior notch.

on the buccal/labial and lingual/palatal aspects of the tooth below the height of contour using the clamp forceps. The clamp retains the sheet under the anterior and central wings or under the platform of the beaks if a wingless clamp is used.

The clamp should be stabilized prior to initiating treatment. Unstable clamps may jeopardize isolation and cause damage to the tooth structure and surrounding soft tissue during treatment. The stability can be checked by rocking the clamp using both thumbs.

Clamps should routinely be ligated with a lengthy section of dental floss through both forceps holes with the floss draped outside the patient's mouth and secured to the patient bib or some other convenient item that cannot be swallowed or aspirated in the event the clamp becomes insecure or breaks. While there are a variety of ways to reduce the risk of aspiration or swallowing of an intact clamp, attaching the floss through both forceps holes (Figure 19-14) offers the added security of retrievability of both elements in the event of a fractured bow.

Clamps are available in variety of shapes and sizes attempting to match the tremendous variety of tooth forms, orientations, and degrees of debilitation. The general classifications are central and lateral incisor, canine, premolar, and molar clamps; and they are available both with and without wings (Table 19-2). Clamps with wings provide better retraction of soft tissue, less salivary leakage; and for placement of the clamp, dam, and frame as a single unit, winged clamps are required.

Dental Dam Holes

The required hole in the dental dam can be placed either by using the dental dam punch or scissors. The punch has a series of holes of varying sizes on a disk that can be rotated to select the appropriate size for the tooth to be isolated. A pair of iris scissors offers an alternative method to create a hole in the sheet. Folding the sheet into four quarters and cutting the corner will create a hole in the center of the dam. The size of the hole can be controlled by the size of the piece cut from the corner (Figure 19-15).

Dental Dam Placement Techniques

Stability of the dental dam system is necessary throughout the procedure. The dam must cover the entire mouth without encroaching on the patient's nose or eyes. Improper dental dam placement may result in leakage and contamination of the working field. Multiple techniques may be used to place the dental dam.

Single-Unit Method

A hole is punched in the dam, and the sheet is then stretched medium tight by attaching it at the four corners of the frame. The central wings of the clamp are inserted, one at a time, through the hole, and the entire system is carried as a unit to the patient's mouth using the forceps. The clamp is placed on the target tooth, and the dam is released from the wings of the clamp with a plastic instrument (Figure 19-16). This is a relatively safe method because the clamp is secured to the dental dam. It is convenient in the case of anterior teeth and premolars, and it is more challenging in the case of molars and teeth with structural compromise due to reduced visibility.

Clamp-First Insertion Method

The clamp is first placed on the tooth. The punched dental dam, mounted loosely onto the four corners of the frame, is then brought to the mouth, and the hole is stretched over the clamp. Floss is used to carry the margins of the dam through the proximal contacts to completely cuff the tooth. The dam is then stretched more fully onto the frame.[75] This is one of the least complicated placement methods because the target tooth is most easily visualized during clamp placement (Figure 19-17).

Multiple Isolation of Proximate Teeth Method

When root canal treatment is performed on multiple teeth that are proximate to each other, or when a tooth cannot retain a clamp due to insufficient structure (Figure 19-18), multiple holes can be placed in the dental dam to allow treatment of the target tooth/teeth. In the case of a single target tooth unable

FIGURE 19-14 Clamp safety strap technique. If a dental dam clamp breaks at the bow, floss ligature on the bow or in only one of the forceps holes will be insufficient to prevent swallowing or aspiration of elements of the clamp. Floss ligation through both forceps holes will secure both elements of a broken clamp as well as an intact clamp should it launch from the tooth. ***A***, Insert the loop of a 20-inch section of floss through what will be the lingual forceps hole of the clamp; ***B***, loop it over the bow; ***C***, insert free ends of the floss through the loop from behind the bow; ***D,E***, draw the loop down tight against the elbow of the clamp; ***F***, take several wraps of the doubled floss around the bow and insert a single free end through what will be the buccal forceps hole; ***G,H***, tie a double knot with the other free end and tie the tail to the dental dam frame or the patient bib (i.e., tie to something the patient cannot aspirate or swallow in the event the clamp breaks or launches from the tooth). Done properly, the free ends of the floss will be on the buccal side of the clamp, and the floss in the forceps holes will be oriented such that it will not be impinged on by the beaks of the forceps which could weaken or break the floss. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

to retain a clamp, the clamp is placed on a tooth distal to the target tooth. In the case of multiple teeth to be treated, the clamp is placed on the most posterior target tooth if it can retain a clamp. If this tooth is excessively compromised, the clamp should be placed on a more posterior tooth capable of retaining a clamp. The most distal hole is then stretched over the clamp, and the remaining holes are drawn over each additional tooth to be exposed for the procedure. It can be helpful in certain cases to place a second clamp on the most anterior tooth to be exposed with the bow facing mesially. Ligation with dental floss may enhance isolation where necessary (Figure 19-19). In multiple tooth isolation of anterior teeth, clamps placed on teeth on opposite sides of the midline will be oriented normally, with bows facing distally (Figure 19-20).

Multiple Isolation of Distant Teeth Method

When root canal treatment is performed on multiple teeth that lie in different quadrants yet in the same arch (maxillary

or mandibular), a clamp may be placed on each tooth to be treated, and two holes can be punched on either side of the dam allowing simultaneous treatment of both teeth (Figure 19-21).

Split Dam Method

The split dam method has many practical applications. It is yet another useful isolation method when the target tooth cannot accommodate a clamp due to insufficient structure.

TABLE 19-2 Dental Dam Clamps Selection

	Clamps
Maxillary teeth	
Central incisor	6, 9, 209, 210, 212
Lateral incisor	6, 9, 209, 210, 00
Canine	6, 9, 210
Premolars	0, 2, 2A, W2A, 209
Molars	26, 26N, 27N
Mandibular teeth	
Incisor	6, 9, 210, 212
Canine	6, 9, 210
Premolars	0, 00, 2, W2A, 209
Molars	26N, 27N,, W3, W8A, 14, 14A

Two holes are punched in the dam separated by several millimeters depending on the clinical circumstance. The material between the holes is snipped with a pair of iris scissors creating the split dam (Figure 19-22). The clamp is placed on a more distal tooth and the sheet is then placed over the clamp and stretched to include the target tooth and at least the next anterior tooth (Figure 19-23).

The split dam method is also effective when treating teeth with calcified canals as it allows exposure of the external contours of the target tooth, providing orientation during deep exploration for the canal remnant. Additionally, the split dam can be a good choice when the target tooth has been restored with a porcelain crown as studies have shown that, even when properly stabilized, clamps can damage porcelain fused to metal crowns.[76,77]

When root canal treatment is performed on two distant teeth connected by a bridge, the split method can result in a large gap that may compromise isolation. In such cases, the margins of the split dam can be approximated from the lingual/palatal to the buccal/labial using suture material, piercing the sheet and passing under the bridge to be tied off on the facial. Any remaining exposed tissue can be blocked out using Oraseal or Liquiddam (Figure 19-24).

OVERCOMING ISOLATION CHALLENGES

Endodontic isolation can be difficult when certain conditions exist, and chief among those conditions is dental caries. Despite worldwide decrease in the incidence of dental caries,[78] it continues to impact all age groups[79] and in many parts of the world, it is the primary reason cited for tooth extraction.[80]

Difficult isolation can be encountered when certain factors are present[81]:

1. Minimal supragingival coronal tooth structure
2. Extreme posterior positioning of the tooth
3. Severe root caries
4. Loose crown or bridge restorations
5. Edentulous areas posterior to the tooth to be treated
6. Tooth prepared for a crown with an "ice cream cone" form
7. Complicated patient management

Various methods can be used to assist in creating ideal endodontic isolation even in complex circumstances (Figure 19-25).

Clamp Modification

Dental dam clamps are manufactured in many different designs, shapes, and sizes attempting to accommodate many clinical circumstances and most tooth groups. Clinical circumstances, however, are infinite, and teeth develop in myriad shapes and sizes and emerge in every imaginable orientation. As a result, even a well-stocked inventory of clamps will not be able to meet every isolation challenge. Clamp modification can be an effective method of overcoming some of these challenges.[82–85] When planning clamp modification, it is important to avoid modifications that might adversely affect the structural integrity of the clamp. For example, avoid cuts to the bow of the clamp that could lead to clamp breakage under function. Likewise, when removing a wing, leave adequate metal around the outer rim of the forceps hole to prevent the hole from breaking open during clamp placement or removal. When altering the mesiodistal reach of clamps, equal amounts should be removed from both the mesial and distal aspects of the beak being modified so as not to skew the orientation of the clamp, unless skewing the clamp is the objective. In all cases, after modification, the cut surfaces must be polished with a Brownie Point, Brownie Wheel, or equivalent to remove metal burrs that can catch and tear the dental dam.

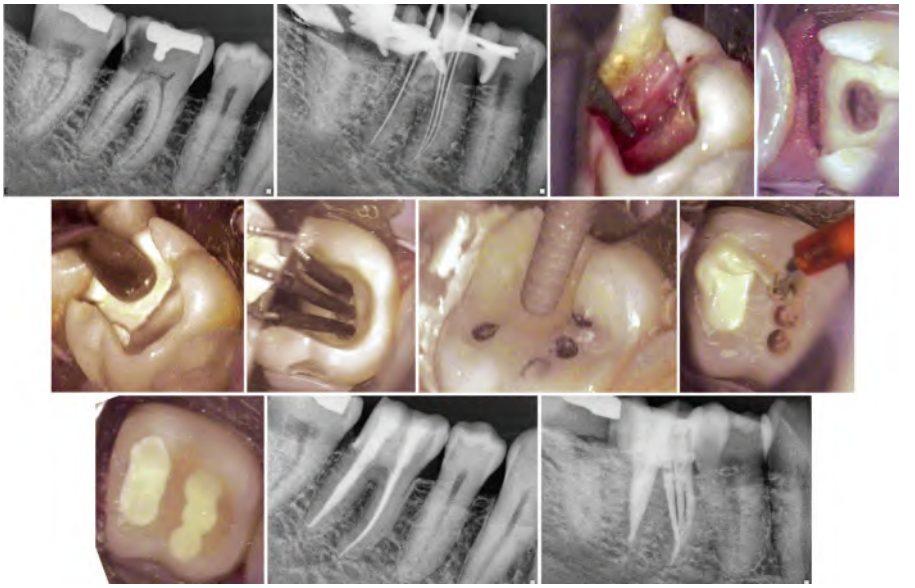

FIGURE 19-25 Challenging isolation resulting from severe coronal breakdown is managed by high-speed diamond tissue troughing, sculptable Cavit matrix barrier and bonded preendodontic build-up via Canal Projection. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

Reducing the Mesio-distal Reach of the Beaks

If the mesio-distal reach of the beaks of the clamp extends beyond the width of the neck of the tooth (Figure 19-26A,B), the dental dam may not invaginate properly to cuff the tooth and provide moisture-proof isolation. This reach can be effectively reduced by first scribing the amount of desired reduction onto the clamp with a fine-tipped indelible marker (Figure 19-26C), prior to removing equal amounts of metal from both the mesial and the distal aspects of the buccal beak, or the lingual beak or both with a high-speed bull-nosed diamond (Figure 19-26D). Any resultant burrs should be removed by polishing with a Brownie Wheel or equivalent (Figure 19-26E). Customizing a stock clamp by reduction of reach (Figure 19-26F) can provide precise cervical adaptation of clamp on both buccal and lingual aspects of the tooth (Figure 19-26G,H).

Removing Tines from the Beaks

If the beaks are tined, the mesio-distal reach can be reduced by removing equal numbers of tines from both the mesial and distal aspects of the buccal beak, or the lingual beak or both with a high-speed bull-nosed diamond (Figure 19-27A,B).

Removing a Wing

Removing a wing from a clamp can be helpful, particularly when working on either maxillary or mandibular second and third molars as the ramus can lie tight against the buccal aspect of these teeth. Also, when a tooth is extremely malposed or when there are exostoses or hyperplastic gingival tissues impinging on cervical aspects of the tooth, wing removal may be necessary to accommodate proper seating of the clamp. The wing can be sliced off with a high-speed fissure bur. Care must be taken not to overly thin the outer rim of the forceps hole to prevent it from breaking open during clamp placement or removal (Figure 19-27C–E).

Removing One Bow from a Butterfly Clamp and Modifying the Reach of the Beaks

A butterfly clamp can be converted into a standard single-bow clamp by removing one bow with a high-speed fissure bur (Figure 19-28A,B). Mandibular incisors present with the unique challenge of a very small mesio-distal width on both the buccal and lingual aspects at the neck of the tooth. Not only are there few clamps manufactured with small enough mesio-distal dimension to perfectly accommodate these teeth, but the pull of the dental dam against a standard nonbutterfly-type clamp with a tiny mesio-distal dimension tends to rotate the bow aspect of the clamp incisally. The symmetry of a butterfly-type clamp can help to offset this rotating effect, but most butterfly clamps lack the tiny mesio-distal dimension required for mandibular anterior teeth. This excessive reach can be effectively reduced by removing equal amounts of metal from both the mesial and the distal aspects of the buccal beak, or the lingual beak or both with a high-speed bull-nosed diamond. In combination with wing removal, this is an effective way to customize a clamp to accommodate small-necked teeth (Figure 19-28C,D)

Sharpening the Tines or the Smooth Beaks

Whether smooth or tined, the beaks of clamps can be effectively sharpened for improved retention by careful hollow-grinding with a high-speed football diamond (Figure 19-29).

Changing the Inclination of the Beaks

The inclination of the beaks can be modified by grasping the clamp at the neck of the bow with a large locking hemostat,

FIGURE 19-26 Reducing the mesio-distal reach of the beaks. See accompanying text for description of steps A through H. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

FIGURE 19-27 ***A***, Removal of tines and a wing from the clamp. ***B***, The tines being removed with a high-speed bull-nosed diamond. ***C***,***D***, Demonstrate the initiation of the cut for wing removal. ***E***, Modified clamp with tines removed from both buccal and lingual aspects and one wing removed. inserting an instrument with a beefy shaft through the forceps hole and bending the beak apically or coronally as required (Figure 19-30).

Flowable Tissue Block-out and Matrix Barrier Materials

Teeth requiring root canal treatment often present in broken-down condition, missing one or more cavity walls or reduced in preparation for a crown. The dental dam alone may not provide complete isolation of the operating field.

Commercially Available Block-Out Agents

There are a number of syringeable materials that have been specifically designed for the purpose of blocking leakage around the dental dam. These products include Kool-Dam (Pulpdent, Watertown, MA, U.S.A.), OraSeal Caulk and OpalDam (Ultradent, South Jordan, UT, U.S.A.) and (Figure 19-31).

Dycal

The low viscosity and flow of Dycal (Dentsply, York, PA, U.S.A.) is ideal for sealing exposed tissue and dental dam gaps (Figure 19-32). It can also be used when standard matrix band application is impractical. A "floating" sectional matrix secured with wedges and luted with Dycal allows placement of a core with ideal margins and contours in the most challenging tooth-defect situations. The setup for placement of Dycal is simple and can be available chair-side at any time during a root canal treatment procedure (Figure 19-33A).

Dycal/Cavit Matrix Barrier

Though multi-factorial, overcoming extreme endo-restorative isolation challenges resulting from significantly compromised coronal-radicular structure nearly always involves, as a first step, control of fluid contaminants migrating into the working field from adjacent deep sulcular tissues. Effective moisture-blocking placement of traditional band-type matrix

FIGURE 19-28 Modifying butterfly clamps. ***A,B***, Removal of one bow from a butterfly clamp. ***C***, Butterfly clamp before modification, reduction of the mesio-distal reach as well as one bow removed. ***D***, Modified clamp precisely seated on a mandibular incisor. barriers, such as Toffelmire matrix bands, sectional matrices, and auto-matrix barriers, can be extremely difficult. Achieving extension of the band beyond the margin of the defect and wedging effectively when the defect is gaping and deep can be a formidable challenge. Durable blockage of the primary entry point for these contaminants over deep margins is an absolute requirement in the development of a preendodontic build-up with marginal integrity. While a flowable moisture-blocking barrier of Dycal can be practical in such cases, at times a more mousse-like barrier is preferred.

FIGURE 19-33 ***A***, Dycal can be simply and efficiently mixed. A Centrix Needle Tube can be used to deliver the Dycal precisely into the areas it is needed to seal gaps and secure matrices after dental dam placement. ***B***, A 4:1 Dycal to Cavit blend provides a more mousse-like consistency. The Cavit portion should be drawn into one of the Dycal portions and mixed before initiating the setting process by drawing in the second Dycal portion.

The flowability of Dycal can be moderated by "cutting" it with a portion of Cavit. There are various formulations for Cavit, and readers may wish to bench-test a combination of different formulations to establish a preference. Consistent results can be achieved, however, using Dycal and Cavit G (3M Espe Dental, St. Paul, MN, U.S.A.) in a 4:1 ratio (4 Dycal to 1 Cavit) that renders a useful moisture-friendly consistency that will flow through either a green or orange AccuDose NeedleTube (Centrix, Shelton, CT, U.S.A.). The ratio may be varied to suit the clinician's preference or to compensate for the fact that Cavit tends to dry out over time. The 4:1 Dycal to Cavit ratio is determined by first dispensing onto a mixing pad or glass slab equal amounts of parts A and B of Dycal, and then a portion of Cavit equal to half of one of the Dycal portions. The Cavit should be drawn into one of the Dycal portions and mixed thoroughly before mixing in the second Dycal portion (Figure 19-33B). This sequence provides more ample working time as the setting process is not initiated until the second Dycal portion is mixed in.

Prior to mixing the Dycal and Cavit together, tissue troughing is often required to allow the flowable barrier to be placed beyond the level of the deep defect (Figure 19-34). Split dam is often required for these types of cases to facilitate troughing of the tissues beyond the deep defect without interference from interseptal segments of dental dam material. Infiltration of lidocaine with 1:50,000 parts epinephrine into crestal and papillary tissues can provide considerable hemostasis. One or two millimeters of axial wall subjacent to the defect should be exposed by troughing with a high-speed tapered diamond laser or via electrosurgery. If necessary, additional hemostasis can be achieved with the application of ferric sulfate-containing agents such as ViscoStat (Ultradent, South Jordan, UT, U.S.A.) or Quick-Stat FS (Vista Dental Products, Racine, WI, U.S.A.).

Dycal and Cavit are mixed and injected by NeedleTube into the gingival trough and over the exposed tissue. It can be helpful to swage the un-set hydrophilic material into the trough and against the adjacent tooth (if present) with a water- or alcohol-saturated cotton pellet; the latter providing greater acceleration of the setting process. The chamber can then be flooded with alcohol to continue the setting acceleration. The mature moisture-proof Dycal/Cavit barrier can be custom-trimmed from within the cavity to the exact deep cavity margin using various-sized slow speed round burs or a high-speed bull-nosed diamond. During this delicate cutback process, the deep margin is where the importance of the gingival troughing plays a key role. If the gingival troughing had not been performed, the flowable barrier would not have been able to be placed beyond the deep marginal defect. In that scenario, the attempt to custom-trim the barrier to the exact margin would perforate the barrier precisely at the critical deep margin, allowing blood, tissue fluids, and saliva to compromise the purpose of the barrier. Once the deep defect is completely isolated by this customized matrix barrier, the walls can be etched and primed, bonding agent can be applied, and a full preendodontic composite build-up or a *Half-Wall* (described in the Half-Wall section under "Pretreatment Build-up" below) can be placed. Prior to dismissal, the Dycal/Cavit is easily cracked away with an explorer.

Clamp Retention Methods

Bonded Composite Buttons

The absence of the typical anatomic height of contour on teeth that have been reduced by crown preparation may hinder clamp stability. Composite buttons can be bonded onto the cervical aspect of both the buccal/labial and/or lingual/palatal crown surfaces to act as an undercuts for clamp retention. A clamp with apically inclined beaks may provide improved engagement of tooth surfaces in select cases (Figure 19-35), and it can be a practical choice when composite "buttons" will be bonded after placement of the clamp.

Composite Donut

Despite the fact that other factors such as crown : root ratio, mobility, and periodontal condition may be within

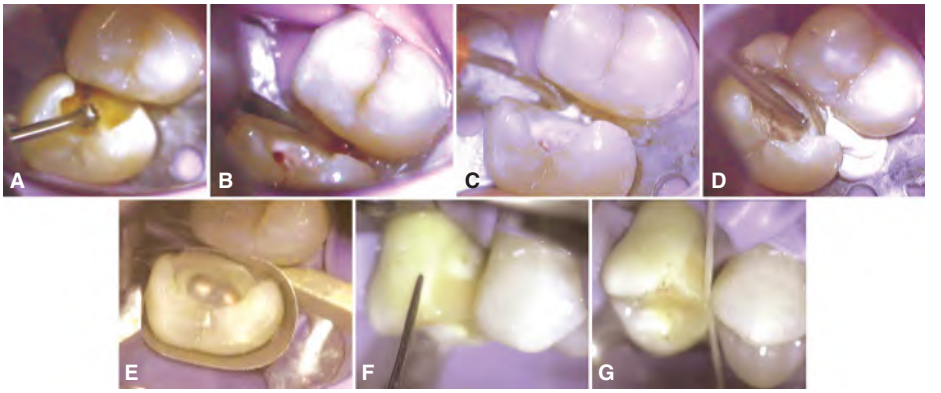

FIGURE 19-34 Dycal/Cavit Matrix Barrier and *Half-Wall*. After extensive caries removal, the prepared margin is deeply subgingival. The gingiva is troughed beyond the deep margin of the defect with a high-speed finger diamond or via laser or electrosurgery. The Dycal/Cavit blend is applied by first syringing a bead with a Centrix Needle Tube into the gingival trough and then flowing additional bulk over the exposed tissues and against the adjacent tooth (if present) to lock the material below the adjacent height of contour. An alcohol-saturated cotton pellet can be used to swage the unset blend into the desired shape to receive the flowable *Half-Wall* material later in the process. On setting of this mix, accelerated by flooding the cavity with alcohol, the durable moisture-proof barrier is custom-trimmed from inside the cavity to the exact margin of the deep defect with long-reaching stiff narrow shafted Munce Discovery Burs (CJM Engineering, Inc., Santa Barbara, CA) of various diameters. If composite will be the *Half-Wall* filling material of choice, as it was in this case, the cavity is etched and primed, and bonding agent is applied. A color-contrasting composite is injected to create a visibly distinct *Half-Wall* at the deep margin for convenience in subsequent crown preparation. Alternatively, compomer, glass ionomer, or a sandwich of glass ionomer and composite can be placed as the *Half-Wall* material. On polymerization of the *Half-Wall*, the flowable Dycal/Cavit matrix barrier is easily cracked away with an explorer. Root canal treatment is then completed, now under ideal endodontic dental dam isolation protocol. To incorporate the *Half-Wall* into the final build-up, the surface of the composite *Half-Wall* is freshened by sandblasting or by lightly brushing with a high speed diamond. A Toffelmire band or other band-type matrix barrier can be placed quite easily, now that there is a bonded *Half-Wall* where there had previously been only a gaping defect and aggressively wedged, creating a reliable gingival seal and facilitating the development of proximal contact (if desired/required as it was in this case). All available tooth structure is again etched and primed, and additional composite is bonded to the prepared tooth structure and to the freshened *Half-Wall* and contoured into a durable endodontic coronal seal and build-up with a color-contrasting deep margin and the desired proximal contact. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

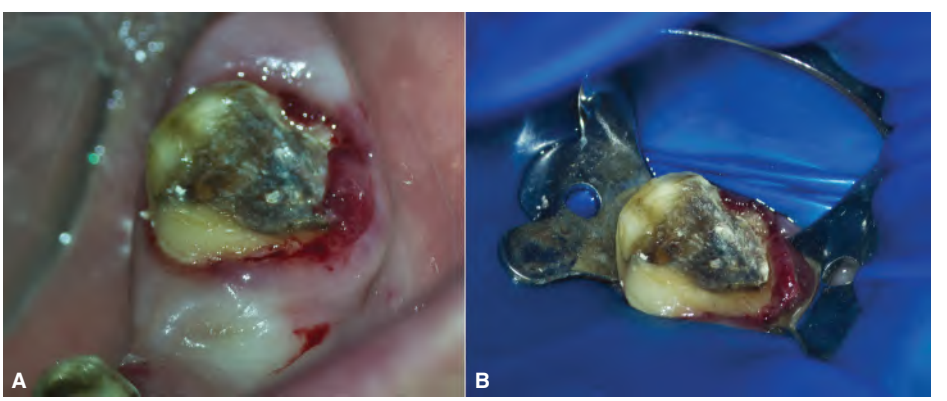

FIGURE 19-35 Isolation of a broken-down mandibular second molar using a clamp with apically inclined beaks to facilitate placement of a bonded composite button on the palatal. (Courtesy of Dr. Adham A. Azim, Buffalo, NY.)

normal limits, and there may even be adequate structure to support a restoration, clamp retention challenges alone can play a key role in the dentist's recommendation to extract a tooth. In addition to severe coronal breakdown, other factors affecting clamp stability include partially erupted teeth, misshapen teeth, or teeth with unfavorable contours such as in the case of teeth prepared with "draw" in anticipation of receiving a crown. Using common dental materials in uncommon ways, the Composite Donut offers the clinician an additional method for saving many teeth that might otherwise be extracted due to clamp retention challenges.

Technique

1. If the defect extends subgingivally, the gingiva is troughed beyond the margin of the defect with a

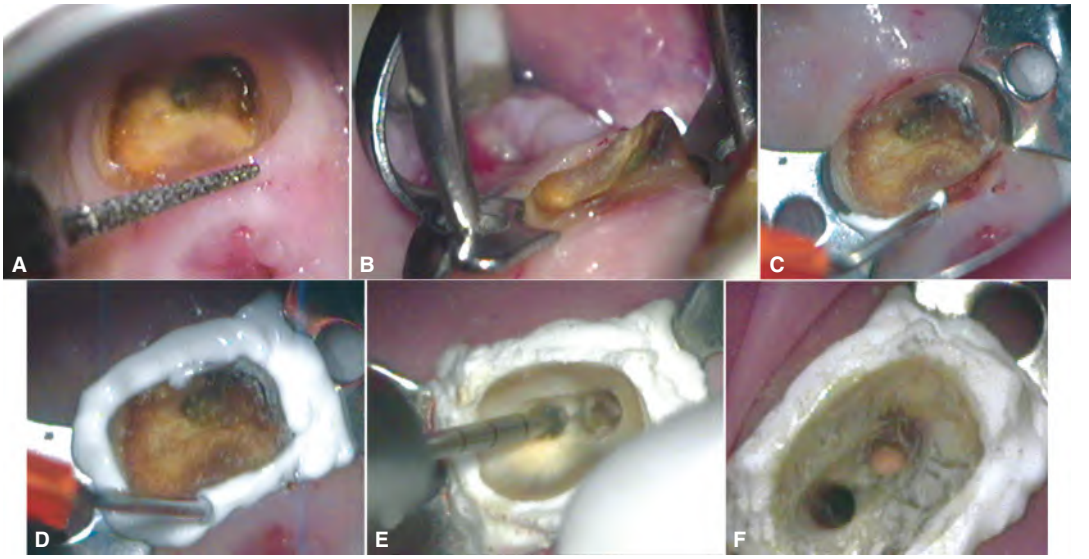

FIGURE 19-36 Composite donut technique. ***A***, Gingival troughing with high speed finger diamond to expose 1-2 mm of axial structure 360°. ***B***, Clamp is then placed. If required, hemostasis is achieved with ferric sulfate, and ***C***, a nonbonded composite bead is injected into the trough, ***D***, circumnavigating the tooth to close the loop, taking care to capture the beaks of the clamp within the bead. ***E,F***, Root canal treatment is then carried out under ideal endodontic isolation protocol. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

high-speed finger diamond (Figure 19-36A), radio-surgery device, or laser.

a. Prior infiltration of lidocaine with 1:50,000 parts epinephrine into papillae and crestal gingiva provides significant hemostasis.
b. 1–2 mm of exposed axial structure 360° is ideal for retention of the nonbonded composite donut.
c. Areas around the cervical perimeter where adequate axial wall is already exposed do not require gingival troughing.
d. As an alternative to 360°-gingival troughing, strategically positioned 1–2 mm deep gingival facets can be created with a high-speed finger diamond, radio-surgery device or laser in at least three well-spaced sites on the gingival cuff surrounding the tooth (Figure 19-37A–C) to provide tripodized stabilization of the composite donut. This can be done with the clamp in place, even if weakly- retained, so that the facets are not placed in areas where the beaks of the clamp will insert.

2. If required, hemorrhage is controlled with ferric sulfate.
3. Clamp is placed (Figure 19-36B) (if not already in place per previously mentioned Step 1d).
   a. If the clamp is secure, then the dental dam is placed at this point (proceed to Step 4).
   b. If the clamp is insecure, the dental dam should not be placed until after a clamp is stabilized with a composite donut.
   c. If single tooth isolation is required, and if there is a tooth on either side or both sides of the target tooth, then a spacer must be placed against the proximal aspect(s) of adjacent tooth/teeth so that the dam will be able to pass between the polymerized composite donut and the adjacent tooth. This spacer could be a material such as Cavit that can be thinly swaged against the proximal surface(s), or it could be a section of plastic matrix band, a short segment of a plastic drinking straw slit longitudinally or a piece of medical-grade Teflon PTFE tape (CS Hyde Company, Lake Villa, IL, U.S.A.) draped against the proximal surface(s) of adjacent tooth/teeth (Figure 19-38B,C).
   d. A flowable composite is syringed with a Centrix Needle Tube into the gingival trough and 360° around the cervical aspect of the tooth, without benefit of bonding, taking care to cover any exposed tissue, to block any gaps in the dam, and to capture the beaks of the clamp within the bead (Figure 19-36C,D).
   e. If facets were created as in previously mentioned Step 1d, the bead must flow into each of the facets as part of the 360°-donut (Figure 19-37D,E).

4. a. A 360° composite bead is critical as it provides the closed-loop reciprocation required for robust retention of the nonbonded donut.
   b. If multiple teeth are exposed, and there is proximal contact on the mesial and/or the distal of the target tooth, the composite bead must flow up and over the marginal ridge and down the other side to close the loop of the 360°-donut (Figure 19-39). In the case where a spacer has been placed against the proximal surface(s) of the adjacent tooth/teeth, removal of the spacer(s) after polymerization of the composite (Figure 19-38D) will

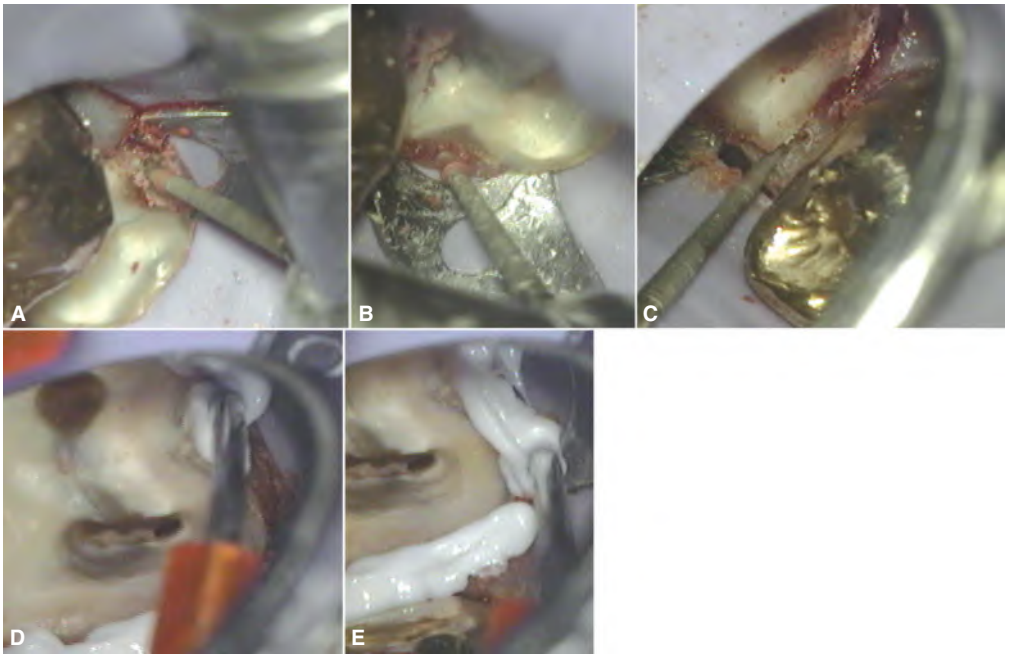

FIGURE 19-37 Gingival facets serve as an alternative to 360° gingival troughing to retain the Composite Donut. ***A–C***, Three or four well-spaced small facets created with a high-speed finger diamond offer the necessary reciprocation to stabilize the nonbonded donut. Facets should be cut with the clamp in place when possible, ***D,E***, to ensure they will not be obscured by the beaks of the clamp, but will remain accessible to the composite bead when the clamp is in place. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

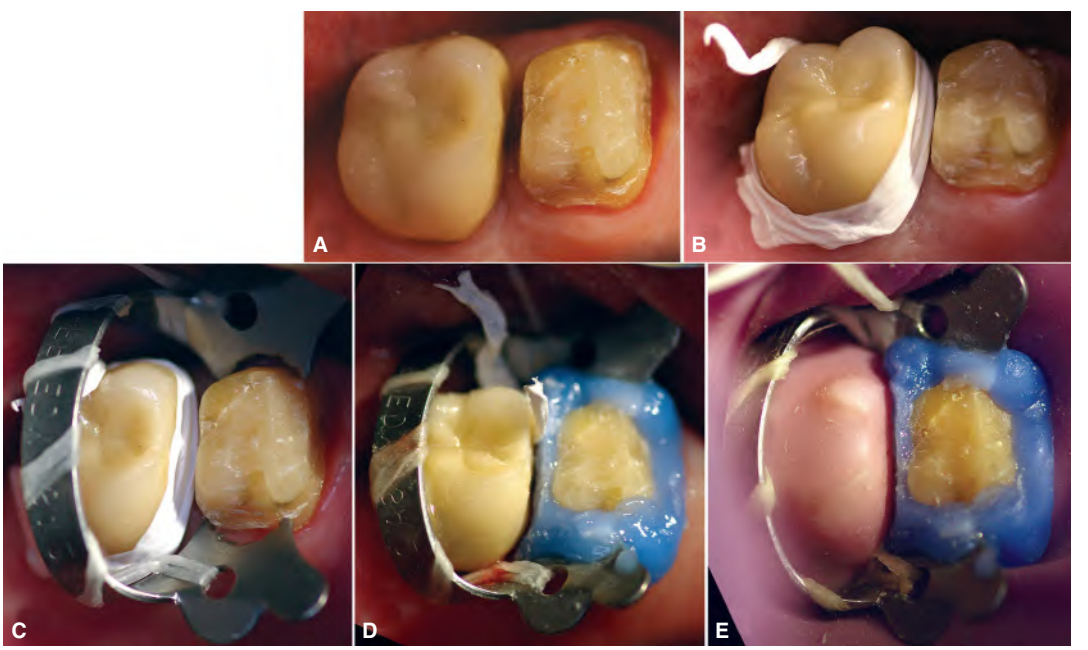

FIGURE 19-38 Various types of spacers. In this case, a section of medical grade PTFE tape can facilitate single tooth isolation with composite donut, allowing the margin of the dam to pass between the donut and the adjacent tooth/teeth after removal of the spacer upon polymerization of the composite. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

allow the margin of the dental dam to slide perfectly under the donut (Figure 19-38E).

5. At this point, the clamp should be completely stabilized, and the tooth under ideal endodontic isolation. If the composite bead overlies any portion of the deep margin(s) of the tooth (Figure 19-40A), it can be carefully cut back from within the cavity to the exact margin(s) with high-speed diamonds and/or surgical-length slow speed round burs (Figure 19-40B,C).

FIGURE 19-39 When multiple teeth with proximal contacts are exposed, the composite bead must flow up and over the marginal ridge, and then back down the other side to close the 360°-loop of the donut. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

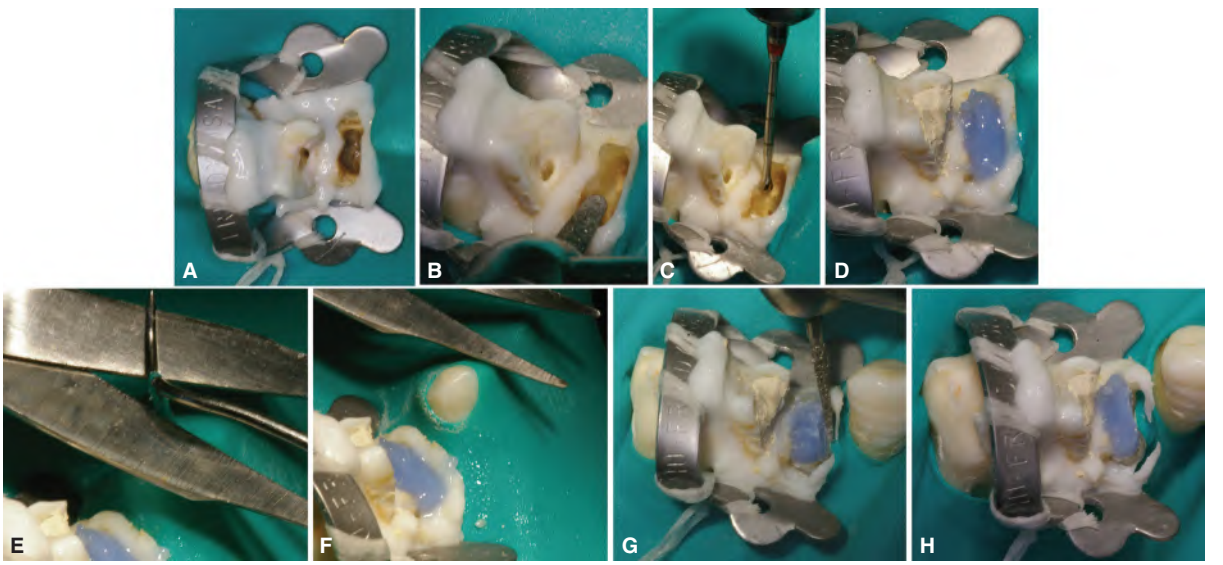

FIGURE 19-40 Any portion of the bead that overlies the margin of the cavity ***A,*** can be cut back to the precise margin with high-speed diamonds and/or surgical-length slow-speed round burs, ***B,C***. In anticipation of a subsequent visit, color-contrasting composite can be bonded to form a *Half-Wall* using the donut as a matrix barrier, ***D***. To facilitate dissection of the nonbonded donut from the bonded *Half-Wall* without interference from the interproximal dam, the dam is lifted from the adjacent marginal ridge with an explorer and snipped with an iris scissors, ***E,*** exposing the adjacent tooth, ***F***. A high-speed finger diamond dissects the composites of dissimilar colors from each other, ***G,H***. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

6. If a second visit is anticipated, a color-contrasting preendodontic bonded *Half-Wall* (see *Half-Wall* in subsequent subsection) can be placed using the composite donut as a matrix barrier (Figure 19-40D). The bonded *Half-Wall* will simplify isolation at the next visit. A *Half-Wall* color that contrasts with the nonbonded donut facilitates clean dissection of the nonbonded donut from the bonded *Half-Wall* with a high-speed finger diamond (Figure 19-40G,H) under high magnification and high-intensity illumination prior to dismissal. It is very important not to leave any residual color-contrasting nonbonded composite overlying the margins and captured under the bonded build-up material, as this would lead to marginal leakage and failure of not only the restoration, but possibly the endodontic therapy as well. Once dissected from the *Half-Wall*, the donut will readily crack away with a tweak of the clamp via the dental dam forceps.
7. If this will be the final visit, the final build-up should be placed at completion of this visit.
   a. If the build-up will be composed of a bonded composite or hybrid material, it should be of a color that contrasts with the nonbonded donut so that the donut can be completely dissected away from the build-up material with a high-speed finger diamond under high magnification and high-intensity illumination prior to dismissal. The donut will then readily crack away from the build-up with a tweak of the clamp via the dental dam forceps (Figure 19-41).
   b. An alloy build-up can be a convenient alternative as the composite donut is a durable matrix barrier able to withstand alloy condensation, and the donut does

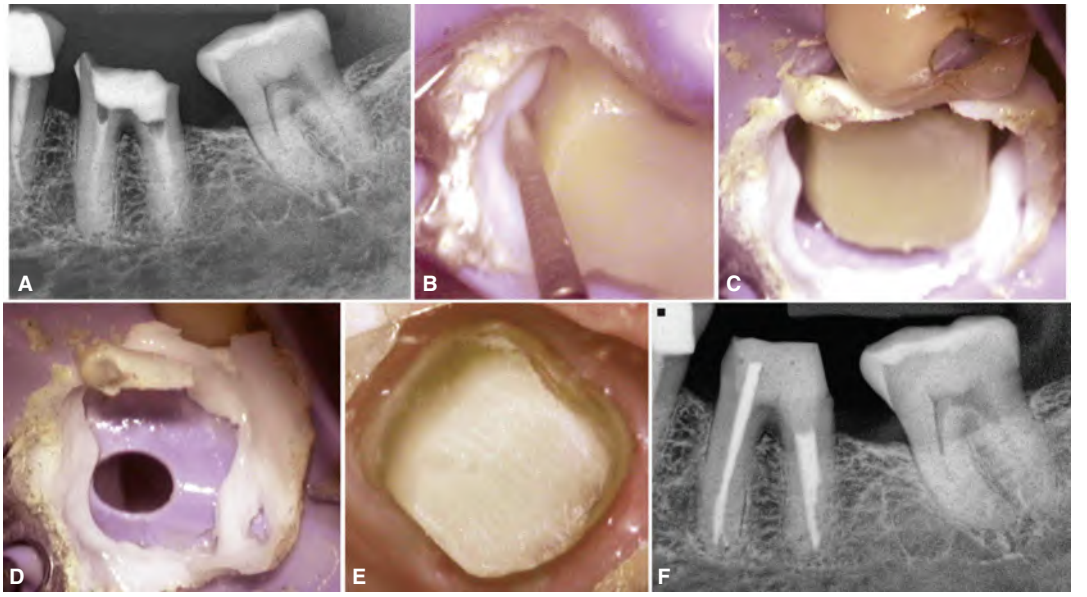

FIGURE 19-41 In a tooth with minimal supra-gingival structure, ***A***, the composite donut aids in clamp retention. At completion of root canal treatment, the color-contrasting donut is dissected from the final build-up with a high-speed finger diamond under high magnification and high-intensity illumination, ***B,C***. With a tweak of the clamp by the forceps, the donut cracks away, often nearly intact, ***D***, leaving the build-up ready for final preparation, ***E,F***. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

not require dissection from the dissimilar material and will readily crack away from the alloy with a tweak of the clamp via the dental dam forceps.

Pretreatment Build-up

Band Isolation

Teeth with more extensive loss of structure may require restorative procedures to facilitate isolation. The use of the copper band or the orthodontic band provides an effective method for building up structurally compromised teeth for the purpose of isolation. An orthodontic band may be quick and easy to place but a copper band can be customized to provide ideal contours and marginal adaptation.[86] The band serves as an external matrix barrier to contain composite, IRM, or other reinforced temporary restorative materials in order to provide adequate crown height. The band can also remain on the tooth until treatment is complete to act as part of the clamp-retention apparatus. Bands, however, may impinge on gingival tissues resulting in irritation and laceration, so caution should be exercised when using this method. Care should also be taken to avoid blockage of the canals with preendodontic build-up material.

The flow characteristics of Dycal make it ideal for securing a copper band so that the margin of the area, to be restored, has the matrix form properly contoured and fit (Figure 19-42). Wedges can be placed to ensure ideal adaptation. If necessary, a clamp with inverted beaks can be positioned on the gingiva to secure the dental dam prior to placement of the copper band. Although virtually all teeth can be aseptically isolated with the combination of a band and a sealing material like Dycal injected from a Centrix Needle Tube, it is very important to assess restorability before placement of a temporary build-up.

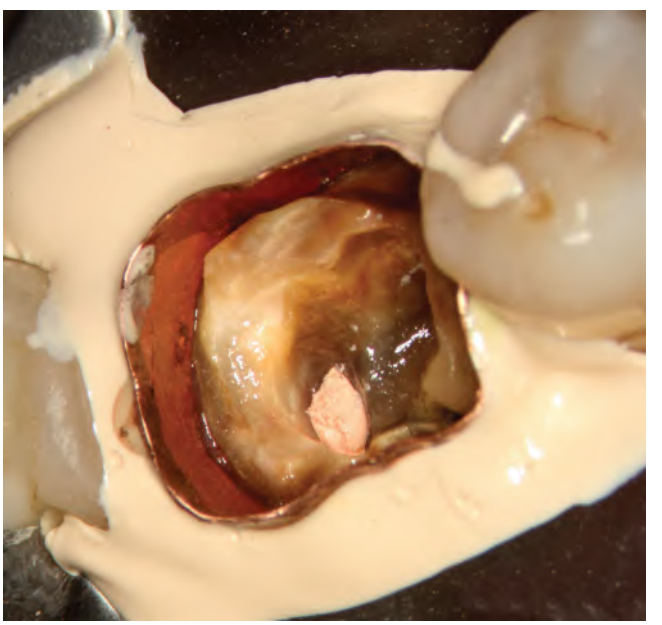

FIGURE 19-42 A copper band secured with Dycal facilitates aseptic isolation of teeth lacking undercuts for secure dam or clamp placement, and also creates an ideal custom matrix for placement of the postendodontic restoration. (Courtesy of Dr. Terrell F. Pannkuk, Santa Barbara, CA.)

Half-Wall

The preendodontic *Half-Wall* is a limited restoration of only that portion of the tooth required in order to facilitate ideal

endodontic isolation (see Figure 19-34, also previously referenced in Dycal/Cavit section). Because of its narrow purpose, the *Half-Wall* does not require development of the marginal ridge(s), proximal contact(s), or occlusal surface detail. The limited scope of the *Half-Wall* allows the clinician to hyperfocus on only the most compromised portion of the tooth and the surrounding tissues, achieving what is otherwise often very difficult, control of fluid contaminants, leaving all successive procedures to be performed under uncomplicated and ideal endodontic isolation protocol. At completion of endodontic procedures, the *Half-Wall* can be easily integrated into the full build-up.

Canal Projection

Canal projection is a technique that facilitates preendodontic build-up of broken-down coronal and radicular structure while preserving individualized access to the canals.[87,88] While any of a number of syringeable materials (glass ionomer, temporary cements, permanent cements, etc.) and even "packable" composites may be used to project the canals, bonded injectable autopolymerizing composites have proven to be the most versatile and reliable build-up material for this technique. The advantages of the technique are numerous.

1. **Isolation**: When deep coronal-radicular defects prevent clamp retention, a tooth is often considered to be endodontically untreatable. Canal projection essentially replaces missing structure to facilitate clamp retention, rendering many structurally debilitated teeth endodontically treatable.
2. **Seal of chamber floor**: The accessory canals that exit the chamber floor into the furcation are well documented[89–91] and can conduct inflammatory agents from the deteriorating pulpal system into the furcation.[92] Additionally, when caries or exploratory procedures lead to a paper-thin chamber floor, the risk of contaminants, extending into the furcal apparatus, increases significantly.[93] Often, such complicated cases require multiple visits, and the interappointment interval with customary temporary coronal seal provides opportunities for serious furcation degradation, particularly if a patient does not return in a timely fashion for completion of treatment.[94] Sealing the chamber floor early in treatment greatly reduces this risk.[95] As an initial step in the endodontic process, canal projection using bonded composite achieves this early objective.
3. **Elongation of canals**: The canal projection process elongates the "hydraulic chamber" of each canal from the access cavity floor to the occlusal surface, offering advantages during the hydraulic condensation of obturation materials. Essentially all currently accepted warm vertical condensation techniques (conventional warm vertical condensation, warm sectional condensation, continuous wave condensation) rely on the rheology that takes place between the chamber floor and the primary exit of the canal.[96] These methods focus their hydraulic effects on the apical region while only incidentally addressing those accessory and lateral canals that exit from the more coronal aspects of the system. In contrast, when the canal is projected, the hydraulic chamber is elongated as much as 5–10 mm such that the rheology occurs not just between the chamber floor and the primary canal exit, but also between the occlusal surface and the primary exit. This allows for additional warm vertical condensation "strokes," additional warm "sections" of gutta-percha, or additional milliseconds spent in the continuous wave of condensation. Regardless of the hydraulic condensation method used, canal projection provides greater opportunity to address coronally-positioned exits.
4. **Overlay of perforation repair**: Early repair of perforation defects can have a significant effect on success of perforation treatment.[97] As such, performing perforation repair, prior to completion of endodontic therapy, is often preferable. The delicate nature of these types of repairs, however, leaves them vulnerable to re-aggravation during subsequent cleaning, shaping and obturation procedures. It can be most disheartening to perform a complicated perforation repair procedure only to see it herniate into adjacent PDL and bone under obturation hydraulics. Delaying the repair until endodontic therapy is completed may put the tooth at risk if the treatment cannot be completed in a single visit. In addition, performing endodontic therapy in the presence of an un-repaired perforation may needlessly expose the perforation site to irritating solvents and irrigants and to accidental penetration by instruments. In many cases, perforation repair with MTA can be performed prior to completion of endodontic therapy. After confirmation that the MTA has set, canal projection offers a means of fortifying the repair by overlaying it with a bonded resin or glass ionomer prior to proceeding with endodontic therapy.
5. **Prevention of perforation**: In those circumstances that lead to a paper-thin chamber floor, the risk of inadvertent perforation with a file, explorer, or bur can be reduced or eliminated by placing a preendodontic build-up via canal projection.
6. **Recontour of irregularities on chamber floor and walls**: Irregularities on the access cavity floor and walls can lead to complications during treatment. Misdirected access cavities, defects and irregularities in canal walls, misdirected post preparations and ledges, and so on can be "corrected" by essentially reconstructing the walls and floor around "internal matrix barriers" via canal projection.
7. **Reduce potential for crack initiation and/or propagation**: On posterior teeth in particular, the time period between initiation of endodontic therapy and placement of a restoration that provides cuspal protection can introduce the risk of coronal-radicular fracture; the longer the time period, the greater the risk.[98] Bonded coronal build-up has been shown to reduce this

risk.[99,100] Bonded canal projection performed at the first endodontic treatment visit imparts a measure of protection against the development of a fracture from the time treatment is initiated until the tooth is permanently restored. In teeth that present with incipient fractures, early placement of a bonded build-up can reduce the likelihood of propagation of these fractures as well.

8. **Prevention of ingrowth of tissues**: When coronal or radicular defects extend to axial walls at or beyond the gingival level, tissue ingrowth leads to contamination during endodontic therapy and subsequent restorative procedures. Preendodontic build-up, as with canal projection, eliminates this complexity.
9. **Individualization of canals**: In multi-canal teeth, as the projectors pass through the build-up material to the occlusal surface, they can be oriented such that they are slightly separated from each other before the build-up material polymerizes. This can simplify management of canals that lie in close proximity to each other on the chamber floor. It also provides for individualization of the canals so that specific solvents, irrigants, medicaments, lubricants, and other agents can be placed into specific canals.
10. **Elimination of "blind exploration" on the chamber floor and improvement of mechanics related to handpiece-driven files**: Once all canals have been located, straight-line access created, and the canals projected to the occlusal surface of the build-up, the resultant projected orifices will lie clearly visible on the surface of the projection build-up, no longer obscured by prominent marginal ridges and other visual obstructions. This also creates a significant advantage for entry of handpiece-driven files, particularly nickel–titanium files, into mesial canals of molars. By virtue of their increased long-axis dimension, the tips of handpiece-driven files can be difficult to introduce into mesial canals, and nickel–titanium files even more so because they will not retain a bend. When the canals are projected onto the occlusal surface of the preendodontic build-up, however, it becomes a simple matter to place the file tip within the rim of the projected canal on the occlusal surface, and then by merely advancing the file, it is driven smoothly into the canal.

Technique Although root canal projectors, invented and patented by Dr. C. John Munce, are currently not commercially available, the technique as described in the fololwing remains a viable preendodontic build-up method, and plastic Capillary Tips (Ultradent, South Jordan, Utah, USA) can be cut to length to serve in every way as "root canal projectors" (Figure 19-43). As used in this section, the term "root canal projector" refers to a cut segment of a capillary tip. A variety of commonly available items have been used to project canals, including gutta-percha cones and silver points, and yet, a tapered plastic sleeve carried to the canal on a fluted file has proven to be most reliable, not only as a matter of remaining securely "pinned" to the canal and centered during the injection of flowable build-up materials, but the sleeve can also serve as a convenient stopper under the temporary seal in multiple-visit cases.

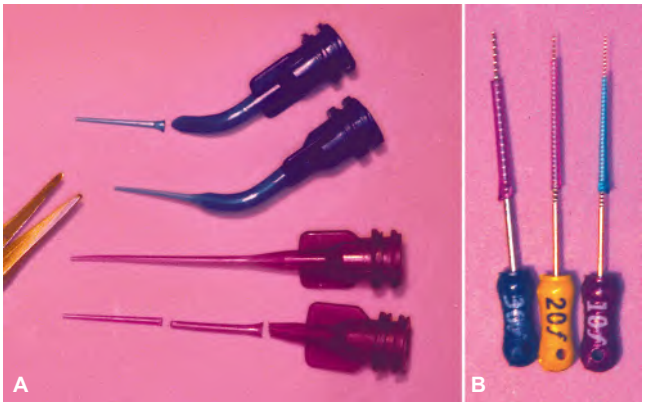

FIGURE 19-43 ***A,B***, Although root canal projectors are currently not commercially available, plastic capillary tips (Ultradent, South Jordan, Utah) can be cut to length to serve in every way as "root canal projectors." (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

1. In a tooth with severe coronal breakdown (Figure 19-44A–C), after gaining access and locating all canals, it is essential to perform a thorough high-magnification examination of the floor and walls and to examine as deeply as possible into all canals to ensure that all branching and other possible irregularities have been identified prior to proceeding.
2. In curved canals, straight-line access is created to the first significant curvature by removing dentin "triangles" (Figure 19-44D) with small slow-speed round burs, working into the bulk of each root (i.e., working away from the furcal aspect of the root). If there is no significant curvature in a particular canal, then the orifice should be dimpled to the depth of a #1 slow-speed round bur (Figure 19-44E).
3. An appropriate matrix barrier is applied, and all bondable surfaces are etched and primed. Files are selected that will fit well into the body of each canal, and root canal projectors, tapered plastic sleeves of various dimensions depending on orifice diameters and canal proximities, are placed onto the files. The files are then inserted into the canals, and the projectors are slid apically until they are drawn into the seat of the previously-prepared dimples or straight-line access. In this particular example (Figure 19-44F,G), medium-sized projectors were used in the distal and palatal canals and projectors of smaller dimension were used in the MB-1 and MB-2 canals to accommodate their proximity to each other. With the canals occupied by the files and projectors, auto-polymerizing bonding agent is applied and distributed over all primed surfaces with a blast of air. Auto-polymerizing composite build-up material is then injected from the chamber floor to the cavosurface of the access cavity with a Centrix Needle Tube.

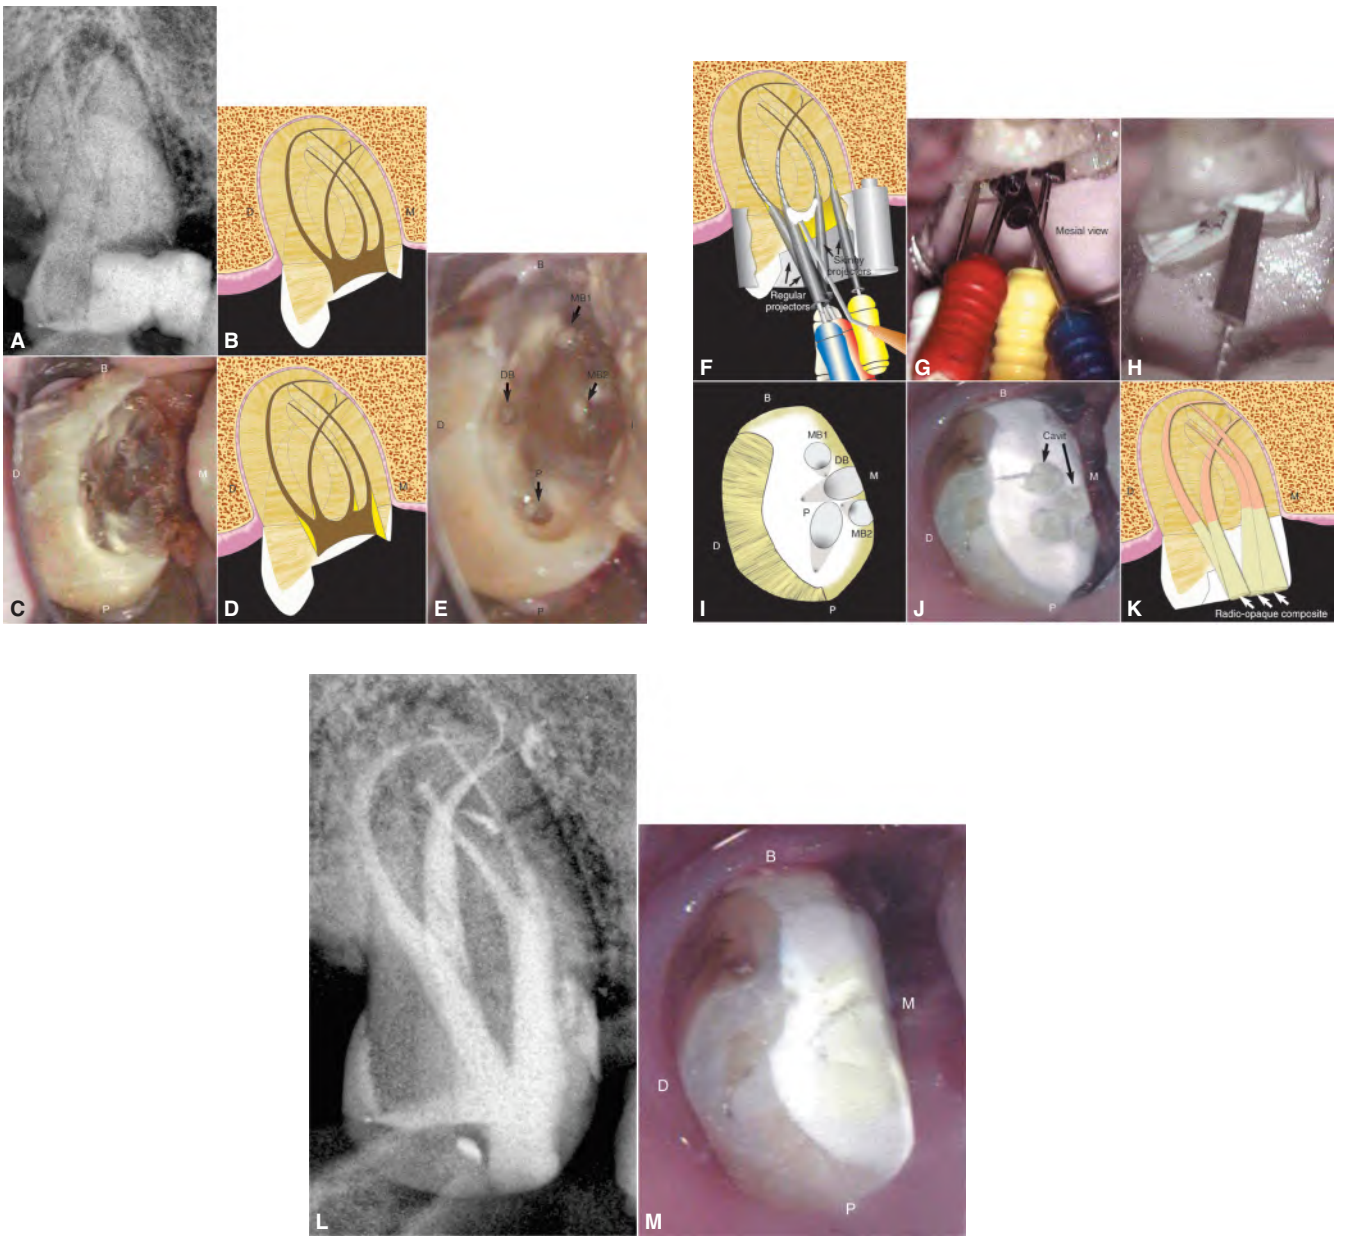

FIGURE 19-44 ***A–C***, Radiograph, illustration, and clinical view of maxillary third molar with severe coronal breakdown. ***D***, Straight-line access is created by removing dentin "triangles" (yellow) with small slow-speed round burs. ***E***, Straight-line access or dimpling of each orifice creates a seat to receive the projectors. ***F,G***, Bondable surfaces are etched and primed, and files with projectors are placed prior to application of bonding agent and injection of composite build-up material from the floor to the occlusal surface. In this example, medium-sized projectors were used in the distal and palatal canals and projectors of smaller dimension in the MB-1 and MB-2 canals to accommodate their proximity to each other. ***H***, On polymerization, the projectors are removed by engaging them with a Hedstrom file and withdrawing. ***I***, Projected orifices may lie in various configurations on the surface of the build-up. ***J***, Between visits, shortened projectors are replaced into their respective canals and sealed with Cavit. ***K***, Illustration of completed canal projection case. ***L***, Radiograph demonstrates "elongated" canals extending from root ends to occlusal surface. ***M***, Canal projection facilitates immediate crown preparation. (Courtesy of Dr. C. John Munce, Santa Barbara, CA. Adapted with permission from Cohen S and Hargreaves, KM (eds), *Pathways of the Pulp*, 9th ed. St. Louis, MO: Elsevier; 2006. pp. 127–132.)

Auto-polymerizing resin is preferred because of the typical depth of endodontic access cavities and because of the light-blocking effect of the files and projectors.

4. On early signs of polymerization, the files are removed, leaving the projectors imbedded in the build-up material. A bull-nosed diamond is used to contour the composite and to flatten the occlusal surface along with the imbedded projectors. Leaving the projectors imbedded at this stage prevents composite debris from collecting in the projected canals.
5. The projectors are removed by engaging a #60 Hedstrom file in the lumen of each projector and withdrawing

(Figure 19-44H). As with the original projectors, the external surfaces of capillary tips exhibit a releasing agent that provides for reliable removal from all types of build-up material. Depending on how the projectors are arranged relative to each other as they traverse from the chamber floor through the access cavity to the occlusal surface, the projected orifices will lie in various configurations on the occlusal surface (Figure 19-44I), and the particular orientation of the projectors is largely adjustable according the clinician's preference. This procedure creates durable endodontic reference points.

6. If a second treatment visit is required, the projected canals may be conveniently sealed by snipping 2 mm from the large-diameter end of the projectors, re-inserting them into their respective canals, and sealing with Cavit (Figure 19-44J). On the patient's return, the Cavit seals are removed with a #6 slow speed round bur, a #60 Hedstrom file is again engaged in the lumen of each projector, and the projectors are withdrawn, leaving the canals free of temporary filling debris.
7. Following cleaning, shaping and obturation, the projected portions of the canals are "dressed" with a high-speed football diamond and/or slow speed round burs to remove residual sealer and to freshen the composite, making it receptive to the final composite that is injected directly over gutta-percha from the sub-chamber level to the cavo-surface of each projected canal (Figure 19-44K). Selecting a composite for this final step that is more radio-opaque than the build-up composite creates a unique radiographic appearance showing each canal continuously flowing from the root end to the occlusal surface (Figure 19-44L). Crown preparation can proceed immediately (Figure 19-44M).
8. A post can be easily placed through the projection build-up at the completion of endodontic therapy. Using either a high-speed football diamond or a slow-speed #6 round bur, the projected portion of the canal to receive the post is enlarged to the level of the chamber floor. According to the particular type of post to be placed, the radicular aspect of the canal is prepared in the typical fashion, and the post is cemented or bonded into the canal. The coronal portion of the post should be surrounded by syringeable composite, effectively anchoring the projection build-up to the natural tooth structure.

Tissue Management Procedures

Large carious lesions or resorptive defects can lead to gingival tissue proliferation into the access cavity, impeding dental dam isolation. Methods for removal of this tissue include resection via scalpel, rotary instruments, laser, or electrosurgery if the remaining tooth structure lies above the bone. Electrosurgery allows clean removal of the gingival tissue combined with controlled hemostasis, simplifying subsequent isolation. Caution should be exercised when using electrosurgery, as it can lead to heat necrosis of the surrounding bone. Soft tissue laser is another method for removal of excessive gingival tissue with minimal resultant hemorrhage.

Crown Lengthening Procedures

Rapid Root Extrusion

The placement and retention of clamps during dental dam isolation can be challenging in teeth exhibiting inadequate coronal tooth structure (Figure 19-45). When indicated, rapid extrusion methods can facilitate clamp placement by repositioning structurally compromised teeth more favorably, coronal to the alveolar crestal bone. The treatment concept requires moving the tooth rapidly to minimize concomitant coronal migration of the supporting periodontium. Following the forced extrusion procedure, a stabilization period allows attachment fibers to accommodate the new coronal location.[101,102] Coronal repositioning can be achieved either orthodontically or surgically. However, unlike conventional orthodontic movement, rapid orthodontic extrusion involves forces greater than 50 grams.[103]

Heithersay[104] introduced the concept of orthodontic extrusion in 1973 as a treatment for fractures located in the coronal third of the root. Simon and colleagues,[105] proposed expanding the indications to include caries, root fractures, and iatrogenic perforations below the crestal bone. In separate reports, Emery[106] and Smit and colleagues[107] demonstrated the effectiveness of rapid extrusion for management

FIGURE 19-45 Maxillary central incisor with post fractured to subosseous level and coronal structure fractured to subgingival level. Difficult to place and retain a clamp and impossible to restore while respecting biologic and mechanical requirements. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

of resorptive defects at or near the crest. Among factors critical to the treatment outcome are crown to root ratio, periodontal health, oral hygiene, esthetic appearance, opposing occlusion, as well as tissue biotype, root length, and root morphology. A clear understanding of the risks, benefits and alternative treatment options will contribute to patient acceptance and compliance.

Rapid extrusion technique In compromised teeth where clamp placement is difficult because of insufficient tooth structure, the split dam technique may be used to create sufficient isolation to facilitate shaping the root canal system and placing calcium hydroxide prior to extrusion[108,109] to accommodate placement of a post hook (Figure 19-46). Orthodontic wire of sufficient rigidity (0.036 gage) is initially adapted to a study model either facially or lingually/palatally depending both on the relationship of the teeth adjacent to the target tooth and intercuspation with the opposing teeth. Though rigid, the wire should be flexible enough to be reshaped to pass directly over the tooth or teeth being treated to ensure a vertical extrusion path (Figure 19-47).

The technique uses one of various types of elastomeric agents to connect a bonded facial or lingual/palatal arch wire to the post hook that is cemented into the root canal of the target tooth. Adequate post retention requires a minimum post length equal to half the length of the remaining root structure.[105] The post hook can be cemented with crown and bridge cement or with IRM. This post hook will typically be removed following the post-extrusion retention period, so

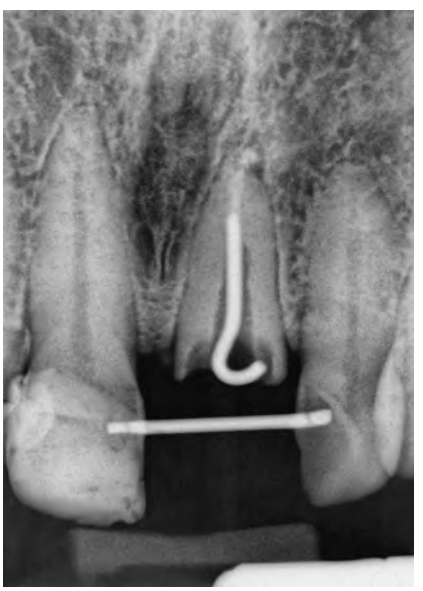

FIGURE 19-46 After removal of fractured threaded post under split dam isolation extending from the maxillary right central incisor to the maxillary left lateral incisor, the canal is shaped, and calcium hydroxide is placed in order to suitably stabilize the system for placement of a post-hook in preparation for extrusion. (Courtesy of Dr. C. John Munce, Santa Barbara, CA.)

FIGURE 19-47 Stainless steel orthodontic wire of at least 0.036 gauge can be bent either in the mouth or on a stone model as in this case. (Courtesy of Dr. Fred A. Berry, Loma Linda, CA.)

the type of cement used should take this into account along with the dimensions of the post space. For example, if the space is long and parallel-sided, a cement of lesser retentive capacity can be used. Conversely, post spaces that are shorter and tapered, will require a luting agent with stronger retention properties. Post removal at treatment completion can be simplified by lubricating either one side of the post or the apical third or half of the post prior to cementation.

The labial arch wire is bonded with composite to the abutment teeth. Silane-enhanced bonding should be used if an abutment tooth has a porcelain crown. In the case of abutment teeth with full metal restorations, orthodontic bands with brackets can be attached to accommodate the wire. A segment of Elastomeric Chain (Rocky Mountain Orthodontics, Denver, CO, U.S.A.) (Figure 19-48A) can be attached to the hook and stretched over the arch wire and back to the hook to activate the appliance. This can be repeated several times with the same segment of chain to increase the extrusive force. Alternatively, many types of elastomeric thread are available (Figure 19-48B) that can be used to activate the appliance by feeding a 5-inch segment of thread through the hook, stretching it tightly, triple-knotting over the arch wire and snipping the ends. Often several such segments will be required to provide adequate extrusive force. Depending on the occlusion, it may be necessary to rotate the knots away from the functional fossa.

The shape of accessible surfaces may allow bonding of orthodontic brackets directly onto both abutment teeth near the incisal edge. A similar bracket can also be gingivally positioned on the target tooth. The apparatus is then activated with either a wire (Figure 19-49) or elastic thread (Figure 19-50). Regardless of the type of elastic agent selected, an additional convenient means of attaching to the target tooth involves placing a TMS pin (Coltene/

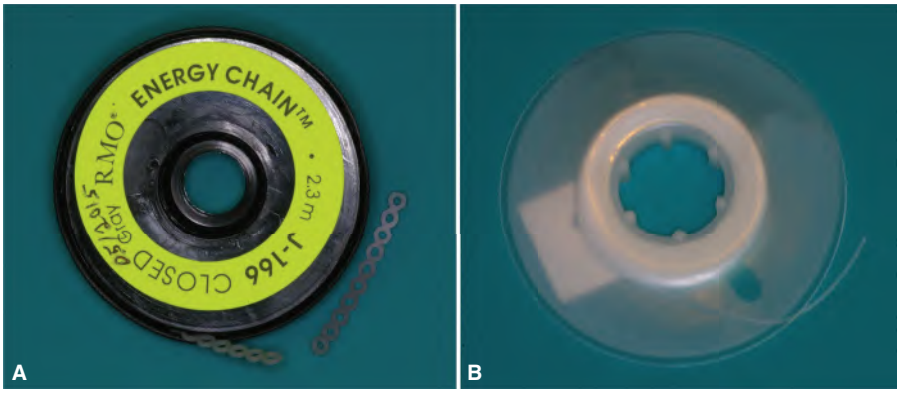

FIGURE 19-48 ***A***, Elastomeric Chain (Rocky Mountain Orthodontics, Denver, CO). For rapid extrusion purposes, chain segments will be short, consisting of only 2-4 "links" in order to exert adequate force when activated. ***B***, Elastomeric Thread (Smart Practice, Phoenix, AZ). For rapid extrusion purposes, thread segments should be 4-5 inches in length for convenience in activating and tying.

Whaledent, Cuyahoga Falls, OH, U.S.A.) (Figure 19-51) at the gingival crest on either the facial or the lingual/palatal, and attaching elastomeric chain (Figure 19-52) or multiple segments of elastomeric thread to the TMS pin (Figure 19-53). Weekly monitoring is recommended to assess extrusive movement.

When using brackets instead of bonding a wire to adjacent teeth, there is a risk of abutment teeth tipping toward each other. Under certain circumstances, tipping can occur even with a bonded wire. Double abutting the wire will usually prevent this complication (Figure 19-54). As a precaution, frequent checks are required in order to arrest unfavorable movement if detected. In 2 weeks of activation, 3–4 mm of extrusion can be expected.[110] Once fully extruded, an 8-week-stabilization period is required to prevent a potential intrusive relapse.[105]

Histologically, extrusion methods have shown evidence of periodontal fiber stretch, osteoblast activation, and

elevation of crestal bone that accompanies tooth eruption. Osteoblastic activity can be arrested by repeated fibrotomy during or immediately after eruption.[103,111] However, if overwhelming extrusive forces are applied, Sharpey's fibers become disorganized along their intermediate portions. Although the fibers retain their end-point attachments to cementum and bone, they become flaccid, losing their capacity to exert tension on the bone and subsequently fail to promote osteoblastic activity.[101,112] According to Simon,[101] the "mid-portion of the PDL appears disjointed, but the fiber attachments remained intact. Attachments to cementum and bone are not lost. The periodontal ligament apparently takes this movement in stride and eventually reorients the fibers in a normal direction. Apparently, our force was within tolerable limits. Surprisingly, new immature bone is laid down within 2 weeks and mature bone within 4 weeks."[101]

This biomechanical phenomenon differentiates rapid extrusion from typical orthodontic movement that uses light forces over extended time periods. During the 8-week-stabilization period, the fibers reorganize into the ideal perpendicular root-to-bone attachment, and the site is characterized by new immature bone formation at 2 weeks and mature bone deposition within four weeks.[101]

Limitations While teeth with tapered, short single roots are simplest to extrude, certain other root morphologies and conditions can adversely impact the effectiveness of rapid extrusion. In its simplest form, rapid root extrusion does not involve osteoclastic activity as it moves a tapered root out of bone to a new, more coronal position, stimulating only osteoblastic activity, and primarily in the apical and mid portions of the root. Osteoclastic activity, however, is involved under certain conditions, such as (a) when there are dilacerations, (b) when the root surface has bumps or indentations, (c) when there are divergent roots, or (d) when the root is bulbous. In such cases, extrusive activity exerts pressure on the bone at the coronal aspect of the irregularity and tension on the bone at the apical aspect. Lighter extrusive forces should be applied in such cases. In the presence of excessive extrusive force, osteonecrosis can occur on the pressure side, and this can halt the extrusion process until the necrosis resolves and lighter extrusive pressures are applied. Because teeth that are candidates for extrusion often have a history of trauma, spot ankyloses, not easily detected radiographically, can be involved and may impede or even prevent extrusion.

Emergence profile presents another limitation, particularly with regard to maxillary central incisors because they are viewed side-by-side. In select cases, when the mesiodistal aspects of both maxillary central incisors are relatively parallel, extrusion of one incisor may not create an emergence profile discrepancy. If tapered, however, there could be an unacceptable esthetic result, and the greater the amount of both the taper and the extrusion, the greater the discrepancy. Lip line is an important determinant in such cases.

Outcome and prognosis There are important factors to consider during treatment that can influence the outcome of rapid root extrusion procedures. Malmgren et al.[113] concluded that there is a risk of relapse after orthodontic extrusion, and therefore suggested that fibrotomy should be performed prior to the retention period to avoid this complication. It was also demonstrated by Weissman[112] in two case

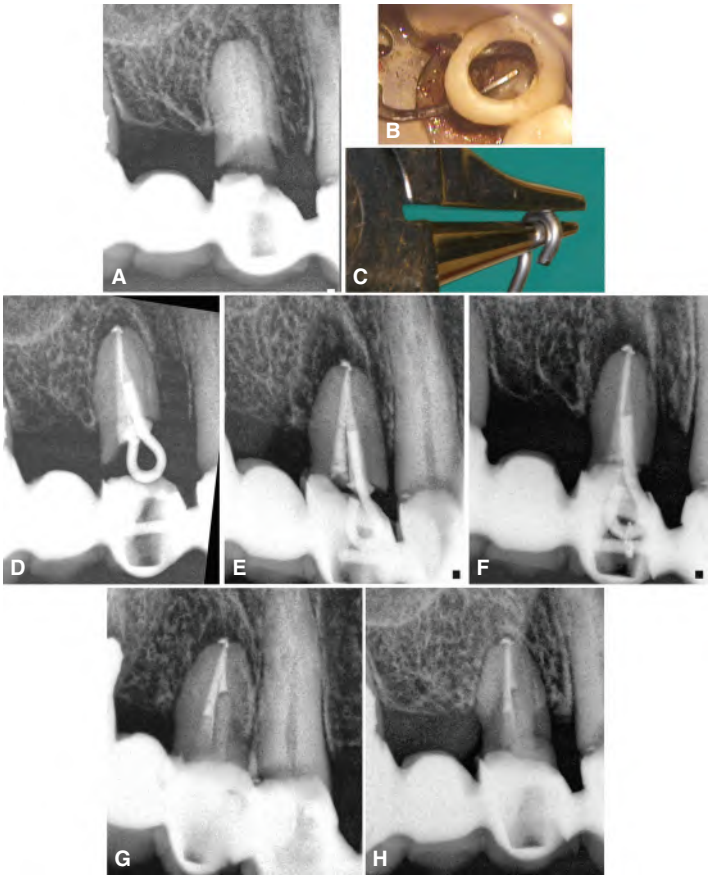

FIGURE 19-55 ***A,B***, Pretreatment radiograph and video frame capture showing the extent of coronal breakdown. ***C***, Hook-post fabricated from stainless steel orthodontic wire. ***D***, Endodontic therapy completed, hook-post cemented and extrusion activated. ***E***, Extrusion completed. reports that immediate gingival fibrotomy before extrusion limits gingival migration. Simon's observations,[101] however, suggest that a primary means of preventing bone from elevating along with the root is the speed with which the root is erupted. Therefore, while selective fibrotomy may be considered as a secondary means of precluding osteoblastic activity in select cases, the extrusion process itself serves to prevent comigration of bone along with the root when the extrusive movement is performed with adequate rapidity.

In a study on dogs by Simon and colleagues,[101] at 2 weeks, extruded teeth showed radiolucent areas surrounding the roots. On histologic examination, these areas were found to contain new immature bone or osteoid and a periodontal ligament of normal width. At 7 weeks, the roots were radiographically within normal limits, and this was confirmed histologically. Figure 19-55 is a compilation of radiographs and clinical images showing the case of rapid extrusion on an 85-year-old patient with severe coronal breakdown on a maxillary right first premolar with radiographic findings demonstrating the sequence of radiographic findings described by Simon and colleagues.

Rapid root extrusion is a treatment option that can be considered for saving compromised teeth exhibiting limited coronal structure or radicular defects at or near the alveolar crest. The goal is to move teeth into a more favorable position to facilitate endodontic isolation and subsequent restoration. This strategy is useful in all tooth groups provided root morphology and other factors are favorable. The technique is critically important in the anterior region because it preserves the natural esthetic contours of the gingiva and papillae. It is a safe and beneficial procedure that predictably retains the natural dentition with minimal risk of complications.

Immediate Surgical Extrusion

Single-rooted teeth requiring endodontic treatment and having simultaneous involvement of the coronal third of their root by caries, fracture, perforation, or resorption can challenge the clinician during the restorative and endodontic phases of treatment. Endodontic treatment demands adequate isolation during treatment and prosthetic rehabilitation demands adequate healthy tooth structure in harmony with the contiguous periodontal soft and hard tissues. In order to reestablish biologic width[114] and an adequate ferrule,[115] various corrective procedures utilized are clinical crown lengthening, orthodontic extrusion, or the forgotten modality of immediate surgical extrusion.[116] Clinical crown lengthening has the limitation of potentially causing collateral damage by removing healthy bone support on adjacent teeth and its effect on esthetics in

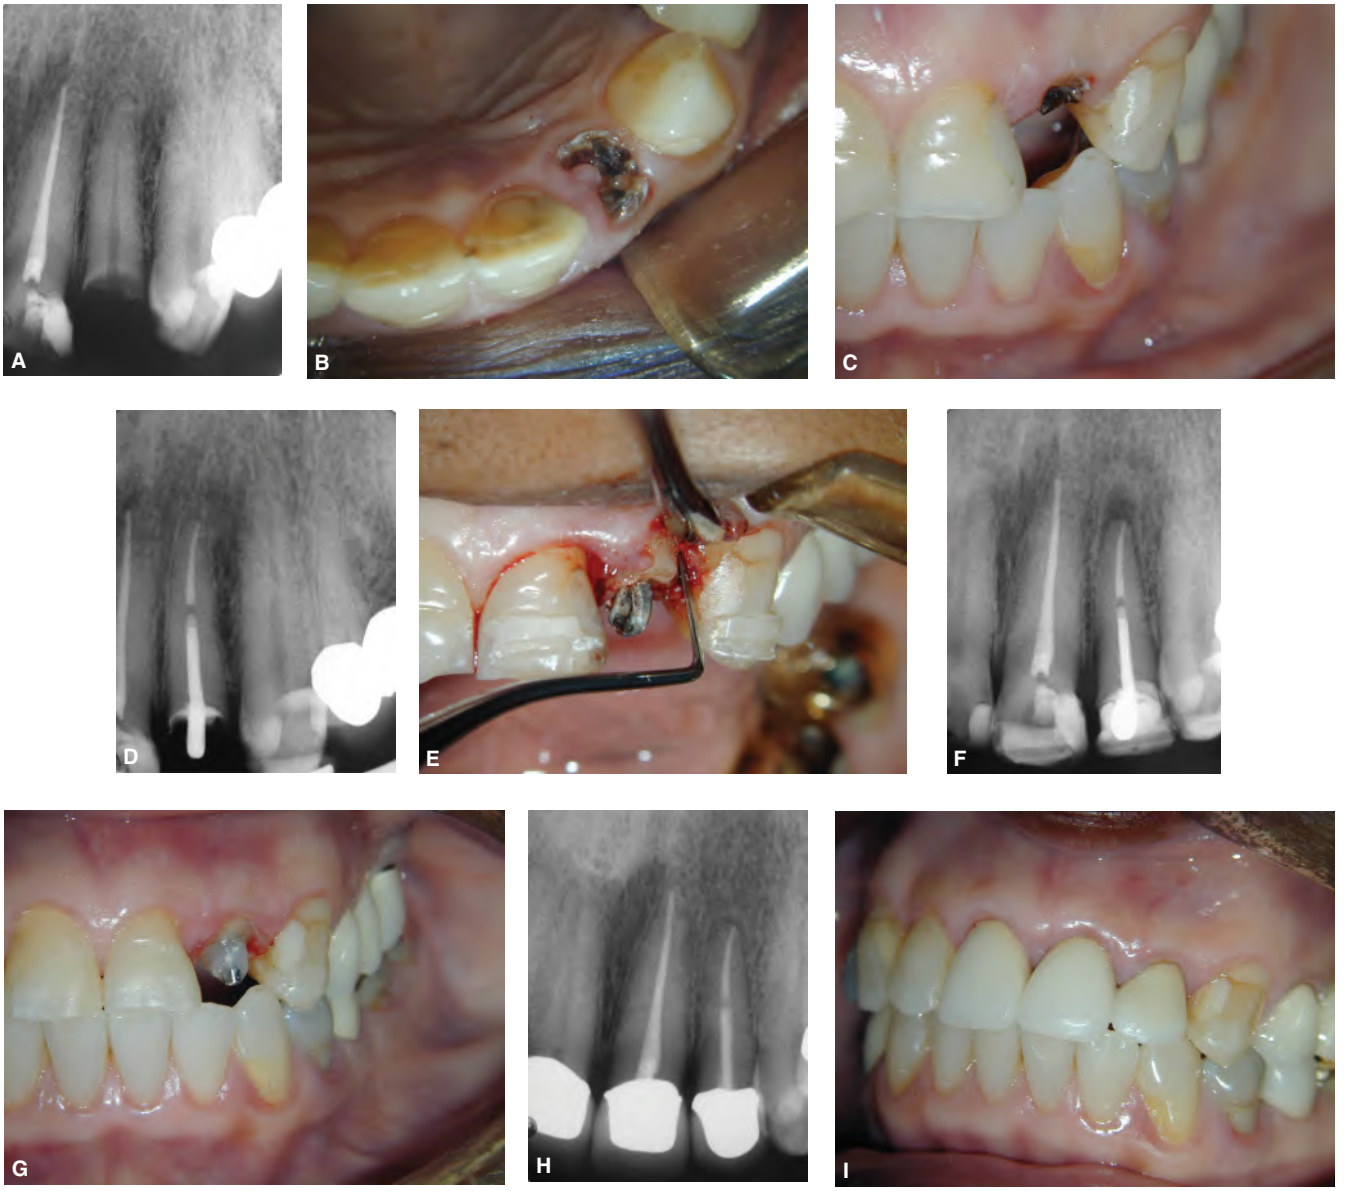

FIGURE 19-56 ***A***, Preoperative radiograph showing carious destruction of maxillary left lateral incisor and its relationship to alveolar crest and adjacent teeth. ***B***, Preoperative clinical view showing compromised tooth structure, occlusal view. ***C***, Preoperative clinical view showing compromised tooth structure, facial view. ***D***, Postoperative radiograph after completion of root canal treatment and internal reinforcement with a temporary post. ***E***, Reflection of an envelope flap and predictable placement of a periotome. ***F***: Immediate postextrusion radiograph demonstrating extent of extrusion. ***G***, Clinical view prior to cementation of crown at 4 months. ***H***, Radiographic follow up after 1 year shows slight periodontal ligament space widening apically. ***I***, Postoperative clinical view showing optimum gingival health and architecture around the permanent crown. Hanover Park, Quintessence; 2015. p. 279.)

the anterior region can be detrimental whereas orthodontic extrusion is time dependent, relying on patient compliance and sometimes the need for additional remedial crown lengthening therapy consequent to mobilization of the tooth.

This section will focus on the modality of immediate surgical extrusion. Immediate surgical extrusion is the intentional and controlled luxation of the root coronally with the objective of stabilizing the root in a favorable restorative position (Figure 19-56).

The information extrapolated from the dental trauma literature with regards to extrusive luxation[117] supports a favorable prognosis with a low incidence of adverse events for the immediate extrusion procedure.

Indications The overall strategic value of the tooth in the comprehensive treatment plan is a prime consideration. Immediate surgical extrusion can be considered in cases where there is involvement of the coronal third of the root by a compromise such as crown root fracture, cervical caries,

root resorption, or iatrogenic perforation. The procedure has an application in selected cases of trauma where an oblique crown root fracture is observed and the rotation of the tooth could position the tooth in a more favorable restorative relationship. Age is an important qualifier for surgical extrusion, especially for young growing individuals with healthy adjacent teeth who are not physically ready for replacement with an implant but esthetics, bone and space, needs to be retained in the interim. On an average, young women complete growth at age 17 years and 8 months and young men at age 20 years.[118]

Clinical considerations With regards to the timing of endodontic intervention, surgical extrusion might be necessary to provide optimum isolation prior to initiation of endodontic treatment. Certain root configurations can benefit from fortification of the root with a temporary composite build up that will prevent any iatrogenic event such as fracture during the application of any luxation forces on the root.

The amount, location and level of healthy tooth structure will determine the crown root ratio anticipated after the extrusion procedure. The level and location of actual tooth structure remaining after caries clean out needs to be noted while making estimations of the desired crown root ratio following the extrusion. A minimum of 1:1 crown root ratio is desirable and will facilitate stability of the tooth in function.[119]

Armamentarium and technique The materials required for the procedure are similar to those necessary for an exploratory surgery. The instruments include Periotomes, forceps, elevator, methylene blue dye, sutures, nylon fishing wire, and composite resin.

The technical procedure involves a full-thickness mucoperiosteal envelope flap extending at least one tooth adjacent to the tooth to be extruded to allow for adequate visualization and atraumatic placement of a periotome. Adequate visualization with the aid of magnification and illumination can minimize the risks associated with the procedure. An atraumatic procedure will minimize trauma to the osseous housing especially in areas with a thin cortical plate. A significant association was found between the type of gingival biotype and a thickness of cortical plate, a thin gingival biotype representing a thin underlying cortical plate.[120]

The periotome is manipulated circumferentially in a rocking crown-down manner with the objective of shearing the attachment apparatus of the root. Light forces with the aid of an elevator might be necessary to facilitate luxation of the root. After sufficient mobility is achieved, the residual healthy root structure is repositioned approximately 4–5 mm above the alveolar crest to allow for establishment of an adequate biologic "height" and ferrule. Methylene blue dye can be used to stain the root surface, highlighting any defects or suspected cracks. The occlusal clearance is verified and a periapical radiograph taken to assess the degree of extrusion. The flap is repositioned and sutured. The tooth is stabilized by using a flexible splint bonded onto adjacent teeth for 2 weeks. The sutures are removed at 48 h. The stability of the tooth is verified at 6 weeks and the root canal treatment completed if it was not completed prior to extrusion. The tooth can be reinforced with a prefabricated post and core or a cast post and core prior to restoration with a crown.

Technical considerations The root geometry, configuration, and density of bone surrounding the root can pose technical challenges during the luxation procedure. The degree of root taper, abrupt curvatures or dilacerations, root divergence or inclination, the type of cross-sectional morphology of the root, root proximity, and the length can all have a consequence on the complexity and risks associated with the surgical extrusion procedure.

The profile of the root being conical in shape, the narrower portion of the root is re-positioned coronally after extrusion. This can create a wider embrasure space. This change in emergence profile, diameter and contour of the root needs to be compensated during the restorative phase, or it can result in compromised esthetics. A high smile line has a potential for exposing the embrasure spaces and can pose an esthetic detriment, whereas a low lip can be an advantage in masking open embrasures.

The type of occlusion can affect the long-term prognosis, for example, parafunction or trauma from occlusion could be the very etiology that resulted in the fracture of a prior restoration. Patients with a collapsed vertical dimension of occlusion may need a more comprehensive treatment plan to restore form and function. There must be sufficient clearance available to extrude the tooth. In case of insufficient clearance alternative therapy such as crown lengthening might be necessary. Periodontally compromised teeth with deep bony pockets and or associated mobility related to the same are poor candidates for surgical extrusion.

Risks The typical risks of resorption, ankylosis, or persistent mobility anticipated with a traumatic luxation are minimal with the controlled procedure of surgical extrusion due to the lack of drying of the periodontal ligament associated with an extended extraoral time and minimal trauma to the attachment apparatus.[121]

A histological study by Kim et al.[122] comparing orthodontic and surgical extrusion in a dog model, confirmed that ankylosis was a minor event in surgical extrusion group and only transient in nature. They also concluded surface and inflammatory resorption were repaired eventually in both groups.

On the hierarchy of the evidence pyramid, this procedure has a reasonably lower level of evidence due to documentation mainly in terms of case series and case reports. In 2014 Elkhadem et al.[123] published a systematic review that involved 8 case series and 11 case reports that included 243 teeth from 226 patients pooled in the study. Most of the case series and case reports were performed between 1978 and 1999. It was found that 30% of cases showed nonprogressive root resorption. Three percent progressive root resorption was observed mainly in teeth with apical surgery and bone

grafts in studies with the older techniques. No ankylosis was reported in any of the teeth. Five percent of teeth were lost mainly due to repeated trauma.

It appears that surgical extrusion is a valid treatment option in restoratively compromised single-rooted teeth.

Surgical Crown Lengthening

The crown length is defined as the distance between the gingival margin and the most incisal/cuspal aspect of a tooth. Crown lengthening surgery is a procedure intended to increase this distance. It is commonly indicated for the management of deep subgingival caries or fractures, perforations, or resorptive defects extending to or beyond the osseous crest. The procedure improves the ferrule effect and contributes to retention for a predictable, long-lasting restoration with minimal periodontal damage. Crown lengthening can also assist in endodontic tooth isolation when tooth structure is compromised. In the presence of both restorative and endodontic indications, it is an ideal solution for exposing additional tooth structure. The procedure involves resection of soft as well as hard tissues (Figure 19-57). Because impingement of restorative margins in the biologic tissue can lead to irreversible damage in the form of tissue recession and bone loss,[124,125] it is essential to consider this procedure to prevent such undesirable ramifications.

In order to perform an effective crown lengthening procedure, it is necessary to know the dimensions of the attachment mechanism around the involved teeth as well as the commonly acceptable restorative principles (such as retention and ferrule effect). A ferrule effect is defined as "a 360°-metal collar of the crown surrounding the parallel walls of the dentin, extending coronally to the shoulder of the preparation."[115] Restoratively, 1—2 mm of healthy tooth structure apical to a build-up is required for the ferrule effect. Additionally, a dimension of about 2 mm of biologic width is necessary to accommodate the connective tissue fibers and junctional epithelium.[114,126,127] Adding both the ferrule effect dimension and the biologic width dimension, it can be concluded that exposure of 3–4 mm of sound tooth structure coronally to bone is necessary for a successful crown lengthening procedure. Restoratively, it is also important to consider the sulcus depth that is variable in different locations along the circumference of teeth. Should subgingival restorative margins be planned, additional crown lengthening may be necessary, depending on the desired margin location and the particular sulcus depth.

Prior to recommending crown lengthening, tooth restorability should be assessed. Additionally, risks and benefits as well as treatment alternatives should be discussed with the patient. The procedure entails tissue resection by design and therefore is contraindicated if the esthetics will be compromised. An alternative to surgical crown lengthening in the esthetic zone is orthodontic extrusion that does not necessitate tissue resection and also preserves esthetics. Preoperative radiographic and periodontal evaluation is crucial to ensure an excellent prognosis following crown lengthening. The surgery reduces the bony support and should not be performed on mobile teeth. If a crown lengthening procedure is not performed, the possible consequences should be discussed with the patient. These include recurrent caries, the inability to obtain proper impressions, and difficulty in removal of cement or bonding material from restorative margins. Periodontal complications due to limited hygiene access and tissue impingement could result in recurrent gingival inflammation and subsequent bone loss, not only on the restored tooth, but adjacent teeth as well.

Crown lengthening performed to accommodate a clamp and dental dam for endodontic isolation will generally provide adequate tooth exposure for restorative purposes. It is important to convey the necessity of the procedure also from an endodontic perspective and reiterate the need for restorative treatment due to anticipated changes in the gingival margin (i.e., an expected side effect of recession).

Crown lengthening surgery involves three main steps that are of equal importance: soft tissue excision, resection of supporting bone (ostectomy), and resection of nonsupporting bone (osteoplasty). The extent of each component depends upon the circumstances of the particular case.

Incision and flap design Tissue quality needs to be assessed prior to the procedure, and the amount of keratinized and attached gingiva should be measured. For teeth that present with an abundance of attached and keratinized tissue, it is acceptable to resect 1–2 mm of tissue as part of the procedure. The incision type will be an internal bevel incision (also termed a reverse bevel incision) that creates a discard of tissue. In order to perform this incision, the blade is positioned at an acute angle to the tooth and bone. The incision is full thickness, through the periosteum to the hard bone and tooth structure in order to ensure a complete severing of tissue to be excised. For teeth that present with minimal to no attached and keratinized tissue, an intrasulcular incision design is preferred. The latter preserves the maximal amount of tissue and will prevent the formation of a mucogingival defect and further periodontal problems.

A blunt dissection with a periosteal elevator is the method of reflection, and the lateral extent depends upon the number of teeth requiring treatment. For example, if crown lengthening one tooth, a full thickness flap reflection is recommended for both of the adjacent teeth. The flap is reflected in an apical direction, beyond the mucogingival junction, to ensure proper mobilization and protection of the soft tissue during osseous recontouring.

Two types of osseous recontouring Upon reflection of a full-thickness flap, the supporting alveolar bone may be assessed. The particular morphology (i.e., bone excess or deficiency) as well as its vertical position will dictate the amount and pattern of osseous recontouring necessary. This osseous recontouring component of the procedure is critical, as it will dictate the healing of the overlying soft tissue. As noted previously, 3–4 mm of sound tooth structure coronal to the alveolar crest should be exposed. This accounts for 1–2 mm of the ferrule effect dimension and 2 mm for the biologic width dimension. Vertical bone reduction should satisfy these requirements. This vertical bone reduction, or ostectomy, is the removal of supporting bone, and constitutes

the first type of osseous recontouring in a crown lengthening procedure. It is accomplished using surgical burs and hand instruments (hoes, chisels, and files). The main bur for this purpose is an end-cutting bur that is atraumatic to the mesial and distal aspects of adjacent teeth. It reduces bone in the vertical dimension and thus creates a step in the bone. This step must then be eliminated with a round diamond bur and hand instruments. The soft tissues will heal based on the new bone height that was created and the biologic width will reform itself in a more apical position. An alternative method to reduce bone height is by thinning the coronal bone using a round diamond bur and carefully removing the resultant thin shell of bone using hand instruments. Regardless of the technique, it is prudent to avoid contact with the root surfaces in order to prevent irreversible tooth damage.

Osteoplasty, the second type of osseous recontouring in a crown lengthening procedure, is performed after the ostectomy is completed, and involves the removal of nonsupporting bone. It is meant to reshape the osseous architecture around teeth and to facilitate both soft tissue healing and proper flap approximation. Excessive bone structures such as tori and exostoses should be recontoured at this time for the same reasons.

Suturing Primary intention closure is not always possible in functional crown lengthening. This is due to tissue resection in the interproximal areas as part of the flap design and tissue discard. It is therefore anticipated that, in certain circumstances, the interproximal areas will heal by secondary intention with very few complications or side effects. For crown lengthening procedures, it is often sufficient to apply simple interrupted or "figure 8" sutures for flap stability. Despite many different and elaborate suturing techniques, the osseous architecture on which the flap will lie is a critical determinant in the success of the procedure. Postsurgical care typically requires minimal use of analgesics or antibiotics as postoperative pain is generally minor and infections are rare (approximately 2%).[128] Patients should be instructed in careful oral hygiene methods and wound care for 2 weeks. Complete healing can be expected in approximately 6 weeks after which definitive restorative treatment may be initiated.

Summary Crown lengthening is a resective periodontal procedure generally intended to expose tooth structure for restorative purposes but it can also assist in endodontic isolation. With proper planning and case selection, followed by soft tissue resection (ostectomy and osteoplasty), clinicians can achieve successful results with predictable periodontal, endodontic, and restorative outcomes.

ELECTRONIC APEX LOCATORS

The Apical Anatomy

Although it remains a matter of controversy, some researchers have advocated that root canal instrumentation should extend from the canal orifice coronally to the dentin-cementum junction apically,[129–131] while others hold that, in order to remove all diseased tissues, treatment should extend to a point more well-defined and consistently measurable than the dentin-cementum junction.[132] The dentin-cementum junction is often the point of the narrowest diameter in the root, forming the apical constriction. The location of the apical constriction can be up to 1 mm or more from the apical foramen.[133] The anatomy of the apical constriction varies among different teeth and even within the same tooth through the course of aging.[130,134] Kuttler recorded an increase in the distance between the apical constriction and the vertex of the root in aged teeth between 0.5 and 0.6 mm.[130] This distance was later used as a measurement to subtract from the radiographic apex to roughly determine the location of the apical constriction.[135]

Despite ongoing debate regarding the exact apical extent of endodontic treatment,[136] there is broad consensus regarding the fact that as much of the canal system as possible should be treated. Used in conjunction with multiangled radiographs, and three-dimensional imaging when necessary, apex locators assist the clinician in being more accurate in determining the apical extent of treatment.[137]

Limitations of the 2-Dimensional Radiographic Methods

For decades, periapical radiographs have been used to determine the root canal length. Despite the advancement in digital radiography and the ability to estimate the tooth length by direct measuring, digital radiography is not universally accepted as superior to conventional radiographs for endodontic length determination.[138–142] Periapical radiographs are susceptible to elongation, shortening, and added magnification.[143] Interpretation of the position of the file in relation to the radiographic apex can often be challenging even when utilizing the bisecting angle technique.[144,145] Root variations and superimpositions of anatomical landmarks can result in error when determining the working length (Figure 19-58). Periapical radiographs

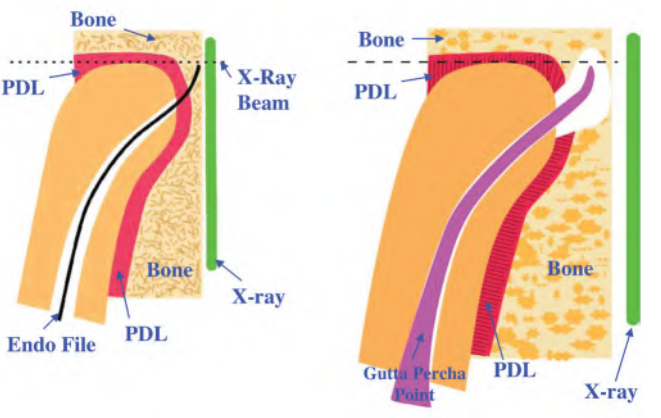

FIGURE 19-58 An illustration showing how endodontic files and gutta-percha can be extruded beyond the apical foramen and appear superimposed on the radiograph apex. (Courtesy of Dr. Allan S. Deutsch, New York, NY.)

present a two-dimensional image of a three-dimensional object and the working length from periapical radiographs can vary from the actual working length. Interpretation of the file position using radiographs has also been shown to vary among clinicians with a decrease in agreement when the file is further away from the radiographic apex.[146] Considering the inaccuracy of the periapical radiographs together with the increased radiographic exposure concerns, the electronic apex locator (EAL) became an acceptable adjunctive method for determining canal length.

Electronic Apex Locator Uses and Designs

EALs are devices used in root canal therapy to determine the position of the apical foramen and thus determine the length of the root canal space. The concept of measuring the canal length electronically was proposed in 1918 by Cluster.[147] The principle design and development of EALs was later reported by Suzuki in 1942.[148] He found that electrical resistance between the periodontium and oral mucous membrane in dogs was of a constant value. Based on these findings, Sunada introduced the first EAL in 1962.[149] He showed that with the use of a direct current, the location of the apical foramen could be estimated since the resistance between the periodontium and the oral mucous membrane was constant at 6.5 KΩ. Since then, EALs have passed through major improvements resulting in more accurate, consistent, and reproducible measurements. EALs have gained popularity among clinicians and are widely used for working length determination. In a recent survey, 77% of the general dentists in the United States used the EAL to determine the root length during root canal procedures.[150] They are useful in situations where anatomic structures are superimposed over apices or when acquiring radiographs is challenging as in the case of handicapped patients, pregnant women, sedated patients, young patients or those with extreme gag reflex. EALs are also capable of differentiating between the canal system and root perforations regardless of the perforation size.[151–153]

Fouad and Reid[154] showed that the use of EAL among dental students resulted in better length control of obturation material and reduction in radiographic exposure. Multiple in vitro studies have shown that EALs are very accurate in determining the apical foramen to within +/–0.5 mm up to 95% of the time.[155–157] Several clinical studies have shown that the effectiveness of EALs varies between 81.5% and 97% for the intervals previously determined in relation to the radiographic apex.[158–160] In a randomized clinical trial that included 188 roots, the accuracy of EALs superseded those of radiograph, 90.4% versus 82.1%.[160] Hassanien et al.[161] compared the accuracy of EALs to radiographs in determining the apical foramen. In 20 patients with teeth scheduled for extraction, canal length was determined by EAL in 10 patients and radiographically in 10 patients. In the EAL group, a file was inserted until the apex locator indicated "apex," and it was then cemented into place. In 10 patients, the termination point was determined radiographically with a file in place. After the radiographic apex was located, 0.5 mm was subtracted, and the file was positioned to this point in all 20 teeth. The teeth were extracted, and the buccal wall of the root at its apical 4–5 mm was trimmed to gradually expose the inserted file and the apical anatomy. The file tip was located, on average, 0.21 mm from the apical foramen when EALs were used, whereas by radiographic determination, it was 0.56 mm. The difference was statistically significant.

Despite their relative effectiveness, studies have shown that the accuracy of EALs may be affected by immature apices, retreatment, calcified or blocked canals as well as severe hemorrhage and inflammatory exudate into the canals.[162–165] The accuracy of EALs may also decrease as the size of the apical diameter increases.[166] For best results, a master cone radiographic control should be taken to minimize possible errors.[167] EAL reading can also be affected by contact between the file and metallic restorations and materials.[168] This can be overcome by drying the pulp chamber, leaning the file away from the restoration or isolating the file with a section of a plastic capillary tip (Figure 19-59).

In the past, it was recommended by EAL manufacturers that these devices should not be used in patients with pacemakers. Garafalo et al.[169] suggested that EALs may be used with caution and only after consultation with the patient's cardiologist. This concern, however, proved to be unnecessary. All modern pacemakers are shielded in hermetically sealed metal cases with capacitors that filter out electromagnetic interference signals.[170,171] In a clinical study, Wilson et al.[172] showed that there was no interference between EALs and the functionality of pacemakers or cardioverter/defibrillators. In a recent bench-top study, different EALs were directly connected to a pacemaker and demonstrated no interference with the functionality.[173] Nevertheless, some manufacturers still warn clinicians not to use EALs in patients with pacemakers.

Since their development, EALs have been evolving in an attempt to improve accuracy and reproducibility of measuring the root canal length in various clinical conditions. Currently, EALs can be divided into six generations:

First Generation

The first generation of EALs, also known as resistance EALs, measure opposition to the flow of direct current or resistance. The first device, The Root Canal Meter (Onuki Medical Co., Tokyo, Japan), was developed in 1969. Pain was commonly felt while using this device due to the high current. The device was later improved and released as the Endodontic Meter and the Endodontic Meter SII that used lower currents of less than 5 μA.[174] Other devices in this generation included Sono Explorer (Salatec) Neosono-D, MC, and Ultima EZ (Amadent) Apex Finder (EIE—old version). These first generation devices caused sensitivity during use, required a dry environment and files that had a snug fit in the canals. They were also contraindicated in patients with pacemakers. Ultimately, they proved unreliable

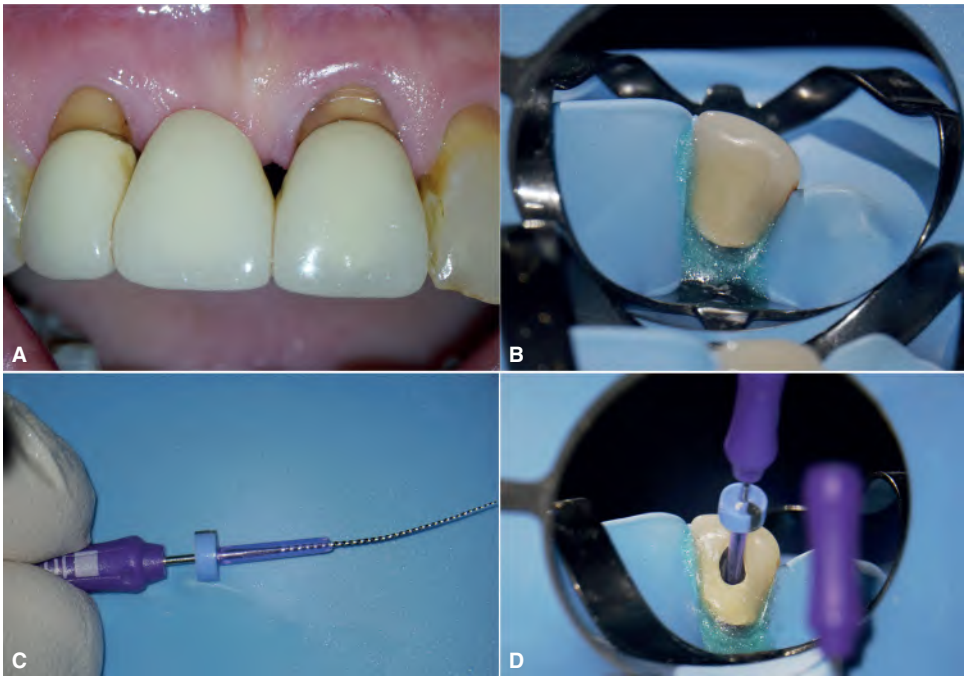

FIGURE 19-59 ***A***, EAL accuracy will be impacted by the porcelain fused to metal (PFM) crown; ***B***, target tooth is isolated; ***C***, use of a segment of a plastic capillary tip (Ultradent, South Jordan, UT) to insulate endodontic file; ***D***, EAL working length determination. when compared with periapical radiographs, as many of the readings were inaccurate.[175]

Second Generation

Second generation EALs, also known as impedance EALs, measure opposition to the flow of alternating current or impedance. These devices operate on the principle that there is electrical impedance across the canal walls. The tooth exhibits variable electrical impedance across the walls of the root that is greater apically than coronally. This method was introduced in 1971 as the Sono-Explorer (Hayashi Dental Supply, Tokyo, Japan). The second-generation EALs used single high frequency impedance measurements instead of resistance to measure locations within the canal. These second generation devices produced measurements that were inaccurate and required calibration at the periodontal pocket of each tooth. Some models, such as the Apex Finder and the Endo Analyzer (Analytic, Sybron Dental, Orange, CA, U.S.A.) were self-calibrating but also delivered varying degrees of accuracy.

Third Generation

Third generation EALs were similar to second generation but used multiple frequency rather than single frequency impedance, and the first one commercially available was the Apit, also known as Endex (Osada Electric Co, Tokyo, Japan). This device worked by comparing the difference in impedances using the relative value of two alternating currents at frequencies of 1 kHz and 5 kHz. As the file advanced apically, the difference increased until it reached its maximum value at the apical constriction. With their powerful microprocessors they were able to handle mathematical quotient and algorithm calculations to provide accurate readings. The Endex was still difficult to operate due to the need for calibration. In 1991, Kobayashi[176] introduced the ratio method that allows two electric currents with different sine wave frequencies to have measurable impedance that can be compared as a ratio. In 1994, the first Root ZX EAL (J Morita, Tokyo, Japan) was launched. The ratio method allowed the Root ZX to self-calibrate by measuring the impedances of 0.4 kHz and 8 kHz at the same time, calculate the quotient of the impedances, and express this quotient in terms of the position of the file inside the canal. This allowed more accurate reading regardless of the type of electrolyte in the canal. Other third generation EALs included the Endo Analyzer Model 8005 (Analytic, Sybron Dental, Orange, CA, U.S.A.) that used five different frequencies (0.5 kHz, 1 kHz, 2 kHz, 4 kHz and 8 kHz).

Fourth Generation

This generation EALs also used multiple frequencies, but only one frequency at a time yielding increased accuracy.[177] In 2003, the Elements Diagnostic Unit and EAL (SybronEndo, Anaheim, CA, U.S.A.) was introduced to the market and claimed by the manufacturer to provide more accurate measurements by comparing the resistance and capacitance measurements to a stored database to determine the distance to the apex of the root canal.[178,179] It used a composite waveform of two signals, 0.5 kHz and 4 kHz, instead of 8 kHz and 0.4 kHz used with the Root ZX. A significant disadvantage of the fourth generation was the requirement of dry or semi-dry canals that rendered it impractical in a variety of clinical conditions.[180,181]

Fifth Generation

This generation EALs were developed in 2003. They also measure the capacitance and resistance of the circuit separately as did the fourth generation EALs, but they were able to overcome disadvantages inherent in the fourth generation devices. Nevertheless, these devices had considerable difficulties operating in dry canals,[180] and they also had measurement reliability factors that varied with pulpal and periapical conditions.[182]

Sixth Generation

The Adaptive Apex Locator is claimed to be a sixth generation EAL with the ability to overcome the problems associated with the fourth and fifth generation devices. This device functions in dry or wet canals by continuously defining the canal humidity via mathematical analysis and algorithm to adapt according to the moisture characteristics of the canal to accurately determine canal length.[180]

EAL Benefits

EALs can accurately measure canal length and may perform better than radiography alone. When combined with canal length radiographs and master cone radiographs, the patient benefits from reduced errors and reduced radiation exposure when determining the working length.[183]

Chapter 20

Preparation of the Coronal and Radicular Spaces

Michael Hülsmann, Edgar Schäfer

INTRODUCTION

Root canal preparation is frequently considered the most important and challenging step during root canal treatment.[1–3] It involves using mechanical and chemical means to remove pulpal tissue, reduce microbial load, and enable appropriate obturation of the radicular spaces. Mechanical preparation can be divided into six main parts:

- Preparation of the coronal access cavity
- Preparation of the pulp chamber
- Identification of root canal orifices
- Preparation of a secondary access to the root canals and coronal flaring
- Preparation of a glide path to the apical foramen
- Preparation of the middle and apical parts of the root canal.

HISTORICAL DEVELOPMENT

In his 1733 book, "Le chirurgien dentiste," Pierre Fauchard described instruments for root canal preparation. The basic treatment technique at that time was cauterization of the pulp with heated instruments. At the end of the 18th century, only primitive hand instruments and excavators, some iron cauter instruments and very few thin and flexible instruments for endodontic treatment were available. In the 19th century, enlargement of root canals was performed with broaches. In 1885, the Gates Glidden drill was introduced, and in 1904, the K-file was developed by the Kerr Company. Although Trebitsch in 1929 and Ingle in 1958 suggested standardizing the shape of endodontic instruments, it was not until 1974 that the ISO-specifications for endodontic instruments were published. In 1961, Dr. Ingle presented a detailed technique for preparation of root canals, the "standardized technique."[4]

Oltramare, in 1892, described the first rotary system for root canal preparation. Fine needles with a rectangular cross-section were mounted onto a dental handpiece, passively introduced into the root canal upto the apical foramen and then rotated. Interestingly, in 1889, William H. Rollins had designed an endodontic handpiece rotating at low speed of approximately 100 rpm and with a 360° rotation, similar to the motors used today for canal preparation with NiTi instruments. In the first half of the 20th century, techniques such as iontophoresis, using electrical current, gained some popularity.

During the 20th century, several motors and handpieces for automated root canal preparation appeared in the market. In 1928, the "Cursor filing contra-angle" (W&H, Bürmoos, Austria) was introduced combining rotational and vertical motions of the file. This handpiece was followed by the Racer-handpiece (W&H, Bürmoos Austria) in 1958 and the Giromatic (MicroMega, Besançon, France) in 1964, operating with reciprocal motions (90° clockwise, 90° counterclockwise)[5] (Figure 20-1).

The Canal Finder System (CFS) (SET, Gröbenzell, Germany), designed in 1984, represented the first endodontic handpiece with a partially flexible motion. The amplitude of the vertical file motion depended on the rotary speed and the resistance of the file inside the root canal. It changed into a 90° rotational motion with increasing resistance. For the first time, the individual root canal anatomy had some impact on the motion of the instruments. The CFS was later used with integrated permanent irrigation (i.e., sodium hypochlorite) and electrical control of working length, features also found in more modern endodontic systems.

An important advance was made by the introduction of ultrasonics and sonics systems by Richman in 1957. It was Martin and Cunningham, however, who made ultrasonic devices popular in the 1970s. The first ultrasonic device was marketed in 1980 and the first sonic device in 1984.

Electrosurgical devices (Endox, Lysis, Munich, Germany) and non-instrumental technique (NIT) by Lussi, using a vacuum pump for cleaning and filling of root canals seemed to be promising, for some time. The NIT was designed to clean the root canal system with intermitted positive and negative pressure and without any instrumentation or removal of root dentin. These techniques did not gain popularity or broader acceptance despite the innovative ideas.[4]

Instruments made from nickel-titanium (NiTi) were first described in 1988. Motors with a 360° rotation or with a reciprocal motion (already developed decades before), became popular again, making the use of NiTi more efficient. In 2010, the SAF system was introduced.

AIMS OF MECHANICAL ROOT CANAL PREPARATION

The aims of root canal preparation, also termed as enlargement, shaping, or instrumentation of the root canal, have been outlined by Herbert Schilder in 1974.[1] In his paper on root canal preparation "Cleaning and shaping the root canal

FIGURE 20-1 ***A***. Endocursor and ***B***. the Racer handpiece were among the first automated devices for root canal preparation.

system" Schilder suggested to define five mechanical and five biological objectives for root canal preparation.

The **mechanical objectives** are:

I. Continuously tapering funnel from the apex to the access cavity.
II. Cross-sectional diameter should be narrower at every point apically.
III. The root canal preparation should flow with the shape of the original canal.
IV. The apical foramen should remain in its original position.
V. The apical foramen should be kept as small as practical (Figure 20-2).

The **biologic objectives** are:

I. Confinement of instrumentation to the roots themselves.
II. Not forcing necrotic debris beyond the apical foramen.
III. Removal of all tissue and debris from the root canal space.
IV. Creation of sufficient space for intracanal medicaments.
V. Completion of preparation in one appointment.

Some of these objectives are still valid more than 40 years later.

The main goals of root canal preparation are as follows:

- Removal of all vital and necrotic pulp tissue.
- Elimination, or substantial reduction, of microorganisms and microbial biofilm (see Chapter 21, Irrigants and Intracanal Medicaments).
- Neutralization of microbial toxins and byproducts in the affected dentin.
- Creation of space for obturation.
- Preservation of the integrity and location of the apical canal anatomy.
- Avoidance of iatrogenic damage to the canal system and root structures.
- Avoidance of further irritation and/or infection of the periradicular tissues.
- Preservation of sound root dentin to allow long-term function of the tooth.

These goals can be achieved by using several techniques of root canal preparation including (a) manual preparation with different instruments; (b) automated preparation with conventional stainless steel instruments; (c) rotary systems using NiTi-instruments; (d) sonic and ultrasonic preparation; (e) lasers; and (f) non-instrumental techniques.[2,3,6]

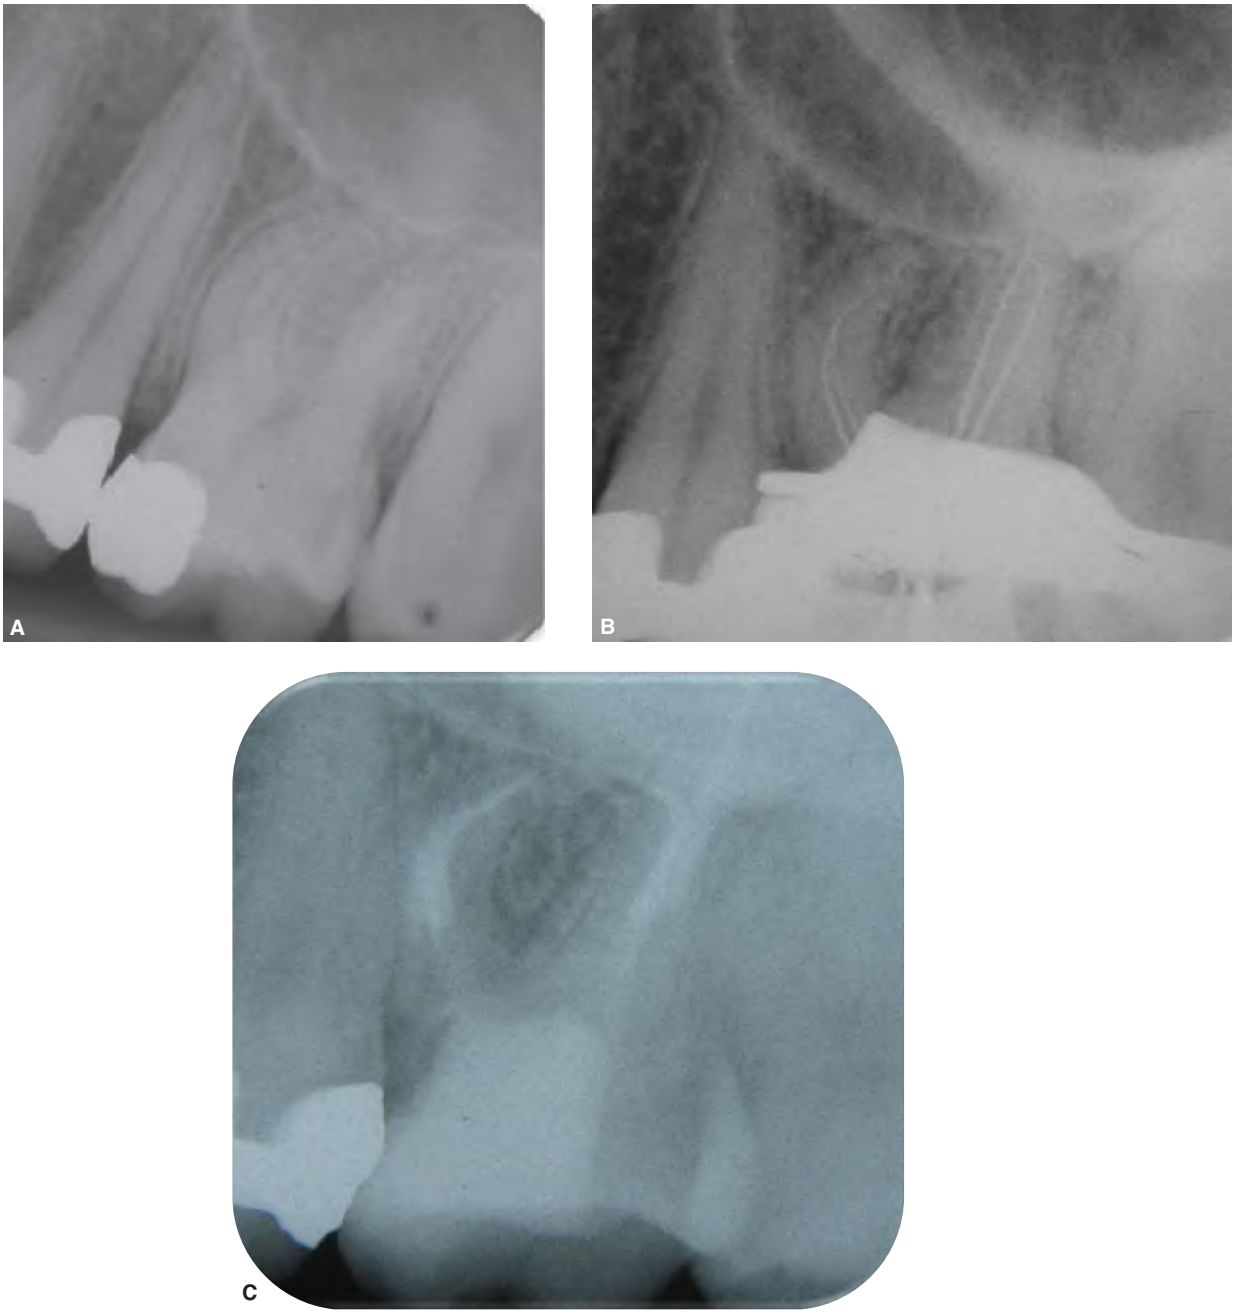

FIGURE 20-2 ***A-C.*** Preparation of these severely curved root canals demonstrates a good flow of the preparation following the original axis of the four root canals without radiographically visible deviation, straightening, or apical transportation. Note complete severity of the curves becomes evident only when the length determination radiograph is taken.

PLANNING FOR ROOT CANAL PREPARATION

No root canal resembles another. Consequently, each root canal has to be addressed individually. Several factors must be considered when planning and performing root canal preparation. These include anatomy, microbiology, and the instruments available for preparation.

Basic principles for canal preparation:

- Each root canal has to be addressed individually.
- Root canal preparation should be planned thoroughly before starting treatment.
- Careful evaluation of radiographs is mandatory.

Root Canal Anatomy

The complex anatomical structures of the root and root canal system make root canal preparation a challenging task. For more details, see Chapter 1, Anatomy and Morphology of Teeth and Their Root Canal Systems. The number of canals, curvature and diameter, cross-sectional shape, lateral and accessory canals and ramifications, isthmi and communications between the root canal and the periodontal tissues, and the furcation area have to be addressed by preparing an adequate access cavity, instrumentation and disinfection (Figure 20-3).

The nature of canal curvatures in terms of radius and angle is of importance for proper selection of instruments (size, taper, flexibility, risk of fracture). The nature of a curve is three-dimensional, with only two planes of the curve visible in the radiograph. It has been demonstrated that in certain cases, three-dimensional imaging using cone-beam computed tomography (CBCT) may be helpful to identify anatomical intricacies, apical pathosis and intraoperative complications.[7] For more details, see Chapters 9C (Cone Beam Computed Tomography) and 10 (Imaging Interpretation).

Microbiology

In case of pulp necrosis, the pulp tissue and root dentin will harbour microorganisms, many in a biofilm form, as well as microbial toxins.[8-10] Adequate preparation will significantly reduce the number of microorganisms. For more details, see Chapter 3, Microbial and Nonmicrobial Etiologies of Endodontic Disease.

Instruments

Mechanical preparation alone, even when using highly flexible instruments, is not sufficient to render a disinfected root

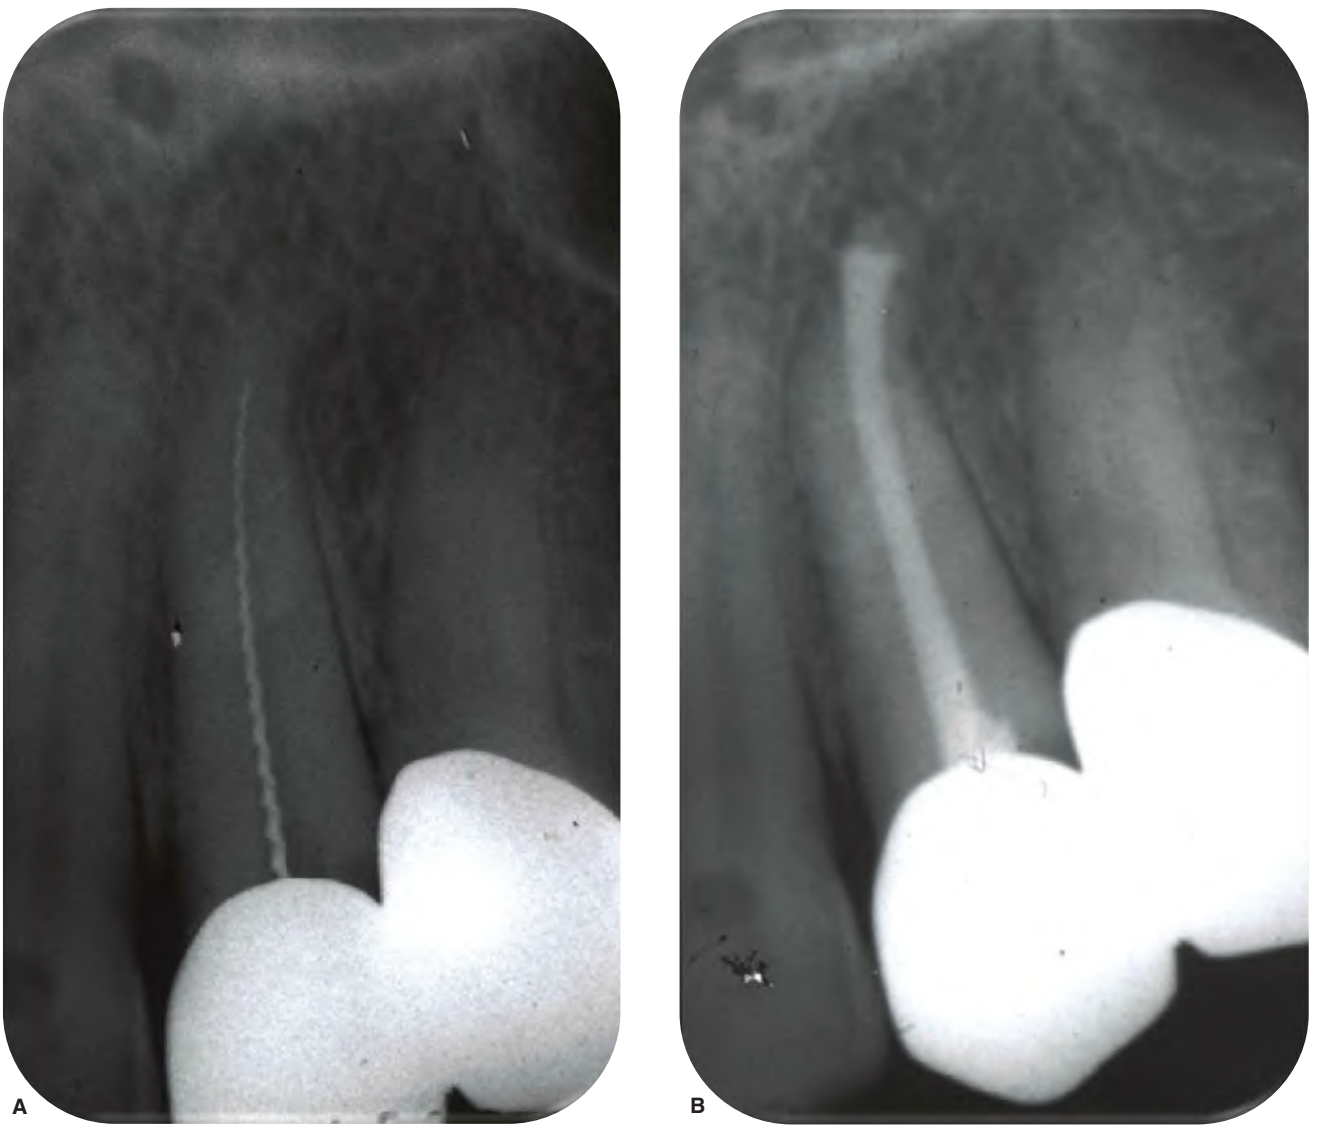

FIGURE 20-3 ***A.*** Underestimation of the curvature has resulted in severe straightening and apical transportation. ***B.*** This is mainly due to improper evaluation of the radiograph and inadequate treatment planning.

canal system. Most endodontic instruments are designed to prepare a round root canal. This may inevitably be associated with under-preparation at one part of the root canal system, leaving behind tissue debris and microorganisms, and over-preparation at the other part, resulting in excessive and unnecessary removal of dentin and possibly weakening the root. Therefore, chemical irrigation should always be done in tandem with mechanical preparation. For more details, see Chapter 21, Irrigants and Intracanal Medicaments.

The final factor influencing the performance of any instrument is the clinician's ability, routine, and skill in steering and guiding the instrument inside a narrow and tricky confines of a root canal. It has been demonstrated that the influence of the operator's skills on the result of instrumentation in terms of shape, working time and number of procedural errors is higher when using stainless steel instruments and lower when using rotary NiTi instruments.[2,3,6]

CRITERIA FOR EVALUATION OF INSTRUMENTS AND TECHNIQUES FOR ROOT CANAL PREPARATION

When evaluating the advantages and disadvantages of any instrument or preparation technique the following points should be considered[2]:

Cleaning Ability

Endodontic instruments are basically designed to cut and remove dentin and create space for effective irrigation. Cleaning of a root canal can be assessed by scoring the treated area for the amount of remaining smear layer and debris, using scanning electron microscopy. It can also be assessed by counting the number of colony forming units (CFUs) of microorganisms remaining after preparation and/or disinfection. Both methods show some specific shortcomings.[2]

Shaping Ability

The shape of the prepared root canal should show a constant taper that flows with the shape of the original canal without transportation of the axis or the foramen.[2] A round diameter of the prepared root canal is essential as long as single-cone obturation techniques (gutta-percha or silver cones) are used. When using cold or warm compaction techniques, the diameter of the root canal seems to be less important, hence, the primary objectives should be to instrument and prepare the canal circumferentially.

In curved canals the continuous taper has to extend to the apical part of the canal to avoid apical straightening and mishaps such as elbow-, teardrop-, and zip-configurations.[2,3]

Shaping ability of root canal instruments and preparation techniques have been well studied. Traditionally, radiographic and microscopic techniques have aided investigations. Lately, micro-CT was introduced allowing an excellent non-destructive visualization of the pre- and post-operative root canal shape and exact qualitative and quantitative measurement of the alterations resulting from preparation.[7]

Work-Related Mishaps and Safety

The most common work-related mishaps are:

- Fracture of instruments.
- Ledging.
- Apical blockage.
- Loss of control of working length during preparation.
- Over-instrumentation.
- Apical extrusion of debris.
- Development of dentinal cracks.
- Heat damage.
- Perforation.

ANATOMY AND PRIMARY ACCESS CAVITY

Preparation of the root canal system starts with preparation of a properly designed access cavity.[11]

The access cavity should:

- Allow full control of the pulp chamber (Figure 20-4).
- Allow removal of all tissue from the pulp chamber and proper disinfection. This will result in elimination of a significant load of microorganisms.

FIGURE 20-4 Incomplete removal of the roof of the pulp chamber resulting in insufficient root canal preparation. At least one root canal has not been detected.

- Allow a proper intracoronal diagnosis (cracks, dentin colors, pulp stones, calcifications).
- Allow location of all root canal systems and relevant anatomical structures (isthmi, lateral extensions) (Figure 20-5).
- Allow fast and straight-line introduction of endodontic instruments without coronal interferences. Ideally, the straight-line access should be extended to the beginning of the curvature (Figure 20-6).

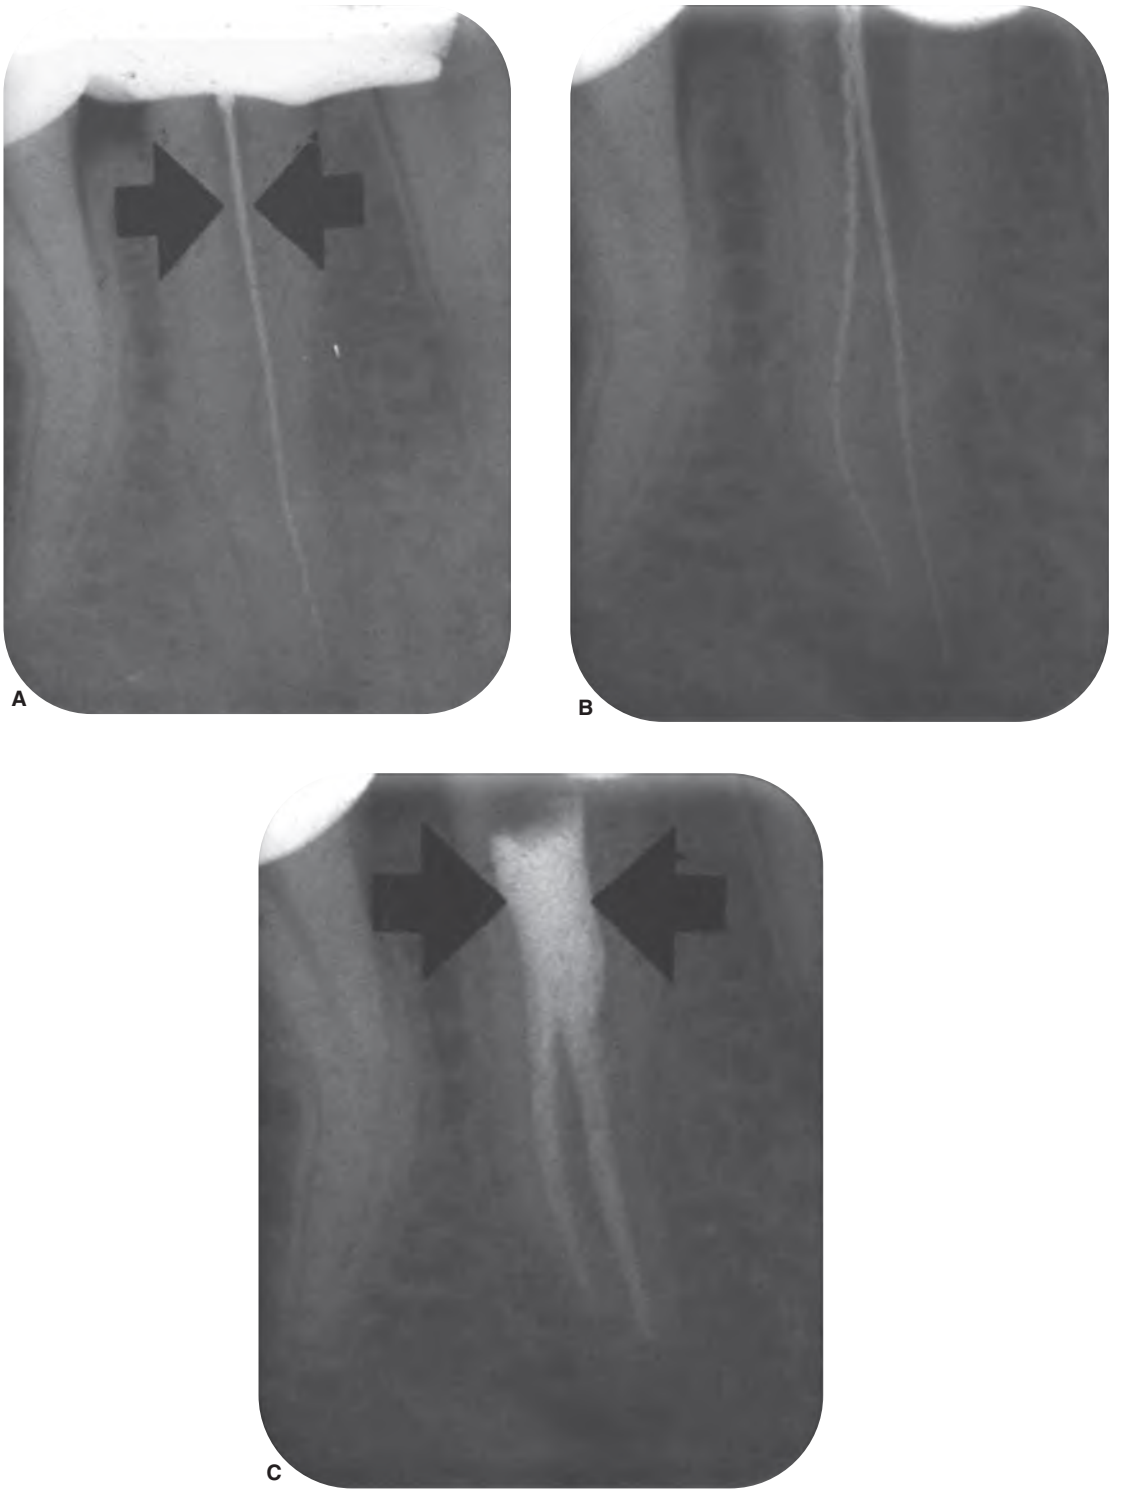

FIGURE 20-5 ***A.*** Improper primary and secondary access did not allow detection and preparation of all root canal systems. ***B.*** Three root canals could be located but improper secondary access still prevents complete instrumentation. ***C.*** Following extension of the access all three root canals could be accessed, prepared and obturated.

Key principle: Most apical problems originate coronally! The severity of coronal problems increases on the way to the apex!

The main objectives of the coronal access preparation are to

- Provide a straight line access to the root canals[11]
- Confirm the etiology of pulp pathosis
- Assess restorability of the tooth

A straight access is necessary to allow unhindered introduction of instruments, irrigants, and medicaments to the entire length and circumference of the canal, with minimal loss of dental structural integrity. Existing restorations, caries, and unsupported enamel and dentin should be removed and the remaining tooth structure examined under an operating microscope for presence of cracks, height and thickness of the remaining dentinal walls for ferrule effect, relationship between the remaining coronal tooth margins and the osseous crest, root length, location of the furcation, and amount and quality of attached gingiva.

A more difficult situation arises when an existing crown is present on the tooth that requires endodontic treatment. Abbott[12] found that there was less than 60% chance to detect caries, fractures, and marginal breakdown, without complete removal of restorations. However, it is impractical to suggest removing all crowns prior to root canal treatment, and therefore a careful assessment of the integrity of the crown must be attempted through history-taking and clinical examination before and during treatment. Preparation of the access cavity requires thorough knowledge of tooth and root anatomy and their variations.[11,13]

Guidelines for Preparation of the Primary Access Cavity

Determination of the point of penetration: Usually, entry is in the center of the occlusal table but in certain teeth (e.g., maxillary molars) it is deceiving, as the center of the occlusal table does not reflect the center of the pulp chamber. Anatomy and strategies for access are detailed in sections on individual teeth below.

Assessment of occlusal and external root form: Once the point of entry has been determined, the bur's angulation in three dimensions has to be mentally envisioned. This is determined by taking into account the angulation of the teeth in the jaws and assessing the external root surface at the level of the CEJ.

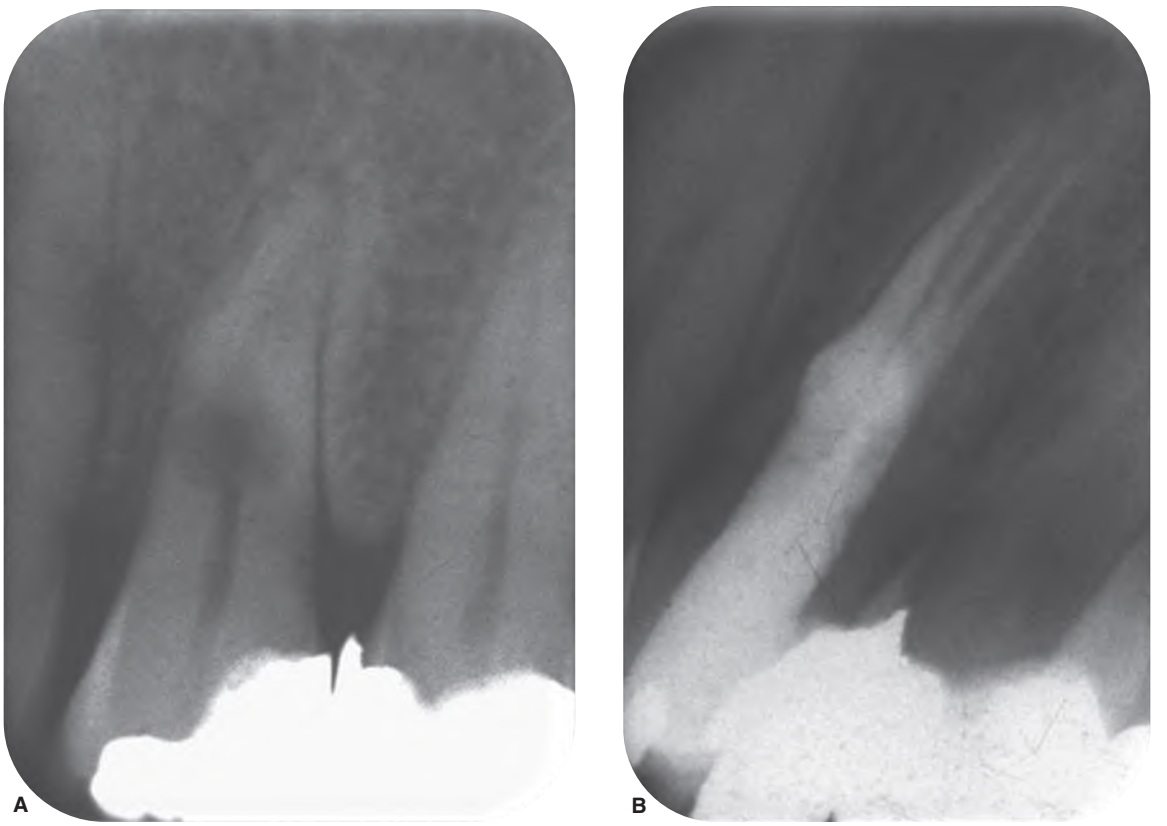

FIGURE 20-6 ***A & B.*** Only after enlargement of the coronal access cavity, proper detection and preparation of all three main root canals became possible.

Radiographic measurement of the depth of the pulp chamber roof from the occlusal table: The initial bur in the high-speed handpiece is placed against a radiograph or a measurement determined from a calibrated digital image.

Assessment of complicating factors: Rotations/tipping of teeth, calcifications (pulp stones, mid-root calcification), deep restorations, buccal/lingual restorations, root length, width, and curvature affect the angle of entry and the degree of extension of the access cavity in the horizontal and vertical dimensions.

Radiographic assessment: Angled views should be taken in an attempt to visualize the breadth of the roots and the position of the canal within it. One also has to assess the angle at which the canal leaves the pulp chamber.

Maxillary Central Incisors

The roots are usually straight and have the least incidence of dilacerations.[14]

Initial penetration should be approximately in the middle of the lingual surface of the tooth, just above the cingulum, almost perpendicular to the lingual surface. After locating the canal, long tapered diamonds can be used to extend the access into a roughly triangular outline (Figures 20-7 and 20-8).

Maxillary Lateral Incisors

The root typically curves to the distal although some can be straight or curving to the mesial. There is often a deep developmental groove running along the cingulum on the lingual surface. Usually the tooth shows one single root canal.

Maxillary Canines

The position of the cusp tip relative to the long axis of the root is in line with the center of the root tip in the labial

FIGURE 20-7 Example of a maxillary central incisor shown in labial, mesial, and incisal views. ***A.*** The access preparation can be assessed from a more incisal view and a lingual view ***B.*** The width of the preparation in the cingulum is 1.1 mm. Note also the extension of the mesial and distal incisal areas to open up the pulp horns.

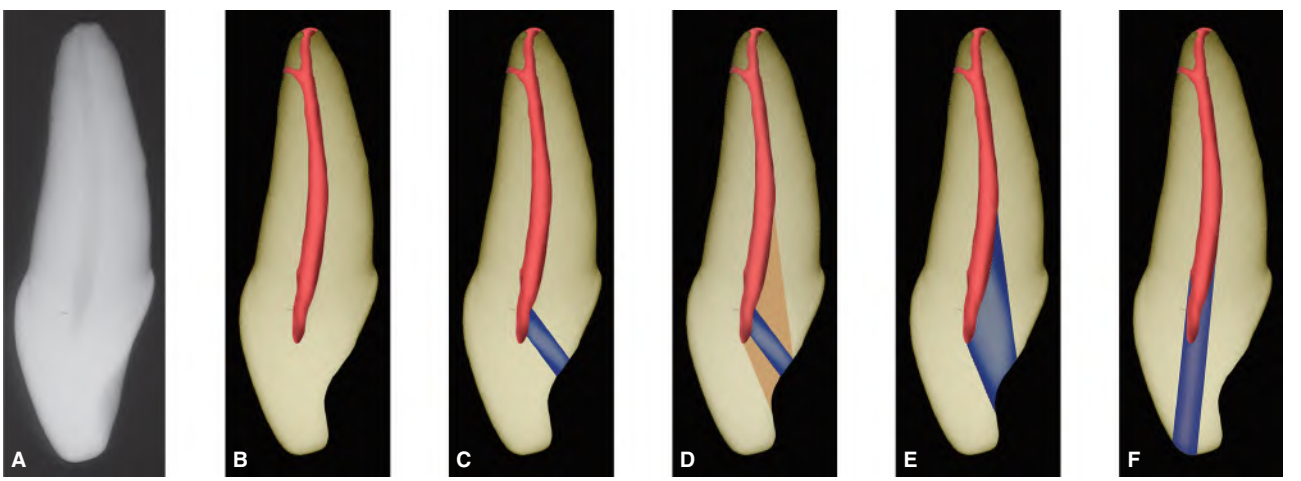

FIGURE 20-8 Potential design of access into a maxillary incisor with schematic drawings based on an original radiograph ***A.*** The preoperative relation of the canal within the root can be estimated ***B.*** Note how the true straight-line access (SLA) is labial to the incisal edge ***C.*** The initial access entry site and angulation ***D.*** tan-colored highlights show the restrictive dentin impeding SLA. ***E.*** The completed lingual access preparation with SLA can be compared to a completed access preparation done from a labial approach ***F.*** Note how far more tooth structure may be conserved with a labial access but at the cost of disrupting the labial esthetic surface.

view but lies labial in the proximal view. It is usually the longest tooth and the largest root in the mouth and often curves apically. As with the central and lateral incisors, the lingual triangle must be removed. The main difficulty with these teeth is that they can be long, often over 30 mm (Figure 20-9).

Maxillary First Premolars

It must be assumed that at least two canals are present, and the third canal is shown to exist in high enough numbers that the access preparation must be designed to search for it.[15] When three canals are present, the pulp chamber morphology resembles that of a maxillary molar (Figure 20-10). The point of entry is centrally in the fossa, aiming at the center point at the CEJ. The outline is an elongated slot and can extend almost to the cusp tips depending on the angle. However, the operator must search for a third canal, usually the mesiobuccal canal. If three canals are found, the orientation is very similar to that of the maxillary molar (Figure 20-11).

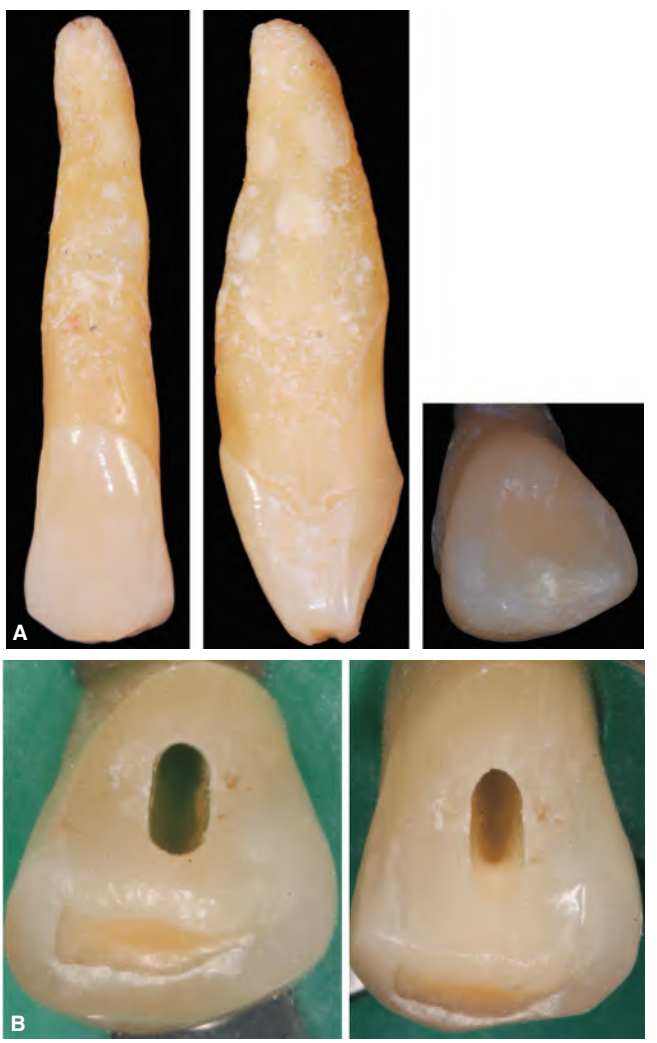

FIGURE 20-9 Example of a maxillary canine shown in labial, mesial, and incisal views ***A***. The access preparation can be assessed from a more incisal view and ***B***. From a lingual view.

Maxillary Second Premolar

This tooth usually has a single root, the incidence of two canals is significantly less but when present they are not spaced so far apart from each other[16] (Figure 20-12).

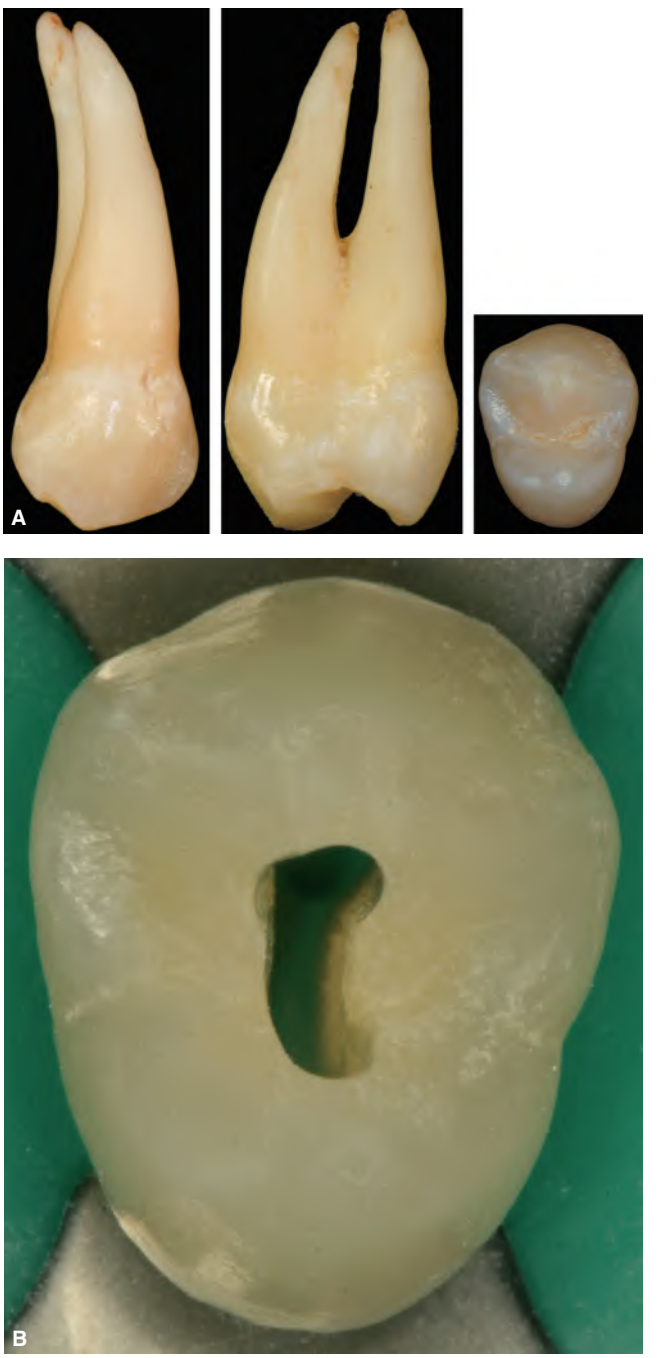

FIGURE 20-10 ***A***. Example of a maxillary first premolar shown in buccal, mesial, and occlusal views. ***B***. A typical access preparation. Note how the buccal part of the preparation has been extended mesiodistally to explore a potential second buccal canal.

FIGURE 20-11 Maxillary premolar with three root canals. The buccal canals separate deeper apically than the palatal and the main buccal root canal orifices.

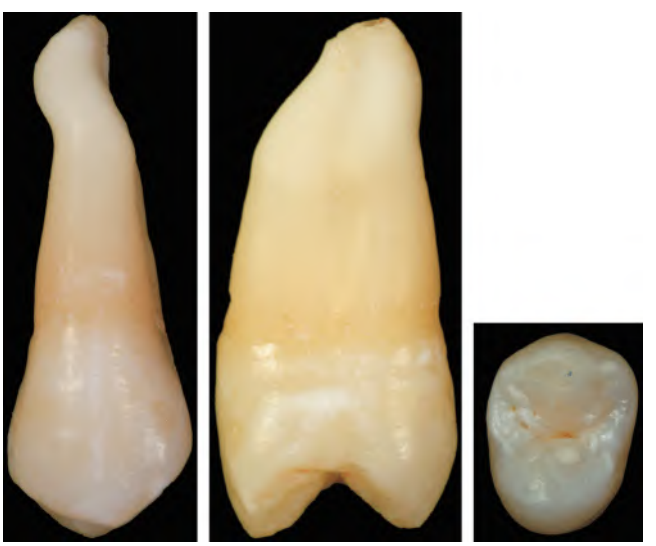

FIGURE 20-12 Example of a maxillary second premolar shown in buccal, mesial, and occlusal views. The access preparation is virtually identical to the one of maxillary first premolar.

Maxillary First Molar

It is the largest tooth in the maxillary arch with four well-defined cusps and a supplemental cusp of Carabelli on the mesiolingual cusp. From the occlusal view, it has a roughly rhomboidal outline. For the purpose of access cavities, the molars can be viewed as having a triangular arrangement of the cusps (without the distolingual cusp). In fact the access cavity is usually kept mesial to the oblique ridge (Figure 20-13).

Maxillary molars can present with mild to severe curvatures and usually have two or three canals in any root (but most commonly in the mesiobuccal root). Locating the second mesiobuccal canal (MB-2) orifice routinely can be difficult as it is often buried under a bridge of dentin.[17-19] The canal can have a severe curvature to the mesial and the buccal in its coronal section and is usually much smaller than the principal first mesiobuccal canal (MB-1). The access shape should be quadrilateral to allow for troughing 2–3 mm lingually to the MB-1 canal to search for the MB-2 canal.

Entry should be in the mesial fossa and should be kept small initially. Initial penetration may be aimed at the large palatal canal orifice. There is ample evidence to demonstrate that the mesiobuccal root has a second canal with such frequency that it must be accommodated for in the initial access and always searched for.[17,18,20]

The mesiobuccal canals have two separate apical foramina or, more commonly, join to exit at one foramen. The access preparation for the DB canals does not have to be extended as far toward its line angle as the mesial canals. The distal canal is distally inclined and so the file projects out of the orifice to the mesial naturally. Therefore, the transverse ridge can usually be preserved.

Maxillary Second Molars

Maxillary second molars are very similar in form and function to the maxillary first molars and the access cavity is similar.

Maxillary Third Molars

From an occlusal viewpoint, this tooth usually presents with a heart-shaped triangular outline similar to the second molar. The roots are often fused forming one large root. The access cavity is similar to the other maxillary molars but needs to be modified according to the specific anatomical variations that this tooth presents.

Mandibular Central and Lateral Incisors

The mandibular central incisor is usually the smallest tooth in the mouth. Bilateral symmetry is common. There are slight differences between central and lateral incisors, but the most important with regard to access is that the crowns of lateral incisors are not as symmetrical as central incisors from the incisal view as they curve distally to accommodate the curvature of the arch and correspondingly the cingulum is displaced slightly to the distal. Lateral incisors are also slightly larger than the centrals.[21,22]

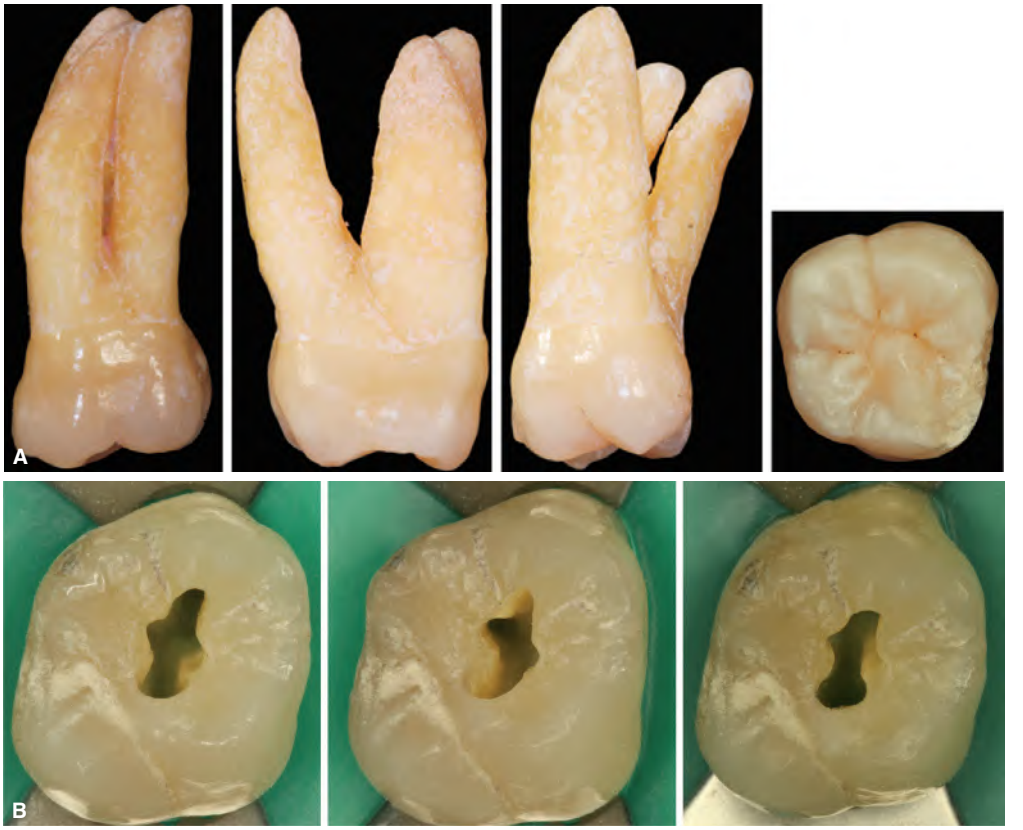

FIGURE 20-13 Example of a maxillary molar shown in buccal, mesial palatal and occlusal views. ***A.*** Access into both mesiobuccal canals and distobuccal and palatal canals is gained ***B.*** Note that the preparation has not been extended much on the occlusal table for the distobuccal canal as the canal projects distally naturally.

The entry point for access should be just above the cingulum with the bur angled perpendicularly to the surface of the entry point (Figure 20-14). As these teeth are narrow mesiodistally, the main concern is the width of the preparation. Once the chamber or the canal is found, the access can be precisely widened for each individual tooth. Approximately 40% of mandibular incisors have two canals, one buccal and one lingual with only 2% to 3% having separate apical foramina (Figure 20-15). It is natural for the hand to angle the bur toward the buccal (thereby running the risk of gouging the labial wall). The lingual canal lies 1 mm to 3 mm away from the buccal, directly under the cingulum. Even when two canals are present, there is often a fin or a groove with pulp tissue between them.

Mandibular Canines

These teeth are very similar to their maxillary counterparts but are usually narrower (approximately 1 mm) and shorter in root length by 1 to 2 mm (Figure 20-16). The mesial edge is almost straight and therefore the access cavity can be prepared more mesially to the center point of the lingual surface. The shape of the preparation ranges from an oval to a rounded slot, depending on the size of the pulp chamber inside.

Mandibular First Premolars

The mandibular first premolars have characteristics of a small canine because of a sharp buccal cusp (only occluding cusp) and a small lingual cusp that sometimes resemble a cingulum. There is a characteristic mesiolingual developmental groove that makes the tooth asymmetrical.[23,24]

The entry point is in the middle of the central groove, and the bur is directed to the buccal. Again, the access shape is an oval slot. As the crown is lingually inclined, the access cavity will result in removal of more of the buccal cusp than the lingual (Figure 20-17).

Mandibular Second Premolar

Access is similar to the first mandibular premolars, taking overall dimensions into account[23,24] (Figure 20-18).

Mandibular First Molars

Access preparations often encroach on the buccal cusp tip (mesiobuccal) but rarely onto the lingual.

Mandibular molars are known to have complex anatomy with usually four canals but three and five canals are well documented. It is important to note that there is almost always a concavity on the furcal side of both the mesial and distal roots; providing a high risk of strip perforation. The roots start to bifurcate 3 mm below the CEJ.[25,26] Both mesial and distal roots are broad and usually have two canals. Often they have an interconnecting fin that can be extremely variable in its persistence at the apex. Two distal roots can occur but are rare.

FIGURE 20-14 ***A.*** Example of a mandibular incisor shown in labial, mesial, and incisal views. ***B.*** The access cavity.

The entry point is just mesial to the central pit. Initially, the access preparation should not be extended further distally as the distal canals project mesially toward the occlusal table. Once the angle of the canals has been determined with files, the decision can then be made to extend the access distally, if needed. However, the access will be located largely in the mesial half of the tooth (Figure 20-19). Sometimes, it is necessary to encroach on the mesiobuccal cusp tip to achieve straight line access.

The groove between the mesiobuccal/mesiolingual and distobuccal/distolingual canals must always be troughed with a bur and/or ultrasonics and checked with files to search for mesial canals. The distal canal is ovoid or figure eight-shaped buccolingually if only one canal is present. There can be a second distal canal that bifurcates in the apical third.

Mandibular Second Molars

Generally, mandibular second molars differ from the first molars in their capacity for variation.[25,26] The access cavity may have to be extended more toward the mesial marginal ridge than for first molars. The roots, and therefore canals, are usually closer together and can be fused to a single conical root with varying internal anatomy or often C-shaped canal systems.

The entry point of the access cavity should be mesial to the central pit similar to the first molars, but may not require the same degree of mesial extension if the roots are closer together. Otherwise, a similar preparation as for the first molar can be made.

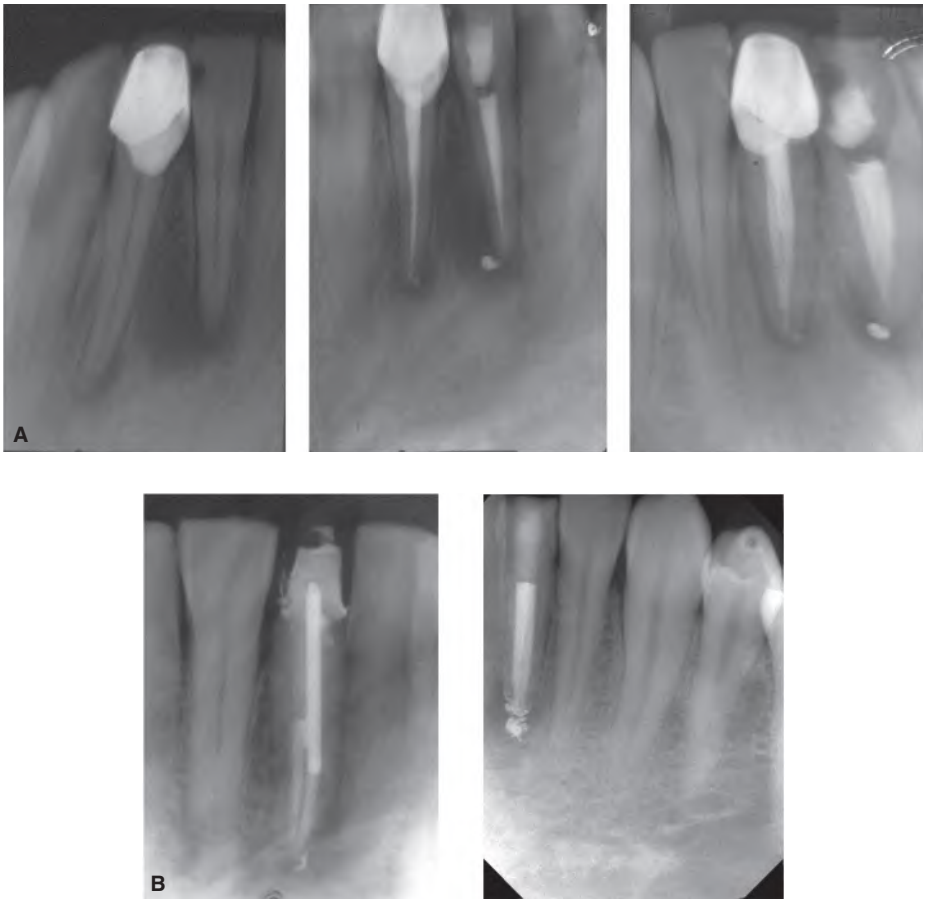

FIGURE 20-15 Radiographs illustrating variations of lower incisors with two canals. ***A.*** Although usually both canals exit from a common apex, they can have two separate or a figure eight-shaped foramen. ***B.*** Preparation can be assessed from a more incisal view and a lingual view. Note how the lingual extension of the access preparation extends well into the cingulum.

Mandibular Third Molars

Third molars have significant variations and anomalies. They are usually less developed, with oversized crowns and undersized roots. Due to the lack of space in the jaws, they are often impacted and may have very curved roots. Usually third molars have two roots—a mesial and a distal root that can be bifurcated or fused. When fully erupted and in functional occlusion, third molars provide excellent protection for the first and second molars by spreading the occlusal load. In such situations, keeping these teeth is beneficial. The access cavity needs to be adjusted according to the specific anatomical variations that this tooth presents.

Procedural Mishaps

Successful endodontic treatment originates from a well-designed and executed access preparation. The opposite is also true; errors during root canal treatment can often be traced back to a problem originating from an inadequate access preparation. Errors generally stem from two access cavity characteristics: underextension and overextension. Additionally, perforations of the pulp chamber walls are possible mishaps.

Underextension

Not opening up the access cavity across the width of the root sufficiently can result in the operator missing canals. They can often be buried under calcified dentin. However, if the canal is found but the cavity is not extended away from the furcation sufficiently, the file will preferentially cut the furcal dentin causing a strip perforation. Another possibility, of not extending the access far enough, is that the coronal canal curvature is not removed. This will increase chances of instrument separation as the file attempts to go around more than one curve, or transportation at the apex as the coronal canal curvature renders the file tip uncontrollable. Underextension of the access preparation also limits the final diameter of the apical preparation size. In anterior teeth, if the pulp horns are not adequately exposed and cleaned, the remaining pulpal tissue will cause coronal discoloration.

Overextension

Generally, overextension will cause unnecessary removal of tooth structure that weakens the remaining crown and ultimately decreases the long-term prognosis of restoration, and therefore the tooth.

FIGURE 20-16 ***A.*** Example of a mandibular canine shown in labial, mesial, and incisal views. ***B.*** The access preparation can be assessed from a more incisal view and a lingual view. Note that the access is extended lingually to detect a second, usually lingually- located canal.

Perforation

Perforations of the pulp chamber may appear on the pulp chamber floor as a result of improper search for root canal orifices. In severely calcified teeth, the pulp chamber sometimes is extremely narrow and forced preparation may result in missing the pulp chamber space and perforation of the pulp chamber floor. Second reason for perforation can be incorrect angled introduction of a bur resulting in lateral perforations, mostly at the mesial or distal aspect of the crown. When in doubt, the access cavity can be prepared before placement of the dental dam, thus allowing orientation at the neighbouring teeth.

Preparation of the Pulp Chamber

Following removal of the pulp chamber's roof, the chamber itself should be cleaned meticulously from all necrotic or vital tissue. Preparation should be extended to a degree allowing complete removal of all tissue remnants even from minor undercuts. It should be noted that in a tooth with a necrotic, infected pulp the majority of microorganisms are located in the pulp chamber. Instrumenting a root canal through a contaminated pulp chamber will force microorganisms further into the root canal and transport them apically. Mechanical cleaning can be done using rose burs, and ultrasonic or sonic instruments (i.e., SonicFlex, KaVo). The pulp chamber is repeatedly flooded with copious amounts of sodium hypochlorite thus initiating disinfection of the endodontic cavity immediately upon starting treatment.

Preparation of the pulp chamber is complete when a completely clean coronal access cavity is achieved. The pulp chamber floor should be completely free from any remnants of hard or soft tissue.

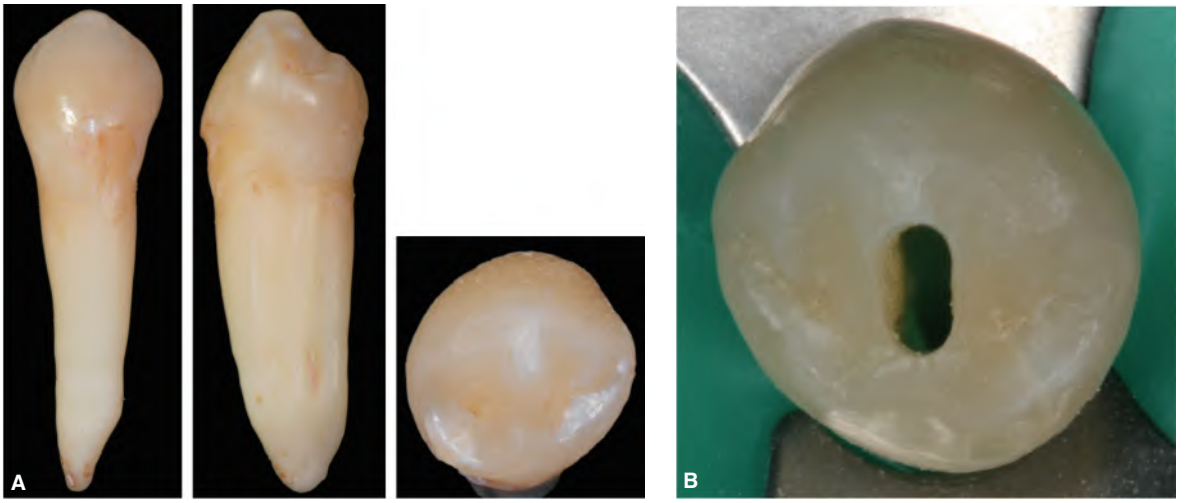

FIGURE 20-17 ***A.*** Example of a mandibular first premolar shown in buccal, mesial, and occlusal views. ***B.*** The access preparation can be assessed from an occlusal view.

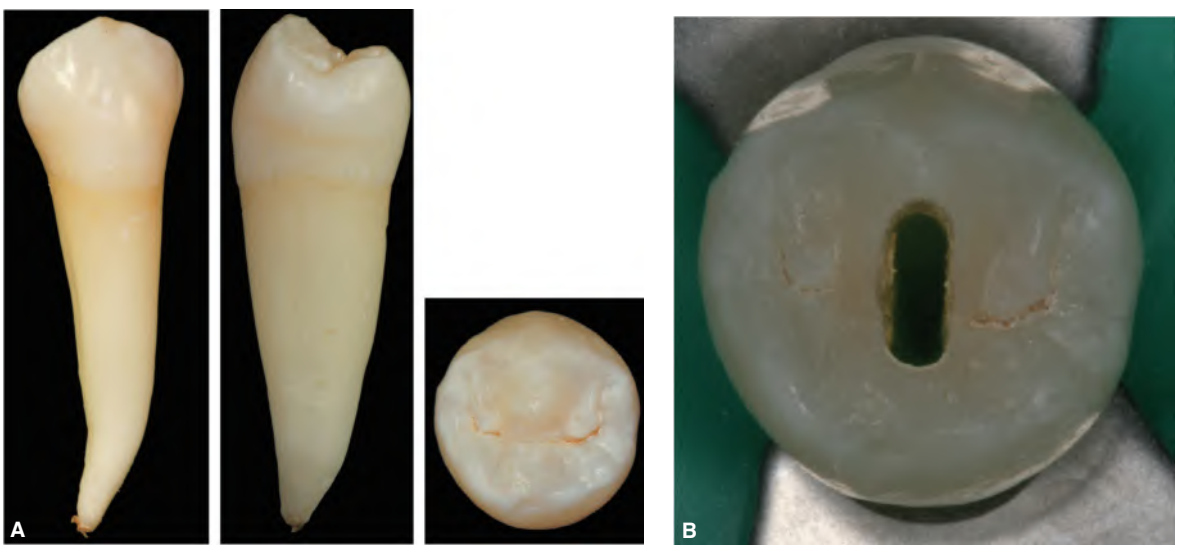

FIGURE 20-18 ***A.*** Example of a mandibular second premolar shown in buccal, mesial, and occlusal views. ***B.*** The access preparation can be assessed from an occlusal view.

Following proper irrigation and drying, the pulp chamber should be thoroughly inspected, preferably by a dental operating microscope or loupes, with proper illumination and magnification (Figures 20-20).[27,28]

Pulp chamber inspection should look for the following:

- Remnants of vital or necrotic soft tissue.
- Remnants of filling materials (amalgam, gold or ceramic particles, cement).
- Caries.
- Secondary and tertiary dentin.
- Perforations.
- Fractures, cracks, and craze lines.
- Calcifications.
- Pulp stones.
- Root canal orifices.

Pulp Stones and Coronal Calcifications

Calcifications and pulp stones may present a challenge even for an experienced clinician since they can cause difficulties to locate and prepare all root canal orifices.[2,29]

Sometimes, larger pulp stones can be identified on radiographs, especially on bitewing or single tooth radiographs. Detection and identification of pulp stones can be best achieved with enhanced illumination (and magnification) of a meticulously dried pulp chamber, as the color and structure of pulp stones are different from that of dentin. Pulp stones show a round or oval form, no sharp contours, and a yellowish, slightly transparent, amber-like color.

The ease and technique of removal depend on the size and type of the pulp stone. If lightly attached to the dentin, pulp stones can often be chipped away using a dental probe or an

FIGURE 20-19 A. Access preparation in a mandibular molar with severe root curvature. B. Hand files can be placed to length in all three mesial canals after adequate access and canal preparation. C. However, the access preparation requires an extreme extension for the mesiobuccal and mesiolingual canals due to the root curvature.

ultrasonic tip. If firmly attached to the dentin, the use of a bur or a diamond-coated ultrasonic or sonic tips is advantageous (Figure 20-21).

It should be noted that pulp stones may be associated with certain systemic diseases such as renal problems or coronary heart diseases, or with consumption of certain medications.[30-32]

Coronal calcifications and constant narrowing of the pulp chamber are a result of deposition of secondary and sometimes also tertiary dentin. Calcification can be accelerated in the presence of active caries, stimulating dentin secretion by odontoblasts, and has been detected in more than 90% of patients older than 40 years.[33] Calcifications can be identified by color and texture following thorough drying of the pulp chamber; enhanced magnification and illumination again are helpful. Small instruments such as pathfinding files and similar files (see later: pathfinding instruments) will facilitate bypassing of pulp stones and locating orifices in calcified pulp chambers.

Complete canal calcification is the exception and can be detected following dental trauma. Otherwise, clacification is usually incomplete and limited to the coronal part(s) of the root canal. Calcification is incomplete if:

- A canal space can be detected on the radiograph.
- The tip of a file is engaging inside the canal.[34]

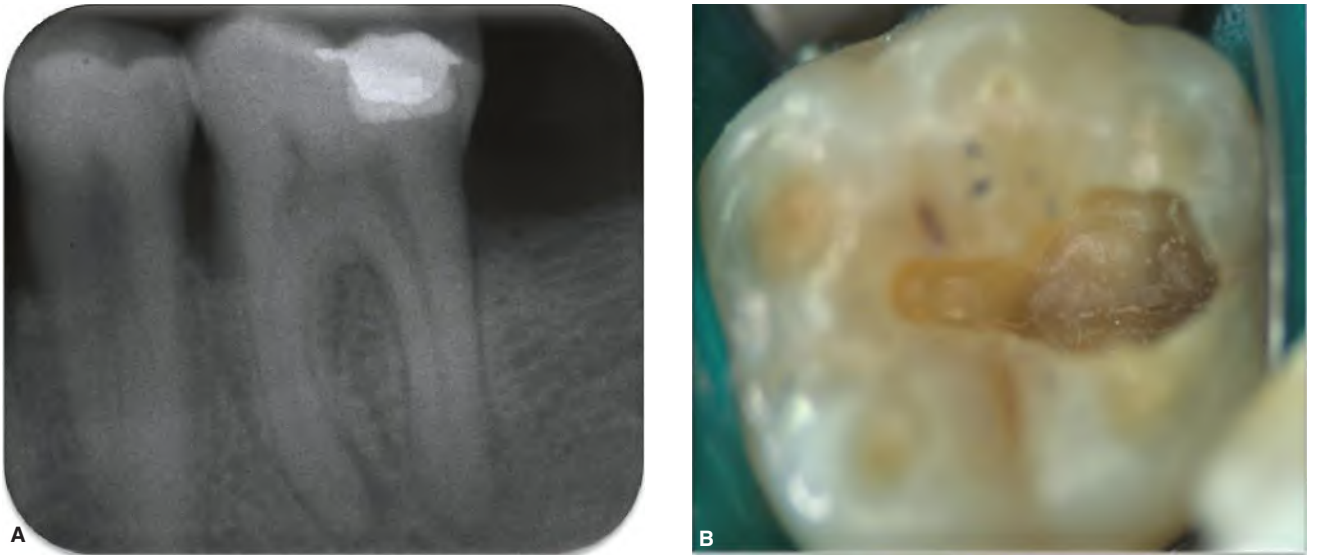

FIGURE 20-20 ***A & B.*** Intracoronal diagnostics. Following removal of the restoration the etiology for pulp necrosis could be identified (i.e., a crack in the pulp chamber's roof).

- Electronic determination of root canal length reveals a signal.
- An apical lesion is present.
- Bubbles can be observed evading from an irrigated root canal (see later).
- Pain upon instrumentation occurs.

Although present, an extremely calcified root canal sometimes cannot be instrumented to sufficient length, due to sharp curvatures or too narrow a diameter of the canal lumen. It has been demonstrated, on extracted teeth, that a patent root canal was present in all teeth with apical lesions but only in 1 out of 14 root canals without apical pathosis[35] (Figure 20-22). In 11 of 12 teeth presenting with apical periodontitis that could not be instrumented to the apical foramen and radiographically did not show a visible root canal, the presence of a root canal could be demonstrated with a contrast medium.[35] A reduced success rate for teeth with non-penetrable root canals was reported only when a preoperative apical lesions was present (97.9% success without lesion; 62.5% with lesion).[36] In a clinical study on 57 cases (114 paired teeth: one tooth with penetrable root canal and one tooth with a non-penetrable root canal), teeth with penetrable canals showed a success rate of 94.7% one year postoperatively.[37] Teeth that could not be instrumented to the foramen showed a success rate of 75.4%. Non-penetrable teeth with an apical lesion showed a 4.8 higher odds of treatment failure.[37]

Identification of Root Canal Orifices

It has been demonstrated that missed root canals contribute to endodontic failures.[38] Several techniques, instruments, and strategies for detection of root canal orifices as well as some basic anatomic rules have been described in the endodontic literature.[39,40]

Anatomic Rules

Krasner and Rankow[40] described some patterns in orifice location, pulp chamber size and shape, and hard tissue color and shape:

Law of Centrality: The floor of the pulp chamber is always located in the center of the tooth at the level of the Cemento Enamel Junction (CEJ).

Law of Concentricity: The walls of the pulp chamber are always concentric to the external surface of the tooth at the level of the CEJ, that is, the external root surface anatomy reflects the internal pulp chamber anatomy.

Law of the CEJ: The distance from the external surface of the clinical crown to the wall of the pulp chamber is the same throughout the circumference of the tooth at the level of the CEJ. The CEJ is the most consistent repeatable landmark for locating the position of the pulp chamber.

Laws of Symmetry:

1. Except for the maxillary molars, the orifices of the canals are equidistant from a line drawn in a mesial–distal direction, through the pulp chamber floor.
2. Except for the maxillary molars, the orifices of the canals lie on a line perpendicular to a line drawn in a mesial–distal direction across the center of the floor of the pulp chamber.

Law of Color Change: The color of the pulp chamber floor is always darker than the walls.

Laws of Orifice Location:

1. The orifices of the root canals are always located at the junction of the walls and the floor.
2. The orifices of the root canals are located at the angles in the floor–wall junction.
3. The orifices of the root canals are located at the terminus of the root developmental fusion lines.

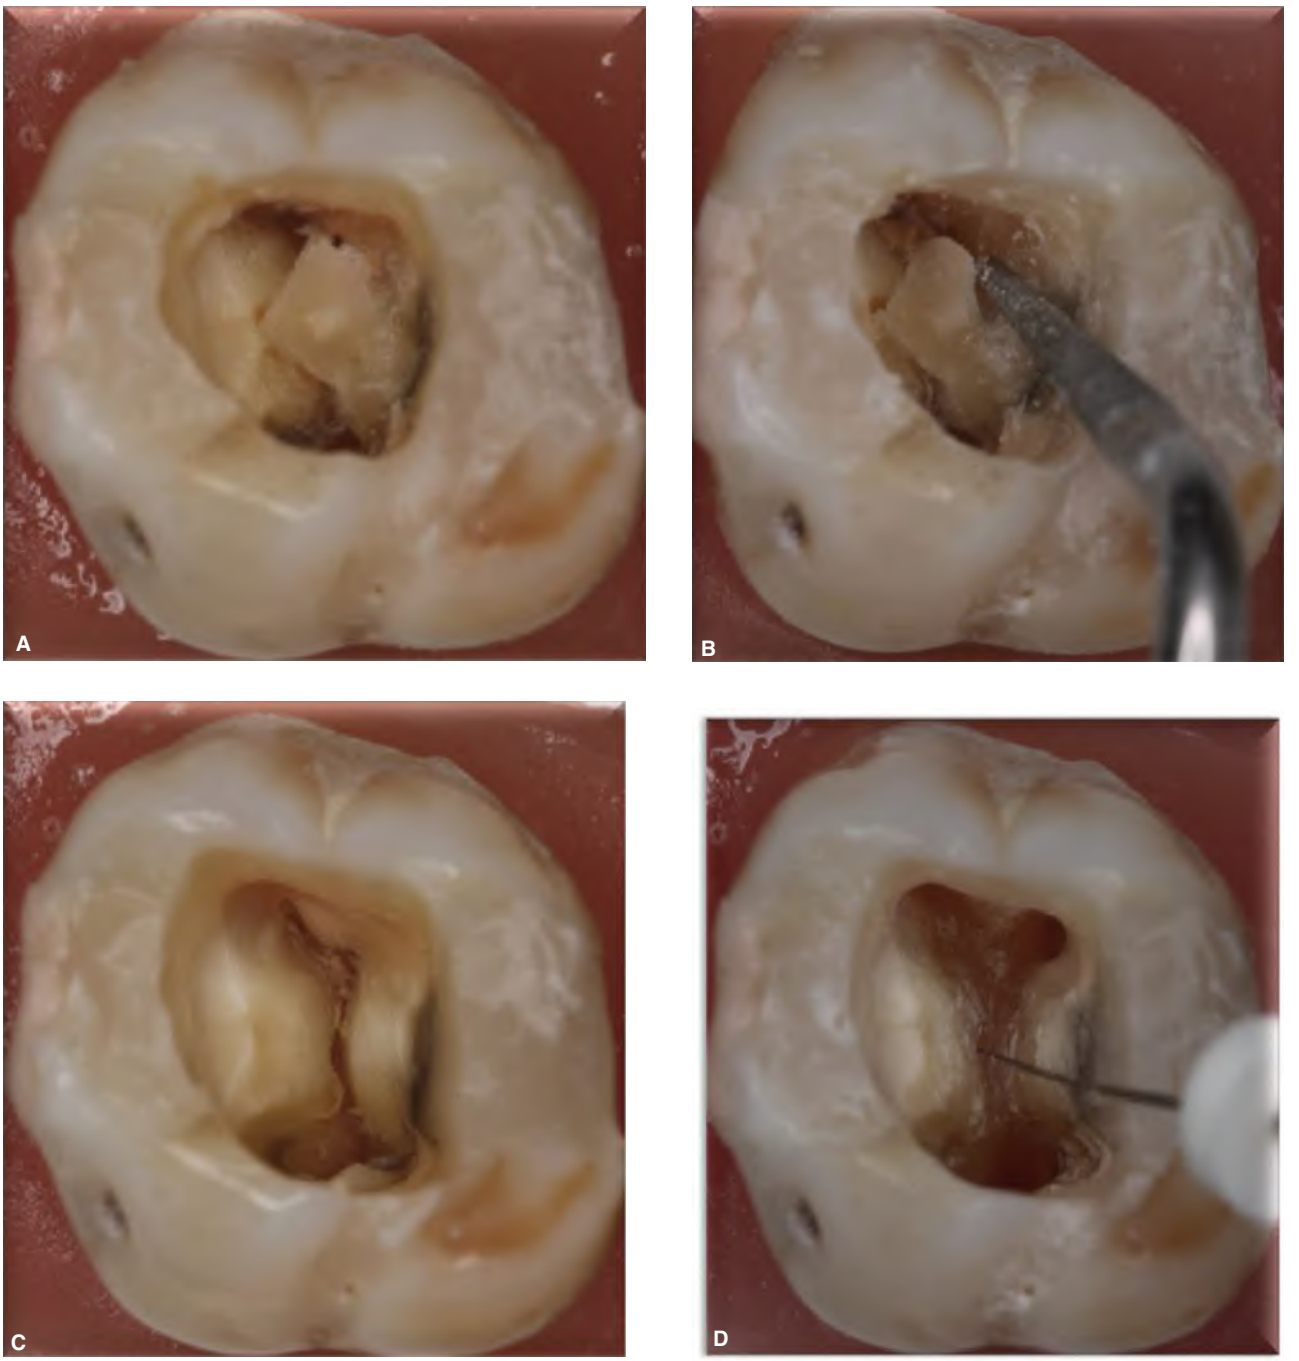

FIGURE 20-21 ***A.*** A large pulp stone blocks the pulp chamber. ***B.*** Removal of the pulp stone. ***C.*** Preparation of the pulp chamber floor and localization of the root canal orifices. ***D.*** Detection of an MB-2 canal.

As the external root surface is a reliable guide, it can be quite frustrating to place a dental dam that completely obscures it. Therefore, in difficult cases, it is prudent to prepare the initial access shape and locate the pulp chamber or at least one orifice prior to dental dam placement.

Key principle: A tooth has only one root canal if no second one can be detected!

Techniques and Devices

Dental Explorer

Using a small and sharp endodontic explorer, all irregularities and grooves on the pulp chamber floor should be probed. Sharp and stiff endodontic files can also be used. Additionally, debris can be accumulated on the pulp chamber floor clogging canal orifices. Chipping away the dentinal shavings with explorers or endodontic instruments can disclose the orifice.

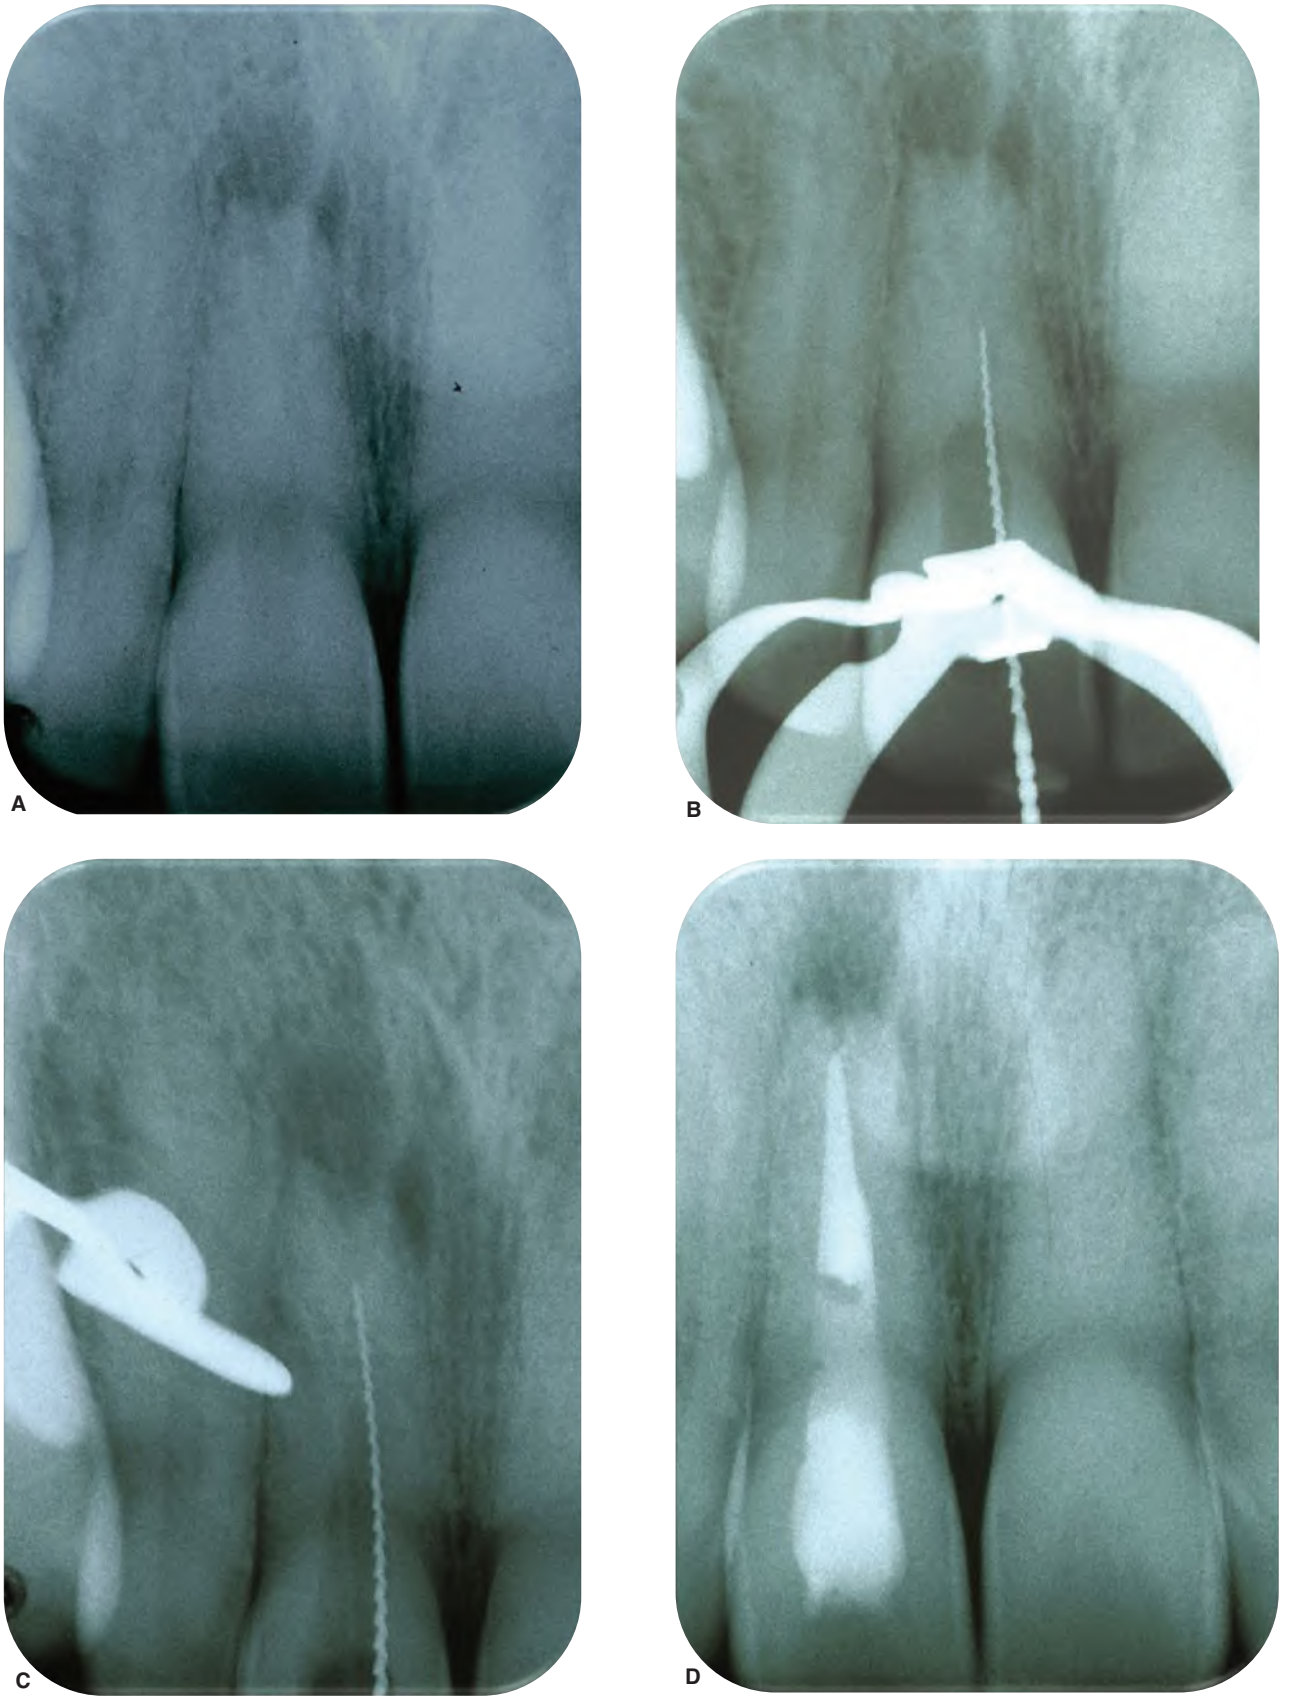

FIGURE 20-22 ***A-D.*** Radiographically calcified root canal system in a tooth with periapical pathosis that was difficult to negotiate.

Dyes

Dyes such as erythrosine (caries detector) or methylene blue can be used. After application of the dye, the cavity is washed out and searched for traces of remaining dye that may indicate the location of a previously undetected orifice.

Sodium Hypochlorite

A drop of sodium hypochlorite is applied to the access cavity floor and observed under magnification and illumination for bubbles evading from a hidden root canal (champagne test). The bubbles are a result of disintegration of remaining pulpal tissue induced by the sodium hypochlorire.

Preparation of the Secondary Access Cavity (Root Canal Orifices)

Coronal Flaring

Coronal flaring should always be done as the first step of canal preparation. Nevertheless, the following should be considered when planning the extent of the coronal flaring:

Key principle: Preparation of the secondary access cavity should never be initiated before preparation of the primary access and cleaning of the pulp chamber are completed.

- A wide orifice facilitates easy insertion of instruments and irrigants and allows large amounts of irrigant to be introduced into the endodontic space
- A wide and deeply flared root canal reduces friction of the instruments and thereby reduces the risk of instrument fracture. Reduced friction allows for better control of the instrument, improves tactility, and allows more precise manipulations of the files in the apical part of the root canal. If an instrument has too much coronal friction, it is difficult or even impossible to direct it apically, as the friction will dictate the extent and direction of the apical preparation.
- Flaring outside of the curvature can reduce the degree of the curvature and facilitate further preparation of the middle and apical thirds of the canal (Figure 20-23).

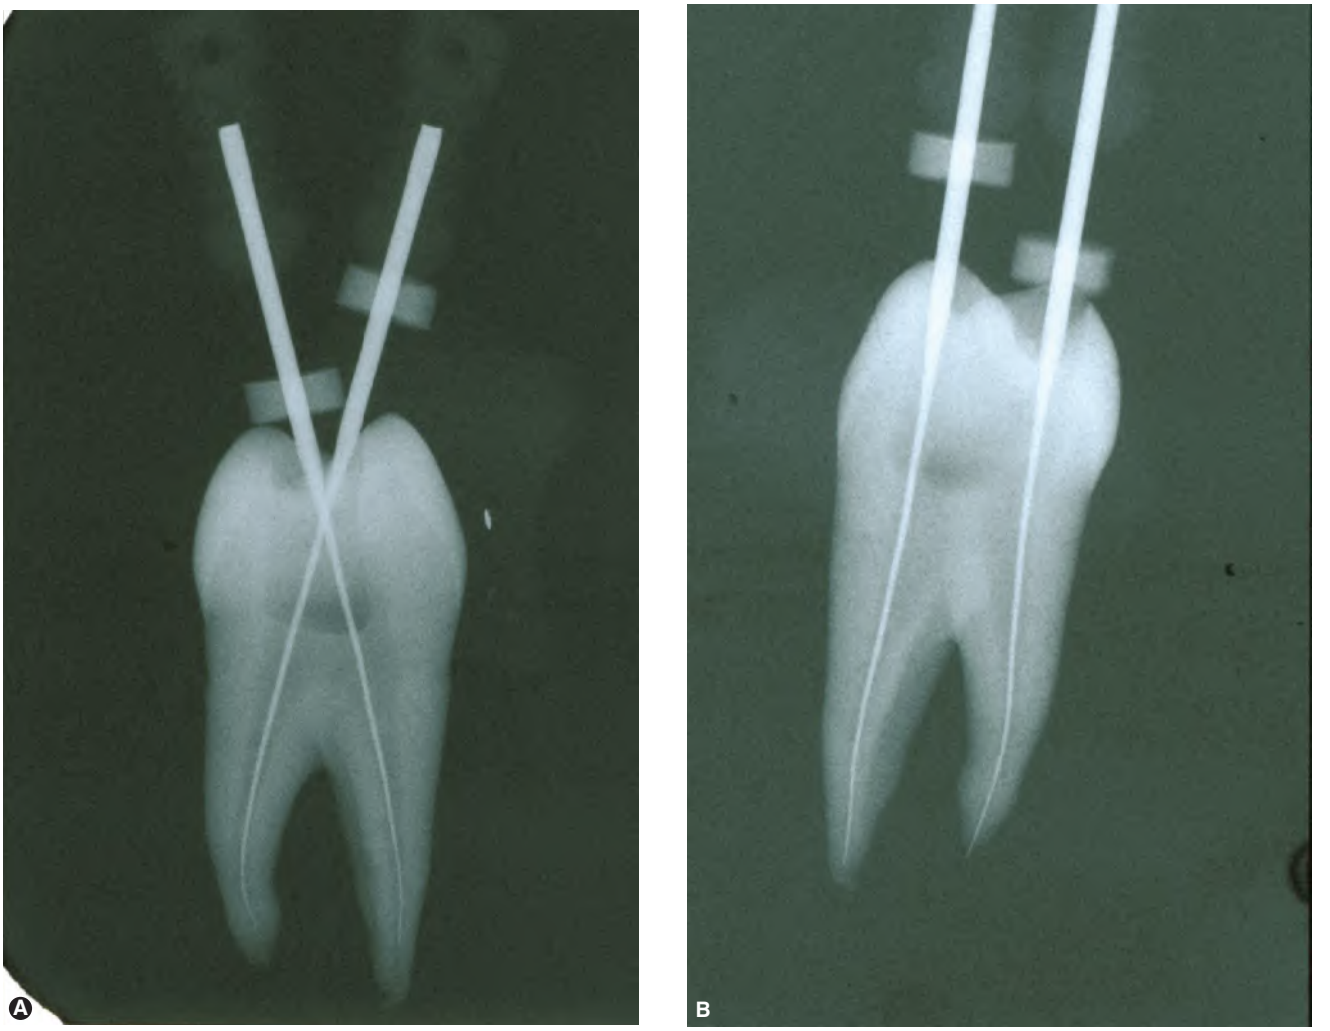

FIGURE 20-23 ***A & B.*** Coronal flaring reduces the degree and length of the curvature and increases the radius thereby reducing the difficulty of preparation.

- On the other hand, a narrow and conservative enlargement of the orifice will save dentinal hard tissue and increase stability and fracture resistance of the root. In molar teeth, the risk of perforation or strip perforation is reduced.

Presently, there are no uniform criteria for the optimal shape preparation of the orifice.

Objectives

Coronal flaring has the following objectives:

- Facilitates insertion of instrument without coronal interferences.
- Improves straight-line access to the middle and apical parts of the root canal.
- Removes reparative dentin at the root canal orifice
- Reduces angle and increases the radius of the root canal curvature.
- Allows early application of sufficient amounts of irrigant into the canal.

Instruments for Coronal Flaring

Gates-Glidden

Gates Glidden (GG) drills are made of stainless steel and are designed with a non-cutting tip. They are also available as NiTi-instruments.

GG are available in six sizes and are rotated in a handpiece at approximately 1000 r.p.m. (manufacturer's recommendation), but frequently are used at higher speed (up to 8000 r.p.m.). GG is safe, relatively inexpensive and effective for root canal preparation. However, it is not intended to prepare the entire root canal. Due to its inflexible shaft, GG cannot bypass a curvature, limiting its action to the coronal straight part of the root canal. GG is an excellent instrument to remove calcifications frequently found just below the orifices of the canal (Figure 20-24). The tip of the smallest GG size (No. 1) equals to an ISO size 50.

The number of rotations till fracture has been reported to be up to 2000 and more,[41] making the instrument relatively safe to use. Fracture usually occurs high at the shaft, making removal easy.

Using larger sizes of GG carry the risk of perforation at the furcal area of the root canal. Crown-down preparation techniques and anticurvature preparation are recommended.[42,43]

The use of GG has been reported to shorten working time and results in better-shaped root canals.[44] When used, the external temperature of the root may rise by 3°C-5°C, depending on dentin thickness, working time, pressure, size of the drill, and rotational speed.[45] This temperature increase is within tolerable levels of the periodontal ligament.

Drux Burs

Drux burs are designed similarly to the GG burs, but have a flexible shaft (Figure 20-25).

Peeso Drills

Peeso drills are designed similarily to the GG but have a longer cutting part. This makes their use in curved root canals hazardous due to the high risk of strip perforations. Today, Peeso drills are not recommended for routine endodontic use.

Orifice Openers

Some rotary NiTi systems are equipped with Orifice Shapers, Intro-Files, or similar instruments. These instruments usually have large tapers and short shafts. Examples are:

- IntroFile (FlexMaster, VDW, Munich, Germany): 12 mm cutting part, 11% taper, non-cutting tip.
- Orifice Opener (ProTaper U, Maillefer, Ballaigues, Switzerland) 14 mm cutting part with 19% taper at the tip decreasing to 3.5% at 9 mm, non-cutting tip.

Preparation of a Glide Path

Contemporary preparation techniques using flexible NiTi instruments start with manual preparation of a glide path for the rotary instruments that follow. The introduction of reciprocal preparation systems, questions the need of a glide path, however, further research is necessary.[46,47]

Objectives

The objectives of preparing a glide path are:

- Early exploration of the root canal system to be prepared.
- Assessment of canal width, content, curvatures, and ledges.
- Reduction of friction of small NiTi instruments thereby lowering the risk of instrument separation.

Pathfinding Instruments

Conventional ISO size instruments, independent of the alloy used, possess a low resistance to buckling. When these instruments are used to penetrate narrow canals they are submitted to a load parallel to their long axis. As a result, instruments with a low resistance to buckling deform easily and their progression towards the apex is hindered. Therefore, it is of clinical importance that special instruments exhibit sufficient resistance to buckling when used for the initial negation of narrow root canals. Thus, these instruments must be resistant to a vertically applied load.

