INGLE'S ENDODONTICS 7

ILAN ROTSTEIN / JOHN I. INGLE

Ingle's

ENDODONTICS 7

About the Editors

Ilan Rotstein

Dr. Ilan Rotstein is Professor and Associate Dean, and Chair of Endodontics, Orthodontics and General Practice Residency at the Herman Ostrow School of Dentistry, University of Southern California, Los Angeles, California.

He has served in leadership roles for various dental organizations, including chair of the Research Committee of the International Federation of Endodontic Associations, member on committees of the American Association of Endodontists and the European Society of Endodontology, and as scientific reviewer for international endodontic and dental journals. He has also served as president of the Southern California Academy of Endodontists, president of the International Association for Dental Research–Israel Division, president of the Israel Endodontic Society, and chair of the Israel National Board of Diplomates in Endodontics.

Dr. Rotstein has published over 150 scientific articles and research abstracts in the dental literature as well as chapters in international endodontic textbooks including *Ingle's Endodontics*, *Pathways of the Pulp*, *Endodontics: Principles and Practice*, *Seltzer and Bender's Dental Pulp*, *Endodontia: Biologia e Técnica*, and *Harty's Endodontics in Clinical Practice*. He has lectured extensively in more than twenty-five countries throughout five continents.

John I. Ingle

Dr. John I. Ingle, is best known as author of *ENDODONTICS*, a leading text in the field, first published in 1965. He is also the author of *PDQ ENDODONTICS*, a compilation of information from the larger text.

Dr. Ingle obtained his dental degree from Northwestern University in 1942. He received his graduate degree in periodontics and endodontics from the University of Michigan in 1948. Among his many contributions to endodontics, in 1957 Dr. Ingle standardized the size and shape of endodontic instruments, an international standard that remains today. In 1965, he was granted the Alumni Merit Award from Northwestern University. In 1987, he received the Ralph E. Sommer Research Award from the American Association of Endodontists, and in 1999 the Edgar D. Coolidge Leadership Award. He has also received the International Louis I. Grossman Award from the French Society of Endodontics.

Dr. Ingle is a Fellow of the American and International Colleges of Dentists and is listed in *Who's Who in America*. He has published over 80 scientific articles in the dental literature and has lectured extensively throughout the world.

Notice: The authors and publisher have made every effort to ensure that the patient care recommended herein, including choice of drugs and drug dosages, is in accord with the accepted standard and practice at the time of publication. However, since research and regulation constantly change clinical standards, the reader is urged to check the product information sheet included in the package of each drug, which includes recommended doses, warnings, and contraindications. This is particularly important with new or infrequently used drugs. Any treatment regimen, particularly one involving medication, involves inherent risk that must be weighed on a case-by-case basis against the benefits anticipated. The reader is cautioned that the purpose of this book is to inform and enlighten; the information contained herein is not intended as, and should not be employed as, a substitute for individual diagnosis and treatment.

In Memoriam: John I. Ingle, DDS, MSD, 1919–2017

FIGURE 1

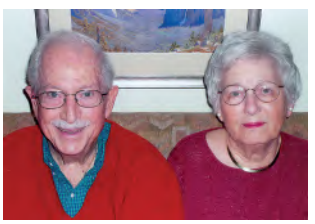

FIGURE 2

FIGURE 3

A beloved endodontic leader, Dr. John I. Ingle, passed away on September 25, 2017 in San Diego at the age of 98. He was predeceased by his wife, Joyce Ledgerwood Ingle, who passed away on March 8, 2014. They leave three children, five grandchildren, and two great grandchildren. John and Joyce Ingle knew each other all their lives: their families were close friends when they were born seven months apart in June 1918 and January 1919, and they attended school together from elementary school through college. Joyce became an accomplished jazz pianist and even learned Braille in order to translate books for blind children. They married on July 11, 1940 (Figure 1), and were married for nearly 74 years (Figure 2).

Dr. John Ingle was born in 1919 in Colville, Washington. His career in dentistry and endodontics spanned more than six decades, beginning with dental school at Northwestern University in Chicago, which he completed in 1942.

After serving the country in the military for four years as a dental officer (Figure 3), Dr. Ingle began a long and distinguished career in dental education. He accepted an offer to teach periodontics at the University of Washington in Seattle. However, Dr. Ingle had an interest in both periodontics and the new emerging field of root canal therapy—endodontics. Because of that interest, he was sent to the University of Michigan, where he earned a graduate degree in both periodontics and endodontics in 1948, returning to Seattle to teach both disciplines. He subsequently earned certification from both the American Board of Periodontics (ABP) and the American Board of Endodontics (ABE).

Establishing the first endodontic specialty program on the West Coast in 1959, Dr. Ingle was involved in the education of many endodontists who followed in his path of endodontic education. He took great pride in inspiring others to become engaged in teaching endodontics. After 16 years of teaching at the University of Washington, Dr. Ingle moved to Los Angeles, California to assume the position of Dean of the School of Dentistry at the University of Southern California, which allowed him to become involved in the expanding endodontic community in Southern California.

Dr. Ingle's interest in endodontics covered all aspects of the discipline, including the instruments used for root canal treatment, the outcomes of treatment, the dissemination of information, and the participation in activities of the specialty. Frustrated with the lack of standardization of root canal instruments, Dr. Ingle tried to interest dental companies in developing a worldwide standard for the size and shape of endodontic files and reamers. In the United States, nonmetric measurements were used while in the rest of the world the metric system was universal. In addition, each manufacturer had its own standards for sizes and shapes of instruments. In an attempt to generate an interest in the problem, Dr. Ingle published a paper pointing out the need for standardization of instruments, and following intensive research he developed the standardization system in 1957—the 0.2 taper and metric measurements—that is still in use today.

The precision in design and manufacturing of endodontic instruments that Dr. Ingle's innovation created so early in the history of endodontics is taken for granted today. It illustrates, however, how he would identify a problem and work hard to find a solution. His constant search for solutions to treatment problems made him open to accepting many innovations in techniques and instruments, and he ensured that they were described in his textbooks. While root canal therapy probably originated in the mid-1800s, the treatment of teeth with root canal infections was set back when in the early 1900s the focal infection theory put a roadblock in the path of such treatments. It took the efforts of pioneers such as Dr. Ingle to change the attitudes of many in the dental and medical professions. Even in the 1950s, endodontics was not widely accepted, and questions were raised about both the success and the safety of such treatments.

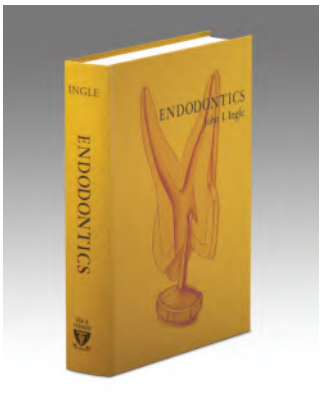

FIGURE 4

Along with pioneers such as Dr. Larz Strindberg in Sweden, Dr. Ingle conducted research in endodontic outcome that enabled us to describe important clinical and radiographic factors associated with the success and failure of root canal treatment. It soon became known as the "Washington Study." Its importance was that it demonstrated a high rate of success in root canal treatment, as well as identifying the main causes of failures: poorly performed treatment procedures. The conclusion was that root canal therapy could be successful if done properly. Thus, the classic "Washington Study" has taken its place in the history of important contributions to endodontics.

One of Dr. Ingle's passions in life was to disseminate information on all aspects of endodontics. That led to the publication of a milestone in endodontic textbooks—*Ingle's Endodontics*—the first edition of which was published in 1965 (Figure 4). It was followed by six additional editions spanning over half a century. *Ingle's Endodontics* gained notice as soon as it was published. The bright yellow-colored book [a color suggested by his wife, Joyce] was an innovative textbook for its day, and its nine by eleven-inch size was unique for medical texts at that time. In addition to the superb illustrations, it contained full-size plates of access preparations. It soon became a textbook that inspired many dentists to pursue endodontics as a specialty and has been a model for other textbooks to follow.