On the basis of these considerations, special stainless steel pathfinding instruments (pilot instruments) for manual use were introduced to improve negotiation of narrow and calcified canals. These instruments are characterized by design features that improve their buckling resistance.[48] Some instruments are heat tempered and their length is reduced to 18 mm or 19 mm, so that more vertical pressure can be used to negotiate calcified

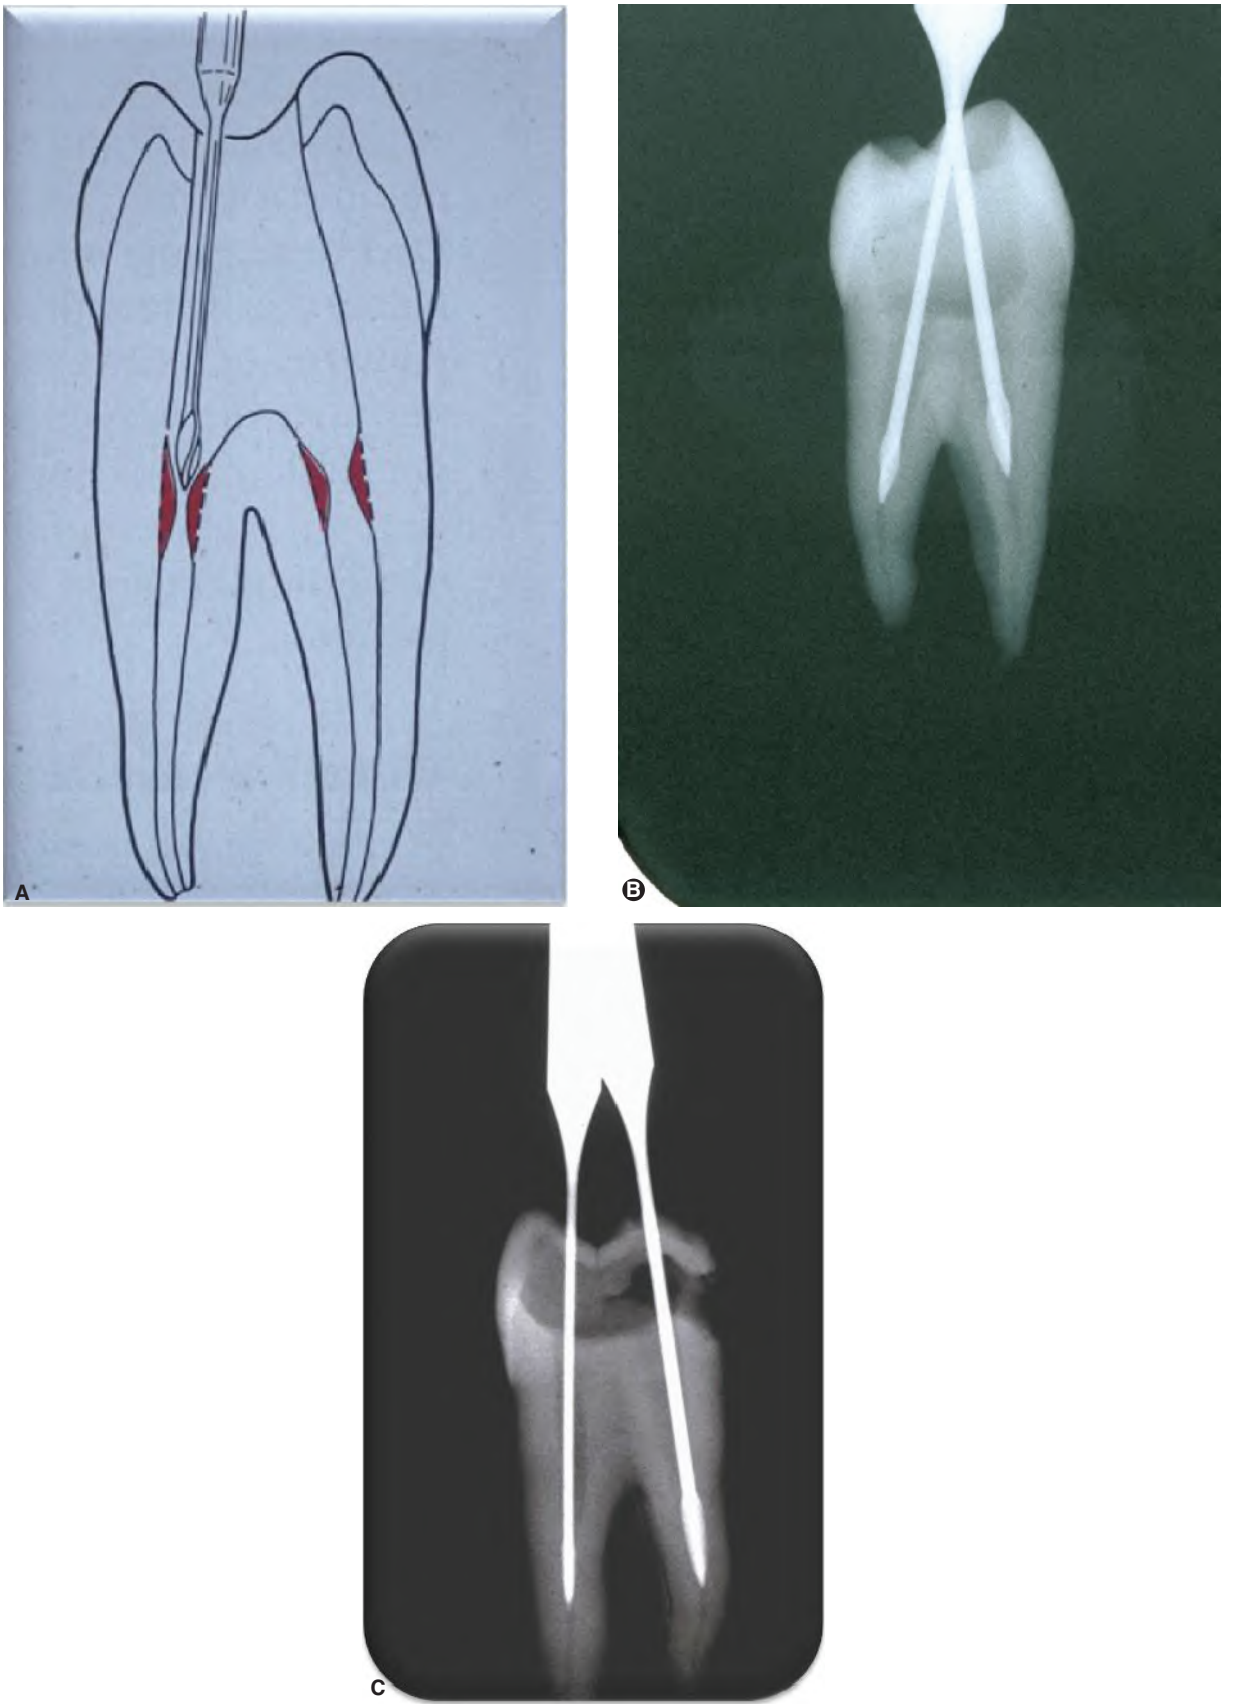

FIGURE 20-24 ***A-C.*** Removal of secondary dentin below the root canal orifice can accelerate and facilitate root canal preparation. Gates Glidden burs can be used safely upto the beginning of the curve.

Scout RaCe (FKG, La-Chaux-de-Fonds, Switzerland)
G-files (MicroMega, Besancon, France)
PathFiles (Dentsply/Maillefer, Ballaigues, Switzerland)
ProGlider (Dentsply/Maillefer, Ballaigues, Switzerland)
PathGlider (Komet, Lemgo, Germany)

canals.[49] The tip design is modified and less angled than the ISO tip (ProFinder with a 65° tip) to improve negotiation of narrow canal orifices. Some instruments are available with intermediate sizes (e.g., sizes 12.5, 13, 17). The conicity of the ProFinder is less than the ISO standard (1.75% at the tip) and decreases over the working part.

A comparative study revealed that the stainless steel pathfinding instruments (C+ and C-Pilot file) were more resistant to buckling than NiTi pathfinding instruments, whereas the C+ files showed significantly better results than the C-Pilot instrument.[50] These pilot instruments possess an excellent tactile feedback and can be pre-bent easily.[51] Therefore, they are best suited for bypassing ledges at the root canal wall. Normally, ledges are located at the outer side of a curved root canal and when probing a ledge with a hand instrument the feeling is of hitting against a hard structure. In such cases, the stainless steel hand instrument should be pre-bent in such way that that the tip of the instrument can slide along the unchanged inner side of the root canal. Sometimes, the ledge can be bypassed, smoothed or rounded off by moving the instrument gently up and down.[52]

Preparation of a glide path includes initial scouting of the root canal with small and flexible, sometimes non-cutting instruments. A number of different instruments are available for scouting and preparation of a glide path (Table 20-1).

K-files (ISO-sizes 06, 08, 10): K-files ISO-sizes 06, 08, and 10 are regarded as the classical instruments for initial instrumentation of narrow and calcified root canals. They are used in a watchwinding motion with slight apical pressure. Negotiation of a narrow canal can sometimes require discarding several bent instruments before completion.

C-Pilot-Files: C-Pilot-Files are available for use in the sizes 06, 08, 10, 12.5, and 15 each with a 2% taper and a rectangular cross-section. They are manufactured by twisting and special hardening procedures in order to increase their stiffness and prevent early distortion and buckling of the tip, enabling the use of slightly increased apical pressure.

MMC Files: MMC files are available in ISO-sizes 06, 08, 10, and 15 with a 2% taper. They are manufactured from especially hardened stainless steel and show the same geometry as K-files.

S-Finder: The S-Finder instrument is manufactured from stainless steel and shows a geometry and design of a Hedstrom file with two cutting blades and an s-shaped cross-section. The size is ISO 10.

C+-Files: These instruments are by grinding stainless steel wires of a square cross-section. The apical 4 mm show a 4% taper to increase the stiffness of the tip; the coronal part shows a 2% taper to maintain flexibility.

RaCe: For automated preparation of a glide path, RaCe instruments size 10 with three different tapers were designed: .02, .04, and .06. These instruments present a non-cutting safety tip, a triangular cross-section, and alternating conical and parallel cutting areas, preventing a screwing effect. The surface of the instrument is electropolished, resulting in an increased resistance to torsion and fatigue.

Following hand preparation with instruments size 08, as deep as possible without pressure, a RaCe-file .06/10 is introduced one millimeter shorter. Near the apex, an instrument size .04/10 is used, and in severely curved canals a file size .02/10. These RaCe instruments are operated at 800 r.p.m.

G-files: The design of the G-files resembles that of the Revo-NiTi-instruments (Micro-Mega). Two sizes are available: .03/12 and .03/17. They are used following hand instrumentation with a size 10 file. Consequently,

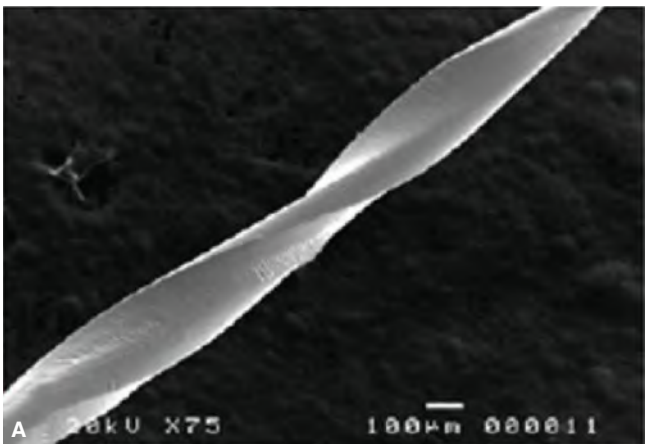
enlargement of the root canal to size 20 is facilitated. The instruments are operated at 400 r.p.m. with a torque of 1.2 N. The tip is rounded and non-cutting and the cross-section is variable across the length of the instrument (Figure 20-26).

PathFiles: PathFiles are available in sizes 13, 16, and 19 with a taper of 2% and a specially designed tip (Figure 20-27).

ProGlider: The instrument size is 016 with a 2% taper at the tip and progressive conicity up to 8.5%. The file is manufactured from M-wire and operated at 300 r.p.m. and a torque of 2 Ncm-5.2 Ncm.)

Summary

- Preparation of a glide path can reduce the incidence of fractures of rotary NiTi instruments, since reduced friction of the instruments is achieved.
- The final size of the glide path depends on the size of the first rotary instrument used for final preparation.



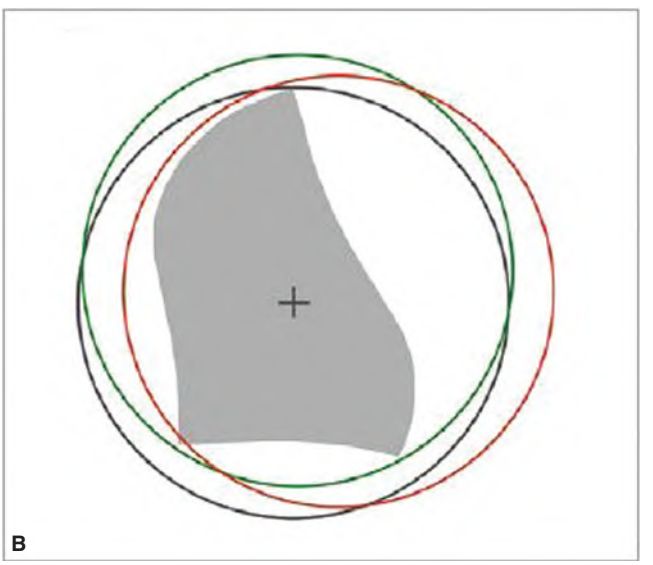


FIGURE 20-26 ***A-B.*** NiTi G-file (MicroMega) with asymmetrical cross-section.

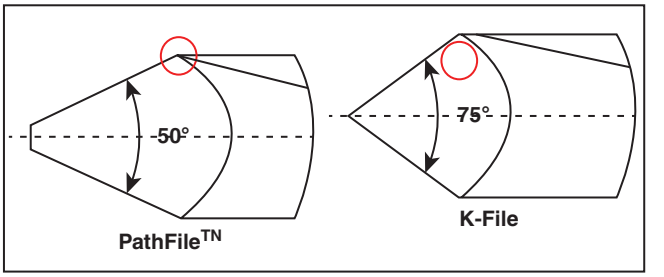

FIGURE 20-27 Differences in tip design of K-Files und PathFiles (Courtesy of Dentsply/Maillefer, Ballaigues, Switzerland.)

- Apical stiffness and high buckling resistance are important parameters for pathfinding files in order to prevent early and frequent buckling of the instrument tip.
- Stainless steel instruments can be used for preparation of the glide path as well as rotary NiTi files. NiTi instruments show slightly better results regarding straightening of curved or double curved root canals.
- Whether preparation of a glide path is mandatory before rotary preparation using NiTi instruments remains controversial.

Instruments for Root Canal Preparation

Hand Instruments

ISO standard 3630-1[53] and the ANSI/ADA Standards No. 28 and No. 58[54,55] specify general requirements of root canal instruments for manual use. These specifications cover design designations, dimensions and taper, resistance to fracture and bending, color coding, alloys, and identification symbols of the different types of instruments. In general, hand root canal instruments can be divided into three types: reamers, K-files and Hedstrom files. Today, the majority of hand root canal instruments are either made of stainless steel or NiTi alloys.

Metallurgy

Until the 1960s root canal instruments were made from *carbon steel* and since then mainly from *stainless steel*.[56] The main disadvantage of these older carbon steel alloys was their considerably low corrosion resistance. Sterilization procedures caused detrimental physical changes and severe corrosion damage.[56]

Stainless steel is considerably more resistant to sterilization hazards. Several studies failed to show any effect of sterilization on torsional and bending properties of stainless steel instruments.[57] Even up to 10 repeated sterilization cycles exerted no negative effect on the cutting efficiency of stainless steel instruments.[56,58]

Another alloy used for hand root canal instruments is *nickel-titanium* consisting of approx. 55% wt nickel and 45% wt titanium.[59,60] Due to the superelasticity of this alloy, NiTi instruments are made by grinding since it is impossible to twist a NiTi blank counterclockwise in order to produce a spiral.[61]

Design Features and Types of Instruments

According to the stipulated standards laid down in the ISO standard all ISO-sized hand instruments possess a constant taper of .02. This means that every millimeter of the cutting part the external instrument diameter increases by 0.02 mm from the tip towards the shank. Hence, engine-driven NiTi instruments with tapers different from the ISO-taper .02 are not covered in the ISO standard and are thus not ISO-sized.

In general, the following design features have a crucial impact on the clinical performance of root canal hand instruments (Figure 20-28):[62,63]

- *Cutting angle*: This angle, also called helical angle, is the angle between the instrument long axis and the tangent to the cutting edge (Figure 20-29).[61,62] The helical angle of instruments used for hand preparation indicates the most efficient working motion of the instrument. Instruments having a helical angle of less than 45° (reamers and K-files) require a rotary reaming working motion to effectively cut dentin, while those having an angle greater than 45° (e.g. Hedstrom files) require a linear filing motion.[61]
- *Tip design*: According to the ISO specification 3630-1, root canal instruments usually possess a sharp, cutting tip.[53] The ridges on the face of a cutting tip enable the tip to cut forward and produce a file-tip shaped cavity, thus creating ledges. Studies indicate that the tip configuration has a crucial impact on the shaping ability of root canal instruments. Currently, there is clear evidence, that independent of the alloy, instruments with modified non-cutting tips perform better in maintaining the original canal curvature than those having a conventional cutting tip.[64,65] These non-cutting tips are characterized by a reduction of the tip, transition angle and the incorporation of a guiding plane (Figure 20-30).[303,66] Instruments having non-cutting tips cause less canal transportation and remove material more equally at the inner and outer aspects of the curved canal compared to similar instruments having conventional tips.[67,68]
- *Pitch*: This is the distance between the edges of two cutting blades measured along the working part of an instrument (Figure 20-29).[62,69] The smaller the pitch, the greater the contact area between the instrument and the root canal walls, thereby increasing the torsional stress of the instrument.[62] The pitch may be regressive, continuous, or progressive.[21] Normally, hand instruments possess a continuous pitch. Only some Hedstrom files (e.g., those manufactured by VDW, Munich, Germany) have a progressive pitch length.
- *Configuration of cutting edges*: The cross-section of any root canal instrument determines the relevant cutting

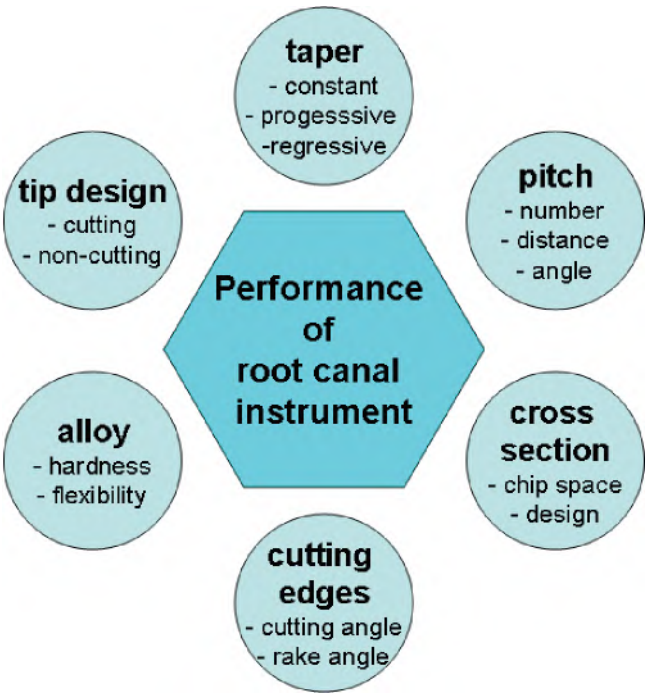

FIGURE 20-28 Factors affecting the performance of root canal instruments.

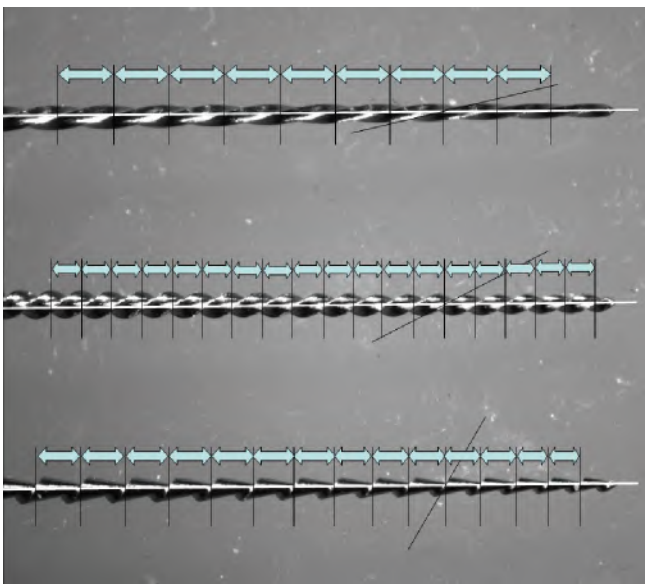

FIGURE 20-29 Helical angle of reamer, K-file and Hedstrom file with their pitch distance.

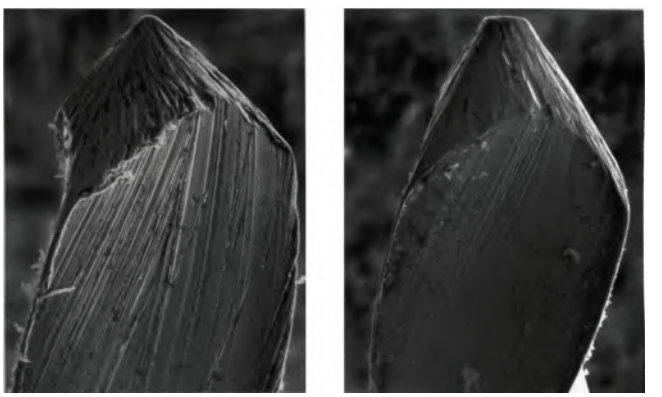

FIGURE 20-30 Scanning electron microscopy image of different tip designs. Left- conventional cutting tip; Right- modified non-cutting tip.

angles that are wedge angle, angle of cutting, clearance angle, and rake angle (Figure 20-31). Very small modifications of the cross-sectional shape may have serious consequences on instrumentation behavior. The wedge angle determines the strength of the cutting blades of the instrument. The greater the wedge angle the stronger the blade.[63] The clearance angle has an impact on the amount of the frictional force arising during the cutting process.[62] The smaller the clearance angle the less is the cutting efficiency. The sum of the wedge and clearance angle build the angle of cutting.[62] The rake angle is the angle between the cutting edge of the instrument and a perpendicular to the root canal surface at the point the cutting edge touches the canal wall.[62] The rake angle may be positive, negative, or neutral (nearly equal to the perpendicular). Instruments with a positive rake angle cut dentin very effectively by creating dentin chips.[62] A positive rake angle reduces the cutting forces. In general, Hedstrom files are characterized by a positive rake angle. However, nearly all root canal instruments requiring a rotary reaming working motion have a negative rake angle, such as reamers, K-file, and rotary NiTi instruments. Although a negative rake angle makes these instruments less effective they can be better controlled inside the root canal as their tendency to penetrate deeper into the root canal dentin is reduced (aka screw-in effect) compared to instruments having positive rake angles.[62] Moreover, a negative rake angle increases the strength and the wear resistance (longevity) of the cutting edges.

- *Chip space*: This is the difference between the area of the canal lumen and the area of the cross-section of the particular instrument used. The chip space is directly related to the cutting efficiency of any root canal instrument and its cleaning effectiveness. Simply stated, the greater the chip space the more efficient is the instrument in transporting dentin and debris out of the canal.[63,69] The greater the chip space, the smaller the cross-section of any instrument and the smaller the cross-section the greater the flexibility of the instrument.
- *Core diameter*: The core diameter of any root canal instrument affects its flexibility as well as its resistance to fracture.[61] A greater core diameter is associated with an increased resistance to fracture but at the same time with a decreased flexibility. The core diameter depends on the cross-sectional shape of the instrument. For hand instruments, the core diameter decreases from square, to triangular and further to S-shaped cross-sections. Usually, reamers, K-files and S-files are symmetrical in cross-section, while Hedstrom files are characterized by an asymmetrical cross-section.
- *Taper (conicity)*: The taper of ISO-sized hand instruments is .02 (or 2%). From the tip to the end of the working part, the diameter of the instruments increases by 0.02 mm every millimeter.[52] The taper may be regressive, continuous, or progressive.[62,70] The more tapered the instrument is, the faster the core diameter increases resulting in reduced flexibility.[70]

Reamers

Reamers are made from square or triangular blanks depending on manufacturer and ISO size.[61] In general, smaller sizes are made from square blanks to increase their core diameter thereby increasing the resistance to fracture. On the other hand, reamers of greater sizes are made from triangular blanks to increase their flexibility as the core diameter of a triangular blank is smaller than that of a square bank. Reamers made from stainless steel are twisted to give the working part of the instrument a spiral form. This is of clinical relevance as twisted instruments are *per se* more resistant to fracture than milled instruments, as the integrity of the blanks will not be damaged.[61]

Reamers have ½ to 1 cutting blades per millimeter in their working part, thus the number of cutting blades is less in the reamer than in the K-file (Figure 20-32).[61] This spiral form of the working part results in blade angles of 10° to 30°

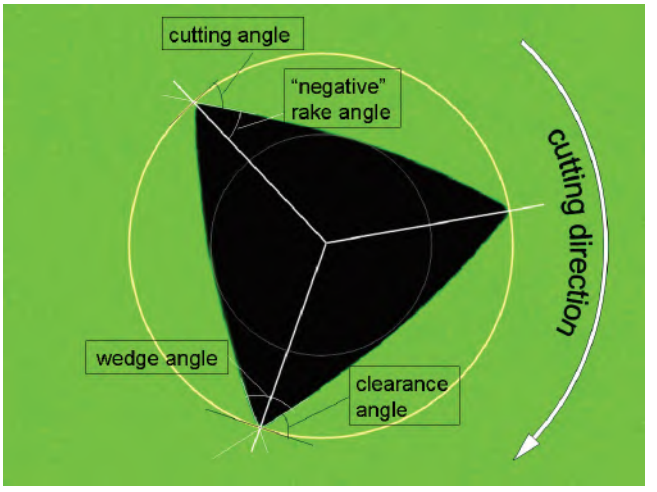

FIGURE 20-31 Cross sectional parameters illustrating the configuration of cutting edges.

FIGURE 20-32 Scanning electron microscopy image of a reamer (left) and K-file (right) showing that the K-file has more cutting blades per millimeter of the working part.

relative to the long axis (Figure 20-29).[61] Due to this angle configuration, reamers are primarily designed to be used in a reaming working motion.[61] They cut dentin by being inserted into the canal, twisted about one-quarter turn clockwise to engage their blades into the dentin, and then withdrawn.[61]

K-Files

K-files made from stainless steel are twisted instruments just like reamers. They are also made from square or triangular blanks, depending on their ISO size and manufacturer.[61] Compared to reamers, K-files show 1½ to 2½ cutting blades per millimeter of their working part, thus there are about twice the number of spirals on a K-file as on a reamer of a corresponding size.[61] The tighter spirals of a K-file establish cutting angles, greater than those of reamers. The cutting angle of K-files is about 25° to 40° (Figure 20-29), hence these instruments are, like reamers, primarily designed to be used in a rotary reaming motion.[61]

It is worth mentioning that although the term "K-files" implies that these instruments should be used in a filing working motion, however, they are by far more efficient when used according to their cutting angle in a rotary reaming motion. The term "file" denotes a cutting instrument that removes substrate by back-and-forth (linear) motions along the surface of the substrate.[62] Thus, the term "file" is incorrectly coined for this type of instruments.

On average, K-files display a greater resistance to bending than reamers. In most cases, K-files show greater angular deflection than reamers of the same brand.[66,71] The greater resistance to fracture of K-files has a direct clinical impact. The angular deflection provides some information about the susceptibility to fracture of an instrument. Hence, under clinical conditions, the risk of torsional fracture is lower for K-files as compared to reamers.[71]

Hedstrom and S-Files

Independent of the alloy used, the cutting blades of Hedstrom and S-files are milled into a round blank.[61] The flutes of the Hedstrom file constitute a spiral (screw shape) and the cross-section is nearly circular (teardrop cross sectional shape), while S-files possess a sigmoidal cross-section.[61] The flutes of S-files are less deep than those of Hedstrom files and S-files are characterized by two spiral grooves.[61]

The angle between the cutting edges and long axis of the Hedstrom files (cutting angle) is 60° to 65° (Figure 20-33) while that of S-files is generally smaller. Due to their cutting angle, both instruments are designed primarily for a linear (filing) motion.[61] Due to their positive rake angle they cut in one direction only, in a withdrawal stroke. Therefore, these instruments are in fact "files."

The manufacturing milling process of Hedstrom and S-files has two clinically relevant implications: (1) As Hedstrom and S-files are milled from circular cross-sectioned blanks, they have sharp cutting edges.[61] Used in linear back-and-forth working motion, they are by far more efficient than reamers or K-files as they cut away more root canal dentin per time unit than K-files.[72] Out of all the hand instruments designed to be used in a linear filing motion, Hedstrom files displayed the best cutting efficiency. The helical angle of Hedstrom files appears closer to 90° than that of S-files and this may explain the superior cutting efficiency of Hedstrom files in linear motion.[70,73] (2) Due to the manufacturing milling process, grinding cracks may result on the surface of the instrument. This fact, together with the relatively low core diameter of Hedstrom and S-files, explains why these instruments show an increased risk of torsional fracture compared to reamers or K-files.[71] In general, milled instruments like Hedstrom files are not recommended for use in narrow or curved canals due to their higher risk to fracture.[66]

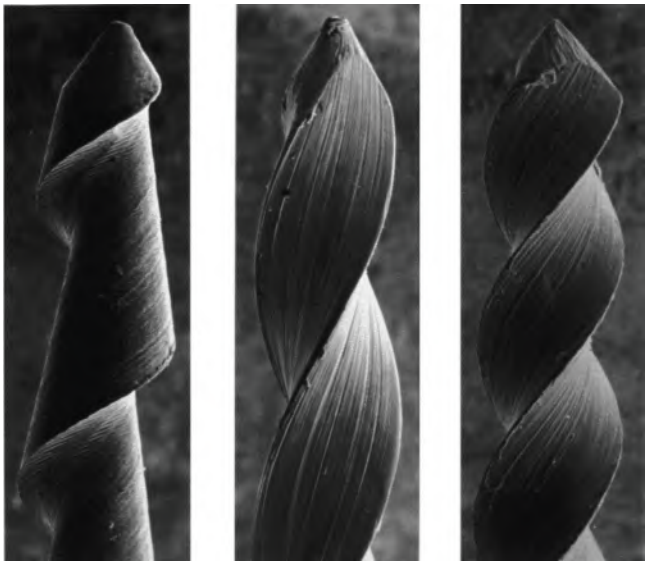

FIGURE 20-33 Scanning electron microscopy image of a Hedstrom file, reamer and K-file (from left to right) showing that the helical angle of the Hedstrom file is considerably greater than those of the reamer and the K-file.

Shaping Ability of Stainless Steel Hand Instruments

Reamers used in a reaming rotary working motion are able to produce a round, tapered preparation, when enlarging straight root canals.[74] However, in curved canals the use of reamers resulted in marked canal transportation, ledge formation and other undesirable deviations from the original path of the canal.[68,75] Currently, the sole use of reamers to prepare root canals is not recommended.[61]

Regarding the shaping ability of K-files, controversial results have been published. While some authors stated that shaping of curved canals with K-files, manipulated in a linear filing motion, resulted in good maintenance of the original canal curvature,[61,75] it was not corroborated by others. One study investigated *in vitro* the ability of K-files used in a linear filing motion to shape simulated curved canals in resin blocks.[76] K-files created pronounced zips and elbows and removed an excessive amount of resin from the outer aspect of the canal curves. These findings are in agreement with those obtained in another study that used extracted human molars.[77] Again, the use of K-files

was associated with marked canal transportation and procedural errors.[77]

Jungmann et al.[78] assessed the shaping ability of K-files when used in a reaming and linear filing motions. Results revealed that canal enlargement using a rotary reaming working motion proved to be better than a linear filing motion. In contrast, other authors stated that using K-files in a rotational cutting action was associated with distinct canal transportation.[68] Therefore, the combined use of these two types of instruments appears to be an effective technique for preparation of curved root canals.[74,79]

Clinically, the main advantage of reamers and K-files is that they can easily be pre-bent. Therefore, these stainless steel instruments are best suited for initial scouting of the root canal prior to full canal instrumentation. NiTi hand instruments are not suitable for probing and scouting due to their superelasticity and increased flexibility and since they cannot be adequately pre-bent.[80] Pre-bent reamers and K-files can be used for passive probing of the canal when used in a gentle watch-winding motion, thereby delivering sufficient tactile feedback. This tactile feedback is of clinical relevance since possible blockages of the canal (root canal branches or calcifications) can be assessed as well as the width of the canal lumen and the consistency of its contents. It is recommended that initial canal scouting and establishment of a glide path should be performed prior to canal preparation with engine-driven NiTi instruments, in order to reduce separation rate of engine-driven instruments.[81,82]

The shaping ability of Hedstrom files when used in curved root canals is controversial. While according to one study the use of pre-bent Hedstrom files resulted in good maintenance of the original canal curvature,[83] other authors recommended that Hedstrom files should not be used in the apical part of curved root canals.[76,84] This recommendation is based on the observation that in curved canals the filing motion of Hedstrom files resulted in a serve straightening of the inner canal wall as well as in excessive material removal on the outer side of the curvature.[76,84] According to extensive investigations conducted by Alodeh et al.[85] and Al-Omari et al.[84] these instruments created numerous procedural errors. Zip and elbow formations, as well as marked loss of working length, occasionally even complete blocking of the canals were common findings.[86]

On the other hand, Hedstrom and S-files are suitable and recommended whenever maximum removal of dentin in a short period of time is desired. From a clinical point of view, these instruments can be recommended for the preparation of straight root canals (occurring in 10% of cases[87]) or for initial conical enlargement of the coronal part of the canal.[61] Moreover, the use of hand Hedstrom files is beneficial following rotary NiTi preparation of root canals having an oval cross-section, or of canals with extensive isthmuses, Preparation of lateral canal extensions using either NiTi hand or engine-driven instruments is not satisfactory as these instruments are too flexible and cannot be properly directed into the extensions of the canal lumen (Figure 20-34).[80] These extensions can be easily cleaned and shaped using stainless steel Hedstrom files applying the circumferential filing technique.[88]

Flexible Stainless Steel Root Canal Instruments

Due to the unsatisfactory shaping results obtained with conventional stainless steel reamers and K-files, further developments led to the introduction of flexible stainless steel instruments characterized by higher flexibility while bending.[89,90] These instruments are similar in shape to conventional reamers and K-files but possess markedly improved properties.[85] Well-known representatives of these flexible stainless steel instruments are the Flexoreamer and the K-Flexofile (both manufactured by Dentsply/Maillefer, Ballaigues, Switzerland).

The Flexoreamer and the K-Flexofile, both having a non-cutting Batt-tip, are twisted instruments (Figure 20-35). When used in rotary reaming motion, the K-Flexofile and

FIGURE 20-34 Cross-section of a root canal showing that the extensions were not adequately cleaned and shaped.

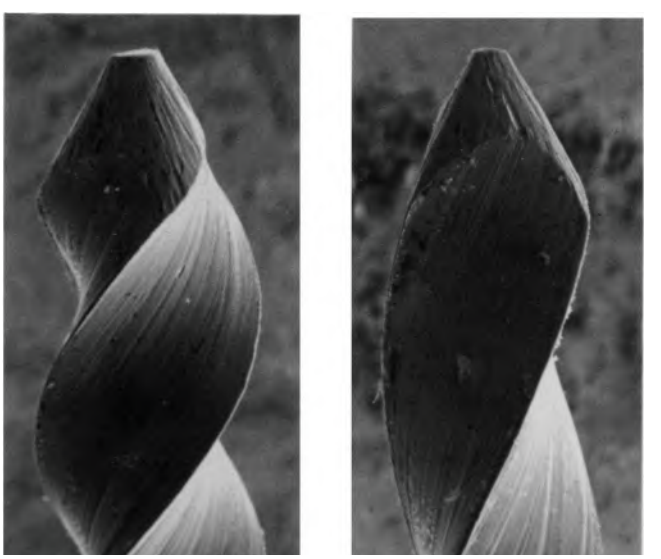

FIGURE 20-35 Scanning electron microscopy image of the flexible stainless steel Flexoreamer (left) and K-Flexofile, both having a non-cutting tip.

the Flexoreamer displayed the highest cutting efficiency of all hand instruments.[71] This increased efficiency can be explained by metallurgical improvements and by the fact that independent of the instrument size, the cross section is triangular, resulting in relatively low core diameters. It is due to the low core diameter that these instruments possess an enhanced flexibility compared to conventional stainless steel instruments.[71] Concerning resistance to fracture, flexible stainless steel instruments displayed less torque than most conventional stainless steel instruments whereas their angular deflection was similar to conventional reamers and K-files.[66,71]

Results of several studies suggested that flexible stainless steel instruments displayed less resistance to bending than conventional stainless steel reamers or K-files.[66,71] This property has a clinical impact since the tendency of flexible stainless steel instruments to straighten themselves in curved canals is much lower compared to conventional stainless steel instruments. There is evidence that these flexible instruments are superior to conventional stainless steel reamers and K-files in maintaining the original canal curvature.[68,83,84] Investigations conducted by Al-Omari et al.[84] demonstrated that shaping of curved canals with flexible instruments appeared to be superior to conventional stainless steel instruments (Figure 20-36).

Nevertheless, despite the decisive improvements associated with these flexible stainless steel instruments with non-cutting tips, satisfactory preparation of severely curved root canals using hand instruments is still challenging. Several studies pointed out that independently of the preparation technique used, even flexible stainless steel instruments with non-cutting tips failed to produce entirely satisfactory results in terms of adequate maintenance of the original curvature of severely curved canals.[68,89] Furthermore, even with these instruments, apical enlargement is limited to relatively small sizes, possibly jeopardizing adequate cleaning and sufficient irrigation of the most apical parts of the root canal.[68,83]

In summary, out of all stainless steel instruments for hand use, flexible stainless steel instruments are the most efficient and best suited to prepare curved root canals.

Nickel-Titanium Root Canal Instruments

Today, nickel-titanium instruments are mainly manufactured from a 55-NiTi-alloy, thus they consist of approx. 55% nickel and 45% titanium by weight.[59] This alloy is extremely flexible and NiTi instruments were shown to have about three times the elastic flexibility in bending and torsion as compared to corresponding stainless steel instruments.[58,69,71,90] NiTi hand instruments are available as reamers, K-files, and Hedstrom files.

The NiTi alloy exhibits superelastic behavior, thus upon unloading following deformation, this alloy returns to its original shape (Figure 20-37).[58,59,91] Superelastic alloys

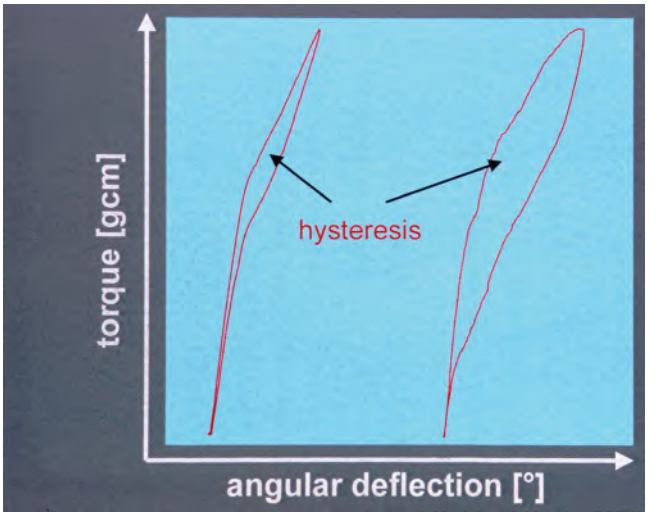

FIGURE 20-37 Nickel-titanium instruments fixed at their tips are rotated clockwise. Upon unloading, the instruments return to their original shape due to the superelastic behavior of the alloy.

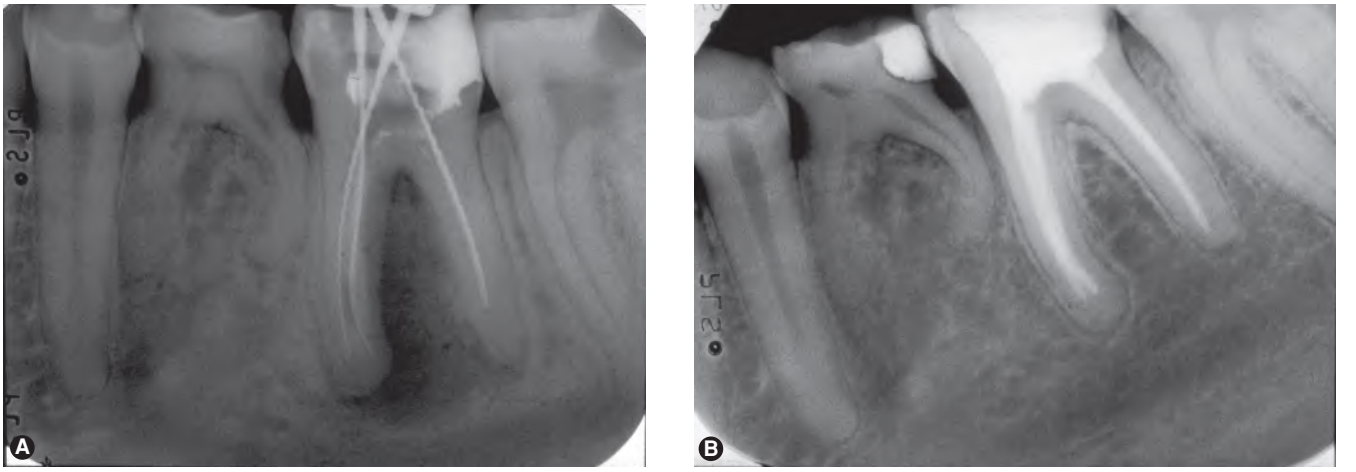

FIGURE 20-36 Flexible stainless steel K-Flexofiles were used for root canal preparation of the mandibular molar associated with peri- and intraradicular lesions. ***A.*** Working length radiograph. ***B.*** One year follow-up radiograph showing evidence of healing of the periradicular lesions.

undergo a stress-induced martensitic transformation from a parent structure that is austenite (Figure 20-38). Upon release of stress, the structure reverts back to austenite, recovering their original shape.[62] This superelastic behavior of NiTi occurs over a limited temperature range with an optimum at 37°C.[91,92] Clinically, the superelastic behavior is of relevance since NiTi instruments suffer no permanent deformation when being used in severely curved canals, whereas deformation of about 1% results in permanent deformation in stainless steel instruments (Figure 20-39). Because of their superelasticity, however, NiTi instruments cannot be pre-bent, making these instruments unsuitable to bypass ledges.[93]

As pointed out, stainless steel reamers and K-files are twisted instruments. Due to the superelasticity of NiTi, it is impossible to twist a NiTi blank counterclockwise in order to produce a spiral, since these alloys usually don't undergo permanent deformation (Figure 20-40).[50] More likely, the blank will fracture when being extensively twisted in order to produce a spiral. Therefore, all hand instruments made from conventional austenite NiTi are grinded instruments. However, grinding of titanium-based alloys is difficult since considerable wear of the milling head occurs within a short time.[63] This leads to structural defects on the surface, especially at the cutting edges of NiTi instruments (Figure 20-41).[58,59,94] These structural defects coupled with the considerable lower surface hardness, compared to stainless steel counterparts,[95,96] are probably responsible for their relatively low cutting efficiency. Cutting efficiency of NiTi K-files was found to be far lower compared to flexible stainless steel instruments.[71,73,97] Cutting efficiency in a linear filing motion of NiTi Hedstrom or S-files was only about 60% less than that of matching stainless steel files.[73]

While some studies showed corrosive tendency of NiTi instruments under simulated clinical conditions (Figure 20-42),[58,98,99] other studies failed to show it.[73,100,101] In addition, there seems to be evidence that

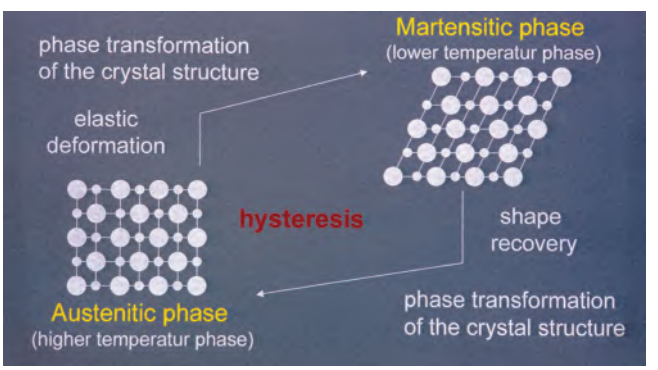

FIGURE 20-38 Stress-induced phase transformation of nickel-titanium from austenite to martensite.

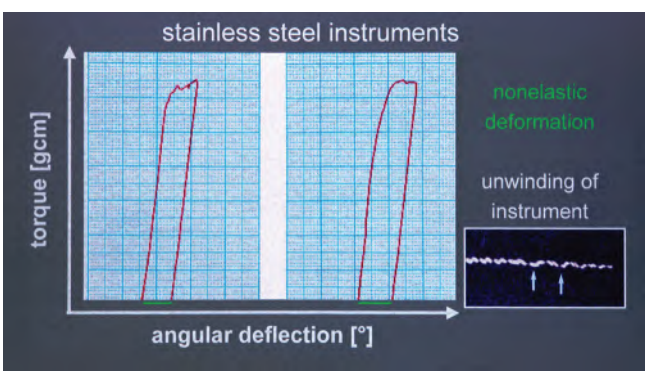

FIGURE 20-39 Stainless steel instruments fixed at their tips and rotated clockwise showing non-elastic permanent deformation.

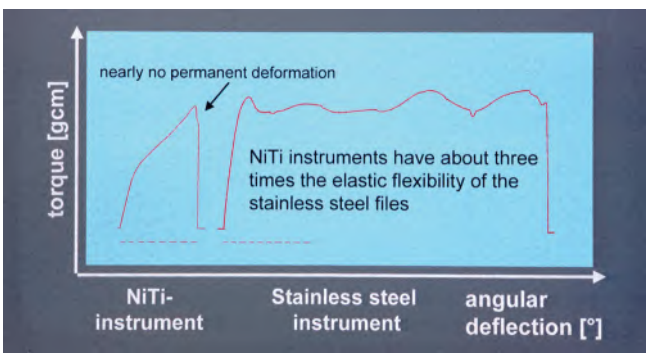

FIGURE 20-40 Nickel-titanium and stainless steel instruments fixed at their tips are rotated clockwise. While the stainless steel instrument exhibits a wide range of permanent deformation before fracture the nickel-titanium instrument shows nearly no permanent deformation.

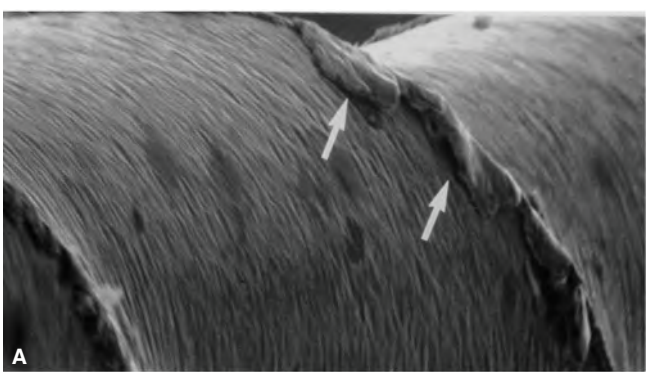

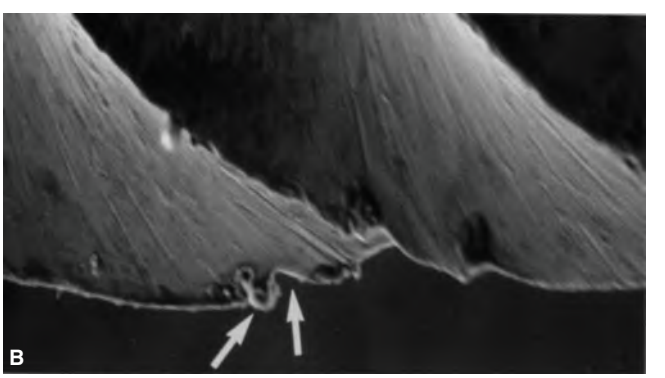

FIGURE 20-41 Scanning electron microscopic image of nickel-titanium hand instruments showing structural defects at their cutting edges (arrows).

FIGURE 20-42 Severe corrosion of a nickel-titanium hand instrument following sterilization.

repeated sterilization cycles have a detrimental effect on the cutting efficiency of NiTi instruments.

Regarding the shaping ability of NiTi hand instruments, studies using simulated curved canals in resin blocks reported a superior shaping ability for NiTi instruments in terms of increased centering ratio, less canal transportation, and less procedural errors compared to stainless steel counterparts.[102,103] These findings are in agreement with those obtained when using extracted teeth with curved root canals.[102] NiTi instruments were significantly more effective in maintaining the original path of the canal when instruments larger than size 30 were used.[104-107] NiTi K-files caused significantly less canal straightening and also the incidence of procedural errors was significantly reduced by the use of NiTi instruments.

One study, however, showed no significant difference regarding the shaping results in curved root canals when NiTi and stainless steel hand instruments were compared.[108] The curvature of 24–52°curved canals was equally maintained with either flexible stainless steel or NiTi K-files when used according to the circumferential filing technique. In this context Gambill et al.[109] stated "The reason that Ni-Ti instruments caused less transportation than stainless steel K-files when the same filing technique was used may not be due to increased flexibility of the Ni-Ti instruments, but rather to the decreased cutting efficiency of the Ni-Ti instruments."

In general, it can be stated that there is evidence that NiTi instruments, as compared to stainless steel instruments, allow for a faster, more efficient and centric preparation of curved canals (Figure 20-43).[104,109] NiTi instruments seem to prepare curved canals more centric and more circular than flexible stainless steel instruments.

Non-ISO-Sized Instruments for Manual Use

Further improvements led to the development of instruments that do not match the requirements regarding diameter and conicity laid down in the ISO and ADA specifications.[52-54]

Half sizes: The percentage increase in diameter from one ISO size to the other is considerably great in the range of smaller sizes. For instance from ISO size 10 to ISO size 15 the diameter of the instrument increases by 50%, whereas the increase from ISO size 50 to ISO size 55 is only 10% (Table 20-2). This unbalanced gradation might impede manual preparation of severely curved and/or calcified root canals. Therefore, some manufacturers introduced instruments with half sizes, having diameters that lay exactly, or nearly, in between two ISO sizes. For example, the flexible stainless steel Flexoreamer and K-Flexofile instruments (Dentsply/Maillefer, Ballaigues, Switzerland) are available in half sizes from no. 12 through no. 37, both having a non-cutting tip. These instruments are named "Golden Mediums."

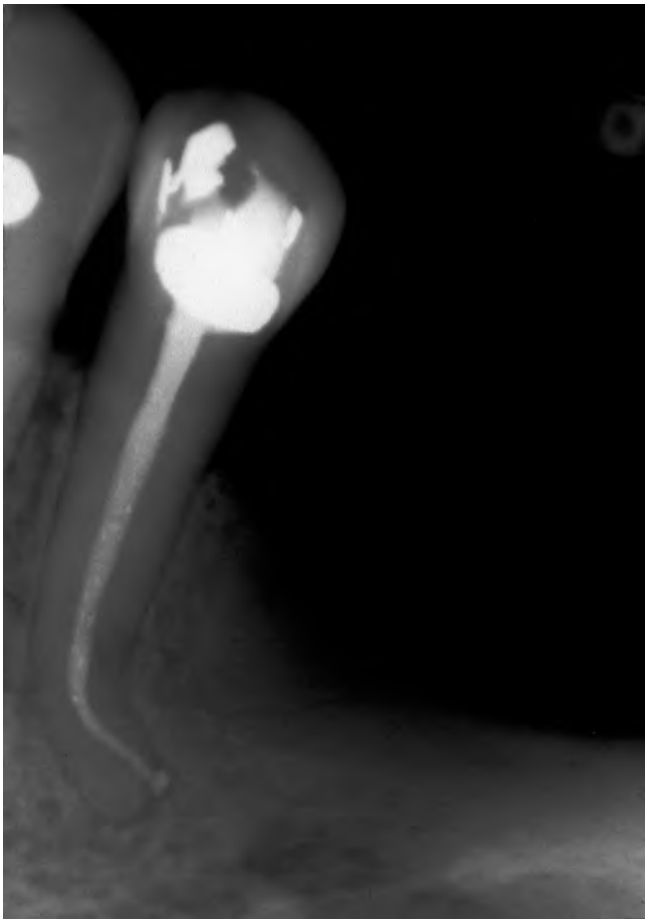

FIGURE 20-43 Severely curved root canal with a small radius of curvature enlarged using nickel-titanium hand instruments. The original curvature was well maintained.

Weine et al.[110] and Schilder[110] recommended the use of incremental instrumentation, especially in narrow and sclerotic root canals. According to these authors, to reduce undesirable instrumentation effects, intermediate increments should be employed. "*This is accomplished by cutting off one millimetre of the tip with sharp scissors and then using a diamond fingernail file to re-establish the bevel and the sharp edges from the tip.*" However, this procedure is time consuming and it is nearly impossible to produce a non-cutting tip with a diamond file.

TABLE 20-2 Gradation of ISO Sizes Showing That the Percentage of Increase in Diameter Is Considerably Greater in the Range of Smaller Instruments

diameter [mm]	increase in diameter [%]

1,2	9
1,3	8,3

Greater Taper Hand Instruments

With the introduction of rotary NiTi instruments having tapers greater than the ISO standard, some manufacturers also developed NiTi instruments with greater taper for manual use. For example, the ProTaper instruments (Dentsply/Maillefer, Ballaigues, Switzerland) are available as rotary and as hand instruments. Currently, studies assessing the properties of greater taper NiTi hand instruments are limited.

One study compared the shaping ability of ProTaper hand and rotary instruments used by inexperienced dental students.[111] The use of rotary instruments resulted in less canal straightening compared to hand instruments. In another study, the root canals of extracted premolars were instrumented with ProTaper hand instruments using the balanced-force technique and 3-D analysis using micro-CT was conducted to assess the percentage of unprepared canal surface.[112] The authors reported that 28%–83% of the root canal surfaces were not prepared by the instruments.[112] In another study,[113] the root canals of human mandibular molars were instrumented with ProTaper by hand, ProTaper rotary, and the rotary NiTi system RaCe (FKG, La Chaux de Fonds, Switzerland). Canal deviation in the apical third of the canals was evaluated by superimposition of pre- and postoperative radiographs. The incidence of canal deviations was 25% for ProTaper used by hand, 25% for rotary ProTaper and 20% for RaCe, respectively, with no statistically significant differences among the three instruments.[112]

In summary, it seems that the hand use of NiTi instruments with tapers greater than the ISO standard offers no significant clinical advantages and that these instruments should be preferably used as engine-driven instruments.

Conclusions

In summary it can be concluded that:

- Out of all stainless steel instruments, flexible stainless steel instruments, having non-cutting tips, show the best shaping ability. However, they do not produce completely satisfactory results, in severely curved canals, since apical enlargement is limited to relatively small sizes.
- Stainless steel Hedstrom files, used according to the circumferential filing technique, are best suited for cleaning oval canals and canal extensions.
- NiTi instruments respect the original canal curvature better than stainless steel instruments, especially in severely curved canals.
- Stainless steel pilot instruments are best suited for bypassing ledges.

PREPARATION TECHNIQUES

The endodontic literature describes many different techniques for root canal preparation, including manual (hand), automated, sonic, ultrasonic, lasers, and non-instrumental techniques (Table 20-3).[2,3] There are only a few comparative studies, making an evidence-based conclusion difficult.

Preparation and Obturation

When planning the preparation phase, the final obturation technique should always be taken into account since each obturation technique requires a specific shape of preparation. For example:

TABLE 20-3 Preparation Techniques Described in the Literature

Standardized	Ingle	1961
Step back	Clem	1969
Incremental	Weine, et al.	1970
Serial preparation	Schilder	1974

Alternated rotary motions	Siqueira, et al.	2002
Reciprocal picking	Yared	2008

Single cone: The preparation shape should match the size of the Master Apical File (MAF); additional step back will reduce the fit of the cone.

Warm vertical compaction: A conicity of 7% or more is required to create a capture zone, preventing extrusion of the warm gutta-percha.

Lateral compaction: A constant conicity, exceeding the 2% taper of the instrument, is necessary to allow insertion of spreaders and thorough compaction of the gutta-percha cones.

Basic principle: Preparation should dictate the obturation technique rather than the obturation technique dictating a certain preparation technique.

Manual Preparation Techniques

Ingle[114] described the first formal root canal preparation technique known as the "standardized technique." In this technique, each instrument is introduced to working length resulting in a canal shape that matches the taper and size of the final instrument. This technique was designed for single-cone filling techniques using gutta-percha or silver cones.

Standardized Technique

This technique was first described by Ingle in 1961.[114] Starting with small instruments, all following instruments are inserted to working length. Preparation results in a root canal with low conicity that theoretically reproduces the shape of the last instrument used (Master Apical File [MAF]). The final shape of the preparation is suited, theoretically, for single cone obturation techniques as a high congruence between the MAF, the shape of the root canal and a matching gutta-percha cone is expected. Studies have shown that this congruence is rather conceptual than real.[115]

Step-Back Technique

The step-back technique[116] or similar techniques such as the telescopic technique or the serial technique aim at a higher conicity by stepwise reduction of working length, once apical preparation has been finished with the MAF (Figure 20-44). Each step back is followed by irrigation and recapitulation with a small file. The step-back technique has been for many years one of the traditional preparation techniques in endodontics. In some studies it produced cleaner root canals than standardized techniques.[116,117]

Circumferential Filing

Circumferential filing[118] aims at reducing the percentage of unprepared root canal walls by intentionally pressing the instruments against the walls. The instrument is inserted to working length, pressed against the canal dentin, and withdrawn. After the next insertion of the instrument to working length, it is pressed against the root dentin in some minor distance from the first file and again withdrawn in a shaping movement. Repetition results in circumferential preparation of the root canal dentin, theoretically touching the entire canal walls. This preparation results in a higher conicity than the techniques described above.

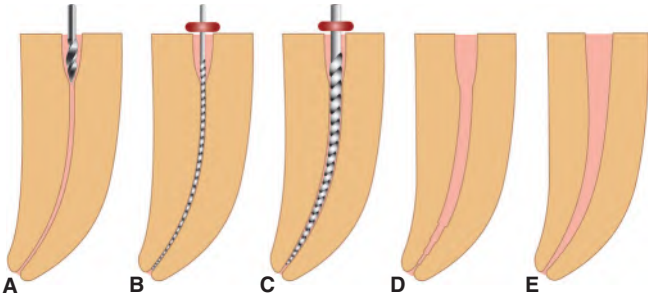

FIGURE 20-44 Sequence of instruments in the step-back procedure. After coronal pre-enlargement with Gates Glidden burs (**A**), apical preparation to the desired master apical file size commences with K-Files to determine working length (**B**) and then files of ascending size to the desired apical dimension (also called Phase I, **C**). Then, working length is progressively decreased ("stepped-back") by 1 or 0.5mm to create a more tapered shape (Phase IIa, **D**). Recapitulation with a small k-file is done to smooth canal walls and to ensure that the canal lumen is not blocked (Phase IIb, **E**). Frequent irrigation promotes disinfection and removal of soft tissue.

Anticurvature Filing

This technique[119] is designed to keep files away from the furcational zone of curved root canals thus preventing excessive removal of dentin and strip perforations at this critical zone.[120] This goal should be achieved by use of precurved instruments (files) at the outer side of the curvature.

Crown-Down Technique

This technique, first presented by Goerig et al.,[121] has gained new popularity with the introduction of rotary NiTi instruments. Following coronal flaring, large instruments are used to enter and enlarge the root canal a few millimeters apically each time. The instrument is followed by a smaller file, preparing only a few millimeters deeper than the previous instrument. This is repeated until working length is reached. As the final step, enlargement of the apical diameter completes the preparation (Figure 20-45).

The advantages of the crown-down techniques are:

- Less friction and stress on the instrument thereby reducing risk of instrument fracture
- Less canal straightening since reduced friction allows a more controlled preparation
- Less contamination of the apical zone of the root canal by reducing transportation of infected debris.
- Early coronal and mid-root enlargement allowing early disinfection of the coronal parts of the root canal system.
- Reduction of extruded debris beyond the apical foramen.

A slightly modified technique, termed as crown-down-pressureless, has been also suggested.[122]

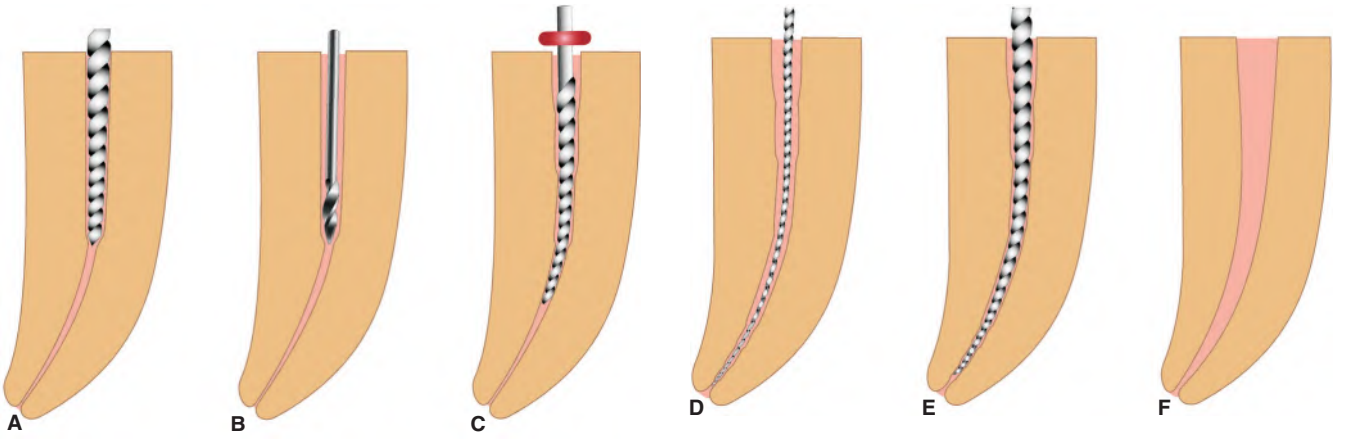

FIGURE 20-45 Sequence of instruments in the crown down approach. Coronal pre-enlargement was originally suggested to commence after determination of a provisional working length with a size #35 hand file (**A**). Then, Gates Glidden burs were used (**B**), followed by hand files starting with a large (e.g., size #60) file and progressing apically with smaller sizes (**C**). The definitive working length was determined as soon as progress was made beyond the provisional working length (**D**). Apical enlargement (**E**) and recapitulation created a homogenous shape that may be similar to the one created with the step-back approach, provided that both techniques were performed with little or no procedural errors. Both step-back and crown-down techniques may be used in conjunction with hand and rotary instruments but *in vitro* evidence suggests that a crown down approach is preferred for tapered rotary instruments. (Reproduced with permission from Blum JY, Machtou P, Micallef JP: Location of contact areas on rotary Profile instruments in relationship to the forces developed during mechanical preparation on extracted teeth. Int Endod J 1999;32:108.)

Step-Down Technique

With this technique the coronal part of the root canal is prepared first, resulting in more straight access to the middle and apical part of the root canal by early elimination of coronal interferences. Early disinfection of the coronal space is expected to reduce apical transportation of microorganisms, apical extrusion of debris and irrigant, and better control of apical preparation.[122]

Balanced Force Technique

The Balanced Force (BF) technique, described by Roane and Sabala in 1985,[123,124] uses specially designed instruments (Flex-R-Files) with non-cutting tips. The concept is to reduce the stress on the instruments thereby reducing the risk of straightening the canal and fracturing the instrument. The instruments are introduced until resistance is felt. The file is rotated at 180° in a clockwise direction (placement phase) with a slight but constant apical pressure, followed by a 120° rotation (cutting phase) in counterclockwise direction with maintained apical pressure, to prevent coronal displacement of the file (Figure 20-46). Finally the file is withdrawn in a clockwise motion (removal phase). The instrument is worked to working length in 1-2 mm steps with repeated constant clockwise and counterclockwise partial rotation, assisted by copious irrigation.

It has been claimed that BF preparation can achieve preparation sizes of 45 in curved canals and 80 in straight canals. The main advantages of the BF technique are good apical control of the file tip since the instrument does not cut over the complete length, and good centering of the instrument due to the non-cutting safety tip.

Good results for the preparation of curved canals without, or with only minimal, straightening[125] have been reported. However, incidence of procedural mishaps such as root perforations[126] or instrument fracture[127] have been described as well. The amount of apically extruded debris was lower than with stepback or ultrasonic techniques.[128] However, some earlier reports have indicated significantly more displacement of the root canal center axes, suggesting straightening.[129,130]

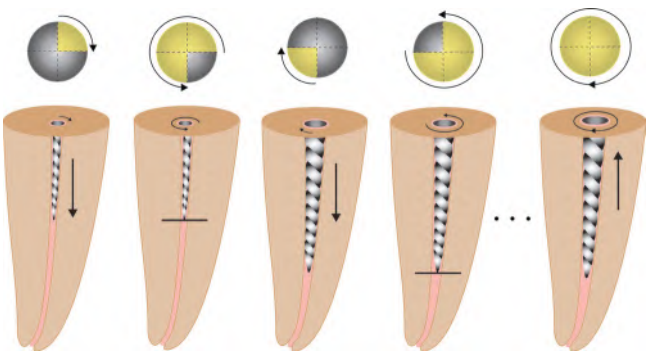

FIGURE 20-46 Principles of the Balanced Force technique. Instruments with a symmetrical triangular cross-section and pilot tips (*e. g.*, Flex-R files, Moyco Union Broach, Montgomeryville PA, USA) were originally suggested to be used in three steps in a rotational movement. A file may be advanced into the canal with a one-quarter clockwise rotation. The second movement involves adequate apical pressure to keep the instrument at this level of the canal while rotate counterclockwise for a half- to three-quarter turn. Currently, it is recommended to use the first two movements repeatedly, progressing more apically. Then the third movement pulls the instrument gently out of the canal with clockwise rotation.

Apical Box Technique

Tronstad[131] suggested preparing the root canal to a larger apical size using an apical box technique. Instead of using

a step-back approach, this technique, following preparation with a MAF, uses three or four larger instruments (K-files) in a filing and rotation action to full working length, thereby giving the apical 2-5 mm a cylindrical rather than a conical shape (shelf) (Figure 20-47).

Single Length-Technique

Single length technique has been recommended for some contemporary NiTi-systems (Mtwo, BioRaCe, Le-Chaux-de-Fonds, Switzerland). Starting with a small instrument, all instruments with increasing sizes are introduced to working length, followed by irrigation and recapitulation with a smaller instrument to working length. Instead of a step back, some NiTi systems use instruments with increasing taper thus increasing the taper of the canal preparation. This technique resembles the standardized technique.

Non-Instrumental Technique (NIT)

The non-instrumental technique (NIT), developed by Lussi et al.,[132] uses a vacuum pump and an electrically driven piston, generating alternating pressure and bubbles in the irrigation solution, inside the root canal. Finally, the root canal may be obturated with a sealer introduced by the vacuum pump.[133]

Studies demonstrated an equal or even better cleanliness compared to hand instrumentation in root canals of extracted teeth.[134] Some intraoperative complications such as severe pain, under-extension and apical extrusion of sealer or breakdown of vacuum have been reported.[135]

Since long-term clinical studies are not available yet, the NIT system cannot be considered a viable alternative to mechanical root canal instrumentation at this time.

Step-Back vs. Step-Down

Surprisingly, there are only few comparative studies assessing these approaches. Indeed, there is no evidence that step-down techniques are superior to step-back techniques or vice versa with the exception of the BF technique, that has been shown to result in less canal straightening.[127,136] In a comparative study of four preparation techniques, no difference between step-back and crown-down was detected in terms of straightening, but crown-down preparation produced more ledges.[137]

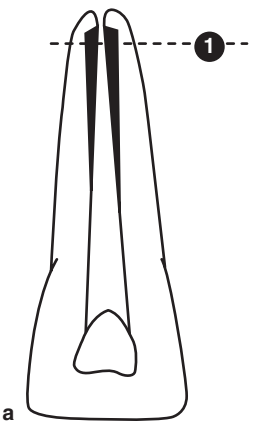

FIGURE 20-47 Schematic drawing of an apical box preparation.

Reciprocal Technique

In 2008, Yared[138] presented a technique using a ProTaper F2 file in a reciprocating motion. It is discussed later in this chapter.

AUTOMATED ROOT CANAL PREPARATION

Conventional Rotary Systems

The group of conventional rotary systems for root canal preparation comprises a number of endodontic handpieces differing in their working motion (e.g., rotation, partial rotation, reciprocal rotation, vertical movement, or a combination of rotation and up and down movement). In most of these handpieces, the motion of the file is rigid and cannot be influenced by the operator. The operator can vary the rotational speed and the frequency and amplitude of vertical strokes by changing the up-and-down movement of the handpiece. All these conventional handpieces were designed for use with stainless steel instruments, reamers as well as Hedstrom files.

In the 1980s, several handpieces with a more flexible working mode were introduced, namely the Excalibur handpiece (W&H; Bürmos, Austria) and the Canal Finder System (SET, Gröbenzell, Germany). Some of the new devices were equipped with integrated permanent supply of irrigant and permanent electronic determination of working length during preparation. Studies demonstrated that preparation of curved root canals often resulted in canal straightening.[139-145] Additionally, insufficient cleanliness[2,146] as well as apical blockages, loss of working length, perforations and instrument fractures also have been reported.[147,148]

In summary, these systems lost popularity after the introduction of rotary NiTi systems.

PREPARATION WITH ROTARY NiTi INSTRUMENTS

Development of Rotary NiTi Systems

Since their introduction, metallurgy, design, shape and philosophy of use of NiTi systems have changed frequently and to a considerable degree. Haapasalo and Chen[149] defined five distinct generations of NiTi instruments related to the evolution in design:

- Generation 1: These instruments include rotary NiTi systems with a constant taper and radial lands and a neutral or negative rank angle. Representative systems of this generation are ProFile, LightSpeed, Quantec, Greater Taper, BioRace, and EndoSequence.

- Generation 2: These instruments are characterized by having actively cutting blades without radial lands. Representative systems are ProTaper, ProTaper U, K3, M*two*, BioRaCe, FlexMaster, and S5.
- Generation 3: These instruments include systems such as Twisted Files, Typhoon, HyFlex, and Vortex Blue. The classical NiTi alloy was replaced withy improved, thermally pre-treated alloys such as M-wire or CM-wire, increasing the flexibility and durability of the files.[150]
- Generation 4: The mode of action of these NiTi systems was altered from a 360° rotation to reciprocal movements with Reciproc and WaveOne being the best-known systems of this generation.
- Generation 5: This most recent group of rotary NiTi instruments shows an irregular cross-sectional design. It includes LightSpeed LX, OneShape, SAF, Revo-S, and ProTaper Next. (Table 20-4).

NiTi systems cannot always be clearly assigned to a specific generation. Further developments in geometry and metallurgy, mode of rotation, and philosophy of use are expected in the near future.

NiTi Systems

NiTi instruments may differ significantly in design, treatment concept, and in their mode of use. Therefore, it seems reasonable to use the term NiTi systems rather than NiTi instruments. Except for the recently introduced single file systems, the majority of NiTi instruments are used in clearly defined (and mathematically designed) sequences. Some typical examples are presented in this chapter. Regarding the treatment concept, two approaches can be identified: crown-down and single length techniques.

Recently, single file systems have been introduced with the aim to of simplifying preparation, shortening time, and reducing costs.

TABLE 20-4 Generations of NiTi Systems According to Haapasalo and Chen[150]

1st generation	ProFile, GT
• 1992 McSpadden	Quantec
• 1994 B. Johnson	LightSpeed
.02, .04 and .06 taper, radial lands, pass, flutes	
2nd generation	ProTaper, K3
active flutes without radial lands	FlexMaster, BioRaCe
→ less instruments needed	
3rd generation	HyFlex, K3XF, Vortex
• 2007 M-wire	Vortex, Vortex blue
• 2010 R-phase	Twisted Files
• 2010 CM wire	
4th generation	Reciproc, SAF
• 2008 Yared	WaveOne
• 2011 Wave One, Reciproc reciprocal motion	
5th generation	OneShape
asymmetrical cross-section	Revo-S, PT Next

Single File Systems

Systems, with a single instrument designed to prepare the entire root canal, are Reciproc, WaveOne, F6 Sky Taper, SAF, One Shape, and OneEndo. These systems are discussed in a separate section of this chapter.

Single Length Systems

Single length systems are compatible to the standardized technique, where each instrument is introduced to working length, after preparation of the glide path. Some systems of this group are LightSpeed, M*two*, and BioRaCe. Each instrument is used to working length starting with small instruments and followed by files of higher taper or increasing diameter. Some systems such as BioRaCe have instruments with cutting tips each second instrument, whereas LightSpeed or M*two* have non-cutting tips.

Crown-Down Systems

Crown-down systems use a different preparation approach. Instead of inserting each instrument to working length at the beginning of the preparation, instruments with large diameter and high taper are used first. The following instruments gradually get smaller in taper and/or diameter (Figure 20-48). This technique, already known from manual root canal preparation, reduces the friction of the instruments inside the root canal. Each instrument has to enlarge only small parts of the root canal, resulting in shorter working time, reduced stress on the file and reduced risk of instrument fracture.

From a biological point of view, necrotic and infected material are removed first from the coronal part of the endodontic cavity and replaced by disinfecting irrigants, before the instrument is inserted deeper into the root canal. When working length has been reached, apical enlargement follows. Typical systems of this group are ProFile 04 and 06, ProTaper, and FlexMaster.

It should be noted that there is no evidence indicating that crown-down techniques, using NiTi instruments are superior, compared to single length techniques, with regard to relevant clinical parameters (shaping quality, safety of use, extrusion of debris, post-operative pain, clinical success). For hand instruments, it has been shown that this technique reduces the extent of straightening curved root canals,

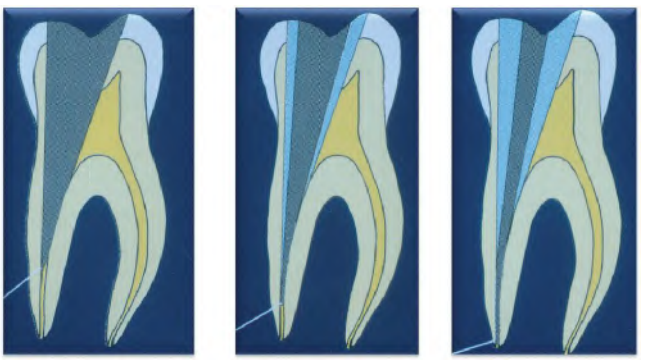

FIGURE 20-48 Systematic crown-down preparation.

reduces the risk of apical blockage and apical extrusion of infected debris.[151]

FIRST GENERATION SYSTEMS

LightSpeed, LightSpeed LX (LightSpeed Technology, San Antonio, Tx, U.S.A.)

Originally, LightSpeed was designed similarly to a Gates Glidden with a small non-cutting tip, radial lands and a long shaft.[152,153] Manufactured from NiTi, LightSpeed instruments were the most flexible instruments at the time. Each working tip showed an individual shape with a slow increase in tip length (0.25 mm – 2 mm), diameter and conicity from one instrument to the next. The instruments were initially used at 1,000 r.p.m. – 2,000 r.p.m. Later, the manufacturer has recommended a slower speed (Figure 20-49).

The principal of the LightSpeed technique was to minimize, as much as possible, the contact between instrument and dentin. Consequently, intermediate sizes were included, that further reduced the work load for each file. This philosophy resulted in a high number of instruments (more than 20), with an extremely short working time for each file. Due to its unique design, larger apical preparation could be achieved, even in severely curved canals.

Following apical preparation, a step-back procedure had to be performed in order to create sufficient conicity along the complete length of the canal allowing proper obturation. It has been recommended to obturate the apical part of root canals prepared with LightSpeed with a tapered 5 mm long gutta-percha cone attached to a metal carrier (SimpliFill).[152]

In a later version, called LightSpeed Xtra, the tip design was changed and the number of intermediate size instruments was reduced, making the file set considerably smaller. LightSpeed Xtra can be regarded as the first system of the fifth generation with an asymmetrical geometry.

FIGURE 20-49 Each LightSpeed file shows a unique tip with tip size, conicity and length increasing slightly from one instrument to the next.

ProFile .04 and .06 (Dentsply/Maillefer, Ballaigues, Switzerland)

ProFiles have been among the first systems to use crown-down preparation with rotary NiTi systems.[149,153] All instruments show a constant taper of 4% or 6%, respectively, and are used in a crown-down sequence at 300 r.p.m. (Figure 20-50).

K3 (Kerr/SybronEndo, Orange, CA, U.S.A.)

K3 instruments mark the transition from first to second generation. The file presents with radial lands as well as with actively cutting blades and a positive rake angle, a non-cutting safety-tip and variable helical flute angle preventing a screw-in-effect.[154]

SECOND GENERATION SYSTEMS

Mtwo (VDW Antaeos, Munich, Germany)

M*two* was one of the first NiTi systems with instruments designed as Hedstrom files. The instruments show two actively cutting flutes making the system very effective for dentin removal. All files of the set (04/10, 05/15, .06/20, .05/30, .04/35, .04/40) are used to working length with the largest instrument in size being .04/40 (Figure 20-51). Two additional sets .04/45, .04/50, .04/60 and .06/30, .06/35, and .06/40 are completing the system. If thermoplastic obturation is used, a final .07/25 instrument is also available.

RaCe and BioRaCe (FKG, La Chaux-de-Fonds, Switzerland)

The design of RaCe, an acronymon for **R**eamers with **a**lternating **C**utting **e**dges, shows alternating conical and parallel sections along the axis of the instrument, a convex triangle cross-section, sharp cutting edges and a chemically treated surface.[155] The system was followed by the more popular BioRace system. All instruments, except an orifice shaper, are used to working length: .05/15 (non-cutting tip) and .04/25

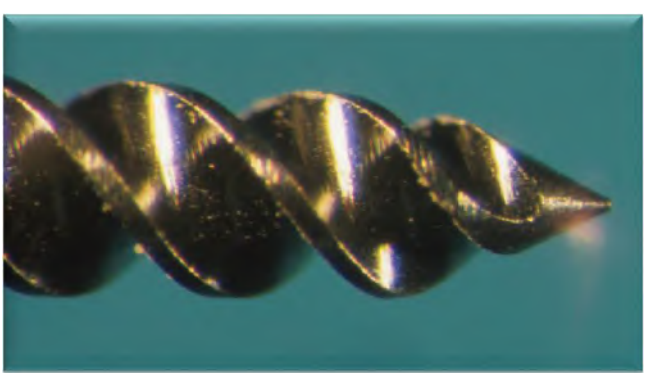

FIGURE 20-50 ProFile .04 showing radial lands and a non-cutting tip.

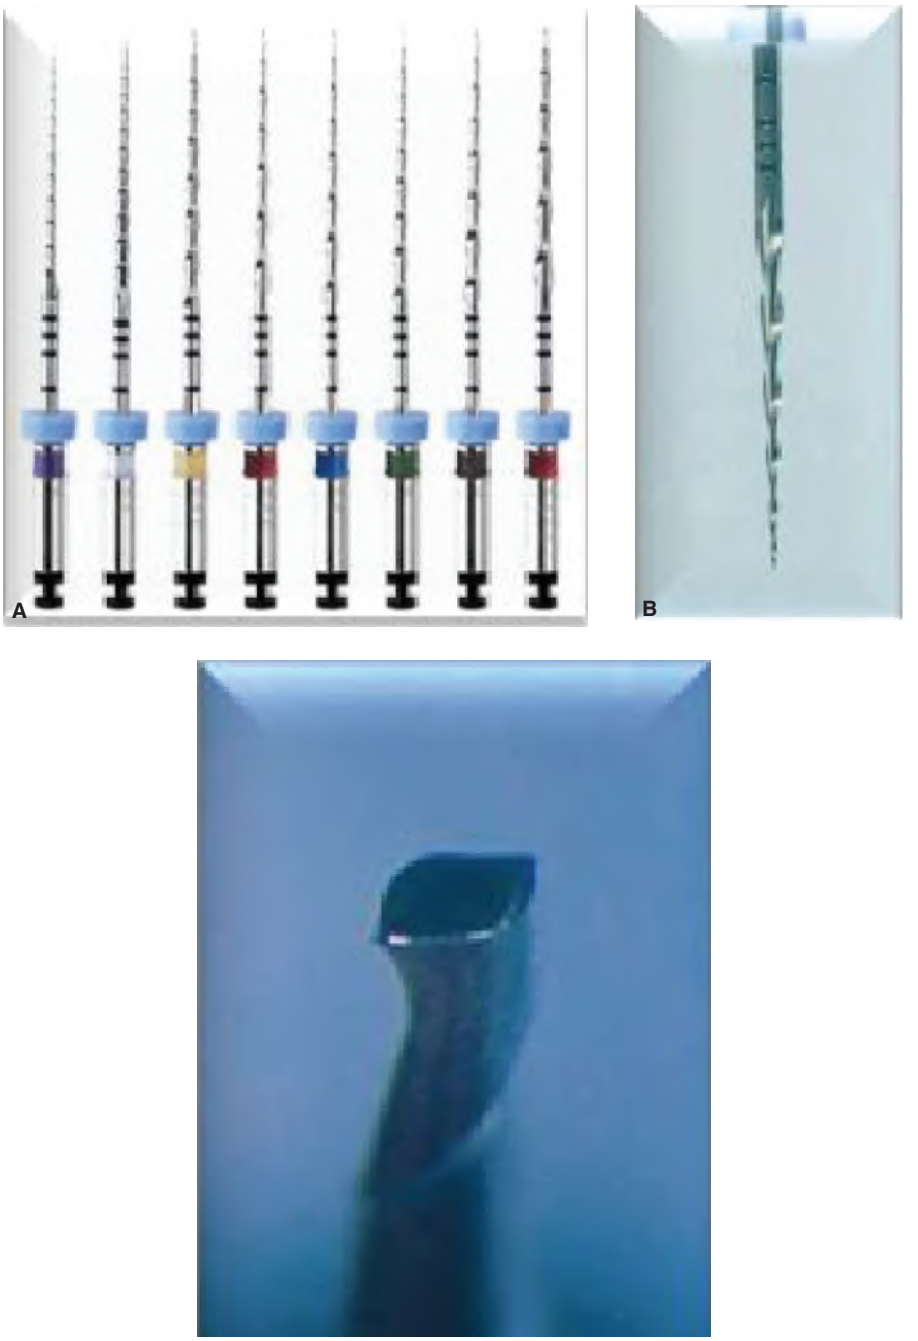

FIGURE 20-51 ***A.*** The set of *Mtwo* instruments. ***B.*** The design of *Mtwo* is similar to a Hedstrom file. ***C.*** Cross-section of *Mtwo*-files with two actively cutting blades.

(cutting tip) working in the most apical area; .06/25 (non-cutting tip) working in the middle and coronal third, 04/30 and .04/40 (cutting tips), working apically. In severely curved root canals, following size .06/25, two flexible instruments sizes .02/35 and .02/40 can be used (Figure 20-52). For large preparations additional sizes .04/50 and .02/60 are available.

BT RaCe (FKG, La Chaux-de-Fonds, Switzerland)

Booster Tip (BT) RaCe is a modified tip with a low taper. Three files with an atypical sequence of instruments are used for preparation: first a .06/10, followed by a non-tapered .00/35 and finally a .04/35 instrument. For larger root canals, .04/40 and .04/50 instruments are also available (Figure 20-53).

FlexMaster (VDW Antaeos, Munich, Germany)

The FlexMaster system comprises of instruments with three different tapers: 2%, 4%, or 6%, non-cutting tips and a triangle, slightly convex cross-section[156] and instrument sizes from 15 to 70, making it one of the systems with the largest variety of instruments (Figure 20-54).

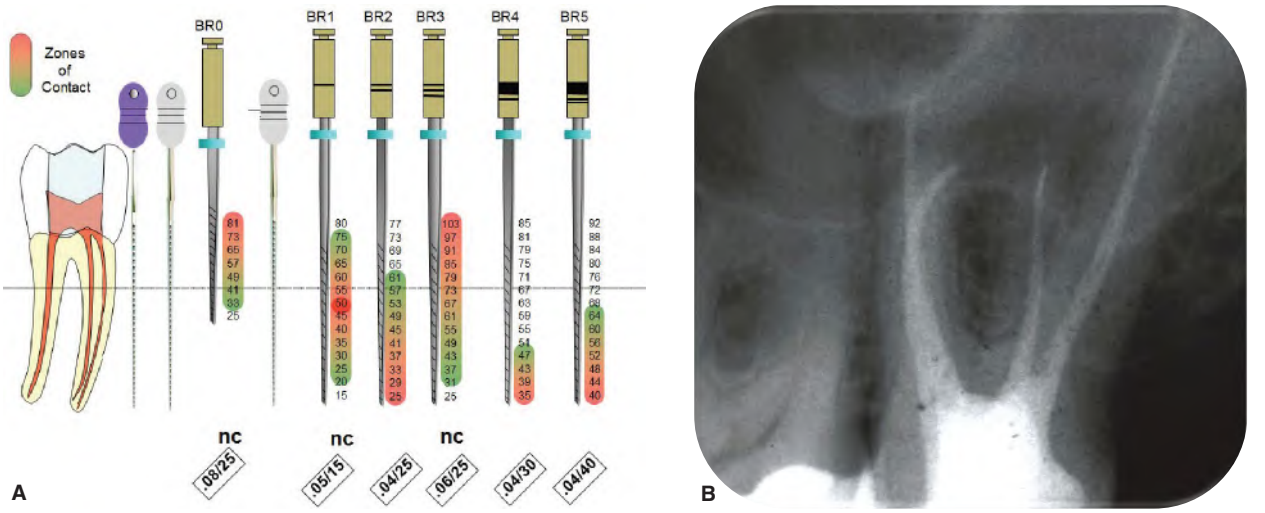

FIGURE 20-52 ***A.*** Regular sequence of BioRaCe instruments (ns: non-cutting tip). The red color marks the regions inside the root canal where the respective file is most active. ***B.*** Maxillary molar prepared with BioRaCe instruments to size .04/40.

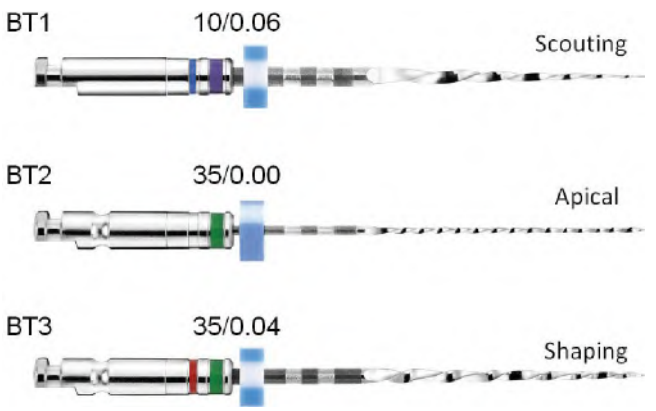

FIGURE 20-53 Sequence of the BT system. Note that the second instrument has a 0% taper.

The instruments are used in a crown-down-sequence starting with an Intro-File (9 mm cutting length, 11% taper) followed by instruments with a 6% conicity. Following each instrument, size or taper are decreased allowing a stepwise deeper penetration of the root canal. Size .02/ 20 has to reach working length, followed by 2% instruments with increasing diameter for apical enlargement. The instruments are used at approximately 300 r.p.m.

ProTaper and ProTaper Universal (Dentsply/ Maillefer, Ballaigues, Switzerland)

ProTaper instruments were the first to show different conicities along the shaft in one instrument. The system consists of six instruments:

- An Orifice shaper with a high conicity and a short cutting part;
- Two Shaping Files with small taper and small size at the tip and a high conicity (9%) near the shaft; and
- Three Finishing Files with increasing sizes (20, 25, and 30) and tapers up to 9% at the tip and 5% towards the handle (Figure 20-55).

This design results in limited contact areas between instrument and root canal dentin. In a later version, called ProTaper Universal, the design was changed. The cross-section was altered, making the file more flexible, the tip was rounded, making the instrument tip non-cutting, and additional sizes (35, 40, and 50, all with a 5% taper) were offered.[157]

THIRD GENERATION SYSTEMS

Third generation NiTi systems present modifications in the composition of the alloys that are thermally pretreatment, making the files more flexible[149,150] (see sub-chapter on metallurgy of instruments).

ProTaper Gold (Dentsply/Maillefer, Ballaigues, Switzerland)

The manufacturer's latest development, ProTaper Gold, shows increased flexibility due to undeclared alterations in the metallurgy of the alloy. The file design is the same as the PT Universal.

Twisted files (Kerr/SybronEndo, Orange, CA, U.S.A.)

Twisted files are manufactured by twisting pretreated M-wire NiTi alloy. The system includes five instruments with varying taper (.04 to .12) and a uniform tip size of 25.

TF adaptive are also manufactured from M-wire NiTi and produced by twisting thermically pretreated alloy.

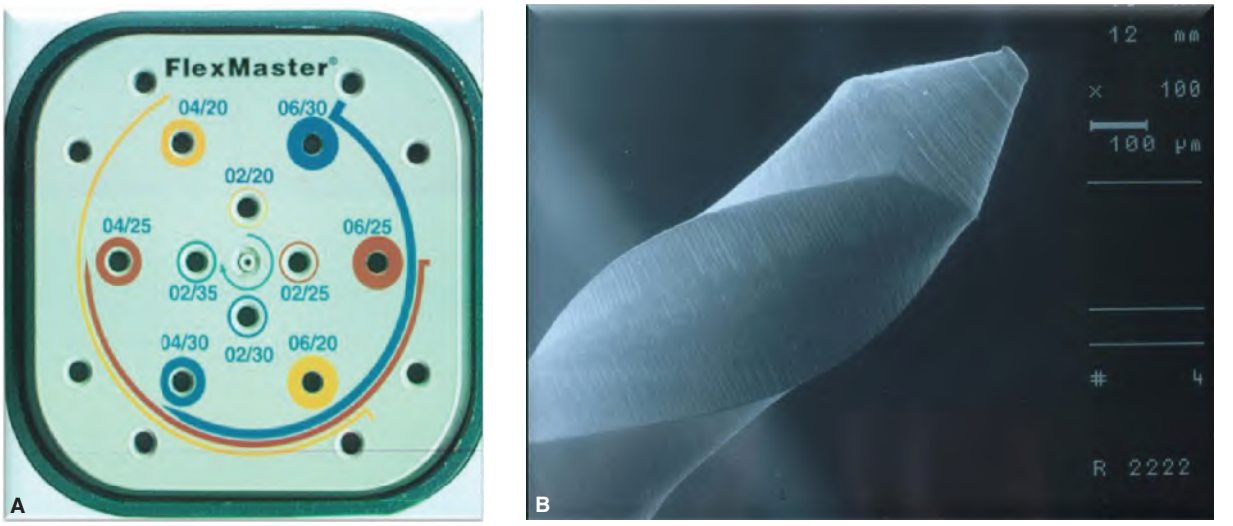

FIGURE 20-54 ***A.*** Basic box of FlexMaster with 10 instruments. More than 10 additional sizes (up to .02/70) are available. ***B.*** The instrument shows a non-cutting tip and a triangular, slightly convex cross-section.

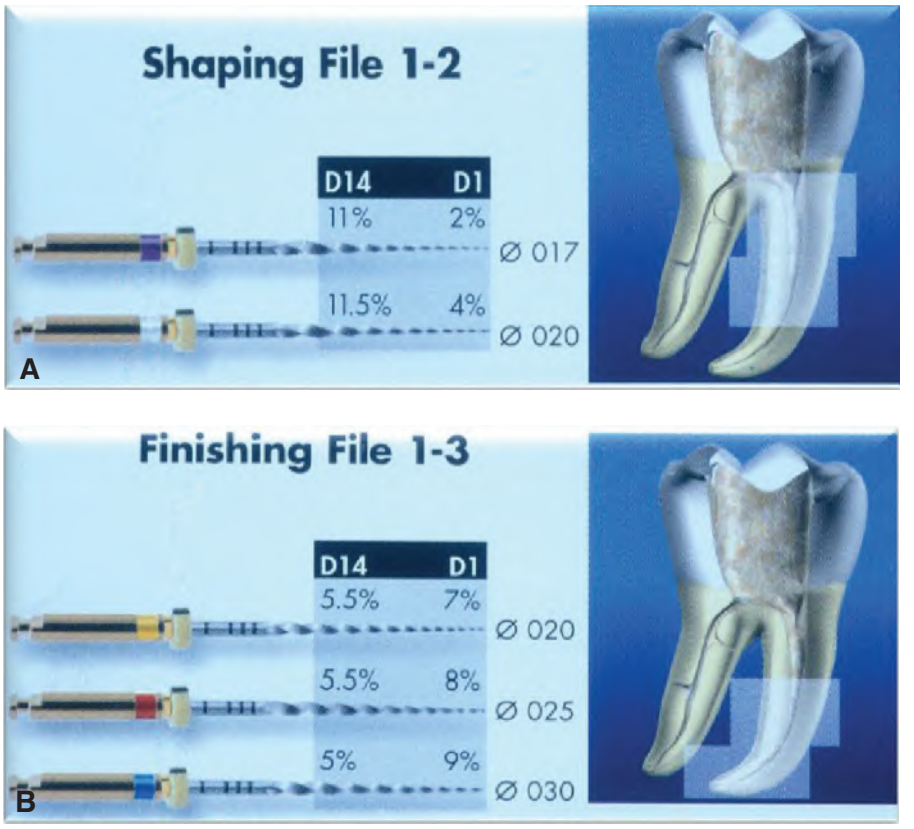

FIGURE 20-55 ***A.*** Sequence of ProTaper instruments. Shaping files have small tips, but a large taper and size at the upper shaft. ***B.*** Finishing files show increasing size and taper at the tip, with a smaller shaft. Instrument no. 6 is an orifice opener with a great taper and reduced working part.

Typhoon (TYP, Clinicians's Choice Dental Products, New Milford, CT, USA)

These instruments are fabricated from Controlled Memory (CM) wire, a thermally pretreated NiTi alloy that significantly increase the resistance to torsional failure.[158]

F 360 (Komet, Lemgo, Germany)

This system consists of two files sizes: .04/25 and .04/35, with two additional sizes for larger root canals (.04/45 and .04/55). The design is of double helix, similar to M*two*-instruments (F360). The instruments, manufactured from

conventional NiTi alloy, are used in a single-length technique with 300 r.p.m. A root canal can usually be prepared with two or three instruments.

F6 Sky Taper (Komet, Lemgo, Germany)

The company has introduced a corresponding One File-System: F6 Sky Taper.

The file has a taper of 6%, two blades, a Hedstrom file design and is used in full rotation (Figure 20-56).

FOURTH GENERATION SYSTEMS

TF adaptive (Kerr/SybronEndo, Orange, CA, U.S.A.)

The system includes two sets of instruments made from R-phase NiTi alloy: for small canals instrument sizes .04/20, .06/25 and .04/35, for larger root canals .06/25, .06/35, and .04/50 are available. Unfortunately, the color code does not keep to the ISO-code: green for the smallest file, yellow for the middle, and red for the largest one, resembling a traffic-light sequence. The instruments rotate in a clockwise direction up to 600°. In case of resistance, the forward rotation is reduced to 370°, followed by a 50° backward motion (Figure 20-57).

FIFTH GENERATION SYSTEMS

These instruments show a modified cross-section.

Revo-S (MicroMega, Besancon France)

These instruments show different cross-sections along the length of the instrument with three cutting blades at the tip and two blades towards the shaft. Files are available in sizes .04/25, .06/25, .06/30, .06/35, and .06/40.

FIGURE 20-56 F6 Sky Taper-instrument.

One Shape (MicroMega, Besancon France)

One Shape instruments also show different cross-sections along the length of the instrument with three cutting blades at the tip and two blades towards the shaft. The main instrument for preparing of the majority of root canals is a size .06/25. Additional two larger instruments (One Shape Apical) with sizes .06/30 and .06/37 are available for preparation of larger root canals.

ProTaper Next (Dentsply/Maillefer, Ballaigues, Switzerland)

ProTaper Next (PTN) presents with a rectangular cross-section and a non-cutting tip. The irregular cross-section increases space for dentinal debris and reduces contact of the instrument with the root canal wall (only a three-point contact is possible). The rectangular cross section directs the file into its optimal position in the root canal. The movement resembles a snake`s movement ("swaggering movement"). PTN is fabricated from M-wire. Instrument sizes are .04/17, .06/25, and for optional use .07/30, .06/40, .06/50. For glide path preparation, the manufacturer recommends PathFiles .03/13 and .02/15.

Mani Silk (Mani, Tohichi, Japan)

The Mani Silk system consists of three size instrument with an asymmetrical teardrop-shaped cross-section, fabricated from thermally pretreated NiTi. Three different sequences can be selected: .08/25, .06/25, and .06/30 for straight root canals; .08/25, .06/20, and .06/25 for moderately curved; and .08/25, .04/20, and .04/25 for severely curved canals.

The selection of the systems presented does not cover the entire range of available systems. Development of new systems with improved designs and metallurgy still continues.

Studies on Root Canal Preparation Using NiTi Systems

It has been demonstrated that NiTi instruments are safe to use provided attention is given to some basic principles:

FIGURE 20-57 TF Adaptive instruments work with a full rotation of maximum 600 degrees if no friction is present. Under friction, the rotation is changed into a 370° clockwise and 50° counterclockwise motion.

Cleaning Ability

Studies showed that the majority of NiTi systems are unable to completely instrument and clean the root canal walls.[159] No NiTi system (SAF, K3, WaveOne) was able to sufficiently clean and prepare all the isthmi.

Shaping

The majority of studies describe good maintenance of curvature even in severely curved root canals. Also, good centring ability with only minor deviations from the main axis of the root canal has been reported.[159-163] No difference in transportation of the foramen was detected between single file WaveOne system and multi-instrument Twisted Files.[27] Care should be taken using large tapered and large-sized instruments such as ProTaper F3 and F4 in curved root canals.[164]

No significant difference in straightening of curved root canals was detected between several NiTi systems (OneShape, ProTaper Next, Reciproc, Twisted Files, ProTaper Universal),[165] and no uniform results were reported suggesting superiority of any particular system.[166]

No difference could be detected between instruments made from conventional NiTi alloy (Revo-S, RaCe, Mtwo, ProTaper Universal) and instruments manufactured by innovative processes (Twisted File, GT series X).[167]

Instrument Fractures and Working Safety

Anatomical conditions such as radius and angle of root canal curvature, frequency of use, torque setting, and operator experience are important factors that affect instrument fractures. Selection of a particular NiTi system, sterilization and rotational speed, when confined to specific limits, seem to be less crucial. Apical blockage and loss of working length have been described in some cases, whilst perforations only rarely occurred.

Working Time

Working time with NiTi systems was significantly shorter with rotary preparation than with hand preparation. Use of single file systems further shortened the time required to complete the preparation.[162]

Conclusions

In summary, it can be concluded, that

- The use of NiTi instruments results in less straightening and better centered preparations, even in severely curved canals, than when stainless steel instruments are used.
- In order to reduce the risk of instrument fractures, a motor with constant speed and controlled torque should be used.
- Good preparation shapes can be achieved with any rotary NiTi system presently in the market.
- Some progress has been made in machining instruments, flexibility, maximum frequency of use, number of instruments needed, decrease of working time and some other technical details.
- Until now, it has not been demonstrated that new file systems, or advanced generations of NiTi systems, resulted in increased clinical success rates.

SINGLE-FILE SYSTEMS

The latest generation of engine-driven root canal instruments are single-file systems. These systems can be subdivided into those using a full clockwise rotary motion (F360 and F6 Sky Taper [both Brasseler, Lemgo, Germany] and OneShape [Micro Méga, Besançon, France]) and those using a reciprocation working motion (Reciproc [VDW] and WaveOne [Dentsply Maillefer]) (Figure 20-58). These single-file systems are claimed to be able to completely prepare and clean root canals with only one instrument. All single-file instruments have a non-cutting tip (Figure 20-59).

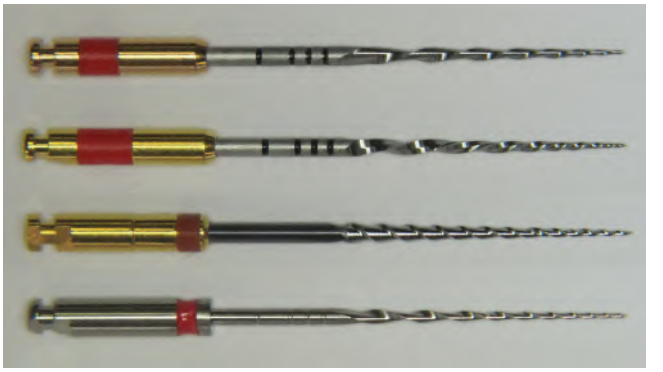

FIGURE 20-58 Different single-file instruments. From above: Reciproc, WaveOne, OneShape and F360.

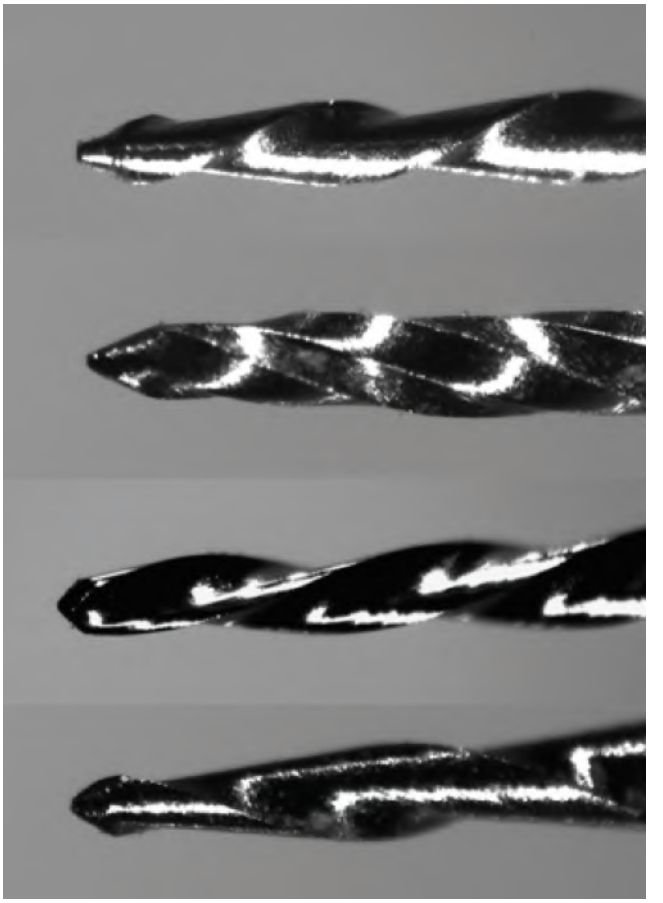

FIGURE 20-59 Tip configuration of different single-file instruments. From above: Reciproc, WaveOne, OneShape and F360.

Reciprocating Single-File Systems

Two instruments, both made from M-wire alloy, belong to this group: Reciproc (VDW) and WaveOne (Dentsply Maillefer). Reciproc instruments are available in different sizes 25.08 (R25), 40.06 (R40), 50.05 (R50), and WaveOne are available in the sizes 21.06 (small), 25.08 (primary), and 40.08 (large) (Table 20-5). Out of these instruments, only the WaveOne size 21.06 has a constant taper while all other instruments are characterized by a regressive taper. Only the first three millimetres of the working part from the tip of the instrument have a constant taper of .08 followed by a continuously decreasing taper. The final tapers near the shaft are .055 for the WaveOne primary, .045 for the WaveOne large, .043 for Reciproc R25 and .04 for Reciproc R40 and R50, respectively.

Reciproc instruments have an S-shaped cross-section along the entire working part of the instruments (Figure 20-60).[168] This cross-sectional design results in sharp cutting edges and a small core diameter with a comparable great chip space. In contrast, WaveOne instruments are characterized by different cross-sectional designs. Near the tip, the cross section shows radial lands, while in the middle part of the working length and near the shaft the cross-sectional design changes from a modified triangular convex cross section with radial lands to a neutral rake angle with a triangular convex cross section (Figure 20-60).[168]

The reciprocating working motion consists of a counter-clockwise (cutting direction) and a clockwise motion (release of the instrument), whereby the angle of the counter-clockwise direction is greater than the angle of the reverse direction (Figure 20-61). The actual angle of

TABLE 20-5 Characteristics of Single-File Systems

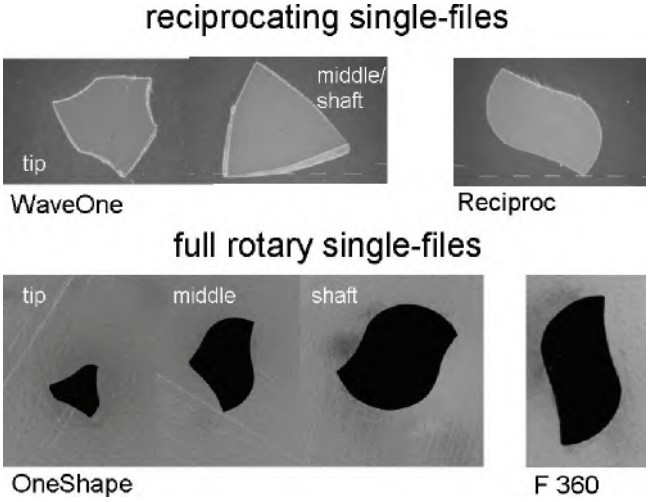

FIGURE 20-60 Cross-sectional designs of reciprocating and full rotary single-file instruments.

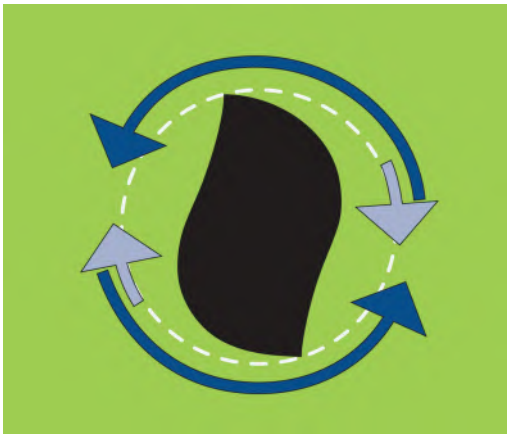

FIGURE 20-61 Schematic illustration of the reciprocating working motion. The angle of the counter-clockwise direction (cutting action) is greater than the angle of the reverse direction (release of the instrument).

counter-clockwise rotation is 158.68° for Reciproc and 159.85° for WaveOne, while the angle in clockwise direction is 34.65° for Reciproc and 41.44° for WaveOne.[169]

The actual cycle rotational speed is 282.92 r.p.m for Reciproc and 343.36 r.p.m for WaveOne.[169] However, these values strongly depend on the type of motor used. It should be noted that the actual values may differ from those set by the manufacturer.[169] Due to the fact that the angle of the counter-clockwise motion is greater than the angle in clockwise direction, the instrument progresses continuously towards the apical end of the root canal. It is important to note that the angles of reciprocation are specific to the design of WaveOne and Reciproc instruments and are programmed in special electronic motors.[169] It is therefore mandatory to use a motor that is able to generate the required counter- and clockwise angles. Reciproc and WaveOne instruments are not suited for sterilization processes since they do not fit into the handpiece again. Therefore, these instruments can only be used for one patient.

Clinically, it is important to consider that these instruments should not be used in a single straightforward motion up to the apical end of the root canal. Instead, the instruments should be used in a slow in-and-out pecking motion with amplitude of less than 3 mm. One in-and-out movement is defined as one peck. Following three pecks, the instruments should be removed, the canal copiously irrigated, the flutes of the instrument cleaned and the canal scouted with a small hand instrument, to avoid canal blockage with debris or dentin chips. Thus, the handling of these reciprocating instruments should be based on a sequence of three pecks where with every peck the instrument progresses deeper into the canal.

Some studies suggest that the use of reciprocating single-file systems is associated with little to nearly no canal transportation, even when preparing severely curved canals (Figure 20-62).[168,170-172] A micro-computed tomographic evaluation found that the use of Twisted Files Adaptive in severely curved root canal of extracted human mandibular molars resulted in less canal transportation and better centering ability than Reciproc and WaveOne.[173]

It appears that these systems considerably reduce the working time for canal preparation compared to other engine driven NiTi systems.[168,170,174] The use of these reciprocating instruments was safe, and fractures were not noticed.[168,171] Data about the cleaning efficiency of reciprocating instruments is controversial.[170]

Regarding cyclic fatigue of reciprocating single-files, several studies suggested that the reciprocating single-file instruments displayed greater flexural fatigue resistance than full-sequence rotary systems.[175,176] In general, Reciproc showed better torsional resistance and less bending resistance than WaveOne.[177,178] The superior behavior of Reciproc might be attributed to the smaller core diameter of these instruments compared to WaveOne and the fact that for Reciproc, the angles of reciprocation are smaller than those of WaveOne. Similarly, the speed of reciprocation is lower for Reciproc than for WaveOne.[168,170] However, the damage that these instruments may cause to dentin is still controversial.

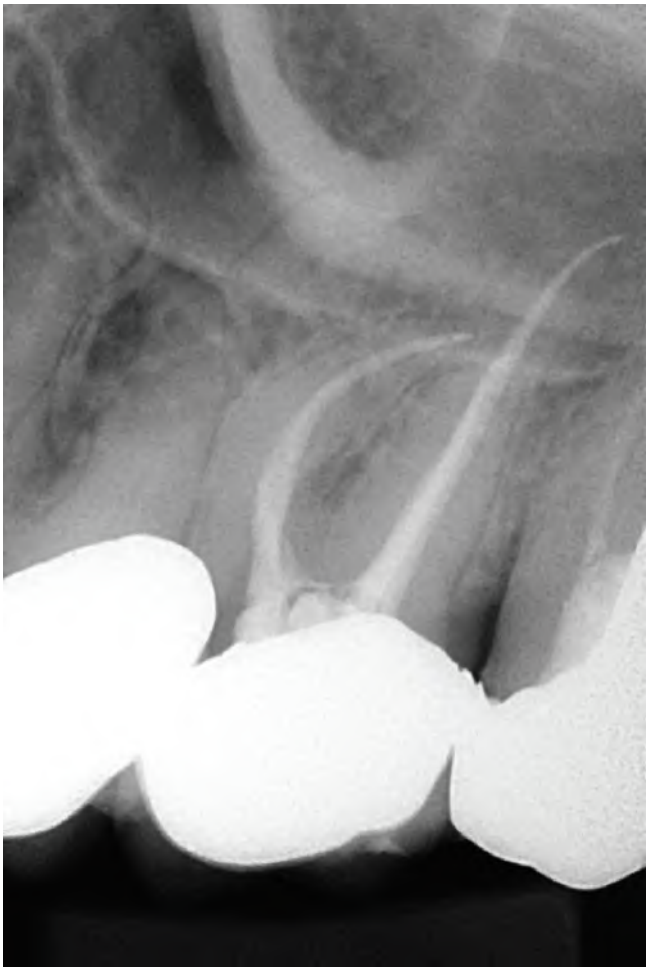

FIGURE 20-62 Adequate root canal preparation without canal straightening. The canals were prepared using a reciprocation single-file system.

Full Rotary Single-File Systems

The single-file systems F360 and F6 Sky Taper (both Brasseler, Lemgo, Germany) and OneShape (Micro Méga, Besançon, France) operate in a full clockwise rotational motion and can be used in every torque-controlled motor and handpiece (Table 20-5). Currently, no data are available regarding the F6 Sky Taper instruments, since these instruments were launched only recently.

All F360 instruments possess a constant taper of .04 and the following sizes are available: 25, 35, 45, and 55.[179] A modified S-shaped cross-sectional design is used for the entire working part of the instruments (Figure 20-60) and the instruments are made of a conventional austenite NiTi alloy.[179] OneShape instruments are available in sizes 25, 30, and 37 with a constant taper of .06. The instruments are made of conventional austenite NiTi and are characterised by different cross-sectional designs over the entire length of the working part (Figure 20-60).[179] In the tip region, the cross section represents three cutting edges while in the middle, the cross-sectional design progressively changes from a three-cutting-edge design to two cutting edges. Near the shaft, the instruments possess an S-shaped cross section with

two cutting edges.[179] OneShape instruments have variable pitch lengths along the working part (Figure 20-58). It is claimed that this design minimizes threading and binding of the instrument in continuous rotation.

According to comparative investigations, F360 and OneShape single-file instruments prepared curved canals equally well compared to reciprocating single-file systems and full-sequence rotary NiTi instruments (Figure 20-63).[172,179] The original canal curvature was well maintained and hardly any procedural errors were noted. The instruments were found to be safe. One study[171] found that the use of OneShape instruments required less time to prepare curved canals in extracted teeth compared with Reciproc and WaveOne, while another study[179] found no difference. However, preparation of severely curved canals was significantly faster with F360 and OneShape compared to the full-sequence Mtwo system (VDW).[179]

Two investigations evaluated the shaping ability of F360 and OneShape instruments compared with the two reciprocating single-file systems Reciproc and WaveOne in simulated S-shaped canals.[180,181] Both studies agreed that the lower tapered rotary single-file systems (F360 and OneShape) maintained both original canal curvatures better than the reciprocating instruments having greater tapers (Figure 20-64).

FIGURE 20-63 No visible canal transportation after preparation with a full rotary single-file system.

OneShape prepared these S-shaped canals significantly faster compared to WaveOne and F360 instruments.[181]

Regarding the tendency of rotary single-file systems to extrude debris apically and to cause dentinal damages, the available data is inconclusive.

Clinical Consequences of Faster Canal Preparation

Preparation time using automated NiTi systems is shorter. It can be decreased by up to 60% when using the single-file systems.[168] Consequently, the time available for irrigation and disinfection of the root canal system is substantially shorter. This must be taken into consideration by increasing the volume of the irrigants used. Passive ultrasonic activation of the irrigant may also be advantageous.

Conclusions

In summary it can be concluded that

- Single-file systems maintain well the original canal curvature, even of severely curved canals, and are safe to use.
- Single-file systems are faster than full-sequence rotary NiTi instruments.
- Due to the faster preparation time with single-file systems, special measures to improve canal cleanliness and disinfection (e.g., passive ultrasonic activation of irrigants, longer contact time) may be required.
- All single-file systems, except Reciproc, require a glide path preparation.
- Currently, controversy exists whether the use of reciprocating single-file systems is associated with increased risk of apical debris extrusion and dentinal damages (cracks).
- For complex canal anatomy such as S-shaped canals, rotary single-file systems with less taper seem to be better than reciprocating single-file systems.

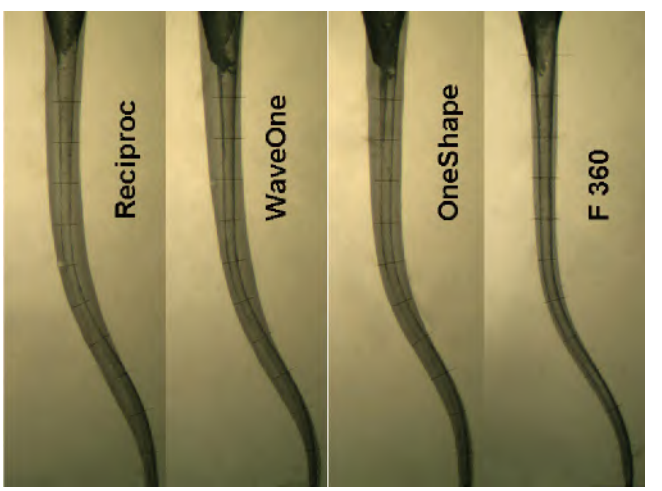

FIGURE 20-64 Canal transportation using different full rotary and reciprocating single-file instruments in simulated S-shaped canals. Preparation was performed to an apical size 25. The full rotary single-file instruments maintained both canal curvatures better than the reciprocating instruments.

SELF ADJUSTING FILE (SAF)

The SAF shows a new conceptual approach to instrument design. It is constructed of two broad lattices of NiTi that are connected by several small wires forming a connective mesh. This principle of construction allows the file to be compressed in small and narrow canals and to extend in root canals with large diameters. If the correct file size is selected, the instrument is designed to touch as much root canal surface as possible. The instrument operates in a special handpiece with slight vibrations in a frequency of 5,000 Hz.[182]

Since the inner part of the instrument is hollow, an irrigant of choice can be introduced via this empty space resulting in continuous irrigation during preparation. The irrigant can be delivered at a maximum rate of 1–10 mL per minute. The two lattices show a rough surface without blades. The file does not cut dentin like conventional instruments that are equipped with cutting blades, but rather removes dentinal hard tissue by brushing or scrubbing and immediately irrigating the shavings and tissue remnants out of the root canal. The tip of the file is asymmetrically designed, allowing the instrument to vibrate itself into the best position, hence the term Self Adjusting File.

The compressibility of the instrument enables a good adaption to the cross-sectional shape of the canal. When inserted into an oval canal with a 0.2 mm mesio-distal diameter, a 1.5 mm SAF will be compressed mesio-distally and thus spread bucco-lingually as far as 2.4 mm (Figure 20-65).[182]

The manufacturer recommends using the SAF for four minutes per canal with a 4 mL per minute flow rate of irrigant in small up and down movements. Ideally, the canal will be uniformly enlarged along its entire circumference, resulting in an undefined, non-ISO shape, magnification of the original canal shape.

Regarding obturation, lateral compaction does not seem to be suitable for the SAF technique since the prepared root canal does not show a specific geometry. Thermoplastic obturation techniques may be difficult since the apical taper is not clearly defined.

The SAF represents an interesting and novel approach of root canal preparation. It is able to save dentin by maintaining the original root canal cross-sectional shape and provides good canal cleaning. However, the SAF system is not widely used. Further studies are still necessary.

MOTORS AND TORQUE CONTROLLED HANDPIECES

Following the improvement in instrumentation systems, endodontic motors have also undergone enhancements in torque control and adjustable kinematics.[183] Modern automated devices can be classified into:

- Torque-limited handpieces
- High- and low-torque electric motors
- Open and closed reciprocating motors

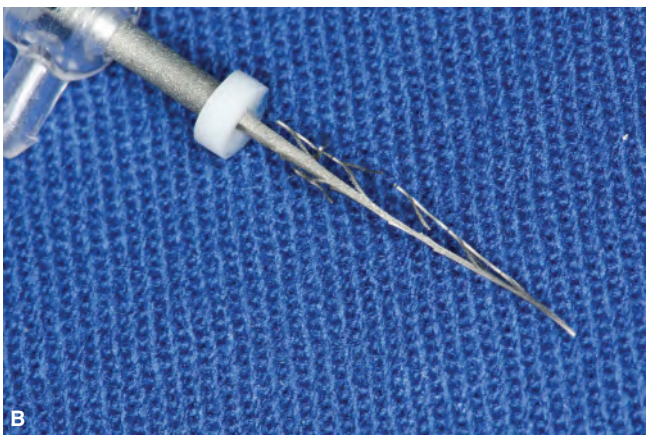

FIGURE 20-65 ***A&B, C.*** Instrument fractures are prevented by the connecting mesh.

- Motors combining rotary and reciprocating motion (adaptive motion)
- Vertical vibration (see "Self Adjusting File")

Torque-Limited Handpieces

These handpieces possess an integrated mechanical torque control. The different torque settings can be chosen by a swivel type adjustment ring of the handpiece (Table 20-6).[184] One of the first torque-limited handpiece was the ENDOadvance (KaVo, Biberach, Germany), that has a maximum speed of 40,000 r.p.m. Due to a 120:1 reduction, instruments are rotating with a speed of 333 r.p.m. The torque setting can be adjusted by a glide clutch to 0.25, 0.50, 1.0, and 3.0 Ncm. A clicking sound and a vibration are noticed as soon as the clutch is activated.[184]

The torque-limited rotation contra-angle air-driven handpiece SiroNiTi (Sirona, Bensheim, Germany) set the instruments in rotation with a maximum speed of 350 r.p.m due to a reduction of 115:1. This handpiece allows the selection of five different torque settings (between 1 Ncm and 3 Ncm) (Figure 20-66). Retro-rotation prevents the instruments from becoming locked in the root canal if excessive torque is reached.[184] The successor model SIRONiTi Air+ (Sirona) can be used either with an air motor or with an electric motor. When used with an electric motor, even instruments requiring higher rotational speeds such as RaCe, BioRaCe, and BTRaCe (all FKG, La-Chaux-de-Fonds, Switzerland) can be used, as the SIRONiTi Air+ has a maximum rotational speed of 600 r.p.m at a motor speed of 40,000 r.p.m.[184]

The Anthogyr NiTi Control handpiece (Dentsply Maillefer, Ballaigues, Switzerland) is another contra-angle handpiece that can be connected to the dental unit with a reduction ratio of 64:1 for pneumatic dental units and 128:1 for electrical ones, respectively. This handpiece permits a maximum speed of 312 r.p.m., and the torque level can be adjusted between 0.7 Ncm and 4.5 Ncm.[184] Especially for Mtwo instruments (VDW, Munich, Germany), the air-driven torque-limited rotation handpiece Mtwo direct (Sirona, Bensheim, Germany) was introduced (Figure 20-67). The torque settings of this handpiece are specially adjusted for Mtwo instruments and can only accommodate these files. (Table 20-7).[184]

A study investigated the influence of a torque-limited handpiece (SiroNiTi; Sirona, Bensheim, Germany) and an electric stepper motor using various full-sequence NiTi instruments in simulated curved canals in resin blocks with curvatures ranging from 0° to 30°.[185] It was found that while the use of the torque-limited handpiece was associated with significant shorter preparation times, no significant differences in canal straightening and loss of working

X-Smart (Maillefer)	0.6 – 5.2	9	120 – 800	yes	possible

length were detected. These results were supported by another study indicating that both systems respected well the original root canal curvature and were safe.[186]

Similar results were obtained when using the full-sequence FlexMaster instruments (VDW) in a crown-down approach.[187] The automated devices compared in this study included two torque-limited handpieces (SiroNiTi and ENDOadvance) and a low-torque electric motor (Endo IT professional). Preparation of simulated curved canals in resin blocks was significantly faster with the electric motor than with the torque-limited handpieces, and ENDOadvance was significantly faster than SiroNiTi. In severely curved canals of extracted teeth, preparation with Endo IT and ENDOadvance was significantly faster than with SiroNiTi and the use of electric motor resulted in less canal straightening as compared to SiroNiTi. Regarding all other parameters, no significant differences were observed.[187]

High- and Low-Torque Electric Motors

Although high-torque motors allow very efficient root canal preparation, the use of these motors was found to be associated with an increased incidence of file deformation and separation.[188] In low-torque motors with torque levels beneath 1 Ncm, torque settings below the estimated torque failure can be selected (Table 20-8). The reduction of cyclic fatigue of NiTi files seems to be more reliable with low-torque motors.[189,190] However, the torque value should not be set too low because a minimum torque is required for any engine-driven instrument to work against friction inside the root canal and to cut-off dentin.

Electric motors usually have an auto-retro-rotation function to loose locked instruments (Figure 20-68). To minimize the risk of instrument separation, in some systems an acoustic warning tone can be adjusted by the operator when a critical torque limit is reached.[184] In the library of these motors, pre-settings of optimal rotational speed and maximum torque values are stored (Figure 20-69) and for most motors, these values can be updated for newly introduced system by an interface (Table 20-7).

For most rotary NiTi systems, the recommended rotational speed is in the range of 150 r.p.m - 600 r.p.m. Data regarding the influence of the rotational speed on the safety and efficiency of the instruments used is inconclusive.[183]

TABLE 20-8 Set Values of Different Closed Reciprocating Motors (CCW=counter-clockwise; CW=clockwise)

Motor	CCW angle (°)	CW angle (°)	Cycle rotation speed (r.p.m.)
VDW.Silver – Reciproc ALL mode	150	30	300
VDW.Silver – WaveOne ALL mode	170	50	350
ATR Technika	144	72	400

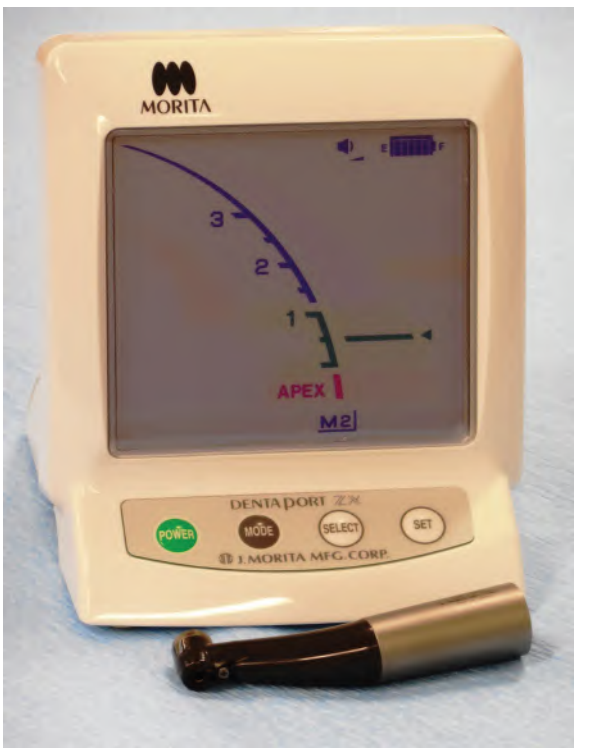

FIGURE 20-68 The Dentaport ZX Set ORT motor (Morita, Japan). The ORT (Optimum Torque Reverse) mode is claimed to relieve the stress on the instrument during preparation. When reaching a specific torque value, the full clockwise rotation of the instrument changes direction to a 90° counter-clockwise rotation and then reverts back to a clockwise rotation. If the instrument is still under stress, it will turn another 180° in a clockwise direction before reversing back to relieve.

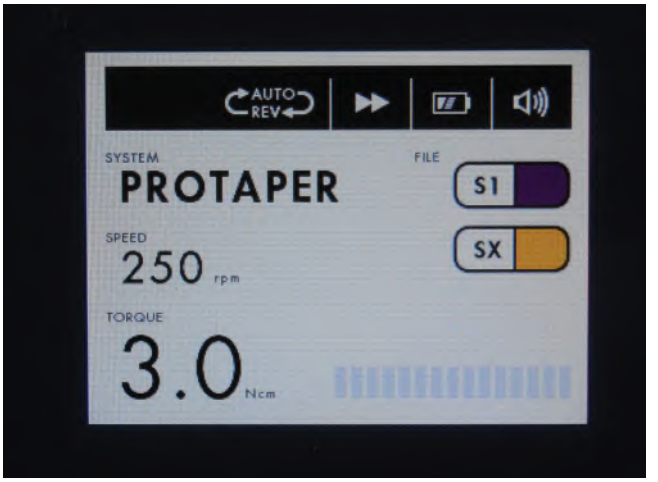

FIGURE 20-69 Display of the X-Smart Plus motor showing the pre-set torque value and the rotation speed.

FIGURE 20-70

Some studies reported that increasing the rotational speed resulted in increased efficiency of the instruments[191,192] and was not associated with an increased risk of instrument deformation, higher torque or higher risk of instrument fracture.[193,194] However, one study reported that an increase in the rotational speed resulted in higher risk of instrument fracture.[195] It appears that the combination of the rotational speed of the instrument and the degree and radius of the canal curvature is mainly responsible for the increased risk of instrument breakage.[196]

While low-torque motors were found to be safer when used by inexperienced operators,[197] no such differences were found for experienced operators.[81,198] However, it should be noted that in some motors, the actual torque values differ from the values indicated on the motors. These can be even higher than the torque causing failure of some rotary NiTi instruments.[183,199]

Reciprocating Motors

Reciprocating motors are available with fixed values of angles and speed of reciprocation (representatives are: ATR Technika, Pistoia, Italy; X-Smart Plus, Dentsply Maillefer, Ballaigues, Switzerland); VDW.Silver Reciproc and VDW. Gold Reciproc (both from VDW, Munich, Germany) (Figure 20-70) (Table 20-8).

In contrast to these closed-system motors, other motors are designed to allow modification of reciprocation.[183] The ATR Vision (ATR, Pistoia, Italy) and iEndo Dual (Acetone, Merignac, France) are representatives of open-system motors.

It is noteworthy that the actual values of reciprocating differ markedly from the set values given by the manufacturers.[169] As long as the actual values are below the set ones, the clinical consequences are negligible as decreasing the reciprocating values results in longer preparation times but simultaneously in increased cyclic resistance of the instruments and less canal transportation during preparation.[200] However, increasing the range of reciprocation was found to reduce the cyclic fatigue resistance of the instruments.[201] Thus, the operator should be aware of the actual reciprocating values of the particular motor used, in order to avoid undesirable effects like instrument fracture during the prolonged used of reciprocating instruments.

Regarding the impact of the reciprocating working motion on the torsional and cyclic fatigue, as well as the life span of the instruments used, the results of the available studies agree that the reciprocating motion is associated with a higher mean life span and an increased cyclic fatigue resistance.[183,202,203] The incidence of instrument fracture has been reported to be considerably low for reciprocating instruments.[204,205] The reciprocating movement seems to be relatively safe as it is assumed that deformation of the instruments during the counterclockwise rotation can be recovered upon unloading.[206]

Most of the torque-controlled and reciprocating endodontic motors are also available with an integrated electronic apex locator (Figure 20-71). Clinical studies showed that the accuracy and reliability of working length determination using these apex locating endodontic motors was comparable to independent apex locators.[207-210]

Reciprocating Handpiece

Recently, a wireless handpiece has been introduced, generating reciprocating working motion and full clockwise rotation. The VDW.Connect Drive (VDW) is a handpiece that can be connected via Bluetooth with an iPad (≥ iOS 8) (Figure 20-72). A special App (VDW.Connect App) offers the opportunity to select the required working motion, either reciprocating or full clockwise rotation. The required angles of reciprocation and the torque and rotational speed values for the different instrument sizes are stored in the library of the App. Additional functions, such as electronic apex locator, can be selected via the App. As customary for Apps, the system can be updated via regular downloads offered by

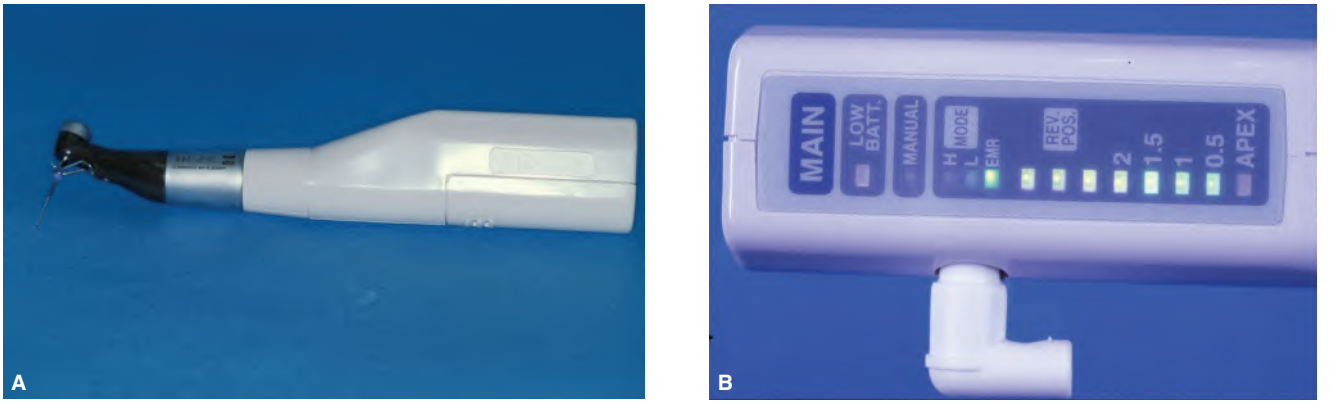

FIGURE 20-71 ***A.*** The torque-control motor TriAuto ZX (Morita, Dietzenbach, Germany). ***B.*** The display showing two different torque settings and the integrated electronic apex locator.

FIGURE 20-72 ***A.*** The VDW.Connect Drive handpiece generates reciprocating working motion and a full clockwise rotational working motion. ***B.*** The VDW.Connect App offers the opportunity to select different working motions.

the manufacturer. Another similar wireless handpiece called X-Smart iQ (Dentsply/Maillefer) has also been recently launched. It has the same features as the VDW.Connect Drive and is also connected via Bluetooth. Studies assessing these handpieces are not yet available.

Motors Combining Rotary and Reciprocating Motion (Adaptive Motion)

The latest developments in the field of automated devices are electric motors that combine the rotary and the rotational reciprocating motion (i.e., adaptive motion). Originally, this adaptive working motion was developed for the use of Twisted File Adaptive instruments and the Elements Motor (both from Kerr/SybronEndo, Orange, CA, U.S.A.).

This motion aims to combine the advantages of the rotary and the reciprocating motion.[183] When the instrument used is not stressed, or only minimally stressed, the motor generates a rotary clockwise motion of about 600° inside the canal and then stops. Thereafter, the clockwise rotation restarts. Whenever the instrument is exerted to intracanal stress (in curved and narrow canals, or during removal of filling materials for retreatment) the motion of the instrument is changed to reciprocal.[183] The angles of reciprocating are not constant but depend on the intracanal stress of the instrument and can be modified in the range of 0°-600° for the clockwise and 0°-370° for the counterclockwise motion.[183]

Data regarding the properties of this new generation of endodontic motors is scarce. However, preliminary results indicate that under cyclic fatigue testing, the adaptive motion increased the time to fracture of TF Adaptive instruments (Kerr/SybronEndo) when compared to full rotary motion.[211]

In summary it can be concluded that

- Torque-limited handpieces seem to be safe and allow a rapid preparation of even severely curved root canals without increased risk of procedural errors. The main advantages of these handpieces in comparison to electric motors are their lower cost and that no separate dental equipment is necessary.

- For electric motors, actual torque values may differ markedly from the pre-set values. Occasionally, actual values may be higher than those values reported at fracture. Selection of rotational speed is crucial as instrumentation speed directly affects instrument failure.
- For reciprocating motors, actual angles of reciprocation as well as speed may differ from the set values of the particular motors.
- The reciprocating motion seems to increase the fatigue resistance of instruments. Also, the incidence of instrument fracture is lower for reciprocating instruments when compared to rotary instruments.
- The adaptive motion seems to have a beneficial effect on cyclic fatigue of the instruments.
- Currently, no evidence exists suggesting that any specific automated device has any impact on treatment outcome.

ULTRASONICS

In 1976, Dr. Martin reported on the use of ultrasonics for root canal preparation and termed the technique "endosonics." Nevertheless, the first report on the use of ultrasonics for root canal treatment was published almost 20 years earlier by Richman in 1957.[212] Cavitation has been discussed as a main mechanism, however, acoustic streaming should be regarded the main mode of action.[213]

Ultrasonic devices are driven by piezoelectricity or magnetostriction, resulting in high-frequency oscillation (25 kHz - 40 kHz) of the inserted file that initiates acoustic microstreaming in the irrigation fluid. This action has been reported to result in excellent cleaning ability exerting antimicrobial activity by destruction of cell membranes.[214]

Shaping

Most studies report unsatisfactory results concerning the quality of preparation,[215,216] due to the high-frequency oscillations resulting in poor control of the file and especially the file tip. Since ultrasonic units are used with stainless steel instruments, the outer aspect of curved root canals is easily straightened or shows severe zipping and ledging. Longitudinal grooves in the root dentin following the use of ultrasonically activated files have been detected[217,218] (Figure 20-73). Nevertheless, when used carefully, ultrasonic instruments can be helpful in removal of obstacles, opening root canal orifices, and widening narrow isthmi.

Cleaning

The cleaning and disinfecting capacity of ultrasonics is still controversial. Excellent or good root canal cleanliness, removal of debris and smear layer compared to conventional irrigation techniques have been reported.[219-222] (Figure 20-73)

Working Safety

Apical blockages, ledging, and increased amount of apically extruded debris[223,224] as well as instrument fractures have been associated ultrasonic preparation.

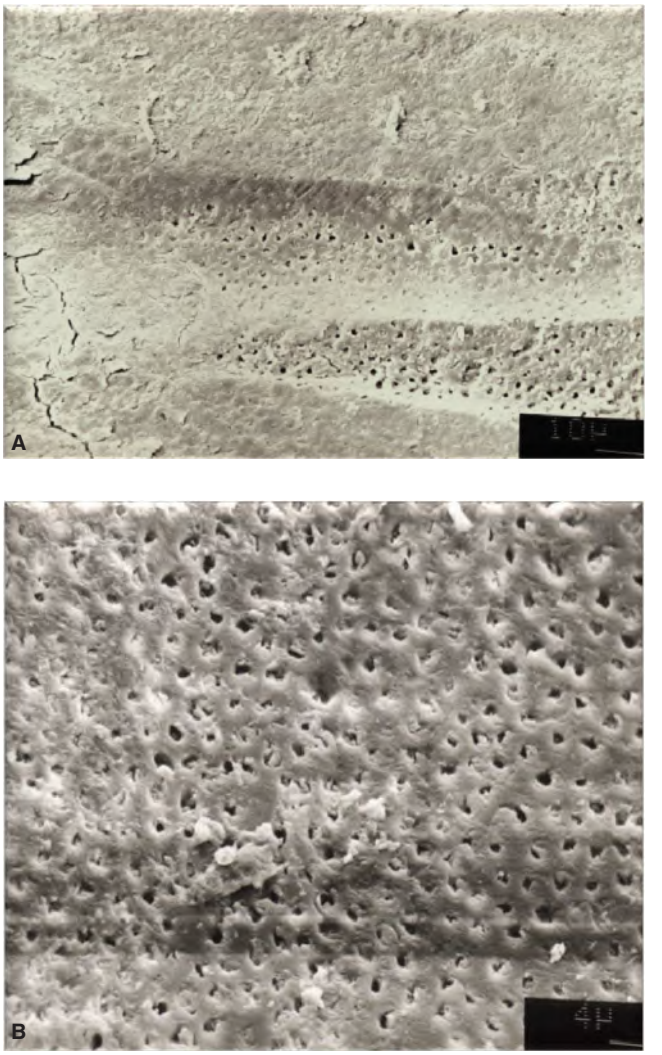

FIGURE 20-73 ***A.*** Longitudinal grooves in the root dentin following the use of ultrasonically activated files. ***B.*** Root canal wall following use of ultrasonics. Smear layer and debris have been removed completely.

Conclusions

It can be concluded that ultrasonics is a good adjunct for irrigation, but cannot be recommended for routine root canal preparation. Ultrasonics can be helpful in selected situations.

CONTROVERSY I: DENTINAL DAMAGE

With the introduction of reciprocating single-file systems, a new controversy has recently been rekindled regarding the impact of mechanical root canal preparation on dentinal damage. During root canal instrumentation and irrigation the structure, composition, and physical properties of dentin can be altered.

The following effects of mechanical root preparation and disinfection on root canal dentin were documented:

- Reduction of fracture resistance
- Preparation marks
- Dentinal cracks

Reduction of Root Strength

Any loss of tooth substance during preparation of the coronal access cavity is associated with a decrease in fracture resistance.[225,226] In general, the fracture resistance of root canal treated teeth is directly related to the amount of remaining sound tooth structure.[227] Currently, hand root canal preparation, using ISO standardized instruments with a constant taper of .02, appears to be associated with less weakening of the tooth compared to engine-driven NiTi instruments with tapers greater than the ISO standard.[228,229] When treating non-infected root canals, the use of greater taper instruments should be reconsidered and kept to a minimum. In cases of vital extirpation, there is no need to excessively enlarge such canals since they are not infected.[226] This will also reduce the risk of cracks or fractures (Figure 20-74).[227]

Preparation Marks

Evidence from several studies indicates that mechanical root canal preparation may cause preparation marks at the canal walls. Such defects have been shown following hand instrumentation as well as following engine-driven canal preparation (Figures 20-74 and 20-75).[2,86]

Dentinal Cracks

Dentinal cracks or root fractures occur when the tensile stress in the root canal wall exceeds the tensile stress of dentin.[228] During root canal preparation, the cutting edges of the instrument used make contact with the dentin walls creating momentary stress concentrations in dentin.[228] The highest tensile and comprehensive stress concentrations occur at the external root surface in the apical part of the canal. The authors demonstrated that the stiffer the instrument is (or the greater the taper of the instrument) the higher the stress concentration in the apical root dentin.[228] These stress concentrations may cause either complete or incomplete dentinal cracks, short- or long-term[230] (Figure 20-76).

It is currently debatable whether or not the use of single-file systems is associated with an increased risk of creating dentinal defects. Data regarding this issue are scarce at the moment. One study also assessed one rotary single-file system (OneShape, Micro Méga, Besançon, France).[231] Results showed dentin cracks in 50% of canals prepared with the full-sequence ProTaper systems (Dentsply Maillefer), in 5% of canals enlarged with Reciproc (Dentsply Maillefer) and in 35% of canals instrumented with OneShape.

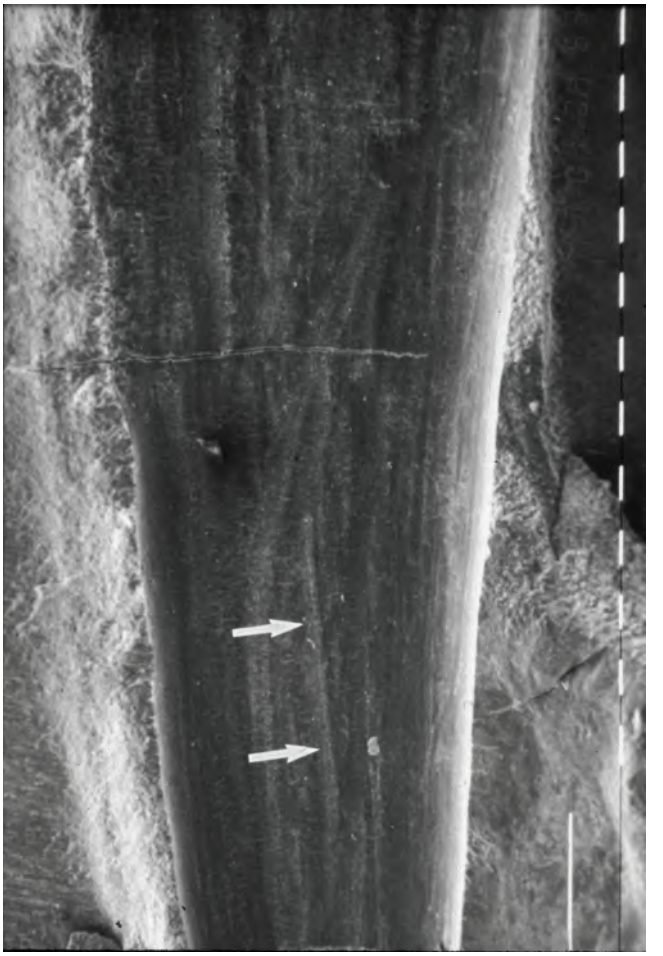

FIGURE 20-74 Scanning electron microscopic image showing grooves at the canal wall (arrows) running from coronal to apical following canal preparation with stainless steel Hedstrom files, used in a linear filling motion (magnification x160).

Definite appraisals of the clinical consequences are not possible and mere speculative at the moment.

Conclusions

In summary it can be concluded that:

- The different steps of root canal treatment are associated with a reduction of fracture-resistance of teeth.
- The use of tapered instruments has a crucial impact on root strength.
- Root canal preparation may cause preparation marks on the canal walls.
- Engine-driven preparation may cause dentinal defects such as complete and incomplete dentin cracks.
- Whether or not reciprocating instruments cause more dentinal defects than full-sequence rotary NiTi instruments is not clear.

CONTROVERSY II: APICAL PATENCY

One of the controversies that existed for some years has been the discussion on the benefits and shortcomings

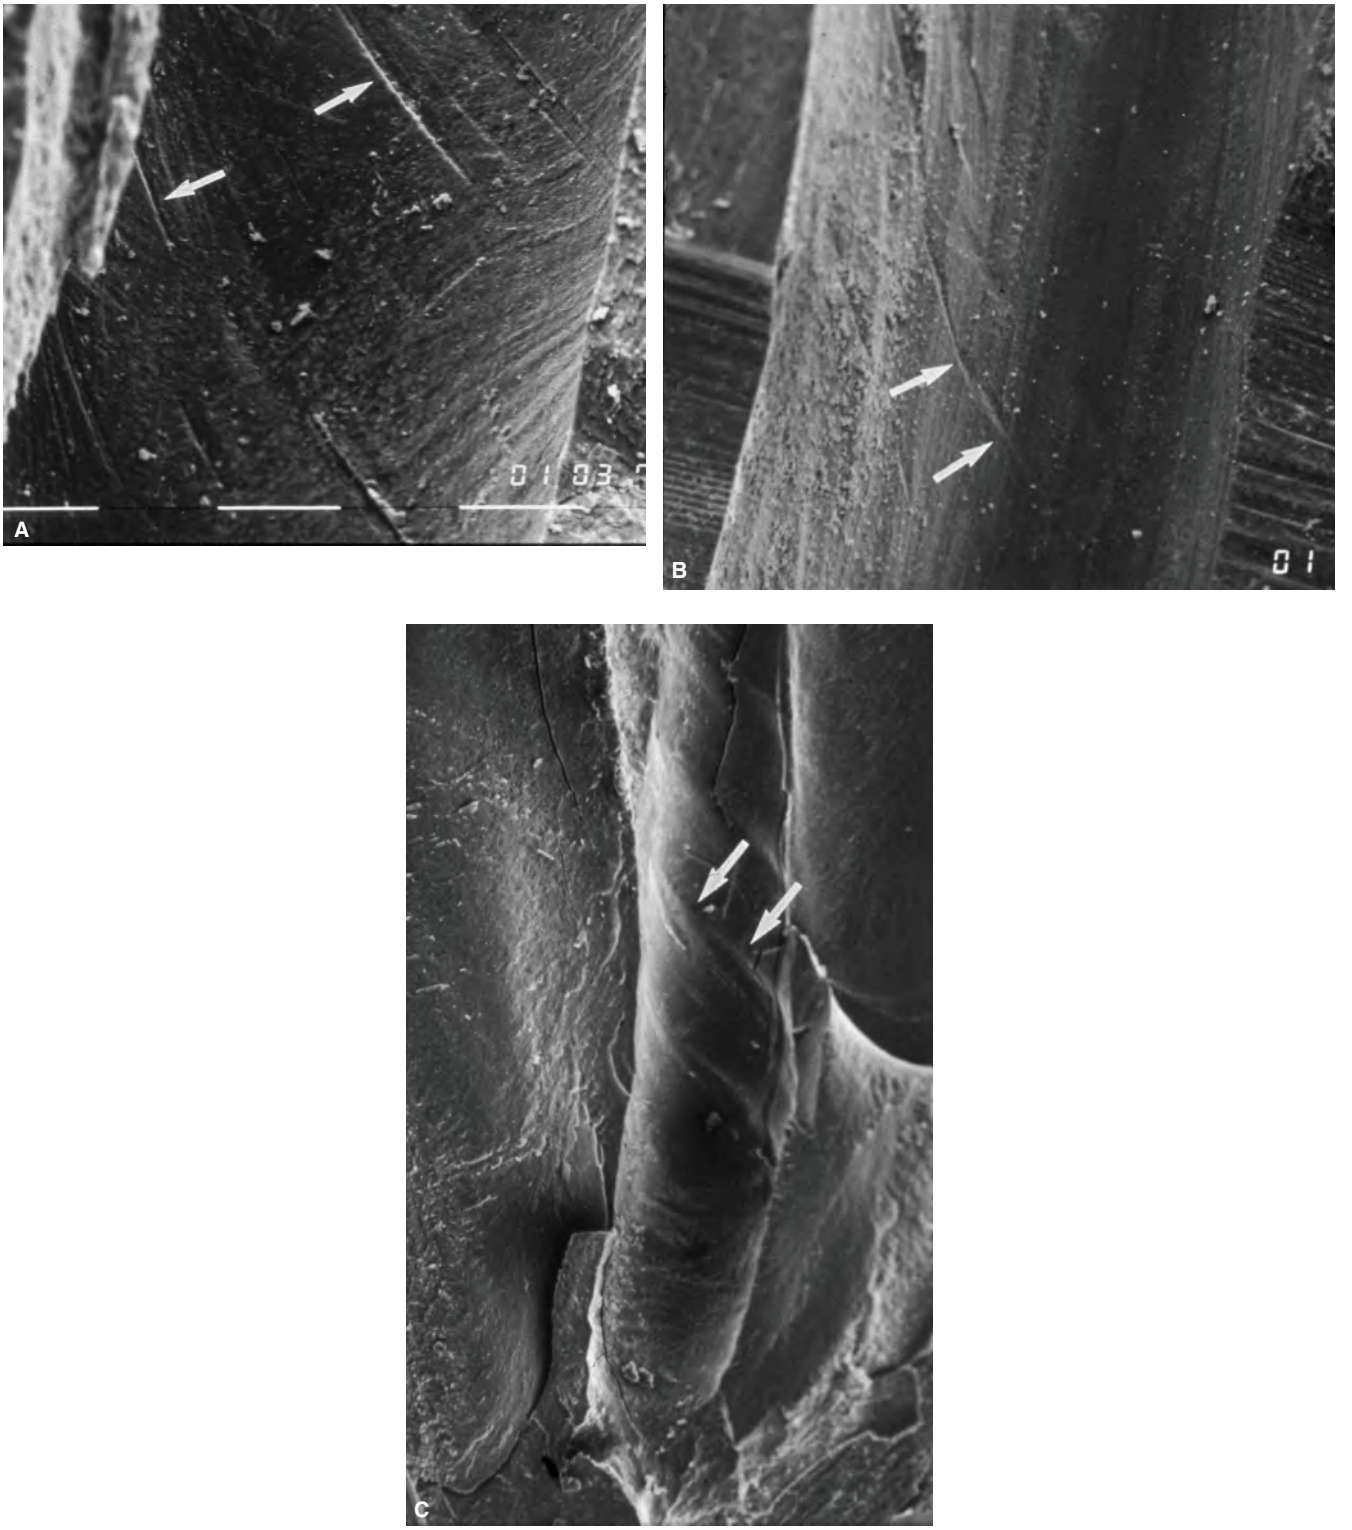

FIGURE 20-75 Scanning electron microscopic images of preparation marks. ***A & B.*** Slight grooves (arrows) following hand instrumentation with stainless steel K-files used in a reaming motion (x160). ***C.*** Clearly defined wave-shaped pattern (arrows) after using stainless steel K-files (x160).

of preparation techniques including "apical patency."[232] Buchanan[233] was credited as the first author introducing the patency concept. The patency file must be a small flexible K-file that should be used passively through the apical constriction without widening it.[234] The definition suggested by the American Association of Endodontists (AAE) is[235]: "A preparation technique in which the apical region of the root is kept clear of debris by recapitulation through the physiological foramen (apical constriction) with a fine file" (Figure 20-77).

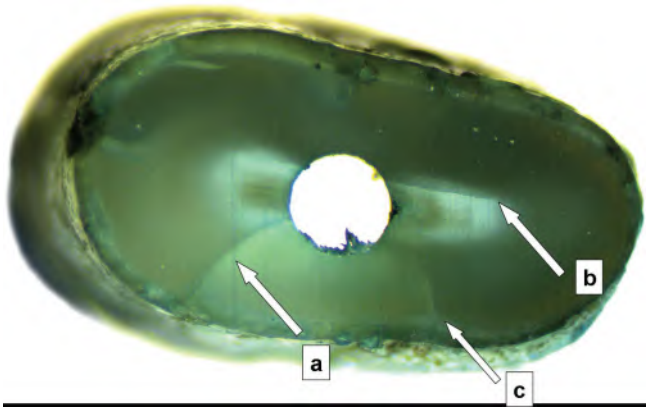

FIGURE 20-76 Cross-section of a root showing complete (a) and incomplete (b & c) dentinal cracks (x25).

It should be noted that some debris could be extruded beyond the apical foramen potentially carrying microorganisms into the periapical tissues and causing post-operative pain.[236,237] Also, only the major foraminal opening, located in the straight axis of the root canal, can be treated with the patency technique. Lateral openings and ramifications remain mechanically untreated and at best can be disinfected chemically by the irrigant (Figure 20-77). For more details, see Chapter 21. Nonetheless, when the patency technique was performed, with a file contaminated with bacteria in root canals filled with 5.25% sodium hypochlorite, no contamination of the periradicular tissue was found[238] (Figure 20-77).

The key concept when applying this technique is the use of very small size files (#8, #10 or #15). Larger files may carry the risk of opening the apical constriction or creating a "zipping effect."

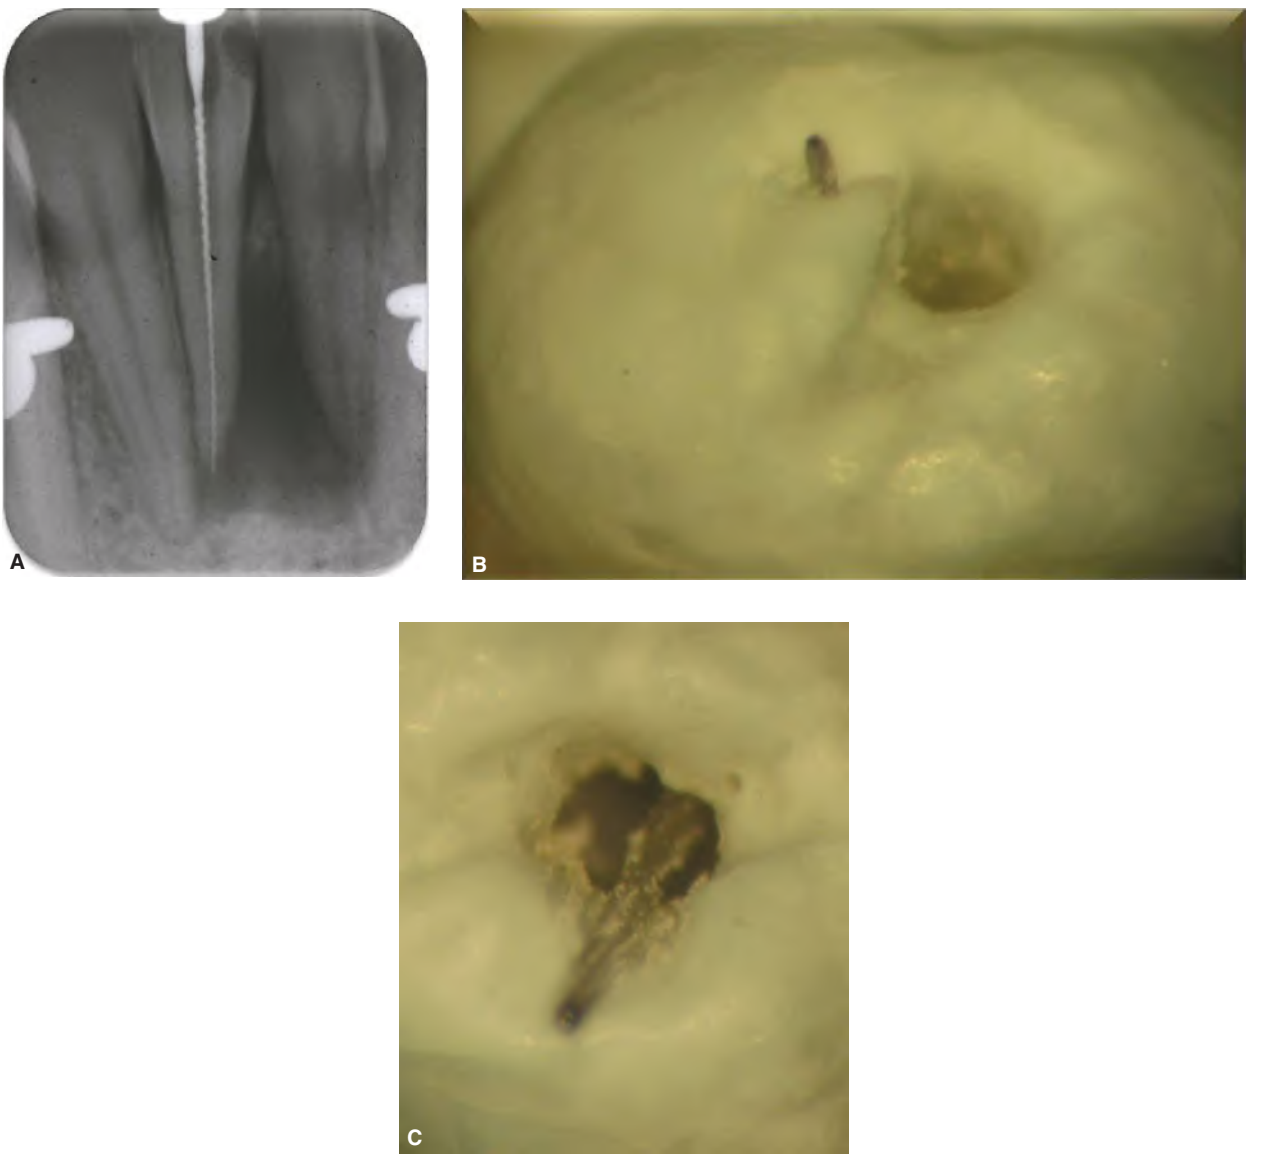

FIGURE 20-77 ***A***. Apical patency aims at keeping the foramen free of debris by intentionally extruding the file tip slightly beyond the apical foramen. ***B***. Patency has been achieved for one foramen, but the larger one remains uninstrumented. ***C***. Even with a small patency file size 010 debris is pushed beyond the foramen. Note that the circumference of the foramen is still covered with debris that could not be removed by use of a patency file.

When patency was assured with sizes 10 and 15 files, all teeth showed apical extrusion of irrigant.[239] Delivery of irrigant into the apical part of large root canals was superior when patency was maintained.[240,241] Also, the presence of gas bubbles inside the irrigant was minimized.[242]

In non-vital teeth, the frequency of posttreatment pain was lower when patency was maintained. Nevertheless, in some cases (mandibular teeth, teeth with pre-existing pain) duration of postoperative pain was extended in teeth with patency.[243]

General Health

In some studies, it has been demonstrated that overinstrumentation results in bacteremia.[244,245] Therefore, apical overinstrumentation or extrusion of infected debris should be avoided in patients with compromised health.[232,246,247]

Conclusions

- Infected debris, extruded through the apical foramen into the periapical tissues may cause periradicular inflammation.
- Apically extruded material may play a role in the etiology of post-treatment pain.
- Only major apical foramina can be treated using the patency technique.
- Controlled clinical trials and prospective studies validating the benefits or disadvantages of patency techniques are lacking.
- Patency techniques should not be used in medically compromised patients.
- When treating teeth with vital pulps, there is no indication or justification for intentional overinstrumentation.

From the limited evidence-based data in the current endodontic literature it is hard to solve the debate on apical patency.

CONTROVERSY III: APICAL EXTRUSION OF DEBRIS

Avoiding extrusion of some debris during root canal preparation is virtually impossible[248,249] (Figure 20-78). During root canal preparation, necrotic or vital pulp tissue, dentin chips, microorganisms, irrigants and in the case of retreatment even certain filling materials may be extruded into the periapical tissues.[248]

The most relevant consequences of apical debris extrusion during root canal preparation are post-treatment symptomatic apical periodontitis and interappointment flare-ups.[236] Thus, from a clinical and biological points of view, it is mandatory to make every effort to minimize the amount of apically extruded debris during root canal preparation.

When comparing different hand preparation techniques to engine-driven rotary preparation, it has been reported that hand preparation techniques using crown-down approach, or employing cervical flaring, were associated with less debris extrusion than techniques involving a linear manual filing motion.[248,250-252] On the other hand, some studies reported that, when properly used, rotary engine-driven preparation does not produce significant debris extrusion.[253,254]

FIGURE 20-78 Debris extruded beyond the apical foramen during root canal preparation.

Single-File Systems

Currently, controversy exists regarding the tendency of reciprocating single-file systems (WaveOne [Dentsply Maillefer, Ballaigues, Switzerland]) and Reciproc [VDW, Munich, Germany]) to extrude debris into the periapical tissues.[255] While one study found that the use of reciprocating single-file systems was associated with greater amounts of apically extruded debris,[256] other investigations reported contradictory results.[257-259] However, concerning the tendency of rotary single-file systems (F360 [Brasseler, Lemgo, Germany] and OneShape [Micro Méga, Besançon, France]) to extrude debris apically, the available data indicate that these systems caused less debris extrusion than the reciprocating single-file systems.[179,260] Although the currently available data are limited, the use of rotary single-file systems does not appear to be

associated with an increased risk of debris extrusion.[261] On the other hand, the impact of reciprocating canal preparation with particular single-file systems is currently debatable.

In this context, a recent meta-analysis study showed a trend that the use of reciprocating single-file systems was associated with greater amounts of extruded debris compared to full-sequence systems.[261] The reciprocating movement could have favored apical packing of debris and dentin, that might result in transportation of this debris beyond the apical foramen.[249,261] However, the cross-sectional design of the instruments was found to be the most relevant parameter that affected debris extrusion.[249] Instruments having greater cross-sectional areas extruded more debris apically and caused greater expression of neuropeptides (substance P and CGRP) than instruments having an S-shaped cross-sectional design.[249] Clearly, a sufficient chip space is a crucial design feature of root canal instruments that seems to have a direct impact on the amount of apically extruded material. Finally, this meta-analysis showed that the number of instruments used has an impact on apical debris extrusion, although current evidence supporting this conclusion is very limited.[249]

The results of this meta-analysis are at least partially supported by the findings of two clinical studies[262,263] Gambarini et al.[262] assessed post-treatment pain after root canal treatment using three different engine-driven instruments: the reciprocating single-file system WaveOne, Twisted Files instruments (Kerr/SybronEndo, Orange, CA, U.S.A.). A statistically significant difference was found between WaveOne and the two other instruments.

Following canal preparation with WaveOne, about 26.6% of patients experienced severe pain. None of the patients of the Twisted File group and only about 6.6% of the Twisted File adaptive group reported pain.

In a randomized clinical trial, root canals of 42 patients were prepared using the full-sequence rotary ProTaper systems and the reciprocating WaveOne instrument (both from Dentsply/Maillefer).[263] Treatments were performed in two appointment and postoperative pain was assessed using a numerical rating scale (NRS) score. Duration of pain and analgesic consumption were also evaluated. After both appointments, the NRS scores and the duration of pain were significantly higher in the WaveOne group. After the first appointment the analgesic consumption was significantly higher in this group as well. The authors explained these findings by the fact that the single-file WaveOne instrument may create a "*piston effect*" inside the root canal thereby extruding more debris apically than the instruments used in a continuous clockwise rotation.

Conclusions

In summary it can be concluded that

- Currently, the use of any types of instrument or preparation technique is associated with some debris extrusion.
- Full-sequence rotary NiTi instruments seem to extrude less debris than hand instruments.
- Full rotary single-file systems seem to extrude less debris than reciprocating single-file systems.
- Reciprocating single-file systems seem to extrude more debris than rotary full-sequence systems.

PREPARATION OF COMPLEX ROOT CANAL SYSTEMS

Confluence of Root Canals

If a confluence of two root canals is not detected, a high probability of over-enlargement and/or straightening exists (Figure 20-79). If the angle of insertion of the

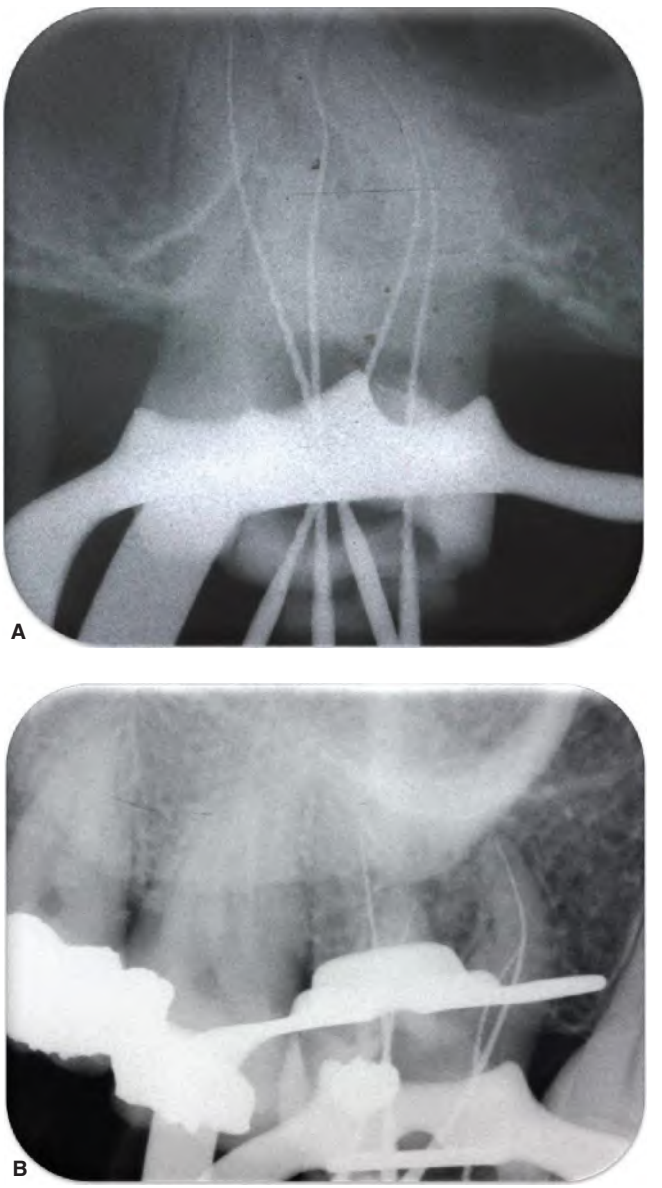

FIGURE 20-79 ***A & B.*** Radiographs demonstrating different locations and angles of confluence.

second canal is too large, there is a high risk of ledging or instrument fracture. Additionally, confusion during obturation may occur, as the estimated working length cannot be reached in the second canal when the first already has been obturated. Radiographically, in many cases, a confluence cannot clearly be diagnosed. Clinically, several methods have been proposed to identify confluencing root canals[80]:

- Endodontic instruments are inserted into both root canals. If only one can be inserted to working length at a time, confluence may be present.
- A gutta-percha point is placed in one root canal and an endodontic instrument into the other one. If joining, the instrument will leave a mark in the gutta-percha at the point of confluence (Figure 20-80).
- Both root canals are filled with an irrigant. When the level of irrigant is sinking in the second canal during drying of the first one, the presence of a confluence is likely. The same is true when calcium hydroxide is placed in one root canal and emerges from the second (Figure 20-81).

It should be remembered that confluences may not always be detected on radiographs.

Deep Splitting of Root Canals

The main challenges with deep splits of a root canal are detection and accessibility to the split. Thorough probing of the canal with a fine and pre-curved instrument is the best way of diagnosing a split. CBCT may also be helpful. For preparation and obturation, a good access cavity is mandatory, allowing accurate placement of gutta-percha, spreaders, or pluggers (Figure 20-82).

S-shaped Root Canals

Preparation of root canals presenting with a double, S-shaped curvature (also termed as bayonet-shaped), presents a major challenge for root canal instruments, whether

FIGURE 20-80 A gutta-percha cone is inserted in the "main" root canal. If an instrument is inserted in a joining canal, the impression on the cone will indicate location and angle of confluence.

FIGURE 20-81 If calcium hydroxide or an irrigant are placed into one root canal and emerge from the second, it is indicative of a confluence.

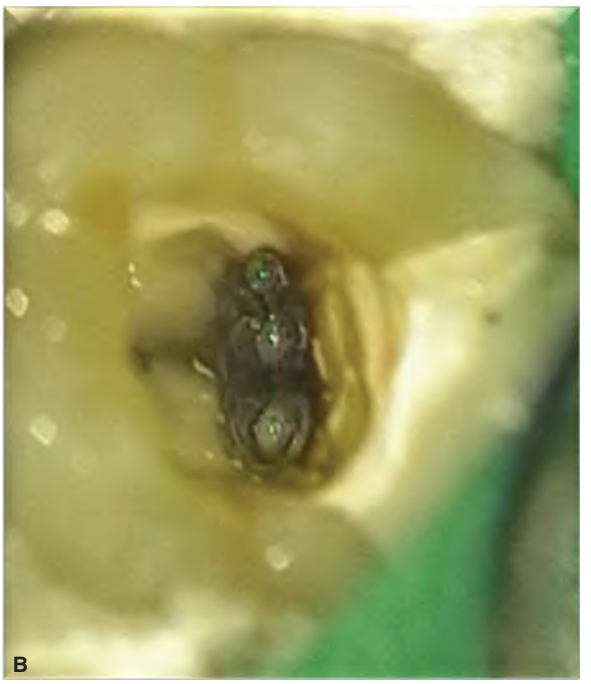

FIGURE 20-82 ***A-C,*** Deep splitting of root canals in the distal root of a mandibular molar. Detection and preparation were performed under the operating microscope.

stainless steel or nickel titanium. The severity of the problem depends on the radius and angle of the curvatures. It should be assumed in many cases, that an additional curve exists.

It has been demonstrated that complex anatomies such as double curvatures, S-shaped curvatures, abrupt curvatures or C-shaped root canals are associated with a higher risk of instrument fracture and unprepared root canal areas as well as of perforation.[264] Unfortunately, double curvatures in many clinical cases cannot be recognized well in a two-dimensional radiograph (Figure 20-83). For more details, see Chapter 26, Endodontic Therapy in Teeth with Anatomical Variations.

Cyclic behavior of the instruments is extremely challenged during preparation of such root canal configurations. Unfortunately, the vast majority of studies have been conducted on simulated root canals in plastic blocks since this is a way to work on standardized anatomy. It should be noted that such studies do not represent clinical reality and the results should be interpreted with caution. Micro-CT seems to have an advantage for this type of research.

Conceptually, it has been recommended to prepare S-shaped root canals in three main steps[265]: Following preparation of a sufficiently large access cavity, the coronal part of the root canal is enlarged upto the beginning of the first curvature. Next, the coronal curvature is shaped to allow access to the apical curve. Finally, the apical part of the root canal with the second curve, is enlarged with small precurved, or even slightly over-curved, hand instruments or flexible low-tapered NiTi instruments (i.e., ProFile .04). This procedure includes slight straightening at the inner aspect of the second apical curve, and the opposite side of the coronal curve.

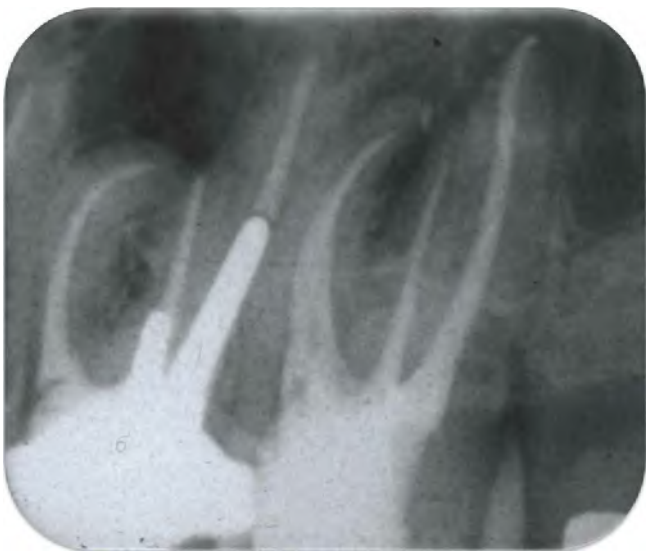

FIGURE 20-83 Maxillary molar with an S-shaped palatal root canal. The double curve in this tooth became visible only in the distal-excentric radiograph.

When multiple curvatures exist, rotary NiTi instruments are undergoing an additional stress. When compared to artificial root canals with single curves, during preparation of double-curved canals, the number of rotations till fracture (NRF) in the apical curve, dropped from 633 to 105 for ProFile .06/25, and from 548 to 93 for Vortex NiTi instruments.[266]

The results and conclusions from studies on preparation of S-shaped canals, using NiTi, instruments are controversial. Preparation of S-shaped root canals, in some studies, has shown less convincing results, regarding canal straightening and increased incidence of instrument fractures.[267,268] One study found that the SAF performed better than a few conventionally designed systems made from Controlled Memory Wire or M-Wire (Typhoon, Vortex).[269]

A final conclusion based on these findings cannot be drawn. However, it is recommended to:

- Prepare a straight-line access to the first curvature, eliminating any interferences in this part of the root canal.
- Prepare the first curvature before addressing the second one. Instruments with a larger taper can be used for this purpose.
- Start apical preparation only when enlargement of the first curvature has been performed.
- Use flexible instruments with a small taper (.05) for apical preparation, preferably hand instruments, and limit preparation to a size 25 or 30 (Figures 20-84).

Oval Root Canals

Depending on the extent of irregularity oval and C-shaped root canals also present some major challenge for preparation, disinfection, and obturation[270] (Figure 20-85). Under-preparation, leaving lateral extensions of the root canal walls untouched, and over-preparation, increasing the risk of strip-perforations, are among the major problems (Figure 20-86). Using hand instruments in a circumferential filing technique is recommended for oval and C-shaped root canals in order to adequately enlarge and clean both lateral extensions without over-preparation in the middle of the root canal.

FIGURE 20-84 Well centered preparation with good maintenance of the curves in this first mandibular molar after preparation with FlexMaster .02/35. (Courtesy of Dr. Sabine Nordmeyer, Berlin, Germany)

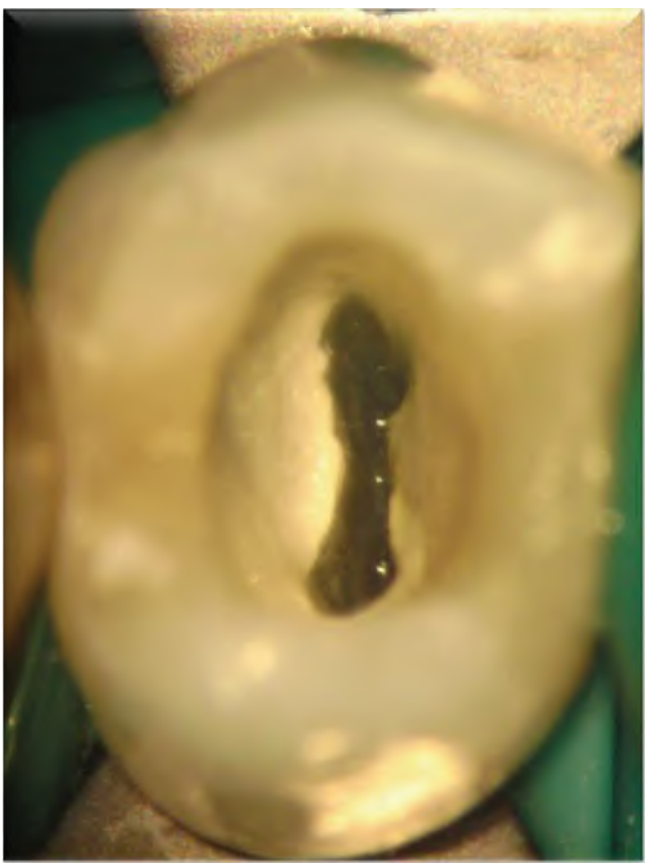

FIGURE 20-85 Long oval root canal system in a maxillary premolar.

FIGURE 20-86 Overpreparation on the inner concave side of the root canal may result in a strip-perforation.

In contrast to stainless steel instruments, flexible NiTi instruments are difficult to manipulate in lateral extensions. These instruments tend to penetrate along the path of least resistance and the file tip cannot be directed exactly into one direction by manipulation of the handpiece. This results is insufficient cleaning using single file, reciprocating, or full sequence NiTi rotary file systems.[271] ProTaper F2 left 24% of the pulp tissue in oval root canals, and the SAF 9.3%.[272]

No technique or system could completely prepare and clean oval canals.[273-275] When reciprocating instruments were used for preparation of oval root canals, no significant differences between the systems in cross-sectional shape were detected once the instruments were used in brushing motions.[275] Good results were achieved with the SAF that prepared long oval root canals with no gross preparation errors and minimal straightening, leaving 23% of the canal wall unprepared.[271] Peters at al.[276] showed that the percentage of untreated canal walls could be reduced from 63% (SAF 1.5 mm, two minutes working time) to 8.6% (using an SAF 2.0 mm for five minutes).

To optimize cleanliness and disinfection of oval root canals, ultrasonically activated irrigation directing the oscillating file into the lateral recesses has been advocated[277] (Figure 20-87).

C-Shaped Root Canals

C-shaped root canals present similar challenges as root canals with oval cross-sections. During preparation, the clinician should consider that the concavity is much more pronounced than in oval canals, increasing the risk of over-preparation, weakening the root, or even perforation. For more details, see Chapter 26, Endodontic Therapy in Teeth with Anatomical Variations.

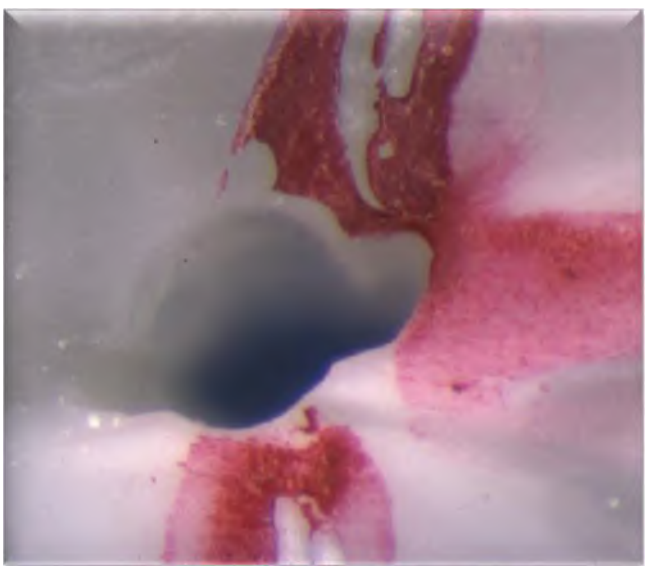

FIGURE 20-87 Postoperative image showing uninstrumented canal extensions that were cleaned by ultrasonic irrigation. The ultrasonic file was actively directed into the extensions.

In summary, it can be concluded that

- Preparation of oval, C-shaped and S-shaped root canal presents a challenge for preparation and disinfection.
- Complete mechanical preparation of the endodontic system in roots with anatomic irregularities may not always be possible.
- SAF NiTi system may offer some advantage in preparing a greater percentage of the root canal walls without excessive weakening of the root.
- Proper chemical disinfection is necessary to compensate for the drawbacks of mechanical preparation in these cases.

CONTROVERSY IV—APICAL SIZE OF THE PREPARATION

There still is some debate on the desirable final size of apical preparation with two opposite concepts: maintaining the apical integrity of the root by preserving as much dentin as possible on one side vs. circumferential removal of the infected dentin on the other side.

Traditionally, it has been suggested to prepare at least three sizes beyond the first file that binds at working length. Based on findings that the preoperative diameter of the apical foramen widely varies[278-289] (Table 20-9). Apical preparation has been recommended to ISO-sizes of at least 25 to 35 or even higer.[278-289]

Coldero *et al.*[290] found no significant differences in reduction of intracanal bacteria following crown-down preparation to size .04/35 and crown-down with GT to size .04/20 followed by stepback to .04/35. With both techniques, the majority of the root canals were rendered bacteria-free. Shuping *et al.*[291] reported on decreasing numbers of intracanal bacteria with increasing instrumentation sizes. In contrast, in a comparative study of five preparation techniques with the size of the final apical file varying from size 25 to size 40, no differences in remaining pulp tissue or debris were found.[292]

Regarding irrigation, not only the apical diameter but also the conicity of the preparation has to be considered. Boutzioukis et al.[293,294] suggested a size .04/40 as appropriate to achieve good exchange of irrigants even in the most apical part of the root canal.

The second concept aims to keep the apical diameter small and includes scouting of the apical third, establishing apical patency with a size 10 instrument passively inserted 1mm through the foramen, gauging and tuning the apical third and finally finishing the apical third at least to size 20.[295] Yared and colleagues[296] in an *in vivo* investigation in 60 single-rooted teeth with apical periodontitis found no significant differences in bacteria reduction following preparation to size 25 or 40, respectively. Bacterial counts were reduced significantly in both groups when compared to the initial number of microorganisms. Card *et al.*[297] could demonstrate *in vivo*

a significantly increased reduction of intracanal bacteria after apical enlargement to larger sizes with NiTi instruments. Preparation with NiTi instruments to size 50 achieved significantly larger reduction of bacteria than preparation to size 35.[298]

Conclusions

Mechanical preparation of the root canal results in a significant reduction of microorganisms independently from the preparation size. Complete microbial-free root canals cannot be achieved.

- Although there seems to be some evidence that larger apical preparation sizes may result in more reduction of intracanal microorganisms, the significance of the final apical preparation size remains to be clarified.
- Preparation technique, instruments and final preparation size should be defined individually for each root canal system.
- Introduction of a gauge 30 irrigation needle to working length minus 1-2mm seems to be the best criterion for apical preparation size. An apical size of .04/40 has been suggested to produce effective irrigation.

COMPLICATIONS DURING PREPARATION

Canal Straightening and Ledging

The American Association of Endodontists (AAE) defines root canal transportation as:[299] "*Removal of canal wall structure on the outside curve in the apical half of the canal due to the tendency of files to restore themselves to their original linear shape during canal preparation; may lead to ledge formation and possible perforation.*" Thus, the characteristic appearance of canal transportation is an asymmetrical dentin removal in the apical curved part of the root canal. As a result, the long axis of the curved root canal is displaced and the angle of curvature is decreased, resulting in a straightening of the original curvature of the root canal (Figure 20-88).

The etiology of canal transportation, as pointed out in the definition of the AAE, is based on the fact that independent of the alloy used, any root canal instrument tends to straighten itself inside the root canal.[69,300] Due to this tendency, an uneven distribution force of the cutting edges of the instrument in certain contact areas along the root canal wall results, leading to an asymmetrical dentin removal.[69,300] These contact areas

are located in the apical part of the canal at the outer side of the curve (convexity) and in the middle or coronal thirds at the inner side of the curve (concavity). As a result, apical canal areas tend to be over-prepared toward the convexity of the canal, whereas more coronally greater amounts of dentin are removed at the concavity, leading to canal transportation or straightening.[69]

In the apical part of curved root canals straightening is associated with further preparation errors[6,52]:

- Damage to the apical foramen: When the curved canal is deviated from the original long axis it is often associated with loss of the apical stop.[2] Clinically, it may result in mechanical irritation of the periapical tissues and increase the risk of extruding irrigation solutions, debris and root canal filling materials.
- Perforation: This procedural error represents a communication between the root canal space and the external root surface. It may be caused from use of instruments with sharp cutting tips in reaming or rotary working motions[2,3] (Figure 20-89). In many instances, a perforation will be located at the apical part toward the outer side of the canal.
- Strip perforation: In contrast to perforation located at the apical part of the canal, strip perforation results from over-preparation along the inner side of the curvature in the middle or coronal third of the canal.[2,42] Strip perforations mainly occur in mesial roots of mandibular molars at the furcal aspect, also know as the "danger zone" (Figure 20-90).
- Zip: The curved part of the canal adopts an elliptical or "teardrop" shape at the apical end point.[52] This is caused because the axis of the curved canal is deviated towards the outer aspect and inadvertently more dentin is removed from the outer side. Due to this irregular cross-sectional shape, the quality of canal obturation is markedly reduced when employing the cold lateral compaction technique.[300]

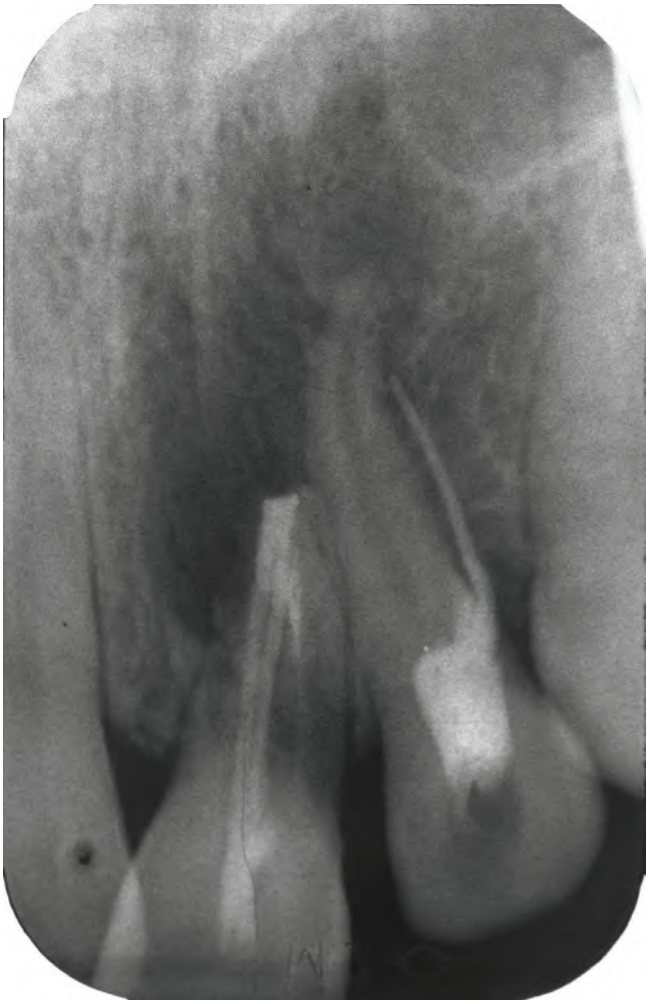

FIGURE 20-89 Uncommon perforation in a maxillary incisor.

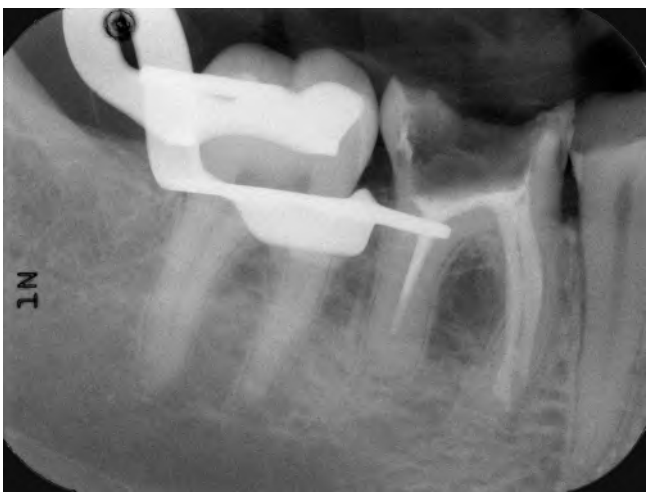

FIGURE 20-88 Root canal filling of a right mandibular molar demonstrating marked straightening of the mesial root canals with ledge and zip formation.

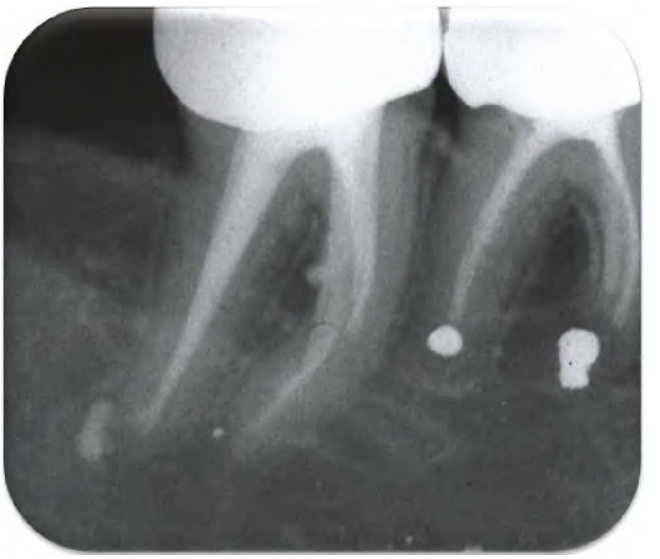

FIGURE 20-90 Strip perforation at the furcational aspect of the curve.

- Elbow-formation: The typical picture of canal transportation is over-preparation along the outer side of the curvature at the apical part and along the inner side more coronally. The elbow-formation usually occurs between two areas of excessive dentin removal and a narrow portion of the canal. Usually, the elbow is located at the point of maximum curvature. The clinically relevant adverse effects of this procedural errors are insufficient debridement and obturation of the canal part located apically to the elbow-formation.[5]
- Ledging: A ledge is a platform created at the beginning of the outer side of the curvature that hinders the instruments from reaching the working length.[2,65] (Figures 20-91 and 20-92). Usually, ledge formations are located in the middle or apical part of root canals.

There is evidence in the literature that the following factors impact the incidence of canal transportation:[69]

- Design of the access cavity
- Experience of the operator[92,301]
- Insufficient irrigation during mechanical root canal preparation[300]
- Properties of the instruments used for canal preparation[302]
- Use of instruments with sharp cutting tips[127,303]
- Instrumentation technique[2,147,304]
- Degree and radius of canal curvature. The greater the degree of curvature and the smaller the radius of curvature, the greater is the risk of canal transportation.[76,305] Preparation of root canals with a great angle and an abrupt short curve is challenging. These canals can hardly be enlarged without any transportation, independently whether rotary NiTi or stainless steel hand instruments were used[306] (Figure 20-93).

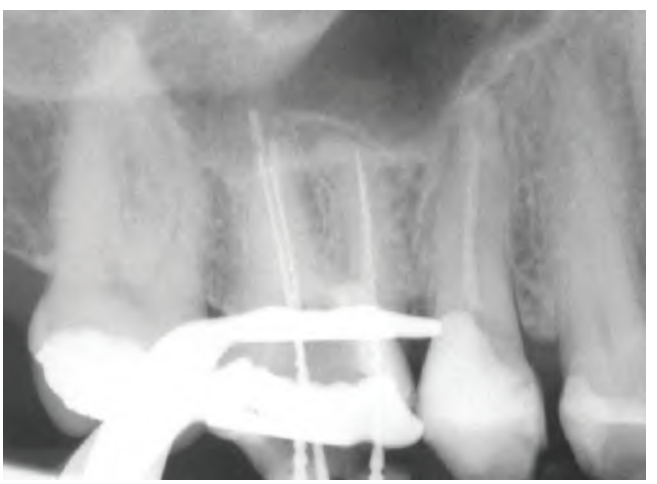

FIGURE 20-91 Ledge formation in the apical part of the mesial root canal in a maxillary molar.

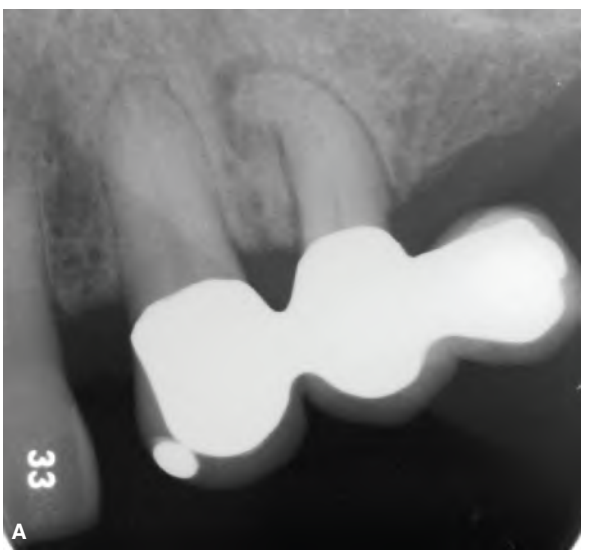
FIGURE 20-92 Root canal filling of a left mandibular molar with ledge formation, loss of working length and canal straightening in the mesial canals.



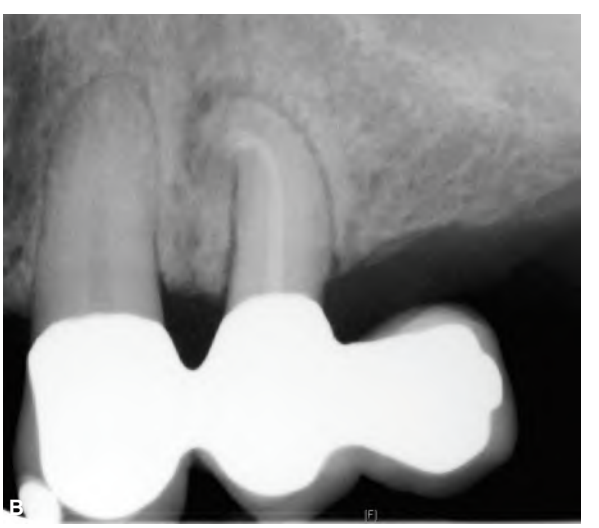


FIGURE 20-93 ***A.*** Maxillary premolar showing an abrupt curve of the root canal in the apical part. ***B.*** Postobturation radiograph. The canal was prepared using engine-driven nickel–titanium instruments.

- Radiographically unseen canal curvatures. In general, proximal curvatures cannot be detected using two-dimensional radiographs. Most often such curvatures are found in the mesial root of mandibular molars. These undetected curvatures may cause unexpected challenges during canal preparation, resulting in canal transportation or strip perforation.

From a clinical standpoint, the most relevant consequences of canal transportation and ledging are insufficient cleaning of the root canal system and over-reduction of radicular dentin (Figure 20-94).

Prevention of Canal Transportation and Ledging

The following is recommended to minimize the risk of canal transportation and ledging:

- The access cavity should be prepared so that unrestricted access of the instruments to the apical foramen is available (Figure 20-95).
- A glide path should be created prior to canal preparation. When using stainless steel hand instruments (e.g., Pilot instruments) for canal scouting, the tactile feedback provides relevant information regarding the consistency of the canal content, possible blockages (e.g., root canal branches) and radiographically unseen curvatures.
- Severely curved canals should be prepared using engine-driven NiTi instruments having non-cutting tips. When using NiTi hand instruments, preference should be given to the balanced-force technique.
- Instruments should not be forced into the root canal. Skipping instrument sizes should be avoided. Frequent recapitulation of the canal using small hand instruments is recommended.
- Copious irrigation should be carried out during canal preparation to avoid any blockage of the canal lumen. Instruments should never be used in dry canals.

FIGURE 20-94 Root canal preparation of this mandibular molar resulted in over-reduction of radicular dentin and a strip perforation at the furcal side of the mesial root.

Management of Canal Transportation and Ledging

Canal Straightening

The extent of apical canal transportation can be classified as follows (Figure 20-96)[307]:

- Type I: minor movement of the position of the apical foramen, resulting in only slight iatrogenic relocation.
- Type II: moderate movement of the physiologic position of the foramen, resulting in a considerable iatrogenic relocation on the external root surface. The resulting communication between the root canal and the periapical tissues is much greater than in Type I. Moreover, it might be problematic to create a more coronal shape as this attempt might weaken or perforate the root.
- Type III: the physiologic position of the root canal is severely moved, resulting in a relevant iatrogenic relocation of the physiologic foramen.

Consequently, apical canal transportation may be managed by different specific treatment strategies:

In general, whenever transportation is noticed during root canal preparation, paper points and an electronic

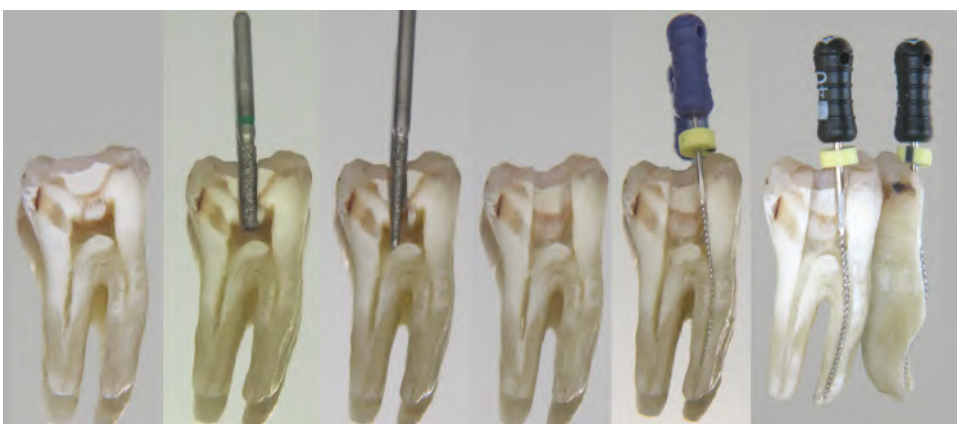

FIGURE 20-95 Adequate design of an access cavity. On one hand, this minimally invasive access cavity maintained healthy tooth structure but on the other hand allowed straight-line access of the instruments to the apical portion of the root canals (instrumentation: mesial, size 40, taper 0.06; distal, size 70, taper 0.02).

apex locator should be used to determine whether perforation has already occurred. In case a perforation is probable, the localization of the suspected perforation should be depicted radiographically with an inserted gutta-percha point or a sterile root canal instrument (Figure 20-97). If possible, the perforation should be sealed using mineral trioxide aggregate (MTA) and pre-bent stainless steel instruments may be used to bypass this area to regain access to the apical canal system (Figure 20-98).

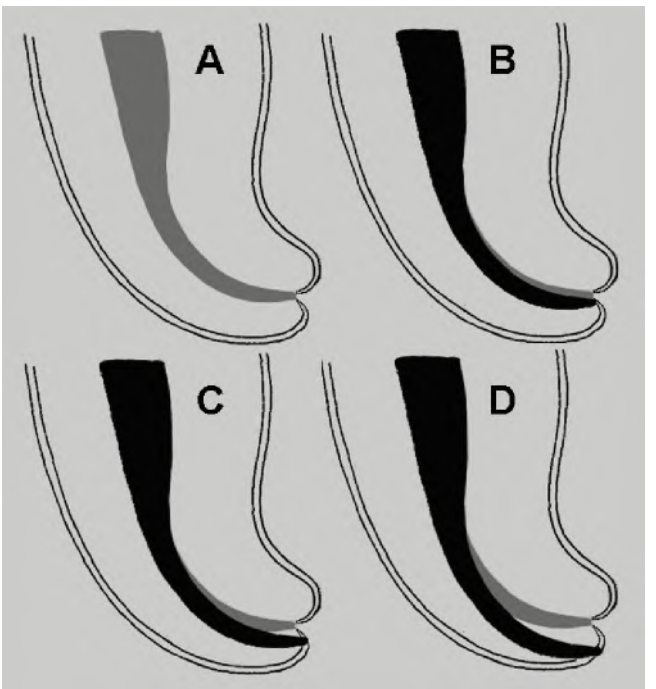

FIGURE 20-96 Schematic illustration of different types of root canal transportation. ***A***. Physiological appearance of a curved root canal. ***B***. Type I canal transportation (minor movement of apical foramen). ***C***. Type II canal transportation (moderate movement of apical foramen). ***D***. Type III canal transportation (severe movement of apical foramen).

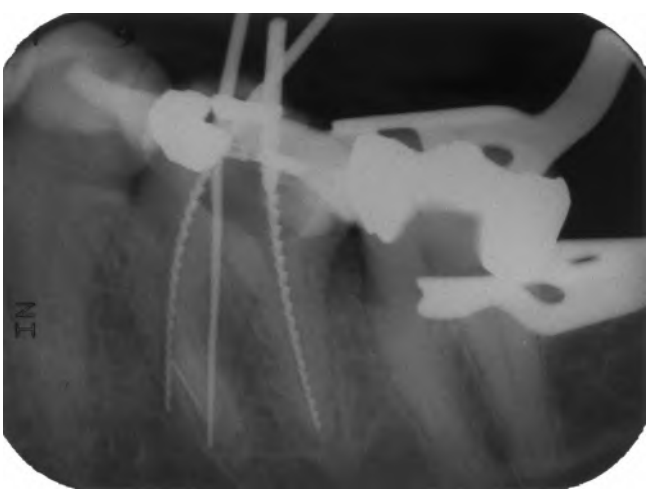

FIGURE 20-97 An attempt to bypass a separated instrument resulted in perforation in the mesial root.

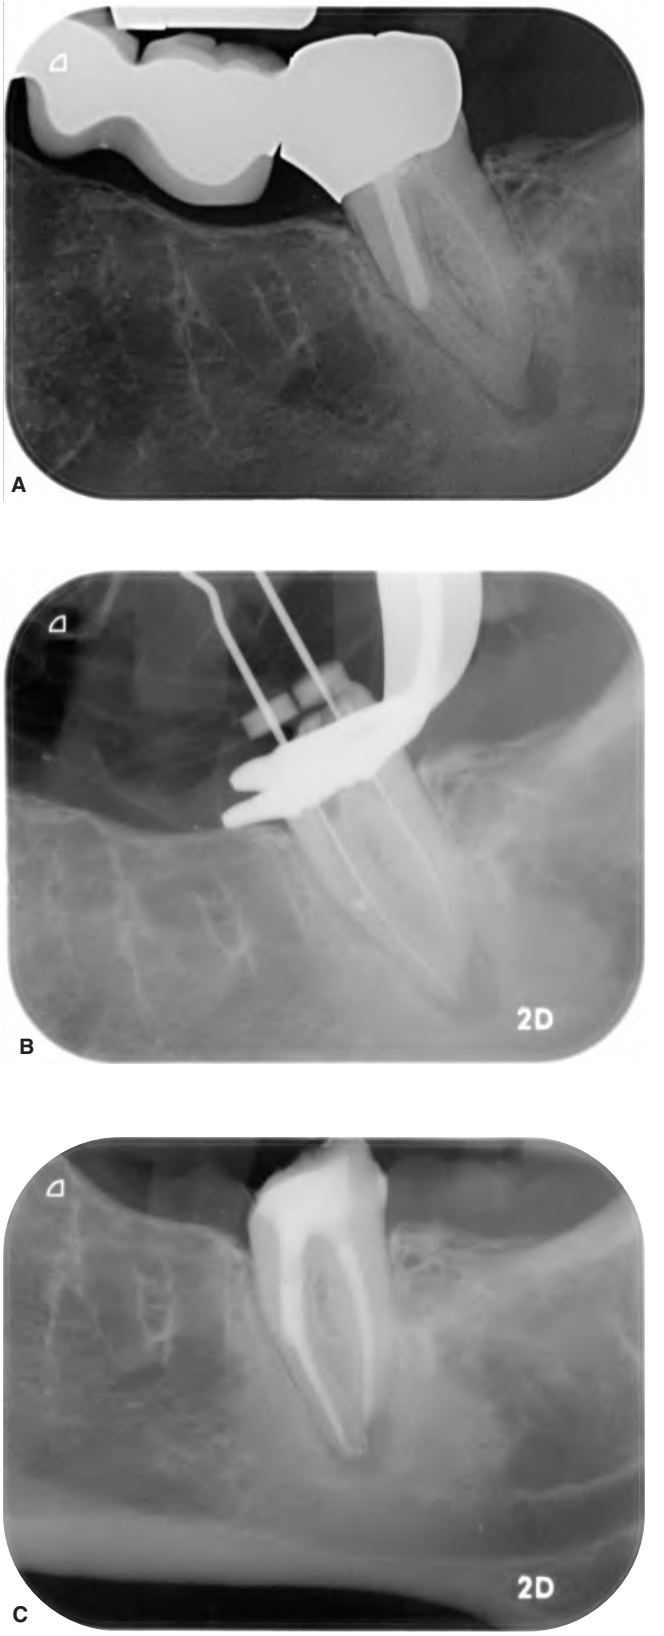

FIGURE 20-98 ***A***. Marked ledging with potential perforation in the mesial resulted in an inadequate post placement; ***B***. Following removal of the bridge and the post the ledge was sealed using MTA and access to the original root canal was regained; ***C***. Post-obturation radiograph.

Since canal transportation is associated with insufficient cleaning of the entire root canal, the canal will need to be irrigated copiously and using passive ultrasonic irrigation in order to remove tissue residues, microorganisms and debris from the non-instrumented canal areas. A thermoplastic obturation technique is preferable in any root canals showing marked transportation (Figure 20-98). For more details, see Chapter 23.

Ledge

The characteristic feature of canal ledging is the sensation of hitting against a hard structure with a non-binding instrument tip when probing the canal.[51] Frequently, ledging is associated with blockage of the canal. This compaction of debris and dentin in the adjoining canal system jeopardizes bypassing of the ledge and regaining access to the canal lumen located apically to the ledge.

In the case of canal ledging, the coronal canal part, up to the ledge, should be enlarged in such way that instruments can be used up to the ledge without any friction. This allows a more targeted use of pre-bent instruments that should be used to try to bypass the ledge. (Figure 20-99). NiTi instruments are less suitable for this procedure than stainless steel instruments as they are considerably more flexible. For more details, see Chapter 23, Endodontic Orthograde Retreatment and Managements of Mishaps.

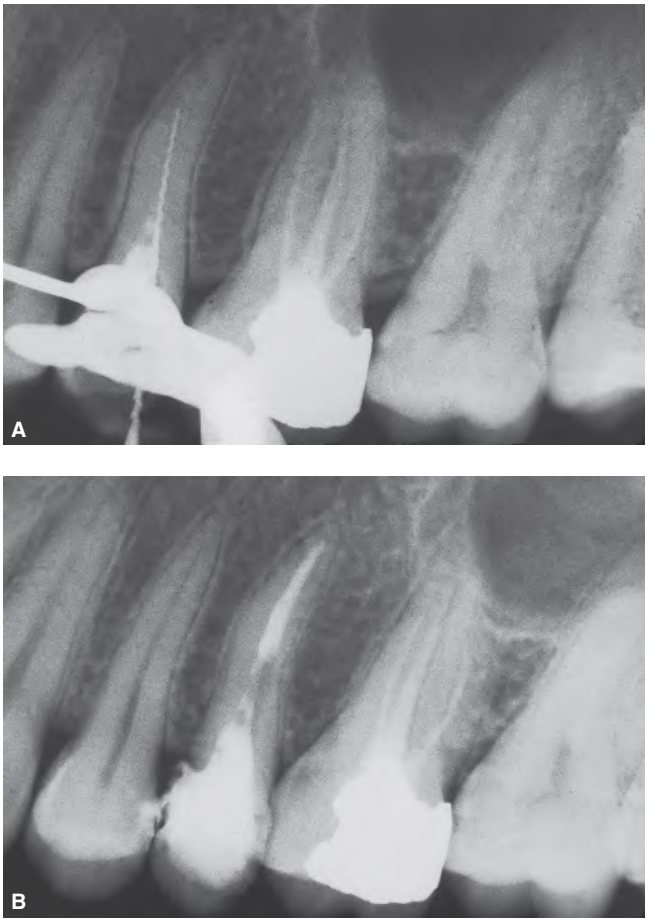

FIGURE 20-99 ***A***, Ledge on the outer side of a slightly curved apical part of the root. ***B***, The ledge was bypassed and rounded off with manual stainless steel instruments.

In summary it can be concluded that:

- Transportation may destroy the integrity of the root and lead to apical perforation.
- Transportation may result in insufficient cleaning of the root canal system.
- Transportation may result in over-reduction of radicular dentin, that may lead to a decreased fracture resistance of the entire root and to strip perforation along the inner side of the curvature.
- Root canals enlarged with instruments of greater taper are more prone to fracture than those prepared with instruments with a smaller taper.
- Straightened root canals should be copiously irrigated.
- Straightened root canals should be obturated using thermoplastic techniques.

Fracture of Instruments

> "The dentist who has not fractured the tip of a reamer, file, or broach has not treated many root canals. When one accepts the challenge of a curved, narrow or tortuous canal, one also assumes the risk of instrument fracture… Considering the delicate diameter of the instrument tip that is expected to cut a substance as hard as dentine, it is remarkable that so few instruments are broken….Who has not felt the pang, the anguish, the mortification caused by the breaking of an instrument? That moment of remorse lives on for days until it is faded out by time" (*L. I. Grossman 1969*)[308]

The fracture of endodontic instruments is not an uncommon mishap during root canal preparation. It may occur in 1%–6% of cases for stainless steel instruments and approximately 0.4%–3.7% for rotary NiTi instruments.[309] Instrument fracture is an inherent risk of root canal preparation. The patient has to be informed of this risk and its consequences before starting root canal treatment in order to avoid (or at least minimize) medico-legal consequences.

Basically, there are two modes of fracture: cyclic fracture and torsional fracture.

Cyclic fracture occurs when an instrument is used for too long. Unfortunately many manufacturers focus on the number of canals treated rather than the duration. A single torturous canal may, often, require a duration exceeding that of several non-complicated root canals.

Torsional fracture occurs when the tip of an instrument is firmly engaged inside the root canal and the motor continues to rotate. The torque will exceed the elastic limit and the instrument will separate. Single overload of NiTi instruments has been identified as a major reason of fractures.[310] It can also occur when the flutes of an instrument are packed with dentinal debris thereby increasing the torque above a critical limit.

The following factors were associated with file fracture: [311]

- Frequency of use
- Number of rotations
- Preflaring and preenlarging
- Angle of the curvature
- Radius of the curvature

Non-contributing factors are:

- Torque
- Sterilization

Controversial factors:

- Rotational speed
- Operator's experience

It has also been reported that larger instruments show faster deterioration of quality than smaller ones.[312,313] Crown-down approaches[314] and preparation of a glide path[38] seem to reduce the number of fractures.

Prevention of Fractures

The basic recommendations to prevent fractures of instruments are:

- Straight-line access (Figures 20-100).
- Proper preoperative radiographic and tactile evaluation of degree and radius of the curvatures and adjustment of size and taper according to the instruments (Figure 20-101).

FIGURE 20-100 Incorrect access cavity resulting in instrument fracture.

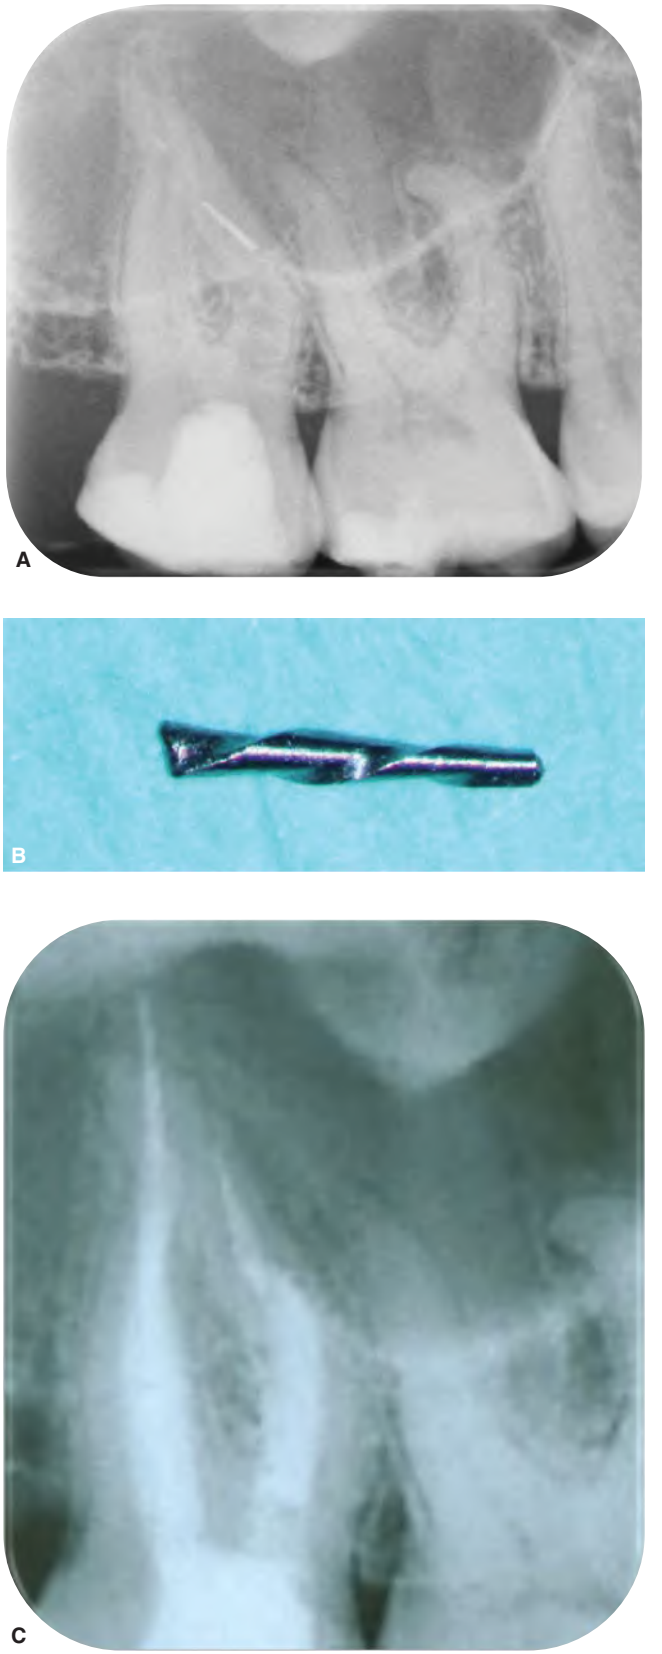

FIGURE 20-101 ***A.*** Fracture of a .08/25 NiTi instrument in a severely curved MB-2 canal. The use of greater tapered instruments in root canals with a small radius of curvature should be regarded as dangerous with a high risk of fracture. ***B.*** Removed fragment. ***C.*** Post-obturation follow up.

- Use of a motor with constant speed; no change of rotational speed during preparation.
- Use of a motor with defined torques, ideally individually adjusted for each file to be used for the preparation.
- Careful manual preparation of a glide path, before use of rotary instruments.
- Visual control of new and used instruments for any deformations (Figure 20-102).
- Passive use of instruments.
- Copious and constant irrigation during canal preparation.
- Use of instruments, only for few seconds, and early replacement of used instruments (single-use instruments are preferred)

Consequences of Instrument Fractures

A fractured instrument may be regarded as a stainless-steel or a NiTi root canal filling. However, this view overlooks two major problems. First, preparation and disinfection at the time of fracture usually have not been completed or performed to a sufficient degree. Second, the fragment has not been carefully and tightly adapted to the shape of the root canal, and in most cases, will not provide the necessary seal.

Regarding diagnosis and preparation technique, there are some basic differences:

- In a tooth with a necrotic pulp, 100% disinfection of the root canal space cannot be achieved. This may result in treatment failure.
- In a non-infected tooth with a vital, but irreversibly inflamed pulp, the most apical part of the pulp cannot be extirpated completely. Nevertheless this apical pulp stump may remain vital.
- When a small instrument fractures in an early stage of treatment, disinfection and removal of tissue are insufficient.
- If a large instrument fractures at a late stage of treatment, several cycles of preparation and irrigation already have been performed resulting in an advanced stage of disinfection at time of separation.

FIGURE 20-102 New instrument (left) and distorted instrument (right).

- When a large instrument fractures during a crown-down preparation, it may be screwed into the area the earlier instrument has created (taper lock), resulting in some congruence between fragment and root canal lumen. The result may be regarded as a NiTi root canal filling with questionable quality of seal.[93,315]
- When a small instrument fractures, there will be hardly any congruence between fragment and root canal.

These factors have to be thoroughly considered when discussing the necessity and technique of fragment removal. It has been shown that clinical success may be expected, even in cases with remaining fragments. However, several studies have shown that instrument fracture during treatment of teeth with apical periodontitis resulted in reduced success rate.[62,63,315,316] A recent meta-analysis study, on the impact of retained fractured instruments, on the outcome of root canal treatment has shown that teeth, either with or without periradicular pathosis, the prognosis of treatment was not significantly reduced.[317]

Additionally, several anatomical and technical factors may play a role when considering instrument removal, making this decision process more complex. Madarati et al.[318] offered a decision-making flowchart for that purpose. Also, several different techniques and instruments for removal of fractured instruments have been described. For more details, see Chapter 23.

IMPACT OF PREPARATION ON TREATMENT OUTCOME

Regarding the improved clinically relevant attributes of NiTi instruments, it is reasonable to assume, and therefore often claim that the use of NiTi hand or engine-driven instruments results in improved clinical outcomes.[319] However, very few clinical trials were conducted, with the main focus on the influence of specific instruments or preparation techniques on treatment outcome.[320-322]

When assessing the impact of root canal preparation on treatment outcome different outcome measures can be considered. The strictest criterion is "periapical health," whereby evaluating success is based on healing of periapical periodontitis, with periapical health (evaluated clinically and radiologically). Meanwhile "tooth survival" has been accepted by the American Association of Endodontists, as a further meaningful and relevant outcome measure. Finally, the criterion "flare-up" should be considered, when evaluating success as absence of interappointment emergency.[323]

Recently, a focused review attempted to systematically assess the impact of root canal preparation using NiTi hand or engine-driven instruments on treatment outcome.[324] This review concluded that evidence is limited regarding the impact of the type of root canal preparation, on treatment outcome of initial nonsurgical root canal treatment.

The available evidence suggests that:

- Preparation to larger apical sizes seems to result in increased success rates when treating teeth with necrotic pulps and periapical lesions,[325] and that preparation to a master apical file sizes of less than size 35, seems to be associated with increased healing time.[326]
- Better maintenance of the original canal curvature and shape seems associated with increased success rates.[327]
- Ledging of root canals seems to reduce success rates[327] and procedural errors seem to decrease treatment outcome.[326]
- The use of NiTi hand and engine-driven instruments does not seem to have a significant effect on long-term success rate of endodontic treatment.[328-331]

For a detailed discussion on treatment outcome, see Chapter 33, Outcome of Endodontic Therapy.

Chapter 21

Irrigants and Intracanal Medicaments

Markus Haapasalo, Ya Shen, James S. Lin, Ellen Park, Wei Qian, Zhejun Wang

HOST DEFENSE AND INFECTIONS

The human body is well prepared to deal with various kinds of infectious challenges. Non-specific and specific immune responses maintain a healthy balance between the normal microbiota and the host. In cases where the first line of defense, the epithelium, is broken, the host's defense system will quickly limit the invasion of microbes into the tissue and eventually eliminate bacteria and other microorganisms. Occasionally, systemic antibiotic therapy or manipulative treatment, such as drainage of pus, is applied in order to resolve the infection. Elimination of endodontic infection, however, follows a different path. Host measures that are sufficient to eliminate the infective microorganisms at other sites of the body, are unable to completely eliminate endodontic infections because of the special anatomical challenges. Eradication of an endodontic infection is achieved by a combination of several host and treatment factors.[1–3] Success in all parts of the treatment will be needed for the elimination of the infection and healing of periapical pathosis. The sequence of events and procedures in control of endodontic infections are host defense system, systemic antibiotic therapy (rarely used, only with specific indications), instrumentation and irrigation ("cleaning and shaping"), intracanal medicaments (not always used) between appointments, permanent root canal filling, and coronal restoration.[1–3]

The host defense is responsible for the prevention of root canal infections spreading to the bone and to other parts of the body. Osteoclast cells resorb the bone surrounding the apical foramen and occasionally around the external openings of large, infected lateral canals. Bone is replaced by highly vascularized inflammatory tissue,[4–6] that is of significant importance in order to keep the bacteria from spreading into the bone and causing osteomyelitis. This defense is usually successful in stabilizing the lesion size and preventing its expansion after the initial growth period. However, because of the lack of circulation, the host defense mechanisms cannot effectively reach and attack the microbes residing inside the tooth, in the necrotic root canal system. While mechanical instrumentation removes a portion of the microbes from the main root canal space, its main purpose is to enhance irrigation and the placement of medication in the root filling. Irrigation supports mechanical instrumentation, by reducing friction and removing dead and living microbes from the root canal.[7] In addition, many irrigating solutions have tissue dissolution and/or antimicrobial activity and effectively clean the canal space and kill residual microbes in the canal and surrounding dentin. Intracanal antimicrobial medicaments are used in multi-appointment endodontic treatments to complete the work started by instrumentation and irrigation and, optimally, to render the root canal system bacteria-free.[1]

Several early studies that examined the presence of bacteria in the root canal indicated that a bacteria-free canal at the time of root filling is a prerequisite for high success rate, and the use of calcium hydroxide [$Ca(OH)_2$] as an intracanal medicament will predictably help reach this goal.[8–11] However, since then a number of other studies have challenged these results, and presently there is no clear consensus regarding the use of intracanal interappointment medicaments, and the microbiological and other advantages from their use.[12–14] Despite such unanswered questions, there is no disagreement of the microbiological goal of the treatment of apical periodontitis, eradication of the microbiota in the root canal system.[15]

This chapter focuses on the methods of irrigation, properties and function of different irrigants, and the role of irrigation and intracanal medication in killing and reducing the number of microorganisms in the root canal system. It is important, however, to always keep in mind, that irrigation and locally used antimicrobial intracanal dressings are part of a concerted effort to eliminate the microorganisms causing endodontic infections. Irrigation and disinfection alone cannot guarantee success if there are problems in the quality of other parts of the treatment.

IS COMPLETE ELIMINATION OF MICROBES FROM THE ROOT CANAL SYSTEM POSSIBLE?

Pulpitis is caused by microorganisms or their antigens, entering the pulp from a carious lesion or leaking filling through dentinal tubules. Although the pulp tissue is affected by inflammation, as long as the pulp remains vital, the number of bacteria in the pulp is considered to be minimal and of no clinical significance.[16] Established biofilms, that are the most resistant to endodontic treatment procedures, are not expected to be found in the root canal space during pulpitis. However, with proceeding infection, necrosis and apical periodontitis, the entire root canal system becomes invaded by microorganisms. It has been shown beyond doubt that microorganisms are the etiological factor

of apical periodontitis (Figure 21-1).[17–19] It has also been suggested that, in a small number of cases, non-microbial factors are responsible for the persistence of the lesion after treatment,[20,21] but opposing views have also been expressed.[15] For more details, see Chapter 3, "Microbial and non-microbial etiologies of endodontic disease."

There is a general consensus that, in an optimal situation, the goal of endodontic treatment is to remove and kill all microorganisms in the root canal and to neutralize any antigens that may be left in the canal. Reaching this goal is expected to guarantee healing of periapical lesions. In a high number of cases, high quality treatment is followed by complete healing.[22–24] However, complete killing and elimination of root canal microbes is a particularly difficult challenge. It has also been shown that a majority of cases harboring living bacteria at the time of filling have healed completely.[8] It is therefore clear that although complete elimination of the infective flora is the optimal goal, complete clinical and radiographic healing can also occur when the microbiological goal of the treatment has not been fully achieved. This situation may be compared to marginal periodontitis and gingivitis where, understandably, it is not possible to gain a totally microbial-free environment in the gingival crevice area. It is evident that good quality periodontal treatment will result in the healing of the periodontal disease.

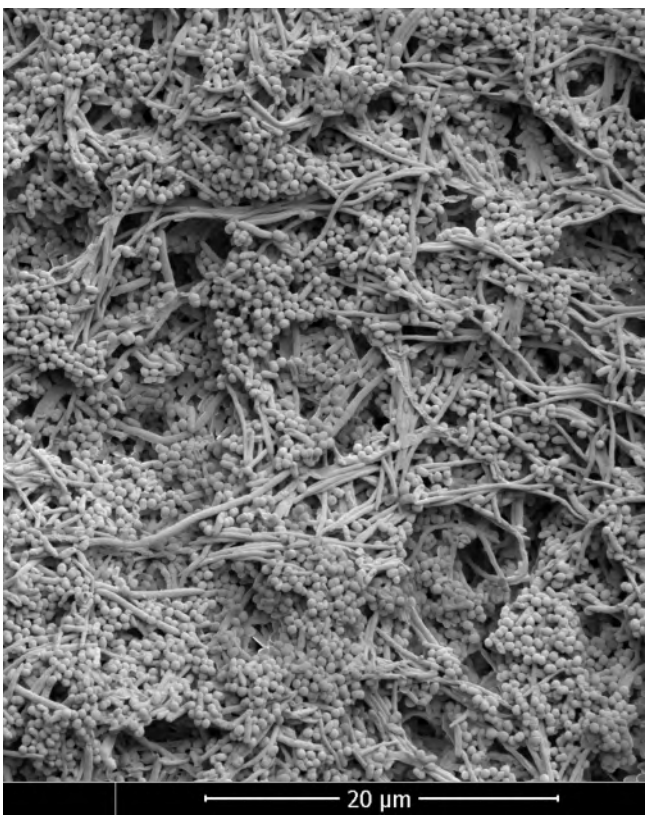

FIGURE 21-1 Microbial biofilm in the root canal is the cause of apical periodontitis and therefore the main target of irrigation and disinfection.

THE GOAL OF ENDODONTIC TREATMENT

The detailed goal of endodontic treatment depends on the diagnosis before treatment is started. In apical periodontitis, that is always caused by microbes, the main goal is the elimination of the microbiota from the pulp chamber and the root canal system. Maintaining or re-establishing the structural integrity of the tooth is another major goal of the treatment. In pulpitis, root canals are microbial free, therefore the goal is the prevention of microbial invasion into the root canal space and thereby deeper into the tissues.

In other words, the goal is prevention or elimination of a microbial infection in the root canal system.[25] In some special situations, such as resorptions and endodontic complications, there may be several intermediate goals of a more technical nature. Even then, the final success is dependent on successful infection control and/or preserving the structural strength of the tooth. There is a widely accepted view that instrumentation and irrigation ("cleaning and shaping") of the root canal system is the most important step toward a canal free from microbes.

THE ROLE OF INSTRUMENTATION IN THE ANTIMICROBIAL STRATEGY IN ENDODONTICS

The goal of instrumentation and irrigation is to remove all necrotic and vital organic tissue, as well as some hard tissue, from the root canal system. Instrumentation shapes the canal system to facilitate irrigation, placement of local medicaments, and placement of a permanent root filling. From a biological point of view, the key objective of instrumentation and irrigation is to remove and eradicate the microorganisms residing in the necrotic root canal system. Furthermore, the goal is to neutralize any residual antigenic material remaining in the canal after instrumentation and irrigation.

The classical Swedish studies from the 1970's have greatly influenced our understanding of the effects of instrumentation and irrigation on the intracanal microflora.[26] In a series of studies on teeth with apical periodontitis, the authors demonstrated that thorough mechanical instrumentation with stainless steel hand instruments, together with irrigation with either physiological saline, ethylenediaminetetra-acetic acid (EDTA), or EDTA and dilute sodium hypochlorite (NaOCl), they were unable to predictably produce bacteria-free root canals. Fifteen root canals were instrumented at five sequential appointments and sampled at the beginning and end of each appointment. The access cavity was sealed with a microbial-tight temporary filling, but the canals were left empty between the appointments. This procedure resulted in a 100 to 1000-fold reduction in bacterial numbers, but it was difficult, or in fact impossible, to obtain completely bacteria-free root canals.[26,27] Corresponding results were also reported by Ørstavik et al.[28]

and Cvek et al.[29] in teeth with closed and immature apices. The antibacterial effect of mechanical cleansing with sterile saline was reported to be very low and limited in teeth with fully developed roots. NaOCl increased the antibacterial effect compared to saline irrigation. Interestingly, no statistical difference was found in the antibacterial effect between 0.5% and 5.0% NaOCl solutions.[29]

The effects of instrumentation and irrigation were investigated in a series of studies by Dalton et al.[30] The authors measured the reduction in microbial counts in 48 patients, in teeth instrumented with 0.04 taper nickel–titanium (NiTi) rotary instruments or with stainless steel K-files using the step back technique with saline for irrigation. Bacteriological samples were obtained before, during, and after instrumentation. All teeth with apical periodontitis yielded positive growth at the beginning, whereas the control teeth with vital pulp and irreversible pulpitis were sterile. A reduction in bacterial counts was detected with progressive enlargement of the root canals with both techniques. However, only 28% of the teeth became bacteria-free following instrumentation. It is important to keep in mind that the results of root canal microbiological studies are only as accurate as the sensitivity of the methods to detect microbes. Cultural methods used in even earlier studies fail to obtain growth (and detection) of fastidious anaerobic bacteria. Moreover, sampling was performed, by paper points or files, in the same areas where the instrument action had been most effective. One can assume that the mechanical removal of microorganisms had been more effective in these areas than more remote, untouched parts of the root canal system. Therefore, use of ultrasound to facilitate the detachment of bacteria from such locations for sampling may give a more reliable picture of the residual microbiota. Even molecular technics depend on effective sampling and a minimum number of cells to allow detection by PCR and probes. However, there are no studies comparing the effect of ultrasound on microbial sampling from the root canal.

Observations similar to Dalton et al.[30] were reported by Siqueira et al.[31] when saline was used for irrigation. Interestingly, this former study showed that increasing the size of apical preparation from #30 to #40 resulted in a significant reduction in microbial counts. *Ex vivo* studies by Pataky et al.[32] using 40 human first maxillary premolars extracted for orthodontic reasons also verified the difficulty of obtained sterility of the infected canal space by instrumentation and saline irrigation. Although a considerable reduction in bacterial counts was detected after instrumentation, none of the teeth became bacteria-free. It should be mentioned, however, that the size of the master apical file in some of the studies was quite small, #25, and that may increase the possibility of positive cultures.[32] It can be concluded that instrumentation and irrigation with saline or directly antimicrobial agents such as sodium hypochlorite cannot predictably eliminate all microorganisms from infected root canals. Therefore, it is not surprising that the focus of activity in root canal disinfection is placed on the development and use of irrigating methods and solutions and other intracanal disinfecting agents with strong cleaning effectiveness and antibacterial activity. In recent years there has been considerable activity in the development of new methods of irrigation which would add effective mechanical or "energy" components to the hydrodynamic, chemical irrigation.[33,34]

RESEARCH ON ENDODONTIC IRRIGATION AND DISINFECTION: METHODS, MODELS, AND CHALLENGES

Our understanding and perceptions of the various root canal irrigants, irrigation methods, and their effects are based partly on clinical experience but also, and even more so, on *in vitro*, *ex vivo*, and *in vivo* studies of the effects, risks, and benefits of irrigation. Studying irrigation is, perhaps surprisingly, not easy.[35] One of the biggest challenges is the special microanatomy of teeth and the root canal system. Also, the difficulty to truly simulate the *in vivo* events in an *in vitro* setting adds to the challenge. In the following, different research strategies and models on irrigation are being critically discussed.

In Vitro Models to Test Antimicrobial Activity

The testing of the antimicrobial activity of various chemical compounds used in endodontics may appear to be straightforward and a simple procedure. In theory this may be true where the microbes of interest are exposed to the antimicrobial agent to be examined. At certain time intervals, microbiological samples are collected and cultured on suitable media. The results are then expressed as the length of time required to kill all microbes. The reality with endodontic disinfecting agents is, however, quite different.[35] Research focusing on the antimicrobial effectiveness of irrigating solutions and temporarily used intracanal medicaments has, in many occasions, adopted techniques originally designed for some other context; for example, testing bacterial susceptibility to systemic antibiotics using agar plates. Testing of systemically used antibiotics is based on tens of years of international standardization.[36–40] The chemical composition of both the antibiotic discs and the culture media used in testing are defined in detail in order to secure predictable diffusion of the active ingredient of the antibiotic and the absence of confounding chemical reactions between the agar medium ingredients and the antibiotic in question. Zones of growth inhibition around the antibiotic disc have been compared through clinical studies to the serum and tissue concentrations that can be reached with safe dosages of low toxicity, as well as assessing the clinical effectiveness of the antibiotics. In addition, reference strains from culture collections with known antibiotic susceptibilities are used as internal standards for quality testing of each new batch of plates. Most aerobic and facultative bacteria can be reliably tested using the disc diffusion method. However, despite years of extensive research, there is still no generally accepted

standard for susceptibility testing anaerobic bacteria using the disc diffusion method.[41] E-test strips impregnated with antibiotics are used to test growth of anaerobic bacteria on specific plates.[42,43] It offers advantages over conventional agar diffusion test with anaerobic bacteria, and has been used also in endodontic research.[44,45] There are no corresponding strip tests for endodontic disinfecting agents or solutions.

The use of agar diffusion method in endodontics, despite good intentions, is not based on standardization of the media or the tested materials. Chemical interactions between the media and the disinfecting agents are largely unknown. Furthermore, there are no true comparative studies enabling to draw conclusions from the size of zones of inhibition to the expected performance of the disinfectants *in vivo* against root canal bacteria. The antimicrobial effect of some endodontic medicaments is based on the pH effect. The buffering capacity of the agar plate is key to determine the diameter of the growth inhibition zone. Another example is EDTA, that causes a zone of inhibition on an agar plate, but fails to reduce the number of viable microbes even after 24-hour incubation in a test tube. Wang et al.[46] reported in a study of irrigant antibacterial effect in dentin that EDTA caused false positive reaction also when viability stain and confocal microscopy were used.

Another matter of importance in testing the antimicrobial effectiveness of different compounds, liquids, or solid materials is understanding the difference between bacteriostatic and bactericidal activities. Bacteriostatic action means prevention of growth of the microbial cells without killing them. Bactericidal activity, on the other hand, kills the affected microbes. In endodontic studies, this difference is not always clearly addressed, and the results are often reported as "antibacterial activity." The agar diffusion test, when properly used in systemic antibiotic testing, is an example of measuring bacteriostatic activity. In endodontics, a bactericidal effect of a disinfecting agent is more important than a bacteriostatic effect. In the necrotic root canal, a temporary prevention of bacterial growth (bacteriostatic) occurs as long as the disinfecting agent remains in the canal is of limited value, because the microbes may still grow back in numbers afterwards and cause a new challenge to the host.

Testing endodontic disinfecting agents *in vitro* can be done in test tubes using a mixture of the microbes (suspended in sterile water) and the medicament. The presence of a culture medium in the bacteria-medicament mixture is commonly reported in endodontic literature. This may pose a problem, because culture medium or other organic material is a confounding factor that may inactivate the disinfecting agent or protect the microbes by some mechanism.[47] Experiments done under such conditions may not give a reliable picture of the characteristics and activity of the medicament/disinfectant against the tested microbe.

"Carry-over effect" means that the medicament (chlorhexidine for example) is carried over along with the sample and the microbes into the dilution series and further to the culture (plate or liquid culture). On the culture medium, even lower concentration of the "carried" medicament may have either bactericidal or bacteriostatic effect and prevent microbial growth. A high enough concentration of the disinfectant, carried to the culture medium, can prevent microbial growth and thus cause a false-negative result.[47] Therefore, carry-over, if undetected, contributes to an excessively positive picture of the antibacterial effectiveness of the medicament. Endodontic irrigants and disinfecting agents, containing local antibiotics, are at particularly high risk of causing false-negative results. Effective inactivators are not available for many antibiotics.[47]

Specific inactivating agents are used to prevent the effects of carry-over. Citric acid has been used in the root canal to neutralize $Ca(OH)_2$, sodium thiosulfate neutralizes NaOCl,[48] and a mixture of Tween 80 and alpha-lecithin inactivates chlorhexidine (CHX).[49] However, inactivation is dependent on the concentration of the medicaments. When medicaments are used in high initial concentration, their inactivation may not be complete. An example of this is CHX that cannot be effectively inactivated with Tween and alpha-lecithin if CHX concentrations of 1% or more are used (Figure 21-2). The importance of the careful design of the experiments and proper controls cannot be overestimated, in order to avoid the possibility of false negative results (Figure 21-3).[47]

Ex Vivo and *In Vivo* Models

In vitro models may give valuable information about the antimicrobial potential of endodontic disinfecting agents. However, information from the *in vitro* experiments is not enough to predict their performance in a clinical situation in the root canal. Despite good *in vitro* results, the effectiveness of the medicament *in vivo* can be weakened by a variety of local factors in the root canal. These include problems in the delivery of the disinfecting agent to all parts of the canal, low overall volume, poor penetration into dentin, short contact time, or inactivation of the activity of the disinfecting

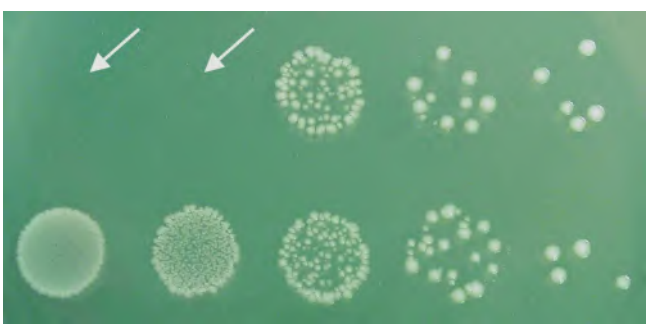

FIGURE 21-2 Samples of *Enterococcus faecalis* from 10-fold dilution series after a brief contact with 2% chlorhexidine (CHX). Because of the short contact time (two seconds), no killing has taken place. However, CHX "carry-over" has prevented growth of the first two samples (arrows) on the plate (upper row, left) despite the presence of Tween-lecithin inactivator in the dilution series. Lower row: control sample with no CHX. If only the first two dilutions had been made after the two seconds CHX exposure, the result would have indicated complete killing of the microbes in just two seconds.

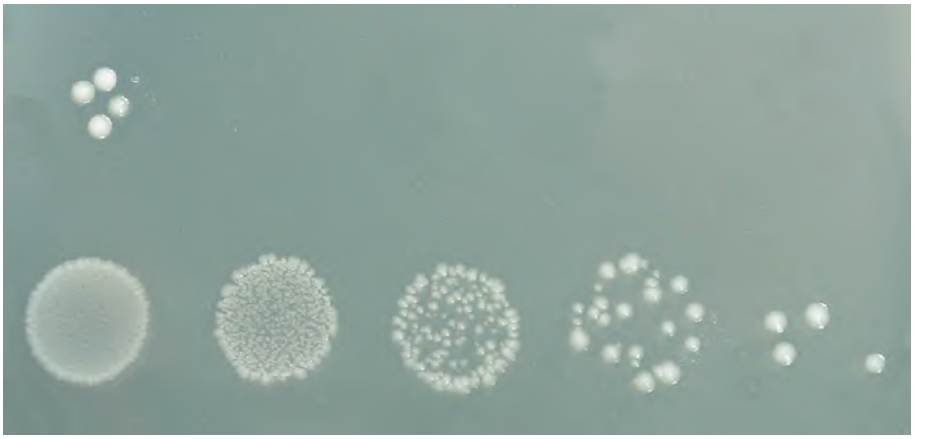

FIGURE 21-3 The size of the initial inoculum and the depth of the 10-fold dilution series determine the accuracy of measurement of the colony forming units. In this example, killing effectiveness can be calculated to a level of about 99.99%. Upper row: medicament has killed so many bacteria that only in the non-diluted specimen (leftmost) a few cells can be seen. Lower row: control specimen (water: no killing).

agent by the different chemical compounds present in the necrotic root canal. Therefore, a number of *ex vivo* and *in vivo* models have been developed in order to meet the challenge by the various confounding factors of the root canal and to improve the correlation between the test results and clinical performance. The *ex vivo* and *in vivo* models include the dentin block model,[50,51] dentin powder model,[52–54] and several modifications using roots/root canals from extracted teeth.[55,56] Recently, a dentin canal model with a massive presence of bacteria in dentinal tubules was developed and used for testing endodontic materials for their antimicrobial activity using confocal microscopy and viability staining.[46,57] Ultimately, clinical and *in vivo* studies are needed.[58,59]

The dentin powder model, with its modifications, makes it possible to obtain information about the inhibition of the medicament activity by dentin and other compounds (biomolecules, microbial biomass, etc.) in various concentrations.[52] It also allows standardization of certain experimental conditions for large series of tests. Prolonged incubation time to create dentin infection is not required because the dentin is powdered. The downsides of the powder model include partial loss of the microanatomical structure of the tooth and the difficulty to create and use biofilms.

The dentin block model has been widely used for testing endodontic medicaments.[50,51] The benefits of the model include simulation of the chemical and microanatomical environment of the tooth and the root canal system. The root canal can be standardized in size, making it easier to obtain comparable samples of dentin in different blocks. It also allows the use of microbial biofilms in the experiments. On the other hand, the dentin block model is quite laborious in use; it cannot be fully standardized as different blocks may vary in thickness and dentin microstructure. Handling of the block presents some challenges that may increase the risk for false-positive results (contaminations from outside the sampling area). A major limitation of the dentin block model with culturing is the limited number of bacteria invading the dentin of root canals as well as inaccuracies in sampling and culturing. Despite its limitations, the dentin block model has contributed to our understanding of dentin disinfection. While it is still used in endodontic research, more advanced methods have started to replace the "classical" block-culture model.

Newer *ex vivo* and *in vivo* models use "natural" root canals either in extracted teeth or directly *in vivo*. The obvious benefit of these experiments is a better simulation of the clinical situation; the results obtained with the various materials may best reflect their true activity clinically. However, in addition to the well-known difficulty to organize and run controlled clinical studies, and to have enough patients for such studies, there are also other potential pitfalls that may weaken the usefulness of the results. These include the difficulty to standardize the size of the apical preparation because of the great natural variation in canal sizes, different total volume of the canals, variations in the microanatomy of the root canals, and differences in the quality and quantity of the microbial infection. In addition to this kind of natural variation, there does not seem to be any standard way of dealing with the smear layer or taking the microbiological samples.[35]

New Biofilm Models

Open biofilm models are nowadays used to measure the effectiveness of antimicrobial solutions (such as NaOCl, CHX) and other endodontic materials (e.g., sealers) against bacteria polymicrobial biofilms.[60–62] In this model, standardized hydroxyapatite or dentin discs are used as the biofilm substrate on which monospecies or multispecies biofilms are grown in liquid media under microaerophilic or anaerobic atmosphere (Figure 21-4).[60–62] Biofilms are exposed to endodontic irrigating solutions, and killing of the bacteria in the biofilm can be measured using culturing or, preferably, by confocal laser scanning microscopy. One of the clear benefits of this model is that true *in vivo* like biofilms can be grown directly from oral/periodontal/root canal bacteria, "cloning" the same biofilm to numerous parallel discs. The model

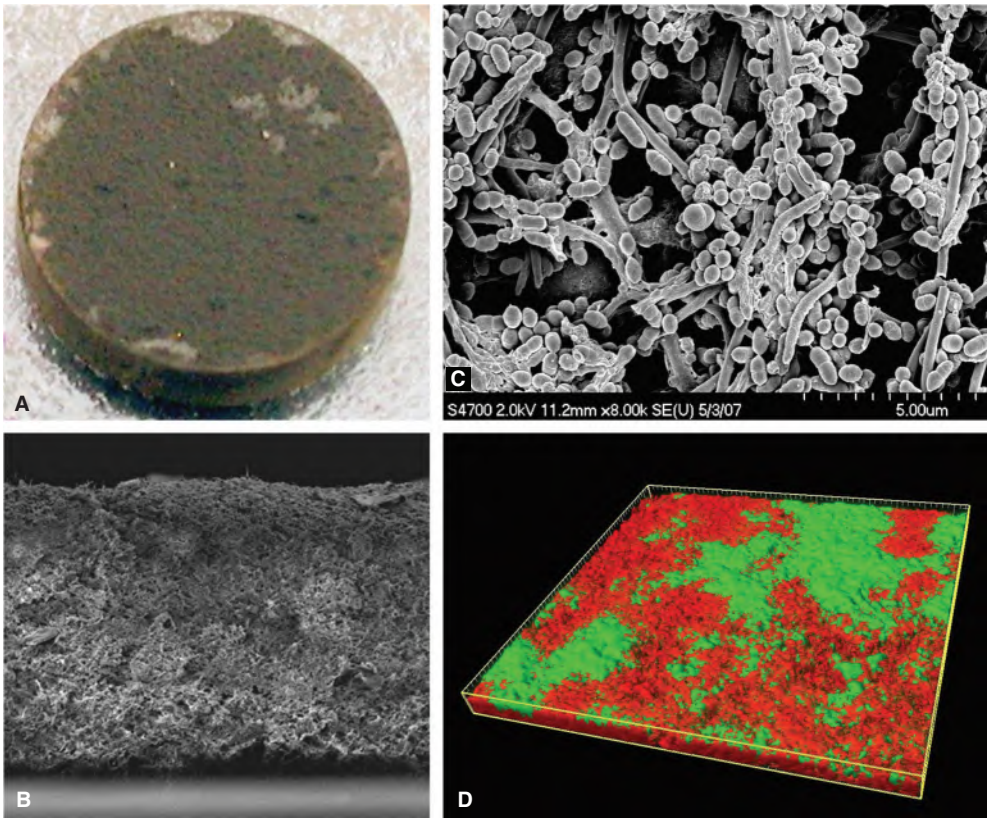

FIGURE 21-4 Research on the effectiveness of irrigation requires good biofilm models. ***A***. Multispecies biofilm grown on a collagen coated hydroxyapatite disc. ***B***. Lateral view of the biofilm, ***C***. SEM image of bacteria on the surface of the biofilm. ***D***. Confocal laser scanning microscopic image of biofilm stained with a "Viability stain" that shows killed bacteria red and live bacteria green.

allows following the disinfectant efficacy along time against biofilms of different age.

Stojicic et al.[62] examined the effect of iodine, NaOCl, and CHX on young and old biofilms and reported that multispecies biofilms from the oral cavity changed from sensitive to resistant to all three medicament groups tested after three weeks of biofilm growth. This is clinically important information as the true *in vivo* root canal biofilms are almost always older than three weeks when the treatment of apical periodontitis is started. After three weeks (and up to 2 months) there was no change in the resistance of the biofilm bacteria to the agents.

Dentin canal infection produced by centrifugation was introduced a few years ago in an effort to improve standardization of the experimental conditions. High numbers of bacteria are forced deep into dentin using the force of centrifugation. The two most important benefits of the model are the predictability of the presence of bacteria in most dentin canals in high numbers that makes it possible to quantitatively measure bacterial killing by confocal microscope, and the presence of the true microanatomy and chemistry of dentin.[46,57] In most of the published studies dentin has not been heat sterilized because possible contamination is not a quantitative problem, therefore dentin chemistry remains unaltered. Figure 21-5 shows a specimen that has been processed using these techniques after exposure to an antibacterial substance and viability staining.

Irrigation Hydrodynamics and Computational Irrigation Models

Irrigation is a balance between effectiveness and safety.[63] In optimal irrigation, the liquids should circulate effectively in all parts of the root canal system, including the main root canal, the area next to apical foramen (but not beyond), fins and isthmuses, and even lateral canals within the tooth structure. The prerequisite for effective positive pressure irrigation is high flow rate and concentration of the irrigant, and deep positioning of the irrigation needle. These may increase apical pressure by the irrigation that may, in some situations, contribute to extrusion of the irrigant into periapical tissues, tissue damage, and even severe pain.[64,65] Studies on irrigation hydrodynamics target this area of irrigation by analyzing patterns of irrigant flow in the canal system, shear stress forces at the canal wall, and pressure created towards the apical foramen.[66,67] Some of these approaches can only be done using computational fluid dynamics models based on complex mathematical calculations.[67–69] Models using small tubes or extracted teeth have been described where small pressure sensors have been used to measure the apical pressure created under a variety of irrigation parameters.[66,70] Recently, several studies have directly measured irrigant extrusion through the apical foramen under standardized conditions in order to better understand the risk of extrusion.[71–73] While these

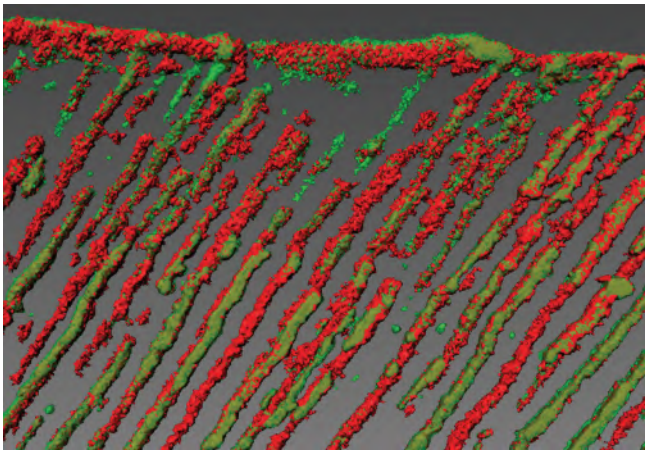

FIGURE 21-5 A root dentin specimen showing killed (red) and live (green) bacteria in dentin canal after hypochlorite irrigation and viability staining and Confocal microscopy. The dentin infection model allows studying the effect of irrigation on bacteria inside the dentin canals.

studies have already increased our understanding of irrigation, more studies are needed to better understand how well these new models reflect the reality of irrigation.

Qualitative or Quantitative Results; Detection Level: More Challenges?

Optimally, the goal of endodontic disinfection is the complete eradication of the microbes from the root canal system of the affected tooth. Although difficult to achieve, this noble goal may have affected the study design of several studies as the results are often expressed qualitatively, only as "growth" or "no growth." This approach may in some cases hide differences in the effectiveness of different treatment protocols and chemicals used for disinfection. For example, two different treatments that cause a 10% and 99.95% reduction in bacterial counts per canal, respectively, may be reported as equal ("growth"). It is possible that some of the poor results with $Ca(OH)_2$ as a disinfecting agent can be partly explained by the fact that qualitative rather than a quantitative approach has been used to measure the effectiveness of the disinfection. Quantitative measurement of the antimicrobial effect of endodontic disinfecting agents should therefore be preferred over qualitative approach. Accordingly, quantitative reporting has been used in some studies.[47,74]

There are a number of factors that create challenges for accurate and comparable counting of microbes in the samples. Residual medicament in dentin may result in a very low number of colony-forming units (CFU) per sample unless neutralizing agents are properly used. Dispersing the sample effectively may be required to detach the viable cells from the dentin chips, in order to increase the CFU numbers to correctly reflect the true number of microbes in the sample. Collection of small dentin samples is technically demanding and requires great care to secure a standardized yield from all samples. When the overall number of CFU in the sample is low, that is often the situation in infected and medicated dentin, it is important not to lose the microbes during a too vigorous dilution process.

Success in both qualitative and quantitative measurements of (surviving) microbes is dependent, among other factors mentioned above, on the design of the microbiological procedures that determine the detection level of the method. Detection level dictates whether the most effective killing can be announced, for example, on the level of 99%, 99.9%, or 99.99% (Figure 21-3). In other words, detection level tells how many cells in the test mixture must be alive so that growth can be detected by the culturing. Detection level is mainly dependent on the total number of cells in the initial reaction mixture/sample, proportion of the initial sample transferred into the dilution series, and the proportion of the mixture plated from each dilution. Theoretically, the detection limit can be easily calculated from the above numbers. In practice, detection limit is often reduced by the carry-over of strong medicaments such as CHX or other compounds (antibiotics for example) that may cause false-negative results. Detection limit provides important information about the design and quality of the methods in studies of endodontic disinfecting agents.[47] Unfortunately, detection limits are only rarely reported, making it more difficult to compare the results from different studies. Hopefully in the future, reporting the detection limit will be a routine requirement for studies on endodontic disinfection.

IRRIGATING SOLUTIONS

The use of irrigating solutions is an important part of endodontic treatment.[63] The irrigants facilitate the removal of necrotic tissue, microorganisms, and dentin chips from the root canal by a flushing action. Irrigants can also help prevent packing infected hard and soft tissue apically in the root canal and into the periapical area. Some irrigating solutions dissolve either organic or inorganic tissue. Finally, several irrigating solutions exhibit antimicrobial activity by actively killing bacteria and yeasts when in direct contact with the microorganisms. On the negative side, many irrigating solutions have cytotoxic activity or may cause severe pain reaction if accidentally pushed into the periapical tissues.[75]

An optimal irrigant should have all or most of the positive characteristics listed above, with none of the negative or harmful properties. Presently, none of the available irrigating solutions can be regarded as optimal. However, with a combined use of selected products, irrigation will greatly contribute to successful outcome of treatment.

SODIUM HYPOCHLORITE (NaOCl)

Antibacterial Effect

Sodium hypochlorite (NaOCl) is the most widely used irrigating solution in endodontics. In water, NaOCl ionizes to produce Na^+ and the hypochlorite ion, OCl^-, that establishes

an equilibrium with hypochlorous acid, HOCl. Between pH 4 and 7, chlorine exists predominantly as HClO, the active moiety, whereas above pH 9, OCl^- predominates.[76] It is the hypochlorous acid that is responsible for bacteria inactivation, the OCl^- ion being less effective than the undissolved HOCl. Hypochlorous acid disrupts oxidative phosphorylation and other membrane-associated activities as well as DNA synthesis.[77,78]

NaOCl is used in concentrations varying from 0.5% to 8%. It is a very potent antimicrobial agent and effectively dissolves pulpal remnants and organic components of dentin (Figure 21-6). It is used both as an unbuffered solution at pH 11 in the concentrations mentioned above and buffered with a bicarbonate buffer (pH 9.0) usually as a 0.5% (Dakin's solution) or 1% solution.[76] Contradicting earlier statements, Zehnder et al.[79] reported that buffering had little effect on tissue dissolution, and Dakin's solution was equally effective on decayed (necrotic) and fresh tissues. In addition, no differences were recorded for the antibacterial properties of Dakin's solution with an equivalent unbuffered hypochlorite solution.[80] However, other studies have indicated that the pH of NaOCl must be reduced more than the level discussed by Zehnder.[79] Kuroiwa et al.[81] reported that the acid used to lower the pH of NaOCl had a significant effect on the antibacterial activity of the solution.

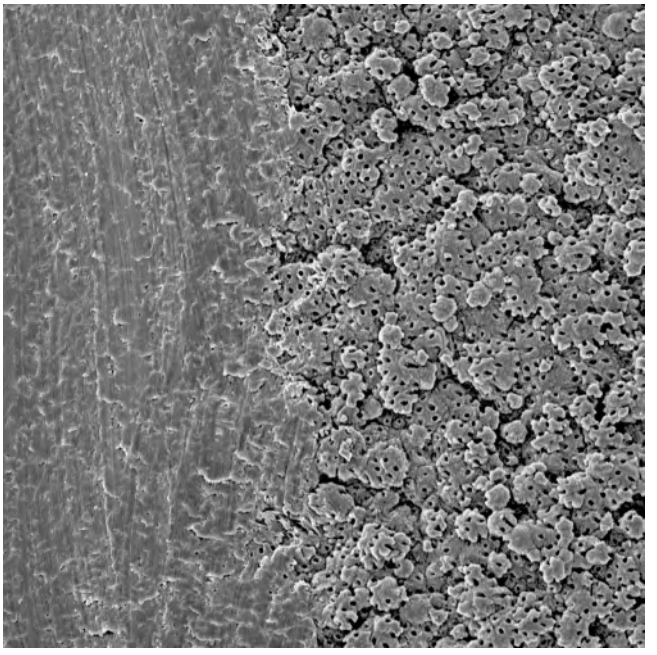

FIGURE 21-6 Instrumented (left half of the picture) and uninstrumented (right half) root canal wall after irrigation with 5% sodium hypochlorite (NaOCl) for several minutes. Pulpal remnants and predentin have been effectively removed with NaOCl while the instrumented part (smear layer) seems relatively unaffected. Notice the typical calcospherite structures at the left half of the image.

NaOCl is best known for its strong antimicrobial activity; it kills microorganisms very rapidly even at low concentrations. Waltimo et al.[82] showed that the resistant microorganism, *Candida albicans*, was killed in vitro in 30 seconds by both 5% and 0.5% NaOCl, whereas concentrations 0.05% and 0.005% were too weak to kill the yeast even after 24 hours of incubation. The high susceptibility of *C. albicans* to NaOCl was recently also verified by Radcliffe et al.[48] Later, Vianna et al.[83] contrasted these results partly, as 0.5% NaOCl required 30 minutes to kill *C. albicans*, whereas 5.25% solution killed all yeast cells in 15 seconds. In the latter study, however, organic material from the broth culture medium may have been present during the incubation with NaOCl that would explain delayed killing. Gomes et al.[84] tested *in vitro* the effect of various concentrations of NaOCl against enterococcus. *Enterococcus faecalis* was killed within 30 seconds by the 5.25% solution, whereas 10 and 30 minutes were required for killing all bacteria by 2.5% and 0.5% solutions, respectively. The higher resistance of *E. faecalis* to hypochlorite compared to the yeast *C. albicans* was suggested also by Radcliffe et al.[48] However, both of these studies are in contrast to the results reported by Haapasalo et al.[52] who demonstrated rapid killing of *E. faecalis* by 0.3% NaOCl, and by Portenier et al.[85] who showed rapid killing of *E. faecalis* strains in logarithmic and stationary growth phase by even 0.001% NaOCl. The reason for slow killing in some studies may be the presence of organic matter from the culture medium during testing which consumes the free chlorine.

Experiments with Gram-negative anaerobic rods *Porphyromonas gingivalis*, *Porphyromonas endodontalis*, and *Prevotella intermedia*, often isolated from apical periodontitis, demonstrated high susceptibility to NaOCl, and all three species were killed within 15 seconds with 0.5% to 5% concentrations of NaOCl.[83]

The differences between *in vitro* and *in vivo* studies include the volume of the medicament available for killing, access to all microbes, and absence of other materials in the *in vitro* experiments that potentially protect bacteria *in vivo*. Many of the *in vivo* studies have failed to show a better antimicrobial effect in the root canal by high concentrations of NaOCl as compared to low concentrations. Byström and Sundqvist[86,27] studied root canals naturally infected, mainly with a mixture of anaerobic bacteria. They showed that although 0.5% NaOCl, with or without EDTA, improved the antibacterial efficiency of preparations compared with saline irrigation, all canals were not bacteria-free even after several appointments. No significant difference in antibacterial efficiency *in vivo* between 0.5% and 5% NaOCl solutions was found in the study. Siqueira et al.,[87] using *E. faecalis*-infected root canals, demonstrated the superior antibacterial affect against root canal bacteria of hypochlorite in comparison with physiological saline. However, no difference was detected between 1%, 2.5%, and 5% NaOCl solutions.

The antimicrobial efficacy of NaOCl has traditionally been measured by culturing the microorganism on agar plates and counting the colonies (CFU).[47,50] Culturing works well in dynamic killing studies (along time) in planktonic suspensions, where the numbers of microbial cells can be easily standardized. However, in studies where sampling is done from contaminated root canals or infected dentin, the sensitivity of culturing faces many problems. Great variations in microbial loads at sampling sites next to each other often result in situations where the standard deviations are very high, that makes it difficult to detect significant differences. Therefore, while planktonic studies show great differences in killing *E. faecalis* cells at different metabolic phases, studies sampling from root canals usually fail to show differences.[87]

Recently, a new approach has been introduced to endodontic studies on the antimicrobial effect of various substances used in the treatment: confocal laser scanning microscopy (CLSM).[46,57] Bacteria are grown in biofilms, that are exposed to NaOCl or other irrigating solutions for different time periods and then analyzed for the proportions of dead and killed bacteria using a viability staining.[60–62] The BacLight viability stain is supposed to stain killed bacteria red, while the live bacteria stain green.[60] The method is based on the use of two fluorescent reagents that penetrate either all cells or just cells with a damaged cell wall. Shen et al.[61] using old, starved biofilms reported that while culturing was unable to detect any living bacteria in the biofilm, viability stain indicated 85% of the bacteria were still alive. The result may indicate that cultural studies from the root canal may contain an important element of uncertainty, as most biofilms in the root canal are likely to be old and in a state of starvation. Other new biofilm-CLSM studies have shown that there is a significant difference in the antibacterial potential of different NaOCl concentrations.[57] Biofilm-CLSM studies have also opened a new era for studies focusing in dentin disinfection.[46,57] These studies have shown the importance of NaOCl concentration in killing biofilm bacteria in dentin of root canals.[57]

In planktonic killing experiments, the death of 100% of the microbial cells usually is merely a question of time.[47] Contrary to this, new biofilm studies using CLSM clearly show that killing all bacteria in the biofilm is perhaps not even possible with the presently available substances and methods in endodontics. Shen et al.[61] and later Stojicic et al.[62] showed that after three weeks of growth, multispecies biofilms from oral bacteria changed from being sensitive to being much more resistant to NaOCl and other substances when used in root canal irrigation.

Sodium hypochlorite has low surface tension and can penetrate into dentin canals (Figure 21-7). Zou et al.[88] measured NaOCl penetration into dentin canals using stained dentin blocks and reported penetration between 77 and 300 μm, depending on the time of exposure. During 20 min of exposure, ca. half of the penetration depth was reached already after two minutes.[88] Using the dentin canal infection model and CLSM, Du et al.[89] reported that while 5% NaOCl killed 53% of *E. faecalis* cells in dentin during the first three minutes of exposure, the killing rate greatly reduced after that, and after 10 minutes almost no additional killing occurred despite refreshing the NaOCl (Figure 21-7). The explanation may be that unlike planktonic cells, biofilm contains sensitive areas and resistant areas. During the first

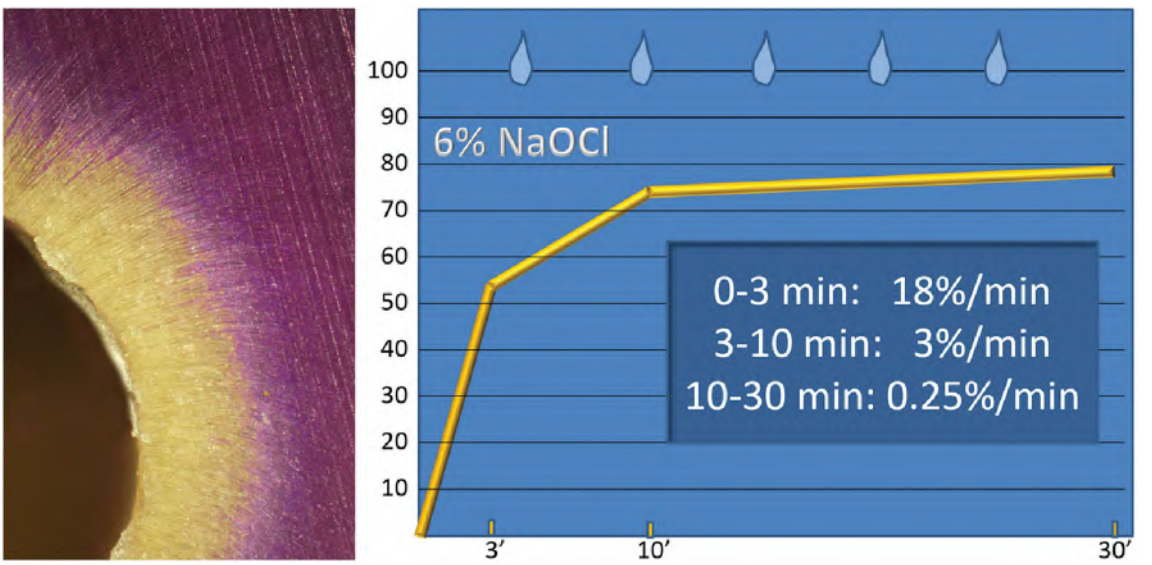

FIGURE 21-7 **Left:** NaOCl penetration into dentin canals as revealed by bleaching of stained dentin. **Right:** Dynamics of killing of *E. faecalis* in dentin canals during a 30-min exposure to 6% NaOCl. The hypochlorite solution was renewed every five minutes. After a rapid killing of bacterial cells during the first three minutes, the killing drastically slowed down, and after 10 minutes of exposure only little additional killing could be achieved. (Adapted from Du et al.[89])

few minutes bacteria in the sensitive areas are killed and after this time achieving more bacteria deaths becomes much more difficult.

Peciuliene et al.[90] studied the effect of instrumentation and NaOCl irrigation in failed, previously root-filled teeth with apical periodontitis. Old root fillings were removed with hand instruments, and the first sample was taken. No chloroform was used in order to avoid false-negative cultures. Bacteria were isolated in 33 of the 40 teeth before further instrumentation. *E. faecalis* was found in 21 teeth (in 11 as a pure culture), yeast *C. albicans* in six teeth, Gram-negative enteric rods in three teeth, and other microbes in 17 teeth. The canals were then hand instrumented to size #40 or larger and irrigated with 2.5% NaOCl (10 mL per canal) and 17% buffered EDTA (pH 7 and 5 mL per canal). After instrumentation and irrigation, *E. faecalis* was still detected in six canals. Other microbes persisted in five canals after preparation. Enteric Gram-negative rods were no longer present in the second sample.[90] The disappearance of yeasts but not *E. faecalis* in the root canals may reflect their different susceptibilities to the described chemomechanical instrumentation or it may be a result of different biofilm characteristics and dentin penetration by these species.

Tissue Dissolution

Dissolution of organic tissue is another main virtue of NaOCl.[63,79] In fact, NaOCl is the only commonly used root canal irrigating solution that dissolves organic matter. This is an important function, as it is crucial to dissolve and remove all necrotic tissue remnants from the canal. Otherwise, such tissue could serve as nutrients to residual microbes in the canal system. Tissue remnants would also have a negative impact on the quality of seal by the root filling. Several studies have shown that the tissue dissolving ability of NaOCl is dependent on its concentration.[91] The higher concentration, the faster soft tissue dissolution. Agitation, by sonic or ultrasonic means, and increased temperature also contribute to faster dissolution of tissue.[91] It has been reported that continuous agitation of 2% NaOCl dissolves soft tissue as fast as non-agitated 6% NaOCl solution. Similarly, heating the solution from 45°C to 60°C speeds up the dissolution.[91]

Sodium hypochlorite acts well on necrotic tissue whereas the effect on vital tissue is weaker.[92] This is good with regard to protection of vital tissue, for example, at perforation sites in the pulp chamber and in accidental or resorption perforations from the root canal to surrounding soft tissue or bone. The full concentration NaOCl can thus be used to disinfect pulp perforation sites before pulp capping. For more details, see Chapter 27. However, because of the limited effect on vital tissue, NaOCl may require more time in pulpitis treatments for the chemical cleaning of those areas of the root canal that are not mechanically cleaned.

In the main root canal where full concentration NaOCl has good access to the canal wall, necrotic tissue can be dissolved quickly; even in one to two minutes.[93] Lower concentrations can take considerably longer times. However, in fins and isthmus areas even prolonged irrigation with NaOCl does not guarantee complete cleaning of these locations.[94] Sodium hypochlorite does not dissolve mineralized tissue. This must be done either with EDTA, citric acid, or some other chelators/acidic compounds.[63]

Harmful Effects

The weaknesses of NaOCl include toxicity, unpleasant taste and its inability to remove the smear layer because of its lack of effect on inorganic material.[95,96] The poorer antimicrobial effectiveness of NaOCl *in vivo* than *in vitro* is also somewhat disappointing. There are several possible reasons for the reduced *in vivo* performance. Root canal anatomy, particularly the difficulty to effectively irrigate the most apical region of the canal, is generally acknowledged as one of the main challenges. In addition, the chemical milieu in the canal is different from a test tube. Haapasalo et al.[52] showed that the presence of dentin caused marked delays in the killing of *E. faecalis* by 1% NaOCl. The effect of other materials present in the necrotic or previously treated root canal, to the antimicrobial potential of NaOCl, has not been studied.

Studies measuring NaOCl cytotoxicity have indicated greater cytotoxicity and caustic effects on healthy tissue with 5.25% NaOCl compared to 1.0% and 0.5% solutions.[97,98] The fear of toxic and chemical complications is the main reason low concentrations 0.5 to 1% NaOCl solutions are used for canal irrigation, instead of the 5.25% solution that is used in many countries.[75] However, more *in vivo* studies on persistent endodontic infections and retreatment are necessary for a deeper understanding of the relationship between NaOCl concentration and its antimicrobial activity against specific microorganisms, before final conclusions can be drawn regarding the optimal NaOCl concentration.

Many dentists use NaOCl again after removing the smear layer with EDTA. However, when used after a chelating agent or an acid, NaOCl causes erosion of the root canal wall (Figure 21-8). While this aids the cleaning by removing the wall surface, it may also weaken the root dentin.[99–101] The reasons for vertical root fracture still remain partly unknown, it is therefore reasonable to avoid using NaOCl after smear layer removal, or at least limit its use to a short time of less than 30 seconds. For smear layer removal, a safer alternative would be to use a combination product that not only removes the layer but also kills microorganisms.

Ethylene Diamine Tetraacetic Acid (EDTA), Citric Acid, and Other Acids

Ethylene Diamine Tetraacetic Acid (EDTA) (17%, disodium salt, buffered to pH 7–7.5) has little if any antibacterial activity. On direct exposure for extended time, EDTA can extract some of the bacteria's cell surface proteins by combining with metal ions from the cell envelope. In theory, this

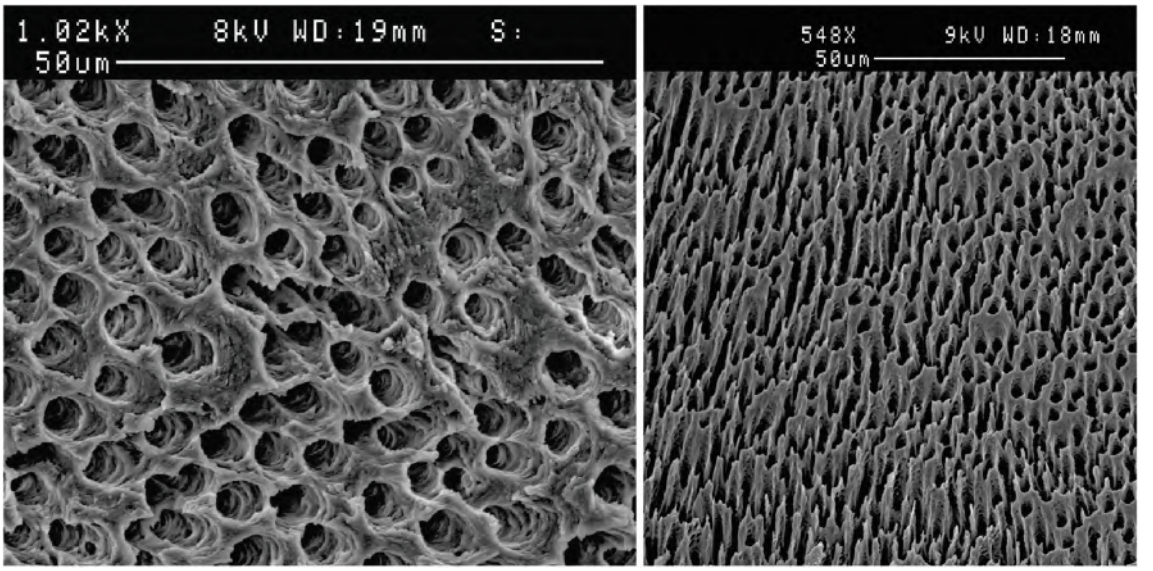

FIGURE 21-8 Erosion of root canal wall dentin after irrigation sequence NaOCl – EDTA – NaOCl. When EDTA or citric acid have been used to remove smear layer, dentin collagen on the surface and also deeper in dentin is exposed as EDTA removes hydroxyapatite. Using NaOCl again will attack the exposed collagen and cause dentin erosion, the magnitude of which depends on the length of the repeated exposure.

can cause even bacterial death. More importantly, EDTA is an effective chelating agent in the root canal.[102,103] It removes smear layer (Figures 21-9 and 21-10) when used together (but not simultaneously) with NaOCl by acting on the inorganic component of the dentin. Therefore, by facilitating cleaning and removal of infected tissue, EDTA contributes to the elimination of microorganisms in the root canal. It has also been shown that removal of the smear layer by EDTA (or citric acid) improves the antimicrobial effect of locally used disinfecting agents in deeper layers of dentin.[50,51] Niu et al.[101] studied the ultrastructure on canal walls after EDTA and EDTA plus NaOCl irrigation by scanning electron microscopy (SEM). More debris was removed by irrigation with EDTA and NaOCl than with EDTA alone. EGTA (ethylene glycol tetraacetic acid) also has the ability to chelate calcium from dentin, but it is weaker than EDTA.[99]

Citric acid can also be used for irrigation of the root canal and for removal of the smear layer.[102,104,105] Similar to EDTA, complete removal of the smear layer also requires irrigation with NaOCl before or after citric acid irrigation. Concentrations ranging from 1% to 50% have been used.[104] In comparison with ultrasound, 10% citric acid has been shown to remove the smear layer more effectively from apical root-end cavities than ultrasound.[106] In another study, powdered dentin-resin mixture was more soluble in a 0.5, 1, and 2 M citric acid than in 0.5 M EDTA.[107] Contrary to this, Liolios et al.[108] reported better removal of the smear layer by commercial EDTA preparations than with 50% citric acid, while other studies have found only small or no difference between citric acid and 15% EDTA in their capacity to remove the smear layer.[109,110] A comparative study showed that 10% citric acid was more effective than 1% citric acid, that was more effective than EDTA in demineralizing dentin.[111] Takeda et al.[112] reported that irrigation with 17% EDTA, 6% phosphoric acid, and 6% citric acid did not remove the entire smear layer from the root canal system. This is not unexpected, however, as it is known that NaOCl is also required for the complete removal of the smear layer. The acids demineralized the intertubular dentin making the tubular openings larger than when EDTA is used. The authors also showed that CO_2 laser was useful in removing the smear layer and that Er:YAG laser was even more effective than the CO_2 laser in smear layer removal. Qian et al.[99] reported stronger dentin erosion when citric acid was used after EDTA than when NaOCl was used after EDTA.

Smear layer removal facilitates penetration of sealers into the dentinal tubules. It also enhances the disinfection of the root canal wall and deeper layers of dentin. Both EDTA and citric acid can effectively remove the smear layer when used after NaOCl. Citric acid and EDTA may have weak antimicrobial activity as standalone products. However, their antimicrobial effectiveness has not been extensively documented and appears to be of minor importance.

Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) is a biocide that has been widely used for disinfection and sterilization.[76] However, in endodontics, H_2O_2 has not been very popular, and presently it is rarely used. H_2O_2 is a clear and colorless liquid. Concentrations from 1% to 30% have been used. H_2O_2 produces hydroxyl-free radicals (HO.) that attack microbial components such as proteins and DNA.[76] H_2O_2 is non problematic from an environmental point of view because it degrades into water and oxygen. H_2O_2 is relatively stable in solution, but many products contain stabilizers to prevent decomposition. H_2O_2 has antimicrobial activity against

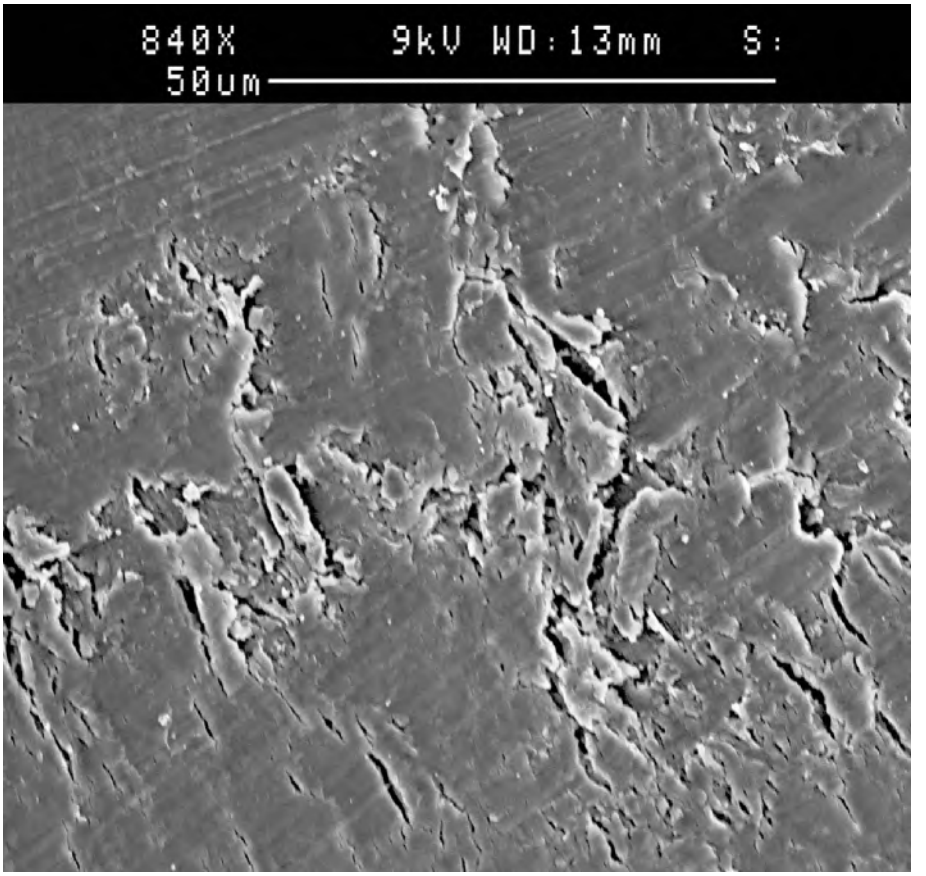

FIGURE 21-9 Smear layer on the canal wall after instrumentation and irrigation with NaOCl.

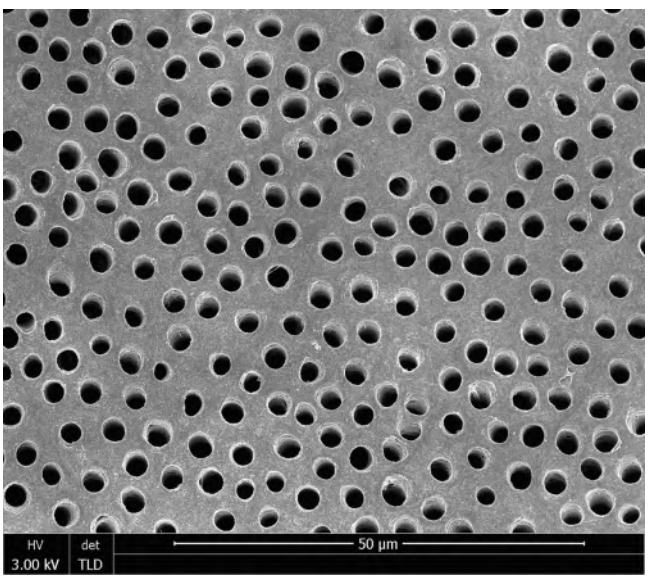

FIGURE 21-10 Root canal wall after removal of the smear layer. NaOCl removes at least partly the organic matter in smear layer, and EDTA (or citric acid) removes the inorganic matter, exposing the clean root canal wall and open dentin canals.

various microorganisms including viruses, bacteria, yeasts, and even bacterial spores.[113] It is more effective against Gram-positive than Gram-negative bacteria. Catalase or superoxide dismutase produced by several bacteria can provide them partial protection against H_2O_2.

Use of H_2O_2 in endodontics has been based on its antimicrobial and cleansing properties. Thirty percent H_2O_2 (Superoxol) has been recommended as the first step in tooth surface disinfection after mechanical cleaning in microbiological studies to prevent contamination from tooth surface.[114] H_2O_2 acts on the organic matter on the tooth making other disinfectants, such as iodine, more effective. It has been widely used earlier for cleaning the pulp chamber from blood and tissue remnants. It has also been used in canal irrigation, but evidence supporting the effectiveness of H_2O_2 as a root canal irrigant is scarce. On the contrary, Siqueira et al.[115] reported that a combination of NaOCl and H_2O_2 gave no advantage over NaOCl alone against *E. faecalis* in contaminated root canals *ex vivo*. Heling and Chandler[116] found strong synergism between H_2O_2 and CHX in disinfection of infected dentin: a combination of the two medicaments at low concentrations was far more effective in sterilizing dentin than these or any other medicament alone.[116] The synergistic mode of action between CHX and H_2O_2 was later documented by Steinberg et al.[117] In a recent study, 10% H_2O_2 was used as part of the irrigating protocol in monkey teeth.[118] Although the bacterial counts were greatly reduced, the study indicated the difficulty to completely eradicate bacteria from infected root canals in monkey teeth.[118] Al-Ali et al.[119] in a

recent study reported that alternating H_2O_2 with NaOCl was effective in removing soft tissues from root canal complexities.

Despite the long history of H_2O_2 use in endodontics, evidence supporting its use inside root canals is rather weak. It still has a role as part of the tooth surface disinfection protocol. Furthermore, the potential benefit of the suggested synergistic effect with CHX in deep dentin disinfection remains to be evaluated clinically.

Chlorhexidine Digluconate (CHX)

Chlorhexidine digluconate (CHX) is widely used in disinfection because of its excellent antimicrobial activity.[120–122] It has gained increased popularity in endodontics as an irrigating solution and as an intracanal medicament. Unlike NaOCl, CHX does not have a bad smell, it is not irritating to periapical tissues, and it does not cause spot bleaching of patients' clothes. Its antimicrobial effectiveness is well documented in endodontics. However, it completely lacks tissue-dissolving capability that is an important reason for the popularity of NaOCl (Figure 21-11).

CHX is perhaps the most widely used antimicrobial agent in antiseptic products. It permeates the cell wall or outer membrane (Gram-negative cells) and attacks the bacterial cytoplasmic and inner plasma membrane of the yeast. In high concentrations, CHX causes coagulation of intracellular components.[76] CHX gluconate has been in use for some time in dentistry because of its antimicrobial properties, its substantivity (long-term continued effect), and its relatively low toxicity compared to some other agents. However, the activity of CHX is dependent on pH and is also greatly reduced in the presence of organic matter.[122]

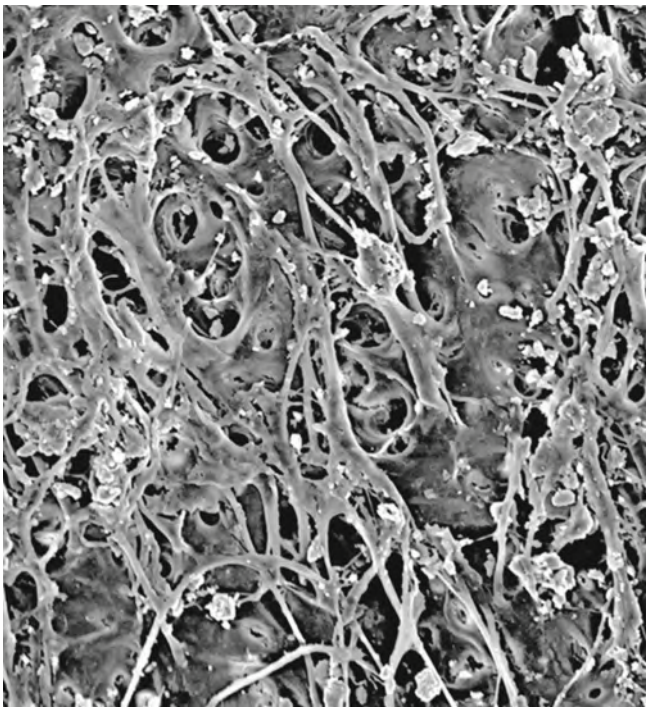

FIGURE 21-11 Chlorhexidine does not have any tissue dissolution activity. Both tissue debris and predentin are left behind in the root canal after irrigating with CHX only.

CHX is effective against both Gram-positive and Gram-negative bacteria as well as yeasts, although the activity against Gram-negative bacteria is not as good as against Gram-positive bacteria.[123–125] Mycobacteria and bacterial spores are resistant to CHX.[120,121] Therefore, CHX is not as suited to chairside sterilization of gutta-percha cones as NaOCl.[126,127] Studies have indicated similar, good performances by CHX and NaOCl in gutta-percha disinfection, but have not used bacterial spores in testing.[128] CHX is not very effective against viruses, its activity is limited to viruses with a lipid envelope.[129] CHX is cytotoxic in direct contact with human cells. A study using fluorescence assay on human periodontal ligament cells showed no difference in cytotoxicity by 0.4% NaOCl and 0.1% CHX.[98] The potential benefits of using CHX in endodontics have been actively researched over the last several years. Several studies have compared the antibacterial effect of NaOCl and CHX against intracanal infection.

While many studies show little or no difference between their antimicrobial effectiveness,[116,130–132] their mode of action may indicate important differences. The effects of 15 minutes of irrigation of experimental biofilms, by mixtures of endodontic bacteria on dentin blocks, have been evaluated by SEM and by culturing.[133] Six percent NaOCl was the only irrigant that completely removed the biofilm, as verified by SEM observations, and killed all bacteria. Two percent CHX was equally effective in bacterial killing, and no growth was detected in any of the samples after CHX treatment. However, an important difference was observed in how the biofilm was structurally affected by irrigation with these two solutions; 6% hypochlorite completely removed the biofilm while the CHX solution had no effect on the biofilm structure.[133] Although the bacteria were killed, the result indicates that as the biofilm remains in the canal after CHX irrigation, it may continue to express its antigenic potential if allowed to communicate with living periapical tissue. Moreover, such residual organic tissue may have a negative impact on the quality of the seal of the permanent root filling.

Some studies have indicated differences in the killing of certain endodontic microbes by hypochlorite and CHX. An *in vitro* study demonstrated differences in the killing of enterococci by CHX and NaOCl. While 5.25% NaOCl killed *E. faecalis* within 30 seconds, lower concentration (4.0% to 0.5%) of hypochlorite required 5 to 30 minutes for complete killing of the bacteria.[84] In the same study, 0.2% to 2% CHX killed the *E. faecalis* cells in 30 seconds or less in all concentrations tested. The result was later supported by two other studies using *E. faecalis* and *Staphylococcus aureus* as test organisms.[83,134] However, the results of these studies have been contradicted by other studies with regard to the effectiveness of NaOCl.[52,85]

Several studies have measured the activity of CHX in gel form against root canal bacteria. Vianna et al.[83] found that CHX in a gel form required a longer time to kill *E. faecalis* than the corresponding concentration in a liquid. Oliveira

et al.[135] reported that 2% CHX gel and 5.25% NaOCl showed excellent activity against *E. faecalis*. When diluted to 1.5% solution, NaOCl reduced the *E. faecalis* counts initially, but the bacterial counts increased during the 7-day follow-up period to the level comparable to the control group.

New studies using biofilms and CLSM with viability staining have to some extent contradicted the results of many of these earlier studies. Stojicic et al.[62] reported that CHX was significantly less effective than 1% and 2 % NaOCl against 3 week old multispecies oral anaerobic biofilm grown on collagen coated hydroxyapatite discs. Studies on dentin canal infection have shown CHX to be equally effective in killing *E. faecalis* inside dentin as one and two per cent NaOCl, but significantly weaker than 6% NaOCl.[57] It is possible that in the "open" biofilm model with hydroxyapatite discs the dynamic of penetration into the biofilm and interaction with local chemistry is different from dentin canal biofilm, where bacteria have been forced into dentin canals by centrifugation.

The antifungal effectiveness of CHX has been shown in several studies.[82,136–138] In a study of the effectiveness of various endodontic disinfecting agents, it was found that combinations of disinfectants were equally or less effective against fungi than the more effective component alone.[82] An interesting, but not yet fully understood synergism has been reported between CHX and H_2O_2.[116] *In vitro* studies using the dentin block model indicated strong synergism between these two agents against *E. faecalis* infection in dentinal tubules. Complementary *in vitro* experiments by Steinberg et al.[117] demonstrated that the combination of CHX and H_2O_2 completely eradicated *E. faecalis* in concentrations clearly lower than required when the compounds were used alone. It is possible that CHX, as a membrane active agent, makes the bacterial membranes more permeable to H_2O_2, allowing easier penetration into the cells and consequently causing damage to the intracellular organelles.[117] Although NaOCl and H_2O_2 are rarely used together in root canal irrigation, such synergistic effect has not been detected between them in the dentin block model.[116] The CHX-H_2O_2 synergism has also been demonstrated in a study of antiplaque mouth rinse.[139] So far there are no published studies of the clinical performance when using combinations of CHX and H_2O_2. Combinations of CHX and carbamide peroxide have been shown to be additive in their cytotoxicity,[140] but corresponding experiments with CHX and H_2O_2 are lacking. Contrary to results of the additive or synergistic action of CHX and H_2O_2, Stojicic et al.[141] reported poor effect of a low concentration of CHX-H_2O_2 combination against several *E. faecalis* strains and mixed plaques, both in planktonic culture and in biofilm. The effect of CHX-H_2O_2 was weaker than that of EDTA-H_2O_2 and CHX–EDTA combinations.

Inhibition of the antimicrobial activity of endodontic irrigants, by substances present in the root canal, has recently been discussed in a number of studies.[52–54] Haapasalo et al.[52] showed in an *in vitro* study that the effect of CHX is reduced or delayed, by the presence of dentin. In following studies by the same group, Portenier et al.[53] detected loss of CHX antimicrobial activity by high concentration (18%, v/w) of bovine serum albumin. In a clinical situation, inflammatory exudate rich in proteins may thus have a negative impact on the effectiveness of CHX. A subsequent study showed that organic dentin matrix and heat-killed microbial cells were effective inhibitors of CHX activity.[54] In a study by Sassone et al.,[142] CHX was incubated together with low concentration (0.5%, v/w) albumin, and no inhibition of the CHX activity could be detected. Albumin concentration in human serum is approximately 2% to 3%, and the total protein concentration is approximately 7%.[143]

Despite some shortcomings, there is evidence that CHX gluconate, as a 2% solution (liquid or gel), may offer an alternative for root canal irrigation. Interestingly, Ng et al.[144] reported in a prospective clinical study that not using CHX in addition to NaOCl had a positive effect on the prognosis of the endodontic treatment. In addition, one should bear in mind that the majority of research on the use of CHX in endodontics is done using *in vitro* and *ex vivo* models and Gram-positive test organisms, mostly *E. faecalis*. The possibility cannot be excluded that the experimental designs give a too positive and biased picture of the usefulness of CHX as an antimicrobial agent in endodontics. More research is needed to identify the optimal irrigation regimen for various types of endodontic treatments. CHX is presently marketed as a water-based solution, as a gel (with Natrosol), and as a liquid mixture with surface-active agents. Future studies of the various CHX preparations will establish the comparative effectiveness of the various CHX combinations *in vivo*. Since CHX lacks the tissue dissolving activity of NaOCl, there have been efforts to simplify the clinical work by combining the two solutions to obtain combined benefits from both. However, CHX and NaOCl are not soluble in each other and a brownish-orange precipitate is formed (Figure 21-12). Although the antimicrobial and other characteristics of the precipitate and the liquid phase have not been thoroughly examined, the precipitate prevents clinical use of the mixture. Marchesan et al.[145] showed that the precipitate was soluble to 0.1 mol/L acetic acid, but the brown/orange color of the solution remained. Atomic absorption spectrophotometry indicated that the precipitate contained iron that may be the reason for the color.

Iodine Potassium Iodide (IPI)

Iodine compounds are among the oldest disinfectants still actively used. They are best known for their use on surfaces, skin, and operation fields. Iodine is less reactive than the chlorine in hypochlorite. However, it kills rapidly and has bactericidal, fungicidal, tuberculocidal, virucidal, and even sporicidal activity.[146] Molecular form, I_2, is the active antimicrobial component.[146] Poor stability of iodine in aqueous solutions motivated the development of iodophors ("iodine carriers"): povidone–iodine and poloxamer–iodine. Iodophors are complexes of iodine and a solubilizing agent that gradually releases the iodine.[146] Iodophors are less active against some yeasts and bacterial spores compared to the

FIGURE 21-12 Orange-brown precipitate forms immediately when CHX and NaOCl are mixed together. The precipitate may contain toxic substances such as para-chloroaniline.

alcoholic iodine solutions (tinctures). Iodine penetrates rapidly into the microorganisms and causes cell death by attacking the proteins, nucleotides, and other key molecules of the cell.[146,147]

Iodine potassium iodide (IPI) has been successfully used in tooth surface disinfection.[114] Potassium iodide is used to dissolve iodine in water, but the antimicrobial activity is carried by the iodine, while potassium iodide has no activity against the microbes.

The effectiveness of 2.5% NaOCl and 10% iodine for disinfection of the operation field (tooth, dental dam, and the clamp) has been compared by bacterial culturing and polymerase chain reaction.[148] The operation field was treated with 30% H_2O_2 and either by 10% iodine or 2.5% NaOCl. No significant difference in the recovery of cultivable bacteria from various sites in either group was detected. However, bacterial DNA was detected significantly more frequently from the tooth surfaces after iodine treatment (45%) than after NaOCl (13%) treatment.[148]

Molander et al.[149] suggested that irrigation with 5% IPI before $Ca(OH)_2$ medication did not have an effect on the overall antimicrobial power. However, it is possible that IPI reduces the frequency of persisting strains of *E. faecalis*. Peciuliene et al.[90] studied the effect of iodine irrigation in 20 teeth with previously root-filled canals and apical periodontitis. The results showed that when used after normal chemomechanical preparation, IPI increased the number of culture negative canals.

In the root canal, iodine compounds come in contact with a variety of substances such as dentin and various proteins. Studies of the interaction of IPI with the chemical environment of the necrotic root canal have shown that dentin can reduce or even abolish the effect of 0.2/0.4% IPI against *E.* faecalis.[52,53] However, pure hydroxyl apatite or bovine serum albumin had little or no effect on the antibacterial activity of IPI. Portenier et al.[54] have shown that dentin matrix (mostly dentin collagen) and heat-killed cells of *E. faecalis* and *C. albicans* inhibit the antibacterial activity of IPI. These studies indicate that inactivation of iodine compounds is one factor explaining the difficulty in obtaining sterile root canals. A study of three minute exposure of *in vitro* multispecies biofilms to different disinfectants demonstrated that 0.6% IPI had equally weak effect on the biofilm as 2% CHX, and weaker than 1% NaOCl.[62]

COMBINATION PRODUCTS FOR CANAL IRRIGATION

In recent years, several new products for root canal irrigation have been introduced that contain more than one active ingredient.[63] The purpose for such development is obviously a desire to make irrigation more effective and also save time. The challenge for combination products is that many substances have interactions that may weaken or even abolish the activity of one or both of the substances. Some interactions may result in formation of toxic by-products. The two most commonly used endodontic irrigants, NaOCl and EDTA cannot be combined without the reduction of activity.[150]

Antibiotic Containing Solutions: MTAD and Tetraclean

MTAD [a mixture of tetracycline isomer, acid, and detergent (Biopure, Dentsply, Tulsa, OK, U.S.A.)] is a combination product for root canal irrigation.[151,152] Tetraclean (Ogna Laboratori Farmaceutici, Muggiò, Italy) is another combination product similar or close to MTAD.[153] MTAD has a low pH (2.15) because it contains citric acid, it removes the smear layer after NaOCl irrigation, and it has antimicrobial activity. The authors who introduced MTAD have recommended the use of 1.3% NaOCl during instrumentation, followed by MTAD to remove the smear layer.[152] However, 1.3% NaOCl may not be strong enough to completely clean the uninstrumented parts of the root canal. Beltz et al.[154] found that MTAD solubilizes dentin, whereas organic pulp tissue is unaffected by it. Zhang et al.[155] showed that MTAD is less cytotoxic than eugenol, 3% H_2O_2, $Ca(OH)_2$ paste, 5.25% NaOCl and EDTA, but more cytotoxic than 2.63% NaOCl.

MTAD contains doxycycline (tetracycline) in high concentration. Shabahang et al.[156] and Shabahang and Torabinejad[157] investigated the effect of MTAD on root canals contaminated with either whole saliva or *E. faecalis* of

extracted human teeth and reported good antibacterial activity. Portenier et al.[47] showed that MTAD killed planktonic *E. faecalis* cells *in vitro* in less than 5 minutes. In an *ex vivo* study, Kho and Baumgartner[158] compared the antimicrobial effectiveness of NaOCl/EDTA and NaOCl/MTAD in extracted roots infected for 4 weeks with *E. faecalis*. After chemomechanical preparation and irrigation, the roots were pulverized in liquid nitrogen and viable bacteria were counted. No difference was measured between the two irrigation regimens. Stojicic et al.[159] reported that QMiX and 1% NaOCl killed all planktonic *E. faecalis* and plaque bacteria in five seconds, while 2% chlorhexidine and MTAD were unable to kill all plaque bacteria in 30s, and some *E. faecalis* cells survived even 3 min of exposure. Using multispecies anaerobically grown biofilms of oral bacteria, the same authors showed that QMiX and 2% NaOCl killed up to 12 times more biofilm bacteria than 1% NaOCl, 2% CHX and MTAD. There are only a few reports so far on the antibacterial effectiveness of Tetraclean, indicating good effect against biofilm.[160,161]

SmearClear, SmearOff, QMiX

SmearClear, SmearOff, QMiX are all EDTA based products for smear layer removal. They also contain other active substances to either alter the surface tension of the product (to facilitate wetting of dentin surface) or to add an antimicrobial effect.[63] The exact composition and concentration of the added substances are not revealed in detail by the manufacturers. One reason to add antimicrobial activity to an EDTA product is to avoid the need to go back to NaOCl after smear layer removal. Studies showed that if the canal is irrigated again by NaOCl, after EDTA or citric acid, this will result in considerable erosion of the canal wall dentin (Figure 21-8).[99] So far no peer review published reports exist on SmearOff.

A few studies have compared the smear layer removal efficacy of SmearClear to 17% EDTA, but there are no studies of its antimicrobial activity.[162,163] QMiX is the most extensively studied of the three. Its efficacy in smear layer removal has been shown to be equal to or better than 17% EDTA,[159,164,165] while dentin microhardness studies have shown that QMiX reduced dentin microhardness less compared to 17% EDTA or 2.25% paracetic acid.[166] Chandrasekhar et al.[167] showed that QMiX was less toxic to the rat subcutaneous tissue than 3% NaOCl, 2% CHX, and 17% EDTA. Alkahtani et al.[168] reported that while both NaOCl and QMiX were toxic to human bone marrow mesenchymal stem cells, QMiX was less cytotoxic than NaOCl. QMiX contains small amount of chlorhexidine that may raise concerns about formation of para-chloroaniline (PCA) if QMiX and NaOCl are intentionally or accidentally mixed in the root canal. However, Kolosowski et al.[169] reported that a precipitate containing PCA was formed in the tubules of dentin irrigated with NaOCl followed by CHX. No precipitates or PCA were detected in the tubules of dentin irrigated with NaOCl followed by saline and QMiX. Arslan et al.[170] mixed NaOCl either with chlorhexidine or QMiX and found that according to nuclear magnetic resonance spectroscopy, para-chloroaniline was present in the mixture of chlorhexidine and NaOCl. However, the mixture of QMiX and NaOCl did not result in para-chloroaniline formation. Other studies have shown better wettability on dentin by resin based sealers such AH+ (Thermaseal) after QMiX than EDTA final rinse, and no effect on dentin binding by Biodentine or MTA.[171,172] In another study, the same author showed that QMiX did not weaken the bonding strength of glass fiber posts cemented with a self-adhesive resin cement to root dentin.[173]

Electrochemically Activated Water

Several new technologies have been introduced during the last few years to improve the effectiveness of root canal disinfection. Increasing attention has been focused on the use of ozone, photoactivated disinfection with low-energy laser, electrochemically activated water, and electric current.[174–178] In a comparative study, 3% NaOCl was more effective than electrochemically activated water in eradicating *E. faecalis* in an *ex vivo* model.[175] Nagayoshi et al.[177] reported relatively equal effectiveness in killing *E. faecalis* with ozonized water and 2.5% NaOCl, when the specimen was irrigated with sonication. However, NaOCl was superior to ozonized water in killing *E. faecalis* in broth culture and in biofilms.[179] Estrela et al.[180] studied root blocks infected for 60 days with a strain of *E. faecalis* and were unable to eradicate all bacteria with any of the methods used, including ozonized water, gaseous ozone, 2.5% NaOCl, and 2% CHX. Many of the new methods offer a biological approach to canal disinfection. However, available evidence so far has failed to show that these methods would be superior or sometimes even equal to existing ones with regard to their antimicrobial effectiveness in the infected root canal.

IRRIGATION OF THE APICAL ROOT CANAL

Despite the great technological advances that have been made in instrumentation and irrigation formulations, decades of research has repeatedly demonstrated the variable success with which we are able to deliver irrigant to the apical root canal (Figure 21-13). Studies have also demonstrated the great extent to which root dentin remains uninstrumented despite the use of endodontic files, especially in the apical 4 mm of a root canal.[181] Uninstrumented recesses in oval canals of mandibular incisors can be present in up to 65% of teeth after balanced force instrumentation of canals,[182] while 65.2–74.4% of the apical 4 mm of the distal roots of mandibular molars can remain untouched by instruments after mechanical debridement has been completed by rotary files.[181] The shortcoming of current rotary and hand instrumentation lies in the fact that they cannot adapt to the anatomical complexity of a root canal system. Studies

FIGURE 21-13 Scanning electron microscope image of apical root canal after finished instrumentation and copious irrigation with NaOCl and EDTA. Dentin debris that was created during instrumentation and packed into the most apical canals was not dissolved or removed by irrigation.

on canal morphology have shown that root canals are rarely conical or straight, and have lateral canals, apical deltas, fins, webs, and transverse anastomoses,[183] that harbor intraradicular biofilm in the apical third in those teeth diagnosed with apical periodontitis.[184] Computational fluid dynamic (CFD) modelling has demonstrated at least the partial irrigation of a simulated lateral canal under ideal and varied placement of a conventional irrigation needle in a root canal model.[185] Thus, it becomes even more important for intracanal irrigants to be delivered to where rotary instruments are unable to perform their function, and the role of root canal instrumentation shifts out of necessity from that of debridement, demonstrated to be variably successful, to one of creating apical radicular access for irrigants.[186]

Fluid Dynamics and Factors Affecting Irrigation Efficacy in Apical Root Canal

Contemporary studies of irrigation have closely examined variables associated with irrigation efficiency, but unlike the previous decades, these studies are utilizing novel experimental models. Hsieh et al. used thermal image analysis to record fluid distribution during irrigation in extracted teeth.[187] They found that a size 27 gauge needle should be placed 3 mm from the apical stop in order to achieve successful irrigation when the canal was prepared to ISO size 30 (0.3 mm). When the needle tip was placed 6 mm from the apical stop, successful irrigation was seen only when the root canal was prepared to at least ISO size 50 (0.5 mm), demonstrating that irrigation was improved by apical placement of the needle tip and larger size of canal preparation. Another study, using real-time imaging of bioluminescent bacteria inoculated into a root canal, confirmed that irrigation is affected by the depth of placement of the needle tip. Emission of bioluminescence was imaged before and after irrigation, showing significant reduction of bacteria when the needle was placed at 1 mm from the working length compared to 5 mm from the working length.[188] The same technique was used to show that increased canal curvature negatively affected irrigation effectiveness.[189] A study by Huang et al.[190] ranked the importance of different factors influencing the removal of a stained collagen bio-molecular film in extracted teeth. The collagen bio-molecular film thickness approximated the thickness of bacterial biofilm. The percentage of canal surface covered with stained collagen was quantified before and after irrigation. The authors found that, in order of decreasing priority, the depth of placement of the needle tip, the apical size and taper of the canal preparation, and the use of dynamic or static irrigation techniques were factors influencing the removal of a collagen film in a root canal.[190] Real-time fluid movement analysis using microparticle image velocimetry in soft lithography-based models have also verified that dynamic irrigation techniques, such as continuous ultrasonic-assisted irrigation, are correlated with significant biofilm reduction and effective fluid flow effects in the apical third in comparison to conventional syringe irrigation.[191]

Irrigant clearance beyond the needle tip (Figure 21-14) was examined in a study by Park et al.[66] that prepared a plastic root canal model and filled the canal with dye. The dye was irrigated from the canal using various needle designs, with the needle held at 3 mm from the working length. The irrigant was delivered at precise flow rates from 1 to 15 mL/min, and the length of dye cleared from the end of the needle tip measured. There was a flow rate dependent increase in the length of dye cleared from the end of the needle tip starting at 1 mL/min, but this length of dye clearance plateaued at irrigation flow rates above 4 mL/min (Figure 21-15), regardless of the needle tip design and needle size.[66] The length of dye clearance beyond the needle tip at irrigation flow rates above 4 mL/min was between 2 to 3 mm, resulting in a similar range of dye clearance regardless of needle design. CFD and analytical modelling have confirmed the existence of a stagnation plane beyond which irrigant will not penetrate from the end of the needle tip (Figure 21-16).[192] One CFD study identified the limit of irrigant replacement beyond the needle tip as 1 to 1.5 mm, regardless of the flow rate used, that included very high flow rates of 15 mL/min.[67] Increased root canal taper and larger apical preparation sizes were shown to improve irrigant replacement through CFD analysis.[193,194] When the depth of needle placement was investigated by CFD analysis, Boutsioukis et al.[195] found

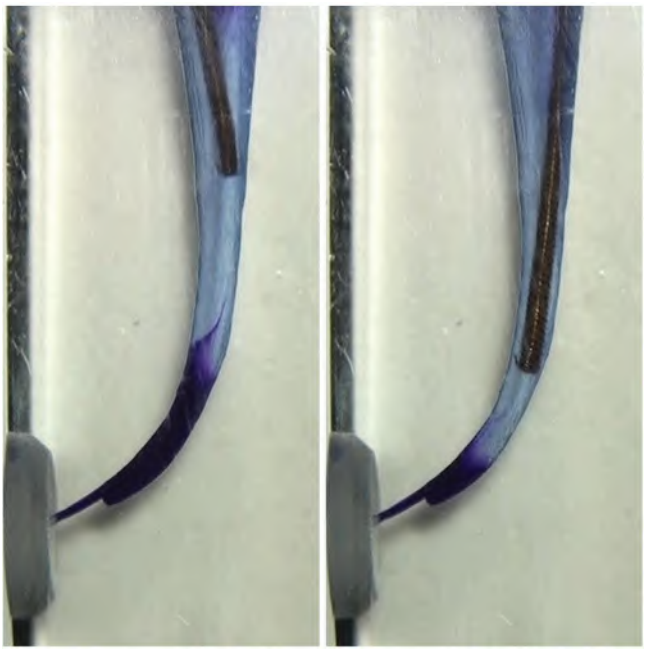

FIGURE 21-14 Irrigant clearance is the length of the zone beyond the needle tip where irrigant penetrates during irrigation. Despite occasional claims to the contrary, irrigants do penetrate longer than the position of the needle tip when side vented ("safety tip") or open-ended needles are used. However, clearance zone is typically limited to 1 mm to 3 mm, and it does not grow anymore longer above flow rates of ca. 5 mL/min.

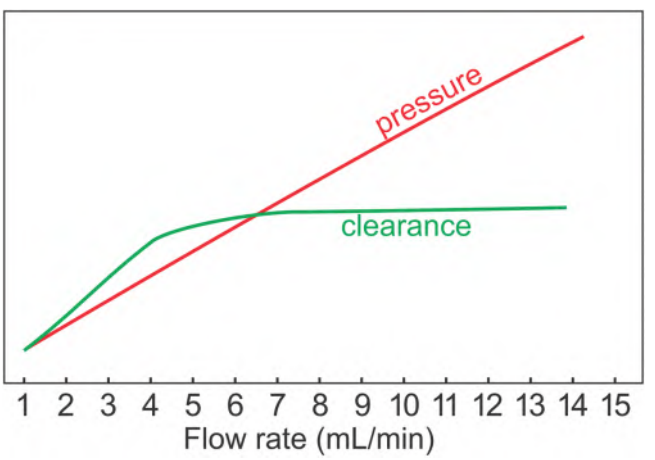

FIGURE 21-15 A study on irrigant flow rate, apical clearance zone, and irrigation pressure towards the apex showed that clearance beyond the needle tip increased when flow rate increased to 5 mL/min. The depth of the clearance zone did not continue to grow at higher flow rates. However, the pressure caused by the irrigation continued to grow in a linear fashion with increasing flow rate.[66]

that a 30 gauge closed-end side-vented needle achieved 1 to 1.5 mm of irrigant replacement apical to the end of the needle regardless of its position in the canal. Hence, it is highly likely that maximum exchange of irrigant without the need for very high irrigation flow rates could be achieved.

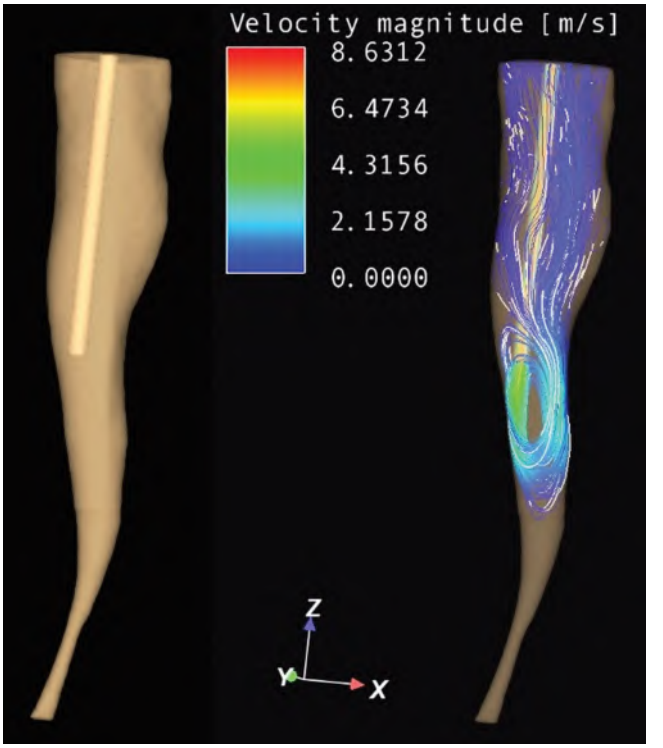

FIGURE 21-16 A computational fluid dynamics model of irrigant flow in a canine root canal virtual model, based on micro-CT scanning of a real canine tooth. The complex mathematical model predicts the extent of the flow beyond the needle tip, flow speed in various parts of the canal and canal wall shear stress caused by the irrigant.

Apical Pressure Measurement; Positive Vs. Negative Pressure

With the recommendations that irrigation needles should be placed approximately 1 mm from the working length or at least in the apical third of the root canal in order to achieve effective irrigation, whether positive pressure or negative pressure methods are used, it is of interest to know what kind of apical pressures are generated when specific irrigation parameters such as different flow rates are used. The available CFD studies are difficult to compare as different simulated irrigation flow rates, a range of simulated needle designs, and different canal preparation sizes were used. Furthermore, the software algorithms used are potentially different. When only similar needles are compared, the apical pressure generated by a beveled needle tip at 3 mm from the working length is reported to be approximately 18 kPa (135 mmHg) by one group using a flow rate of 15.6 mL/min,[196] but only 1.707 kPa (13 mmHg) by another group using an irrigation flow rate of 6 mL/min.[68] If one compares a side-vented closed-end needle design, the apical pressure generated at 3 mm from the working length is reported to be approximately 10 kPa (75 mmHg) by one group using a flow rate of 15.6 mL/min,[196] and 0.256 kPa (2 mmHg) by another group using a flow rate of 6 mL/min.[68] These pressures differ by several orders of

magnitude. The rotational orientation of a side-vented needle has also been shown to influence irrigant flow pattern and apical pressure in a root canal.[185]

It is not possible to compare the reported apical pressures to a reference point at the current time, and it is also unknown what pressures might result in a sodium hypochlorite extrusion accident, but it is interesting to consider that the average capillary pressure in the human body is 25 mmHg, or 3.3 kPa.[197] Khan et al.[70] suggested that irrigation pressure of as low as 5.88 mmHg (human central venous pressure) may be an upper limit for safe irrigation. Park et al.[66] measured the pressure generated during positive and negative pressure irrigation at the periapex of an *in vitro* tooth model using a novel method of measurement, investigating the effect of flow rate and needle design. A mesiobuccal canal of a mandibular molar was instrumented and placed into a chamber coupled to a pressure transducer. Irrigation was performed via a digital peristaltic pump using flow rates from 1 to 15 mL/min with irrigation needles of different size and design. Positive pressure irrigation revealed a flow rate dependent increase in apical pressure (Figure 21-15). The apical pressure at high irrigation flow rates was several times higher than at low flow rates. Needle designs with closed ends and/or side vents yielded statistically significant lower apical pressures than blunt open-ended needles. In contrast, measurement of apical pressure during apical negative pressure irrigation revealed that no positive pressures were generated, even when any of the needles used were placed at 1 mm from the working length, thus confirming the safety benefit of this irrigation method for patients.[66] Coupling this finding with the evaluation of dye clearance beyond the needle tip during negative pressure irrigation, using a blunt open-ended needle tip, should prove to be effective and safe.

Negative pressure irrigation is reported to address the limitations associated with positive pressure irrigation, such as the difficulty in delivering and replenishing irrigant to the apical third, and also the safety issues that might occur when a needle is placed close to the root apex and apical foramen in attempting effective delivery and replenishment. The ability of the EndoVac irrigation system to remove significantly more debris than conventional syringe irrigation has been reported in several studies. Some studies report no difference in debris removal at the 3-mm level but a significant difference at the 1-mm level.[198,199] A different study reported significantly less debris after use of the EndoVac compared to conventional syringe irrigation at 1.5 mm and 3.5 mm from the apex.[200] The antimicrobial efficacy of irrigation with the EndoVac system in comparison to syringe irrigation and supplementary sonic agitation techniques has shown that these techniques are comparable and highly effective in bacterial reduction.[201,202] Apical negative pressure is at least comparable to that of conventional irrigation in its ability to obtain culture-negative root canals in necrotic teeth.[203] One study also reports the superior antimicrobial efficacy of the EndoVac system,[204] but these differences can be attributed to differences in bacterial sampling after irrigation.

The major benefit of apical negative pressure for irrigation is the prevention of irrigant extrusion apically, even when placed very close to the root apex. This has been verified in several studies and tested in several different ways. One such study collected the volume of irrigant extruded during irrigation from the root end of teeth and reported that the EndoVac microcannula and macrocannula did not extrude any irrigant at all even when placed at full working length, in comparison to other techniques such as manual or ultrasonic activation.[205] As an extension of the ability of apical negative pressure irrigation to prevent extrusion of irrigant yet deliver irrigant to the full working length, one group has reported that the incidence of post-operative pain in patients where the EndoVac was used was significantly less than in those patients where positive pressure syringe irrigation was used.[206]

PHYSICAL MEANS OF FACILITATING CANAL CLEANING AND DISINFECTION

Syringe-needle Irrigation

Conventional positive pressure irrigation using a syringe and needle is the most common way of irrigating root canals.[63] Small syringes of 1 to 5 mL offer easier handling and better tactile control of irrigant flow than large syringes of 10 mL and higher. Luer lock attachment of the needle to the syringe should be regarded as mandatory in order to avoid unintended accidents. While there is no clear consensus of the optimal needle design, it seems that the preferred needle type and size is a 30-gauge side vented needle with closed end (Figure 21-17). Needles of this type, by various manufacturers, usually have a rounded tip that facilitates smooth gliding of the needle in the canal despite mild curves and canal wall irregularities. In severely curved canals needles with a non-metallic tip allow better access to the apical canal (Figure 21-18). The Endovac system (Kerr Co., Orange, CA, U.S.A.) constantly irrigates the canal system and evacuates debris (Figure 21-19)

It is important to understand that syringe-needle irrigation does not guarantee flow of the irrigant to all areas of the root canal system. In fact, careless irrigation may leave large areas of the canal(s) un-irrigated.

Sonic Devices

Sonic devices transmit mechanical energy through vibrations. The best known sonic device in endodontics probably is the EndoActivator, that has thin, plastic tips of different sizes attached to a special hand piece.[205,207–210] The pulp chamber and the canal are filled with the irrigant and the tip is placed close to working length to "activate" the solution. "Activation" in fact means that the solution is mechanically agitated with

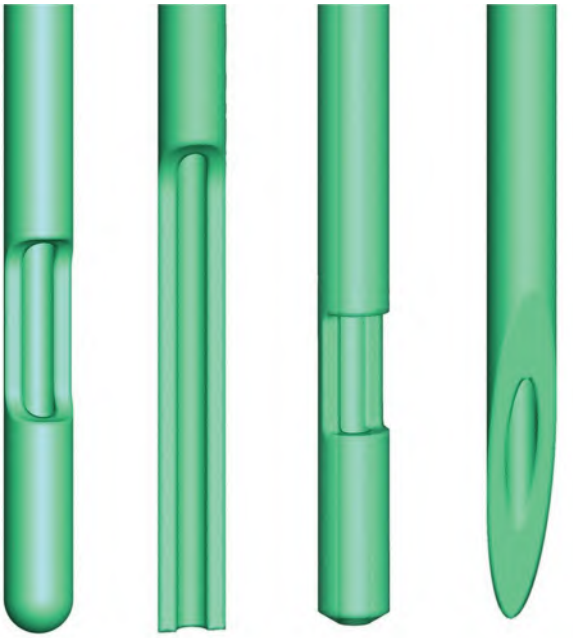

FIGURE 21-17 Four different needle designs, produced by computerized mesh models based on true and virtual needles. From left to right; side vented ("safety tip"), notched, side vented open ended, beveled.

the vibrating tip. The 3-speed sonic motor provides options of two, 6000 and 10,000 vibrations per minute. As the plastic tip is softer than dentin, it does not create a smear layer. A number of studies comparing different irrigation methods have demonstrated some improvement in cleaning of the canal space by EndoActivator, while other studies have not reported such differences.[205,207–210] In short, EndoActivator is an easy-to-use, safe facilitator of canal irrigation.

Ultrasonic Cleaning

Ultrasound is used in a variety of tasks including finishing access cavity preparation, removing pulp stones, locating canal orifices, opening calcified canals, fractured instrument removal, placing cements and root filling materials, and retro canal preparation during surgical procedures.[211] The use of ultrasonic energy for cleaning of the root canal and to facilitate disinfection has a long history in endodontics. The comparative effectiveness of ultrasonics and hand instrumentation techniques has been evaluated in a number of earlier studies.[211–215] The majority of these studies concluded that the ultrasonics, together with an irrigant, contributed to a better cleaning of the root canal system than irrigation and hand instrumentation alone. Cavitation and acoustic streaming of the irrigant contribute to the biological chemical activity for maximum effectiveness.[216] Analysis of the physical mechanisms of the hydrodynamic response of an oscillating ultrasonic file suggested that stable and transient cavitation of a file, steady streaming, and cavitation microstreaming all contribute to the cleaning of the root canal.[217] However, it has also been suggested that cavitation using traditional ultrasonic equipment with files may not extend further than a few micrometers from the file.

Several different methods and criteria have been used to study the effect of ultrasound on the cleanliness of the canal. These include bacteriological, histological, and microscopic techniques.[218–222] Studies focusing on the ability of ultrasound to remove the smear layer have shown contradictory results. This is not, in fact, surprising because it is generally known that the smear layer can be removed primarily by chemical means only, or by appropriate laser treatment.[223,224] It has also been shown that to work effectively, ultrasonic files must be free in the canal without contact with the canal walls.[225]

Among the areas that are particularly difficult to clean are anastomoses between double canals, isthmuses, and fins (Figure 21-20). Several studies have indicated the importance of ultrasonic preparation for optimal debridement of the root canals and isthmuses.[224,226–228] Ultrasonics also eliminated bacteria from canals more effectively than hand instrumentation.[228–230] However, not all studies have supported this finding.[231] It has been proposed that canal anatomy is more important than ultrasound for effectiveness of the cleaning procedures.[232]

The direct bactericidal effect by ultrasonic energy seems to be very limited at best.[233,234] Ultrasonics seems to exert its antimicrobial effect when used together with irrigants, perhaps via the physical mechanisms of cavitation and acoustic streaming. It is also possible that ultrasonics helps irrigants penetrate into areas, in complex canal systems, not easily reached by normal irrigation.

In a series of studies on the effect of canal shape (taper) and instrument design, Lee et al.[235] demonstrated in simulated plastic root canals that the diameter and taper of root canal influenced the effectiveness of ultrasonic irrigation to remove artificially placed dentin debris. After ultrasonic irrigation, the amount of debris in the size #20/.04 taper group was significantly higher than that for the size #20/.06 group and the size #20/.08 group. Van der Sluis et al.,[236] using roots from human teeth *ex vivo*, reported that there was a tendency for ultrasonic irrigation to be more effective in removing artificially placed dentin debris from simulated canal extensions of canals with greater tapers.

A study using a split tooth technique found that ultrasonic irrigation *ex vivo* was more effective than syringe irrigation in removing artificially created dentin debris placed in simulated uninstrumented extensions and irregularities in straight, wide root canals.[235] In another study, passive ultrasonic irrigation with 2% NaOCl was more effective in removing $Ca(OH)_2$ paste from artificial root canal grooves than syringe delivery of 2% NaOCl or water as an irrigant.[237]

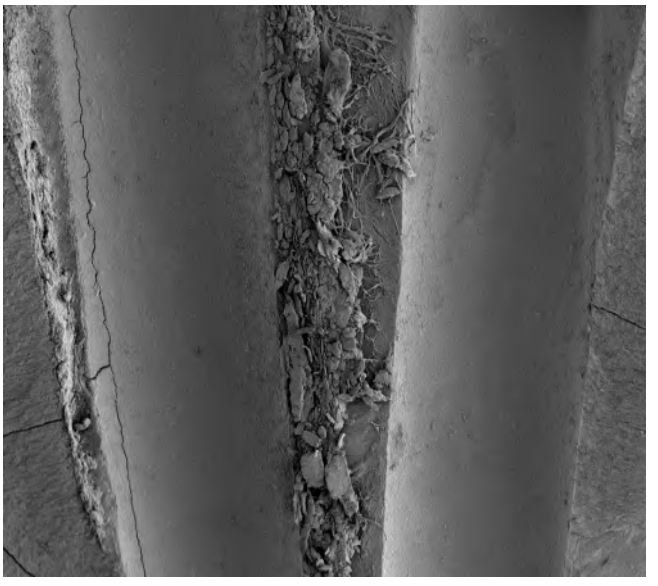

FIGURE 21-20 Scanning electron microscope image of two joining canals with a narrow isthmus between the canals. Instrumentation has packed dentin debris and organic matter (fibers) into the isthmus. Prolonged syringe-needle irrigation of over 10 minutes was not able to remove the debris.

Ultrasonic instrumentation can also have an impact on canal dimensions and in some cases can cause unwanted complications such as straightening of the canal (transportation), perforations, and extrusion of infectious material beyond the apex.[225,238–243] A histobacteriological study of teeth with non-vital pulps showed compacted debris and bacteria in the apical region and in the dentinal tubules after ultrasonic instrumentation.[242] In one study, the step preparation technique was shown to cause more extrusion than the standard technique, whereas the least extrusion was detected with the crown down and ultrasound techniques.[241] Interestingly, Van der Sluis et al.[236] suggested that a smooth wire during ultrasonic irrigation is as effective as a size 15 K-file in the removal of artificially placed dentin debris from grooves in simulated root canals in resin blocks. It is possible that using an ultrasonic tip with a smooth, inactive surface, means preparation complications are less likely to occur. Studies using micro-CT have examined the effectiveness of ultrasonic activation to remove dentin debris from fins and isthmuses where it was packed with rotary files.[244] The results showed that only some but not all of the debris could be removed. In line of this result, other studies about removal of interappointment calcium hydroxide paste from molar root canals have shown that sonic or ultrasonic energy together with copious irrigation failed to remove all residual calcium hydroxide from the canals.[245–248]

Ultrasonic irrigation has traditionally been done as passive ultrasonic irrigation, "PUI." The pulp chamber and the root canals have been filled with the irrigant, followed by the introduction of the ultrasonic tip into the canal and setting on the energy. One of the new models for ultrasonic irrigation, EndoUltra (Figure 21-21) (Vista Dental Products, Racine, WI, U.S.A.) has a high frequency of 40 kHz, instead of the common 20 to 30.000 kHz. Some of the modern ultrasonic devices combine continuous flow of the irrigant into canal with continuous use of ultrasound. These devices have hollow needle-like tips that allow flow of the irrigant into the pulp chamber or into coronal/middle root canal while vibrating at the same time by ultrasonic energy.[249–252] ProUltra PiezoFlow (Dentsply Tulsa Dental Specialties, OK, U.S.A) (Figure 21-22) irrigating system is one of the

FIGURE 21-21 EndoUltra high frequency (40-kHz) unit for passive ultrasonic irrigation.

FIGURE 21-22 A ProUltra PiezoFlow active ultrasonic system for irrigation of root canals. The irrigant flows through the hollow needle into the coronal/mid root canal while the needle is activated by ultrasonic energy.

commercial devices based on studies of its prototype at the University of Ohio. These studies showed good/excellent results in cleaning the usually hard-to-reach areas such as fins and isthmuses.[249–252]

Lasers

The potential of different endodontic lasers in eradicating root canal microbes has been a focus of interest for many years. Early comparative studies indicated, however, that the antibacterial effectiveness of lasers in the root canal was inferior to NaOCl irrigation.[253–255] Excellent antibacterial efficiency against *E. faecalis* was reported by Gutknecht et al.[256] using a holmium:yttrium–aluminum–garnet (Ho:YAG) laser on root canals infected with this species *in vitro*, 99.98% of the bacteria were eliminated. However, Le Goff et al.[257] obtained only an 85% decrease in the bacterial counts by a CO_2 laser, clearly less compared to irrigation with 3% NaOCl. Contrary to the main stream of results with laser treatment, Kesler et al.[258] indicated that complete sterility of the root canal can be obtained with a CO_2 laser microprobe coupled onto a special hand piece attached to the delivery fiber. Schoop et al.[259] in subsequent studies indicated that the effect of laser is dependent on the applied output power and specific for different bacteria. Complete sterility still seems to remain a challenge with laser treatment.[260,261] Another important aspect of laser radiation in endodontics is the effect of lasers on the smear layer, that may also facilitate effective disinfection of the canal. Recently, a new technology using laser-activated irrigation was introduced. Photon Induced Photoacoustic Streaming (PIPS™) uses an Erbium 2,940 laser to pulse extremely low energy levels of light to generate a photoacoustic shockwave throughout the entire root canal system without the need to enlarge the canals (Figure 21-23).[262,263] Using extremely short bursts of laser energy with high peak powers, a specially designed tapered and stripped tip creates a pressure wave that streams irrigants throughout the root canal system. Unlike other conventional hand and ultrasonic systems, the PIPS tip is placed in the pulp chamber only and not in the canals. The resultant effect is a passive reflux of tissue debris that exits coronally up and out of the roots while cleaning the canal system.

Mathew et al.[33] compared antimicrobial effect by irrigation using three different devices. They reported that the diode laser group showed better antibacterial efficacy and least viable bacteria when compared to conventional needle irrigation, PIPS and EndoActivator groups in minimally instrumented, experimentally instrumented

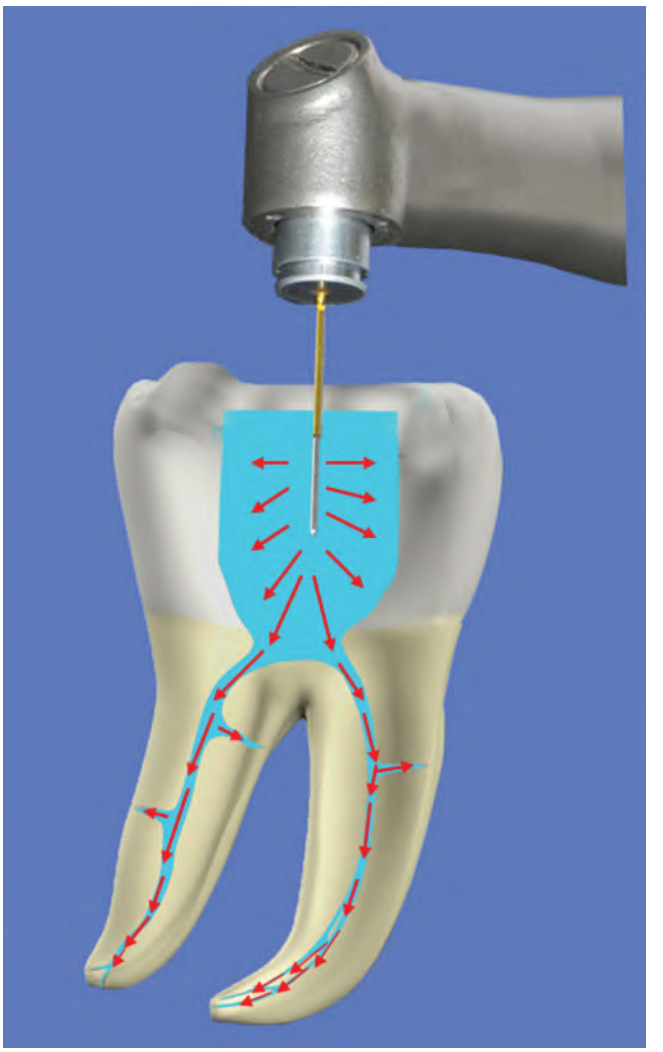

FIGURE 21-23 Photon Induced Photoacoustic Streaming (PIPS™) uses an Erbium 2,940 laser to pulse extremely low energy levels of light to generate a photoacoustic shockwave throughout the entire root canal system. (Courtesy of Dr. Enrico DiVito, Scottsdale, AZ.)

root canals. PIPS and EndoActivator were more effective than conventional needle irrigation.[33] Pedullà et al.[262] and Zhu et al.[264] reported no difference in the antibacterial effect on root canal microbes in an *ex vivo* study that compared PIPS to NaOCl only. However, Al Shahrani et al.[265] showed better effect by PIPS + 6% NaOCl against *E. faecalis* biofilm in root canal compared to 6% NaOCl alone.

Arslan et al.[209] found that PIPS was superior in removing $Ca(OH)_2$ compared to needle irrigation, sonic irrigation, and ultrasonic irrigation from artificial grooves in straight root canals. Olivi et al.[266] reported that PIPS appears to be effective in enhancing the effect of the irrigants commonly used in endodontics. Lloyd et al.[267] examined the removal of dentin debris by irrigation using either standard needle irrigation or PIPS. The authors found that irrigation using PIPS increased the canal volume and eliminated debris from the canal system 2.6 times more than needle irrigation. Tissue dissolution effectiveness were compared by Guneser et al.,[268] who reported that 5.25% NaOCl with Er:YAG laser dissolved ca. 50% more pulp tissue than same concentration NaOCl alone, while NaOCl with PIPS dissolved 20% more pulp tissue than NaOCl alone.

Wide Spectrum Sound Energy for Cleaning of Root Canals

A new device using sound energy far beyond the ultrasound range, GentleWave (Sonendo, Orange, CA, U.S.A.), was recently tested for its ability to dissolve soft tissue, and compared it to other forms of irrigation, including ultrasound.[34] The device consists of a central unit from which high pressure pumps send high speed degassed irrigant flow to a special hand piece (Figure 21-24), with a tip of the handpiece placed into the pulp chamber of the tooth. The irrigant stream hits the tip of the nozzle and spreads as a cloud to the root canal system (Figure 21-25). According to the manufacturer the effect is based on wide spectrum sound energy, cavitation, and chemical reactions. The irrigant is sucked back through several small holes in the hand piece covering the access cavity, and creating a stable negative pressure throughout the root canal system. The study of tissue dissolution showed that even using water, organic tissue was dissolved as well as using 2% NaOCl and ultrasonic irrigation.[34] This may indicate the presence of cavitation, as water is not expected to dissolve soft tissue. Overall, the study showed that soft tissue dissolution was up to 8 times faster than with conventional irrigation with 6% NaOCl and ultrasound. Another study showed that GentleWave was the only system that completely removed calcium hydroxide from molar root canals, whereas syringe-needle irrigation with and without ultrasound always left some calcium hydroxide in the canal space, particularly in the apical third of the root canals.[269]

FIGURE 21-24 GentleWave handpiece delivers the "high speed" irrigant into the pulp chamber, from where it spreads into the root canal system.

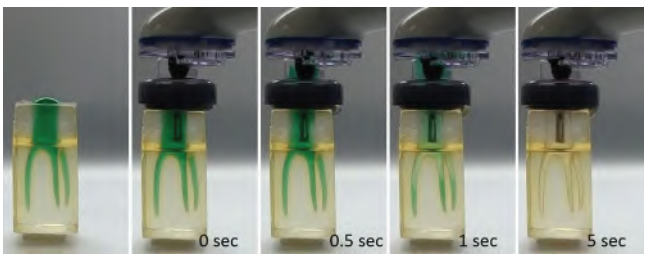

FIGURE 21-25 A demonstration of the exchange of colored liquid by the GentleWave system in root canals of a molar. Irrigant in all canals has been refreshed in a few seconds simultaneously. The tooth model is based on micro-CT imaging of a real tooth.

INTRACANAL INTERAPPOINTMENT MEDICAMENTS

In the treatment of teeth with a vital pulp that is inflamed but not necrotic, there is no need for intracanal medication for microbiological reasons. However, if time does not allow completion of the treatment in one appointment, it is generally recommended that the root canal should be filled between appointments with an antimicrobial dressing, for example, $Ca(OH)_2$, to maintain sterility in the canal space until a permanent root filling is placed. However, there are no studies comparing the bacteriological status of root canals following pulpectomy, when the canals have been left empty or filled with an antibacterial dressing.

The question of the role of intracanal medicaments becomes more relevant, and complex, in the treatment of pulpal necrosis and apical periodontitis. There is overwhelming evidence in the literature that many, if not most, root canals contain viable microorganisms after the completion of the chemomechanical preparation at the end of the first appointment.[12–14,27,86,90,270–273] Therefore, a variety of intracanal medicaments have been used between appointments to complete disinfection of the root canal. In addition to killing microorganisms, intracanal medicaments may have other beneficial functions. $Ca(OH)_2$ neutralizes the biological activity of bacterial lipopolysaccharide and makes necrotic tissue more susceptible to the solubilizing action of

NaOCl at the next appointment.[274,275] Another aspect in using intracanal medicaments may be that a more thorough cleanliness is achieved because of the longer overall time used for the treatment. On the other hand, several appointments can also increase the risk for aseptic complications, for instance, through a leaking temporary filling and poor patient compliance.[276]

Several studies have indicated a poorer prognosis of the treatment of apical periodontitis if viable bacteria are residing in the root canal system at the time of filling.[9–11] Other studies, however, have contradicted these results and reported no significant differences in healing between teeth filled after positive or negative cultures from the root canal,[12] or between treatments performed in one or two appointments.[12,13] It has also been suggested that "intracanal sampling techniques suffer from deficiencies that limit their predictive value."[277] A permanent root filling of high quality, using endodontic cements with antimicrobial activity, can effectively seal and entomb residual microorganisms in the canal, and prevent communication with periradicular tissues. Continued killing of the microorganisms could take place due to the antimicrobial activity of the root-filling materials[74,278] and unavailability of nutrients. However, some antimicrobial root canal filling materials may also be cytotoxic. Systematic reviews of single-visit vs. multiple visit root canal treatment have not found much difference in healing between the two strategies.[279,280]

Calcium Hydroxide [$Ca(OH)_2$]

Calcium hydroxide [$Ca(OH)_2$] has a special historical position in endodontics. Indications for the use of $Ca(OH)_2$ in the prevention and treatment of various pulpal and periapical conditions have been numerous. In addition to endodontic infections, use of $Ca(OH)_2$ has been widely advocated in dental traumatology and in the treatment of resorptions. The classical studies in the 1970s and 1980s at the University of Umeå, Sweden, were a strong stimulus for the wide spread use of $Ca(OH)_2$ as a local disinfecting medicament in the root canal for the treatment of apical periodontitis. Byström et al.[10] reported that $Ca(OH)_2$ was an effective intracanal medicament, rendering 34 out of 35 canals bacteria free after a 4-week period. The effectiveness of interappointment $Ca(OH)_2$ was also reported by Sjögren et al.,[281] who demonstrated that a 7-day dressing with $Ca(OH)_2$ eliminated all bacteria in the root canal. However, these pioneering studies have been challenged by others who reported a residual flora from 7% to 35% of teeth after one or more weeks with $Ca(OH)_2$ in the canal.[28,282–284] Kvist et al.[285] reported the antimicrobial efficacy of endodontic procedures performed in a single visit, with 10-minute iodine irrigation, compared to a two-visit procedure, with an interappointment dressing with a $Ca(OH)_2$ paste. Residual microorganisms were detected in 29% of the one-visit teeth and in 36% of the two-visit-treated teeth, with no statistically significant differences between the groups. A systematic review by Sathorn et al.[14] concluded that calcium hydroxide has minimal effect in reducing root canal microbes.

Zerella et al.[58] compared the antibacterial activity of $Ca(OH)_2$ mixed either with water or with 2% CHX in vivo. Pure $Ca(OH)_2$ completely disinfected 12 out of 20 teeth, while the $Ca(OH)_2$-CHX paste disinfected 16 of 20 teeth. The difference, however, was not statistically significant because of small sample size. Siqueira et al.[286] examined bacterial reduction in teeth with apical periodontitis, after instrumentation and irrigation with 0.12% CHX solution and after 7 days of intracanal medicament with a $Ca(OH)_2$-CHX (0.12%) mixture. After finishing the chemomechanical preparation, 7 of the 13 cases still showed growth, while after the $Ca(OH)_2$-CHX treatment only one of 13 teeth was culture positive.

Vivacqua-Gomes et al.[55] examined the benefit of interappointment $Ca(OH)_2$ medicament in root canals in an *ex vivo* model. The premolar teeth were infected with *E. faecalis* for 60 days, and the canals were instrumented using rotary instruments. Irrigation, interappointment medication, and root filling were performed following five different protocols, either in a single visit or in multiple visits. A second bacteriological sample was obtained 60 days after the root filling, where the root fillings were removed and samples taken. Bacteria were found in 3 of 15 teeth (20%) irrigated with 2% CHX gel and filled in single visit, and in 4 of 15 teeth (25%) irrigated with CHX and filled with $Ca(OH)_2$ for 14 days before the gutta-percha/sealer root filling was placed. Teeth that were left empty for one week after irrigation and before root filling, or irrigated with saline only instead of CHX, or filled without sealer showed bacteria in 40 to 100% of the teeth 60 days after the root filling was placed. Because of the small size of the experimental groups, far-reaching conclusions cannot be made. However, the results support the finding of other studies indicating that interappointment $Ca(OH)_2$ may not add to the antibacterial effectiveness of the treatment. Moreover, the results emphasize the importance of not leaving the root canal empty (no medicament, no root filling) as well the role of sealer in the joint effort to combat infection.

$Ca(OH)_2$ was earlier the material of choice in treating young teeth with open apex and large canal space. Apexogenesis and apexification were the long term goals, with up to one to two years of $Ca(OH)_2$ treatment.[287,288] However, reports of the weakening of root dentin because of longstanding $Ca(OH)_2$ in the canal[289,290] and the introduction of MTA and other bioceramic material, such as Biodentine and Root Repair materials, have led to a clear change in the treatment strategy of young teeth with open apex.[290,291] However, a recent study of the long-term effects of three calcium hydroxide preparations did not detect any weakening of the root dentin as compared to control group after six months of calcium hydroxide treatment.[292] For more details, see Chapter 28.

Several studies in recent years have focused on a familiar clinical challenge; the difficulty in removing $Ca(OH)_2$ from the root canal before root filling.[247,293,294] Syringe-needle irrigation, sonic activation, and even ultrasound have all been shown to be ineffective in removing all $Ca(OH)_2$

from the canals. However, a laser based system, PIPS, has shown to remove more $Ca(OH)_2$, than irrigation with ultrasound from artificial grooves in straight canals,[209] and the wide spectrum sound energy based GentleWave was reported to completely remove $Ca(OH)_2$ from molar root canals (Figure 21-26).[269]

Chlorhexidine Digluconate

CHX has been used by many as an irrigating solution during or at the end of instrumentation. However, CHX has also been used as an intracanal medicament between appointments. As a disinfecting agent, interest has been focused on the effectiveness of CHX in gel form or as a mixture with $Ca(OH)_2$ as an intracanal interappointment dressing.[294,295] The information available is based mostly on *in vitro* and *ex vivo* experiments in which several intracanal medicaments have been compared for their activity against induced dentin infection. Siren et al.,[295] using a bovine dentin block model, reported that $Ca(OH)_2$ mixed with CHX was much more effective in disinfecting dentin infected with *E. faecalis* than pure $Ca(OH)_2$. Ercan et al.[294] reported 2% CHX gel was significantly more effective than $Ca(OH)_2$ combined with 2% CHX, or $Ca(OH)_2$ alone, against root dentin infected with *E. faecalis* and the yeast *C. albicans* after 7, 15, and 30 days of incubation. Similarly, it has been reported that 2% CHX gel alone completely inhibited the growth of *E. faecalis* after 1, 2, 7, and 15 days in the root canal, whereas $Ca(OH)_2$ allowed some microbial growth at all experimental times.[56] Interestingly, in this study, the combination of the CHX gel and $Ca(OH)_2$ had killed all bacteria in the one- and two-day samples, but failed to secure sterility in the 7- and 15-day samples. The antibacterial efficacy of intracanal medication with $Ca(OH)_2$, 2% CHX gel, and a combination of both was assessed in a clinical study in teeth with chronic apical periodontitis.[59] Bacterial samples were taken before and seven days after filling the canals temporarily with the medicaments. CHX and $Ca(OH)_2$, alone as well as their mixture, all performed equally well, and no statistically significant differences could be detected in their antibacterial effectiveness. Saatchi et al.[296] published a systematic review of the combined use of chlorhexidine and $Ca(OH)_2$ and concluded that mixing chlorhexidine with CHX did not improve its *ex vivo* antibacterial property as an intracanal medicament against *E. faecalis*.

Other Alternatives for Interappointment Medicaments

Intracanal Medicaments Containing Antibiotics

Throughout the history of endodontics, there have been time periods with increased interest in the use of local antibiotics as temporary canal dressings for root canal disinfection.[297–304] Locally used antibiotics have not, however, become an established part of root canal disinfection and eradication of the infection. There are several reasons for the failure of antibiotics to overtake endodontic infection control. Many of the antibiotics tested are bacteriostatic, that may not be a good strategy for treating endodontic infections. Generally, bacteriostatic antibiotics prevent the growth of the microorganisms without killing them, giving the host defense a possibility to deal with the infection. However, in the necrotic root canal there is no host defense because of the lack of blood circulation. Therefore, the antibacterial effect of such antibiotics in the root canal may be

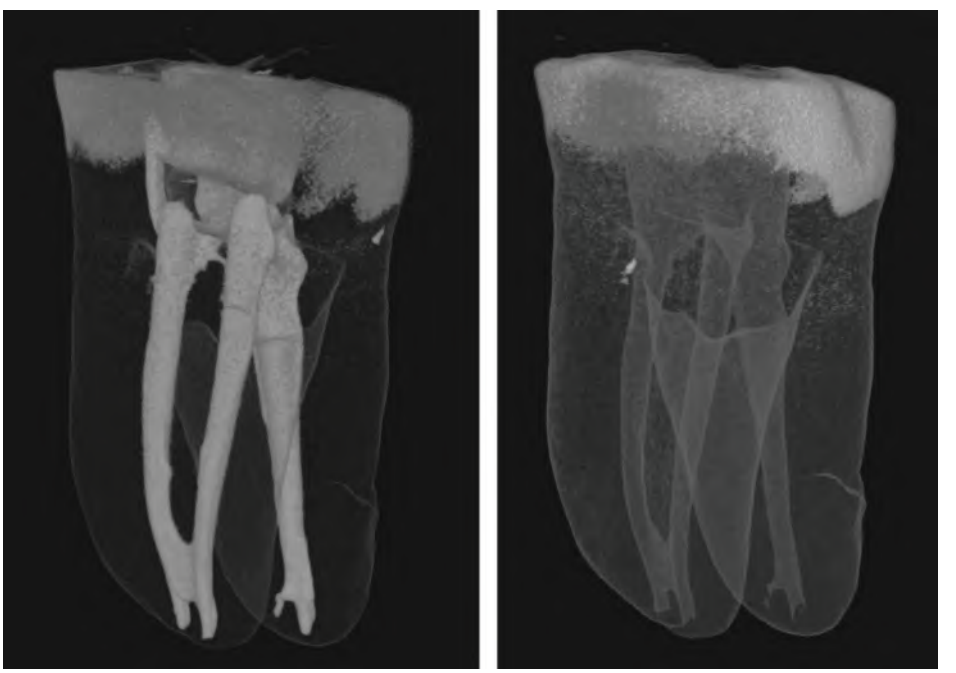

FIGURE 21-26 Micro-CT scans of a mandibular molar. **Left:** canals filled with calcium hydroxide paste; **Right:** same tooth scanned after removal of the calcium hydroxide using the GentleWave multisonic irrigation.

only temporary. On the other hand, it is possible that some bacteriostatic antibiotics can have a bactericidal effect when used in high concentrations; usually this is the case with locally used antibiotics. However, information about this is scarce and presently there is no direct evidence of bacteriostatic antibiotics used in the root canal, although one study indicated that mixing erythromycin with $Ca(OH)_2$ improved the effectiveness against *E. faecalis* as compared to $Ca(OH)_2$ alone.[305]

With bactericidal antibiotics, the potential problem in the root canal may be the metabolic and physiological state of the microorganisms. Many bactericidal antibiotics are most effective when the microbial cells are in active growth phase, that may not be the case in the necrotic root canal where only limited nutrients are available. In general, specific information about the effectiveness of intracanal antibiotics in infection control in endodontics is limited. In regenerative endodontics, antibiotic cocktails have been used in the treatment of teeth with immature apices and apical periodontitis.[306,307] It is possible that better circulation and survival of sufficient pulpal cells in the apical root canal are among the key factors for the promising results been reported so far. Future research will show whether this approach can be extended to the treatment of teeth with closed apices and apical periodontitis.

Phenol Compounds

Chemicals of the phenol group such as phenol, formocresol, cresatin, parachlorophenol (monoparachlorophenol), camphorated phenol, and camphorated parachlorophenol (CMCP) have a long history in endodontics as locally used root canal disinfecting agents. They have been applied into the pulp chamber via a moist cotton pellet (vapor effect), or the whole canal has been filled with liquid, using various concentrations of the phenol compound.[10,308–315] The rationale of using phenol compounds for root canal disinfection is their past role as general disinfecting agents. However, emphasis on safety in addition to effectiveness has resulted in a dramatic decline in their general use. Also in endodontics, concerns have been raised regarding the toxicity and possible mutagenicity of the disinfecting agents of the phenol group.[311,316–319] There are several demonstrations of their cytotoxicity,[316,320,321] however, other studies indicate that the risk of genotoxicity by the various phenol compounds used in endodontics is small.[317–319] Comparative studies of the antimicrobial effectiveness of the phenol compounds have not been able to show superiority of one over the other.[308,312,316] In addition, Byström et al.[10] reported that $Ca(OH)_2$ was superior to camphorated parachlorophenol (CMCP) in its antibacterial potential when used for four weeks as the local intracanal medicament. Several studies have indicated relatively rapid loss of activity of CMCP in the canal, although the results show variation.[313,322] Considering the benefits and the demonstrated and potential weaknesses of phenol compounds, it can be predicted that they will soon be replaced by other, more biological disinfecting agents.

Current Irrigation Recommendations

Based on growing amount of research evidence, current recommendations for irrigation protocol in conventional positive pressure needle suggests the use of a small size needle, such as a 30 gauge needle, with a side-vented or closed-end design, and with the needle placed in a non-binding manner 1 to 3 mm from the working length or at least in the apical third.[68,154,196] In order to avoid high apical pressure, and yet to gain maximum exchange of irrigant beyond the needle tip, one should use an irrigant flow rate of 4 to 6 mL/min, without sacrificing irrigation effectiveness. If open-ended needles are used, the safe distance from the apical foramen/working length is approximately 3 mm.[66] Negative pressure irrigation offers excellent safety and good cleaning in apical canals. Use of various means of physical energy to facilitate irrigation is recommended. It should be emphasized that without proper apical instrumentation of sufficient size effective irrigation of the apical root canal is not possible.

CONCLUDING REMARKS

Irrigation remains an important part of root canal treatment. Cleaning of the canal of organic matter and debris, together with the eradication of the microbial biofilms, are crucial components for a successful treatment. While numerous studies have shown the difficulty to completely clean and disinfect the root canal, the introduction of new strategies and various types of energy sources to enhance the action of the existing materials promises an exciting future in this area.

Chapter 22

Obturation of the Radicular Spaces

Arnaldo Castellucci

The ultimate clinical objective of root canal treatment is the three-dimensional obturation of the endodontic spaces after being completely cleaned, shaped, and disinfected. The purpose of obturation is to seal the main root canals and all "portals of exit" to impede any future communication, or exchange, between the endodontium and periodontium. The filling must, therefore, completely and durably fill the root canal space so that no empty spaces should remain. It has been demonstrated that many endodontic failures are related to incomplete root canal obturation.[1–3]

BIOLOGICAL CONSIDERATIONS FOR ROOT CANAL OBTURATION

In 1931, Rickert and Dixon[4] proposed the "hollow tube" theory: an empty space within a living organism tends to fill with tissue fluids within a short period of time. This theory was based on the observation of an inflammatory reaction around the ends of hollow steel and platinum anesthetic needle fragments implanted in experimental animals. This reaction did not occur if the implant was made of a solid, non-porous material.[4] Two years later, Coolidge[5] arrived at the conclusion that, just as within unfilled or underfilled root canals, fluids that accumulate within empty spaces are rapidly colonized by microorganisms reaching these spaces by means of "anachoresis" and causing inflammtory reaction. The term anachoresis refers to bacteria transported by the blood circulation (bacteremia) colonizing a tissue, where they remain sheltered from phagocytosis by the organism's defenses.

For years, this theory has influenced the concept that the root canals must be filled to the apex. If not, empty spaces would quickly be colonized by bacteria, through anachoresis, and would prevent or delay healing of the periapical tissues.

Later studies have shown evidence refuting the "hollow tube" theory.[6–10] It has been demonstrated, in experimental animals, that empty spaces made inside plastic teeth, implanted in fresh sockets, did not produce any inflammation around the open ends.[9] Furthermore, in many cases these spaces were subsequently filled with fibrous tissue or bone.[9] The latter occurred more frequently with larger size apical openings.[9] Delivanis et al.,[11] using an animal model, could not prove the existence of anachoresis within an empty tube filled only with tissue fluids or in a root canal following pulpectomy. These studies indicated that empty spaces within a living tissue are not necessarily accompanied by inflammation or tissue destruction; on the contrary, they can be associated with physiological repair (Figure 22-1).[7,8]

The selective localization of blood-borne bacteria in areas of chronic inflammation is a well known phenomenon.[12–17] It may explain the egress of microorganisms into a pulp that has not been exposed to the oral environment but has been compromised by a trauma. In order for anachoresis to occur, the presence of blood vessels is necessary. Microorganisms can easily invade a space where tissue is present, inflamed, or partially necrotic, traveling via the blood circulation. However, this is not the case where active blood circulation doesn't exist.

It is prudent that clean and shaped root canals must be completely obturated to prevent re-infection. However, it

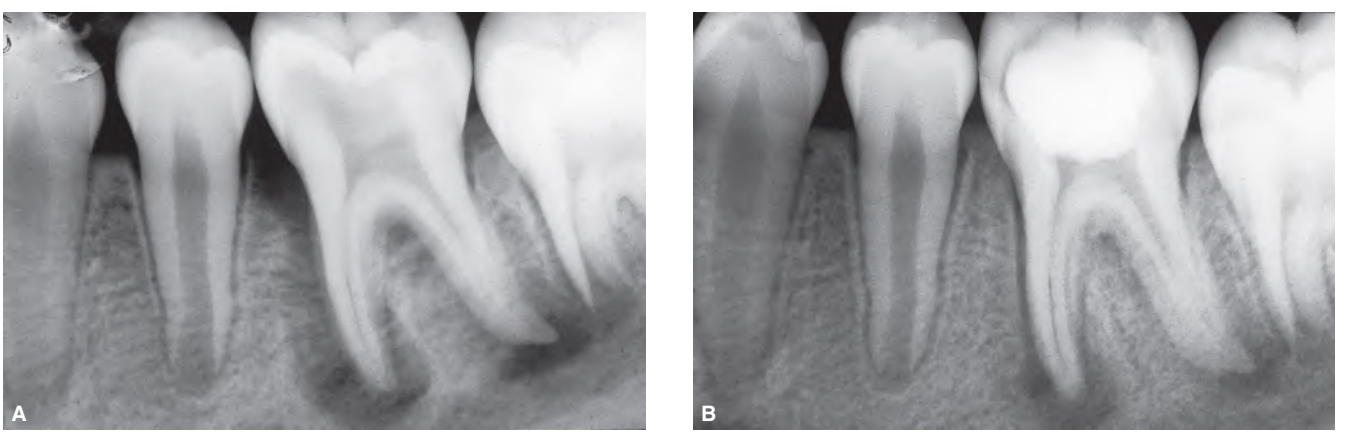

FIGURE 22-1 ***A***. Preoperative radiograph of a mandibular left first molar. ***B***. Radiograph taken two months later. The gap in treatment was due to negligence on part of young patient. Four canals had been cleaned, shaped, and medicated with Cresatin. Note the reduction in the periapical radiolucency in spite of the canals not been obturated.

is recognized that complete *sterilization* and removal of *all* pulpal debris from an infected root canal is very difficult, if not impossible[18–23] (Figure 22-2). What is achieved, in most cases, is the *disinfection* of the root canal system. For more details, see Chapters 3 and 21.

Residual microorganisms may remain inside the root canal system, mainly within dentinal tubules.[24] Presence of necrotic pulp remnants, together with the accumulating exudate, can contribute to their viability. If, however, the root canal system is completely obturated in all three dimensions, any remaining microorganism may be "entrapped" without nutritional sources and with reduced possibility of proliferation[25–29] (Figure 22-3).

Sjogren et al.[30] studied the influence of the presence of infection at the time of root canal filling, on the outcome of endodontic treatment, in teeth with apical periodontitis. They theorized that success obtained, despite positive bacterial cultures, was due to the bacteria "entombed" in the canal. Confirming Morse's findings,[31] Moawad[32] has demonstrated that bacteria entrapped within a completely filled root canal become nonviable within five days after root canal filling. Peters et al.[29] demonstrated that there is no evidence that special measures (calcium hydroxide or iodoformic paste) should be taken to kill the bacteria in the dentinal tubules. Those bacteria either do not survive the treatment, become inactive, or remain in insufficient numbers to cause or sustain infection.[33–35] Other in vivo studies demonstrated that most bacteria in the dentinal tubules died within 24 hours after removal of the nutrient medium.[36]

In conclusion, the reason for a complete root canal obturation is not only to prevent *apical leakage* but also to prevent *coronal leakage*. Figure 22-1 shows healing in progress without any obturating material in the root canals. However, if the coronal seal was compromised, the entire root canal system would be reinfected and a periapical lesion would reappear.

Obturation with gutta-percha and sealer after chemomechanical cleaning and *disinfection* with sodium hypochlorite also deprives the remaining microorganisms from their nutrient supply, thereby reducing their ability to cause or maintain disease. It has been demonstrated that most microorganisms in the dentinal tubules died within 24 hours after removal of the nutrient medium.[36] Gutta-percha has a certain bacteriostatic activity, perhaps due of its zinc oxide content.[37]

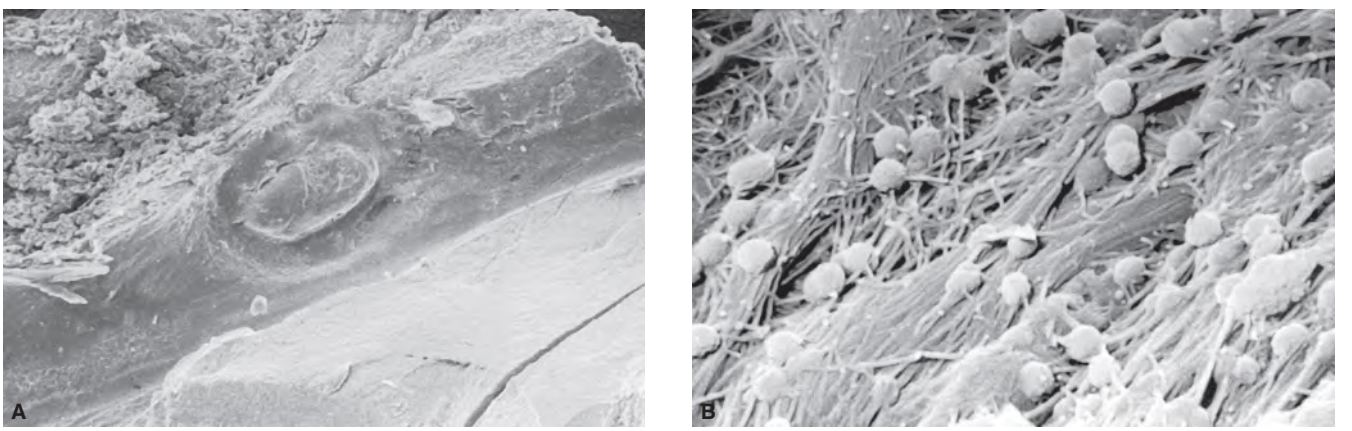

FIGURE 22-2 ***A***. Scanning electron microscopy (SEM) view of the apical third of a cleaned and shaped mandibular incisor. Note the presence of a large calcification adhering to the canal wall a few millimeters from the foramen (original magnification ×60). ***B***. Higher magnification view of A showing the presence of organic material in the area immediately apical to the calcification, where the instruments could not reach (×4,000).

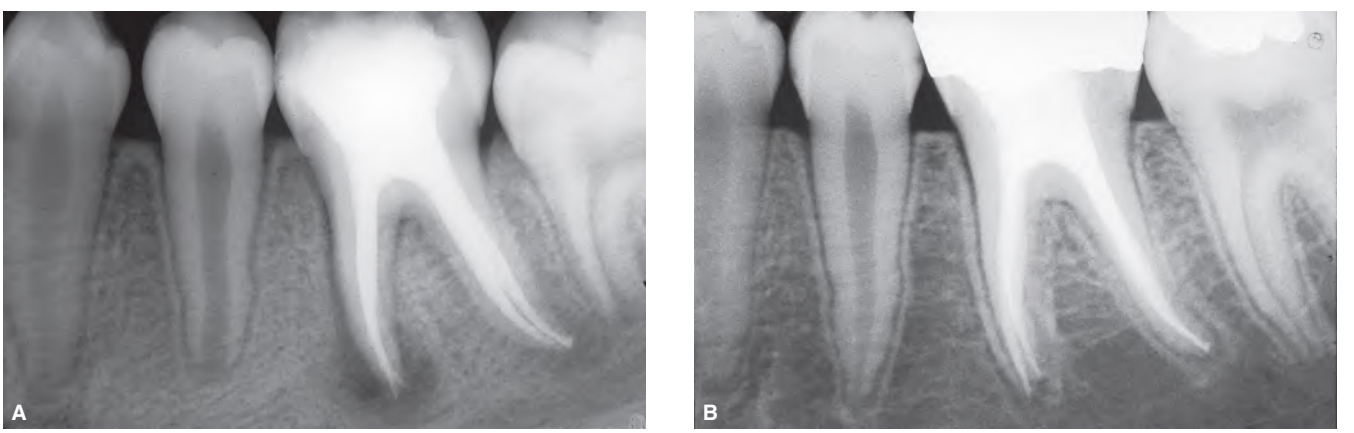

FIGURE 22-3 ***A***. Postoperative radiograph following canals obturation of the case shown in Figure 22-1. ***B***. Two-year recall radiograph showing active healing.

However, this antimicrobial activity is very limited and gutta-percha and sealer alone should not be used without prior disinfection and shaping of the root canal system.

SELECTING THE CORRECT TIME FOR OBTURATION

Once cleaning and shaping of the root canal system has been completed, the clinician may proceed to the obturation procedure when the following requirements are met:

- The tooth is asymptomatic and the patient must feel perfectly comfortable.
- There is no exudate from the canal.
- The canal can be proporly dried.
- There is no foul odor indicating the presence of microorganisms.
- The temporary filling is intact if the root canal has been shaped in a previous visit.

In the past, obtaining a negative bacterial culture was advocated prior to obturation. Today, bacterial cultures are obtained less frequently[27]. Bacterial growth occurs only in the presence of substrates in the canal, but if the canal is completely free of such protein degradation products, bacteria cannot reproduce. Bacterial cultures may not necessarily determine the success of therapy, nor does not performing them lead to failure. While some consider culture obsolete, others have found them to be important.[27] Clearly, a reliable chair-side culturing method that produces immediate results would be beneficial.

APICAL EXTENT OF OBTURATION

Cemento-dentinal Junction

Grove,[38] in 1929, suggested that canal obturation must stop at the cemento-dentinal junction, that corresponds to the maximal apical constriction. The pulp tissue terminates at this point, and the tissue of the periodontal ligament begins. The walls are no longer of dentin, but of cementum. In theory, this view is correct in that the apical constriction should ensure a good barrier to the filling material respecting the periodontium. By obturating to this point, the root canal is obturated without invading the periapical tissues.

On the other hand, Coolidge,[39] also in 1929, claimed that the site of the cemento-dentinal junction is so variable that attempting to use it as a landmark is of little help to the endodontist. This junction often has unclear limits and can be found at different levels within the root canal (Figure 22-4). The cemento-dentinal junction can sometimes be found on the external surface of the root.[40] Skillen[41] emphasized that it is histologically impossible to define a clear line of demarcation between the pulp on one side and the "periodontal membrane." It is also histologically impossible to find a point within the root canal where the pulpal tissue ends and the periodontal tissue begins (Figure 22-5). In agreement with Coolidge, Orban[42] stated that from a practical point of view

FIGURE 22-4 The exact position of the cemento-dentinal junction is difficult to locate, even histologically.

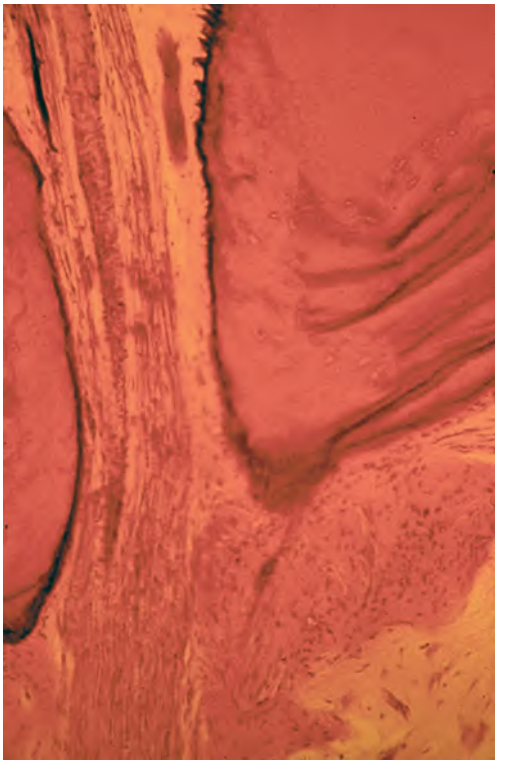

FIGURE 22-5 The neurovascular bundle of the pulp has the same characteristics both before and after crossingthe apical foramen.

it is not possible to use the cemento-dentinal junction as a boundary of endodontic obturation. When identified, more often than not, it is by chance.

Additionally, relying on tactile sensation to locate the cemento-dentinal junction can also be misleading. The maximal constriction of the canal lumen may be due to the narrowing of the canal (Figure 22-6) or to a calcification that may vary in distance from the true end of the endodontium (Figure 22-7).

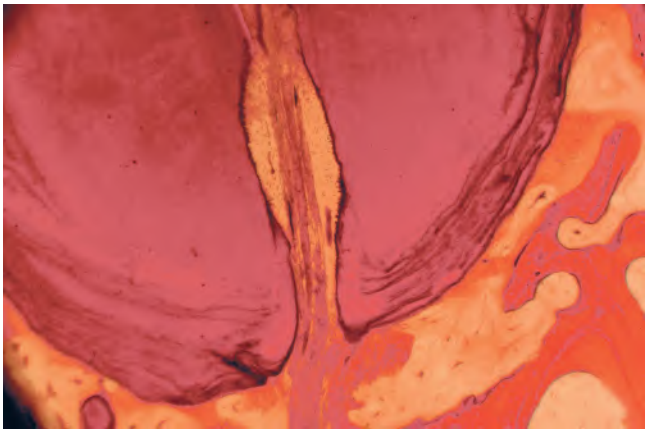

FIGURE 22-6 The apical constriction in this case is due to a narrowing of the canal lumen, not due to the cemento-dentinal junction.

FIGURE 22-7 Apical constriction occurred due to a calcification located further away from the cemento-dentinal junction.

Ricucci and Langeland[43] suggested that the apical limit of canal instrumentation and obturation should not be the radiographic terminus of the canal, nor should it be the cemento-dentinal junction or the distance of 1 mm from the radiographic apex, but rather the "apical constriction." This anatomical location, however, cannot be determined clinically with accuracy since it is "ever-changing"; it has been demonstrated as far as 3.8 mm from the anatomic apex.[44] Therefore, "the instrumentation and the obturation should terminate where the instruments stop" (Figure 22-8).[43] Others[45,46] suggest that the arbitrary rule that canal preparation should terminate 1 mm short of the radiographic apex should not be accepted in modern endodontic therapy. The "one millimeter" technique could result in instrumentation short of the true canal terminus, possibly leaving necrotic and infected debris behind, leading to treatment failure. According to Schilder,[47] having *three-dimensionally* obturated root canal as far as 0.5–1 mm from the radiographic terminus of the canal is in practice equivalent to having filled it completely, leading to the success of the therapy.

To address the conflicting views in the literature, one must note that the *radiographic terminus* of the canal refers to the point at which the endodontic instrument, within the root canal, radiographically encounters the external profile of the root. It is not to be confused with the *anatomical apex*, that represents the geometric vertex of the root, or with the *radiographic apex*, that represents the anatomic apex as seen on the radiograph. The terminal point of the root canal is not always at the radiographic apex (Figure 22-9) and therefore cannot be used as a reference point to the actual working length. The *endodontic* or *physiologic apex* indicates the cemento-dentinal junction, which usually (but not necessarily) corresponds to the narrowest area of the canal lumen. The term *apical foramen* refers to the opening of the root canal on the external surface of the root (Figure 22-10).

Radiographic Terminus of the Canal

Some authors claim that it is preferable to extend the obturation to the radiographic terminus of the canal, since this gives the greatest assurance of having obturated the entire root canal system, even if this sometimes leads to overfilling of few fractions of a millimeter beyond the apex. On the other hand, it is well known that some very curved canals emerge in the roots at points that are not radiographically visible, several millimeters away from the anatomic apex. In these cases, obturation to the radiographic terminus of the canal is to be avoided, because this would entail considerable excess, but at the same time filling the root canal 0.5-1 mm short is also to be avoided, because the filling material would be equally in the periapical tissues (Figure 22-11). Therefore the author of this chapter suggests to use the "electronic apex" as a landmanrk, in addition to the radiograph.

The successful outcome of cases obturated to the radiographic terminus of the canal (Figure 22-12) is therefore due to the completeness and three-dimensional cleaning,

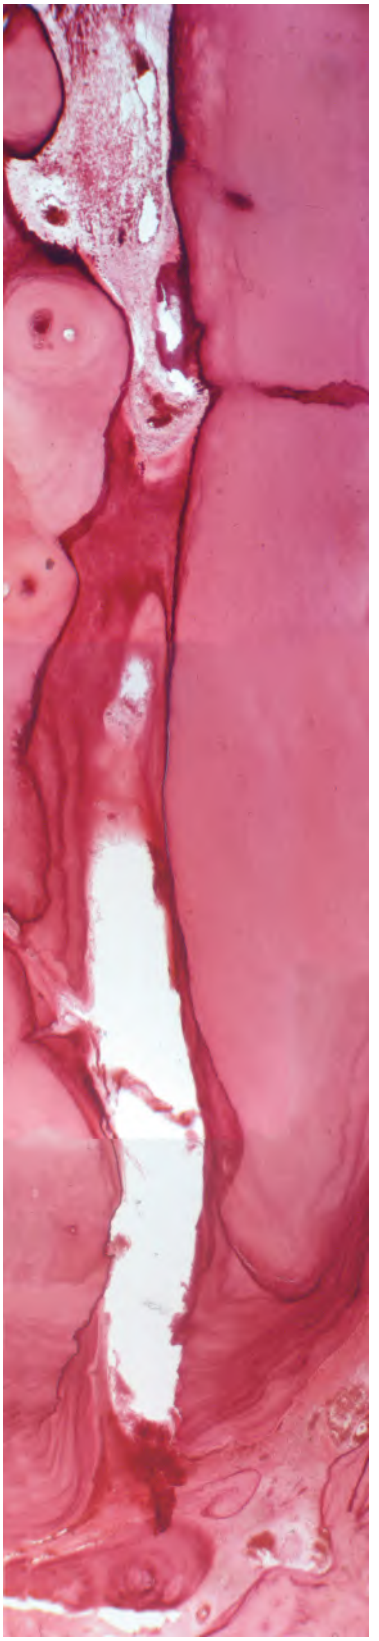

FIGURE 22-8 Completion of instrumentation and obturation at the "constriction" means clinically to remain 7 mm short (or even more), since the calcification causing a constriction is located more coronally. It will impede the introduction instruments more apically, thus not reaching the "correct" working length.

FIGURE 22-9 Postoperative radiograph of mandibular molar treated endodontically. In the distal canal, the canal apical foramen does not coincide with the radiographic apex.

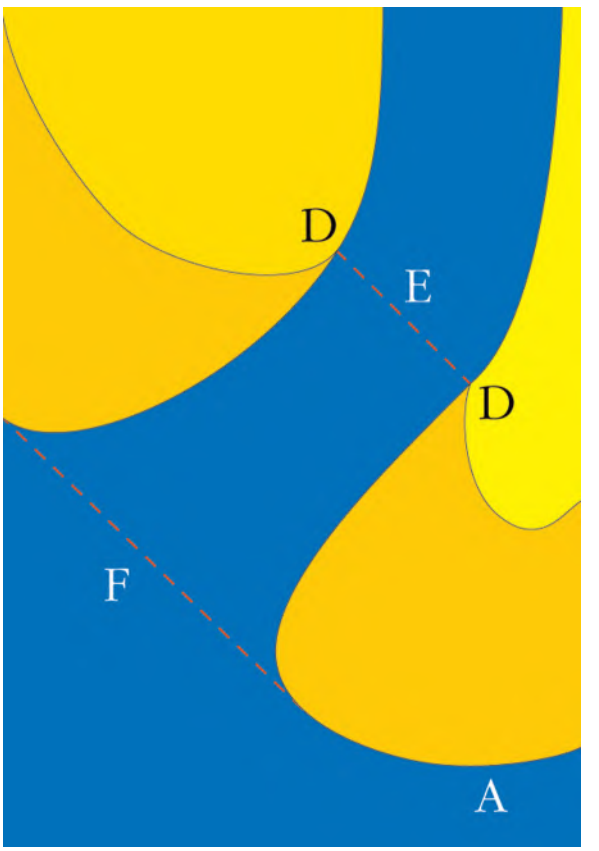

FIGURE 22-10 Schematic illustration representing the apical area of the root showing anatomic apex (A), radiographic apex (F), cemento-dentinal junction (D), and endodontic apex (apical foramen) (E).

shaping and of the obturation. The minimal overfilling is irrelevant, just as minimal underfilling is.

Sjogren et al.30 looked at root canals filled short and long, with positive and negative culturing results in each group. They showed that high success rates were achieved regardless of long or short filling when the culture came back negative, but when the culture came back positive only the fully filled cases worked predictably. The authors theorized that success was achieved because the remaining bacteria were **entombed** in the canal. Infected or not (among the bacteria present at the time of root filling in cases that healed successfully, the authors of the study found Peptostreptococcus anaerobius, Actinomyces naeslundii, Fusobacterium nucleatum and Enterococcus faecalis), all of the cases worked when the canals were filled to or beyond the terminus. From this interesting study, we can conclude the following: because no one can insure sterility in any given root canal space, the surest chance of clinical success is gained when root canal systems, in all of their complexities, are filled to their full apical and lateral extents, even though that means that there may be surplus material beyond the confines of the root canal space. This is in agreement with the findings of Peters et al.[49] who demonstrated that the presence of a positive bacterial culture at the time of filling did not influence the outcome of treatment.

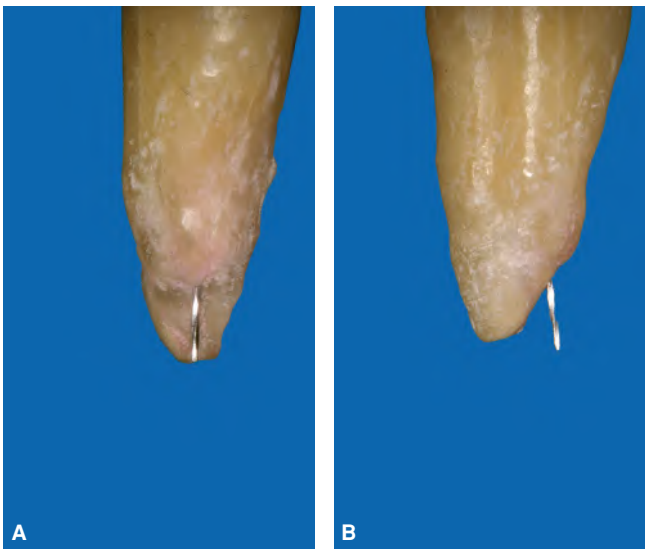

FIGURE 22-11 The apical foramen of this mandibular premolar opens on the buccal aspect of the root and is therefore not visible in a 2-D radiograph. ***A***. A buccal view photograph showing the distance between the opening of the apical foramen and the tip of the root. ***B***. Mesial view. This typical example illustrates the importance of terminating the canal preparation and obturation at the "electronic apex." Obturation of 0.5 to 1 mm short of the the radiographic will cause extrusion of material beyond the apical foramen.

In conclusion, the difference between the "radiographic apex" and the "radiographic terminus of the canal" must be well underdstood. If the root canal is not straight and the foramen is on the distal, or on the mesial aspect of the root, it is obvious that it has nothing to do with the "radiographic apex", therefore it makes no sense to advocate an instrumentation and then an obturation .05 mm or more from the radiographic apex. On the other hand, the mesial or distal opening of the foramen can be radiographically appreciated as the "radiographic terminus of the canal". On the other hand, when the foramen in on the buccal or on the lingual aspect of the root it is impossible to radiographically see the teminus of the canal. In such a case the instrumentation and obturation are performed at the "electronic apex" and the final result will appear to be "radiographically short".

Many reliable electronic apex locators are available today, and we know that they indicate the end of the canal (which is the foramen) and for sure they don't indicate the location of the cemento-dentinal junction or the apical constriction. Therefore we can assert that all of our endodontic treatments are performed at the "electronic apex", which about

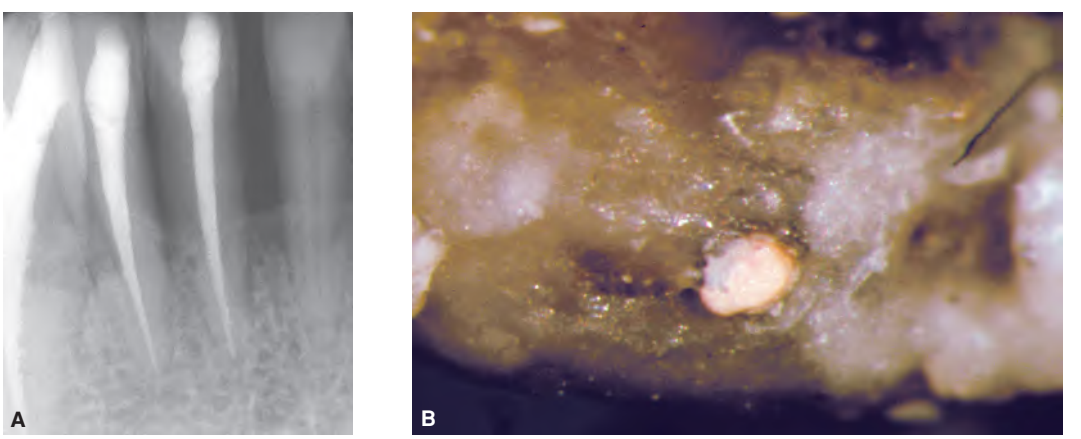

FIGURE 22-12 ***A***. Postoperative radiograph of two mandibular incisors treated endodontically. The obturation was done to the radiographic apex. ***B***. The central incisor was extracted for periodontal reasons eight years later and was photographed under a stereomicroscope. Note the gutta-percha that seals the apical foramen without extrusion (original magnification x64).

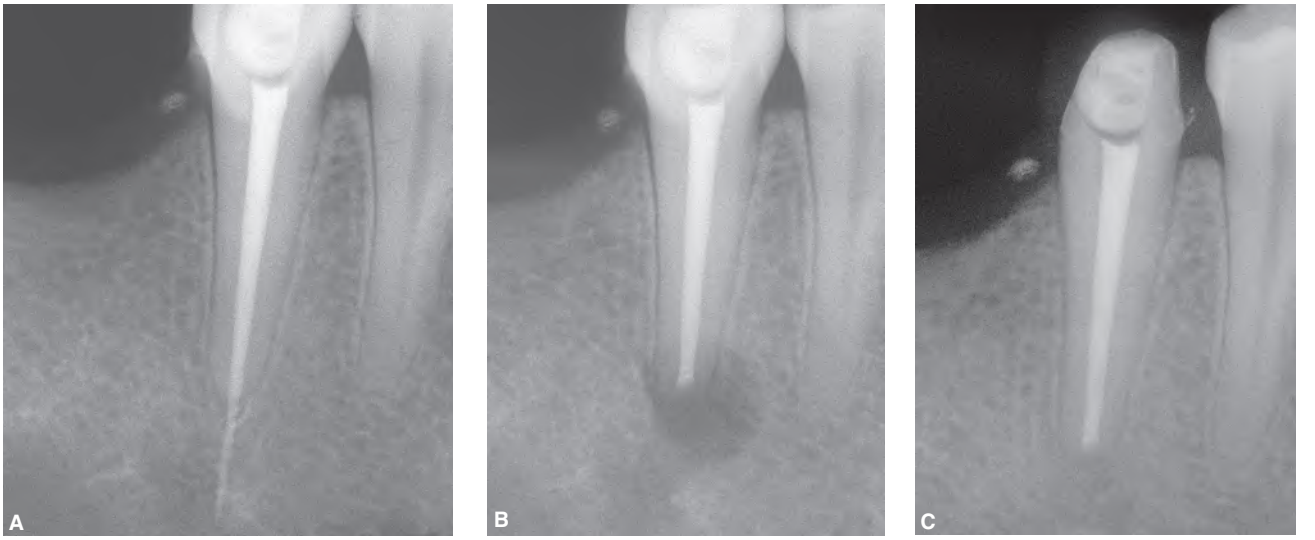

FIGURE 22-13 Excess of obturation material is an indication for surgical treatment if it does not seal the root canal system, or if it has been pushed against anatomical structures and the patient is symptomatic. In this case, the gutta-percha cone was pushed against the mental nerve and the patient developed paresthesia. ***A***. Preoperative radiograph. ***B***. Radiograph taken immediately after the apical surgery. Ultrasonic tips (piezoelectric surgery) were used since high speed burs could have further damaged the nerve bundle. Two weeks after the surgery the paresthesia disappeared completely. **C**. 2-year follow-up radiograph. The patient was asymptomatic and paresthesia did not recur.

50% of the times coincides with the radiographic apex because the root canal is straight. The other 50% of the times the root canal is not straight but is curved and when it makes a curvature, about 40% of the times the curvature is to the mesial or to the distal (so that the "radiographic terminus of the canal" can still be seen on the radiograph), and only about 10 % of the times the curvature is to the buccal or to the lingual. These are the cases where we must rely on the electronic apex locators only and these are the cases that appear to be "radiographically short".[48]

Overextension and Overfilling

Over- and under-extension refer to the vertical component of the obturation; either beyond or short of the apical foramen. Underfilling refers to obturation that has been performed inadequately in all dimensions (e.g., short filling in a longer and wider root canal, or only a cement filling with voids). Overfilling refers to obturation, that has been performed in three dimensions, in which a portion of material extrudes beyond the foramen. The situation of a canal with a slight overfilling is quite different from that of a canal with a vertical overextension and an underfilling. In the former, the obturation fills the entire endodontium in its three dimensions, and an excess of material extrudes from the apical foramen. In the latter case, the obturation material protrudes beyond the apex without sealing the apical foramen and thus without three-dimensionally obturating the root canal system (Figure 22-13).

Ingle[49] stated that high success rates can be achieved in spite of overfillings. Weine[50] states that fortunately, since

FIGURE 22-14 Radiograph of the maxillary left central incisor reimplanted after a traumatic avulsion that occurred 3 years previously. The root underwent replacement resorption. Radiographically, the gutta-percha appears to be in direct contact with bone and there is no radiographic evidence of inflammation.

gutta-percha is so well tolerated by periapical tissue, only rarely is a post-treatment failure noted in conjunction with an overfilling. Most instances show no abnormal radiographic evidence (Figure 22-14), and in some cases there is an actual amputation of the overfilling with phagocytosis of the extra mass (Figure 22-15). It appears that the major factors associated with endodontic failures are inadequate root canal debridement or incomplete root canal seal,[51–54] while the apical extent of root canal fillings is not a determining factor.[30,55,56,57]

Histologic studies on experimental animals by Deemer and Tsaknis[57] and by Tavares et al.[58] have demonstrated

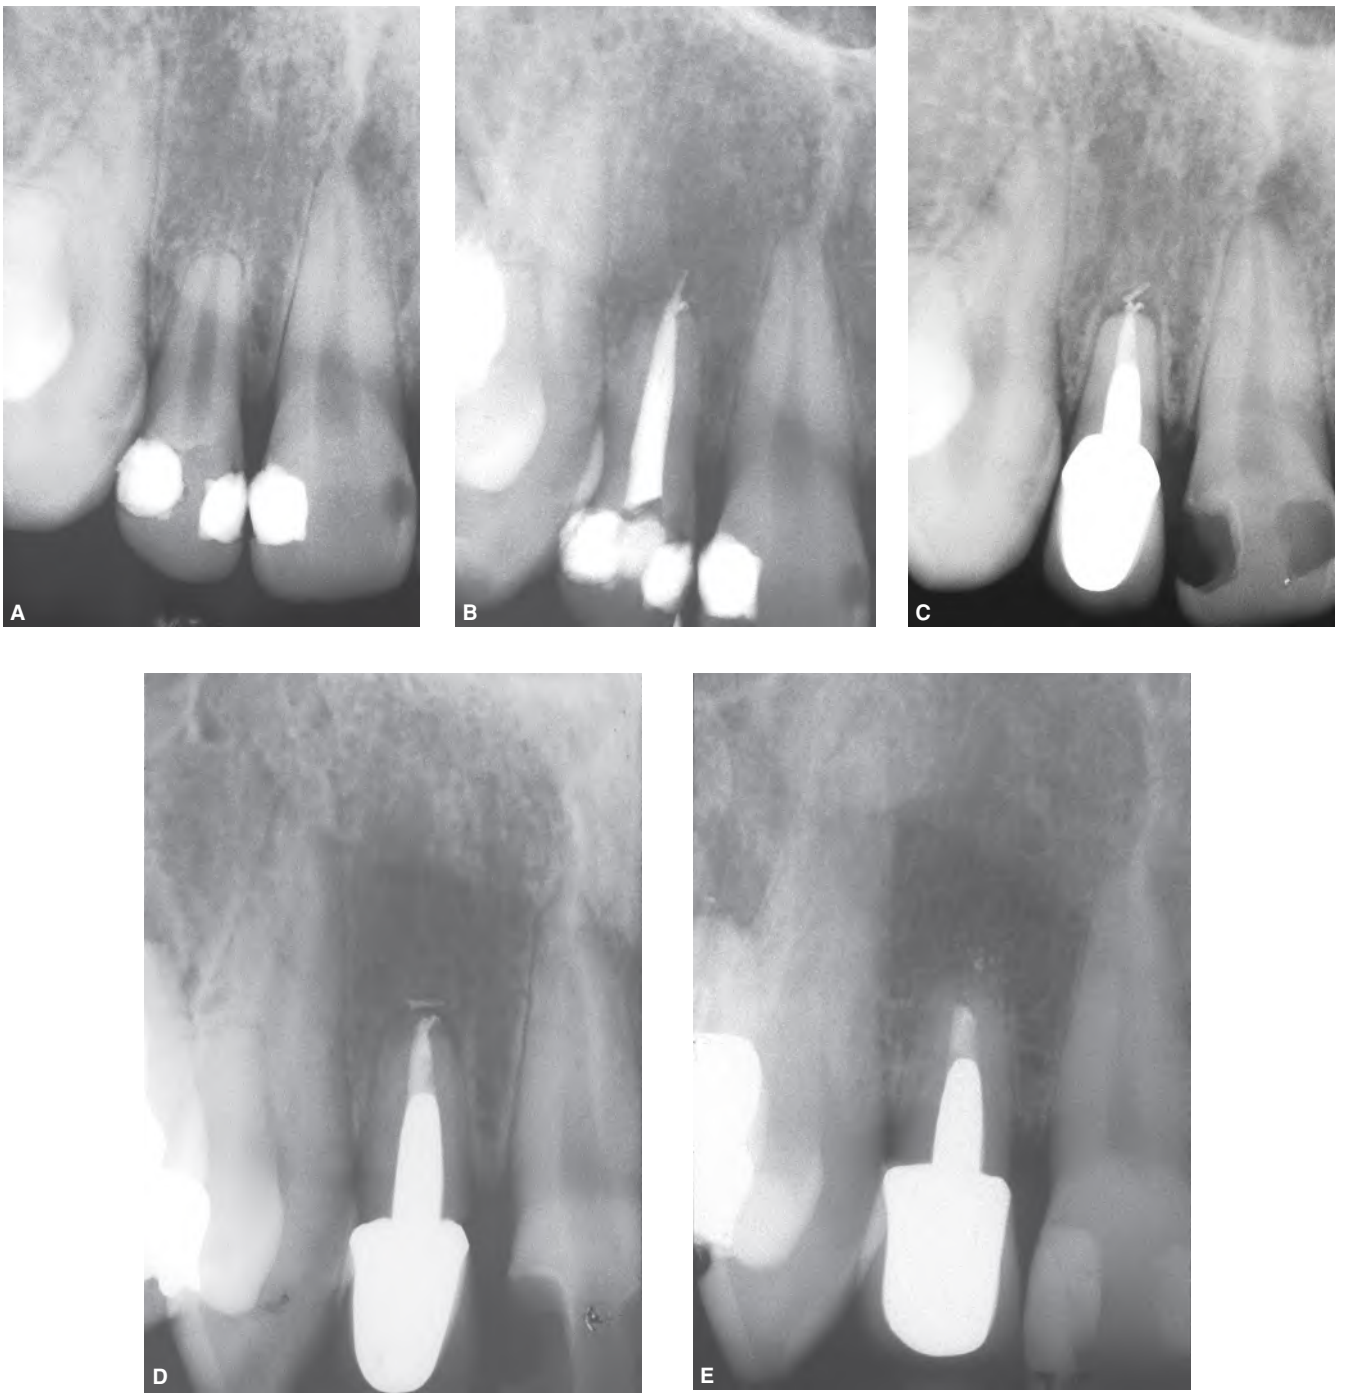

FIGURE 22-15 Endodontic treatment in a maxillary right lateral incisor with a resorbed root. ***A***. Preoperative radiograph. ***B***. Postoperative radiograph. The tip of the cone slid 2–3 mm beyond the apex, probably bacause the "tug-back" of the cone was not at the apical area. ***C***. One year later, the excess material appears to be sectioned at the apical foramen. ***D***. Two-year postoperative radiograph. The tip of the cone lies horizontally over the root apex. ***E***. 34-year recall confirmed that an overfilling in a three-dimensionally obturated root canal was NOT necessarily an indication for surgery or cause for endodontic failure.

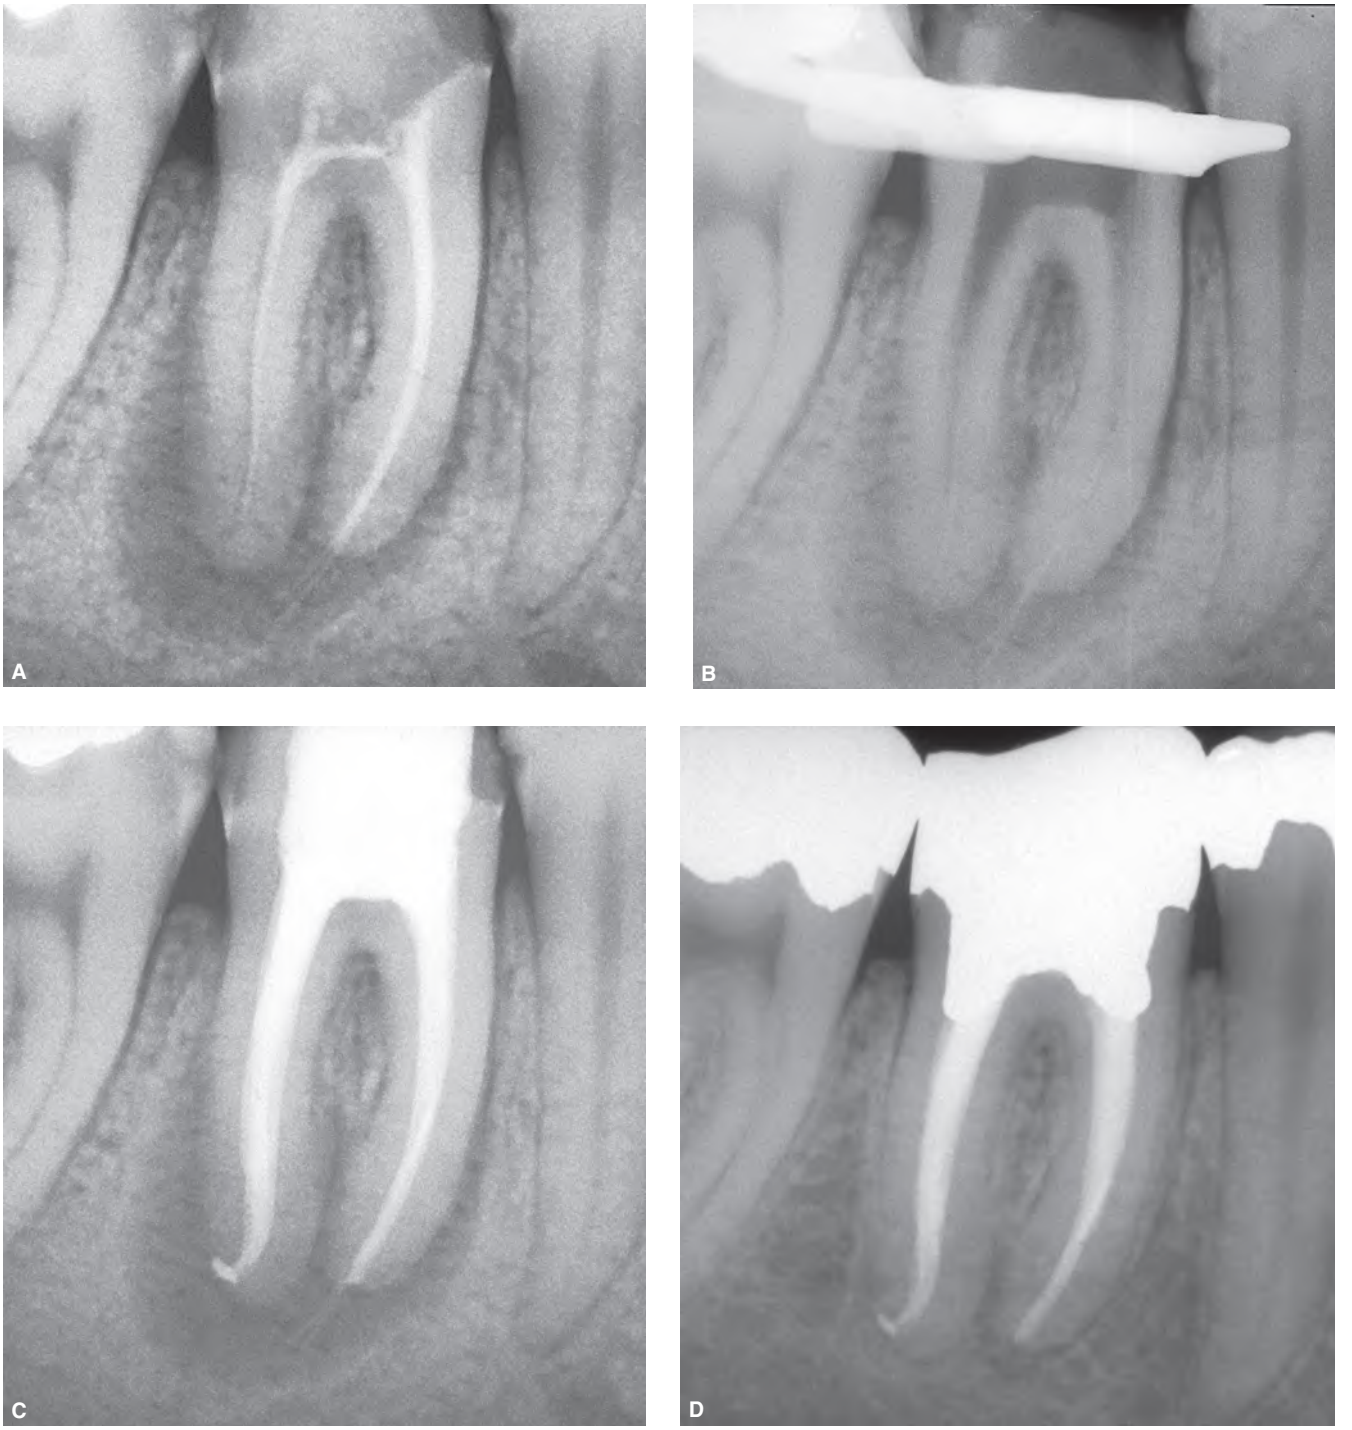

FIGURE 22-16 ***A***. Preoperative radiograph showing an improperly treated mandibular right first molar. The distal canal is underfilled and the mesial canals have gutta-percha cones overextending into the periapical tissues. ***B***. Intraoperative radiograph showing a failed attempt to remove the gutta-percha protruding beyond the apical foramen. ***C***. Immediate postoperative radiograph showing the two gutta-percha cones still present in the lesion. ***D***. 3-year recall radiograph. The apical lesion has resolved and the two gutta-percha cones completely disappeared. The apical lesion was most probaly caused by an infected root canal system and NOT by a foreign body reaction to the overextended gutta-percha.

that gutta-percha is well tolerated by the surrounding tissues. Their results agree with those of Schilder [59] on human specimens. Gutierrez et al.[60] demonstrated in experimental animals that gutta-percha in contact with the tissues and tissue fluids disintegrates and is subsequently removed by macrophages. This corresponds to the clinical phenomenon noted in the periapical region of human teeth. Bergenholtz et al.[61] stated that in the case of overfilling, the filling

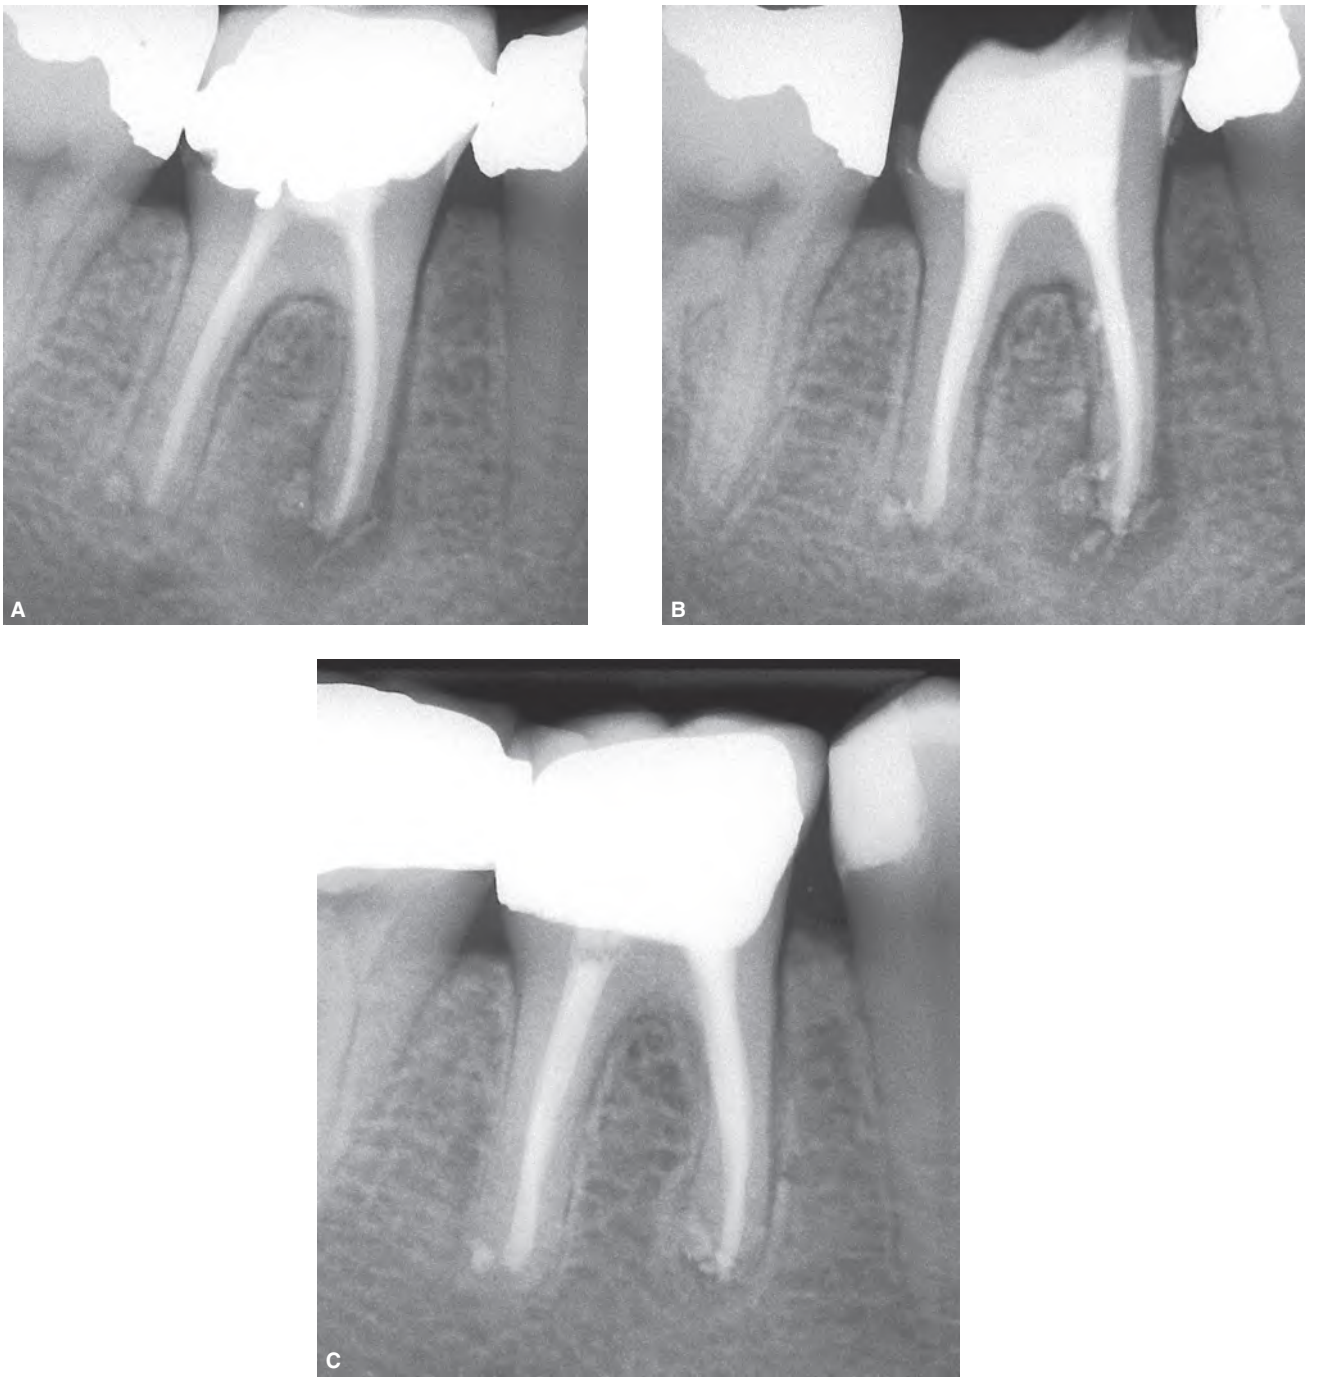

FIGURE 22-17 ***A***. Preoperative radiograph of the mandibular right first molar improperly treated. A radiolucency is associated with the apex of the mesial root. Filling material (sealer and/or gutta-percha) is present in the lesion. ***B***. Postoperative radiograph. During retreatment two missed root canals from the prior treatment were found. The distolingual and the middle mesial canals had independent foramina. ***C***. Seven-year recall radiograph showing that the apical lesion has resolved and the excess material disappeared. Again, the apical lesion was most probably caused by an infected root canal system and NOT by a foreign body reaction to the overextended gutta-percha.

material *per sé* is not necessarily the immediate cause of failure. Gutta-percha, both *in vitro* in cell cultures,[62] and in *in vivo* implants in experimental animals,[63,64] has been shown to be biocompatible. Recent radiographic studies have shown that, given time, the extruded canal filling materials would not cause chronic inflammation and eventually be removed from the periradicular tissues.[55,65–70] The factors that impede healing in cases of overfilling need further investigation.

Yusuf[66] has demonstrated inflammation around the small pieces of dentin and cementum found beyond the apex in the granulation tissue, where they act like a foreign body.

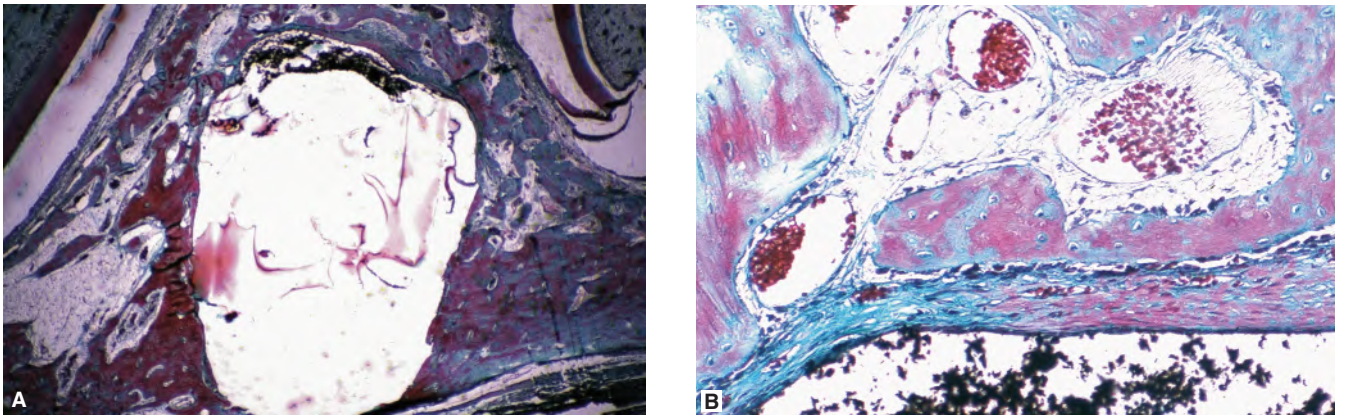

FIGURE 22-18 Osseous reaction to implanted Pulp Canal Sealer at four weeks. ***A***. Normal bone marrow (Original magnification: ×5; Masson's Trichrome). ***B***. Layer of fibrous connective tissue between the Pulp Canal Sealer and bone, without evidence of inflammatory cells. FIGURE 22-19 Osseous reaction to implanted Pulp Canal Sealer at 12 weeks. ***A***. Normal bone marrow with new bone ingrowth into the implant (Original magnification ×5; Masson's Trichrome). ***B***. New-formed bone is in direct contact with the Pulp Canal Sealer without fibrous interposition or inflammatory cells (Original magnification ×10; Masson's Trichrome). ***C***. Normal appearance of newly formed bone with viable osteocytes and normal bone marrow (Original magnification ×50; Hematoxylin-eosin). (Courtesy of Dr. Wilhelm-Joseph Pertot, Paris France.)

In contrast, small pieces of amalgam or other canal obturation materials were usually associated with a fibrous reaction and encapsulation, without active inflammation. Thus, accidental minor overfilling of a properly cleaned, shaped, and three-dimensionally filled canal is *not* desired but is *not* an indication for surgical removal of the excess material unless there are clear signs of treatment failure (Figures 22-16 to 22-23).

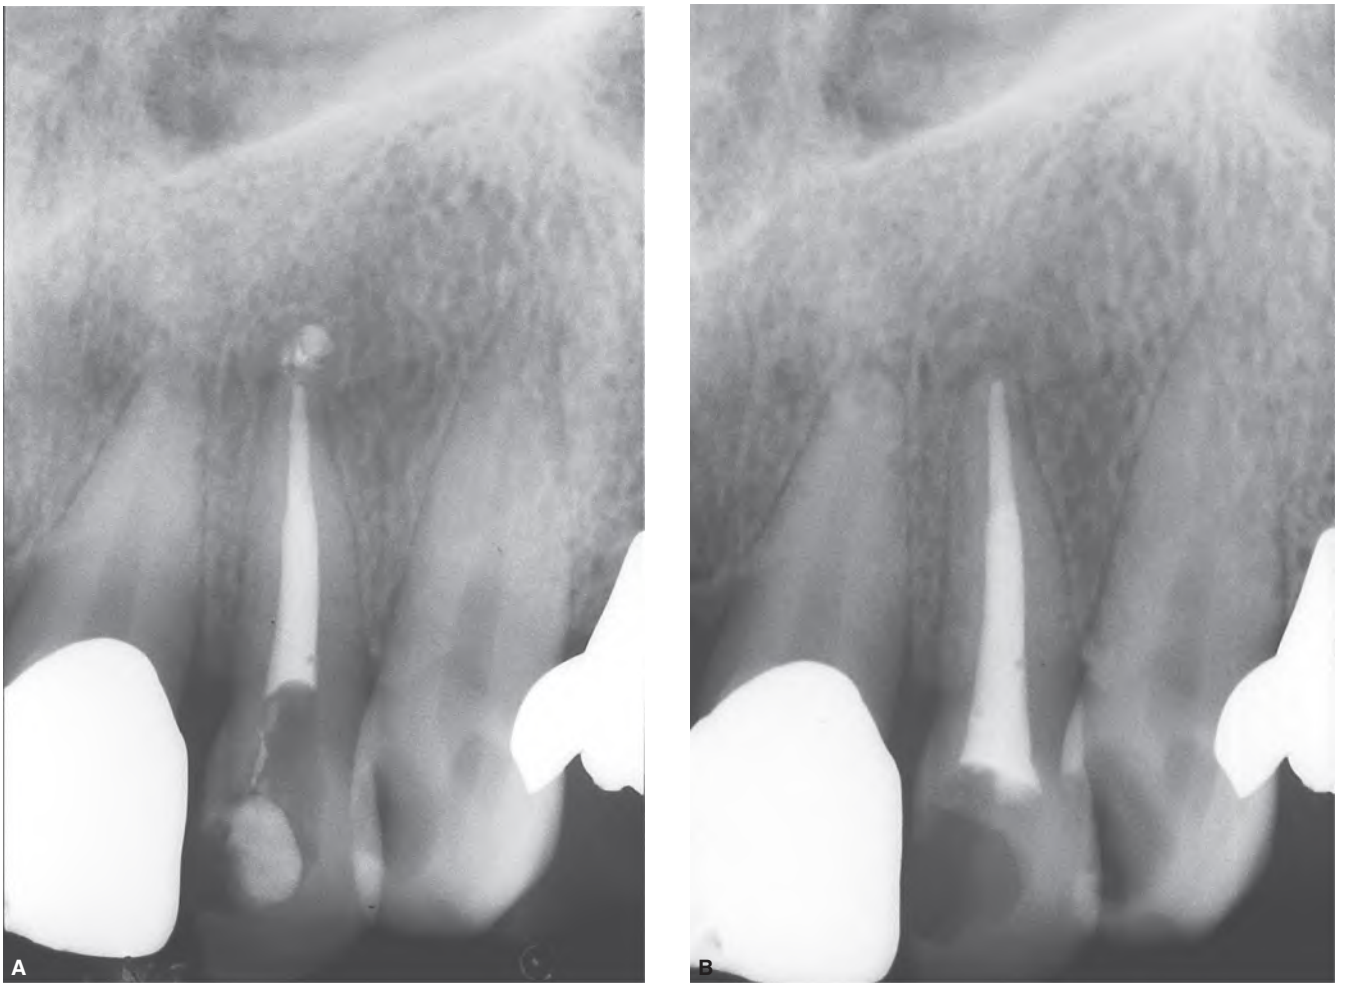

FIGURE 22-20 ***A***. Postoperative radiograph of a maxillary left lateral incisor treated endodontically. Note extruded material (probably sealer) beyond the apical foramen. ***B***. Radiograph taken 7 months later showing the excess material has disappeared.