In recognition for his many contributions to our specialty, Dr. Ingle received the American Association of Endodontists's (AAE) Ralph F. Sommer Award in 1987 and the Edgar D. Coolidge Award, the AAE's highest honor, in 1999. The Sommer Award had a special meaning for Dr. Ingle in that Dr. Sommer had been one of his teachers at the University of Michigan. In 2015, the AAE General Assembly, at the Annual Session, honored Dr. Ingle with a special recognition for his contributions to endodontics. He was also honored by many other international organizations.

Dr. Ingle's interests spanned many areas. After completing six years as Dean of the School of Dentistry at the University of Southern California, he was honored by being appointed Senior Staff Officer to the Institute of Medicine in the National Academy of Sciences in 1972.

The words "icon," "legend," and "giant" are so overused that John Ingle would not have wished to be described in such terms. He would likely have been pleased to be remembered as a mentor, a teacher, and a friend to numerous colleagues in the United States and abroad, and one who has had a lasting impact on the lives and careers of dental professionals and endodontists worldwide.

—Leif Bakland

Bilbao, Spain

Foreword

Fifty-three years ago, the year I graduated from the University of Southern California School of Dentistry with John Ingle as our dean he published, unknown to me at the time, his first edition of *ENDODONTICS* — now celebrating its 50th Anniversary Edition. This is remarkable on several different levels.

First, John hired me in 1968 as an Assistant Professor of Biochemistry and Nutrition in the USC School of Dentistry to start my 46-year tenure on the full-time faculty of the University of Southern California.

Second, I have been able to join with others over the years to celebrate John's birthdays. We celebrated John's 98th birthday in January 2017 while he continued to savor the pleasures of authorship, editing, friendship, and staying connected to his passion for endodontics.

Finally, this is a very special occasion to also celebrate my colleague and dear friend Ilan Rotstein who has joined with John to produce the 7th edition of *Ingle's ENDODONTICS*. Together, John and Ilan have organized an excellent and authoritative edition that includes 40 chapters contributed by internationally recognized experts in the field. Collectively, these contributions reflect the most comprehensive textbook in modern endodontics worldwide. Further, they emphasize the science of endodontics, the practice of endodontics, and the interdisciplinary nature of endodontics.

I celebrate their accomplishment with this 7th edition of *Ingle's ENDODONTICS* and encourage the reader to learn and enjoy this fascinating field. Cheers!

—Harold C. Slavkin, DDS
Professor and Dean Emeritus
6th Director of the NIDCR, National Institutes of Health

Preface to the 7th Edition

Endodontic treatment is an important therapeutic modality that allows retention of the natural dentition in the oral cavity and its return to health and function.

The specialty of endodontics has gone through many groundbreaking changes over the past several years. Recent advances in concepts, technology, materials, and equipment have changed the way endodontics is being practiced today. These advances have made it possible to efficiently perform successful endodontic treatment with improved precision and predictability and with greater patient acceptance and comfort.

The seventh edition of *Ingle's ENDODONTICS* is the most recent revision of the text that has been known as one of the most authoritative in the field for half a century. This 50th anniversary edition includes 40 chapters written by internationally renowned authors from six continents, contributing new, cutting-edge knowledge and updates on topics that have formed the core of the specialty. The evidence-based information provided in this edition continues to influence what is thought, what is taught, and what is practiced in modern endodontics worldwide. It is the standard against which all other endodontic texts will be measured.

The three main themes of this edition are The Science of Endodontics, The Practice of Endodontics, and Interdisciplinary Endodontics. Endodontic treatment is an art requiring clinical skills that build upon a robust foundation of scientific evidence. In tandem, the endodontic professional must play a significant role as part of a team of specialists in order to attain the correct diagnosis, proper treatment decision-making, and a predictable outcome.

I wish to thank the authors for their most valued contribution, especially under a very intensive and ambitious timeline. Their efforts and dedication have made this edition the most comprehensive textbook in endodontics today.

I owe a special debt of gratitude to Dr. John Ingle, a pioneer, leader, mentor, and educator for entrusting me with one of his most precious treasures: *Ingle's ENDODONTICS*. I was surprised and humbled when Dr. Ingle asked me to be the Editor-In-Chief of this textbook. Thank you, John, for the mentorship, trust and support. For me, it made this project an extraordinarily enriching learning experience and a labor of love.

A hearty thank you to Dr. Leif K. Bakland and Dr. J. Craig Baumgartner for their advice, guidance, and unconditional help.

I hope you, the reader, enjoy this book and that it will become a well-used reference in your practice.

—Ilan Rotstein

Preface to the 6th Edition "Pull and be Damned Road" Revisited

The original sign for Pull and be Damned Road has been pilfered so many times the authorities have had to place a new sign over 20 feet above the ground. (Courtesy of Dr. James Stephens.)

Over 40 years ago, the preface to the first edition of *Endodontics* featured "**Pull & Be Damned Road.**" Nothing from the first edition left such a lasting impression as that saying. Even today, "old timers" come up to me at meetings to reminisce about this preface. They may not remember the details of endodontic cavity preparation or the chapter on pain first expressed in that edition. Those features have become an integral part of any endodontic practice. But they do remember "Pull and Be Damned Road." And for good reason.

Forty years ago it was more prevalent to extract teeth than to save them by root canal therapy. A plea was made in this preface to trust endodontic treatment and to reverse this trend toward "oral amputation." Gradually this became a fact, as endodontics spurred ahead and full dentures declined.

And this brings to mind an incident I long have savored. I was a speaker at the Hinman Dental Meeting in Atlanta. Joining me as a headliner was Dr. Will Menninger, head of the famous Menninger Psychiatric Clinic, then based in Topeka, Kansas. Dr. Menninger and his brother Karl were unquestionably the world's most famous psychiatrists. Dr. Will had been a brigadier general in World War II, head of all the army's psychiatrists. In 1948 he was the first psychiatrist on the cover of *TIME* magazine. It was an honor for me to be on the same program with him, and I eagerly attended his first lecture that preceded mine.

When I began my lecture, there was Dr. Menninger seated in the front row. I considered it professional courtesy on his part, but I did notice him taking notes.

The Hinman had a format wherein each lecturer would repeat his same lecture the next day. I didn't attend Dr. Menninger's second lecture but he attended mine. There he was again, seated in the front row. I was flattered beyond measure. At the end of the lecture I asked him why his sudden interest in endodontics. His reply was startling.

"Dr. Ingle," he said, "I was so impressed with your lecture, but I was also terribly embarrassed. On behalf of my profession I must apologize to you for my past behavior. When I think of how many patients I have recommended that they have their teeth extracted, I am appalled at the destruction I have caused. I had no idea. Now I find these teeth could have been saved and their abscesses healed. You have no idea how thankful I am to you, for directing me from my past behavior." Spoken like a psychiatrist!

We've come a long way since those days, a time of wholesale extractions. But we face a new challenge today; not wholesale extractions but selective extractions; for the sole purpose of placing an implant. Once again, dentists are urging patients to have teeth extracted, ignoring the fact that a healthy root is far preferable to a mechanical implant; less costly, less painful, less time consuming, and above all, more biological.

Now I'm not saying implants are unhealthy or less successful. What I am expressing is my concern that many salvable teeth are being sacrificed on the altar of insatiability. Back to pull and be damned. I'm not against implants! As a matter of fact, implant therapy is now being taught in a number of endodontic post doctoral programs. The thesis being, however, that teeth

that cannot or should not be saved by endodontics may well be extracted and replaced by an implant rather than a bridge. And who better to place that implant than a well-trained endodontist who has just made that judgment?