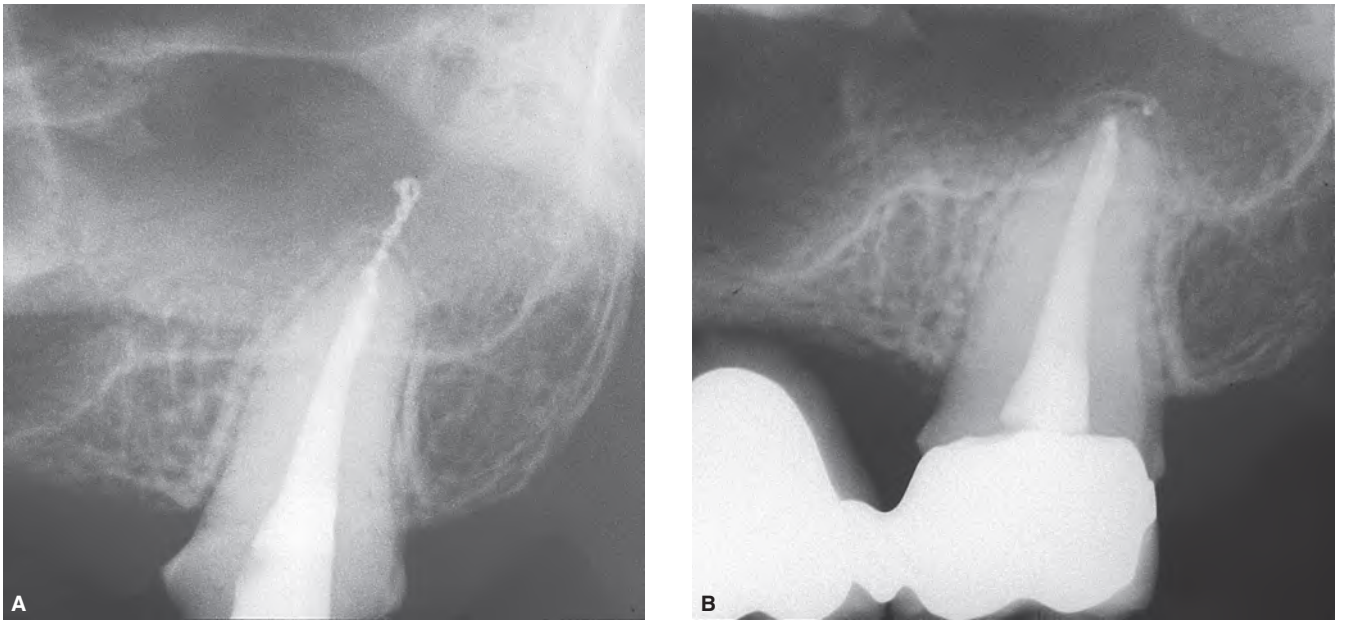

FIGURE 22-21 ***A***. Postoperative radiograph of a maxillary left second molar treated endodontically. Note extruded material beyond the apical foramen. ***B***. Radiograph taken eight months later showing the excess material is no longer present.

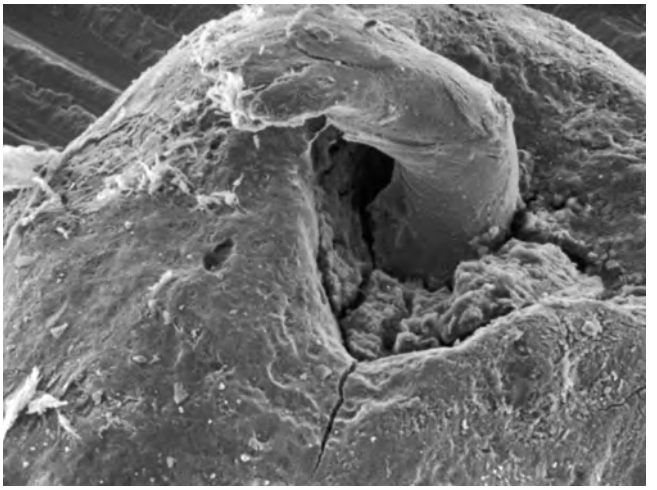

FIGURE 22-22 Scanning electron micrograph of a trasported root apex causing extrusion of the gutta-percha cone. The cone, although surrounded by sealer, is not sealing the foramen.

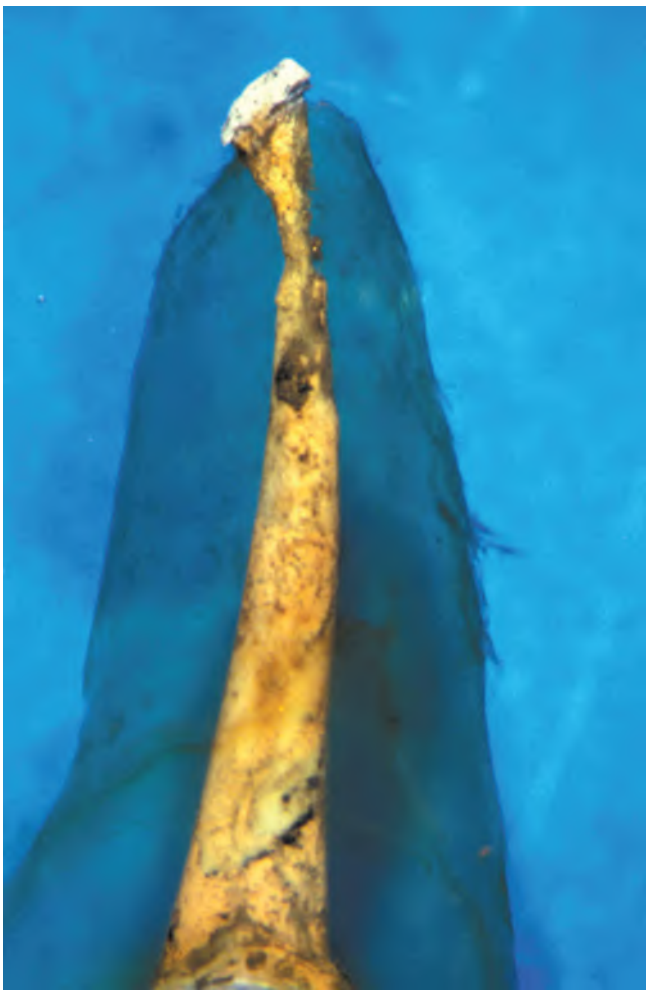

FIGURE 22-23 The root of this maxillary lateral incisor has been cleared. Transportation of the apical foramen, and extrusion of material through the tear-drop foramen had occured. Following such a mishap, properly sealing the apical foramen is very challenging.

REQUIREMENTS FOR AN IDEAL ROOT CANAL FILLING MATERIAL

Many substances have been used to obturate the root canals. Grossman,[71] in 1958, wrote: "I doubt very much whether there is any hollow cavity in the body that has been plugged with as many different materials as the root canal of a tooth."

Requirements for the ideal root canal filling material have been suggested.[72–76] According to West,[3] the ideal material must be:

1. Capable of being fully adapted to the prepared root canal walls
2. Dimensionally stable
3. Non-resorbable for an indefinite period of time
4. Non-irritating
5. Bacteriostatic, or at least should not encourage bacterial growth
6. Nonstaining to teeth
7. Preferably semisolid upon insertion and solid afterward
8. Capable of sealing canals laterally as well as apically
9. Impervious to moisture
10. Radiopaque
11. Sterile or sterilizable
12. Easily removed from the root canal, if necessary
13. Easily manipulable
14. Sticking to the canal walls
15. Nonconductor of thermal changes
16. Slightly expandable after placement
17. Able to set in a reasonable period of time.

Generally, root canal filling materials are divided into pastes and cements, solid materials and semi-solid materials.[77]

PASTES AND CEMENTS

Sealers are self-hardening ***cements*** used in conjunction with solid or semi-solid materials that serve as the core of the obturation. Sometimes, clinicians use certain ***cements*** to fill the entire root canal without another core obturation material. These cements set and transform into a firm mass after insertion in the canal. ***Pastes*** (such as Iodoformic paste or calcium hydroxyde) are used to fill the entire canal. In contrast to sealers/cements, however, they do not harden once placed in the canal and are easily resorbable. Consequently, they are not used as permanent filling materials.

Endodontic sealers are resorbable,[78] (some more than others) even within the root canal. Their use as the sole filling material is not encouraged.[79]

It would be desirable to fill the entire canal with a core solid or semi-solid material. In practice, however, this is not possible, because empty spaces (voids) will remain between the canal walls and the filling material. Sealers, therefore, have become indispensable to fill those voids and adhere the core obturation material to the canal walls.

Ideal sealers should be:

- easily manipuled with ample working time
- easily mixed in very fine powder particles and liquid form
- tacky when mixed and adhesive to the canal walls when set
- biocompatible
- expansible while setting
- inert
- physically stable (nonshrinking after setting)
- nonresorbable
- insoluble in tissue fluids
- radiopaque
- nonstaining of tooth structure
- bacteriostatic
- easily removable with common solvents, if necessary
- nonimmunogenic in the periapical tissues[80–82]
- neither mutagenic nor carcinogenic[83,84]

Sealers are designed to improve the seal (hence their name "sealers") provided by the core obturation material.[85] The sealer should be used in small amounts; as minimal as practical. It should be deposited on the canal walls as a microfilm of only a few microns in thickness.

Zinc Oxide-based Sealers

Zinc oxide is the major component of many sealers used in endodontics.[86] The most commonly used are *Grossman's Sealer*, *Roth's 801 Sealer*, and *Rickert's Sealer.*

Grossman's Sealer contains zinc oxide, staybelite resin, bismuth subcarbonate, barium sulfate, and sodium borate (anhydrous) with eugenol as the liquid component.[87] It has been marketed as Procosol Sealer, as well as under other commercial names. *Roth's 801 Sealer* is similar to the Grossman's sealer, containing bismuth subnitrate instead of bismuth subcarbonate.

Rickert's Sealer has been used for many years, meeting most of Grossman's requirements for an ideal sealer. For radiopacity, it contains silver and, therefore, may stain tooth structures.[88] It has been marketed as Kerr's Pulp Canal Sealer (Sybron Endo/Kerr, Orange, CA, U.S.A.). It's original formula had a rapid setting time, especially in hot and humid environments.[88] Subsequently, another formula became available under the name of Pulp Canal Sealer EWT (Extended Working Time) (Sybron Endo/Kerr, Orange, CA, U.S.A.) that provides a longer setting time.

Tubuli-Seal (Sybron Endo/Kerr, Orange, CA, U.S.A.) is a two-paste system contained in two separate tubes. It has been developed as a nonstaining alternative to the silver-containing Pulp Canal Sealer. Barium sulfate is used for radiopacity. Tubuli-Seal is easy to mix but has the disadvantage of rapid setting time.[88]

Resin-based Sealers

AH 26 (Dentsply Detrey, Konstanz, Germany) is a bisphenol epoxy resin sealer that, for polymerization, uses hexamethylenetetramine (methenamine). It is marketed as a liquid-powder system. It was claimed that this formula might release small amounts of formaldehyde during the setting phase.[86]

AH Plus or *ThermaSeal Plus* (Dentsply Detrey, Konstanz, Germany) is also an epoxy resin sealer that has been formulated to avoid the formation of formaldehyde.[89] It is marketed as a two-paste system (unlike AH 26). AH Plus has a working time of 4 hours and a setting time of 8 hours.

A resin sealer called "*Russian Red,*"[90] has been used as a permanent filling material in some countries in Eastern Europe, Asia, and the Pacific Rim. This is a resourcin-formaldehyde cement, a type of phenol-formaldehyde or Bakelite resin.[91] It can be toxic and has no efficient solvent. Its removal from the root canal for retreatment purposes can be extremely difficult; sometimes impossible.

Therefore, the use of this sealer and similar products is not recommended.[92]

Paraformaldehyde Sealers

The use of sealers/cements containing paraformaldehyde (just as, until a short time ago, were N-2, Rocanal, and Endomethasone) is not encouraged, especially if used as the sole canal filling material. N-2, like all other cements containing paraformaldehyde, is highly cytotoxic.[93–106] In 1974, the Council on Dental Therapeutics of the American Dental Association[107] classified N-2 as an "*unacceptable*" preparation, in light of the scientific studies indicating its potentially hazardous effects.[99,108–110]

Medicated Sealers

There are numerous medicated sealers in the market. Many contain iodoform[111] or calcium hydroxyde.[88] There is no biological justification for their use as permanent materials to seal root canals and they haven't shown any clinical advantage.

Mineral Trioxide Aggregate

Mineral Trioxide Aggregate (MTA) (ProRoot MTA, Dentsply Tulsa Dental Products, Tulsa, Oklahoma) (Figure 22-24) appears to possess many characteristics of an ideal cement and has been used for mechanical and carious pulp exposures,[112,113] iatrogenic perforations,[114–117] open apices,[118–120] resorbed apices, and as a root-end filling.[121–123]

MTA provides a good seal and is capable of stimulating healing and osteogenesis. It is a powder consisting of tricalcium oxide, silicate oxide, bismute oxide, tricalcium silicate, and tricalcium aluminate. Hydration of the powder results in formation of a colloidal gel with a pH of 12.5, that solidifies to a hard solid structure in approximately three to four hours.[112] MTA is biocompatible,[124–126] causes no cell damage to fibroblasts and osteoblasts, and can stimulate formation of dentin bridges when used for direct pulp capping. It has also been suggested that its sealing ability and biocompatibility are superior to many other commonly used materials.[121,127–131]

An important characteristic that distinguishes MTA from other materials used to date in endodontics is its hydrophilic properties. It sets in the presence of moisture. Moisture can affect the physical properties and sealing ability of restorative materials.[112] However, the presence or absence or blood doesn't seem to affect the sealing ability of the material.[129] In fact, MTA sets well only in the presence of moisture.[112]

Due to its sealing ability and biocompatibility, the use of MTA can be advantageous when more conventional core filling materials cannot be safely used (e.g., extensive root resorption or apical foramen that is too large) (Figure 22-25).

SOLID MATERIALS

In the past, silver cones were among the most commonly used solid materials for root canal obturation. They were not the only solid materials used. Techniques of canal obturation that require the use of reamers, files, or endodontic probes intentionally separated in the root canal have been described. Silver points are not recommended for use in modern endodontic practice. They are briefly decribed here only for historical purposes and because clinicians may still encounter them in some retreatment cases.

Jasper[132] introduced the use of silver points to dentistry in 1933. He proposed that they be used to obturate very narrow and tortuous canals. It was conceived that, in such cases, a more rigid material than gutta-percha was needed to be delivered to the desired working length.

The ease of handling silver points, coupled with less canal enlargement, led to the misuse and abuse of silver points causing numerous treatment failures. This was mainly due to their introduction in canals that had not been sufficiently cleaned and shaped. Radiographically, however, they gave the appearance of a perfectly filled canal due to their high radiopacity. Nevertheless, silver cones couldn't fill or be compacted into all spaces within the root canal system. Leakage was also a major problem. It caused corrosion and production of cytotoxic silver salts.[133–137]

The main disadvantages of silver points are:

1. They do not adapt well to the inner canal anatomy. The canal will, therefore, remain inadequately obturated (Figure 22-26) or mostly filled with sealer.
2. The canal often has an irregular shape; it is elliptical, eccentric, and the apical foramen doesn't have a round cross-section like the silver point.[59,138] As a result, the silver point will only touch the walls in two points, will not be able to seal an elliptical foramen, and consequently filling mishaps may occur (Figure 22-27).
3. If the silver point is positioned at the apical foramen, or protruding beyond the apex,[135] (Figure 22-28) once the surrounding sealer has been resorbed, metallic corrosion sets in as a result of oxidation.[134,139] This leads to the formation of cytotoxic byproducts containing sulfur and chloride.[133] Corrosion results from the contact of the silver point with tissue fluids that penetrate from the apical foramen or from a deficient coronal restoration. It can also lead to disintegration of the metal.[140]

If the silver point has been sectioned at the canal orifice (this was used in several silver points techniques) or, worse yet, within the root canal itself, its removal can be very difficult, if not impossible.

The only advantage of silver points was their rigidity allowing their easy introduction into narrow and curved root canals. However, with the advent of advanced techniques that allow for successful obturation of smaller canals with gutta-percha, the use of silver points has declined substantially. Today, silver points are considered obsolete. There is no indication or justification for their use, in as much as they have been superceded by semi-solid materials, that offer a much higher versatility and predictable clinical results.[141]

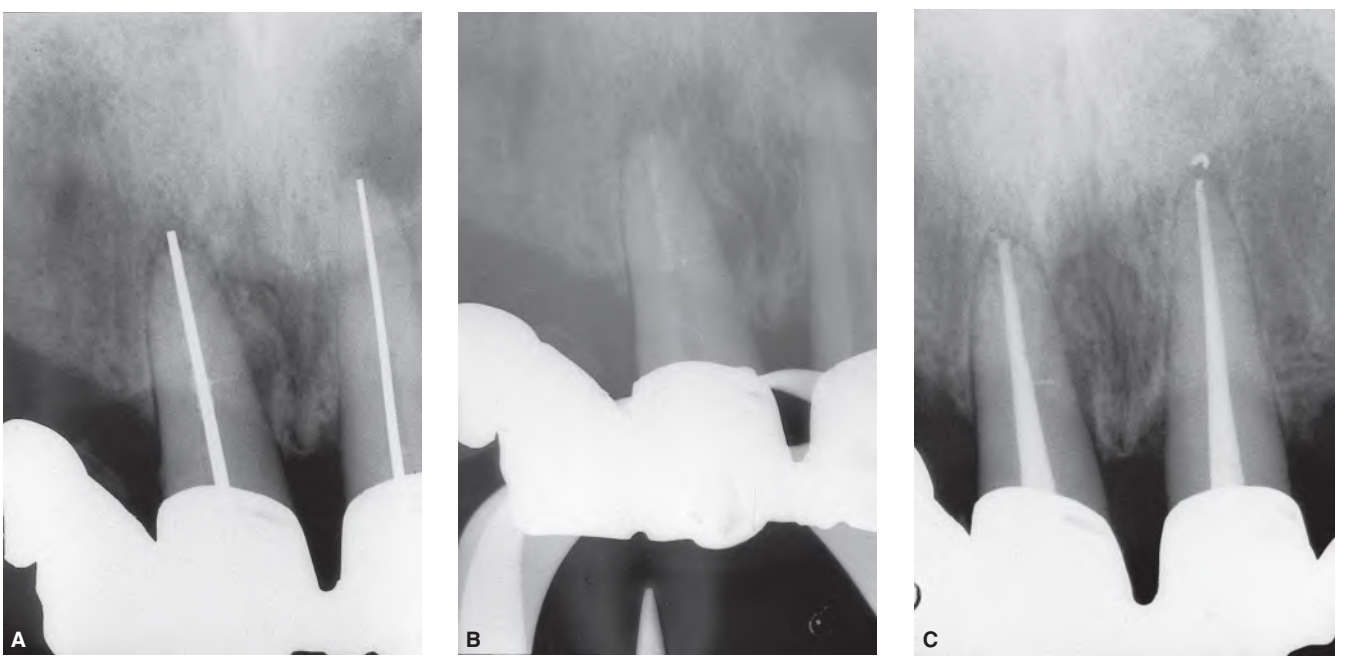

FIGURE 22-26 ***A***. A maxillary right central incisor obturated with a silver cone presenting periradicular radiolucencies. Note sealer extruding via a small lateral canal midway along the root. ***B***. The silver cone was removed. ***C***. Three years later, the periapical lesions associated with the two central incisors have resolved. However, the lateral lesion associated with the right central incisor has not completely resolved. It is possible that some infected material is still present within the lateral canal.

Preoperative radiograph. ***B***. The silver cone has been removed from the distal canal, but the segment beyond the apex has remained. The patient developed an abscess that was left to drain from the tooth. ***C***. One week postoperative radiograph after obturation. The silver cone fragment was "drained" externally, together with the purulent exudate.

SEMI-SOLID MATERIALS

The semi-solid material most widely used in endodontics today is gutta-percha. It is derived from a rubber base obtained from certain tropical plants (from Malaysia, Borneo, Indonesia, South Africa, and Brazil) belonging to the genera Sapotaceae.[142] It has been successfully used in endodontics for over 100 years. While not perfect,[143,144] today, gutta-percha is still the material of choice for most canal obturation cases. Until a better material is found, the only issue is how to make better use of it.[40]

The composition of commercially available gutta-percha points consists of 18% to 22% gutta-percha, 59% to 76% zinc oxide, 1% to 4% waxes and resins, and 1% to 18% metal sulfates.[86] Although gutta-percha is not the major ingredient, it serves as the matrix. Zinc oxide acts as the filler, whereas the waxes and resins serve as plasticizers. Metal sulfates, such as barium sulfate, provide the radiopacity to identify the material radiographically. [86]

The advantages of gutta-percha are:

1. It adapts to the canal walls because of its compactability. In fact, gutta-percha is neither molecularly condensable nor compressible. However, once softened by heat, it can be compacted against the canal walls and collapse any voids present in the commercial product.[145]
2. Once set, gutta-percha is stable in size. It shrinks only when chemically softened (e.g., with chloroform) following evaporation of the solvent, or if it is physically softened (e.g., by heat), during the cooling phase. For these reasons, chemical softening of gutta-percha is to be avoided, since it may create voids. Softening by physical means must be accompanied by compaction of the material to compensate for the volumetric changes that occur during the cooling phase.
3. Although constituted primarily of zinc oxide, gutta-percha has a very low solubility rate. Nonetheless, there are some cases where gutta-percha, that had inadvertently been forced beyond the apex, was partially resorbed over the course of several years (Figure 22-15).
4. It is well tolerated by tissues.[57] Of all materials used in dentistry, gutta-percha is perhaps the most inert.[138]
5. It may have certain (weak) bacteriostatic activity, attributed to zinc oxide.
6. It is semi-solid when introduced in the canal. This allows easy manipulability. It becomes malleable if heated, so that it may assume any shape when compacted with appropriate instruments. This allows a three-dimensional filling of all canal spaces, both apically and laterally.
7. It is radiopaque because of its sulfate content (usually barium sulfate) and thus easily recognizable radiographically.
8. It can be easily disinfected. Immersion in 5%–6% sodium hypochlorite for 60 seconds is sufficient to eliminate both gram-positive and gram-negative microorganisms and even the most resistant *Bacillus subtilis* spores.[146,147]

9. If necessary, it can be easily removed from the root canal when endodontic retreatment is indicated. For more details, see Chapter 23, "Endodontic orthograde retreatment and management of mishaps." Solvents such as chloroform, chlorothene, eucalyptus, and rectified white turpentine have been used.[148–150]
10. Gutta-percha is a poor heat conductor. This implies optimal control of its plasticity in its most apical portion, when heated.
11. Once introduced into the root canal and heated, gutta-percha expands. This characteristic helps to ensure a tighter seal. As mentioned previously, gutta-percha shrinks during the cooling phase; thus, to compensate for thermal shrinkage, any technique requiring heating must also include a compaction phase.[151] In a study on the thermomechanical properties of gutta-percha, Schilder et al.[145] found that under clinical conditions, compaction, not compression, occurs. The reduction in volume that takes place during mechanical compaction of gutta-percha is due to the consolidation and collapse of internal voids in the material.

Disadvantges of gutta-percha points are:

1. Lack of sufficient rigidity especially in small sizes; it cannot always be pushed beyond a ledge that might be present.
2. It adheres to the dentin walls without establishing any bonds. To rectify this shortcoming, one must always use a sealer.

Gutta-percha points should be stored in a cool location with low humidity, otherwise they become brittle with time.

Gutta-percha is available commercially in the form of standardized ISO (International Standards Organization) sizes and in the so called "non-standardized points." Standardized points follow the same ISO numbers of root canal instruments. They are available in numbers 25 to 140, and their apical diameter and taper (0.02) correspond to those of the instrument of the same number. These points are indicated for the lateral condensation technique where the master cone is selected based on the last instrument used. In such cases, cone standartization is very useful (Figure 22-29).

Non-standardized cones, on the other hand, are much more conical and pointed. Rather than being distinguished by number, they are distinguished by size: extra-fine, fine-fine, fine, medium fine, fine-medium, medium, medium-large, large, and extra-large. These cones closely match the final shape and size of the instrumented root canal and are indicated for vertical compaction techniques, since their greater conicity allows for better adaptation to the tapered preparation (Figure 22-30).

Recently, new rotary shaping systems have been introduced, each having their own gutta-percha points to match the shape created by the particular rotary file system used. This is valid for many rotary or reciprocating NiTi File systems, like GTX Rotary, ProTaper Universal, WaveOne, ProTaper Next and similar ones (Figure 22-31).

FIGURE 22-29 ISO-standardized gutta-percha cones used with the lateral condensation technique.

FIGURE 22-30 Nonstandardized gutta-percha cones used with vertical condensation of warm gutta-percha.

With the thermoplasticized injectable techniques, the gutta-percha is produced in a pellet form that is loaded into a heating device like Obtura (Obtura Spartan, Earth City, Missouri) B&L Beta 2 (B&L Bio Tech, Seoul, Korea) (Figure 22-32), or as prepackaged cannulas or cartriges like Ultrafil (Coltene/Whaledent, Cuyahoga Falls, Ohio), Calamus (Dentsply Tulsa Dental Specialties, Tulsa Oklahoma), Elements, (SybronEndo, Orange, California) (Figure 22-33). Carrier-based gutta-percha products have gutta-percha around a plastic carrier (Thermafil, GT Obturators; Dentsply Tulsa Dental Specialties, Tulsa, Oklahoma) or around a cross linked gutta-percha carrier (GuttaCore; Dentsply Tulsa Dental).

The use of medicated gutta-percha cones containing iodoform,[111,152] calcium hydroxyde,[153] or chlorhexidine[154] is not encouraged and is not discussed in this chapter.

TECHNIQUES FOR ROOT CANAL OBTURATION WITH GUTTA-PERCHA

The most common obturation techniques using gutta-percha are ***lateral*** and ***vertical*** compaction methods, surrounding which there has been considerable debate for years. However, both "lateralists"[155] and "verticalists"[156] consider this debate artificial since it is physically impossible to condense either laterally or vertically alone[155] and on the other hand the softened gutta-percha mass, that is being compacted vertically into the conically shaped canal preparation, automatically assumes a lateral component of force. This follows routine laws of physics and requires no lateral direction of the instrument on the part of the operator.[156] One can discuss which technique is superior, but should not do so in terms of "lateral" or "vertical" forces, but rather of "cold compaction" versus "warm compaction."

VERTICAL COMPACTION OF WARM GUTTA-PERCHA

Many endodontists prefer to be familiar with several techniques of canal obturation, since each technique is indicated in certain situations.[21,155] Weine[138] discussed the various techniques of gutta-percha use, emphasizing that vertical compaction is to be preferred in certain well-defined cases, such as when the fitting of a conventional master cone to the apical portion of a canal is impossible, or when there is a ledge formation, perforation, or unusual canal curvatures, internal resorptions, or large lateral canals. The vertical compaction method then affords the operator a chance to achieve success in a case that might fail if any other kind of treatment were used.

The vertical compaction technique of warm gutta-percha, conceived and described by Schilder[40] in 1967, combines a reasonable ease of execution with maximal efficacy in obturating both simple and more complex canals.[157] Gutta-percha softened by heat is vertically compacted into the conically shaped canal preparation.

Armamentarium

The instruments used for compacting the gutta-percha in this technique are similar to amalgam compactors. However, they differ from them by being longer and narrower. These instruments are referred to as compactors or "pluggers" (Figure 22-34). Serrations at five millimeter intervals help to assess the working depth each instrument specifically made to prevent it coming into contact with the dentin. Particularly useful are the double ended pluggers: one end is in NiTi, smaller and flexible, and the other end is stainless steel, larger and rigid, like the ones manufactured by Obtura Spartan (0.80, 1.00, and 1.20 mm in the stainless steel end and 0.40, 0.50, and 0.60 in the NiTi end) and by B&L (0.70, 0.80, 1.00, and 1.20 mm in the stainless steel end and 0.35, 0.40, 0.50, and 0.60 in the NiTi end) (Figure 22-35).

The other instrument that this technique requires is the "heat carrier," that is used to deliver heat to the gutta-percha cone in the root canal. Several types of heat carriers are available, like the Touch 'n Heat (SybronEndo), the Elements (SybronEndo), the Calamus (Dentsply Tulsa Dental), or the new cordless Alpha 2 from B&L (Figure 22-36). These instruments are provided with tips of different tip diameter and different taper.

Gutta-percha Cones

The gutta-percha cones indicated for this technique are tapered. Although they have the same chemical composition

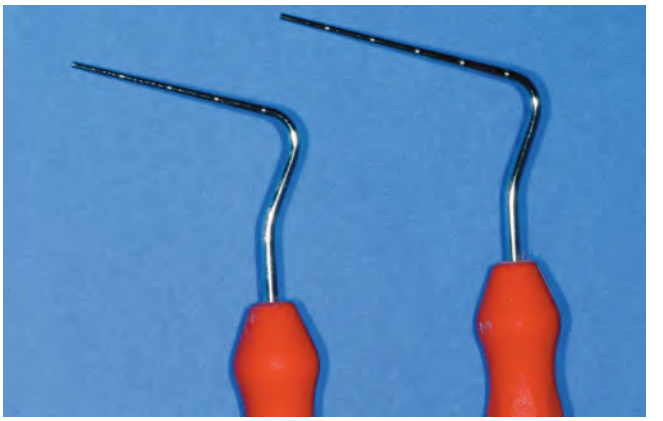

FIGURE 22-34 A plugger of the "Posterior" series, for teeth of 25 mm or less (left). A plugger of the "Anterior" series, for teeth of 30 mm (right) (Dentsply Maillefer, Ballaigues, Switzerland).

as the standardized ones, they are more conical and thus provide a larger amount of gutta-percha on which to exert vertical force with the working surface of the pluggers. In the original Schilder technique the sizes most commonly used were "fine," "fine-medium," "medium," and "medium large" (Figure 22-30). Today, many shaping systems are available each having gutta-percha points that correspond to its shaping files (Figure 22-31).

FIGURE 22-35 The three most frequently used pluggers from B&L (B&L Bio Tech, Seoul, Korea).

Sealer

A minimal amount of sealer is necessary to ensure better adaptation of gutta-percha to the canal walls. Therefore, the ideal sealer for this technique is one that can be spread onto the canal walls as a microfilm of few microns in thickness.[156,158] Many commercially available endodontic sealers can be used, as long as they are inert, biocompatible (or at least well tolerated by the tissues), nonshrinking, and nonresorbable.

Weiner and Schilder[159] found that there was a correlation between the sealer's setting time, its resorbability, and its

FIGURE 22-36 ***A***. The "Touch 'n Heat" carrier (SybronEndo). ***B***. The "Alpha 2" heat carrier (B&L). ***C***. The Elements Obturation Unit (SybronEndo). ***D***. The Calamus (Dentsply/Tulsa Dental).

shrinkability; the longer the setting time, the easier the sealer will shrink and be resorbed. Sealers that appear to be the least affected are the Pulp Canal Sealer (Kerr), that has a relatively short setting time (Figure 22-37A), and the Pulp Canal Sealer E.W.T. (Kerr), that allows an easier manipulation due to its extended working time (Figure 22-37B). The composition of this sealer, in Rickert's 1931 formulation, is:[160]

Powder (%)	
Silver	24.74
Zinc oxide	34
Thymol iodide	10.55
Oleoresin	30.71
Liquid (%)	
Eugenol	78
Balsam of Canada	22

Phases of obturation

Cone Fit

If feathered gutta-percha cones are used, they must be slightly shortened (Figure 22-38) up to the size of the apical foramen, and a radiograph taken to check the cone fit. The gutta-percha point should reach the working length and show to have retention inside the root canal (tug-back). After the appropriate cone fit has been confirmed on the radiograph, the tip of the cone is cut so as to be slightly short with respect to the preparation (Figure 22-39).

In accordance with the second mechanical objective of shaping descibed by Schilder,[161] the apical cross-sectional diameters of the prepared root canal must diminish coronoapically. As a consequence, the cross sectional diameter of the shortened gutta-percha point is bigger than the cross

FIGURE 22-37 The Pulp Canal Sealer ***A***. and the Pulp Canal Sealer EWT (Kerr Corporation, Orange, California, U.S.A.) ***B***. are best suited for the Schilder technique.

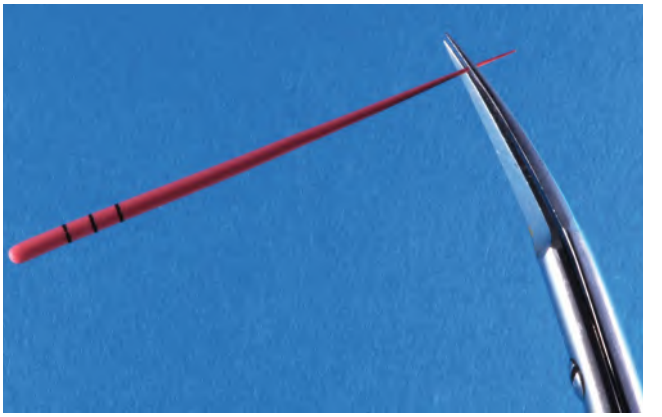

FIGURE 22-38 The feathered gutta-percha cone just removed from its wrapper must always be blunted with a pair of scissors.

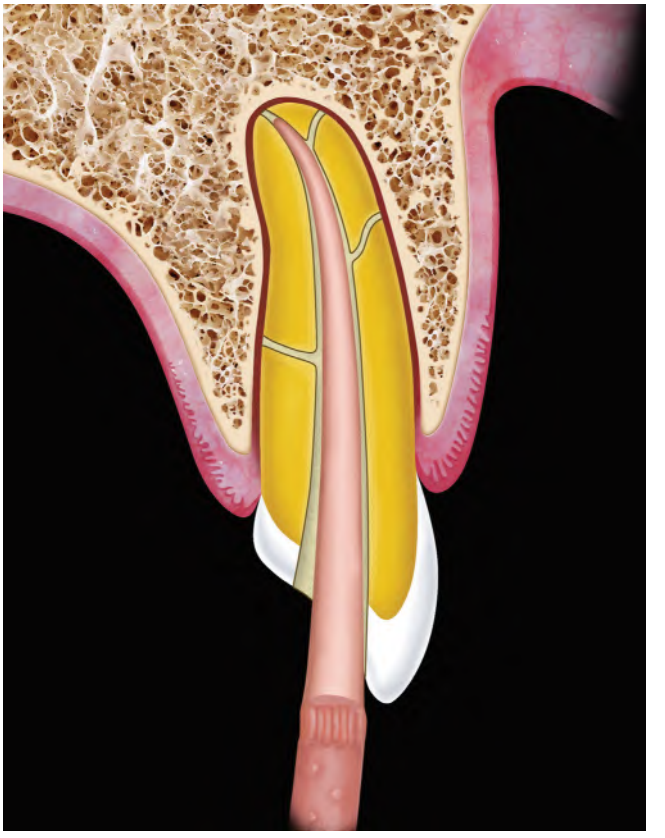

FIGURE 22-39 The cone must be slightly shorter than the preparation. A notch is made by cotton pliers at the level of the reference point.

sectional diameter of the foramen. When one begins to compact and push the cone vertically, the cone moves apically, and its tip will become engaged in progressively smaller portions of canal. This will lead to deformation of the cone ensuring a good seal and a good apical control of the obturating material. On the other hand, if the gutta-percha cones are not shortened, they will protrude beyond the apical foramen as a result of the vertical force until its cross-section is almost equal to, if not greater than, the diameter of the apical foramen.

The tip of the gutta-percha cone is shortened by using a special gauge (Figure 22-40) or small scissors and selectively removing varying amounts of the apical tip until it enters the canal comfortably and binds. This must occur at the working length and the depth is marked on the cone with a notch made by cotton pliers at the reference point of the stop. The fit is initially checked by comparing the length of the cone with that of the last instrument at the terminus of the respective canal (Figure 22-41), followed by a control radiograph.

If the canal was prepared using NiTi instruments systems like GTX Rotary Files, ProTaper Universal, ProTaper Next, WaveOne, and similar ones, the cone fit is much easier and the clinician will choose the cone corresponding to the taper prepared in the root canal (Figures 22-30 and 22-31).

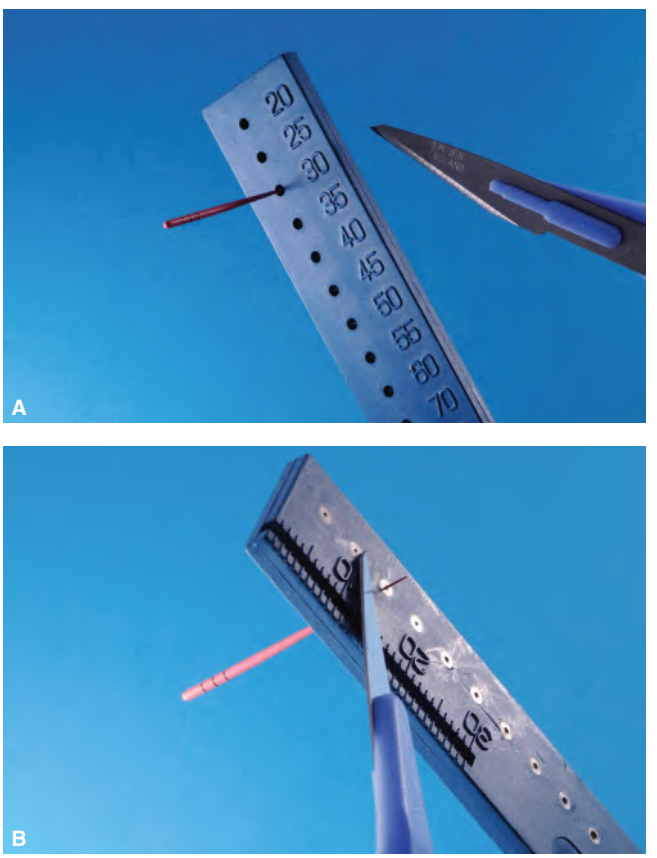

FIGURE 22-40 ***A,B***. The gutta-percha cone is cut off using a special gauge (Dentsply, Maillefer) for gutta-percha points. This gauge is very useful to cut off the gutta-percha cones to the desired diameter.

However, the principles are exactly the same: the cone should have an adequate tug-back, should fit slightly short of the working length, and should then reach the apical foramen during compaction, to assure an adequate apical seal of the root canal system.

Prefitting of Pluggers

The pluggers must be prefitted in the canal to determine the depth to which they can be introduced without touching the dentin walls. The essence of the technique is to capture the maximal cushion of softened gutta-percha and compact it vertically.[162] Starting with a sufficiently wide plugger, that descends in the coronal one third of the canal (e.g., a Maillefer #10 or a blue B&L) and advancing to smaller sizes. If the plugger has been supplied with a rubber stop, the instrument is introduced into the canal and the stop is positioned just before the instrument touches the dentin walls (Figure 22-42A). Next, a second plugger (e.g., #9 or a yellow B&L) is selected, that descends into the middle one third of the canal, again adjusting its rubber stop (Figure 22-42B).

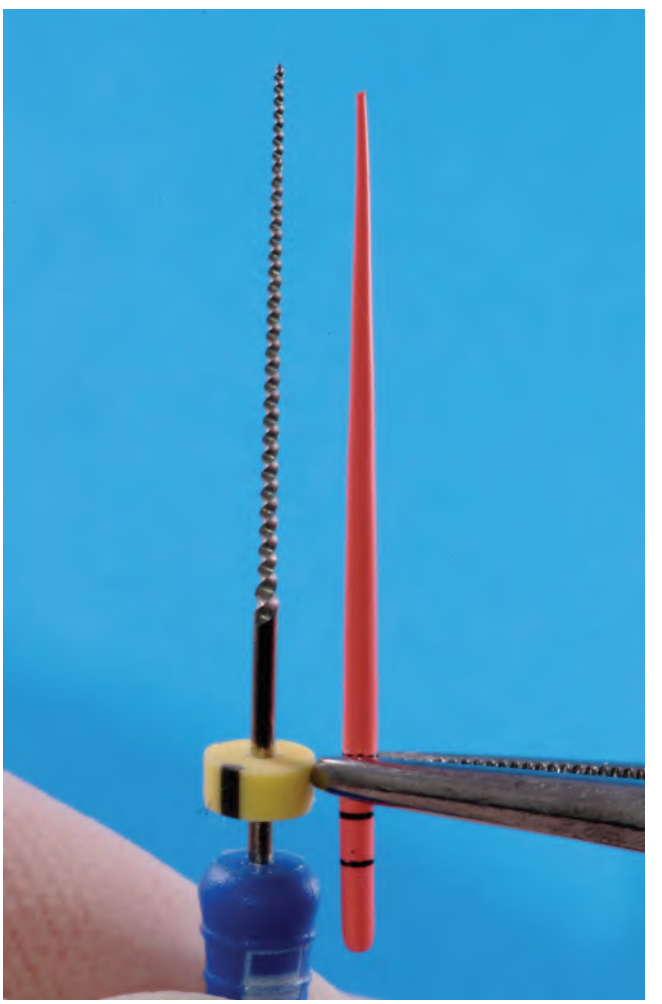

FIGURE 22-41 The relation between the gutta-percha cone and the reference instrument informs the operator how short the cone is relative to the canal preparation.

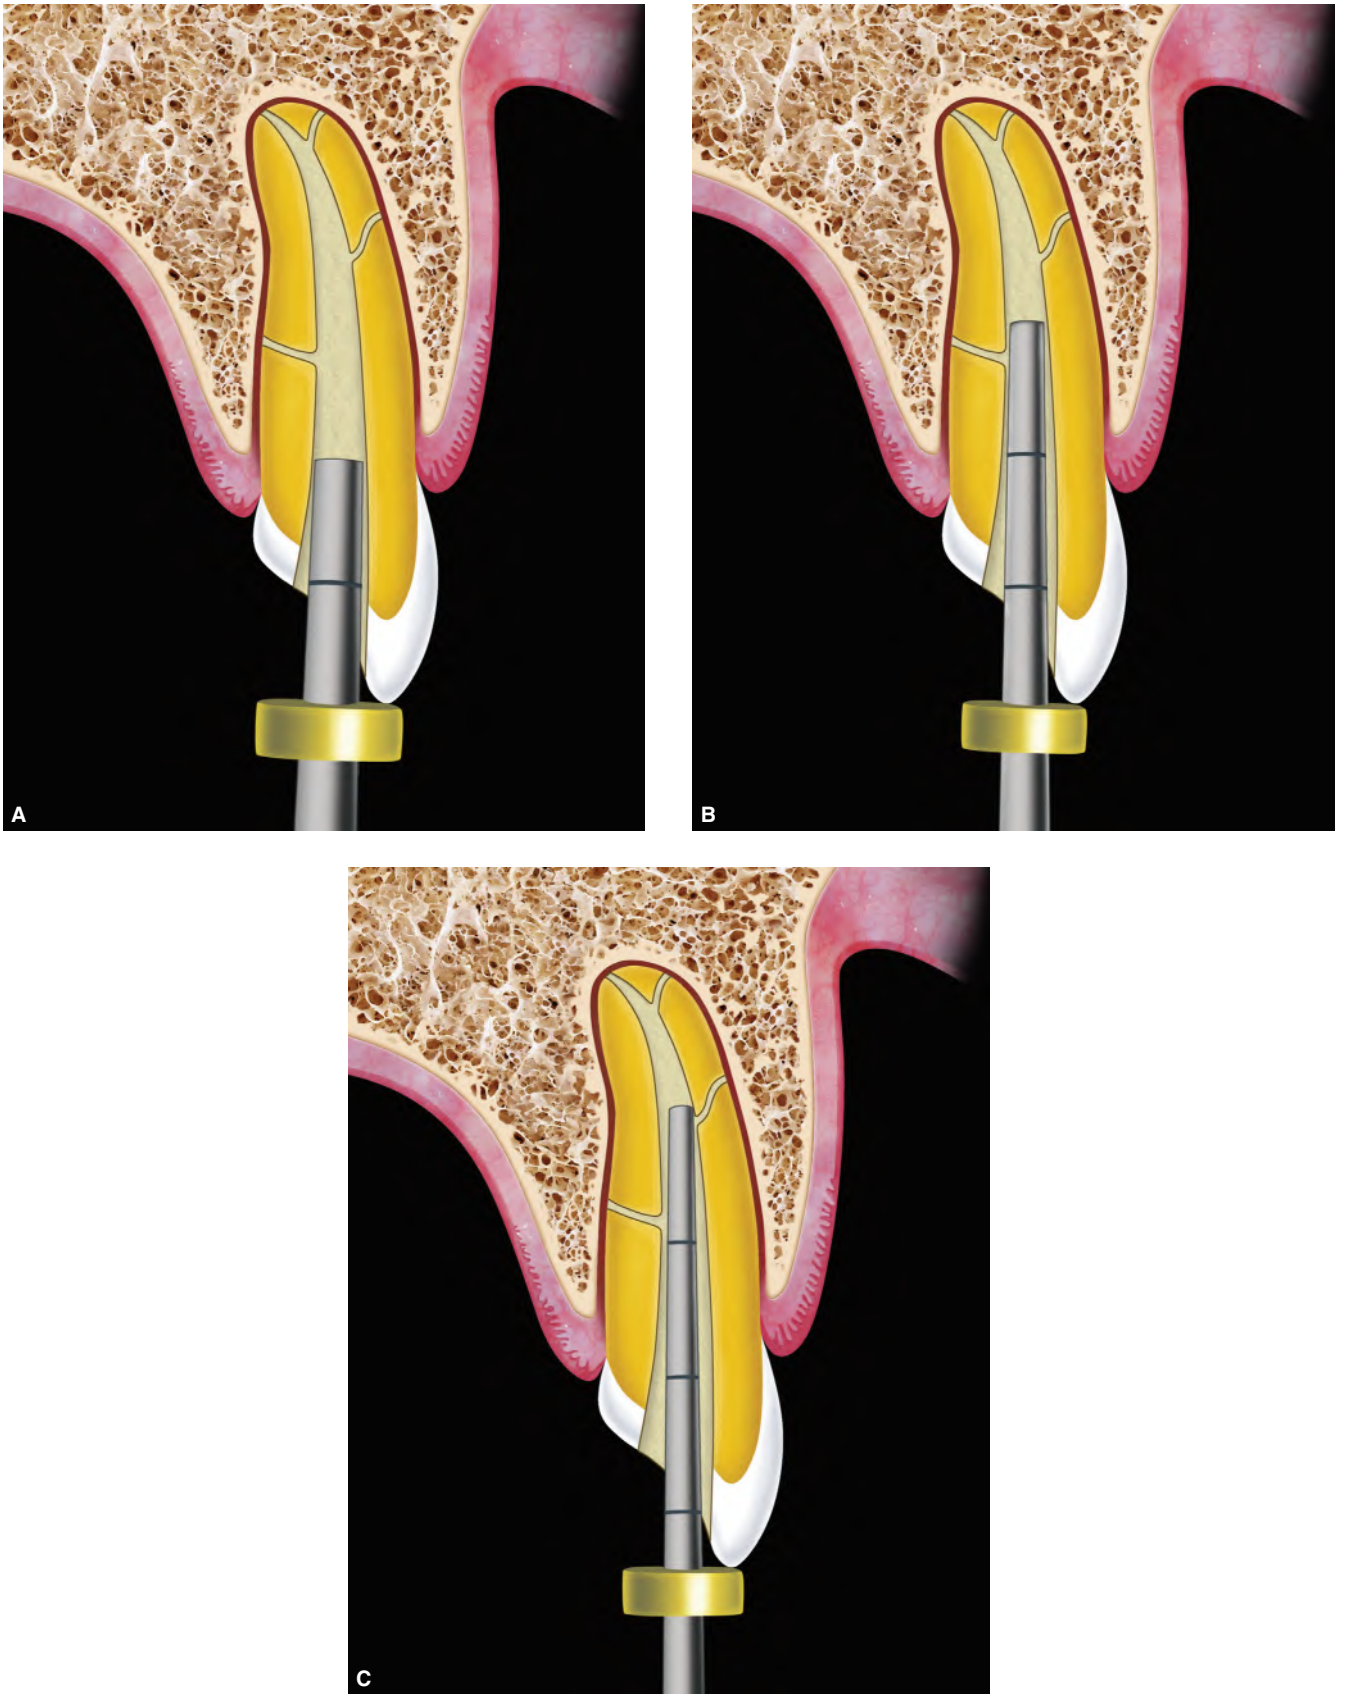

FIGURE 22-42 ***A***. Prefitting the first plugger in the coronal one third. The rubber stop is positioned immediately and before the tip of the instrument makes contact with the dentin walls. ***B***. Prefitting the second plugger in the middle one third. ***C***. Prefitting the smallest plugger. Its working depth is about 5 mm from the apical foramen.

Finally, a third, narrower plugger, that descends into the apical one third is advanced to a point about 5 mm from the apical foramen (e.g., a #8 or 81/2 or a black B&L), and its stop is also adjusted (Figure 22-42C). The pluggers must never touch the dentin walls, since by doing so it will no longer exert any pressure on the gutta-percha for compaction purposes while potentially causing root damage (e.g., crack or fracture) by their wedging action.

Sealer Preparation

A good type of sealer for this technique is the Pulp Canal Sealer E.W.T. (Kerr). Commercially, this sealer is marketed in 2 bottles; one with powder and one with liquid. It should be prepared according to the manufacturer's instructions. A study by Casanova[163] demonstrated that an increase of the powder/liquid ratio diminishes the solubility and resorbability of the sealer without affecting its fluidity and thus its capacity to spread as a microfilm. It is therefore advisable to prepare some extra amount of powder on a glass slab and two drops of liquid (Figure 22-43). At least two-thirds of the powder is dissolved in one drop of liquid to obtain a uniform, creamy mixture. Freshly-prepared sealer must be viscous enough to exhibit at least a 10 cm of "string" (Figure 22-44). The powder remaining on the glass slab can be applied to the tip of the plugger to prevent the heat-softened gutta-percha cone from adhering to it. This reduces the risk of the gutta-percha being pulled out the root canal during the process. The second drop of liquid can be used in case the mixture inadvertently became too thick.

Sealer and Master Cone Placement

The prefitted master cone is soaked in alcohol and dried with a sterile gauze. The entire length of the cone, that will contact dentin in the root canal, is coated with a thin uniform layer of sealer (Figure 22-45). It is then placed in the canal orifice and, with gentle pushing strokes, is made slide slowly and carefully to the maximal depth designated by the notch. The slow, careful introduction of the cone into the canal causes the air and any excess sealer apical to the cone to exit laterally and coronally, without creating any increased pressure or pushing sealer into the periapical area.

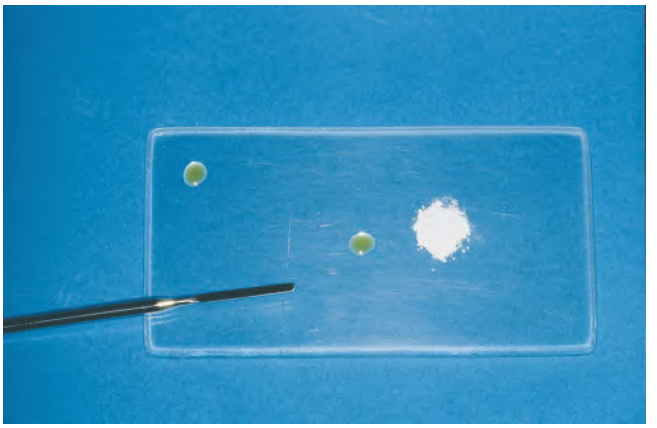

FIGURE 22-43 On a sterile glass slab, a small amount of powder and two drops of liquid (one of which is kept in reserve) are prepared. It is then mixed to achieve the desired consistency.

FIGURE 22-44 Properly prepared sealer must not "drip," but make at least a 8–10 cm "string."

FIGURE 22-45 The entire surface of the cone entering the root canal is coated with a thin layer of sealer.

If the canal has an extreme elliptical shape in its coronal third, an auxiliary cone is introduced alongside the master cone (Figure 22-46). The purpose is not to condense it laterally but to have a greater mass of gutta-percha to compact apically.

Down-packing

The heat-carrier is used to remove the excessive portion of gutta-percha extruding in the pulp chamber (Figure 22-47). Next, the wider prefitted plugger (after having powdered its tip with sealer powder to prevent adhesion to the tacky gutta-percha and sealer) is introduced to initiate the vertical compaction (Figure 22-48). The plugger is then returned, while the heat-carrier is handed back. It is introduced for 3–4 mm into the gutta-percha mass (without touching the dentin walls), where it remains for a fraction of a second (Figure 22-49).[162] The heating element is then deactivated and released after a quick short pause. The instrument is removed, along with some remnants of gutta-percha (Figure 22-50). In this manner, the gutta-percha is heated

FIGURE 22-46 In very wide or elliptical canals, it is advisable to introduce a supplemental cone(s) alongside the master cone for added bulk of gutta-percha to be compacted apically.

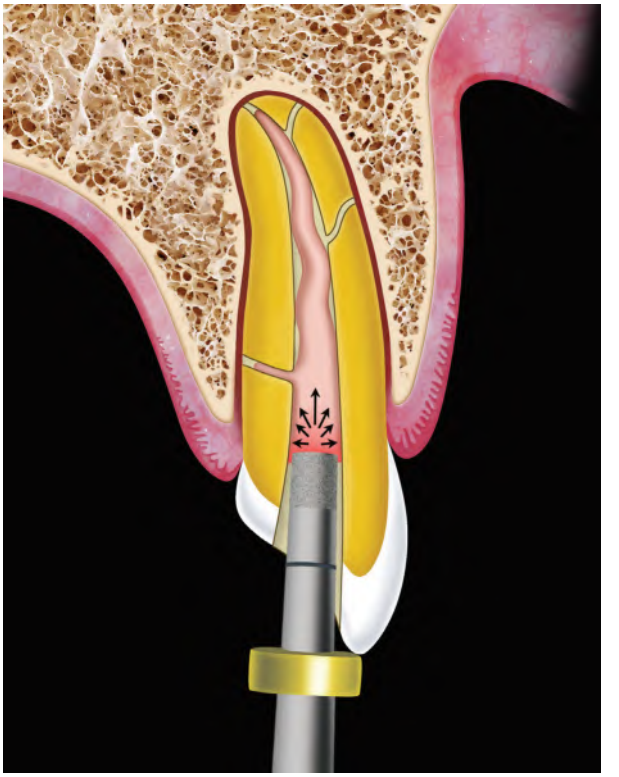

FIGURE 22-48 The first plugger (whose tip is powdered with left-over sealer so the gutta-percha cone does not attach to it) initiates the vertical compaction of the gutta-percha just heated by the preceding heat carrier.

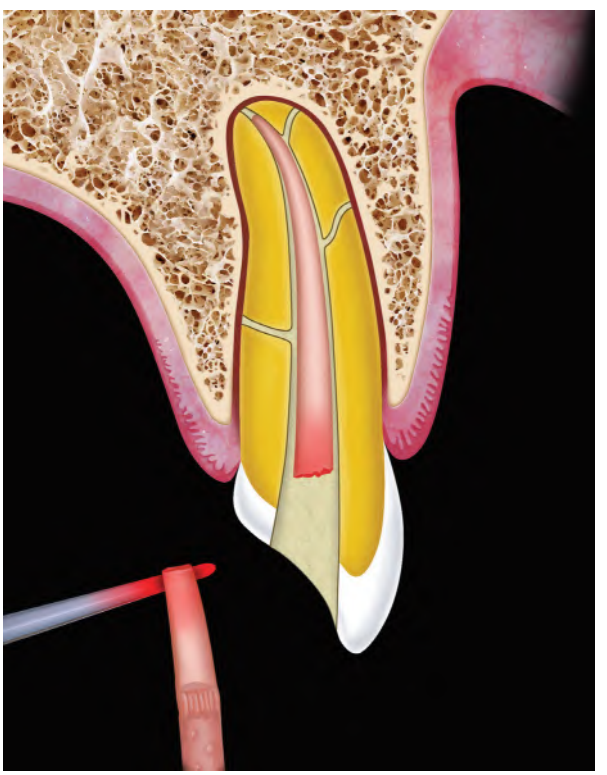

FIGURE 22-47 The gutta-percha that protrudes into the pulp chamber is seared off with a heat carrier.

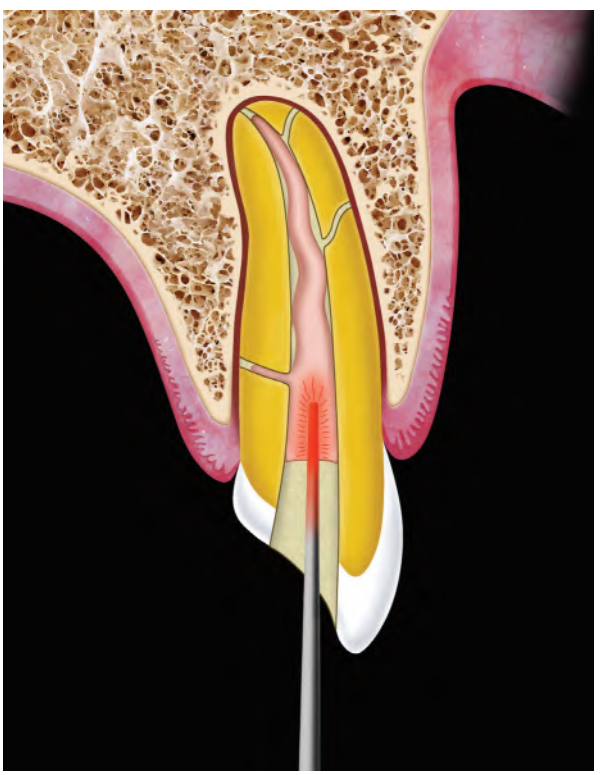

FIGURE 22-49 The heat-carrier is introduced into the center of the gutta-percha cone in the root canal.

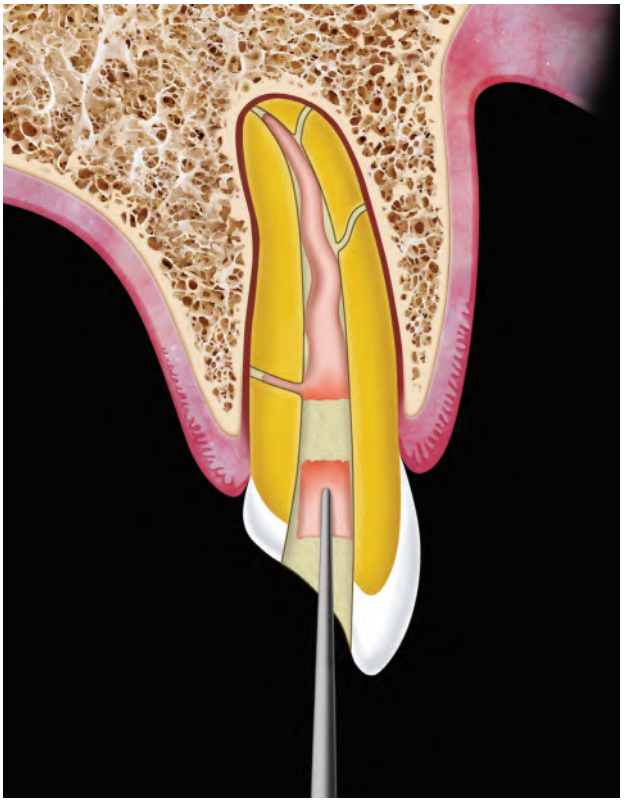

FIGURE 22-50 The heat-carrier is heating the gutta-percha apically to its tip and removes the surrounding material from the canal.

around the heat-carrier and about 3–4 mm apically (no more, because gutta-percha is not a conductor of heat).[164]

When the instrument is withdrawn from the root canal, the attached remnants of gutta-percha are removed and the instrument cleaned (Figure 22-51). Meanwhile, the prefitted plugger is introduced again to compact and push apically the gutta-percha that has just been heated in the root canal (Figure 22-52). Next, the heat carrier is again introduced into the canal to a depth of 3–4 mm and is removed once again covered with remnants of gutta-percha (Figure 22-53) and the same prefitted plugger is used to compact the softened gutta-percha apically as well as laterally. The cyclic use of heat carrier and pluggers continues until the smallest plugger compacts the material at about 5 mm from the working length (Figures 22-54 to 22-57).

The cyclic use of the heat-carrier and pluggers casues the following phenomena:[156]

1. From the very beginning, the force is exerted in a "closed" space where a significant hydraulic effect is produced. Coronally, the plugger of adequate size exerts its pressure against the maximal amount of heat-softened gutta-percha that, compacted, will make immediate contact with the dentin walls, while at the other end the cone, by virtue of its "tug-back," occludes the apical foramen. Thus the force is dissipated in a closed environment and the hydraulic

FIGURE 22-51 The heat-carrier is withdrawn, carrying out the cooled gutta-percha around it. This way, the level of the next compaction will be more apical.

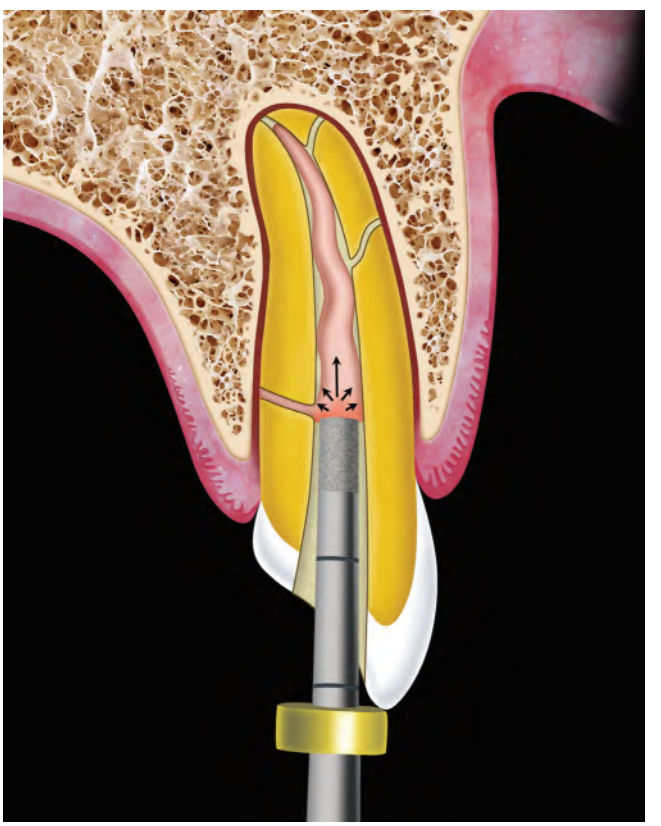

FIGURE 22-52 The first plugger repeats and completes the vertical compaction process in the coronal third of the root. Once the rubber stop is approaching the reference point, it is time to select a plugger of slightly smaller diameter.

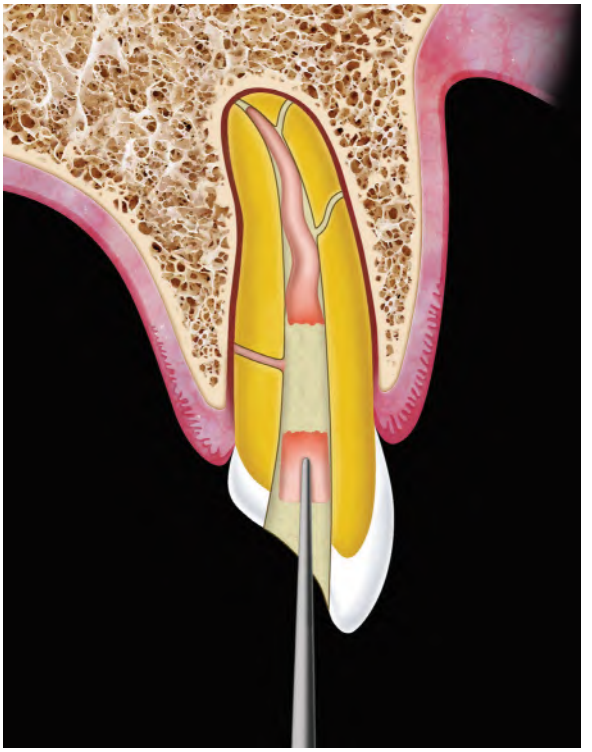

FIGURE 22-53 The heat-carrier is returned and is activated for just one second once it makes contact with the gutta-percha inside the root canal. It is then inserted directly into the central portion of the gutta-percha mass to a depth of 3–4 mm and quickly inactivated and withdrawn while cooling, removing another piece of gutta-percha from the root canal.

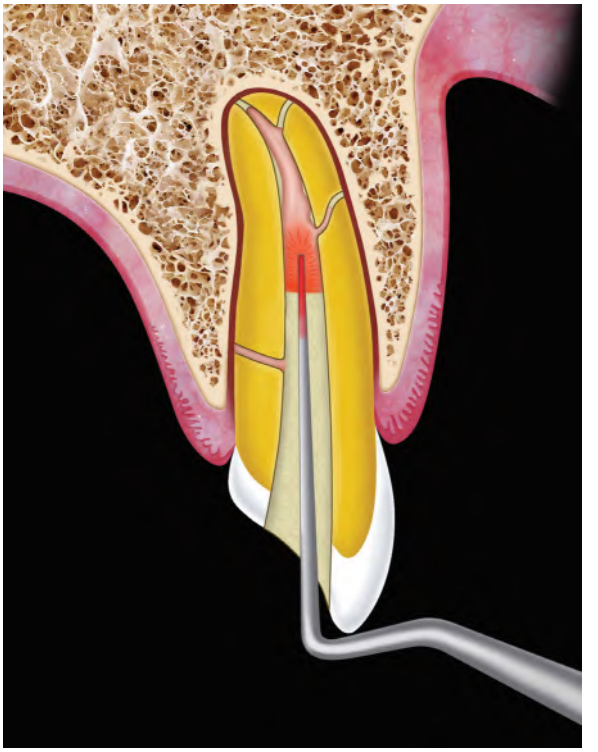

FIGURE 22-55 Reintroduction of the heat-carrier is softening the gutta-percha in the apical one third.

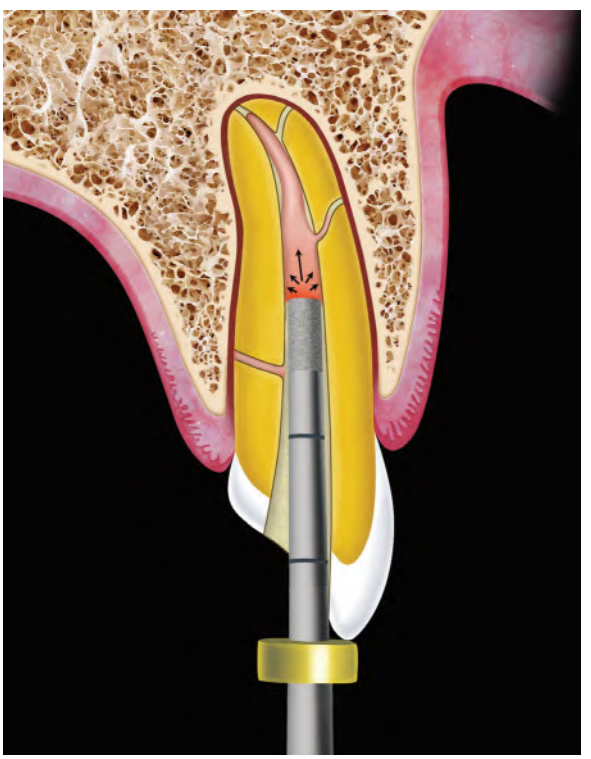

FIGURE 22-54 The second plugger has completed its vertical compaction to the maximal working depth.

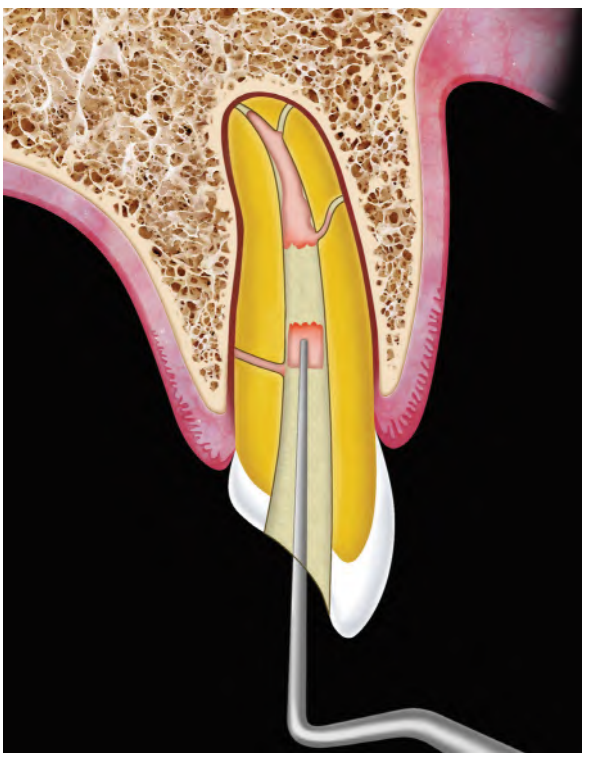

FIGURE 22-56 Another piece of gutta-percha has been removed. Now it is time to use the smallest plugger.

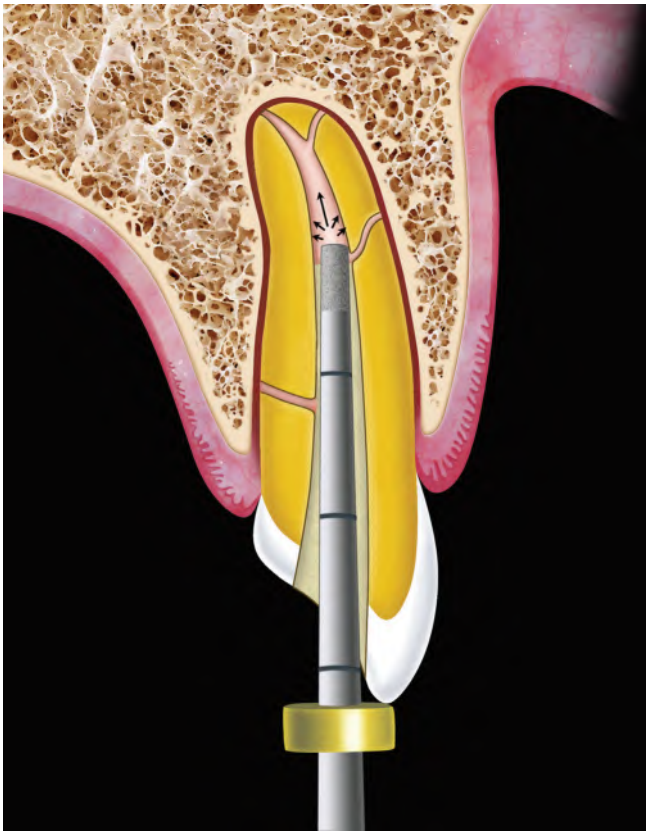

FIGURE 22-57 The smallest plugger has advanced, compacting the gutta-percha mass about 5 mm from the canal terminus.

pressure that develops within causes the sealer and the heat-softened gutta-percha to fill all the available spaces in a true corono-apical "wave of condensation." The more coronal lateral canals are filled first, then gradually as the condensation wave moves apically, those of the middle third of the canal and finally those of the apical third and the ramifications of the delta. This hydraulic pressure is absent in the lateral condensation.

2. The working level of compaction of the gutta-percha moves increasingly apically for two reasons. The first is that the softened gutta-percha mass, which is being compacted verticallyinto the conically shaped canal preparation, automatically assumes a lateral component of forces. This follows routine laws of physics and requires no lateral direction of the instrument on the part of the operator.[156] Second, each introduction of the heat-carrier in the root canal is followed by the removal of a certain amount of gutta-percha that remained attached to the tip of the heating instrument as it begins to cool. Consequently, the wave of condensation and the working level of the pluggers are displaced increasingly apically and it becomes necessary to advance to the plugger of narrower size.
3. The temperature of the apical gutta-percha gradually increases by a few degrees above body temperature. Since gutta-percha is a poor conductor of heat, its temperature will not rise immediately after the first or second application of heat. It will require several applications and even then the temperature will not rise to hazardous levels. A thermocouple study[165] has demonstrated that the apical gutta-percha becomes moldable at a temperature range of 3°C-7°C above body temperature and will not be elevated more than 9°C above the initial temperature.[168] Once the heat-carrier followed by the narrower plugger have descended to a depth of about 5 mm from the apical foramen, thermal increase occurs gradually in concomitance with the various applications of heat (Figure 22-58). If heat is not intentionally added, the gutta-percha returns to body temperature and will resist further movement beyond the terminus of the canal preparation.[165,166] Apical control of the obturation is thus excellent, since the gutta-percha at the apex is never molten.

It is contraindicated to descend further apically with the heat-carrier to heat the gutta-percha 2–3 mm from the apical foramen.[167] Overheating and excessively plasticizing the apical gutta-percha increase the possibility of gutta-percha extruding beyond the terminus of the preparation.[59] Stopping 5–6 mm short is more than sufficient to obtain an effective sealing or "corkage" of the canal preparation and filling of small lateral canals (Figure 22-59) or the apical delta (Figure 22-60) with gutta-percha and/or sealer.

Reverse Filling ("back-packing")

Once the gutta-percha has been compacted to about 5–6 mm from the terminus of the preparation, a radiograph is taken to verify that the gutta-percha is seated at the desired location and that the obturation is well compacted (Figures 22-61 and 22-62). The remainder of the canal (middle and coronal thirds) is filled in a backwards fashion. It can be achieved via two different methods:

1. Introducing small pieces of gutta-percha into the root canal, and rhythmically heating and compacting and them.
2. Using thermoplastic gutta-percha.

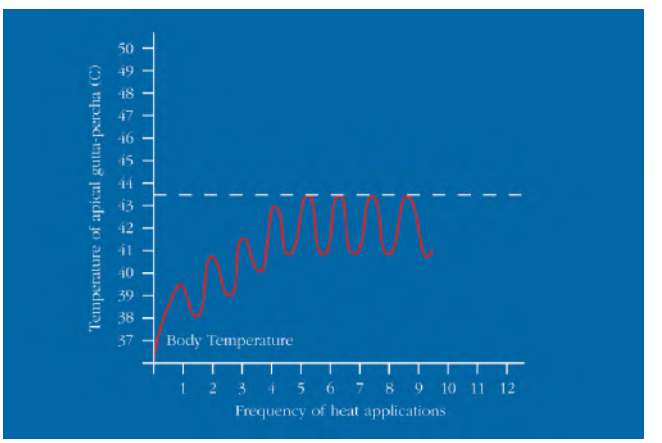

FIGURE 22-58 Thermal profile of gutta-percha in the apical portion of the canal preparation.[168]

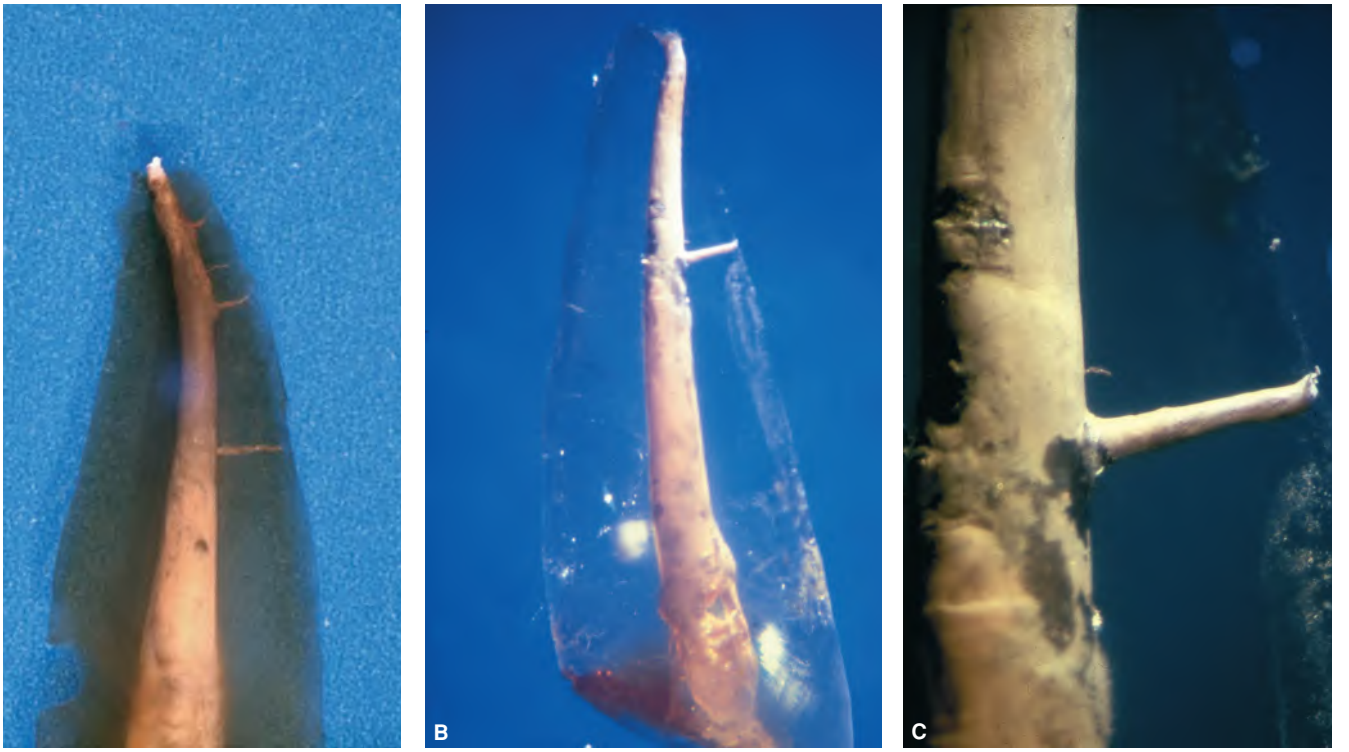

FIGURE 22-59 ***A***. An endodontically-treated maxillary central incisor extracted for periodontal reasons and cleared. Four lateral canals filled mostly with gutta-percha are evident. In this case, the compaction halted 5 mm from the canal terminus. ***B***. Maxillary premolar treated endodontically *in vitro* and then cleared. A lateral canal present about 4 mm from the apical foramen, is completely filled with gutta-percha. Heating and compacting was carried up to 5 mm from the terminus. ***C***. Higher magnification of 22-59B.

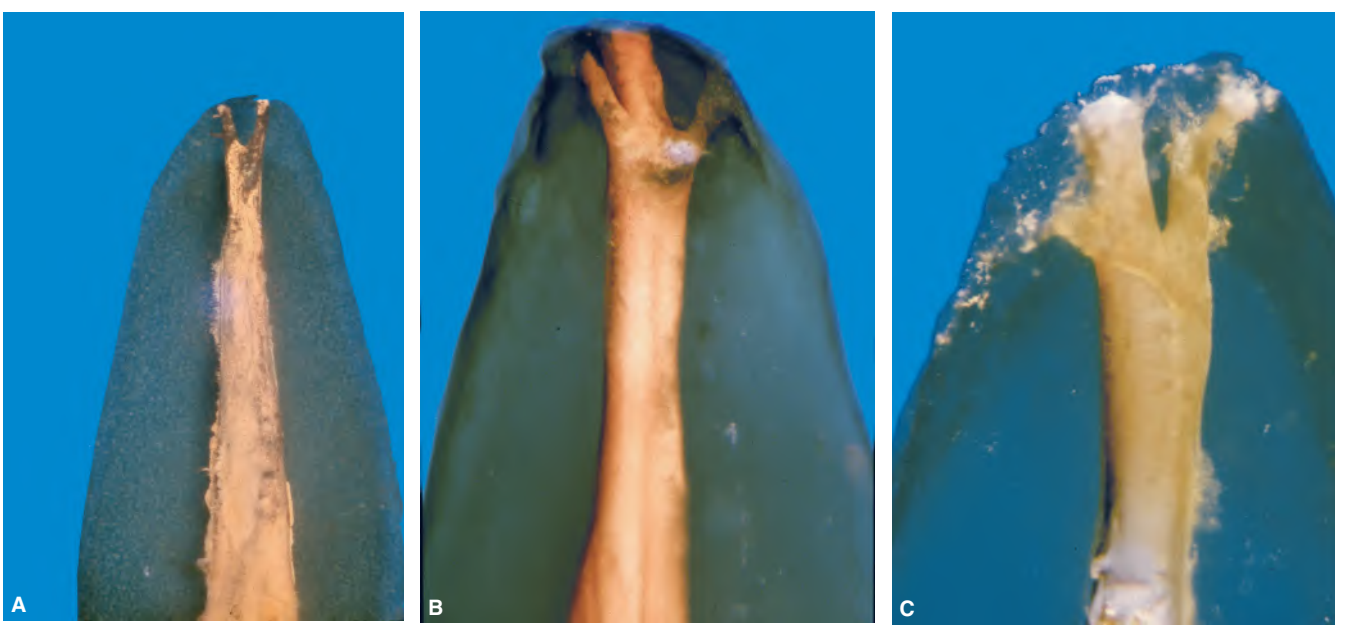

FIGURE 22-60 ***A***. A cleared root demonstrates a small apical bifurcation filled with gutta-percha and sealer. The compaction occurred 5 mm from the canal terminus. ***B,C***. Other examples of apical delta filled mainly with gutta-percha, heated, and compacted about 5 mm from the end of the canal preparation.

If remnants of gutta-percha or sealer are left attached to the dentin walls from the previous phase of compaction, the gutta-percha used for the back-packing phase may adhere to this material before fusing with the apical mass of gutta-percha, thus leaving empty spaces affecting the uniformity of the obturation (Figure 22-63).[157]

If post space or canal retention are needed for prosthetic purposes, the clinician may choose to terminate the

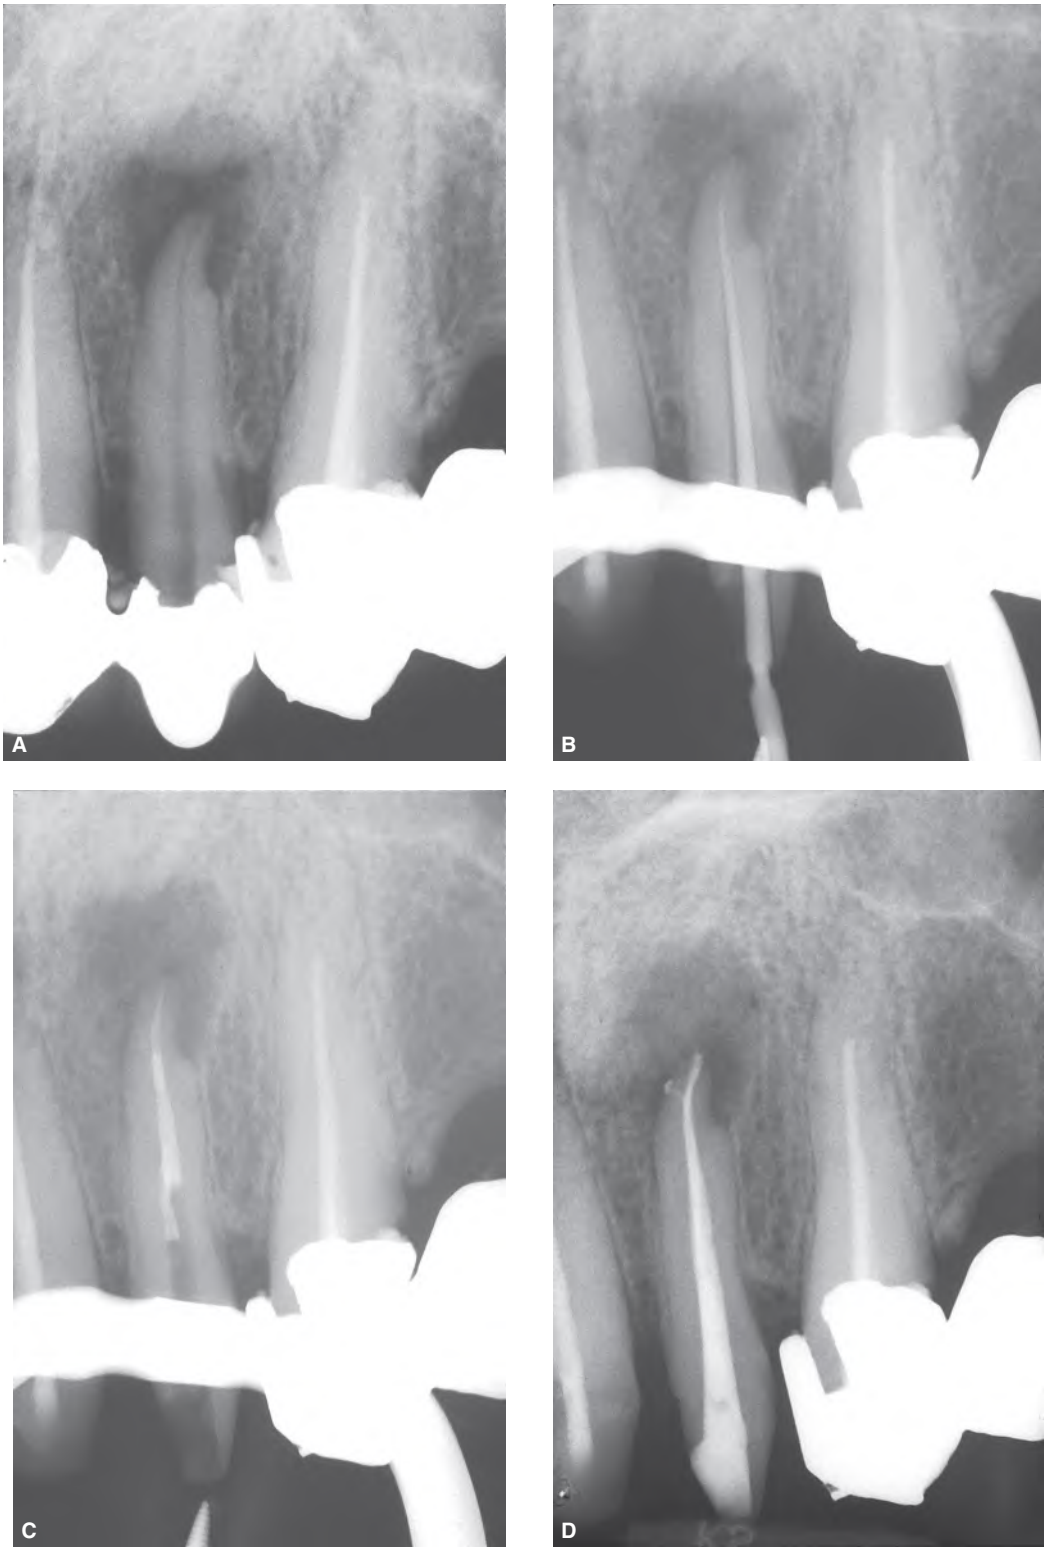

FIGURE 22-61 ***A***. Preoperative radiograph of maxillary left lateral incisor. ***B***. Intraoperative radiograph of the cone fit. ***C***. Radiograph of the apical compaction. The gutta-percha appears to be compacted for about 4 mm and then seems to fold. This is because the material has not been modified in the most apical portion. It is necessary to advance more apically with the heat-carrier and better compact the gutta-percha. ***D***. Postoperative radiograph showing the obturation material being homogeneous and well compacted. The presence of a lateral canal has also been demonstrated by the filling material.

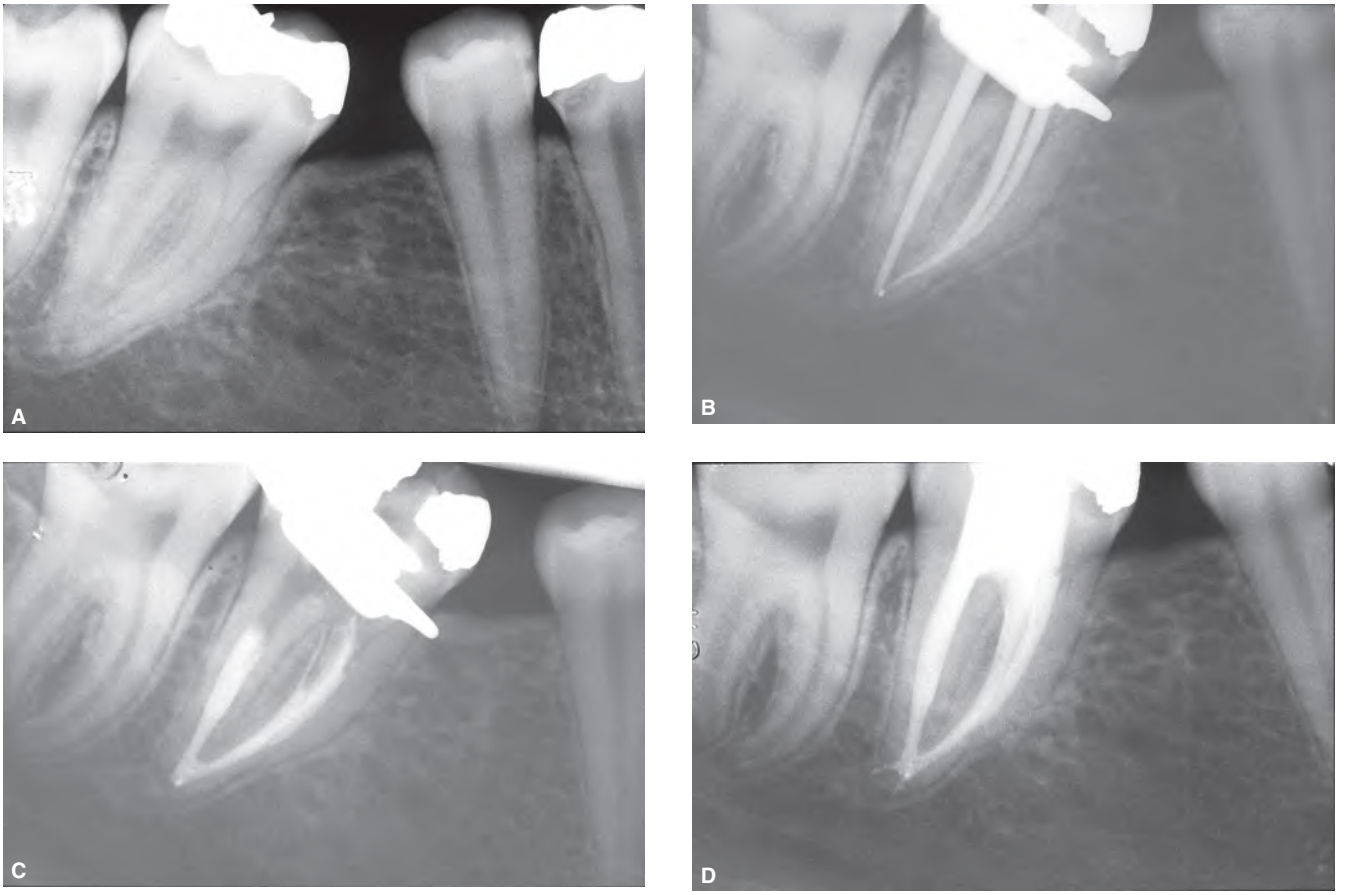

FIGURE 22-62 ***A***. Preoperative radiograph of a mandibular right second molar. ***B***. Cone fit. ***C***. Intraoperative radiograph of the apical compaction. The material appears to be homogeneous, but the obturation is slightly short. It is necessary to descend further apically (5 mm from the working length) with the heat-carrier and compact the gutta-percha better. ***D***. Postoperative radiograph showing filling material also in the small apical bifurcation.

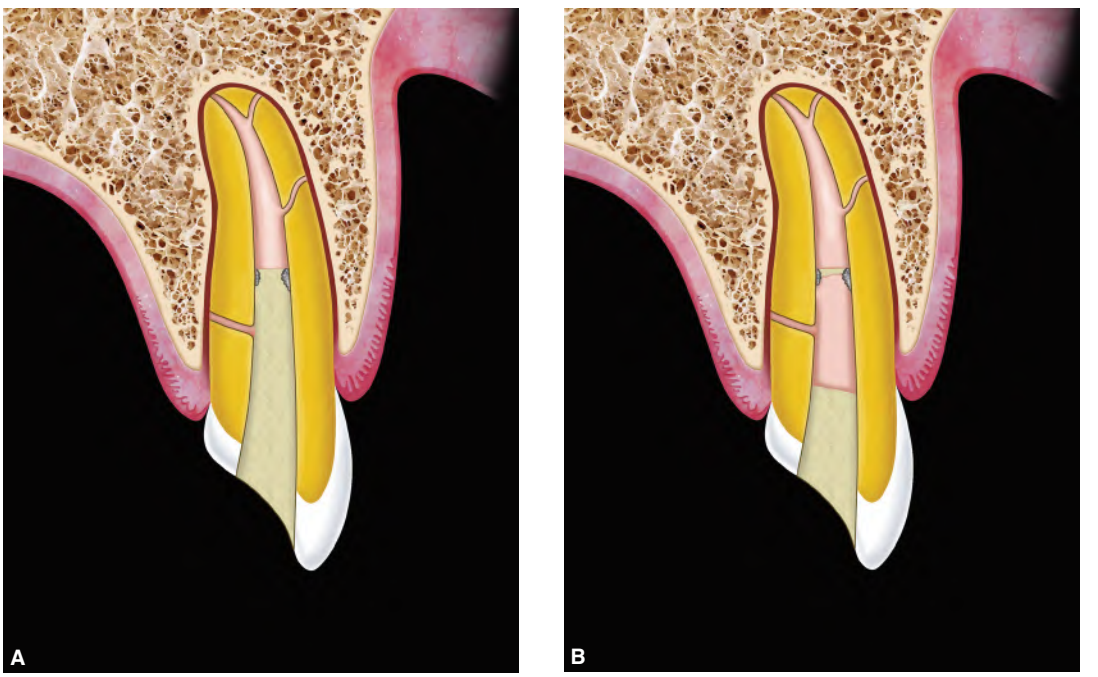

FIGURE 22-63 ***A***. During the initial phase of compaction, the plugger can leave streaks of gutta-percha along the walls (gray in the illustration). They must be re-directed toward the center of the root canal. ***B***. Streaks left behind can create voids during the "back-packing" phase.

obturation at the deepest point of the apical compaction or at any point of the reverse filling. Otherwise, the obturation can be completed up to the canal orifice and later partially removed to allow the necessary prosthetic space. In the single rooted tooth, the "back-packing" can be completed at any level since lateral canals that may have been present in the coronal or middle third of the canal have already been addressed during the downpacking (Figure 22-64). Furthermore, in anterior teeth, it is important to limit the backfilling to at least 2 mm below the gingival margin to prevent discoloration. Gutta-percha colorants reflecting through the coronal root and crown are unesthetic.

In multirooted tooth, however, complete "back-packing" and obturation of the canals and pulp chamber are imperative due to the presence of accessory canals on the floor of the pulp chamber. In these cases, once the canals have been filled, it is also necessary to seal the pulp chamber. If left unsealed it may cause an inflammatory reaction in the tissues associated with the furcation area.[160,168] For more details, see Chapter 36.

"Back-packing" with Thermoplastic Gutta-percha

When using thermoplastic gutta-percha such as Obtura III (Spartan Corporation), Beta 2 (B&L) (Figure 22-65), Elements (SybronEndo), Calamus (Dentsply Tulsa Dental) (Figure 22-36C & D), the reverse filling of the canal can be performed effectively in a significantly shorter time, especially in multirooted teeth.

This procedure is performed by introducing the narrowest needle (#23 or #25) into the root canal, and squeezing the trigger of the gutta-percha gun gently but decisively so as to feel the pressure of the gutta-percha. The pressure of the gutta-percha will push the operator's hand coronally while filling the canal. After the introduction of a small amount of gutta-percha, it is compacted by a corresponding size plugger. It is then re-heated by the heat-carrier and compacted again (Figure 22-66).

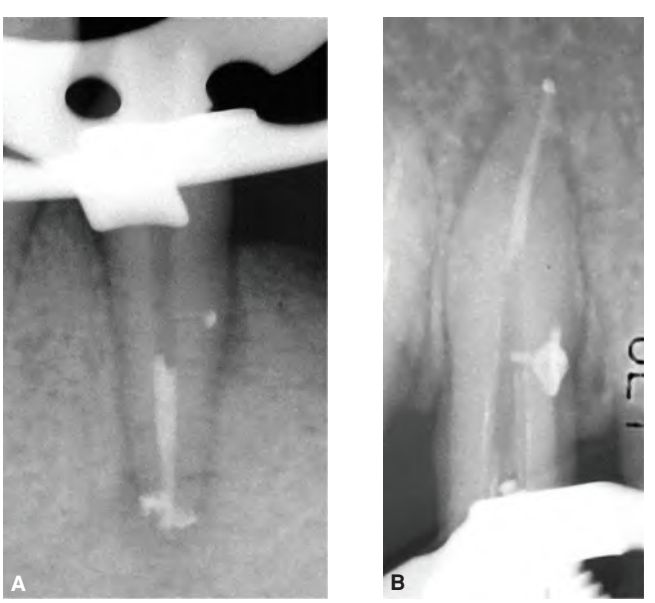

FIGURE 22-64 ***A,B***. Lateral canals can be filled during the downpacking.

FIGURE 22-65 ***A***. The Obtura II (Obtura Spartan Corporation, Earth City, MO, U.S.A.). ***B***. The Beta 2 (B&L Bio Tech, Seoul, Korea).

In general, with three successive introductions of material, "back-packing" of a canal is complete. It is always advisable to perform canal filling with thermoplastic gutta-percha in three or more injections (sectional technique), since better results are obtained (no entrappment of air bubbles) as compared to fillings performed in a single injection (single technique).[169] The single injection technique is more prone to leave voids.

LATERAL CONDENSATION OF GUTTA-PERCHA

Once the root canal has been cleaned and shaped, a gutta-percha cone is selected that fits well to the apical preparation (master cone). Usually, standard cones are peferred because they have less taper and permit a deeper penetration of the spreader (see later). The master cone should fit perfectly at the working length and show resistance to displacement ("tug back") (Figure 22-67). After the canal is irrigated and

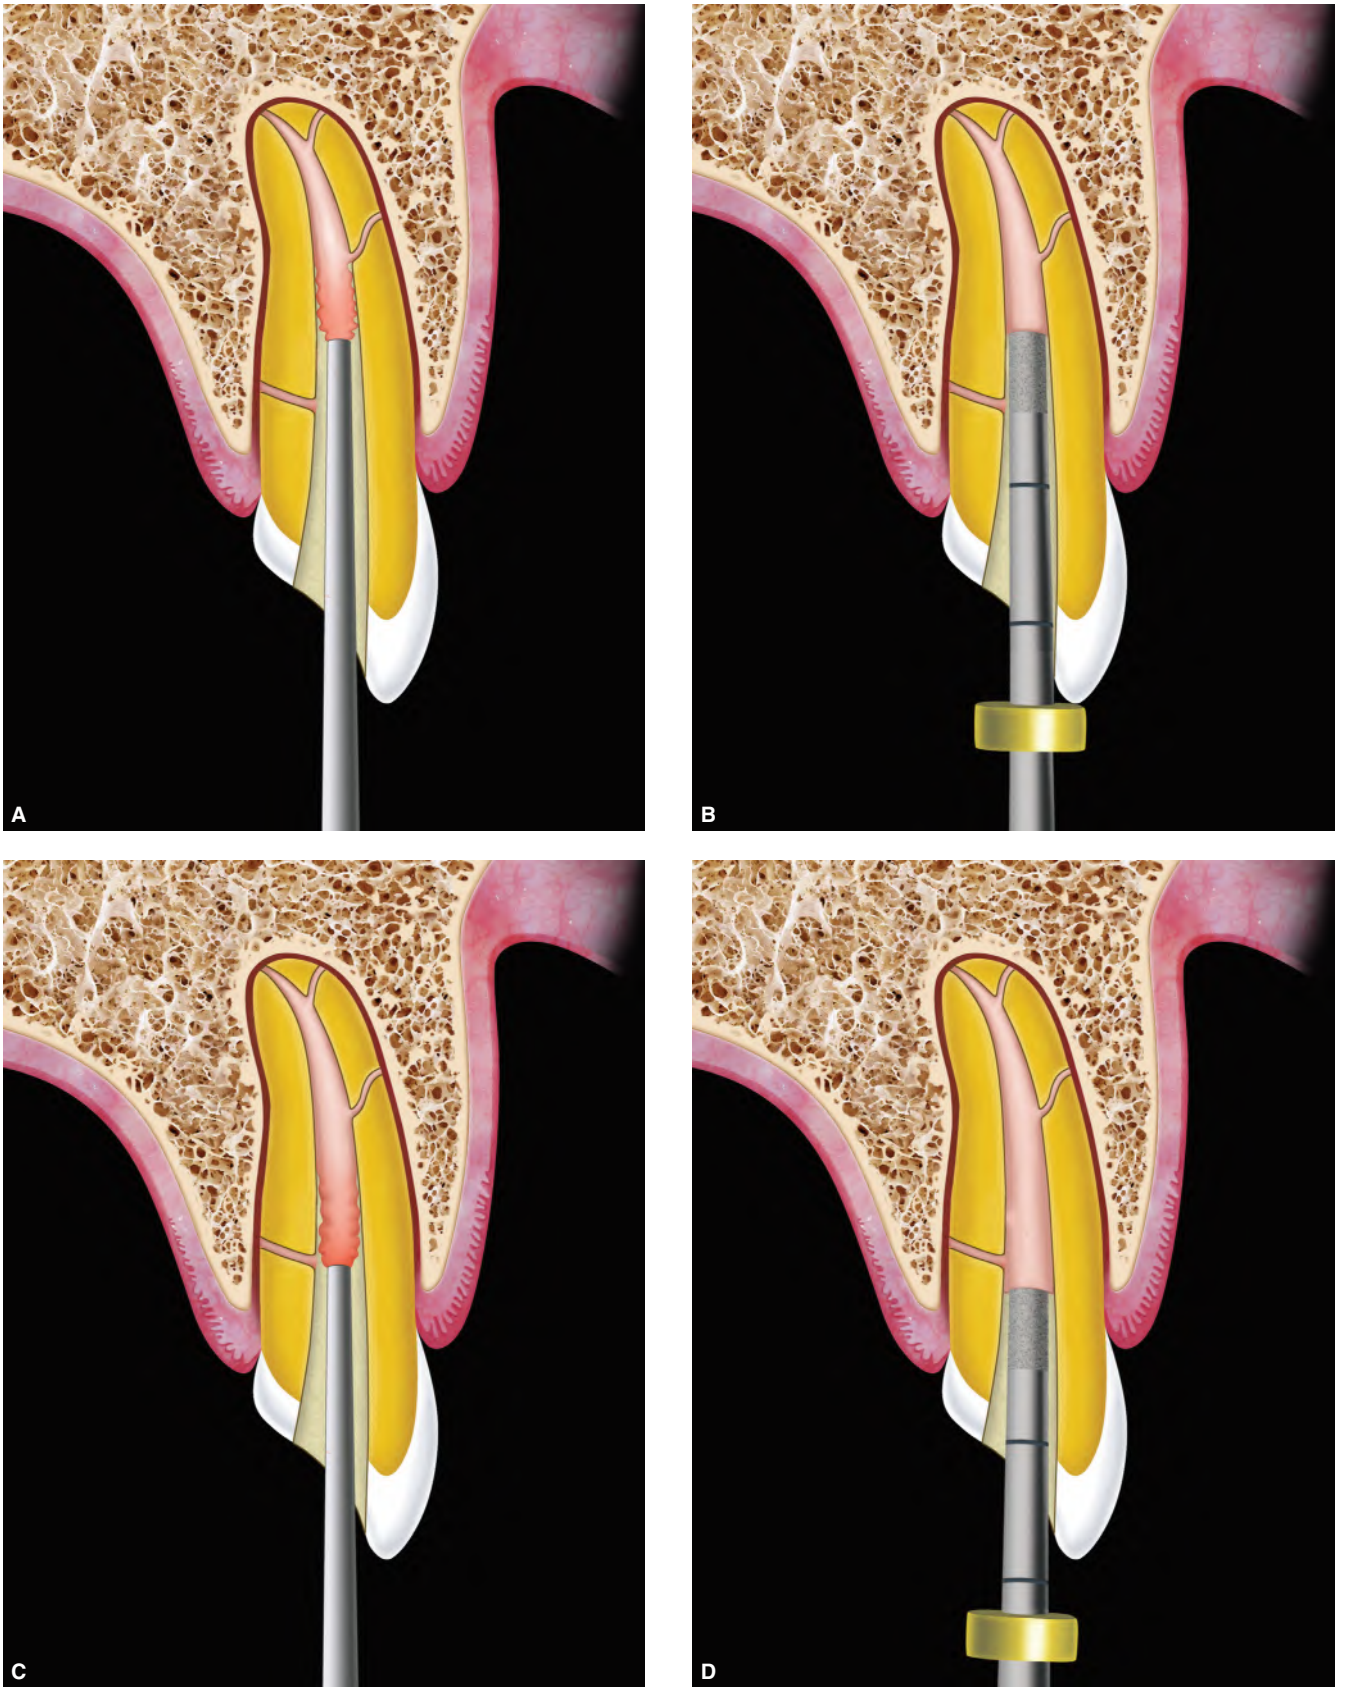

FIGURE 22-66 ***A***. The needle of the device touches and heats the apically compacted gutta-percha. Then a small amount of material is injected, in order to fill no more than 5 mm of space at a time. ***B***. The plugger, previously used in the middle third, is now used to firmly compact the material until the gutta-percha is plastic. ***C***. Additional 5 mm of gutta-percha are injected into the root canal. ***D***. The compaction is completed using the larger plugger.

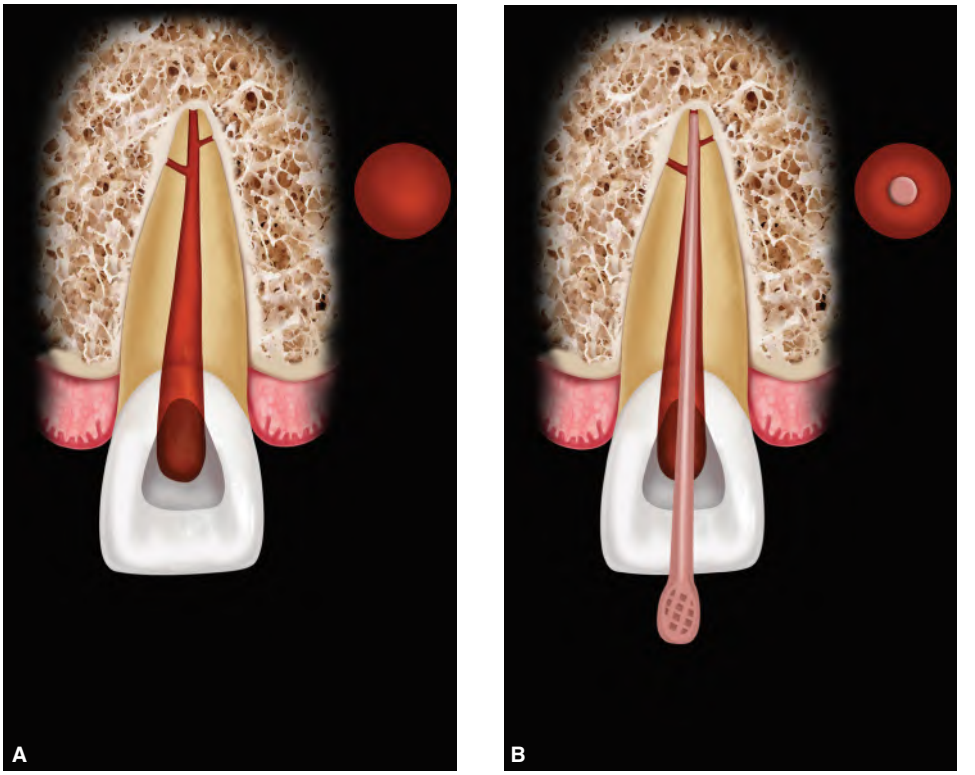

FIGURE 22-67 ***A***. Schematic illustration of the prepared root canal. ***B***. Fitting of the master cone. The cone is binding only in the apical portion of the prepared root canal.

dried with paper points, the master cone fit is confirmed with a radiograph.

A spreader is pre-fitted in the canal allowing its insertion to within 1.0–2.0 mm from the working length. Auxiliary cones are also selected to closely match the size of the spreader. The use of finger spreaders is suggested since they provide a better tactile sensation and are less likely to exhert excessive force on the root than the more traditional D-11T hand spreaders.[170–172] Spreaders are also available in nickel-titanium. These spreaders show increased flexibility,[173] reduce stress,[174] and provide deeper penetration as compared to stainless steel instruments.[175,176] The spreader should fit to within 1 mm to 2 mm of the working length (Figure 22-68) and when first introduced into the root canal alongside the master cone should penetrate up to 2 mm of the working length.[177]

After introducing a small amount of sealer in the prepared root canal, the master cone is slowly inserted to the working length. The spreader is then introduced between the master cone and the dentin walls to make room for the first auxiliary cone (Figure 22-69). The master cone is now laterally (and somewhat vertically) compacted, rotating the instrument in 180-degree motions.[178] During this movement the cone is compacted against a canal wall while, at the same time, space is created laterally to the master cone for the auxiliary cones. The spreader is then removed by rotating it back and forth as it is withdrawn from the canal and an auxiliary cone is inserted in the empty space (Figure 22-70). The spreader is now reinserted

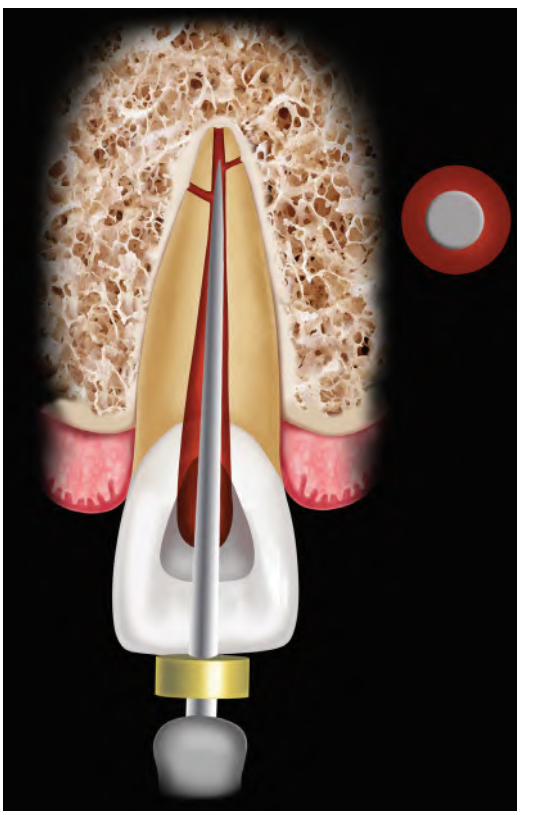

FIGURE 22-68 Spreader fit within 2 mm of the prepared canal without binding. Note the space available adjacent to the spreader.

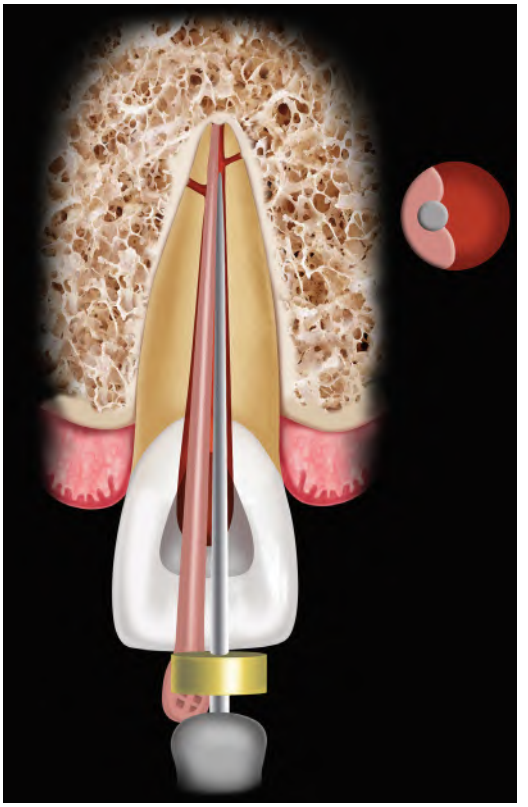

FIGURE 22-69 The spreader is introduced alongside the master cone to the proper apical depth.

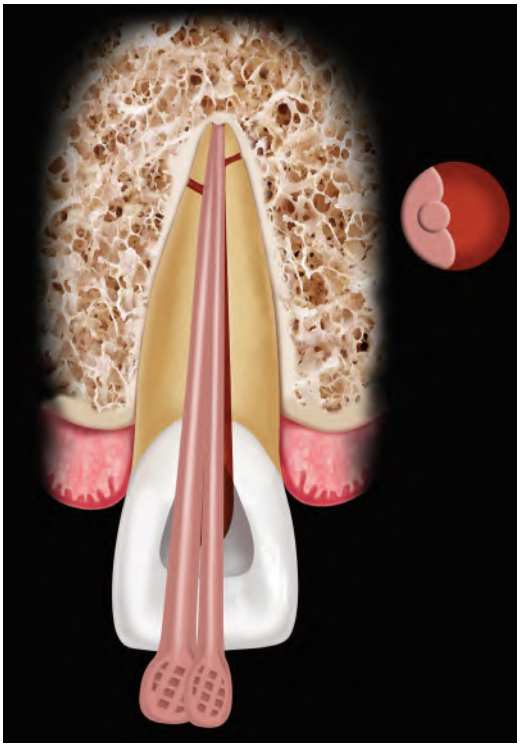

FIGURE 22-70 After careful removal of the spreader, an accessory cone, lightly coated with sealer, is introduced to the apical depth created by the spreader.

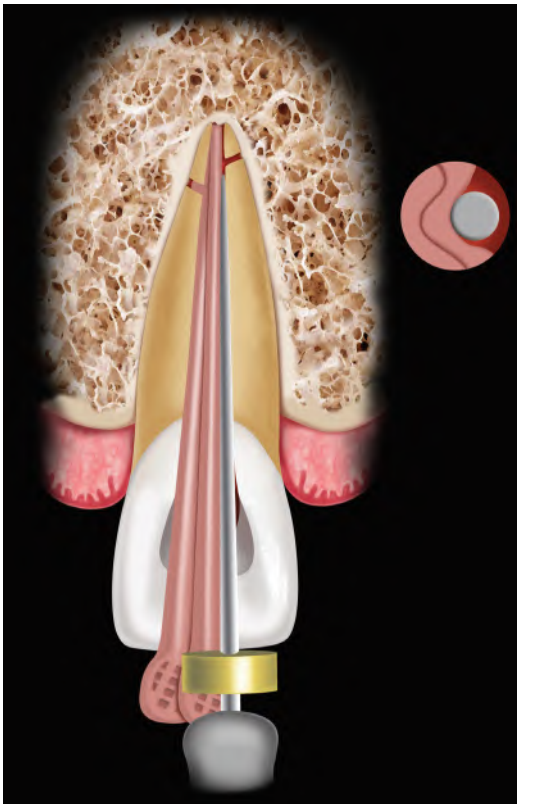

FIGURE 22-71 The spreader is reinserted to make room for an additional accessory cone.

(Figure 22-71) to make room for the next auxiliary cone. This sequence is repeated until there is no more room for insertion of the spreader or for additional auxiliary cones (Figure 22-72).

The auxiliary cones are selected based on the size of the spreader, the size of the canal, and the position of the space created inside the canal. Prior to their insertion, the auxiliary cones are lightly coated with sealer and are introduced to the same depth that the spreader has last reached. When the spreader can only penetrate 2 or 3 mm into the canal orifice, the obtutation is completed. The pressure exerted during lateral condensation should be very light because gutta-percha is not compressible, and since as little as 1.5 kg of pressure is capable of fracturing the root.[179]

Finally, the excess of gutta-percha protruding in the pulp chamber is seared off with a heat carrier and is vertically compacted with prefitted pluggers. The pulp chamber is cleaned with cotton pellets soaked in alcohol to remove any residual particles of gutta-percha or sealer.

The lateral condensation technique has several drawbacks:

1. Being a "cold" technique, the gutta-percha cones don't form a homogeneous, compact mass. The final filling will comprise of a number of gutta-percha cones separated by a greater or lesser amount of sealer,[180] depending on the clinician's profeciency with the technique.

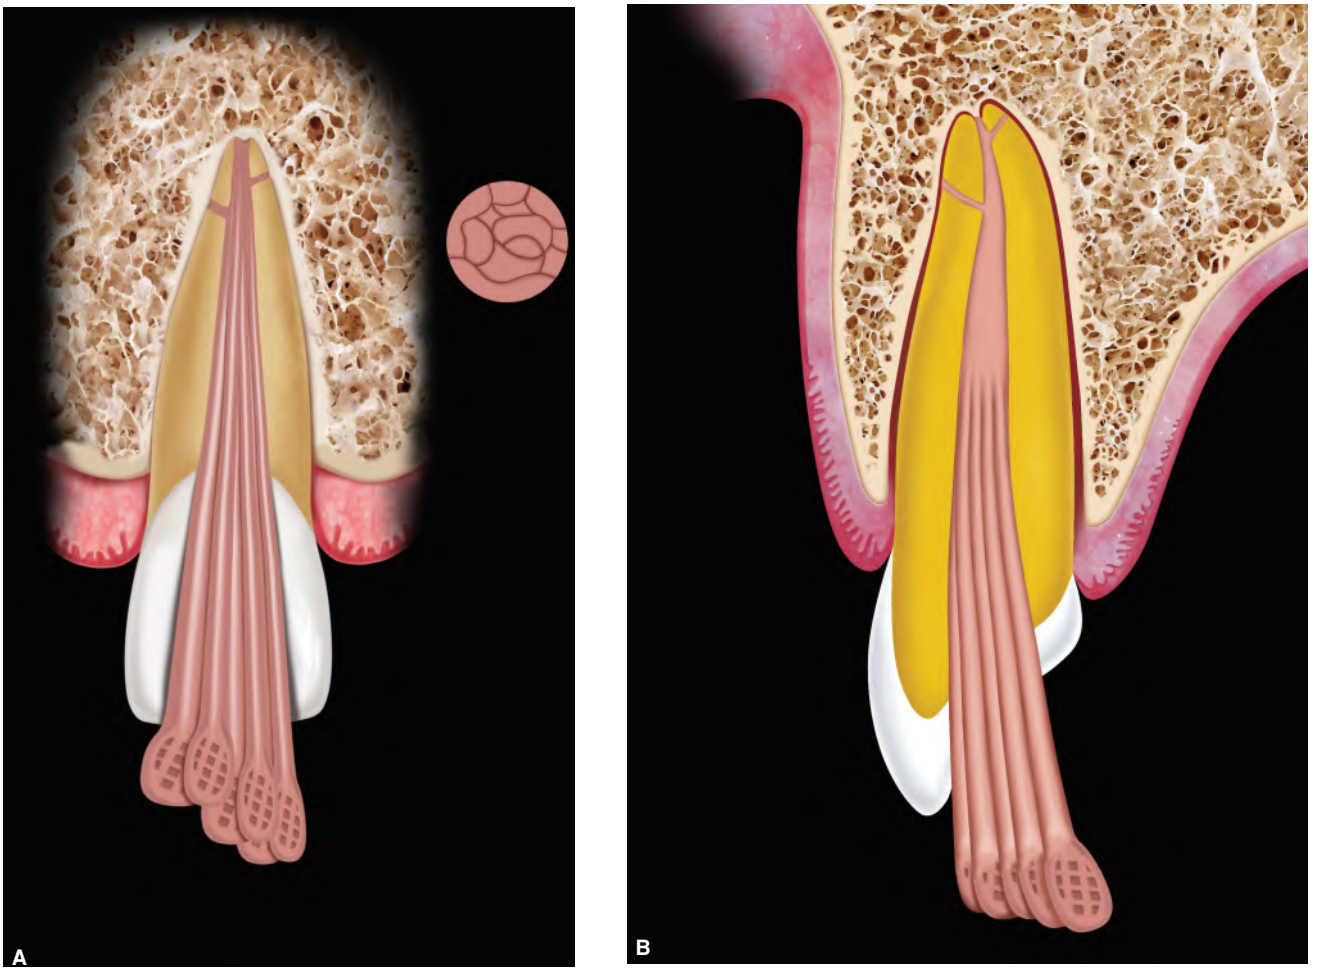

FIGURE 22-72 ***A***. The obturation process is continued until there is no more room for additional insertions of the spreader or further condensation of accessory cones (Facial view). At this point, the obturation is completed. ***B***. Proximal view of the obturated canal.

2. Filling of lateral portals of exit occurs less frequently than when vertical compaction is performed and is always constituted of sealer, not gutta-percha.[181]
3. The spreader should be placed within 1 mm to 2 mm of the working length.[88] If not carefully done, it may exhert excessive lateral forces, increasing the risk of root fracture.[182] For more details, see Chapter 14, "Vertical root fractures."
4. When considering that heat is not used, the most apical portion of the master cone does not undergo significant modification. The seal in this area is, therefore, mainly entrusted to the sealer.

In vitro studies[183,184] demonstrated that cold lateral condensation may show more volumetric leakage as compared to other techniques. Gilhooly et al.[185] found increased apical leakage to dye when teeth were obturated, with lateral condensation, *in vitro*, as compared to heated multiphase gutta-percha obturation. Other studies regarding density and fill by weight of obturation showed heat-related techniques of compacting gutta-percha to have advantages over lateral compaction as well as gutta-percha to sealer ratio.[186]

Studies by Gimlin et al.[182] demonstrated that the stress produced in the apical area is greater during lateral than vertical condensation. Furthermore, when forces are applied to create identical apical stress, the average force registered throughout the entire length of the canal, is higher in vertical than lateral condensation thereby producing forces that are uniformly distributed along the entire root surface.[181,182] On the other hand, lateral condensation may create stress only in a small area, near the tip of the spreader. Such concentration of stress may cause fractures, if the technique is not applied correctly (Figure 22-73).

While one study[187] reported a 10% greater success rate with warm vertical compaction versus cold lateral compaction in cases with apical periodontitis, not many studies support this finding but rather show no difference. For more details, see Chapter 33, "Outcome of endodontic therapy."

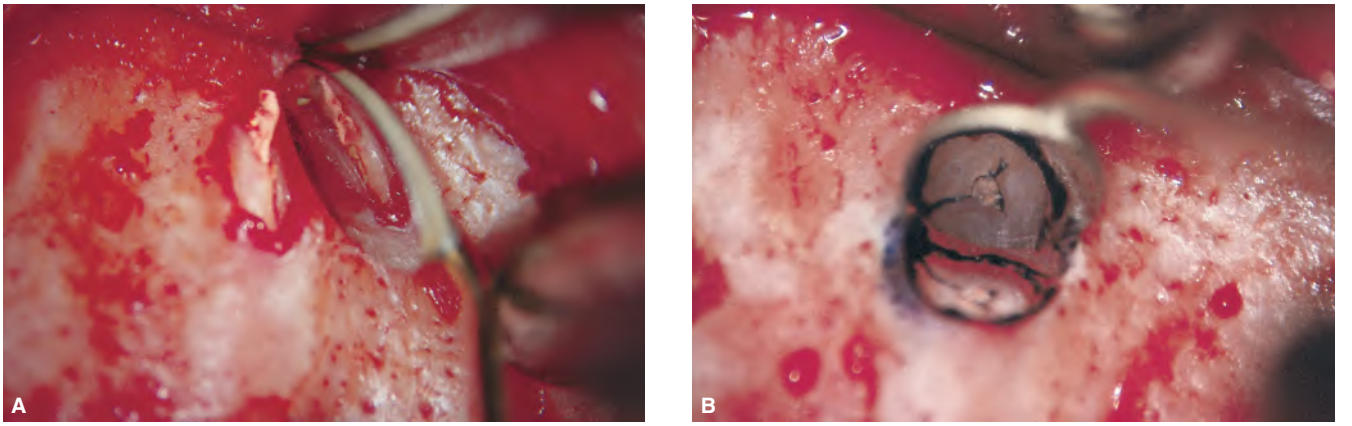

FIGURE 22-73 ***A***. Intraoperative photograph taken during surgical endodontic treatment in a maxillary first premolar, previously obturated by lateral condensation. The clinician probably used excessive force during obturation. An apical vertical root fracture is present. ***B***. After removal of the apical fractured fragment, a fracture line is still present on the bevel of the root (stained with methylen blue). The tooth had no coronal probing, confirming that the fracture was apically induced.

THERMOPLASTIC GUTTA-PERCHA TECHNIQUES

The thermoplastic gutta-percha technique was introduced by Yee et al.,[188] Torabinejad et al.,[183] and Marlin et al.[189] It consists of injecting gutta-percha, heated by an electrical device, into a prepared root canal. The instrument has a gun-like shape (Figure 22-65) whose cartridges are small gutta-percha cylinders that are heated to a temperature regulated by the user. Exerting pressure on the "trigger" activates a piston that presses the gutta-percha toward the tip of the instrument. The gutta-percha is then conveyed through a thin silver needle that, when appropriately bent, allows its operation in root canals of various sectors of the mouth.

This technique uses sealer that also lubricates the plastic material on its path toward the apex,[148] in addition to ensuring a better seal.[190] Yee et al.[188] demonstrated that it is possible to obtain dense obturation, without entrapped air bubbles, if the technique is accompanied by the use of a sealer. They also demonstrated the presence of filling material in lateral canals, in addition to a good apical seal.

Torabinejad et al.[183] observed that, in this technique, the gutta-percha adapts well to the dentin walls. The adaptation was similar to that obtained with other conventional techniques, apart from the presence of some small voids, that were not visible radiographically. Weller et al.[191] observed that the thermoplasticized injectable technique exhibited the best adaptation to the prepared root canal walls, when compared to Thermafil and cold lateral condensation. Marlin et al.[189] showed that this technique produces good clinical results and a significant reduction in working time. The same authors also emphasized the importance of combining gutta-percha with a sealer, also suggested by subsequent studies,[192–194] and warn against the danger of extrusion of material beyond the apex.

A drawback of this technique is that it lacks good and predictable apical control during obturation.[195–197] The gutta-percha injected from the syringe is already warm and plastic. Moreover, the user does not have precise control on either the pressure that is exerted or the amount of gutta-percha being introduced into the root canal. To prevent it, the operator must form, during the shaping procedure, a good "apical barrier"[198] to avoid extrusion of excessive material into the periodontium.[199] The needle of the syringe should be positioned no less than 4–6 mm from the end of the preparation, otherwise, a high percentage of underextended obturation will result.[200]

The technique may be confidently used only when there is no risk of introducing material beyond the apex, in the following circumstances:

1. Back-packing, to fill the coronal aspects of the canal following the initial placement and compaction of gutta-percha in the apical portion of the canal.
2. Unnegotiable canals where it is necessary to fill the canal space as much as possible, via coronal approach, prior to surgical root-end filling (Figure 22-74).
3. In partially unnegotiable canals when sometimes, thermoplastic gutta-percha succeeds in obturating portions of canal that had remained unnegotiable to endodontic instruments. In many cases, endodontic surgery or root amputation may not be necessary[201] (Figure 22-75).
4. After closure and maturation of the root following apexification (Figure 22-76).
5. After obtaining an apical barrier with MTA[202] (Figure 22-77).
6. Root canals with internal resorption, after the apical third of the root canal has been obturated in the traditional manner (Figure 22-78).
7. Root canals in which, due to inadequate previous shape, the operator is unable to fit a traditional gutta-percha cone with the tug-back in the appropriate position

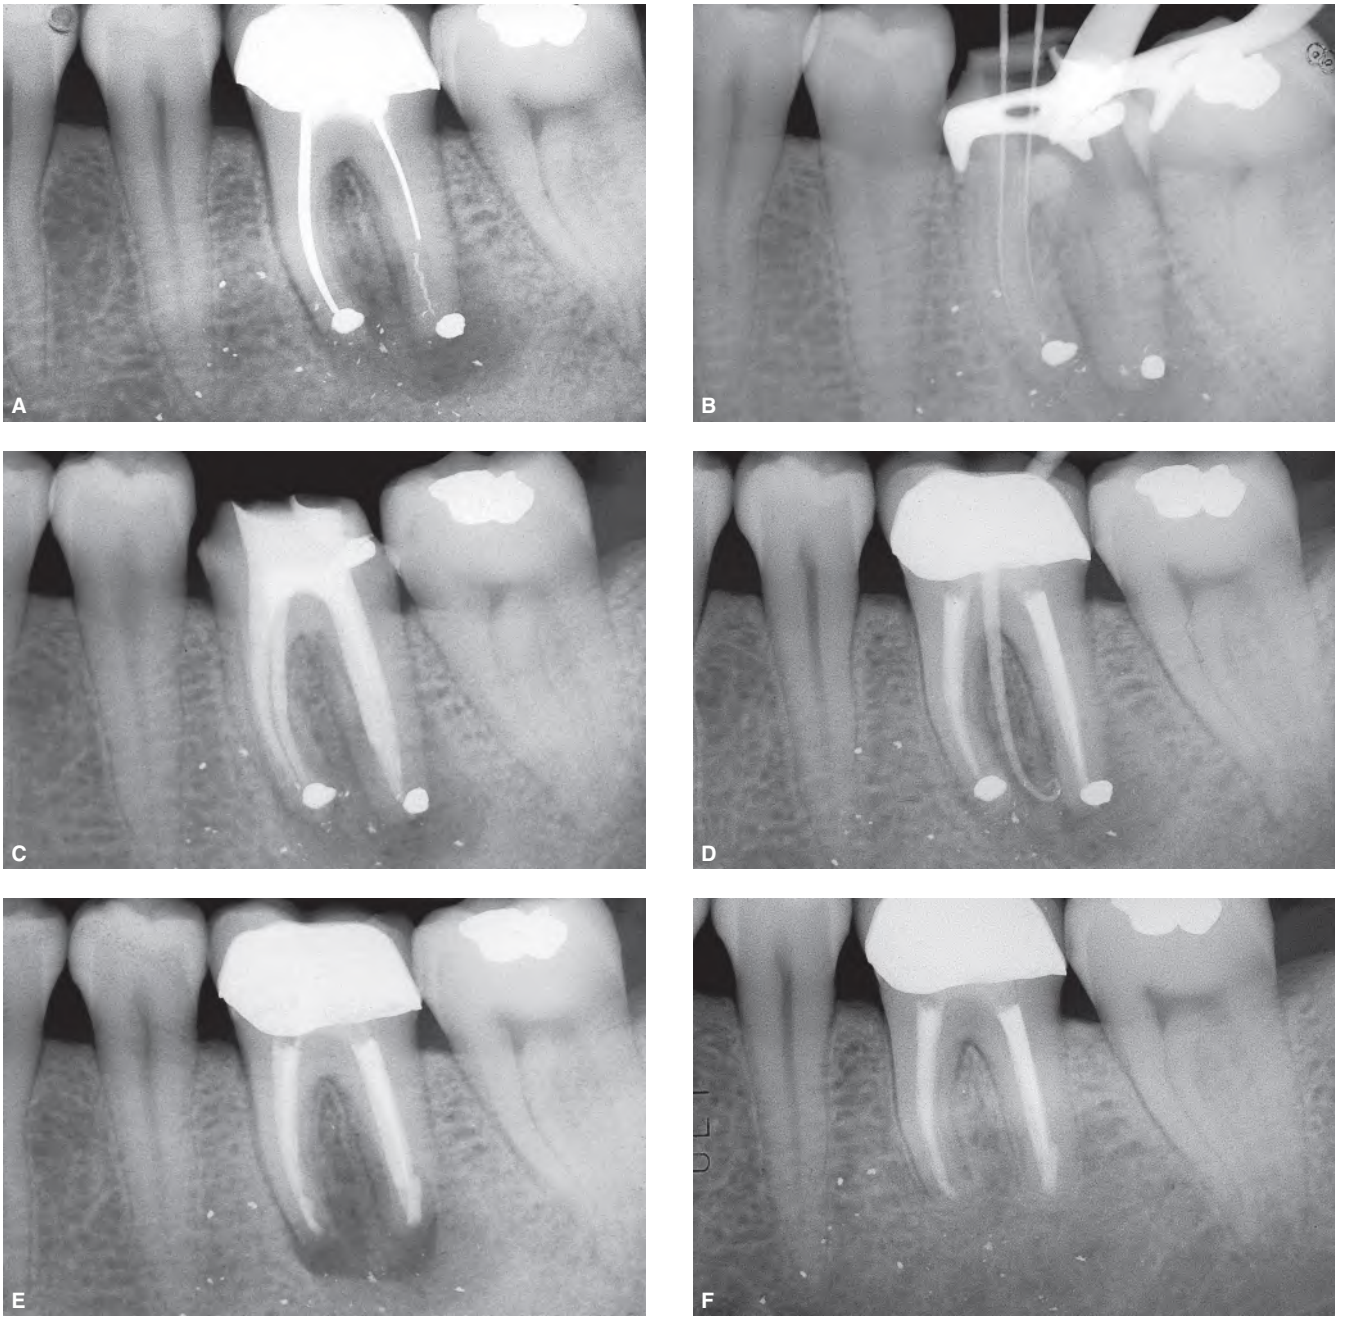

FIGURE 22-74 ***A***. Preoperative radiograph of a mandibular left first molar. The tooth was obturated with silver cones. A separated instrument is also present in the distal root. ***B***. Intraoperative radiograph during non-surgical retreatment. The silver cones and the separated instrument were successfully removed. ***C***. Immediate postoperative radiograph. ***D***. Two-year recall radiograph showing a healing of the bony lesion.

(Figure 22-79), or root canals in which, due to unusual anatomy or presence of a ledge, it is very challenging to introduce a traditional gutta-percha cone (Figure 22-80).

8. Root canals where a perforation is present in the apical third of the root (Figure 22-81).
9. During endodontic surgical procedures,[203] applying obturation of the root canal from the apical end, before positioning a root-end filling (Figure 22-82).
10. In non-surgical retreatment of surgical failures (Figure 22-83).

Another limitation of this technique is the high temperature that the gutta-percha reaches within the syringe (160°C or more) before being introduced into the root canal. Techniques using heat and compaction, for example, the Schilder's warm gutta-percha technique, require substantially less heat (45°C to 55°C).[151, 204]

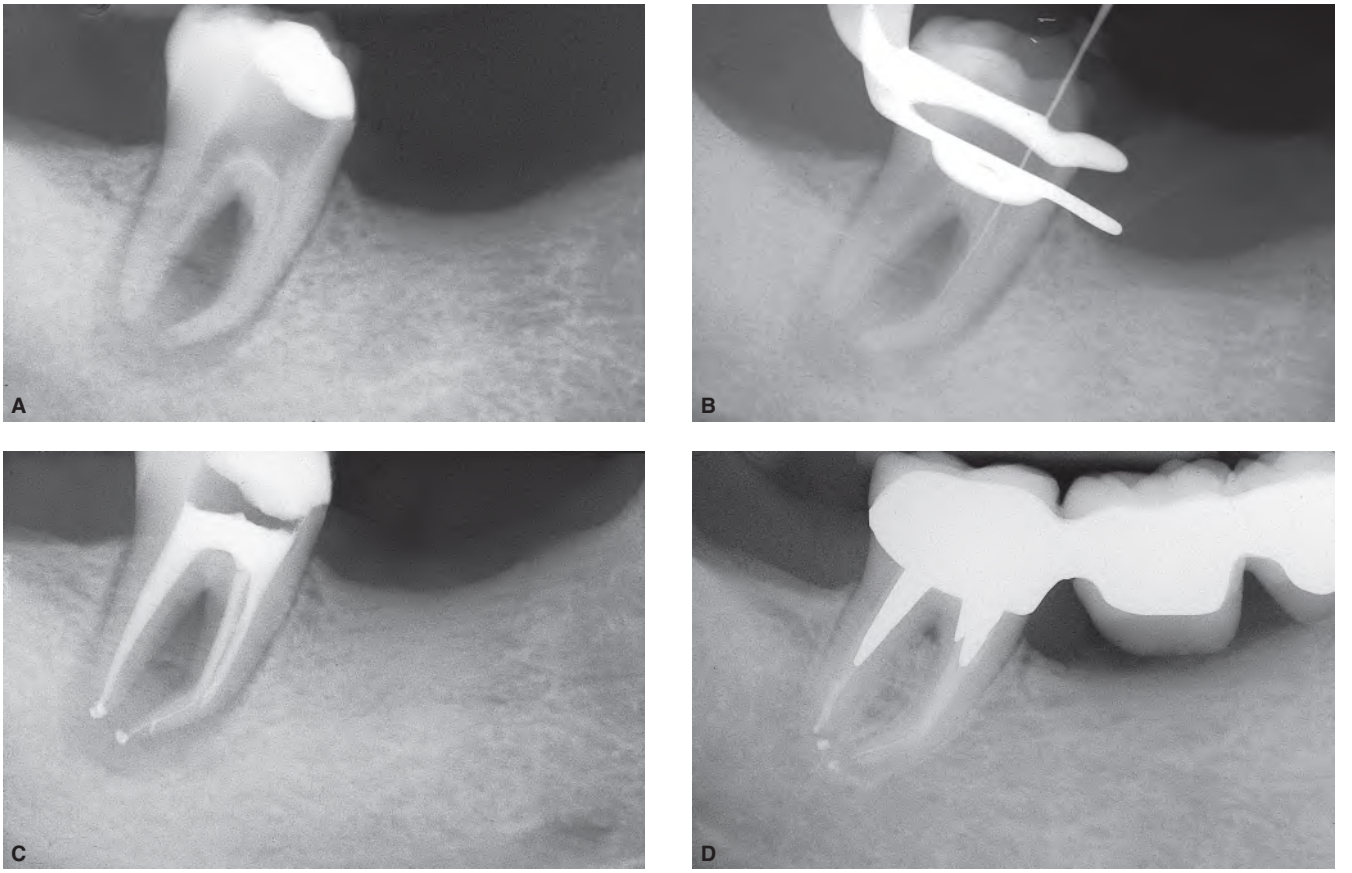

FIGURE 22-75 ***A***. Preoperative radiograph of a mandibular right second molar. The patient was referred for treatment after the distal canal had been prepared and the mesial canals were only partially negotiable. ***B***. A ledge was present at the beginning of the curvature of the mesial canals. ***C***. Postoperative radiograph. The distal canal was obturated with warm gutta-percha, and the mesial canals with thermoplastic gutta-percha. Note the filling of the non-instrumented portion of the mesial canals. ***D***. Three-year recall radiograph showing successful results.

Commercial gutta-percha is found in the "beta" molecular configuration at 37˚C and begins to transform into the "alpha" configuration when heated to 42˚C–49˚C. It then passes to an amorphous phase when heated to 53˚C–59˚C.[205] During cooling, amorphous gutta-percha crystallizes (with a consequent diminution of volume) and returns to the "beta" configuration between 37˚C and 40˚C, without passing through the "alpha" configuration, unless it is slowly cooled. Under clinical conditions, cooling of thermoplastic gutta-percha occurs rapidly. Consequently, there is a diminution of volume in the recrystallization phase.[204] Therefore, it is important that vertical pressure be applied during cooling to compact the gutta-percha and compensate for its volumentric diminution.[151] Studies[198–208] have not demonstrated any damage to the periodontal tissues. This is because the heated gutta-percha cools rapidly once introduced into the root canal.[209]

Voids may be formed while using this technique. In order to avoid them, the operator's hand should be driven coronally by a light pressure exerted by the gutta-percha as it accumulates in the root canal (passive injection). A steady force can push the material beyond the apex. On the other hand, if the gun is withdrawn coronally too quickly, voids can be formed within the obturation. Another cause for voids formation is the injection of gutta-percha that is not sufficiently warm or plastic.

To avoid voids or entrapment of air during obturation, the following is recommended:

- Before injecting into the canal, squeeze the gutta-percha out of the needle, so that the material introduced in the canal comes directly from the heating chamber and, therefore, is warmer than the material inside the needle.
- Insert the needle into the canal orifice and wait for a few seconds before injecting. The needle will lose some heat after insertion, so it is necessary to wait until it becomes warm again.
- Inject small amounts of gutta-percha, no more than five millimiters each time. Only 5 mm of gutta-percha can be effectively compacted at a time.

Michanowicz et al.[210] introduced a device for thermoplastic gutta-percha at a temperature of 70˚C (Figure 22-84). The instrument resembles the Peripress syringe for intraligamental anesthesia. It is loaded with carpules of gutta-percha with needles and placed in a device that externally heats the carpule and the needle to 70˚C. The gutta-percha used

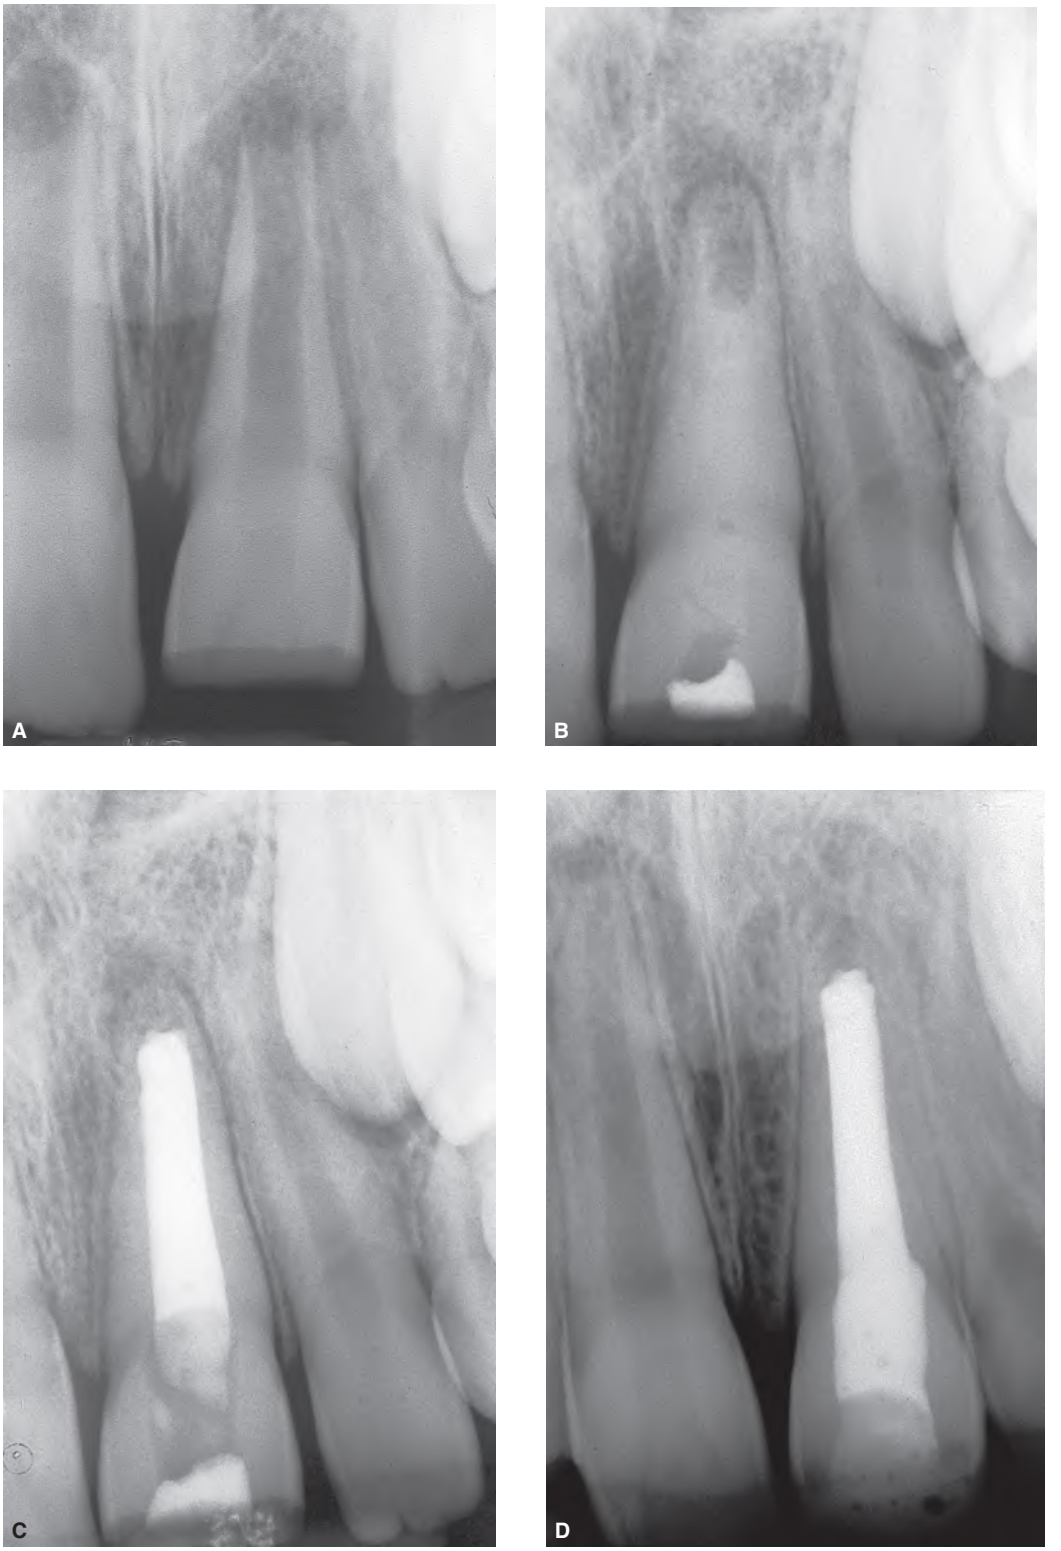

FIGURE 22-76 ***A***. Preoperative radiograph of a maxillary left central incisor with an immature apex and necrotic pulp in a 9-year-old patient. ***B***. Three millimeters of MTA were placed at the foramen, using the apical barrier technique. ***C***. 2-year recall radiograph showing successful results.

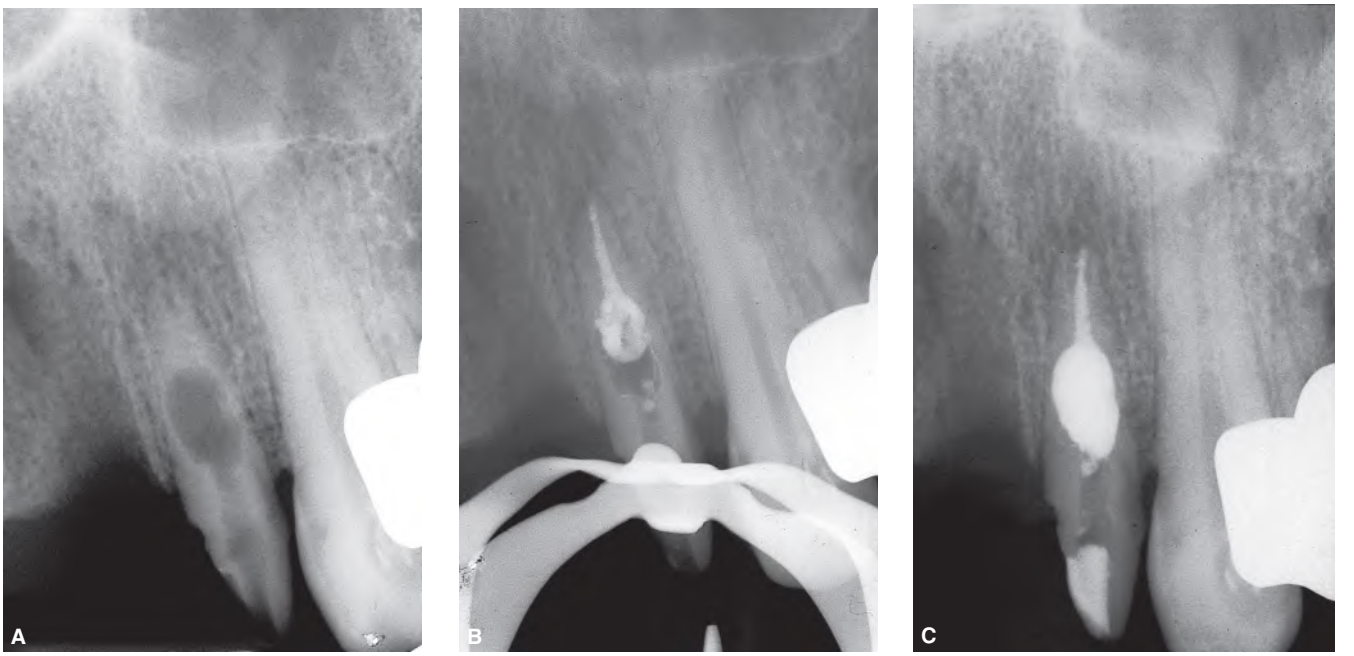

FIGURE 22-78 ***A***. Preoperative radiograph of a maxillary left lateral incisor with a large internal resorption defect. Once this type of resorption is diagnosed, it is necessary to intervene immediately because the lesion tends to progress. ***B***. Intraoperative radiograph of the apical condensation. ***C***. Postoperative radiograph. The area of internal resorption has been filled with thermoplastic gutta-percha.

in this case differs from other commerical gutta-percha by its higher paraffin content. This contributes to rendering it malleable at a lower temperature than that required by the Obtura or the B&L syringe. On the other hand, it is more difficult to compact.

Michanowicz et al.[211] suggested that this technique can be more successful in filling the dentinal tubules of the coronal and middle thirds of the canal with gutta-percha. However, in contrast to the preceding instrument, that was ready for use with one minute after being turned on, and

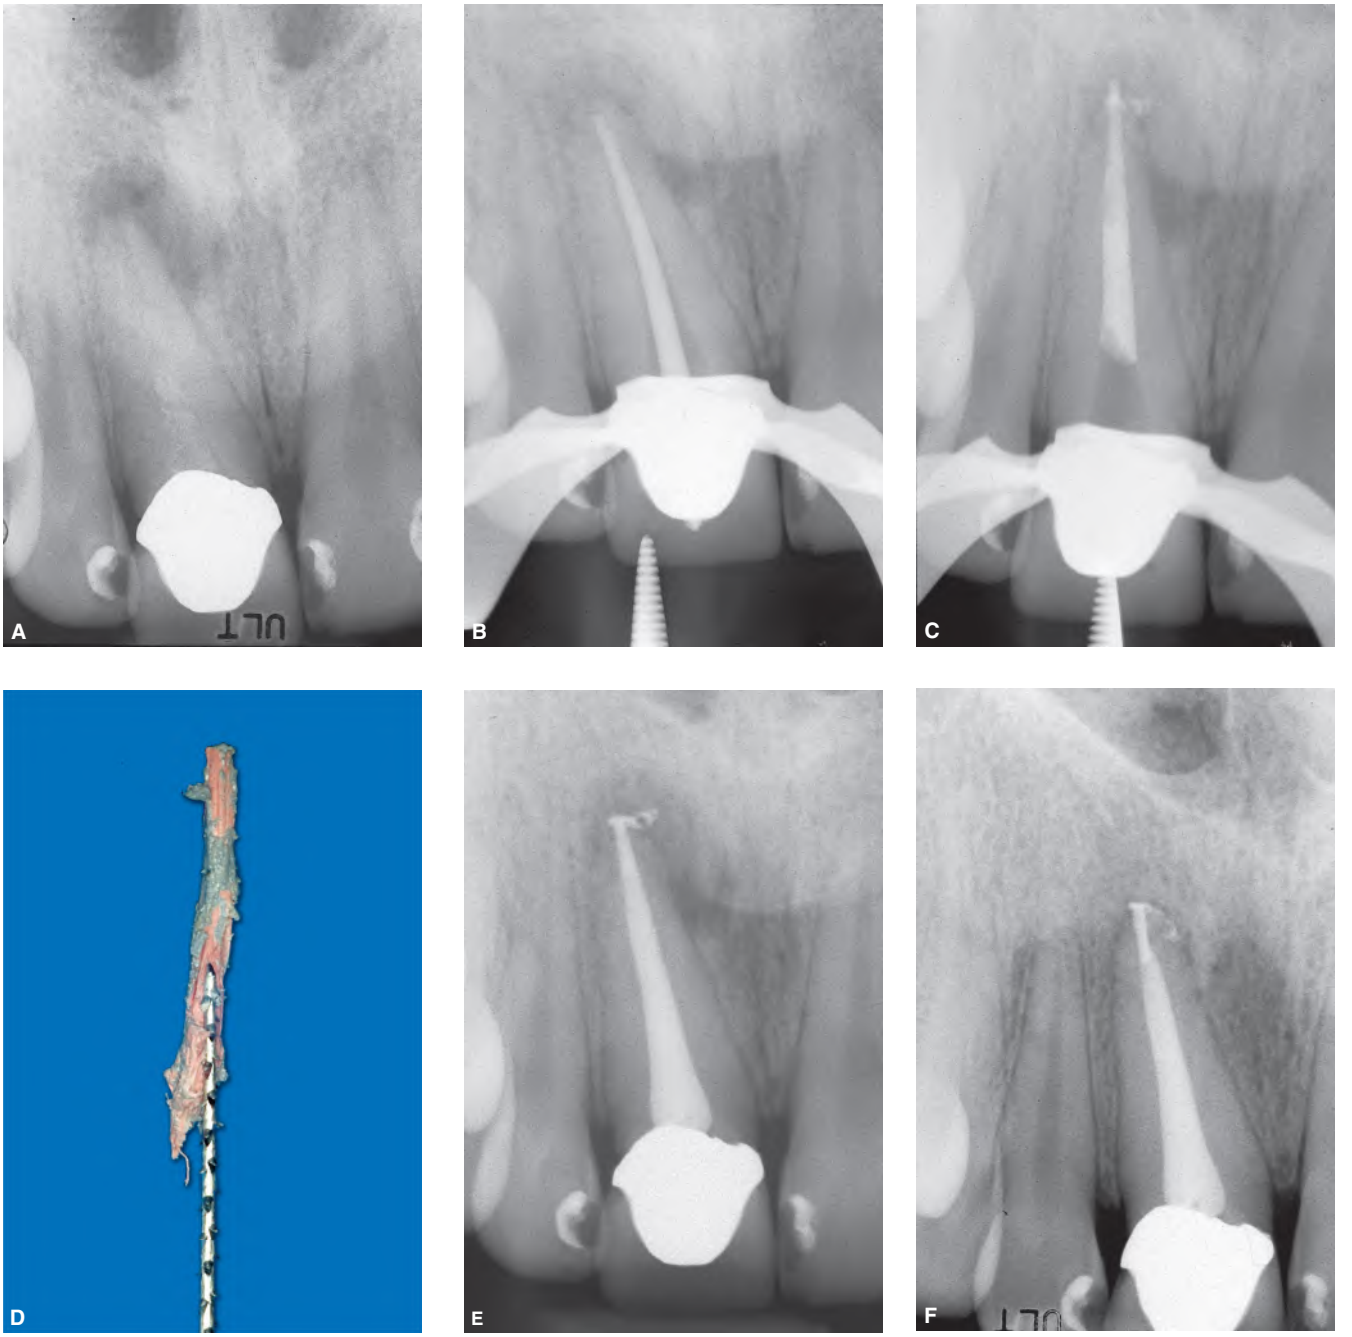

FIGURE 22-79 Owing to a previous improperly performed shaping, the master cone had a tug back only in the middle third of the canal, resulting in an inevitable extrusion of filling material beyond the apical foramen. The extruded gutta-percha was removed and the obturation completed with an Obtura syringe, using the sectional technique. ***A***. Preoperative radiograph. ***B***. Radiograph of the cone fit. Clinically, the cone presented a tug-back. ***C***. Evidently, the tug-back was in the middle third of the canal. ***D***. Using a large barbed broach, the gutta-percha cone was removed from the canal. ***E***. Postoperative radiograph following obturation with the sectional technique of thermoplastic gutta-percha. ***F***. Two-year recall radiograph showing successful results.

could have been left in the unit constatntly, this instrument requires heating for 15 minutes, and the syringe cannot remain in its hub for more than 4 hours.[199] Furthermore, once the syringe has been removed from the heating device, it can only be used for about one minute, after which the gutta-percha cools off and is no longer flowable. Several minutes are required to re-heat it.

The first commercially available thermoplasticized gutta-percha system was the Obtura system. Recently, another device became available on the market, the B&L Beta 2, that appears to be easier to handle as it is cordless. It is fast in reaching the selected temperature and has a silver needle that can be rotated and oriented without any risk of breakage. It uses the same type of gutta-percha pellets as the original

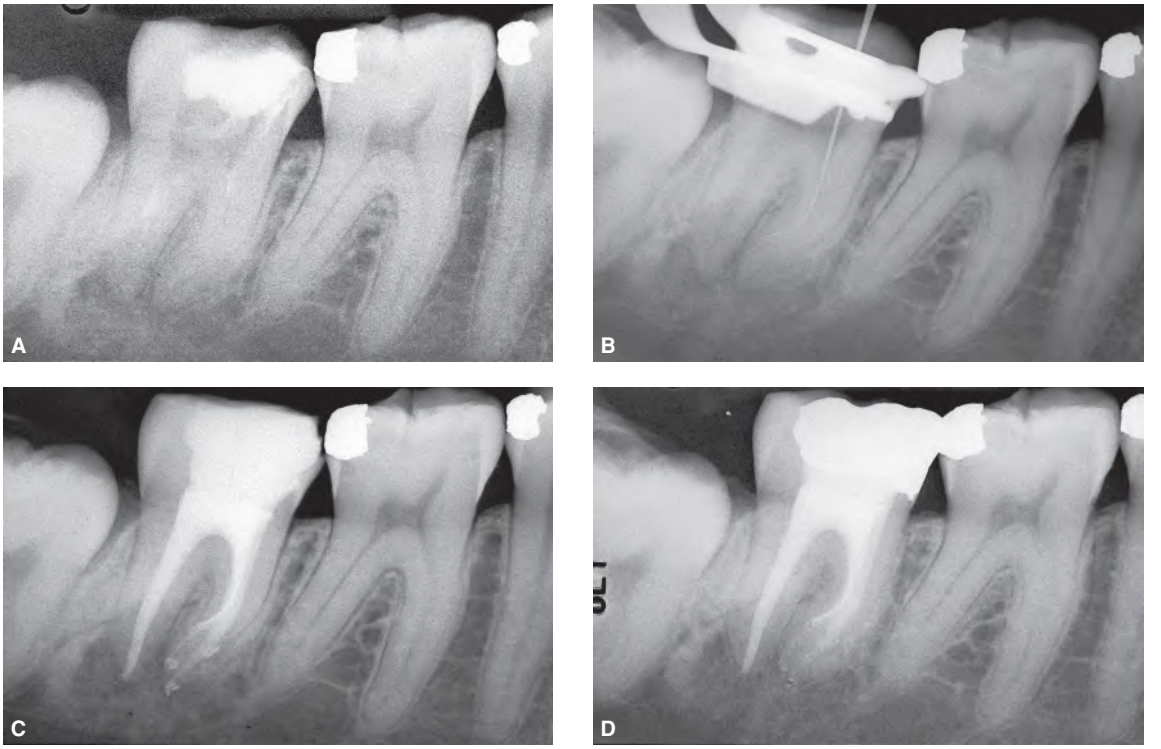

FIGURE 22-80 ***A***. Preoperative radiograph of a mandibular right second molar requiring retreatment. ***B***. A marked bayonette curvature of the mesiolingual canal was detected. The apical third of this canal was cleaned and shaped only with #08 and 10 K-type files. ***C***. Postoperative radiograph. The distal and mesiobuccal canals have been obturated using the Schilder's warm gutta-percha technique, while the mesiolingual canal was filled with thermoplastic gutta-percha. ***D***. Three-year follow-up radiograph showing successful results.

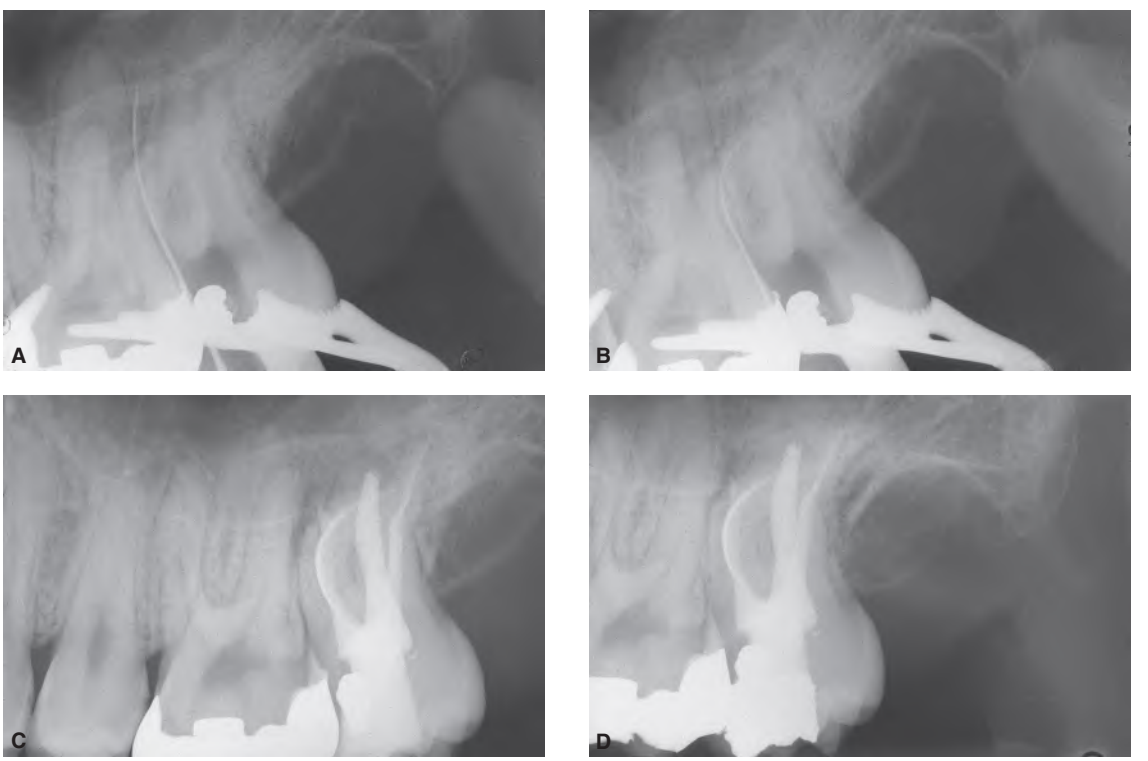

FIGURE 22-81 ***A***. A #20 file demonstrating the presence of a root perforation. ***B***. Using a #08 file, the original path of the canal was located. Cleaning and shaping can therefore be completed. ***C***. Postoperative radiograph. The perforation was obturated as if it were a lateral canal, using thermoplastic gutta-percha. ***D***. One-year follow-up radiograph showing successful results.

FIGURE 22-84 The Ultrafil syringe (Coltene, Whaledent, Cuyahoga Falls, Ohio, U.S.A.).

Obtura. The temperature varies from 150°C to 230°C, and the needles are of different sizes: 20-, 23-, or 25-gauge. Like the Obtura, it can also be used with Resilon pellets (see later in this chapter). Lower temperatures are required to thermally soften Resilon.

Other high-temperature thermoplastcized gutta-percha systems are currently available; Elements System (Sybron Endo, Orange, California) (Figure 22-65C) and the Calamus System (Tulsa Dental Products, Tulsa, Oklahoma) (Figure 22-65D). These units use preloaded gutta-percha cartridges, and the heated material is extruded by an activation button.

In the author's opinion, these units have a few disadvantages when compared to the use of syringes like Obtura or B&L Beta 2. For example:

- The cartridges are more expensive compared to the simple gutta-percha pellets.
- The operator needs to electrically extrude the piston from the used cartrige, insert a new cartrige, and wait unit the material is ready for use. This is more time consuming.

The Ultrafil (Hygienic Corp., Akron, Ohio) is a low-temperature thermoplasticized gutta-percha delivery system that contains prepackaged cannulas with attached 22-gauge needles. The gutta-percha is prepared in the alpha phase

form so that it softens in the heating unit at temperatures between 70°C to 90°C. According to Lipski,[212] the temperature transmitted to the periodontal ligament with the Ultrafil system is below the level that can cause damage or injury.

THERMOMECHANICAL COMPACTION OF GUTTA-PERCHA

This technique was first introduced by McSpadden about 40 years ago. In this technique a new instrument was used to condense the gutta-percha—the McSpadden compactor. It resembled a reverse Hedstrom file, having the blades turned towards the tip instead of towards the shaft. The compactor, mounted on a 1:1 contra-angled handpiece, was inserted in the canal next to a gutta-percha cone and rotated at up to 20,000 rpm. Heat generated by friction softened the gutta-percha and the blades pushed the material apically. This allowed the adaptation of the obturation material three dimentially to the canal walls.[213–217]

Later, McSpadden developed a new technique, combining the principle of the thermomechanical compaction with new materials. The previous compactor was replaced with Nickel Titanium Condensers, of different diameters and tapers, and with "alpha phase" gutta-percha. This gutta-percha was preplasticized in a MicroSeal heater and then introduced into the canal with a rotating instrument, at lower speeds (1,000 rpm to 4,000 rpm) than the original McSpadden Compactor. This system uses MicroSeal gutta-percha master cones and a specially formulated Alpha Phase gutta-percha (low-fusing or ultra-low-fusing) in a cartridge, that is heated in the MicroSeal heater. The NiTi condenser is coated with heated gutta-percha and inserted into the canal next to the master cone. The rotating instrument generates heat from the friction that, in turn, thermally softens the master cone. It also flows laterally, by centrifugal force, into all areas of the canal.[218] The material is therefore pushed both apically and laterally, providing a three-dimensional obturation of the root canal system.

The most important characteristics of this technique are:[205,219–221]

- Lower point of fusion of the gutta-percha
- Longer working time
- Less shrinkage during cooling
- High fluidity of the gutta-percha allowing for a good adaptation of the material to the canal complexities.[222]

On the other hand, it requires good apical control of the obturating material.

CARRIER-BASED GUTTA-PERCHA

The Thermafil obturation technique was developed by W.B. Johnson in 1978.[223] Originally, the first Thermafil obturators were stainless steel K-files covered with a uniform layer of gutta-percha. The obturators were then heated and placed in the canal, already coated with sealer, and sectioned at the level of the pulp floor. The final obturation was characterized by the presence of a stainless steel instrument surrounded by gutta-percha and sealer, with consequent difficulties in retreatments, preparation of a post space or surgical root-end filling. Later, the Thermafil obturators were modified and the K-file was replaced by a grooved plastic carrier made from a biocompatible radio-opaque plastic. The purpose of the groove was to increase flexibility and facilitate retreatment.

The product is marketed today in different versions based on the size and shape of the root canal system.[224] Classic Thermafil obturators were available in 17 sizes with tip diameter ranging from 0.20 to 1.40 mm and taper that varied between .04 and .05. Later, every rotary shaping system has introduced different obturators, such as GT and GTX obturators (Tulsa Dental Products, Tulsa, OK, U.S.A.), designed to be in conjunction with GT or GTX rotary files; ProTaper obturators (Tulsa Dental Products), to be used in conjunction with ProTaper Universal rotary files; WaveOne obturators (Dentsply Maillefer, Ballaigues, Switzerland), and similar systems.

Recently, the plastic carrier was replaced with a gutta-percha carrier and the obturator is now called GuttaCore (Dentsply Tulsa Dental, Tulsa, Oklahoma). This product has the carrier made from a cross linked gutta-percha that is intimately adherent to the surrounding gutta-percha. The advantage is eliminating the existing gap between the carrier and the gutta-percha. GuttaCore obturators are available to be used in conjunction with ProTaper Next and ProTaper Gold.

Thermafil Gutta-percha

The Thermafil gutta-percha covers the carrier for approximately 16 mm overextending the tip of the core by about 1 mm. It is hard and friable in the solid state. When heated, it becomes sticky, shiny, and expanded, assuming excellent adhesive and flow characteristics.[225,226] Because of its properties, in particular its low viscosity, Thermafil gutta-percha was initially considered as Alpha gutta-percha (compared to the Beta gutta-percha of conventional cones), elastic and malleable in the solid state but more viscose and less adhesive once thermoplasticized.[219,221] However, fusion temperature analysis[221] for Thermafil gutta-percha shows a fusion temperature of about 56°C, that is 14°C less than the fusion temperature (70°C) required from Alpha gutta-percha.[219,221] Furthermore, once plasticized, Thermafil gutta-percha resolidifies after 90 seconds, reassuming the initial characteristics of friability and hardness. However, if reheated again, it does not show any changes in physical properties. It therefore appears then that Thermafil gutta-percha is not a stereo isomeric crystalline Alpha form but has the physical behaviour of the Alpha type.[224] Due to its low viscosity, Thermafil gutta-percha has a better capacity to penetrate dentinal tubules (Figure 22-85).[226] It should be noted that the clinical significance of obturating dentinal tubules with gutta-percha has not yet been demonstrated. It may play a role in blocking the ingress of microorganisms and their byproducts[227] and

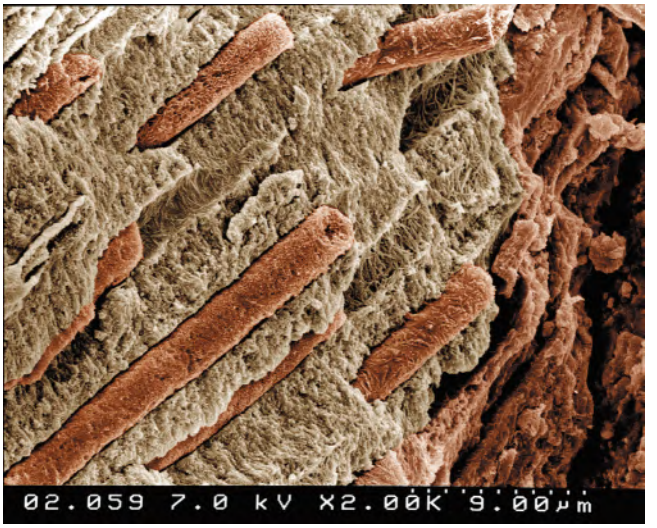

FIGURE 22-85 Scanning electron microscopy analysis of extracted teeth obturated with Thermafil without sealer (×1000). Penetration of Thermafil gutta-percha into the dentinal tubules is evident. (Courtesy of Dr. Giuseppe Cantatore, Rome, Italy.)

possibly improve the seal of the obturation. However, this remains to be further investigated.

Size Verifiers

The best method to select the correct size of Thermafil is to remove the gutta-percha from the plastic carrier and check the plastic carrier itself inside the root canal. The plastic carrier that stops about 1 mm short of the working length should be selected and checked radiographically. However, this is not possible when using the new GuttaCore system, since the gutta-percha carrier is intimately adhered to the surrounding gutta-percha so that it cannot be removed. In such cases, a size verifier is used. This comprises of a nickel titanium instrument, similar to a hand Profile, with a non-cutting tip and radial lands.[224]

The Oven

The Thermaprep oven enables one to thermoplasticize two Thermafil obturators in a few seconds (Figure 22-86). It requires inserting the obturators in the necessary inserts, selecting the diameter of the obturator and initiation of the heating process. Consequently, the thermoplasticized gutta-percha is ready for use in a few seconds. Once the obturators have been removed from the oven, the operator should check if the gutta-percha is ready for use by appearing expanded, shiny and sticky. If not, the heating cycle should be repeated.[224]

Blum et al.[228] studied the condensation forces that develop during Thermafil obturation and found that they were lower than those produced during lateral condensation, vertical condensation and System-B. Dulak et al.[229] and Goldberg et al.[230] compared Thermafil obturation with other techniques regarding its capacity to obturate lateral canals and found that Thermafil was equal to vertical condensation and System-B, but significantly superior to lateral condensation, warm lateral condensation and Obtura.

FIGURE 22-86 The heater for thermoplastisizing Thermafil obturators (Dentsply Tulsa Dental Specialties, Tulsa, Oklahoma, U.S.A.).

The relationship between gutta-percha, sealer, carrier, and the canal walls in Thermafil obturation has been the subject of numerous "morphological" studies.[191,231–238] The results of these studies show that the Thermafil technique has a good ability to completely adapt to the canal walls, comparable to the Obtura II injectable technique and superior to the lateral condensation.[191] Coronal micro-infiltration tests indicated that Thermafil behave better than cold lateral condensation, especially in the short term. After four months the two techniques tend to show the same results.[239–241] Other studies suggested that Thermafil provided a better seal than laterally condensed gutta-percha and was similar to vertical compaction (Figure 22-87).[241,242]

Regarding apical leakage, the following should be noted:

- Thermafil obturation, notwithstanding the excellent characteristics of its gutta-percha, requires sealer, otherwise a drastic increase in microleakage results.[224] The role of the sealer is twofold: (1) to lubricate the canal walls aiding the flow of the gutta-percha, that otherwise tends to adhere to the dentin, and (2) to compensate for the cooling contraction of the gutta-percha.[191,243,244]
- Thermafil obturation appears to exhibit superior results when compared to laterally condensed gutta-percha.[238,245–251]
- Compared to warm vertical condensation and System-B, the Thermafil technique behaves equally well; the difference between the three methods was not found to be statistically significant.[252–254]
- Temperatures produced by heated carrier-based gutta-percha were found to be at safe levels and did not cause damage to bone and periodontal ligament.[255,256]

Thermafil obturation is best indicated in narrow, curved canals where spreaders, heat carriers, and pluggers are difficult, or impossibile, to use in the apical one-third. On the other hand, the technique should not be used in cases of large, short root canals, open apices, bi- or tri-forcations of the middle and apical thirds of the root canal, internal resorption or anatomical variations like C-shaped canals.

SYSTEM B TECHNIQUE

The System B technique or "single wave of condensation technique" is an aditional heat-assisted gutta-percha compaction technique introduced by Buchanan in 1996.[257] It can be considered a variation of the Schilder technique, where instead of using a heat carrier and cold cylindrical pluggers only one tapered heated plugger is used during the down-packing. The hydraulics that develop here are higher then in the Schilder technique because of the wedging effect produced by the heated tapered plugger introduced in the gutta-percha cone in the tapered preparation of the root canal.

Pommel and Camps[254] studied, *in vitro*, the apical leakage of this technique and found that System B was as effective as vertical condensation and Thermafil in resisting apical leakage.

After one month, System B, Thermafil and vertical condensation showed less leakage than lateral condensation and single cone technique. Jacobson et al.[258] evaluated the coronal bacterial leakage in teeth obturated with the System B continuous wave of condensation technique and compared it to Obtura II backfill, and lateral condensation technique. The results indicated that microbial coronal leakage occurs more quickly when using lateral condensation than when the System B continuous wave of condensation technique and Obtura II backfill were used.

Goldberg et al.,[259] using simulated lateral canals, found that a greater number of lateral canals were obturated using Ultrafil, Thermafil and System B + Obtura II in comparison to the hybrid technique, Obtura II or lateral compaction of gutta-percha. The difference was statistically significant.

Romero et al.[260] studied the heat transfer to the periodontal ligament during root obturation. They found that the "Continuous Wave Technique," when performed with a controllable heat source, such as System B, causes only negligible temperature increases in the PDL. Guess et al.[261] studied the effect of System B plugger depth on gutta-percha filling adaptation to the canal walls using the continuous wave technique, and found that the best results were obtained when pluggers were used at a depth of 3 mm to 4.5 mm from the working length.

Lea et al.[262] compared quantitatively the density of standard cold lateral gutta-percha compaction and warm vertical compaction using the continuous wave of condensation technique. They concluded that warm vertical compaction, using the System B, resulted in a greater gutta-percha fill by weight, as well as a significantly greater density compared to standard cold lateral gutta-percha compaction.

Galvao Barbosa et al.[263] compared the frequency, location, and direction of accessory canals filled with the Schilder technique and with System B and didn't find any difference between the two filling techniques.

CHEMICAL SOFTENING OF GUTTA-PERCHA

This technique was described by Callahan and Johnston at the beginning of the last century. It used chloroform to chemically soften gutta-percha. The technique is still practiced today with various types of chloroform sealers. Gutta-percha particles are added to chloroform to produce a sealer (chloropercha), that has the same color as gutta-percha. The mixture can then be used as a sealer with gutta-percha cones for obturation of the canal. There is more shrinkage with the chloroform solvent techniques and this often translates into leakage, with the material pulling away from the canal walls as it shrinks thereby creating voids.[266]

The technique has several drawbacks:

1. When the chloroform evaporates, the material undergoes a significant shrinkage, compromising the long-term apical seal.[267] If the root canal is filled with chloropercha alone, two thirds of the material will be lost once evaporation of the chloroform has occurred.[268]
2. The operator must be very careful to avoid overfilling, because of the reported tissue toxicity of chloroform.[110]

Studies by the American Food and Drug Administration[269,270] have demonstrated that chloroform is potentially carcinogenic. Consequently, the Council on Dental Therapeutics of the American Dental Association[107] has decided to withdraw chloroform from *Accepted Dental Therapeutics*. Chloroform can be substituted with eucalyptol,[271] an organic solvent derived from eucalyptus trees. Its tissue toxicity is much lower than chloroform, and it is used in medicine as a decongestant and rubefacient.[21] Eucalyptol was also reported to possess antibacterial action and antiinflammatory properties.[272]

TECHNIQUE OF WARM LATERAL CONDENSATION: THE ENDOTEC

This technique was introduced by Martin in 1987.[273] It uses a special spreader whose tip is electrically heated transmitting heat to the gutta-percha while laterally condensing (Figure 22-88). While the lateral condensation technique is based on pressure that only causes a stratification of the gutta-percha cones, the Endotec system permits the coalescense and fusion of the various cones into a dense, homogeneous mass of gutta-percha,[274–276] with less stress on the dentinal walls.[277] This is a significantly simpler technique to execute.[278]

To date, there are insufficient experimental studies on this technique. Kersten[279] found that the lateral condensation technique appeared to be markedly improved by use of the Endotec. Luccy et al.[280] have claimed positive results following *in vitro* experimentation, as well as Castelli et al.[281] and Guldener.[282]

More recently, the instrument has been modified.[283] The Endotec II is a new, advanced, endodontic condenser incorporating several clinical benefits. The resistor has been placed within the body of the handle, allowing for cost reduction of the condenser tip. The heating element temperature has been raised to ensure proper thermosoftening of the gutta-percha.

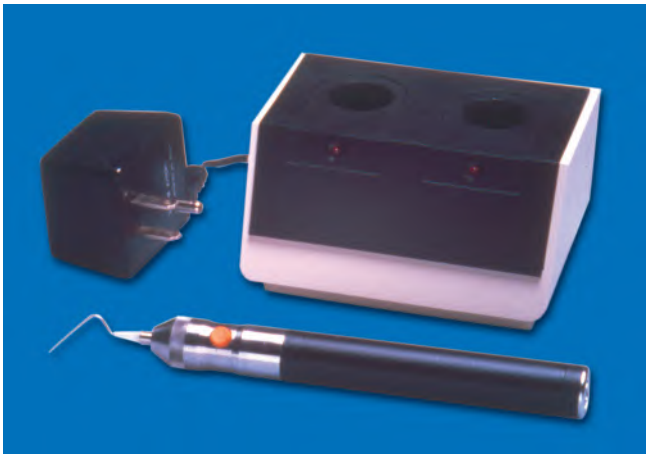

FIGURE 22-88 The Endotec unit (Medidenta, Woodside, New York, U.S.A.).

The quick-change condenser tips are now autoclavable, and can provide an angle of canal insertion ranging from 90° to 180°. Furthermore, charged by two AA batteries inserted into the handle, the unit does not require constant recharging. In the author's opinion, the Endotec II system is a marked improvement allowing for predictable softening of the gutta-percha with heat and subjecting the mass to vertical or lateral pressure.

THE ENDOTWINN

Recently, a new device has been developed for both warm lateral and vertical condensation, the EndoTwinn (MDCL N.V. Corporation, Amsterdam, The Netherlands) (Figure 22-89). This device combines application of heat and vibration. Like the Endotec, the EndoTwinn is a hand-held, self-contained, heat-carrying instrument with spreader or plugger tips. Sonic vibrations are also incorporated to augment the compaction and obturation effectiveness of EndoTwinn's heated tips.[284]

The EndoTwinn system comes with one rechargeable cordless handpiece and several pluggers for compacting, softening and cutting gutta-percha cones. The pluggers are available in the standard series with 0.5 mm diameter and a range of sizes F, FM, ML, and L, and in the Ultrasoft series, that can be easily pre-bent before entering the root canal. For narrow and curved canals, another tip is available with a 0.3 mm tip diameter and .04 taper. The kit also includes a "tip spoon" specifically designed for cutting plastic carriers.

The EndoTwinn tips can be used with and without vibrations. The combination of heat and vibration seems to provide better results. Presumably, the low vibration, in combination with heat, provides the gutta-percha better flow properties. Several studies have reported, that when using this feature, the average percentage of gutta-percha in the canal space can increase significantly, especially in narrow tapered canals.[285–287]

In early 2007, efforts to improve and refine the EndoTwinn led to the introduction of the DownPak (Hu-Friedy, Chicago, Illinois). The DownPak system enables the clinician to employ variable temperature settings and to turn the vibration feature on or off.[288] The variable temperature settings are useful when different obturation materials are used. For example, Resilon is softened at a lower temperature than gutta-percha. The DownPak is cordless and light weight, with an ergonomically balanced hand-held grasp; all of the switches and adjustments are easily accessible on the handle.[284]

RESILON

Resilon obturating points (Pentron Clinical Technologies, Wallingford, Connecticut) and the resin sealer Epiphany or RealSeal (Sybron Endo) have been proposed to be used in combination with a self etch primer after smear layer removal, to allow creation of a solid "monoblock" (a material that is contiguous from its resin tags in cleared dentinal tubules through sealer to the core canal filler).[289] The material seems to fully obturate canals with anatomical variations (especially through the compaction of warm obturation techniques). Resilon Products (RP) are marketed as RealSealTM (SybronEndo, Orange, California), and Epiphany (Pentron, Wallingford, Connecticut) (Figure 22-90).

Resilon is a polycaprolactone core material with difunctional methacrylate resin, bioactive glass, and radio opaque fillers.[86] The polyester core material is available in ISO-sized points with accessory points for lateral compaction and warm vertical techniques, or pellets for use in thermplasticized techniques.[91]

The RealSeal points handle and feel like gutta-percha. It can be used with all current obturation techniques (vertical compaction of warm gutta-percha, cold lateral condensation, lateral/vertical combinations). This allows the clinician to use this new technology with only two added steps relative to common endodontic treatment regimens, clearing the smear layer and placing the self etch primer. The only difference between RealSeal and gutta-percha is that the temperatures used in the thermoplasticized techniques are lower than

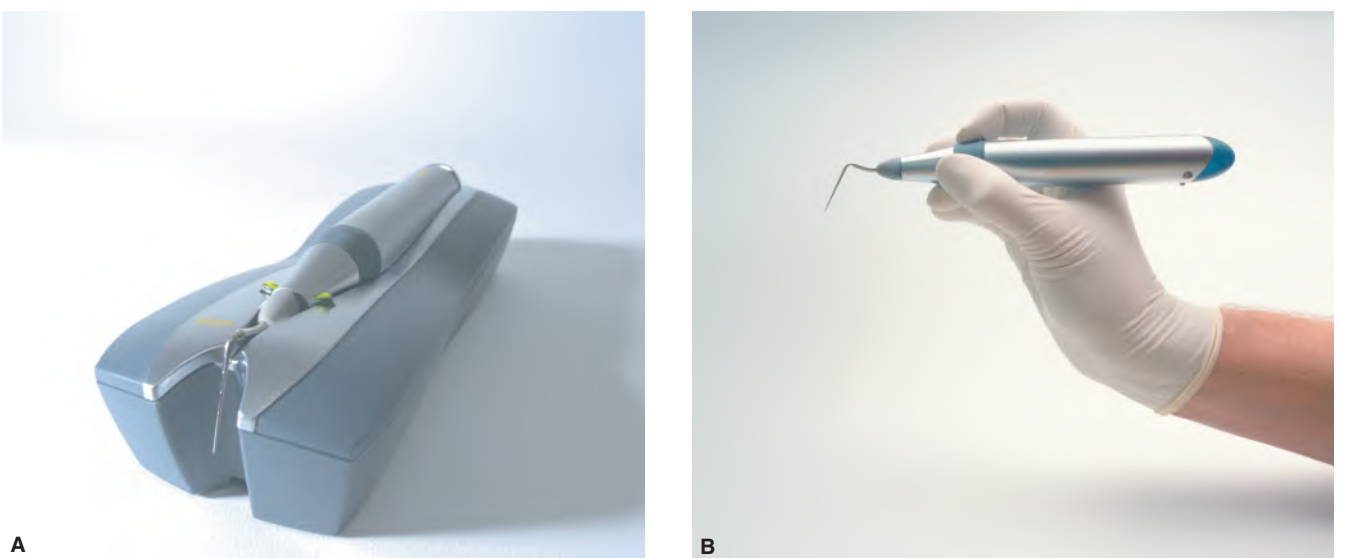

FIGURE 22-89 ***A***. The EndoTwinn system (MDCL N.V. Corporation, Amsterdam, The Netherlands). ***B***. The EndoTwinn handpiece.

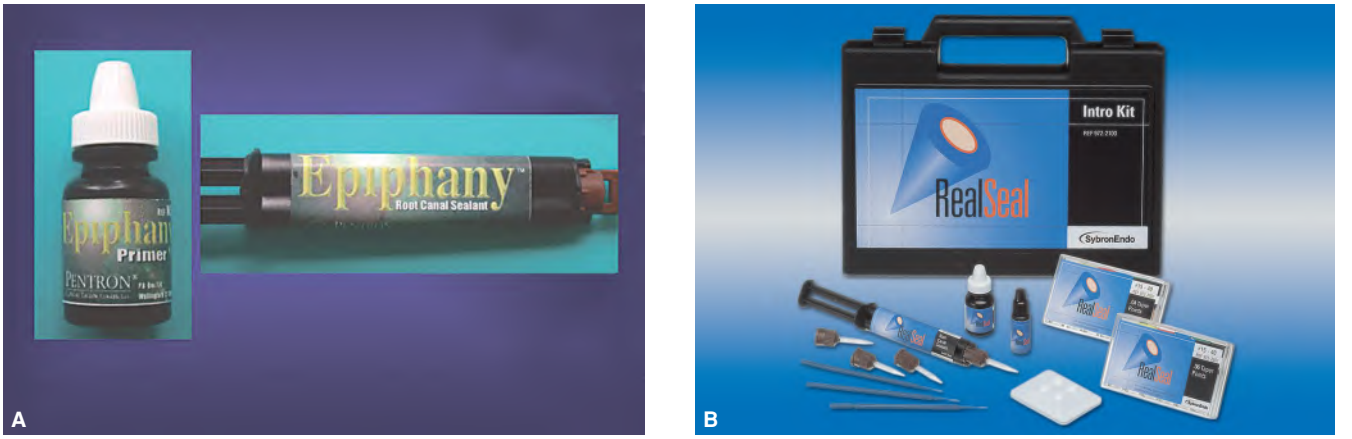

FIGURE 22-90 ***A***. Resilon™ and Epiphany Sealer™ (R/E) (Resilon Research LLC, Madison, CT, U.S.A.). ***B***. RealSeal™ (R/S) (SybronEndo, Orange, California, U.S.A.).

those used for gutta-percha techniques.[289] RealSeal is also amenable for retreatment.

Gutta-percha has been used for decades as the preferred root filling material for endodontic obturation due to its advantages of being nontoxic, biocompatible, thermoplastic, and retreatable. Gutta-percha alone, however, cannot prevent coronal microleakage and it does not bond to canal walls.[289–293] Coronal seal plays a critical role for endodontic success.[294,295] Shipper et al.[296] reported that Resilon showed minimal leakage. The sealing ability of Resilon and Epiphany sealer versus gutta-percha and AH Plus sealer were studied by Stratton et al.[297] and by Von Fraunhofer et al.,[298] who found significantly less leakage when using Resilon.

With RealSeal, after removal of the smear layer, produced during instrumentation, it may be possible to bond the obturating material to the dentinal tubules and create a "monoblock" of resin sealer and resin core filling material (Figure 22-91).[289]

Resilon "monoblock" (×650). ***D***. Sealer tags and Resilon (original magnification ×1,000). (Courtesy of Drs. Rich Mounce and Gary Glassman, Toronto, Canada, U.S.A.)

RealSeal points are available in kits of various configurations and as individual components (.02, .04, .06 tapered cones with a variety of tip sizes along with accessory points ranging in size from x-fine to large). RealSeal cones are very flexible and pellets of the material are available for the Obtura gun (Spartan Obtura, Fenton, Missouri) or the B&L Beta 2.

Canal cleaning actions can remove certain amounts of dentin. If excessively removed, it may weaken the root, making it more susceptible to root fracture. Gutta-percha exerts no strengthening action to the root after obturation. It is claimed that RealSeal may have the potential to do so. Teixeira, et al.[299] found that the resistance to root fracture with Resilon was superior ($P = 0.037$) to gutta-percha/AH 26 sealer using either lateral or vertical condensation. On the other hand, another study compared the cohesive strength and stiffness of Resilon to gutta-percha, under dry conditions also after one month of water storage. It was reported that both Resilon and gutta-percha had relatively low cohesive strength and module of elasticity and did not have enough stiffness to reinforce the root after endodontic therapy.[300]

Chapter 23

Endodontic Orthograde Retreatment and Management of Mishaps

Pierre Machtou, Clifford J. Ruddle

INTRODUCTION

Longitudinal endodontic outcome studies performed in university-based institutions or by specialists have shown a high percentage of success estimated from 90% to 95%.[1] Assuming that 90% of the treatments are successful over time, the reciprocal failure rate is 10%. In the United States alone, where the number of canals treated per year now exceeds 50 million,[2] a 10% failure rate could represent five million treatment failures per year. Extrapolating these numbers over the past three to four decades reveals that the number of failing endodontically treated teeth is very high and could approach tens of millions.[3]

Such a high number of failed root canal treated teeth has been corroborated by Figdor in Australia and Sweden.[4] Furthermore, when root canal treatment is performed in a general practice, cross-sectional studies conducted in different countries show a high and alarming prevalence of endodontic treatment failures, as evidenced by the presence of apical periodontitis in a range from 30% to 65% of cases[5] (Figure 23-1). A recent systematic review and meta-analysis, including 33 cross-sectional studies conducted in several countries in the world, show that the prevalence of apical periodontitis on 28,881 endodontically treated teeth was 36%.[6] As a result, it appears that there is a high demand for retreatment of failing cases.

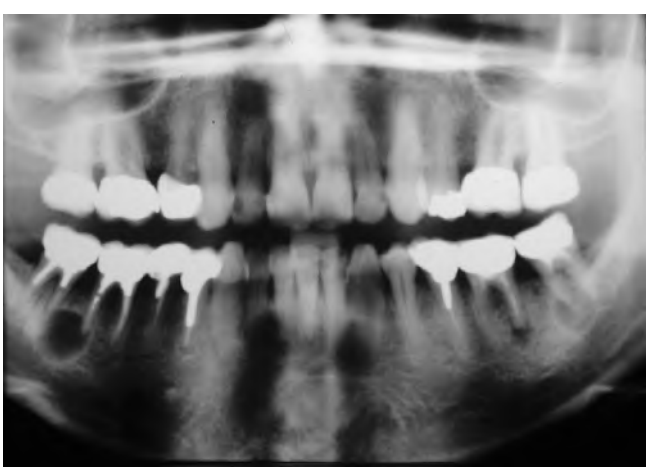

FIGURE 23-1 Treatments performed in general practice show a high prevalence of endodontic failures.

Retreatment Definition

The Glossary of Endodontic Terms published by the American Asssociation of Endodontists[7] gives the following definition: "Retreatment (revision): A procedure to remove root canal filling materials from the tooth followed by cleaning, shaping, and obturating the canals." Such a definition seems to be oversimplistic and restrictive, because in many situations, retreatment is indicated when there is no root canal filling to remove. Such is the case when a failure results from a missed canal during initial treatment. Oftentimes, the previous dentist was unaware or unable to locate one or more canals, or refers a patient during active treatment. A more precise definition involving all situations was needed.

Carr[8] defined endodontic retreatment as a procedure that is performed on a tooth that previously has had attempted defintive treatment and now requires further treatment to ensure a successful result. It is noteworthy that the term, "revision," has been substituted for retreatment in order to rule out a pejorative connotation that implies a dentist made a mistake during the initial treatment. However, "revision" is not appropriate, since retreatment is directed toward addressing deficiencies in initial treatment, as opposed to, for example, performing elective facial plastic surgery where periodic revisions may be considered as one ages.

Retreatment Vs. Initial Treatment

In terms of objectives, there is no difference between initial treatment and retreatment. In both situations, microorganisms must be eradicated from the root canal system through shaping canals and 3-D cleaning, filling, and sealing the endodontic space (Figure 23-2). It must be appreciated that, in both straightforward and complex initial treatment cases, all root canal systems are patent and anatomic complexities can, in most instances, be overcome by a skillful practitioner. In contrast, the original canal patency is oftentimes lost or severely compromised in the retreatment situation. Further, most of the teeth to be retreated have already been restored, further compounding the retreatment challenges. The radicular obstacles that obstruct canals include different types of filling materials, posts, and fractured instruments (Figure 23-3). Additionally, other formidable radicular challenges include blocks, ledges, canal transportations, and root perforations. Recognizing the scope of so many retreatment challenges, Schilder[9] introduced a new term in 1986, "Retreatodontics,"

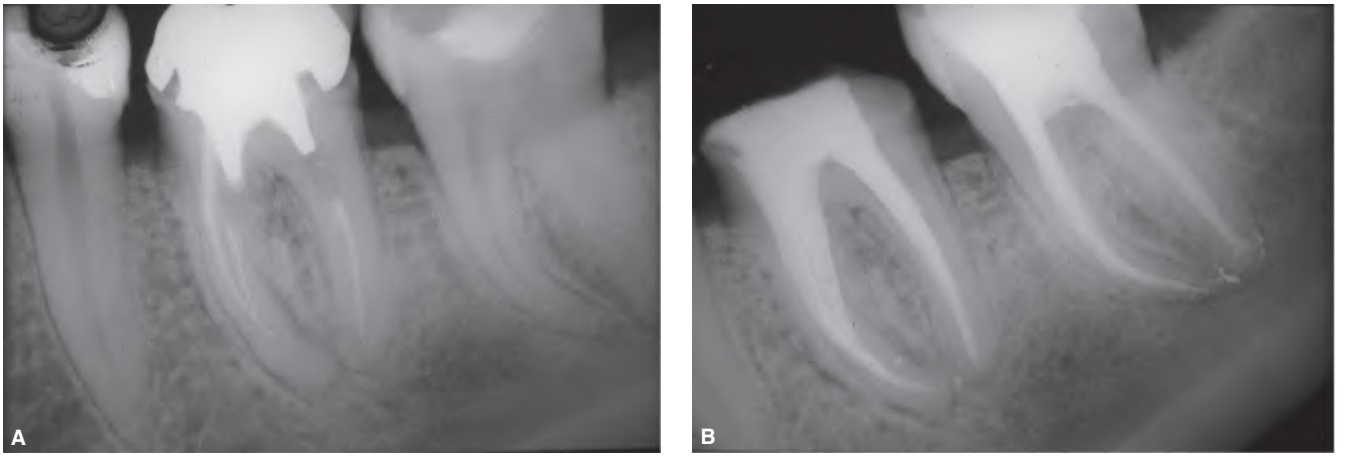

FIGURE 23-2 ***A.*** Retreatment is indicated on the mandibular first molar. In contast to the second molar, many coronal and intracanal obstacles are present. ***B.*** A post-operative radiograph demonstrates the two treatments completed.

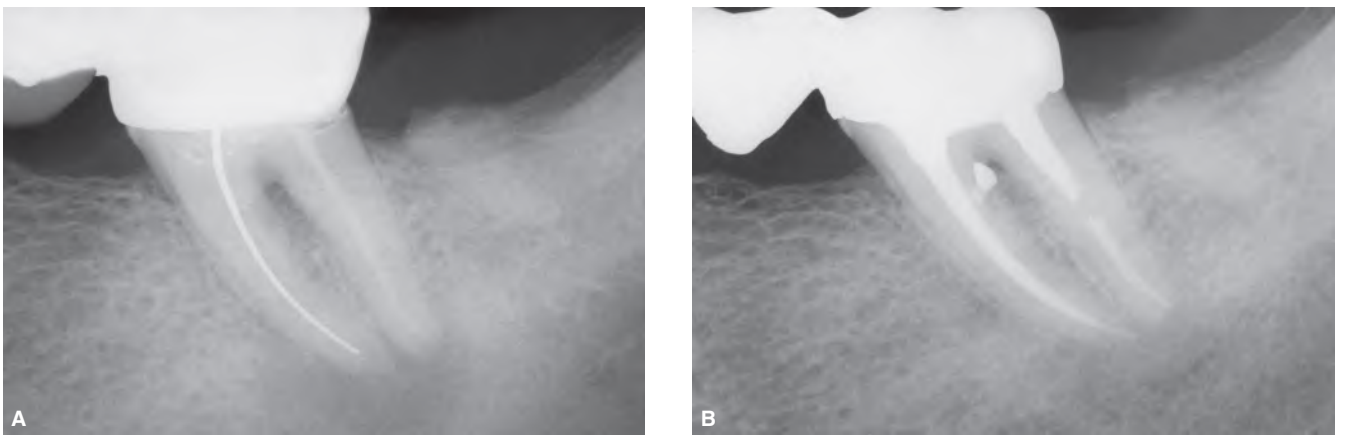

FIGURE 23-3 ***A.*** A radiograph of a mandibular left second molar reveals a poorly-fitting bridge, canals holding a silver point and paste, and evidence of furcal and apical pathoses. ***B.*** Ten-year recall radiograph shows the importance of three-dimensional endodontics and restorative excellence.

to emphasize the complexity and specificity of endodontic retreatment and he predicted that the future of endodontics would be largely focused on retreating failing cases.

Decision Making

Failure of endodontic therapy is usually based on the observation of clinical symptoms and/or radiographic findings. However, the presence of apical periodontitis in previously endodontically treated teeth is rarely associated with clinical symptoms. Therefore, lesions of endodontic origin are often discovered during routine radiographic examination. It has been found that the diagnosis of a periapical lesion was not a sufficient reason to retreat. Amazingly, a retreatment decision was only made in 39% of the cases,[10] even if painful symptoms were present.[11] Many studies have shown that radiographic interpretation of periapical changes can be subjective and large discrepancies in attitudes toward endodontic retreatment have been observed.[10–14] For example, when radiographs were shown to general dentists and specialists from different fields of dentistry to assess the periapical health status, no agreement was found.[15] Furthermore, when the same radiographs were re-examined six to eight months later by the same practitioners, about 20% of them disagreed with their former opinions.[16]

These discrepancies can be influenced by a variety of factors and variables, including the training and experience of the examiner, the conditions under which the radiograph was viewed, and the type and settings of the x-ray system used. Similar results were also obtained when digital radiography was used.[17] Paralleling the importance of utilizing the dental operating microscope is the increasing adoption of cone-beam computed tomography imaging (CBCT) in endodontics. CBCT is a diagnostic adjunct, providing three-dimensional (3-D) images, a low radiation dose, and good resolution for endodontic treatment planning. The possibility to navigate through axial and coronal slices allows the clinician to detect hidden periapical lesions, root curvatures, missed canals, and to identify the location and extent of resorptive and perforation defects and vertical root fractures (Figure 23-4).[18] For more details, see Chapters 9C and 10.

The Praxis Concept

The decision-making process is a complex task for a practitioner, who may be faced with 30 different clinical situations combining different qualities of the seal, the presence of a post, and the locations and sizes of different lesions of endodontic origin (Figure 23-5). A multiplicity of factors complicate the decision-making process, including diagnostic variation,[19] risk assessment,[20] clinical context,[12,14,21] cognitive factors,[20] and treatment plans.[22]

To explain the behavior of dentists to perform endodontic retreatment, Kvist and his team developed the Praxis concept model.[23] In this model, periapical health and disease are not viewed as two different situations. The periapical status is perceived as a continuum of health ranging from no lesion (perfect health) to a large lesion (high degree of poor health). Yet, the periapical status is subjective, based on the attitudes of the dentist. Rather, the periapical status should be based on objective criteria, including clinical and radiographic findings and the risks vs. benefits of retreatment. However, the decision to initiate retreatment is, in fact, influenced by factors unrelated to the disease *per se*, including successfully managing the technical challenges, potential for pain, and costs (Figure 23-6).

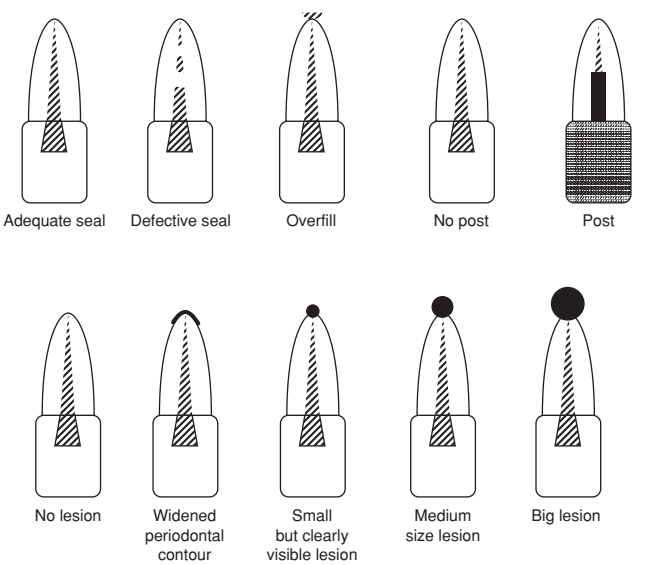

FIGURE 23-5 Different clinical situations may be encountered making the decision to retreat difficult. (Reprinted with permission from Kvist et al.[23])

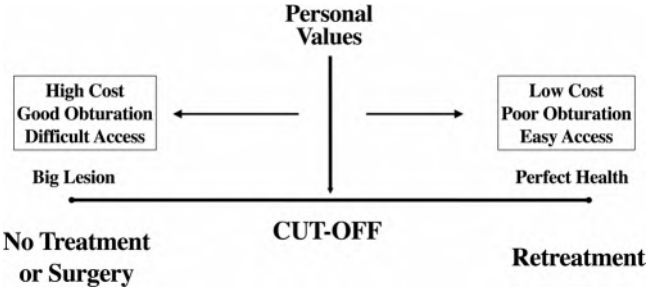

FIGURE 23-6 The Praxis model concept. (Reprinted with permission from Reit and Gröndahl.[13])

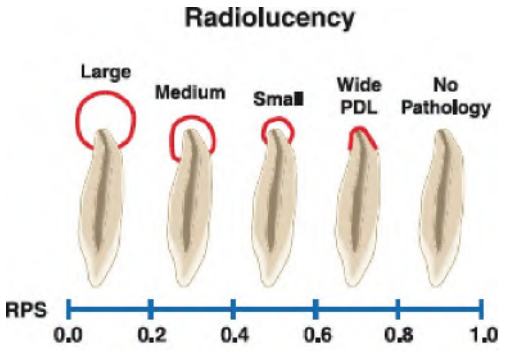

FIGURE 23-7 Calculation of the Retreatment Preference Score (RPS). Clinicians assessed five periapical conditions and chose a periapical situation as their cut-off point for retreatment. The mean score chosen was very close to medium-sized lesion (RPS = 0.38). (Adapted from Kvist and Reit[24] and reprinted from Ingle's Endodontics 6th ed., Chapter 31: Treatment of non healing endodontic therapy and management of mishaps. Hamilton, ON: BC Decker; 2008:1091.)

Two main types of tendencies have been found among dentists. The first tendency is to retreat when a periapical lesion is present, especially when the lesion is deemed large. Yet, the decision to retreat is oftentimes modified by individual values. As an example, graduate students at three universities used a "retreatment preference score" (RPS) to numerically quantify the size of a lesion. In this RPS scale, 0.0 represents a large lesion, whereas 1.0 represents no lesion. Ironically, students generally quantified the size of a lesion as 0.3 (Figure 23-7).[23] A similar study conducted with endodontic specialists showed they followed the same behavioral pattern as the "novices."[24,25]

Decision Analysis

From an analytic point of view, the RPS can be structured as a decision tree, illustrating the various clinical options and providing a rationale basis for thinking and making the right decision.[13] Moreover, this method serves as a way to present the different treatment options in order for the patient to be invoved in the decision-making process.

The retreatment decision-making process should be seen as a 3 "**D**" process.[21,26,27]

Decide if the Endodontically Treated Tooth is a Failure Two situations are encountered regarding the presence or absence of a lesion.

A. The first situation corresponds to a tooth with technical deficiencies in primary treatment, yet there are no clinical signs or symptoms or radiographic evidence of failure. The absence of a lesion is not always synonymous with an absence of microorganisms in the root canal system.[28] When microorganisms are in a dormant stage, a balance may exist between the host defenses and the intracanal irritants. This delicate equilibrium can be upset by a change in the microbial flora or in the host resistance, or by microbial recontamination through coronal leakage when there is a deficient coronal restoration. If there is a coronal seal, and/or when the coronal restoration does not require replacement, radiographic and clinical monitoring may be considered. A study by Van Nieuwenhuisen, Aouar, and D'Hoore[29] showed that, in this situation, a wait-and-see approach over a six-year period led to complications in as little as only 2.8% of cases. On the other hand, if a new restoration is scheduled, these cases should be considered as potential failures[30] and retreatment should be considered prudent (Figure 23-8).[31] However, retreatment of these cases has been shown to lead to failure in 6% of the cases,[32] mainly due to over-instrumentation and overfilling (Figure 23-9).
B. In the second situation, the patient is also asymptomatic, yet a periapical lesion exists. In these instances, the question is whether these lesions will heal without additional intervention. The quality of the root canal filling must be assessed and, if practical, information should be gathered on how and when the initial treatment was performed. Usually, when the quality of treatment appears adequate, the healing process will take place after a minimum period of one year. However, it has been shown that some lesions required 10 years or more to heal.[33,34] Nevertheless, according to the current consensus, most periradicular lesions will heal in four years.[30] It is important to note that, when contamination occurs during intracanal procedures, apical periodontitis oftentimes develops quickly, within one year of the original treatment.[35] In these instances, healing should not be expected and retreatment is indicated. Infrequently, a small radiolucency can be the result of an inflammatory reaction due to the toxic effects of some root canal filling materials. Importantly, the diagnostician should make the distinction between a root canal that radiographically appears well filled with surplus vs. a root canal that is laterally underfilled and vertically overextended. In the instance of a well-filled root canal system, toxicity generally decreases with time and the lesion resolves. Such a hypothesis should also be considered when the lesion is associated with recent treatment that was carried out months earlier.[36]

Decide to Treat A differential diagnosis must be made when a radiographic radiolucency has been detected to rule in or out a lesion of endodontic origin. Histologic studies have shown the presence of granulomatous tissue or cysts in 95% of cases.[37] These inflammatory reactions are frequently the result of a persistent root canal infection[28,38,39] or, less frequently, attributable to extra canal infection.[40,41] On the other hand, some patients will present asymptomatic, yet may exhibit a

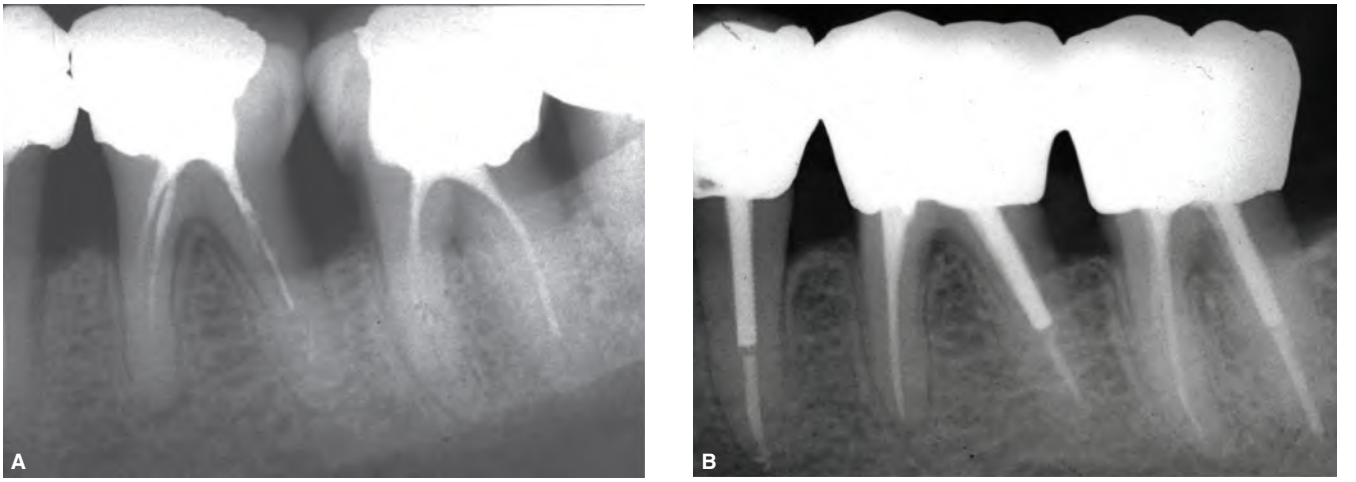

FIGURE 23-8 ***A***. Retreatments are indicated in teeth with poorly sealed canals when a complex treatment planning involving periodontics and prosthodontics is scheduled. ***B***. 12-year follow-up radiograph after retreatments and final restoration.

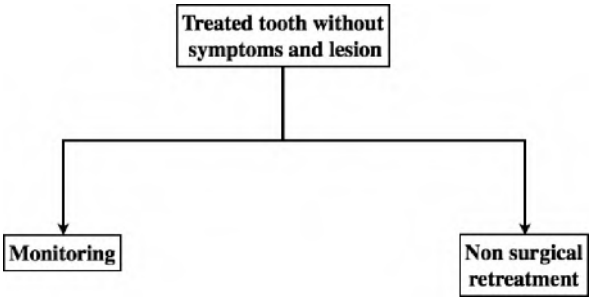

FIGURE 23-9 Decision tree: Tooth without symptoms and periapical lesion.

periapical radiolucency that may, in fact, be healing by scar tissue formation.[37,42]

The benefits vs. risks of endodontic retreatment must be assessed and weighed. Currently, little evidence exists connecting the presence of a periapical lesion with the systemic health of the patient,[43] except for coronary heart disease.[44] Similarly, scarce information is available about the risk of flare-ups when retreating quiescent periapical lesions. According to Eriksen,[45] the estimated incidence of quiescent lesions spontaneously exacerbating appears to be less than 5% per year. In contrast, asymptomatic patients with quiescent lesions have a flare-up incidence of 20% to 40% when retreatment is initiated.[46,47] One explanation may be related to the difference in the composition of microbial flora present during initial treatment of a necrotic tooth vs. retreatment.[39]

With that said, it is appreciated there are some risks associated with the retreatment procedure, itself. For example, when a post and crown restoration has to be removed, the residual tooth structure can be weakened, resulting in a tooth fracture. Further, procedural errors, like root thinning or perforations, may result from excessive re-instrumentation.[30] When a patient reports signs or symptoms associated with an endodontically treated tooth and the radiographic examination is nondiagnostic, CBCT examination is indicated. CBCT provides three-dimensional images and more diagnostic information than a well-angulated periapical radiograph, alone (Figure 23-10).[18]

Decide What Type of Treatment is to be Undertaken

Depending on the situation, three therapeutic options can be considered: extraction, orthograde, or surgical retreatment (Figure 23-11).

As mentioned earlier, many teeth that are candidates for endodontic retreatment have been already restored. If orthograde retreatment is selected, the presence of remaining tooth structure must be anticipated before disassembly. Sufficient cervical tooth structure must be present in order to achieve a new and reliable restoration.[48] Where there is insufficient tooth structure and periodontal crown lengthening is contraindicated, tooth extraction is indicated and a new treatment plan is required. Orthograde retreatment is the treatment of choice in cases that radiographically exhibit poorly sealed canals. Therefore, the goal is to improve the quality of the previous treatment (Figure 23-12). In these instances, the rate of success is comparable to initial treatment when access to the root canal terminus is possible, the canal(s) can be well shaped, and their related root canal system can be disinfected and filled.[49] Indications for a surgical approach arise from the limitations to achieve these goals.

Surgical correction may be considered when there are iatrogenic errors radiographically noted in the apical region, when access to the root canal system is too dangerous, when the tooth to be retreated is involved in a complex or long-span splint restoration, or when what appears to be adequate treatment is associated with signs or symptoms. Over years, follow-up studies comparing orthograde retreatment and endodontic surgery have shown a poorer rate of success for a surgical approach.[30] On the other hand, surgical success increases when nonsurgical retreatment is first undertaken to more fully address the root canal system. It is appreciated that today's surgeon has many advantages due to advancements in armamentarium. These advancements include the microscope, ultrasonic tips, and biocompatible retrofilling materials.[50–52] It is

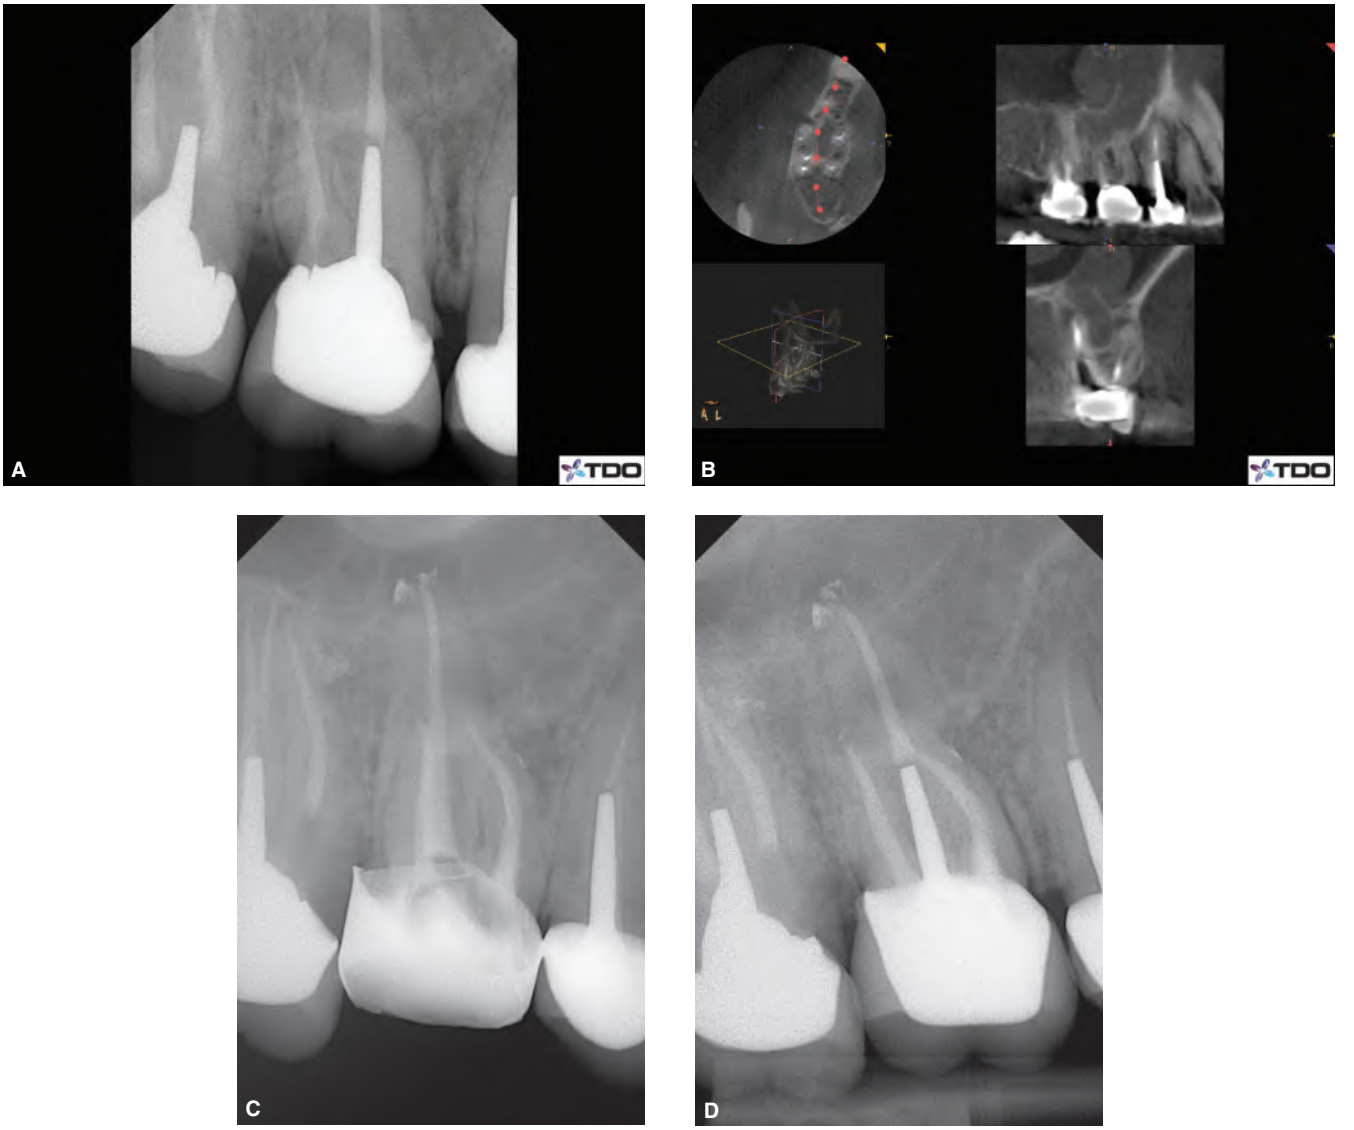

FIGURE 23-10 ***A.*** The patient complained of pain on the right first molar. Clinical examination and radiographs were non contributory. ***B.*** Coronal images from a CBCT showed two periapical lesions on the MB and palatal roots. ***C.*** Postoperative radiograph after retreatment and 3-D filling. ***D.*** Pain was relieved. A new restoration was placed two weeks later.

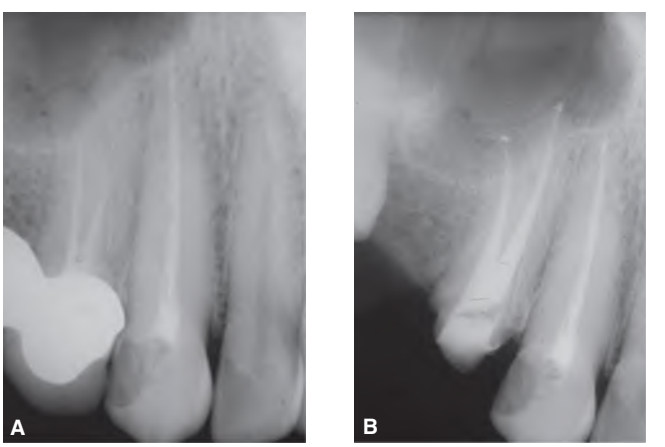

FIGURE 23-12 ***A.*** Poorly sealed canals are an indication for orthograde retreatment. ***B.*** Tooth retreated.

noteworthy that healing after surgical retreatment is faster than after nonsurgical retreatment and can be observed at one year. However, after four years, these two procedural results are balanced.[53] Nevertheless, surgical access and techniques are restrictive in their ability to remove the harmful content from the root canal system.

Patient Preferences

It is essential to disclose the different therapeutic options in order for the patient to participate in the decision-making process. Full information should be given in simple and understandable language so the patient is more involved in the therapeutic act and becomes an actor in the decision. Simple principles to follow have been given by Reit[26] in order to make the best decision:

- 1st principle: Any persistant lesion after treatment must be retreated.
- 2nd principle: A persistant lesion *may not* be retreated if:
  - ◊ Retreatment is not the patient's choice.
  - ◊ The risks outweigh the benefits.
  - ◊ Global cost exceeds predictable alternatives.

Attitudes toward periapical disease vary among individual patients. Some patients worry about living with an infection and readily accept a recommendation for a retreatment procedure. Asymptomatic patients are less concerned about a chronic lesion, weigh the pros and cons, and may finally decide to do nothing. Even when the decision is contrary to the dentist's opinion, the patient's right to choose must prevail.

Clinical Procedures and Sequencing Dissassembly

Endodontics is a matter of strategy and tactics, and this is particularly true in the case of retreatment. First, the clinician has to understand the cause of the failure and then ask the question if he/she has the judgment, experience, and training to give the patient the best chance for success. Importantly, the clinician must have the technology to help guide each retreatment procedure toward longterm success. This approach can be summarized by the triad: ***analyze***, ***plan***, and ***execute***.

General and local objectives must be well integrated before attempting to retreat. General objectives include technical and pathological indications. In the first circumstance, the goal is to improve the quality of the treatment and avoid any contamination. The second objective is to control, then eliminate, infection. Local objectives involve coronal disassembly, complete access, ruling in or out hopeless fractures, identifying all orifices/canals, removing previous obturation materials, eliminating post and retrieving broken/separated instruments, and repairing iatrogenic perforations and apical transportations. When properly performed, all of these activities promote shaping canals, when indicated that in turn encourages 3-D disinfection and filling root canal systems. This is the essence of nonsurgical retreatment.

The authors recognize that the way endodontics is being taught and practiced can vary from country to country. For example, in some parts of the world, there is more emphasis on placing posts in virtually all endodontically treated and restored teeth; whereas, in other parts of the world, a core build-up is performed without a post. Therefore, retreatment sequencing will vary according to the clinical examination and diagnostic radiographs associated with each presenting patient. When there is no post, for example, finding missed canals or removing endodontic root canal fillers may commence upon regaining access. Therefore, sequencing endodontic treatment and initiating the appropriate treatment approach varies according to each patient's specific condition, radiographic examination, and clinical discovery following coronal disassembly.

GAINING ACCESS TO THE ROOT CANAL/CORONAL DISASSEMBLY

Apical periodontitis may be the result of persistent microorganisms following intracanal instrumentation and disinfection. But a secondary infection may occur through coronal leakage due to defective restorations; a cause for late failures.[54,55] Therefore, prior to retreatment of a failing case, amalgam and defective restorations should be systematically removed. This enables the clinician to clean out potential recurrent decay, assess the value of the remaining crown structure, and possibly discover the presence of cracks. The next step to facilitate retreatment is to place a new temporary restoration, usually a glass-ionomer cement, either a copper or orthodontic band, or a prefabricated crown to rebuild the missing tooth structure (Figure 23-13). Pretreatment is a a mandatory step in orthograde retreatment and a prerequisite for future work in the best aseptic conditions. For more details, see Chapter 19, "Preparation for endodontic treatment."

Most of the teeth to be retreated have been restored with crowns and sometimes posts. It is prudent to disassemble all restoratives from the pulp chamber to promote identifying canal orifices that may be hidden by cements, and composite or metal materials.[56] Occasionally, access to the pulp chamber can be created through an existing crown if it is judged to be functionally designed, well-fitting, and esthetically pleasing (Figure 23-14), or if the tooth is part of long-span fixed bridges. However, when the axial alignment of the crown and root are different, caution must be exercised regaining access so as to not needlessly destroy tooth structure or perforate. When access procedures could potentially damage the crown, or if the restorative is deemed inadequeate, then the restoration should be sacrificed. When an access cavity is created through a metal restoration, the axial walls should be extended laterally to eliminate interferences and provide freedom for the subsequent use of shaping instruments. Access cavities should be designed to prevent debris, such as metal filings, from falling into the canal that could serve to create an irreversible blockage. Owing to their own weight, metal shavings will not stay in suspension within the irrigating solution.[56]

Factors Influencing Restorative Removal

The removal of a restorative is dramatically enhanced when there is knowledge, respect, and appreciation for the concepts, materials, and techniques utilized in restorative and

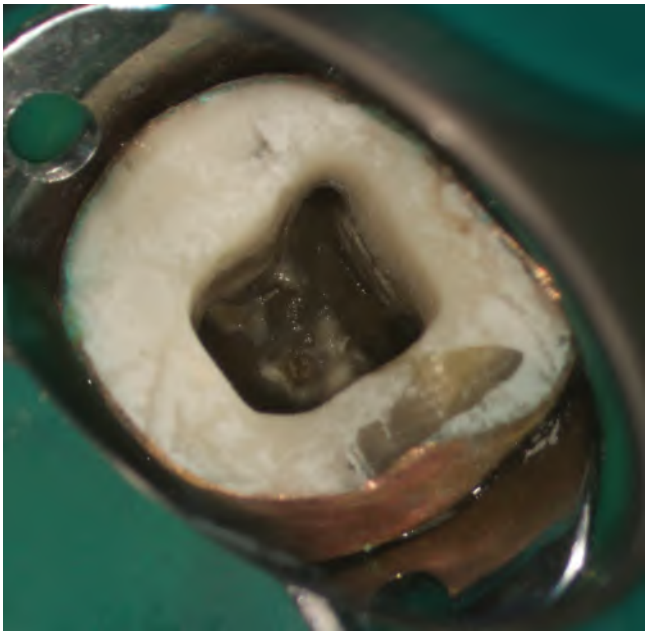

FIGURE 23-13 A copper band was placed to rebuild the missing tooth structure and allowed the creation of a four-wall access cavity.

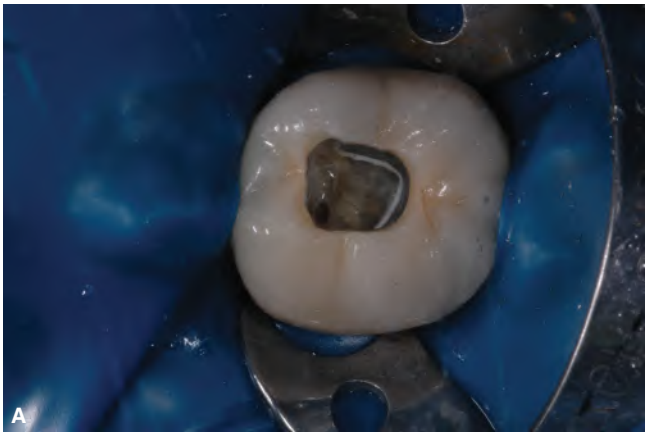

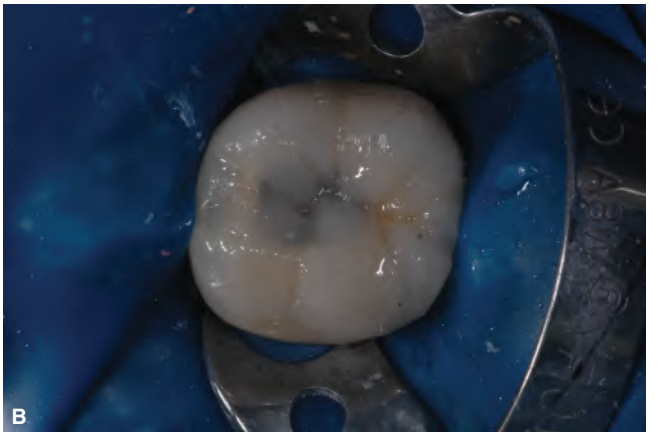

FIGURE 23-14 ***A.*** Access is made through a well fitting and esthetically pleasing crown. ***B.*** After retreatment. A composite resin was used to restore the crown.

reconstructive dentistry. The safe dislodgement of a restorative is dependent on five factors that must be considered.

1. *Preparation Type*: Preparations vary in retention depending on the total surface area of the tooth covered and the height, diameter, and degree of taper of the axial walls.
2. *Restoration Design and Strength*: The design and ultimate strength of a restorative is dependent on its physical properties, thickness of material(s), and the quality and techniques of the laboratory technician.
3. *Restorative Material(s)*: The composition of a restoration ranges from different metals to tooth-colored restoratives, such as porcelain. How these materials behave related to the stresses and strains required during removal must be appreciated.
4. *Cementing Agent*: The retention of cements ranges from weak to strong, generally progressing from zinc oxide-eugenol, polycarboxylate, silico phosphate, zinc phosphate, glass ionomers, resin modified glass ionomers to bonded resins. Clearly, the new generation bonding materials, in conjunction with well designed and retentive preparations, have made restorative removal more difficult[57] and, at times, unwise.
5. *Removal Devices*: The safe and successful dislodgment of prosthetic dentistry requires knowledge regarding the selection and use of a variety of devices. Clinicians need to identify and become familiar with each device, its safe application, effectiveness, limitations, and costs.

The clinician must obtain a good history, confer with the original treating dentist if possible, and then consult with the patient to clearly define the risk versus benefit when entertaining the intact removal of an existing restorative.

Coronal Disassembly

Coronal disassembly can be carried out in three distinct ways: destructive, minimally destructive, and conservative.

Destructive Disassembly

Destructive disassembly involves cutting through the crown with a carbide bur (transmetal bur, *Dentsply Maillefer; Ballaigues, Switzerland* or H4MC bur, *Komet; Rock Hill, South Carolina, USA)*. On the facial surface of a restorative crown, a slot is made from the cervical margin and extends toward the cavo surface, then to the middle of the occlusal surface. Ultrasonics is applied inside this slot to disintegrate the luting cement. Subsequently, an elevator (Figure 23-15) or the Christensen Crown Remover (*Hu-Friedy, Chicago, Illinois, USA*) may be used to flex apart the crown and loosen it. This procedure is predictable and safe, and if needed, the crown can be relined to serve as an interim restorative (Figure 23-16). This is also an excellent method for removing long span bridges, where each abutment is individually managed. In single-rooted teeth, the slot should involve both buccal and palatal faces (Figure 23-16).

Minimally Destructive Disassembly

In this approach, a minimally invasive procedure is performed and results in a small amount of force required to dislodge

FIGURE 23-15 Different types of elevators used for crown removal.

the restorative. Some examples of minimally destructive disassembly devices are as follows:

- WAMKeys (*WAM; Aix en Provence, France*, or *WAM; Montréal, QC, Canada*): This system is easy-to-use and convenient to safely remove the majority of metallic and/or porcelain crowns and short bridges. The intro kit includes three narrow-handled instruments with distal ends that each provide a different sized cam (Figure 23-17). Three steps should be followed. First, a horizontal slot is created with a transmetal bur in the middle of the facial aspect of the crown or about one millimiter below the central groove of the occlusal restorative surface. In the instance of a procelain-fused-to-metal crown, a 016 diamond round bur (*Komet*) is used with a water coolant to protect the porcelain and cut a class V tapered cavity through the porcelain and to the underlying metal substructure (Figure 23-18A). Second, a transmetal bur is used to cut through the metal and create a trench to the middle of the occlusal surface (Figure 23-18B). Third, an appropriately-sized WAMKey is selected, inserted inside this trench, and gently rotated to elevate the restorative crown along its own axis (Figure 23-18C and D).[56]

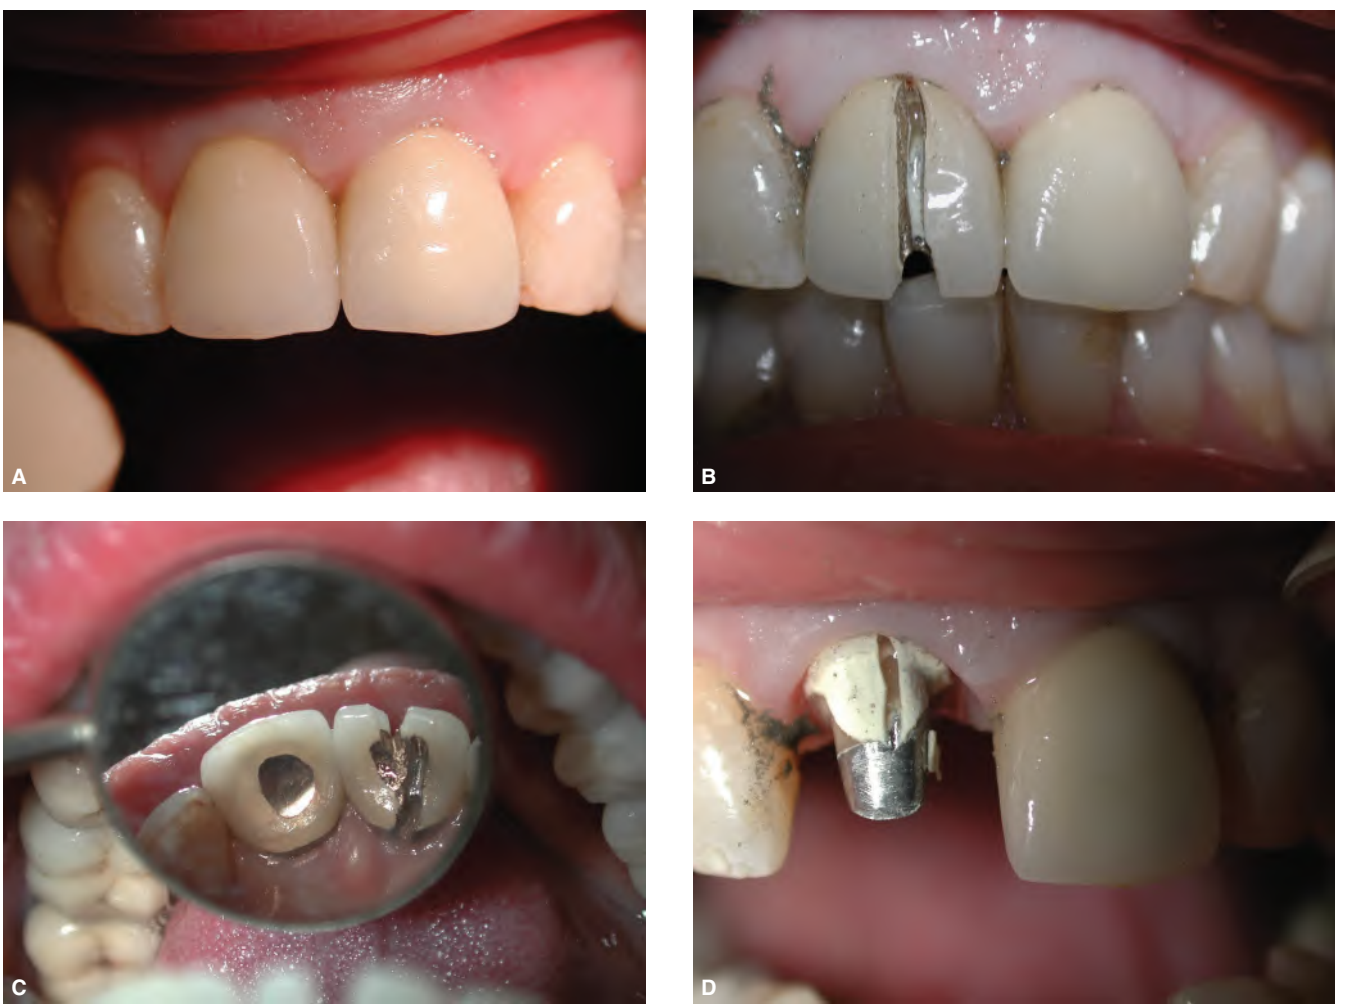

FIGURE 23-16 ***A.*** Orthograde retreatment is indicated in the crowned maxillary right central incisor. ***B.*** Starting from the cervical area and following the tooth structure, a slot is made on the buccal surface. ***C.*** The slot should involve both the buccal and palatal faces. ***D.*** Crown removed.

- Metalift™ *(Classic Practice Resources; Baton Rouge, Louisiana, USA)*: The Metalift (Figure 23-19A) is designed to safely remove inlays, onlays, three-quarter crowns, full crowns and fixed bridges in a minimally-invasive way so these restoratives can be reused, if desired. The kit includes all items needed to perform the procedure, as follows: One, in the instance of a procelain crown or bridge, the cylindrical diamond bur is utilized to precisely remove the porcelain and expose the underlying metal (Figure 23-19B). Two, with the help of magnification, create a pilot hole with a small carbide round bur through the metal and to solid structure (Figure 23-19C). Three, a twist drill is used to create a precision channel in the metal that exactly matches the size of the Metalift instrument to be used later in step five (Figure 23-19D). Four, substructure material is carefully removed on the bottom side of the metal so as to not damage the precision channel and to prevent threading the Metalift instrument into tooth structure. Five, the Metalift instrument is threaded through the metal until its distal end contacts tooth structure and rotation is continued to lift off the crown (Figure 23-19E and F).
- The Kline Crown Remover *(Brasseler; Savanna, Georgia, USA)*, and the Higa Bridge Remover *(Higa Manufacturing; West Vancouver, BC, Canada)* operate with the same concept.

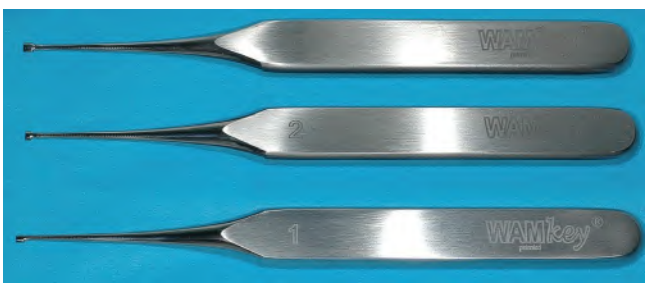

FIGURE 23-17 WamKeys (*WAM, Aix en Provence France, WAM, Montréal, QC, Canada*).

Conservative Disassembly

Conservative disassembly involves utilizing percussive devices and techniques.[57] In this approach, safe and successful removal of a prosthesis is accomplished by disintegrating the luting cement. This removal method utilizes manual sliding hammers or pneumatic crown removers. The tip of these devices grasps the cervical crown margin on the buccal or lingual aspect and a controlled series of impact strokes are delivered to loosen the restoration. However, these impact shocks may induce misdirected forces that can be extremely harmful and predispose to coronal or radicular fractures. Therefore, the authors caution against their routine use. Examples of this type of crown remover device include the manual sliding hammer *(Miltex; Plainsboro, New Jersey, USA or Anthogyr; Atlanta, Georgia, USA)* and Crown-A-Matic *(Peerless International, Inc; North Easton, Masssachusetts, USA)*.

FIGURE 23-18 ***A.*** A diamond round bur is used with a water coolant to protect the porcelain and cut a class V tapered cavity through the porcelain to the underlying metal substructure. ***B.*** A trench is made with a transmetal bur through the underlying metal substructure to reach the middle of the occlusal surface. ***C.*** The WamKey is inserted inside the trench and gently rotated to elevate the crown. ***D.*** It's not necessary for the WamKey to encroach the core.

On the other hand, a special consideration must be given to the Coronaflex (*Kavo Dental; Charlotte, North Carolina, USA*). The Coronaflex (Figure 23-20) is an elegant and very useful technique to perform bridge removal. This removal method encourages an axial pulling direction that serves to mitigate damaging a prosthesis. The procedure is easy, quick, and safe, as well as comfortable for the patient. The Coronaflex utilizes compressed air to produce ultrashort impulses at the tip of

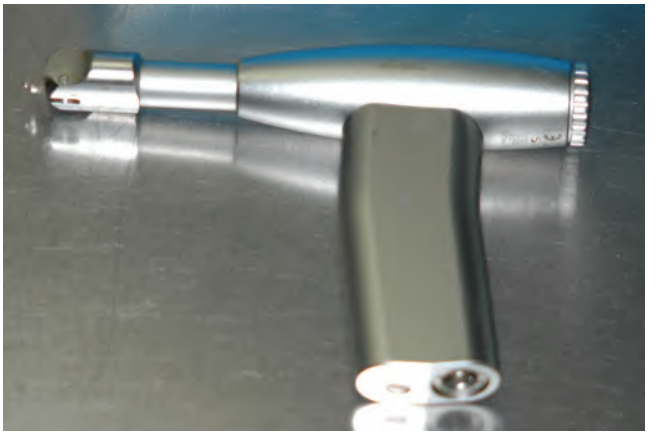

FIGURE 23-20 Coronaflex.

the instrument to break the luting cement. The recommended method of use is the so-called "parachute technique." Metallic wires are looped through two or more embrasures of the bridge, that, in turn, are connected to a metal rod. The tip of the pneumatic handpiece is then placed against the rod and, upon activation, delivers a series of micro-pulses that break the cement bond, allowing for the removal of the bridge along its own axis of insertion. Similarly, when a tooth is soundly embedded in the periodontium, the parachute technique is an expedient way to remove a cast post and core, in one piece, from any given tooth.[56]

Grasping devices are inefficient to remove fixed cemented prosthesis. They are best utilized in removing provisionalized dentistry[57] and include K.Y. Pliers (G.C. America; Alsip, Illinois, USA), the Wynman Crown Gripper (Miltex Instrument Company; Lake Success, New York, USA), and the Trident Crown Placer-Remover (Trident Dental Inc; Hendersonville, North Carolina, USA).

REMOVAL OF POSTS AND CORES

It is common for clinicians to encounter endodontically treated teeth that contain posts. Frequently, when endodontic treatment is failing, the need arises to remove a post to facilitate successful nonsurgical retreatment. In other instances, the endodontic treatment may be judged successful, but the restorative needs require the removal of an existing post to improve the design, mechanics, or esthetics of a new restoration. Over time, many techniques have been advocated for the removal of posts and other large intracanal obstructions.[58–60]

Factors Influencing Post Removal

There are many factors that influence successful post removal, such as operator judgment, training, experience, and utilizing the best technologies and techniques.[3] Further, clinicians should have knowledge and respect for the anatomy of teeth and be familiar with the typical range of variation associated with each tooth type.[61] As an example, it is important to know tooth morphology, including the length, circumferential dimensions, and curvature of any given root, as well as the depth of an external concavity, if present. This information is best appreciated by obtaining three well-angulated preoperative radiographs. Radiographs also assist the clinician in visualizing the length, diameter, and direction of the post, and aid in determining if it extends coronally into the pulp chamber.[62]

Other factors influencing post removal are the post type and cementing agent.[63,64] Posts can be catalogued into parallel versus tapered, active versus nonactive, and metallic versus non-metallic compositions (Figure 23-21).[65,66] Posts retained with the classic cements like zinc phosphate can generally be removed; however, posts bonded into the root canal space with materials like composite resins or glass ionomers are oftentimes more difficult to remove.[67] In addition, other important factors that impact post removal are the available interocclusal space, existing restoration, and whether the coronal most aspect of the post is supra or subcrestal (Figure 23-22). In general, post removal becomes more challenging moving from anterior to posterior teeth. The difficulty in removing a post substantially increases in furcated teeth containing multiple posts joined coronally with single or multiple interlocking key-ways (Figure 23-23).

When evaluating a tooth for post removal, the clinician must weigh risk versus benefit before proceeding with this procedure.[68,69] As an example, the relative radiodensity between a titanium or a titanium alloy post can appear very similar, or even identical, to gutta-percha when viewed radiographically. As such, when considering nonsurgical retreatment, clinicians need to be familiar with the radiographic characteristics of these nonmetallic posts.[70] A root can be structurally weakened, perforated, or fractured during any phase of retreatment ranging from radicular disassembly to subsequent shaping and filling procedures. In some instances, it may be wise to consider a surgical approach to resolve an endodontic failure. However, surgery should not be performed promiscuously because of lack of training in the best, presently developed techniques utilized for post removal.

Ultrasonic Removal of Prefabricated Post Associated with a Composite or Amalgam Core

The goal is to carefully remove the restorative material with a high-speed carbide long shank bur, paying attention not to damage the protruding head of the post. In the case of a composite core, the difference in color between the metallic post and the filling material makes this procedure easy. After freeing the head of the post, residual fragments of the restorative material and the luting cement must be carefully removed by using a thin ultrasonic tip (Start-X #3, Dentsply, Maillefer; Ballaigues, Switzerland), ProUltra (#3 Dentsply Tulsa Dental Specialties; Tulsa, Oklahoma, USA) (Figure 23-24), or ET20 (Acteon USA; Mt. Laurel, New Jersey, USA). The post is then vibrated with a dedicated ultrasonic tip (Start-X #4, ProUltra #1, or ET PR) with a water coolant until it can be removed (Figure 23-25). The ultrasonic tip should be kept in intimate contact with the post to maximize energy transfer

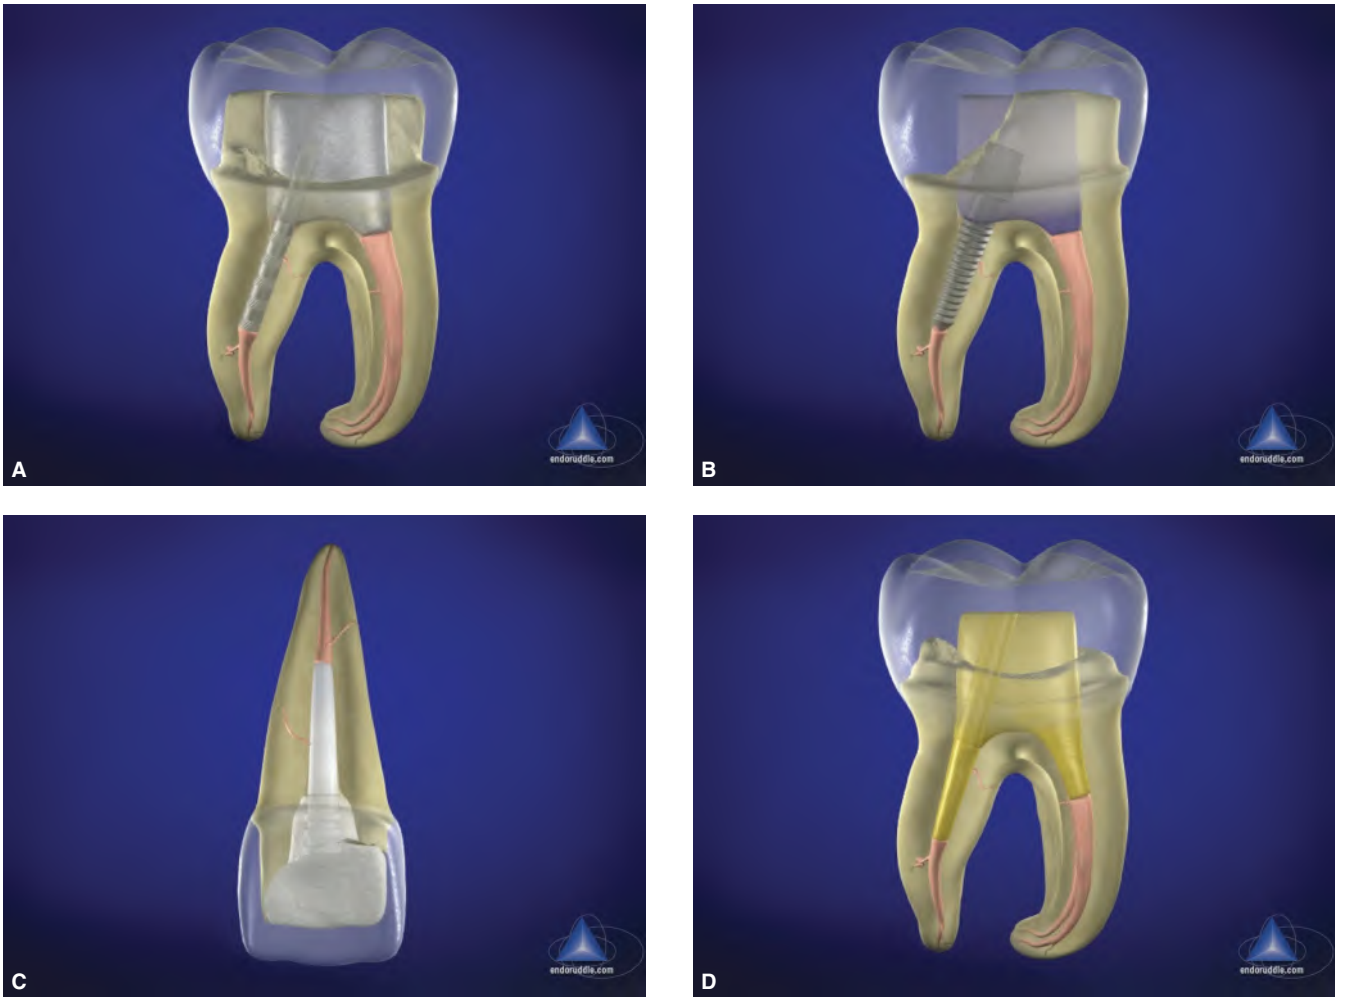

FIGURE 23-21 ***A.*** Parallel post. ***B.*** Screw post. ***C.*** Composite post. ***D.*** Cast gold post/core.

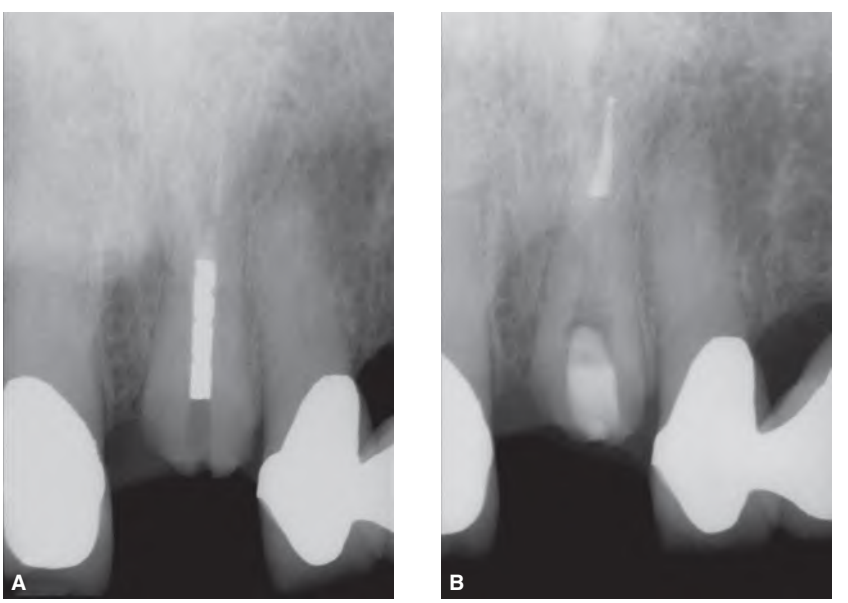

FIGURE 23-22 ***A.*** Preoperative radiograph of a maxillary central incisor showing a post fractured subcrestally; this example serves to emphasize the importance of treatment planning. ***B.*** Post-treatment radiograph following post removal, retreatment, and post space done prior to crown lengthening and restorative treatment.

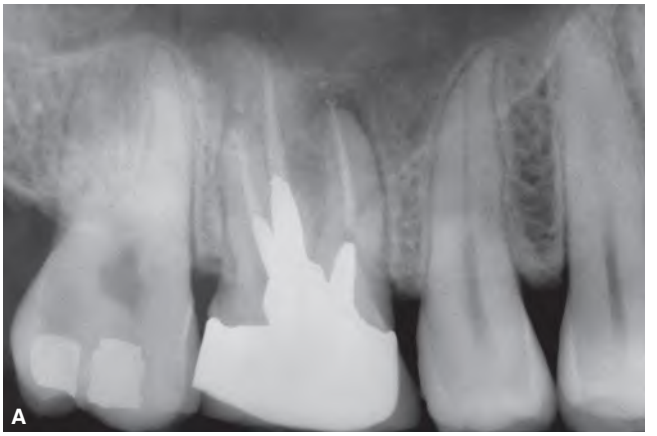

FIGURE 23-23 ***A.*** Preoperative radiograph reveals the MB root of the maxillary first molar is failing endodontically. Note, 3 cast posts interlocking within the pulp chamber. ***B.*** A distal angulated radiograph demonstrating the retreatment effort of the MB root. and promote cement/bond failure. In the case of an amalgam filling, it is important to work the high-speed bur from the periphery toward the location of the post so as to not damage it. In the presence of a screwpost, the ultrasonic tip is rotated counterclockwise (CCW) around the post to dislodge it.

It must be recognized that the byproduct of ultrasonic energy is heat.[71–73] When performing ultrasonic procedures

FIGURE 23-24 The ProUltra ENDO 1-5 ultrasonic instruments have an abrasive zirconium nitride coating to improve efficiency, precision and clinical performance. The ProUltra ENDO-6, 7, and 8 titanium ultrasonic instruments provide longer lengths and smaller diameters, and are utilized when space is restrictive.

for longer periods of time and against larger conductive metal posts, the field should be frequently flushed with water to decrease heat buildup and the potential for dangerous heat transfer to the attachment apparatus. Experience suggests that, after removing all circumferential restorative materials, the majority of posts can be safely and successfully removed within approximately 10 minutes.[3,73] However, certain posts resist removal even after ultrasonic efforts using this "10-Minute Rule." As such, clinicians need a safe and efficient fallback position to liberate these posts.[3,74,75]

For safety, the following precautions should be followed:

- Carefully examine the preoperative radiograph to assess the thickness of the radicular walls between the post and the periodontal tissue. If the thickness is less than 1 mm, the risk of overheating the attachment apparatus quickly increases.
- One or two minute breaks are recommended between ultrasonic sessions.
- Intermittent use of an ice spray (Endo Ice) on the head of the post is recommended. Indeed, a permanent water spray is insufficient to reach and cool down the apical tip of the post. If this ultrasonic attempt is unsuccessful, dedicated mechanical post removal devices should be used.

Another vibrating post removal method employs Rotosonics. This method provides a straightforward technique to potentially loosen and remove a fully exposed post or screw-post. The Regular Tip Roto-Pro bur (Ellman International; Hewlett, New York, USA) is a high-speed, friction grip bur whose six faces are joined by six edges and, when rotated one revolution, its edges produce six vibrations per revolution. When the instrument is rotated at 200,000 rpm, it produces 1.2 million vibrations per minute, or 20,000 vibrations per second. This instrument provides an inexpensive method to remove posts and screw-pots. The bur is kept in intimate contact with

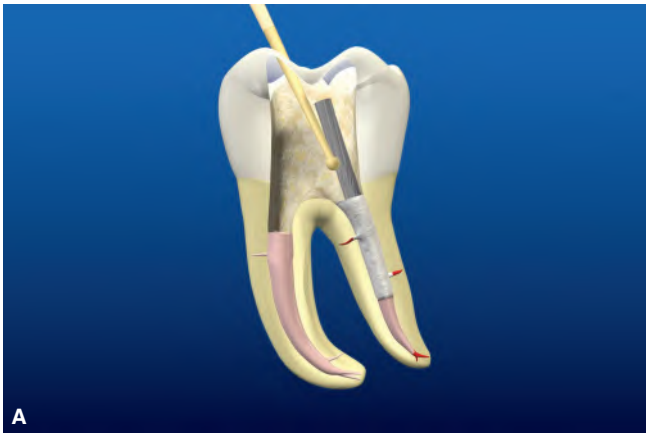

FIGURE 23-25 ***A.*** The ProUltra ENDO-1 is activated and used to powerfully vibrate against all aspects of the exposed post. ***B.*** Illustration demonstrating the importance of using an external water source to reduce temperature and eliminate heat transfer. ***C.*** Following post removal, an ultrasonic instrument breaks up intracanal cement and a White Mac Tip collimates air and blows out debris.

the obstruction and is generally carried CCW around the post. Clinically, rotosonic vibration provides a low-tech method to potentially remove a screw-post or post retained with a more traditional cement, such as zinc phosphate.

Removal of a Fiber Post

A fiber post is usually associated with a composite restorative material. The composite and the protruding head of the post are first removed with a carbide bur mounted on a high-speed handpiece. It is noteworthy that the post should be ground down to the canal orifice. When approaching the pulpal floor, an ultrasonic tip replaces the bur to carefully help eliminate any residual material. For fiber post removal, the goal is to break the bond between the fibers by heating. After creation of a pilot hole in the center of the post with a thin ultrasonic tip (Start-X #3, Dentsply Maillefer; Ballaigues, Switzerland or ET25, Acteon USA; Mt. Laurel, New Jersey, USA) or the pointer drill included in the new Gonon kit (FFDM Pneumat; Bourges, France), the same ultrasonic tip is used with direct vision and without a water coolant to bore through the middle of the post and disintegrate it. The orientation of the fibers helps keep the activated tip in the proper alignment. The last step is to eliminate adhesive fibers from the canal walls with the ultrasonic tip that is used at a low intensity setting with a light, brush-cutting motion. Additionally, fiber posts may be removed with a Unicore drill (Ultradent; South Jordan, Utah, USA), rotated at 15,000 rpm. Start with the small-sized drill (0.6 mm), identified with a white stripe on its handle, then proceed to the yellow-striped drill (0.8 mm), and continue with the red, blue, and green sizes, as necessary, until the fiber post is eliminated. Ceramic and zirconium posts should be avoided since their retrieval is very difficult, thermally dangerous, and virtually impossible.[65]

Removal of Metallic Cast Cores

Metallic cast cores are usually associated with cast posts. In the case of a single-rooted tooth with a cast post and core, two techniques may be used:

1. Utilization of the Coronaflex, as described earlier, when the periodontal environment is sound.
2. Reduction of the core with a transmetal bur without damaging radicular tooth structure. Reduction commences circumferentially around the periphery to the estimated location of the post. The goal is to keep only a cylindrical portion of the core as an extension of the post. Then, ultrasonics and/or a post removal system is used to retrieve the post (see section on mechanical post removal).

In the case of an inlay core within the pulp chamber of a multi-rooted tooth, there may be a single or multiple interlocking key-ways. In these instances, the core must be separated into as many pieces as there are posts present. In the case of a very hard core, such as one fabricated of NiCr, special care is exercised so the bur follows tooth structure, yet does not damage the floor of the pulp chamber. Due to the large amount of vibration delivered during the drilling process, portions of the core devoid of the posts are usually quickly eliminated (Figure 23-26).[56] The head of the post is then cleared from the remaining core portion and post removal is achieved with ultrasonics and/or a post removal system.

Post Removal: Mechanical Options

A number of different devices have been designed to mechanically remove a post.[58,60] However, many of these devices, such as the Masserann kit (Micromega; Besançon, France) and the

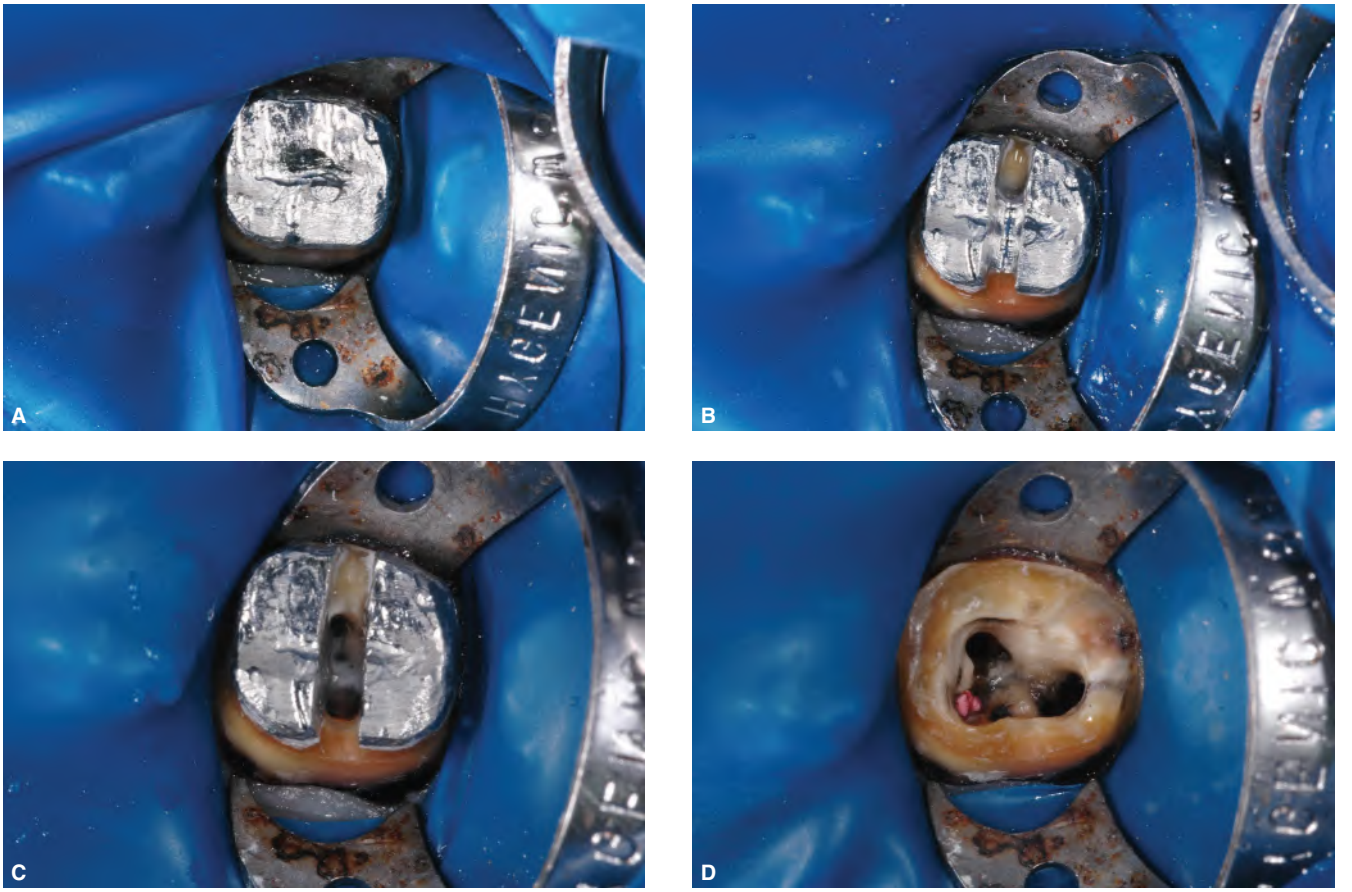

FIGURE 23-26 ***A.*** The mandibular first molar was restored with a NiCr cast core and two posts. ***B.*** Following the tooth structure, a bucco-lingual trench is initiated to separate the core in two pieces. ***C.*** Special care is exercised not to damage the pulp chamber floor. ***D.*** Posts are easily removed due to the combined action of the vibrations delivered during the drilling process and ultrasonics energy.

Post Puller (Brasseler USA; Savannah, Georgia, USA) have had limited success because they frequently require the excessive removal of tooth structure that predisposes to ledges, perforations, or root fractures. The Gonon Post Remover System (EFDM-Pneumat; Bourges, France) represents a definite improvement over the Masserann and the Post Puller devices in that it is less invasive, safe,[68] and has enjoyed good success,[75] but regrettably, by a limited number of clinicians in North America. The Post Removal System (PRS) (Sybron Endo; Orange, California, USA) is a similar device and operates on the corkscrew principle: one force is applied against tooth structure, providing the fulcrum, while the pulling force is placed on the post, creating enough leverage to overcome the bond. Both systems may be predictably used to remove passive conical or parallel posts, cast posts and screw posts. Their respective techniques will be described.

Gonon Post Remover System

Recently, the former Gonon kit has been revisited providing several advantages. It offers fewer instruments with better sizing and can be sterilized. Two trephines are available with matching color-coded and correspondingly sized tubular taps. The tubular taps feature a reverse threading to unscrew serrated and screw posts. The beaks of the extracting pliers are thinner and shorter to facilitate their placement when there is narrow occlusal space. Three sizes of silicone washers and a fiber post kit are included in the kit (Figure 23-27).

The Gonon post removal technique is as follows.

1. After crown removal, circumferential reduction of the core is performed to free the head of the post.
2. To facilitate the centering of the trephine, the head of the post is tapered with a dedicated bur.
3. The largest high-strength trephine is used to bore, grind down, and gauge the protruding head of the post to the exact correspondingly-sized tubular tap. This tubular tap serves to thread down the head of the post and provide a good grip. The more cylindrical the head of the post is bored, the better the trephine efficiency. A high-torque handpiece is used at 15,000 to 20,000 rpm, with short pecking motions, to machine down the head of the post 2 to 3 mm.
4. Before manually screwing the tap onto the post, three washers are placed in the correct sequence onto its shank. They serve to distribute the forces onto the root surface as the post is being extracted. The flat metallic washer is inserted onto the tubular tap first, the concave washer is next inserted onto the top toward the root, and the silicone washer is positioned last and acts as a cushion.

FIGURE 23-27 The Gonon Universal Post remover. Note the color-coding matching trephines and taps. Arrows on tubular taps indicate reverse threading.

5. The extracting pliers are connected to the tubular tap and the beaks of the pliers are expanded by turning the knurled knob. This procedure and resultant force will generally separate the post from the root (Figure 23-28). If too much resistance is felt when rotating the knob, it is useful to reduce resistance by turning the knob CCW a millimeter or two before continuing the clockwise (CW) rotation. In addition, indirect ultrasonics may be applied on the tap to help break the bond.[73] In a study conducted on the incidence of root fractures and methods used for post removal, it was shown that post removal is a predictable procedure with a extremely low rate of root fracture: 0.06% on a total of 1,600 posts removed.[68] This figure is slightly higher than the 0.002% reported in a survey of Australian and New Zealand endodontists.[60]

After post removal, some residual luting cement may be present in the canal beyond the apical tip of the post. With good vision below the orifice, this material can be easily removed with an ultrasonic tip.

Post Removal System

The Post Removal System (PRS) is designed to mechanically engage and remove different kinds of post types or other intracanal obstructions with cross-sectional diameters of 0.60 mm or greater.[3,77] The PRS kit contains extracting pliers, a transmetal bur, five trephines of varying internal diameters, five corresponding tubular taps with internal diameters ranging from 0.60 to 1.60 mm, a torque bar, tube spacers, and a selection of rubber bumpers (Figure 23-29). The preparatory procedures before utilizing the PRS require straightline access and complete circumferential visualization of the post within the pulp chamber.

A transmetal bur is used to round off or taper the coronal most aspect of the post (Figure 23-30A). "Doming" the head of the post will serve to effectively guide the subsequent instruments over the post. A drop or two of chelator, such as RC Prep, Glyde or ProLube, is then placed on the head of the post to act as a lubricant to facilitate the machining process. In order to ensure circumferential milling, the largest trephine that will just engage the post is selected. The latch-type trephines should rotate at approximately 15,000 rpm in a CW direction, in a slow-speed, high-torque handpiece. The trephine is used with a "peck" drilling motion to maintain rpm and to keep the head of the post cooler so it does not work-harden and become more difficult to machine. The trephine is utilized to machine down a 2 to 3 mm length of the most coronal aspect of the exposed post (Figure 23-30B). If the chosen trephine fits passively, then a sequentially smaller size trephine is selected to ensure proper circumferential milling. In some instances, the configuration of the coronal-most aspect of the post, such as a cast post/core, dictates the use of a transmetal bur or diamond to grind down the head of the post to create a relatively round cylinder. The trephine can then machine a precisely round cross-sectional diameter on the post.

In general, the trephine used for machining the post dictates the subsequent selection of a correspondingly-sized tubular tap. An appropriately-sized protective rubber bumper is selected and inserted over the distal end of the tap. The bumper serves to cushion, evenly distribute the loads, and protect the tooth during the removal procedure. The tubular tap is pushed against the head of the milled-down post and is manually turned CCW to form threads (Figure 23-30C). Firm apical pressure and small quarter-turn CCW motions will generally draw down and securely engage the tap to the post. The tap can be screwed over the post as little as 1 mm or, more optimally, up to a maximum of 3 mm. Caution should be exercised so that the tap is not drawn down too far over the post because its maximum internal depth is 4 mm. If the tap bottoms out against the post head, it can predispose to stripping the threads, breaking the wall of the tap, or shearing off the obstruction inside the lumen of the tap. When the tubular tap has snugly engaged the post, the protective rubber bumper is pushed down onto the biting surface of the tooth (Figure 23-30D).

The post removal pliers are then selected and the extracting jaws are mounted onto the tubular tap. The instrument is held securely with one hand, while the fingers of the other hand begin opening the jaws by turning the screw knob CW. As the jaws slowly begin to open, increasing pressure will be noted on the screw knob. The clinician should repeatedly verify that the compressing rubber cushion is properly protecting the tooth. Further, when utilizing this removal method, the clinician should visually confirm the post is being safely withdrawn along the long axis of the root canal. If turning the screw knob becomes increasingly difficult, the clinician should either hesitate a few seconds before continuing and/or use the indirect ultrasonic technique to vibrate on the post-engaged tubular tap (Figure 23-30E). In combination, the PRS and indirect ultrasonic techniques enhance post retention failure, encourage the screw knob to turn further, and are potent adjuncts to successful post removal (Figure 23-30F).[3]

Ultimately, the PRS provides clinicians an important post removal method that can be safely employed when ultrasonic techniques are unsuccessful. Clinicians also encounter

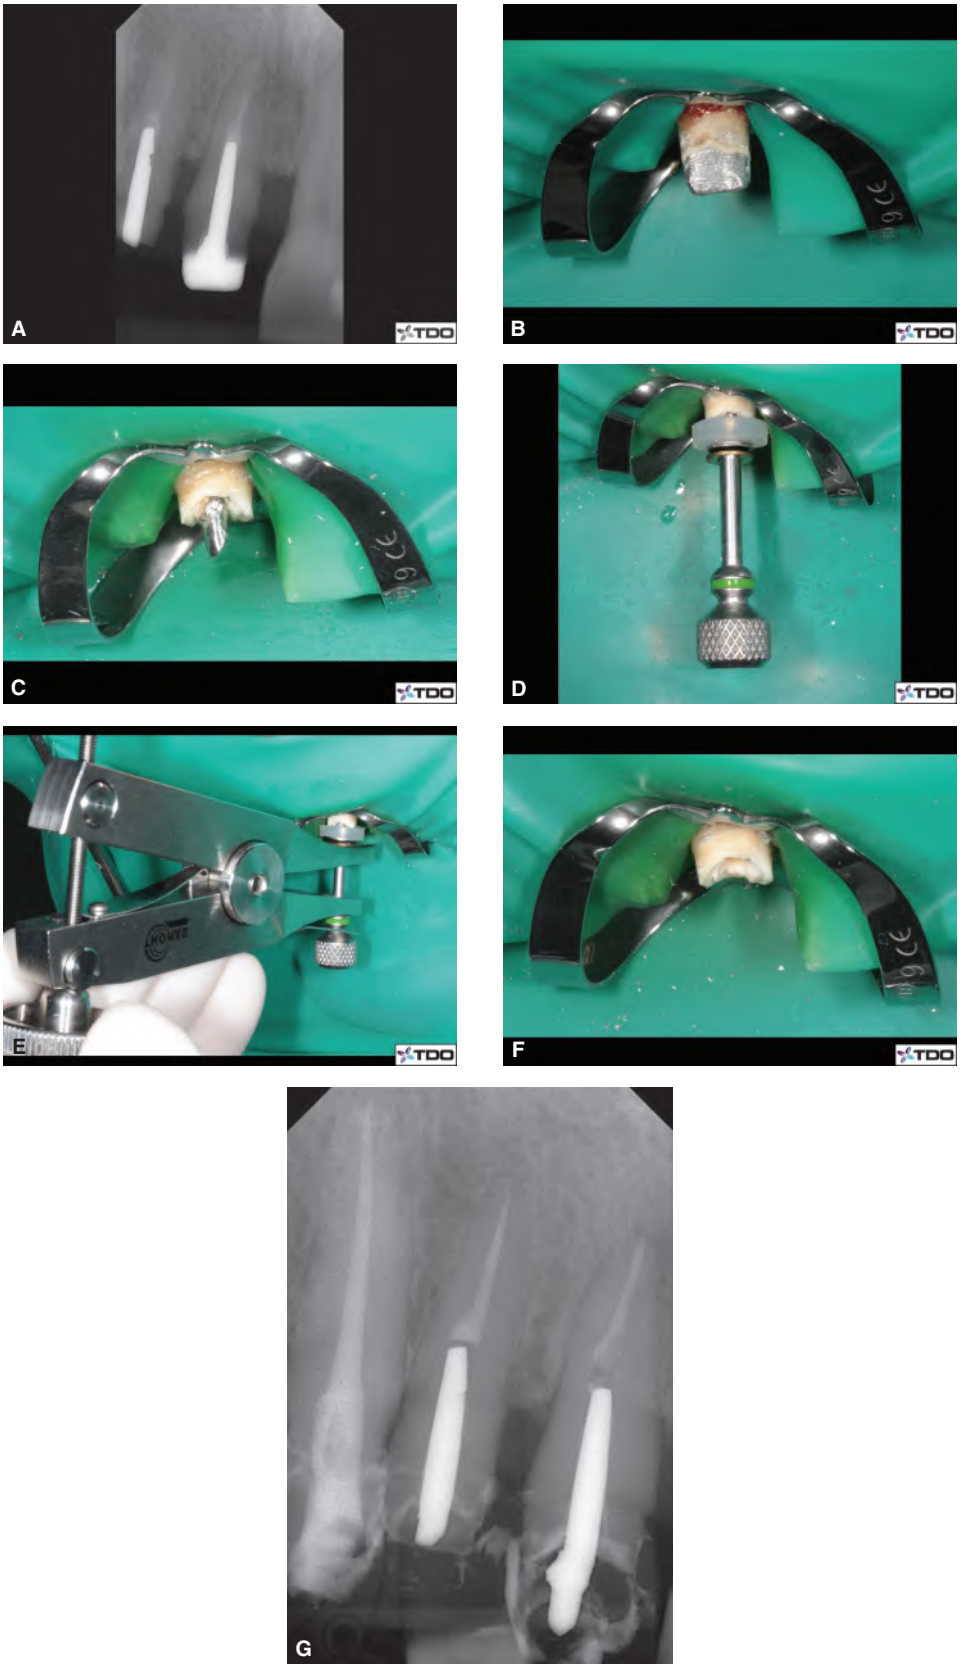

FIGURE 23-28 ***A.*** Two metallic posts must be removed before retreatment. ***B.*** Clinical view of the metallic core. ***C.*** Circumferential pre-reduction of the core before tapering the head of the post to facilitate the centering of the trephine. ***D.*** The tubular tap with the three washers creates a threading on the post. ***E.*** The pliers are connected to the tubular tap. ***F.*** Post removed from the root. ***G.*** Postoperative radiograph of the teeth after retreatment and placement of provisional restorations.

FIGURE 23-29 The Post Removal System is a kit designed to mechanically engage and potentially remove different types of posts.

actively engaged threaded posts that require removal. The PRS is specifically designed to address this scenario because each tubular tap turns in a CCW rotation. The post head is milled down as previously described and a tubular tap threaded until snug. In instances where threaded posts are encountered, the use of the extracting pliers is contraindicated. Typically, the clinician backs the post out of the canal using a CCW rotation with finger pressure. If the post is strongly anchored, an ultrasonic instrument may be used to vibrate on the tap, and if necessary, the torque bar may be inserted into the handle port to increase leverage.

Masserann Kit

When a post is broken deep inside the root, the Masserann kit may be considered to conserve root structure (Figure 23-31).[56] A wide range of trephines manufactured with soft steel are available and the one matching the post space is

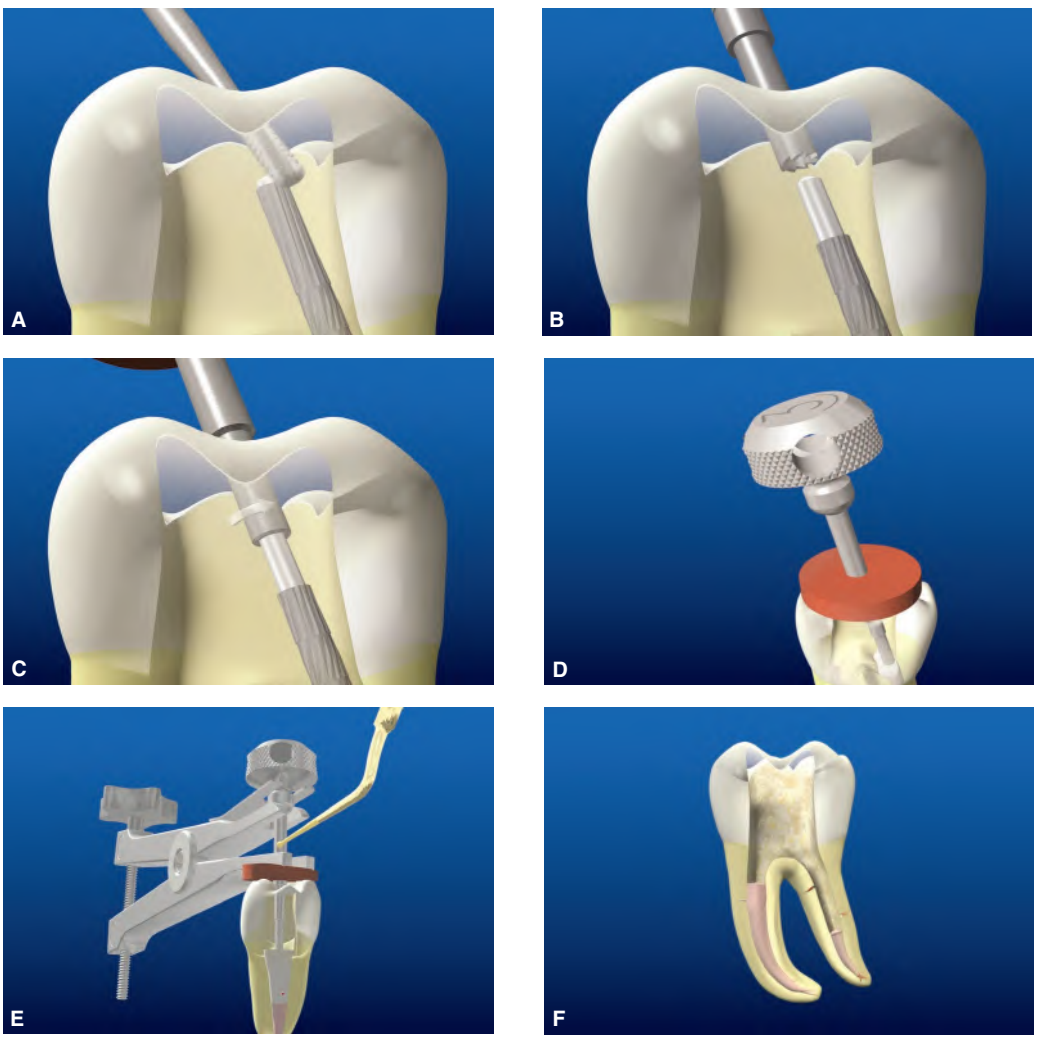

FIGURE 23-30 ***A.*** Illustration of a transmetal bur efficiently doming the post head. ***B.*** No. 3 trephine has precisely machined down the coronal 3 mm of the post. ***C.*** Tubular tap is turned counterclockwise to form threads, draw down, and strongly engage the post. ***D.*** Once the tap is securely engaged to the post, the rubber bumper is seated against the occlusal surface to protect the tooth. ***E.*** Mounted and activated PRS extracting pliers. selected. The trephine is mounted onto a mandrel and rotated CCW to create a thin trench around half the length of the post. During the procedure, the trephine must be regularly cleaned of dentine dust. Next, the smaller trephine is placed and used in a CCW motion around the broken post trying to reach the depth of the trench. The soft steel trephine deforms during apical progression and, at any given moment, the friction between the trephine and the post becomes greater than the retention of the post, allowing it to be removed. Such a procedure is time-consuming and the clinician must weigh risk vs. benefit when using this method.

MISSED CANALS

The etiology of endodontic failure is multi-faceted, but a statistically significant percentage of failures are related to missed root canal systems. Missed canals hold tissue, and at times microorganisms and related irritants that inevitably contribute to clinical symptoms and lesions of endodontic origin (Figure 23-32).[76–81]. Historically, and still too often, surgical treatment has been directed toward "corking" the end of the canal with the hopes that the retrograde material will incarcerate biological irritants within the root canal system over the life of the patient (Figure 23-33).[82,83] Although this clinical scenario occurs anecdotally, it is not nearly as predictable as nonsurgical retreatment. Endodontic prognosis is maximized in teeth whose root canal systems are cleaned, shaped, and filled in *all* their dimensions (Figure 23-34).[84–85]

Canal Anatomy

There are several tooth groups whose roots notoriously hold additional systems.[86,87]

- *Maxillary Central Incisors* on occasion may contain one or more extra canals.[88,89]
- *Maxillary 1st Premolars* are at times three-rooted and have mesiobuccal (MB), distobuccal (DB), and palatal root canal systems.[90]
- *Maxillary 2nd Premolars* contain broad roots buccal to lingual and, although the orifices are commonly ribbon-shaped, clinicians need to expect deep canal divisions or apical bifidities.[91]
- *Maxillary 1st Molars* have two systems in the MB root more than 90% of the time and these two systems oftentimes communicate anatomically via an isthmus.[92] According to the literature, about 40% of the time, the two root canal systems merge and exit as one apical portal of exit; about 60% of the time, the two canals are separate and have their own individual portals of exit. These systems can be identified and treated in over 75% of the cases *without* a microscope and in approximately 90% of the cases *with* a microscope.[93,94]
- *Maxillary 2nd Molars* should be suspected of having a second canal in the MB root until proven otherwise.[93] Some maxillary molars exhibit bizarre anatomy within the MB root; the grooves should be explored for the possibility of a third system.
- *Mandibular Incisors* have broad roots facial to lingual and have a second more lingual canal approximately 45% of the time.[95] Access cavities should be carried more lingual at the expense of the cingulum to address this potential system.
- *Mandibular Premolars* have roots that frequently hold complex root canal systems. The anatomical variations include displaced orifices, deep divisions, loops and branches, and multiple portals of exit apically.[96]
- *Mandibular 1st and 2nd Molars* routinely have significant variations within what has become known as "normal anatomy."[59,86] Clinicians need to check the mesial root for a third system that may be displaced or located within the groove between the MB and mesiolingual (ML) orifices.[97,98] The broad distal root commonly contains an extra canal that may be separated along its length or become contiguous, following cleaning and shaping procedures. However, even when distobuccal (DB) and distolingual (DL) systems become common, deep branching with multiple apical portals of exit are normal.
- *C-Shaped Molars* pose challenges in endodontic treatment; they tend to have fused roots, deep pulp chambers, and the cul-de-sac furcation is toward the lingual aspect. Clinicians need to be familiar with this aberrant canal form and be well aware of its radiographic features and its incidence within various population groups.[99]

Armamentarium and Techniques

There are multiple concepts, armamentarium, and instruments that are useful to find missed canals. The following represents the most important.

- *Anatomical familiarity*: Any dentist can become a serious student of endodontic anatomy by reviewing the historic work of Walter Hess or visualizing state-of-the-art μCT images (www.ehumanlearning.com). Knowledge, understanding, and appreciation for root canal system anatomy influence predictably successful endodontic treatment outcomes. For more details, see Chapter 1, "Anatomy and morphology of teeth and their root canal systems."
- *Radiographic analysis* is critical when evaluating an endodontic failure.[100,101] Well-angulated periapical films should be taken with the cone directed straight-on,

FIGURE 23-32 ***A.*** Radiograph of a maxillary right second premolar reveals pins, a post, incomplete endodontic treatments and an asymmetrical lesion. ***B.*** Photograph at 12× magnification shows the post is out of the buccal canal, thread marks in the gutta-percha from the screw post, and evidence of a missed palatal canal system. ***C.*** Photograph at 12× magnification demonstrates complete access and identification of the palatal orifice/system. ***D.*** Ten-year recall radiograph shows excellent osseous repair. This case demonstrates the importance of 3-D endodontics, and a well-designed and sealed restoration.

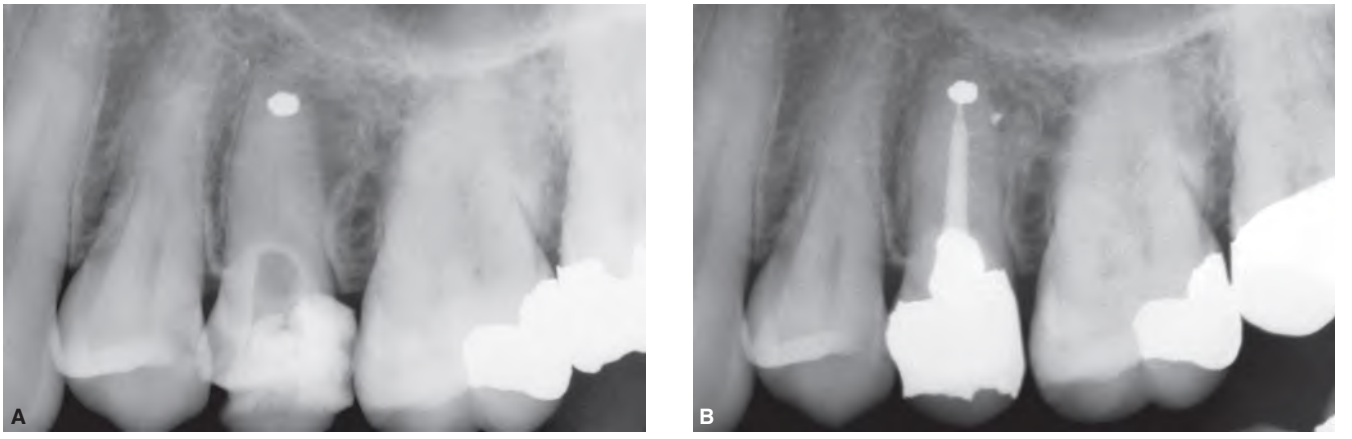

FIGURE 23-33 ***A.*** Preoperative radiograph reveals a failing treatment in a maxillary premolar with a laterally positioned lesion of endodontic origin. mesioblique, and distoblique. This technique oftentimes reveals and clarifies the three-dimensional morphology of the tooth. In teeth where complete endodontic treatment has been performed, obturation materials are seen radiographically as centered within the root, regardless of the selected angle of the radiograph. Conversely, if the obturation materials appear positioned asymmetrically within the long axis of the root, a missed canal should be suspected (Figure 23-32).[102] Digital Radiography (Kodak; Atlanta, Georgia) affords a variety of software features significantly

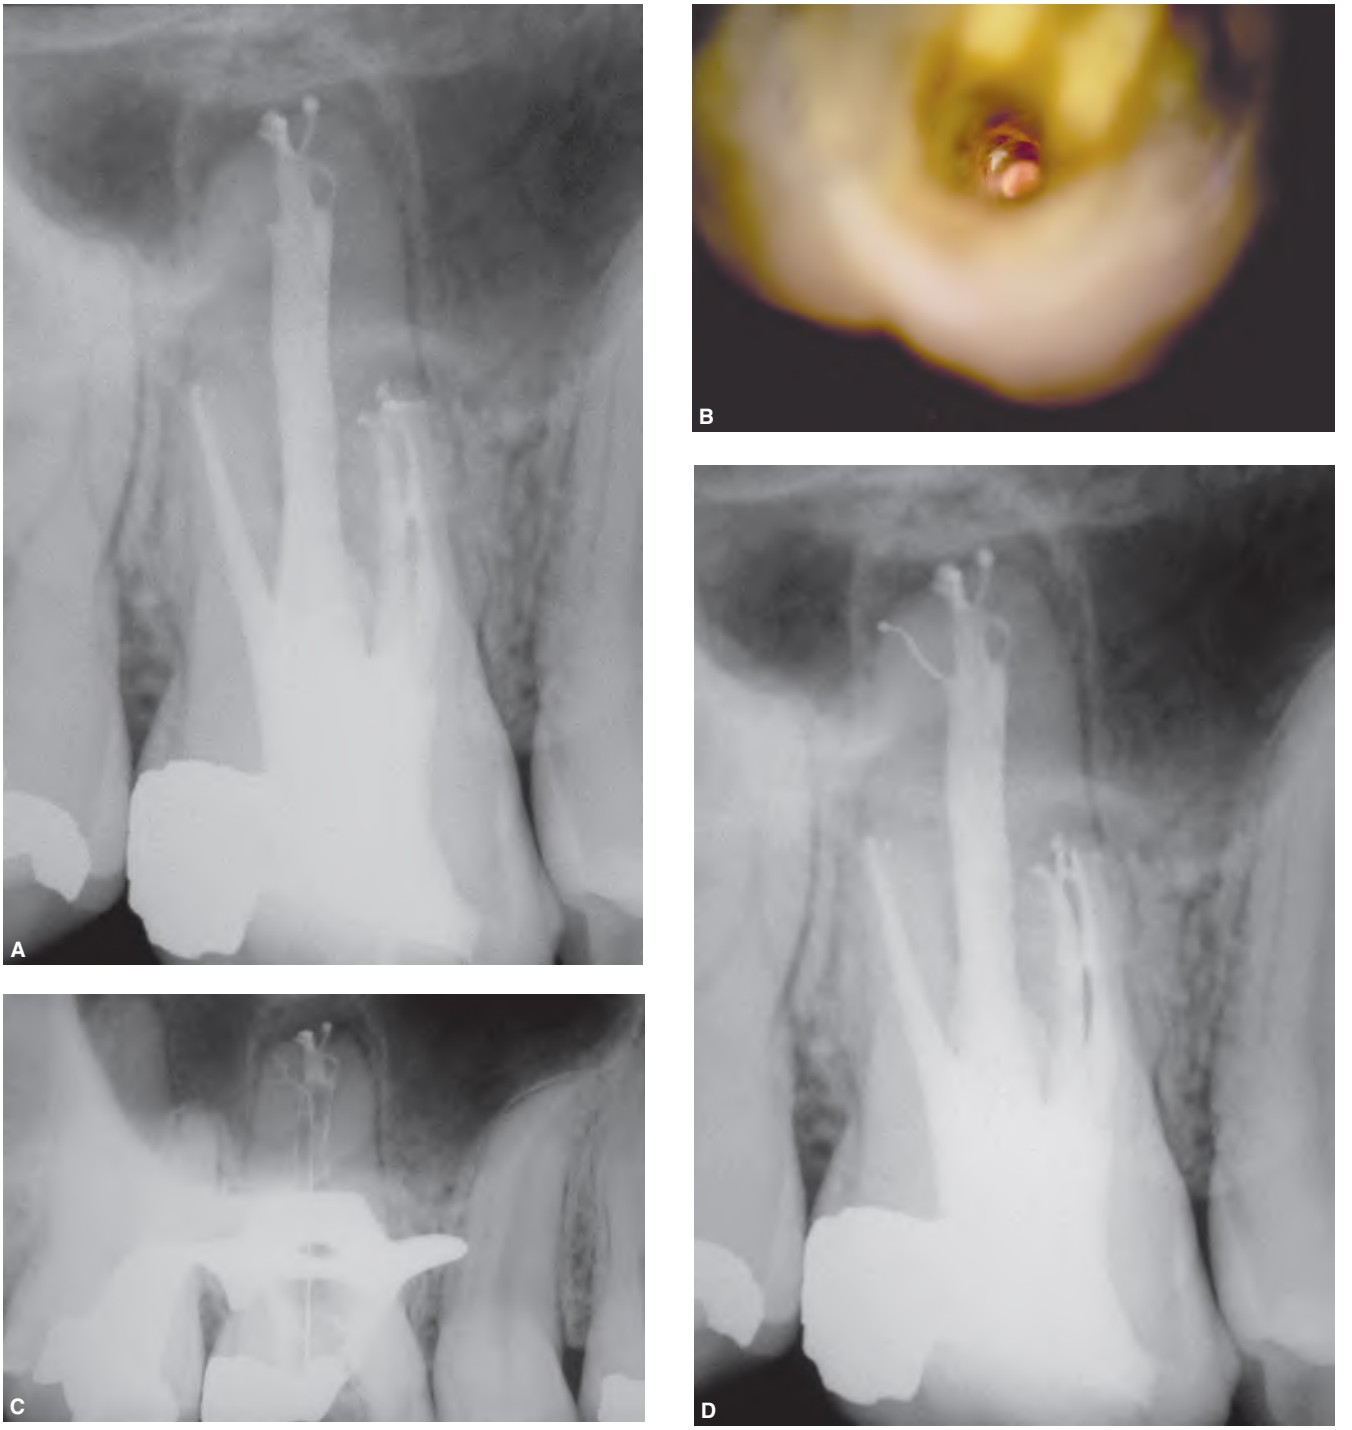

FIGURE 23-34 ***A.*** Radiograph of a maxillary right first molar with a failing treatment in the palatal root. ***B.*** A deep look into the apical one-third of the palatal canal reveals debris in the entrance to a lateral canal. ***C.*** Working radiograph demonstrates a no. 10 file moving through this ramification to its terminus. ***D.*** Post-treatment radiograph depicting the retreatment effort.

enhancing radiographic diagnostics in identifying hidden, calcified, or untreated canals. Certainly, CBCT technology represents a major advancement in radiographic diagnostics and facilitates identifying aberrant, mineralized, or previously missed canals.[18] For more details, see Chapter 9, "Imaging devices and techniques."

- *Vision* is enhanced with magnification glasses, headlamps, and transilluminating devices. The dental operating microscope (Carl Zeiss Surgical; Thornwood, New York, USA) affords extraordinary light and magnification, and gives the clinician unsurpassed vision, control, and confidence in identifying or chasing extra canals (Figure 23-34).[102] Operating microscopes typically have a range of magnification from about 2.5× to around 20×. Magnification plus lighting equals vision. Surgical length burs enhance direct vision by

importantly moving the head of the handpiece further away from the occlusal table and improving the line of sight along the shaft of the bur.

- *Access cavities* should be prepared and expanded so their smallest dimensions are dictated by the separation of the orifices on the pulpal floor and their widest dimensions are at the occlusal table. The isthmus areas and/or developmental grooves are firmly probed with an explorer in an effort to find a "catch" (Figure 23-35). In general, the access preparation should be prepared, so the operator can look in the mouth-mirror of a furcated tooth and visualize all of the orifices without moving the mirror. Importantly, axial walls should be flared, flattened, and finished to provide straightline access to the orifice(s).
- *Piezoelectric ultrasonics* provides a breakthrough for exploring and identifying missed canals (Figure 23-36). It should be fully appreciated that ultrasonic instruments perform optimally when they are designed, manufactured, and tuned for a specific generator. Synergistically, a piezoelectric generator (Newtron P5, Acteon USA; Mt. Laurel, New Jersey, USA) in conjunction with ultrasonic instruments (ProUltra ENDO Instruments, Dentsply Maillefer; Ballaigues, Switzerland) are utilized to transfer energy and perform a variety of clinical procedures.[103] Ultrasonic systems importantly eliminate the bulky head of the conventional handpiece that notoriously obstructs vision. The working ends of specific ultrasonic instruments are 10 times smaller than the smallest manufactured round burs and their abrasive coatings allow them to precisely sand away dentin when exploring for missed canals (Figure 23-24).
- *Micro-Openers* (Dentsply Maillefer; Ballaigues, Switzerland) are flexible, stainless steel hand instruments that feature ergonomically designed off-set handles. Micro-Openers have limited length cutting blades that, in conjunction with their .04 and .06 tapers, enhance tensile strength, making it easier to locate, penetrate, and perform initial canal enlargement procedures. These instruments provide unobstructed vision when operating in difficult teeth with limited access (Figure 23-37).
- *Various dyes*, like methylene blue, can be irrigated into the pulp chambers of teeth to aid in diagnosis. The chamber is subsequently rinsed thoroughly with water, dried, and visualized. Frequently, the dye will be absorbed into orifices, fins, and isthmus areas that serves to "roadmap" the anatomy. This technique can aid in the identification and treatment of missed canals and enhance diagnostics, including the visualization of fractures.
- *Sodium hypochlorite (NaOCl)* can aid in the diagnosis of missed or hidden canals. This has been called the *"champagne test."*[8] Following cleaning and shaping procedures, the access cavity is flooded with NaOCl and the solution is observed to see if oxygen bubbles are emanating toward the occlusal table. A positive *"bubble"* reaction signifies that sodium hypochlorite is either reacting with residual tissue within a missed canal or with residual chelator that is still present within a canal being prepared.[56]
- *Transillumination* is accomplished by positioning a fiber optic wand either above or below the dental dam and directing light buccal to lingual. Diagnostics are, at times, improved by turning off the overhead or microscope light source to achieve a different perspective.
- *Explorer Pressure*: The endodontic hand-held explorer should be strong, thin, and have a durable pointed tip. Firm explorer pressure provides a safe way to punch through a thin layer of secondary dentin and expose a hidden, receded, and more mineralized canal.
- *White Line Test:* Oftentimes, a shelf of dentin meets the pulpal floor and forms a groove. It is important to recognize that extra canals can be more readily identified by progressively sanding away this shelf of dentin with abrasively coated or micro-milled ultrasonic instruments. During ultrasonic procedures in necrotic teeth, dentinal

dust moves into available anatomical space, such as the isthmus, and forms a visible white line. The white line test is a visible road map that can be followed and diagnostically aid in identifying, as an example, an MB2 orifice/canal.

- *Red Line Test:* In vital cases, blood frequently moves into an isthmus area. Like a dye, blood absorbs into orifices, fins, and isthmuses, and serves to roadmap and aid in the identification of the underlying anatomy. This is called the red line test.

- *Restorative Disassembly*: Removing a full-coverage dental restoration provides direct visualization of the underlying tooth preparation. Coronal disassembly improves the predictability of safely entering the pulp chamber and identifying any given orifice.
- *Perio-Probing* is another important idea for locating canals. Probing the sulcus can provide important information as to the relationship between the long axis of the clinical crown and the underlying root.
- *Symmetry* is an important visual test that can encourage looking for another orifice/canal or confirm that all canals have been properly identified. The rules of symmetry suggest that if any given root contains only one canal, then regardless of its anatomical configuration, the orifice should be positioned an equal distance from the external cavo surface of the root.[104]
- *Color* roadmaps the anatomy. Oftentimes, a dark groove on the pulpal floor of a multi-canal tooth can be followed and will lead to another canal orifice. Additionally, orifices frequently appear a darker color than the surrounding dentin in teeth exhibiting calcification.

Persistent apical periodontitis is often the result of a missed MB-2 canal in maxilllary molars. If discovered, missed canals can usually be three-dimensionally cleaned, shaped, and packed. However, if a missed canal is suspected but cannot be readily identified, then an endodontic referral may be prudent to avoid further complications. Caution should be exercised when contemplating surgery due to the aforementioned concerns; but at times, surgery may be necessary in the hopes of salvaging the tooth.

GAINING ACCESS TO THE CANAL TERMINUS

Removal of Filling Materials

Once the coronal obstacles have been removed, intracanal obstacles, mainly radicular filling materials, should be eliminated before attempting to negotiate the unfilled portion of the root canal system (Figure 23-38). Apical to the previously placed obturation material, it is normal to encounter a variety of mishaps, such as blocks, ledges, fractured instruments, transportations, and perforations. Utilizing illumination and magnification with the operating microscope, dedicated ultrasonic tips, MTA, and bioceramic cements have served to push the limits of therapeutic possibilities, enabling successful retreatment and salvaging many cases that would not have been treatable in the past.

The obturation materials most frequently found in the root canal space generally reflect a past era of knowledge, a current school of thought, or a personal philosophy of treatment. Experience reveals there are four commonly encountered materials found in obturated root canal systems. These materials are *gutta-percha*, *carrier-based obturators*, *silver points* and *paste fillers*. In addition, new obturation materials have recently been recommended for filling root canal systems; as an example, resin-based materials can generally be removed using the same technique as will be outlined for the removal of gutta-percha. Frequently it is necessary to remove

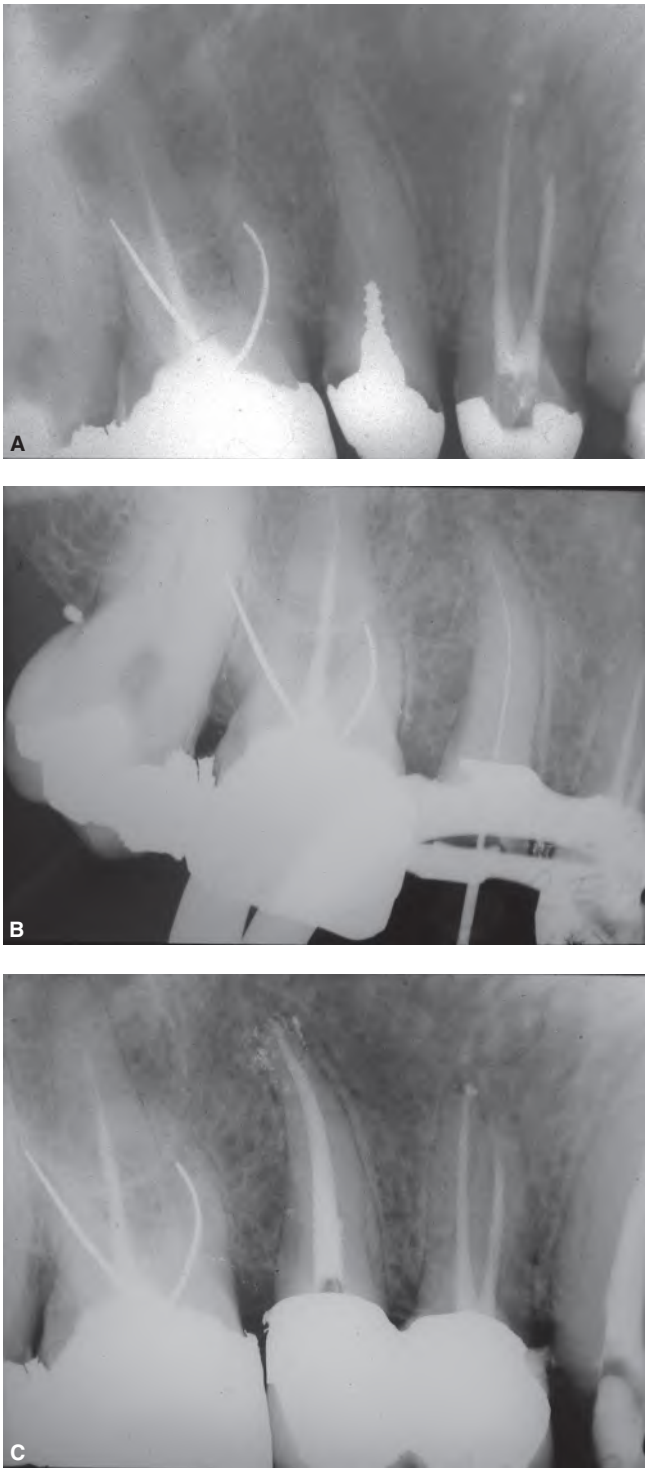

FIGURE 23-38 ***A.*** The maxillary second premolar is scheduled to be retreated before placement of a new restoration. Coronal and intracanal obstacles must be removed. ***B.*** The root canal is negotiated. ***C.*** Postoperative radiograph demonstrating obturating material in a lateral canal and apical ramifications.

an obturation material to achieve endodontic retreatment success or to facilitate placing a post for restorative reasons. The effective and efficient removal of an obturation material requires utilizing the most predictable methods from the past, in conjunction with the timely integration of the best presently developed techniques.

Gutta-Percha Removal

The relative difficulty in removing gutta-percha varies according to the canal's length, cross-sectional diameter, and curvature. Regardless of technique, gutta-percha is best removed from a root canal in a *progressive* manner to avoid the risk of definitive canal blockage and prevent inadvertent displacement of irritants periapically. Dividing the root into thirds, gutta-percha is initially removed from the canal in the coronal one-third, then the middle one-third, and finally eliminated from the apical one-third. In canals that are relatively large and straight, single cones can, at times, be removed with one instrument in one motion (Figure 23-39). For other canals, there are a number of possible gutta-percha removal schemes. The techniques include rotary files, ultrasonic instruments, heat, hand files with heat or chemicals, and paper points with chemicals.[105] Of these options, the best technique(s) for a specific case is selected based on preoperative radiographs and clinically assessing the diameter of the orifices after re-entering the pulp chamber. Certainly, a combination of methods is generally required, and, in concert, provide safe, efficient, and potentially complete elimination of gutta-percha and sealer from the internal anatomy of the root canal system.

Rotary Instruments

Rotary instrumentation is the most efficient method for removing gutta-percha from a previously treated root canal (Figure 23-40). The first step is to assess precisely the level of the previous obturation. The ProTaper Retreatment Kit (Dentsply Maillefer; Ballaigues, Switzerland) is an innovative system comprised of 3 nickel titanium (NiTi) instruments that vary in length (16 mm, 18 mm, and 22 mm respectively for D1, D2 and D3), diameter, and taper (30/09, 25/08, 20/07) (Figure 23-41). Rotary instruments should be used with caution in underprepared canals and are generally not selected for removing gutta-percha in canals that do not accept them *passively*. When attempting gutta-percha removal, it is useful to mentally divide the root into thirds and then select two or three appropriately-sized rotary instruments that will fit passively within these progressively smaller regions.

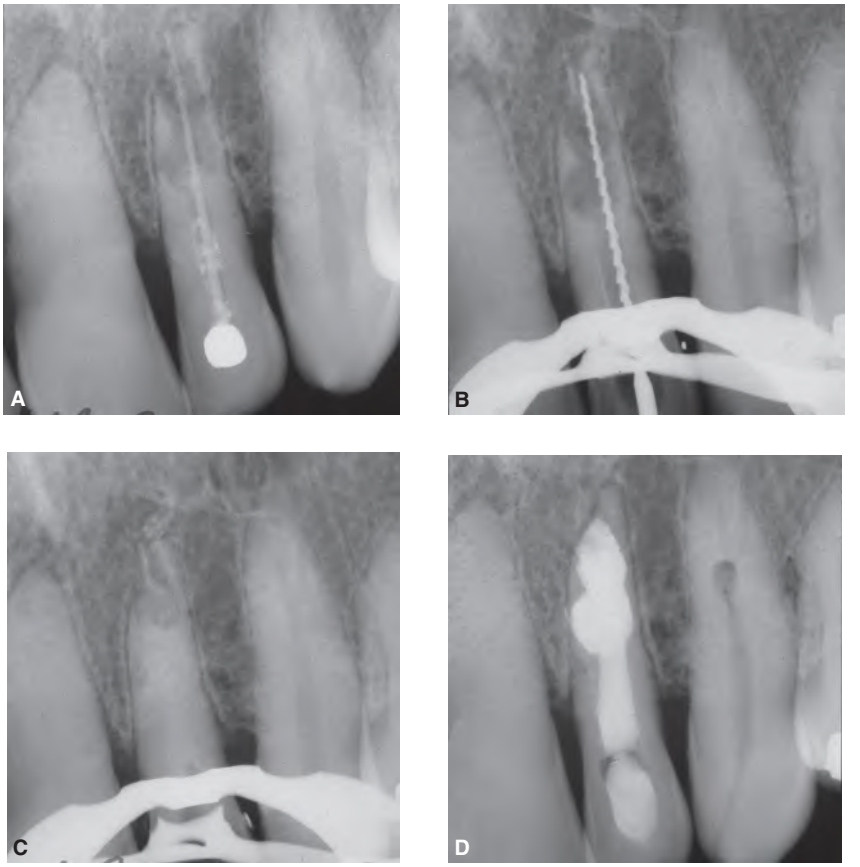

FIGURE 23-39 ***A.*** Radiograph showing a poorly sealed lateral incisor with a gutta- percha cone floating in the canal. An extensive internal resortion perforates the root in apical and mesial areas. ***B.*** In relatively large and straight canals, single gutta-percha cones can be removed with one H-file in one motion. ***C.*** The root canal was medicated with calcium hydoxyde for three months. ***D.*** Postoperative radiograph after root canal filling demonstrating excellent repair and formation of a new periodontal ligament in the perforated areas.

Postoperative radiograph demonstrating the value of nonsurgical retreatment and its potential to address root canal systems and improve quality of treatment.

To mechanically soften and engage gutta-percha, rotary instruments must turn at speeds ranging from 800 to 1200 rpm. Ultimately, the rotational speed selected is based on the friction required to mechanically soften and effectively remove gutta-percha coronally, owing to the fluted design of the instrument. Using a well-angulated radiograph to precisely assess the level of the previous obturation, care should be taken to use short pecking motions to engage the gutta-percha. The file should be removed and frequently inspected to assure filling material can be visualized on the apical flutes. Following initial engagement of the gutta-percha, a brushing motion on the outstroke helps improve its removal. If resistance to progression is felt, a radiograph should be taken to assess if all material has been removed or not. If there is no

FIGURE 23-41 The ProTaper Retreatment Kit *(Dentsply Maillefer; Ballaigues, Switzerland)*.

radiographic evidence of residual filling material, it is wise to continue the procedure with stainless steel hand K-files.

Heat

A power source, in conjunction with specific electric heat carrier instruments (Touch'n Heat 5004, SybronEndo; Orange, California, USA or Calamus, Dentsply Maillefer; Ballaigues, Switzerland), may be used to thermosoften and remove "bites" of gutta-percha from root canal systems. The cross-sectional diameter of the heat carrier limits its ability to plunge into underprepared canals and around pathways of curvature; however, in larger canals, this method works quite well. The technique is to activate the instrument so that it is red-hot and then plunge it into the coronal-most aspect of the gutta-percha. The heat carrier is then deactivated and, as it cools, will typically freeze a bite of gutta-percha on its working end. Instrument withdrawal generally results in the removal of an attached bite of gutta-percha. This process is repeated as long as it continues to be productive.

File and Chemical

The file and chemical removal option is best utilized to remove gutta-percha from small, curved, and densely filled canals. A pilot hole is first created in the coronal portion of the canal with either a hot heat carrier or by using the Protaper Retreatment D1 instrument. Two or three drops of chloroform are then introduced into the newly created reservoir inside the root canal. Chloroform is still the reagent of choice and plays an important role in chemically softening gutta-percha.[106–109] A sequential technique is advocated to remove the filling material. It involves the use of H-type files, 21 mm in descending order to gently "pick" into the chemically softened gutta-percha. Shorter instruments are preferred since they provide more stiffness and have less tendency to flex. Without trying to engage the more apical material, a lateral motion is used with the H-file to remove gutta-percha remnants at this level. This method is repeated to progress apically until gutta-percha is no longer evident on the cutting flutes of the file when it is withdrawn from a solvent-filled canal. Such a progressive removal technique helps prevent the needless extrusion of chemically softened gutta-percha periapically. Once the "file and chemical" gutta-percha removal technique has been completed, clinicians need to appreciate that they still need to address the residual sealer and gutta-percha that remain in the irregularities of the root canal system.[105] The wicking technique and canal re-instrumentation will overcome this problem.

Paper Point and Chemical

Gutta-percha and most sealers are miscible in chloroform and solvents and, once in solution, can be absorbed and removed with appropriately-sized paper points. Drying solvent-filled canals with paper points is known as "wicking" and is *always* the final step of gutta-percha removal.[3] The wicking action is essential in removing residual gutta-percha and sealer out of fins, cul-de-sacs, and aberrations of the root canal systems. In this technique, the canal is first flushed with chloroform and the solution is then absorbed and removed with appropriately-sized paper points. Paper points "wick" by pulling dissolved materials laterally into the shaped canal. Chemical flushing and wicking procedures more effectively liberate residual gutta-percha and sealer from the root canal system (Figure 23-42D). This process is repeated as long as it continues to be visibly productive. Alternatively, the EndoActivator is a powerful adjunct to help eliminate residual sealer from the canal walls. Solvent is flooded into the pulp chamber before using the EndoActivator. A preselected polymer tip is activated and serves to vigorously agitate the solvent, create turbulence, and enhance the cleaning efficiency. Paper points are then used to absorb the dissolved materials.

Even when paper points come out of the canal clean, white, and dry, the clinician should assume residual gutta-percha and sealer are still present. At this point, the chamber is again flooded with chloroform, but it is now introduced with more of an irrigation and vacuum "flushing action." The irrigating canula is placed below the orifice and the solvent is passively and repeatedly irrigated, then aspirated. This alternating method of irrigating-then-aspirating creates a vigorous back-and-forth turbulence that powerfully promotes the elimination of the root canal filling materials. Following chloroform wicking procedures, the canal is liberally flushed with 70% isopropyl alcohol and wicked to further encourage the elimination of chemically softened gutta-percha residues (Figure 23-42D). Removal of all residual material, in this manner, will enhance the efficacy of sodium hypochlorite when it is utilized during subsequent cleaning and shaping procedures.

Carrier-Based Gutta-percha Removal

Carrier-based obturators were originally metal and file-like, yet over the past several years, they have been manufactured from easier-to-remove plastic materials. Recently, a cross-linked gutta-percha core has replaced the plastic carrier, making retreatment easier.[110] Metal carriers, although no longer distributed, are occasionally encountered clinically and are more difficult to remove

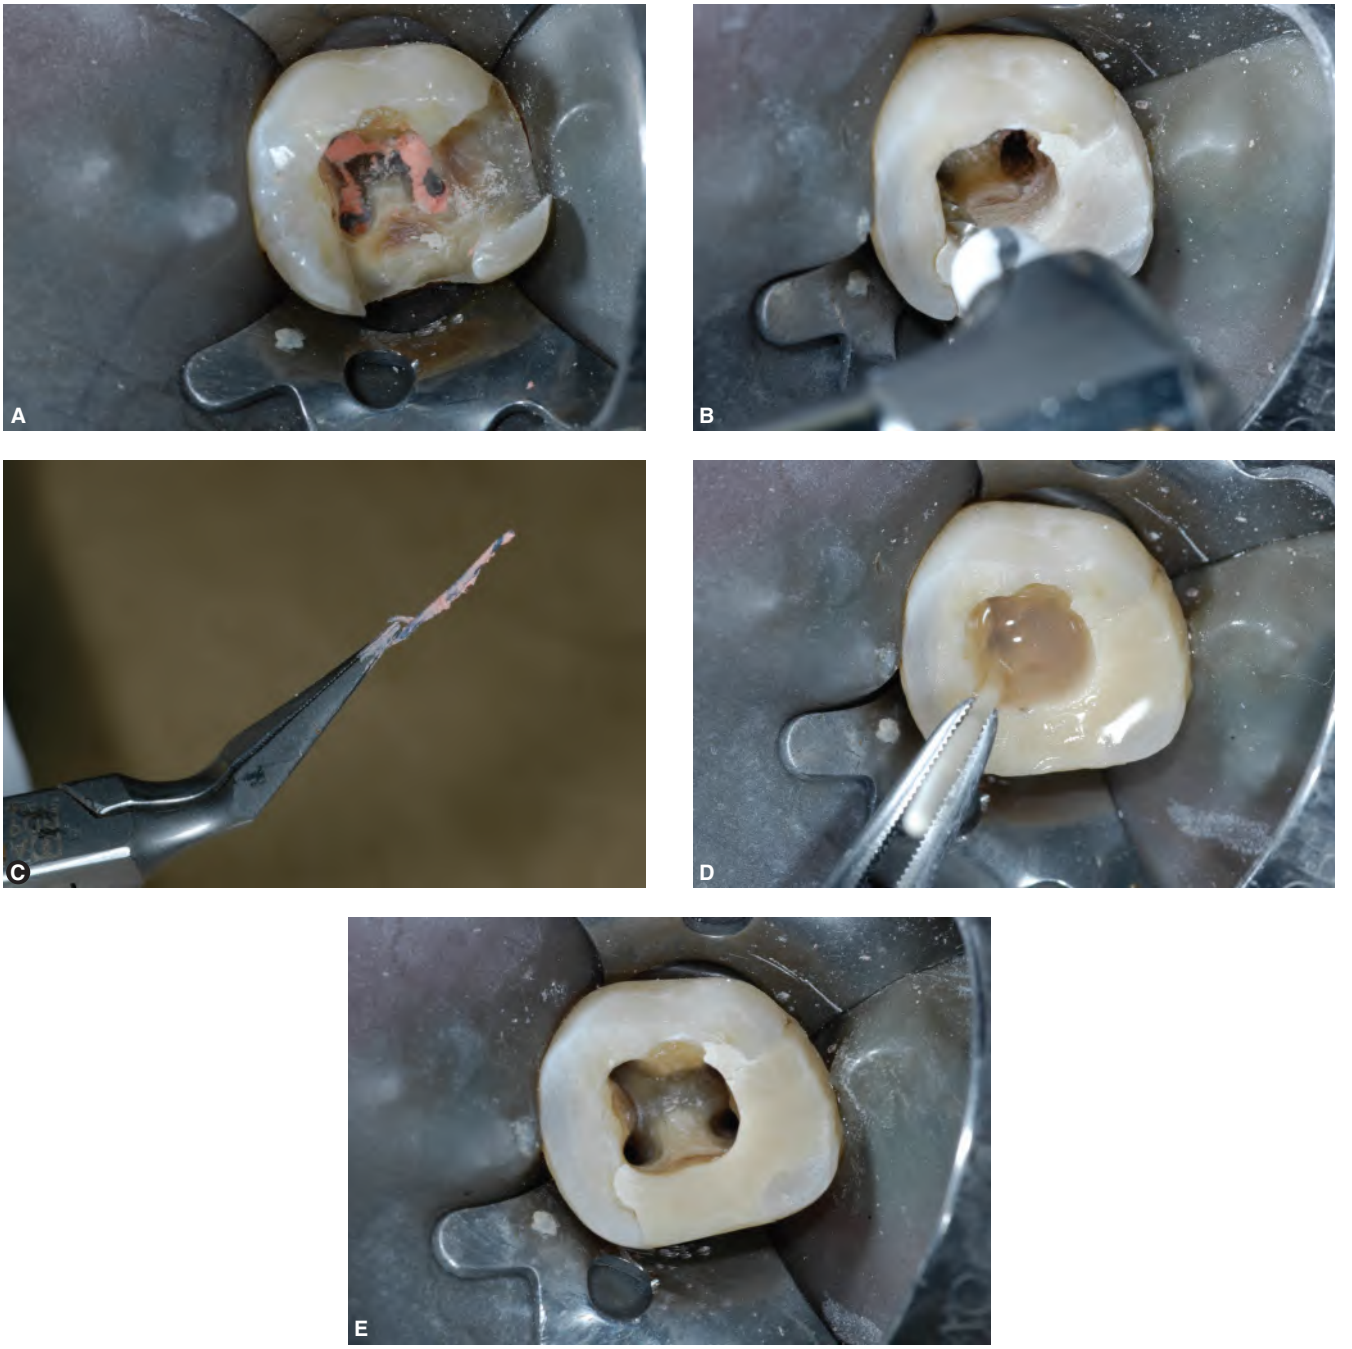

FIGURE 23-42 ***A.*** After removal of the coronal restoration, plastic carriers are clearly seen in the canals of this mandibular molar. ***B.*** Following pre-treatment and access cavity, a Protaper Retreatment instrument is used to remove the plastic carrier in the ML canal. ***C.*** Plastic carrier was removed and grasped with Stieglitz pliers. ***D.*** The wicking procedure. The pulp chamber is filled with solvent and a paper point absorbs the residual sealer. ***E.*** Cleanliness of the pulp chamber and canals before obturation.

than silver points because their cutting flutes, at times, engage lateral dentin.

Following careful access and complete circumferential exposure of the carrier, suitable grasping pliers are selected and a purchase is obtained on the carrier. When possible, the relative tightness of the carrier within the canal can then be tested utilizing pliers. Successful removal in these cases is enhanced by recognizing that the carrier is frozen in a sea of hardened gutta-percha. With this in mind, the following techniques are used to remove carriers:

- Rotary instrumentation can be used to effectively and efficiently auger a plastic carrier out of a canal. This should only be attempted if there is sufficient space between the carrier and the canal walls. A ProTaper Retreatment D2 instrument is placed at the carrier groove location and rotated at 800 rpm with light pressure. The frictional heat melts the gutta-percha that allows the instrument to advance apically. Owing to the greater taper, the instrument will bind between the plastic carrier and the dentin, allowing the carrier to be extricated coronally (Figure 23-42).

- Another method involves the use of a heat carrier to be placed alongside the carrier to produce heat and thermosoften the gutta-percha in the coronal aspect. This step should be immediately followed by a forceful insertion of an H-file into the softened gutta-percha to grasp the carrier, and then a pulling action to retrieve it.
- Using solvents to remove plastic carriers is also effective and quite predictable. Chloroform will chemically soften the gutta-percha and allow H-files to work deeper, progressively undermining and loosening a carrier for removal.[111]
- The File Removal System (FRS) may be considered, in certain cases, to remove a carrier. This method of removal is especially appropriate if the core of the carrier is metal and has cutting flutes that are engaging lateral dentin.

If any of these efforts are successful, the carrier will be extricated from the canal. The canal can then be retreated, as if it were a gutta-percha case, using any of the gutta-percha removal strategies followed by chemical flushing and paper point wicking procedures.

Paste Removal

A great variety of paste types exists with the difference being chemical formulation. Originally, paste use was intended for those patients who could not afford conventional endodontics and this modality of treatment was considered a benevolent alternative to extraction. Regretfully, countless cases were unsuccessful and too often the "magic" paste was used with hopes of overcoming deficiencies in the removal of tissue and related irritants during canal preparation (Figure 23-43).

When evaluating a paste case for retreatment, it is useful to clinically understand that pastes can generally be divided into soft, penetrable, and removable versus hard, impenetrable, and at times, unremovable.[112,113] Typically, the paste used in the United States remains soft within the canal and is readily removed. Notoriously, the whitish-colored paste oftentimes used in Russia and the reddish-brown resin paste commonly utilized in Eastern Europe and the Pacific Rim pose formidable challenges in removal because they set-up brick-hard. However, it is important to understand that, due to the method of placement, the densest portion of the paste in the canal is coronally and the material is progressively less dense moving apically (Figure 23-44). In addition, retreatment of paste-filled cases is often wrought with surprises, as clinicians frequently encounter calcifications, resorptions, and flare-ups, which should be anticipated and communicated.

Solvents and Hand Files

Reagents like Endosolv "E" or DMS IV (Dentsply Maillefer; Ballaigues, Switzerland) and Endosolv "R" (Endoco; Memphis, TN, USA) can be helpful in chemically softening soluble and hard pastes.[113] The "R" designates the solution of choice for the removal of resin-based pastes and the "E" and DMS IV are the solution for the elimination of eugenate-based pastes (Figure 23-45). For soluble pastes, the floor of the access cavity is first cleared of paste residues with an ultrasonic tip and then flooded with the solvent. A DG16 explorer firmly probes the canal orifice and brings the solvent in contact with the paste. If a good catch is felt, the efficiency of the solvent is confirmed. The technique to be implemented is similar to that described for gutta-percha removal (see *File and Chemical*

FIGURE 23-43 ***A.*** Preoperative radiograph of a failing endodontic treatment with a paste canal filling in a mandibular left second molar. Note the extra DL root. ***B.*** Five-year recall radiograph showing the treatment of multiple apical portals of exit and excellent osseous healing.

FIGURE 23-44 An illustration demonstrating that the decrease in density of paste-fillers is usually directly proportional to the length of the filling.

Removal). Depending on the canal volume, 21 mm H-files are used in descending order to progressively eliminate the material. Regular renewal of the solvent is needed.

For hard pastes like epoxy resins, bakelites, glass ionomers, and zinc phosphate, no efficient solvents are available.[112,113] Alternatively, reagents can be placed interappointment against a paste-type material via paper points or cotton pellets to promote shrinkage and potentially facilitate subsequent removal.[113] The best method to remove them is with ultrasonics.

Ultrasonic Energy

Ultrasonic instruments, in conjunction with the microscope, afford excellent control in removing paste from the straight-away portions of a canal.[114,115] Specifically, the ProUltra ENDO-3, 4, and 5 zirconium nitride-coated ultrasonic instruments may be used below the orifice to remove brick-hard resin-type paste (Figure 23-46). To remove paste apical to a curvature, small-sized hand files must be used first to negotiate this region of the canal. Once a pilot hole has been created, then an appropriately-sized precurved file may be attached to a specially designed adapter (File Adapter 11, SybronEndo; Orange, California, USA) that mounts onto and is activated by the ultrasonic handpiece.

Heat

Certain resin pastes soften with heat. Heat carriers can be selected if this modality of removal is chosen.

Rotary Instruments

Stainless steel .02 tapered hand files may be used to negotiate through paste fillers. These files can potentially create a pilot hole for safe-ended NiTi rotary instruments to follow and effectively auger the toxic material coronally. The procedure is as follows.

1. On a well-angulated pre-op radiograph, precisely asses the endpoint of the previous obturation.
2. Use solvent and hand files, or rotate the Protaper Retreatment D1 file to create a pilot hole.

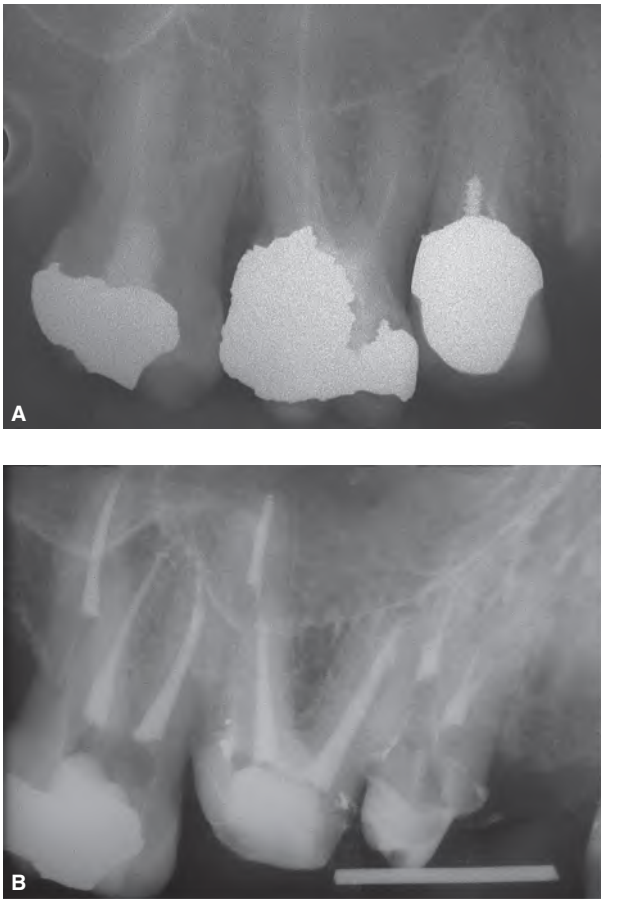

FIGURE 23-46 ***A.*** The maxillary premolar and molars teeth have been filled with a resin-type paste and must be retreated. ***B.*** Ultrasonic tips have been used in the straight portion of the canals to remove the brick-hard resin type paste. Deviation occured in the buccal canal of the premolar. At this stage, the procedure was stopped and the canal filled.

3. Use the D2 and D3 files with a short pecking motion at 500 rpm and check for the presence of material along the active portion of each file's more apical extent.
4. If resistance is met, go to stainless steel hand K files.

Dangerous, but at times helpful, is the use of end-cutting NiTi rotary instruments (Quantec NiTi Rotary Instruments, SybronEndo; Orange, California, USA) to penetrate paste.

Micro-Debriders

After removing the paste filler and shaping the canal, it is axiomatic that residual paste will still be noted within the irregularities of the root canal preparation. Micro-Debriders (Dentsply Maillefer; Ballaigues, Switzerland) are specially designed instruments to precisely remove residual paste materials from a root canal system. These stainless steel instruments enhance vision due to their ergonomically designed offset handles, have D_0 diameters of 0.20 and 0.30, and are available in .02 tapers with 16 mm of efficient Hedstrom-type cutting blades (Figure 23-47).

FIGURE 23-47 Micro-Debriders have offset handles to enhance vision, 16 mm of efficient Hedstrom-type cutting blades, and are used to remove residual obturation materials from the irregularities of canal systems.

Solvents and Paper Points

Following paste removal, chemical flushing with solvents, in conjunction with paper point wicking, is important to further remove and liberate material from the irregularities of the root canal system.

Silver Point Removal

The relative ease of removing failing silver points is based on the fact that chronic leakage, breakdown, and bacterial infection greatly reduce the seal, and hence, the lateral retention. Before a given silver point retrieval technique is selected, it is useful to recall the canal preparation prescribed for this method of obturation. Typically, the apical 2 to 3 mm of the canal was prepared relatively parallel and then flared coronal to this apical zone. When clinicians evaluate silver point failures, they should recognize that the silver point is parallel over length, hope for a coronally shaped canal, and take advantage of this space discrepancy when approaching retreatment.[116] Many techniques have been developed for removing silver points, primarily due to their varying lengths, diameters, and positions they occupy within the root canal space.[3,117–119] Certain removal techniques evolved to address silver points that bind in unshaped canals over distance. Other techniques arose to remove silver points with large cross-sectional diameters, approaching the size of smaller posts. Finally, other techniques are necessary to remove the split cone or intentionally sectioned silver points lying deep within the root canal space.

Access

Typically, the coronal heads of silver points are within pulp chambers and generally entombed in cements, composites, or amalgam cores. Access preparations must be thoughtfully planned and carefully performed so as to minimize the risk of inadvertently foreshortening the silver points (Figure 23-48). Initial access is accomplished with high-speed, surgical-length cutting tools. Subsequently, ultrasonic

FIGURE 23-48 ***A.*** Illustration of a mandibular molar reminding the clinician how silver points are commonly entombed within various restorative materials. ***B.*** When caution is not exercised upon re-entering the pulp chamber, silver points may be inadvertently foreshortened.

instruments may be carefully utilized within the pulp chamber to brush-cut away restorative materials and progressively expose the silver point.

Pliers Removal

After completing access and fully exposing the part of the silver point confined to the pulp chamber, a suitable grasping instrument (Stieglitz Forceps, Hu-Friedy; Chicago, Illinois, USA) is selected. To identify the best removal strategy, obtain a strong purchase on the silver point and gently pull to confirm its relative tightness. Oftentimes, dentists make the mistake of over-manipulating the head of the silver point, which needlessly foreshortens it, making subsequent retrieval efforts difficult, if not impossible. When grasping a silver point, rather than trying to pull it straight out of the canal, the pliers are rotated and levered, using fulcrum mechanics, against the restoration or tooth structure to enhance removal (Figure 23-49).[3]

Indirect Ultrasonics

When a segment of a silver point is encountered below the orifice and space is restricted, the appropriate

ultrasonic instruments should be selected (ProUltra ENDO-3, 4, and 5, Dentsply Maillefer; Ballaigues, Switzerland). These ultrasonic instruments have parallel walls and provide progressively longer lengths and smaller diameters. The appropriate instrument is selected based on its anticipated depth of use and the available canal diameter. The ultrasonic instruments are used to trephine circumferentially around the obstruction, break up cement, and safely expose as much of the silver point as possible. Caution should be exercised so that ultrasonic instruments are *not used directly* on silver points because elemental silver is soft and rapidly erodes during mechanical manipulation. Once the surrounding material is removed, ultrasonic energy may then be transmitted directly onto grasping pliers to synergistically enhance the retrieval efforts. This form of *indirect* ultrasonics advantageously transfers energy along the silver point, breaks up material deep within the canal, and enhances removal efforts.

Files, Solvents, and Chelators

If grasping techniques and/or indirect ultrasonics are unsuccessful, then the clinician should immediately abort this approach and appreciate that silver points are perfectly round and root canal systems are typically irregular in their cross-sectional shapes. This discrepancy between the round silver wire and an irregularly shaped canal provides the clinician with an opportunity to use solvents and a size 10 or 15 stainless steel file. In a solvent-filled chamber, files are used lateral to the silver point to break up cements, and to undermine and loosen the silver point for removal. In underprepared canals, chelators are at times better than solvents, as they allow the instrument to "slip and slide" and work laterally to the silver point. At this stage, a size 15 K file is inserted into an ultrasonic handpiece and placed alongside the silver cone. Once accomplished, this file is activated and used in a short amplitude, in-and-out movement with copious water irrigation to float out the cone (Figure 23-50).[56] If sufficient space exists or can be created between the silver point and the canal wall, a size 20, 25, or 30 hedstrom file can be inserted into this space. The "Hedstrom displacement technique" powerfully promotes the removal process, as the instrument's positive rake angle bites, engages, and establishes a strong purchase on any metallurgically soft silver point (Figure 23-51).

Microtube Removal Options

There are several microtube removal methods, both old and new, that are designed to mechanically engage an intracanal obstruction, like a silver point. However, it must be understood and fully appreciated that many, if not most, of these microtube removal methods frequently require the excessive removal of dentin and oftentimes prove ineffective. For clinicians, the critical distinction when considering microtube removal methods is not the inside diameter of a device, but importantly, its outside diameter, that dictates how deep it can be safely introduced into a canal. The following represents the various microtube removal methods and techniques:

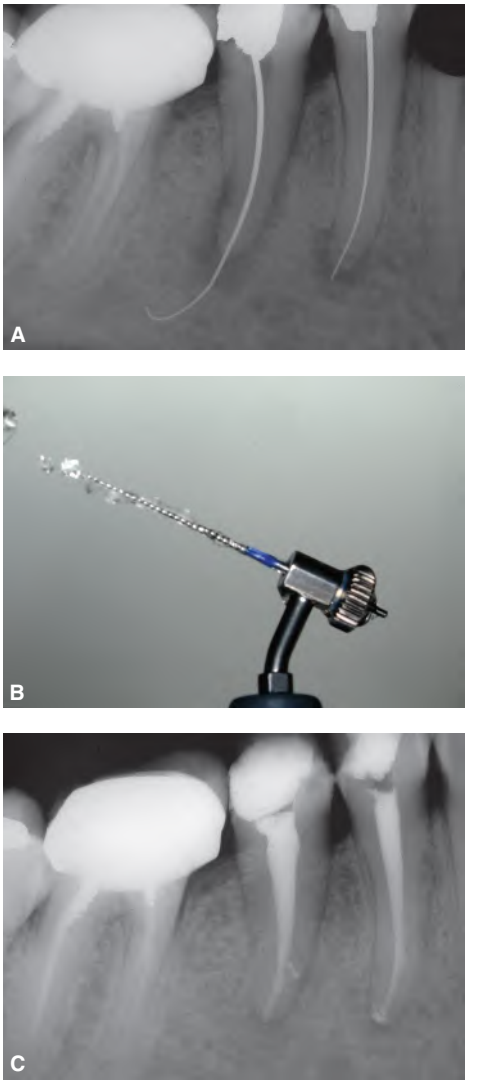

FIGURE 23-50 ***A.*** Preoperative radiograph depicting failing endodontic treatments in mandibular premolars obturated with silver cones. ***B.*** Ultrasonic files or Stainless K files can be mounted on the ENAC handpiece. ***C.*** One-year recall radiograph shows complete healing. Desappointingly, the teeth had not been restored.

- Lasso and Anchor: In this removal method, an appropriately-sized microtube is selected, a wire passed through the tube, then looped at one end and passed back through the tube. This loop can potentially lasso a coronally exposed obstruction and, when successful, form a purchase by pushing the tube apically, while simultaneously pulling the wire ends coronally.[119] Although reported in the literature, this removal method has been essentially replaced with more practical techniques.
- Tube and Glue: The Cancellier Extractor Kit (SybronEndo; Orange, California, USA) contains four different sized microtubes with outside diameters of approximately 0.50,

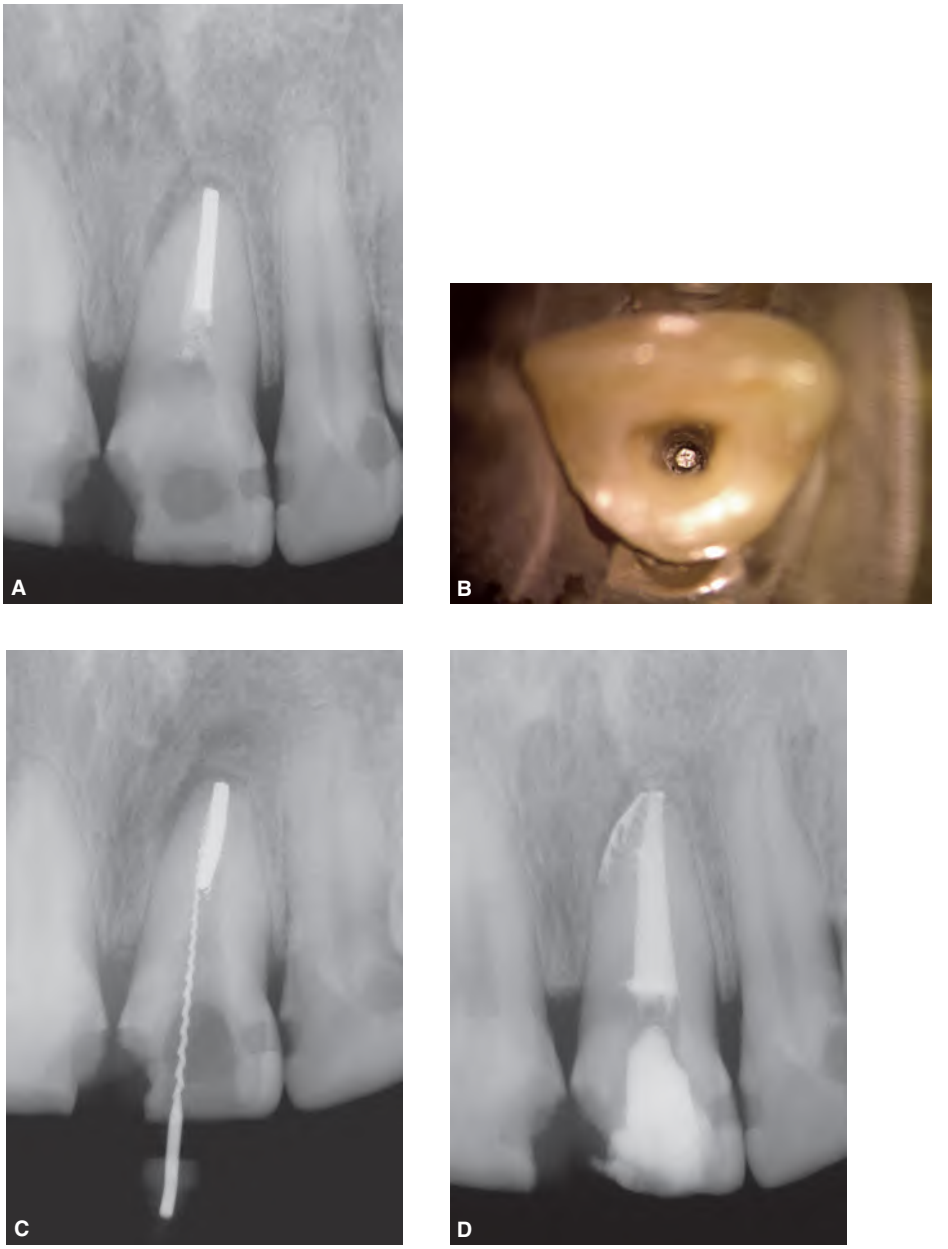

FIGURE 23-51 ***A.*** Preoperative radiograph of failing endodontic treatment in left central incisor. 0.60, 0.70, and 0.80 mm. An abrasively-coated ultrasonic instrument is typically used to trephine around and ideally expose the coronal 3 mm of an obstruction. A microtube is prefit to ensure its internal diameter can just fit over the coronally exposed obstruction. The prefit microtube may now be bonded onto the obstruction with a self-curing composite core build-up, such as Core Paste[3,8] (DenMat; Lompoc, California, USA). The Cancellier microtubes are safely scaled for progressively deeper placement into canals of posterior roots. This removal method is quite effective for retrieving a silver point, a non-fluted broken instrument, or when there is difficulty retrieving a separated file that is already loose. Caution should be exercised to not use too much composite, which could inadvertently block a canal.

- Tap and Thread: The Post Removal System (PRS) kit (SybronEndo; Orange, California, USA) contains five microtubular taps. The smallest PRS tap can be used to internally form threads and mechanically engage the most coronal aspect of any obstruction whose diameter is 0.60 mm or greater.[3] These microtubular taps contain a reverse thread and engage an obstruction by turning in a CCW motion. Because intracanal space is often restrictive, this system is generally used to engage obstructions that extend into the pulp chamber (Figure 23-29).

- Masserann: The Masserann kit (Micromega; Besançon, France) represents a time-honored method to purchase and remove a broken instrument.[120] Although this device has been around for over 40 years, it is superbly made and can form a strong purchase. However, its smallest tubular extractors have outside diameters of about 1.20 mm and 1.50 mm, which limit their safe use to generally larger canals in anterior teeth.
- Spinal Tap Needle: A spinal tap needle *(Ranfac; Avon, Massachusetts*, USA*)*, in conjunction with its metal insert plunger or a Hedstrom file, is another technique advocated to remove broken instruments.[3] With limitations, this method of removal involves sizing the correct microtube so it can be placed over an ultrasonically exposed obstruction. Microtube sizes that are clinically relevant are 19, 21, and 23 gauge needles, corresponding to outside tube diameters of approximately 1.00, 0.80, and 0.60 mm, respectively. Because of their unique ability to engage, smaller sized hedstroem files may be selected and inserted into the coronal-most aspect of the microtube.[3,77] The hedstroem is passed down the length of the tube until it wedges tightly between the obstruction and the internal lumen of the microtube (Figure 23-52). However, because ISO files taper 0.32 mm over 16 mm of cutting blades, the taper of the file oftentimes restricts its placement through a smaller sized parallel microtube. In this instance, the spinal tap needle's metal insert plunger must be used to potentially form a purchase on the obstruction. This method is quite effective when removing obstructions from larger canals.
- Endo Extractor / Meisinger Meitrac: The Endo Extractor System (Roydent; Rochester Hills, Michigan, USA) and the recently released Meisinger Meitrac Instrument System (Hager & Meisinger GmbH; Neuss, Germany) are able to gain a strong mechanical purchase on a silver point or a broken instrument. The Endo Extractor System is a "Jacob Chuck-like" device featuring three short-sized instruments. After selecting an appropriately-sized extractor, the ring is rotated CCW to open the jaws. The extractor is carefully placed over the head of the silver point and the ring is rotated CW, enabling the jaws to circumferentially grasp it (Figure 23-53) The indirect ultrasonic method may then be used against the handle to encourage the removal procedure.[56] The Meitrac Instrument System has been reported in a trade journal to be able to remove broken files from otherwise inaccessible locations. However, the smallest Meitrac I trephine and extractor have outside diameters of approximately 1.50 mm. This diameter limits the practical use of this instrument to the coronal aspects of larger canals.
- File Removal System: The File Removal System (FRS) *(Dentsply Maillefer; Ballaigues, Switzerland)* provides another mechanical method for the removal of intracanal obstructions such as silver points, carrier-based obturators, or broken file segments (Figure 23-54). The FRS is indicated when ultrasonic efforts prove to be unsuccessful and may be used to remove broken instruments lodged in the straightaway portions of the root or partially around the canal curvature.[3,77] The method of use of this device will be discussed in the next section.

BROKEN INSTRUMENT REMOVAL

Every clinician who has performed endodontics has experienced a variety of emotions ranging from the thrill-of-the-fill to an upset like the procedural accident of breaking an instrument. During root canal preparation procedures, the potential for instrument breakage is always present. When instrument breakage occurs, it immediately provokes frustration, despair, and anxiety.[121] In fact, the broken instrument dilemma has caused such emotional distress that this event is frequently referred to as a "separated" or "disarticulated" file.

Many clinicians associate a "broken instrument" with a separated file, but the term could also apply to a sectioned silver point, a segment of a lentulo, a gates glidden drill, a portion of a carrier-based obturator, or any other device obstructing the canal.[122,123] With the advent of rotary NiTi files, there has been an unfortunate increase in the occurrence of broken instruments and the factors contributing to breakage have been identified.[124,125] The prognosis of leaving versus removing broken instruments from the canal have been discussed in the literature.[83,126,127] Over the years a variety of approaches for managing broken instruments have been presented.[128–130]

Today, separated instruments can usually be removed due to technological advancements in vision, ultrasonic instrumentation, and microtube delivery methods.[77,131] Specifically, the increasing integration of the dental operating microscope into clinical practice is allowing clinicians to visualize the coronal-most aspect of most broken instruments.[132] The microscope fulfills the age-old adage, "If you can see it, you can probably do it." In combination, the microscope and ultrasonic instrumentation have driven *microsonic* techniques, that have dramatically improved the potential and safety of removing broken instruments.[3,133,134]

Factors Influencing Broken Instrument Removal

The factors influencing broken instrument removal should be identified and fully appreciated.[135,136] The ability to nonsurgically access and remove a broken instrument will be influenced by the diameter, length, and position of the obstruction within a canal. Additionally, the potential to safely remove a broken instrument is guided by anatomy, including the diameter, length, and curvature of the canal. Importantly, the potential for safely removing a broken instrument is limited by root morphology, including the circumferential dimensions and thickness of dentin and the depth of an external concavity.[137,138] In general, if one-third of the overall length of an obstruction can be exposed, it can usually be removed. Instruments that lie in the straightaway portions of the canal can typically be removed. Separated instruments that lie partially around canal curvatures, although more difficult, can oftentimes be removed if straightline access can be established to their most coronal extents (Figure 23-55).[3,134] If the broken instrument segment is apical to the curvature of the canal and safe access cannot be accomplished, then removal is usually not possible and, in the presence of signs or symptoms, surgery or an extraction will, at times, be required. On occasion, an attempt to bypass the instrument can be successful (Figure 23-56).

The type of material comprising an obstruction is another important factor to be considered. As an example, stainless steel files tend to be easier to remove, as in general, they do not further fracture during the removal process. NiTi broken instruments may break again, albeit deeper within the canal, during ultrasonic efforts, presumably due to heat buildup.[8] Perhaps the most important factors central to successful instrument removal are knowledge, training, and competency in selecting the best presently developed and proven technologies and techniques. Importantly, no one removal method will always produce the desired result. As such, successful removal oftentimes requires patience, perseverance, and creativity. However, no removal method should be attempted until access has been made to the head of an intracanal obstruction.

Coronal and Radicular Access

Prior to commencing with efforts to remove a broken instrument, the clinician should thoughtfully observe different horizontally-angulated pre-operative radiographs. Coronal

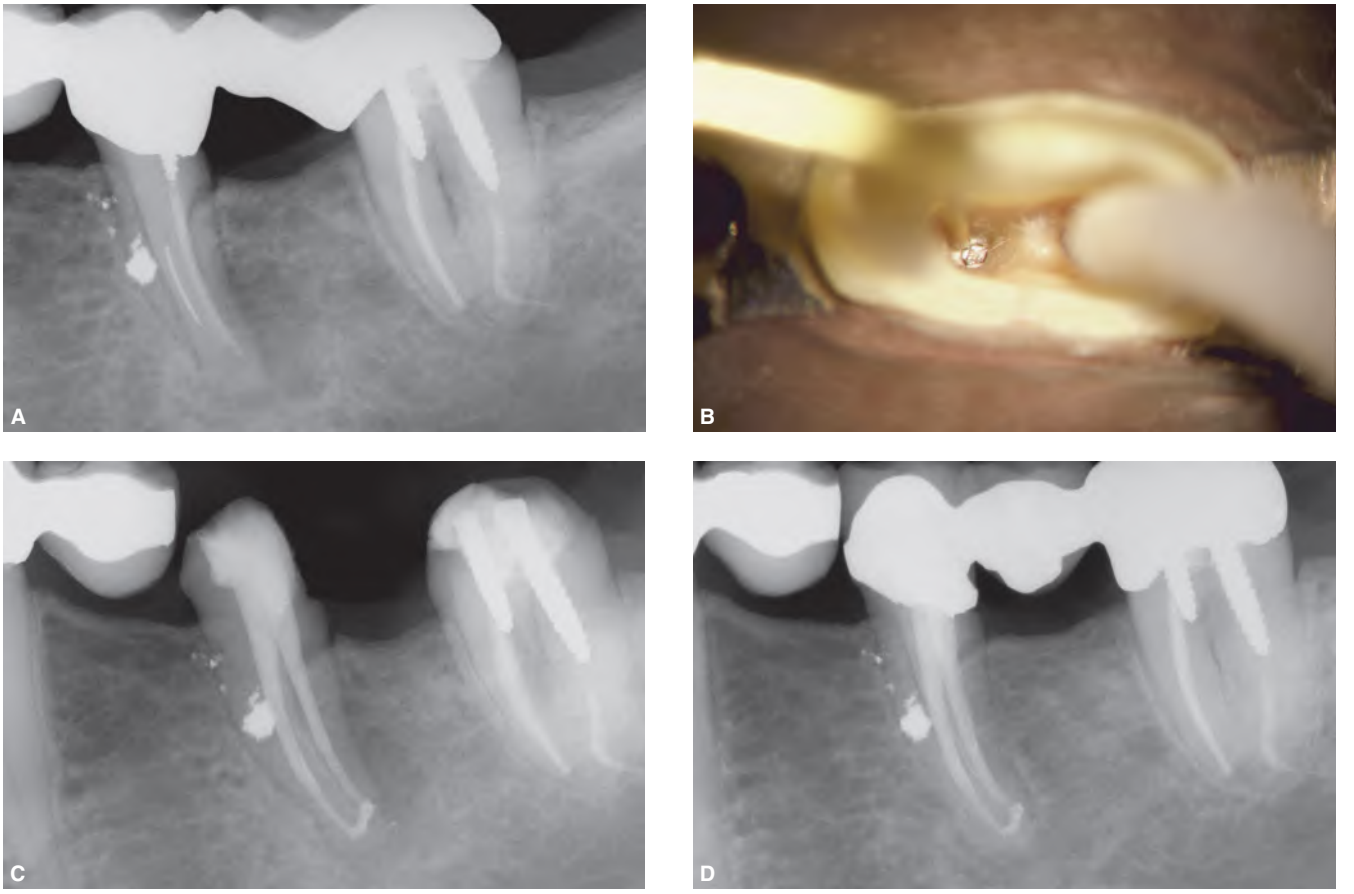

FIGURE 23-55 ***A.*** A failing endodontic treatment in a mandibular first molar. Note, a short screw post, a separated instrument and amalgam debris from the hemisection procedures. ***B.*** Photograph showing the splint removed, the post taken out, and an ultrasonic instrument trephining around the broken separated file. ***C.*** Postreatment radiograph reveals successful retreatment. access is the first step in the removal of broken instruments. Highspeed, friction grip, surgical length burs are selected to create straightline access to all canal orifices. Special attention should be directed towards flaring the axial wall that approximates the canal holding the broken instrument in efforts to subsequently improve microsonic techniques below the orifice.

Radicular access is the second step required in the successful removal of a broken instrument. However, before commencing with radicular access, it is useful to review a few concepts that can potentially guide our clinical actions. With exceptions, the vast majority of teeth range from 19 to 25 mm in overall length. Most clinical crowns are about 10 mm and most roots range from 9 to 15 mm in length. If the root is divided into coronal, middle and apical one-thirds, then each third is between 3 and 5 mm in length. The question frequently asked is, how big can a canal be optimally flared without creating an iatrogenic problem? The answer is to review the dimensions of a typical preparation in a longer, narrower, and more curved root form. In this situation, if a 20 file is snug at length and each successively larger instrument uniformly moves away from the foramen in 1/2 mm increments, then the apical one-third of the canal would taper 10%. In this specific example, the diameter of the canal 4 mm coronal to the foramen would be equivalent to at least a 60 file or 0.60 mm. This analogy is useful and can serve to safely guide how big to prepare the apical one-third and the coronal two-thirds of a canal when there is a broken instrument.[139]

Clinical experience suggests the majority of broken files separate towards their terminal extents at between D_3, D_4, or D_5. Files most frequently break in the apical 3 to 5 mm because this is the region where a canal usually has its smallest diameter and exhibits its greatest degree of curvature or propensity to divide. Even if a file breaks at the working length, the position of the head of the instrument typically lies at about the junction of the middle and apical one-thirds. Fortuitously, straightline radicular access can generally be created through the coronal two-thirds of a canal to the head of a broken instrument.[3,140]

A number of different techniques may be employed to flare the canal coronal to an intracanal obstruction. However, experience suggests a predictable way to create safe radicular access is to initially use hand files, small to large, coronal to the obstruction. Hand files create sufficient space to safely accommodate NiTi rotary files, or preferably Gates Glidden (GG) drills (Dentsply Maillefer; Ballaigues, Switzerland). GG sizes 1 to 4 are most typically employed in furcated teeth and have maximum diameters of 0.50, 0.70, 0.90, and 1.10 mm, respectively. GGs are used to create radicular access and a uniform tapering funnel to the obstruction. GGs are more safely rotated at speeds

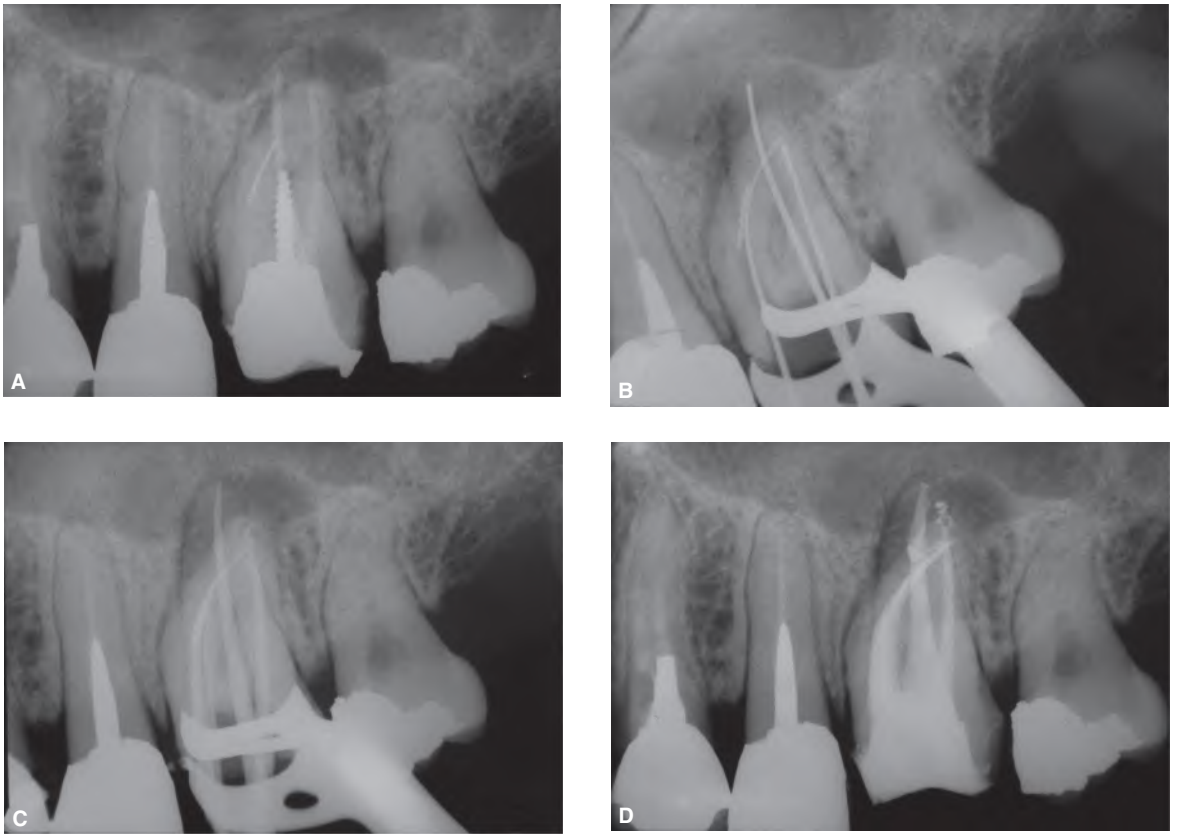

FIGURE 23-56 ***A.*** Preoperative radiograph of the first molar showing a separated instrument located beyond the curvature of the mesial root. ***B.*** After radicular access to the head of the fragment, the instrument could be bypassed with small hand files. ***C.*** During cleaning and shaping, the fragment was floated out with irrigation. Cone fit radiograph showing instrument removed. ***D.*** Postoperative radiogaph showing canal obturation.

of about 750 rpm and, importantly, are used with a *brushing motion* to create a tapered shape and maximize visibility.[3] Increasingly larger GGs are uniformly stepped out of the canal to create a smooth flowing funnel, that is largest at the orifice and narrowest at the obstruction. GG drills should be limited to the straightaway portions of the canal. Generally, a GG-1 or GG-2 can be carried to the depth of the head of a separated instrument. The GGs are used cautiously in approximation to the obstruction, with attention to brush-cutting out of the canal and away from furcal danger. Deliberately relocating the coronal one-third of a canal away from the furcation maximizes remaining dentin, produces a more centered preparation, and improves straightline radicular access.[3,140,141] The GG-3 is carried short of the level where the GG-2 was used and, in furcated teeth, the GG-4 is confined to a depth of no more than one bud length below the orifice. Importantly, radicular access should be performed so that the canal is pre-enlarged and ideally shaped no bigger than it would otherwise be prepared if there was no broken instrument obstructing the canal.

Creating a Staging Platform

When the canal has been optimally shaped, then microsonic techniques are usually the first option selected to remove a broken file segment. At times, when an ultrasonic instrument is introduced into a pre-enlarged canal, its activated tip does not have enough space, lateral to the broken file segment, to initiate trephining procedures. As such, if more lateral space is required, then the bud of a GG can be modified and used to create a circumferential staging platform.[3,8] The staging platform is made by selecting a GG drill with a maximum cross-sectional diameter slightly larger than the visualized instrument. The bud of the GG drill is altered by cutting it perpendicular to its long axis, at its maximum cross-sectional diameter (Figure 23-57). This modified GG is carried into the pre-enlarged canal, rotated at a reduced speed of approximately 300 rpm, and directed apically until it lightly contacts the coronal-most aspect of the obstruction. This clinical step creates a small staging platform which facilitates the introduction of an ultrasonic instrument. If properly performed, straightline coronal and radicular access, in conjunction with magnification and lighting, should enable the clinician to fully visualize the coronal-most aspect of a broken instrument. To facilitate excellent vision to the intraradicular obstruction, the canal should be vigorously flushed and thoroughly dried prior to beginning ultrasonic procedures.

Techniques for Removing Broken Instruments

A number of devices, technologies, and techniques have been reported to remove an intracanal obstruction, such as a broken instrument.[134,136] However, many of the removal techniques previously described in the literature did not have the benefit of the operating microscope. Today, virtually all broken

FIGURE 23-57 Photograph showing selected GG drills and their subsequent modification.

instruments can be eliminated if straightline access can be safely made to the coronal-most extent of a broken instrument.[3,134,140] The most important, predictable, and safe removal schemes utilize the microscope in conjunction with optimally designed ultrasonic instruments and/or a microtube method.[3,140]

Ultrasonic Techniques

Prior to performing any radicular removal techniques, it is wise to place cotton pellets over other exposed orifices, if present, to prevent the nuisance re-entry of the fragment into another canal. The first option to remove a broken instrument is to utilize piezoelectric ultrasonic technology and specific ultrasonic instruments (Figure 23-24). An ultrasonic generator should provide a broad range of power, precise adjustment within the lower settings, and electrical feedback to regulate amplitude and safe tip movement. Ideally, ultrasonic instruments should have a contra-angled design to provide access into all regions of the mouth, parallel-sided walls to create a line of sight between the instrument and the tapered canal, and non-aggressive coatings, such as zirconium nitride, to precisely sand away dentin during trephining procedures. Further, an appropriately-sized ultrasonic instrument is selected, such that its length will reach the broken obstruction and its diameter will passively fit and afford a favorable line-of-sight into the previously shaped canal.

The tip of this ultrasonic instrument is placed in intimate contact against the obstruction and typically activated within the lower power settings (Figure 23-58A). *The clinician should always work at the lowest power setting that will efficiently and safely accomplish the clinical task*. ALL ultrasonic work below the orifice is conducted DRY so the clinician has constant visualization of the energized tip against the broken instrument. To maintain vision, the dental assistant utilizes the Stropko three-way adapter with an appropriate luer-lock tip to collimate and direct a continuous stream of air and blow out dentinal dust. Microsonic techniques, as advocated for removing broken instruments, do not generally generate sufficient heat to become harmful to the attachment apparatus.

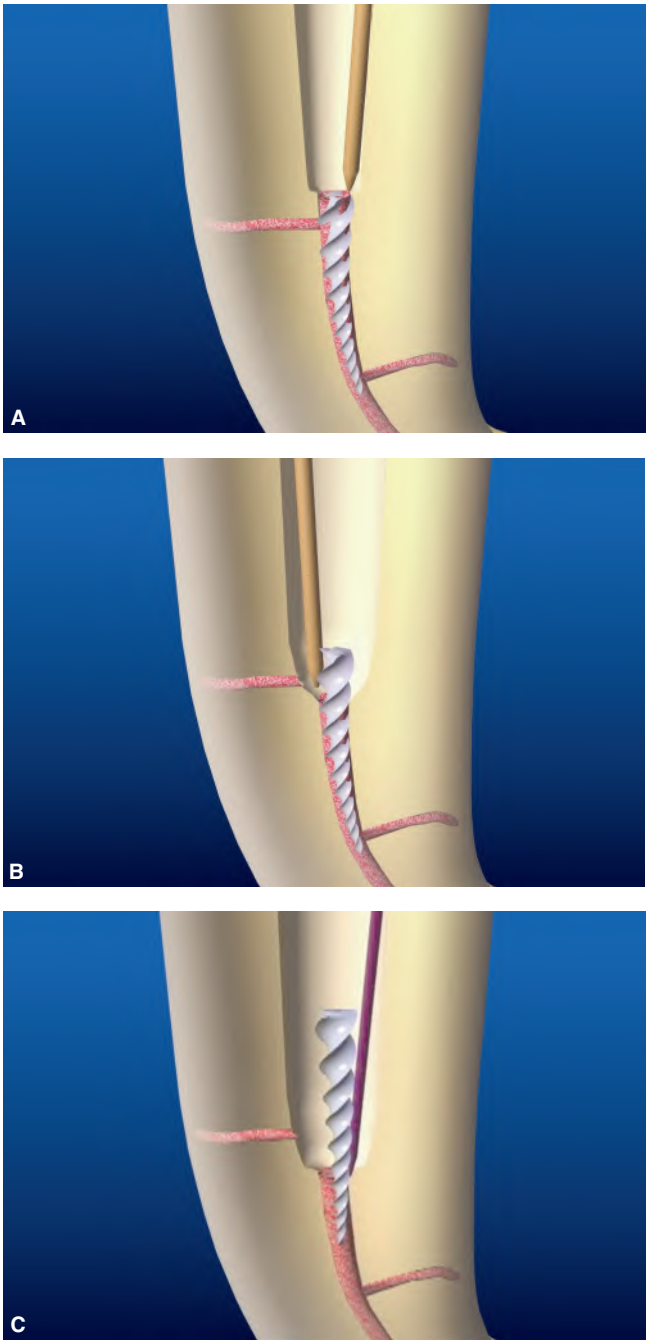

FIGURE 23-58 ***A.*** Illustration demonstrating the importance of coronal and radicular access, the staging platform and the ultrasonic instrument just laterally to the separated broken file. ***B.*** The ultrasonic instrument maintains contact with the separated file, precisely sands away dentin, and progressively exposes the coronal aspect of the file. ***C.*** A longer length and smaller diameter titanium instrument is selected to conserve dentin and successfully displace the separated instrument.

The selected ultrasonic instrument is moved lightly, in a CCW direction, around the obstruction, except when removing a file that has a left-handed thread, in which case the direction would be CW. This ultrasonic action trephines, precisely sands away dentin, and exposes the coronal few

millimeters of the obstruction (Figure 23-58B). Typically, during ultrasonic use, the obstruction begins to loosen, unwind, and then spin. Gently wedging the energized tip between the tapered file and canal wall oftentimes causes the broken instrument to abruptly jump out of the canal. In the instance where a broken file lies deep and ultrasonic procedures are restricted by root bulk and form, then select a longer length and smaller diameter, abrasively-coated ultrasonic instrument to promote safe retrieval efforts. In longer roots, or when space is even more restrictive, then an appropriately-sized titanium instrument may be chosen. Titanium instruments provide a smooth cutting action, that promotes safety when trephining deeper within a canal (Figure 23-58C). At times, weighing risk versus benefit, ultrasonic trephining procedures may have to be aborted. In these instances, the sharp cutting edges of a hypodermic needle may be safely used manually to further expose the head of a broken file.[142] Exposing 2 to 3 mm of the coronal-most aspect of an obstruction, or about one-third of its overall length, will generally produce the desired result. The clinical steps for broken instrument removal utilizing microsonics are shown in Figure 23-59.

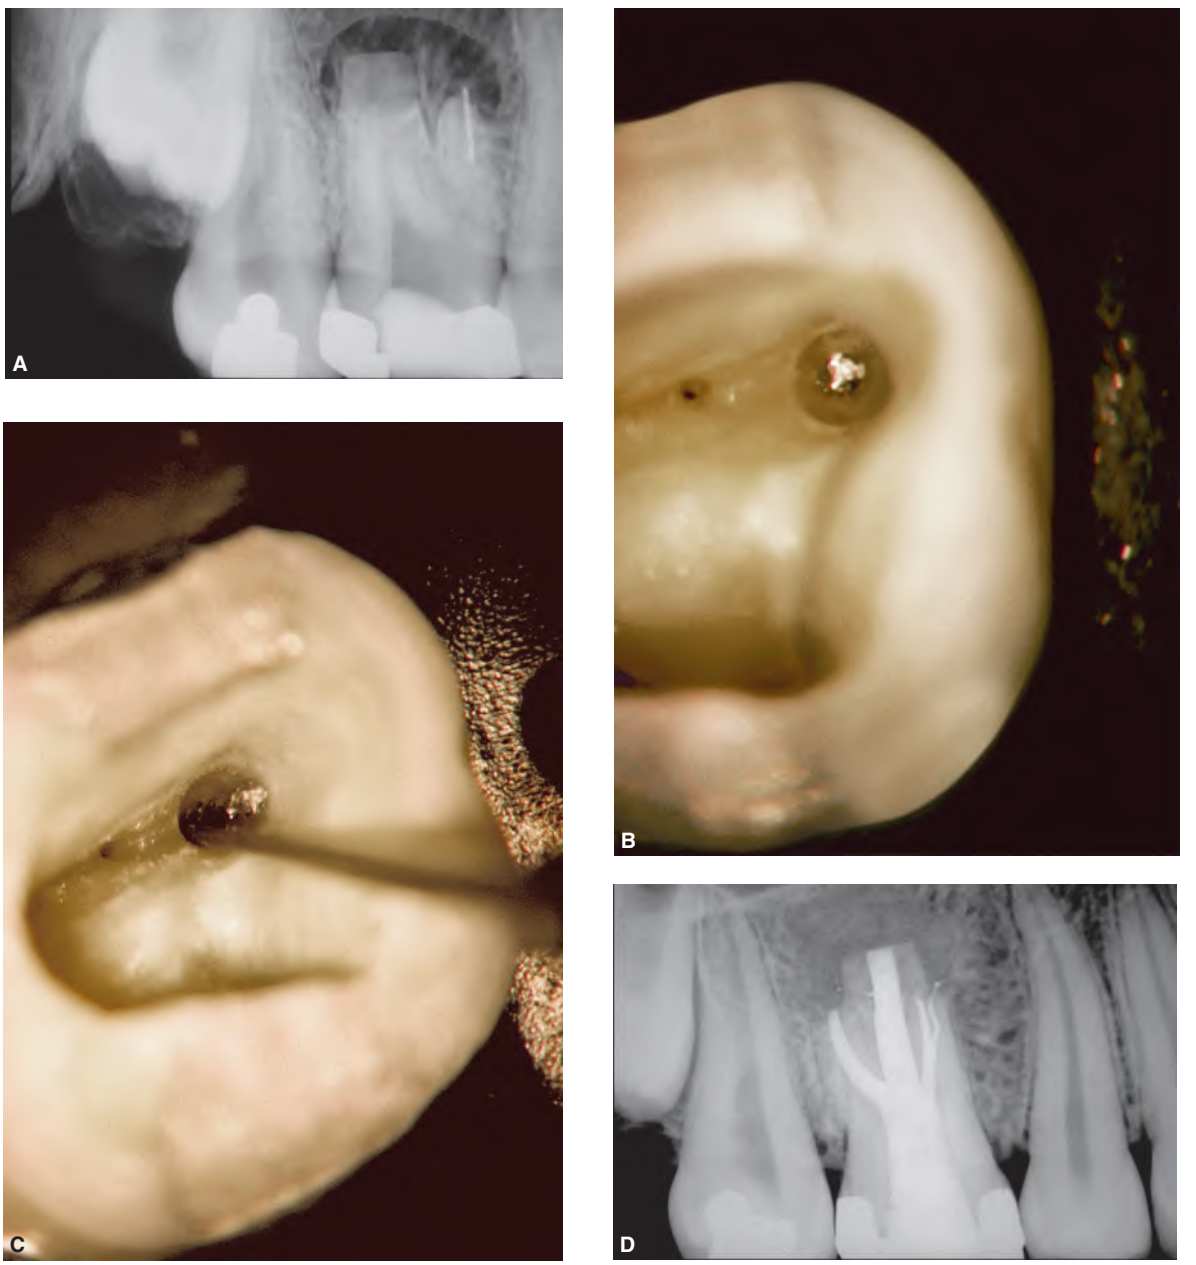

FIGURE 23-59 ***A.*** An off-angled radiograph of a maxillary first molar reveals a separated instrument, a possible MB-2 system and resected roots from a previous surgical procedure. ***B.*** Photograph showing access, an MB-2 orifice, the separated instrument, and the circumferential staging platform to facilitate ultrasonics. ***C.*** Documentation reveals an ultrasonic instrument has loosened and coronally displaced the separated instrument. ***D.*** A recall radiograph showing evidence of initial healing. Barriers were utilized in the DB and P canals to facilitate control and encourage three-dimensional filling.

On occasion, the clinician may create excellent coronal and radicular access, identify and expose the separated instrument, perform ultrasonic trephining procedures, and still be unable to loosen and jettison the instrument out of the canal. Further, it may be unsafe to continue trephining around a broken instrument due to lack of vision or anatomical restrictions. In this instance, small hand files may be used with an aqueous or viscous chelator, to partially or completely bypass, and hopefully remove a broken instrument through irrigation. Even when this tedious removal method is unsuccessful, oftentimes a little space can be created along a portion of the overall length of a broken instrument. To maximize efficiency and success, the handle from a stainless steel hand file can be intentionally removed and the shaft of the instrument inserted into a device called the File Adapter (Figure 23-60). The File Adapter threads onto the ultrasonic handpiece and its chuck will retain a 0.02 tapered hand file. Small stainless steel hand files can be precurved, if indicated, inserted into available space, and used at low power in an ultrasonic effort to remove a broken instrument. This technique is, at times, useful when the root is thin or a portion of the file lies apical to a canal curvature.[143]

Another clinical challenge is encountered when trying to remove a broken NiTi file that lies partially around a canal curvature. In these situations, it is axiomatic the head of a broken NiTi file will always lie against the outer wall even after optimal ultrasonic trephining procedures. Even when loose, the angle formed between the coronally flared canal and the head of the broken instrument oftentimes precludes its removal. This situation is best managed using a microtube removal method (Figure 23-61).[3,77,140]

The FRS Option

As previously mentioned in *"Silver Point Removal,"* there are several microtube removal methods that are designed to mechanically engage an intracanal obstruction. The File Removal System (FRS) has provided a breakthrough in the retrieval of broken instruments lodged deep within the root canal space.[3,77] The FRS is composed of variously-sized microtubes and insert wedges that are scaled to fit and work deep within the root canal space (Figure 23-62). The FRS is indicated when ultrasonic efforts prove to be unsuccessful and may be used to remove broken instruments that are lodged in the straightaway portions of the root or partially around the canal curvature. The black instrument has an outside diameter of 1.0 mm and is designed to work in the coronal one-third of larger canals, whereas the red and yellow instruments have outside diameters of 0.80 and 0.60 mm, respectively, and can be placed deeper into more narrow canals. Each complete instrument is comprised of a color-coordinated microtube and screw wedge (Figure 23-62B). Each microtube has a small-sized plastic handle to enhance vision during placement, a side window to improve mechanics, and a 45° beveled end to "scoop up" the coronal end of a broken instrument. Each screw wedge has a knurled metal handle, a left-handed screw mechanism proximally, and a solid cylinder that transitions into 0.02 tapered K-type file blades towards its distal end to facilitate engaging an obstruction.

FIGURE 23-60 Photograph showing that when the handle of an endodontic file is removed, its shaft can be quickly secured into the ultrasonically activated adapter.

As has been emphasized for any removal technique, straightline coronal and radicular access is required to expose and subsequently visualize the coronal-most end of the broken instrument. As previously described, the clinician utilizes ultrasonic instrumentation to circumferentially expose 2 to 3 mm of the separated file. However, ultrasonic instruments can only circumferentially trephine, sand away dentin, and expose the portion of the obstruction that lies in the straightaway portion of the canal. Therefore, the goal is to expose 2 to 3 mm, or about one-third of the total length, of a separated instrument (Figure 23-63A).

An FRS microtube is then selected that can passively slide through the pre-enlarged canal and drop over the exposed broken instrument. As previously mentioned, in a curved canal, the head of a broken NiTi file will always lie against the outer wall. In these instances, the microtube is inserted into the canal with the long part of its beveled end oriented to the outer wall of the canal to scoop up the head of the broken instrument and guide it into the microtube (Figure 23-63B). Once the microtube has been positioned, it is rotated 180° so the head of the file is oriented adjacent to the lateral window. The same color-coded screw wedge is then inserted and slid internally through the microtube's length until it contacts the obstruction. The obstruction is engaged by gently turning the screw wedge handle CCW. A few degrees of rotation will serve to tighten, wedge, and oftentimes, displace the head of the obstruction through the microtube window (Figure 23-63C). If any given color-coded screw wedge is unable to achieve a strong hold on the obstruction, then another color-coded screw wedge may be chosen to improve engagement and successful removal. When engaged, the obstruction can be potentially unwound and removed by rotating the microtube and screw wedge assembly CCW (Figure 23-63). The direction of rotation,

in the instance of a broken file, is generally CCW, but ultimately should be appropriate to the thread design of the obstruction. If difficulty is encountered when rotating the microtube and screw wedge assembly CCW, then proceed with a limited CW rotation of 3° to 5°, which will promote staying engaged, followed by turning the assembly CCW until snug. This repeated reciprocating handle motion will serve to loosen and facilitate the removal process. Placing

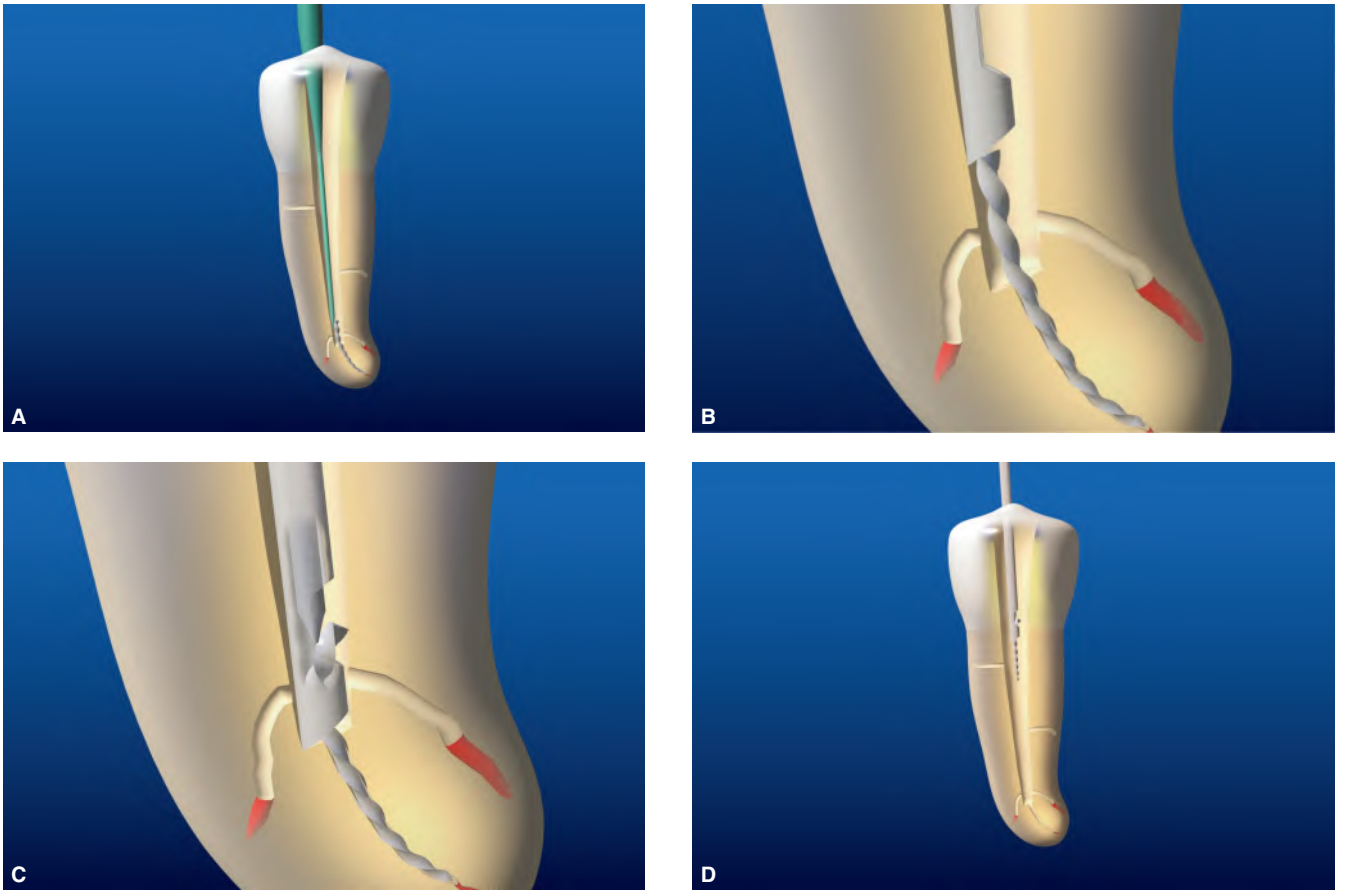

FIGURE 23-63 ***A.*** Illustraion demonstrating a titanium ProUltra ENDO-8 trephining deep around the coronal aspect of the separated file. ***B.*** When ultrasonic procedures prove ineffective, the beveled end of an iRS microtube is designed to "scoop up" the head of the separated file. ***C.*** Introduction of the screw wedge rotated counterclockwise to engage and potentially displace the head of the file out the side window. ***D.*** The iRS can form a strong purchase on, unwind and remove a separated instrument.

an activated ultrasonic instrument on the engaged assembly is another potent adjunct that will oftentimes promote removal success. If a microtube cannot be placed over a broken instrument such that the head of the obstruction lies within the side window, then in these instances, the microtube's beveled end can be easily reduced or eliminated to achieve better mechanics. A clinical case utilizing the FRS option is shown in Figure 23-64.

The Endo Rescue Kit 4601 Option

The Endo Rescue kit (Komet; Rock Hill, South Carolina, USA) has recently launched for the removal of broken instruments.[144] The kit is comprised of five instruments: namely, a cylindrical bur with a noncutting tip, two short Gates Glidden drills (GG-3 and GG-4), a dedicated centering drill, and a trephine. The centering drill has the same external diameter as the GG-3 (0.90 mm) and its concave tip is designed to go over the fragment and keep the preparation centered (Figure 23-65). The trephine has the same external diameter as both the GG-3 and the centering drill (0.90 mm). Specifically, the trephine has an internal lumenal length of 5 mm and a diameter of 0.50 mm. The trephine must be used in a CCW rotation.

After creating straightline access to the broken instrument with the cylindrical bur, the GG-3 is used to reach the head of the fragment. The centering drill is then used at 300 rpm, such that its outer blades bore and cut dentin around the broken file. The correspondingly-sized trephine is used in a CCW rotation, either mechanically at 300 rpm or manually, with the mandrel included in the kit. Trephining serves to cut a 2 mm-length thin trench around the head of the broken fragment. The activity of trephining serves to produce dentin chips that in turn, jam between the inner walls of the trephine and the fragment. When successful, the fragment is pulled inside the trephine. If unsuccessful, the microtube technique may be considered. In this instance, a microtube is selected that has the same outside diameter as the previously used trephine (Ultradent; South Jordan, UT, USA). This microtube is prefit over the fragment, filled with a self-curing composite core material, and then replaced in the canal and over the fragment. Once the composite has set, the microtube is rotated CCW to encourage the removal of the broken fragment (Figure 23-66). A radiograph is taken to confirm instrument removal.

When using the microtube technique, care should be taken to dry the canal with pure alcohol. Further, only the

internal lumen of the microtube should be filled with composite, without surplus. In thin roots, when a staging platform is not practical, NiTi file fragments may be abraded with thin ultrasonic tips to facilitate utilizing a bypass technique (Figure 23-67).[145]

Broken Instrument Prevention

The best antidote for a broken file is prevention. Adhering to proven concepts and utilizing safe techniques during root canal preparation procedures will virtually eliminate the broken instrument procedural accident.[3,141] Prevention may also be greatly facilitated by thinking of negotiating and shaping instruments as disposable items. Simply discarding all instruments after the completion of each endodontic case will reduce breakage, lost clinical time, and prevent upsets. However, on occasion, an instrument will break and the treating dentist must decide on the best treatment option.[146] Weighing risk versus benefit, certain broken file segments may not be able to be retrieved or bypassed. However, "Failing is not always failure," so, in these instances, the canal should be cleaned up to the fragment and sealed. The case should be followed over time (Figure 23-68), and in the presence of clinical symptoms and/or radiographic pathology, surgery,[56] or extraction may be the best treatment option.

BLOCKS, LEDGES, & APICAL TRANSPORTATIONS

It is important to understand and appreciate the biological and mechanical objectives for shaping canals and cleaning root canal systems.[139,147] Failure to respect these objectives increases frustration and predisposes to needless complications such as blocks, ledges, apical transportations, and potentially, perforations. Regrettably, these iatrogenic events *do occur* and are clinically encountered (Figure 23-69). Perhaps the most overlooked and unsaid method to negotiate a blocked canal, bypass the ledge, or manage a transportation is determination, perseverance, and patience.

Techniques for Managing Blocks

Generally, when managing blocked and/or ledged canals, the shortest file that can reach working length is selected. Shorter instruments provide more stiffness and move the clinician's fingers closer to the tip of the instrument, resulting in greater tactile control. Appreciate that canals are frequently more curved than the roots that hold them. The armamentarium needed to successfully negotiate through a canal blockage is generally a series of 21 mm-length stainless steel files in sizes 0.06, 0.08, and 0.10 mm. Importantly, the obstructed and blocked canal is filled with full-strength sodium hypoclorite or a lubricant, such as Glyde, ProLube, or RC Prep.

The first step is to precisely locate the level of the block, then preshape that portion of the canal that is coronal to this blockage. During this exercise, care should be exercised to avoid contacting the block. An abrupt curve is placed on the apical extent of a size 0.06 or 0.08 K-type file. This precurved file can now be passed through the pre-enlarged canal and will reach the obstruction, curved. C Pilot files (*VDW, United Dental Manufacturers, Inc; Tulsa, Oklahoma, USA)* are available in sterile blister packs of six instruments and are recommended because they have a high resistance to bending, due to a special thermal hardening process. The precurved file is placed in contact with the block. A single back-and-forth reciprocating motion is used in conjunction with light apical pressure. The file is immediately removed from the root canal with an envelope movement.[148] The goal is to disintegrate the block with the tip of the file. Irrigate with 1.0 ml of NaOCl, repeat the same procedure three times, and then discard the file. A new file is selected and precurved, as the reciprocating action described dulls the tip of the file. Indeed, a new file ensures a sharp tip, which is mandatory for a successful outcome. The same handle motion and file movement is continued with as many files as required until a light catch is felt. At this stage, a size 0.08 C-Pilot file is usually selected and utilized, as

described, to expand the pathway following the use of the size 0.06 K files. In some clinical situations, up to a dozen files may be needed to negotiate through and bypass a blockage. Once the canal has been negotiated and patency established, the file is repeatedly used in a slip, slide, and glide manner to refine, expand, and smooth the glide path. Clinicians need to demonstrate perseverance when blocked canals are encountered, as oftentimes patience will be rewarded (Figure 23-70).

If no progress is made after diligent efforts over a timeframe of approximately two to three minutes, then the sodium hypochlorite is removed from the root canal system and replaced with a viscous chelator, such as RC Prep, Glyde, or ProLube. As the chelator begins to work deeper into the canal, the same technique as described above is then utilized.

At times, there are clinical situations where the aforementioned techniques have been carefully attempted, but either the file is not progressing apically or is not tracking the

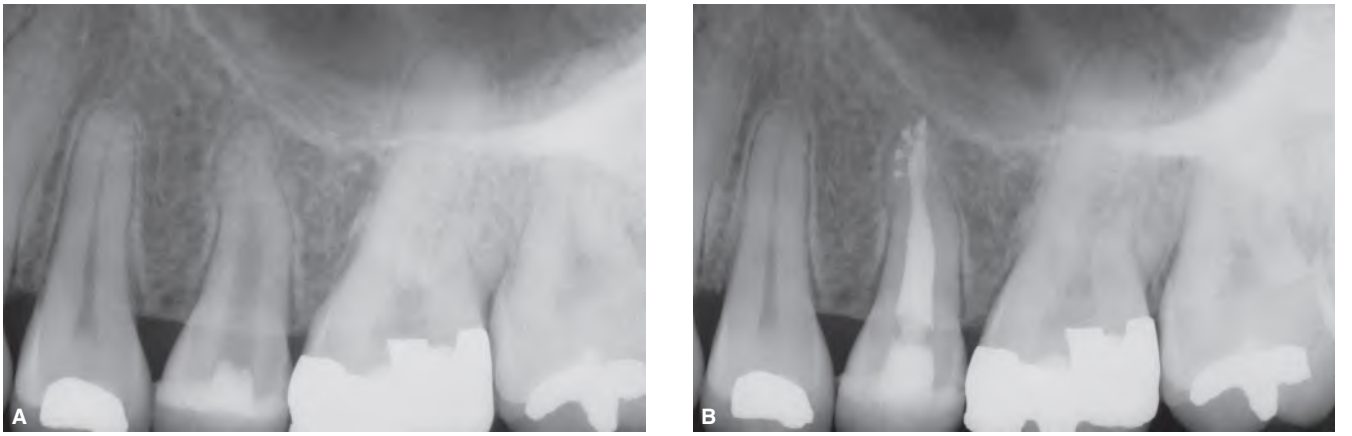

FIGURE 23-70 ***A.*** A preoperative radiograph of a maxillary left second premolar showing previous access and pre-enlargement of the canal in its coronal two-thirds. ***B.*** Postoperative radiograph provides an explanation as to the etiology of the original block. Note, the canal bifurcates apically and has four portals of exit.

pathway of the physiologic canal. What to do next requires a thoughtful treatment decision.[56] If the patient is truly asymptomatic and symptoms are not masked by a pharmaceutical, and if the periodontium is healthy and there are no lesions of endodontic origin, then the preparation is finished to the level of the obstruction and packed. The patient is informed of this less-than-ideal outcome, the importance of periodic recalls, and the possible need for future surgery. If the blocked canal is not negotiable and if clinical symptoms, periodontal breakdown, and/or a lesion of endodontic origin are present, then three-dimensionally pack the case, for at times post-operative films demonstrate hydraulics and obturation material to length. Regardless of the packing result, the patient needs to be advised of the importance of recall and that future treatment options include surgery, re-implantation, or extraction.

Techniques for Managing Ledges

An *internal* transportation of the canal is termed a "ledge" and frequently results when clinicians are preparing a curved canal and work short of length (Figure 23-71A). Many ledges are successfully bypassed using the techniques described for blocks. Once the tip of the file is apical to the ledge, it is moved in and out of the canal utilizing very short push-pull movements with emphasis on staying apical to the defect. When the file moves freely, slightly longer push-pull strokes are used to reduce the ledge and confirm the presence or absence of any residual internal canal irregularities. If the file is sliding easily, it is turned CW upon withdrawal because this motion will tend to straighten the apical one-third of a stainless steel file and allow it to rasp, reduce, smooth, or eliminate the ledge, which is typically on the outer wall of the canal curvature. During these procedures, try to keep the file coronal to the full working length so the apical foramen is handled delicately and kept as small as practical. When the ledge can be predictably bypassed, then efforts are directed towards establishing patency with a size 10 file. Gently passing a .02 tapered size 10 file 1.0 mm through the foramen increases its diameter to 0.12 mm and paves the way for the size 15 file.

Advantageous to ledge management is the utilization of ProTaper NiTi hand files (Dentsply Maillefer; Ballaigues, Switzerland). The major advantage of using NiTi files of greater taper to remove a ledge is their tapers are three to six times larger than conventional 0.02 tapered files. Once a precurved NiTi hand file has been inserted into the canal and its precurved tip has successfully bypassed the ledge, then its larger taper oftentimes eliminates or reduces the extent of the ledge using a minimum number of files. NiTi files are *not* introduced into the canal until the ledge has been bypassed, the canal negotiated, and patency established. Bypassing the ledge and negotiating the canal up to a size 15, and if necessary, a size 20 file, creates a pilot hole so the tip of the NiTi instrument can passively follow this secured glide path. To move the apical extent of a NiTi file past a ledge, the instrument must be precurved, preferably with the Bird Beak Pliers (Hu-Friedy; Chicago, Illinois, USA) (Figure 23-71B). To successfully precurve a NiTi instrument, the working end of the NiTi file is securely grasped between the jaws of the pliers and the handle is pulled through a radius of between 180 and 270 degrees. NiTi has shape memory and efforts to bend it must be exaggerated so that when the instrument is released from the pliers, it will have the desired curvature in its apical extent. The rubber stop on a manual NiTi instrument is oriented so the file's precurved working end can be directed to bypass and move apical to the ledge (Figure 23-71C). The ProTaper Shaping files, termed S1 and S2, may be used in this secured region of the canal until the full working length is reached (Figure 23-71D). Following the use of the S1 and the S2, the size 10 hand file is slidded down the canal to check if the ledge has been either reduced or eliminated. Regardless, the canal needs to be further enlarged to at least the ProTaper F1, and ultimately in accordance with the ProTaper finishing criteria.[149,150] A clinical case depicting ledge management is illustrated in Figure 23-72.

Based on preoperative radiographs, the clinician must make a decision whether to continue shaping procedures in hopes of eliminating the ledge or to abort if continued

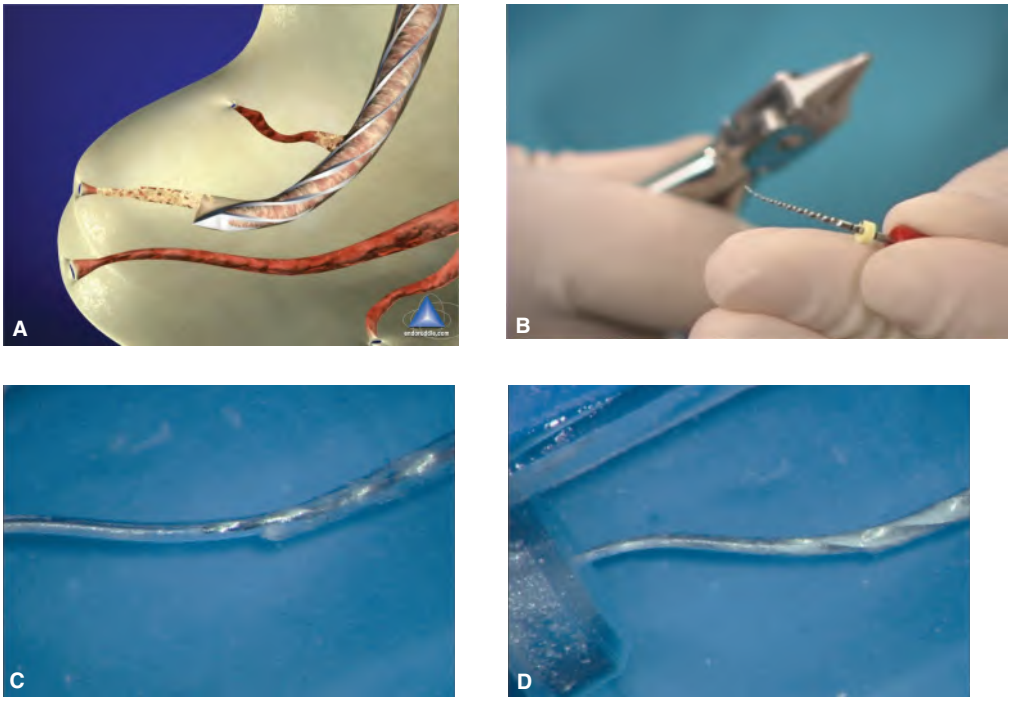

FIGURE 23-71 ***A.*** A ledge is created in a curved canal when pressure is applied on the file to reach the working length. ***B.*** Photograph showing how the Bird Beak Pliers can precurve a manual NiTi ProTaper file. ***C.*** A plastic block image demonstrates a manual, precurved ProTaper S1 file apical to the ledge. ***D.*** A plastic block image demonstrates a manual, precurved ProTaper S2 file has eliminated the ledge and is at length.

efforts will weaken or perforate the root. Not all ledges can or should be removed. Clinicians must weigh risk versus benefit and make every effort to maximize remaining dentin. Ultimately the five mechanical objectives of cleaning and shaping should guide each clinician's actions.[139,141,147]

Cone fit is usually possible when the ledge is located in the middle portion of the canal. In the instance when the ledge cannot be eliminated in the apical one-third, fitting the master gutta-percha cone can be challenging. In these cases, the master cone is trimmed so its terminal diameter equals the D_0 diameter of the file that was snug at length. The cone is then precurved to simulate the curvature of the canal and its radicular portion placed in a dappen dish of 70% isopropyl alcohol. The master cone is removed after a few seconds and the clinician will appreciate the significant increase in its rigidity. An orientational notch is then placed on the butt-end of the master cone so as to identify working length and the direction of the cone's curvature. This technique greatly

facilitates the placement of the master cone during the packing procedure.

Techniques for Managing Apical Transportations

Moving the position of the canal's physiologic terminus to a new iatrogenic location on the external root surface equates to a transportation of the foramen.[151] Foraminal rips, zips, or tears are caused by carrying progressively larger and stiffer files to length.[151,152] If a transportation has occurred, then the canal exhibits reversed apical architecture and fails to provide resistance form to hold gutta-percha. This contributes to poorly packed cases that are vertically overextended, but internally underfilled.[3,77,153] In general, apical transportations can be categorized into three types, each requiring a specific treatment.

Type I

A *Type I* transportation represents a *minor* movement of the position of the physiologic foramen, resulting in an iatrogenic relocation on the external root surface (Figure 23-73A). In this instance, the clinician must weigh risk versus benefit when trying to create positive apical canal architecture. Generating shape coronal to the foramen requires the additional removal of dentin and could predispose to root weakening or to a lateral strip perforation. If sufficient residual dentin can be maintained and shape created above the foramen, then some of these iatrogenic cases can be three-dimensionally cleaned, shaped, and packed) (Figure 73B–D).[3] Regretfully, many canals whose foramens have been progressively transported are not amenable to a Type I-related treatment approach and will require an escalation in procedural steps.

Type II

A *Type II* transportation represents a *moderate* movement of the physiologic position of the foramen, resulting in a bigger iatrogenic relocation on the external root surface (Figure 23-74). As such, the apical one-third of the canal exhibits more reverse architecture than in a Type I transportation. In these instances, wet canals are common and attempting to create more coronal shape would risk weakening and/or perforating the root. In treating these canals, a barrier must be selected to control bleeding and provide a backstop to pack against during subsequent obturation procédures.[3]

The barrier of choice for a Type II transportation is mineral trioxide aggregate (MTA) (ProRoot, Dentsply Maillefer; Ballaigues, Switzerland) (Figure 23-75A).[154,155] MTA represents an extraordinary breakthrough for managing radicular repairs and can be used in canals that exhibit reverse apical architecture, such as those in immature roots and in Type II transportations. Additionally, MTA is used for nonsurgical and surgical perforation repairs or as a surgical root-end filling material. Remarkably, cementum grows over this nonresorbable and radiopaque material, thus allowing for a normal periodontal attachment apparatus.[156] Although a dry field facilitates visual control, MTA is apparently not compromised by slight moisture and typically sets brick-hard within 4 to 6 hours, creating a seal as good as or better than the best materials used today.[156]

MTA is easy to use and the powder is mixed with anesthetic solution, or sterile water, to a heavy viscous consistency. A fiberless 2 × 2 gauze may be used to wick-off surplus moisture and achieve the ideal viscosity.[77] A small aliquot of this cement is picked-up and introduced into the prepared canal with any microtube carrying device (Figure 75B and C). Generally, these devices will allow MTA to be placed in the middle one-third of virtually any posterior root and well-shaped canal. MTA is then gently tamped and coaxed down the canal to approximate length using a customized nonstandard gutta-percha cone as a flexible plugger. The gutta-percha cone should be trimmed apically to have sufficient diameter to effectively condense MTA.[3,77] This flexible gutta-percha plugger may be utilized to move MTA around root canal curvatures and into root defects.

At times, when pressing MTA into narrowing cross-sectional canal diameters, the material will become dehydrated and not move. Pressing on MTA with an apically trimmed, flexible gutta-percha plugger tends to compress the material and squeeze out water content from the MTA. In these instances, the MTA should be rehydrated in order to get it to slump, move, and adapt into any given root defect. Rehydration is accomplished by dispensing one or two drops of water into the canal. Gently insert a size 10 or 15 hand file into the MTA. Pump the file in short 1-2 mm strokes within the MTA to rehydrate the material so it can be readily moved and adapted. At this point, if there is excess water, simply wick it off using paper points. It is of critical importance to tamp a 3 to 5 mm aliquot of MTA to within 3 to 4 mm of any given defect or root apex.

When a sufficient volume of MTA is radiographically confirmed to be in position, it can be vibrated and moved into the defect and to length using the sonic EndoActivator system. As previously mentioned, the EndoActivator handpiece drives highly flexible, noncutting, polymer tips and three tip sizes are available in different D0 diameters and tapers. The tip selected is based on the length and diameter of the canal and position of the root defect. The tip is vibrated at the lowest power setting and is never placed closer than 2 to 3 mm from the root end. The sonic EndoActivator vibratory energy will generate a wave-like motion that will encourage MTA to slump, move, and adapt to the configurations of the canal laterally, as well as control its movement to and gently against the periapical tissues. Prior to initiating subsequent procedures, a dense 4 to 5 mm zone of MTA in the apical one-third of the canal should be confirmed radiographically.

MTA needs moisture to drive the cement to set and become brick-hard. Fluids are present external to the canal

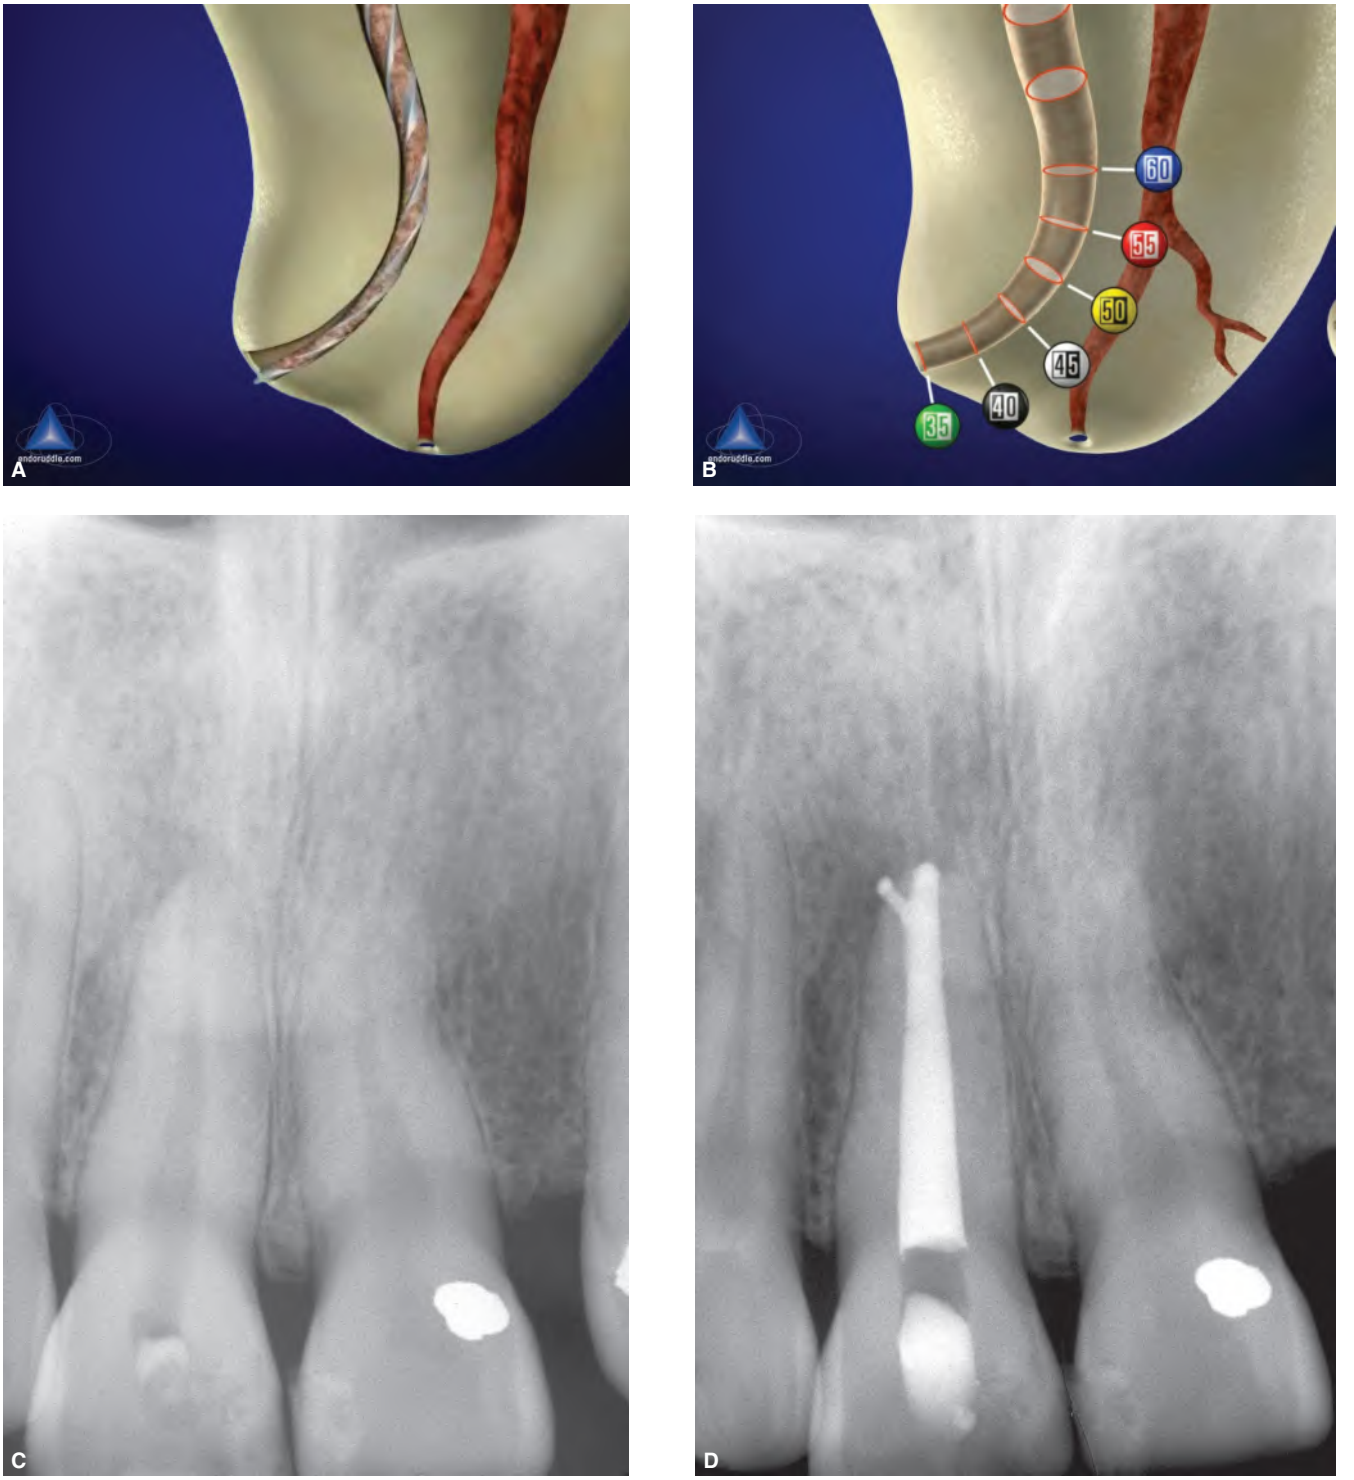

FIGURE 23-73 ***A.*** Illustration demonstrating a Type I transportation. Note, there has been a minor "shift" of the foramen. ***B.*** Management of a Type I transportation is directed towards creating shape above the foramen. ***C.*** Preoperative radiograph showing that the maxillary central incisor has been previously accessed, over-instrumented, and its canal exhibits reverse apical architecture. ***D.*** Post-treatment radiograph showing treatment of a *Type I* transportation. Shaped canals provide resistance form to hold gutta-percha.

and will fulfill the moisture requirement for the apical aspect of the positioned MTA. However, a cotton pellet will need to be sized, moistened with water, and placed against the coronal most aspect of the MTA that is within the canal. The tooth is then temporized and the patient dismissed. At a subsequent appointment, the temporary filling is taken out and the wet cotton pellet removed. The MTA cement is probed with a sharp explorer to determine its hardness. Typically, the material is brick-hard and the clinician can then obturate against this barrier. If the material is soft, it

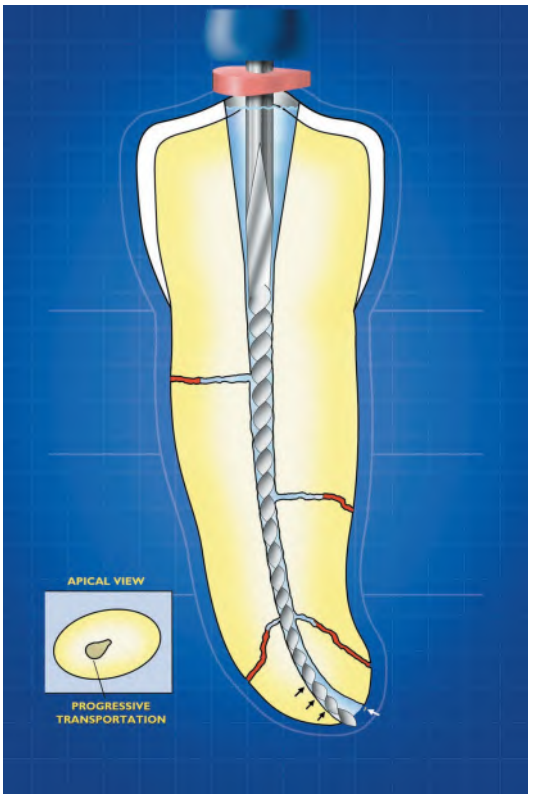

FIGURE 23-74 Illustration of a *Type II* transportation. Note, there has been a moderate "shift" of the foramen.

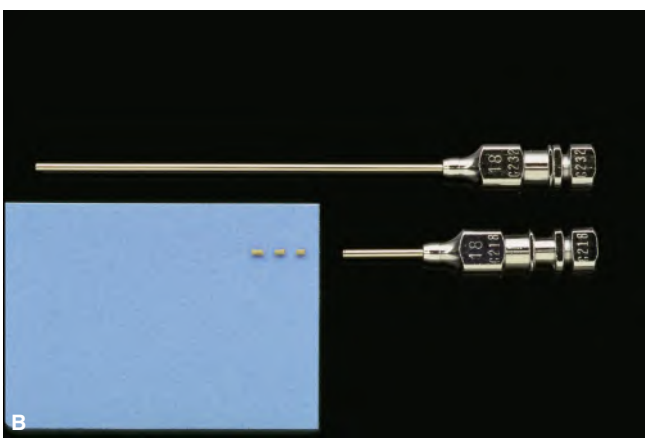
should be removed, the area flushed, dried, and a new mix of MTA placed. Upon subsequent re-entry, a hard barrier should exist which will provide a backstop against which to pack. The clinical steps for managing a *Type II* transportation are illustrated in Figure 23-76.

Type III

A *Type III* transportation represents a *severe* movement of the physiologic position of the foramen, resulting in a significant iatrogenic relocation on the external root surface (Figure 23-77). In this situation, the terminal extent of the canal is so badly mutilated that a barrier technique is usually not feasible and hence, three-dimensional obturation is impossible. If a tooth with a *Type III* transportation is to be salvaged, it requires obturation as best as possible with follow-up corrective surgery (Figure 23-78). Severe foraminal transportations that cannot be treated surgically are extracted.

ENDODONTIC PERFORATIONS

Perforations represent pathologic or iatrogenic communications between the root canal space and the attachment apparatus. The causes of perforations are resorptive defects, caries, or iatrogenic events that occur during and after endodontic treatment. Regardless of etiology, a perforation is an invasion into the supporting structures that initially incites inflammation and loss of attachment, and ultimately may compromise



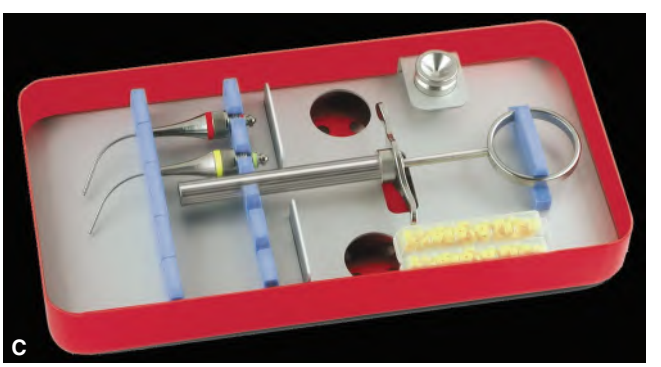


FIGURE 23-75 ***A.*** ProRoot, or MTA, is packaged in a powder form and then mixed with sterile water to a heavy cake-like consistency. ***B.*** A regular length 18 or 20 gauge spinal tap needle is appropriately shortened and utilized to carry small aliquots of MTA. ***C.*** The MAP system® (Micro Apical Placement system), Tulsa, Oklahoma, U.S.A.

the prognosis of the tooth. Perforations at or below the crest of bone certainly pose a serious threat to an otherwise favorable endodontic prognosis. The interdisciplinary team must decide whether to extract or direct efforts towards nonsurgical retreatment, surgical correction, or both.

Considerations Influencing Perforation Repair

When evaluating a perforated tooth, there are a number of variables that must be considered individually and collectively to properly guide treatment. Treating clinicians must identify the four dimensions of a perforation and understand how each of these entities critically affects treatment selection and prognosis.[3] Microscopes, paper points, electronic apex locators, and a suitable diagnostic radiopaque contrast solution are useful in determining the level, location, and extent of a perforation and the potential for successful management.[3,77] The four dimensions of a perforation always occur in combination, which synergistically complicates treatment outcomes.