The 6th edition of *Endodontics* is replete with new innovations and knowledge. Now, more than ever, it remains the "Bible of Endodontics" a name long applied by others to the previous editions.

I feel most comfortable as I "pass the torch" to the new editors, Leif Bakland and Craig Baumgartner. And I have a feeling the profession will come to its senses; veering off "Pull and Be Damned Road" and onto the "Road Best Traveled."

Chapter 1

Anatomy and Morphology of Teeth and Their Root Canal Systems

Blaine M. Cleghorn, William H. Christie

Successful root canal therapy requires a thorough knowledge of tooth anatomy and root canal morphology,[1–3] which may be quite variable within the norm. Anomalies or deviations in the usual shape and root number in the adult human dentition outside the norm may also occur. When an anomalous form of tooth or root anatomy occurs fairly frequently in a given population or ethnic group, it should be considered a variant form and recognized.

Root canal treatment may fail if the root canal system is not fully identified and treated. Lack of knowledge of the variability of human root morphology, misadventure, and weakening of root structure may result in a search for a nonexistent canal. Therefore, a thorough knowledge of both normal and abnormal morphologic variations is required.

For each tooth in the permanent dentition, there is a wide range of variations reported in the literature. It specifically focuses on the frequency of occurrence of number and shape of root canals with each root, number of roots,[2,4–17] and incidence of molar root fusion.[18–24] A range of variations in the length of roots, overall size, and curvatures within root morphology are also treatment considerations but should be addressed outside this chapter.

A number of factors contribute to the variations in morphology, which are discussed in a few studies (Table 1-1). Root canal morphology of teeth is often extremely complex and highly variable,[2,4,6,13,15–17] as illustrated in the three-dimensional (3-D) models of the maxillary first molar in Figure 1-1.[6] Variations may also result from ethnic factors, age, and gender of the population studied.

Data generated from a series of teeth that were presented for endodontic treatment in a specialty endodontic practice may not represent the overall frequency of incidence in a general population, as more complex cases are more likely to be referred to a specialist,[62] thus skewing the sample reported in some clinical studies. Differences in reported results may also be due to the study design (clinical radiographs versus laboratory, gross morphology or microscopic)[63] or even unintentional bias in the selection of teeth to study and publication bias.

The "gold standard" for assessing canal morphology in laboratory studies is the clearing method, where extracted teeth are rendered transparent and a dye is injected into the canal systems. A 3-D shape of the entire length of the canals may be viewed under magnification and assessed according to the criteria predetermined by independent observers.

Results from early clinical studies generally reported fewer canals than *in vitro* bench studies. In recent years, however, data from clinical studies are becoming more comparable to laboratory studies. The use of dental loupes, headlights, surgical operating microscopes (SOMs), and ultrasonic methods has greatly improved the clinical detection of canals (Table 1-1).

The increased use of computed tomography (cone beam computed tomography [CBCT], spiral CT, helical CT, and micro-CT) has improved the accuracy of identification of canals and dramatically changed the reported results. Although there are some limitations with CBCT, both practically and economically, it has been shown to provide comparable results to those laboratory studies that used clearing methods.[199–207]

Another source of variations in the reported number of canals in clinical studies may be due to the authors' definition of what constitutes a canal. In some studies, a separate canal is defined as a separate orifice found on the floor of the pulp chamber,[26] two instruments placed simultaneously into two mesiobuccal canals of a maxillary first molar, to a minimum depth of 16 mm from the cusp of an intact tooth,[27] of which one can be instrumented to a depth of 3 to 4 mm,[12] or an analysis of treatable canals in retrospective clinical studies.[28] Other studies failed to provide a clear definition of a separate canal and may only look at radiographic outcomes.

CLINICAL ENLIGHTENMENT

From the Three-Canal Molar Tooth to the Four or More Canal Molars

In 1969, Weine et al.[122] provided the first clinical classification of more than one canal system in a single root and used the mesiobuccal root of the maxillary first molar as the sample specimen. Pineda and Kuttler[31] and Vertucci[14] further developed a system for canal anatomy classification for any tooth having a broad buccolingual diameter and is more applicable for use in laboratory studies (Figure 1-2). All canal types reported in this chapter are based on the

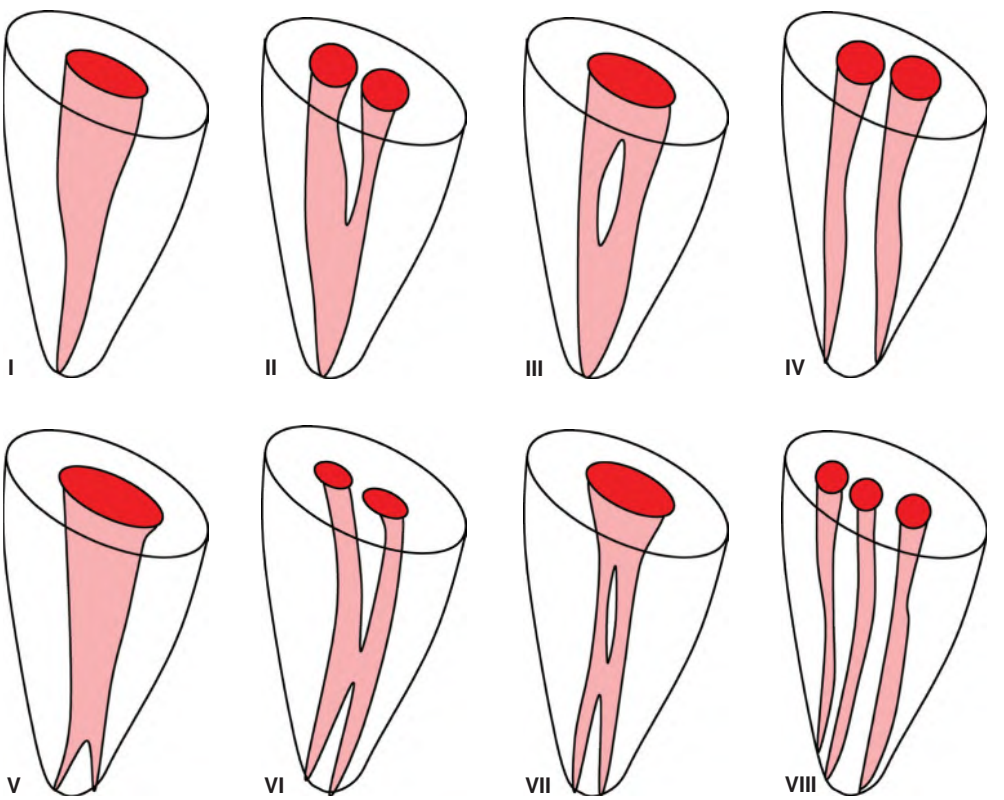

FIGURE 1-2 Vertucci's classification of root canal systems (Types I–VIII).

Vertucci's classification. Additional canal types not included in Vertucci's original classification system have been reported by Sert and Bayirli (Figure 1-3)[11] and Gulabivala et al.[91] Sert and Bayirli[11] reported an additional 14 new canal types that had not yet been classified.

Vertucci[14,208] found the proximity of the canal orifices to each other as indicative of whether they joined or remained as separate canals. If the separation of the orifices was >3 mm, the canals tended to remain separate through their entire length. In contrast, canals were usually joined together if the

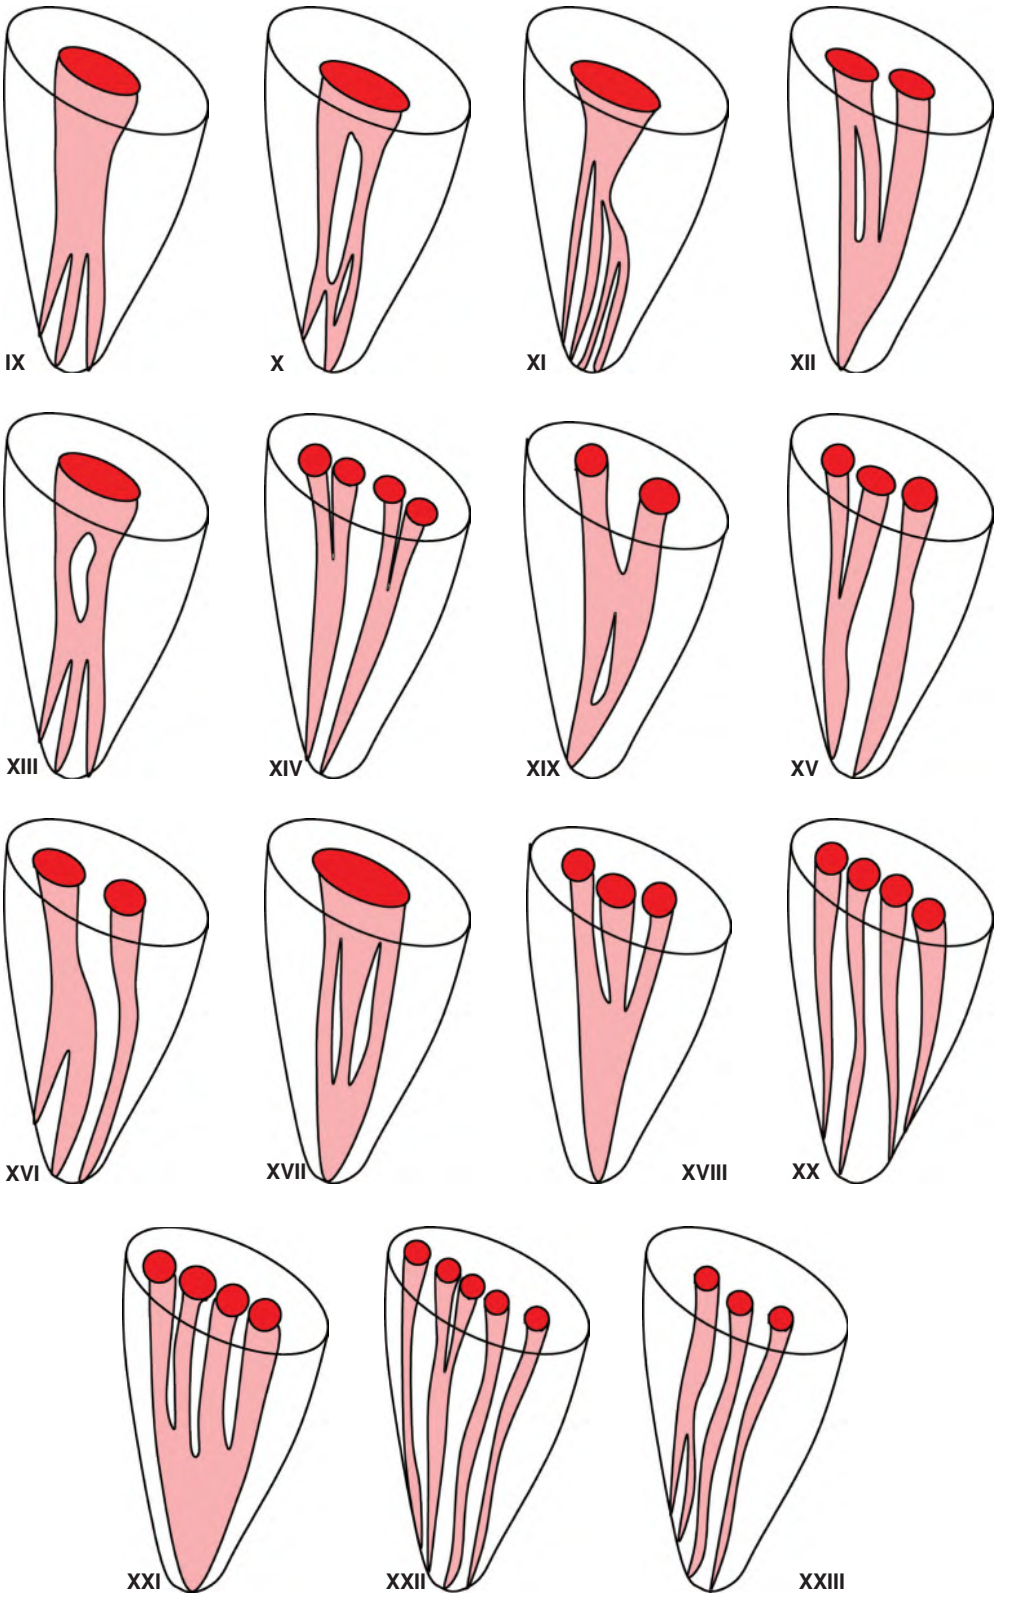

FIGURE 1-3 Sert and Bayirli's additional canal types to Vertucci's classification of root canal systems (Types IX–XXIII).

orifices were <3 mm apart. Canals were found to join more coronally as the distance between the orifices decreased.

As stated before, successful endodontic therapy is dependent on the cleaning, shaping, and obturation of the entire root canal system in three dimensions.[1–3] The presence of lateral canals and the ability to cleanse and seal these canal branches can also have an impact on prognosis.[209] Lateral canals include both accessory and furcation canals. These canals are smaller than the main canal but branch from (or into if one considers blood vascularity) the main canal to the periodontium.[2,208] Pineda and Kuttler[31,77,209] found that 30.6% of teeth had such ramifications. The majority of the ramifications or accessory canals were found in the apical third of the root. Zolty[209] and others have indicated that endodontic failure can be due to infection in these accessory canals. Clinical studies have demonstrated that careful recleansing and sealing of the root canal system can result in healing of associated periapical disease.[209,210]

This chapter provides evidence-based information on the root and root canal morphology, both the number of roots and number of canals within each of the tooth in the permanent dentition from the central incisor to the second molar in both maxillary and mandibular arches. The permanent third molars have not been included in this review due to their high degree of variability of crown and root morphology.

External root anatomy, canal numbers and types, and root canal system anatomy are described through a literature review of anatomical studies and case reports. The percentages reported in the tables may exceed 100% due to rounding of numbers to tenths or due to incorrect tabulations from papers cited. The following is a description of the normal and many variations in human tooth anatomy and root morphology as gleaned from the available literature to date.

MAXILLARY CENTRAL INCISOR

External Root Morphology

The cross-sectional root anatomy of the maxillary central incisor is triangular to ovoid in shape and tapers toward the lingual[1,3,4,6,13,15,17] as illustrated in Figure 1-4. Root concavities are normally not present in maxillary central incisors.[211] The root trunk is generally straight and tapers to a blunt apex. The overall average length of the maxillary central incisor is 23.5 mm with an average crown length of 10.5 mm and an average root length of 13 mm.[4]

Root Number and Form

The majority of anatomic studies found that the maxillary central incisor is a straight, single-rooted tooth (Table 1-2), unless rare developmental anomalies are present.

Canal System

The maxillary central incisor is usually a single root canal system (Table 1-3). Over 99% of the teeth in the studies cited in Table 1-3 had a single root canal and a single apical foramen. Mid-root and apical lateral canals and apical delta canals are common (Figure 1-5). These lateral canals with small arterioles and venules serve as collateral circulation. When the pulp becomes diseased, Schilder[210] referred them as "portals of exit" into the surrounding periodontal ligament space.