1. *Level*: Perforations occur in the coronal, middle, and apical one-thirds of roots. Furcal perforations have similar considerations as coronal one-third perforations. Perforations at this level threaten the sulcular attachment and pose different treatment challenges than more apically occurring perforations. In general, the more apical the perforation, the more favorable the prognosis.
2. *Location*: Perforations occur circumferentially on the buccal, lingual, mesial, and distal aspects of roots. The location of the perforation is not so important when nonsurgical treatment is selected, but its position is critical and may preclude surgical access if this approach is considered.
3. *Size*: Perforation size greatly affects the clinician's ability to establish a hermetic seal. The area of a circular shaped perforation can be mathematically described as πr^2. Therefore, doubling the perforation size with any bur or instrument increases the surface area to seal by four-fold. Clearly, many perforations are ovoid in shape due to the nature of occurrence and represent enormous surface areas to effectively seal.
4. *Time*: Regardless of etiology, a perforation should be repaired as soon as possible to discourage further loss of attachment and prevent sulcular breakdown. Chronic perforations exhibiting a loss of sulcular attachment pose treatment challenges that potentially escalate to surgical correction and efforts directed toward guided tissue regeneration procedures.[157–159]

Periodontal Condition

Teeth that have been perforated must be thoroughly examined periodontally. Specifically, the sulci of these teeth must be carefully probed.[160,161] If the attachment apparatus is intact, then timing is critical, and the treatment is ideally directed toward nonsurgically repairing the defect. However, if there is periodontal breakdown with resultant loss of attachment, then interdisciplinary consultations, including ortho, perio, endo, and restorative, should guide treatment planning, sequencing, and prognosis. In these instances, a decision must be made between a nonsurgical repair versus surgical correction, recognizing that, at times, combined treatment may be required to salvage the tooth. Importantly, extraction may be wise and a fixed bridge or restored implant considered.

Esthetics

Perforations in the anterior region can definitely impact esthetics. Patients that exhibit a high lip line can be esthetically compromised by soft tissue defects such as clefts, recessions, or discrepancies in the inciso-gingival dimensions of a crown, as compared to the adjacent teeth.[162,163] Importantly, tooth-colored restoratives must be carefully chosen in areas that demand esthetics and are selected from the best materials currently available in adhesion dentistry.[164] Sadly, certain traditional restoratives contributed to tooth discoloration, soft tissue tattoos, and a serious compromise in esthetics.

Note, the packed buccal canal does not conform to the mechanical objectives of cleaning and shaping. ***B.*** Following flap elevation, a surgical photograph at 12× magnification shows gutta-percha exiting through a significantly ripped and relocated foramen. ***C.*** Surgical photograph at 12× magnification shows osteotomy, apicoectomies, and ultrasonic root-end preparation of the buccal canal. ***D.*** Surgical photograph at 12× magnification through a sapphire-plus micro-mirror depicts the finished buccal root-end preparation. ***E.*** Ultrasonic root-end preparation of the lingual canal. ***F.*** Four-year recall film showing the apically corked canals and excellent osseous repair.

Vision

Magnification glasses, headlamps, and transilluminating devices facilitate vision and are important adjuncts in addressing perforations. However, the dental operating microscope has become the standard of vision and may be utilized to more predictably repair perforation defects nonsurgically, thus reducing the need for surgical intervention and its associated risks.[3,77]

Treatment Sequence

When there is a perforation and the canal has not been fully prepared, then the defect should be repaired prior

to proceeding with definitive endodontic treatment. Repairing the perforation will enable the clinician to control bleeding into the canal, confine irrigation, and achieve a controlled and hydraulic fill. However, any given perforated canal should be optimally enlarged and prepared, when necessary, to improve access to the defect, enhance visualization, and to importantly minimize post-repair instrumentation. When repairing a perforation, it is important to maintain the pathway to the physiologic canal because the barriers and restoratives utilized could inadvertently block the canal. A gutta-percha segment or a collagen plug can by placed apical to the defect to prevent canal blockage during the perforation repair procedures. In failing endodontic cases exhibiting a perforation, the existing obturation material may be used to hold the position of the canal. This allows the clinician to first repair the perforation before proceeding with endodontic disassembly and retreatment efforts. However, in this sequence of treatment, caution must then be exercised not to disrupt the perforation repair material during subsequent disassembly, canal preparation, and obturation procedures.

Materials Utilized in Perforation Repair

Hemostatics

Many perforation defects exhibit massive bleeding upon re-entry. As such, clinicians need to be familiar with a few hemostatic agents and materials that can predictably arrest bleeding.[165] A dry field enhances vision while creating an environment for the predictable placement of a restorative agent. Calcium hydroxide, a time-honored material, can be passively syringed into the canal, hydraulically moved to place, and allowed to remain in the canal/defect for four to five minutes or longer. The calcium hydroxide is then flushed from the field using sodium hypochlorite. Two or three applications of placing and then removing calcium hydroxide usually begins to control the bleeding. When the clinician can not obtain hemostasis, calcium hydroxide can be advantageously left in the canal until a future appointment.[166] Other increasingly important materials that can be used to achieve hemostasis by various mechanisms include collagen, calcium sulfate, freeze-dried bone, and mineral trioxide aggregate (MTA).[159,165,167] There are other hemostatics that exist, but they are not generally selected due to factors such as cost, ease of handling and placement, or their byproducts. Ironically, some of the best hemostatics, like ferric sulfate, leave a coagulum behind which may promote bacterial growth, compromise the seal at the tooth-restorative interface, and jeopardize the prognosis.[169]

Barrier Materials

The two main challenges a clinician faces when attempting to repair a perforation are hemostasis and the controlled placement of a restorative material. Barriers help produce a "dry field" and also provide an internal matrix or "backstop" against which to condense restorative materials.[3] In general, barriers can be divided into resorbable and nonresorbable; however, it is critical to note that the restorative material utilized oftentimes dictates the barrier that is selected.

Resorbable Barriers Bleeding into the tooth must be arrested in order to successfully manage perforations. Hemostasis is accomplished by passing a resorbable barrier nonsurgically through the access cavity, internally through the perforation defect, and ideally into a three-walled osseous defect. Resorbable barrier materials are intended to be placed within the bone and not left inside tooth structure. The barrier should conform to the anatomy of the furcation or root surface involved. Although a variety of resorbable barriers exist, collagen and calcium sulfate materials are best employed due to supporting research, ease of handling, and observed clinical results.

- *Collagen materials*, such as CollaCote (Sulzer/Zimmer Dental; Carlsbad, California, USA), exhibit excellent working properties that provide complete hemostasis.[165] CollaCote is biocompatible, supportive of new tissue growth, resorbable in 10 to 14 days, and left in situ.[158,167] Based on the size of the defect and the available access, pieces of CollaCote are cut to appropriate sizes and carried into the access cavity. The material is incrementally placed through the tooth and *into the osseous defect* until a solid barrier is established at the cavo surface of the root. Hemostasis is typically achieved in two to five minutes. Collagen barriers have been widely used in conjunction with amalgam, super EBA, and other non-bonded restoratives.[169] CollaCote is contraindicated as a barrier if adhesion dentistry is contemplated, as it absorbs moisture and will contaminate the restorative.
- *Calcium sulfate*, such as Capset (Life Core Biomedical; Chaska, Minnesota, USA), can be used as both a barrier and hemostatic material in perforation management.[159,169,170] Calcium sulfate creates a tamponade effect, mechanically plugging the vascular channels once it sets. Capset is remarkably biocompatible, does not promote inflammation, and is bioresorbable in 2 to 4 weeks. This material is syringed through the tooth and into the osseous defect utilizing a microtube delivery system. During its placement, the calcium sulfate will fill the osseous defect and a portion of the space within the root defect. Calcium sulfate rapidly sets brick-hard and may be sanded back flush to the external root surface with ultrasonic instruments. Calcium sulfate is the barrier of choice when utilizing the principles of wet bonding.[164,170,171] Importantly, the perforation defect can be rinsed of contaminants in preparation for adhesion dentistry.

Nonresorbable Barriers: Calcium-Silicate based Cements

- *Mineral Trioxide Aggregate (MTA)*, available in gray and white colors, exhibits excellent tissue biocompatibility and can be used both as a nonresorbable barrier and restorative material (Figure 23-75A).[172] MTA has

many clinical applications and represents an extraordinary breakthrough for managing radicular repairs.[173–175] MTA is the barrier of choice when there is potential moisture contamination or when there are restrictions in technical access and visibility. Furthermore, MTA can be used as the sole radicular restorative material or as a barrier against which to pack another material. The mixing and use of MTA was previously discussed in the *"Techniques for Managing Apical Transportations"* section earlier in this chapter.

- *Biodentine™*[176,177] is a new calcium silicate-based cement, initially created as a dentine substitute (Figure 23-79). It is a synthetic nano-particle multipurpose material, indicated to replace damaged dentine, both in the crown and in the root. Its chemical composition is different from that of MTA, as it has no gypsum and less water. Biodentine combines the biocompatibility of MTA with many additional and desirable characteristics. These characteristics include bioactivity-inducing hard tissue formation, good handling characteristics, self-adhesion to dentine, no shrinkage, and a better antibacterial action.

Further, Biodentine has a setting time significantly shorter than MTA (12–15 minutes). In endodontics, the indications for using Biodentine are the same as for MTA; namely, pulp capping, partial pulpotomy, deciduous teeth pulpotomy, apexification, perforation, and apical surgery.

Restoratives

Central to success when repairing a perforation is to select a restorative material that is easy to use, nonresorbable, biocompatible, esthetically pleasing, and one that provides a complete seal. The materials commonly employed to repair perforations include the time-honored but decreasing in popularity amalgam, SuperEba resin cement (Henry J. Bosworth; Skokie, Illinois, USA), composite bonded restoratives (Geristore, DenMat Corporation; Santa Maria, California, USA) calcium phosphate cement, MTA, and Biodentine.[175–180] The choice of the restorative repair material is based on the technical access to the defect, the ability to control moisture, and the esthetic considerations.

FIGURE 23-79 The Biodentine™ package.

Techniques for Repairing Perforations

The specific barrier and restorative selected to repair a perforation site should be based on sound research, judgment, experience, training, esthetics, ease of handling, and the advantages or disadvantages of a particular material in a specific clinical setting. This section describes the armamentarium, materials, and techniques required to repair perforations.

Management of Coronal One-Third and Furcal Perforations

The major difference between *coronal one-third* and *furcal floor* perforations is the shape of the resultant root defect. Mechanical perforations that occur in the furcal floor are generally round, while those occurring in the lateral aspects of roots are ovoid by nature of occurrence. When managing these perforations, the clinician must first isolate the perforation site. Generally, if the perforation is mechanical and has just occurred, it is non-infected and hence clean. In this situation, and if hemostasis is achieved, the defect can be immediately repaired. However, if the perforation is chronic and exhibits microleakage, then the defect needs to be cleaned and prepared before receiving the restorative. Ultrasonic instruments are ideal for preparing perforation sites because of their geometries and coatings, and because they afford unsurpassed vision.

Once the defect has been properly prepared, an appropriate barrier material and restorative are then selected based on the following esthetic considerations:

- In a coronal one-third perforation where esthetics is a concern, a calcium sulfate barrier in conjunction with adhesion dentistry is generally utilized.[171]
- Historically, amalgam and more recently SuperEBA have been utilized to repair coronal one-third perforations when esthetics was not an issue. Presently, MTA is rapidly becoming the material of choice for repairing non-esthetic coronal one-third defects because of its many desirable attributes. Biodentine is a good alternative to MTA.

Following perforation repair, the tooth can be three-dimensionally shaped, cleaned, and packed if this has not already been accomplished (Figure 23-80).

Management of Perforations in the Middle One-Third

Iatrogenic perforations in the *middle one-third* of roots are generally caused by endodontic files, Gates Glidden drills, or large misdirected posts. By nature of occurrence, these defects are ovoid in shape and typically represent relatively large surface areas to seal.

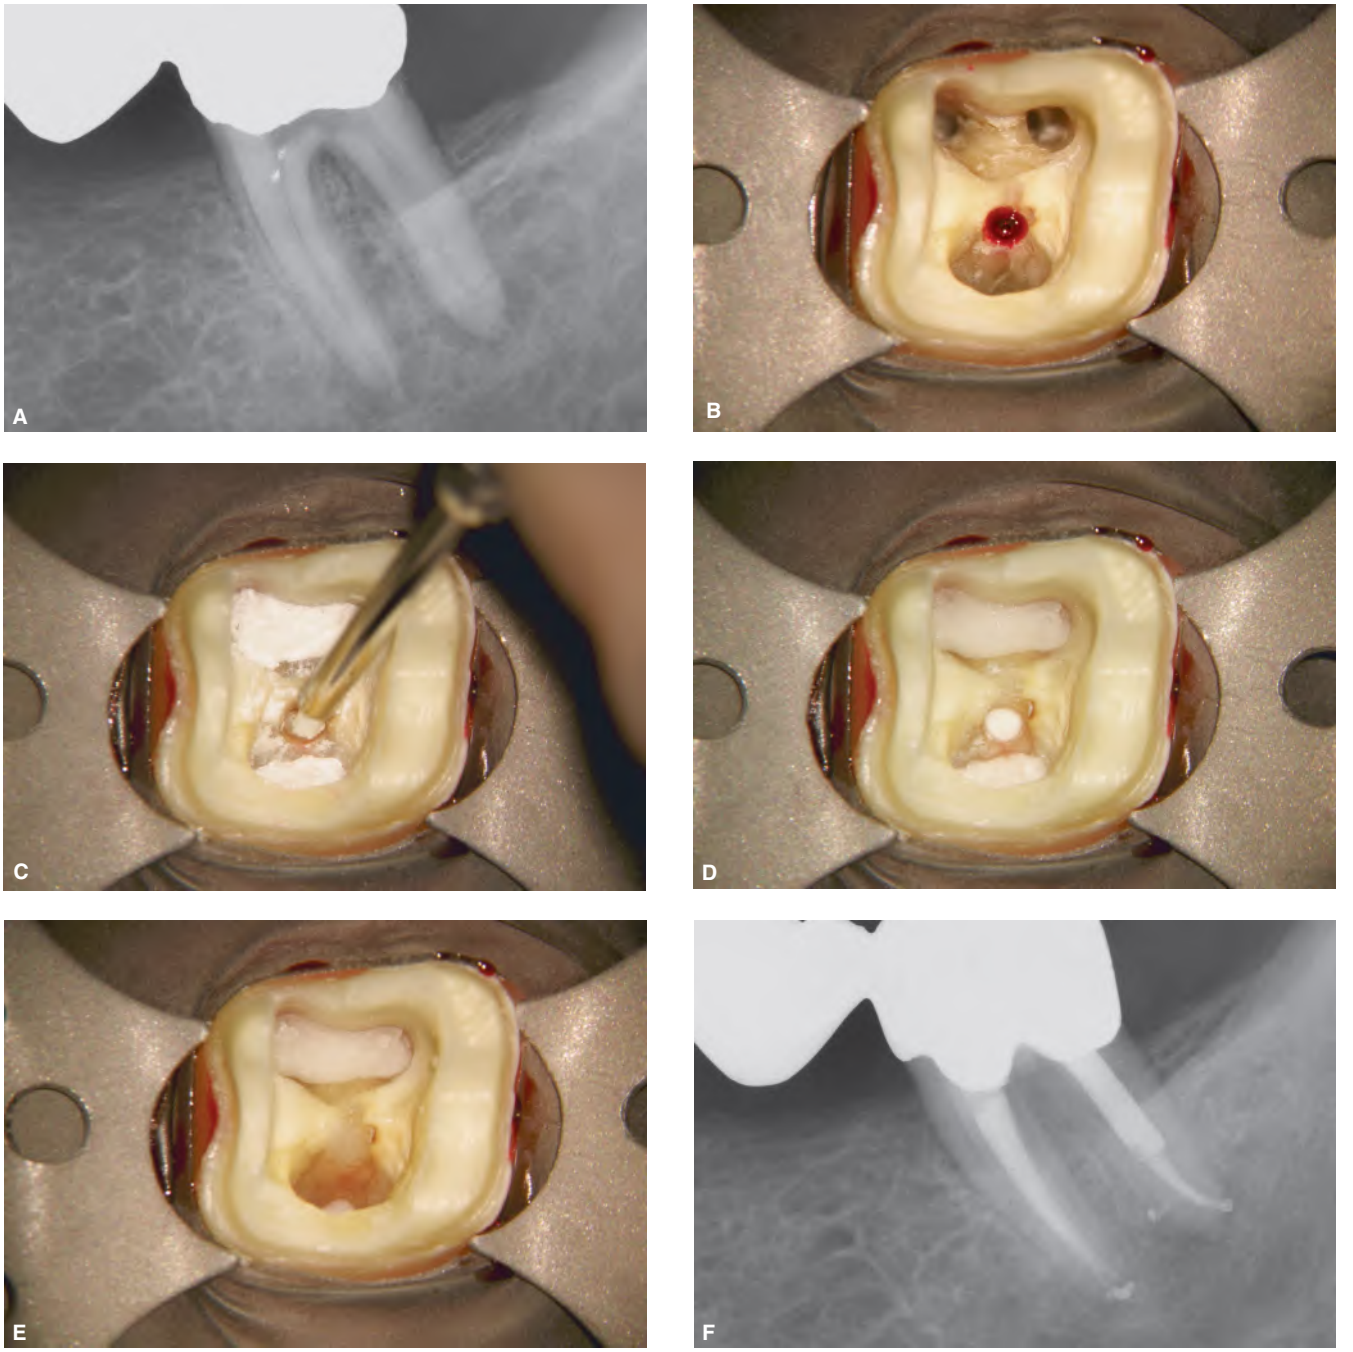

FIGURE 23-80 ***A.*** Preoperative radiograph of an endodontically involved mandibular left second molar serving as a bridge abutment. Note the previous access and possible pulp chamber floor perforation. ***B.*** Photograph showing the identified canal orifices and a furcal floor perforation. ***C.*** Segments of Collacote overlying the canal orifices and calcium sulfate being introduced into the perforation via an STN. ***D.*** Furcal management. The absorbable barrier is placed flush to the external cavo root surface. ***E.*** Perforation repair utilizing a dual cured composite restorative material. ***F.*** Five-year recall radiograph showing a new bridge and osseous repair furcally and apically.

Middle one-third or strip perforations have the same technical considerations as coronal one-third perforations, *except* the clinician is now dealing with defects located deeper and further away from the occlusal table. The factors that must be addressed in order to successfully treat these more apically-positioned perforations are hemostasis, access, utilization of micro-instrumentation techniques, and the selection of best materials in a challenging environment. When managing deeper defects, positioned on the lateral walls of canals, vision is enhanced when direct access exists or can

be safely created. In some instances, direct access may not be possible without irreversibly compromising the structural integrity of the tooth and indirect repair techniques are required. Generally, perforations that occur secondary to overzealous canal instrumentation are sterile and do not require further modification utilizing micro-instrumentation procedures. However, failing endodontic cases are associated with microleakage and bacterial invasion and may require ultrasonic instrumentation to clean and refine the defect in preparation for repair.

When the middle one-third perforation is a small defect, if the bleeding can be arrested and the canal dried, then the perforation can be sealed and repaired during three-dimensional obturation. However, if the defect is large and there is nuisance moisture, and/or the canal cannot be definitively dried, then the perforation must first be repaired before three-dimensional obturation. It is wise to prepare the canal as optimally as possible prior to initiating the perforation repair procedures. As has been stated earlier, a prepared canal will facilitate access to the defect *and* minimize post repair instrumentation. To prevent obstructing the root canal space during the repair procedures, any readily retrievable material is placed in the canal and apical to the defect before the perforation is repaired.

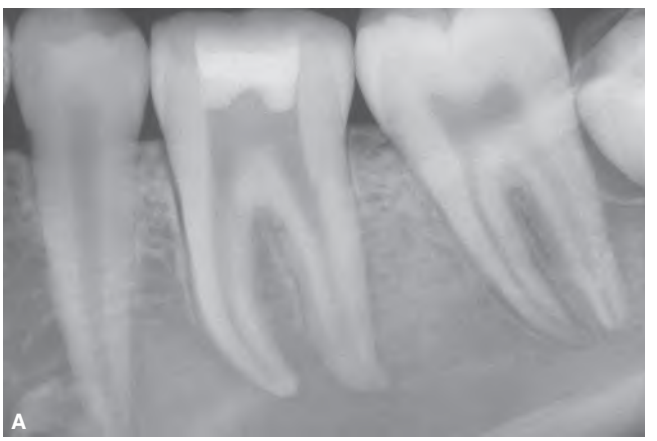
In these teeth, due to the difficult access, limited visibility, and the uncertainty of a moisture-free environment, the restorative/barrier material of choice is MTA. MTA is mixed and carried into the field and managed in accordance with the techniques discussed earlier in this chapter. Upon reappointment, MTA will invariably be hard and the clinician can proceed with the required treatment (Figure 23-81). A similar case was treated with Biodentine (Figure 23-82).

Management of Perforations in the Apical One-Third

Perforations occurring in the apical one-third of roots primarily result from iatrogenic shaping procedures. Blocks and ledges invite deep perforations and result from inadequate irrigation, inappropriate instrumentation, and failure to maintain patency. Roots perforated in their apical one-third can pose surprises and frustration during nonsurgical retreatment. It is quite common that a root perforated in its apical one-third holds a canal that is both blocked and ledged. Recognizing the etiology of this type of perforation has led to surgical correction utilizing apicoectomy and root-end-type procedures. However, it is generally best to first attempt nonsurgical retreatment to enhance the existing endodontic treatment and, if present, to identify and treat missed canals.

The clinician should attempt to negotiate the physiologic terminus with the concepts, instruments, and techniques previously discussed under *"Techniques for Managing Blocks"* and *"Techniques for Managing Ledges."* On occasion, the apical extent of the file will stick, handle flutter will be noticed, and the instrument will begin to track along the true canal pathway. The file is gently worked to negotiate the physiologic pathway, establish patency, and pave the way for the next successively larger instrument. The next sequentially larger precurved file is then inserted and carried apical to the perforation, but not necessarily to length. This "holding file" maintains the pathway of the true canal and prevents it from being blocked during subsequent repair.

MTA is the material of choice for repairing deep perforations, especially when a dry environment and technical access are not possible. MTA is placed, as has been previously described. To prevent the holding file from being frozen in a sea of MTA as it hardens, the instrument is grasped with Stieglitz pliers and moved up and down in short 1 to 2 mm amplitude strokes. The loosened holding file is then sectioned so its coronal-most aspect is below the occlusal table. A radiograph should be taken to confirm the position of the MTA and the quality of the repair. A wet cotton pellet is placed within the pulp chamber and against the MTA, the tooth is provisionalized, and the patient dismissed. Upon re-entry, the holding file is removed, and if the MTA is brick-hard, then



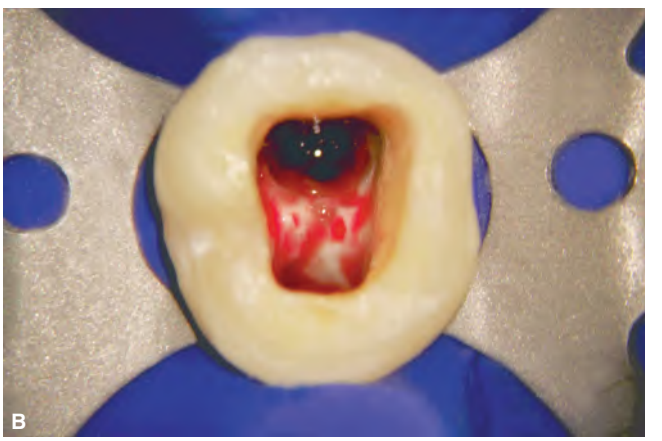


FIGURE 23-81 *(Continued on facing page)*

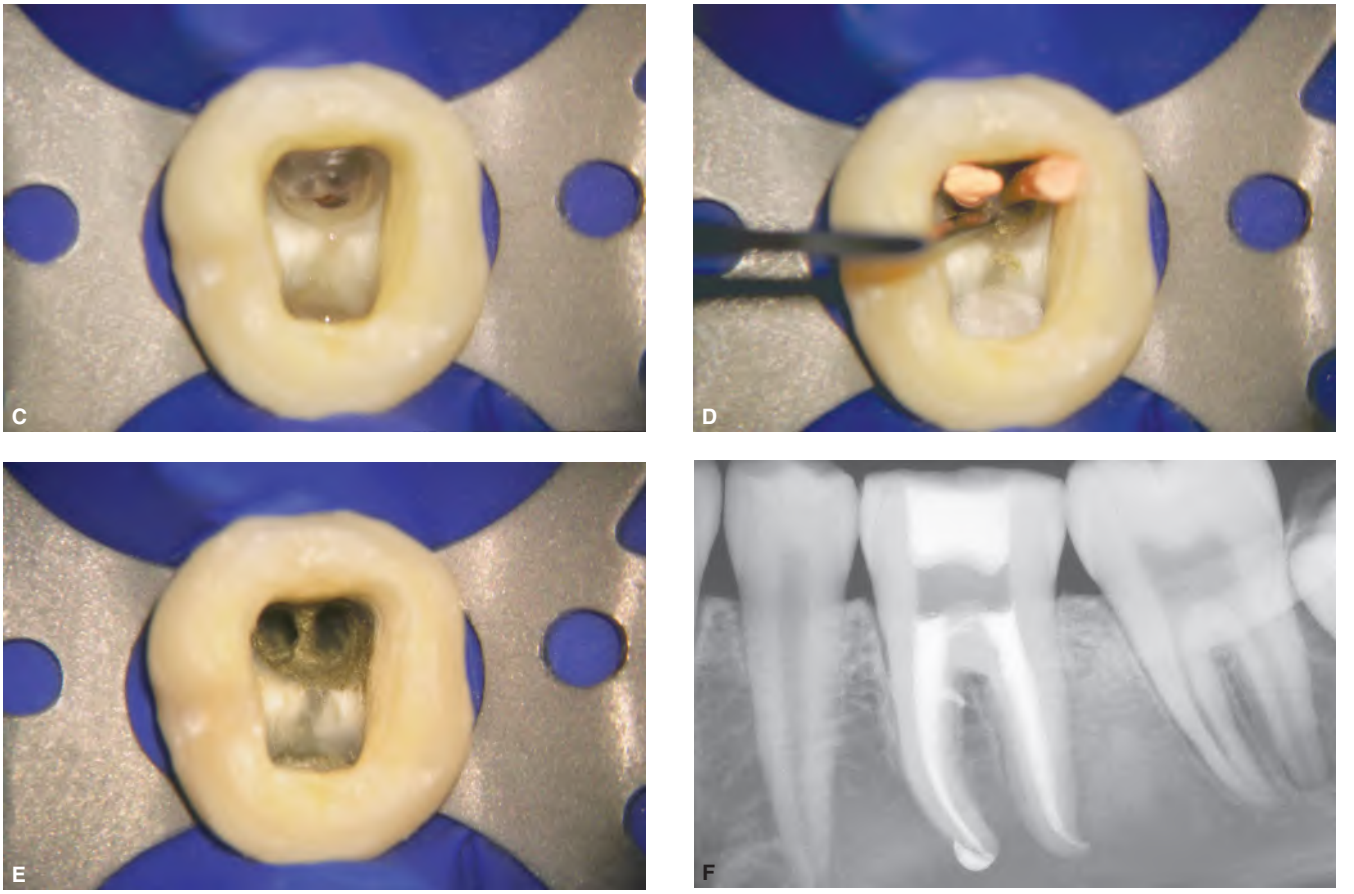

FIGURE 23-81 ***A.*** Preoperative radiograph of an endodontically involved mandibular left first molar. Note the previously over-enlarged mesial root. ***B.*** A photograph taken upon re-entry showing significant bleeding emanating from the mesial root. ***C.*** Photograph demonstrating hemostasis and the position of the strip perforation. ***D.*** Gutta-percha cones in the MB/ML canal systems to prevent their blockage. MTA is being vibrated into the perforation defect. ***E.*** At the subsequent visit, the gutta-percha cones are removed, the perforation repaired and the canals ready to pack. ***F.*** Postoperative radiograph showing the provisionalized tooth, four canal systems packed and the apical one-third anatomy.

voluminously irrigate and gently finalize the preparation, fit a gutta-percha master cone, and three-dimensionally obturate. It is wise to provisionalize these cases and follow up periodically before placing a definitive restoration. The clinical steps for managing apical one-third perforations are illustrated in Figure 23-83. It is also important to acknowledge that not all perforations can be corrected nonsurgically, even when the best technologies are utilized in the hands of the most skilled practitioners. Certain cases will still require surgical treatment or extraction (Figure 23-84).

FUTURE

As we have seen in this chapter, a variety of techniques exist to address endodontically failing teeth and the ultimate aim of orthograde retreatment is to improve the previous treatment (Figure 23-85). However, not all failures are amenable to successful nonsurgical retreatment. Clinicians need to weigh risk versus benefit and recognize that, at times, a referral, surgery, or extraction might be in the patient's best interest. The future of endodontics is bright and the demand for initial treatment and retreatment will grow significantly in the years immediately ahead. This growth will be attributable to better trained general dentists and specialists, alike, advancements in technologies, and the public's growing recognition that the naturally retained tooth is the ultimate dental implant. New advancements in root canal disinfection methods will continue to move our discipline ever closer, toward eliminating all the contents from both the instrumentable and noninstrumentable portions of the root canal system.[181–183] Properly performed, endodontic treatment is the cornerstone of restorative and reconstructive dentistry.

Chapter 24

Surgical Endodontics

Mahmoud Torabinejad, Mohammad Sabeti, Gerald N. Glickman

Nonsurgical initial root canal treatment is a highly successful procedure when diagnosis and technical aspects are carefully performed (Figure 24-1). Several studies with large sample sizes have reported that nonsurgical root canal therapy has a survival rate of over 90% when adequately performed.[1–3] Lazarski et al.[1] reported a functional survival rate of 94% for 44,613 cases over 3.5 years in the United States. Salehrabi and Rotstein[2] reported 97% survival for 1.1 million patients over eight years in the United States, and Chen et al.[3] reported 93% survival for 1.5 million teeth over 5 years in Taiwan. Torabinejad et al.,[4] in a systematic review, showed that initial root canal treatment is associated with a very high survival rate of 97% over six years. Iqbal and Kim[5] found similar results in another systematic review when they compared the survival rates of restored endodontically treated teeth with those of implant-supported restorations. When initial nonsurgical root canal therapy is unsuccessful, the treatment alternatives are nonsurgical retreatment (revision) and surgical treatment (Figures 24-2 and 24-3). When these are not feasible or practical, extraction with or without replacement is indicated. Studies have shown that between 77% and 89% of retreated cases are successful after retreatment of the original root canal therapy.[6–8] However, there are situations in which surgical treatment (surgical endodontics) is needed to retain a tooth that would otherwise be extracted.

Surgical endodontics is a delicate procedure, involving more than simply cutting off the apex of a root and placing a filling at the root end(s). The purposes of surgical endodontics are the sealing of all portals of exit from the root canal system, eliminating microorganisms and other antigens from contaminating the periapical tissues, providing an environment for complete regeneration of periapical tissues, and saving natural dentition. During the past two decades, the science and art of surgical endodontics have significantly changed. With the use of the operating microscope, ultrasonic tips, and new root-end filling materials, surgical endodontics has enabled clinicians to retain many teeth that might otherwise be extracted.[9]

This chapter describes the history of surgical endodontics, indications and contraindications, procedures involved in incision for drainage, periapical surgery, and corrective surgical procedures such as root resection, hemisection, and root

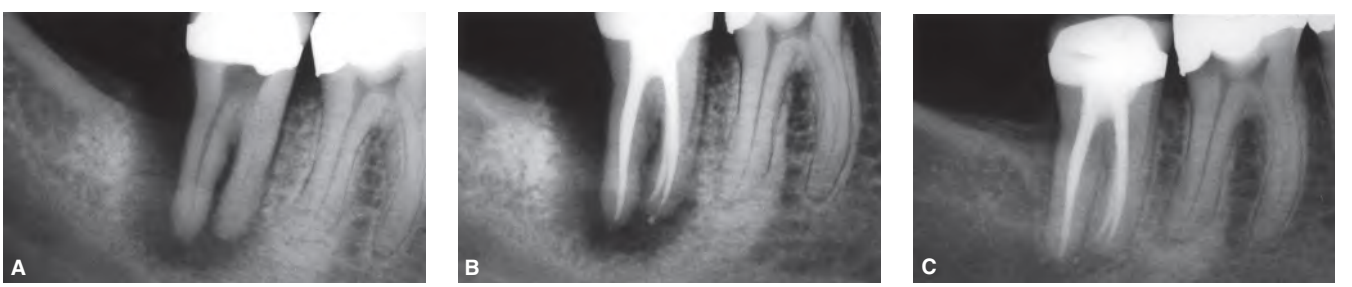

FIGURE 24-1 ***A.*** Preoperative radiograph of a second molar with pulpal necrosis and evidence of severe asymptomatic apical periodontitis. ***B.*** Postoperative radiograph of the tooth. ***C.*** Postoperative radiograph two years after root canal treatment shows complete resolution of the periapical pathosis. (Courtesy of Dr. David Steiner, Gig Harbor, Washington, U.S.A.)

FIGURE 24-2 ***A.*** A search for the MB canal in a partially calcified chamber resulted in a furcation perforation and extrusion of filling materials into the periapical tissues. An apex locator reading or an angled radiograph would have detected this type of error. ***B.*** The initial treatment was redone and the perforation was sealed with MTA. ***C.*** Radiograph taken three years later shows no evidence of pathosis in the repaired area. (Courtesy of Dr. George Bogen, Los Angeles, California, U.S.A.)

FIGURE 24-3 ***A.*** Periapical radiograph shows extensive radiolucency around the apex of the maxillary right incisor with an overextended silver point and an inadequate coronal seal. ***B.*** The root canal treatment was retreated nonsurgically and surgically using MTA as root canal filling material. ***C.*** Radiograph taken three years later shows complete resolution of the periapical lesion. extraction, bicuspidization, tooth replantation, transplantation, as well as the outcomes of these procedures.

HISTORY OF SURGICAL ENDODONTICS

Surgical endodontics has a long history (Table 24-1). The first recorded endodontic surgical procedure is related to the replantation of a tooth in the 11th century by Abu al-Qasim al-Zahrawi (Albucasis).[10] Hunter[11] discussed replantation and emphasized the need for preservation of the periodontal ligament for successful replantation. There are reports indicating that the first root resection was performed by C.S. Smith[12] in 1871. However, there are some documents contradicting these reports, supporting an argument that root-end resection was being performed for more than a century before Smith. For example, Berdmore[13] performed root-end resection in the middle of the 18th century.

In 1886, G.V. Black recommended the resection of the apex of the root of a tooth by using a fissure bur and saving the tooth.[14] During the annual session of the American Dental Association, Rhein[15] suggested that the treatment of a tooth with chronic apical abscess should include filling of the root canal followed by removal of the abscess. Ottolengui,[16] in 1892, recommended root-end resection following the filling of a root canal.

The period from 1900 to 1939 was the era of focal infection theory and wholesale extraction of teeth with pulpal and periapical diseases. William Hunter discussed and supported "the role of sepsis and of antisepsis in medicine" in his presentation and supporting focal infection theory. Due to the clinical success of surgical techniques, focal infection theory did not impact surgical endodontics in Europe. In two separate articles in the 1890s, Partsch[17,18] described root-end resection techniques by using a semilunar incision (Partsch incision). The endodontic surgical techniques, especially molar surgeries, were developed, practiced, and published in Europe. In 1915, Neumann[19] discussed both the theoretical and clinical techniques of mandibular molar surgeries. He provided the details of anatomical considerations for periapical surgery. Neumann described a surgical flap in attached gingiva that was similar to that proposed by Oschenbein and Luebke. A review of surgical flap designs was discussed by Hofer[20] in 1936.

In 1936, Peter[21] published a textbook on surgical endodontics that served as a prelude for today's surgical

endodontics. This book reviewed the literature, elaborated on historical developments, outlined the indications of surgical endodontics, and described the flap design for posterior teeth. Peter[21] discussed the position of the inferior alveolar canal in relation to the mandibular molar roots and the relationship of the maxillary sinus to the apices of the maxillary teeth. Different techniques for management of root-end resection and preparation were also developed in this era. Von Hippel[22] in 1914 described the vertical slot root-end preparation. Rudd[23] proposed a retentive groove, and Matsura[24] later on introduced this concept for contemporary surgical endodontics.

Root resection is a procedure that has been performed since the 1800s. In a 10-year study on the evaluation of the success of root resections, Langer[25] described this procedure for maintenance of a multi-rooted tooth that has a furcation defect. Bauer[26,27] and Kronfeld[28] recommended histological evaluations of root-end resections, based on the findings of their studies. Cavina[29] introduced the histological findings of Bauer to clinical procedures in 1930. At the same time, Gottlieb[30] and Steinhardt[31] discussed the healing of periapical tissues and provided a histological report that addressed the regeneration of the cementum and periodontal ligament. Hartzel recommended obturation of the root canal providing a "sterile" canal prior to root-end resection.[32]

In an article by Grossman,[33] many different surgical endodontic procedures were discussed that were available at the time. For example, he discussed hemisection, radisectomy (root amputation, root resection), endodontic implants, tooth replantation, transplantation, and implantation.[33] At that time, he stated that a transplanted tooth would exfoliate within two to three years because of resorption. However, advances and understanding at that time were making it possible to maintain a transplanted tooth. Grossman discussed the indications of tooth replantation in 1966. They include complex anatomy, extruded materials, or to repair a perforation when apical surgery is not feasible.[34]

In 1964, endodontics was recognized as a specialty in the United States and multiple universities established training programs. The surgical endodontics chapter became an integral part of endodontic textbooks. Various aspects of surgical endodontics such as indications, contraindications, anesthesia, flap designs, root-end resection and preparation, root-end filling materials, and outcomes were reported.

The first modern endodontic textbook on surgical endodontics was published by Arens, Adams, and DeCastro,[35] followed by other textbooks in 1998.[36–39]

The results of scientific investigation and the clinical application of the techniques and concepts developed during the second half of the 20th century represent the foundation of what is known and are being practiced in the 21st century. However, surgical endodontics is dynamic and it is imperative that scientific investigation continues; concepts, techniques, and materials used in "microsurgical endodontics" must be continually evaluated, modified and more emphasis must be placed on the assessment of long-term clinical outcomes with a better understanding of the molecular basis for surgical wound healing.[40]

Surgical endodontic procedures consist of fistulative surgery (incision and drainage, cortical trephination, and decompression procedures), periapical surgery and corrective surgery (perforation repair, management of periodontal defects by root resection, hemisection and root extraction, bicuspidization) as well as tooth replantation and transplantation.

INCISION AND DRAINAGE

The objective of incision and drainage is to evacuate exudates and purulence from a soft tissue swelling. The objective of incision for drainage is to evacuate inflammatory exudates and purulence from the soft tissue swelling and reduce discomfort from the buildup of pressure. This procedure not only results in patient's comfort, but it also speeds healing and recovery.

Indications

The best treatment for swelling originating from an acute apical abscess of pulpal origin is the establishment of drainage through the offending tooth (Figure 24-4). When adequate drainage is not accomplished through the tooth itself, drainage through the soft tissue incision should be attempted. Occasionally drainage is performed through the soft tissue without obtaining drainage through the offending tooth. The reason for this is the presence of separate, non-communicating abscesses to the apices of the offending tooth. Drainage through the soft tissue is accomplished most effectively when the swelling is fluctuant (Figure 24-5).

FIGURE 24-4 Establishment of drainage through the offending tooth with an acute apical abscess is the first step in treating these conditions.

A fluctuant swelling is a fluid-containing mass in which a wave-like sensation is felt when pressure is applied. Incisinga fluctuant swelling releases purulence immediately and provides rapid relief. If the swelling is non-fluctuant or firm, incision for drainage often results in drainage of only blood and serous fluids. Incision and drainage of a non-fluctuant abscess reduce pressure and facilitates healing by reducing irritants and increasing circulation in the area.

Contraindications

There are very few contraindications for the incision for drainage. Patients with bleeding disorders must be approached with caution. Hematological screening is indicated for these patients. Anatomic landmarks such as the mental foramen, maxillary sinus, incisive foramen, and an inferior alveolar canal near the apical abscess should be approached carefully during incision and drainage.

Procedures

Anesthesia

Obtaining profound anesthesia is difficult when severe inflammation and swelling are present. Because achieving infiltration anesthesia is difficult and painful in some cases, regional block anesthetic techniques such as mandibular blocks for posterior areas, bilateral mental blocks for the anterior mandible, posterior superior alveolar blocks for the posterior maxilla, and infraorbital blocks for the premaxillary area should be attempted.

After the application of topical anesthetic, the anesthetic solution should be injected slowly with limited pressure away from the center of the abscess. This injection is then followed by additional injections in previously anesthetized tissue, moving progressively closer to the center of the swelling. Using this technique usually results in improved anesthesia without causing extreme pain or discomfort for the patient.

Use of topical ethyl chloride has been suggested to reduce pain during injection, incision, and drainage of acute apical abscesses.[41] A stream of ethyl chloride liquid solution is directed onto the swelling from a distance, permitting the liquid to volatilize on the tissue surface. Within seconds, the tissue at the site of application becomes white and numb, allowing the operator to perform anesthesia, incision, and drainage. When none of these procedures provide adequate anesthesia, nitrous oxide sedation, oxygen sedation, or intravenous (IV) sedation should be considered as adjunctive treatments for obtaining adequate anesthesi and maximum patient comfort.

FIGURE 24-5 A fluctuant swelling in a tooth with an acute apical abscess.

Incision

After obtaining adequate anesthesia, the incision is made vertically with a No. 11 scalpel at the height of swelling (Figure 24-6A and B). A vertical incision should be made firmly through the periodontium to the underlying bone. If the swelling is fluctuant, drainage is usually obtained immediately. The drainage starts with pus followed by blood. If the swelling is nonfluctuant, the drainage is only blood.

Drainage

After making an incision, a small hemostat can be placed in the incision line to enlarge the draining tract.[37] To maintain a path for drainage, a drain cut from a dental dam can be sutured in the incision line (Figure 24-6C). The drain should be removed two to three days after the procedure.

FIGURE 24-6 ***A.*** A fluctuant swelling caused by an acute abscess originating from the maxillary left canine. ***B.*** A vertical incision is made. ***C.*** A drain is sutured in the incision line to maintain a path for drainage for a few days after I&D.

PERIAPICAL SURGERY

The purpose of performing periapical surgery (PAS) is to stop egress of irritants from the root canal system into the periapical tissues. This is accomplished by gaining access to the root end or any part of it and sealing the portals of exit with a biocompatible material that allows complete regeneration of periapical tissues.

Indications

The indications for periapical surgery have undergone dramatic changes in the last two decades.[40] These changes have been evident, especially when dealing with the treatment of failed nonsurgical endodontic treatments. The primary modality for endodontic treatment failure should be non-surgical endodontic retreatment whenever possible. The importance of thorough and meticulous pre-surgical planning cannot be overemphasized. Not only must the practitioner and staff be thoroughly trained, but also all necessary instruments, equipment, and supplies must be readily available in the treatment room. This requires that every step of the procedure be carefully planned and analyzed. The potential for possible complications must be anticipated and incorporated into the presurgical planning. Good patient communication is essential for thorough surgical preparation. It is important that the patient understands the reason surgery is needed as well as other treatment options available. The patient must be informed of the prognosis for a successful outcome and the risks involved in the surgical procedure in addition to the benefits. It is also important that the patient is informed of the possible short-term effects of the surgery such as pain, swelling, discoloration, and infection. Signed consent forms are essential.

The indications for PAS are the anatomical complexities of the root canal system that prevent complete cleaning, shaping, and obturation of the root canal system through the coronal access, symptomatic cases, irretrievable materials in the root canal, procedural accidents, and exploratory surgery.

Anatomical Complexity of the Root Canal System

These complexities include unusual canal anatomies such as severe curvature, complex anatomy, and canal calcifications (Figure 24-7).

Irretrievable Filling Materials

Most filling materials can be removed from the roots through a coronal access of a tooth. However, there are situations when obturating materials or posts cannot be removed without jeopardizing the whole tooth (Figure 24-8). Insistence on removing every filling material at the expense of weakening the root is a contraindication for nonsurgical retreatment.

Persistent Symptoms

Performing endodontic treatment usually results in relief of pain and symptoms in most patients. However, there are cases when they remain symptomatic after cleaning and shaping or following obturation. These are indications for surgical retreatment (Figure 24-9).

Procedural Accidents

Like other complex disciplines of dentistry, performing root canal treatment can result in unwanted or unforeseen challenges that are collectively termed procedural accidents. Examples of these mishaps include root perforation, ledge formation, separated instruments, and underfilled or overfilled canals. Most of these accidents can be corrected nonsurgically as described in Chapter 23, "Endodontic orthograde retreatment and management of mishaps." When unfeasible or impractical, periapical surgery is indicated to retain these teeth (Figure 24-10).

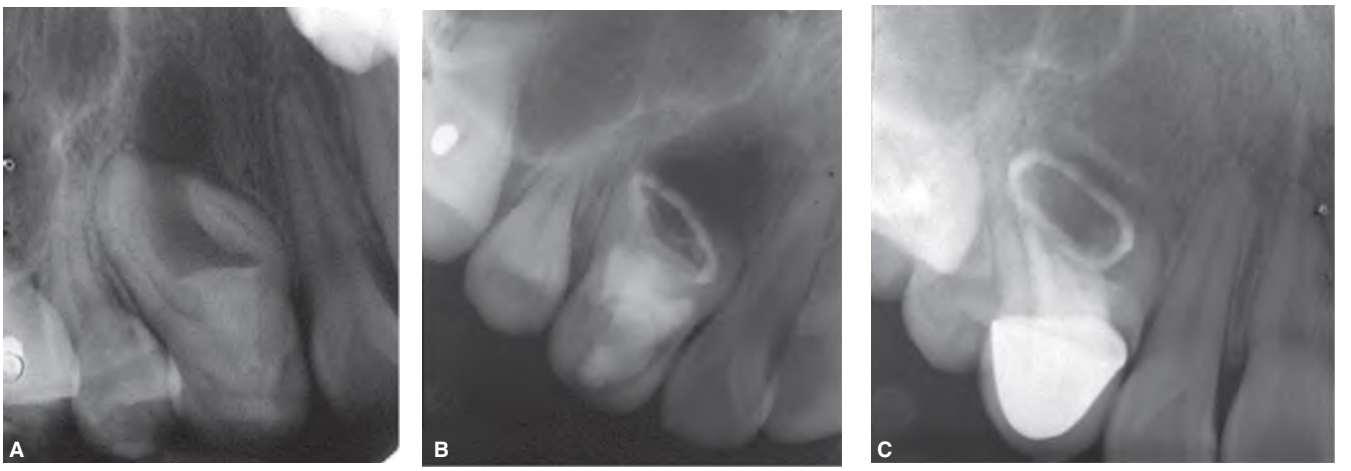

FIGURE 24-7 ***A.*** Preoperative radiograph of the right region shows presence of dens invaginatus in the canine. ***B.*** Because of the presence of this anomaly in the tooth and a large lesion, in addition to the inability to perform nonsurgical root canal treatment, periapical surgery was performed. ***C.*** Postoperative radiograph taken 20 months later shows complete resolution of the lesion associated with the canine.

MTA was used as a root-end filling material. ***C.*** Periapical radiograph taken 32 months later shows complete healing.

EXPLORATORY SURGERY

Studies have shown that the majority of periapical lesions are caused by infection of root canal systems.[42] However, there are some radiolucencies that are not caused by root canal infection. If suspected, exploratory surgery is indicated to determine the cause of these pathological entities (Figure 24-11).

Contraindications

There are very few contraindications for PAS. They include (1) medical or systemic complications, (2) indiscriminate use

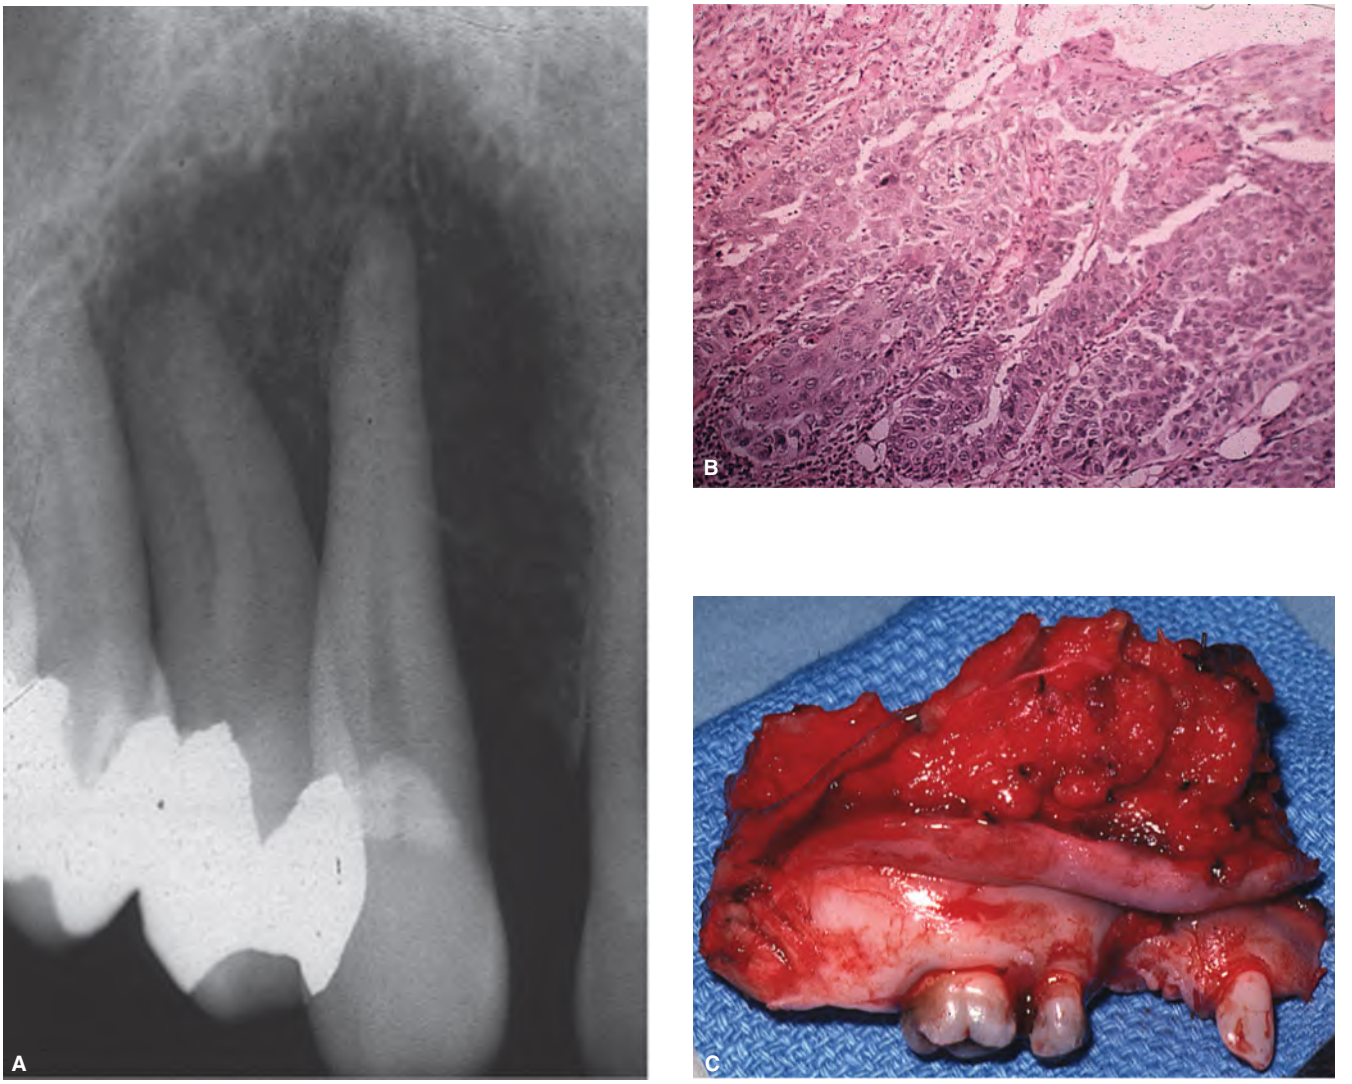

FIGURE 24-11 ***A.*** Periapical radiolucent lesion of nonpulpal origin. ***B.*** The pulp responded normally to pulp sensibility tests. Histologic examination of the tissue confirmed a diagnosis of carcinoma. ***C.*** The maxilla was completely removed to save this patient.

of periapical surgery, (3) anatomic factors, and (4) an unidentified cause of treatment failure.[37]

Medical or Systemic Complications

Serious systemic diseases in patients with blood disorders, terminal diseases, uncontrolled diabetes, severe heart diseases, and compromised immune systems are contraindications for PAS. For more details, see Chapter 31, "Management considerations for the medically complex endodontic patient."

Indiscriminate Use of Surgery

Periapical surgery is not indicated when a nonsurgical approach is feasible and would probably result in successful outcomes. Indiscriminate use of PAS for those cases that can be handled with a nonsurgical approach is unethical and contraindicated (Figure 24-12). A systematic review comparing treatment outcome for surgical endodontics versus

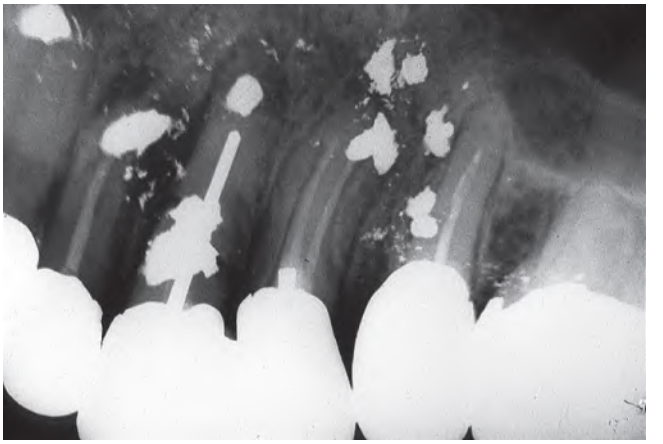

FIGURE 24-12 Indiscriminate use of periapical surgery in patients is unethical and is one of the contraindications of this procedure.

nonsurgical retreatment showed an initial higher success rate for surgery at two to four years, but a significant shift in favor of nonsurgical retreatment at four to six years.[7] This finding supports the concept that nonsurgical retreatment should be the first choice before attempting PAS.

Anatomic Factors

Anatomical structures that may be of importance during surgical endodontics include the neurovascular bundle associated with the greater palatine foramen, the mandibular canal and the mental foramen, the floor of the nose, the maxillary sinus, and any other anatomical structures that limit or compromise visualization and access to the surgical site.[40] During surgical procedures on maxillary incisors, the floor of the nose will infrequently be encountered unless the roots of the incisors are extremely long or the periapical lesion extends superiorly and has eroded through the bony floor of the nose. The greater palatine foramen (Figure 24-13) is most frequently located between the maxillary second and third molars in a position approximately one centimeter from the margin of the palatal gingiva toward the midline of the palate. The greater palatine foramen and its contents generally do not pose a problem because so few apical surgical procedures are performed on the palatal root of maxillary second and third molars.

Exposure of the maxillary sinus may occur when apical surgical procedures are performed on the roots of any of the teeth located in the maxillary posterior quadrants. Eberhardt et al.[43] reported that the apex of the mesiobuccal root of the maxillary second molar is closest to the floor of the maxillary sinus (mean = 0.83 mm), and that the apex of the buccal root of the maxillary first premolar is furthest away (mean = 7.05 mm). The root apices of the maxillary second premolar and the mesiobuccal and distobuccal root of the maxillary first molar were all approximately 2.8 mm from the floor of the sinus. Twelve autopsy specimens and 38 human patients were subjected to computed tomography to arrive at these means.

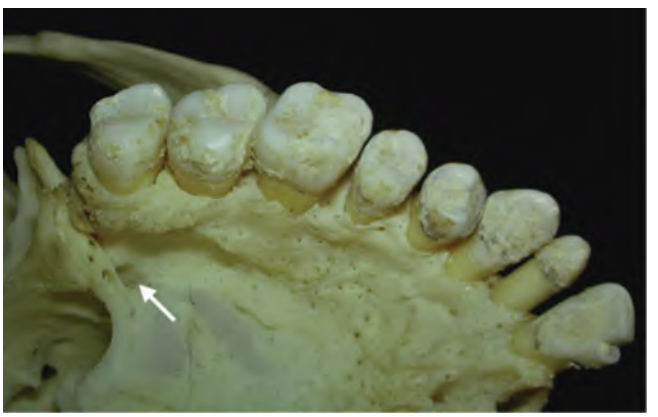

FIGURE 24-13 Opening of greater palatine foramen (arrow). The neurovascular bundle courses in posterior portion of the palate.

In a clinical study, Ericson et al.[44] noted in 314 apical surgical procedures performed on maxillary canines, premolars, and molars in 276 patients that oroantral communication occurred in 41 cases (13%). Sinus communication did not impair healing, as there was no difference in the success rate between those cases with or without sinus exposure. In another clinical study by Rud and Rud,[45] a sinus perforation occurred in 50% of 200 maxillary first molars treated with an apical surgical procedure. Of the cases with a sinus exposure, only two developed postoperative sinusitis.

When performing surgical procedures on teeth in situations where the apical lesion has not penetrated the cortical plate, the surgeon should be aware of the mean thickness of bone that must be penetrated to reach the root apices.

Jin et al.[46] calculated the mean distance from the root apices to the buccal or palatal cortical plate for the root or roots of every tooth group except third molars. One thousand eight hundred and six teeth were evaluated using computed tomography in 66 Asian patients. The greatest mean distance between a root apex and the buccal cortical plate reported in the two studies was for the distal root of the mandibular second molar with a mean distance of 8.51 mm. The tooth with the root apex closest to the buccal cortical plate was the maxillary canine (mean = 1.64 mm) in one study and the buccal root of the maxillary first premolar (mean = 1.63 mm) in the second study.

When performing apical surgery on mandibular premolars and molars, it is not only important to know the location of the root apices in relationship to the buccal cortical plate, but also to note the relationship of the root apices to the mandibular canal. The distal root of the mandibular second molar is located furthest from the buccal cortical plate and as one progresses forward in the arch, the root apices of each succeeding tooth become progressively closer to the buccal cortical plate.[46,47] The mandibular canal follows an "S-shaped" pathway as it moves from a position inferior and buccal to the distal root apex of the mandibular second molar to a more lingual position inferior to the mesial root apex of the mandibular second molar and the apices of both roots of the mandibular first molar. The canal then crosses back to a more buccal position beneath the apex of the mandibular second premolar.[48] Denio et al.[49] found that the root apices of the mandibular second molar (mean = 3.7 mm) and the mandibular second premolar (mean = 4.7 mm) were closest to the mandibular canal. The mesial root apex of the mandibular first molar was found to be furthest from the canal (mean = 6.9 mm). Similar results were noted in the study by Littner et al.[48]

The anatomy and location of the mental foramen have been studied by multiple investigators. The mental foramen may be located anywhere between the apex of the mandibular first premolar and the mesial root of the mandibular first molar. In two reports[50,51] Tebo and Telford as well as Tebo where 100 adult mandibles were studied, the most frequent

location was apical to the mandibular second premolar (Figure 24-14). This was also the most frequent location in another study that looked at 75 dry mandibles.[52] In a study of 105 cadaver specimens, the most frequent location was found to be between the apices of the mandibular first and second premolars.[53] In another study[54] that reviewed 1,000 full-mouth series of radiographs, 70% were found to be located between the apices of the two premolars. It is obvious that the mental foramen can be quite variable in location for different individuals.

Phillips et al.[52] compared the size of the mental foramen as measured on dry mandibles with the size measured on periapical and panoramic radiographs. The mean horizontal measurement on the 75 dry mandibles was 4.6 mm and the mean vertical measurement was 3.4 mm. The periapical radiographic measurement was smaller with a mean of 2.6 mm for the horizontal and 2.3 mm for the vertical. The measurements from the panoramic film were slightly larger than those obtained from the periapical radiographs (horizontal mean = 2.9 mm and vertical mean = 2.5 mm). In two-thirds of the 75 dry specimens, the foramen was found to exit in a posterior and superior direction.

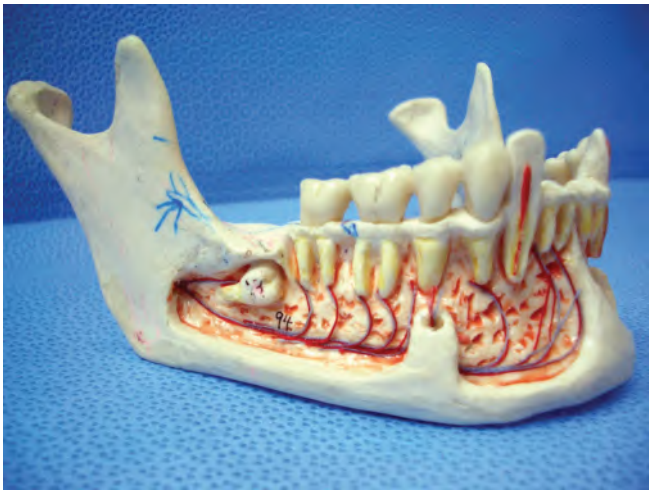

FIGURE 24-14 The mental foramen is usually located inferior to the apex of the root of the mandibular second premolar.

When performing apical surgery on a root containing more than one root canal system, the surgeon must be aware that an isthmus may exist between the canals. Weller et al.[55] were among the first to point out the significance of the isthmus in surgical endodontics. In mesiobuccal roots of the maxillary first molar with two root canal systems, they reported the highest incidence of an isthmus occurred in the apical 3 to 5 mm, and that an isthmus was present 100% of the time at the 4-mm level. In a more recent clinical study by von Arx,[56] an isthmus was found in 76% of mesiobuccal roots of maxillary first molars with a 3 to 4 mm apical root resection. In a microcomputed tomographic study by Mannocci et al.,[57] an isthmus was found to be present 85% of the time in the mesial root of the mandibular first molars evaluated. This incidence of isthmuses in the mesial root of mandibular first molars is very close to the 83% reported in a clinical surgical study.[56] In von Arx's clinical study, an isthmus was found 36% of the time when the distal root of mandibular first molars presented with two canals.[56]

Proximity to the neurovascular bundles in the mandibular posterior teeth can be, in some cases, a contraindication for PAS. These cases require caution and skill to handle surgically (Figure 24-15). The presence of a thick external oblique ridge associated with a mandibular molar or apices contiguous with the mandibular canal can compromise surgical access. These cases are indications for other surgical procedures such as tooth replantation, transplantation, or extraction with or without replacement.

Unidentified Cause of Treatment Failure

Using PAS to correct a failed nonsurgical case without a clear cause is a contraindication for this procedure.

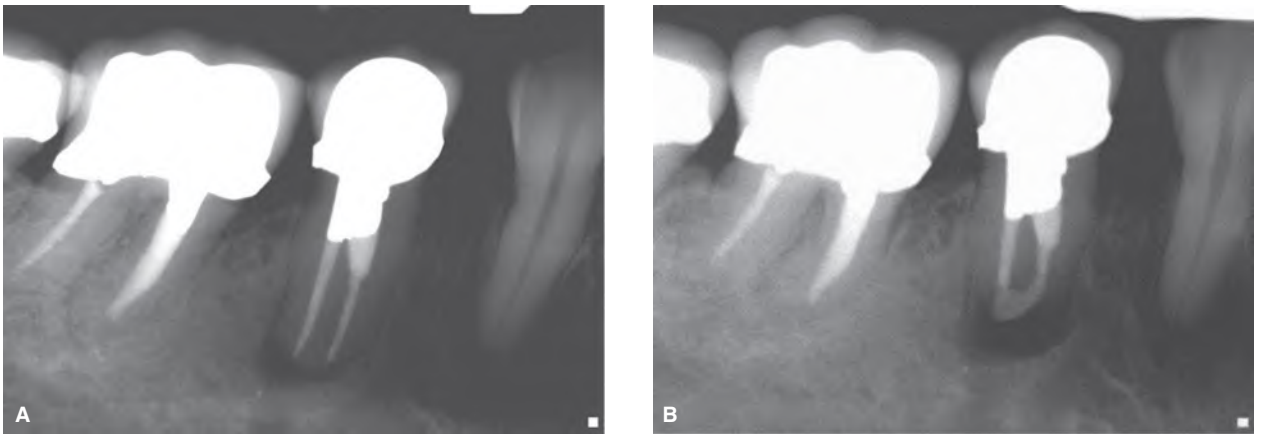

FIGURE 24-15 ***A.*** Proximity of the apex of the mandibular first premolar to the neurovascular bundle can be a contraindication for periapical surgery, and ***B.*** It requires caution and skill if surgical endodontics is performed. (Courtesy of Dr. Tory Silvestrin, Loma Linda, California, U.S.A.)

RECENT ADVANCES IN SURGICAL ENDODONTICS

A number of advances in PAS techniques, instruments, and materials have occurred within the last two decades.[58] These include enhanced magnification and illumination, ultrasonic tips, micro-instruments, and newer root-end filling materials. Enhanced magnification and illumination have greatly improved the ability of the operator to perform PAS more efficiently and predictably. Using magnification in PAS has led to the miniaturization of endodontic surgical instruments (Figure 24-16). Development of biocompatible root-end filling materials with better sealing ability such as MTA has increased the predictability of PAS. The cone beam computed tomography (CBCT) in PAS provides high-resolution images in three dimensions. The use of CBCT eliminates superimposition of surrounding anatomical structures for better diagnosis and surgical approach.[59] These advances have significantly improved the art and science of PAS and have increased the feasibility and predictability of this procedure to save natural dentition.

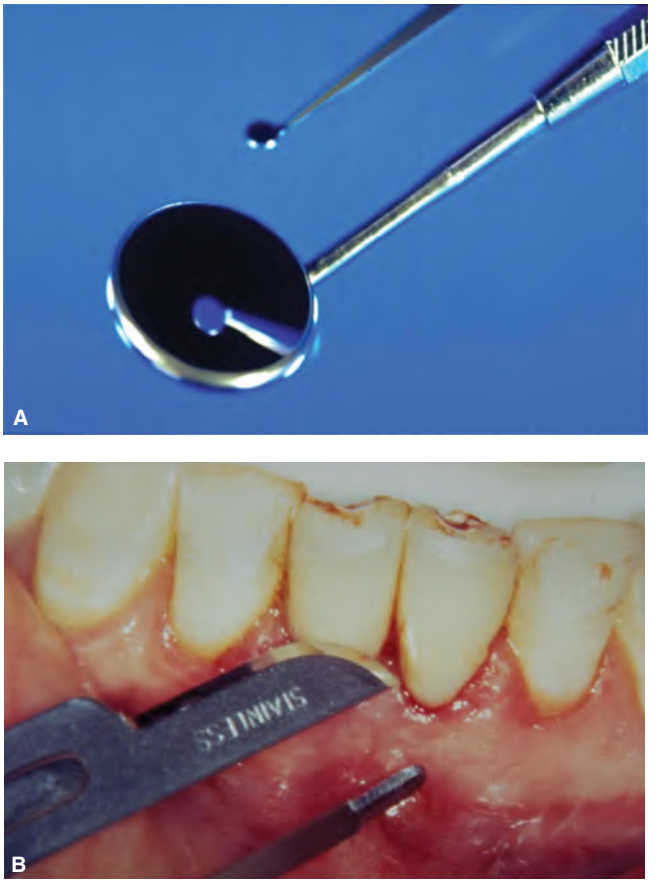

FIGURE 24-16 ***A.*** Comparison of standard intraoral mirror and micro mirror, as well as ***B.*** A 15C blade and a micro blade used for endodontic microsurgery.

PROCEDURES INVOLVED IN PERIAPICAL SURGERY

The procedures involved in PAS are anesthesia, homeostasis, flap design, incision and reflection, apical access, periapical curettage, root-end resection, root-end cavity preparation, root-end filling, flap replacement and suturing, post-operative care as well as instructions, and suture removal and evaluation.

Anesthesia

Giving local anesthesia during PAS has three purposes. They include (1) complete comfort for the patient, (2) hemostasis during the surgical procedure, and (3) prolonged pain control following surgery. Achieving profound local anesthesia and establishing effective hemostasis depend on the selection of local anesthetic solution and proper use of vasoconstrictor medications, utilizing proper injection technique, rate of injection, and the use of supplemental injection when needed. Proper use of local anesthetic with a hemostatic agent not only causes patient comfort, but also improves the ability of the operator to perform PAS more effectively.[45] For more details, see Chapter 18, "Management of pain, fear, and anxiety in the endodontic patient."

Local Anesthetic in Surgical Endodontics

Based on their chemical structures, local anesthetic medications are classified as esters or amides. The esters include Procaine, Tetracaine, Propoxycaine, and Chloroprocaine. The amides include local anesthetics such as Lidocaine, Mepivacaine, Prilocaine, and Etidocaine. Lidocaine is currently the most commonly used local anesthetic. The reasons for its popularity are (1) its rapid onset, (2) its production of profound anesthesia, (3) its prolonged action, (4) its low toxicity and antigenicity, (5) its high diffusion rate, and (6) its different concentrations of vasoconstrictors.

Choice of Vasoconstrictor

The type and concentration of vasoconstrictor in the local anesthetic have an effect on both the duration of anesthesia and the quality of homeostasis at the surgical site. Vasoconstrictor agents used in dentistry include epinephrine, levonordefrin, and norepinephrine.[60] Because the use of norepinephrine causes marked tissue ischemia, it should not be used in surgical endodontics for the purposes of hemostasis.[60] Epinephrine is the most effective and most widely used vasoconstrictor material in dental anesthetics.[61] Infiltration injection of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine produces about a threefold increase in the plasma concentration of epinephrine with little or no significant systemic cardiovascular effects. It appears that cardiac effects of local anesthetics containing epinephrine are minimal and that they can be safely used in stable cardiovascular disease patients.

A randomized double-blind controlled clinical trial reported that homeostasis was judged significantly better in

1:100,000 epinephrine containing local anesthetics compared to 1:200,000 epinephrine containing local anesthetics.[62] Buckley et al. demonstrated that the use of lidocaine containing 1:50,000 epinephrine produced more than a 50% improvement in homeostasis compared to 2% lidocaine containing 1:100,000 epinephrine in patients undergoing periodontal surgery.[63] The use of a local anesthetic containing 1:50,000 epinephrine has been advocated for local infiltration in the surgical field. Clinical trials indicate that injection of local anesthetic containing 1:50,000 epinephrine produces a transient tachycardia that returns to normal within 4 minutes.[64]

Systemic Effects of Vasoconstrictors in Local Anesthetics

Because a high concentration of vasoconstrictor containing anesthetic such as 1:50,000 epinephrine is preferred to obtain effective vasoconstriction for lasting homeostasis (Figure 24-17), there is a concern related to its effects on systemic circulation.[58,65,66] Although the systemic effects such as pulse rate and blood pressure are minimal in response to the amount of epinephrine used in surgical procedures, one study clearly demonstrates that the plasma level of epinephrine is elevated when a high dose of epinephrine is utilized.[66] It appears that virtually all of the adverse effects associated with epinephrine are dose-dependent.[58] The cardiovascular effects are usually minimal and short-lived and are well-tolerated by the majority of patients except in patients with severe cardiovascular disorders or patients who have had cardiovascular surgery. The use of 1:50,000 epinephrine with 2% lidocaine is recommended for local anesthesia in the majority of cases of PAS.[58] The selection of an appropriate anesthetic agent and concentration of vasopressor should always be based on the medical status of the patient and the discretion of the operator. Consultation with physicians is recommended in patients with moderate to severe medical conditions. These recommendations should be obtained in writing and documented in the patient records.

Flap Design, Soft Tissue Elevation, and Tissue Retraction

Comprehensive knowledge of head and neck anatomy is essential when planning for a PAS. A thorough understanding of head and neck anatomy is necessary to avoid unwanted complications during surgical endodontics. Knowledge related to the anatomy of soft tissue and bony landmarks can assist the operator to reduce the risk for postoperative morbidity. Periapical, panoramic, and CBCT radiographs can provide evidence of important hard tissue structures. However, the details of soft tissues are not seen by traditional radiography. Serman[67] described the course of the inferior alveolar canal once it emerged from the mental foramen in cases where two foramens are present, which requires greater attention from the clinician. Naitoh et al.[68] studied the presence of the accessory mental foramina using CBCT and found it to be present in 7% of the population. There are fewer anatomic considerations when maxillary teeth require PAS. However, when a palatal approach is considered, the location of greater palatine foramen where the greater palatine artery and nerve pass through should be considered very carefully. Severing the palatal artery is life-threatening and should be avoided. Tomaszewska[69] performed a morphometric analysis of the routes of the greater palatine canal and a systematic review of the literature related to the anatomy of this canal. The results indicate that the greater palatine foramen has four different opening directions: inferior-anterior-medial (82.1%), inferior-anterior-lateral (4.0%), anterior (7.6%), and vertical (5.3%). Yu et al.,[70] using a surgical microscope, reported the distance from the cementoenamel junction (CEJ) to the branch of greater palatine artery to be 9.04 ± 2.93 mm (canine), 11.12 ± 1.89 mm (first premolar), 13.51 ± 2.08 mm (second premolar), 13.76 ± 2.86 mm (first molar), and 13.91 ± 2.20 mm (second molar).

Muscle attachments to the jaw bones can pose problems during surgical flap dissection. If attachment levels are close to the apex of a tooth or if the tooth is very long, full reflection may be difficult. A shallow vestibule may also

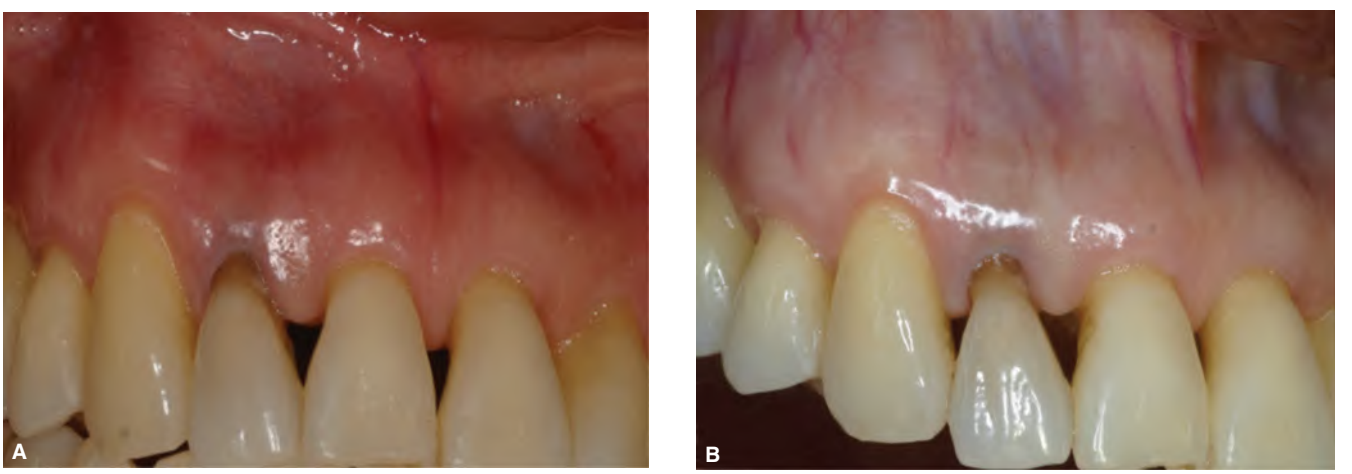

FIGURE 24-17 ***A.*** Gingival tissues before injection of a local anesthetic. ***B.*** Gingival tissues after injection of a local anesthetic containing 1:50,000 epinephrine.

complicate reflection and therefore limit surgical access.[71] It is important to predict and be prepared for these challenges prior to beginning PAS.

Prior to initiating an incision, the surgeon should evaluate clinically and radiographically the location and size of the periapical lesion and the number of the teeth needed to be included in the field of operation. After initial incision and during flap reflection, there are important principles to follow for achieving the best healing and reducing postsurgical patient morbidity. An operating microscope can be used during incision and reflection to allow for better handling of soft tissue.[72] The use of a dental operating microscope will provide superior illumination as well as magnification to aid the operator during endodontic microsurgery.[72]

The factors that influence the healing of the mucoperiosteal tissues during surgical endodontics include flap design, tissue handling, wound closure, and post-surgical care. Here is a list of surgical do's and don'ts during flap design and reflection:

Don't place incisions over a bony defect. A suture during primary closure should be placed over sound bone structure whenever possible.[71–73] Five millimeters of space should separate the bony defect from the incision line.[74]

Don't place an incision over the root eminence. Root eminences, as well as the flutes between these protrusions, can be visualized and palpated before the first incision is made.[73]

Don't traumatize the flap during retraction. The flap will have a tendency to slip free from the retractor. Pinching the flap with the retractor should be avoided. Any unnecessary trauma to the soft tissue should be avoided to decrease postoperative morbidity. The vascular bed within the flap[71,75] can be damaged by the sharp edges of instruments.

Do create a passive or tension-free flap during wound closure. Larger flaps may be required to achieve a tension-free flap.[76] Keep soft tissues hydrated during PAS. Soft tissue during surgery should not be allowed to dehydrate. A dry flap runs the risk of shrinkage.[77] Evaluate soft tissue morphology, smile line, and periodontium before making any incision.

*E*valuate hard tissue structures before incising the soft tissues. Try to use a single pass to incise the soft tissue to the desired depth. Create incision edges that are consistently perpendicular to the tissue's surface. Secure the suture knot away from the incision line to prevent delayed healing.

Flap Design

Flap design is one of the most important steps in PAS. There are many different flap designs available to choose for apical surgery. The proper selection can make a significant impact on the outcomes of the surgery. The primary goal of raising a flap is to provide access to the surgical site while considering the aesthetics of the soft tissue. The surgeon should evaluate the surgical area clinically and radiographically to determine the size of the lesion, the number of teeth to be included, and the closure of the surgical wound. If the lesion involves more than one tooth, or a larger lesion is expected, the flap should be designed accordingly. A small flap makes retraction difficult, more traumatic, and can delay healing. Large flaps heal as well as small flaps.

A larger flap is more desirable than a smaller flap since the larger flap prevents tear and trauma to the flap and provides more access and visibility to the surgical site. A vertical incision is usually required for PAS. It provides better access and visibility during surgery. Vertical incisions should always be placed at the line angles, and the papillae should be included in the flap for wound closure.

Aesthetic consideration during flap design is an important part of today's surgical endodontics. All treatment planning must have a proven scientific basis to provide successful outcomes. A review of current endodontic literature reveals disagreement related to the indications and contraindications for various flap designs. In the past, different flap designs were introduced in order to gain access to the surgical site. Yet very few of these designs took aesthetics into consideration, especially in such aesthetically sensitive areas as the maxillary anterior region. Crestal bone loss and gingival recession are detrimental to gingival health and aesthetics (Figure 24-18). Human studies have shown an average of 0.5 to 0.62 mm crestal bone loss after raising a full thickness flap.[78–82] Harrison and Jurosky,[77] as well as Chindia and Valdehaug,[83] did not find any difference in the healing of intrasulcular and submarginal incisions. Since Chindia and Valdehaug[83] measured the clinical attachment level (CAL) preoperatively and did not report CAL postoperatively and only referred to changes in pocket depths, the results of their study are questionable. The results of these two studies differ considerably from those of Kramper et al.[84] who clinically and histologically evaluated the healing of three common surgical flap designs. They found that intrasulcular wounds showed no epithelial closure at two days post-operation and continued to show persistent inflammation up to 156 days later.[84] More importantly, these authors reported the loss of

FIGURE 24-18 Severe crestal bone loss and gingival recession after a periapical surgery.

alveolar bone of approximately 0.5 to 1 mm with intrasulcular incisions. Grung[82] also found gingival recession of 0.5 mm (on average) three months after raising full mucoperiosteal flaps.

Current surgical techniques used in PAS have been mimicking the results of periodontal flap surgery and wound healing. Use of such evidence may be misleading when used for surgical endodontics. Wound healing in surgical endodontics is, by primary intention, different from periodontal surgical wound healing. The Luebke-Ochsenbein flap design may be used when sufficient attached gingival and keratinized mucosa exist (Figure 24-19). However, it cannot be used in areas where there is insufficient attached and keratinized gingiva, short roots, large lesions, sinus tracts coronal to the horizontal incision, or anatomical obstructions such as the frenum. The incision in this design can cross the osseous defects created during osteotomy that can result in an unpredictable outcome. In addition, sharp corners in this flap design where the vertical and horizontal incisions meet may result in necrosis and possible scarring of soft tissues. The following factors should be considered for flap designs during PAS:

- Tissue biotypes.
- Location of lip line.
- Presence of restorations, crown margins, and presence of a pontic.
- Access to the surgical site.
- Mucogingival consideration such as gingival recession, dehiscence, or fenestration.
- Periodontal considerations.
- Thickness of the soft tissue.
- Depth of vestibule, muscle attachment, and frenum location.

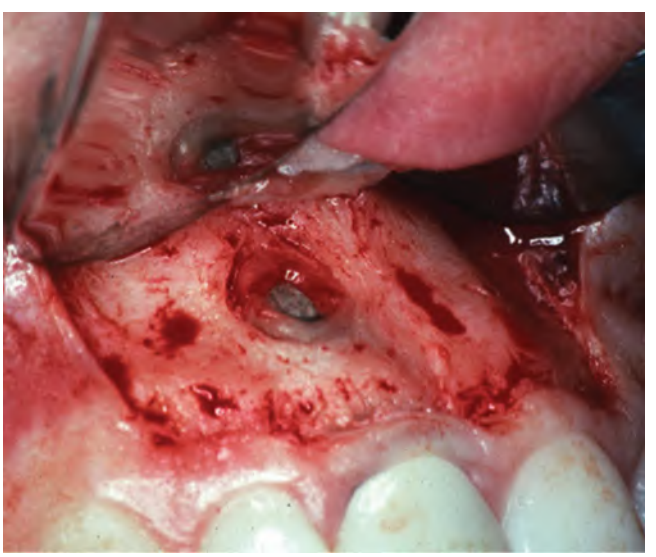

FIGURE 24-19 The Ochsenbein-Luebke flap design is used to prevent esthetic issues. It is made in the attached gingiva with two accompanying vertical incisions to reach the apex of the offending tooth.

- Location and extent of the lesion.
- Number of teeth involved in the surgery.
- Length of the involved tooth or root.
- Proximity to vital structures.

An important factor during evaluation for flap design is the determination of the tissue biotypes (Figure 24-20). The flap design is different for a thin biotype (thin triangular periodontium and papilla) versus a thick biotype (square tooth with thick and flat periodontium and wide papilla). Tooth shape, crestal bone height, and interdental papilla should also be considered as these features influence gingival shape. Tarnow et al.[85] described the relationship between crestal bone height and the interdental contact point. They examined 288 human papillae and discovered that if the distance between the contact point and the crestal bone was 5 mm or less, the papilla usually fills the embrasure space 100% of the time. At distances of 6 mm and 7 mm, the percentage decreases to 56% and 27%, respectively.[85] Velvart et al. warned that during reflection, mobilized papilla that is thin, narrow, and high may not have sufficient blood supply and may increase the risk of necrosis and subsequent decreased papilla height after healing.[86] A well-designed flap had the following characteristics:

1. *It can be easily performed by the operator.*
2. *It can be easily reflected by the operator.*
3. *It provides adequate access to the lesion.*
4. *It does not compromise the aesthetic.*

FIGURE 24-20 ***A.*** A thin biotype (thin triangular periodontium and papilla). ***B.*** A thick biotype (square tooth with thick and flat periodontium and wide papilla).

5. *It does not compromise blood flow to the flap or the remaining gingival margin or papilla.*
6. *It does not impinge on important anatomical structures.*

Flap Designs

Soft tissue flaps used in surgical endodontics can be categorized as full mucoperiosteal flaps and submarginal flaps.

Full Mucoperiosteal Flaps

Full mucoperiosteal flap requires the reflection of the entire soft tissue overlying the cortical plate. This flap usually has a horizontal incision and one or two vertical incisions (Figure 24-21). The horizontal incision is an intrasulcular one that needs to incise the medial area and separate the buccal and lingual papilla to prevent double papilla formation. The greatest disadvantage of the horizontal incision is that it may cause slight shrinkage along the gingival crest that leads to recession.[73]

The vertical incision in these flaps is made between root eminences. The vertical incision in these flaps should not be made over eminences because of the presence of thin mucosa at this location. The main advantage of this flap is the preservation of supraperiosteal vessels within the flap and therefore retention of the blood flow to the flap. Depending on the number of vertical incisions and their angulations, these flaps are categorized as: triangular, rectangular, or trapezoidal.

A triangular flap has a single vertical-releasing incision and a horizontal incision (Figure 24-22). This flap allows relatively good access and visibility, precludes incising over a bony defect, and has a lower tendency for a hemorrhage. Advantages of the triangular flap include minimally disrupted vasculature, that results in sufficient blood flow to the free flap.[58] The limited incisions lead to lower morbidity. The triangular flap is easy to perform and provides sufficient reflection to the coronal and middle thirds of the root.[87]

A disadvantage of the triangular flap is an insufficient reflection to the apical third of the root. If this occurs, the flap may have to be extended both mesially and distally to expose a larger area. Another disadvantage of this flap is the high risk of gingival recession due to the fully released papilla.[87] This is the main disadvantage of sulcular flaps and is due to tissue shrinkage.[86] Moiseiwitsch[53] criticized the profession for shying away from periapical surgery in the mandibular premolar region. He pointed out the common practice of placing the vertical incision for a triangular flap at the mesial line angle of the canine so the mental nerve would be stretched within the flap to achieve adequate access for surgery on a tooth posterior to mental foramen. He suggests placing the vertical incision distal to the surgical site so that good access is achieved without stretching the content of the mental foramen. One complication of this method is compromising blood supply to the soft tissue of this region. On the other hand, Kim[39] suggests placing a vertical incision mesial to the first premolar when performing a surgery on the mandibular first molar. The reason is to avoid the mental foramen and also to avoid the muscle attachment at the second premolar, which heals poorly if damaged.

The rectangular flap is advantageous in the anterior area (especially when the roots are long) and provides better access than the triangular flap (Figure 24-23).[39] Since the vertical incisions are parallel to the larger vessels, the blood supply is minimally disrupted. They provide better access in the case of long roots with shallow vestibules, and visualization is improved.[87] Kim[39] argues against making the flap wider in the base (i.e., trapezoidal flap design) due to inadequate supporting evidence and also due to the cutting of the blood vessels obliquely rather than parallel to them. Mormann and Ciancio[88] have shown that the circulation is disturbed when the ratio of the length to the base of the flap is more than 2:1.

Limited Mucoperiosteal Flaps (Submarginal Flaps)

The horizontal and vertical incisions in the submarginal (limited mucoperiosteal) flaps do not involve gingival margins and papilla. The horizontal incision in these flaps is made in the attached gingiva, and the vertical incisions are made in

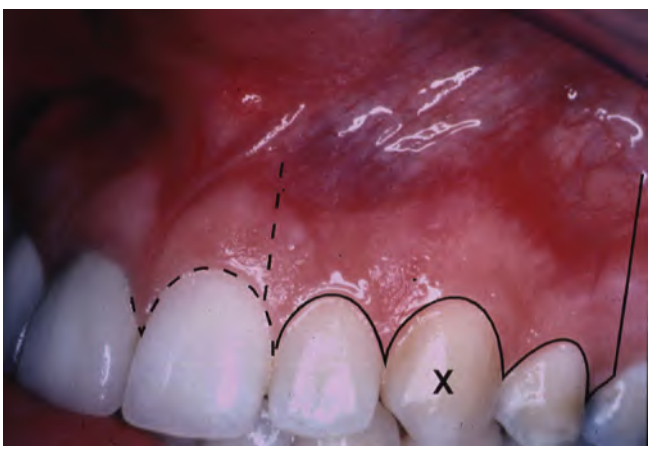

FIGURE 24-21 A full mucoperiosteal flap usually has a horizontal incision and one or two vertical incisions. The vertical incisions should be made at least one tooth away from the apex of the target tooth.

FIGURE 24-22 A full mucoperiosteal triangular flap has a single vertical-releasing incision and a horizontal incision. The vertical incisions are made one tooth away from the apex of the right lateral incisor tooth.

FIGURE 24-23 A full mucoperiosteal rectangular flap is raised to perform a periapical surgery on maxillary central and lateral incisors with long roots.

both alveolar mucosa and attached gingiva (Figure 24-19). In this design, there is a need to maintain at least 2 to 3 mm of attached gingiva. This action prevents mucogingival complications and achieves an adequate wound closure.

This design was developed by Ochsenbein and Luebke in 1974 and is commonly used when crowns and bridges are present. This flap is created by placing scalloped incisions in the attached gingiva about 1 mm away from the mucogingival junction and 2 mm apical to the depth of the sulcus followed by two vertical-releasing incisions to provide adequate access to the apical site. The placement of incisions in the attached gingiva aids in blood supply to the area and also allows for rapid wound healing.[89] This design allows blood supply to the gingival margins from the crestal bone and through the papilla from the lingual side. Since the attached gingiva around crown margins are not incised, there is reduced risk of recession.[73,87] The scalloped design allows for exact positioning of the wound edges. This design is preferred in aesthetic locations with porcelain restorations. Postoperative soft tissue contraction is minimized by this design, and aesthetics are usually preserved.

The limitation of this flap design is its requirement for at least 2 mm of attached gingiva coronal to the incision line.[90] It also requires ideal periodontal health and bone support. When periodontal pocket depths are excessive or inadequate attached gingiva is present, using this flap can lead to complications such as dehiscence or fenestrations. Furthermore, there is no access to the surface of the root beneath the band of attached gingiva. Moreover, an unpredictable scar line is a common occurrence with this design (Figure 24-24).[91]

A variation of this design was developed by Vreeland and Tidwell.[92] In this variation, a split thickness flap is first incised for the first 2 mm until it reaches the bone, followed by full thickness reflection. This technique allows for less exact positioning of the wound edges.[92] However, the complications are similar to those of the previous design.

To prevent scarring by submarginal flap designs, Velvart[89] developed papilla-based incisions (Figure 24-25). He states

FIGURE 24-24 ***A.*** An Ochsenbein-Luebke flap after suture placement. ***B.*** Scar formation three months after the surgery.

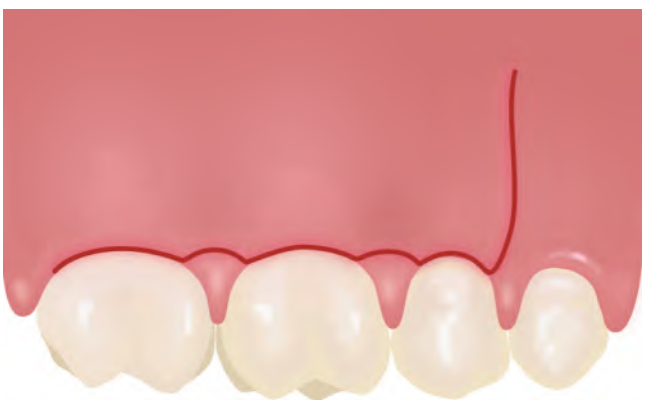

FIGURE 24-25 A submarginal flap is used to preserve the papilla and prevent gingival recession.

that maintaining the integrity of papilla during the surgical procedure is significant for functional, phonetic, and aesthetic reasons. Recession is a significant risk when incisions are placed in the crown margins. Velvart[89] has shown a mean of 0.05 ± 0.39 mm of papillary height one month after surgery. After three months, virtually no recession was evident when a papilla-based incision was made. In contrast, the adjacent papilla with a sulcular flap incision had 1.25-mm recession.

Velvart[89] recommends atraumatic handling of soft tissue as a required note for success of this flap design. This technique involves two incisions at the base of the papilla: one a shallow incision to a depth of 1.5 mm through epithelium and connective tissue and a second incision directed to the crestal bone. This method prevents thinning of the coronal aspect of the flap, which is important for healing. Velvart[89] states that the papilla-based incisions not only prevent recession of papilla, but also cause minimal scarring. Von Arx et al.[93,94] showed the loss of papillary height to be greatest with a sulcular incision compared to papilla-based or submarginal incisions. Sargolzaie et al.,[95] in a randomized controlled trial, showed significant decrease in gingival margin height using a full thickness flap compared to a papilla-based technique at a one-month recall. However, no statistical difference was present in bleeding on probing, attachment loss, probing depth, or the gingival index between the two approaches.

Sabeti et al.[96] described a modified papillary horizontal incision to preserve the papillae and enhance the aesthetic outcome of the surgical endodontics (Figure 24-26). The purpose of this technique is to produce an endodontic surgical flap design that underscores the importance of soft tissue preservation, repair, and reconstruction. For this technique, using a microsurgical blade, horizontal papillary incisions are made at a right angle to the papillae at the level of the CEJ extending two teeth beyond the target tooth mesially and distally, thus creating a butt joint at the papillae. The papillary incisions are connected later, extending the incision intrasulcularly at the labial aspects of all involved teeth in the procedure (Figure 24-26). Depending on the amount of access needed, either a pouch design or one or two vertical incisions will be placed at the line angles of the flap (Figure 24-26). Vertical incisions should be placed at the most distal (most distant proximal) line angle of the tooth in order to use the adjacent unincised papilla for suturing (Figure 24-26). The incision usually extends two teeth beyond the target tooth mesially and distally. This allows sufficient access and visibility. Holding the microsurgical blade at a 45-degree angle, a beveled vertical incision is made to prevent scarring during healing by attaching connective tissue to connective tissue and epithelium to epithelium.[97]

FIGURE 24-26 A modified submarginal flap is used to preserve the papillae and enhance the aesthetic outcome of the surgical endodontics.

The vertical incision is made in the form of a c-shape (curved) and will extend at least 4 mm apical to the extension of the bony defect. Then the incision will end 2 to 3 mm horizontally towards the defect (cutback) to prevent scar formation. The c-shape vertical incisions are composed of a horizontal component at the coronal part, an internally curved component at the mid-part, and a cutback component at the apical part within the mucosa. The advantage of the c-shape incision is that it gives more access and better flexibility for repositioning of the flap than straight vertical incisions. The horizontal component improves tissue adaptation at closure. The internally curved and cutback components provide flap flexibility and reduce tension by increasing the length of the incision. Using blunt dissection, a mucoperiosteal flap is carefully reflected away from the neck of the teeth and available bone to expose the bony margin of the defect.

The advantages of the modified horizontal papillary incisions design are:

- The incision preserves papillae and leaves the marginal gingiva minimally disturbed.
- Wound healing may be enhanced as a result of reduced disruption of vascularity.
- Scar formation is prevented or minimized. Good access and visibility are provided as a result of flap flexibility.
- The flaps may be incised and reflected without much difficulty.
- Repositioning of the flap is easy and precise.
- Patient compliance and ability to maintain good oral hygiene are improved because the marginal gingiva are minimally disturbed, and the patient can brush more comfortably. Root coverage may be achieved.

Flap Elevation and Reflection

Flap elevation is the process of separating the soft tissues (gingiva, mucosa, and periosteum) from the surface of the alveolar bone. This process should begin in the vertical incision a few millimeters apical to the junction of the horizontal and vertical incisions. The periosteal elevator of choice (Figure 24-27) should be used to gently elevate the periosteum and its superficial tissues from the cortical bony plate (Figure 24-28A). Once these tissues have been lifted from the cortical plate, and the periosteal elevator can be inserted between them and the bone, the elevator is then directed coronally. This allows the marginal and interdental gingiva to be separated from the underlying bone and the opposing incisional wound edge without direct application of dissectional forces. This technique allows for all of the direct reflective forces to be applied to the periosteum and the bone. This approach to flap reflection is referred to as "undermining elevation."[71]

This undermining elevation should continue until the attached gingival tissues (marginal and interdental) have been lifted from the underlying bone to the full extent of the horizontal incision (Figure 24-28B). After reflection of these tissues, soft tissue elevation is continued in an apical

FIGURE 24-27 Examples of endodontic tissue retractors (Top—Arens Tissue Retractor; Middle—Seldin retractor; Bottom—University of Minnesota retractor).

direction, lifting the alveolar mucosa, along with the underlying periosteum, from the cortical bone until adequate surgical access to the intended surgical area has been achieved. Small bleeding tissue tags will often be noted on the exposed surface of the cortical bone once the flap is fully reflected (Figure 24-28C), especially in the interradicular depressed areas. Bleeding from these tissue tags will stop in a few minutes and they should not be damaged or removed. Research evidence strongly suggests that these bleeding tissue tags are cortical retained periosteal tissues and may play an important role in healing and reattachment of the flap to the cortical bone.[98]

Flap retraction is the process of holding in position the reflected soft tissues. Proper retraction depends on adequate extension of the flap incisions and proper reflection of the mucoperiosteum. It is necessary to provide both visual and operative access to the periapical and radicular tissues. The tissue retractor must always rest on solid cortical bone with light but firm pressure. In this way, it acts as a passive mechanical barrier to the reflected soft tissues. If the retractor inadvertently rests on the soft tissue at the base of the flap, trauma to the alveolar mucosa may result in delayed healing and increased post-surgical morbidity.

Selection of the proper size and shape of the retractor (Figure 24-27) is important in minimizing soft tissue trauma. If the retractor is too large, it may traumatize the surrounding tissue. If the retractor is too small, flapped tissue falls over the retractor and impairs the surgeon's access. This results not only in increased soft tissue trauma, but also in extending the length of the surgical procedure. An axiomatic principle of surgical endodontics is that the longer the flap is retracted, the greater the postsurgical morbidity. This is a logical conclusion based on the probability that blood flow to the flapped tissues is impeded during flap retraction. In time, this will result in hypoxia and acidosis with a resulting delay in wound healing.[71]

Regardless of whether the retraction time is short or long, the periosteal surface of the flap should be irrigated frequently with saline (0.9% sodium chloride) solution. Saline should be used rather than water because the latter is hypotonic to tissue fluids. It is not necessary to irrigate the superficial surface of the flap because the stratified squamous epithelium prevents dehydration from this surface. Limited mucoperiosteal flaps are more susceptible to dehydration and may require more frequent irrigation than full mucoperiosteal flaps.[71]

Local Hemostatic Agents

Obtaining local hemostasis during surgical endodontics is essential to successful management of this procedure. Hemostasis during PAS is achieved primarily by the epinephrine present in local anesthetic. The local hemostatic agents used during surgical endodontics are good adjuncts for hemostasis and are intended to control bleeding from small blood vessels. Many hemostatic agents have been advocated for use during PAS. Their mechanism of action, ability to control bleeding, and effect on healing vary considerably. They generally assist coagulation by inducing rapid development of a blood clot.[65] The most commonly used hemostatic agents in PAS are: bone wax, epinephrine pellets, ferric sulfate, calcium sulfate, collagen-based materials, Surgicel, Gelfoam, aluminum chloride, and HemCon.

Bone Wax

Bone wax was introduced as a hemostatic agent by Horsley in 1892.[99] It is a non-resorbable material composed of approximately 88% highly purified bees wax and 12% isopropyl palmitate, which acts as a softening and conditioning agent.[99] The function of bone wax as a hemostatic agent is

FIGURE 24-28 ***A.*** Initial flap elevation. ***B.*** Partially reflected flap. ***C.*** Completely reflected flap.

purely mechanical. It induces a tamponade effect when it is packed firmly against the bone surface. Bone wax does not affect the blood clotting mechanism.[58]

When using bone wax for the purpose of hemostasis, the entire bony crypt is usually filled with the material under firm pressure. The excess is then carefully removed to expose only the apex of the tooth. Following root-end filling, the bone wax should be completely removed.[58] Studies have reported that remnants of the bone wax in the bony crypt cause persistent inflammation, foreign body reaction, sinus tract formation, and delayed healing.[100–104] Because of these adverse effects, the use of bone wax is not recommended when other alternatives are available.[38,65,101,105]

Epinephrine Pellets

Vasoconstrictors have been recommended as topical agents for hemorrhage control during PAS. Many clinicians use epinephrine as the primary hemostatic agent during periapical surgery.[38,58] Before placing an epinephrine pellet in the bony crypt, granulation tissue should be removed from the periapical tissue. This action ensures direct contact of epinephrine with the bone. A combination of chemical and mechanical hemostatic actions by use of epinephrine and application of pressure has a profound effect on hemostasis.[58] Cotton pellets containing racemic epinephrine HCl (Racellet #3; Pascal Co, Bellevue, WA, U.S.A.) are commercially available (Figure 24-29). Each pellet contains an average of 0.55 mg of racemic epinephrine hydrochloride and usually provides good local hemostasis during periapical surgery.[106] However, two concerns arise with the use of epinephrine-impregnated cotton pellets for topical hemostasis: (1) systemic cardiovascular effects and (2) the retention of cotton fibers in the wound.

Because cancellous bone is highly vascular and contains a large amount of capillary distribution, direct application of epinephrine to the bone during periapical surgery may produce marked cardiovascular changes.[107] Wood et al.[108] compared the heart rate of patients after local application of intraosseous injection with that of patients who had infiltration injection. Significant increase in the heart rate was identified in those patients who had intraosseous injection compared with those who had infiltration injection after two minutes.[108] Besner reported that the pulse rate of patients did not change when one Racellet pellet containing an average of 1.15 mg of epinephrine HCl was used during periapical surgery.[65] Vickers et al.[106] measured blood pressure and pulse rate changes in 39 patients when #3 Racellet pellets were left in the bony crypt for two to four minutes. Based on their results, they concluded that there was no evidence for significant cardiovascular changes when #3 Racellet pellets were compared with saline-saturated pellet controls.[106] These findings were later confirmed by Vy et al.[109] who showed that placement of 2.25% racemic epinephrine in CollaCote collagen had little or no effect on the blood pressure and pulse rate of patients during surgical endodontics.[109] Kim and Kratchman claim that topical application of epinephrine has a local vasoconstrictive effect on the capillaries and has little or no systemic effect.[58] Based on the available evidence in the literature, it appears that the systemic cardiovascular effect of cotton pellets containing epinephrine is minimal.

The retention of cotton fibers present in the cotton pellets saturated with epinephrine used during PAS is a critical issue.[37,110] Gutmann and Harrison[37] stated that loose cotton fibers left in the surgical site may affect the root-end seal by becoming trapped between the root-end cavity preparation and the root-end filling material. They also note that cotton fibers may serve as foreign bodies in the surgical site and may delay wound healing. To address this concern, each pellet applied during periapical surgery must be accounted for and the bony crypt should be lightly curetted to remove any embedded cotton fibers before wound closure.[105] The retention of cotton fibers in the crypt can be eliminated by use of CollaCote saturated with 10 drops of 2.25% racemic epinephrine with cotton pellets.[109]

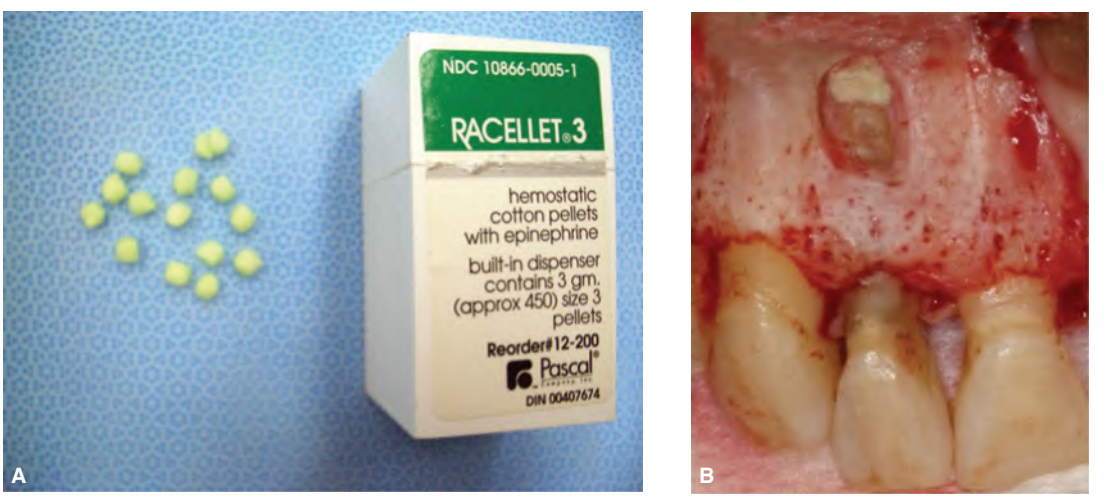

FIGURE 24-29 ***A.*** Cotton pellets containing racemic epinephrine HCl are commercially available. ***B.*** Topical application of these pellets has a local haemostatic action.

Ferric Sulfate

Ferric sulfate is a chemical that has been used as a hemostatic agent since it was first introduced as Monsel's solution (20% ferric subsulfate) in 1857.[58] It is a necrotizing agent with a pH of 0.8 to 1.6.[101] Ferric sulfate causes agglutination of blood proteins and plugging of the capillary orifices. When it comes in contact with vital tissues, it immediately causes color change. Because of its low pH, this material is very cytotoxic and must be used with caution. Complete removal of coagulum produced after its use is recommended.[58,111]

Lemon et al. reported a significant adverse effect on osseous healing when ferric sulfate was left in standardized osseous defects created in rabbit mandibles. They reported impaired healing, a foreign body reaction, or, in some cases, abscess formation when ferric sulfate was left in the rabbit mandibles (Figure 24-30A).[112] In a follow-up study using the same model, the authors reported no significant difference in healing between the experimental and untreated control groups when the surgical sites were curetted and irrigated with saline following a five-minute application of ferric sulfate (Figure 24-30B).[111] Therefore, application of ferric sulfate as a hemostatic agent is safe as long as the coagulum is completely removed from the surgical site.[58,101,111,112]

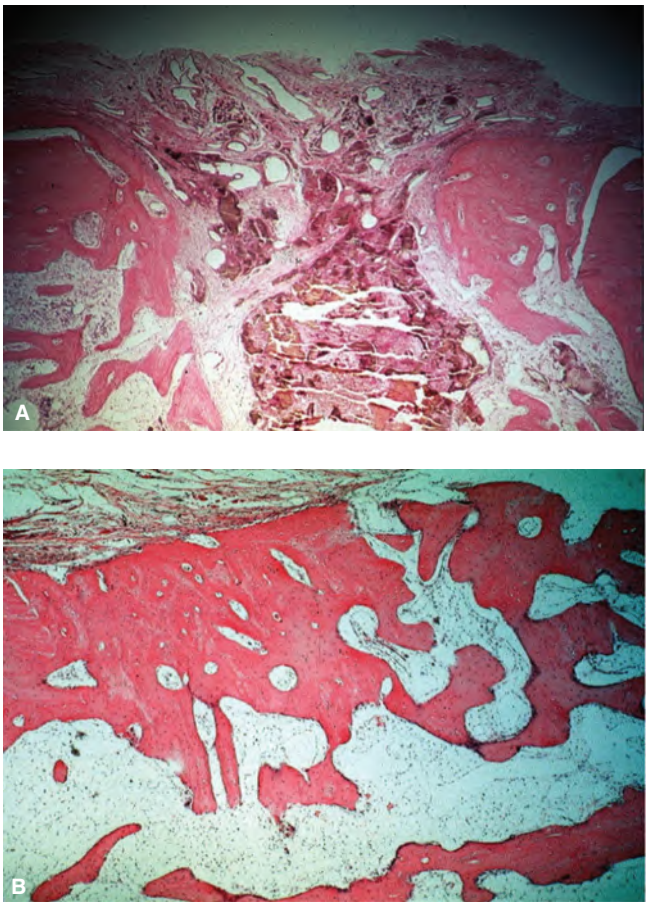

FIGURE 24-30 ***A.*** Impaired healing, a foreign body reaction, and abscess formation are observed when ferric sulfate was left in the rabbit mandibles.[111] ***B.*** No adverse effects are noted when the surgical sites are curetted and irrigated with saline following an application of ferric sulfate.[112]

Calcium Sulfate

Calcium sulfate, also known as plaster of Paris, has been used as a substitute bone graft material to fill bone defects since the late 1800s.[105] It has been primarily used in dentistry to fill large surgical bone defects, as a barrier material in guided tissue regenerative procedures, and repair of furcation defects.[65] Calcium sulfate has been recommended as a hemostatic material during periapical surgery. It serves as a physical barrier and plugs vascular channels.[58,113] It is a resorbable material and after placing it in the bony crypt, using wet cotton pellets, and packing it against the crypt walls, it can be carved away to allow access to the root-end.[65, 113,114] After completion of root-end filling, the residual calcium sulfate can be removed or left in the bony crypt.

Collagen-based Materials

The collagen used for surgical hemostasis is obtained from bovine sources and is supplied in sheets and sponge pads.[65] Studies have shown that osseous regeneration in the presence of collagen usually takes place uneventfully and without a foreign body reaction or infection.[115] A study that examined the effects of hemostatic agents on peripheral nerve function in rats showed that bovine collagen is the most suitable hemostatic agent compared to bone wax, gelatin sponge, and Surgicel.[116]

Surgicel

Surgicel is a material that resembles surgical gauze and is prepared by the oxidation of regenerated alpha cellulose (oxycellulose).[100,101] It primarily acts as a physical barrier and, after coming in contact with blood, becomes a sticky mass that serves as an artificial coagulum.[100,101,105] In an animal study that compared the osseous response of three different hemostatic agents (i.e., bone wax, Surgicel, and Gelfoam), when left *in situ*, Surgicel retarded the rate of healing and caused the most intense inflammatory reaction between the test materials.[100] Because of the difficulty in removing all of the Surgicel from bony wounds, the small fragments left behind result in a prolonged inflammatory response and foreign body reaction.[100]

Gelfoam

Gelfoam is a gelatin-based sponge that is water insoluble and biologically resorbable.[58,100,101] It stimulates the intrinsic clotting pathway by promoting platelet disintegration and the subsequent release of thromboplastin and thrombin.[58,100,101] Ibarrola et al. compared the response of rat tibias to bone wax, Surgicel, and Gelfoam histologically.[100] At the end of the 120-day experiment period, Gelfoam usually resorbed completely and the bone defects healed adequately.

Aluminum Chloride

Expasyl (Kerr Corp., Orange, CA, U.S.A.), a paste containing aluminum chloride and kaolin has been advocated for gingival retraction to ensure separation of the marginal gingiva and drying of the sulcus before impression-taking and insertion of

restorations.[117,118] Several studies have shown that aluminum chloride elicits inflammatory tissue reactions.[119,120] Von Arx et al.[117] compared the three different hemostatic agents, bone wax, Expasyl, and ferric sulfate (Stasis), in a rabbit calvarium model for periapical surgery. Expasyl was found more effective than Stasis in controlling the bleeding. Expasyl in combination with Stasis proved to be the most effective test materials to control the bleeding within the bony defects. However, in that same study, aluminum chloride demonstrated a foreign body reaction and the presence of giant cells and other inflammatory cells after three weeks and 12 weeks post-operatively. New bone formation was minimal and delayed in contrast to the control sites. To prevent these reactions, it is currently recommended to curette and freshen the walls of the bony crypt with a round bur and rinse the surgical site with saline before wound closure when using aluminum chloride as a hemostatic agent in periapical surgery.[117]

HemCon

HemCon dental dressing (Patterson Dental, St Paul, MN, U.S.A.) has been recently suggested as a potential hemostatic agent. This material not only is hemostatic, but also has bactericidal properties; an additional benefit when compared to other hemostatic agents.[121] It is manufactured from freeze-dried chitosan and molds to form a highly electropositive sponge-like material that binds to negatively-charged red blood cells. As such, it results in the formation of a viscous clot that facilitates hemostasis.

Osteotomy

By definition, osteotomy is the removal of cortical and cancellous bone covering the root end(s) at the site of surgery (Figure 24-31). The location and size of entry to the bony crypt where the root-end resection and preparation as well as root-end filling are performed is an important phase of PAS. Complete radiographic examinations are essential components of any aspect of root canal treatment.[122] Periapical radiographs have limited value for the diagnosis and extent of periapical lesions and their relationship to vital structures. The use of CBCT is essential to determine the location and size of periapical lesions, their relationship to the vital structures, and thickness of cortical bone plates.[69,70]

Proper osteotomy provides access to the periapical aspects of a tooth. A thorough understanding of anatomy and bone physiology is necessary to avoid mechanical trauma and injury and prevent unwanted complications during and after surgical endodontics. Since bone is a vital tissue, it has to be removed gently and effectively with minimal heat generation. Heat generation during osteotomy is affected by bur size and design, speed of cutting, amount of penetration, amount of pressure during cutting, and irrigation as well as aspiration of generated debris.[123-133]

Effect of Heat, Bur Design, and Speed

Heat generation during osteotomy can cause irreversible damage to an already vulnerable bone that has had a reduction of blood flow into it due to the use of vasoconstrictor. Eriksson et al.[123] reported that the threshold for irreversible damage to the bone is between 44°C and 47°C for one minute. During osteotomy, the use of saline coolant is imperative to lower the temperature of the cut tissues. Another contributing factor to the generation of heat during osteotomy is the method of bone removal. Matthews and Hirsch[124] conducted cadaver studies and examined the effect of incremental and constant drilling. They found incremental drilling resulted in effective temperature reduction and reduction of generated debris.[124] Based on these results, osteotomy should be performed with light stroking motions and copious saline irrigation to maximize cutting efficiency and minimize heat generation.

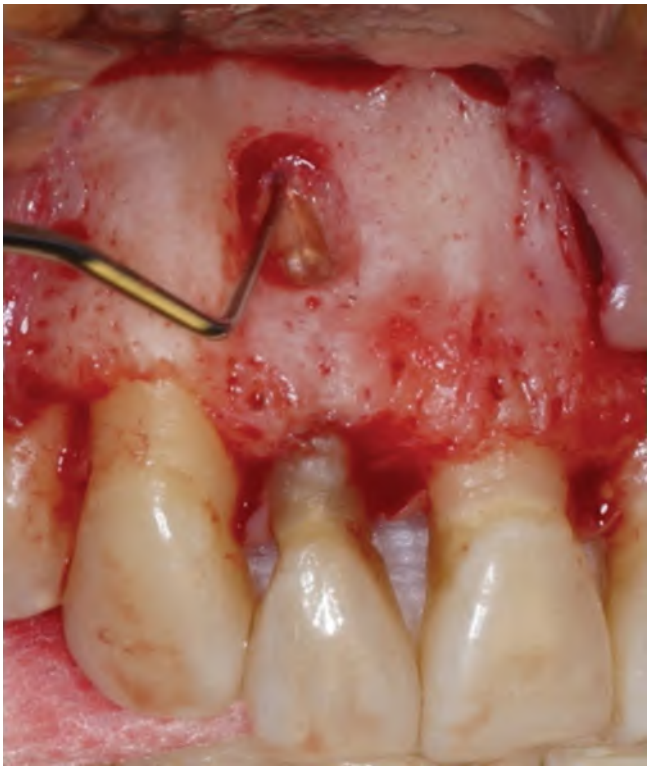

FIGURE 24-31 A complete osteotomy has been performed to carry out periapical surgery on the maxillary right lateral incisor.

Another factor that might affect osteotomy is the speed of the bur during this procedure. The influence of drilling speed, axial drilling force, and feed rate have been extensively studied in relation to bone drilling temperature without much consensus.[125] Vaughan and Peyton[126] found that the increased drill speed during cavity preparation resulted in increased temperature. However, on the contrary, a cadaver study conducted by Matthews and Hirsch[124] found no significant change in temperature during drilling from 345 rpm to 2900 rpm. Nam et al.[127] found that increasing the speed (600 rpm and 1200 rpm) or the force (500 g and 1000 g) affects temperature in the bone.

Several histological studies in the 1960s compared the effect of high speed and low speed handpieces and reported less injury or no injury to the bone with the use of a high-speed handpiece. Despite this inconsistency in the literature,

there have been case reports of surgical emphysema causing subcutaneous emphysema of the face, which may be fatal from the use of high-speed dental handpieces during surgical procedures.[128] The shape of the bur, type of bur, and drill specifications such as rake angle and clearance angle all play a role in the cutting efficiency, and, therefore, heat generation. Kalidindi[129] found that with increasing drill diameter, the temperature increases exponentially, resulting in an increase in overall friction and heat.

The clearance angle or the angle by which the flank of the drill clears the material during drilling is critical as this may cause frictional heat.[129] It is generally recommended that a clearance angle of 15° be used for better cutting efficiency and less heat generation.[130] Moss[131] and Boyne[132] compared different bur types and shapes and reported a No. 6 or 8 round bur produces smoother cut surfaces, less inflammation, and shorter healing times compared to using a fissure or diamond bur. Moss reports that a No. 6 round bur causes a smaller zone of necrosis than a fissure bur.[131] According to Calderwood et al.,[133] diamond burs are the least effective burs for bone removal and cause delayed healing.

Osteotomy Size

A debate exists regarding the size of the osteotomy during PAS. Boyne[132] examined nine patients with 21 periapical defects in the anterior region with at least one cortical plate intact. Lesions were divided into two groups: 5 to 8 mm and 9 to 12 mm. He found complete bone regeneration in smaller defects compared to the larger defects, which contained herniation with fibrous tissue formation. Hjorting-Hansen and Andreason[134] conducted a similar study on dogs where they found complete healing of defects that were about 5 mm or less when one cortical plate was intact. However, when both plates were removed, incomplete healing occurred with formation of fibrous tissue. These results suggest that smaller-sized defects have better chances for complete healing. Microsurgical techniques currently used in surgical endodontics allow the operator to create a significantly smaller-sized osteotomy compared to the traditional technique of periapical surgery. Rubinstein and Kim state that small lesions heal faster than large lesions.[135]

Osteotomy Procedure

A sharp round bur is usually used to remove the bone until the apex is located (Figure 24-32). Using a light brushing motion for removal of the bone is recommended. CBCT is extremely helpful to determine the location of the apex, inclination of roots, thickness of bony plates, and dimension and extension of the periapical lesion. When the lesion has perforated the cortical plate buccally or lingually, a thin bone covers the root, or a fenestration exists, osteotomy can be achieved easily. However, in cases where intact cortical bone is present, the procedure is more complicated and requires removal of the intact cortical plate to expose the apical portion of the tooth.

Placing a radio-opaque material at the site of osteotomy assists in localizing the root(s). The root is generally darker and has a yellowish color, lacks bleeding when probed, and has smooth and hard texture with surrounding periodontal ligament.[136] Use of an operating microscope along with 1% methylene blue dye can assist in separating root from the bone.

Periapical Curettage

The goal of periapical curettage is the removal of pathological soft tissue surrounding the apex (Figure 24-33). This procedure allows optimal access and visibility to the

FIGURE 24-32 A sharp round bur in a high-speed handpiece is used to remove the bone. This action should be accompanied with continuous spraying of sterile water.

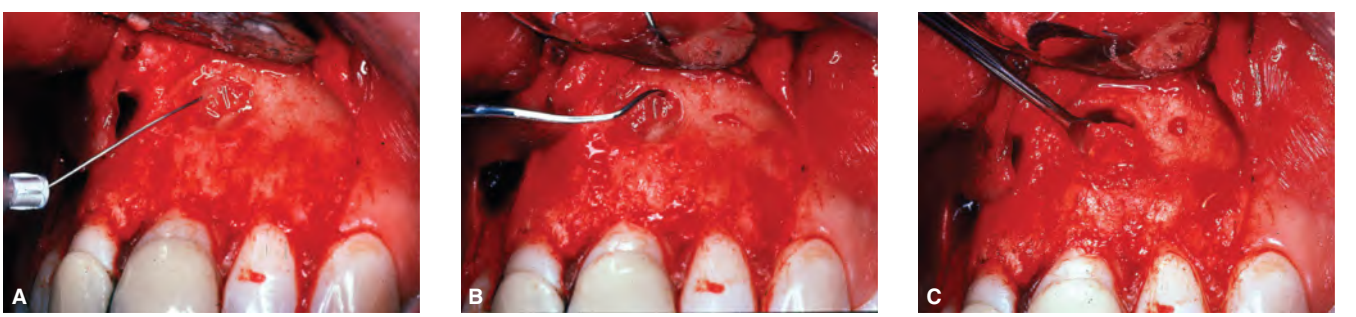

FIGURE 24-33 ***A.*** Injection of local anesthetic into the periapical lesion. ***B.*** Peeling away the lesion with an explorer. ***C.*** Removal of periapical lesion with a curette.

surgical site. Removal of a periapical lesion reduces bleeding and provides a biopsy specimen for histological examination. The soft tissue should be carefully peeled away with a suitable curette. The cavity should be examined under magnification to ensure a clean bony crypt and no tissue tags. Injection of a local anesthetic facilitates removal of the lesion and reduces pain and discomfort during the rest of the operation.[137,138] If the Schneiderian membrane is involved in the soft tissue lesion, careful removal of the lesion is recommended to avoid sinus penetration and perforation.[139] Total removal of the lesion is not necessary to ensure successful outcomes.

Suitable instruments to remove soft tissue include Lucas 86 bone curettes, Columbia 11/12 periodontal curettes, and 13/14 periodontal curettes. A sample of soft tissue should be submitted for biopsy.

Root-end Resection

The purpose of root-end resection is to remove anatomic variations, correct operator errors, evaluate and create an apical seal, and reduce fenestration of root apices. Root-end resection involves beveling the apical portion of the root end (Figure 24-34). Root-end resection removes the untreated apical portion of the root and enables the surgeon to determine the cause of failure. It also provides a flat surface that allows the operator to create a root-end cavity preparation and place a root-end filling material.

There is no consensus regarding the amount of root resection during PAS. Gilheany et al.[140] suggest removal of at least the apical 2 mm of a root to minimize bacterial leakage. Morfis et al.[141] in anatomical studies of the root apices have shown the presence of accessory foramina in all groups of teeth. Kim and Kratchman[58] have suggested that at least 3 mm of the root end must be resected to include 98% of the apical ramifications and 93% of lateral canals. It is not recommended to remove more than 3 mm of the root end, thus preserving 7–9 mm of the root for strength and stability.[58]

Another significant factor to proper root-end resection is the angle of beveled root. One of the major benefits of microsurgery is minimization of the angle of bevel necessary for visualization. In the traditional technique, a bevel of 45° to 60° was necessary with the large surgical instruments. Kim and Kratchman[58] believe that this procedure can expose many tubules, cause greater loss of buccal bone, and weaken the root. However, with the modern microsurgical technique, they recommend little or no beveling of the root during root-end resection.[58]

It is crucial to analyze the anatomy of the root outline after root-end resection. According to Kim and Kratchman[58] this is one of the most important steps for microsurgery and critical for the success of the treatment. Carr[142] attributes failed surgical cases to the missed lingual canal or inadequate cleaning of the isthmus. Observing the shape and the outline of the root as well as identifying isthmuses under the microscope with methylene blue dye can assist in avoiding this misstep. Under high magnification, any cracks, canal aberrations, missed canals, or isthmuses can be identified after a complete root-end resection.[143]

Root-end Cavity Preparation

Conventional root-end cavity preparation technique utilized rotary burs in a micro-handpiece. This technique had many shortcomings such as difficulty of access (especially with limited working space), risk of perforation of the root, and insufficient depth of root-end cavity preparation to place an adequate root-end filling material. In addition, a large number of infected isthmus spaces could not be cleaned and filled.[144] In 1957, the first ultrasonic instrument in endodontics was introduced by Richman. Since then, Carr introduced retro-shaped ultrasonic tip design.[142] One of the most significant advances in periapical surgery was the introduction of ultrasonic micro-surgical tips for the root-end preparation. The use of ultrasonic tips is currently considered the standard of practice in surgical endodontics.

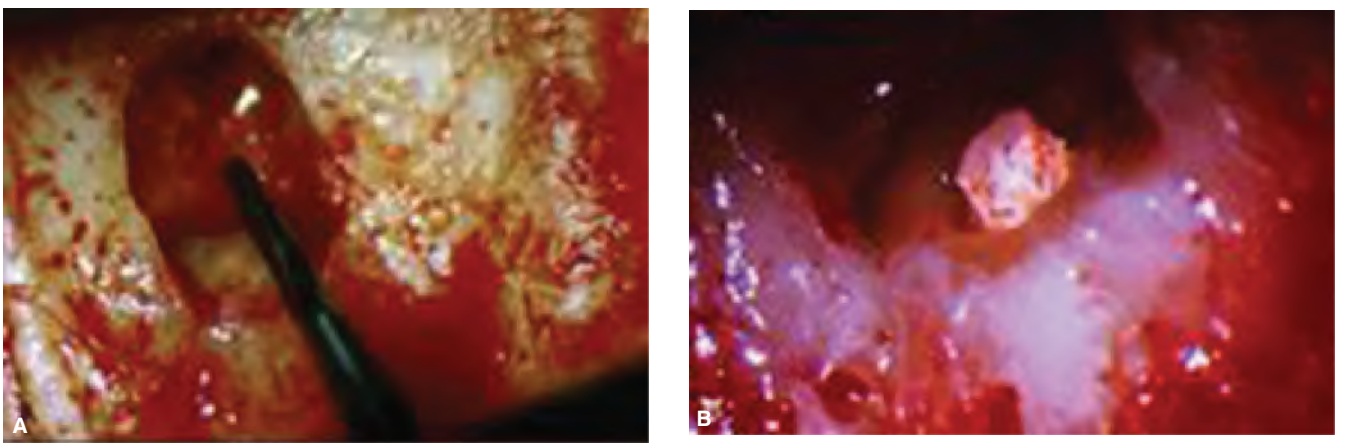

FIGURE 24-34 ***A.*** Root-end resection is performed using a fissure bur in a high-speed handpiece with continuous spray of sterile water. ***B.*** The entire apex should be resected and be visible for inspection.

Several studies reported the advantages of using ultrasonic tips over conventional instruments. There are several ultrasonic tips designed for root-end cavity preparation during surgical endodontics (Figure 24-35).[145] In a scanning electron microscope (SEM) study, Wuchenich et al.[146] compared ultrasonic and conventional bur root-end cavity preparations in cadavers. They found that the ultrasonic tips produced more parallel walls and cleaner surfaces compared to bur preparations (Figure 24-36). In another SEM study, Gorman et al.[147] reported that the root-end cavities prepared with ultrasonic instruments showed significantly less smear layer compared with those made by conventional burs. In a prospective randomized controlled treatment of 399 patients, the overall success rate in teeth whose roots were prepared with ultrasonic tips was 80.5%. This dropped to 70.9% when the roots were prepared with conventional burs.[148] This clinical study showed a significantly better outcome when ultrasonic tips were utilized to prepare deeper and cleaner preparations and address anatomical difficulties.[148]

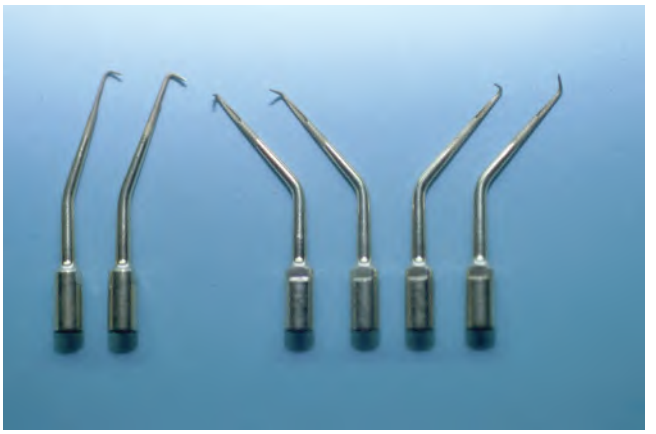

FIGURE 24-35 Currently, a variety of ultrasonic tips are available to prepare root-end cavities for various roots with different characteristics.

However, despite many advantages, ultrasonic tips can cause root crack formation and apical leakage.[149] As found in an *in vitro* study by Layton et al.,[150] root-end cavities prepared by ultrasonic tips can increase the number of micro-fractures significantly compared to roots that only had root-end resections. The study suggested that lower power settings may reduce the number of micro-fractures. Contrary to these findings and other investigations, Gray et al.[151] conducted a study in cadavers and found an insignificant number of cracks with ultrasonic preparations. This difference might be due to the presence of periodontal ligament in cadaver teeth that absorbs vibrations during root-end preparations with ultrasonic tips.

In most of these studies, stainless steel ultrasonic tips were used during root-end preparations. Recently, many diamond-coated tips have entered the market along with the belief that they cut more quickly and efficiently and reduce contact time with the tooth. Although the microfractures may occur as a result of the use of ultrasonic tips during root-end preparations, there is a lack of evidence correlating the presence of the fractures with success rates of surgical endodontics. Thus, the advantages of ultrasonic techniques outweigh the unknown clinical significance of the occurrence of microfractures.[148]

Currently, a variety of tips is available to accommodate virtually all access situations. When used, the tips are placed at the root-end parallel to the long axis of the root. A Class I cavity preparation is made with ultrasonic tips to a minimum depth of 3 mm into the canal (Figure 24-37). More complicated root anatomy may require other types of preparations.

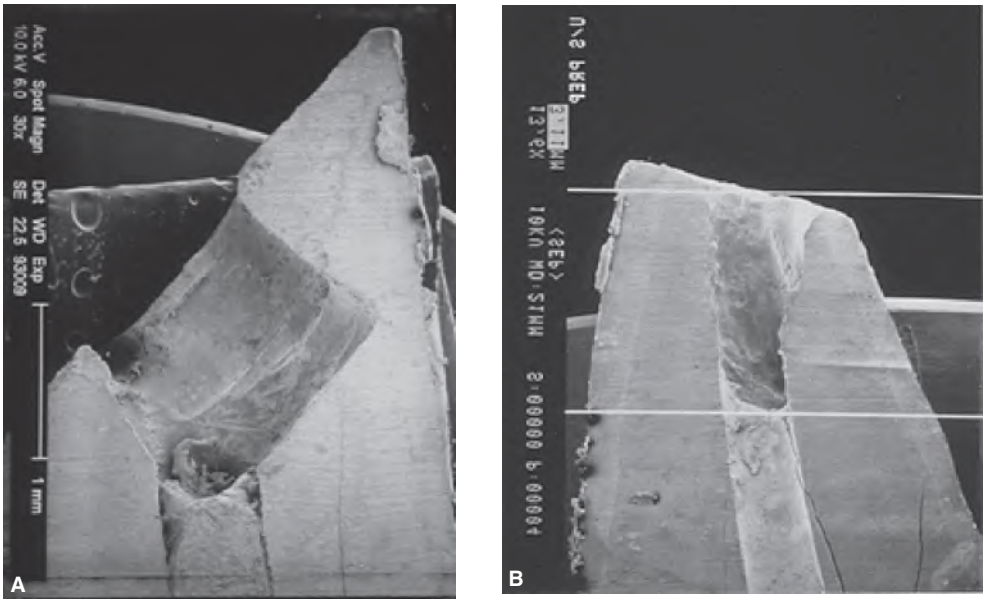

FIGURE 24-36 ***A.*** SEM image of a root-end cavity prepared by a small inverted bur. ***B.*** SEM image of a root-end cavity preparation by an ultrasonic bur.

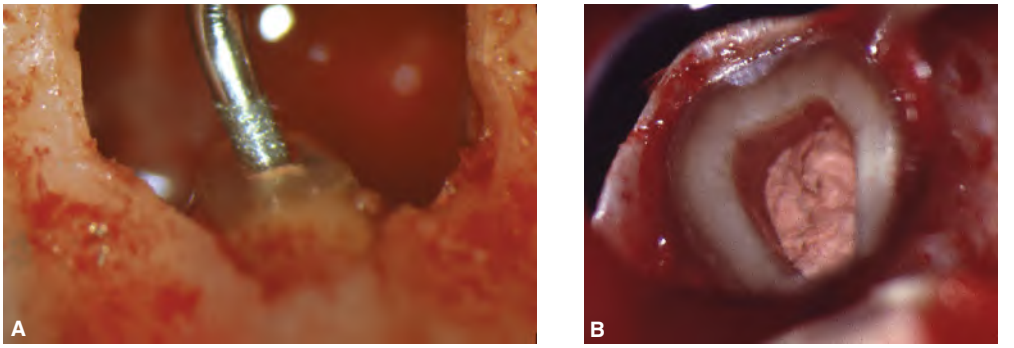

FIGURE 24-37 ***A.*** An ultrasonic tip is used to make a root end cavity preparation. ***B.*** A Class I root cavity preparation is prepared with the ultrasonic tip to a depth of 3 mm into the canal.

The ultrasonic tips offer the advantages of control and ease of use and permit uniform depth of preparation.[152] In addition, the ultrasonic tips produce smaller apical preparations, allow easier preparation of an isthmus, follow the direction of the canals, clean the canal surfaces better than burs, and create less fatigue for the operator.[151,152]

Root-end Filling Materials

The purpose of a root-end filling is to establish a seal between the root canal space and the periapical tissues. An ideal root-end filling material should be: 1) able to prevent leakage of bacteria and their by-products into the periapical tissues, 2) non-toxic, 3) non carcinogenic, 4) biocompatible with the host tissues, 5) insoluble in tissue fluids, 6) dimensionally stable, 7) unaffected by moisture during setting, 8) easy to use, 9) radiopaque, 10) nonstaining, and 11) bioinductive (promote cementogenesis).[153] Numerous materials have been introduced as root-end filling materials including gutta-percha, amalgam, polycarboxylate cements, zinc phosphate cements, zinc oxide eugenol paste, IRM cement, EBA cement, Cavit, glass ionomers, composite resins, gold foil and leaf, silver points, cyanoacrylates, polyHEMA and hydrogen, Diaket root canal sealer, titanium screws, and Teflon.[37] The suitability of root-end filling materials has been tested by their leakage assessment, marginal adaptation, cytotoxicity, and usage in experimental animals and humans. Although a plethora of materials is available, no material has been found that fulfills all or most of the properties for ideal retrograde filling material.

In 1993, Mineral Trioxide Aggregate (MTA) was developed as a new root-end filling material by Torabinejad et al. at Loma Linda University, CA, U.S.A. The main ingredients of MTA are tricalcium silicate, tricalcium aluminate, tricalcium oxide, and silicate oxide.[154] MTA has been evaluated extensively for microleakage (dye penetration, fluid filtration, and bacterial leakage), marginal adaptation (SEM), and biocompatibility (cytotoxicity, tissue implantation, and *in vivo* animal histology). The sealing ability of MTA has been shown to be superior to that of Super-EBA and was not adversely affected by blood contamination.[155] Its marginal adaptation was shown to be better than that of amalgam, IRM, or Super-EBA.[156] MTA has also been shown to be less cytotoxic than amalgam, IRM, or Super-EBA.[40] Its pH, when set, is 12.5 and its setting time is three hours and 45 minutes, which is much longer than that of amalgam, IRM, or SuperEBA. The compressive strength of MTA is reported to be 40 MPa immediately after setting, which is less than that of amalgam, IRM, and SuperEBA, but increases to 70 MPa after 21 days, that is comparable to that of amalgam, IRM, and SuperEBA.[154] Unlike other root-end filling materials that do not tolerate moisture, MTA requires moisture to set. Hydration of MTA powder results in a colloidal gel that solidifies into a hard structure.[157] Several studies reported low or no solubility of MTA. However, a long-term study showed increased solubility over a 78-day period.[158] Although some of the studies showed conflicting results, an investigation confirmed that MTA has limited antimicrobial effect against some facultative bacteria.[159] Animal usage tests in which MTA and other commonly used root-end filling material were compared have resulted in less observed inflammation and better healing with MTA. Histological sections in these studies have demonstrated the regeneration of new cementum over the MTA root-end filling,[160,161] a phenomenon not observed with other commonly used root-end filling materials (Figure 24-38). Recent clinical studies have shown significantly better outcomes when MTA was used compared with other commonly used root-end filling materials.[95,162]

Root-end Filling Placement

The method for placement of the root-end filling material will vary depending on the type of filling material used. Zinc oxide-eugenol cements (IRM and Super-EBA) are best mixed to a thick clay-like consistency, shaped into a small cone, and attached to the back side of a spoon excavator or the tip of a plastic instrument or Hollenback carver, and placed into the root-end preparation.

MTA is a unique root-end filling material with physical properties much different than those of other materials. It is a very fine, gray-colored powder that is mixed with a sterile liquid, such as saline or local anesthetic

FIGURE 24-38 Complete periapical regeneration of tissues including formation of cellular cementum *(C)* adjacent to the MTA are observed when MTA is used as a root-end filling material in dogs.

solution, on a sterile glass slab. It cannot be mixed to a clay-like consistency, similar to IRM or Super-EBA, because, as more powder is added to the liquid, the mix becomes dry and crumbly. If the mix is too wet, it is runny and very difficult to handle due to its lack of form. The surgical area must be kept very dry during its placement and care must be taken not to wash out the filling material by irrigation prior to closure of the soft tissue. The setting time of MTA is 2.5 to 3 hours. Properly mixed, MTA should be free of excess moisture—firm but not crumbly. It can be delivered to the root-end preparation by various carriers (Figure 24-39).

FIGURE 24-39 Different carriers for placement of MTA into root-end preparations.

Wound Closure

After final inspection of the root-end filling and removal of all visible excess filling material and any surgical packing, a radiograph should be taken to evaluate the placement of the root-end filling and to check for the presence of any root fragments or excess root-end filling material. A thorough examination of the underside of the flap and in the depth of the fold between the mucoperiosteum and the alveolar bone should be done prior to repositioning the flap in order to remove any debris or foreign material that may be present. The final steps in periapical surgical procedures are wound closure and soft tissue stabilization.

Repositioning and Compression

The elevated mucoperiosteal tissue should be gently replaced to its original position with the incision lines approximated as closely as possible. The type of flap design will affect the ease of repositioning, with full mucoperiosteal flaps generally providing less resistance to repositioning than limited mucoperiosteal flaps. Using surgical gauze, slightly moistened with sterile saline, gentle but firm pressure should be applied to the flapped tissue for two to three minutes (five minutes for palatal tissue) prior to suturing (Figure 24-40). Tissue compression, both before and after suturing, not only enhances intravascular clotting in the severed blood vessels, but also approximates the wound margins, especially the dissectional wound. This reduces the possibility of a blood clot forming between the flap and the alveolar bone. Coagulum formation under the flap delays healing. There are many factors that may promote, compromise, or delay wound healing.[163]

Healing

Although wound closure is performed at the end of PAS, it is no less important than other steps of this procedure. It is essential that the operator has a good scientific and technical aspect of wound healing so that the tissues are managed for predictable outcomes. Soft tissue management is a crucial part of a clinician's skill, and it not only ensures a successful endodontic outcome, but it also produces aesthetic results.

FIGURE 24-40 A large piece of gauze sponge moistened with saline is applied to flap after suturing.

Different types of wounds have different rates of healing. Selvig and Torabinejad[164] compared wound healing in cats after flap surgery. They reported that the fastest healing was observed in the region of the free gingiva (seven days), whereas healing of the attached gingiva (14 days) and the alveolar mucosa (28 days) took considerably longer. If healing occurs more quickly in some areas than others, it can be anticipated where complications might arise. The findings by Selvig and Torabinejad[164] help to explain why dehiscence and healing by secondary intention occur more frequently in the alveolar mucosa.

Once the thin blood clot beneath the flap is replaced with parallel fibers for collagen adhesion, the sutures should be removed. This process takes place in two to four days. At three days, the incisional wound is covered with two to three cell layers. Therefore, the earliest reasonable time to remove sutures is four days after surgery.[164]

Suturing

Sutures do not perform miracles on their own; flap designs and handling of the soft tissues are important factors, too. The soft tissue flaps should remain in position after suturing even when the lips and tongue move (Figure 24-41). The purpose of placing sutures is to reapproximate the wound edges and stabilize the flap accurately in the desired position. This process should ensure primary intention healing with formation of a thin fibrin clot with little or no movement.

Sutures are used to assist in the initial attachment. They can be removed once the blood clot has been replaced by collagen fibers. If sutures remain for an extended period of time, a peri-suture epithelial sleeve can develop in as little as three days. The entire suture track can be enrobed in seven days.[165] Sutures should not be incorporated into healing, but should facilitate initial attachment.

An ideal suture should support the incision while it heals, conform to the tissues, not harbor bacteria, cause minimal tissue reaction, and dissolve when it is no longer needed. Sutures are available in many different materials, the most common being synthetic fibers (nylon, polyester, polyglactin, and polyglycolic acid), collagen, gut, and silk. Sutures are classified as absorbable or nonabsorbable, by size according to the manufacturer's minimum diameter, and by physical design as monofilament, multifilament, twisted, or braided.

FIGURE 24-41 The soft tissue flap has remained in proper position and location after suturing and pulling the lips.

The classification of suture size is complicated by the existence of two standards, the United States Pharmacopeia (USP) and the European Pharmacopeia (EP). The USP size is designated by two Arabic numerals (one of which is always a zero) separated by a hyphen (3-0, 4-0, 5-0, etc.). The higher the first number, the smaller the diameter of the suture material. The EP system is a number that represents the manufacturer's minimum diameter tolerance in millimeters (1 = 0.10 mm, 1.5 = 0.15 mm, etc.) of the suture.

Monofilament sutures are advocated by multiple authors. The smooth sides of a monofilament suture decrease the inflammatory reaction and limit tissue adhesion to the suture. Multifilament sutures allow for the attachment of tissue while producing a wicking action that allows harmful bacteria to invade the suture track.[166,167] Silk sutures are not recommended because they tend to accumulate plaque and allow rapid bacterial colonization.[168]

SUTURING TECHNIQUES

There is a wide variety of suturing techniques designed to accomplish the goals of closure and stabilization of flaps involving oral mucoperiosteal tissues. All suturing techniques should be evaluated on the basis of their ability to accomplish these goals. Several authors have compared the effects of continuous and interrupted suture techniques. Their findings indicate that the interrupted suturing technique provides for better flap adaptation than the continuous technique and, therefore, is the recommended and most commonly used technique for surgical endodontics.[169,170]

Sutures are holding mechanisms and should not pull or stretch the tissue as a tear in the flap margin may result. Sutures that close an incision too tightly compromise circulation and increase chances for the sutures to tear loose upon swelling.

Before placing sutures, bleeding should be controlled to prevent the formation of a hematoma under the flap. A hematoma will prevent the direct apposition of the flap to the bone and can act as a culture medium for bacterial growth. The suturing techniques that are most conducive to rapid surgical wound healing are the single interrupted suture, the interrupted loop (interdental) suture, the vertical mattress suture, and the single sling suture.

SINGLE INTERRUPTED SUTURE

The single interrupted suture is used primarily for closure and stabilization of vertical releasing and relaxing incisions in full mucoperiosteal flaps and horizontal incisions in limited mucoperiosteal flap designs (Figure 24-42). The initial needle penetration should be through the independent (movable) tissue. The point of needle entry should be from the buccal or facial and 2 to 3 mm from the incision margin

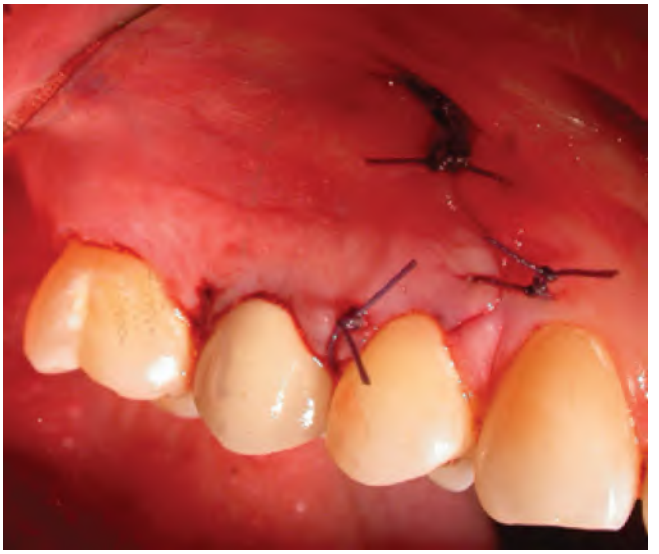

FIGURE 24-42 The single interrupted sutures have been used for closure and stabilization of horizontal and vertical incisions of a full mucoperiosteal flap on a maxillary second premolar.

in order to provide sufficient tissue to minimize suture tear-out. The needle should then enter under the surface of the mucoperiosteum of the dependent (immovable) tissue and penetrate through the mucoperiosteum at a point 2 to 3 mm from the incision margin. In order to accomplish this, it is often necessary to elevate the attached mucoperiosteum from the underlying bone for a distance of a few millimeters at the point of needle insertion. It is important that the periosteum is included with the tissue bite, otherwise the suture will most likely tear out of the fragile attached gingiva.

After the suture needle has been passed through the mucoperiosteum on both sides of the incision, the suture material should be drawn through the tissue until the end opposite the needle is approximately one to two inches from the tissue. The suture should be tied with a secure knot. A surgical knot is the most effective and least likely to slip. The surgeon's knot is best tied by wrapping double loops or throws of the long end (end with the needle attached) of the suture around the needle holder. By then grasping the short end of the suture with the needle holder and slipping the throws off, the first half of the surgical knot is tied. After adjusting the tissue tension, the second half of the knot is tied by repeating the same process, only wrapping the loops of suture around the needle holder in the opposite direction from the first tie, like a square knot. Suture knots should be placed to the side of the incision. Suture knots collect food, plaque, and bacteria, thus resulting in localized infection and a delay in healing when placed directly over the incision.

INTERRUPTED LOOP (INTERDENTAL) SUTURE

The interrupted loop, or interdental suture, is used primarily to secure and stabilize the horizontal component of full mucoperiosteal flaps. The surgical needle is inserted through the buccal or facial interdental papillae, then through the lingual interdental papillae, and then back through the interdental embrasure. It is tied on the buccal or facial surface of the attached gingiva. This suture technique highly predisposes the fragile interdental tissue to inflammation and retarded healing, resulting in a loss of the outer gingival epithelium, with possible blunting or formation of double papillae.

A modification of the interrupted loop suture described above is as follows. After the surgical needle has been passed through the buccal and lingual papillary gingiva, the suture is passed over the interdental contact and secured with a surgeon's knot. This modification eliminates the presence of suture material in the interdental embrasure, thus reducing post surgical inflammation to this delicate tissue. In clinical situations where the horizontal component of a full mucoperiosteal flap involves teeth with full coverage crowns, this modification allows for a slight incisal or occlusal repositioning of the mucoperiosteal flap. This can be accomplished by placing slight tension on the suture over the interdental contact and may compensate for a loss of gingival height resulting from the sulcular incision.

VERTICAL MATTRESS SUTURE

The vertical mattress suture has the advantage that it does not require needle penetration or suture material being passed through tissue involved in the incisional wound (Figure 24-43). The surgical needle enters and exits the flapped mucoperiosteum some distance apical from the incision line. The suture is then passed through the interdental embrasure, directed to the lingual of the adjacent tooth and passed back through the opposite interdental embrasure. The needle then enters and exits the flapped mucoperiosteum again and is passed through the embrasure, lingual to the tooth and through the opposite interdental embrasure to be tied on the buccal surface with a surgeon's knot. This suture technique also provides for the opportunity to return the flapped tissue

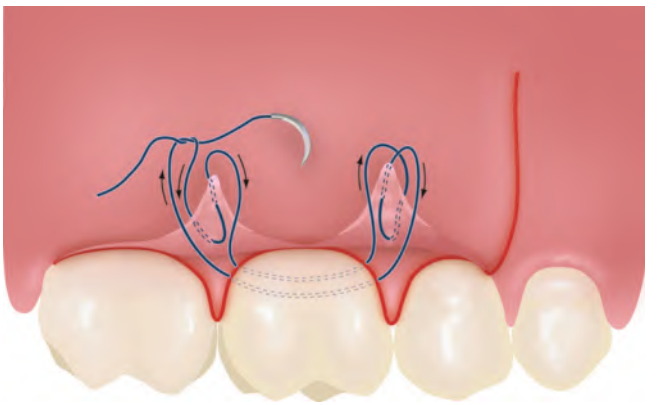

FIGURE 24-43 A vertical mattress suture avoids penetration of tissues in the incisional wound and it supports the interdental papilla in a coronal direction.

to a slightly incisal or occlusal position from its original in order to compensate for a loss of gingival height.

SINGLE SLING SUTURE

The single sling suture is similar to the vertical mattress suture (Figure 24-42). The surgical needle is passed through the attached gingiva of the flap, through the interdental embrasure but not through the lingual soft tissue. It is then directed lingual to the tooth and passed through the opposite interdental embrasure and over the incisal or occlusal margin of the flap. The needle is then passed through the attached gingiva of the flap, from the buccal or facial, back through the embrasure, passed lingual to the tooth, through the opposite embrasure, passed over the flap margin, and tied with a surgeon's knot (Figure 44A and B). This suture technique is particularly effective for achieving the maximum incisal or occlusal level when repositioning the flap. Because the lingual anchor is the lingual surface of the tooth and not the fragile lingual tissue, tension can be placed on the flapped tissue to adjust the height of the flap margin.

POST-OPERATIVE CARE AND INSTRUCTIONS

All patients who undergo PAS should receive both oral and written postoperative care and instructions. The patients should be informed of the possibility of postoperative swelling and discomfort. To reduce postoperative swelling and discomfort, the patient should use an ice pack with moderate pressure on the outside of the face (20 min on, 5 min off) for a few hours after the surgery. Mild analgesics such as ibuprofen should be prescribed for relief of post-operative pain. Some oozing of blood is expected after PAS. To reduce minor bleeding, the patient should place a moistened gauze pad over the area and put finger pressure on it for 15 minutes. The patients should be warned against lifting their lips and should check the surgical site. This may dislodge and untie the sutures. Twenty-four hours after surgery the patients can use warm salt water after each meal. Gentle brushing is recommended 24 hours after the surgery. Drinking lots of fluid and eating soft foods that contain high levels of protein are recommended. Patients who smoke should refrain from smoking for at least three days after the surgery. Excessive bleeding, pain, swelling, or a high temperature should be reported to the operator immediately. Sutures should be removed three to seven days after PAS.

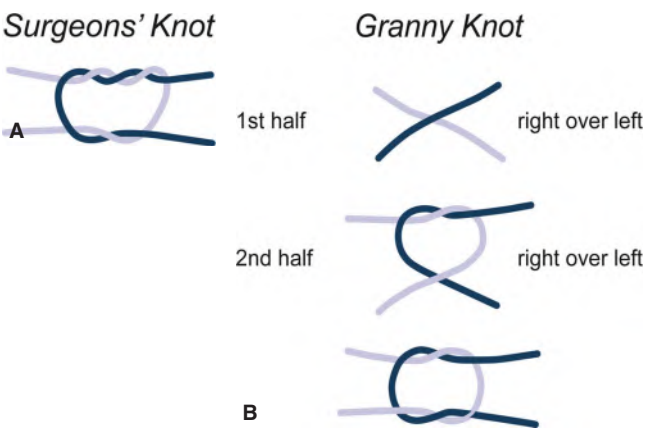

FIGURE 24-44 ***A.*** Surgeon's knot is a modified square knot in which the first overhand knot is doubled; the doubling prevents slippage especially when flaps are under tension. ***B.*** Granny knots result when a throw (complete twist of two strands) is followed by another throw in the same sequence. Granny knots result in knot slippage with less security than a surgeon's knot.

HEALING

Soft and hard tissues are manipulated during periapical surgery. Depending on the location and procedure involved, incisional, dissectional, and/or excision wounds are created during PAS.

Soft Tissue Healing

The soft tissue healing consists of clotting, inflammation, epithelialization, and connective tissue healing, as well as maturation and remodeling.[77] The main event during clotting is the conversion of fibrinogen to fibrin. The clot formation should be limited between the edges of the soft tissue incisions. The clot forming between the soft tissue wound and underlying hard tissues should be thin and minimal. Pressing the soft tissue flap against the underlying hard tissues with a wet piece of gauze usually prevents thick clot formation. Failure of the clot to form results in leakage of blood into the wound site and causes delayed wound healing. Acute and chronic inflammatory reactions occur after surgery and are part of the healing process.[77]

The soft tissue healing consists of formation of the epithelial bridge between the edges of the soft tissue incisions and the underlying connective tissue. Surface epithelial cells migrate on the fibrin surface until they make contact with their counterparts from the opposite border of the wound, forming an epithelial bridge.

The connective tissue under the epithelial layer and in contact with the underlying hard tissues contains all of the normal elements found in any connective tissue in the body. As healing progresses, there is a decrease in the amount of inflammation and maturation of connective tissue.[77,98]

Hard Tissue Healing

Harrison and Jurosky examined the healing of osseous incisional wounds in monkeys.[171] Their findings show that the hard tissue healing starts by the proliferation of endosteal cells into the wound coagulum. At about 12 to 14 days, woven bone appears at the site of surgery. The healing process occurs from inside to outside, ending in the formation of mature lamellar bone.

OUTCOME OF SURGICAL ENDODONTICS

Mead et al.[172] searched (electronically and manually) the literature related to the success and failure of periapical surgery since 1970 and assigned levels of evidence to these studies. This search located 79 clinical studies. Their research found seven low-level RCTs (LOE-2), four cohort studies (LOE-4), and 12 case control studies (LOE-3). Fifty-six studies were classified as LOE-4 case series. They reported that the majority of frequently quoted "success and failure" studies were case series. Rubinstein and Kim,[173] in a prospective study, examined the one-year healing rate of surgical endodontics performed under the surgical operating microscope (SOM) in conjunction with microsurgical techniques and reported a 96.8% success rate. A follow-up of the same cases showed a 91.5% success rate after five to seven years.[174] Maddalone and Gagliani[175] studied the outcome of periapical surgery using microsurgical technology and ultrasonic root-end preparation and reported a similarly high success rate. Torabinejad and Rubenstein[9] in 2004 discussed important advances in surgical endodontics and the impact of microsurgical techniques and new root-end filling materials on retaining teeth that may otherwise be extracted. Sechrist et al.[176] examined the success rate of surgical endodontics in 25 patients whose root-end cavities had been filled with MTA. Based on their findings, they reported that 93% of these cases were functional and asymptomatic. Kim and Kratchman[58] published an article in 2006 discussing the advantages of modern microsurgical techniques such as ease of distinguishing root apex from bone, the ability of the operator to make a smaller osteotomy, better hemostasis control, and ergonomic benefits to the operator. In this article, the authors state that "on the basis of published research, [they] believe that endodontic microsurgery with MTA is a predictable procedure to save teeth."

In a systematic review in 2009, Torabinejad et al.[7] compared the clinical and radiographic outcomes of nonsurgical retreatment with those of surgical endodontics. They reported a significantly higher success rate for traditional surgical endodontics at two to four years (77.8%) compared with nonsurgical retreatment for the same follow-up period (70.9%; $P < .05$). At four to six years, however, this relationship was reversed, with nonsurgical retreatment showing a higher success rate (83.0%) compared with surgical endodontics (71.8%; $P < .05$).

In a meta-analysis of the literature, Seltzer et al.[177] compared the outcomes of traditional surgical endodontics to current endodontic microsurgery techniques and materials and reported a 94% success rate with endodontic microsurgery compared to a 59% success rate when using older techniques and materials. In a recent systematic review, Torabinejad et al. compared the outcomes of tooth retention through endodontic microsurgery to tooth replacement using a single implant.[178] Their findings show that teeth treated by microsurgical technique had survival rates of 94% at two to four years and 88% at four to six years, indicating that microsurgically-treated teeth tend to be lost at low rates over time (Table 24-2). The outcomes of surgical endodontics have significantly improved because of the use of the microscope and new root-end filling materials such as MTA and other bioceramics.

TABLE 24-2 Survival Rates of Microsurgery Between Two to Four and Four to Six Years[178]

CORRECTIVE SURGERY

Corrective surgery can be defined as the surgical procedure required to repair defects that occur in root or furcation areas as a result of therapeutic misadventures or pathologic processes. These defects are located in areas of the root other than the apex and are not amenable to nonsurgical repair. When a periodontal pocket is associated with a defect located in the cervical one-half of the root, it will be necessary to reflect a mucoperiosteal flap to ensure proper repair of the root defect and correction of the periodontal defect. Furcation defects are generally repaired nonsurgically, but there are situations where a periodontal component is present and can only be corrected via a surgical approach. Therapeutic misadventures requiring corrective procedures include, but are not limited to, perforations that occur during complicated endodontic access, root canal location and preparation procedures, or as a result of misdirection of burs during the preparation of post space. Pathological processes that may cause some of these defects include caries, periodontal lesions, external resorption, and perforating internal resorption. Traumatic injuries that result in fractures of the root may require a surgical approach to treatment in order to retain the remaining root or combination of root and crown structures.

Corrective surgical procedures include periapical surgery where access is gained through a flap procedure to repair the root and periodontal defects. Root resection or tooth-root resection is also a possibility when a defect can only be corrected if an entire root of a multi-rooted tooth is removed and the remaining crown of the tooth is re-contoured and retained.

In mandibular molars, a hemisection procedure may be required to remove the entire crown and root on the side of the tooth where the defect is present. A tooth replantation or transplantation procedure is only a treatment option when all other nonsurgical and surgical procedures have already been attempted and failed or have been deemed impossible to perform. In these cases, the tooth is extracted, the defect is repaired, and the tooth is repositioned back into its original socket.

PERFORATION REPAIR

Perforations in the floor of the pulp chamber in multi-rooted teeth may occur during endodontic access preparation, post space preparation, or in conjunction with extensive caries or resorption lesions. The multi-rooted teeth with the greatest potential for furcation perforations are the maxillary and mandibular molars. When a perforation occurs in this area of the tooth, the initial attempt at repair should be from an internal, nonsurgical approach (Figure 24-45). Corrective surgery is reserved for those teeth where nonsurgical repair is not a treatment option or the attempted nonsurgical repair has failed. When surgery is necessary, a buccal mucoperiosteal flap is reflected, the furcation bony defect is curetted to remove any pathologic tissue, and the perforation site is repaired.

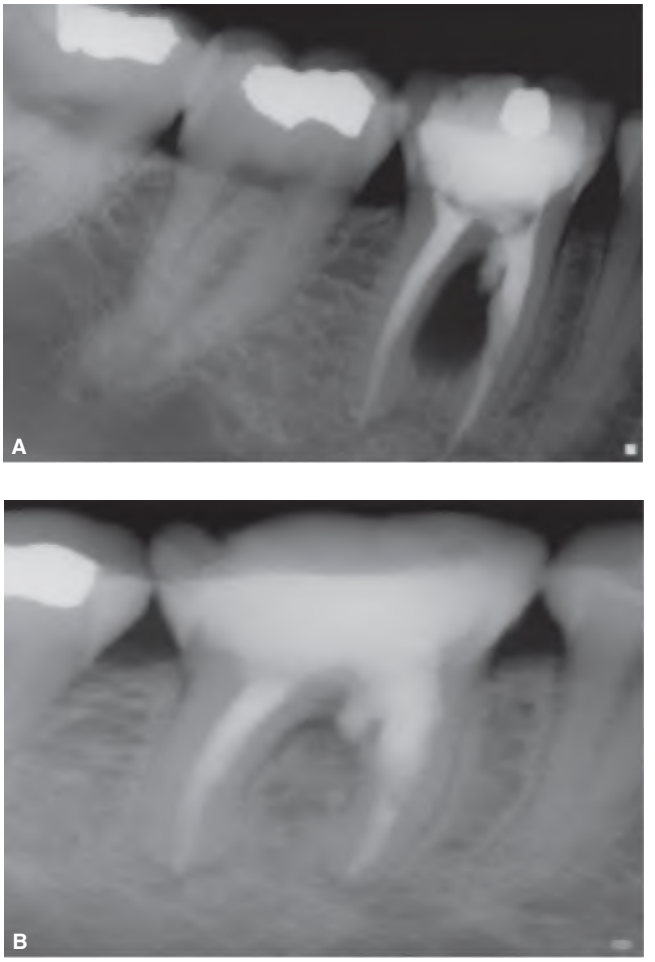

FIGURE 24-45 ***A.*** A strip perforation that occurred during cleaning and shaping was repaired internally with MTA. ***B.*** Radiograph taken 9 months later shows no evidence of pathosis in the repaired area. (Courtesy of Dr. Albert Goerig, Olympia, Washington, U.S.A.)

In an animal study, Dean et al.[179] reported that when the perforation defect was repaired surgically, the associated bone defect was filled with decalcified freeze-dried bone, and the window in the bone was covered with a periodontal membrane, the percentage of osseous healing was 75% to 100%. In those cases where the perforation was repaired, the bone defect was allowed to fill with blood, and the bone window was covered with a periodontal membrane, the percentage of osseous healing was 92% to 100%. When only the perforation was repaired and the other two procedures were not done, the osseous healing was only 52% to 70%. In the remaining three groups, the same blood clot, membrane, and osseous fill were performed on the bone defect, but none of the perforations in these three groups was repaired. The amount of osseous repair for these three groups ranged from 0% to 15%. The results suggest that, in this particular model, repair and sealing of the perforation site were necessary to achieve significant osseous healing.

Strip perforations in the cervical one-third of the root occur most frequently in the thin distal aspects of the mesial roots of mandibular molars and the mesiobuccal roots of maxillary molars (Figure 24-46A). Nonsurgical repair should be the first treatment option in these cases. If surgical repair is deemed necessary, the perforation must be accessed and visualized through a window created in the buccal bone (Figure 24-46B–D). In many cases, surgical repair will be very difficult, if not impossible, and the bony window may be so large that a periodontal defect is created. If neither the nonsurgical nor surgical options is feasible, other possible treatment options include root resection, hemisection, tooth replantation, or extraction followed by the placement of a bridge or osseointegrated implant.

If an external cervical root defect is present as a result of root caries or cervical root resorption, the treatment approach may be different from that proposed for a perforation defect in the same area. If the carious or resorptive defect does not penetrate into the pulp canal space, a surgical approach to treatment is the first choice. A limited envelope soft tissue flap is generally adequate to visualize, cleanse, and repair the affected area. If the defect is in a cosmetic area, an appropriate composite resin or glass ionomer material will be the material of choice. MTA is the material of choice if the defect is in an area where cosmetics are not an issue. Periodontal pocketing is often associated with these cervical defects, so crown lengthening or vertical root extrusion may also have to be performed in order for the area to be properly restored and cleansed.

Perforations occurring at the mid-root level are usually the result of burs being misdirected or over-thinning of the root canal walls during post space preparation. If possible, these defects should be immediately sealed via an internal approach. If surgery is necessary (Figure 24-47), the same

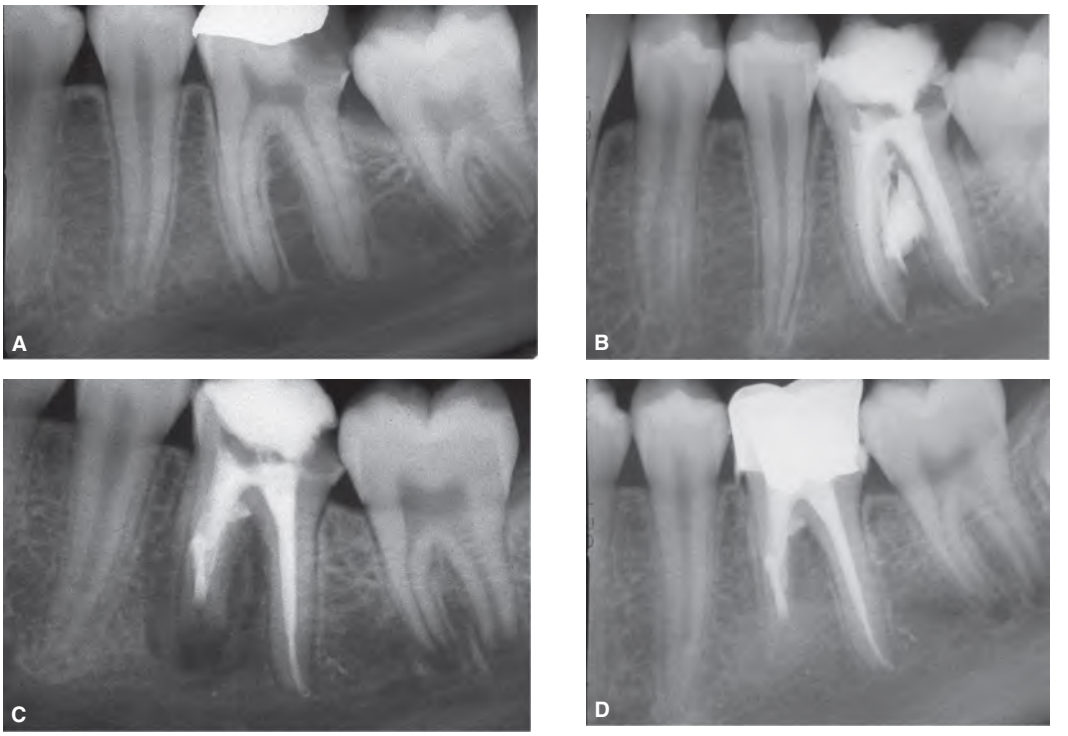

FIGURE 24-46 ***A.*** A preoperative radiograph of the first mandibular molar shows presence of a thin distal walls of the mesial roots. ***B.*** A severe strip perforation occurs during cleaning and shaping of the root canals along with extrusion of root canal filling materials into the periapical tissues. ***C.*** The perforation was repaired with MTA. ***D.*** A radiograph taken one year later shows healing of the repaired area.

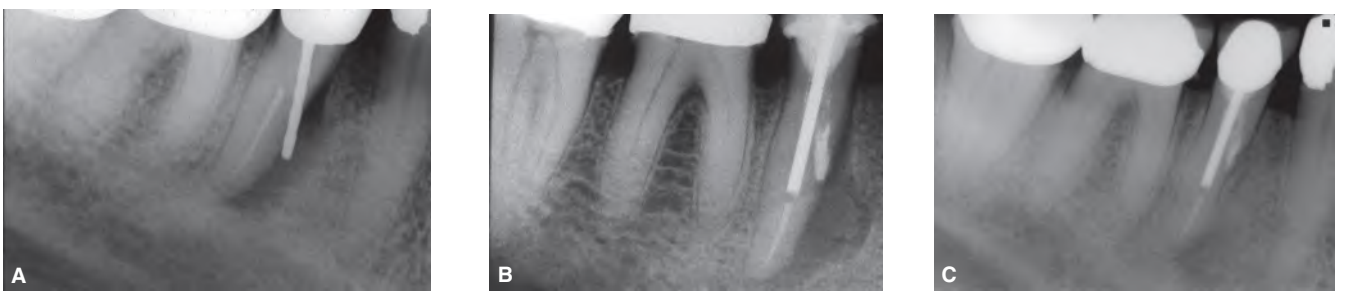

FIGURE 24-47 ***A.*** An off-center post has perforated the root and caused a bony lesion. ***B.*** Internal and external perforation repairs with MTA. ***C.*** Three years later, full resolution of the bony lesion is evident. (Courtesy of Dr. N. Chivian, West Orange, New Jersey, U.S.A.)

steps are followed as for the other areas that require surgical repair. If there is cortical bone covering the root surface coronal to the level of the mid-root repair site, there will be less chance of creating a chronic periodontal problem. A perforation located in the apical third of the root is treated surgically by removing that portion of the root apical to the perforation site and, if necessary, placement of a root-end filling.

The management of external root resorption lesions located apical to the cervical area will depend on whether the defect communicates or does not communicate with the pulp canal space. Those lesions that do not communicate with the pulp canal space will need to be corrected surgically in order to arrest the active resorptive process. The location of the resorptive defect on the root surface will be a key factor in determining if a successful surgical repair can be accomplished. If the lesion is located on the distal or the lingual surface of the root, it may be impossible to visualize and correct the defect from a surgical approach. In these situations, tooth replantation for a single-rooted tooth, root resection, or hemisection may be the only treatment choices if an attempt is to be made to retain the tooth. Otherwise, extraction may be the only option.

When these external resorptive defects are approached surgically, a full thickness mucoperiosteal flap is reflected, the bony window over the defect site is enlarged for visualization, the resorptive defect is curetted, and the site is repaired with MTA. If there is no bone covering the root surface coronal to the defect, a periodontal regenerative procedure may also be performed in conjunction with the corrective surgical procedure.

When an external root resorptive defect communicates with the pulp canal space or an internal resorptive defect communicates with the external root surface, a combination nonsurgical and surgical approach to treatment may be required. The first step in either of these situations is to cleanse and shape the root canal system and place an internal dressing of calcium hydroxide. At a subsequent visit, the calcium hydroxide is removed, the root canal is dried, and that portion of the root canal system apical to the perforating defect is obturated with an appropriate obturating material. The external portion of perforation defect is then packed with a matrix/barrier material, and the repair site is repaired internally. If it is impossible to adequately dry the root canal system so that root canal obturation can be performed or the external resorptive process remains active, then a combination treatment must be performed.

With a combination treatment, a mucoperiosteal soft tissue flap is reflected, the pathologic defect on the root surface is curetted, the root canal space can then be dried, and the portion of the root canal space apical to the defect can be obturated. The perforation defect on the root surface and into the root canal space is then repaired with an appropriate repair material. Another technique that has been suggested is to place a tight-fitting gutta-percha cone into the root canal space without sealer, repair the external defect, let the repair material set, and then remove the gutta-percha cone and proceed with the internal root canal obturation procedure. The inherent danger with this latter technique is that the compacting forces required to perform the obturation procedure may displace the external repair material. Once the soft tissue flap is sutured, the access opening is closed with a temporary sealing material. Any additional nonsurgical treatment can be completed at a subsequent visit after the soft tissue flap has healed. If there is an extensive bone loss over the external root surface, a periodontal regenerative procedure may also be required. If the defect is found to be so extensive that the root cannot be retained, one of the alternative treatment options noted above must be considered.

ROOT RESECTION

Root resection is the removal of one or more roots from a multi-rooted tooth (Figure 24-48). It is usually performed in maxillary molars, but can also be performed for mandibular molars. The indications for this procedure are presence of severe bone loss in a periodontally-involved root, untreatable roots with broken instrument, perforations, caries, resorption, vertical root fracture, and calcified canals in a multi-rooted tooth. The contraindications for root amputation are absence of sufficient bony support for the remaining root or roots as well as fused roots. After raising a sulcular flap without a vertical-releasing incision, root resection is performed by making a horizontal cut to separate the root from the crown. The crown remains intact and the remaining stump is gradually shaved to the buccal aspect of the root, resulting in good anatomic contour and hygiene.

HEMISECTION

Hemisection is the surgical division of a multi-rooted tooth into two segments (Figure 24-49). It is usually performed in mandibular molars, but can also be performed for maxillary molars. The indications and contraindications for this procedure are very similar to those for root resection. In mandibular molars, the tooth is divided buccolingually through the bifurcation. In maxillary molars, the tooth is sectioned mesiodistally through the furcation. After raising a sulcular flap without a vertical-releasing incision, hemisection is usually

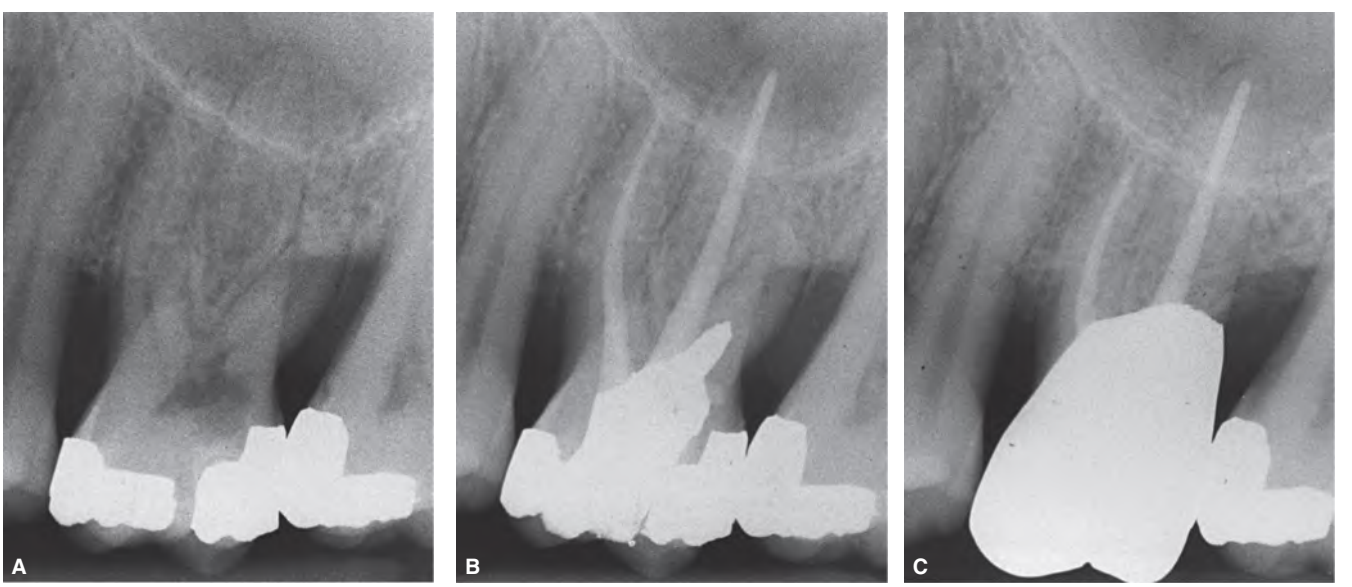

FIGURE 24-48 ***A.*** A severe bone loss around the distobuccal root of the first maxillary molar was noted. ***B.*** Root canal treatment was followed by an amalgam core extending 4 mm into the distobuccal canal. ***C.*** The root was resected and a crown subsequently placed.

carried out by making a vertical cut through the crown into the furcation. This action results in complete separation of the tooth in two segments. The unsalvageable root and its coronal segment are then removed (Figure 24-49).

BICUSPIDIZATION

This procedure is usually performed on a mandibular molar, making two bicuspids out of a molar that has severe bone loss or destruction in its furcation area (Figure 24-50). The indications for bicuspidization of mandibular molars are the presence of irreparable furcation perforation, furcation pathosis from a periodontal abscess, presence of buccolingual cervical caries, or a fracture in the furcation. The contraindications for bicuspidization are the presence of deep furcation, unrestorable crowns, absence of adequate bony support for roots as well as fused roots and presence of fused roots. After raising a buccolingual sulcular flap without a vertical-releasing incision, bicuspidization is performed by making a vertical cut through the crown into the furcation using a fissure bur. This procedure results in complete separation of the roots and creation of two separate segments similar to two premolars after restoration.

FIGURE 24-49 ***A.*** A mandibular second molar has a fracture across the distal marginal ridge extending to the midroot level. ***B.*** An amalgam core has been placed. ***C.*** A hemisection procedure has been completed and the distal root is ready for extraction. ***D.*** The mesial half of the tooth has been retained as a bicuspid to form an occlusal stop to prevent the extrusion of the opposing maxillary molar.

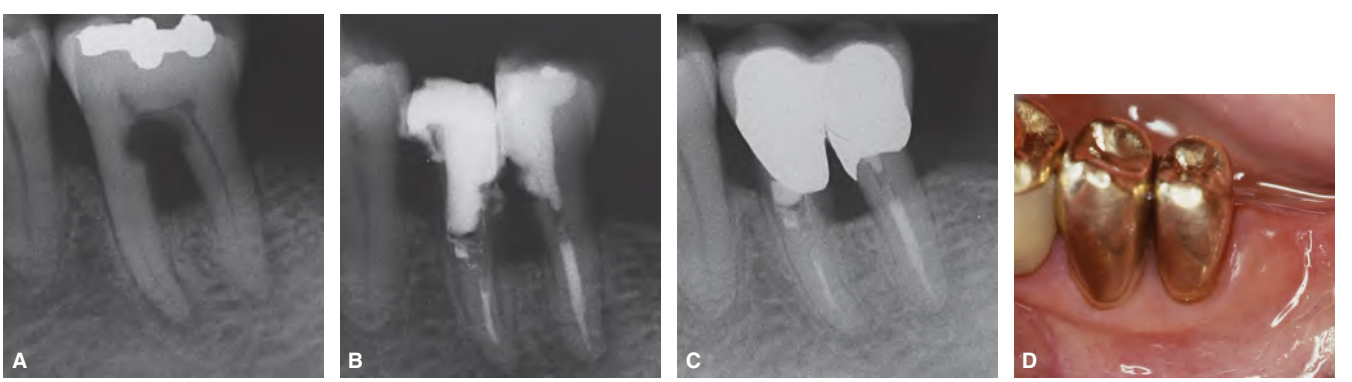

FIGURE 24-50 ***A.*** Caries in the furcation and furcal bone loss are evident in the mandibular first molar. There is adequate bony support for both roots. ***B.*** Root canal treatment and bur separation through furcation and crown. ***C.*** Restoration with a porcelain fused to metal crown splinting the two roots. ***D.*** Good gingival response at 30-month recall with no probing defects.

PROGNOSIS

Prognosis of teeth that have had root amputation, hemi section for bicuspidization varies according to the situation. If these procedures are performed correctly and the tooth is restored properly, the major factor affecting success is the patient's oral hygiene. The patient must be willing and able to perform extra procedures to prevent plaque accumulation. Failure to do so will result in the failure of the procedure.

TOOTH REPLANTATION

Tooth replantation involves extracting a tooth, correcting its deficiencies outside of the mouth, and replanting it into its original socket (Figure 24-51)[181]. The indication for this procedure is when an apical surgery is contraindicated as a result of patient medical conditions, proximity of anatomic structures such as the mental foramen or mandibular canal to the surgical site, and/or presence of thick bone. When properly performed this procedure is very successful. Torabinejad et al. compared the survival rates of replanted teeth with those of implant-supported single crowns.[180] Meta-analysis of current data revealed a weighted mean survival rate of 88% (95% CI, 81%–94%) for intentionally replanted teeth. Root resorption occurred in 11% of these cases. For more details, see Chapter 25.

TRANSPLANTATION

Transplantation is defined by extraction of an erupted, embedded, or impacted tooth from one part of the mouth into

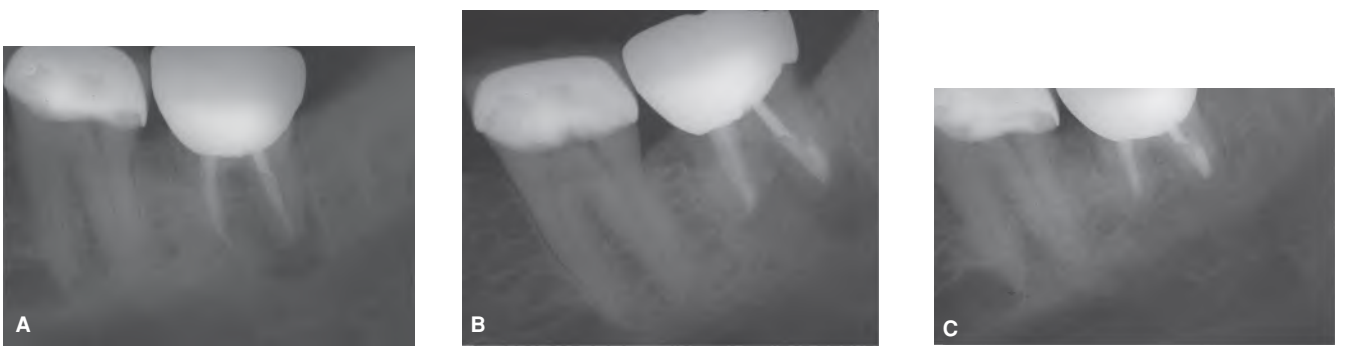

FIGURE 24-51 ***A.*** Preoperative radiograph of a second mandibular molar associated with symptomatic apical periodontitis. ***B.*** Postoperative radiograph of the tooth after replantation procedure. ***C.*** A follow-up radiograph two years after the procedure shows complete resolution of the periapical pathosis.

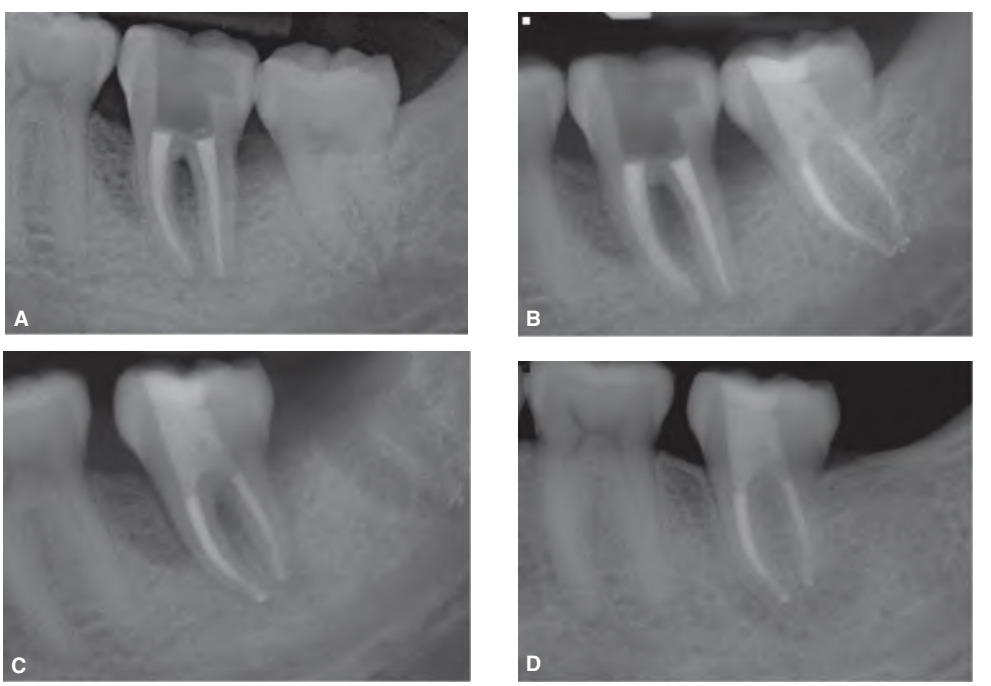

FIGURE 24-52 ***A.*** Preoperative radiograph of a second mandibular molar shows presence of symptomatic apical periodontitis and sever bone loss. ***B.*** Postoperative radiograph of the tooth after root canal treatment of the third molar. ***C.*** After auto transplantation of the third molar into the socket of second molar. ***D.*** A radiograph taken 46 months later shows complete healing of the periapical tissues around this tooth.

an extraction site or surgically prepared recipient site within the same individual (Figure 24-52).[181] Transplantation of a tooth has long been an acceptable treatment and is indicated for either a nonsalvageable or missing tooth.[182–184] Transplantation is contraindicated if the transplanted tooth is badly broken down, has inadequate bony support, is difficult to extract, and does not fit the extraction site. After extracting the unsalvageable tooth and preparing the socket for transplantation of a new tooth, the new tooth is extracted atraumatically with minimal damage to the periodontium. Its roots are resected, and Class I cavity preparations are prepared and filled with a root-end filling material outside of the mouth. The tooth is then replanted into its new socket. During the latter procedures, the tooth must be kept in moist gauze to prevent dehydration and necrosis of the periodontal ligament. When appropriately indicated and performed, autotransplanted teeth have a good prognosis.[184] Ankylosis and resorption are the most common causes of this procedure. Torabinejad et al.[181] compared the survival rates of autotransplanted teeth with those of implant-supported single crowns.[181] Meta-analysis of available data showed a weighted mean survival rate of 89% (95% CI, 81%–94%) for autotransplanted teeth.

Chapter 25

Intentional Replantation of Endodontically Treated Teeth

Stephen P. Niemczyk

The advent of the surgical operating microscope (SOM) heralded a new era in periapical surgery. In conjunction with innovative root-end preparation devices and root-end filling materials with enhanced biocompatibility, the specialty experienced a *renaissance* of possibilities previously unimagined. Difficult scenarios were somewhat less daunting, and the degree of precision offered more optimistic prognoses in most cases. Indeed, contemporary studies[1,2] demonstrate a sharp contrast of success rates when compared to those procedures performed a few decades earlier with traditional armamentarium and methods.[3] However, there remain instances where an *in vivo* approach would be deemed contraindicated. Anatomical considerations with regard to root angulations and positions, cortical plate thicknesses, and arch position may compromise the access and reflection of the selected site and jeopardize the surgical management of the root end. Preexisting conditions, either natural or iatrogenically induced, might exacerbate the situation; in this case a conventional surgical approach would be ill advised. Even with local factors notwithstanding, the physical or psychological health of the patient may contraindicate a protracted surgical intervention. It is in these clinical circumstances that the technique of intentional replantation (IR) represents a viable treatment solution.

References to the splinting and adornments of teeth can be found in the ancient Mayan and Egyptian cultures; however, the earliest recorded instructions detailing the extraction and replantation of teeth may be attributed to Abul Kasim (known as Albucasis in the West), the renowned Arabic surgeon of the tenth century. His treatise *Al-Tasrif* (*The Method*) was later translated into Latin as *De chirurgia*, distinguishing him as the first Oral Surgeon of note.[4] Several hundred years later the renowned French dentist, Pierre Fauchard, completed his epic work, *Le chirurgien dentist; ou, traité des dents* (The Surgeon-Dentist; or, Treatise on the Teeth), in which he describes the replantation and transplantation of teeth from one individual to another.[5] Intra-operative treatment of the tooth was both imaginative and innovative. Thomas Berdmore,[6] advocated filling the cavity of the extracted tooth with lead or gold prior to its reinsertion into the socket, and the English barber-surgeon, John Hunter,[7] proposed boiling the tooth to facilitate the removal of disease. This father of modern surgery was also a proponent of harvesting "scion" teeth (immature teeth from young individuals) for replantation in his adult patients, often having several "donors" in attendance. The teeth would be removed from sequential individuals until one, demonstrating the proper fit, could be inserted into the recipients extraction site! Although his attempts were more often than not unsuccessful, his intuitions and insights are prophetic when considered in the light of modern day medicine.

A more scientific examination of the procedure would occur almost two centuries later when assessing the role of the periodontal ligament (PDL) in re-attachment. Fredel and Scheff[8,9] noted, in their dog studies, that the absorptive (resorptive) process did not occur in teeth protected by the PDL (referred to as the periosteum). They surmised that the PDL was essential for the reunion of the tooth within its respective alveolus. In 1955, Hammer[10] reported that a viable PDL was instrumental in the re-attachment and reintegration of replanted teeth, with "an average 10 year life span expected when the replantation was accomplished in a technically flawless manner." In spite of these discoveries, the procedure was still considered either a by-product of a traumatic event[11] or a treatment option of last resort[12,13] due to the overwhelming incidence of ankyloses and root resorption. However, emerging technologies and a significant variation of the technique have minimized the two major complications of the replantation: tooth fracture and physiologic dehydration.

In its simplest terms, the IR could be thought of as a "Controlled Avulsion"; the forces exerted on the tooth, both in magnitude and direction, are more precisely regulated, and an extra-oral environment is created to maintain PDL viability. Although the level of evidence for this procedure in humans consists primarily of case reports,[14–16] controlled studies outlining the cause and effect on hard and soft tissues during the extraction and replantation are well documented in animals.[17,18] Extrapolation of these and other retrospective studies in the literature serve as treatment guidelines when establishing protocols for this procedure. Careful case selection and strict adherence to modified handling and replantation protocols will minimize the most prevalent complications of the IR: root fractures and resorptions. Finally, as with conventional microendosurgery, the IR is not meant to substitute for the nonsurgical treatment of infected canal spaces. Without adequate debridement and obturation to reduce the etiology, periapical healing may be delayed or inhibited.[19] In instances where conventional endodontic therapy has been rendered incomplete, or improvement of the existing intra-canal condition via retreatment is not attempted first, diminished success rates have been demonstrated.[20–23]

INDICATIONS AND CONTRA-INDICATIONS: TRADITIONAL AND CONTEMPORARY

Several investigators[12,24,25] set forth guidelines for IR, the majority of which were also indications for more traditional surgical corrections at that time.

Indications:

1. Unsuccessful endodontic therapy where endodontic retreatment is not feasible.
2. Failure to negotiate the canal completely, either because of calcifications or curvatures, or failure to adequately debride and obturate the canal spaces.
3. Presence of separated instruments or other iatrogenically introduced foreign objects (Figure 25-1).
4. Presence of a large post/core or other intentionally inserted prosthetic that cannot be easily removed.
5. Iatrogenic perforation or root resorption invading the canal space.
6. Gross overfill or root anatomy that is not conducive to conventional obturation methods (immature/blunderbuss apices).
7. Deciduous teeth. Here, IR is performed as a space maintenance operation (Figure 25-2).
8. Root fracture. Visual inspection can be performed, and the tooth replanted, if no fracture can be detected.
9. Presence of a large area of rarefaction, where root resection is not feasible.
10. Anatomical constraints and proximity to vital structures. This may include root apices that approximate the mandibular nerve or the maxillary sinus, and natural skeletal formations that would inhibit surgical access.
11. Patient declines an *in vivo* surgical intervention.

Several of these factors could conceivably overlap into indications for a surgical correction; the direction of the treatment would often be dependent on the skill of the operator, the degree of the correction, and the willingness of the patient.

Contra-indications:

1. Periodontal disease with marked mobility and/or furcation involvement.
2. Labial or inter-septal bone is missing.
3. Root curvatures that would precipitate fractures during the extraction.

The availability of the microscope and specialized root end instruments has dramatically expanded the realm of treatment possibilities. Therefore, a more valid listing of the indications[26] is reflected in the scenarios that are incontrovertible when contemplating an *in vivo* surgical approach, two of which persist even decades later:

1. Second/third molar root end surgery. The inclinations of the root apices, particularly of mandibular molar teeth, are often more lingual, requiring a deeper and more extensive osteotomy to uncover them.
2. Limited access due to anatomical structures, particularly skeletal. Overlying external oblique ridges and malar processes (Figure 25-3) can create retraction and access issues. Palatal approaches to the root apex in patients with a shallow vault could risk a vascular accident if misdiagnosed.
3. Medically compromised patient unable to safely endure a prolonged or involved *in vivo* approach. This is especially significant for those who are at risk due to cardiovascular disease or pulmonary compromise.
4. Patient noncompliance and refusal of a conventional surgical procedure.
5. Risk/presence of neural injury (Paresthesia).

These conditions establish boundaries for feasibility and safety from both the patient's perspective and the surgeon's preoperative assessment. Likewise, a pragmatic guide to the true contra-indications would include:

1. Severe periodontal involvement. The tooth presents with more than 2+ mobility and/or is depressible into the socket.
2. Extensive caries that is clinically detectable at or below the osseous crest.
3. Extensive loss of cortical/septal bone.
4. Difficult or impossible nonsurgical extraction.

Maintenance of the bone and other supporting/attachment structures are of paramount importance to the success of the IR procedure. Compromising the soft tissue response because of chronic periodontitis can potentially inhibit reattachment to the socket. If the level of hard tissue is diminished secondary to a crown lengthening or surgical extraction window, critical support post extraction is lost, and the replanted tooth may require more involved prosthetics to secure retention.

Case Selection and Armamentarium

Critical assessment of root anatomy of the proposed tooth is essential to affect delivery from the socket without overt stresses that could precipitate a partial or complete fracture. This is the overwhelming complication of this procedure, and is a significant condition in the informed consent. The initial appraisal is performed with radiographs from several angles, but is limited by its two-dimensional representation. A far more accurate appraisal is accomplished by obtaining a cone beam computerized tomography (CBCT).[27,28] Not only are root length and widths more accurately measured, but the degree and direction of curvatures present are immediately apparent and appreciated. For more details, see Chapter 9C.

The "Virtual Extraction"™ can be planned with regard to application of force and delivery direction, with a preview of the possible obstructions that could hinder an efficient and successful removal of the root from the socket (Figure 25-4).

Factors to consider when planning the extraction are:

1. ***Tooth (root) length/width***. The longer the root, the greater the force required to begin the luxation motion and sever the PDL. This is also true with root forms

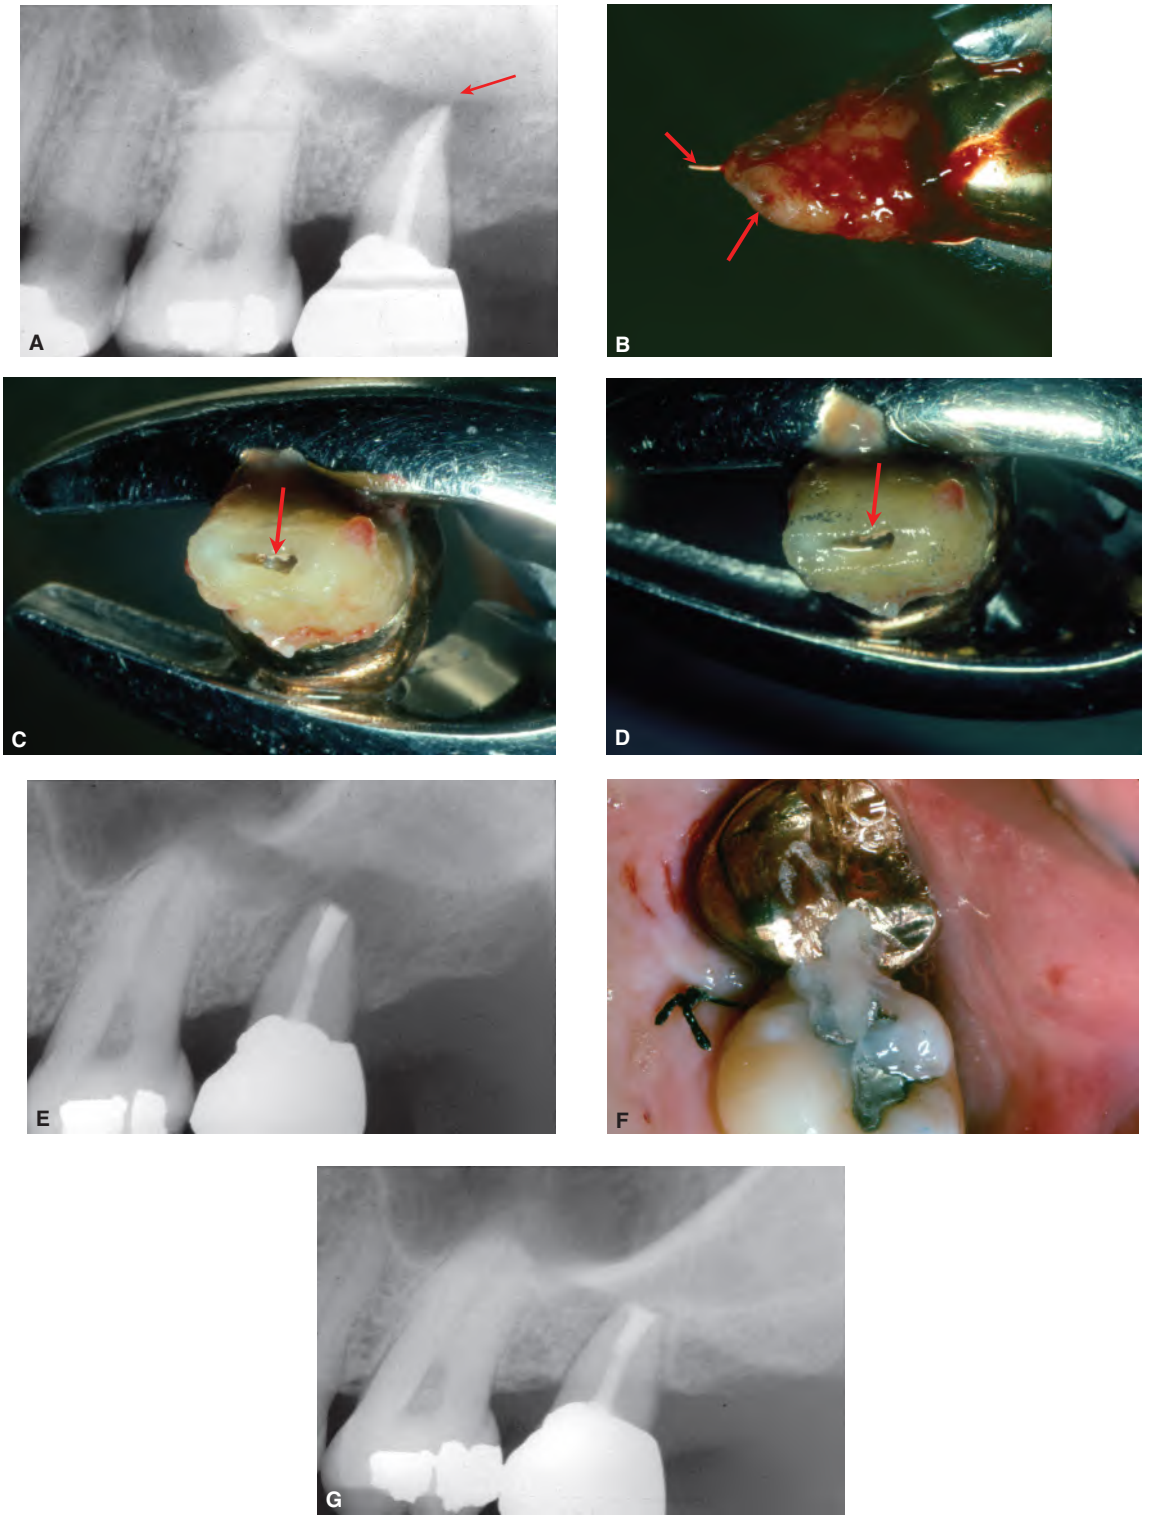

FIGURE 25-1 Intentional replantation of a maxillary left second molar with canal obstruction. ***A.*** Preoperative radiograph. A titanium carrier (Thermafil, Tulsa Dental, OK) was used to obturate the canal space, and was not retrievable. There is evidence of a small overextension of filling material (arrow), and a large periapical radiolucency. ***B.*** Extracted tooth in the forceps prior to placement in the basin. Note the overextended gutta-percha point and the titanium carrier protruding from the apical foramen (arrows). ***C.*** The root end after resection. Some of the gutta-percha has been removed from around the carrier, disclosing a large isthmus between the two canals. This "ribbon" configuration began in the pulp chamber and continued to the apical foramen (arrow). ***D.*** Root-end preparation was achieved using a small (#1) round diamond bur to sever the titanium carrier in the canal space (arrow). A conventional carbide would cause excessive vibration on the titanium, possibly fracturing the tooth. ***E.*** The tooth immediately after replantation. ***F.*** The tooth was stabilized with an acid-etched composite splint between the adjacent marginal ridges. A 4/0 silk suture coapts the mesial papilla. The splint will be removed in 14 days. ***G.*** Four-year recall radiograph showing complete healing. The tooth was asymptomatic and functional.

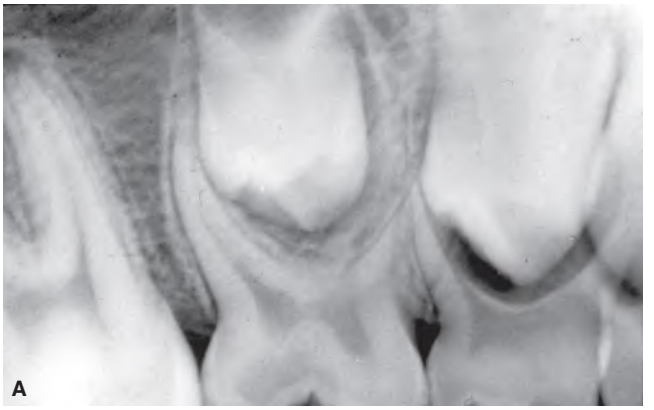

FIGURE 25-2 Intentional replantation for space maintenance in a maxillary right second deciduous molar. ***A.*** A large carious lesion compromised the pulp. The tooth is required to maintain the space for the developing permanent successor. Patient behavior prevented normal restorative treatment. ***B.*** The excess curvatures will be resected away to ease the replantation. The tooth will be accessed, and the pulp chamber and canals filled with Zinc Oxide Eugenol cement. ***C.*** The tooth has been replanted. Root resorption is common, and any materials introduced into the canal system should allow for that event. (Courtesy of Dr. Israel B. Bender, Philadelphia, PA, U.S.A.)

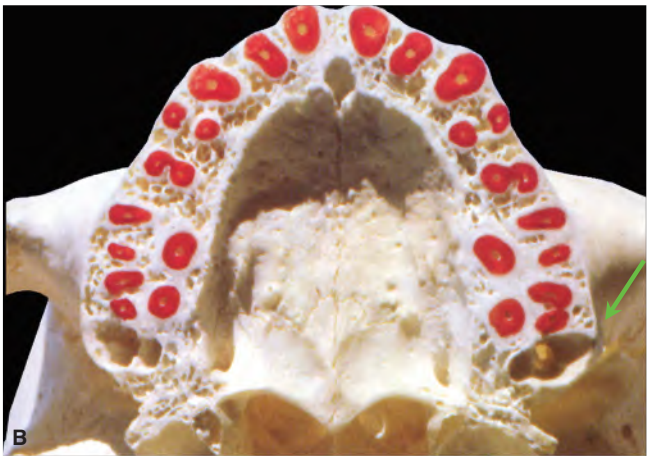

FIGURE 25-3 ***A,B.*** Adequate access to root end structures can be inhibited or prohibited by the overlying skeletal anatomy. In the mandible, the external oblique ridges (red arrows) effectively thicken the width of the buccal cortical plates from the distal root of the first molar to the third molar. This dramatically increases not only the extent of the osteotomy required to reach the root-end, but also the depth the bur must extend to complete the resection operation (black arrow). In the maxilla, the malar process of the zygomatic arch, combined with the restriction of the overlying soft tissues, presents a considerable challenge to a buccal surgical access in the second and third molar sites (green arrows).

that are wider buccal-lingually than mesial-distally. The areas of the root surface most prone to resorption postoperatively are the convex surfaces subject to these luxation motions.[29] Minimizing these forces is the key to reducing this postoperative complication. Conversely, roots that are long and thin have a greater chance of fracturing during the luxation phase of the procedure.

2. ***Root curvatures***. Although there are no "arrow straight" roots, if the curvature is gentle and, in multi-rooted teeth, if they all curve in the same direction, then a single path of draw can be directed from the socket. If the curvature is too severe, or abruptly dilacerated (Figure 25-5), the chances of separating the root at the apex of the

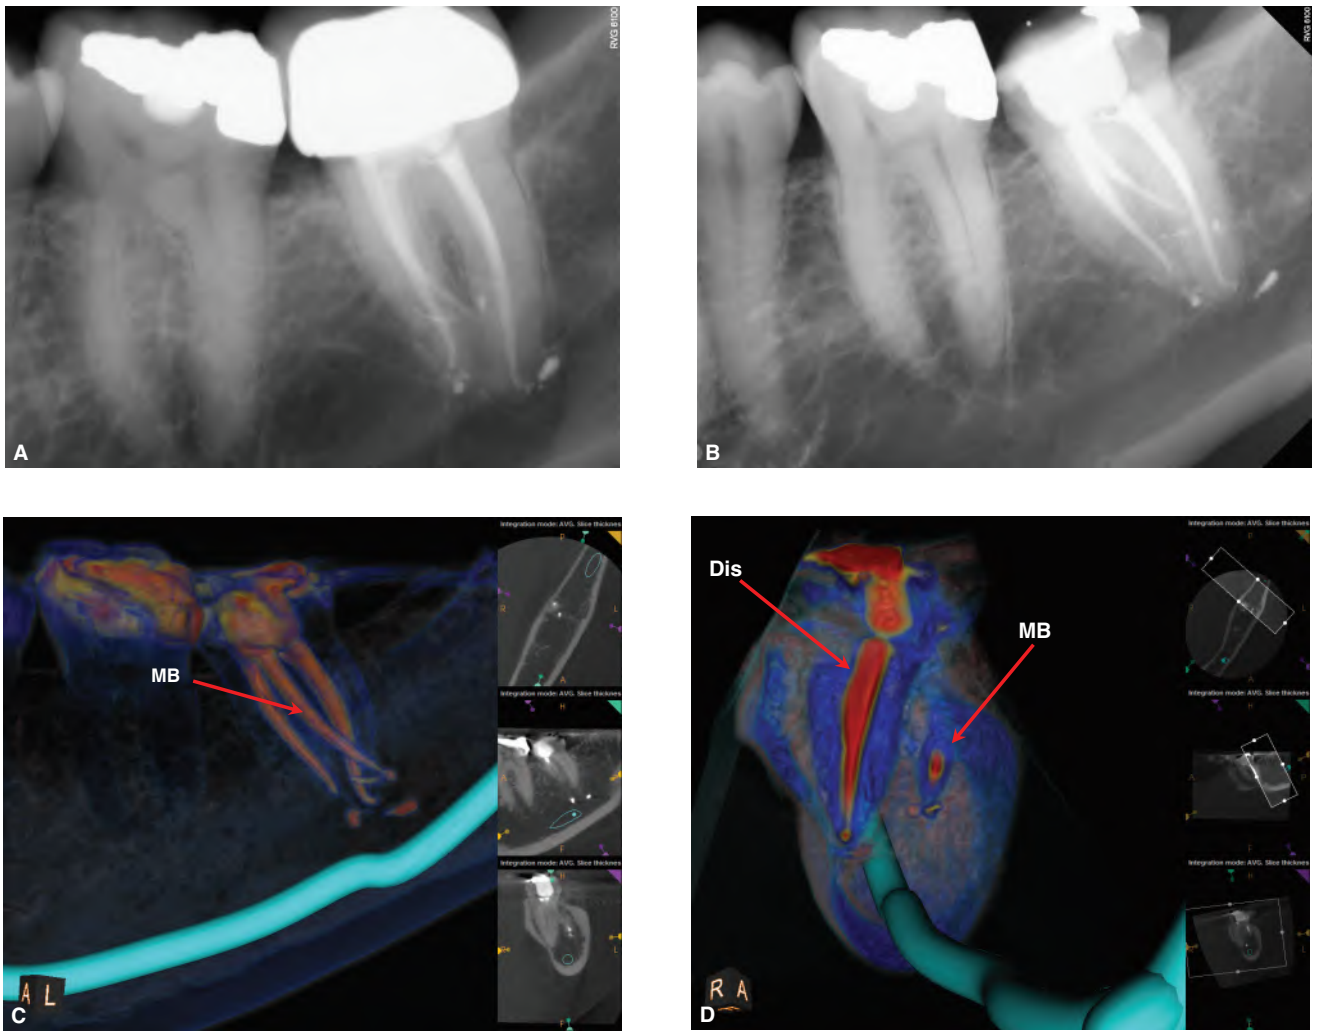

FIGURE 25-4 The inability to accurately assess the clinical environment with conventional radiographs is dramatically demonstrated in this case series. The patient presents with the chief complaint of sensitivity to biting, the onset being the completion of the endodontic treatment. A clinical examination revealed no evidence of deep periodontal probing or vertical fracture, and percussion and palpation findings were within normal limits. ***A.*** Postoperative radiograph from 2011 reveals the presence of several small extrusions of sealer from the apices of the mandibular left second molar. ***B.*** Radiograph taken prior to the patient receiving a new crown in 2014. The extruded material has not resorbed. ***C.*** The MB root is a separate root, coursing more distal and buccal than the main root form. There is no overt periapical pathology, but small extrusions of material are present. The material is not in the mandibular canal. Any foreign body is ordinarily removed via curettage, but the overlying bone thickness measures 11.5 mm to the distal root apex (nearly one-half inch). ***D.*** The excavation would be further complicated by the location of the MB root centered in the proposed osteotomy, itself 5.5 mm below the surface of the cortical plate. Access to the periapical extrusions could be realized during an IR procedure, but the atypical root anatomy presents a considerable challenge to an atraumatic extraction, and needs to be addressed during the informed consent.

curvature are high and should be anticipated. This effect is magnified in multi-rooted teeth, where divergent roots, especially in maxillary molars, hamper the safe extraction. Convergent root forms present a similar dilemma, but if the inter-radicular bone is absent, it may not pose a problem. Even if there is bone between the roots, it is a relatively small amount in terms of area. It may be spontaneously fractured during the extraction and delivered with the tooth without consequence.