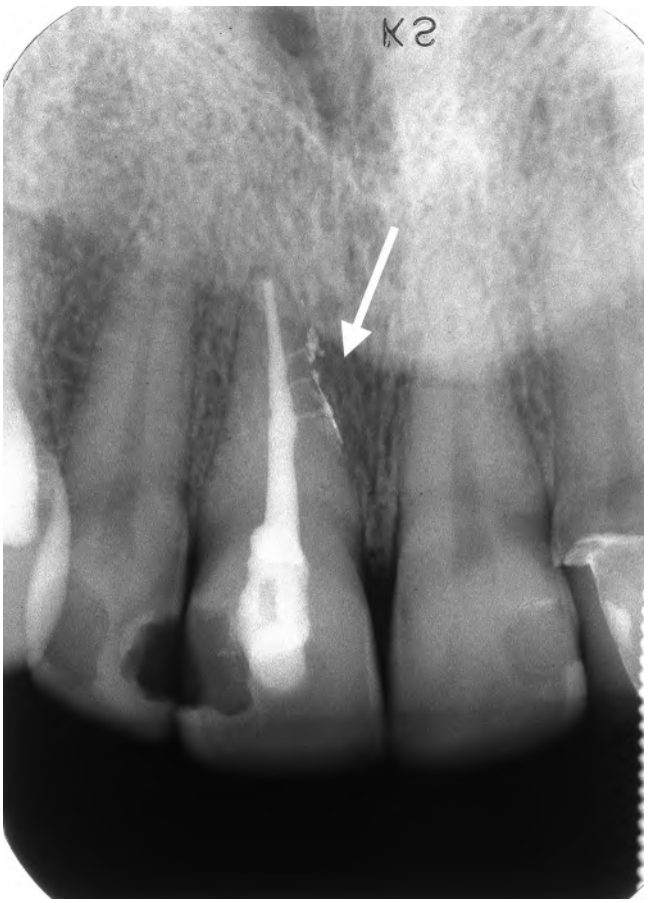

FIGURE 1-5 Maxillary right central incisor with normal anatomy. Presence of lateral canals is demonstrated by sealer extrusion (arrow). (Courtesy of Dr. William H. Christie, Winnipeg, MB, Canada.)

Relatively few studies have investigated the apical root anatomy of teeth. Altman et al.[212] investigated 20 extracted maxillary central incisors. On histological examination, accessory or lateral canals were found in three quarters of the specimens, exhibiting one to four accessory canals. One specimen was found to have 20 separate foramina, but this anomalous canal anatomy occurred on a central incisor from a 9-year-old individual. They concluded that radiographic examination was not accurate in diagnosing accessory canals and that resorptions, appositions, pulp stones, and accessory canals were commonly found in the apical 2.5 mm of the maxillary central incisors.

The classic stereomicroscopic study of root apices by Green,[213] in 1956, found that the average diameter of the major foramen in the 50 teeth studied was 0.4 mm, while the accessory foramina were 0.2 mm or less in diameter. The average distance of the major apical foramen from the anatomical root apex was found to be 0.3 mm. Approximately 12% of the maxillary central incisors exhibited accessory foramina in their sample.

Mizutani et al.[214] investigated the anatomic location of the apical foramen in 30 maxillary central incisors. The root apex and apical foramen were displaced distolabially in the majority of the specimens. Coincidence of the apical foramen and root apex was found in only one out of six specimens (~17%).

Kasahara et al.[215] assessed the apical anatomy of 510 extracted maxillary central incisors. Apical ramifications were found in about 12% of cases. Lateral canals were present in 49%. Only 38.6% of the teeth had a simple main canal without lateral canals or apical ramifications. In this study, 90% of the foramina were located within 1.0 mm of the anatomical apex.

Variations and Anomalies

Seventy-five case reports of abnormalities of the maxillary central incisor were identified in a review of the literature (Table 1-4). The four most common variations or anomalies identified in decreasing order were talon cusps, two roots and two canals, one root and two canals and fusion. Ethnic variations have been attributed for some coronal traits. Shovel-shaped incisor crowns with heavy lingual ridge formation and even labial buttressing to varying degrees are a common feature in Asian (including North Americans), Natives formerly described as "Mongoloid" populations, but are relatively rare in Caucasian populations.[13,53,216–220]

A study by Pecora and da Cruz Filho[65] assessed the incidence of radicular grooves in the maxillary incisors of 642 patients. Loss of periodontal attachment associated with these grooves can result in a deep, narrow, vertical periodontal pocket. The incidence of radicular grooves was found to be 0.9% in the maxillary central incisors and 3.0% in maxillary lateral incisors. The prognosis, even with combined periodontal-endodontic treatment, in such cases can be poor.[221] Reports of other types of root anomalies associated with the maxillary central incisor are relatively uncommon.

The prevalence of fusion and gemination was assessed by Hamasha and Al-Khateeb[222] from within a large sample size of 9373 teeth in a Jordanian population. The prevalence of fusion was found to be 2.6% while gemination of the tooth bud was found in 0.94% of the samples for a total incidence of 3.6% of so-called "double teeth." The maxillary central incisor had the highest incidence of fusion and gemination of all permanent teeth.

TABLE 1-4 Variations and Anomalies Associated with the Maxillary Central Incisor

Total number of case report references and cases	75	74

al-Nazhan[223] reported a case of a central incisor with enamel hypoplasia and two canals in a single root.

Examples of fusion with a supernumerary tooth,[222,224–226] fusion with a maxillary lateral incisor,[227] gemination,[222,224,228,229] talon cusps,[228–232] two canals,[233,234] dens invaginatus,[235] and maxillary central incisors with two roots[236–241] are occasionally documented in case reports. A single case of gemination and fusion with a supernumerary tooth resulting in a tooth with three canals was reported by Hosomi et al.[242]

An unusual combination of anomalies was reported by Lorena et al.[243] Anomalies in the maxillary arch included shovel-shaped incisors, dens invaginatus, peg-shaped supernumerary teeth, and Carabelli cusps on the maxillary first molars in the absence of any developmental anomaly. McNamara et al.[244] also reported a combination of anomalies that included maxillary central and lateral incisors that had talon cusps, short roots and dens invaginatus, premolars with short roots, and Carabelli cusps on the maxillary first and second molars. A rare case of a labial talon cusp on a maxillary central incisor was reported by de Sousa et al.[231]

MAXILLARY LATERAL INCISOR

External Root Morphology

The cross-sectional root anatomy of the maxillary lateral incisor is described as being circular, oval, or ovoid in shape and tapers toward the lingual as illustrated in Figure 1-6.[1,3,4,6,13,15,17,214] Root concavities are normally not present on the root of the maxillary lateral incisors.[211] The root trunk

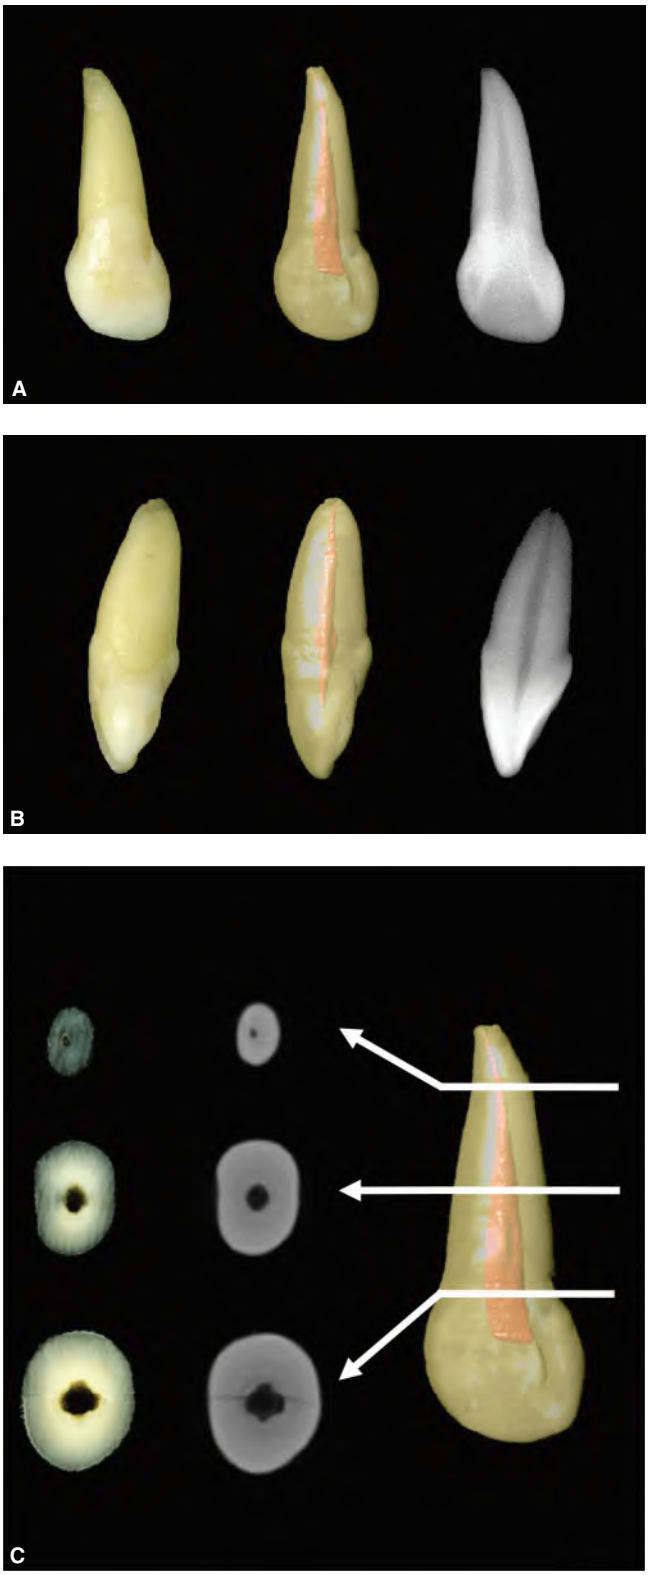

FIGURE 1-6 Maxillary right lateral incisor. ***A.*** Labial view. ***B.*** Mesial view. ***C.*** Root cross-sections. (Reprinted with permission from Brown P, Herbranson E. Dental Anatomy and 3-D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary Lateral Incisor- Rotations and Slices.)

is generally smaller than a central incisor and has a finer root tip, often terminating in a curve to the distal or lingual, or both (Figure 1-7). The overall average length of the maxillary

lateral incisor is 22 mm with an average crown length of 9 mm and an average root length of 13 mm.[4]

Root Number and Form

Anatomical studies indicate that the maxillary lateral incisors are single-rooted virtually 100% of the time[5,7,11,14,31] as shown in Table 1-5. However, numerous case reports demonstrate significant variability in anatomy. Most reported cases of two-rooted maxillary lateral incisors are a result of fusion or gemination and are usually associated with a macrodont crown. There are a few reported cases of two roots associated with normal crown dimensions.[294–297] Anomalous two-rooted maxillary lateral incisors are usually associated with a developmental radicular lingual groove. Even in single-rooted maxillary incisor teeth, a deep gingivo-palatal groove may often result in localized periodontal disease.

Canal System

The maxillary lateral incisor usually presents with a single canal as demonstrated by the anatomical studies shown in Table 1-6. Mizutani et al.[214] investigated the anatomic location of the apical foramen in 30 maxillary lateral incisors. The root apex and apical foramen were displaced distolingually in a majority of the specimens. Displacements in all directions were also found in the study. Coincidence of the apical foramen and the anatomic root apex was found in only 2 (6.7%) of the specimens. Therefore, exploration of the apical foramen and constriction, with a fine pre-curved #10 size file tip, delicate tactile sense, and the electronic apex locator, is essential to locate the foramen. The use of CBCT, although not essential, may also help determine the degree and direction of curvatures of the canal system.

An early stereomicroscopic study of root apices by Green[213] found that the average diameter of the major foramen in the 50 maxillary lateral incisors studied was 0.4 mm while the accessory foramina were 0.2 mm or less in diameter. The average distance of the major apical foramen from the anatomical root apex was found to be 0.3 mm. Approximately 10% of the maxillary lateral incisors exhibited accessory foramina.

Variations and Anomalies

One hundred and thirty cases presented in 107 references illustrate the high degree and range of variability in the morphology of the maxillary lateral incisor (Table 1-7). The most common variation reported was dens invaginatus (46 cases), followed by dens evaginatus (talon cusp), palato-gingival grooves, and two roots and two canals in decreasing order of frequency.

Maxillary lateral incisors often present with anomalous anatomy, resulting in diagnostic and treatment challenges. Complications resulting from radicular grooves have been well documented by Simon et al.[221] The incidence of radicular

grooves is 3.0% in maxillary lateral incisors (Figure 1-8) in a study by Pecora and da Cruz Filho,[65] and there are several case reports in the literature confirming the high probability of this finding.[140,296,299–311] Peikoff and Trott[309] reported the histology of an endodontic-periodontic failure in a maxillary lateral incisor with an accessory root and a radicular groove (Figure 1-9).

An SEM investigation of 14 extracted maxillary lateral incisors with radicular grooves concluded that direct communication between the groove and the pulp was evident in these specimens and that accessory canals were the primary mechanism of communication between the periodontium and the pulp.[140] As with maxillary central incisors, the degree of shovel-shaped feature of the crown is varied and is often based on ethnic background. Again, this feature is common in Asian populations and rare in Caucasian populations.[13,53,216,217,219,220] Reports of this and other coronal anomalies associated with the maxillary lateral incisor are common.

Dens invaginatus or "*dens in dente*" can be present in various forms.[65,231,266,285,310,312–325,330–342,350–358,379,382] Oehlers[384] classified dens invaginatus into three types based on the severity of the defect. Type 1 dens invaginatus is an invagination confined to the crown. Type 2 extends past the cementoenamel junction but does not involve periapical tissues. The most severe form and most complex to treat is a Type 3 defect. The invagination extends past the cementoenamel junction and may result in a second apical foramen. Combination of non-surgical and surgical therapy is often used to successfully treat Type 2 and Type 3 cases.[310,312,316,318,320,322–324,331–333,335,336,338,341,342,354,355,358,366] Non-surgical management of the dens invaginatus, including the more severe Type 3 defects, have also been reported.[310,313–315,317,321,325,334,337,339,340,376,385] Occasionally, the vitality of the pulp in the main canal has been shown to be maintained while treating (surgically, non-surgically, or both) the accessory root and canal system, when there has been no communication between the two.[319,323,337–339] (For more details, see Chapter 26, "Endodontic retreatment and management of mishaps.")

Mupparapu et al.[382] reported a rare finding of both dens invaginatus and dens evaginatus associated with one maxillary lateral incisor. It could be noted that most case reports

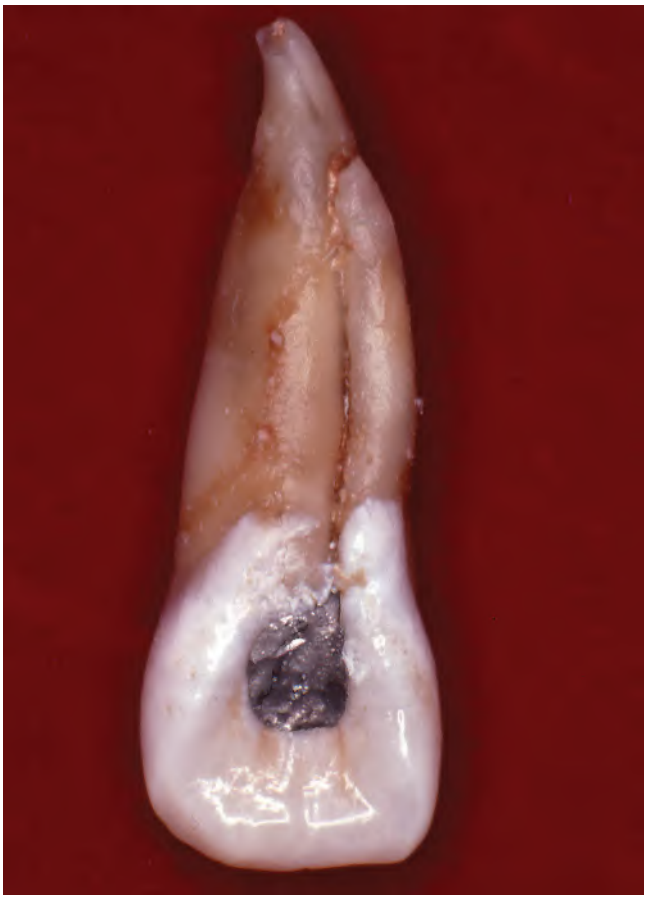

FIGURE 1-8 Radicular developmental groove (lingual view) in a maxillary left lateral incisor caused periodontal failure and was extracted. (Courtesy of Drs. William H. Christie and Colin Dawes, Winnipeg, MB, Canada.)