3. ***Periradicular lesions and mobility***. It would seem advantageous to have some mobility associated with the selected tooth. However, if the mobility is due to absence of adequate cortical plate(s), then the tooth may be too periodontally compromised to be considered for replantation. Periapical lesions will oftentimes be attached to the extracted root, eliminating the need for periapical curettage. Radiolucent areas alongside the root surface, especially when accompanied by deep, discreet probing depths, are highly suspicious of vertical root fracture, and should be examined postextraction with great diligence until proven otherwise.

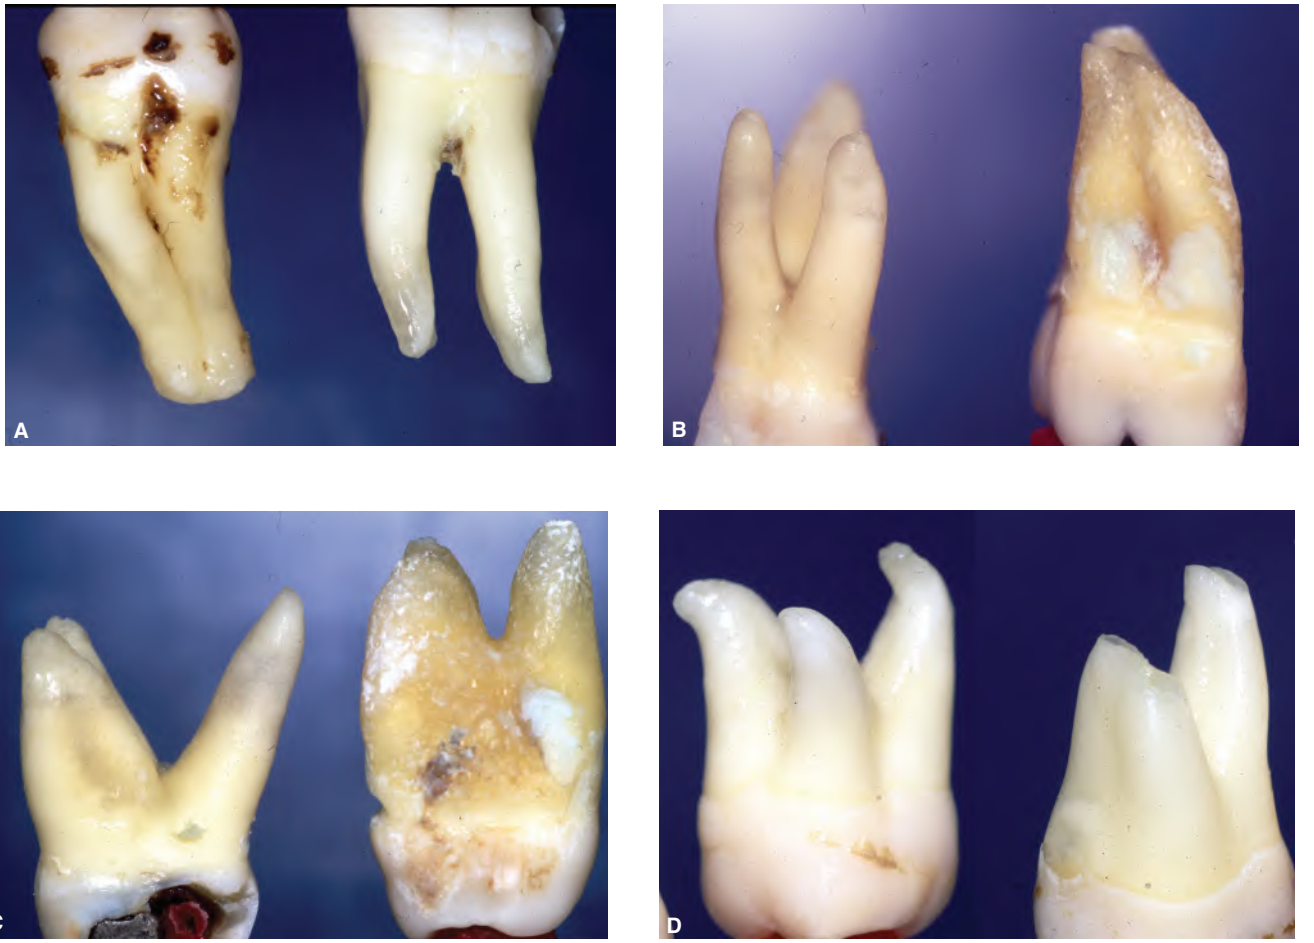

FIGURE 25-5 Root configurations and curvatures play a significant role in the success of the extraction. ***A,B.*** When the roots are fused (left tooth in A, right tooth in B), the extraction may be less complicated. Surface invaginations and concavities provide a positive index for replantation and resistance to exarticulation. The exception to this is when there is a partial fusion, with the apical segments joined, but the furcation separation is intact. In those instances, if there is significant bone through the furcation, conservative extraction without hemisecting the two roots may be impossible. ***C.*** When the root curvatures are mild, and have a similar orientation and direction, the tooth can be delivered along the appropriate path of draw. However, if the roots are widely divergent (left tooth), then fracture of either the root(s), cortical plate(s) or both is likely to occur. ***D.*** When the root-ends are severely dilacerated, fractures often occur at the angle of the dilacerations. The level of the fracture frequently coincides with the planned level of the resection (right tooth). Nevertheless, the orphaned root tip and any associated pathology must be delicately and completely harvested from the socket. Failure to do so may result in persistent periapical inflammation and incomplete replantation. Postoperative stabilization of multi-rooted teeth is generally a minor concern, even for teeth with fused root forms.

The armamentarium for IR is simple and readily available (Figures 25-6 and 25-7):

1. ***Emesis basin***. Once the tooth is delivered from the socket, it will be submerged in a basin containing a tissue culture solution. This basin should be deep enough to accommodate the forceps containing the tooth, while being compact enough so as to not be unwieldy. The stainless steel emesis basin satisfies the requirements of strength, utility, and sterility.
2. ***Nonairstream high-speed handpiece***. The Impact Air™ (Palisades Dental, South Hackensack, NJ, U.S.A.) has a liquid only stream that bathes the bur when activated. The drive air is exhausted through the back of the handpiece, minimizing the overspray during the resection of the root under the fluid surface in the basin. There are similarly configured handpieces from other manufacturers, and they are equally suitable if they satisfy the criteria outlined above.
3. ***Forceps***. The traditional extraction forceps, of the pattern appropriate for the selected tooth, were until recently the only instruments available for removal of the tooth. In 2003, the Physics Forceps™ (Golden Dental Solutions, Detroit, MI, U.S.A.) (Figure 25-7) was introduced and allows for a less traumatic delivery of the tooth. It utilizes first-class lever mechanics, with one jaw functioning as a bumper-fulcrum and the other as an elevating arm. Once correctly positioned, minimal effort is required to elevate the tooth 2–3 mm from the socket. The tooth is then delivered from the socket with a different transfer forceps. If executed properly, there is minimal damage to the PDL, and the cortical plate remains intact.

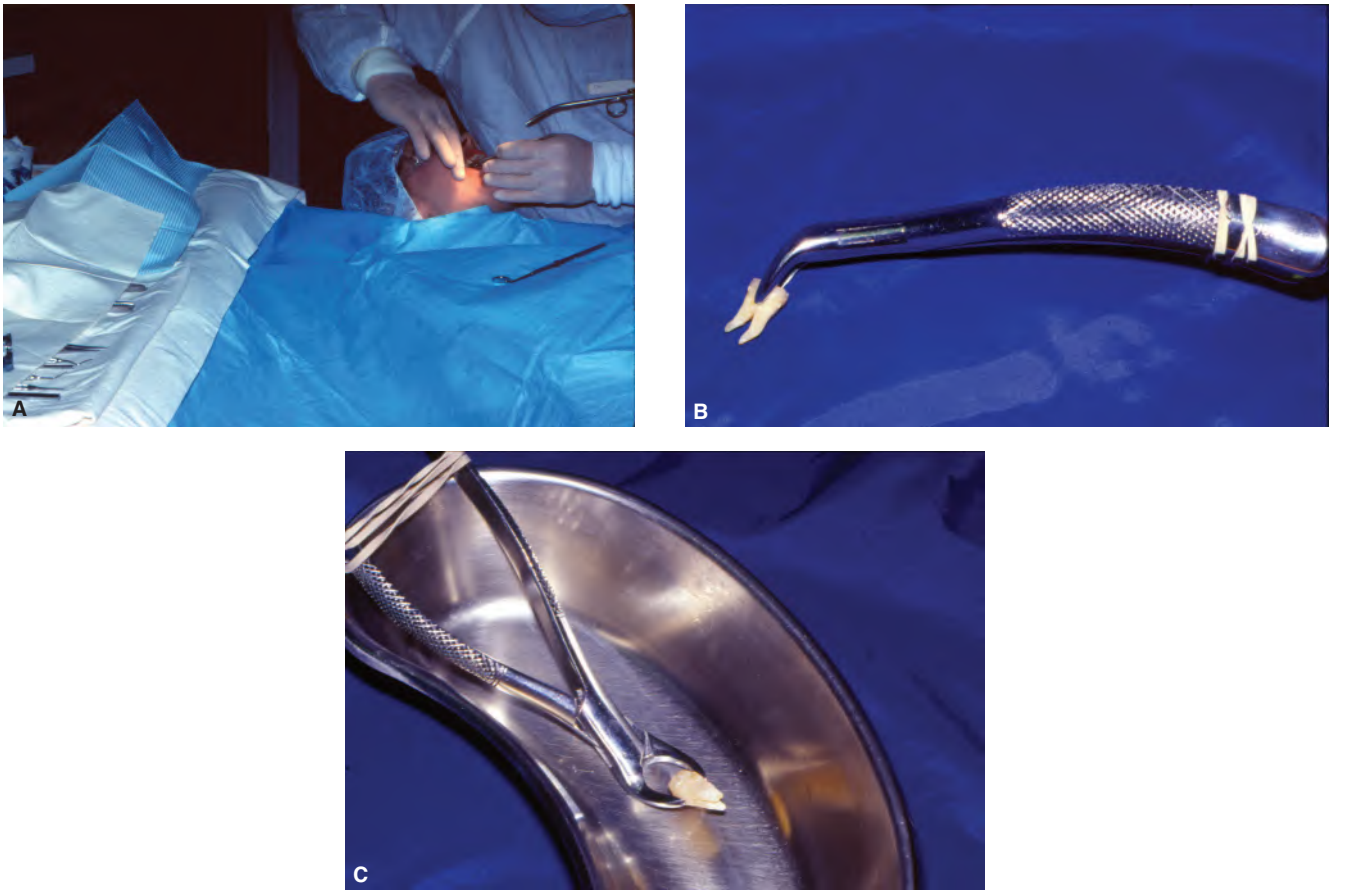

FIGURE 25-6 Preparation for IR procedure. ***A.*** A sterile field is secured from the extraction site side of the jaw to the adjacent mobile surgical table. This will safeguard the asepsis of the tooth if it dislodges from the transfer forceps during delivery to and from the operating table. ***B.*** Once the tooth is mobile enough to be removed from the socket, a transfer forceps (the pattern will be dictated by the tooth location) is gently adapted to deliver the tooth from the extraction site. The beaks of the forceps are coronal to the attachment tissues, and a sterile ligature band is wound around the handles to exert a mild closing pressure on the crown of the tooth. This makeshift hemostat allows the forceps to secure the tooth without the clinician having to actively squeeze the handles together. ***C.*** The forceps with the tooth is placed in the emesis basin containing HBSS, fully submerging the tooth beneath the surface of the fluid. Once safely in the solution, the tooth can be repositioned in the forceps beaks for improved access and manipulation. The basin can also be repositioned and tilted slightly for surgeon's comfort and ease of access, then stabilized with in this new position with sterile towels.

Modified IR Technique

The keystone to any replantation, intentional or posttraumatic, is the maintenance of the PDL cell vitality on the root surface. Both the extra-alveolar time period and the manner in which the tooth is stored or transported are critical in the preservation and regeneration of these cells.[30] If the PDL becomes desiccated secondary to dehydration, or the structure of the cells is distorted while in the incorrect storage environment, ankyloses and root resorptions are a likely scenario.[31-34] Traditionally, isotonic saline was considered the fluid of choice for the hydration of the root surface during replantations,[35-37] either dripped onto the root surface or soaking the gauze containing the extracted tooth. The rationale was the osmolality comparable to that of the PDL cells. It also prevented the air drying of the root surfaces. However, because saline lacks any nutritional benefits, it fails to sustain the healthy metabolism of the periodontal fibroblasts,[38] with marked reduction in cell viability after prolonged storage.[39] For the aforementioned reasons, the recommendation was to complete the *ex vivo* surgical procedures as rapidly as possible, replacing the tooth in the alveolus within 5–10 minutes. Unless the surgical staff was well orchestrated in the procedure, the time constraints could induce procedural mishaps and anxiety for both the surgeon and patient.

In 1983, an animal study[40] compared post replantation resorptions in monkey teeth when stored in either milk or saliva. It was found that teeth stored for up to six hours in milk demonstrated healing patterns similar to teeth that were replanted immediately (little or no ankyloses or resorptions). This, and a previous study by the same investigators,[41] inspired a search by the chapter's author to find a more physiologic replacement for saline in the IR procedure. Several laboratory tissue culture solutions were considered, selecting the sterile Hank's Balanced Salt Solution (HBSS) with phenol red indicator (Life Technologies, A Thermo Fisher Scientific Brand, Grand Island, NY, U.S.A.). This solution contains the essential metabolites to support cell survival including D-glucose, calcium chloride, and magnesium

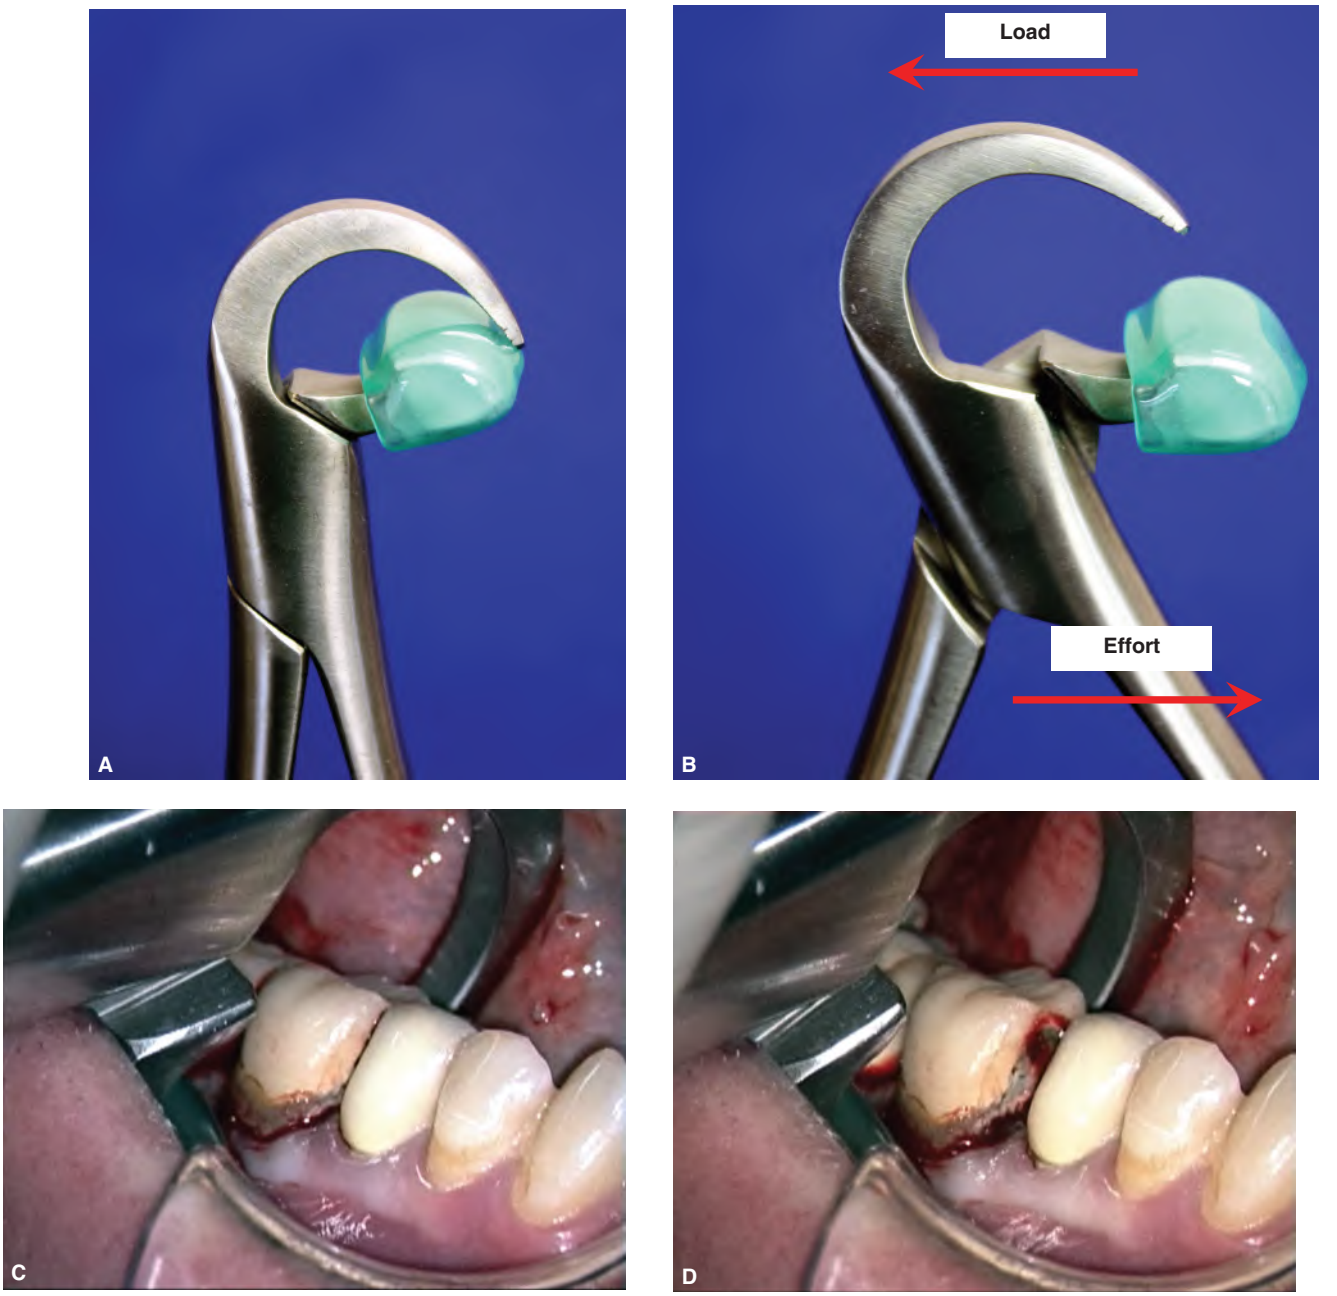

FIGURE 25-7 The Physics Forceps is available in a wide range of patterns and applications, specific for tooth and jaw location. The device employs first class lever mechanics, where the fulcrum is between the effort (handles) and the load (tooth surface). ***A.*** The assembled forceps. ***B.*** The fulcrum, or bumper, is covered with a disposable silicone bumper guard. When the force is applied in one direction, the beak exerts an elevating force in the opposite direction, extracting the tooth. ***C.*** Clinically, the bumper is placed at the mucogingival junction of the tooth to be extracted, and the beak engaged on the opposite side of the tooth above the periodontal attachment by closing the handles. The handles of the forceps are then rotated a few degrees until resistance is felt; the rotation stops, but the pressure is statically maintained. Shortly, the fibers of the PDL begin to separate, and a small hemorrhage may form in the sulcus. ***D.*** The handles are then rotated a few more degrees, until the tooth has moved 1–3 mm in the socket. The forceps are disengaged, and the tooth can be delivered from the socket into the emesis basin.

sulphate anhydrous. It demonstrates both the ideal pH (7.4) and osmolality range (280 mosmol kg^{-1}), and can maintain this preservation environment for up to 24 hours with replenishment.[42-44] (Note: the phenol indicator is used to signal depletion of the metabolites in solution; the abbreviated time frame of the procedure does not warrant this feature, so HBSS without the phenol red is the preferred solution.) Continuous immersion of the extracted tooth in this solution supported the safe expansion of the extra-oral treatment window. This allowed for a more careful scrutiny of the root surfaces and, by extension, greater precision in the diagnosis and root end treatment. In a clinical teaching setting, this "time buffer" enables the clinician to carefully execute the procedure and develop the proper skill set.

This modification to the traditional IR procedure was implemented in the private practice setting, and the results were debuted in 1993 as part of a microsurgical course. It was subsequently presented in 1994 at an international specialty conference in Philadelphia.[45] Since then, dozens of articles and case reports have been generated using this tissue culture solution for IR, with remarkable degrees of success. Subsequent research comparing HBSS to other media for storage and transport has confirmed its superiority with regard to biocompatibility, cost, and availability.[46-48] The following section will detail the new protocols using HBSS.

The technique consists of six stages (Figure 25-8):

1. Prophylaxis
2. Anesthesia
3. Luxation/Delivery
4. Evaluation
5. Root-End Resection/Filling
6. Replantation

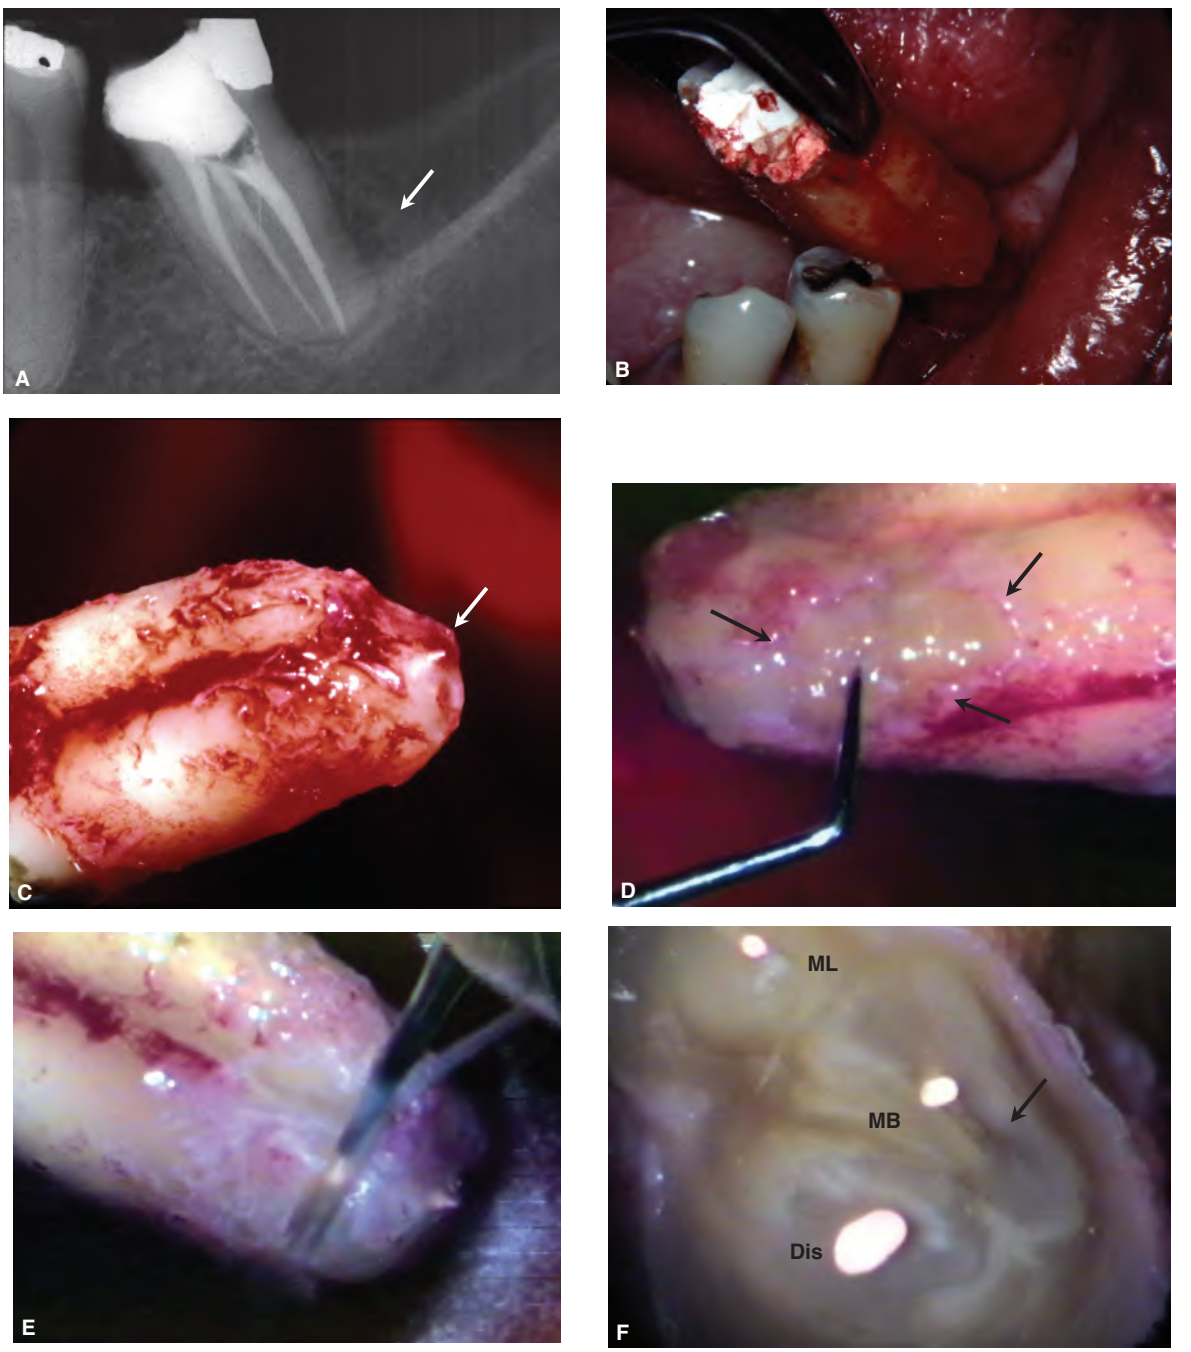

FIGURE 25-8 (*Continued on next page*)

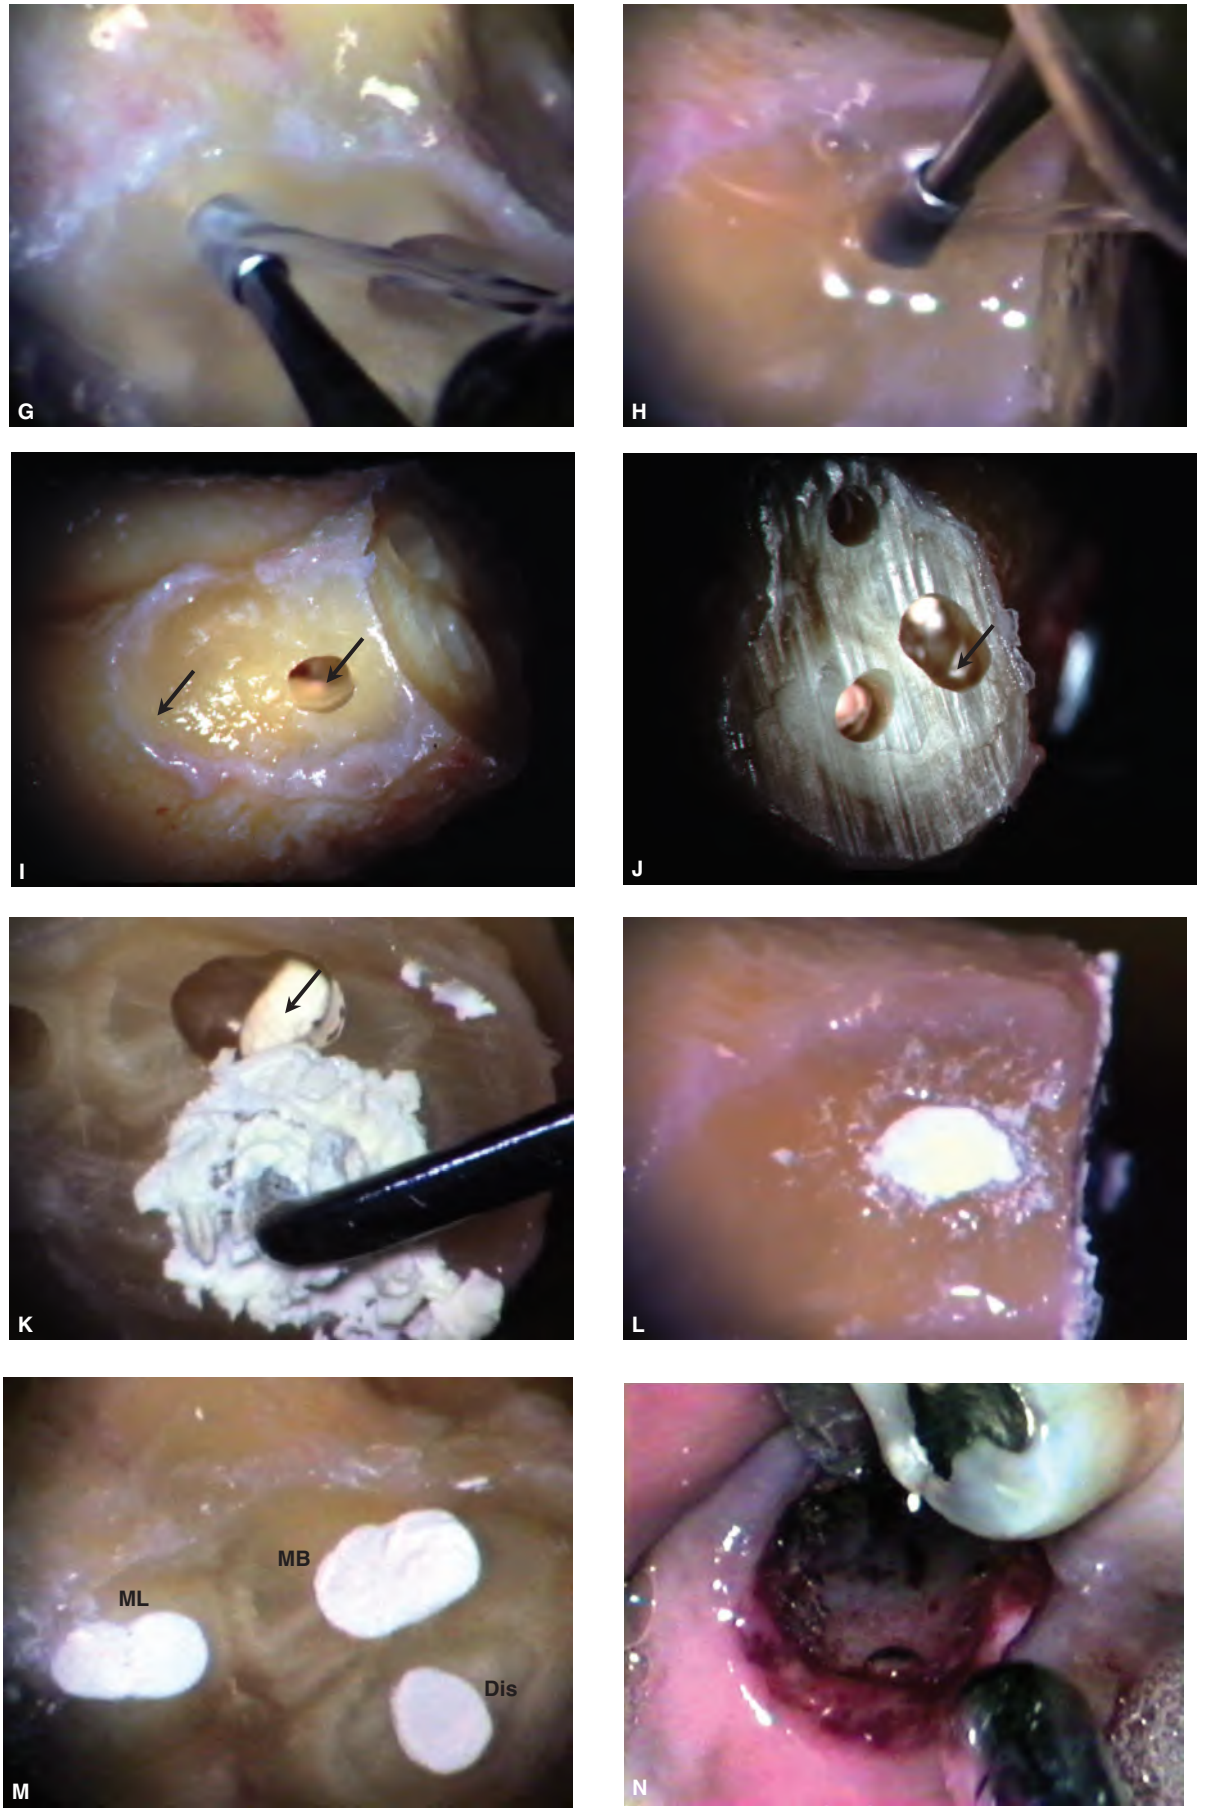

FIGURE 25-8 (*Continued on facing page*)

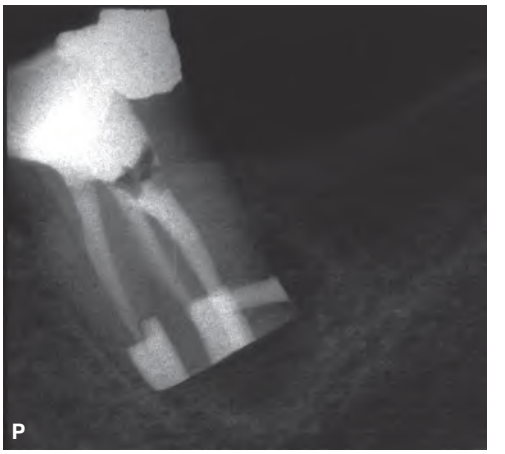

FIGURE 25-8 Step-by-step IR of a mandibular left first molar. ***A.*** Preoperative radiograph. Note the lesion at the distal aspect of the distal root (arrow) indicating possible presence of a lateral canal. ***B.*** The tooth is removed from the socket, and delivered to the basin containing the HBSS. The socket will be flushed with saline, and a sponge placed over the opening. ***C.*** The root is carefully examined in all aspects, noting any fractures, lateral canals, lesions or other anomalies. The overextended gutta-percha can be seen protruding through the apical lesion (arrow). The tooth is kept submerged during these, and all subsequent, observations and procedures. ***D.*** A low power view of the distal aspect of the distal root reveals the presence of a large lateral canal. Note the withdrawal of the PDL from the vicinity of this canals' foramen (Explorer tip). ***E.*** The tooth is positioned so that the root is horizontal and just below the surface of the HBSS. Resection of the root is performed with the root submerged in the fluid. The amount to be removed will be dictated by usual surgical protocols. ***F.*** A high power view of the resected surface reveals a "C shaped" anatomy, with an isthmus extending from the MB canal towards the distal root. The root-end preparation of the MB root will need to include this isthmus and any connections with the distal canal. ***G.*** The ML canal is being prepared using a #330 bur. The distal and MB canals have already been prepared; the MB preparation can be seen behind the fluid stream. All the preparations are 3 mm deep, prepared in the long axis of the selected canal. ***H.*** Preparation of the lateral canal, using the #330 bur. It was prepared to the same depth (3 mm) and centered on the long axis of the canal. Note the denuded root surface corresponding to the lack of PDL and cementum. ***I.*** Low power view of the relationship of the lateral and apical root end preparations. Note the PDL "halo" and the hint of gutta-percha in the lateral canal. ***J.*** High power view demonstrates the proximity of the MB and distal preparations. The communication can be seen at the depth of the preparations, as well as the communication with the lateral canal. ***K.*** Compaction of the root-end filling material (ZOE) into the distal canal resulted in extrusion of the ZOE into the base of the MB preparation; further evidence of the communication. The remaining apical root-end preparations were filled in a similar manner. ***L.*** Compaction of the root-end filling material in the apical preparations resulted in the extrusion of the material from the lateral canal; the excess was carved to the cavosurface and removed. ***M.*** The root end fillings were examined for extent and finish, with the excess removed prior to replantation. ***N.*** The sponge overlying the socket is removed, and the alveolus is thoroughly rinsed with saline or HBSS. This is done to remove any occult blood clots and present a fresh, bleeding surface on the bone. The surrounding gingival tissues are also swabbed with CHX prior to replantation of the tooth. ***O.*** The tooth is replanted, and the soft tissues gently readapted to the cervical portion of the tooth. The replantation position is verified radiographically and, if complete, the tooth is splinted (if required) and the occlusion checked before dismissal. ***P.*** Immediate postoperative radiograph. The radiolucent areas correspond to the resection space and the lateral lesion. ***Q.*** Nine-year postoperative recall radiograph demonstrates complete healing. The tooth is asymptomatic and functional.

Prophylaxis

Antibiotic premedication is prescribed when dictated by the patients' medical history, particularly if there are cardiovascular or prosthetic concerns. The most current recommendations and guidelines can be obtained from the American Heart Association (AHA) and American Association of Orthopaedic Medicine (AAOM) websites. Postoperatively, antibiotics are not routinely required unless a graft has been placed to augment the postreplantation support, or the rupture of a periapical lesion during the extraction occurs within the socket. In this case, a transient bacteremia may result, and antibiotic coverage for three to five days would be prudent.

Nonsteroidal anti-inflammatory drugs (NSAIDs) and/or analgesics, if not contraindicated, are recommended per os prior to the surgical procedure. In concert with the administration of a long-acting local anesthetic, preoperative administration of these drugs has been shown to minimize the inflammatory response and increase patient's comfort postoperatively.[49-51]

Chlorhexidine gluconate 0.12% (CHX) rinses are prescribed starting 24 hours prior to the replantation appointment, and continuing for the 14-day-postoperative period. This has been shown to minimize microbial contamination on the sulcus from plaque on the replanted tooth and on surrounding teeth.[52] This will also augment the local oral hygiene care, as the patients will be prohibited from brushing or flossing the involved areas until reattachment can be confirmed.

"Legal Prophylaxis" or informed consent for this procedure should contain all the elements normally found in the presurgical documentation, with particular emphasis concerning tooth fracture during the extraction, and postoperative re-attachment/resorptive complications. In the author's experience, most patients declining a conventional *in vivo* surgical correction elect, instead, to have the tooth extracted. In these instances, where patients have already resigned themselves to the loss of the tooth, an offer is made to extract the tooth for them. If the tooth can be removed without fracture, and the etiology of the periapical disease identified, the surgeon will perform the required root end procedure and replant the tooth. The rationale for the procedure is explained as a corollary to the accidental loss of a tooth by trauma, and the success of those replantations. It is also justified when the exarticulation force will be well controlled, and the tooth is not subjected to microbial contamination and desiccation effects, reducing the postoperative resorption potentials. Conversely, if the root does manifest a previously undisclosed irreparable condition (i.e., extensive root fracture), then the tooth should be safely removed, and appropriate socket preservation methods implemented. Offered this choice, nearly all patients will acquiesce and decide to give the tooth "one more chance"!

Anesthesia

The route of administration of the anesthetic for this procedure should not differ from a standard surgical protocol, that is, block or regional infiltrations, with the exception of interligamentary injections. Placement of the needle tip onto the coronal root surfaces could exert a physical disruption of the cementoblast layer already predisposed to resorption from the extraction forces.[29] The action of the locally pressurized injection will precipitate a temporary disruption of the microcirculation, with potential damage to the affected tissues, particularly the PDL.[53] Instead, a trans-osseous delivery (Stabident™) should be considered. Following the manufacturers' directions for use with regard to placement of the trephinating tip and rotational speeds, one carpule (1.8 ml) is all that is usually required to achieve the desired anesthetic effect.[54] Caution should be exercised with selection of the anesthetic for this administration route, as there will be transient systemic effects (tachycardia, cardio-pulmonary) due to the intraosseous nature of the injection and the microcirculation of the bone. Larger volumes of anesthetic with higher vasoconstrictor concentrations are contraindicated in those patients at risk for anticipated systemic reactions.

The choice of anesthetic type will also be similar to that of the surgeons' standard protocol, with the recommendation being one with extended duration. In combination with preoperative NSAIDs/analgesics, the use of a long acting anesthetic (bupivacaine, Marcaine™) has been determined to dramatically reduce the incidence of postoperative discomfort for the patient by delaying the onset of peripheral sensation.[55,56]

Finally, the opportunity for "vocal anesthesia" presents itself while awaiting the onset of the injected drugs. The procedural steps are outlined, with reiteration of the possible complication of root fracture but, moreover, to reassure the patients of their choice of the IR and confidence in the procedure. During the actual *ex vivo* surgical manipulations, the microscopic images are broadcast onto a video monitor while the patient is sitting upright and watching the screen. Oftentimes, patients will ask questions about what they are viewing, forgetting for the moment that this is their tooth on the screen. If there is a fracture present, they can visualize it firsthand. If the root repair is taking place, they gain an appreciation for the precision and elegance that is required. For the patient, it is truly a unique and an "out of body" experience!

Luxation/Delivery

The patient is reclined and draped with a sterile field that extends from the site of extraction to the table/cart where the operative procedures will take place. This is to insure that if the tooth dislodges from the forceps beak during the transfer from the patient to the basin, it will be captured on a sterile surface and can be retrieved without consequence. The tissues surrounding the extraction field are swabbed with CHX and the excess suctioned away. The coronal gingival attachment is severed circumferentially to the alveolar crest either with a small microblade or sharp periosteal elevator. The gingival tissues are carefully reflected to the depth of the sulcus, and the beaks of the selected forceps are adapted on the buccal (facial)/lingual (palatal) aspect of the crown, always mindful to keep the beaks away from the cementum surfaces.

The choice of forceps pattern will be dictated by the tooth type, location, and available coronal tooth structure. Limiting the adaptation to the level of the CEJ, or just slightly apical to that margin, will assure the safe occlusal-apical dimension and thus prevent a crushing force on the cementum during the exarticulation. The forceps are then used to exert a gentle buccal-lingual motion, slowly expanding the alveolus and allowing the PDL fibers to separate within the socket. Every effort is made to avoid undue force, so rapid rocking motions are too forceful and contraindicated.

Minute hemorrhages from the sulcus, in addition to decreased resistance to the forceps motion, signal the imminent delivery of the tooth from the socket. The extraction process is paused, and a different forceps is applied to the crown to secure the tooth from the extraction site to the emesis basin. These forceps have a sterile ligature wrapped around the handles. The tension of the ligature will convert the forceps into a makeshift hemostat, permitting a gentle and constant securing force while the root end procedures are performed. This relieves surgeons from having to maintain this force with their hands, thereby limiting their fatigue. The new forceps delivers the tooth from the socket and submerges it into the emesis basin that has been partially filled with HBSS. The socket is rinsed with saline and inspected with the SOM; if clear, the socket opening is occluded with 2 × 2 gauze sponges, and the patient is allowed to relax and close his or her mouth.

A recent change to the extraction phase utilizes a different type of forceps, the Physics Forceps™. There is no back and forth luxation in its use; instead, the movement is more akin to a pivoting elevation of the tooth, lifting it from the socket after the PDL fibers have fatigued and separated. One to two millimeters of elevation is all that is required (Figure 25-7C and D); at that point, the beaks of the transfer forceps are introduced, and the tooth delivered to the basin as described above.

If there is a full coverage crown on the tooth, a strong likelihood exists that it will become dislodged during extraction. If there is sufficient coronal core structure remaining, the surgeon can readapt the beaks to a fresh location and continue the procedure. However, if the crown shears horizontally at the gingival level, with little tooth structure protruding above the gingiva, the surgeon must reassess the availability of sound tooth structure above the level of the attachment. If there is sufficient room to adapt the beaks of the forceps without impinging on the attachment/cementum location, then the extraction can proceed with caution. When there is insufficient structure remaining, or the root has fractured below the alveolar crest, the extraction may not be possible without employing a root elevator or periotome. The use of these instruments is absolutely contraindicated because of the scraping/crushing damage they inflict on the cementum and PDL, with the ensuing resorption response all but guaranteed. This particular scenario should be well explained in the informed consent, with both parties in full disclosure as to how to proceed next (i.e., extract and graft the site, extract and place an endosseous implant, or other).

In those cases where such complication is anticipated because of root configurations or weakness due to multiple retreatments, a novel approach may provide a solution.[57] The tooth identified as one that poses a significant extraction risk (complicated root structure, thick cortical plate, and extensive core prosthetics) undergoes a two- to three-week period of preoperative orthodontic extrusion prior to extraction with their preferred instrument, the Physics Forceps™.[58,59] No extraction failures have been reported in the extrusion group, with over 25 months postoperative survival rate of 98.1%. Although the time required for extraction of the teeth was not significantly different between the extruded and nonextruded groups, the clinical impression was that the extruded teeth were easier to deliver than anticipated, given their preoperative complication set. Of singular importance is the fact that there were no signs of resorption observed in the extruded teeth, while 10 out of 123 teeth in the nonextruded group manifested some signs of resorptive defects. These authors proposed that the preextraction extrusion serves to increase the PDL volume around the tooth, which provides a protective component to the root surface and deterrent to root resorption. This theory is based on the observations of Hayashi[60] and his work on ortho-transplantation.

Evaluation

Once the tooth is submerged in the basin containing HBSS, the socket is examined for evidence of fracture or pathology. A partial or "green-stick" fracture of the alveolar cortical plate, even if it prolapses into the socket space, is of little concern as long as it can be repositioned prior to replantation. Complete fractures, especially if fixation is questionable postoperatively, should be removed to reduce the risk of spontaneous sequestration. In these instances, bone graft augmentation can be considered if the tooth is rigidly splinted after replantation.

The apical lesions are normally attached to the root apex(ices) and are recovered as a matter of course during removal of the tooth. Occasionally, a bolus of tissue remains in the depth of the socket. If it cannot be evacuated by gentle aspiration with the surgical suction, and it does not interfere with the repositioning of the tooth, it can and should remain undisturbed. Aggressive curettage of the socket, and root surfaces, have been reported to initiate root resorption, and should be considered when contemplating any manipulations in the socket.[33,61] The same rule applies to any root tips that have splintered off during the extraction; if they are mobile and easily harvested with minimal instrumentation and destruction, removal is indicated. Conversely, if it is firmly attached and smaller than 3 mm radiographically, it should remain in the alveolus to be subsequently remodeled and resorbed. Once the inspection of the socket is complete, it is rinsed with saline and covered with saline-moistened gauze sponges. The patient is then directed to gently bite down to hold the sponges in place, and returned to a comfortable seated position.

While fully submerged in the HBSS, the surfaces of the tooth are inspected with the aid of the SOM, noting any

fractures, lateral canals or other portals of exit (POE) from the root canal spaces. Any lesions loosely connected to the root surface can be teased off using Addison forceps. If no fractures are evident, then the root end resection(s) (RER) can be planned. The tooth can be readjusted in the forceps beak so that they are solely on the crown, and have a solid purchase that will resist dislodgement during the cutting motions of the handpiece. Resection is accomplished with the selected apex(ices) just below the surface of the fluid; this may necessitate the surgeons' fingers or even hand be placed in the basin to secure a solid finger rest position. The basin can be stabilized using surgical towels, propped up on one end to affect a more comfortable access position for the operations, and aid in the visualization with the surgical operating microscope. If there is more than one root resection planned, the angle of the resections may be different and will often oblige changes in the position of the forceps in the basin, or even readjustment of the tooth in the beaks itself.

Bur selection is based on a fast cutting and nonclogging flute design. Carbide fissure burs, either straight or tapered and of surgical length, are the instrument of choice. Diamonds, regardless of grit, leave a roughed surface that may create finishing issues during the root end filling (REF). Any rounded bur configuration can create a ripple effect in the resected surface unless it can fully span the breadth of the resection.

Once the root is submerged and comfortably stabilized just below the surface of the fluid, 1–3 mm of the root tip is resected at right angles to the long axis of that particular root. The amount to be removed is guided by microsurgical protocol and clinical judgment, with one minor exception; severe curvatures/dilacerations, if projected to hinder or prohibit a smooth replantation, should be resected to eliminate the offending curvature, regardless of the length. Only the tip of the fissure bur is used in the resection, with each cutting pass slightly deeper than the previous one. When done in this manner, the dentin at the interface of the bur will be adequately cooled and flushed, minimizing any frictional burning events. The fluid passing through the handpiece tip onto the revolving bur should also be HBSS. This is readily accomplished in a closed delivery system, where the solution is contained in a removable pressurized canister. The HBSS is flushed completely through the dental unit handpiece lines, delivering fresh fluid to the resection site continually during the procedure.

Once all the root resections are complete, the resected surfaces can be stained with a disclosing dye (methylene blue) and examined to discover the extent and location of canal(s), isthmus, or fractures. If the fractures are minor, and can be removed via resection, it is accomplished at this juncture. Otherwise, the tooth is repositioned in the forceps beaks in readiness for the root end preparation (REP).

The REP is most efficiently accomplished using an inverted cone- or pear-shaped carbide bur, cutting in the long axis of the canal to a depth of 3–4 mm, again according to microsurgical protocols. All canal spaces present, including the isthmus, are prepared to the same depth. The tooth has been repositioned so that the resected surface is just below the fluid surface in the basin, and facing towards the microscope. In this orientation, the REP motion with the handpiece is comparable to a drill press; a repeatable vertical motion vector with precise depth control.

The use of an ultrasonic root end preparation (USREP) tip has been reported in the literature[14,28,62] but should be utilized with caution in small, narrow roots. Early investigations into the safety and efficacy of these instruments reported incidences of fractures and cracking after USREP in extracted teeth.[63,64] The evaluation of these instruments was repeated in cadaver specimens[65] and clinical surgical patients,[66] using resin replica impressions of the prepared root ends in situ. Observations of the prepared replica casts revealed no evidence of cracking. It was hypothesized that the PDL afforded some cushioning effect to the ultrasonic vibrations, dampening the magnitude of the transmitted vibratory force through the root end. When executing IR preparations with an USREP tip, the surgeon is essentially duplicating the bench top study that produced the increased rate of observed fractures. There were no observed incidences of fracture when carbide burs were used to prepare the root ends,[64] and the root end preparation with a carbide bur can be accomplished in a matter of seconds, versus minutes with a USREP tip.

The completed REP(s) are evaluated for extent and depth under the SOM with low and high power magnification; if they are satisfactory, they are flushed with HBSS and dried using a Stropko™ irrigator (www.stropko.com) with microneedle tip. Again, the tooth is positioned so that only the resected surface is above the level of the HBSS.

The choice of an REF varies considerably in the literature, and most are multi-purpose restorative materials adapted for root end surgery; IRM,[67] ZOE,[26] Super EBA cement,[14,68] dentin bonding agent,[69-71] Spherical[72-74] or Zinc-free[36,75]amalgam, Calcium-enriched mixture (CEM),[76,77] Mineral Trioxide Aggregate (MTA),[57,78] or glass ionomer.[79] Selection is usually based on availability, ease of mixing and placement, and biocompatibility and stability during the replantation. The materials that complete their setting shortly after placement are easier to finish and are resistant to displacement, but are not as biocompatible as the bioceramic REF's, such as MTA.

The disadvantages of MTA for the purpose of IR are difficulty in delivery and placement, long setting time period (four to six hours) and lack of resistance to displacement (wash-out). The handling issues are easily addressed by using instruments meant to carry the material to the surgical site such as MAPS (Micro Apical Placement Syringe, Roydent, Johnson City, TN) or Dovgan carrier. The MTA is moisture sensitive, so the resected surface of the tooth must be above the level of the HBSS to prevent an influx of the fluid and premature soaking of the MTA. Once the

MTA has been condensed and finished, the surface of the MTA in the preparations is gently desiccated with a gentle stream of air from the Stropko™ irrigator directed across the surface of the material. This will effectively "skin" the surface of the MTA, forming a thin barrier for the material deeper in the preparation. The tooth is then completely submerged and allowed to remain undisturbed for five minutes. This allows for further setting of the MTA in a hydrated environment.

If a moisture-tolerant material is chosen instead, the preparations are dried as above but, because the materials are hydrophilic, the presence of small amounts of moisture, or fluid, in the preparations is not critical. Placement, condensing, and finishing of the REF material is done following the same protocols of conventional root end surgery. Regardless of the materials used, the excess REF is removed from the preparation site, and final inspection of the extracted tooth is conducted under the SOM.

Replantation

Prior to replantation, the socket is reexamined for fractures of the alveolus and any foreign material that may have contaminated the site. It is rinsed with sterile saline, or HBSS, to remove any occult blood clots, and the surrounding soft tissue surfaces are swabbed with CHX. The clots are evacuated because of their association with increased incidences of inciting postoperative ankyloses,[80] and the rinsing action creates a fresh bleeding surface. The security of the extracted tooth in the transfer forceps beaks is reexamined to confirm its' stability, and the tooth is removed from the basin and immediately redelivered to the socket. Gentle apical pressure is applied to reduce the tooth to its' original location and depth. If there is resistance to the reinsertion, the tooth is returned to the basin, and the socket reexamined to ascertain the obstruction. Once the tooth has been fully reinserted into the socket, the cortical plates are carefully coapted back against the root surface (if they were displaced or spread during the extraction), and a small gauze sponge is placed across the occlusal surface of the tooth. The patient is directed to carefully occlude down onto the sponge for a few minutes, after which a radiograph is taken to confirm the complete placement of the tooth in the socket. If the operator is satisfied with the placement, the tooth and surrounding tissues are swabbed once again with CHX, and the necessity for postreplantation splinting is evaluated.

The need for postoperative stabilization is dictated by several factors: length of the root, lack or loss of interseptal bone, excessive postreplantation mobility, and concerns about postoperative patient compliance.[81-84] The choice of splinting material should allow for a small amount of physiologic mobility, as this has been shown to aid in periodontal reorganization and healing.[85,86] If the fixation is too rigid, it increases the likelihood that remodeling will take place on the root surface, resulting in replacement resorption (ankyloses).[75,87,88]

The design can range from a single suture crisscrossed over the crowns' occlusal surface[89] to a 0.7 mm orthodontic wire reinforced composite splint[90] (Figure 25-9). The degree of instability will dictate the amount of rigidity required. The most commonly employed method utilizes a small amount of light-cured composite material (reinforced or not) spanning the interproximal gap to a stable adjacent tooth.[91-93] Once the splint is in place, the occlusion should be verified and all interferences removed. This is especially imperative if there is a suspicion of grinding, clenching, bruxism, or other parafunctional habit, as evidenced by wear facets or abfraction lines on the surrounding teeth. If present, but not accounted for, this degree of postreplantation occlusal stress can inhibit the reattachment, or prevent it completely.

The duration for the splinting can vary depending on the presplinted support and environment. However, generally, the tooth is stable enough after 7–14 days. At that time, the splint can be removed.[67,81,94,95] If a simple composite splint is affixed, the composite span can be severed with a small bur; if the tooth is stable, then the remaining material can be removed. If, however, the tooth is still slightly mobile, additional material can be adapted into the resected gap, and the splint reactivated.

The postoperative instructions mimic those for routine postsurgical care:

1. Soft diet (no seeds or hard/sticky foods) until the splint is removed, and chewing on the opposite side, if possible.
2. Avoid brushing or flossing the splinted area until it is removed. Instead, the area is gently rinsed with plain, lightly salted water to dislodge and remove any food debris.
3. CHX rinses twice a day until splint removal.
4. NSAIDs/Analgesics as prescribed for two to four days postoperatively. Antibiotics, if prescribed, should be taken as directed.
5. Avoid strenuous exercise or activity that can precipitate a hypertensive event. This rise in blood pressure can cause a local throbbing and, if significant enough, hemorrhaging in the sulcus or surrounding tissues. This will manifest as an ecchymosis if uncontrolled.
6. Cold compresses can be gently applied externally as a palliative comfort measure; hot packs should be avoided.

The patient is directed to return in seven days for re-evaluation of the site and splint assessment. Any sutures, other than those acting as a splint, are removed at this visit. The patient is seen again at day 14 for splint assessment and removal, if appropriate. Once the reattachment is confirmed, the patient is instructed to resume normal oral hygiene routines and schedules, with the caveat of no elective crown and bridge on the replanted tooth until the attachment has matured (usually three to four months). This also applies to any elective periodontal manipulations such as scaling, root planning,

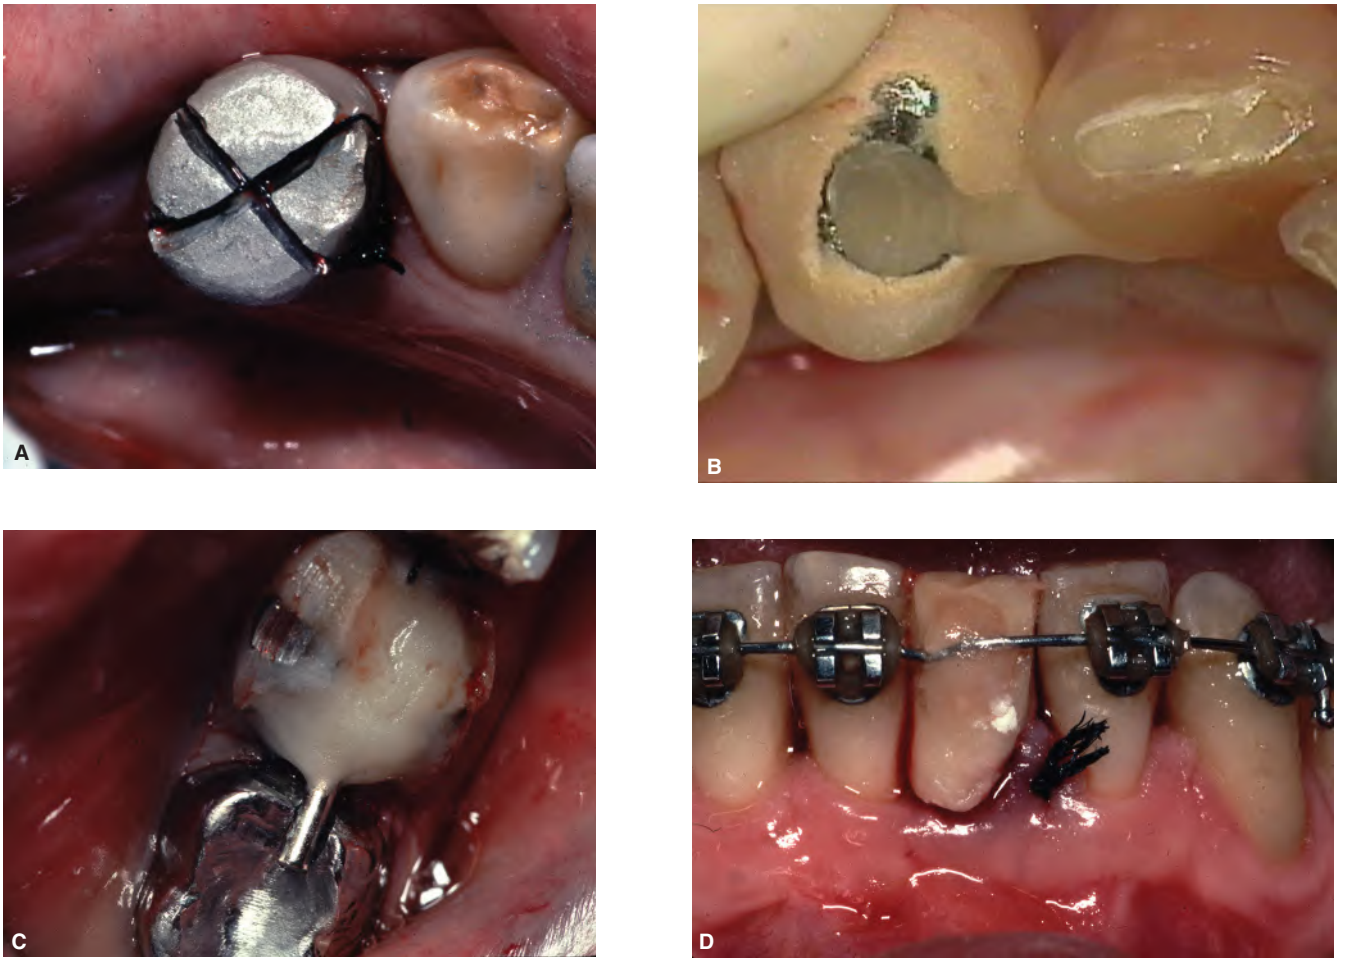

FIGURE 25-9 Stabilization of the intentionally implanted tooth. ***A.*** Depending on the degree of stability required, postoperative splinting can be a simple suture encircling the tooth or crisscrossed over the occlusal surface. ***B.*** When more rigid fixation is indicated, an acid-etched composite connection between two adjacent marginal ridges can be placed. This will allow for the connection to be sectioned and mobility of the tooth ascertained before removing the splint totally. ***C.*** If there has been a fracture of the alveolus bone, appropriate immobilization of the replanted tooth for a longer time period is warranted. ***D.*** If there are already splinting elements in the arch, such as an orthodontic wire, then the tooth can be temporarily secured to the wire with self-cured acrylic.

or curettage. The surgeons' postoperative recall schedule is enacted, traditionally six months and one year from the date of treatment. A clinical and radiographic examination is performed, evaluating periodontal and periapical healing, with notations of healing or abnormality/delayed/non resolution of the presenting signs and symptoms. While traditional radiographs provide preliminary insights into the progress of the periapical healing status, the resolution of the lesion may be more accurately evaluated and monitored using the CBCT.[96-98]

Complications

Complications of IR can manifest as either intra-operative or postoperative in nature. The intra-operative complications are usually technically derived. They may result from overt or misdirected application of force, inappropriate or incorrect instrument manipulation, or misdiagnosis of the root anatomy. The end result is often root fracture; the extent of which can be pivotal in whether the remaining tooth fragment is salvageable or not. As stated previously, this is one of the scenarios that should be discussed during the presurgical consult visit, with alternate treatment plans outlined in the informed consent. This discussion serves to streamline the decision tree if and when this complication does occur. If the remaining fragment is undamaged, and is large enough to be of prosthetic value, then the modified replantation can proceed as planned. An example of a salvaged root fracture and outcome is demonstrated in Figure 25-10.

Postoperatively, the two most common complications are nonattachment and resorptions. Aside from a failure of the splint to stabilize the replanted tooth, there is evidence to support that smoking and, in particular, nicotine can inhibit or prevent reattachment of human gingival fibroblasts (HGF). A recent study[99] demonstrated that high concentrations of nicotine and cotinine have adverse effects on the cell adhesion and proliferation of HGF cells. If these

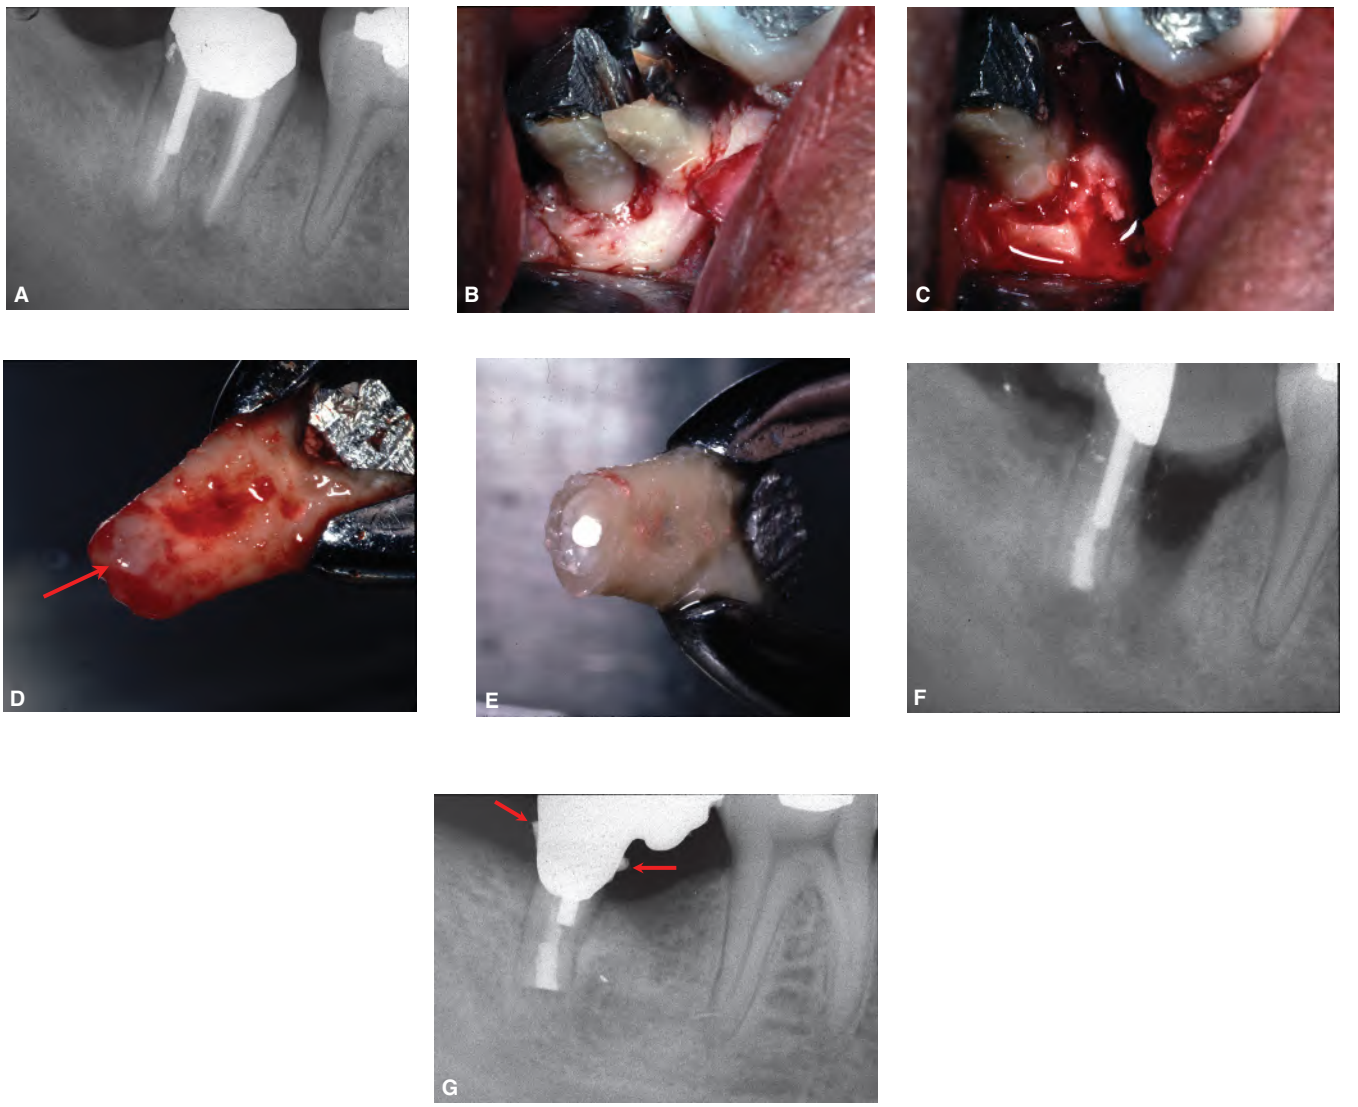

FIGURE 25-10 Salvaged root fracture in a mandibular right second molar. ***A.*** Preoperative radiograph. Note the large post in the distal canal, the convergence of the root forms and periapical areas on both root apices. The tooth has an amalgam buildup, and a temporary crown is in place. ***B.*** The mesial aspect of the root has fractured during the extraction, and the tooth has been hemisected through the furcation. The convergence of the mesial and distal roots is the most likely reason why the tooth was resistant to extraction and fractured. ***C.*** The mesial root has been atraumatically extracted, with minimal buccal cortical plate involvement. ***D.*** The distal root apex prior to resection. Note the small lesion attached to the root (arrow); it will be removed with the resected root tip. ***E.*** The distal root-end has been resected, and the root-end filling (Super EBA) has been placed and finished. ***F.*** Immediate postoperative radiograph. The distal root has been replanted, and the temporary crown relined and provisionally cemented over the root. Stabilization was achieved by bonding the temporary crown to the lingual of adjacent first molar, using orthodontic bonding resin. A small mylar plastic strip was placed over the exposed mesial extraction socket during the reline procedure to prevent migration of the acrylic into the socket. ***G.*** Eight-year recall radiograph. The area healed and periodontal probing depths were normal, in spite of the presence of deposits (arrows) on the abutment crown of this inlay mini-bridge.

are the cell populations and mechanism of action that need to be optimal for successful outcomes in IR, then the procedure may be contraindicated in patients who are heavy smokers. This is especially evident in teeth with trifurcations (i.e., maxillary molars). The large amount of surface area to be reattached can be adversely affected by exposure to the inhaled nicotine stream. Empirically, this is speculated to be the cause of the failures seen in the success and failure bar chart (Figure 25-11).

Resorptions are universally caused by alterations of the PDL or cementum, either as a response to necrotic pulpal tissue and infection, or as physical destruction of the attachment microstructures. As previously discussed, revision of an inadequate initial RCT by retreatment has a positive effect on successful outcomes.[20,21,23,100] This principle is relevant whether the surgical procedure is *in vivo* (conventional) or *ex vivo* (IR). Minimizing the impact of intracanal etiologies (necrotic debris, microbial infection)

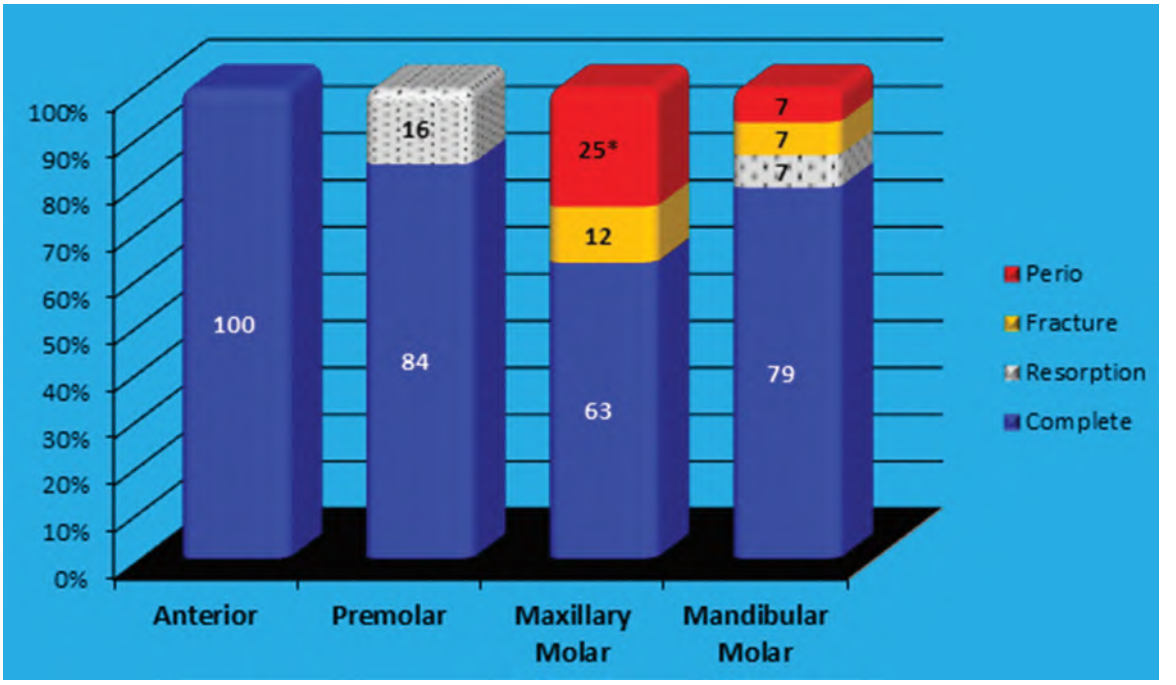

FIGURE 25-11 Bar graph comparing % success and complications of intentionally replanted teeth in different tooth groups. Resorptions that developed postoperatively coincided with sockets that received aggressive curettage. The fracture group represents those teeth where a portion of the tooth was fractured, but the remaining segment was replanted. In the periodontal category (recession, decreased attachment level, impaired re-attachment) the percentage in the maxillary molar contains an asterisk. In those patients, a significant number (66%) were moderate to heavy smokers; smoking affects periodontal healing and may have been the contributing factor in the complication seen.

theoretically decreases the likelihood that an inflammatory root resorption (IRR) will develop secondary to the intracanal contamination. The remaining consideration is the viability and structural integrity of the PDL and alveolus. Atraumatic extraction methods,[101] minimal contact with the root surfaces,[29,102] and constant hydration with the HBSS[46] safeguard the integrity of the tissues on the root surfaces.

What may not be as apparent is the health and disposition of the alveolar socket. Surgical alterations to the socket in the animal model[103] have resulted in significant differences regarding the extent (greater) and time of onset (shorter) of the root resorptions observed. The presence of an occult blood clot[80,104] or a socket that has been allowed to degrade[61] or become contaminated will also contribute to the initiation of the resorptive cascade on the replanted root surface. For these reasons, aggressive curettage of the alveolus is contraindicated. Gentle lavage of the socket, followed by careful insertion and evacuation of the socket via surgical suction, is usually sufficient to remove any infected tissues remaining after the extraction. Prior to repositioning the tooth, the alveolus should be thoroughly rinsed with saline or HBSS. This will assure the evacuation of any accumulated blood, and create a fresh, bleeding surface. When forceful apical curettage is done, a resultant resorption can develop.

Efforts to guide the cellular reattachment response with the aim of delaying or preventing resorption have been investigated for some time in animal studies and human trials. Application of fluorides to the root surfaces,[105] systemic and local steroid administration,[106,107] topical sodium alendronate (bisphosphonate)[108] and enamel matrix derivatives (EMD)[109-111] have all been employed, with the last (EMD) showing the most promising clinical results. One of the commercially available EMD preparations, Emdogain (Straumann USA, Andover, MA, U.S.A.) was developed specifically for the regeneration of periodontal tissues, either alone or in combination with other guided bone or tissue regenerative materials. (Note: the Straumann company announced in 2008 that the import detention on Biora products in the U.S.A that has been in place since the beginning of 2007, has been lifted following a re-inspection of the Group's Biora facility in Sweden by the FDA [US Food and Drug Administration], and the product is once again offered for sale.) Available as a gel, it contains an enamel matrix protein derived from developing porcine embryonic enamel in a sterilized aqueous solution of propylene glycol alginate.[112] These proteins are incorporated into the acellular cementum matrix during development, and are coincident with the site of Sharpey's fiber attachment on the root surface,[113,114] suggesting that topical treatment with Emdogain may stimulate

periodontal reattachment. However, the exact mechanism by which this occurs is still unknown.

Lyngstadaas et al.[115] proposed that a major component of EMD, amelogenin, interacts with cells and induces the release of signaling molecules and secondarily initiating the regenerative process. Healing of the supporting tissues in a replanted tooth depends on various cellular activities such as migration, reattachment, proliferation, and differentiation of various periodontal cells (cementoblasts, osteoblasts, and PDL cells). EMD appears to orchestrate this well *in vitro*, stimulating the migration and proliferation of osteoblasts, endothelial cells, and epithelial cells.[116] Although more controlled studies are required, a recent meta-analysis[117] concluded that, in the presence of a PDL, use of EMD resulted in an increase of normal periodontal healing (compared to the absence of the PDL), with greatly reduced incidences of inflammatory or replacement resorptions.

Auxiliary Procedures Employing Intentional Replantation

Delayed Replantation for Periodontally Hopeless Teeth

One of the contraindications of the IR procedure mentioned previously is compromised health and stability of the periodontal tissues. Incumbent in this recommendation is the stipulation that the root surface and/or the socket will remain unaltered. In the presence of overt periodontal disease and bone loss, spontaneous reattachment is doubtful. There are instances, however, where retention of the natural tooth is preferable to extraction, especially when considering the prosthetic rehabilitation. It has been demonstrated that following loss of a tooth, there is a 25% decrease in local ridge bone volume in the first year alone, with a 40–60% loss of width in the succeeding three years post extraction.[118,119] Augmentation and site preservation of the socket can reduce, but not predictably eliminate, these sequelae. The extracted tooth, once suitably prepared and stabilized, can serve as a "biologic space maintainer," preserving bone volume and function. Even if the root eventually succumbs to resorption, the resultant replacement resorption will result in an increase of the alveolar height, and in a more favorable platform for a removable or implant-supported prosthesis. This process, termed "Delayed Intentional Replantation" (DIR),[120] is predicated on two conditions: sufficient decontamination of the root surface (plaque, calculus, necrotic PDL, infected cementum) and delayed re-implantation into the socket.

The removal of necrotic PDL was advocated by Lindskog et al.[121] where resorptions of the root surfaces occurred whenever the diseased PDL was allowed to remain upon replantation. These authors concluded that chemical debridement and removal of the PDL tissue rendered the remaining cementum less vulnerable to clastic attack and subsequent replacement resorption. This effect was also reported by other investigators, with no evidence of resorptions or ankyloses evident radiographically at the six-month re-evaluation.[122] In DIR, the extracted tooth root surfaces are gently debrided with an ultrasonic scaler, then polished with a fine diamond bur. Subsequently, the tooth is stored in a dexamethasone-fortified medium at 4°C for 10–14 days. Prior to replantation, the root ends is ultrasonically prepared, and filled with a suitable root end filling (Super EBA was used in this study).

Any granulation tissue in the socket is removed by curettage, the socket rinsed with saline to evacuate any debris, and a blood clot is allowed to form. The socket is allowed to partially heal, undisturbed, for two weeks. Ten to fourteen days following an extraction, woven bone begins to form in the socket.[123,124] This will function as a scaffold for the regenerating tissues, and provide some apical support for the replanted root. At this stage, the socket transitions from the inflammatory phase (three to seven days post extraction) to the healing phase, where woven bone formation and angiogenesis are actively evolving.

After two weeks, the coronal portion of the socket is incised, and the stored tooth is replanted under local anesthesia. A resin wire splint is applied for initial stabilization, and the occlusion adjusted to remove all interferences. The patient is given oral antibiotics for three days, and instructed to rinse with 0.12% chlorhexidine (CHX) for two weeks. The replantation site is rinsed with saline after seven days, and the splint removed at the one-month recall appointment. At this appointment, the exposed tooth surfaces are polished and radiographs are taken to monitor the reattachment.

In one study,[120] a success rate of 66% was reported at 21-month follow up. Results showed an increase (45%) in the amount of bone gained around the replanted tooth, and no radiographic evidence of resorptions. These results are encouraging with regard to the observations of a similar study[125] where the roots were debrided (chemically), but replanted within a short period of extra-oral time. The increase in bone gained was lower (16%), but these teeth were splinted for the duration of the study (six months), and may not be representative of the true clinical outcome. An interesting corollary to this procedure involves preparation of the socket using water-cooled implant drills of corresponding size to the replanted root. The sites are prepared to allow the conditioned teeth to be replanted in infra-occlusion. The replanted teeth are then splinted for a period of three to six months, with osseous grafts either at the time of replantation,[126] or at the three-month recall appointment.[127]

Prosthetic Repositioning

There are numerous reports of parents repositioning their child's tooth quickly after an avulsion, only to realize they have rotated to tooth 180° in the process. As long as the cells are viable, the tooth reattaches without consequence, for the PDL is not unique from one side of the tooth to

the other. This phenomenon has been utilized in the treatment of crown-root fractures,[128,129] where the teeth have been removed and intentionally repositioned into a more favorable prosthetic position. A similar scenario, where a conventional surgical approach would have removed too much bone, and the tooth being orthodontically repositioned for crown placement purposes, are demonstrated in Figure 25-12.

FIGURE 25-12 Intentional replantation in a mandibular left central incisor. ***A.*** Preoperative radiograph showing a large post, root bevel from the previous surgery, and periapical radiolucency. The tooth is undergoing orthodontic movement to rotate the tooth and correct the root proximity problem mesial and distal. (Note: the notch of the post is facing distal.) ***B.*** Clinical appearance of the extracted root. The lesion is removed and the root disclosing the bevel from the previous apicoectomy. ***C.*** The root apex is shaved to preserve as much length as possible, and prepared with a #330 carbide bur to a depth of 2 mm. The root end filling is placed and carved flush to the shaved surface. ***D.*** The root replanted and rotated 180°. Note the notch on the post is now facing mesial, and there is more space between the adjacent roots. ***E.*** The clinical image of the tooth replanted 180°. The arch wire was re-bent to accommodate the new orientation of the temporary crown. ***F.*** The temporary crown was cemented backwards, reflecting the 180° rotation of the tooth. The crown was splinted to the wire with acrylic, and a 4/0 silk interrupted suture placed to secure the distal papilla. ***G.*** Immediate postoperative radiograph showing the replanted tooth with the temporary crown in place. The tooth remained splinted for four weeks, and the tooth re-prepared after eight weeks to readjust to the new orientation. The soft and hard tissues healed without complication. ***H.*** 17-year recall radiograph showing evidence of complete healing. The tooth has been asymptomatic and in good function.

Replacement Resorption (Ankylosis)

The development of replacement resorption can be a consequence of a traumatized tooth. In the adult patient, the prosthetic options are more varied because skeletal maturation is complete and inter-arch relationships are established. In the child and adolescent, however, replacement root resorption proceeds at an accelerated rate, with the potential to exert a profound effect on the growth of the alveolus in the affected area. If the tooth remains in infraocclusion, the arrested eruption could affect function and phonetics. If the tooth is extracted, the resultant osseous defect may be difficult to correct with conventional augmentation methods. Classically, the treatment options for these ankylosed teeth were autotransplantation (usually a canine or premolar) or decoronation. A third option offers a compromise between those two concepts.[130]

Once the diagnosis of ankyloses, or evidence of infraocclusion, is confirmed, using a Periotest® (Gulden, Bensheim, Germany), the tooth is extracted atraumatically, and the resorbed areas of the root resected away. The canal space is prepared through the crown with a standard post drill (in this study, the Retropost, Brasseler-Komet, Lemgo, Germany was used), and a titanium post cemented. The length of the post approximates the original length of the tooth, and the appearance is similar to the endodontic implant devices that were placed in the early 1960's through 1975, although not extending apically nearly as long. The teeth are rinsed and dried with sterile gauzes, and Emdogain™ is applied to all exposed root surfaces before replantation. The teeth are physiologically splinted for 10–14 days, and appropriate recalls scheduled to monitor the healing and recurrence of resorptions. A six-year survey reported favorable results when small areas of ankylosis are diagnosed,[109] but more extensive areas of resorption tend to recur, and are better managed with the more traditional modalities such as autotransplantation[131] or decoronation.[132]

Perforation Repair

In cases where the location of the perforation is inaccessible by conventional microsurgical approach,[133] or the risk to surrounding structures is deemed unacceptable,[77] then extraction and repair or revision of treatment are indicated.

Patient Refusal of Treatment

Patients who have been subjected to multiple nonsurgical endodontic therapies, with perhaps a surgical revision of one of those teeth, are understandably reluctant to undergo a second surgical intervention. This is not an atypical scenario, and affords the perfect opportunity to suggest IR as an alternative to extraction (the patient desires to retain their tooth, but is unwilling to present for another invasive procedure). An example of this is outlined in a case report,[73] detailing the endodontic treatment of a mandibular second molar with suspected C-shaped anatomy and persistent symptoms.

Maxillary Sinusitis

Sinus complications secondary to an endodontic infection are not unusual. Resolution generally coincides with correct diagnosis and root canal therapy. In a case report,[89] the patient presented with persistent, painful symptoms eight months post endodontic treatment, and sinus occlusion associated with the tooth was evident on a CT scan. The surgery began as an *in vivo* approach, and the tooth was extracted upon suspicion of a vertical fracture. Upon close examination, the "fracture" was revealed to be a radicular defect, and the IR was proposed. When the tooth was extracted, a purulent discharge was observed. Prior to replantation, the alveolus and affected sinus membranes were lightly curetted and rinsed with saline. The root ends were prepared and sealed with amalgam root end fillings, and the tooth secured postreplantation with 3/0 silk sutures. Healing was uneventful, and the patient was comfortable and symptom-free two years postoperatively.

Paresthesia

Paresthesia is a classical sensory response resulting from neuropraxia, and is defined as "a burning or prickling sensation or partial numbness caused by neural injury."[134] Inferior Alveolar Nerve (IAN) injuries can arise from many causes, both disease based and iatrogenically induced. The most common endodontic etiologies are over-instrumentation, irritation from root canal medicaments, over-extension of root canal obturative materials, and root end surgery.[135]

The mechanisms by which paresthesia can occur are direct mechanical disturbances via over-instrumentation, neurotoxic effect of a chemical applied, or introduced, and pressure edema of a foreign object inserted into the neurovascular canal.[136] In the instances of over-instrumentation/over-extension of obturation materials, it is imperative to relieve the edema and harvest the material from the proximity of the bundle as quickly as possible. Delay in decompression and retrieval of the offending material can inhibit, or prevent, a successful recovery of sensation and function. Figure 25-13 demonstrates this very scenario. The patient had undergone conventional therapy, with under-instrumentation of the mesial canals, and over-instrumentation of the distal. Patient experienced a mild paresthesia after the first visit that degraded to a dysesthesia following the final obturation. The condition persisted three weeks after completion of endodontic treatment. Periapical surgery was contraindicated due to the proximity to the mandibular canal, and the preexistence of neural injury. The patient was apprised of IR. Possible complications were explained, and the patient elected to have the procedure performed. The procedure was completed, with a minor complication, and her dysesthesia resolved within three weeks. She was symptom-free after three months, and remained so throughout her subsequent recall appointments.

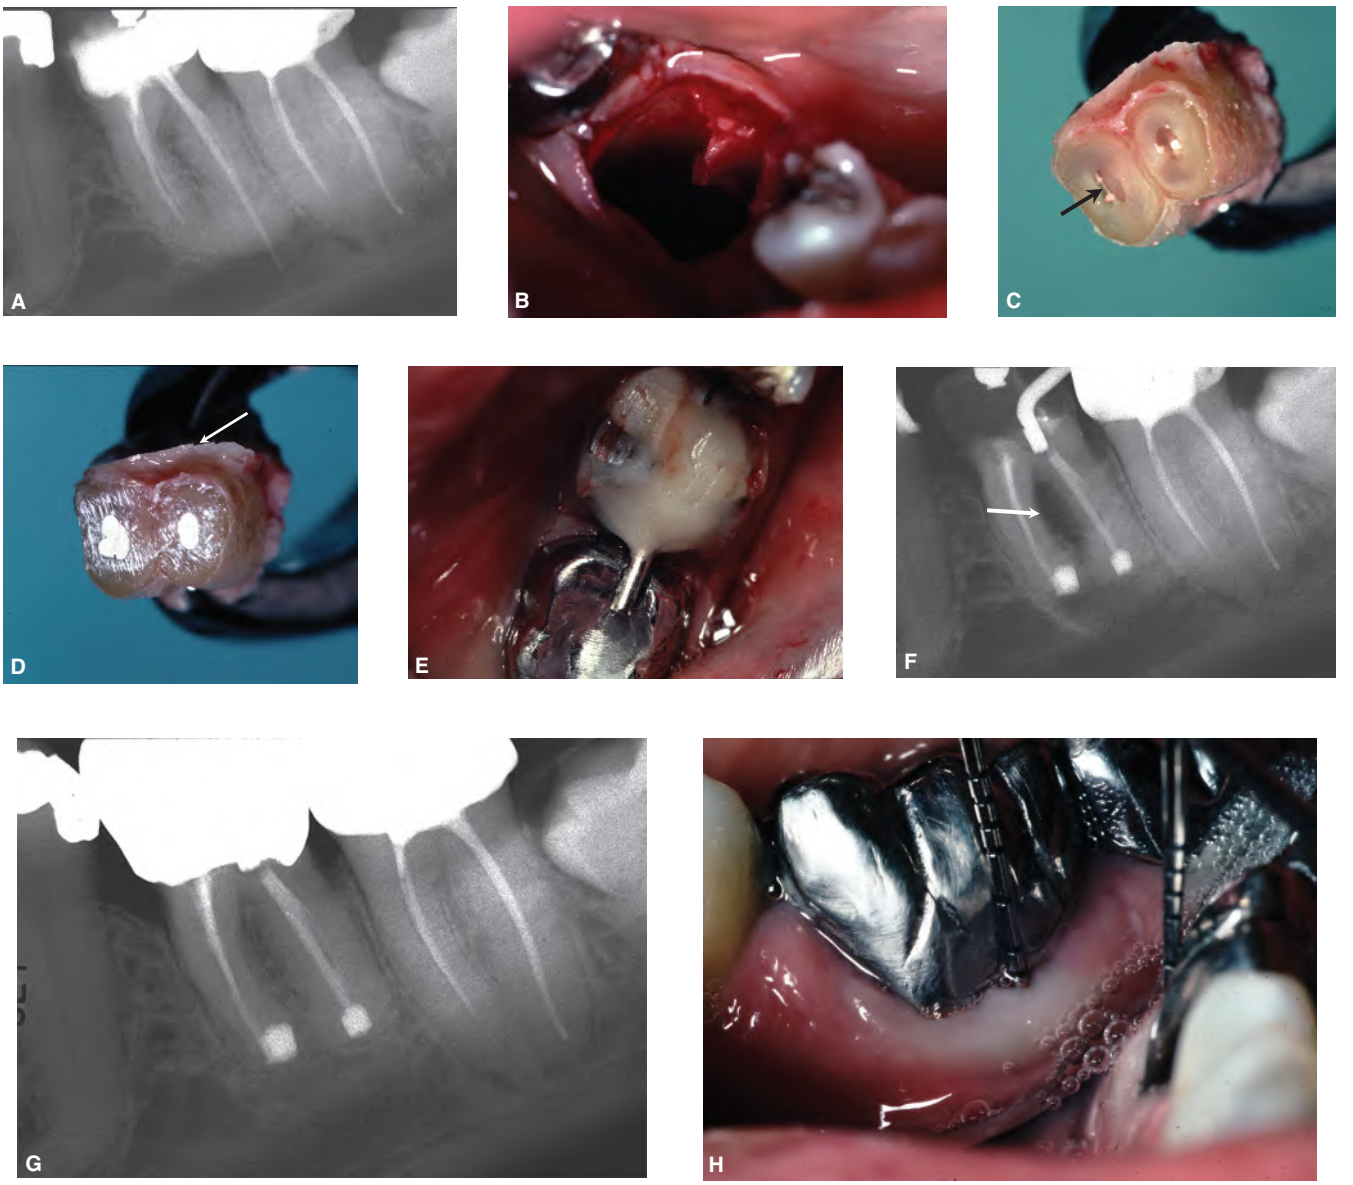

FIGURE 25-13 Intentional replantation in mandibular left first molar with dysethesia following root canal treatment. ***A.*** Preoperative radiograph. Evidence of over-instrumentation/overfilling in the distal canal, and underfilling/blockage in the mesial canals. The patient has had dysethesia since the completion of the RCT, and the apices may be in contact with the mandibular canal (radiographically). Conventional apical surgery is very risky, and may result in a permanent neurological deficit. ***B.*** During the extraction, a "snap" was heard. The tooth was delivered in whole, with no evidence of root fracture. Examination of the socket revealed that the buccal cortical plate fractured from the furcation, and was retained on the surface of the extracted tooth. The lingual portion of the plate will function as an index for the replanted tooth. ***C.*** Root-end resection and preparation has been completed. Note the isthmus between the MB and ML canals in the mesial root (arrow). ***D.*** Root-end fillings (Zinc Oxide Eugenol) in the mesial and distal root-end preparations. The buccal plate (arrow) inhibited replantation and was removed. The tooth will now require rigid splinting. ***E.*** The tooth has been replanted, and an orthodontic wire is secured in the access space, bent to index with the mesial marginal ridge of adjacent second molar. This will prevent a buccal luxation of the tooth, and the lingual index of bone prevents an occlusal displacement from the socket. ***F.*** Immediate postreplantation radiograph. The tooth is reduced in the alveolus to the correct depth, and will remain splinted for four to five weeks. Note the radiolucent area in the furcation corresponding to the loss of the buccal cortical plate (arrow). ***G.*** Eight-year recall radiograph. The bone has reformed in the furcation, and crowns have been placed on the first and second molars. The dysethesia resolved within three weeks, and normal sensation returned within six months. The patient is asymptomatic despite the poor endodontic treatment in the second molar; the patient declines any retreatment of the tooth, electing instead to have the IR done in case it becomes symptomatic. ***H.*** Periodontal probing depth of the buccal sulcus at an eight-year recall visit; 1.5 mm depth recorded in the furcation where the cortical plate was lost, indicative of regeneration of the plate.

CONCLUSION

Clinical experiences with the modified IR technique are represented by these two graphs (Figures 25-11 and 25-14). It is no surprise that the majority of the teeth chosen for this surgical procedure were mandibular molars. A survey of the case reports in the literature are overwhelmingly from that location. The combination of a thick cortical plate of bone and complex apical anatomy can present significant challenges to an in situ correction. Providing the tooth can be extracted without incident, it can afford unencumbered visualization and access to the root end, thereby increasing the chances for a successful outcome.

With the exception of maxillary molars, the observed long-term healing rates rival those reported for more conventional microsurgical approaches. The reasons for the lower success rates encountered with maxillary molars may be multifactorial; more delicate root anatomy, divergent curvatures and complex furcation configurations all combine to thwart atraumatic extraction and uneventful reattachment. Until a more predictable method can be developed to safely remove these teeth, an accurate three-dimensional survey preoperatively will either enhance the planned extraction, or discount that tooth from the procedure.

The IR technique has been shown to be a valid clinical alternative to extraction. In select situations where a conventional *in vivo* surgical approach is difficult or places the patient at unacceptable risk, the IR technique serves to expand the potential treatment alternatives while permitting the patient to retain their natural tooth.

Good prognosis of IR can be achieved provided that the following principles are followed:

1. Crushing or scraping contact with the root surface or socket lumen should be avoided.
2. The exposed root surfaces must be continually hydrated with the HBSS.
3. The tooth should be supported postoperatively to enhance reattachment.
4. Soft diet and hygiene instructions must be reinforced and strictly followed.

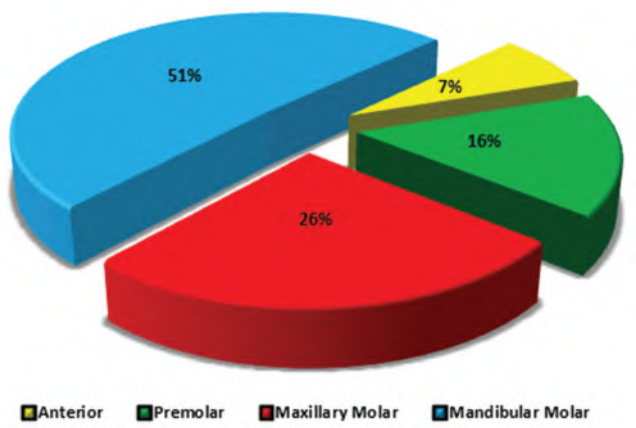

FIGURE 25-14 Graph demonstrating the distribution of intentionally replanted teeth by tooth groups. The majority of the teeth undergoing this procedure are mandibular second molars. Maxillary second and third molars comprise of about 25% of teeth treated.

Chapter 26

Endodontic Therapy in Teeth with Anatomical Variations

Ilan Rotstein, Eduardo Llamosas, Kyung-Soo Choi

Teeth with anatomical variations can present a challenge to the clinician when endodontic diagnosis, case selection, treatment, and prognosis assessment are required. While not common, these variations are definitely not rare.

Dental anatomical variations are classified according to their size, shape, number, structure, or growth alterations.[1,2] Variations in ***shape*** are the ones most commonly referred for treatment in an endodontic practice. In many such cases, long-term success of endodontic treatment is obtained, and the natural tooth may be retained.

This chapter discusses the most common anatomically shaped variations treated in an endodontic practice. For more details on radicular anatomy and morphology, common and uncommon, see Chapter 1, "Anatomy and morphology of teeth and their root canals."

GEMINATION AND FUSION

Definitions

Gemination is an anomaly resulting from abnormal division attempt of a single tooth bud. ***Fusion*** is a union of two, or more, separately developing tooth buds.[3,4]

Teeth that are fused or joined together by dentin have been referred to as *double teeth*, *fused teeth*, *joined teeth, linking teeth*, *twinning dichotomy*, *connation, geminfusion*, *vicinifusion, synodontia*, *schizodontia*, *mirror-image double teeth*, and *germinated composite odontomes*.[5–8]

Characteristics

Clinically, it is often difficult to differentiate between gemination and fusion. Gemination usually presents as a tooth with two crowns, either totally or partially separated, with a single root and one canal.[9] Fused teeth may have more than one canal system.

Often, the total number of teeth in the arch can provide a clue. Generally, if a tooth is missing from the arch, it is reasonable to assume that the affected tooth is fused.[10–12] However, in cases of fusion with a supernumerary tooth (Figure 26-1), this diagnostic method is not accurate.

Mader[7] suggested a "two-tooth rule" to differentiate between gemination and fusion. If the resulting anomaly is counted as two teeth and the normal number of teeth is present, then fusion is suggested. If it is counted as two teeth and an extra tooth is present, then gemination or fusion between a normal and supernumerary tooth is suggested. However, in adult dentition, an exact differentiation between gemination and fusion may not be possible with absolute certainty because of the clinical similarity between the two. Furthermore, it has little clinical significance for endodontic treatment.[13,14] The mere recognition of these anomalies should suffice to enhance vigilance and consideration of treatment options.[15]

Geminated and fused teeth have bifid crowns, or grooved incisal edges, in a buccolingual direction that are continuous with well-defined vertically running grooves on the buccal and lingual surfaces.[16] This gives the appearance of two or more separate structures with varying degrees of conjunction between the dental units.[5] The conjunction may occur either in the crown or root; sometimes in both. This depends on the developmental stage of the tooth/teeth when the anomaly occurred.[17] Radiographically, a single broad root with a common pulp canal space is visible.[4]

There is usually a union between the dentin of fused teeth. In some cases of complete fusion, there may be a single pulp chamber and root canal. The pulp chamber may be continuous, whereas the root canals are separate. On the other hand, it may have a discrete pulp chamber and root canals. The dentin, however, throughout the fused tooth, is not uniform. The interstitium between the root canal systems, with a common pulp chamber, may have dentin that closely resembles irregular secondary dentin, with numerous vascular channels, named vasodentin.[16]

Etiology

The exact etiology of gemination and fusion is not completely clear, however, developmental aberration of both ectoderm and mesoderm is involved.[6] There are several theories attempting to explain their formation. One theory suggested that fusion occurs purely by chance,[18] whereas others proposed that contacts of individual tooth germs is brought about by a physical force or pressure, acting on the tooth germs, leading to necrosis of the intervening tissues.[16] This allows the enamel organ and dental papillae of two or more adjacent teeth to fuse. If fusion takes place, prior to the commencement of calcification, it is regarded as complete, whereas if it happens thereafter it is regarded as partial. Other theories have suggested genetic predisposition, nutrition factors, and local metabolic interferences as the etiology.[19–21]

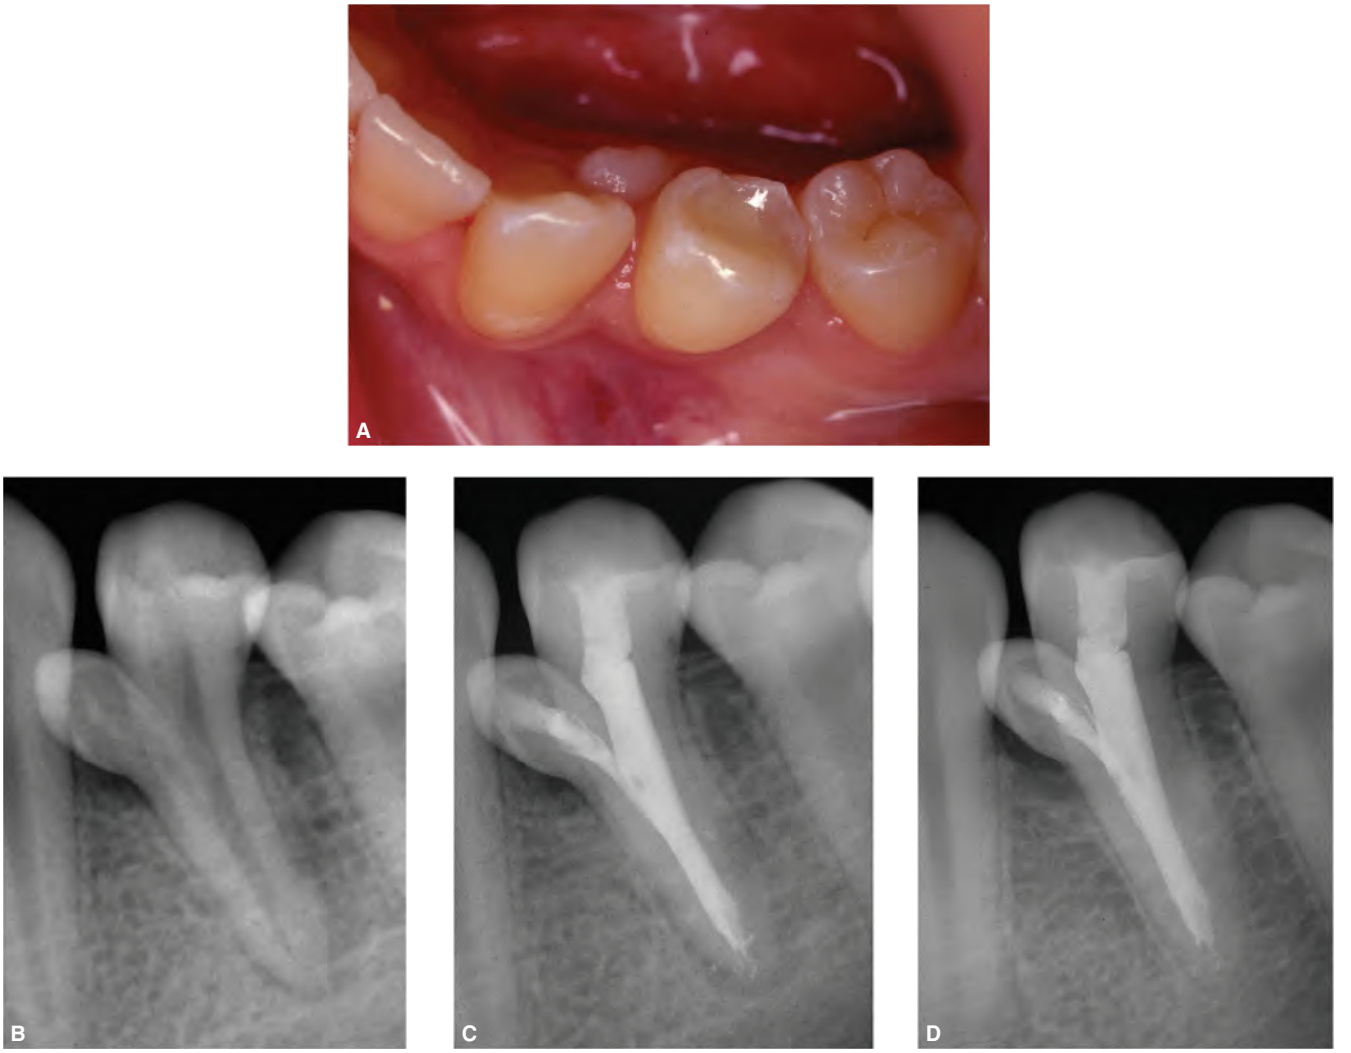

FIGURE 26-1 Fusion of a mandibular first premolar with a supernumerary tooth in a 15-year-old male. ***A.*** Clinical view. The crown of the supernumerary tooth is located mesio-lingually to the premolar. ***B.*** Preoperative radiograph showing the fused teeth with a joint root canal system. Periapical radiolucency is evident. Pulp vitality tests were negative. ***C.*** Immediate post operative radiograph. ***D.*** Four-year follow-up radiograph showing resolution of the periapical radiolucency. (Courtesy of Dr. Fernando Goldberg, Buenos Aires, Argentina.)

Prevalence

The reported prevalence, in the primary dentition, varies between 0.5%-2.5%.[22,23] In the permanent dentition, however, it is estimated to vary between 0.1%-1%.[5,24,25] Gemination and fusion occur predominantly in incisors and canines with apparent equal distribution between the maxilla and the mandible[25] as well as between males and females.[8] Occurrence in the posterior arch (Figure 26-2) is less frequent than in the anterior arch.[25] Bilateral occurrence is rare, not exceeding 0.6% in the permanent dentition.[26]

Clinical Implications

Teeth affected with this anomaly are usually wider and often have a distinctive groove on the crown in the union between the dental units involved. This causes an esthetic defect as well as arch spacing alterations such as diastema, loss of proximal contact, tooth crowding, and even impaction of neighboring teeth.[27] Consequently, malocclusions and functional impediments may develop.[7] When the grooves are deep, plaque can easily accumulate, making the tooth more susceptible to caries and periodontal disease.[28]

Numerous treatment options have been proposed including extraction, recontouring, reduction of tooth size, or hemisection.[3,21] Surgically dividing or reducing the size of the tooth may result in pulpal exposure due to microscopic extensions in the pulp chamber occupying the dentin adjacent to the main pulp chamber, in an irregular manner, requiring endodontic treatment.[14,29]

Careful clinical examination and a thorough imaging analysis are necessary to assess the complex internal anatomy and root morphology of the tooth, before starting endodontic treatment. Cone beam computed tomography (CBCT) could be advantageous.[30]

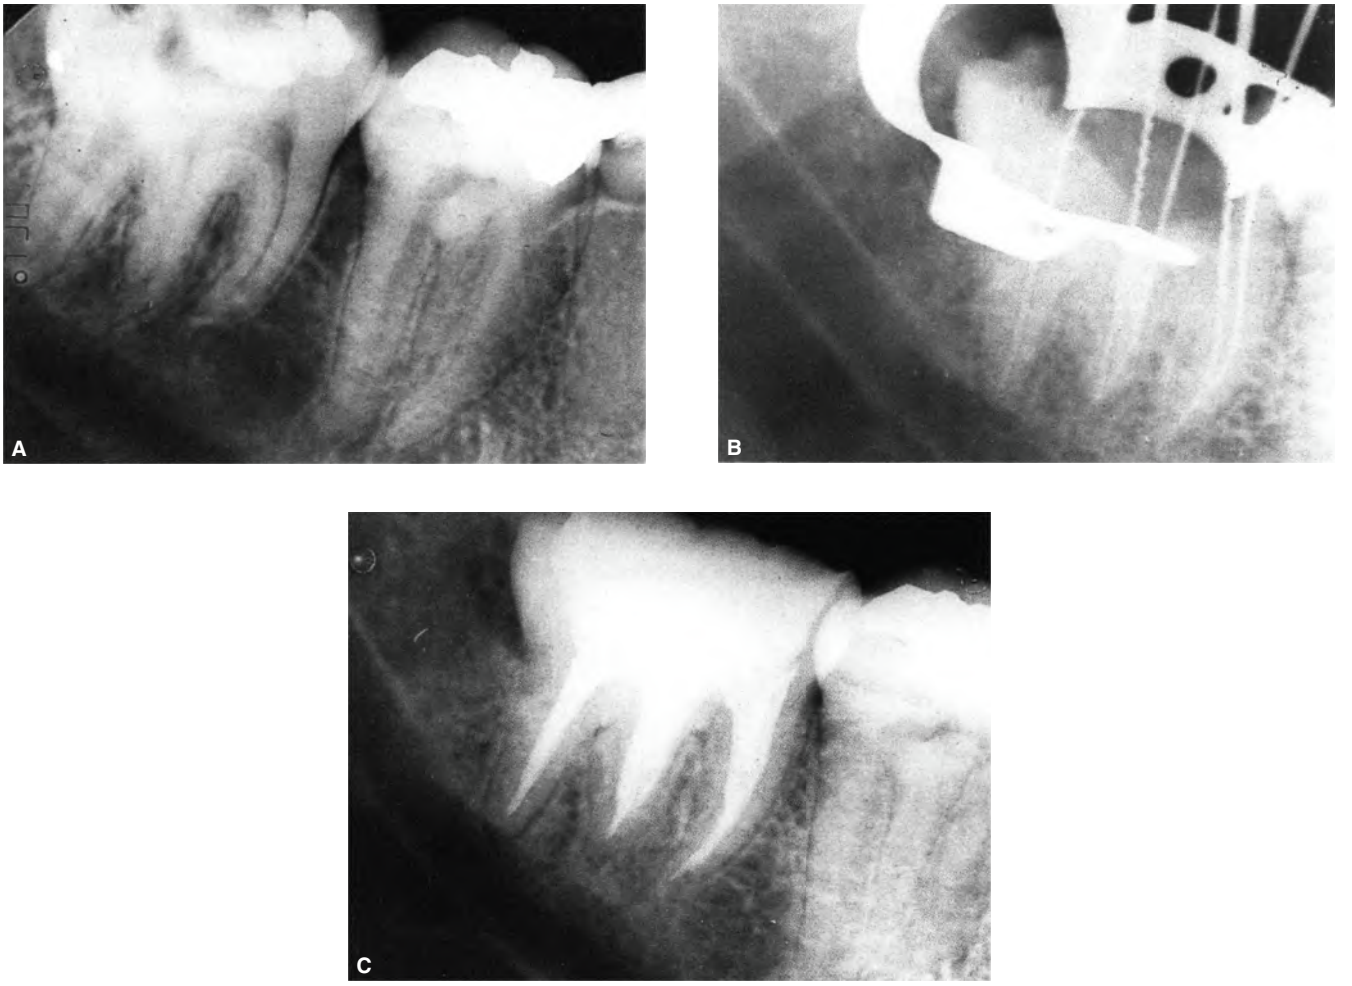

FIGURE 26-2 Fused mandibular right second molar in a 25-year-old male. The patient complained of irradiating pain to the right ear. The tooth was tender to percussion and the surrounding mucosa was slightly inflamed. ***A.*** Preoperative radiograph. ***B.*** Working length assessment radiograph showing five endodontic instruments in five separate root canals. There were two canal orifices in the mesial aspect of the pulp chamber floor, two on the middle and one on the distal aspect. ***C.*** Immediate postoperative radiograph of root canal obturation with gutta-percha and sealer. (Courtesy of Dr. Ilan Rotstein, Los Angles, CA, U.S.A. Adapted with permission from Rotstein et al.[31])

Whenever a gemination/fused tooth is treated endodontically, the root canal should be considered as one system, even if a communication between the pulp chambers or root canal systems is initially not clinically discernible.[31] Separate endodontic access cavities may be necessary. Communication between the pulp chambers of geminated or fused teeth is a common feature.[15,32,33] Careful examination of the pulp chamber and removal of overlaying dentin will facilitate the location and treatment of all root canals.[31]

DILACERATION

Definition

Dilaceration (Latin: *dilacero* = tear up) is an angulation or a sharp bend in the root or crown of a formed tooth.[1,2] The term *scorpion tooth* was suggested when the dilaceration is labial, and *bayonet* when the tooth presents more than one dilaceration.[34]

Characteristics

Dilaceration is characterized by an abrupt deviation in the longitudinal axis of a tooth.[34] It may affect any part of the tooth and follow any direction[35] (Figure 26-3). It is observed in both erupted and unerupted teeth and may be associated with prolonged retention of the primary predecessor, or with apical fenestration of the labial cortical plate.[37]

A dilacerated tooth can become ectopic, or not erupt, because the longitudinal axes of the root and crown are not aligned.[34] The more apically and less severe the dilaceration, the greater is the chance for spontaneous tooth eruption.[38]

Coronal dilaceration may be observed visually, however, radicular dilaceration requires radiographic images.[39] Radiographically, if the root is curved mesially or distally, the dilaceration is clearly apparent. If the dilaceration is directed labially or lingually, the root may not appear severely curved. When the root is curved labially, it may present a rounded opaque area with a dark spot in its center,

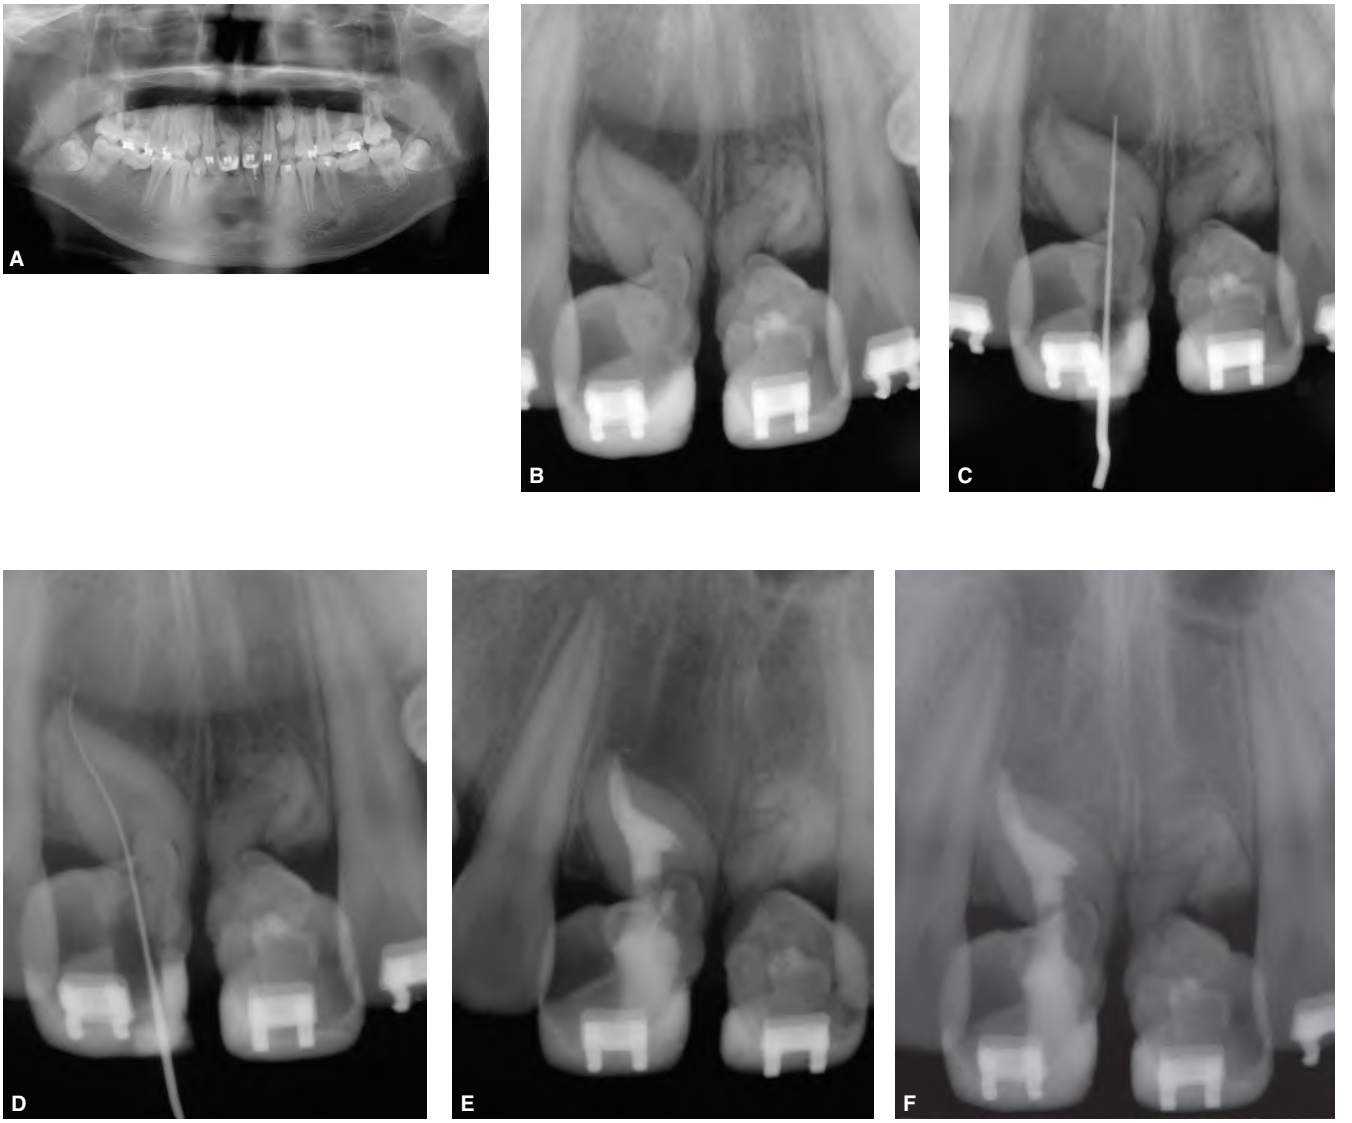

FIGURE 26-3 Endodontic treatment in a dilacerated maxillary right central incisor of a 12-year-old male. The tooth showed class II mobility with swelling and a sinus tract in the buccal mucosa and periapical radiolucency. The tooth was previously treated by the referring dentist. The palatal access cavity was sealed with a temporary filling material. ***A.*** Panoramic radiograph showing multiple dental anomalies. Medical history revealed that the patient suffered from cerebral meningitis at four months after birth and cerebral subdural emphysema at six months that required head surgery and long-term anticonvulsant medication for one year. ***B.*** Preoperative radiograph showing the affected tooth associated with a large periapical radiolucency. ***C.*** Radiograph taken by the referring dentist. Endodontic file demonstrates a perforation at the cervical area of the root. Perforation occurred during attempts of the referring dentist to access the root canal. ***D.*** The perforation site was repaired with MTA and resin-modified glass ionomer and the canal was accessed correctly. Following cleaning and shaping, the canal was dressed with calcium hydroxide paste for a period of 4 months. ***E.*** Postoperative radiograph. The canal was obturated with gutta-percha and sealer and the coronal access restored with light-cured composite resin. ***F.*** Three-month recall radiograph following obturation. The periapical radiolucency has resolved and the tooth was asymptomatic. (Courtesy of Dr. S-Y Kim, Seoul, Korea. Adapted with permission from Byun C et al.[36])

showing the apical foramen.[37] This appearance is frequently referred to as a *bull's eye* or *target*.[40]

The periodontal ligament space around the dilacerated portion of the root may appear as a radiolucent halo. The radiopacity of the dilacerated segment appears greater than the rest of the root. This is due to increased thickness of the tooth structure that the x-ray beam has to transverse.[37,41] Additional radiographs, from different angles, can assist in diagnosis.[42]

Etiology

It has been suggested that the cause of dilaceration is mechanical trauma disturbing the relations between the calcified and noncalcified portions of the tooth during development.[43,44] This hypothesis proposes that an acute mechanical injury to the primary predecessor may cause the calcified part of the permanent tooth germ to displace in such a manner that the remainder of the noncalcified part of the permanent

tooth germ forms an angle.[45,46] Some authors propose that trauma may result in an imbalance of dentinogenesis causing the Hertwig's epithelial root sheath to produce dentin in a certain area at a markedly reduced rate.[47] However, this may not be the only etiologic factor. In several reported cases of trauma to the predecessor primary teeth, root formation of the succedaneous permanent teeth has not yet been started.[48]

Dilacerations have been also reported in patients without history of trauma.[39,49] High prevalence of dilacerations in mandibular third molars suggests that ectopic development of the tooth germ and lack of space, rather than trauma, may play an important role.

Other factors that may contribute to the formation of dilaceration include scar formation, developmental anomaly of the tooth germ, facial clefting, infection, cysts, tumors, premature extraction of primary teeth, ankylosed primary teeth, hereditary factors as well as anatomical structures such as cortical bone of the maxillary sinus, mandibular canal, or the nasal fossa.[37] Certain syndromes and developmental disorders, such as Smith-Magenis syndrome, hypermobility type of Ehlers-Danlos syndrome, Axenfeld-Rieger syndrome, and congenital ichchyosis, have also been implicated.[48]

Prevalence

Dilaceration may be found in both permanent and primary teeth, yet the prevalence in the latter is much lower.[45,50,51] Radicular dilacerations are more common than coronal dilacerations[37] (Figure 26-4).

The reported prevalence of radicular dilaceration depends on its exact definition. Reports vary considerably, ranging from 1.8% to 98%.[42,52] Different criteria for defining root dilacerations may explain the vast difference in the reported prevalence. When a 20-degree angle or greater deviation from the long axis of the tooth was used as criteria, the reported prevalence of root dilacerations in maxillary lateral incisors was 98%.[52] However, when a 90-degree angle or greater was used as criteria, the prevalence dropped to less than 7%.[39,49]

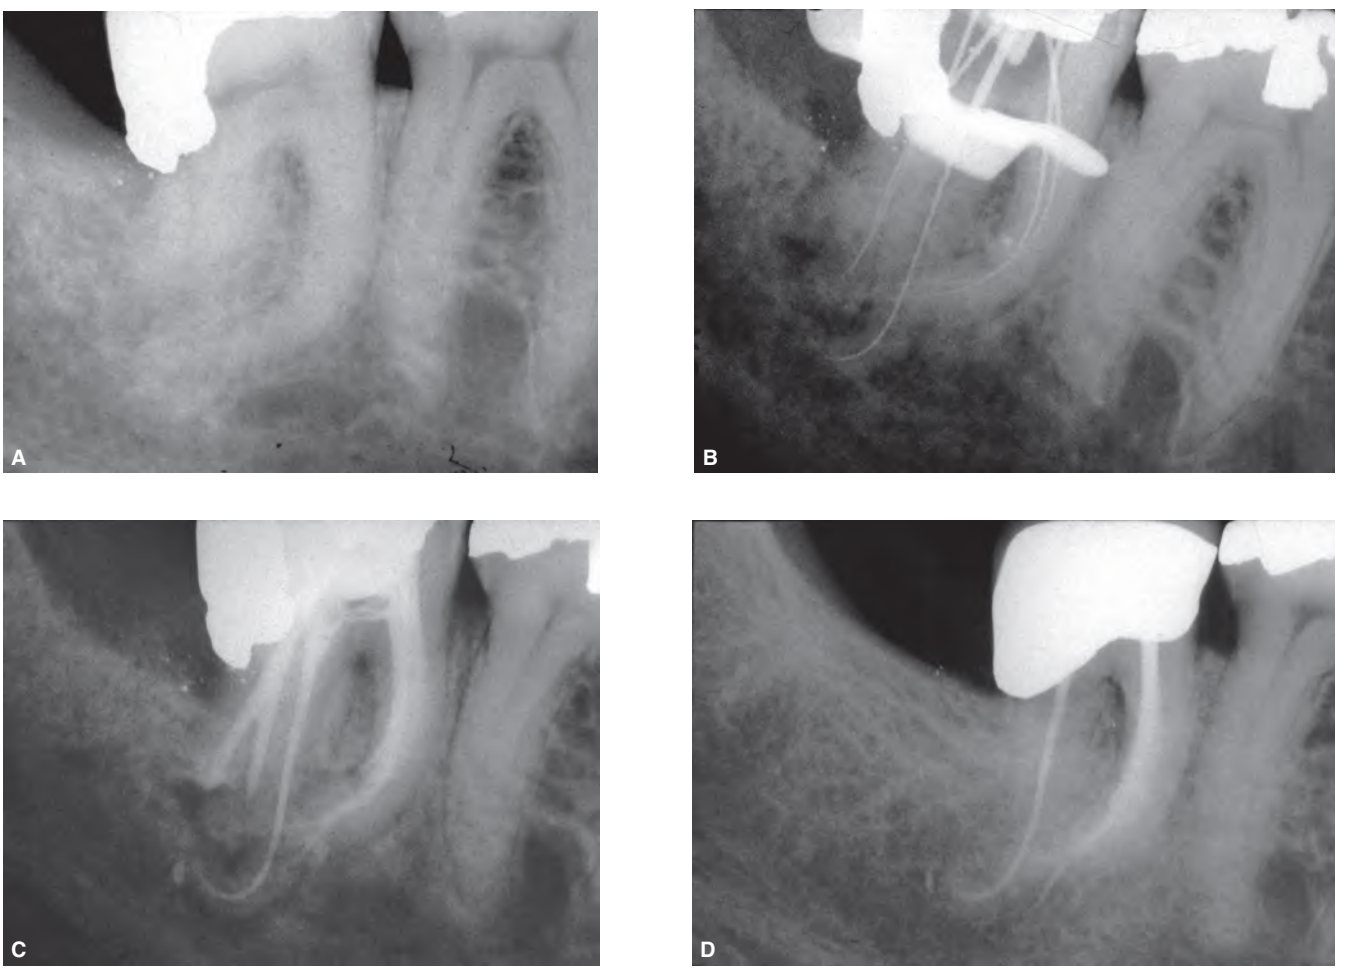

FIGURE 26-4 Endodontic treatment in severely curved roots of a mandibular second molar of a 38-year-old male. (Courtesy of Dr. Stephen P. Niemczyk, Broomall, PA.)

Root dilaceration is more frequently observed in the apical third of the root in incisors, canines and premolars, in the middle third of the root in first and second molars, and in the radicular cervical third of the root in third molars.[49]

Clinical Implications

An erupted dilacerated tooth requiring root canal treatment may present some clinical challenges to the clinician.[53] Diagnosing root dilacerations before initiating endodontic treatment is important to prevent potential procedural complications. Preoperative radiographs from different angles should be taken to recognize the multiplanar nature of the dilaceration. CBCT can confirm the diagnostic findings and help to recognize a dilaceration that may not be completely identified by conventional 2-D periapical radiographs.[54, 55]

Straight-line access cavity preparation is essential for the safe use of endodontic instruments. Sufficient tooth structure needs be removed in order to allow endodontic instruments to move freely. The use of a scouting file will provide critical information about the extent and direction of the dilaceration. Copious irrigation and frequent file recapitulation are recommended.[37,56] Rotary instruments should be used with great caution.

DENS INVAGINATUS

Definition

Dens invaginatus is a developmental malformation resembling the appearance of a "tooth within a tooth". Many terms have been used to describe this anomaly, such as *dens in dente*, *dilated composite odontome*, *gestant odotome*, *invaginated odontome*, *tooth inclusion*, and *dentoid in dente*.[1,2] Dens invaginatus, however, is considered a more accurate terminology since it describes a wider range of variations of this tooth anomaly.[57,58]

Characteristics

Dens invaginatus presents a wide variety of morphological variations affecting the tooth crown, root, or both (Figures 26-5 to 26-7). The shape of the crown may vary from a normal appearance,[59] exaggerated or bifid cingulum, hypoplastic appearance,[60] to a substantial deep infold that reaches the apical foramen.[61] Other crown malformations such as peg shape (Tsurumachi 2004), barrel shape,[62] conical shape,[63] and increased labio-lingual diameter[64] have been described.

Dens invaginatus is usually detected during routine radiographic examination.[65] It may be symmetric or asymmetric and occur either unilaterally or bilaterally.[66–69] An invagination shape, varying from a narrow and undilated fissure to a tear-shape loop pointing towards the main body of the pulp, may be detected on the radiograph.[69,70] The invagination may appear as a radiolucent pocket surrounded by a radiopaque border of equal density to the enamel and extending from the crown toward the root canal.[41] It may be completely separate from the pulp (pseudocanal) and manifested as a deep enamel-lined fissure with its own opening into the periodontal ligament. In such cases, response to pulp sensibility tests can remain normal despite the presence of a periapical radiolucent lesion associated with the psuedocanal.

Different classifications have been suggested to describe dens invaginatus.[66,71,72] The most commonly used was proposed by Oehlers,[57] dividing it to 3 types according to depth of penetration and communication with the periapical tissues or periodontal ligament. In t*ype I*, an enamel lined minor invagination occurs within the coronal part of the crown without extending beyond the cemento-enamel junction. In *type II*, an enamel lined invagination extends into the root, beyond the cemento-enamel junction and remains as a blind sac without reaching the periodontal ligament, or periapical tissues. In *type III*, an invagination penetrating through the root perforates the apical or the periodontal area. There is no immediate communication with the pulp. The invagination may be completely or partially covered by a thin layer of enamel or cementum.

Etiology

The etiology of dens invaginatus is controversial.[60,65,66] It was suggested that it may result from infold of the enamel organ into the dental papilla prior to the calcification stage of tooth development.[66] Rushton[73] hypothesized that the invagination may be a result of rapid and aggressive proliferation of a part of the internal enamel epithelium invading the dental papilla. On the other hand, Kronfeld[74] suggested that the invagination was the result of retardation, or focal growth failure of the internal enamel epithelium while the surrounding epithelium continued to proliferate normally and engulfing the static area. Atkinso[75] suggested that the invagination was the result of external forces, from growth pressure during development of adjacent tooth germs, causing the enamel organ to buckle. Other external factors such as trauma and infection were also suggested.[1,2]

Dens invaginatus was associated with certain genetic disorders.[65,68,76,77] Other dental anomalies, such as microdontia and hypodontia, were also associated with dens invaginatus. It therefore appears that genetic factors may play a certain role in the occurrence of dens invaginatus.

Prevalence

The reported prevalence of dens invaginatus, in the permanent dentition, varies from 0.17%[78] to 26.1%.[42] It is more common in the primary dentition. Maxillary lateral incisors are most frequently affected.[79,80] Kirzioglu and Ceyhan[80] reported that maxillary lateral incisors were the most affected teeth (62%), followed by maxillary central incisors (35%) and maxillary canines (3%). Occasionally, permanent premolars may be affected.[81] However, posterior permanent teeth are less likely to be involved.[82–84]

Using Oehlers' classification, *type I* occurs most frequently.[60] Kirzioglu and Ceyhan[80] reported an overall

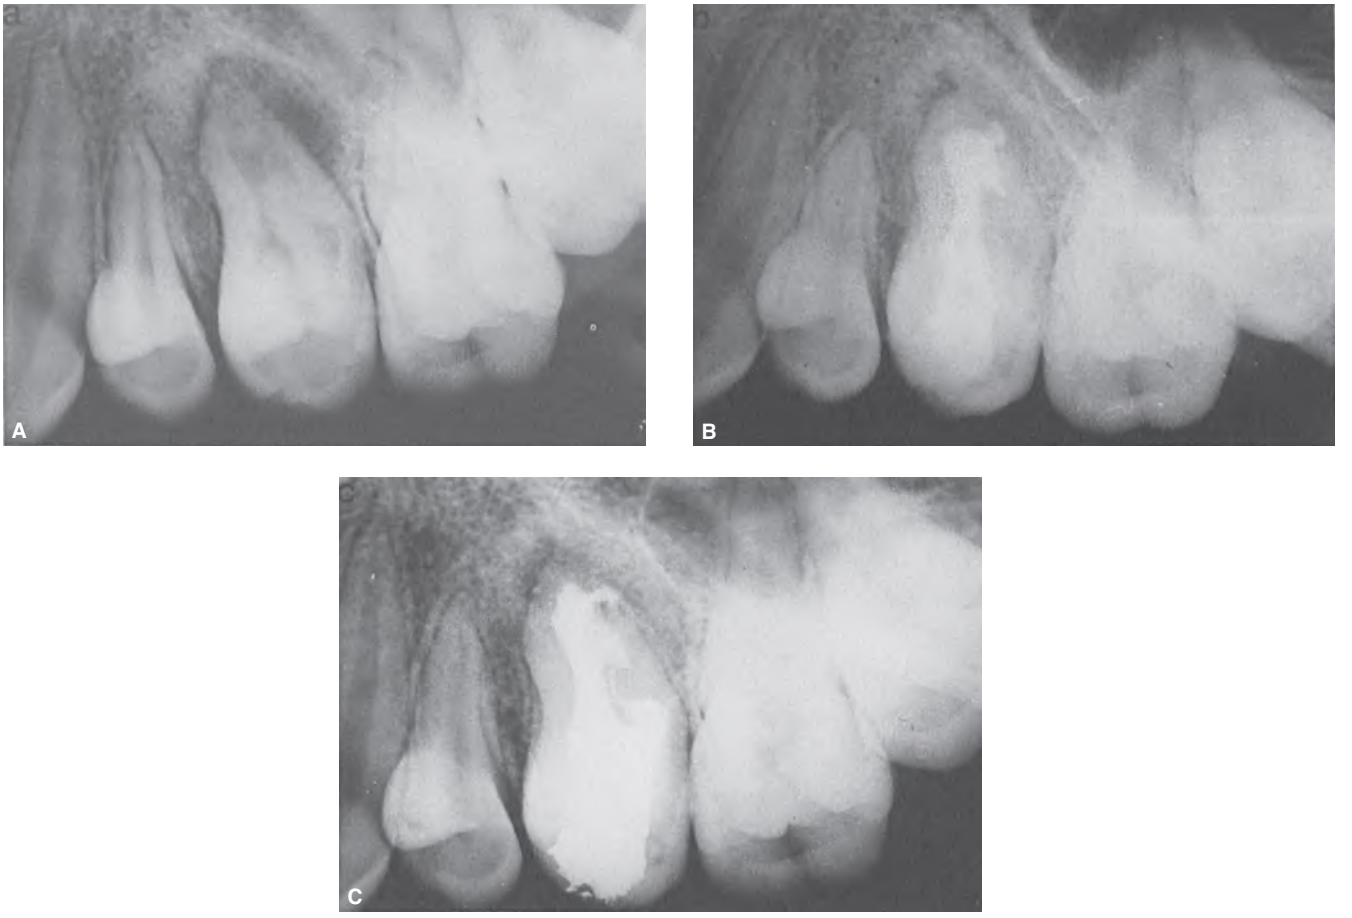

FIGURE 26-5 Endodontic therapy of dens invaginatus in a permanent maxillary second premolar of a 14-year-old female. Pulp sensibility tests were negative. ***A.*** Preoperative radiograph showing large periapical radiolucency associated with the tooth. ***B.*** Six months following introduction of calcium hydroxide to facilitate apical closure. Note considerable reduction in size of the periapical radiolucency. The patient was asymptomatic. ***C.*** Postoperative radiograph. Adapted with permission from Rotstein et al.[88])

prevalence of 94% for *type I*, 3% for *type II*, and 3% for *type III*. Colak et al.[78] found that *type I* occurred in 73% of cases, *type II* in 20% and *type III* in 7%.

Clinical Implications

The main clinical concern associated with dens invaginatus is the ingress of microorganisms and irritants into the pulp via the invaginated area where dentin is covered only by a thin layer of enamel. The dentin of the invaginated tissue may contain vital connective tissue,[85,86] or fine canals that communicate with the dental pulp.[57,73,74] This dentin may be hypo-mineralized, or irregularly structured.[72,85,87]

The structure and thickness of the enamel lining also varies.[75,87] The invagination may contain remnants of the dental papilla or periodontal connective tissue that becomes necrotic, and a nutrient-rich environment following microbial contamination from the mouth.[74,86]

Teeth affected with dens invaginatus are more prone to developing pulpal pathosis a short time after eruption. The risk of pulpal complication is due to the inherent poor anatomical features, both on a macro and microscopic level that encourage microbial contamination.[65] Early diagnosis and preventive treatment measures can reduce the future need for endodontic treatment.[60] Rotstein et al.[88] suggested early sealing of the invagination by means of restorative materials in cases where no pathosis has yet been detected. Use of dye such as methylene blue and high power magnification and illumination can help identify the openings. When the tooth does not present a detectable entrance clinically, and a minimal invagination is seen radiographically, acid-etched fissure sealant or flowable composite resin should be used.

Unerupted teeth with dens invaginatus (diagnosed by a radiograph) should be considered for preventive treatment as soon as practical after tooth eruption. When dens invaginatus is suspected, additional radiographs from different angulations should be taken.[58] CBCT can be helpful for diagnosis and accurate anatomic representation.[89]

When a periradicular pathosis is present but the pulp in the main canal is healthy, efforts should be made to preserve pulp vitality. In such cases, the invagination can be treated

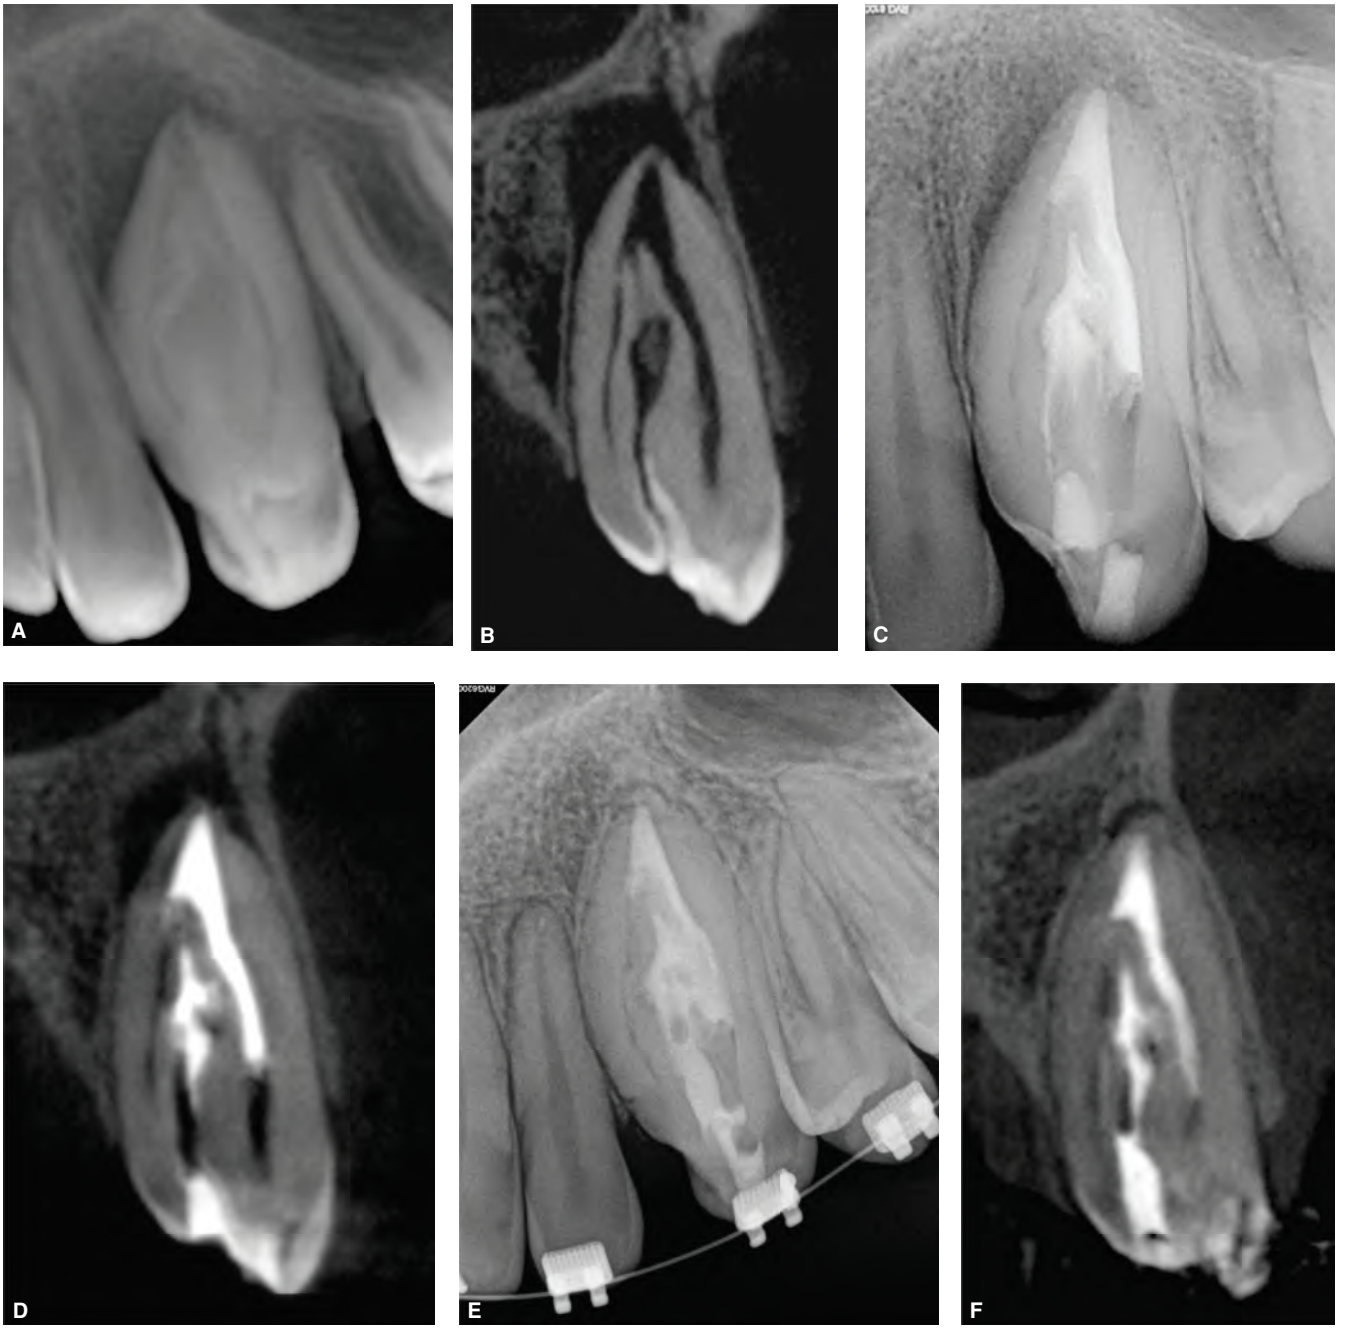

FIGURE 26-6 Dens invaginatus in a maxillary left canine of a 14-year-old male associated with traumatic injury 2 months previously. The tooth was painful to percussion and exhibited localized swelling. Pulp sensibility tests were negative. ***A.*** Preoperative radiograph showing periapical radiolucency associated with the tooth. ***B.*** Cone beam computed tomography (CBCT) sagittal cross-section was taken using a CS 9300 unit at 90 µm voxel size (Carestream Health, Rochester New York). separately from the root canal.[58] When the pulp is necrotic, the entire root canal system needs to be treated. Occasionally, it may be possible to treat the root canal and invagination separately.[90–95] Care should be taken when joining the root canal with the invagination because it may weaken the tooth structure or compromise the apical constriction. Therefore, attempting to keep the invagination and root canal separately during endodontic treatment is advisable whenever possible.[58] Nevertheless, the proximity of the root canal to the invagination may often necessitate treating them both.

The large and irregular volume of the root canal system in dens invaginatus makes proper cleaning and shaping

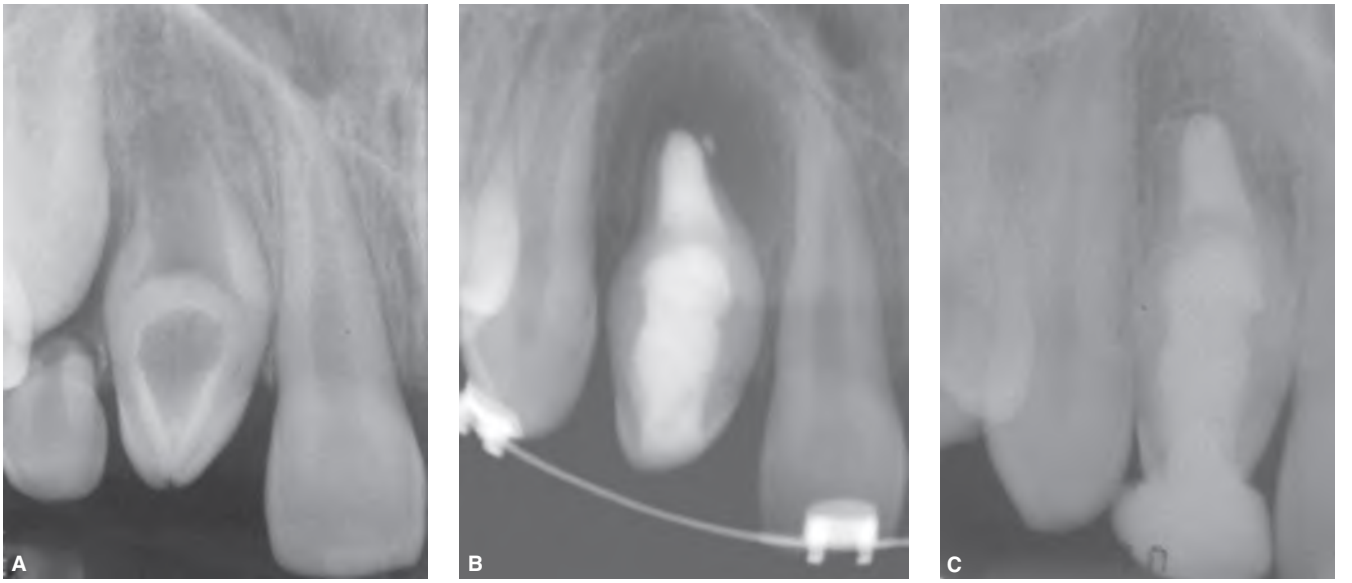

FIGURE 26-7 Dens invaginatus variant in a symptomatic maxillary left lateral incisor with necrotic pulp of a 9-year-old male. ***A.*** Periapical radiograph taken three years prior to endodontic treatment. ***B.*** Postoperative radiograph at age 12 showing large periapical radiolucency associated with the tooth. The root canal system was obturated with MTA and bonded core was placed. ***C.*** 11-year recall radiograph showing resolution of the periapical radiolucency. difficult. The use of ultrasonics with irrigation for thorough chemo-mechanical preparation may be beneficial.[65] Surgical treatment should be considered when conservative treatment has failed.[88]

DENS EVAGINATUS

Definitions

Dens evaginatus is a developmental malformation presenting a tubercle, elevation, protuberance, excrescence, extrusion, or bulge from the involved surface of the affected tooth.[96,97] It is also referred to as an *interstitial cusp*, *tuberculated premolar*, *Leong's premolar*, *odotome of the axial core type*, *evaginated odontome*, *occlusal enamel pearl*, *occlusal anomalous tubercle*, and *supernumerary cusp*.[98,99] However, the term "dens evaginatus" is mostly used today because the protuberance can include enamel as well as dentin and pulp tissue.[100,101]

Usually, when the tubercle is present on the lingual surface of an anterior tooth, projecting either from the cingulum or the cementoenamel junction, the term *talon cusp* is used.[102,103] However, a talon cusp may also occur on the labial surface of anterior teeth.[104,105]

Dens evaginatus and talon cusp are basically the same tooth anomaly. Talon cusp is a subset of dens evaginatus presenting similar developmental, morphological, and histological characteristics.[96,106]

Characteristics

The tubercle of dens evaginatus appears as a pronounced elevation on the occlusal surface of premolars often in the form of a drop, nipple, or a pointed or cylindrical cone of varying size. It is most often located between the buccal and lingual cusps, usually on the buccal triangular ridge or in the central groove.[107] The location of the tubercle on the occlusal surface may vary from the central groove to the inclined plane of the buccal cusp.[6]

The tubercle dimensions in posterior teeth have an average of 2 mm width and up to 3.5 mm length.[97,108] Other than the cusp-like variable sized and shaped tubercles of teeth with dens evaginatus, the remaining portion of the crown presents a normal anatomy.[97,107] The tubercle often contains variant forms and extensions of pulp tissue that are surrounded by dentin and enamel.[100,101] Dens evaginatus is considered as the antithesis of dens invaginatus.[109]

When tubercles occur in anterior teeth (talon cusp), the projection may appear as an exaggerated cingulum, or a prominent well-defined accessory cusp, that can extend beyond the incisal edge, forming a T-shaped or a Y-shaped crown contour.[102,104,110] Tubercle dimensions in anterior teeth are of 3.5 mm width and 6.0 mm length on average.[111] A talon cusp is delineated by deep developmental fissures or grooves, that accumulate plaque and can become susceptible to caries.[103]

Etiology

The exact etiology is not completely understood. The anomaly is considered a result of an outward folding of the inner enamel epithelial cells proliferating into the stellate reticulum of the enamel organ or due to a transient focal hyperplasia of the mesenchymal peripheral cells of the dental papilla.[101,103] It has been viewed as one variation of a range of hyperactivity of the dental lamina.[112,113]

It has been suggested that both autosomal dominant and chromosome X-linked traits may play a role.[106] Localized developmental pressure exerted upon the developing tooth

bud due to trauma has also been suggested.[97,110] It, therefore, appears that the etiology may be multifactorial, combining both genetic and environmental factors and causing aberrant hyperactivity of the dental lamina.[113,114]

Prevalence

Dens evaginatus has been reported to occur predominantly in people with Mongoloid genetic traits such as Chinese, Thai, Malaysians, Japanese, Indians, Eskimos, and Filipinos. The prevalence ranges from 0.5% to 4.3 %.[96,97] Isolated cases in African-Americans and Caucasians have also been reported.[115,116]

Dens evaginatus frequently occurs bilaterally without sex predilection.[96,107] Premolars are the most frequently affected posterior teeth, and mandibular premolars tend to have higher prevalence than maxillary premolars.[100]

The reported prevalence of talon cusps varies from 0.06% to 7.7%. The large variation is probably due to the lack of uniform classification criteria.[104,117,118]

Talon cusps are mainly found in the permanent dentition with twice, or higher, male predilection than female.[104,113] They are most frequently found in maxillary lateral incisors, followed by central incisors and canines that are the least affected teeth.[98,119] Although talon cusp has not been linked to any specific syndrome, it has been reported in patients with Rubinstein-Taybi syndrome, Mohr syndrome, Struge-Weber syndrome, incontinentia pigmentia achromians, Ellis-van Creveld syndrome, hypomelanosis of Ito, and Alagille's syndrome.[104] It has also been associated with peg-shaped lateral incisors, unerupted permanent canines, and impacted mesiodens.[110]

Clinical Implications

Because the tubercle of dens evaginatus extends above the occlusal surface, traumatic occlusal interference with opposing teeth may occur following tooth eruption.[97] Traumatic occlusion causes abnormal wear or fracture of the tubercle leading to pulpal inflammation and necrosis (Figure 26-8), sometimes

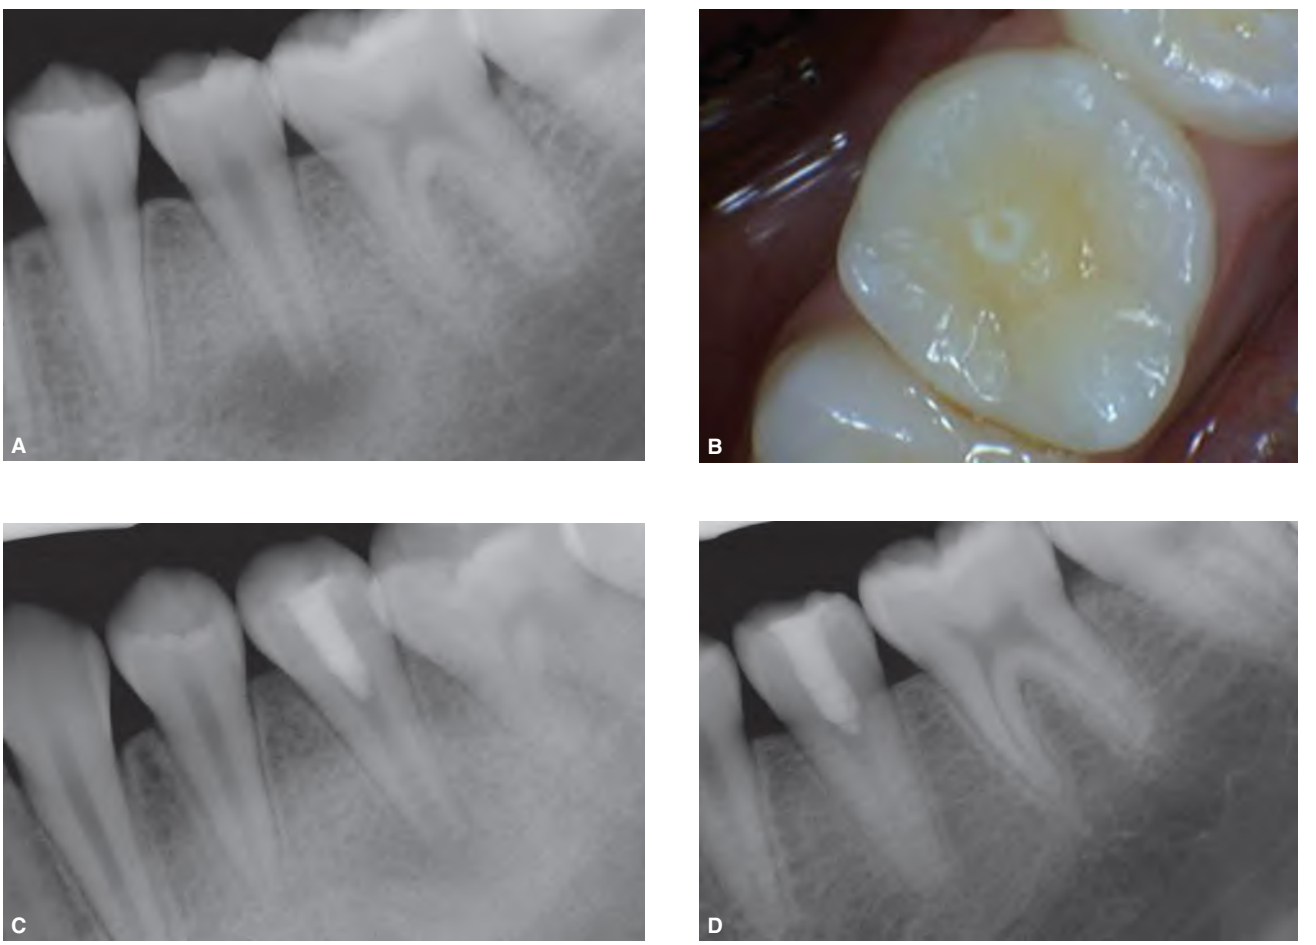

FIGURE 26-8 Dens evaginatus in a mandibular second premolar of a 12-year-old male. Patient complained of pain while biting on his left side. Pulp sensibility tests were negative. ***A.*** Preoperative radiograph showing periapical radiolucency associated with the tooth. ***B.*** Clinical view showing fractured occlusal protuberance (arrow). This frequent occurrence causes pulpal irritation, and often pulp necrosis at an early age. Pulp regeneration therapy with a triple antibiotic paste was performed (for more details about this procedure, see Chapter 29, "Regenerative endodontics"). ***C.*** Immediate postoperative radiograph. ***D.*** 18-month recall radiograph showing evidence of active bony healing. Note the narrowing of the pulp space. The patient was asymptomatic and the pulp responded positive to sensibility tests. (Courtesy of Dr. Rajiv G. Patel, Flower Mound, TX.)

before the completion of root formation.[96] In these cases, caries is usually not the prime cause of pulpal damage.[109]

It is imperative to recognize this anomaly early during clinical and radiographic examination, even before eruption, to take appropriate preventive measures.[96,97,106] Several methods have been advocated to prevent pulpal damage. Levitan and Himel[97] proposed that occluding surfaces of opposing teeth be reduced to eliminate traumatic occlusion with the tubercle. This should be followed by an application of topical fluoride to increase the enamel's hydroxyapatite resistance to acid breakdown. Subsequently, incremental layering of an acid-etched flowable light-cured resin should be applied to the tubercle and surrounding surface to support the base of the tubercle and to prevent the fracture.[97] The occlusion should be examined at six-month intervals in teeth with mature apices (3–4 months in immature teeth) and any necessary adjustments performed. Once radiographs have confirmed adequate pulp recession, the tubercle should be reduced to the level of the normal occlusal plane. Any exposed dentin should be protected with acid-etched microhybrid light-cured resin.[97]

Patients showing heavy occlusal forces on the tubercle may have the projection excised aseptically under dental dam isolation. This is followed by indirect or direct pulp capping (or parital pulptomy) and placement of a restorative material.[120,121] The superficial layers of the pulp are gently removed to a depth of 2 mm below the exposure where pulp capping material is placed onto the remaining pulp tissue to promote calcific bridge formation and continued root development.[97]

Past treatment modality suggested "spot grinding" or "selective grinding" of the tubercles to stimulate reparative dentin formation.[99,122] However, this method may not be always reliable since grinding of the tip of the tubercle would only stimulate a minor deposition of reparative dentin, running an additional risk of exposing the pulp under the tubercle.[100] It may only be successful in cases with no pulpal extension into the tubercle.[96]

Treatment becomes more complex when the pulp develops necrosis in teeth with immature roots. Some authors recommended extraction.[109] Conventional root canal therapy can be successfully performed after obtaining root-end barrier.[123–126] However, the affected tooth may remain with thin and fragile dentinal walls that are susceptible to fracture. Additionally, in young permanent teeth, the amount of root length remaining, general alignment of the tooth, and the overall arch length adequacy should be assessed prior to the treatment decision.[127] Regenerative endodontic techniques may be applied to allow continued root development.[128]

TAURODONTISM

Definition

The term ***taurodontism*** derives from Latin and Greek ("*tauro*" = "bull" and "*odus*" = "tooth"). It was first introduced more than a century ago to describe molar teeth resembling those of cud chewing animals, particularly bulls.[129]

Characteristics

Taurodontism is an anatomical variation in tooth morphology characterized by a vertically enlarged pulp chamber.[1,2] The pulpal chamber is displaced apically and the roots are short, presenting bifurcations, or trifurcations (Figures 26-9 and 26-10). Anatomically, this malformation shows a normal crown, but it lacks constriction at the cemento-enamel junction (CEJ) level, creating the appearance of a rectangular shaped root.

Etiology

Taurodontism is caused by failure of the Hertwigs' epithelium root sheath to invaginate at the proper horizontal level. Usually, taurodontisms can be observed in healthy individuals without any signs of systemic disorders.[130] However, it has also been associated with autosomal dominant conditions such as Apert syndrome, Axenfled-Reiger syndrome, basal cell nevus, ectodermal dysplasia, otodental dysplasia, tricho-dento-osseous syndrome, as well as chromosomal linked conditions such as Klinefleter syndrome and Down syndrome.[131] Therefore, identifying patients with taurodontism may sometimes aid in early recognition of certain systemic disorders.

Taurodontism can be classified into 3 types depending on the severity of the condition: *hypo-*, *meso-* and *hyper-*taurodontism. Hypotaurontsim is the least pronounced form, mesotaurodontism is moderate, and hypertaurodontism is the most pronounced. In cases of hypertaurodontism, the pulp chamber is unusually large, nearly reaching the root apex.[130,132]

Prevalence

The reported prevalence of taurodontism ranges from 0.1%[61] to 48%.[133] This wide range may be due to the different subjective diagnostic criteria used. Biometeric methods such as taurodontic index,[134] or other indices,[135,136] can help to objectively diagnose this anomaly.

Taurodontism can be found in both deciduous and permanent teeth, unilaterally, or bilaterally, and in any combination of teeth or quadrants.[137–139] A higher prevalence was observed in molars; prevalence increasing from the first to the third molar.[137] Similar prevalence was found in both genders.[140] One study, however, suggested a higher prevalence in Chinese females.[141]

Clinical Implications

Taurodontism may present a wide variety of pulp chamber size, shape, configuration, and position of canal orifices. Identifying the canal orifices, negotiating, instrumenting, and obturating the large root canal system may present some challenges. Because of the unusual anatomical features of the pulp chamber and root canal system, a careful exploration of all grooves between canal orifices is recommended. CBCT can be helpful for diagnosis and treatment since each of the taurodont root canal can be visualized individually.[142]

A buccal apical swelling was detected. ***A.*** Preoperative radiograph. ***B.*** Postoperative radiograph following obturation with thermoplasticized gutta-percha and sealer. The patient is asymptomatic. (Courtesy of Dr. Lourdes Lanzagorta Rebollo, Instituto de Endo-Meta-Endodoncia, México.)

Due to the voluminous pulp tissue in the pulp chamber, in some cases, excessive bleeding can be observed during access preparation. This should not be confused with root perforation. Cervical dentin should be removed carefully, particularly in cases of hypertaurodontism, since the cervical tooth structure is thinner.[143]

Because the roots of the taurodont tooth are short, usually only the apical active part of the file is used, making the canal instrumentation time consuming.[144] Irrigation of the root canal system with sodium hypochlorite activated by ultrasonic energy may be beneficial to ensure complete removal of the pulp tissue.

Endodontic treatment in teeth with taurodontism can be very successful.[130,139,145] When performing endodontic treatment on a taurodont tooth, the operator should be aware of the complex anatomy of the root canal system. Judicious practice of endodontic principles such as identifying the canal orifices under magnification, thorough canal instrumentation and irrigation, and careful obturation of the entire root canal system is paramount for endodontic treatment success.

It has been suggested that only a small surface area of a taurodont tooth is embedded in the alveolus, thus compromising the stability of the tooth. Therefore, its use as an abutment for prosthetics or orthodontic anchorage purposes may be less desirable.[146] Post placement in a taurodont tooth is not recommended due to the large and elongated pulp chamber and short roots.[148]

From periodontal and surgical standpoints, the apically located furcation area may present a more favorable prognosis to treatment since attachment loss, resulting from a periodontal pocket or gingival recession, would involve less of the furcation area. Additionally, if the roots are not widely divergent, extraction of the tooth is easier. This can be beneficial in case intentional replantation procedure is indicated.

C-SHAPED CANAL

Definition

This anatomical variation presents a continuous slit connecting some or all canals, and forming a shape of the letter "C" in a cross-sectional configuration (Figure 26-11).

Characteristics

C-shaped canals are typically found in teeth with fused roots presenting with longitudinal grooves on the root surface. The groove can be located either on the buccal or lingual aspect of the root, or on both sides.[149] The floor of the pulp chamber is often deeply situated, assuming an unusual anatomical appearance.[150] The canal orifice may appear as a single, continuous ribbon-liked shape and often does not present the same configuration throughout the entire root length. It may present with a 180° or more arc that links the main canals, instead of having several discrete orifices. The arc may start at either the mesio-lingual or mesio-buccal line angle and sweeps around the tooth buccally, or lingually, to end at the distal aspect of the pulp chamber.[151,152]

Significant variations of root canal configurations at different levels of the root are found below the pulp chamber orifices without a consistent pattern.[153,154] The main anatomic feature of the root canal system is the presence of fins or webs that connect the individual canals.

Melton et al.[155] proposed a classification based on cross-sectional shape. *Category I* represents a continuous C-shaped orifice configuration without any separation of the outline; *Category II* represents a canal orifice shape resembling a semicolon (;) where dentin separates the main C-shaped outline from the same buccal or lingual direction, making a discrete canal to discontinue the "C" outline; and *Category III* represents two or more discrete and separate canals. Fan et al.[150] proposed a modified classification by adding two more categories. *Category IV* represents a single, round or oval, canal in the cross-section; and *Category V* where no canal lumen is observed near the root apex.

Etiology

It is hypothesized that failure of the Hertwig's epithelial root sheath to fuse on the lingual or buccal root surface is the main cause for this variation.[156–158] Fused roots may form by coalescence of cementum deposition over time.

Prevalence

C-shaped canals are not rare. The reported prevalence ranges from 2.7% to 44.5%.[152,159] Ethnic variation is considered an important factor. This particular tooth variation is more commonly seen in Asian ethnic groups.[156] Chinese populations[160,161] have shown higher prevalence of C-shaped mandibular second molars than Caucasians.[151]

Generally, C-shaped canal is most frequently found in mandibular second molars (Figures 26-11 and 26-12). In such cases, it may also be found in the contralateral tooth in over 70% of cases.[162] Mandibular second premolars are the second most frequent site, with a reported incidence rate varying from 14% to 18%.[163,164]

C-shaped canals, however, may also occur in other teeth such as mandibular first molars,[165,166] maxillary first molars,[167–169] maxillary[170] and mandibular[171] third molars, and even in maxillary lateral incisor.[172]

Clinical Implications

C-shaped canals should be carefully diagnosed and treated. Radiographically, an endodontic instrument placed in the canal may appear to perforate the furcation. Radiographs taken from several horizontal angulations[157] or CBCT images[173] will prove beneficial.

There are several radiographic hints that can help the operator diagnose C-shaped canals prior to accessing the pulp chamber. Simon[174] suggested the following:

1. The root appears conical and as if representing one root with a furcation. This is usually in contrast to adjacent molars (especially the first molar), that have two distinct roots with a normal furca.

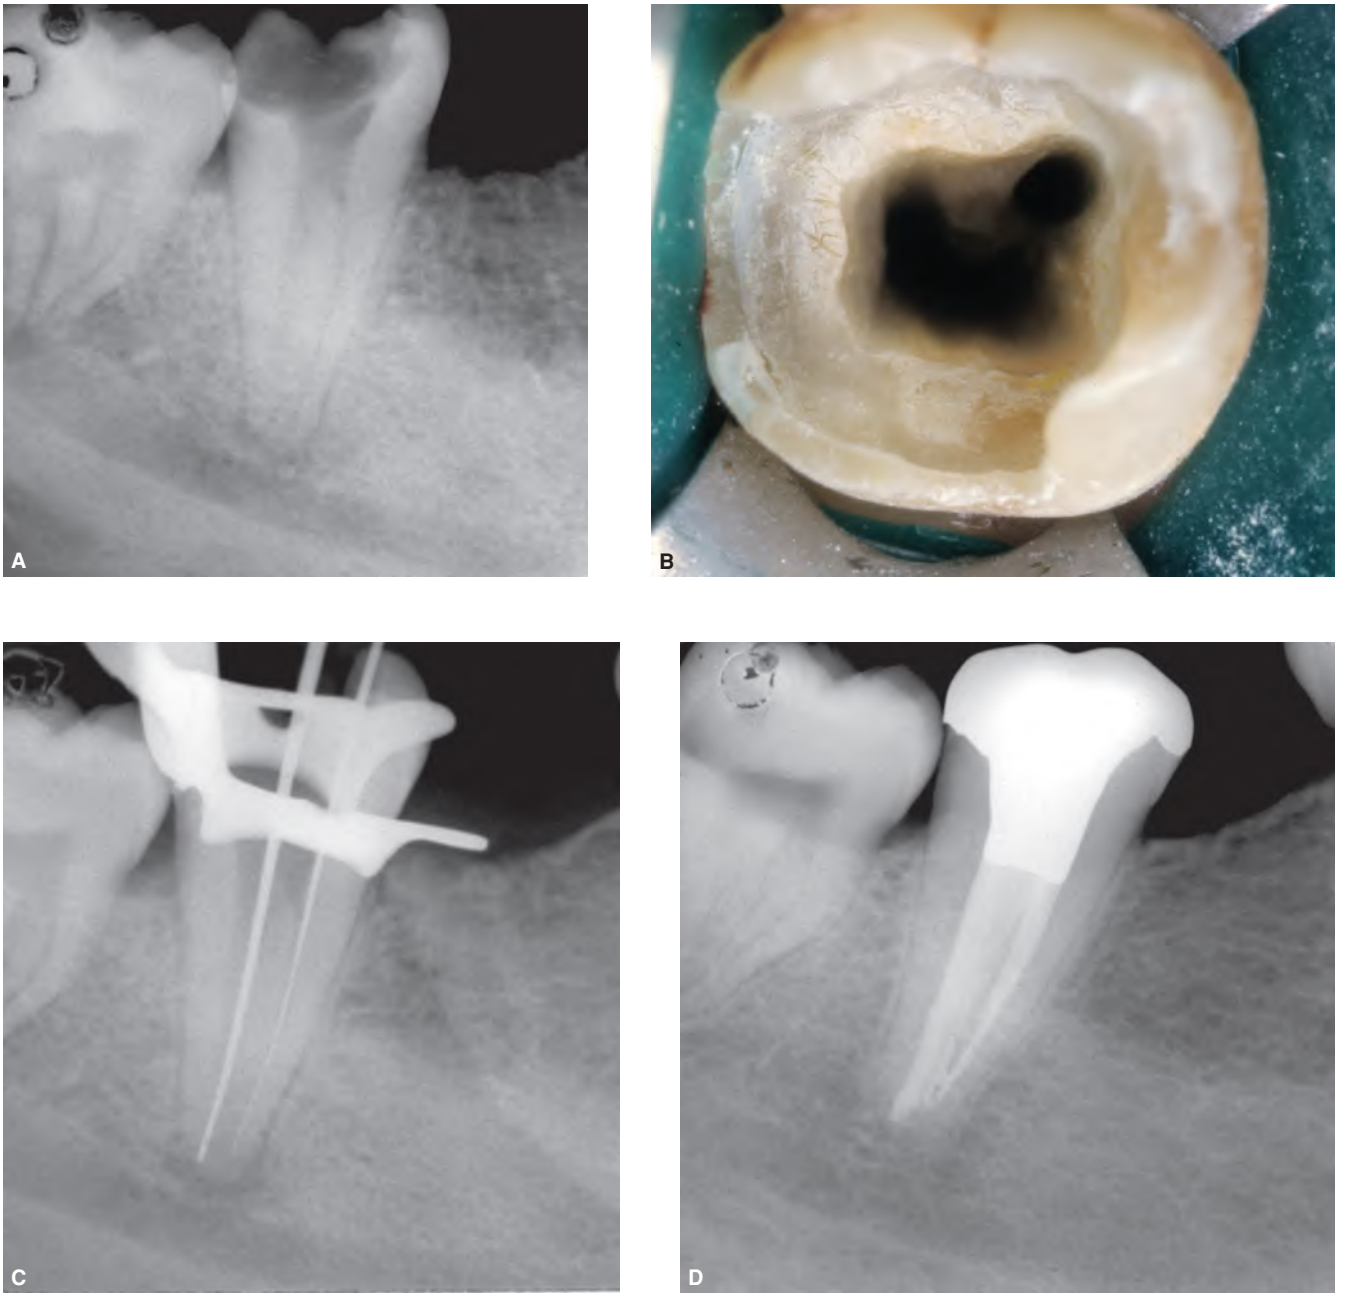

FIGURE 26-11 Endodontic treatment in a mandibular second molar with C-shaped canal and necrotic pulp of a 25-year-old male. ***A.*** Preoperative radiograph showing the affected tooth associated with a periapical radiolucency. ***B.*** Clinical view of the access cavity showing an independent mesiolingual canal and a C-shaped configuration connecting the mesiobuccal canal to the distal canal. ***C.*** Working length assessment radiograph. ***D.*** Three-year recall radiograph showing resolution of the periapical radiolucency. The patient is asymptomatic and the tooth is functional. (Courtesy of Dr. Domenico Ricucci, Cetraro, Italy. Adapted with permission from Ricucci et al.[147])

2. The pulp chamber appears longer than that of the adjacent molars.
3. The pulp chamber becomes indistinct apically. The pulp chamber's floor is not usually visible and little or no furca is apparent on the radiograph.
4. At the apex, the periodontal ligament is indistinct or indiscernible. Canals cannot be followed in the apical third portion of the tooth. The exit of the apical foramina are not clearly observed.

Thorough debridement of the C-shaped canal can be exhausting due to the multiple connecting fins and isthmi.[149,155,175] Since canal bifurcations may be observed at any level between the orifice and apical terminus, careful exploration with a small, pre-curved endodontic file using the operating microscope is helpful.[153]

Supplemental canal cleaning with ultrasonics may be beneficial.[176–178] Canal preparation by mechanical instrumentation should follow the same configuration as

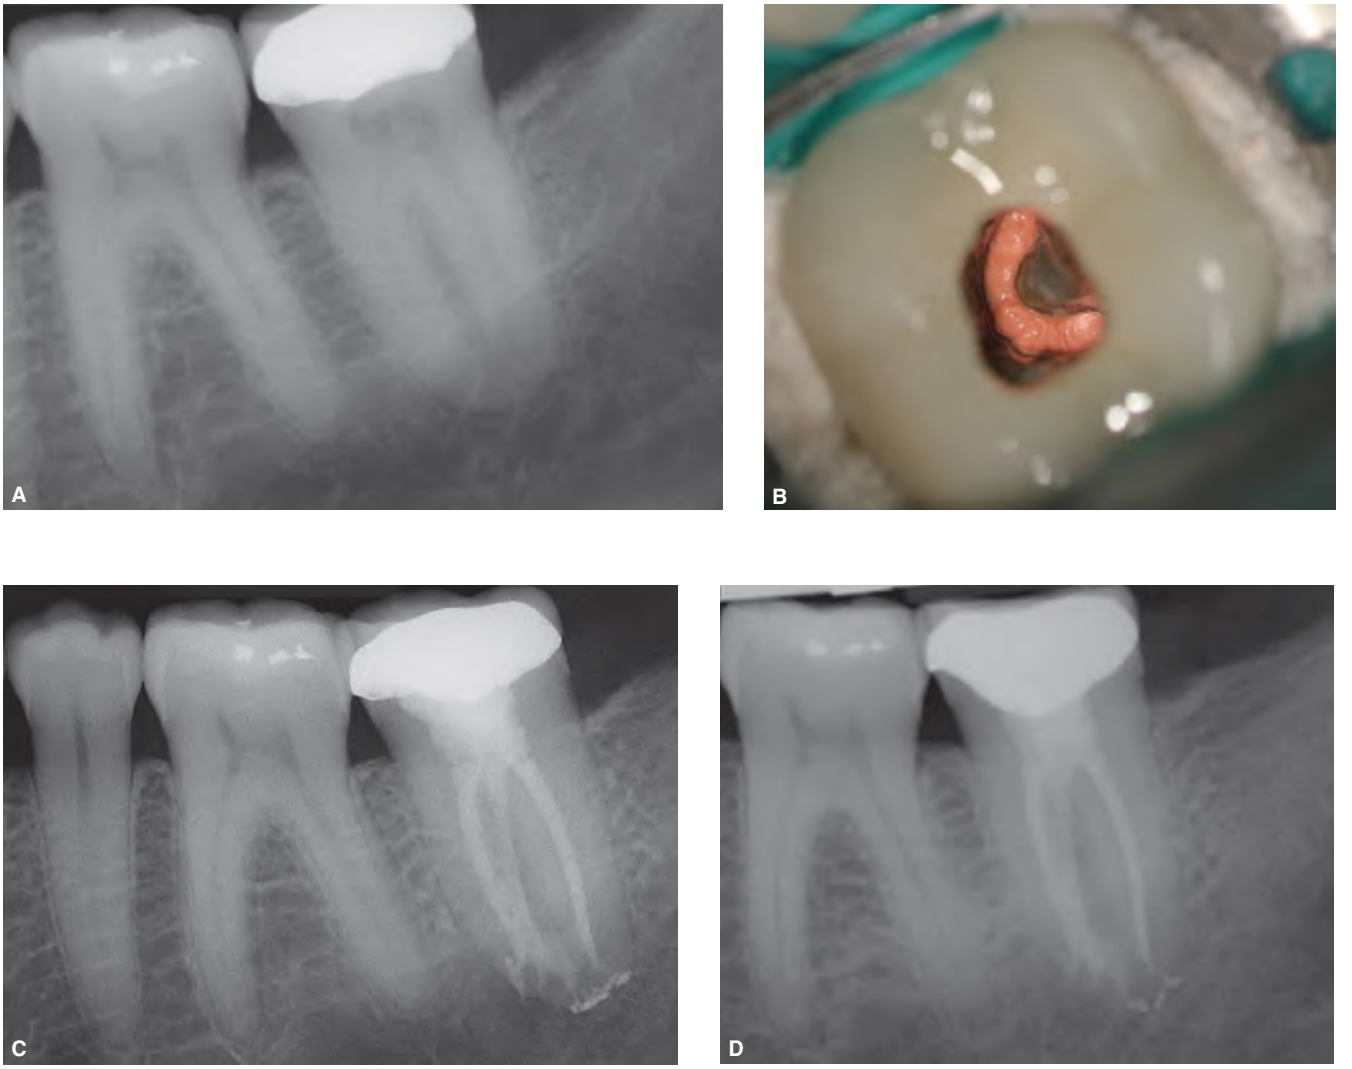

FIGURE 26-12 C-shaped canal in a mandibular second molar of a 40-year-old female. Pulp sensibility tests were negative. ***A.*** Preoperative radiograph. ***B.*** Clinical view of the access cavity after obturation of the root canal system. ***C.*** Immediate postoperative radiograph. Note the "shift" of the mesial canal toward the furcation area. This is a typical phenomenon. ***D.*** One-year recall radiograph. The patient is asymptomatic and the tooth is functional. (Courtesy of Dr. Rajiv G. Patel, Flower Mound, TX.)

the canal because the deep groove and the thin connecting isthmi are prone to perforation.[159] A simple enlargement of the canals can lead to perforation, stripping, or both[174]

Obturation may require technique modification.[179] Thermoplasticized gutta percha obturation technique is preferred over cold lateral condensation since softened gutta-percha and sealer will adapt more effectively to the aberrant canal walls.[180]

Restoration of the C-shaped root will require special attention when placement of post or core are needed. Thin dentin is usually present between the canal walls and the outer surface of tooth. Both the buccal and lingual canal walls are frequently narrower at the mesial aspect.[181]

When sound biological treatment principles are followed, a tooth with C-shaped canals should have equal prognostic outcome as other teeth.[174]

SUPERNUMERARY ROOTS AND CANALS

Definitions

Extra roots or root canals are those that show up more than the average detected in the population. Their presence in the human dentition varies considerably.[182] Often, the name of the supernumerary root or root canal derives from its location as related to the main root/canal (e.g., middle-mesial, mesiobucal/MB-2). However, sometimes

they receive specific names (e.g., *radix entomolaris*, *radix paramolaris*, *radix distomolaris*).[183,184] In maxillary molars, *radix distomolaris* was proposed to describe a supernumerary root located distally and *radix distolingualis* or *mesiolingualis* when it is located distolingually or mesiolingually respectively.[185,186] In maxillary premolars, the term *ridiculous* has been proposed because of their resemblance to the adjacent maxillary molar.[187,188]

Characteristics

The characteristics of supernumerary roots and root canals vary.[189] External contour of the supernumerary root furcation is more complex than the one with average root anatomy.[190–192] An extra cusp (*tuberculum paramolare*), or more prominent occlusal distal or distalolingual lobe, in combination with a cervical prominence or convexity, may indicate the presence of an additional root. Radiographically, if the mesiodistal width of the root appears equal to or greater than the crown, variation in root number is likely to exist.[193–195]

An increased number of cusps is not necessarily related to a greater number of roots/canals.[197] However, an additional root is almost always associated with a greater number of cusps and root canals.[192]

Etiology

The exact etiology is not completely understood. In cases of dysmorphic supernumerary root formation, it could be related to external factors occurring during odontogenesis, or to atavism (reappearance of a trait after several generation of absence). In eumorphic roots, racial genetic factors, influencing the more profound expression of a particular gene, result in the more pronounced phenotypic manifestation.[192,198]

Prevalence

Supernumerary roots and root canals can affect any tooth (Figure 26-13) but are more prevalent in molars (Figure 26-14) and premolars (Figure 26-15). The presence of a separate root in the mandibular first molar is associated with certain ethnic groups.[199–205] While European and African populations present a prevalence lower than 5%,[197,204] populations with Mongoloid traits may reach more than 40%.[199] Because of the high prevalence in these populations such tooth anomaly is considered a normal morphological variant of mandibular first molars.[192] It also tends to appear bilaterally. The reported bilateral occurrence ranged between 50% and 69%.[192,204]

Radix root (Figure 26-16) may be found in all mandibular molars. However, it is most frequently found in the first molar and least frequent in the second molar.[202] Its occurrence is similar in males and females.[206–208] The entomolaris type occurs more frequently than the paramolaris type.[192]

The prevalence of four rooted maxillary molars can vary between 0.4% and 1.4%.[209,210] The occurrence of two canals in the distobuccal root of maxillary molars may rage between 1.9% and 9.5%,[211–213] and of three canals or more in the mesiobuccal root of maxillary molars between 1.3% and 2.4%.[214] Nevertheless, no specific predilections of supernumerary roots and root canals in maxillary molars have been established.

Middle mesial canals in mandibular molars have been reported to occur in up to 36% of cases,[215] 20% showing independent apical foramen.[216]

The reported prevalence of two roots in the mandibular first premolar was 1.8%; in three roots, 0.2%; and in four roots, fewer than 0.1% of cases.[182] Three root canals have been reported to range from 0.4% to 5%.[195,211] Maxillary premolars have been reported to present 3 roots in fewer than 2% of cases.[217]

Clinical Implications

An accurate diagnosis of supernumerary roots and root canals is important, to avoid complication or a "missed canal" during endodontic treatment.[218] Radix entomolaris is often located in the same buccolingual plane as the distobuccal root, resulting in superimposition of both roots on the preoperative 2-D radiograph.[192,219] A thorough inspection of the preoperative radiograph and interpretation of particular marks such as an unclear outline of root/canal contour, may indicate the presence of a supernumerary root. Additional radiographs, taken from several angles, may help the diagnosis. Multiple intraoral radiographs, however, do not guarantee the identification of all relevant anatomic variation of the tooth, prior to commencing root canal therapy.[204] CBCT can be advantageous for some of these cases.[219]

Using a periodontal probe may aid in identifying additional roots during clinical inspection of the crown and examination of the cervical morphology of the roots.[192,198] Also, the location of the orifice of the root canal may provide clues, whether additional canals are present or not. For example, the orifice of the radix entomolaris is often located distolingually to the main distal root.[204,218] The middle mesial canal in mandibular molars is frequently located closer to the mesio-buccal canal than to the mesio-lingual canal.[216,220] A modification of the access cavity and eliminating the dentinal protuberances may be necessary to better locate and access the additional canals.[192,213,218,221] Enhanced magnification, illumination, and ultrasonics are excellent adjuncts for a better identification and localization of the supernumerary root canal orifices.[219]

Supernumerary roots and root canals are treated routinely in an endodontic practice. A thorough knowledge of the complexity of root canal systems, operator's skill, and increased time per appointment can aid in identifying and managing these anatomical variations for endodontic purposes.

Chapter 27

Vital Pulp Therapy

George Bogen, Nicholas P. Chandler

Science is nothing but perception

—Plato

Vital pulp therapy is advanced treatment devised to conserve, protect, and maintain a healthy pulp. This includes pulp tissue that may have been compromised by anatomical anomalies, caries, trauma, or restorative procedures. The prime objective of the treatment strategy is to promote the formation of a reparative hard tissue barrier after pulpal injury, in order to retain the tooth as a functional unit. This is critically important in the immature adult tooth, where apical root development may be incomplete.

This chapter describes advances in direct pulp capping and pulpotomy, where treatment therapies have been redefined by the introduction of bioactive capping materials, and clinical protocols that more predictably encompass the microbiological aspects of failure. Attention will be directed toward the preservation of the pulpally involved **permanent tooth**, based on the contention that pulp tissue has an inherent active repair capacity, when microorganisms and their by-products are effectively excluded.[1,2]

Over the last two decades, remarkable progress has been made in the field of vital pulp therapy, primarily due to the introduction of bioactive materials.[3] Since Pierre Fauchard, in the 18th century, first introduced the concept of indirect pulp capping, clinicians have recognized the innate healing capacity of dental pulp tissue, for cell reorganization and calcific bridge formation.[4] Phillip Pfaff is credited with placing gold foil against an exposed pulp in order to promote pulpal healing; this could be the first documented direct pulp capping procedure.[5] Ever since the early times of modern dentistry, researchers and clinicians have endeavored to expand their knowledge of pulp physiology, microbiology, and caries progression, in order to improve pulp preservation methods. Progress has coincided with the quest to identify physiological mediators and bioinductive materials that reliably promote reparative bridge formation and protect the pulp against further injury from microbial ingress.

There has been a long-standing view that direct pulp exposures, in a carious field, have an unfavorable prognosis. Unfortunately, more aggressive procedures, such as pulpotomy or pulpectomy, are still being recommended.[6–8] These treatment strategies were based on traditional protocols and capping materials, that did not provide a uniform environment for pulp cell recruitment, differentiation, and hard tissue repair. Furthermore, prior to treatment, the histological condition of the pulp can be difficult to ascertain, based on the limitations of pulp testing methods, a limited knowledge of pulpal physiology, the subjectivity of the patient's symptoms, and the presence of inflammatory mediators that cannot be assessed clinically.[9] Careful and prudent case selection, based on our current understanding of inflammatory mechanisms that are responsible for producing irreversible changes in pulpal tissue, can successfully identify teeth with a higher likelihood for favorable outcomes.

The major challenge in vital pulp therapy has been to identify a reliable pulp capping/pulpotomy agent and a simplified/reliable delivery technique. The introduction of Mineral Trioxide Aggregate (MTA) and other calcium silicate-based cements (CSCs) has provided a new paradigm for treating the reversibly inflamed pulp. This changes the long-held, yet venerable, perception that pulp capping the cariously exposed tooth is unpredictable and, therefore, contraindicated. Additionally, the impact and success of vital pulp therapy will depend largely on the patient's age, size of the pulp, degree of microbial contamination, pulp capping material, and the seal of the final restoration. Moreover, proper case selection based on an accurate differential diagnosis, using multiple diagnostic tests to establish pulpal status, is essential for a predictable outcome. According to the American Academy of Pediatric Dentistry,[10] "Teeth exhibiting provoked pain of short duration, that is relieved, upon the removal of the stimulus, with analgesics, or by brushing, without signs and symptoms of irreversible pulpitis, have a clinical diagnosis of reversible pulpitis and are candidates for vital pulp therapy."

The assessment of a definitive pulpal status, prior to treatment, can be challenging in younger patients. However, a diagnosis of reversible pulpitis increases the probability of favorable healing and repair. A negative patient report, that is variable and subjective, does not always indicate that the pulp capping/pulpotomy procedure cannot proceed successfully. Moreover, pain or discomfort prompted by cold testing prior to treatment, or a direct pulp exposure during caries excavation, does not necessarily condemn the tooth to a poor prognosis and more aggressive therapies.

THE VITAL DENTAL PULP

The dental pulp is a highly vascular tissue that has the unique distinction of being encased within a rigid chamber composed of dentin, cementum, and enamel.[11] These hard tissues provide mechanical support and protection from oral microorganisms.[12] The tissue provides several important functions,

including immune cell defense, dentinogenesis, calcified barrier formation, nutrition, and proprioreceptor cognizance. The survival and maintenance of the dental pulp is crucial to the long-term retention and function of the tooth, since the healthy pulp produces secondary, tertiary, and peritubular dentin as a protective response to various biological and pathological stimuli.[13]

Composed of four distinct zones, the dental pulp exhibits a cell-rich zone, a core composed of major vessels and nerves, a cell-free zone, and the odontoblastic layer at the periphery. The major cell populations found in the pulp include undifferentiated mesenchymal stem cells, fibroblasts, odontoblasts, macrophages, and other immunocompetent cells. The odontoblasts have the distinction of forming a single layer lining the entire perimeter of the pulp and feature odontoblastic processes extending into the dentin, sometimes to the dentoenamel junction.[14–16] For more details, see Chapter 2, " Structure and function of the pulp–dentin complex."

If the hard casing of the tooth is compromised and the pulp is subjected to microbial invasion, inflammatory changes can lead to pulp necrosis and further pathological changes, including infection and its consequences.[17,18] Circulating immune competent cells limit microbial challenges, and functioning proprioceptors and pressoreceptors guard against excessive occlusal loading.

When cariogenic microorganisms challenge the healthy pulp, odontoblasts, in concert with circulating immune cells, exhibit both innate and adaptive immune responses.[19] Innate responses begin within the dentinal tubule at the carious front, where acidogenic Gram-positive bacteria are initially exposed to a positive outward flow of dentinal fluid containing immunoglobulins and serum proteins, that slow the diffusion of bacterial antigens. The odontoblasts also exhibit Toll-like receptors that stimulate pro-inflammatory cytokines such as interleukin 1,8,12, tumor necrosis factor alpha, transforming growth factor beta, gamma-interferon, and the complement system.

If the bacterial front advances, vasoactive neuropeptides are released that increase vascular permeability and intrapulpal blood flow.[20] Innate immune cells that participate in this progression include lymphocytes, dendritic cells, monocytes, and macrophages. Increases in neuropeptide concentration and nerve sprouting characterize neurogenic inflammation that can increase transient and interstitial tissue pressure contributing to painful pulpitis. Persistent infection engages the adaptive immune system characterized by increased edema, intrapulpal pressure, tissue destruction, and cell death, leading eventually to pulpal necrosis. Odontoblasts also participate in adaptive responses by synthesizing a mineralized matrix known as reactionary dentin, a hard tissue differentiated by reduced tubularity. Because of the specific location of microorganisms during caries progression, bacterial neutralization by phagocytosis (killing) is not activated until the caries front is in direct contact with the dental pulp (Figure 27-1).[21] It has been proposed that bacterial colonization (a focus of necrosis) represents the histological transition from reversible to irreversible pulpitis.

When the dental pulp is injured by carious exposure, or trauma, and competently treated, the mechanism of healing is similar to that observed in normal connective tissue. Hemostasis, inflammation, proliferation, and remodeling characterize the continuous healing process sequenced over four overlapping phases.[22] Tissue near the exposure is characterized by extravasated erythrocytes, inflammatory cells, and potentially necrotic tissue, directly after injury. Neutrophils dominate the acute pulpal response in the presence of blood coagulation and exudated fibrinogen. Proinflammatory cytokines, released by immunocompetent cells, alter vascular permeability in response to both trauma and bacterial by-products. Transmigration of inflammatory cells is enabled by chemotactic signaling that prompt adhesion molecule interactions between leucocytes and endothelium. Chemoattractant/activator molecules, interacting with sets of cell adhesion molecules, form an adhesion cascade through these cell interactions.[23] Since the vital pulp is, therefore, capable of demonstrating competent immune defense mechanisms, it is desirable to preserve the vitality of an exposed pulp and promote repair since its retention (longevity) is paramount to the tooth's long-term survival.

REPARATIVE BRIDGE FORMATION

The formation of a protective hard tissue barrier is the goal of vital pulp procedures. After the loss of the primary odontoblasts, due to direct pulp exposures, pulpo-dentinal defects are repaired by the development of a hard tissue barrier by cells recruited from the pulp. These odontoblast-like cells are, theoretically, derived from either perivascular cells, bone marrow stem cells, or dental pulp stem cells.[24,25] The resultant hard tissue generation has long been regarded as tertiary reparative dentin, or described as reparative "dentinogenesis" after the death of the original odontoblasts for lack of a better term. However, histological examinations of reparative bridge formation, in directly capped human teeth using calcium hydroxide (CH), have revealed that the initial cellular response proximal to CH generates pulpal necrosis and stimulates the formation of a dentin-like hard tissue bridge forged by cells that morphologically resemble fibroblasts.

A recent light microscopy study examined ninety-six extracted human teeth, characterized by either untreated deep caries, large restorations or treated by direct pulp capping procedures after carious exposures.[26] Observational data revealed that the reparative hard tissue formed in teeth with deep caries and large restorations without pulp exposures, exhibited tubules continuous with the tubules of the secondary dentin, consistent with tertiary (reactionary) dentin generation. This tertiary dentin was associated with a reduced

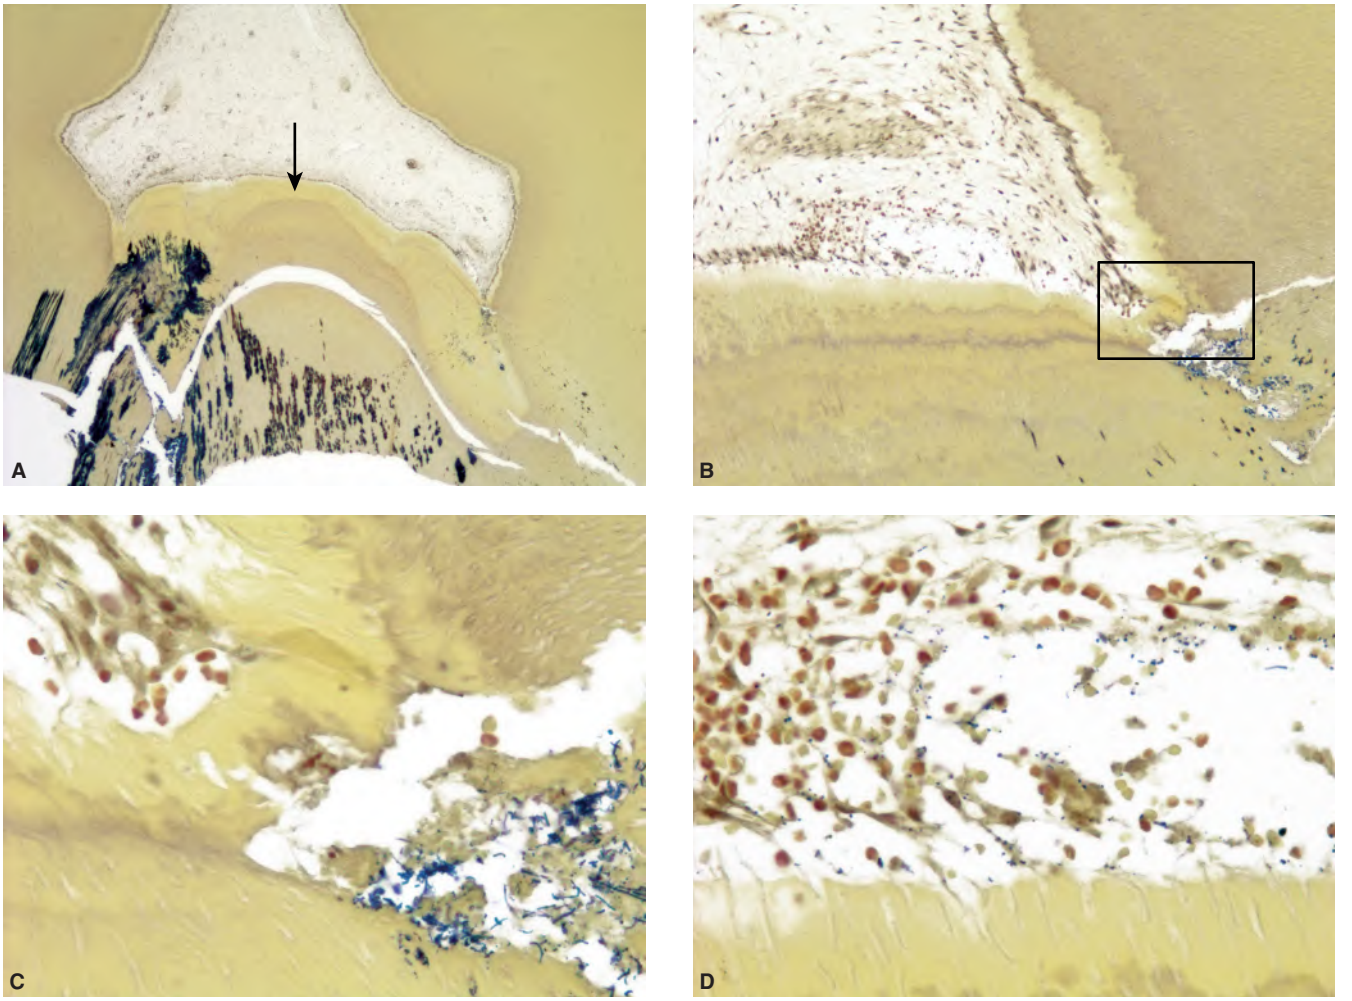

FIGURE 27-1 ***A.*** Photomicrograph of a pulp chamber in a symptomatic human maxillary third molar exhibiting a deep occlusal carious lesion and bacterial invasion with a clinical diagnosis of irreversible pulpitis (longitudinal section). Note presence of abundant reactionary (tertiary) dentin on the pulp chamber roof (arrow) and the relatively normal appearance of the pulp tissue, except in the area of the mesial pulp horn (right), where a small empty space can be seen. The empty spaces in the carious dentin are artifacts, due to detachment of soft dentin during processing (Original magnification ×16). ***B.*** Detail from the right pulp horn in A (×100). ***C.*** High-power view of the carious tissue adjacent to the pulp horn demarcated by rectangle in B. Note presence of inflammatory cells associated with bacterial penetration (×400). ***D.*** Higher magnification of the empty space in the pulp horn. single palisade layer of flattened primary odontoblasts. To the contrary, teeth that had been directly pulp capped in the absence of the primary odontoblasts, histological examination showed the exposures were repaired by an amorphous and atubular calcified tissue, sometimes exhibiting remnants of embedded necrotic tissue and pulp capping material. These dystrophic calcific bridges were affiliated with collagen fibrils and the direct presence of pulpal fibroblasts (Figure 27-2).

During pulpal healing, electron microscope images show that initial calcification of the bridge is characterized by a profusion of extracellular matrix vesicles situated between the amputated pulp surface and the forming cells.[27] The vesicles contain needle-like crystals and an osmiophilic material that accumulate and form a calcified front after the disappearance of the vesicular membrane. Similar to calcification in other biologically normal or diseased tissues, the accumulation of calcium and phosphate ions within the crystals suggests their generation during the calcification process. Calcific bridge formation can be seen after one month at the site of the surgical wound. However, pulp healing defects in the hard tissue can include tunnel defects, pulpal inflammatory cell activity, operative debris, and bacterial microleakage, depending on the pulp capping agent.[28] Reparative bridge mineralization may actually be more dependent on the extracellular matrix than the pulp capping or pulpotomy agent applied.[29–31]

It is apparent that reactive tertiary dentinogenesis can only occur with the retention of the primary odontoblasts during

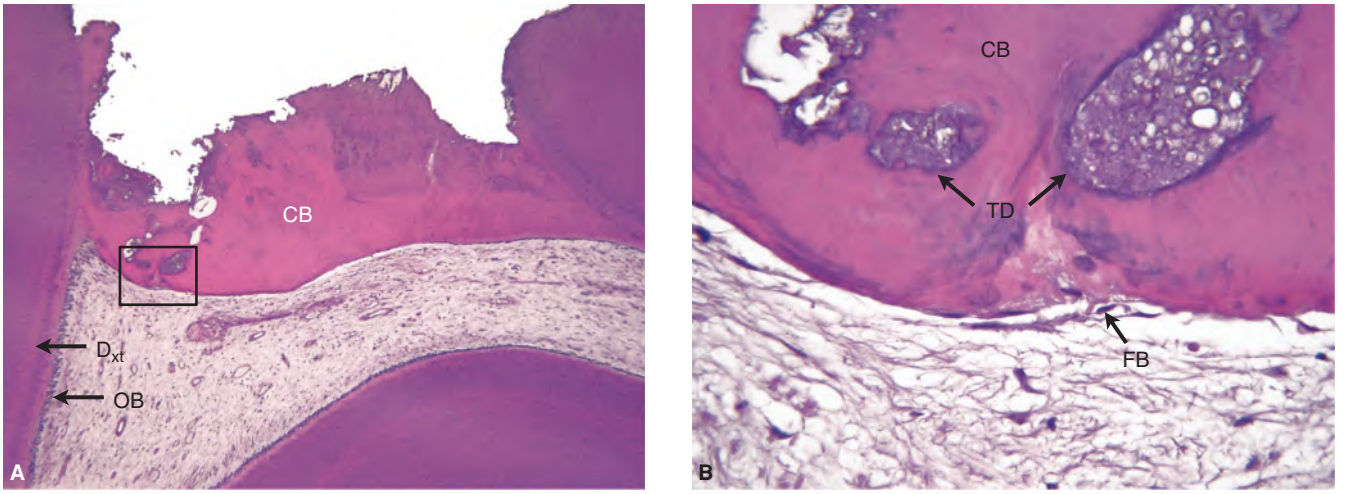

FIGURE 27-2 ***A.*** Reparative bridge formation in a human mandibular third molar directly pulp capped with calcium hydroxide and extracted after two years and four months. Photomicrograph shows calcified barrier (calcific bridge) formation (CB), dentin and predentin (D) associated with palisading odontoblasts (OB). Note absence of primary odontoblasts directly below the reparative bridge (pulp capping area) (Original magnification ×50). ***B.*** Higher magnification of area demarcated by rectangle in A. The calcified repair tissue (CB) is devoid of dentinal tubules and associated with tunnel defects (TD) containing necrotic debris. Note presence of collagen fibrillar material, scattered fibroblasts (FB) and no evidence of an odontoblast layer. (H & E, ×400). (Courtesy of Dr. Domenico Ricucci, Cetraro, Italy.)

caries progression and in indirect pulp capping procedures. Hard tissue barriers, formed after the loss of the primary odontoblasts, in direct pulp capping and pulpotomy procedures, are calcified hard tissues produced by cells that appear to mirror pulpal fibroblasts, and histologically the hard tissue produced in response to trauma is dentin-like rather than being genuine dentin. This new understanding of intrapulpal repair mechanisms does not change the common goals; to induce pulp healing, protection and survival. Further studies are required, to elucidate the bioactive molecules, growth factors and cellular mechanisms, responsible for regenerating hard tissue and physiological dentin.

TECHNIQUES FOR GENERATING REPARATIVE BRIDGES

Direct Pulp Capping

For permanent teeth, direct and indirect pulp capping and partial or complete pulpotomy are the most widely employed strategies in vital pulp therapy. ***Direct pulp capping*** is defined as the "treatment of an exposed vital pulp by sealing the pulpal wound with a dental material placed directly on a mechanical or traumatic exposure to facilitate the formation of "reparative dentin" and maintenance of the vital pulp."[32] Pulp exposures, as a result of caries removal, tooth preparation, or trauma are all indications for direct pulp capping. However, pulp tissue jeopardized by acute inflammation, with longstanding exposure to oral microorganisms, may be an inappropriate candidate for direct pulp capping. Direct pulp capping for carious exposures will be reviewed in detail later in this chapter under treatment recommendations (Figure 27-3).