FIGURE 1-9 Maxillary left lateral incisor with accessory root. Note, sealer extruding through accessory root canal. (Courtesy of Dr. Marshall D. Peikoff, Winnipeg, MB, Canada.)

of anomalous root formation in maxillary lateral teeth document single (unilateral) teeth. Kannan et al.[356] documented two unilateral and one bilateral incidence of dens invaginatus in their case report. The presence of bilateral Peg-lateral teeth with conical crowns and small root and root canal system is a common finding.

MAXILLARY CANINE

External Root Morphology

The root of the maxillary canine is oval in shape and tapers toward the lingual as illustrated in Figure 1-10C.[1–4,6,13,15,17] The root is wider labiolingually and is the longest root in the dentition.[4] Prominent developmental depressions that appear as a double lamina dura on periapical radiographs can be present on both its mesial and distal surfaces, especially in the middle third of the root as shown in Figure 1-10A and B.[4,6] The root tip may be blunt or it may end in a fine, often curved tip (Figure 1-10A–C). The overall average length of the maxillary canine is 27 mm with an average crown length of 10 mm and an average root length of 17 mm.[4]

Root Number and Form

Most studies have found that the maxillary canine has a single root 100% of the time[5,7,11,14,31,386] as shown by the

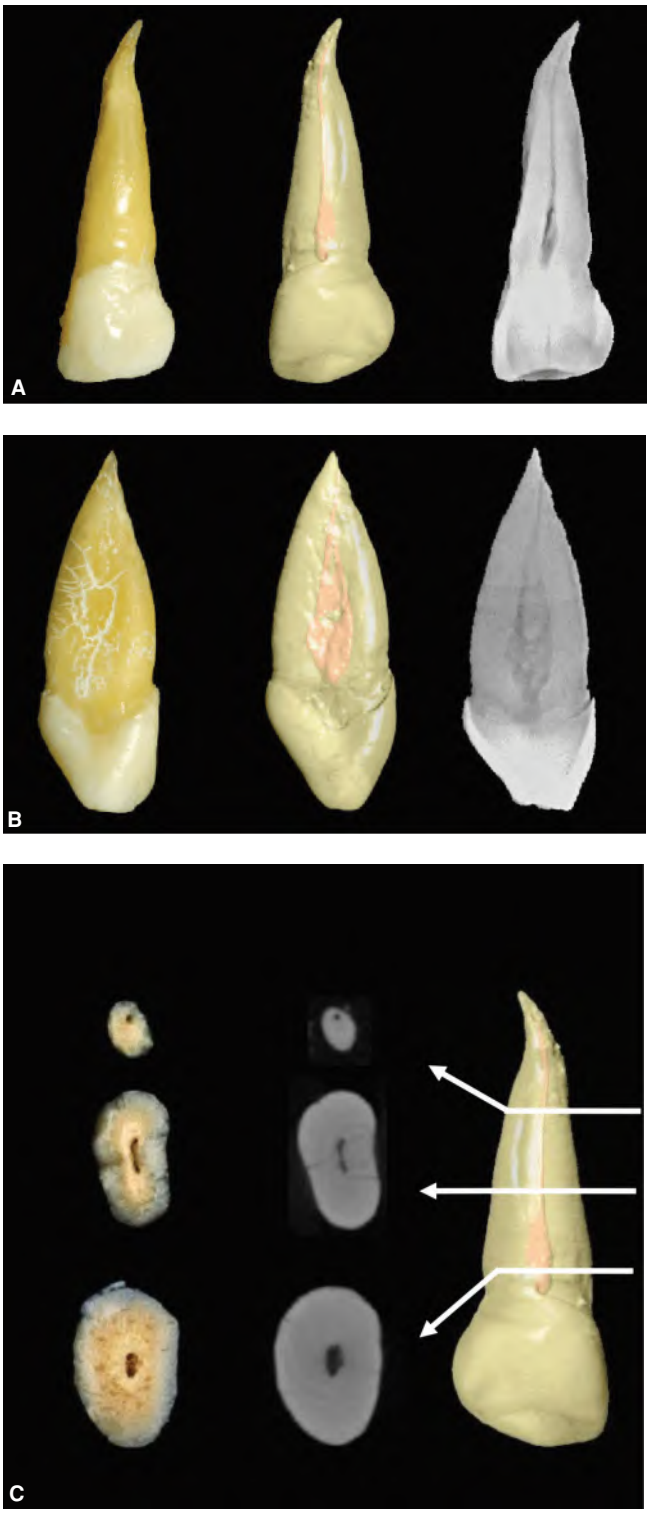

FIGURE 1-10 Maxillary left canine. ***A.*** Labial view. ***B.*** Mesial view. ***C.*** Root cross-sections. (Reprinted with permission from Brown P, Herbranson E. Dental Anatomy and 3-D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary Canines-Rotations and Slices.)

anatomic studies in Table 1-8. However, there are case reports of two-rooted maxillary canines.[387,388]

CANAL SYSTEM

The maxillary canine usually has a single canal. A small percentage of maxillary canines have two canals in a figure "8" form (4.7%) as shown in Table 1-9.[5,7,11,14,31,78,298] Of those having two canals, the majority (98.0%) join in the apical third and exit through a single foramen. Accessory (lateral) canals are not uncommon and become evident radiographically as midroot radiolucencies or sealer-puff (Figure 1-11) after completion of root canal treatment. The majority of lateral canals occur in the apical third of the tooth, but midroot lateral canals can also occur (Figure 1-11). Mizutani et al.[214] investigated the anatomic location of the apical foramen in a sample of 30 maxillary canines. The root apex and apical foramen were displaced distolabially in the majority of the specimens. Coincidence of the apical foramen and root apex was found in only 5 (16.7%) of the specimens. The use of the electronic apex locator is more reliable than the radiograph in determining the apical foramen or constriction in most canine teeth.

Green[213] found that the average diameter of the major foramen in 50 maxillary canines studied was 0.5 mm while the accessory foramina were 0.2 mm or less. The average distance of the major apical foramen from the anatomical root apex was found to be 0.3 mm. Approximately 12% of the maxillary canines exhibited accessory foramina.

Variations and Anomalies

The maxillary canine usually presents very few anatomical variations. An extensive literature review found 17 case reports (Table 1-10). When variations do occur, the root is more frequently affected than the crown. However, there are occasional reports of both coronal and radicular anomalies. The root can be dilacerated[16] or can have extreme variations in length.[2,4,6,13,16] One individual with an extremely long root (41 mm) was reported by Booth.[389] His patient was a 5′2″ height, 31-year-old woman of Dutch ancestry.

Dens evaginatus, in a form of a lingual tubercle or talon cusp, was the most common variation or anomaly found associated with the maxillary canine. There are also reports of labial tubercles.[400] Dankner et al.,[40] in an extensive literature review and radiographic examination of 15,000 anterior teeth, found the overall incidence of dens evaginatus to be ~1%. Their survey found no occurrences of dens evaginatus in the maxillary canine. Between 1970 and 1995, there were only four case reports of dens evaginatus in the maxillary canine in their review.