Indirect Pulp Capping

Indirect pulp capping is defined as "a procedure in which a material is placed on a thin partition of remaining carious dentin that, if removed, might expose the pulp in immature permanent teeth."[32] Non-symptomatic teeth with no radiographic evidence of pathosis now show remarkable success using this technique, although it has been controversial for decades.[33,34]

Caries removal is completed using various techniques, to a perimeter near the tissue, without directly exposing the pulp. Selected teeth with deep carious lesions that receive conservative caries excavation, where direct pulp exposures were avoided, have demonstrated strong potential for repair since the primary odontoblasts are preserved.[35,36] One or two-stage (step-wise) indirect pulp capping techniques are completed using either CH, zinc oxide-eugenol materials (ZOE) or CSCs. A major challenge with the clinical procedure (one or two-stage) is determining at what point the excavation is terminated. Other important considerations include the voids under the restorative material that form during the remineralization process, as the carious dentin desiccates and volume diminishes. Other complications can be the rapid reactivation of a dormant lesion or restoration failure.[37] Improvements in indirect pulp capping techniques have been made and currently show remarkable potential as a treatment strategy for immature permanent teeth (Figure 27-4).[38–40]

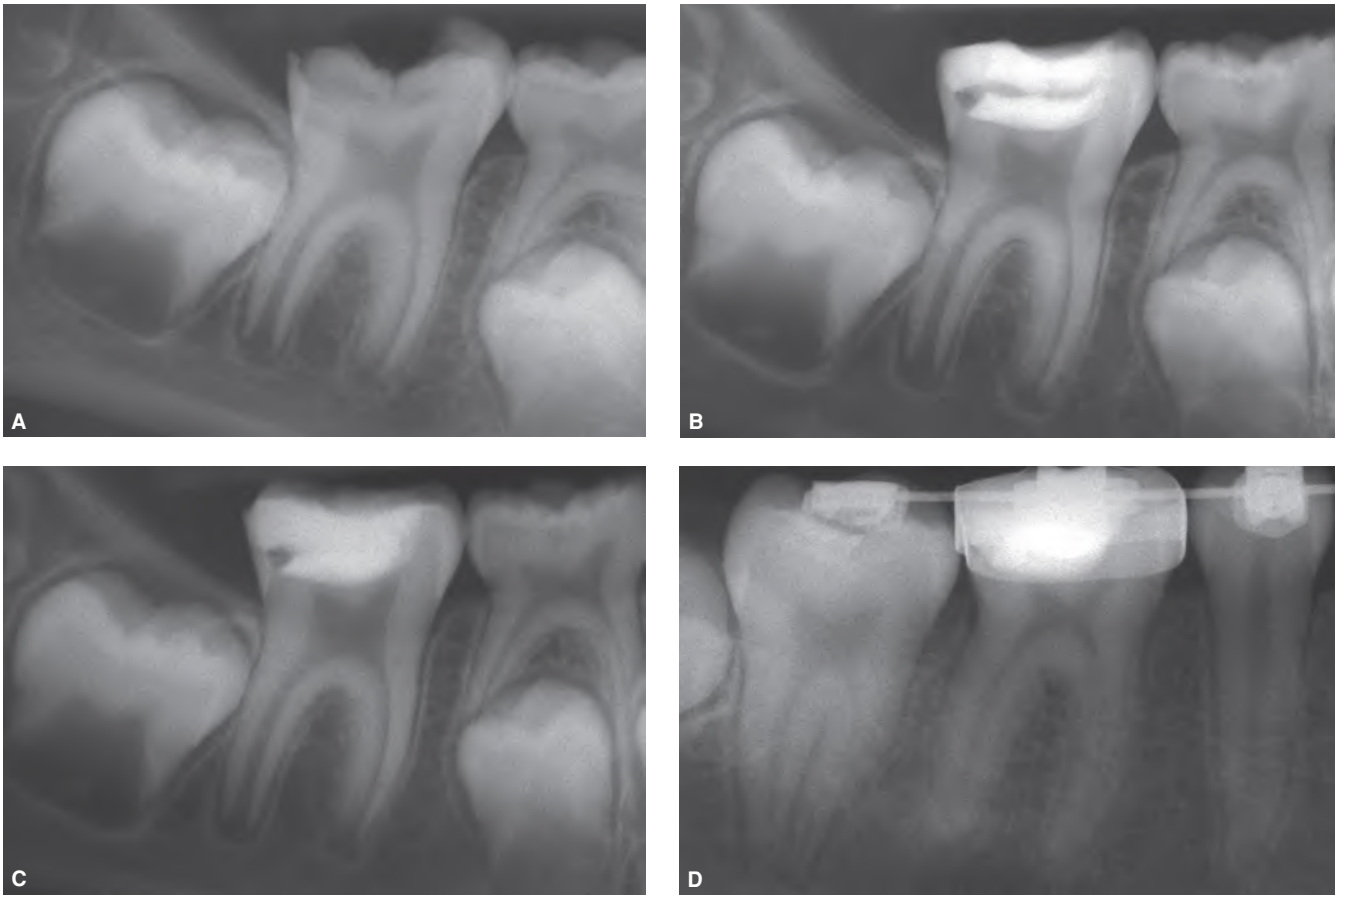

FIGURE 27-3 ***A.*** Seven-year-old female patient presents with a symptomatic mandibular first molar exhibiting deep caries and open apices. ***B,C.*** Patient received direct MTA pulp capping and bonded restoration in a two-visit sequence. ***D.*** Radiographic recall at seven years shows mature apices. Pulpotomy

Pulpotomy is a more invasive procedure defined as "the removal of the coronal portion of a vital pulp as a means of preserving the vitality of the remaining radicular portion. It may be performed as an emergency procedure for temporary relief of symptoms or therapeutic measure, as in the instance of a Cvek pulpotomy."[32]

The entire coronal pulp is removed to the level of the pulpal floor, or cementoenamel junction, and a capping material is placed over the canal orifices, or remaining radicular tissue. Some dressing materials with varying toxicity used for this purpose include ferric sulfate, phenol, creosote, glutaraldehyde, polycarboxylate cement, ZOE, CH, and formaldehyde that embalm the remaining tissue.[41] Although studies indicate that short-term success rates are favorable, this procedure is generally recommended for deciduous rather than permanent teeth. For more details, see Chapter 38, "Endodontic therapy in the pediatric patient." However, recent studies using partial and complete pulpotomies on adult permanent teeth have been published showing favorable outcomes in teeth exhibiting irreversible pulpitis.[42] Although formocresol is used widely as a pulpotomy agent in young adult teeth, the material presents distinct disadvantages.[43,44] Data suggests that the material possesses potential harmful systemic effects in humans and experiments in nonhuman primates have demonstrated a greater incidence of internal resorption.[45] Furthermore, conventional root canal treatment is difficult to complete due to the changes in the pulp apical to formocresol placement.[46] Recent investigations support MTA and other CSCs as practical replacements for formocresol in primary and immature permanent teeth (Figure 27-5).[47–50]

Partial Pulpotomy

Partial pulpotomy (Cvek pulpotomy) is described as "the removal of a small portion of the vital coronal pulp as a means of preserving the remaining coronal and radicular pulp tissues."[32] Healthy coronal pulp tissue is, therefore, exposed after removing inflamed or necrotic tissue.[51] Both direct pulp capping and partial pulpotomy are considered comparable procedures and differ only in the extent and volume of vital tissue remaining after treatment (Figure 27-6).

INDICATIONS FOR VITAL PULP THERAPY

Vital pulp therapy is indicated whenever the remaining pulp exhibits reversible pulpitis. It can be induced to generate a reparative hard tissue barrier that protects the dental pulp from further microbial invasion. In order to potentiate long-term pulpal preservation, direct pulp capping is recommended for teeth with deep caries, mechanical exposures, or traumatic injuries. The initial diagnosis, based on radiographic evaluation, pulp testing, patient history and clinical evaluation, will determine the suitability and probable outcome for direct pulp capping and pulpotomy procedures. The prime objective is to maintain pulp vitality, and therefore, postpone more aggressive endodontic and restorative therapies that may decrease the long-term prognosis. Teeth receiving orthograde root canal therapy (RCT), post and core placement, cuspal or full coverage, will exhibit lower long-term survival rates than teeth with vital pulps.[52–57] Moreover, teeth that have undergone RCT and are restored with prosthetic crowns show a higher vulnerability for root fractures, caries, and other plaque-related complications.[58–60]

VITAL PULP THERAPY MATERIALS

To identify ideal biocompatible and bioactive materials, researchers have, for decades, investigated a multitude of vital pulp therapy agents. These have included CH compounds,[61–66] zinc phosphate and polycarboxylate cements, zinc oxide, calcium phosphate, calcium-tetracycline chelate, calcium phosphate ceramics, antibiotic and growth factor combinations, Bioglass, Emdogain, cyanoacrylate, hydroxyapatite, resin-modified glass-ionomers, hydrophilic resins and recently MTA and other CSCs.[67–78] Similar research has focused on materials such as Ledermix, dimethyl isosorbide, glycerrhetinic acid/antibiotic mix, and potassium nitrate.[79]

Advanced methods to eliminate caries progression include laser and ozone technology and also strategies that activate pulpal defenses using bioactive agents.[80–82] Outcomes from former human retrospective studies, evaluating direct pulp capping in permanent teeth, are variable and depend on techniques and materials that show a wide range of success rates between 30% and 85% over 5- to 10-year periods.[61–66]

The ideal pulp capping material should be sterile and display the following characteristics[83]: stimulate hard tissue repair, maintain pulpal vitality, release fluoride to prevent secondary caries, should be bactericidal or bacteriostatic, adhere to dentin, adhere to restorative material, resist forces during restoration placement, resist forces under the restoration during its lifetime, be radiopaque, and provide a bacteria-tight seal.

Calcium Hydroxide

Calcium hydroxide has long been considered the "standard" material in vital pulp therapy. Although the compound has been shown to have some desirable properties, investigations in humans have shown that success rates decrease as observation periods increase.[63–66] The high alkaline pH provides a favorable bactericidal characteristic that also promotes pulp tissue irritation, which in turn stimulates pulpal defense and repair.[70] However, CH exhibits disadvantages that include cell culture cytotoxicity, pulp cell apoptosis, poor marginal adaptation to dentin, and inconsistent stimulation of reparative hard tissue formation.[84–87] The material can also degrade and absorb beneath restorations, is associated with primary tooth resorption, and can encounter interfacial failure during amalgam condensation.[88–90] When used in conjunction with bonding resins, the compound demonstrates gap formation at the dentin interface.[91] Moreover, hard tissue bridges beneath CH exhibit tunnel defects and the material is ineffective at providing a long-term seal against microleakage when used as a pulp capping agent.[84,90] The instability and disintegration of CH under permanent restorations, coupled with defects in the hard tissue bridge, afford microorganisms a pathway for penetration into vulnerable pulpal tissue and the subsequent activation of circulating immune cells, thus promoting pulpal irritation, pulpal calcification and potential canal obliteration (Figure 27-7).

Adhesive Resins and Resin-Modified Glass-Ionomers

In the early 1980s, researchers in Japan first introduced hydrophilic resin systems for direct pulp capping.[92–94] Encouraging results were seen in preliminary research based on ISO standards using non-human primate models.[95–99] Favorable biocompatibility and reparative bridge formation was documented in exposed pulps directly capped with various resins and evaluated histologically for pulpal reaction, microbial presence and reparative hard tissue formation.

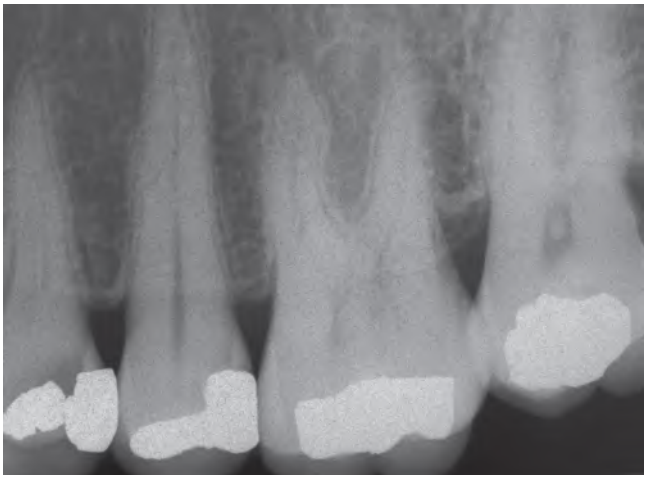

FIGURE 27-7 Periapical radiograph of a maxillary left molar in a 46-year-old female. The patient received a direct pulp cap in the second molar with hard setting calcium hydroxide (Dycal®) approximately 10 years before. The molar exhibited a delayed response to cold testing. Dystrophic calcification can be seen including a large pulp stone.

However, although these favorable results were observed in non-human primates, the transitional use of these materials was not mirrored in human subjects.[100–104] Unfavorable histological reactions to adhesive systems have been observed in clinical investigations when directly placed against pulp tissue in humans. Histological sections from various studies reveal cellular incompatibility characterized by mononuclear inflammatory infiltrates, PMN's, macrophages, multinuclear giant cells, blood extravasation between the layers of the bonding resin, and an absence of calcific tissue formation.[100,101,104,105]

Direct pulp capping with either a hydrophilic resin or resin-modified glass-ionomer cement has been compared in two clinical studies in human subjects.[106,107] Histological results from one study showed that both Clearfil Liner Bond 2 (Kuraray Co., LTD, Osaka, Japan) and Vitrebond (3M Espe Dental Products, St. Paul, Minnesota) initially generated a moderate to intense inflammatory cellular response failing to stimulate reparative bridge formation after 300 days. The unpredictable nature of reparative hard tissue formation using hydrophilic resins, and the potential contamination of calcific bridges by microorganisms, has been confirmed in other non-human investigations. One contemporary study measured the degree of bacterial contamination, associated with "tertiary dentin" bridge formation in primates, revealing contamination in 18.6% of resin-based composite, 22.2% of resin-modified glass-ionomer, and 47.0% of CH pulp-capped specimens.[108]

These investigations suggest that some pulp capping materials do not promote predictable pulpal healing, nor do they provide a hospitable environment for reparative bridge formation and the exclusion of microorganisms.[109,110] However, repair should proceed successfully beneath the material when bacterial microleakage is prevented and hydrophilic resin capping can be successful in some cases (Figure 27-8). Progressive studies, incorporating growth factors and hard tissue promoting agents, coupled with adhesive resin systems to encourage repair and wound healing are emerging.[111,112]

Mineral Trioxide Aggregate

Mineral Trioxide Aggregate was the first CSC, introduced as a root canal repair material in the early 1990s.[113] The initial composition of this bioactive CSC included tricalcium

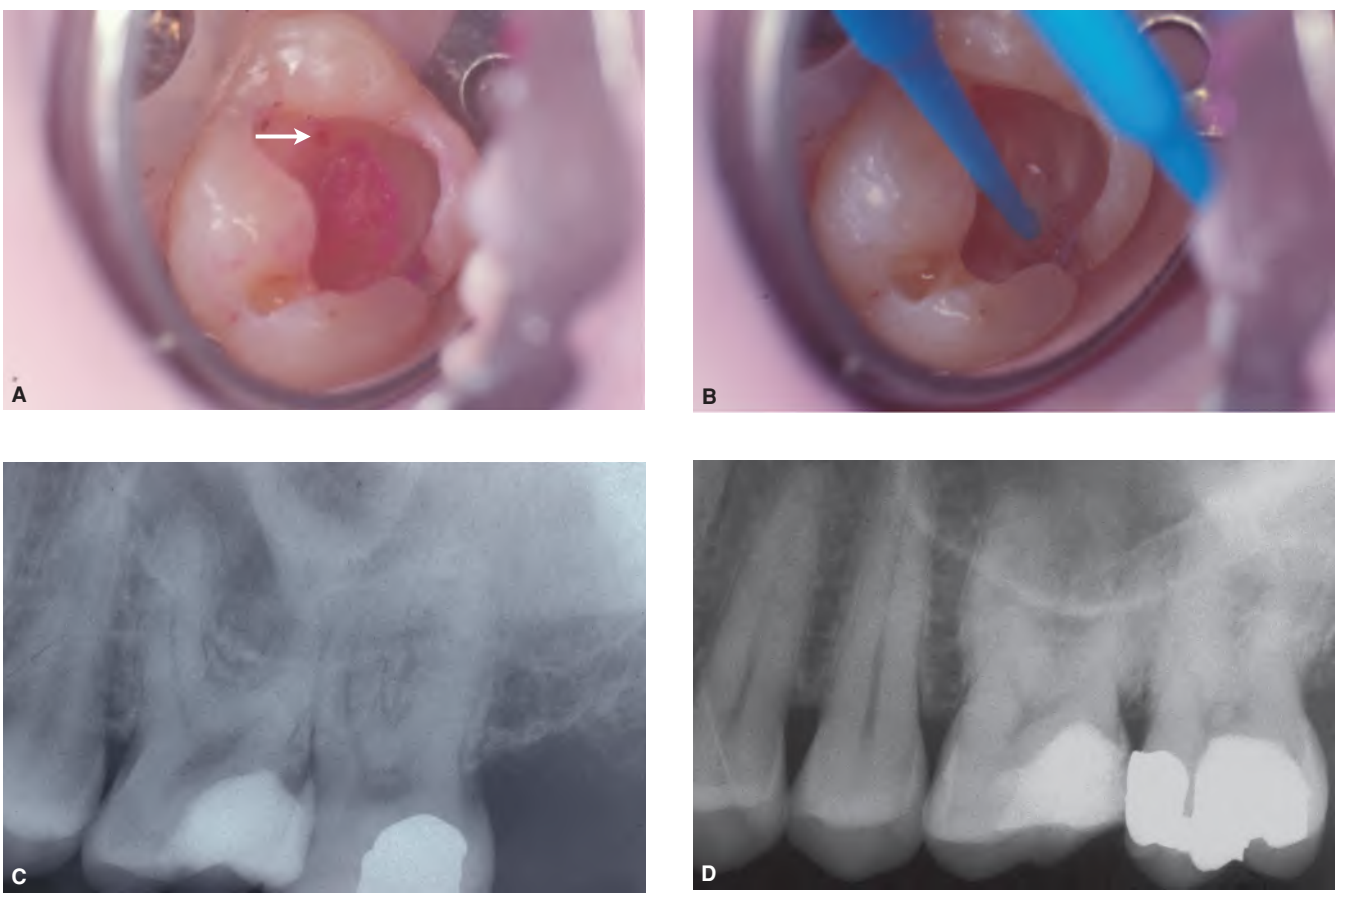

FIGURE 27-8 16-year-old female patient with a deeply carious maxillary left first molar diagnosed with reversible pulpitis. ***A.*** Pulp exposure (0.5 mm) after caries detector dye staining (arrow). ***B.*** Direct hydrophilic resin pulp cap after NaOCl hemostasis. ***C.*** Two-year radiographic recall showing reparative bridge formation. ***D.*** 15 years and 6 month radiographic review. The patient was symptom free and the tooth responded to cold testing within normal limits. silicate, tricalcium aluminate, tricalcium oxide, silicate oxide, and other mineral oxides.[114] The composition of the original cement, ProRoot MTA®(Tulsa/Dentsply, Tulsa, OK), has changed since its introduction with the substitution of dicalcium silicate for tricalcium silicate and the addition of tetracalcium aluminoferrite, calcium sulfate dehydrate and bismuth oxide; the latter was added to impart radiopacity.[115] White MTA (WMTA) was later produced to resolve esthetic concerns by ferrite (Fe_3O_3) reduction with no detectable change in clinical performance compared to the original gray powder.[115–118] However, staining from WMTA is still an undesirable characteristic, and innovative methods have been recommended to overcome this drawback.[119]

The favorable physicochemical properties exhibited by MTA make it a superior material when used as a cement for partial or complete pulpotomy and direct pulp capping in both primary and permanent teeth.[120–122] Portland cement is structurally similar to MTA, and shares MTAs favorable properties that include the ability to harden in the presence of blood and moisture.[123] Set MTA exhibits superior marginal adaptation and the cement is non-resorbable. It forms a reactionary interfacial layer with dentin, resembling hydroxyapatite in structure when setting in the presence of calcium ions and tissue fluids.[124,125] The slow release of calcium ions, small particle size, and sustained alkaline pH also characterize this bioactive cement.[126] On a cellular level, MTA stimulates cytokine release, induces pulpal cell proliferation, and promotes hard tissue formation.[127,128] The slow calcium release and combined alkaline pH of 12.5 may contribute to the reduction of microorganisms remaining after caries excavation.

When curing, MTA and other CSCs exhibit crystal formation within dentinal tubules, in the presence of alkaline phosphate, that are responsible for microbial entombment and neutralization.[129] The high pH also encourages the extraction of growth factors nested in the adjacent dentin that contribute to calcific bridging.[127,130] Direct pulp capping using MTA demonstrates a strong capacity to generate reparative calcific barriers in primate and canine models.[74,131–134] Current investigations in humans using MTA for partial or complete pulpotomies and direct pulp capping have shown favorable short and long-term outcomes.[135–141] These and other studies confirm that the material does provide a biocompatible, noncytotoxic and antibacterial environment, and a favorable surface morphology that allows for cell attachment and proliferation.[142] The soluble components of MTA, released during setting at the dentin interface that form hydroxyapatite, may also encourage the release of growth factors and other bioactive molecules such as transforming growth factor beta (TGF-β1) and adrenomedullin.[143] Increased levels of dentin extracellular proteins are stimulated by the presence of MTA and culminate in hard tissue bridge formation after stimulating calcific repair mechanisms.

Recent investigations in humans comparing the efficacy of MTA with CH for direct pulp capping have revealed the distinct biological advantage of MTA in promoting repair and maintaining prolonged pulp vitality.[140,141] Mineral trioxide aggregate direct pulp capping was examined using a two-visit protocol in permanent teeth, diagnosed with reversible pulpitis.[144] Forty-eight of 49 teeth (97.96%) with an average observation period of 3.94 years showed favorable outcomes, based on subjective symptomology and cold testing. Pulpal calcifications were seen in 10.6% (5/49) of cases and all immature permanent teeth (15/15) exhibited complete root-end closure (apexogenesis) when open apices were present initially.

A practice-based, randomized clinical trial evaluated 376 teeth for up to two years comparing the success of direct pulp capping in permanent teeth using either MTA or CH. It revealed that the probability of failure at two years for CH was 31.5% versus 19.7% for MTA, confirming the superior clinical performance of MTA.[140] Another controlled cohort study examined 229 teeth and compared MTA direct pulp capping with CH during 2 to 10 year recall period using logistic regression and equation logit models; 80.5% of teeth in the MTA group showed better long-term results compared to only 59% of teeth in the CH group.[141]

The remarkable outcomes for direct pulp capping using MTA are attributable to its inherent bioactive and bioinductive properties.[145] The anti-bactericidal characteristic of the set cement, due to the sustained alkaline pH, coupled with sodium hypochlorite (NaOCl) application, contribute to the elimination of the majority of residual microorganisms remaining at the dentin/pulp interface after caries removal and pulp exposure. MTA is hygroscopic and hardens in the presence of moisture, so direct contact with blood, or tissue fluids, does not significantly affect its curing properties. Moreover, microleakage and bacterial growth are impeded due to the small particle size and the close adaptation of the CSC to dentin.[125,129] Hard tissue formation is encouraged by the slow release of calcium ions that stimulate growth factors from the dental pulp and promote signaling molecules such as TGF-β, IL-1α, IL-β and MCSF.[143,146] The surface texture and compressive strength of the set cement also allows for intimate chemical bonding with adhesive restorations and provides minimal compression under heavy occlusal loading when a final restoration is provided.

Calcium Silicate-Based Cements (CSCs)

Since the introduction of MTA, a broad assortment of newly formulated CSCs have become available for applications in endodontics and specifically vital pulp therapy.[78,147–150] The major constituents of these new cements include dicalcium and tricalcium silicate, the central components of both MTA and Portland cement. Due to their hydraulic properties, calcium silicate compounds attain immediate strength on hydration and investigations have shown these aggregates to up-regulate angiogenic and transcription factors as well as pulp fibroblasts and stem cells. Other characteristics of

CSCs include bioinductive capacities that positively influence cell proliferation, differentiation and induction of hard tissue barriers while producing minimum inflammation. Although clinical investigations in humans using the new CSCs are minimal, they all appear to have suitable properties for use as pulp capping and pulpotomy agents.[151–155]

There are currently over 25 MTA-like materials available and initial investigations demonstrate comparable physiochemical and bioinductive properties that appear beneficial for vital pulp therapy. Often referred to as bioceramic materials, some of these CSCs include MTA Angelus, MTA BIO and MTA Branco (MTA-Angelus, Londrina PR, Brazil), Biodentine™ (Septodont, Cambridge, Ontario, Canada), BioAggregate® and iRoot® BP Plus (Innovative Bioceramix, Vancouver, BC, Canada), Calcium Enriched Mixture (CEM) (Bionique Dent, Iran), EndocemMTA (Maruchi Inc., Wonju-si, Gangwon-do, South Korea) and Endosequence root repair material (Brasseler USA, Savannah, Georgia). Recently introduced hydraulic silicate cements also include RetroMTA and OrthoMTA (BioMTA, Seoul, Korea), Grey MTA Plus (Avalon Biomed Inc., Bradenton, Florida), MTA plus (Prevest-Denpro, Jammu City, India), Tech Biosealer Endo (Isasan SRL, Revello Porro, Italy), and Micromega® MTA (MicroMega, Besançon, France). Ongoing laboratory and clinical investigations of other calcium silicate–based compounds are currently confirming their safety and efficacy.[151]

MTA-Angelus is composed of 75% Portland cement and 25% bismuth oxide and has strong potential in vital pulp therapy. The removal of calcium sulfate in the formulation allows for a shorter setting time of 10 minutes, making the CSC superior for one-visit pulp capping or pulpotomy procedures.[156] The crystalline structures of MTA-Angelus are similar to gray and white ProRoot MTA, and when used as a pulp capping material in humans, MTA-Angelus produces hard tissue bridges histomorphologically comparable to those of ProRoot MTA.[155,157,158] The cement has demonstrated exceptional results when used in primary tooth pulpotomies[159] and as a pulp-capping agent on direct exposures in caries-free teeth.[158]

Biodentine™ also features a short setting time of 10 minutes and shows remarkable bioactive properties that can have beneficial applications for pulptomies and both indirect and direct pulp capping procedures. The cement does not alter human fibroblast cytodifferentiation and when measured with the Ames' mutagenicity test shows an absence of genotoxic/cytotoxic effects.[160–162] The sealing ability of Biodentine™ at the dentin interface appears to be similar to that of MTA when analyzed by SEM.[163] This compound exhibits pulp tissue compatiblity that induces fibroblast (odontoblast-like) cell recruitment and encourages calcific bridge formation comparable to MTA when used as a pulp capping or pulpotomy agent.[134,164,165]

BioAggregate® is another bioactive CSC cement that shows an exceptional capacity to stimulate hard tissue bridge formation. The cement has been shown to promote mineralization in osteoblast cells, inhibit osteoclast differentiation, and inhibit inflammatory bone resorption *in vivo*, similarly to MTA.[166–168] When in contact with human dental pulp cells, both MTA and BioAggregate promote cellular adhesion, migration, and attachment demonstrating excellent cytocompatibility.[169,170] BioAggregate, Biodentine, and MTA all stimulate hard tissue formation by advancing odontoblast-like cell differentiation and nodule formation during the mineralization process. The favorable properties of these new CSCs suggest applications in regenerative endodontic procedures as well as vital pulp therapy. (Figure 27-9). For more details, see also Chapter 29, "Regenerative endodontics."

Endosequence root repair material shows a high potential as a pulp capping and pulpotomy agent demonstrating low cytotoxicity, exceptional bioactivity, and impressive healing characteristics when used in endodontic surgery.[171–173]

Calcium enriched mixture (CEM) cement has demonstrated excellent bioactivity and remarkable efficacy when used in vital pulp therapy.[174] In a 5-year study CEM, when used as a pulpotomy agent in permanent molars diagnosed with irreversible pulpitis, showed similar outcomes to conventional root canal treatment in a multicenter randomized clinical trial.[42] The findings of this study could have a strong impact on treatment options for patients in economically challenged geographical areas worldwide. The future potential for the new generation of CSCs as beneficial agents in vital pulp therapy and regenerative endodontics will accelerate as research expands and innovative CSCs are further developed.

DIAGNOSTIC CRITERIA FOR SUCCESSFUL OUTCOME

Treatment for the immature permanent tooth with advanced carious lesions include several options that preserve the remaining and identifiable healthy tissue. The coronal pulp tissue can be preserved *in toto*, partially removed, or removed entirely to the base of the pulpal floor, as long as the critical radicular pulp tissue is preserved to allow continuing development and apical maturation (apexogenesis) in teeth with open apices. Induction of apexogenesis should be the clinician's primary goal, with the pulp protected and encouraged to remain vital in cases of trauma where tooth development may be interrupted.[175–177] For more details, see Chapter 28, "Management of teeth with immature apices."

The clinician must make a careful assessment of all available information before treatment can be initiated. Critical aspects of vital pulp therapy include a differential diagnosis based on medical history, radiographic evidence, and patient report combined with pulp sensitivity (cold) and percussion testing. Clinical assessment should include the degree of mobility, periodontal probing and the presence of localized swelling or sinus tracts. Both periapical and bitewing radiographs must be evaluated for evidence of caries, periapical disease, internal/external resorption defects, furcation radiolucencies, and pulp calcification due to trauma or prior restorations.

Subjective symptomology must be considered after clinical and radiographic assessments have established an absence of disease. The majority of patients with deep carious lesions often experience sensitivity to heat, cold, and certain acidic or sweet foods. However, the subjective response to cold testing can be inconsistent and a short lingering response (one–two seconds) may not be a signal that the pulp is irreversibly involved. Moreover, cold testing responses have been shown to be unpredictable, especially in some individuals with immature permanent teeth.[178,179] The clinician must also recognize that pain to percussion is most often associated with irreversible pulpitis. In teeth diagnosed with irreversible pulpitis and open apices, promotion of root-end closure (apexogenesis) is recommended using MTA or other CSC with pulpectomy or regenerative procedures.[177,180,181] (Figure 27-10). For more details, see Chapter 28.

Teeth with initial caries have a higher probability for repair and calcific bridge, or tertiary dentin formation, than teeth that have a history of previous restorations or trauma.[182,183] Direct pulp capping may not be indicated for mature permanent teeth planned for full coverage restorations, or with a prior history of extensive restorative care. However, from a technical standpoint, full crown preparations with occlusal pulp exposures may have a more favorable prognosis. Pulp exposures on the axial walls of full coverage preparations are extremely difficult to treat clinically due to the handling properties of MTA and other CSCs. Considering the technical challenge of placing the material against an exposure on a vertical wall, orthograde RCT can be recommended as a more predictable treatment option in permanent teeth.

Selecting an appropriate vital pulp treatment should be based on the extent of the remaining tooth structure. Pulpotomy rather than direct pulp capping is recommended for teeth in young patients exhibiting advanced caries and severe coronal breakdown, or requiring full coverage. In patients with rampant caries, pulpotomies are recommended as opposed to direct

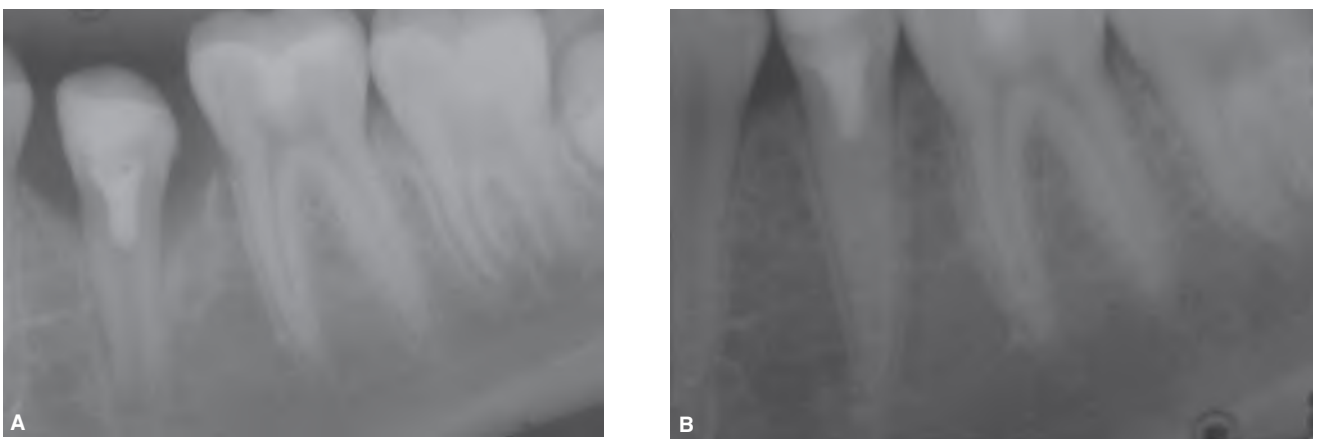

FIGURE 27-10 ***A.*** Post-operative radiograph of a hypocalcified mandibular left second premolar in an 11-year-old female patient. The tooth received a full pulpotomy after a large carious exposure. (Courtesy of Dr. David Taylor, Rolling Hills Estates, CA.)

pulp capping, since the majority of these patients will exhibit recurrent caries at a higher rate.[184–186] However, young patients who have caries associated with reversible pulpitis on all first molars can still be considered excellent candidates for direct pulp capping. It is also evident that the prognosis for vital pulp therapy diminishes with the increasing age of the patient.[64,186] Nevertheless, clinical success can be seen in older patients when diagnosed with reversible pulpitis (Figure 27-11).

When the pulp exposure is visualized under magnification, and hemorrhage control assessed, the clinician can reconfirm the initial diagnosis. If non-hemorrhaging tissue is discovered, it is most likely necrotic, and must be removed until bleeding tissue is encountered. After achieving hemostasis, a partial or miniature pulpotomy can be completed with a high-speed round diamond bur using MTA or a CSC placed directly against the entire wound and surrounding dentin. When bleeding cannot be controlled on direct pulp exposures with 5.25% to 8% NaOCl after a 10- to 15-minute contact period, the diagnosis must be changed to irreversible pulpitis and pulpotomy or pulpectomy is recommended. The option that offers the greatest benefit to the patient and secures the optimum prognosis for the long-term retention of the tooth determines which type of vital pulp therapy to be selected (Figure 27-12).

A greater risk of an unexpected and sizeable pulpal exposure may possibly occur since pulp sizes are underestimated on radiographs.[187] However, it is known that the size of an exposure has no influence on the outcome in direct pulp capping.[188] Some clinicians erroneously assume that larger exposures have a poorer prognosis and may consider size in their decision-making process. In a study involving the examination of simulated exposures (0.5–0.9 mm), dentists overestimated exposure size by a mean of 26% when not using a ruler or prior calibration.[189] Pulp dimensions between the genders and among racial groups may also vary considerably.[190]

CARIES REMOVAL

Thorough caries removal under dental dam isolation, aided by optical magnification and a caries detector dye, are essential tools in attaining favorable outcomes for direct pulp capping and pulpotomy procedures. Our understanding of the carious process was redefined in the mid-1970s when an objective

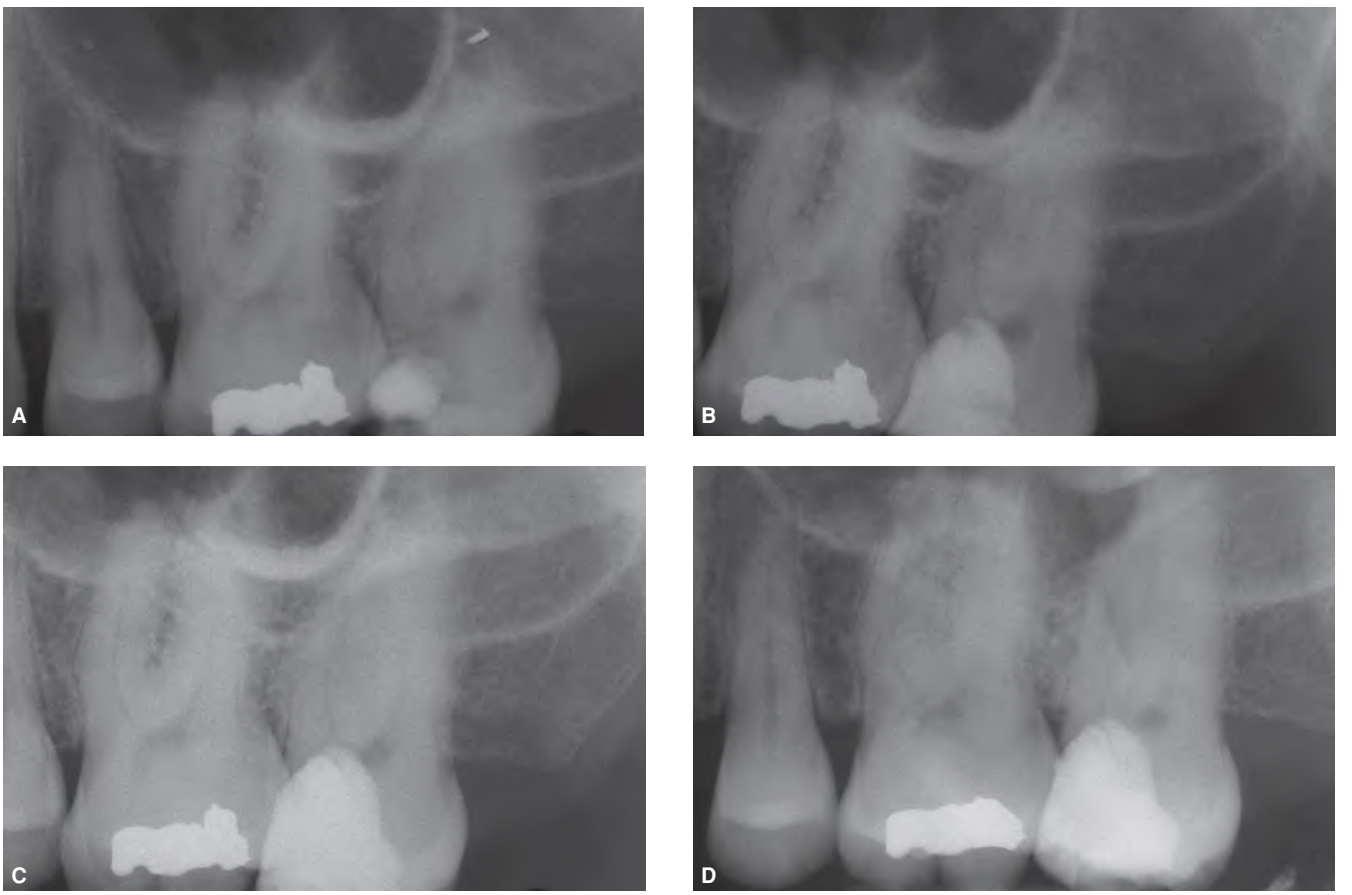

FIGURE 27-11 48-year old male presents with a deeply carious and asymptomatic maxillary left second molar. ***A.*** Pre-operative radiograph reveals extensive mesial caries, pulp calcification and ZOE provisional restoration. ***B.*** Post-operative radiograph after 1.0 mm exposure, NaOCl hemostasis, MTA direct pulp cap, wet cotton pellet placement and Photocore® provisionalization. ***C.*** Radiograph taken one year after pulp capping and placement of a permanent bonded composite restoration. technique for removing the outer infected carious layer was discovered. This technique, using a caries detector dye, preserved the remineralizable inner carious layer, thus preserving tissue critical for continued pulpal protection and survival.[191,192] The staining process of carious dentin is based on the principle that acidogenic Gram-positive bacteria, whose main byproduct is lactic acid, first break down hydroxyapatite and subsequently collagen in the outer carious layer, but spare bound collagen in the second layer, where the intermolecular crosslinks are still intact.[193,194] When the outer layer of two distinctive carious layers can be selectively stained and carefully removed, repair and pulpal preservation can proceed normally when teeth are sealed with advanced bonded composite systems.

The invading bacteria at the furthest point of microbial penetration are responsible for the production of proinflammatory mediators at the pulp/dentin interface. This challenge to the pulp is minimized by removing the necrotic dentin in the outer layer and by preserving the second (caries affected) layer that will remineralize. This remineralization process occurs when whitelockite crystals are formed in the presence of calcium and phosphate ions that block the tubules. Evidence of caries-affected inner layer dentin remineralization has been demonstrated in both non-human primate and dog models.[195,196] Contributing further to pulpal survival are adhesive composite restorations that are no longer dependent on retentive cavity preparations, hence sparing more tooth structure and generating less trauma to the dental pulp. Conservative objective caries removal promotes pulpal preservation by not injuring the remaining nonstaining ***caries-affected dentin***. The use of caries detector dyes allows the operator to visually inspect infected dentin using the dental operating microscope (DOM) that may have been overlooked and potentially compromise the treatment outcome.[197–200]

The efficacy of caries detector dyes has been controversial, since the possibility for residual acidogenic bacteria exists in unstained dentin while non-infected dentin can potentially be stained.[197,201,202] It has also been shown by atomic force microscopy and transverse digital microradiography that heavily stained carious dentin still contains mineralized tissue and may be worth retaining.[203] These drawbacks to using caries detector dyes could serve as a strong argument for indirect pulp capping strategies. However, the clear advantage during direct pulp capping procedures is reducing the probability of leaving active carious tissue that may have been otherwise gone undetected, together with improved caries removal guidance while using the DOM.

TISSUE HEMOSTASIS

Many antimicrobial materials and hemostatic agents have been recommended for use in vital pulp therapy. These include ferric sulfate, disinfectants such as Tubulicid ® (Global Dental Products, North Bellmore, New York) and Concepsis ® (Ultradent Products Inc., South Jordan, Utah), epinephrine, varying concentrations of hydrogen peroxide (H_2O_2) and NaOCl. Direct pressure at the exposure site with cotton pellets moistened in saline, or sterile water, is the most universally accepted method to control hemorrhaging of exposed pulps. Lasers and electrosurgery have demonstrated limited efficacy in hemorrhage control.[204] However, NaOCl is an accepted antimicrobial irrigant used in orthograde endodontic therapy and has been promoted since the late 1950s as an effective hemostatic agent in direct pulp capping and pulpotomy.[205,206]

When used in vital pulp therapy, NaOCl solutions provide several advantages that demonstrate its superiority over other agents. This agent contributes to the chemical amputation of the fibrin and blood clot, biofilm removal, clearing of dentinal chips, cavity interface disinfection, removal of damaged cells at the exposure site, and provides excellent hemostasis.[204,207,208] Concentrations of 5.25% to 8.0% NaOCl primarily affect the peripheral pulp cells without impairing underlying pulp tissue.[188,209] Although NaOCl exhibits a strong organic dissolving capacity, the reaction toward the the pulp tissue appears relatively benign.[210] However, when used for care of burn victims, as a fluid dressing in concentrations greater than 0.025%, it has shown to be detrimental in wound healing.[210]

The importance of hemostasis in vital pulp therapy was demonstrated in a landmark study where teeth were directly pulp capped in a carious field, using a fast set CH.[188] The 2-year success rate was 81.8% using a caries detector dye and hemorrhage control, completed with 10% NaOCl. Statistical analysis demonstrated that responses to thermal stimuli and percussion, diameter of the pulp exposure, age of the patient and types of teeth, had little influence on the success rate. However, the ability to arrest bleeding at the exposure site was the foremost variable and prognosticator for a successful outcome. This observation accentuates the relevance of complete hemostasis when employing an effective agent and how it affects the outcome of direct pulp capping and pulpotomy procedures.

Inflammatory mediators including IgA, IgG, IgM, prostaglandin E_2, and elastase are present at higher levels in clinically inflamed pulps.[211] Greater levels of mediators during neurogenic inflammation can affect the level of intrapulpal pressure and, therefore, the probability of securing pulpal hemostasis. Observational data suggests that if pulpal hemostasis cannot be attained within 10 to 15 minutes, the diagnosis should be revised to ***irreversible pulpitis*** and pulpotomy or pulpectomy should be initiated.

Exposed vital pulp tissue was investigated histologically in beagle dogs by studying freshly cut dentin prepared to depth of 2 mm and treated with 5.25% NaOCl. No inflammatory cells were detected at one and four week periods after the cavities were sealed with Cavit®. Teeth with vital dentinal tubules and recently prepared dentin do not appear to show any further pulpal damage when rinsed with undiluted 5.25% NaOCl.[212] In addition, pulps of non-human primates, directly capped with adhesive resins, were not adversely affected by NaOCl at varying concentrations.[207,208]

One investigation examined human primary teeth pulp capped with either CH or various adhesive bonding agents.[213] The teeth were clinically and radiographically evaluated for a period of 24 months after 1.25% NaOCl was used for 60 seconds, to ensure hemorrhage control. Results revealed a 93% survival rate when exfoliations were excluded. Sodium hypochlorite hemostasis did not impair biological repair and subsequent calcific barrier formation when used as a hemostatic agent. This finding was again demonstrated in a study where the outcomes for pulpotomies were compared using either ferric sulfate ($FeSO_4$) or NaOCl on primary teeth restored with an IRM base/stainless steel crowns.[214] A short-term one year evaluation revealed a 100% retention rate of teeth in the NaOCl group with 79% radiographic success, superior to the $FeSO_4$ group. Ferric sulfate has been recommended as a replacement for formocresol in pulpotomies on deciduous teeth due to its effective hemostatic characteristics. However, the agent interferes with the bond strength of adhesive resins and its use is not recommended when bonded restorations are intended.[215]

Direct pulp caps were also examined in a histological study completed on human third molars 30 and 90 days after pulp capping with either CH or a self-etching adhesive system and using 2.5% NaOCl for hemostasis.[216] The study revealed that CH performed better biologically than the adhesive resin and that pulpal repair was not compromised by the use of NaOCl. At 90 days, neither exposure to 0.9% saline, 5.25% NaOCl, or 2% chlorhexidine digluconate incapacitated healing after direct pulp capping with CH when examined in healthy human pulp tissue.[217] In an investigation that measured parameters of success in direct pulp capping in a carious field, 10% NaOCl was used without any marked affect on continued pulpal vitality and repair.[188] It is clearly evident that the use of ***NaOCl*** in concentrations of 5.25% to 8.0% for direct pulpal exposures **can be recommended** and is a relatively safe and practical method to predictably achieve hemostasis (Figure 27-13).[213,214,216–218]

Another effective hemostatic agent is MTAD (Biopure®, Tulsa/Dentsply, Tulsa, Oklahoma), an antimicrobial agent and irrigant introduced for smear layer removal during root canal treatment and retreatment.[219] The solution is a commixture of a detergent (Tween 80), tetracycline isomer (doxycycline), and acid (citric acid). The irrigant exhibits many favorable characteristics and may be a useful replacement for EDTA in conjunction with NaOCl. The agent cleans the dentin/pulp tissue interface without affecting the flexural strength and modulus of elasticity of dentin. It also shows a notable antimicrobial effect against some strains of *Enterococcus faecalis*.[220–224]

Direct Pulp Capping

Treatment Recommendations

Recommended steps for direct pulp capping with MTA using a two-visit format:

1. Following diagnosis, the tooth has been identified as having either reversible pulpitis or a normal healthy pulp. After profound local anesthesia, the tooth is isolated with a dental dam, further sealed with an agent such as Oraseal® (Ultradent Products Inc., South Jordan, Utah), or comparable product, if required, and the crown disinfected with either chlorhexidine solution or NaOCl. Illumination and magnification (DOM) of the area is highly recommended. The undermined enamel is removed with a diamond or carbide bur and soft debris is removed with a spoon excavator.
2. After the carious dentin is air dried, a caries detector dye is applied for 10 seconds, and the tooth washed and dried. Caries removal is completed with slow speed #4-2 carbide round burs and spoon excavators until minimal (light pink) or no profound stained dentin is evident. The caries detector is again reapplied on air dried dentin for 10 seconds, and the process carefully repeated (possibly five to seven applications) until no or only a light pink staining is evident.
3. If a pulp exposure occurs during caries removal, the bleeding can be controlled by placement of a cotton pellet moistened with 5.25% to 8% NaOCl for 20 to 60 seconds and the staining and caries removal continued carefully around the exposure site until little or no staining is visible. Areas that are identified as reparative dentin with little or no staining should not be removed.
4. After caries removal, the exposure(s) should be hemorrhaging to some degree. A cotton pellet moistened with 5.25% to 8% NaOCl is placed directly against the exposure(s) for a contact time of 5 to 10 minutes. After hemostatsis is achieved, the cavity is gently rinsed with water and dried with air using a two-way syringe. However, if no exposure is encountered, it is still recommended to clean the dentin with the application of NaOCl for five minutes. When hemostasis is not achieved within 10 to 15 minutes, the diagnosis is changed to irreversible pulpitis and more aggressive treatment is indicated. Conversely, if bleeding is not evident after pulpal exposure, the tissue is most likely necrotic, and a miniature, partial or complete pulpotomy, or pulpectomy, must be initiated using a high speed round diamond bur. If during the course of caries removal, the entire pulpal roof or axial wall is removed, a pulpotomy must be considered.
5. The MTA or CSC is mixed according to the manufacturer's instructions (3:1, MTA:H_2O) and will have the consistency of wet sand. The cement is brought to the site in bulk with either a hand instrument (Glick or spoon excavator) or an MTA carrier gun. The MTA or CSC should be placed directly over the exposed pulp tissue and all surrounding dentin. The material is gently patted down with a small moist cotton pellet (or a dry pellet if the mixture is too wet) and when in place, it should be a minimum of 1.5 mm in thickness. If MTA is pushed inadvertently into the pulp chamber, it will not impact the outcome negatively. A circumferential region of dentin and enamel measuring approximately 1.5 mm, or more, should be cleared around the MTA with a small (2–3 mm) moist cotton pellet placed at the end of an explorer. This will allow an adequate area for the future bonded restoration to provide an effective seal.
6. A custom fabricated, flat (1–2 mm thickness), moist, cotton pellet, or gauze, is then placed over the entire area of the MTA. If the area involves a Class II preparation exposure including the axial wall, then the moist covering may require placement in two sections. If the patient is willing to return within four hours, a large moist cotton pellet, or gauze, can be placed with the patient instructed not to eat or chew during the interim, since this may dislodge the slow setting cement.
7. After cotton pellet placement, a strong interim restoration is provided, preferably an unbonded composite material that will facilitate removal during the second visit (e.g., Photocore®, Kuraray Co., LTD, Osaka, Japan). Unless amalgam is the designated restorative material, eugenol-based interim restorations such as IRM, or ZOE, that may interfere with adhesion and bond strengths of adhesive resins should be avoided.[225]
8. The second appointment can be scheduled 5 to 10 days after MTA or CSC placement. Before attaining profound anesthesia, the patient is questioned about sensitivity, mastication comfort, or presence of pain. The tooth is then cold tested (CO_2 ice or Endo-Ice®, Hygienic Corp., Akron, Ohio) to confirm continued normal vitality. After injection of a local anesthetic, the tooth is isolated as before. The interim material is removed with a high-speed diamond or carbide bur, under water spray. The cotton pellet, or gauze, is removed and the embedded cotton fibers removed with a spoon excavator, or similar hand instrument. Working with high magnification (DOM) is strongly recommended. The MTA or CSC is checked to ensure proper curing and a bonded (self-etching) composite restoration placed following the manufacturer's recommendations.
9. After the permanent restoration is placed, the occlusion is checked and adjusted as required. The patient is then recalled at 6 weeks and subjective symptomology and cold testing evaluated. If it appears that the procedure was successful, radiographic follow-up, cold testing, and subjective symptomology can be evaluated at 6 and 12 months. The patient, if compliant, should then be evaluated on a yearly basis.

One-Step Pulp Capping [115]

According to one manufacturer of MTA (ProRoot® MTA, Dentsply, Tulsa, Oklahoma), pulp capping can be completed

in one visit. In some situations, treatment of the immature permanent tooth can be difficult, especially in young patients with challenging medical or behavioral problems that may require treatment under sedation. When one step is indicated, the manufacturer recommends the following protocol:

1. Complete a cavity preparation outline under dental dam isolation, using high-speed burs under constant water cooling.
2. Excavate any carious tooth structure using a round bur at low speed or use hand instruments.
3. Rinse the cavity and exposure site(s) with 2.6% to 5% NaOCl. Heavy bleeding may be controlled with a cotton pellet moistened with NaOCl.
4. Prepare ProRoot® MTA according to listed instructions.
5. Apply a small amount of MTA over the exposure using a small ball applicator or similar device.
6. Remove the excess moisture at the site with a dry cotton pellet.
7. Apply a small amount of Dyract Flow™ flowable compomer (Dentsply International, York, Pennsylvania) (or an equivalent light-cured resin, glass-ionomer liner) to cover the MTA material, and light cure according to its instructions.
8. Etch the remaining cavity walls with 34% to 37% phosphoric acid gel for 15 seconds. Rinse thoroughly.
9. Dry the cavity gently, leaving the dentin moist, but not wet. Apply Prime and Bond NT material, or an equivalent bonding material. Cure according to its instructions.
10. Place TPH Spectrum (Dentsply/Caulk, Milford, Delaware) composite material or an equivalent composite resin to complete the restoration.
11. Assess the pulp sensibility (responsiveness to tests) every six months and evaluate the tooth radiographically every three to six months or as needed.

The authors recommend that caries removal be completed under magnification (DOM) with the aid of a caries detector dye (Step 2). Also, during MTA placement against the exposure site (Step 5), a larger bulk of MTA can be placed that includes the majority of surrounding dentin at a thickness greater than 1.5 mm, to ensure bacterial neutralization. With newly introduced fast setting CSC products, manufacturers recommendations must be followed. However, caries removal under DOM using caries detector dyes and NaOCl hemostasis will provide superior results. Unfortunately, these adjunctive procedures are often overlooked by many operators and instructional brochures published by manufacturers.

THE FINAL RESTORATION

The long-term maintenance of pulp vitality and continued normal function of the pulp capped/pulpotomized tooth is largely dependent on the quality and seal of the final restoration. Bacterial microleakage around restorations is directly associated with the degree of pulpal inflammation and the frequency varies according to the material used.[226] The pulp will have the highest probability for wound repair and survival if microleakage is minimized or eliminated.[227–229] It has even been proposed that cavity preparations that are unfilled and left open, are less harmful than leaking restorations.[230] The appropriate restorative material for each case must be carefully selected and the delivery executed with a high level of skill to provide the best likelihood of a predictable seal against microleakage. Since the delivery of adhesive restorative materials can be technique sensitive, manufacturer's guidelines must be followed and specific composite materials matched with their respective and recommended bonding resins.[231]

Restorative options for immature permanent teeth include full coverage restorations, composite resins, and bonded or unbonded amalgam restorations. The probability of pulp survival increases with conservative restorative treatment that best preserves the remaining healthy tooth structure.[194] The practice of placing stainless steel crowns on immature permanent teeth with adequate remaining tooth structure should be avoided. The age of the patient, the size and depth of the cavity preparation, and the choice of restorative material are all factors affecting repair mechanisms within pulp tissue.[232]

Although amalgam has proven to be a reliable material because it is inexpensive and relatively simple to place, it has disadvantages that include esthetic concerns and potential health risks for dental providers.[233–236] Amalgam restorations can also be associated with coronal infractions or cuspal fracture, particularly if cusps are not protected.[237,238] In structurally compromised immature teeth, the difference in the modulus of elasticity between amalgam (28–60 GPa) and dentin (12–18 GPa) can contribute to a greater risk of coronal and radicular fractures.[239–241] Also, it may not provide an impenetrable seal against microleakage and bacterial contamination.[242,243] However, amalgam restorations, when elected, may exhibit less microleakage if placed in conjunction with a bonding resin or resin-modified glass-ionomer liner.[227,244,245] Survival rates for composites are improving as material technology advances and tooth isolation requirements are acknowledged.[246–249] Even though amalgam restorations remain a reliable and predictable long-term treatment option, the clinical transition to adhesive systems is advancing as technology improves and amalgam use declines.

POST OPERATIVE FOLLOW-UP

Accurate predictors for measuring survival rates in vital pulp therapy include clinical recall and radiographic evaluation. Recall compliance of asymptomatic cases is generally more challenging than teeth that become irreversibly inflamed or progress to symptomatic apical periodontitis after treatment. Since the presence of recurrent caries, restoration failure, poor oral hygiene, or other conditions requiring attention can be identified during a recall appointment, the follow-ups after vital pulp therapy can be beneficial and provide a stronger impact. Unfortunately, some parents and guardians lacking basic oral health knowledge do not practice

preventive measures and may not appreciate the importance of follow-up care thus compromising recall rates.[250,251] Proper follow-up assessment is based on the common practice of the six-month recall. The recall period is related to the frequency of oral prophylaxis; this practice has recently been challenged.[252] It is now recommended that it be based on the patient's need and thus optimal recall rates should be established individually. Factors such as caries index, periodontal status, symptomology, and assessment of cranio-facial development in younger patients should be considered.[253]

An adequate time period for a tentative diagnosis of pulp survivability was determined to be 3 months in an investigation where direct pulp capping was completed with CH.[188] An observation period of 21 to 24 months was shown to establish the prognosis for long-term pulp survival in the same study. The two-visit protocol (described earlier in this chapter) allows clinicians the opportunity to examine the treated tooth at 5 to 10 days after initial treatment. If the procedure appears favorable at the second appointment, the provider can confidently schedule the future follow-up at six weeks, and then at 6 and 12 months if possible.[144]

Apexogenesis of the immature adult tooth is the essential objective in vital pulp therapy. Radiographic confirmation of root-end closure in ***immature permanent teeth*** treated with direct pulp capping, or pulpotomy procedures, is the most reliable indicator of successful treatment. The physiological development and formation of the root-end should advance uneventfully in healthy patients at a constant rate after the application of MTA or other CSC, whether direct pulp capping or pulpotomy was performed (Figure 27-14).[136,137,254–256]

The natural succession of tooth development in vital teeth should follow a predictable pattern when viewed chronologically and compared radiographically to contralateral untreated

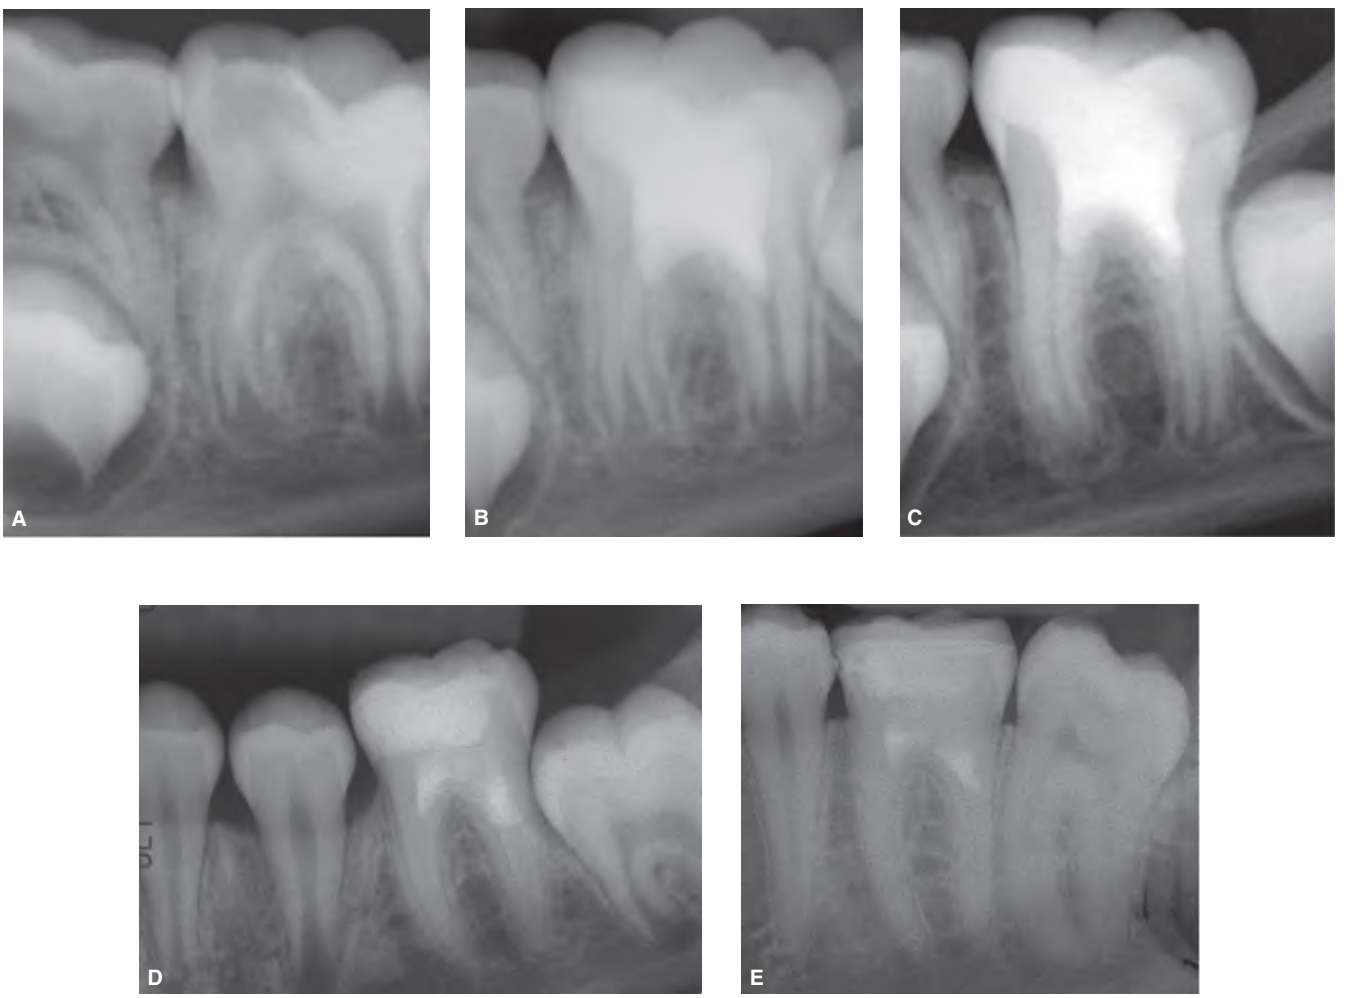

FIGURE 27-14 Seven-year-old patient presenting with moderate to severe pain associated with a dens evaginatus of the mandibular left first molar. ***A.*** Preoperative radiograph showing immature apices and presence of a coronal defect that was clinically filled with hyperplastic tissue. ***B.*** Postoperative radiograph after complete pulpotomy with MTA. The access cavity was sealed with glass ionomer cement and bonded composite. ***C.*** 15-month follow-up radiograph demonstrating continued root development and apical closure. ***D.*** Five-year recall radiograph showing completed root development. ***E.*** 12-year radiographic follow-up. The patient was asymptomatic and the molar in full function. Note, no cuspal coverage restoration was placed. (Courtesy of Dr. Mark Olesen, North Vancouver, BC, Canada.)

teeth.[257] Comparison of contralateral tooth development at the same time intervals, is therefore a superior way to assess the success of vital pulp therapy. Teeth with necrotic pulps and periapical pathosis that have sustained trauma have traditionally been treated with CH to stimulate apical barrier formation and augment root-end closure.[258] Variable times from 5 to 20 months can be required to complete barrier formation.[259]

Mineral Trioxide Aggregate and other CSCs are now widely accepted as replacements for CH in direct and indirect pulp capping, pulpotomy, and apexogenesis procedures and can be expected to promote apical maturation at coinciding time periods.[260] The dental pulp and surrounding tissue have an exceptional regenerative capability when a ***microbe free environment*** is implemented.[231,261,262] The recent introduction of these advanced bioactive materials that reliably promote pulp repair and healing have made a progressive and substantial contribution to our understanding and ability to protect and maintain the living pulp.

Chapter 28

Management of Teeth with Immature Apices

Shahrokh Shabahang

ROOT APEX AND CORRECT LEVEL OF OBTURATION

Grove, in 1930, proposed that root canals should be filled to the cemento-dentinal junction (CDJ).[1] Based on his observations, the CDJ is on average 0.5 mm–0.75 mm from the apical foramen (Figure 28-1). In 1958, Kuttler[2] confirmed that the CDJ is the ideal terminus of a root canal filling, and that over-extension of the obturation material is not desirable because these materials constitute foreign bodies, that prevent deposition of new cementum. In his paper, he further cited that following extirpation of pulp tissue, the periodontal membrane that remains in the cemental (most apical) portion of the canal is capable of giving rise to new cementum. In examination of the clinical correlation of the root apex and its surrounding structures, Moodnik[3] concluded that the root apex must be viewed as a vital dynamic tissue that is capable of development, growth, and repair.

TOOTH DEVELOPMENT

Prior to manipulation of immature permanent teeth, an understanding of tooth development is paramount.[3–7] This holds true whether devising an accurate diagnosis and appropriate treatment plan in the clinic or developing new materials and techniques in laboratories. For more details, see Chapter 2, "Structure and function of the pulp–dentin complex."

During tooth development, the inner and outer dental epithelia fuse and form the cervical loop.[5] From this region root formation begins, initiated as an apical proliferation of the two fused epithelial structures forming a double layer of cells known as the Hertwig's epithelial root sheath (HERS). The sheath is similar to the inner enamel epithelium and acts as the stimulus and template for the differentiation of odontoblasts and formation of root dentin.[7] The HERS is located at the end of the developing root (Figure 28-2), with its cells lining the pulp space and it is responsible for increasing root length and closure of the apical foramen.[8] The root sheath determines the number, size, and shape of the roots and the future cementoenamel junction.[5] Fragmentation of the HERS allows the cells of the investing follicle to pass through and contact the newly formed dentin surface where the cells differentiate into cementoblasts and initiate cementum formation. In many teeth, a network of the fragmented root sheath persists in the periodontium in close proximity to the root after root development has been completed to form the epithelial cell rests of Malassez (ECRM).

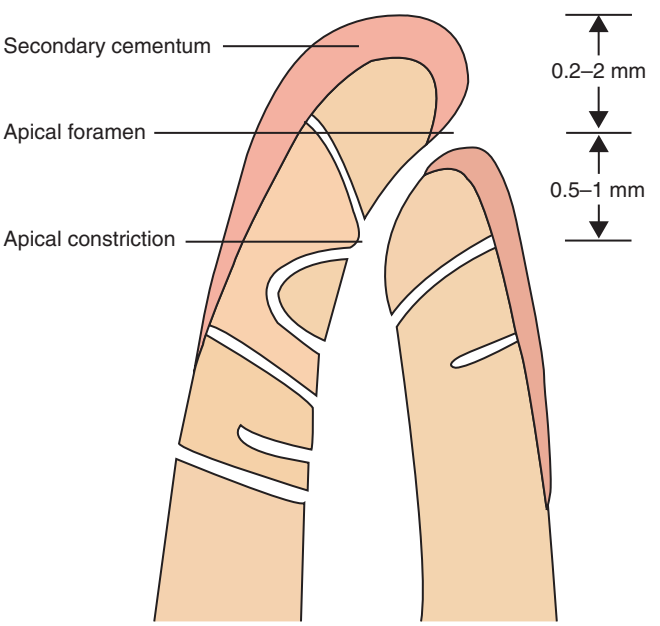

FIGURE 28-1 Illustration of apical root anatomy depicts location of the apical foramen, that is typically short of the root apex and exits on the lateral border of the root apex.

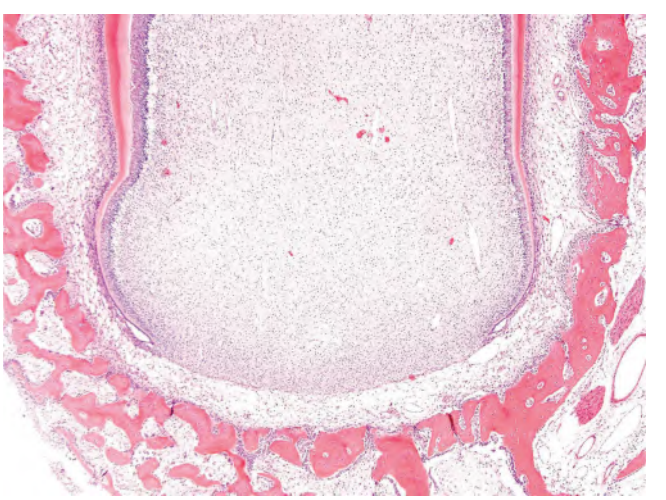

FIGURE 28-2 Photomicrograph of the apical segment of an immature root and its surrounding periradicular tissues. The inner and outer enamel epithelia join to form the HERS.

Facial injuries between the ages of 6 and 14 years have the potential for interrupting, altering, or arresting root development.[8] In general, trauma to the teeth can cause either the complete arrest of odontoblast function or accelerate their activity, resulting in pulp calcification (Figure 28-3).

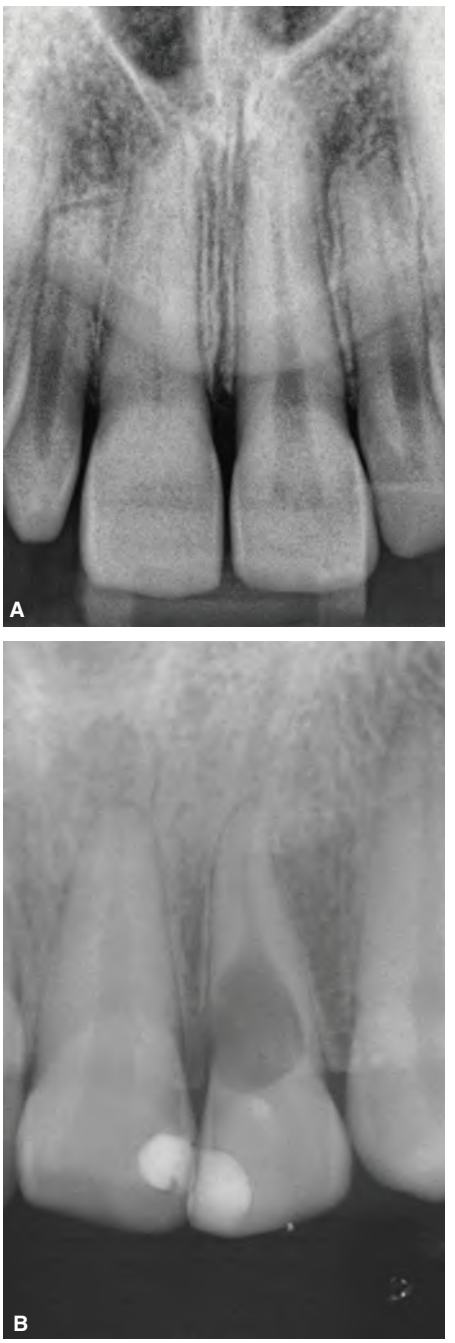

FIGURE 28-3 Radiographic images illustrating that, subsequent to traumatic injuries, the pulp may either increase dentin deposition or initiate dentinoclastic activity. ***A.*** The canal space in the maxillary right central incisor has undergone calcific metamorphosis due to an increase in dentin deposition in reaction to trauma sustained by the tooth. ***B.*** Large internal resorptive defect in the maxillary left central incisor, which is another possible scenario resulting from increased dentinoclastic activity due to trauma.

Complete destruction of the HERS can arrest any further lengthening of the root, but previously differentiated odontoblasts and cementoblasts can complete apical closure. HERS forms the outline for the root and apex, but without a vital pulp, root development cannot continue to completion.[9]

BONE AND DENTIN

Bone consists of three different components: (1) a mineral component, (2) collagen and (3) other organic components including growth factors. The growth factor component has bone morphogenetic activity and can be extracted after demineralization of bone.[10] Mechanisms that generate new bone formation include: Osteogenesis, the transfer of viable bone-producing cells within the graft to a new anatomic location; osteoconduction, creeping substitution or bony ingrowth; and osteoinduction, the stimulation of mesenchymal cells to differentiate into osteogenic cells that produce new bone.[11]

Implantation of devitalized decalcified bone, following hydrochloric acid treatment in extra-skeletal sites, stimulates host cells to differentiate and produce bone through a transient inflammatory reaction.[12] Differentiation of the osteoprogenitor cells is elicited by local alterations in cell metabolic cycles. Chondroprogenitor cells produce cartilage, that later becomes vascularized, to set up a second or delayed induction system for bone formation. Whether progenitor cells produce bone or cartilage is determined by the microenvironment or local factors. When implanted in experimental periodontal bony defects in dogs, decalcified allogeneic bone matrix results in enhanced bone formation.[13] Inoue and associates[14] evaluated the effects of demineralized dentin and bone matrix in rats. They reported that the implants induced formation of cartilage most rapidly and abundantly in muscle, and most slowly and in the smallest quantity in periodontal ligament.

Smith et al.[15] implanted dentin matrix components in exposed pulps in ferret teeth. Significant deposition of new extracellular matrix was observed at the pulp/dentin interface after 14 days. The dentin matrix expressed a local response as there was no deposition of reactionary dentin at any other sites in the teeth. In the absence of implanted proteins, there was no evidence of deposition of reactionary dentin beneath the cavities at any time.[15]

BONE MORPHOGENETIC PROTEINS

Bone morphogenetic proteins (BMPs) can be divided into subgroups based on the primary amino acid sequence in the mature region of the molecule. BMP-2 and BMP-4 are closely related proteins with 92% identity in the cysteine region.[10] BMP-5, BMP-6, BMP-7 (also known as osteogenic protein-1), and BMP-8 (osteogenic protein-2) form another subgroup with approximately 75% amino acid homology.[16] These two subgroups are interrelated by nearly 60% amino acid homology, while BMP-3 is in a subgroup of

its own. Additionally, a sub-group of BMP-related molecules known as growth and differentiation factors (GDF) have been identified.[16] Most BMPs that have been cloned share structural similarities to members of the transforming growth factor-β (TGF-β) superfamily.[17] TGF-β belongs to a family of disulfide-linked homodimers, which are involved in the migration, proliferation, and differentiation of mesenchymal cells during embryogenesis and tissue repair.[18,19]

To study the effect of BMP on reparative dentin formation, pulps of teeth in young dogs were amputated and 3 milligrams of crude BMP were implanted in the cavity on the surface of the amputated pulp.[20] Canine serum albumin was implanted in other teeth to serve as control. Pulp responses were categorized in four stages:

Stage 1 (Immune response): BMP evoked a cell mediated response within one week.

Stage 2 (Proliferated response): BMP was almost completely absorbed; spindle-shaped mesenchymal cells migrated and proliferated between the first and second week.

Stage 3 (Osteodentin formation): Between two and four weeks, in some parts of the cavity, especially adjacent to the dentinal walls and just beneath the cement-filling surface, osteodentinoblasts and/or osteodentinocytes differentiated to form osteodentin.

Stage 4 (Tubular dentin formation): Between four and eight weeks, odontoblasts differentiated to form tubular dentin. In the control sites containing serum albumin implants. The cavity was filled with pulp tissue much more slowly than in the experimental group.

On the basis of these results, the author concluded that BMP has desirable properties as a pulp-capping agent because it is completely absorbed and can produce a large amount of reparative dentin on the amputated pulp without affecting the radicular pulp.

Lianjia et al.[21] implanted 200 μg of BMP directly onto the surface of amputated pulps in the premolar teeth of adult dogs and compared these findings with the control group that was treated with the same amount of calcium hydroxide. Their results showed that in the bell stage of tooth development, the outer and inner enamel cells and differentiated odontoblasts demonstrate a positive reaction to BMP-monoclonal antibodies. Incorporation of [^{3}H]thymidine into pulp cell nuclei and alkaline phosphatase activity in the pulp cell cytoplasm were much higher in the BMP group when compared with the control group. These results suggest that BMP not only stimulates DNA synthesis of dental pulp cells, but also promotes calcification. After one week, all pulps capped with BMP showed minimal signs of inflammation and by the second week, the pulp tissues were free of inflammation. Starting at week three, dentin formation was induced and the dentin bridge was complete and had begun to calcify. In the control group, only some osteodentin formation was present at the fourth postsurgical week and a dentin bridge did not form.

OP-1 may recruit mononuclear phagocytes and stimulate proliferation of mesenchymal cells that differentiate into osteogenic cells that ultimately lead to ectopic bone formation.[22] Transcripts of *bmp-2* and *bmp-7* have been identified at bud and cap stages in the area of the enamel knot in the dental epithelium. Postlewaite et al.[23] compared the ability of recombinant human OP-1 (rhOP-1) and recombinant human TGF-β1 (rhTGF-β1) to induce migration of fibroblasts and to affect a fibrogenic phenotype in these cells *in vitro*. The results demonstrated that although both are potent chemoattractants for neutrophils, monocytes and fibroblasts, only TGF-β1 upregulates fibroblast functions associated with a fibrogenic phenotype (i.e., stimulation or proliferation and synthesis of collagen). In contrast to rhTGF-β1, rhOP-1 neither affected the rate of mitogenesis of fibroblasts nor enhanced synthesis of collagen or hyaluronan by fibroblasts (functions that may be important in soft tissue repair). Neither protein stimulated the production of prostaglandin E2 (PG-E2).

The extent of osteogenic activity was histological examined in implants containing 25 mg of rat collagen carrier with varying amounts of OP-1.[24] Alkaline phosphatase activity and calcium content of the implant have been used as biochemical markers for osteogenesis (calcium content of the implant is directly proportional to the total amount of bone formation). Results indicate that the carrier alone does not induce bone, whereas implants containing both carrier and OP-1 induce endochondral bone formation in a dose-dependent manner. Furthermore, OP-1 samples show evidence of hematopoietic bone marrow recruitment. Histological evaluation of hOP-1 implants in rats has similarly shown that as little as 5–10 ng of the protein in 25 mg of matrix carrier is sufficient to induce endochondral bone formation in a dose-dependent manner.[22] At a concentration of 1 μg/25 mg of matrix carrier (that is the level at which rhOP-1's activity plateaus), the bone-forming activity of the implant is four times greater than the activity elicited by intact demineralized bone matrix.

OP-1 has also been used to induce bone formation in close apposition to titanium dental implants placed in tooth sockets of monkeys. Rutherford et al.[25] used a bovine protein preparation in combination with monkey bone collagen carrier. They found that at the three-week observation period, OP-1 induces bone formation in close apposition to at least some portion of the titanium surface, while similar findings are not observed in the absence of OP-1. Substantially more new bone formation is also evident in sockets filled with OP-1 implants compared to those filled with the collagen matrix alone or those left empty.

In a comparative study with calcium hydroxide, OP-1 in a collagen carrier was used as a pulp-capping agent in the premolars of adult monkeys using 1.5, 3.0, and 6.0 mg of the material per tooth.[26] Calcium hydroxide was used in a setting paste (Dycal). In a third group, teeth were filled with the collagen carrier alone, while a fourth group did not receive any material. The animals were sacrificed six weeks after the surgical procedures and the samples were histologically evaluated. Reparative dentin formation was present in all teeth treated with hOP-1/collagen carrier in which the material had been retained in the teeth for the duration of the six-week healing phase. The 6.0-mg group induced significantly more reparative dentin. Three of the five pulps treated with calcium hydroxide contained partial dentin

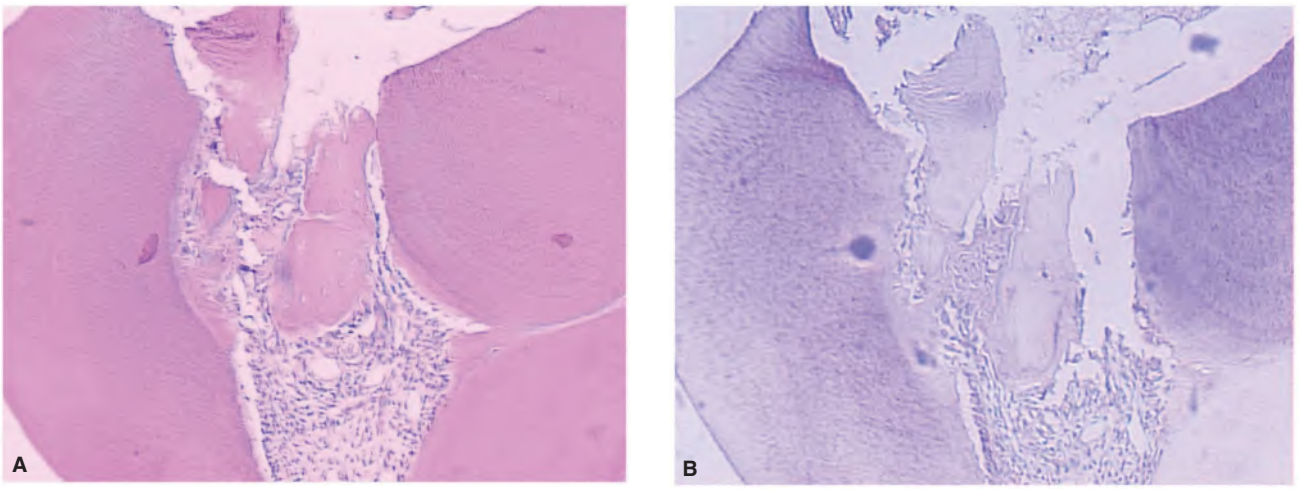

FIGURE 28-4 Photomicrographs showing ectopic bone formation in the pulp chamber of a rat molar following pulp capping with OP-1. ***A.*** H&E staining shows bony morphology with lacunae. ***B.*** Represents an immunohistochemical section stained with antibody against dentin sialoprotein (DSP), that is found approximately 200-fold more concentrated in dentin than in bone. bridges, while no dentin bridge formation was noted in the collagen carrier and sham control groups. In the experimental groups, the pulps appeared normal with an intact odontoblastic layer. In the calcium hydroxide group, the dentin bridges formed at the expense of the pulp chamber. Furthermore, calcium hydroxide remained in the tooth superficial to the dentin bridge while the hOP-1/collagen was resorbed and replaced with a mineralized fibrous connective tissue. Conflicting results have been reported by other investigators.[27] In their study, Andelin et al. found ectopic bone formation rather than dentin (Figure 28-4). This finding is, in fact, consistent with Sampath's findings with ectopic bone formation observed when OP-1 was subcutaneously implanted in rat dermal tissues.[24]

In 1999, Shabahang and coworkers examined whether OP-1 has superior abilities to calcium hydroxide in induction of root-end formation.[28] Immature premolars in dogs were infected to allow periapical lesion formation. All root canals were debrided using sodium hypochlorite as an irrigant and then dressed with calcium hydroxide for one week to disinfect the canals.[29] The canals were then filled with calcium hydroxide, OP-1 in a collagen carrier, collagen carrier alone or MTA. At the end of the 12-week observation period, OP-1 showed similar results to calcium hydroxide with 5 of 13 roots in each group demonstrating complete barrier formation at the root-end while the remaining eight roots remained open. When a barrier was formed, the mean thickness was significantly greater in the OP-1 group compared to the calcium hydroxide group (Figure 28-5). Interestingly, when the collagen carrier alone was used, none of the 11 evaluable samples showed barrier formation (Figure 28-6). This finding suggests that the collagen carrier may inhibit root-end induction or that root canal disinfection alone may not be adequate and an active material is required to aid in induction of root-end closure.

To induce root-end formation mesenchymal cells must be stimulated to differentiate into odontoblasts and cementoblasts

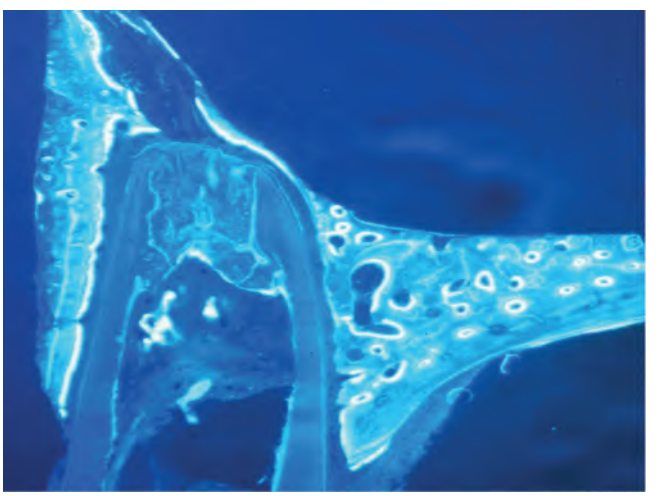

FIGURE 28-5 A fluorescent photomicrograph of a specimen showing formation of a thick layer of mineralized tissues in the apical region of an immature tooth that was treated with OP-1.

in order to produce dentin and cementum, respectively. This inductive process will require proper signaling to ensure that the pluripotent cells differentiate into the appropriate cells to produce the desired tissues.

DIAGNOSIS AND CASE SELECTION

When the pulp is vital and the apex is not formed, it is imperative to make every attempt to maintain the vitality of the pulp in order for the apex to complete its formation.[9] Only odontoblasts, the specialized cells in the pulp, are capable of producing dentin. In addition to interruption of root apex formation, in the absence of a vital pulp, thickening of dentin will not occur along the entire root length. Thin dentin in the cervical region teeth is more susceptible to fracture if subsequent traumatic injury occurs (Figure 28-7).

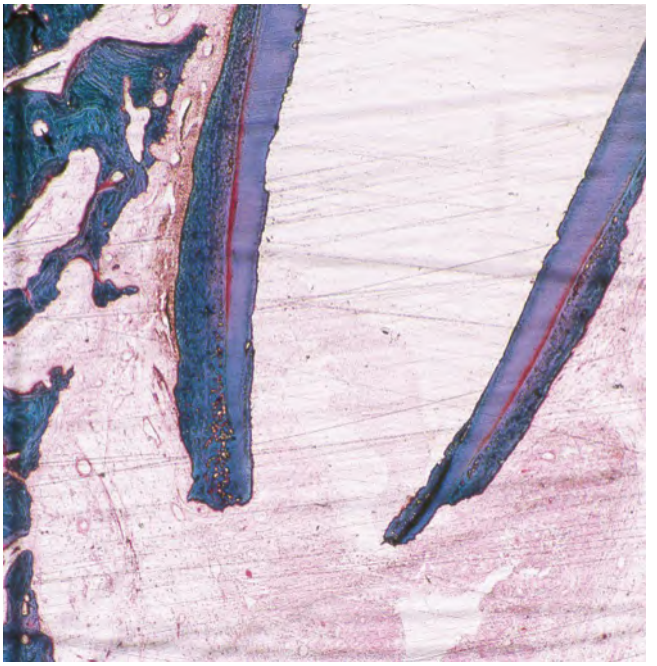

FIGURE 28-6 Specimen stained with Masson's Trichrome showing absence of apical closure in an immature tooth that was treated with collagen carrier alone. Figure illustrates cementum covering the inner and outer surfaces of dentin walls.

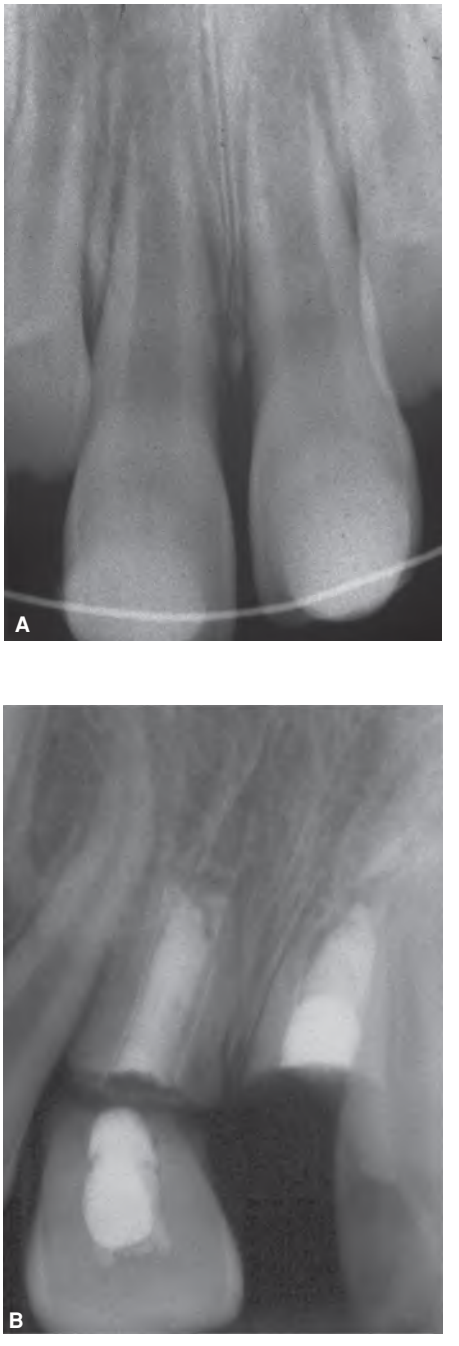

FIGURE 28-7 Radiographs show maxillary central incisors that were subjected to a traumatic incident. ***A.*** Teeth are splinted shortly after injury. ***B.*** Eighteen-month follow-up radiograph shows cervical root fractures in both teeth subsequent to apexification. (Courtesy of Dr. Leif K. Bakland, Loma Linda, CA, U.S.A.)

Pulp tissues should be removed only when irreversibly inflamed or necrotic. In young patients, the pulp has been typically exposed to less irritation and restorative treatment, is larger and more cellular, and has a higher likelihood to recover from injury. Cvek et al.[30] found that teeth that have been subjected to crown fractures and pulp exposure maintain a vital pulp for up to seven days post injury. Inflammation in these fractured teeth is limited to the surface 2 mm of the pulp just beneath the exposure level.

Accurate diagnosis is imperative prior to determining the treatment plan for teeth with underdeveloped roots. For this, careful assessment of pulp status is required. Radiographs are used to assess the maturity of the developing root and presence or absence of periradicular pathoses. Clinical evaluation should be based on history and clinical testing. Less reliable pulp testing data pose a special challenge in children. Verbal communication may be impacted by the young patient's linguistic development and apprehension.[31–33] Assessment of the true histologic status of the pulp is complicated by unpredictable and subjective symptomology reported by the patient.[34] The response to pulp testing is also less predictable than in adults and therefore less accurate. The most reliable test may be cold testing while[35,36] electric pulp testing in teeth with immature apices can result in less accurate results.[37] While assessment of nerve impulses is less reliable, determination of pulpal blood flow may be a more accurate means to determine the condition and prognosis of an injured young pulp in an underdeveloped tooth. Strobl et al.[38] used laser dopplers to evaluate changes in pulpal blood flow (PBF) in teeth that were subjected to various types of traumatic injuries. They were able to show that, immediately after removal of the stabilizing splint, while lateral and extrusive subluxation injuries do not significantly impact PBF, intrusive injuries consistently lead to diminished PBF, and ultimately, pulp necrosis (Figure 28-8). Thus, teeth that have a history of intrusive injuries will most likely require endodontic therapy due to a high incidence of pulp necrosis. A potential shortcoming with laser

Doppler measurement of PBF is interference from the blood circulation in the gingival tissues.[39] For a more accurate measurement, placement of dental dam may be indicated to block out any interference from gingival tissues.

The flow chart in Figure 28-9 can serve as a guide to aid in the decision-making process when treating permanent teeth with incomplete root development. As the chart shows, in immature teeth with vital pulps, pulp vitality must be preserved. If the pulp is irreversibly inflamed or necrotic, the decision to perform conventional root canal treatment or a root-end closure procedure is based on the level of apical root development.

Whilst pulp testing is important to obtain an accurate diagnosis of the condition of the pulp, determination of the degree of root development is primarily achieved radiographically. Conventional 2-dimensional periapical radiographs have significant limitations because they primarily illustrate the mesio-distal view of the root. In developing roots, the buccal-lingual dimension of the root canal is typically greater than the mesio-distal dimension (Figure 28-10). Thus, while a periapical view of an incisor may show a closed apex in the

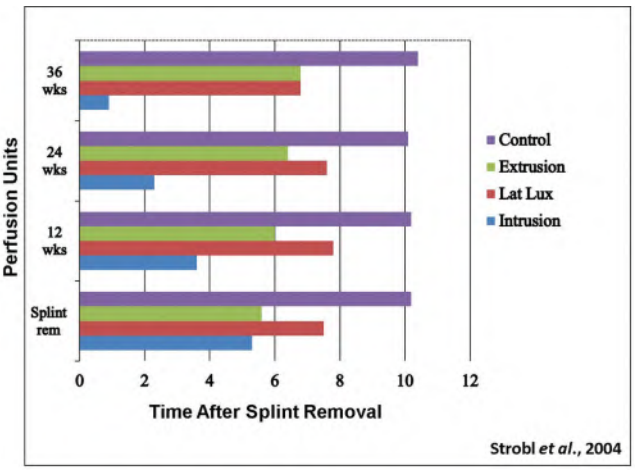

FIGURE 28-8 Data from Strobl et al.[38] show that intrusive injuries result in the greatest amount of damage to teeth. While pulps in teeth that sustain lateral luxation and extrusive injuries are associated with minimal changes in pulpal blood flow (PBF), intrusive injuries result in rapid decrease in PBF.

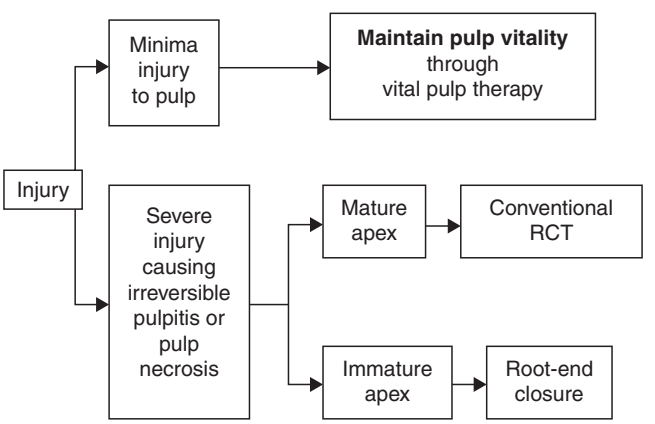

FIGURE 28-9 Decision-making for permanent, immature teeth. Algorithm to aid in the decision making process for immature permanent teeth that sustain injuries affecting the pulp.

mesio-distal dimension, the obscured bucco-lingual angle may be open. A root with apparently parallel walls mesio-distally may have divergent walls and greater width bucco-lingually; a canal with tapering walls mesio-distally tends to have parallel walls and greater width bucco-lingually. This developmental pattern can be misleading with respect to convergence and divergence. Since the bucco-lingual aspect of the root canal is the last dimension to become convergent as the root develops, a radiograph may be showing an apically convergent root canal, that in the bucco-lingual plane is divergent.[40] A more complete and accurate visualization of anatomic structures is now possible with the use of 3-dimensional CT imaging.[41] Figure 28-11 demonstrates the utility of 3-dimensional radiographs for a full view of a premolar with open apices.

INFECTION CONTROL

Immature permanent teeth present unique challenges during conventional root canal treatment not only because of a blunderbuss root apex, but also because of thin and fragile dentin walls (Figure 28-12). In order to maintain maximum root dentin, debridement should be achieved primarily through chemical means to remove any remaining pulp remnants and for disinfection. Minimal mechanical instrumentation is required because the canals are already wide. An added difficulty is determination of accurate root length measurement. Accurate canal length measurement is required to ensure complete canal debridement without over-instrumentation and over-extension of the obturation material. Extrusion of foreign materials might damage the periapical tissues including the remaining and vital HERS. Electronic apex locators are not accurate in immature teeth or teeth with wide open apices and radiographic determination of root length is recommended (Figure 28-13).[42,43]

FIGURE 28-12 Ground section of an immature tooth stained with Masson's Trichrome showing thin and fragile root dentin.

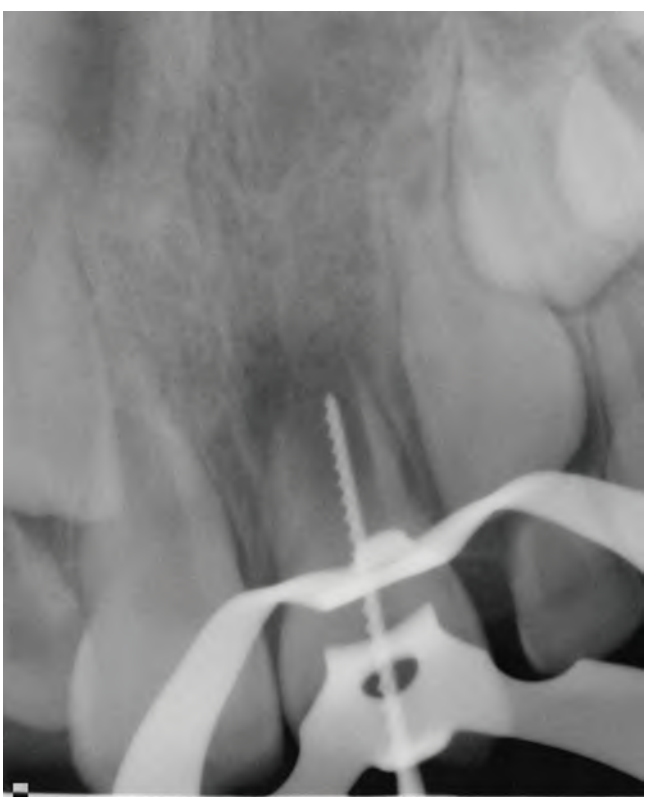

FIGURE 28-13 Radiograph of a maxillary left central incisor with an endodontic file illustrating radiographic root length determination in a tooth with a wide open apex. (Courtesy of Dr. Atosa Mehrfar, Loma Linda, CA, U.S.A.)

Sodium hypochlorite (NaOCl) and calcium hydroxide have tissue dissolving and antimicrobial properties.[44–53] NaOCl possesses more potent activity and exerts its activity during chemo-mechanical debridement. Calcium hydroxide, on the other hand, requires increased exposure times. Obturation of the canal space with calcium hydroxide allows disinfection along with dissolution and removal of pulp remnants.[29,50] While these properties of NaOCl and calcium hydroxide are required and important for canal debridement, neither may be effective in completely disinfecting the root canal system.[53–56] NaOCl can be readily inactivated by heat, light, and exposure to air.[57,58] It is most effective when mixed into solution just before use.[59]

Increased exposure times to these chemicals may also have detrimental effects on dentin structure. Machnick et al[60] showed that when dentin is exposed to NaOCl for periods exceeding 20 minutes, structural changes occur that may ultimately result in weakening of the root dentin. Similarly, exposure to calcium hydroxide for periods exceeding one month may result in structural changes in dentin that leading to significantly higher susceptibility to root fracture.[61–68] This finding may be especially significant in immature permanent teeth that have thin dentin walls in the cervical region of the tooth.

Due to these shortcomings, investigators have searched for more effective irrigants and medicaments to disinfect root canals. Use of antibiotics for root canal disinfection is not a new concept in endodontics. Ball,[69] in 1964, used antibiotic pastes for root canal disinfection. Das[70] used oxytetracycline HCl ointment after root canal debridement and found that disinfection of the root canal system can successfully induce root-end closure in a tooth with an open apex.

More recently, there has been renewed interest in adding antibiotics to root canal debridement protocols. BioPure MTAD was introduced in 2003 as a final root canal rinse for smear layer removal and disinfection. Torabinejad et al.[53,54,71–73] published a series of papers to report findings from systematic studies that were designed to demonstrate the advantages of a mixture of doxycycline, citric acid, and detergent over NaOCl and other commonly used root canal irrigants. The benefits presented include safe removal of smear layer (Figure 28-14) without damage to the underlying dentin[71,72]; antimicrobial activity including contact killing of resistant strains[53,54]; and substantivity.[73]

Iwaya and associates[74] reported the effectiveness of a double antibiotic paste to disinfect a premolar with a necrotic pulp that exhibited a large periradicular lesion. Three years later, Banchs and Trope[75] published a similar case. In their studies, Trope's group recommended the use of a triple antibiotic paste composed of metronidazole, ciprofloxacin, and minocycline. This antibiotic combination has proven effective in disinfecting the root canal system *in vitro*.[76,77] Animal experimentation has confirmed that significantly better disinfection can be achieved when root canals are disinfected with the triple antibiotic paste compared with biomechanical debridement using 1.25% NaOCl.[78] One potential drawback to the use of this mixture is staining of the tooth structure caused by longer exposure times to minocycline. For this reason, some have recommended omission of minocycline and use of a double antibiotic mix.[79,80]

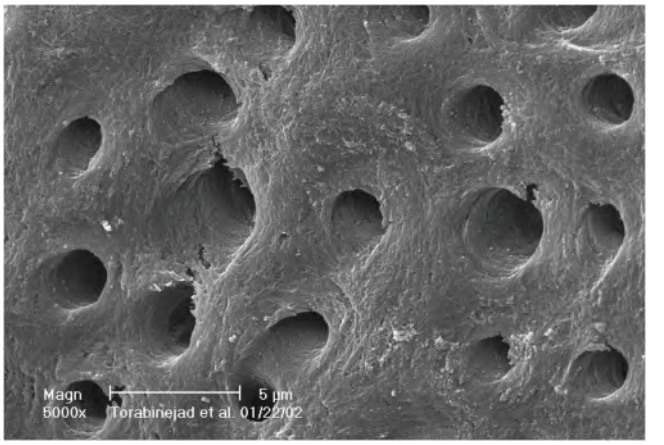

FIGURE 28-14 Scanning electron photomicrograph of root dentin after removal of smear layer with BioPure MTAD. The image shows complete removal of the smear layer without damage to the underlying dentin. The open dentinal tubules are clearly open and free of debris.

Another important factor to consider when selecting an appropriate root canal disinfectant for root-end induction procedures is their potential impact on viable cells (including stem cells of the apical papilla) in the periapical tissues. The double and triple antibiotic pastes can significantly reduce the survival of these cells in contrast to calcium hydroxide.[81] In a similar study, unlike NaOCl and EDTA supported cell survival, 2% chlorhexidine did not support survival of stem cells derived from apical papilla.[82]

Complete disinfection of the infected root canal system is a critical step during root-end induction procedures. Regardless of the protocol employed to induce apical closure, remaining bacteria in the root canal system will lead to continued irritation that can interfere with root-end development.

APEXIFICATION

In young teeth with incomplete root-end formation, severely inflamed or necrotic pulp tissues must be removed and the root canal system must be debrided in the conventional manner.[5] The young pulpless tooth, frequently, has thin and fragile walls making it difficult to adequately clean and to obtain the necessary apical seal.[83] Completion of endodontic therapy should therefore be delayed until root-end closure has been completed by apexification.

Torneck and associates[84] examined the effect of injury and oral contamination on the dental pulp of monkeys. Pulp injuries were induced in incisors of young *Macaca irus* monkeys with incompletely formed roots and observed for 7–95 days. Periapical radiolucencies were visible as early as 14 days following injury. As early as 28 days postoperatively, varying

degrees of inflammatory cell infiltration were visible in the residual portion of the apical pulp. At the end of the observation period (95 days), the specimens displayed post-operative root formation with some attempt at apical closure. The apical closure was a result of deposition of tubular and cellular dentin as well as cementum along the inner walls of the root canal. This phenomenon was attributed to the potential for portions of the dental pulp, including the peripheral layer of odontoblasts, to remain vital and active despite the presence of severe pulpal and periapical pathoses.

Some investigators believe that continuation of root apex development in nonvital teeth may be resumed by removal of the nonvital tissue and control of infection alone. In his 1980 publication, Das[70] reported a case of a 12-year-old child who was seen two years after a traumatic injury to a maxillary central incisor. The root canal was debrided, irrigated with sodium hypochlorite, and medicated with oxytetracycline hydrochloride ointment. Two months following initial treatment, the patient presented with resolution of symptoms. Continued root development had ensued.

Cameron[85] reported two cases in which he attributed the continuation of root-end closure to infection control using ultrasonically activated sodium hypochlorite. Calcium hydroxide was also used in these teeth as intra-canal dressing.

Lieberman and Trowbridge[86] reported a case in which apical closure of nonvital permanent incisors was observed in the absence of intervention. An 11-year-old patient had presented with maxillary central incisors that had been traumatized four years previously without any treatment. Teeth were examined and determined to be nonvital with radiographic evidence of large root canal spaces and periapical lesions. Radiographic evaluation also revealed closed apices in both incisors. The incisors were extracted due to severe malocclusion and general restorative difficulties. Histological examination indicated that the mineralized tissue that had formed at the apices of the teeth was composed of atubular dentin and cementum. The authors concluded that hard tissue formation occurred in the presence of vital tissues at the apices following which the pulps became inflamed and eventually underwent necrosis.

Various procedures and medicaments have been recommended for apexification including Tricresol and Formalin,[87] antibiotic pastes,[69] tricalcium phosphate,[88] and calcium hydroxide. Calcium hydroxide has been used in different mixes such as camphorated parachlorophenol (CMCP),[83,84,89–91] iodoform,[92] water,[93,94] local anesthetic solution, isotonic saline solution, glycerol, and other liquids.[40,95–98]

Ham[91] and associates evaluated the apical closure of immature pulpless teeth following experimentally induced blood clots. Seventeen teeth in three young monkeys were subjected to pulp exposures, contaminated with saliva and sealed with zinc phosphate cement. Radiographs were taken to confirm the presence of periradicular lesions. Teeth were then instrumented and medicated with CMCP and beechwood creosote. Eight samples were filled with calcium hydroxide mixed with CMCP and the remaining nine were treated with induced blood clots. The coronal halves of the latter group were filled with gutta-percha and sealer. None of the teeth in either the calcium hydroxide or blood clot group demonstrated complete bridging of the apex with calcified hard tissue.

Nevins[99] reported a case of a pulpless maxillary lateral incisor with an open apex in an eight-year-old boy. The young patient had developed thermal, percussion, and palpation sensitivity following traumatic intrusion of the incisor. The tooth underwent an apexification procedure using a mixture of collagen-calcium phosphate gel. The six-month postoperative radiograph showed continued root formation that was similar to the unaffected contra-lateral tooth. In a follow-up study, Nevins[100] concluded that the collagen-calcium phosphate gel provides a suitable medium for hard tissue formation. In a conflicting study, Citrome and associates[97] found severe inflammatory lesions with no evidence of apexification or cementogenesis in two 5-month-old dogs whose premolars were treated with collagen-calcium phosphate gel. In contrast, five of seven teeth treated with calcium hydroxide showed no evidence of inflammation and all teeth had apexification and apical cementogenesis. The hard tissue bridge was identified as cementum or amorphous calcified matter.

Regardless of the vehicle used, calcium hydroxide has historically been the material of choice for apexification procedures. Numerous studies have reported successful induction of apical closure or the formation of a hard tissue barrier against which gutta-percha and sealer may be condensed. In 1966, Frank[83] proposed placement of a thick paste of calcium hydroxide and CMCP and recommended follow-up evaluations at three- to six-month intervals until closure of the apex. He also recommended confirmation of a calcified barrier radiographically or clinically with an endodontic instrument (Figure 28-15). Frank further proposed that with

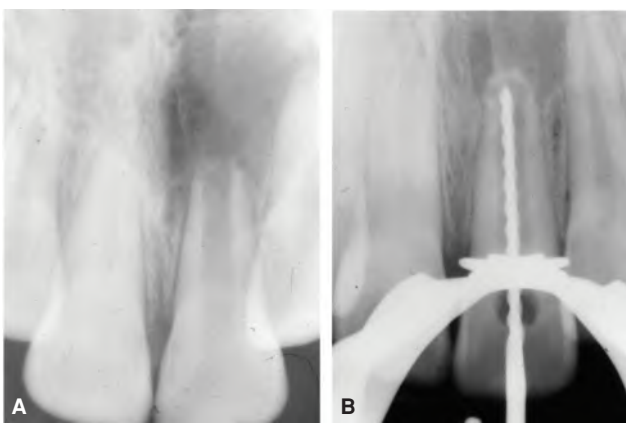

FIGURE 28-15 Radiographic images of a maxillary left central incisor in an 8-year-old patient with a history of trauma. ***A.*** initial radiograph shows an open apex and a large periapical lesion. Calcium hydroxide was replaced two to three times over a six-month period. ***B.*** Radiograph obtained at follow-up shows formation of an apical barrier that is visible radiographically and detectable with an endodontic instrument. (Courtesy of Dr. Leif K. Bakland, Loma Linda, CA, U.S.A.)

this procedure, the clinical results might vary. Outcomes may include any of the following: (1) An apex that closes with a definite though minimal recession of the root canal (the apical aspect continues to develop with a seemingly obliterated apex); (2) the obliterated apex may develop without any change in the root canal space; (3) there may be no radiographic evidence of continued root and apex development, however, an instrument inserted into the canal encounters a definite stop that would allow for obturation of the canal space; or (4) a calcific bridge may form just coronal to the apex that can be visualized radiographically.

Feiglin[101] similarly classified apex formation following apexification procedures with calcium hydroxide and listed them as follows: (1) The apex appears bridged over with hard tissue that is assumed to be osteocementum or osteodentin; (2) a perfectly normal apex is formed from the point of trauma to the apex of the tooth; (3–4) variable amounts of vital tissue remain above the point of trauma, that allow the root canal to heal or bridge over, and the apex to continue forming and to calcify; and (5) apex appears lifted off during tooth movement.

Dylewski[89] evaluated histologically the efficacy of calcium hydroxide-CMCP paste in incisor teeth of a young rhesus monkey with artificially induced open apices. In three of the teeth, instrumentation and obturation were limited to within the canal, and in the remaining teeth, the files were manipulated 1–5 mm beyond the apex, in an attempt to disrupt the epithelial diaphragm. His findings showed that instead of continued normal root development, a state of repair is observable at the apices characterized by proliferation of connective tissue. The connective tissue differentiates into a calcified material identified as osteodentin. Presumably, the bridging that occurs across the apex is not via the formation of typical dentin from odontoblastic activity but rather from the proliferation of connective tissues at the apical area. In this report, the HERS was not detectable in any of the sections and complete root-end closure could not be demonstrated in any of the teeth studied.

Harrison and Rakusin[102] also noted the presence of a cellular, atubular cementum bridge at the root apex during histological examination of a maxillary central incisor treated with calcium hydroxide (Figure 28-16). In their fourth paper in a series of publications, Torneck[84] et al. used a thick paste of calcium hydroxide-CMCP-mix in root canals of partially developed permanent teeth in monkeys. Injury to the pulp and periradicular tissues was induced and all teeth were left open to the oral environment for a period of 39–196 days to allow root canal contamination and periradicular lesion formation. Prior to the placement of the intra-canal dressing, the root canals were cleaned, shaped, and irrigated with sterile saline. Radiographic findings at the end of the observation period demonstrated reduction in the width of the root canal space and increase in root length. Closure of the foraminal opening was also observed as a result of deposition of calcified tissues. The hard tissue bridge was composed of a mixture of osteodentin, tubular dentin, and cementum or

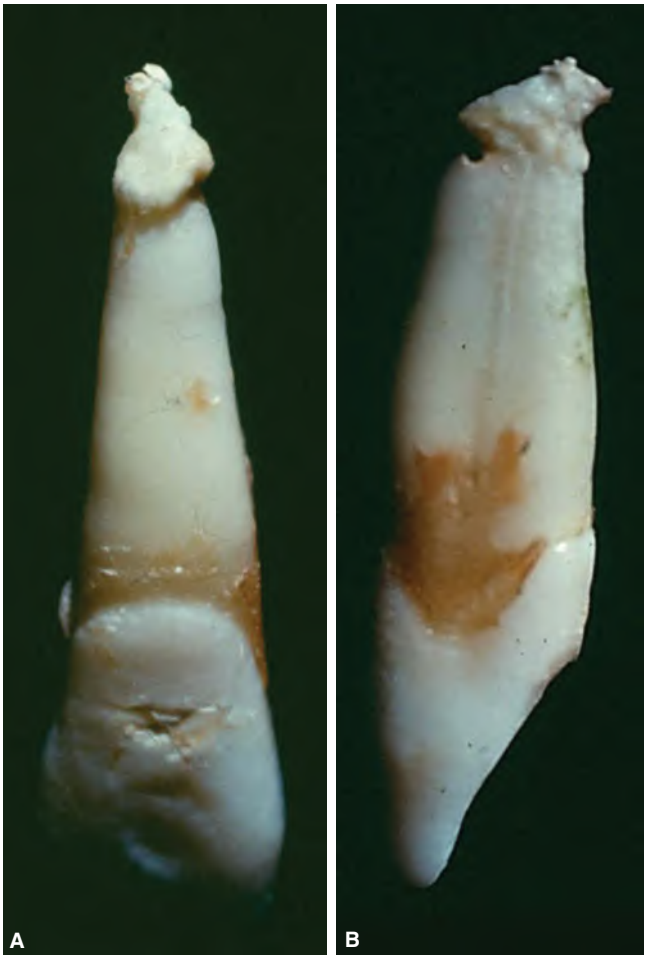

FIGURE 28-16 The hard tissue barrier that forms at the root apex following root-end closure procedures is typically an amorphous material that appears to be comprised of dentin, cementum, and bone. ***A.*** Buccal view of a maxillary central incisor showing formation of an irregularly shaped hard tissue barrier at the root apex. ***B.*** Lateral view of the same tooth showing a different angle. ***C.*** Fluorescent photomicrograph of a tooth following root-end closure shows a hard tissue barrier that is a mixture of various mineralized tissues. (Courtesy of Dr. Leif K. Bakland, Loma Linda, CA U.S.A.)

bone (Figure 28-16). Despite the absence of control teeth, the authors concluded that the use of a calcium-hydroxide-containing paste as a root canal dressing appears to accelerate the rate at which apical growth and foraminal closure occur in treatment of experimentally injured, partially developed incisor teeth.

Heithersay[95] studied a series of clinical cases that were treated with calcium hydroxide over a 14- to 75-month observation period. He used Pulpdent paste (Pulpdent, Pulpdent Corp., Watertown, MA, U.S.A.), that is dispensed in a methyl cellulose carrier. Results showed that in teeth with continued apical development, a definite fine apical canal is visible radiographically, but there is no definite apical barrier.

Calasept (Nordiska Dental, Ängelholm, Sweden) is another commercially premixed calcium hydroxide paste (calcium hydroxide, calcium chloride, sodium chloride, sodium bicarbonate, potassium chloride, and Aqua Steril). Ghose et al[103] used Calasept in traumatized, partially developed permanent central incisors of 43 patients between the ages of 8 and 12 years. All of the teeth had crown fractures with pulp exposures. The pulps had been exposed to the oral environment for one month to three years and were necrotic. Forty-nine of 51 teeth developed an apical barrier that could be confirmed clinically and radiographically. The required time for hard tissue formation ranged from 3 to 10 months.

Leonardo et al.[104] compared two commercially available calcium hydroxide pastes (Calan and Calasept) in dogs. Over an observation period of 187 days, they found that both pastes are able to induce closure of the apex with mineralized tissue. While apical closure did occur even in the presence of inflammation in the periradicular tissues, when inflammation was severe, hard tissue formation was interrupted.

Rationale for Calcium Hydroxide Therapy

Calcium hydroxide has been advocated for apexogenesis and apexification procedures for various reasons. When implanted subcutaneously in the dorsal tissues of adult rats, calcium hydroxide pellets induce heterotopic ossification in the soft tissues around the implants with a high level of predictability. The earliest sign of ossification appeared 10 days after implantation.[105] In this study, ossification was seen more frequently around calcium hydroxide pellets. When other materials were implanted, only 3 of 11 materials demonstrated any evidence of calcification.[105] The high pH of calcium hydroxide may activate alkaline phosphatase activity, and the presence of a high calcium concentration may increase the activity of calcium-dependent pyrophosphatase, which plays an important role in the mineralization process.[106]

Impact of pH

Tronstad and associates[107] studied the effects of calcium hydroxide on the dental tissues of incompletely formed roots of maxillary and mandibular incisors in monkeys. After induction of pulp necrosis, endodontic treatment was performed on replanted and non-replanted teeth. The root canals were filled with a paste of calcium hydroxide mixed with Ringer's solution and the animals were observed over four weeks. Changes in pH were registered in the periodontal ligament, cementum, in four zones of the dentin, and in the root canals. The results indicated that teeth with incomplete root formation had pH values in the normal physiologic range, while the root canal of teeth with complete root formation had a pH in the range of 10–12.2. Control teeth had pH levels ranging from 6.4 to 7.0. In another study, Javalet and associates[108] evaluated the role of the hydroxyl ions in calcium hydroxide by comparing the effect of calcium hydroxide (pH = 11.8) and calcium chloride (pH = 4.4) on the induction of apical closure. Periradicular lesions were induced in immature incisors of monkeys by repeated inoculation of the teeth with *Staphylococcus aureus*. Three of six animals were sacrificed after three months and three after six months. In the three-month samples, calcium hydroxide-treated teeth were the only ones exhibiting apical closure. In the six-month specimens, all roots filled with calcium hydroxide showed evidence of partial or complete apical closure. In contrast, only two of the calcium chloride-filled roots showed partial apical closure and two showed no evidence of hard tissue formation. The results of the study suggest that the pH of calcium hydroxide plays a more significant role in the induction of root-end closure than the presence of exogenous calcium ions.

Although there is clearly a change in intra-canal pH levels when root canals are dressed with calcium hydroxide, changes in the periradicular pH may not be as consistently reported. Some studies have shown no appreciable effect from intra-canal calcium hydroxide on the pH of the periradicular tissues[109,110] while a rise in the pH on the root surface has been reported by others.[111] When calcium hydroxide paste is placed inside root canals of extracted teeth, the pH in cavities prepared on the surface of the roots increases.[111] There is a rapid rise in the pH by day three and the increased pH value remains at approximately 10 (120-day observation period). Whether these results can be duplicated *in vivo* or whether the physiologic buffering would neutralize the pH remains to be investigated.

Impact of Calcium Ions

The action of calcium hydroxide has also been linked to its high calcium ion concentration. To substantiate this hypothesis, radioactive calcium has been used to determine whether a diffusion of calcium ions occurs from the calcium hydroxide placed over amputated pulps into the dentin bridge or pulp tissues in dogs.[112] These investigators exposed pulps and covered them with a paste of calcium hydroxide containing 120 μCi of radioactive calcium chloride per gram of calcium hydroxide powder. No evidence of radioactivity was observed within the area of new dentin formation. Almost 30 years following this experiment, Kawakami and associates[113] attempted to determine the fate of radioactively labeled calcium hydroxide paste that was embedded

in rat subcutaneous tissues. ^{45}Ca-labeled calcium hydroxide was mixed with an unlabeled root canal filling paste containing calcium hydroxide. An incision was made and the paste was embedded subcutaneously in the abdominal connective tissue. Each animal received 500 mg of the paste with 1,000 μCi of ^{45}Ca. The animals were sacrificed 7 or 13 days after the procedure. The osseous tissues demonstrated the presence of the label in the animals. Evaluation using electron microscopy confirmed that the material was calcium salts that presumably originated from the paste. Using whole-body autoradiography, movement of ^{45}Ca was also recognized. The authors concluded that the calcium component moved into bone through blood circulation. This conclusion was made based on the visualization of ^{45}Ca in the capillaries as shown by microscopic autoradiography. While these experiments demonstrate movement of calcium ions, they do not prove that the calcium ions cause mineralization or ossification of tissues.

Outcomes

Several studies have evaluated traditional apexification using calcium hydroxide to determine the time required for successful closure of the apex and the overall outcome of this procedure in general. Heithersay[95] evaluated calcium hydroxide delivered in a methylcellulose carrier (Pulpdent, Pulpdent Corp., Watertown, MA, U.S.A.) for its ability to induced root-end closure in 21 patients. Teeth were followed between 14 and 75 months. Results showed that when continued apical root development occurs, a fine canal space is visible radiographically in the apical region rather than a well-defined apical barrier. When Calasept was used in partially developed permanent central incisors with pulp exposures resulting from crown fractures, 49 of 51 teeth treated developed an apical barrier.[103] The pulps in these teeth had been exposed to the oral environment for one month to three years rendering them necrotic. Apical barriers developed in 3–10 months and were confirmed clinically and radiographically.

Morfis and Siskos[114] used calcium hydroxide powder mixed with anesthetic solution to treat 34 teeth in 12 patients ranging from 8 to 40 years in age. Root development continued in six cases; in three cases, the investigators observed formation of an apical bridge in addition to continued root development; bridge formation alone was reported in 21 cases; and, in four cases there was a complete absence of root-end closure. Lee and associates[115] evaluated the time required for calcium hydroxide to induce apical closure in immature permanent incisors of patients ranging in age from 7 to 10 years. All 32 incisors were necrotic due to traumatic injury with some exhibiting radiographic evidence of a periapical lesions. The mean duration for apical closure was 10–14 weeks. In a retrospective study designed to evaluate the efficacy of calcium hydroxide to cause apical closure in non-vital immature incisor teeth, a 100% success rate was reported.[116] Apical closures developed at variable times but within one year. The time variability was attributed to several factors: (1) Older children with narrow open apices required shorter treatment times than younger children; and, (2) the necrotic teeth that did not have evidence of periradicular infection demonstrated more rapid root development and apical closure compared with teeth with periradicular infections.

Dominguez-Reyes et al.[117] also examined calcium hydroxide treatment of necrotic permanent incisors with open apices in young patients to determine the required time for apical closure. While all 26 teeth responded well with confirmed apical closures, 23 required three to four sessions of calcium hydroxide replacement in order to obtain apical closure. In this study, the average time needed for apexification was slightly more than 12 months. In contrast, preoperative symptoms and presence of a periradicular lesion did not affect the outcome of treatment.[117] In a more recent study, incisors with necrotic pulps and open apices were treated in children ranging in age from 6 to 13 years.[118] Apical closure was reported in all 28 cases with mean treatment duration of 8.6 months (ranging from 3.24 to 13.96 months). All patients were observed for additional two years following completion of endodontic treatment. Root canal re-infection occurred in 7.1% of the cases highlighting the importance of a good root canal seal to maintain long-term success.

While these outcomes studies demonstrate a high level of success, traditional apexification using calcium hydroxide therapy may be unpredictable. The shortcomings of apexification with long-term calcium hydroxide therapy include: (1) Variability in the time required for open apices to close; (2) multiple visits necessary to replace and refresh the calcium hydroxide paste; (3) potential for coronal leakage and canal re-infection; (4) variable and undefined types of tissue laid down as an apical barrier; and (5) potential coronal fracture, if the patient doesn't adhere to a strict follow-up protocol.

Apical barrier formation may take from 3 months to 2 years.[83,119,120] This time period frequently necessitates multiple re-applications of the calcium hydroxide paste.[121–127] To date, there has been no consensus on the optimal timing to change the dressing material and the impact of calcium hydroxide replacement on the rate and quality of apical barrier formation. Recommendations by researchers for re-application of calcium hydroxide varies from once every month, once every three months, once every six to eight months, or not at all.[120,124,125,128,129]

While coronal leakage and canal re-infection intuitively should impact outcomes of apexification procedures, a clear impact of infection on the success of apexification procedures has not been established. Some studies report that treatment time is increased in the presence of infection,[130,131] and other studies have found no statistically significant differences in treatment outcomes when infection is present versus when there is an absence of bacteria.[103,119,122,126]

The type and quality of bridge formed at the apex following apexification with calcium hydroxide therapy may also be unpredictable. The barrier may be an incomplete bridge that does not cover the entire apex.[132] While a traditional two-dimensional periapical radiograph may indicate

the appearance of a complete bride in one plane, a view from another angle may show incomplete bridge formation. The calcified bridge formed following apexification is a porous structure[116] that may be permeable to microbial irritants. Furthermore, the pores themselves may contain remnants of necrotic tissue and can result in persistent periradicular irritation and inflammation.[88]

Recently, another potential issue has been identified with the long-term exposure of dentin to calcium hydroxide. While in the past, susceptibility of cervical root fracture was primarily attributed to the thin dentin walls, researchers have found that long-term application of calcium hydroxide has deleterious effects on the structural integrity of root dentin.[61–68] These studies have demonstrated that placement of calcium hydroxide in root canals for longer periods of times (typically required for apexification) changes the structure of dentin and significantly reduces the tooth's ability to resist forces that may lead to fractures.

APICAL BARRIERS

Based on the shortcomings of apexification with long-term calcium hydroxide therapy, there has been continued research to identify alternative means to promote apical closure in immature permanent teeth. Long-term therapy increases the risks of patient attrition; repeated appointments may be disruptive to patients' schedules and difficult for young children who may be apprehensive about dental visits, and therefore, compliance may become an issue; geographic relocation renders difficulties in following patients to continue therapeutic replacement of calcium hydroxide; and, calcium hydroxide therapy may be ineffective in some cases and root-end closure may never occur (Figure 28-17).

Kuttler[2] stated that radiographic and clinical signs of a more rapid periapical regeneration can be observed when dentin shavings are implanted in the terminal portion of the root canal. Teeth with apical plugs of calcium hydroxide have demonstrated mean leakage values that are significantly less than those obturated without plugs.[133] Pitts and associates[134] compared histologically calcium hydroxide to dentin to determine which material is more effective as an apical plug. They used a cat model and over-instrumented the cuspid teeth to simulate open apices. Based on their findings, both materials are effective in controlling the filling materials within the confines of the canals. Formation of a calcified tissue barrier is more rapid, however, when using dentin plugs (one month in the majority of specimens containing dentin plugs in contrast to three months in samples plugged with calcium hydroxide).

Tricalcium phosphate has also been proposed as an apical barrier in a single-appointment technique.[135] When compared to calcium hydroxide-CMCP paste used in multi-appointment treatment of open apices, tricalcium phosphate shows no overfills in the apices of permanent human teeth. In contrast, calcium hydroxide treatment can result in overextensions of the obturation material. Because of its larger particle size, tricalcium phosphate may offer improved resistance against compaction, and therefore, less material is extruded.

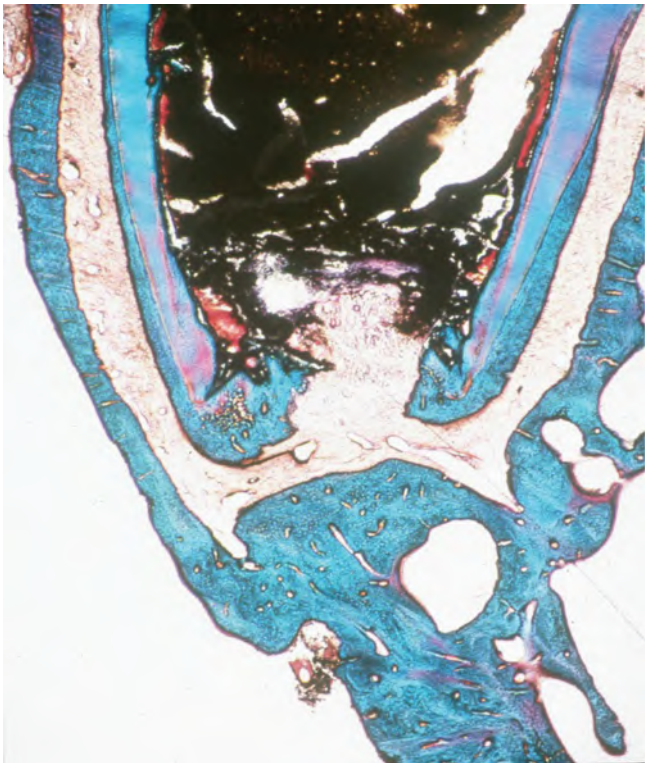

FIGURE 28-17 Photomicrograph of a specimen stained with Masson's Trichrome. This tooth was treated with calcium hydroxide for three months. Figure shows presence of an open apex.

Brandell and associates[136] created open apices in incisor teeth of monkeys by over-instrumenting canals with a size #50 K-file to a level 0.5 mm beyond the radiographic apex. Then they evaluated apical closures produced by three different materials. Teeth were divided into four groups and the apical 2 mm of each root canal was packed with: (1) Demineralized dentin (organic component); (2) hydroxyapatite (a substitute for inorganic dentin); or (3) dentin chips. Teeth in group 4 did not receive an apical plug and served as negative controls. Four of the monkeys were sacrificed after three months. Of the 24 samples evaluated in this time period, only one (packed with demineralized dentin) demonstrated complete closure of the apex. At the six-month observation period, none of the demineralized dentin plugs showed complete apical closure. In contrast, four of six roots filled with hydroxyapatite exhibited complete apical closure, and three of six roots with dentin chips showed similar findings. The authors concluded that the organic component of dentin may not be effective in inducing apical hard tissue formation.

Mineral trioxide aggregate (MTA) is another material that has been used as an apical barrier. The principle components of MTA include tricalcium silicate, tricalcium aluminate, tricalcium oxide and silicate oxide. MTA powder consists of fine hydrophilic particles, that set in the presence of moisture and

result in a colloidal gel that solidifies to a hard structure.[137] Microanalysis of the powder has shown that calcium and phosphorous are the main ions present. Dye leakage[138] and bacterial leakage[139] studies have demonstrated that MTA leaks significantly less than amalgam and Super EBA. Mutagenicity and cytotoxicity experiments using the Ames Test have shown that MTA does not produce higher reversion rates[140] and that set MTA is significantly less toxic (Figure 28-18) than set amalgam, composite, Super EBA or set IRM.[141] MTA has been successfully used as root-end filling during apical surgery[142] and repair of root perforations.[143] A significant benefit of MTA when placed in contact with periradicular tissues is its ability to induce cementum formation around the repair area.[142] The cementum layer may provide an additional biological seal to enhance the apical resistance to microbial leakage into the periapical tissues. The high pH of MTA after mixing (reported to be 10.2, rising to 12.5 at three hours and thereafter), similar to that of calcium hydroxide,[137] may be one of the mechanisms by which induction of hard tissue formation may occur in its presence.

The use of MTA as an apical plug in the treatment of immature non-vital teeth has potential as well. In 1999, Shabahang et al. [28] compared MTA plugs to calcium hydroxide apexification and induction of root-end formation with osteogenic protein-1. In this study, MTA induced hard tissue formation with the most degree of consistency. Similar to previous findings in other applications of MTA, a continuous band of cementum formed (Figure 28-19). In two cases, MTA was extruded beyond the confines of the root apex. In one, cementum formed around the extruded MTA (Figure 28-20). Again, the benefit of this cementum layer is an added biological seal that can enhance healing of the periradicular tissues.

Ham et al.[144] compared the healing of immature non-vital teeth in monkeys. Teeth were treated with an apical plug of MTA or underwent traditional apexification with calcium hydroxide. Based on their findings, MTA-treated teeth display less inflammation and a greater amount of hard tissue formation. In a dog model, investigators examined the effects of calcium hydroxide paste used before placement of an MTA apical plug. It was discovered that MTA promoted apical root formation and periradicular healing. The initial use of calcium hydroxide paste was not necessary for apical root formation to occur. Furthermore, the use of calcium hydroxide was directly proportional to an increase in extrusion of

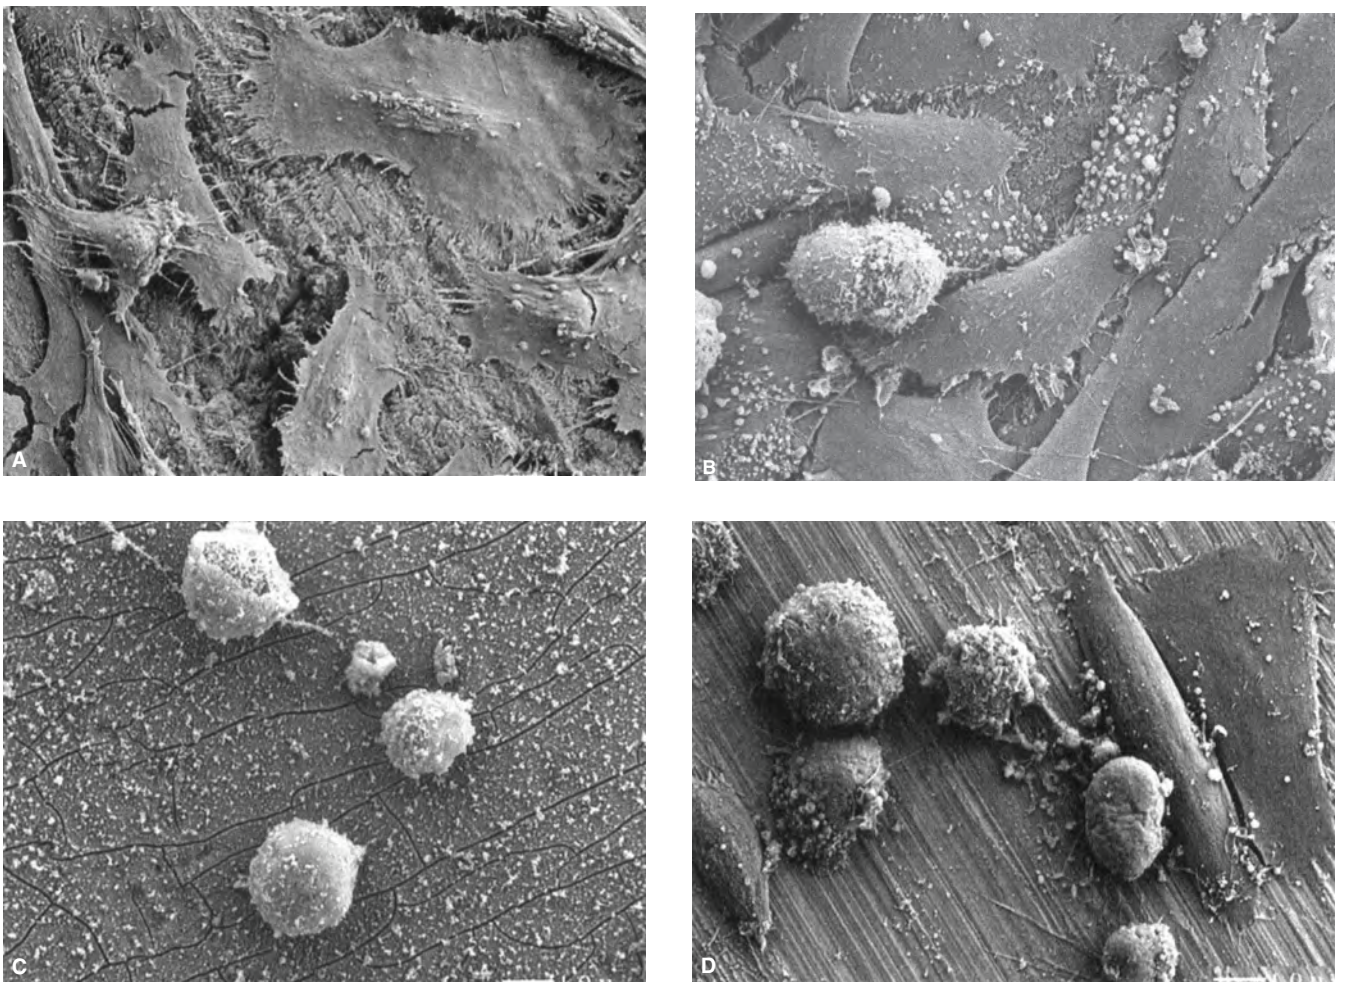

FIGURE 28-18 Scanning electron photomicrographs of cells cultured on various materials. The images show that cells grow nicely on MTA (A) and composite (B) as depicted by expanded cells but poorly on amalgam (C) and IRM (D).

MTA and formation of barriers beyond the limits of the root canal walls.[145] In contrast to the previous study, other investigators have found that intra-canal medication with calcium hydroxide for one week results in better marginal adaptation of an apical plug of MTA.[146] This finding may be related to the ability of calcium hydroxide to eliminate pulp tissue remnants or organic components remaining on the dentin surface thus allowing a closer adaptation of MTA to dentin. Hachmeister et al.[147] examined the bacterial leakage patterns in a simulated model of immature non-vital teeth and concluded that the technique of placing MTA rather than the intrinsic characteristics of the MTA material itself has the greatest impact on the degree of bacterial leakage.

Technique

Once root canal debridement is completed, pluggers that are commonly used for warm vertical compaction of gutta-percha are sized to fit sequentially in the root canal space. The smallest plugger should fit loosely at a level ~ 0.5 mm from the working length. A small increment of MTA is then placed in the middle to apical third of the root canal system using one of several commercially available MTA carriers (Figure 28-21). The MTA is compacted with the pre-fitted pluggers. Ultrasonic vibration can be used on the pluggers to help advance MTA towards the apical extent of the canal.[148–151] The use of a matrix material is generally not required to limit the movement of MTA into the periradicular tissues. The movement of MTA into the apical area of the canal can be facilitated

FIGURE 28-21 Radiographic image of a maxillary left lateral incisor with incremental placement of MTA in the mid to apical third of the root canal. The MTA is then further advanced with endodontic pluggers and if necessary, via ultrasonic vibration. (Courtesy of Dr. Douglas H. Snider, Chico, CA, U.S.A.)

by mixing the first increments of MTA in a moist consistency and by using smaller increments initially. The moist material will require light pressure application.

Once an adequate apical plug of MTA is compacted to the working length and confirmed radiographically, excess material can be removed from the coronal and middle thirds of the root canal system with the use of moist paper points. Thickness of the MTA plug should be approximately 3–5mm (Figure 28-22) to minimize the possibility of future apical leakage.[148,150–152,153–156] In many instances, MTA can be compacted to a level just below the cemento-enamel junction. If the canal space is long, gutta-percha and sealer may be used to obturate the coronal segment of the canal space. This may necessitate an additional appointment to allow setting of the MTA prior to obturation of the remaining segment of the canal space with gutta-percha and sealer. The restorative core material can then be placed over the gutta-percha. Extension of the core layer into the coronal third of the canal may enhance fracture resistance of the tooth.[153]

Outcomes

Following the publication of an animal study proving the utility of MTA as a suitable material for root-end closure procedures,[28] several clinical cases were published to report successful management of non-vital immature teeth with MTA[157–165] including a case where calcium hydroxide apexification had failed.[166]

Pace et al.[167] published a report on 11 teeth with immature root apices that were treated with MTA apical plugs.

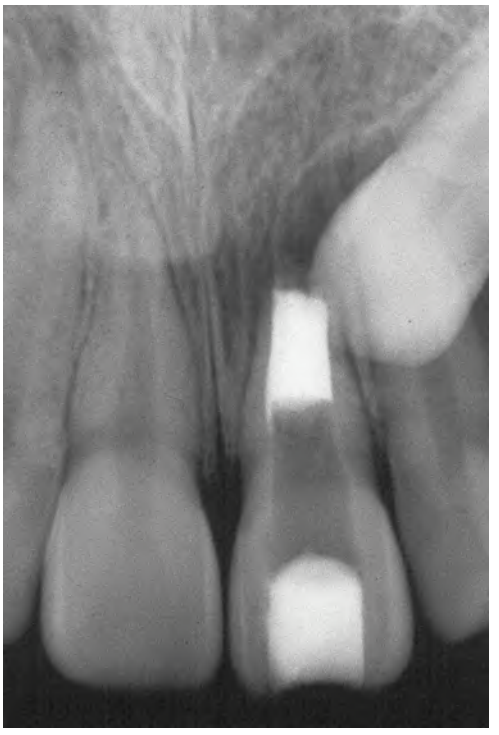

FIGURE 28-22 Radiographic image of maxillary left central incisor demonstrating placement of a 3- to 5-mm thickness of MTA. (Courtesy of Dr. Marshall E. Gomes, Lodi, CA, U.S.A.)

Each tooth received intra-canal calcium hydroxide for one to two weeks followed by a 3- to 5-mm apical plug of MTA. At the two-year posttreatment follow-up, 10 of 11 cases had completely healed while the remaining tooth showed incomplete healing. Based on these results, the authors concluded that MTA apical plugs present a viable treatment protocol for root-end induction. In a similar case series, five immature teeth with necrotic pulps were treated with an apical plug of MTA after one to six weeks of calcium hydroxide dressing for canal disinfection. Four of five teeth showed clinical and radiographic signs of healing after two years. MTA had extruded beyond the root apex in the case that did not heal.[168] Extrusion of MTA more than 2 mm beyond the root apex may retard healing and cementum formation (Figure 28-23).

Sarris et al.[169] treated teeth of children with an MTA plug. The mean age in the study population (n = 15) was 11.7 years and all 17 teeth were diagnosed with a necrotic pulp and an immature apex. Following initial canal debridement, all teeth were dressed with calcium hydroxide for one week. Each canal then received a 3–4 mm thick plug of MTA at the root apex. Patients returned after one week for final obturation of the root canal space with thermoplastisized gutta-percha. MTA placement was considered adequate in 13 of 17 teeth treated. Teeth were followed from 6 to 16 months with a mean follow-up time of 12.53 months. A clinical success rate of 94.1% and a radiographic success rate of 76.5% was reported. At the final follow-up visit, 17.6% of the teeth had uncertain healing radiographically.

In a retrospective study, 20 teeth with open apices were evaluated in 19 patients.[150] Calcium hydroxide was placed in the canals for at least one week prior to placement of a 4 mm thick MTA apical plug. Of the 20 teeth evaluated, 16 were of young patients with under-developed apices. The follow-up period ranged from 12 to 44 months (26.7 month average). Based on periradicular index scores of 1 or 2 and absence of clinical signs or symptoms at the follow-up examination, 93.75% were considered healed.

In a case series study, Nayar et al.[170] published the outcomes of 38 permanent teeth with immature apices that were treated with an apical plug of MTA. Presence of pre-operative periradicular radiolucency did not impact the healing outcome. Based on a 100% clinical and radiographic success rate at the 12-month follow-up examination, the authors concluded that treatment of immature permanent teeth with an MTA apical plug is a predictable procedure. These findings were corroborated by Annamalai and Mungara[171] a year later. In their report, all 30 teeth tested were clinically and radiographically successful at the 12-month follow up visit. Complete root-end closure was documented in 86.6% of cases and root growth in 30% of cases. Moore et al.[172] treated 22 necrotic immature permanent incisors with an apical plug of white MTA. The mean age in the 21 children was 10 years. Again, calcium hydroxide was used as intra-canal medication to disinfect the canals prior to placement of the MTA plug. The mean follow-up time in this study was 23.4 months. Based on clinical and radiographic evaluations, a success rate of 95.5% was reported. A side effect that was noted by the authors was coronal discoloration in 22.7% of the teeth that were treated.

Since the introduction of MTA, more apical plug cases have been completed with MTA and have become available for evaluation. Two studies with larger sample sizes examined the outcomes of MTA in non-vital immature teeth. In a prospective study, the outcomes of 57 teeth with open apices were studies in 50 patients. In this report, no interim medications were used and MTA apical plugs were placed in a single appointment. Forty-three cases provided a minimum follow-up period of 12 months. Using the Periapical Index score to determine decrease in the size of apical lesions, healing was recorded in 81% of cases. The authors concluded that MTA can be used in a single appointment protocol in teeth with open apices with predictable results as an alternative to calcium hydroxide apexification.[173] The second study was a retrospective analysis of 144 teeth in 116 patients.[174] All teeth were treated in the same private endodontic office between 1999 and 2006. Fifty-two teeth were medicated with calcium hydroxide for three weeks prior to placement of the MTA apical plug. Treatment in the other 92 teeth was completed in one visit. Of the 144 teeth that received treatment, 78 (54%) were available for follow-up evaluation (approximately 60% of the one-visit cases and 40% of the two-visit cases) with a mean follow-up period of 19.4 months. Overall success rates were 93.5% in the single visit cases and 90.5% in the two visit cases. In this study, while all teeth had open apices, 119 of the 144 teeth treated were considered immature teeth. The remainder were mature teeth that had open apices. Forty-five of immature teeth were medicated with calcium hydroxide and treated with an apical plug on the second appointment and 74 were treated in a single appointment. Sixty-eight of the 119 teeth with immature apices (57%) were available for follow-up examination (same distribution of approximately 60% one visit and 40% two visits). Of the 74 teeth that had at least one year follow-up, 96.5% healed in the single visit group and 89% healed in the two visit group. Only one case in each treatment category failed with respect to apical healing. Four patients that were initially treated with calcium hydroxide did not return to complete treatment in a timely manner and when they did, the teeth were no longer restorable.[174]

Studies have also directly compared the outcomes of MTA used as an apical plug to calcium hydroxide apexification. In one of these two armed studies, El-Meligy and Avery[175] selected 15 children each with at least two necrotic permanent teeth requiring root-end closure procedures. At the 12-month follow-up, two of the teeth treated with calcium hydroxide became re-infected. In contrast, all MTA-treated teeth showed absence of infection and appeared clinically and radiographically intact. In the same year, Pradhan et al.[176] conducted a comparative study to determine the success rates and length of time required to achieve closure of open apices using a calcium hydroxide apexification protocol versus the MTA plug protocol. Twenty non-vital permanent maxillary incisors with immature apices were assigned to either the calcium

hydroxide treatment or MTA treatment groups. The MTA protocol consisted of 7 days of disinfection with a calcium hydroxide dressing followed by placement of an MTA plug that was placed in the apical third of the root canal. The calcium hydroxide apexification protocol involved placement of intra-canal calcium hydroxide until an apical barrier was evident. In both groups, the remaining portion of each canal was obturated with gutta-percha and sealer. While no significant difference was observed in the healing of the periradicular lesions, completion of treatment was significantly more rapid when MTA was used as an apical plug (0.75 ± 0.5 months) compared to traditional calcium hydroxide therapy (7 ± 2.5 months). This significant reduction in treatment time is clinically important because it reduces chair-side time for clinicians and enhances convenience for patients.

In a systematic review and meta-analysis comparing the outcomes of calcium hydroxide apexification and MTA apical plugs, the authors concluded that the two protocols have similar success rates.[177] When combining the data in the two studies discussed earlier by El Meligy and Avery[175] and Pradhan et al.,[176] the difference in clinical success between the two treatment regimens was not *statistically* significant. Yet 100% of the MTA cases were successful at the final follow-up evaluation in comparison to a 92% success rate in the calcium hydroxide treated cases.[177]

Based on the existing body of evidence, treatment of immature permanent teeth with an apical plug is a good alternative to long-term calcium hydroxide therapy. The advantages include more predictable closure of the apical opening, reduced treatment time, and fewer appointments. With the availability of materials such as MTA that provide a good seal and biocompatibility, placement of an apical plug provides a more predictable treatment option. The plug presents a barrier that provides a matrix for immediate obturation. Histologic evaluation of MTA in periradicular regions has shown consistent apposition of hard tissues including cementum and bone. The formation of this added layer of biologic seal confirms the biocompatibility of MTA.

Another possible benefit of single visit root-end closure procedures is minimized exposure to medicaments that may have deleterious effects on the dentin structure. In addition to their antimicrobial activity, sodium hypochlorite and calcium hydroxide have tissue dissolving properties. This characteristic is valuable when removing pulp remnants; however, dissolution of organic components of dentin during longer exposure times by these chemicals can also alter the structural integrity of dentin. These changes may be, at least partially, responsible for fractures, that have been previously reported in the cervical region of immature teeth that had undergone apexification procedures.

The requirement for fewer appointments is especially valuable in young patients. Children are frequently apprehensive and intolerant of longer appointments. Therefore, techniques that can minimize return visits enhance the patient and doctor experience. In addition, failure to return for completion of treatment can have a significant impact on outcomes and ultimately restorability of these teeth.[86]

Despite its advantages, treatment of immature teeth with apical plugs has certain shortcomings. Most importantly, placement of an apical plug only addresses the apical opening. Generally, failure in immature teeth with a history of apexification has been due to fractures in the cervical region of the tooth rather than the root apex. The primary causes of cervical root fracture are thin dentin walls in these immature teeth and long exposure times to chemicals that can alter dentin structure. Substitution of apical plugs in lieu of long-term calcium hydroxide therapy to achieve root-end closure can eliminate the latter issue. Nevertheless, while treatment of an immature permanent tooth with an apical plug can address the apical opening, continued root development ceases once a vital pulp is removed. The remaining thin dentin walls of the root structure stay weak and susceptible to fracture if subjected to future traumatic injuries. Another potential drawback is the possibility of tooth discoloration resulting from MTA placement in the canal. This issue is clearly significant in anterior teeth. To minimize color changes in the coronal portion of anterior teeth, MTA plugs can be limited to the apical 4–5 mm of the root canal space. The remaining segment of the canal space may be restored with bonded resin in shorter roots. In longer roots, a layer of gutta-percha and sealer can be used to obturate the coronal two-thirds of the root canal space prior to restoring the coronal area with bonded resin. Placement of bonded resin below the cemento-enamel junction may also increase the fracture resistance of the tooth.[178,179]

Future efforts in pulp revascularization and pulp regeneration protocols will provide a more complete solution for treatment of permanent teeth with immature roots that have sustained traumatic or carious injuries to the pulp. The benefit of restoring circulation or regenerating pulp include re-establishment of viable tissues that allow the affected tooth to mount an immune response against microleakage of microorganisms into the root canal system, and continued root development along the entire root length. Achievement of this objective requires proper disinfection and seal to prevent re-infection; proper signaling for stem cells to promote regeneration of pulp rather than ectopic formation of tissues that are not desirable in the canal space (e.g., bone); and a suitable scaffold that allows timely release of the signaling proteins while serving as a barrier for guided tissue regeneration to prevent ingress of bone (Figure 28-24). Timely release of signaling proteins requires a scaffold material that is absorbed over a suitable time period thereby gradually releasing the signaling material. This gradual release of the protein would allow differentiation of the stem cells into the desired specialized cells and ultimately regeneration of the desired tissue. For a more detailed discussion of this topic, see Chapter 29, "Regenerative endodontics."

Chapter 29

Regenerative Endodontics

Anibal R. Diogenes, Anthony J. Smith

INTRODUCTION

The concept of the regeneration of organs or organisms can be traced back to ancient Greece, and regenerative medicine has a rich history,[1–3] providing a foundation for our vision of the field today. The Human Genome Project together with exciting advances in stem cell biology, tissue engineering and biotechnology, over the last couple of decades, have all contributed to "the coming of age" of regenerative medicine and its clinical translation.

Dentistry has played an important role in the history of regenerative medicine, including early attempts at dental transplantation by Charles Allen in 1687[4] and pulp capping by Pfaff in 1756 and others[5] subsequently. The introduction of calcium hydroxide[6] and, more recently, the widespread use of Mineral Trioxide Aggregate (MTA)[7] and parallel products such as the calcium trisilicates[8] have all emphasized the central role for biologically-based therapies in endodontics. In a review of the current status of regenerative research in endodontics, there was a call for action, to exploit recent progress in stem cell and other areas of biology, to clinically translate regenerative endodontic therapies.[9] A wide range of strategies are now emerging, from which to exploit the biological responses within the pulp for tissue regeneration.

This chapter discusses the biological principles upon which the development of future regenerative endodontic therapies will be based and the progress and challenges at the present time.

BIOLOGICAL PRINCIPLES ASSOCIATED WITH REGENERATIVE ENDODONTICS

Odontoblasts show an intimate relationship with the other cells of the pulp, and their extracellular matrices reflecting its pivotal role in determining the structure and functional activities of the dentin-pulp complex. While the odontoblast has long been recognized for its synthetic/secretory actions leading to dentin deposition,[10] its environmental sensing functions, and their contributions to the innate and immune defence responses of the tooth, are being increasingly identified.[11,12] Thus, cellular activity within dentin-pulp is important not only for its development but also, its subsequent homeostasis and responses to environmental challenges.

A long tradition of vital pulp therapy in endodontics emphasizes a common goal of developing effective biological approaches, to address the effects of more aggressive carious challenge to the tooth. Historically, empirical pulp capping protocols have provided the foundation for these biological approaches. However, the parallel deepening of our understanding of the biological behaviour of dentin-pulp in health and disease has provided a platform for exciting developments with biologically-based therapies in endodontics. These developments encompass a broad spectrum of approaches, ranging from simple exploitation of existing biological activities within dentin-pulp, to ambitious tissue engineering approaches at both the tissue and whole tooth levels.[13]

Tissue engineering has been defined as "an interdisciplinary field that applies the principles of engineering and life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function or a whole organ."[14] Importantly, tissue engineering relies upon "understanding the principles of tissue growth, and applying this to produce functional replacement tissue for clinical use", and depends upon the basic supposition that "the employment of natural biology of the system will allow for greater success in developing therapeutic strategies aimed at the replacement, repair, maintenance, and/or enhancement of tissue function."[15]

Thus, any biological consideration of dentin-pulp in the context of repair and regeneration and maintenance/facilitation of vitality requires an understanding of the cells and their extracellular matrices in dentin-pulp and the molecular signaling networks, that influence the behavior of these cells in health and after injurious challenge, whether of microbial or traumatic origin. Of particular importance in the context of regenerative endodontics is the presence of stem and progenitor cell populations in pulp and the surrounding tissues.

Oral Stem and Progenitor Cells

During embryonic development, migration of cranial neural crest cells to the mesenchyme of the first branchial arch results in generation of the ecto-mesenchymal cells giving rise to the various cell populations of the dental papilla and dental follicle of the tooth germ. Genetic-based cell lineage analysis has confirmed that physiological primary odontoblasts are derived from these cranial neural crest cells.[16] After the last division of the peripheral cells of the dental papilla in the bell stage of tooth development, the daughter cell closest to the dental basement membrane undergoes terminal differentiation to an odontoblast, while the other daughter cell is not exposed to this morphogenic influence and contributes

to the cell-rich layer of Höhl underlying the odontoblast layer. Thus, as tooth development is completed, the mature tooth will contain undifferentiated cells within the cell-rich and other regions of the pulp.

These various undifferentiated cells in the mature pulp contribute to the different stem cell populations reported to be present in dental pulp. These cells all demonstrate mesenchymal stem cell (MSC)-like properties, in respect of their expression of cell surface markers and multipotent differentiation potential along mesenchymal cell lineages. Such MSCs are generally considered to be responsible for tissue cell turnover and reparative responses following tissue injury. Bone marrow represents the classical niche for MSCs, although they have now been reported in many tissues and organs. Whether all those in pulp are derived from cranial neural crest cells remains to be established, since some of the cells of the central pulp do not appear to be neural crest derived.[16] Furthermore, a dual origin for MSCs from both within and out with the tooth has been identified using genetic cell lineage tracing.[17] Minimal criteria for defining multipotent mesenchymal stromal cells have been published[18] and slight variations in cell surface marker expression, and differentiation potential between cells isolated from different sources, may reflect the influences of their local tissue niches and growth conditions. The impact of these slight variations in properties between different MSC populations, on their responsiveness to various potential morphogens and multipotent lineage differentiation, remains to be fully elucidated. Interestingly, however, cell surface expression of CD271 (p75NTR) or nerve growth factor receptor (NGFR), may be associated with maintenance of the undifferentiated status of MSCs,[19] and allows selection of neural crest derived cells.[20,21]

Isolation of MSC-like stem cells has now been reported from both deciduous and permanent teeth. Dental pulp stem cells (DPSCs) were the first population of dental stem cells to be described.[22] In contrast to bone marrow stromal cells (BMSCs), a significant proportion of DPSCs express the pericyte marker 3G5,[23] and this possibly reflects their probable perivascular tissue niche. Characterization of their expression of surface markers identified the presence of STRO-1, CD29, CD44, CD73, CD90, CD105, CD146, CD166 and CD271.[24]

More recently, a population of cells termed stem cells from the root apical papilla (SCAP) has been reported.[25] Transplantation of these SCAPs, and a population of periodontal ligament stem cells (PDLSCs) in a mini-pig model, allowed generation of a root/periodontal complex capable of supporting a porcelain crown.[25] The development of therapeutic applications for SCAPs in immature teeth with incomplete root development offers significant potential. The opportunity to isolate SCAPs from extracted third molars allows a ready source of these cells. Use of autologous cells should always be a priority in clinical applications to avoid potential problems from immune rejection.

The isolation of Stem cells from Human Exfoliated Deciduous teeth (SHED) provides a further valuable potential source of autologous cells, that can be isolated non-invasively.[26] SHED are distinct from DPSCs, exhibiting higher proliferation rates and exposed to appropriate morphogenic signals, are capable of differentiating into functional odontoblast-like cells,[27] and being used to tissue engineer dental pulp.[28] A population of Dental Follicle Precursor Cells (DFPCs) has also been reported.[29] While these cells can form mineralized nodules *in vitro*, transplantation *in vivo* did not result in cementum or bone formation. These various dental stem/progenitor cell populations offer exciting opportunities for future exploitation in regenerative endodontics (Figure 29-1). Characterization of each population, and detailed comparison with MSCs from other sources,[31] will help to underpin their clinical application, although the challenges of generating sufficient numbers of pulp stem cells to GMP standards,[32] and their translation to robust clinical regenerative protocols should not be underestimated.[33]

Signaling Networks (Growth Factors, Cytokines, Morphogens) for Regenerative Endodontics

Physiological tooth development is characterized by an elaborate sequence of reciprocal epithelial-mesenchymal

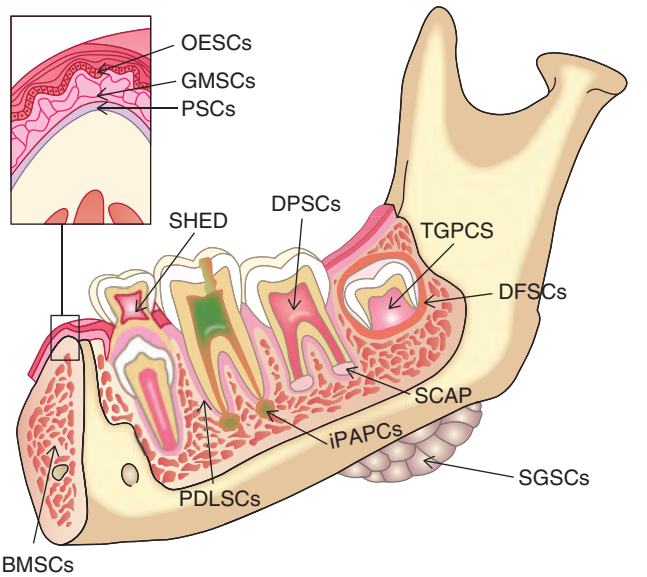

FIGURE 29-1 Schematic illustration showing potential sources of postnatal stem cells in the oral environment. Cell types include tooth germ progenitor cells (TGPCs), dental follicle stem cells (DFSCs), salivary gland stem cells (SGSCs), stem cells of the apical papilla (SCAP), dental pulp stem cells (DPSCs), inflamed periapical progenitor cells (iPAPCs), stem cells from human exfoliated deciduous teeth (SHED), periodontal ligament stem cells (PDLSCs), bone marrow stem cells (BMSCs), and, as illustrated in the inset, oral epithelial stem cells (OESCs), gingival-derived mesenchymal stem cells (GMSCs), and periosteal stem cells (PSCs). (Adapted with permission from Hargreaves et al.[30])

interactions that are temporo-spatially regulated, resulting in the very reproducible formation of an appropriately shaped tooth in the correct anatomical position from previously uncommitted cells. The regulation of these developmental events is achieved through the temporo-spatial expression of various signaling mediator molecules (transcription factors, growth factors and other proteins).[13,34]

Our understanding of the molecular signaling involved in tooth development provides a potential blueprint from which we might build therapeutic strategies for regenerative endodontics. However, the absence of both dental epithelial signaling networks and the physiological control processes in the mature tooth during repair and regeneration, requires the identification of alternative signaling sources. In particular, molecular signaling of the following cellular events is required: recruitment of stem/progenitor cells (chemotaxis/cell homing) in adequate numbers (cell division); induction of terminal differentiation of odontoblast-like cells (to replace any primary odontoblasts lost through cell necrosis); up-regulation of synthetic/secretory activity of odontoblast-like cells (and also, up-regulation of primary odontoblasts in the case of reactionary dentinogenesis) and subsequent down-regulation when complete to avoid pulp canal obliteration; stimulation of local angiogenesis at sites of injury to support dentinogenic events. The combination of all of these cellular events, represents the process of reparative dentinogenesis, that is the tertiary dentinogenic sequence of events seen after focal death of primary odontoblasts, beneath a more active carious lesion, and is responsible for the matrix secretion comprising a dentin bridge at sites of pulp exposure. The other variant of tertiary dentinogenesis is reactionary dentinogenesis that represents the focal up-regulation of primary odontoblast secretion of dentin beneath a less aggressive carious lesion, where primary odontoblasts have survived.[35]

Consideration of the pathogenic events taking place during dental caries, the principal cause for endodontic disease, provides valuable clues as to how much of the molecular signaling during natural repair and regeneration in the tooth may occur, also provides ideas for development of potential therapeutic intervention for tissue regeneration. In caries, the metabolic products of plaque bacteria, especially organic acids, will diffuse into dentin causing demineralization and degradation of the matrix. Dentin matrix is now recognized to contain a very heterogeneous mixture of non-collagenous protein (NCP) components, in addition to its predominant structural component, collagen.[10,36] Many of the NCPs will be acid-soluble leading to their release during carious demineralization and subsequent diffusion towards the pulp along the dentinal tubules. Even those NCPs, which are insoluble or incompletely released from the matrix, may still be exposed to contact and interaction with pulp cells at sites of injury in the tooth. The ability of soluble preparations of dentin NCPs to signal regenerative events in dentin-pulp[37] has allowed further investigation of the possible signaling role(s) of individual molecules in these more complex preparations.[38] As well as a diverse mixture of dentin specific and more ubiquitous matrix components, these dentin NCP preparations contain a rich cocktail of growth factors and cytokines with potent cell signaling properties. The growth factors and cytokines include several members of the TGF-ß superfamily, angiogenic, neurotrophic and other bioactive molecules.[39–43] Some of the dentin specific NCPs demonstrate previously unrecognized biological activities.[44] Others may well be found in the future.

Considerable progress has been achieved in identifying bioactive NCPs in dentin matrix preparations, but our understanding is still incomplete and other molecules with potential actions on regenerative processes may still be characterized. Importantly, the bioactive molecules sequestered within the dentin matrix can be considered to exist in a fossilized state since they are both immobilized their biological activities are protected by their interaction with the mineral phase of dentin. Thus, these bioactive molecules may be present in dentin into old age and may only be released after injury to the dentin leading to its partial or complete focal dissolution. However, opportunities exist for targeted release of some of these molecules for therapeutic purposes through the actions of irrigants, intracanal/cavity medicaments and various restorative materials.[45–50] Some similar bioactive molecules may also be present in dental pulp as a result of cellular activities.[51] However, pulp-derived bioactive molecules will likely have quite a high and more rapid turnover. Their presence in pulp may be relatively short-lived. Some growth factors have half lives of the order of minutes and thus, their continued presence during regenerative events will be dependent on continuing cellular activity responsible for their generation.

There has been considerable interest in correlating specific bioactive molecules with the various signaling steps involved in the recruitment, commitment and differentiation of odontoblast-like cells and other cellular events in dentin-pulp regeneration. It is clear, however, that networks of molecules may be involved in some of these signaling steps. Also, more than one molecule sometimes appears to be able to exert the same action. Whether the latter represents an example of biological redundancy or an as yet undiscovered nuance of signaling remains unclear. Several dentin and pulp matrix components, including growth factors, cytokines and matrix molecules, can stimulate pulp cell migration.[38,44,52,53] These molecules may be important for cell recruitment during regeneration.

Signaling odontoblast-like cell differentiation may show parallels to that occurring for primary odontoblast terminal differentiation during physiological tooth development with involvement of growth factors, especially of the TGF-ß superfamily.[13,54,55] Criteria for identification of differentiation of odontoblast-like cells as opposed to other cell phenotypes will often include expression of several genes (or their protein products) characteristic of odontoblasts and importantly, secretion of a tubular matrix. While valuable, the rigor of these criteria are such that some odontoblast-like cells may show aberrations from physiological odontoblasts as emphasized by the range of tubular structure seen in dentin

during reparative dentinogenesis. Regulation of odontoblast secretory activity is critical to maintenance of normal tooth and pulp chamber/root canal morphology. It is also fundamental to our concepts of the up-regulation of odontoblasts during reactionary tertiary dentinogenesis. TGF-ß1 has been implicated in the signaling of odontoblast secretory activity,[56–58] and the p38-MAPK pathway can mediate this signaling in tertiary dentinogenesis.[59,60] The p38 pathway may be a target for therapeutically controlling odontoblast secretory activity in pulp regenerative strategies. Signaling of the angiogenic events that accompany pulp regeneration may be achieved through the effects of growth factors and other proteins released from the dentin matrix after injury.[28,40,61]

ENVIRONMENTAL INFLUENCES (MICROBIAL AND INFLAMMATORY) ON REGENERATIVE EVENTS

With continuing carious injury to the tooth, microorganisms and their metabolic products penetrate dentin matrix and invoke cellular responses in the underlying pulp. Initially, these responses arise from diffusion of microbial products to the pulp, although in time, the microbial load will significantly increase and microorganisms may be found within the pulp itself causing further escalation of defense responses. The odontoblasts, with their peripheral localization in the pulp chamber, play important environmental sensing and defense roles in addition to their well-established matrix synthetic/secretory functions.[11,62–65] The significance of this localization is further enhanced by the extensive network of lateral processes, in addition to the main odontoblast cell process facilitating communication between the odontoblasts and dentin matrix.[66]

Microbial Sensing: Odontoblast sensing of microorganisms will invoke defense responses, including release of antimicrobial peptides and various cytokines and chemokines with autocrine and paracrine actions.[62,64–66] These defense responses, however, may be overwhelmed as disease progression increases and evidence for regeneration, seen as tertiary dentinogenesis, is limited to more slowly progressing carious lesions, but not in more aggressive, rapidly advancing lesions.[67–69] Microorganisms and their byproducts are detected by a family of pattern recognition receptor (PRR) molecules, called Toll-like receptors (TLRs),[70] that sense pathogen-associated molecular patterns (PAMPs). Of the 11 members of the TLR-family, TLRs 1 to 6 and 9 are expressed on odontoblasts and pulp fibroblasts, and can be envisaged to sense a range of oral microorganisms PAMPs.[63,71–73] Nucleotide-binding oligomerization domain (NOD) -1 and -2 proteins in the pulp also contribute to oral microorganisms sensing[74–76] and with the Nod-like receptor (NLR) pyrin domain containing 3 (NLRP3) molecule[77] can be assembled into multi-protein "inflammasome" structures, capable of detecting microbial and tissue danger signals.[78] These various microbial sensing responses will then trigger activation of several intracellular signaling pathways including nuclear factor-kappa B (NF-κB), p38 MAP-kinase and Jun N-terminal kinase (JNK).[62,63,71–73,76,79,80] The outcomes of these signaling pathways will be the release of inflammatory mediators in the extracellular milieu,[74,75] that will amplify the defense responses and contribute to the recruitment of immune cells.[81,82] The involvement of various immune cells, signaling mediators and defense responses reflects a complex interplay of events and our understanding of these interactions will continue to grow.

Modulation of the Pulpal Environment During Disease Progression

The combination of both direct microbial and indirect inflammatory/immune influences on the pulpal environment, provides significant opportunity for carious disease to impact on regenerative events. However, characterization of these influences is challenging since the intensity of microbial infection and inflammatory challenge may impact on responses, as well as the nature of the experimental model in which these influences are investigated.

At the cellular level, there are conflicting reports as to the effects of inflammation on dental pulp stem cell differentiation and regeneration.[83–85] Stem/progenitor cells have been isolated from inflamed dental pulps and their ability to participate in regenerative events *in vivo,* as examined in an animal model,[83] and a number of their properties *in vitro* appear similar to cells isolated from healthy pulp.[83,84] However, exposure of isolated dental pulp stem cells to TNF-α *in vitro* to mimic inflammation has been reported to impair their differentiation.[85] In contrast, LPS treatment *in vitro* has been suggested to promote regenerative events in pulp stem cells.[86–88] These various apparently conflicting reports may well reflect the experimental model systems in which the cells have been investigated. Isolation of these cells and their study using *in vitro* culture will place them in a growth environment that is significantly different from that *in vivo*, both in the absence of the cells' tissue extracellular matrix/niche environment and exposure of the cells to the complexity of microbial and inflammatory challenges, normally encountered in the inflamed dental pulp.

Such limitations are common to many *in vitro* cell culture studies where compromises in cellular environments have to be balanced against reproducibility, control of variables and feasibility of experimental models. Likewise, most studies of pulp regeneration *in vivo* have adopted experimental models lacking ongoing microbial/inflammatory challenge where regenerative events will likely differ from when such challenges persist. Clearly, there is a need to interpret reports of developments in pulp regeneration with care as we strive for clinical translation.

As well as effects on cells, microbes and inflammation will also act on the various molecular constituents of pulp resulting in their partial or complete degradation potentially influencing their functional activities. While such degradation might be predicted to negatively impact on function, this does not necessarily appear to be the case. Acid and

enzymatic breakdown of pulp and dentin extracellular matrix components enhanced their chemotactic activities and contributed to selective recruitment of stem/progenitor cells involved in reparative processes.[38] The effects of these partial degradation products of pulp and dentin ECM components on other regenerative events require further study to understand their relative importance to the cellular signaling milieu present in pulp after injury.

Inflammatory/Immune Response-Regeneration Interplay

Mesenchymal stem cells (MSCs) can modulate the proliferation and functions of various types of immune cells.[89] Pulp stem cells also demonstrate such immuno-modulatory properties.[90–93] Our understanding of the activation of these immuno-modulatory properties is still limited, but involvement of TLR agonists has been reported.[93] While TLRs are typically activated by PAMP sensing of microorganisms, they may also be activated by host ligands (e.g. heat shock proteins, fibronectin and fibrinogen) or synthetic agonist molecules,[94] reflecting the diverse and complex nature of environmental sensing by cells. Interestingly, it is becoming apparent that considerable interplay exists between inflammatory/immune and regenerative responses, especially during the early stages of disease progression, or later stages of its resolution when low-level cytokine stimulation may mediate events.[95] The cytokine, TNF-α, can activate p38-MAPK signaling,[96] the latter of which may be a key regulatory switch for tertiary dentinogenesis.[59,60]

Low levels of immune cell-derived cytokines and reactive oxygen species (ROS) can also promote dental stem cell differentiation and mineralization.[97,98] It appears that regenerative events are stimulated by lower levels of inflammation and impeded by higher levels of inflammation; such biphasic responses are well recognized in biology, being termed hormesis.[99] These correlate well with clinical and histological observations of disease progression in teeth.[67–69] Increasing evidence for this interplay between inflammation and regeneration emphasizes some of the challenges for the clinical translation of regenerative endodontics.[12]

REGENERATIVE STRATEGIES

The biological strategies underpinning Regenerative Endodontics are dependent upon those elements associated with normal tissue development and tissue engineering: cells, extracellular matrix/cellular scaffold and signalling molecules. Targeting of these elements has been approached in a variety of ways that can generally be categorized under the headings of cell-free and cell-based approaches.

Cell-free Approaches

Cellular synthesis and secretion of tissue components are fundamental to the formation of any tissue. However, even where localized areas of cellular necrosis exist within a tissue, its regeneration may be achieved without the need to directly transplant cells to the injury site. Natural tissue wound healing responses stimulate the recruitment of stem or progenitor cells to injury sites thereby facilitating wound healing. Cell lineage studies suggest that cell recruitment, from both tissue-resident and other sources, may occur in the pulp after injury.[17] Such recruitment of stem/progenitor cells also provides the cells for differentiation of odontoblast-like cells in reparative dentinogenesis for dentin bridge formation following direct pulp capping. Thus, cell-free regenerative approaches avoid some of the issues associated with cell-based therapies, including the generation of sufficient numbers of cells of the necessary clinical quality and sourcing cells that will not result in immune rejection. These cell-free strategies are dependent upon providing a conducive environment in which regeneration can take place and thus, as well as providing cellular signaling, they will also generally consider how the cell matrix or scaffold might be optimized. The provision of cellular signaling for regenerative strategies may involve the direct application of either tissue recombinant, synthetic or tissue-derived bioactive molecules. It may also be achieved through chemical treatment of the tissue, to release and expose endogenous fossilized stores of bioactive molecules sequestered within the dentin matrix.

The currently employed strategies in regenerative endodontics to treat immature teeth with pulp necrosis, constitute a good example of cell-free approaches. These procedures (discussed later) depend on stem cell transfer from the apical tissues into a disinfected root canal system. This transfer of cells has been commonly achieved by mechanically releasing cells from the apical tissues along with bleeding.[100] The blood containing the cells also works as a fibrin scaffold, favouring tissue formation. Another clinically used approach is the use of platelet-rich plasma or platelet-rich fibrin as scaffolds.[101,102] These two natural scaffolds contain various chemotactic factors capable of recruiting undifferentiated mesenchymal stem cells.[103]

Cell-based Approaches

Cell-based regenerative strategies will include the transplantation of cells to the site of injury in the tissue to promote regeneration. Clearly, such cells should be of the highest good manufacturing practice (GMP) quality and ideally, should be from autologous sources to minimize any risks of immune rejection. These requirements and the necessity for appropriate clinical facilities to handle these cells, provide a number of challenges, and in the current context of endodontic practice, cell-based therapies are only likely to be undertaken in a hospital setting. As well as the direct transplantation of cells, these cell-based approaches may also involve the application or local release of signalling molecules and include the use of cell matrix/scaffolds.

TRANSLATIONAL STUDIES IN REGENERATIVE ENDODONTICS

The pulp-dentin complex is a tissue with intricate morphology and composition. This highly specialized tissue

has very unique characteristics compared to other tissues in the body. These include exquisite nociceptive innervation, a rich capillary network and highly specialized cells such as odontoblasts and fibroblasts with pleiotropic functions. As stated above, all of these cell types are active participants in the process of repair and regeneration following injury. The understanding of the complex interaction among these different cells, within the microenvironment of an infected root canal, remains a major gap in knowledge.

Translational science can be defined as the multidirectional integration of basic science and patient-oriented clinical research and practices, with the long-term goal of improving clinical procedures and practice to promote public health. This crucial cross-talk between bench and clinical research requires a focused multidisciplinary effort in order to move the field of regenerative endodontics forward. Indeed, there has been a substantial increase in translational studies aimed to understand and improve the biologic processes associated with the current procedures while paving the way for future generation regenerative endodontic procedures. This fertile area of endodontic research has gained substantial momentum, and has resulted in several improvements to vital pulp and non-vital pulp therapies. These studies often used models that mimic important aspects and challenges seen in the clinical setting. These models include: in-vitro, ex-vivo, and in-vivo animal models.

In-vitro Models

Tissue engineering involves the combination of stem-cells, growth factors and scaffolds. In the context of regenerative endodontics, these three important components of tissue engineering must interact with a complex array of molecular signals such as attachment molecules and local growth factors, antigens, residual microorganism-derived molecules and inflammatory mediators. Researchers often rely on *in-vitro* experimentation to test and evaluate these complex interactions.

Various MSCs have been used in regenerative endodontic research including dental pulp stem cells (DPSCs),[22] stem cells from human exfoliating deciduous teeth (SHEDs),[26] and stem cells from the apical papilla (SCAP).[25,104] In addition, mixed populations of cells have also been used such as cultured dental pulp cells,[105] that represent a heterogeneous population of cells that include MSCs.

It is important to emphasize that the characterization of "true" MSCs is still controversial. Surface markers such as cluster differentiation molecules (CD) have been extensively used to characterize different population of MSCs.[106] However, their expression alone is not often sufficient to ascertain the cellular identity. The potential use of these cells in cell-based therapeutics demanded the establishment of minimal criteria for the identification of these cells. In 2009, Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy established that MSCs are characterized by adhering to plastic in culture, the expression of CD73, CD90 and CD105, while lacking the expression of CD45, CD34, CD14 or CD11b, CD79 alpha or CD19 and HLA-DR, and the differentiation potential into adipocytes, chondrocytes and osteocytes in culture.[18]

As discussed previously, care should be employed when directly translating information from *in vitro* studies to the clinical practice since stem cells in culture lack the environmental cues that govern their fate, such as attachment molecules and growth factors. The culture of these stem cells in different *ex-vivo* biological environments has been used by researchers to mimic physiological conditions and minimize shortcomings of *in vitro* experimentation alone.

Ex-vivo Models

The combination of stem cells with the correct composition of scaffolds, and mixture of growth factors that most commonly resemble the conditions in tooth regeneration is daunting. Instead, millions of teeth are extracted every year offering ample opportunity for whole teeth (e.g., whole tooth culture) or parts of the tooth (e.g., root segments used in orgnotype root canal models). In addition, tissues can be harvested from animals and maintained in culture allowing for experimentation in tissues that more closely resemble conditions found in the body.

The culture of a whole tooth was reported by Tecles et al.[107] and allowed for the evaluation of stem cells response in the human dental pulp to a direct pulp capping with either MTA or calcium hydroxide. Stem cells or progenitor cells proliferated and were recruited to the site of injury (capped pulp exposure) and formed a mineralized matrix over the exposed pulp, similar to the mineralized bridge formed in direct pulp capping procedures, while the tooth was maintained suspended in culture for 21 days.

This elegant model allows for the examination of cellular responses in their niches with the correct composition of scaffolds (attachment molecules) and growth factors and a plethora of cell-to-cell interactions, although such responses occur in the absence of more systemic influences that exist *in vivo*. This same model was later used to demonstrate that Biodentin, similarly to MTA, allowed for the formation of a mineralized barrier over the capped pulp, and that this process was mediated at least in part through the release of TGF-beta 1 from the adjacent pulp cells.[108]

The *ex-vivo* culture of tissues can become increasingly complex, including sectioned jaws containing teeth still in their natural niche without the added trauma of extraction.[109] This model was developed to test the regenerative potential of teeth while allowing their interaction with cells and growth factors from the periradicular tissues. It facilitates the evaluation of the impact of immune reactions and microorganisms on the repair and regeneration of the pulp and periradicular tissues.[110,111]

Organotype root canal models have also been employed. These models are composed of either tooth slices (e.g., transection of pulp chambers),[28] or prepared root canals in root segments of extracted teeth.[112] The addition of stem cells

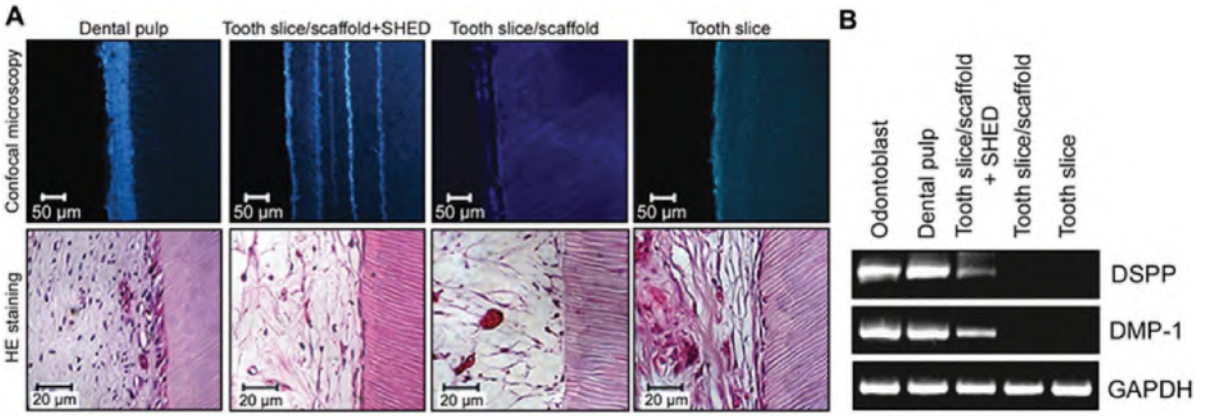

FIGURE 29-2 SHED differentiate into functional odontoblasts that generate new tubular dentin *in vivo*. ***A.*** Photomicrographs of confocal microscopy (top row) and hematoxylin and eosin staining (bottom row) performed in specimens retrieved from immunodeficient mice 32 days after implantation. ***B.*** RT-PCR analysis of DSPP and DMP-1 mRNA expression on tissues retrieved from the pulp chamber of tooth slices from the four experimental groups (i.e., tooth slice/scaffolds seeded with SHED, negative control tooth slice/scaffolds without SHED, negative control tooth slices without SHED and without scaffold, and positive control tooth slices with pulp tissue) 32 days after transplantation into immunodeficient mice. Positive controls were odontoblasts retrieved from freshly extracted human third molars. (Adapted with permission from Sakai et al.[118])

in a suitable scaffold to these "dentin culture environments" allows for the *in vitro* evaluation of their interaction, being particularly important for the investigation of the effect of conditioning dentin with different irrigants and medicaments on stem cell fate.[49,112–114] A study found that SCAP in PRP placed in root canals previously treated with either 6% NaOCl or irrigant combinations that contained 2% chlorhexidine did not survive in culture. However, they thrived if the dentin had been treated with 17% EDTA.[112] Another study, using a tooth slice model found that dentin treatment with 6% NaOCl prevented the differentiation of SHED into an odontoblastic phenotype when cultured in contact with the conditioned dentin. Conversely, dentin conditioning with 17% EDTA increased the expression of odontogenic markers.[114] These studies highlight the value of these models to test clinically relevant questions.

In vivo/Animal Models

The use of animal models of regeneration is a natural transition from the *in vitro* and *ex-vivo* evaluation of mechanisms and interactions between stem cells, growth factors, and scaffolds. Animal model experiments can involve the use of the animal's own dentition as a regenerative model,[25] or the implantation of "constructs" of human teeth (whole of fragments) seeded with stem cells in a suitable scaffold.[50,115]

The severely compromised immune deficient (SCID) mouse is a murine strain that lacks functional T cells and B cells, among other immune deficits. These animals accept allografts and xenografts with minimal to no rejection risk. Thus, they have been widely employed as hosts for the implantation of human teeth[53] and human stem cells.[116] Extracted immature third molar implanted subcutaneously into the dorsum of SCID mice demonstrated continued dental development with new dentin formation and no rejection or immunogenic reaction to the xenograft.[117] Tooth slices with SHED in a tooth slice/scaffolds were implanted subcutaneously in SCID mice injected periodically with tetracycline allowing formation of a pulp-like tissue after 32 days with cells that expressed the odontogenic markers dentin sialophosphoprotein (DSPP) and dentin matrix acidic protein-1 (DMP-1).[118] Importantly, de novo tubular dentin formation was visualized by tetracycline staining seen under confocal microscopy (Figure 29-2). Thus, the use of SCID mice as a host or "living bioreactor" allows for direct evaluation of tissue engineering approaches that are conducive for regenerative endodontics.

Another translational model involves procedures and techniques tested in animal models of regenerative endodontics. These procedural experiments usually employ larger animals, such as dogs,[119–123] minipigs[25] and ferrets that allow for better simulation of conditions and procedures more applicable to patients. Revitalization or revascularization procedures performed in dogs have demonstrated successful healing of apical periodontitis, and radiographic root development.[119,120,123] However, the tissues formed in these procedures did not resemble the native pulp tissue and the mineralized tissue resembled cementum or osteoid tissues. It is important to note that these findings closely resemble those found human teeth treated with these techniques (discussed later in this chapter). This strong correlation suggests that these models are valid and important for the investigation of treatment modifications that could become the next generation of regenerative endodontic procedures.

REGENERATIVE ENDODONTIC PROCEDURES (REPS)

Patients undergoing cranio-skeletal development with mixed dentitions are at risk of pulpal injury. Permanent teeth erupt in the oral environment with a very immature or undeveloped root structure. Upon eruption, teeth are exposed to a new

environment that contains microorganisms and is susceptible to traumatic injuries. It takes approximately up to three years for a root to be fully formed from the time of the first signs of eruption[124]. Trauma to immature teeth has been recognized as the primary etiology for pulpal necrosis in these teeth followed by dental anomalies (dens evaginatus for example).[125] Unfortunately, trauma to permanent immature teeth is a relatively common occurrence affecting approximately 30% of all children.[126] Despite an elaborate pulpal defense system that includes specialized dendritic cells,[127] odontoblasts,[65] fibroblasts,[65] neurons[128] and a vascular arteriovenus (A/V) shunt mechanism,[129] the dental pulp may succumb to the ingress of microorganisms and/or ischemia following trauma. The subsequent liquefaction necrosis of the dental pulp arrests the dental development leaving immature teeth with thin, fragile dentinal walls and open "blunderbuss" apices. For more details, see Chapter 12, "Endodontic considerations in dental trauma."

For many decades, the management of many such cases had been considered unpredictable. Tooth loss in patients still undergoing cranio-skeletal development has devastating consequences that include: altered maxillary and mandibular bone development, interferences with phonics, breathing and mastication, and importantly, there is a severe detrimental psychosocial effect on young patients.[130,131] Since implants are contraindicated in growing young patients, tooth replacement is not possible until they mature (usually >18 years old).

Until recently, the clinical treatment of immature teeth with pulpal necrosis applied the prevailing traditional philosophy of disinfection, followed by providing a "microbial-tight" seal of the root canal system with an inert material such as gutta-percha. From a biological perspective, this approach is not without challenges since the large root canals found in immature teeth harbor high microbial loads. In addition, these microorganisms penetrate further into dentinal tubules in immature teeth than fully formed teeth, making disinfection a harder goal to be achieved.[132] Conventional root canal treatment relies on chemo-mechanical debridement for the removal of planktonic microorganisms and biofilms in the infected dentinal surface. This approach, that includes the mechanical removal of dentin, is challenging, since these canals have greater diameter than most available instruments, and its practice is ill advised in immature teeth with thin dentinal walls, that are also prone to fractures. Furthermore, adequate obturation to achieve a microbial-tight seal is challenging due to the large canal volume, inverted taper (wider apically) and lack of apical constriction.

Apexification procedures were introduced in the United States by Frank in 1966, who demonstrated that an apical calcific barrier may be formed in immature teeth following adequate debridement and intracanal placement of calcium hydroxide.[133] Several studies demonstrated successful outcomes, that used the dependent measure of resolution of the disease process, and the formation of a calcific barrier (apexification), following the use of calcium hydroxide for several months.[134–136] Furthermore, it became clear that the formation of this natural calcific barrier depended on the arrest of the infection and inflammatory process.[137] Therefore, when this approach is employed, clinicians commonly use calcium hydroxide as an intracanal dressing until symptoms are resolved, and the apical barrier is formed, a process that may take upto 18 months.[137] Calcium hydroxide has been shown to reduce tooth resistance to fractures in a time dependent-fashion,[138] with significant decrease occurring with its use for longer than 3 months.[139] Indeed, teeth treated using calcium hydroxide-induced apexification have been found to show greater rate of fractures and reduced survival.[140,141]

The introduction of mineral trioxide aggregate (MTA) in 1993 addressed several unmet needs in endodontics, allowing its use in root perforations, capping procedures and apexification procedures.[7,142] It was recognized at an early stage that MTA was not only biocompatible but also, it induced the "regeneration" of mineralized tissues upon direct contact. Indeed, MTA predictably induced the formation of a calcific barrier in dogs demonstrating that it could be used as an osteo-inductive artificial barrier or "apical plug."[143] These findings, in conjunction with many successful reports of "osseous regeneration" induced by MTA, quickly accelerated its use in apexification procedures. The possibility of sealing the apical foramen with MTA revolutionized the treatment of immature teeth with pulpal necrosis since the procedures could be performed in a single appointment, or short-term in multiple appointments with similarly high success rates, without any concern of apical extrusion of the material.[144–146] Although MTA apexification procedures allowed for resolution of symptoms, and did not further weaken teeth following the long-term use of calcium hydroxide, they did not promote continued root development and reestablishment of pulpal functions (discussed later in this chapter).

Regenerative endodontic procedures emerged in 2001 as a case report demonstrating striking evidence of root development, and regain of responses to vitality testing, following a procedure that involved the use of an intracanal antibiotic paste containing metronidazole and ciprofloxacin (later called double antibiotic paste) (Figure 29-3).[147] This case report was followed by another noteworthy report demonstrating similar results with the use of a triple antibiotic paste as an intracanal dressing (Figure 29-4).[148] Importantly, the biologic foundations and philosophy for these procedures were established many decades previously with the pioneering work of Dr. Nyggard-Ostby,[149] that aimed to investigate the role of the blot clot in healing following endodontic infections. In his seminal studies, it was observed that reestablishment of a vital tissue within the root canal spaces was possible when apical blood was allowed to ingress into a disinfected root canal. In these studies, the included teeth had mature, fully formed roots, and canals were disinfected without consideration for making the environment hospitable for the cells, including stem cells (not yet identified at that time). Nonetheless, remarkable results were found that included: 1) resolution of symptoms of inflammation related to foraminal enlargement and over-instrumentation, 2) resolution of signs and symptoms of pathosis for the necrotic cases, 3) radiographic evidence of apical closure, and 4) ingrowth of connective tissue into the canal space, and varying deposition of mineralized tissue found along the canal walls, as well as "islands" of mineralized tissue embedded within the newly

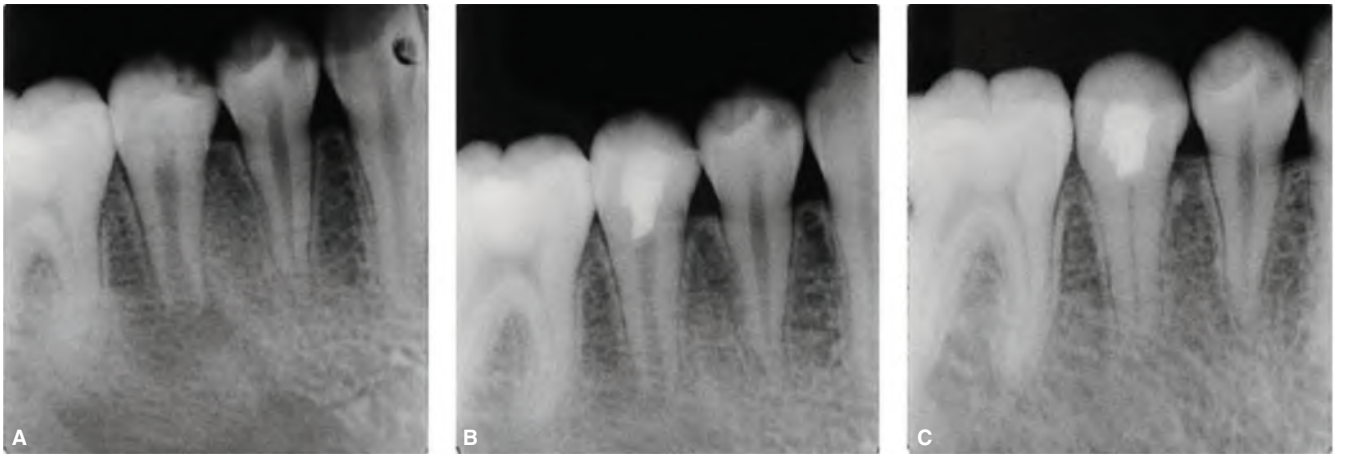

FIGURE 29-3 A case treated with a regenerative endodontic procedure using double antibiotic paste (ciprofloxacin and metronidazole) as intracanal medicament. ***A.*** The immature mandibular second premplar was diagnosed with pulpal necrosis and acute apical abscess. ***B.*** Five-month follow-up reveals complete resolution of apical radiolucency and formation of a coronal mineralized bridge and thickening of the dentinal walls. ***C.*** 30-months follow-up reveals completion of root development with apical closure, thickening and elongation of root structure. FIGURE 29-4 An 11-year-old male patient was diagnosed with pulpal necrosis and chronic apical abscess in the mandibular second premolar. The tooth was treated with a regenerative endodontic procedure (revascularization) using triple antibiotic paste (minocycline, ciprofloxacin and metronidazole) as intracanal medicament. ***A.*** Preoperative radiograph shows large periradicular radiolucency and immature root with open apex. ***B.*** Post-operative radiograph taken 26 months after treatment showing signs of healing; ***C.*** 12-month follow-up showing complete resolution of radiolucency and continued root development. ***D.*** 18-month follow-up showing further root development. The patient remained asymptomatic during the follow-up period and the tooth responded to both electric and cold sensitivity tests. (Adapted with permission from Banchs and Trope.[148])

formed tissue. Although some studies followed this thought-provoking initial report, the exploration of biologic-based endodontic therapies was not prioritized for many decades until the surge of the contemporary regenerative endodontic procedures (REPs) in the early 2000's.

COMMON FEATURES OF REGENERATIVE ENDODONTIC PROCEDURES

Since the initial case report in 2001, more than 200 cases have been reported in the scientific literature.[125,150] Despite pronounced variations in clinical protocols, some common features can be identified in these procedures, regarding case selection, disinfection strategies, evoked-bleeding and restorative approaches. Although most of these reports consist of case reports, they provide immediate documentation of procedures that may or may not have worked in patients, while providing crucial feedback to researchers for the development of future REPs. Therefore, it is important to highlight some of the features present in most REPs.

Case Selection

Trauma to the permanent developing dentition is the underlining etiology of approximately 49% of all the published cases using REPs as therapy.[125] This finding is not surprising, since it is consistent with the reported high incidence of dental trauma affecting up to 35% of children,[126] particularly between the ages of 7 and 15 years old,[151,152] when most permanent teeth are in an incomplete stage of root development. Unfortunately, approximately 50% of the traumatized teeth may be diagnosed with pulpal necrosis,[153] with greater incidence occurring following severe injuries such as intrusions and avulsions[154,155] and combination injuries.[156–158] Therefore, the high incidence of trauma-evoked pulpal necrosis reported in the patients included in case reports and retrospective and prospective studies in regenerative endodontics is likely biased by the high incidence of these injuries. Moderate to severe trauma to the developing dentition can potentially damage the Hertwig's epithelial root sheath (HERS), that is crucial to dictating root formation and maturation by directing the concerted proliferation and differentiation of MSCs.[159] However, the effects of the etiology (trauma versus dens evaginatus, for example) on the outcomes of REPs are still unknown. This is largely due to the relatively small sample sizes of the existing studies, constraining statistical analysis of outcome predictors, and importantly, contributing to the prevailing confusion on what should be the expected outcomes of these procedures (discussed later).

The second most common etiology is the presence of an existing dental anomaly that renders the developing tooth susceptible to pulpal necrosis. Dens evaginatus is considered a prominent etiologic factor for pulpal necrosis in 33% of all the reported cases, followed by dens invaginatus (3% of the cases).[125] Dens evaginatus is manifested as an additional cusp, typically projecting into the occlusal table of a mandibular premolar (more common) or the facial or lingual surfaces of maxillary anterior teeth (less common). The incidence of dens evaginatus has been reported to affect up to 6% of the population with greater incidence in certain ethnic groups.[160,161] Although the incidence of this dental anomaly is relatively rare, its presence is often associated with the fracture or wear of the enamel-dentinal tubercle leading to the direct exposure of the pulp to the oral environment, and the rapid development of pulpal necrosis in immature teeth.

Most published regenerative endodontic cases, but not all,[162] report treatment outcomes in immature teeth with an open apex.[125] These teeth have been shown to have greater chance of becoming "revascularized" upon reimplantation. Indeed, the clinical outcome of these reimplanted teeth appears to be directly related to the degree of maturity based on the stage of root development and apical closure with more desirable outcomes being seen in teeth with a radiographic apical diameter of at least 1 mm.[163] Although the process of tissue formation in regenerative endodontics greatly differs from the process of revascularization of an existing sterile pulp as seen in reimplantation, it equally relies on angiogenesis and the ingress of newly formed blood vessels through the apical opening.[164,165] It is probable that an immature tooth with a wide apical opening shows a much greater vascularity than seen in the roots of more mature teeth, and this could have significant influence on regenerative endodontic treatment outcomes.[166]

It is important to note the effects of stage of root development and apical diameter on clinical outcomes have never been established. Interestingly, a recent study found that vascularized tissue could be formed in teeth with an apical diameter of approximately 0.3 mm, that is similar to the apical diameter of most canals in fully mature roots.[167,168] In summary, most REPs have been performed in immature teeth, but the minimum clinical critical apical diameter for successful outcomes has not been established. A recent animal study and a case report challenge the preconceived notion that an apical diameter of greater than 1 mm is a requirement for desirable outcomes in REPs.[162,167]

Clinical Protocol

There are more than 200 published cases of REPs. Notably, these published cases are marked by a tremendous heterogeneity in the clinical protocols used. This is largely due to the empirical nature of the protocols adopted in the original reports that preceded the more translational studies aiming to provide a more targeted approach to REPs. The American Association of Endodontists (AAE) have established a long-standing committee that periodically evaluates both clinical and translational studies to help establish clinical considerations and guidelines for regenerative endodontics.

Despite this heterogeneity in the treatment protocols reported in published cases, some common features can be readily seen. Most cases have been performed with minimal to no instrumentation and with the use of copious irrigation with sodium hypochlorite as a means of disinfecting and debriding the root canal space. Intracanal medicaments were used in all cases with exception of one published case report.[169] On the last visit, the canal was commonly irrigated once more, dried and the intracanal bleeding evoked by instrumentation of the apical tissues.

Certain cases were performed without intracanal bleeding and with its substitution by the application of platelet rich plasma (PRP)[102] or platelet rich fibrin (PRF).[170] The use of intracanal bleeding represents an important step in these procedures since it is capable of transferring a substantial number of undifferentiated MSCs into the root canal system[100] and the blood clot can act as a scaffold. Both PRF and PRP have also been found to serve as scaffolds and provide chemotactic factors that are likely to promote MSC recruitment into the root canal system.[171]

Another important step seen in most published cases is the coronal placement of a bioactive "coronal plug" using pro-mineralizing dental materials such as MTA or Biodentine. These materials have been shown to promote the differentiation of MSCs into an odontoblast-like phenotype while allowing for greater proliferation of MSCs.[8,107,108,172] Importantly, these materials provide a "safe zone" barrier to the restorative material used to seal the pulp chamber that is typically noxious to stem cell survival and differentiation. Interestingly, there have been case reports of REPs performed without the use of these materials with acceptable clinical outcomes.[150] Therefore, the role of the bioactive coronal plug in promoting the proliferation and differentiation of MSCs through the length of the canal is not fully understood. Nonetheless, in certain cases a calcific barrier can be seen immediately underneath the material, suggesting that these materials induce the formation of at least a biological coronal seal.

Common Challenges

The clinical techniques usually employed in REPs are not without challenges. The diameter of the root canals in most immature teeth far exceeds the diameter of the larger endodontic instruments. This makes mechanical instrumentation technically challenging. In addition, the mechanical preparation of immature teeth could further weaken already fragile thin dentinal walls.[140] Due to these limitations, most cases are treated without instrumentation. However, bacterial biofilms have been found in a failed regenerative endodontic procedure.[173] Clinicians rely on the disinfection and tissue dissolution properties of sodium hypochlorite for debridement followed by placement of intracanal medicaments. Resistant bacterial biofilms represent a "reservoir" of continuing microbial insult that could jeopardize treatment outcomes. Therefore, it is prudent to lightly brush circumferentially the canal walls with endodontic instruments (e.g., Hedstrom files) to aid in the disruption of the bacterial biofilms without any aggressive removal of dentin. The use of ultrasonic activation of irrigants is warranted in these cases as long as the instrument is positioned at least 2 mm from the radiographic apex to prevent direct damage to the apical tissues. Lastly, the inclusion of a final irrigation with 17 % EDTA for approximately two minutes in the first visit, opens dentinal tubules and allows for greater antimicrobial effect of the intracanal medicament. EDTA treatment may also contribute to release and exposure of endogenous bioactive signaling molecules in the dentin that can promote regenerative events (Figure 29-5).

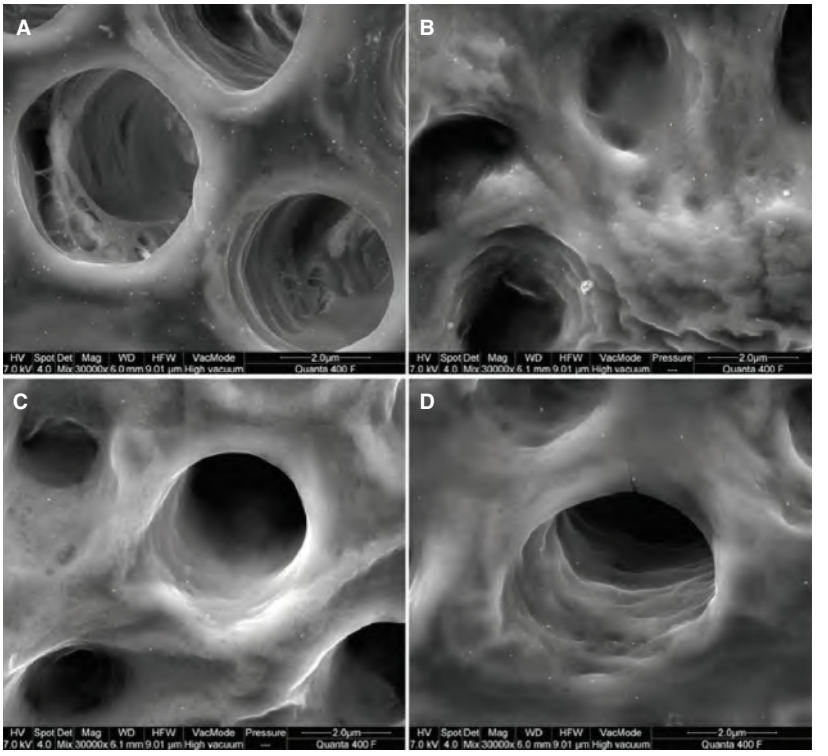

FIGURE 29-5 Gold labeling on dentin disks after EDTA conditioning (10%, pH 7, 10 minutes) of ***A.*** collagen; ***B.*** TGF-β1; ***C.*** FGF-2; and ***D.*** VEGF. *Dots* indicate gold nanoparticles after antibody binding that show growth factor exposure on the dentin surface. (Adapted with permission from Galleret al.[50])

Tooth discoloration has been identified as an adverse event associated with many REPs.[174,175] Tooth discoloration may have three origins in these procedures. The most common origin of discoloration is the intracanal use of tetracycline-like drugs, such as minocycline commonly present in the triple antibiotic paste (minocycline, ciprofloxacin and metronidazole).[176] The staining evoked by this antibiotic combination is often severe,[177] but it can be minimized by occluding the coronal dentinal tubules with a dental adhesive, or completely prevented by the use of calcium hydroxide as an intracanal medicament instead.[177–180] The second cause of coronal discoloration is the intracanal bleeding that is a part of the currently recommended protocols. Blood when present in the dentinal tubules, as often seen following trauma, is capable of causing coronal discoloration.[181] Paradoxically, blood should ideally be encouraged to flow as coronally into the pulp chamber as possible, and not below the CEJ as suggested and promoted in most published protocols. The placement of a coronal plug of a bioactive material (e.g., MTA or Biodentine) at the CEJ prevents root development in this region that is crucial for providing cervical strength to the tooth.[182,183] The application of dentin bonding agent to the dentinal tubules of the pulp chamber allows for placement of blood above the CEJ while minimizing the chances of blood-induced discoloration. The third possible cause of discoloration is the use of MTA as a "coronal plug" that often causes substantial discoloration, even when the white form of the material is used.[184–187] This undesirable results can be prevented by the use of other materials such as tricalcium silicate (e.g., Biodentine) in esthetic zones.[188,189] In addition, the use of a dentin-bonding agent to seal the dentinal tubules in the pulp chamber is beneficial also to minimizing any possible discoloration from the coronal plug material.[176,190] Therefore, the root canal system should be temporarily sealed with a sterile sponge and a temporary filling material, such as Cavit, followed by etching and bonding of the pulp chamber with a dental adhesive prior to placement of intracanal medicament to minimize the possibility of discoloration from the 3 sources (medicament, bleeding and restorative material).

Inadequate intracanal bleeding has been identified, as another challenge to REPs. The clinician should refrain from using vasoconstrictor-containing local anesthetics in the second visit to minimize challenges associated with achieving adequate bleeding into the tooth. Mepivacaine without epinephrine is a commonly used alternative to other dental local anesthetics containing vasoconstrictors. However, it is important to appreciate that unlike most local anesthetics that have robust vasodilator effect, it evokes moderate vasoconstriction by itself.[191,192] Conversely, lidocaine has been recognized as a potent vasodilator.[193] The use of lidocaine without epinephrine is not expected to provide long-lasting anesthesia due to its high rate of absorption by the systemic circulation.[194] However, its use minutes before the attempted apical bleeding may increase the chances of having adequate bleeding from the apical region. Although not ideal, clinicians may elect to place the bioactive coronal plug more apically if bleeding was found to be insufficient and not reaching the desirable level (above the CEJ) (Figure 29-6). Alternatively, PRP or PRF could be used after intracanal bleeding attempts are unsuccessful, as discussed above. Unfortunately, the use of these alternative scaffolds is not trivial since it requires drawing intravenous blood in young patients followed by laboratorial preparation of the bioactive scaffold.[101,170,195,196]

Example of a Clinical Protocol

The field of Regenerative Endodontics has seen substantial advances in our understanding of the biological processes that provide explanation for clinical findings, such as radiographic continued root development and vitality responses.[125] Translational research has been crucial to this gain in knowledge, especially emphasizing that the disinfection process to be employed in regenerative procedures needs to be fundamentally different to that employed for conventional nonsurgical root canal treatment. Chemicals and medicaments must be chosen and have their concentrations adjusted to provide the greatest possible antimicrobial effect while creating a microenvironment conducive for stem cell survival, proliferation and differentiation. The technical recommendations below represent the current status of these procedures taking into consideration clinical and translational scientific findings. These recommendations are likely to change as the new field of regenerative endodontics rapidly evolves.

The Initial Visit

First Treatment Visit

1. Patient's informed consent, including explanation of risks and alternative treatments or no treatment.
2. After ascertaining adequate local anesthesia (2% Lidocaine with epinephrine), dental dam isolation is obtained.
3. The root canal systems are accessed and working length is determined.
4. The root canal systems are slowly irrigated first with 1.5% NaOCl (20 ml/canal, 5 min). The irrigant is then aspirated from the canal space.
5. Canals are dried with paper points and temporarily sealed with a sterile sponge and a thin layer of temporary filling material, such as Cavit or IRM at the CEJ level. The pulp chamber is etched, primed and bonded with a dental adhesive.

6. The temporary filling material and sponge are removed, and the canals irrigated with 17% EDTA (10 ml in 2 min). The canals are then dried, and calcium hydroxide, or antibiotic paste at a combined concentration of antibiotics of no greater than 1 mg/ml is delivered to canal system.
7. Access is temporarily restored.

Final (Second) Treatment Visit

(The second visit is scheduled 2 to 4 weeks after the first visit)

1. A clinical exam is first performed to ensure absence of symptoms to palpation or percussion. If such symptoms of persistent disease, or a sinus tract or swelling are noted, then the treatment provided at the first visit is repeated. At this point, the clinician may elect to apply triple antibiotic paste (at no more than 100 μg of each drug/mL).
2. After ascertaining adequate local anesthesia with 3% mepivacaine (no epinephrine), dental dam isolation is obtained.