Other variations reported in the literature include case reports with one root and two canals,[396,397] two roots,[387,388] dens invaginatus,[235,390–395] and bilateral, supernumerary canines in a non-syndrome case.[398] The two-rooted maxillary canine should be considered extremely rare, unlike the two-rooted mandibular canine, which in some genetic populations can be a more frequent anomaly.[5,401]

MAXILLARY FIRST PREMOLAR

External Root Morphology

The root anatomy of the maxillary premolar can vary depending on whether one, two, or three roots are present (Figures 1-12, 1-13, 1-14). Also, a variation may exist in the depth of the bifurcation or trifurcation of the root trunk. The more common two-rooted form is illustrated in Figure 1-12. As with all multirooted teeth, two radiographs exposed at different angulations or even CBCT images (if indicated), may be needed to better understand the actual root and canal morphology.

The maxillary first premolar does exhibit ethnic variations with respect to root number (Table 1-11). There are some common features to the various forms. The overall length of the maxillary first premolar is 22.5 mm with an average crown length of 8.5 mm and an average root length of 14 mm.[4]

Prominent root concavities are present on both the mesial and distal surfaces of the root trunk. The mesial root concavity is more prominent and extends onto the cervical third of the crown.[1,3,4,6,13,15,17,402] This results in a root that is broad labiolingually and narrow mesiodistally with a kidney shape when viewed in cross-section at the cementoenamel junction.[4] These anatomical features have implications in restorative dentistry and in periodontal treatment, and are common areas for inadvertent endodontic root perforations.

Gher and Vernino[403] examined the external root shape as it is related to the development of periodontal defects. The

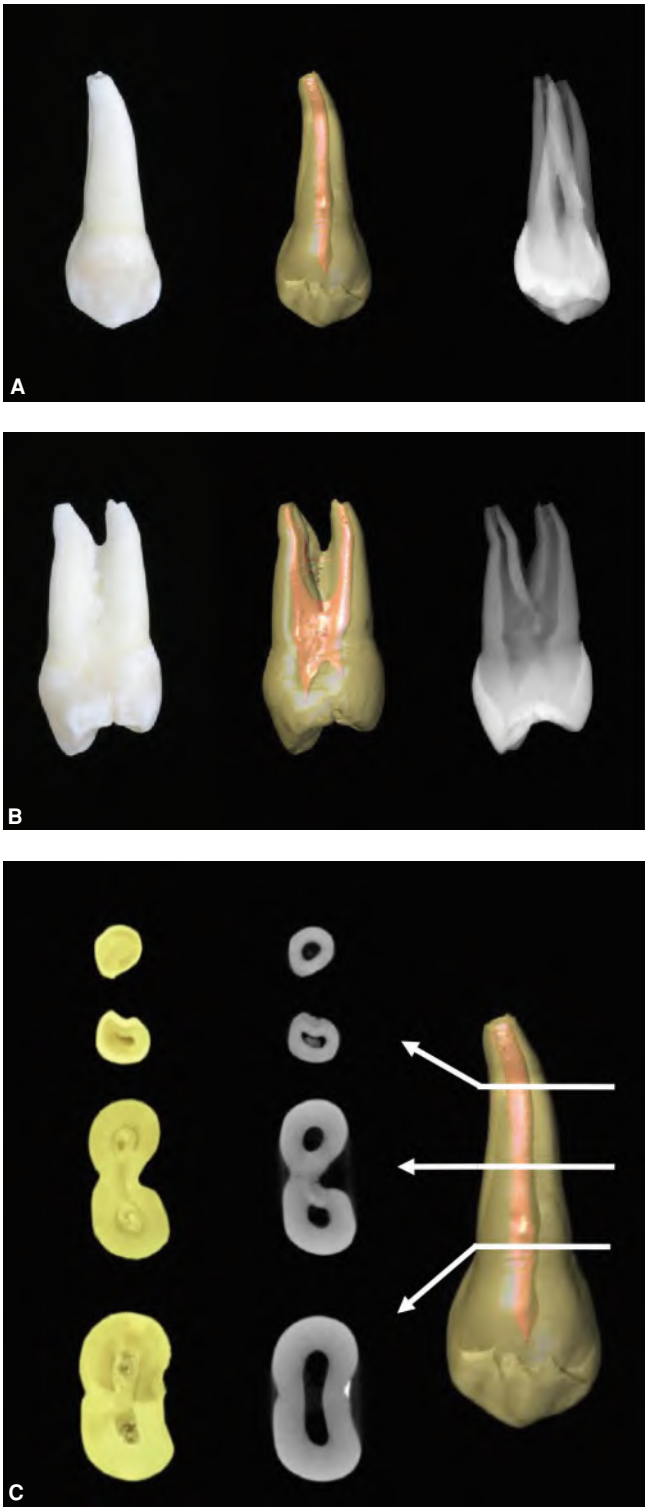

FIGURE 1-12 Maxillary right first premolar. ***A.*** Buccal view. ***B.*** Mesial view. ***C.*** Root cross-sections. (Reprinted with permission from Brown P, Herbranson E. Dental Anatomy and 3-D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary First Premolar- Rotations & Slices.)

palatal aspect of the buccal root tip of two-rooted maxillary first premolars usually has a deep longitudinal depression along its length. About 78% of the 45 teeth in their study

FIGURE 1-13 Maxillary left first premolar with three roots and three canals (MB, DB, and Palatal). Palatal root has a coronal post-space preparation. (Courtesy of Dr. William H. Christie, Winnipeg, MB, Canada.)

exhibited a buccal furcation groove. They concluded that a buccal root furcation groove was a normal anatomical feature in those two-rooted maxillary first premolars that have well-formed buccal and lingual roots. The groove was not generally found in those two-rooted specimens with a furcation located in the apical third of the root. A study by Joseph et al.[404] found an incidence of the buccal furcation groove in 62% of teeth with bifurcated roots.

Root Number and Form

The majority of anatomic studies found that the most common form of the maxillary first premolar is the two-rooted form (Table 1-11). There was a wide variation in incidence of the number of roots in the anatomical studies cited. The incidence of three-rooted maxillary first premolars ranged from 0%[5,54,69] to 6%.[135] The ethnic background of the patients in many of the studies was not identified. The majority of studies reporting that the two-rooted form was most common had a probable Caucasian cohort, forming the majority of the population. Studies, which do identify ethnic background, have demonstrated distinct differences between Asian and Caucasian populations. Single-rooted maxillary first premolars are the dominant forms in Asian population[54,94,138,180] and three-rooted forms are rarer by 1:4 ratio.[54,69,138,180] Because of the significant influence of ethnic background in root number for this tooth, Table 1-11 reports the means for all studies and separates the data between Asian and North American Native populations (both Sundadont and Sinodont Mongoloid) versus non-Asian populations.[405,406]

FIGURE 1-14 Extracted maxillary right first premolar with three very fine roots (MB, DB, and Palatal). (Courtesy of Dr. William H. Christie, Winnipeg, MB, Canada.)

In addition to ethnic differences, studies vary in their definition, or do not identify what constitutes a bifurcated root. Walker[54] utilized Turner's classification and does not consider a root to be separate unless it is a distinct and separate root for at least half of the overall root length. However, Loh[69] grouped teeth into one root, two roots (including two-root distinct and two-root fused), and three roots. The

two-root fused category was defined as teeth with roots joined almost to the apex and with two canals at their origin. The normal external three-root anatomy configuration is that of a mesiobuccal, distobuccal, and palatal root with morphology similar to that of a miniaturized maxillary three-rooted molar.

Sabala et al.[22] studied all aberrant root and root canal morphology in 501 patient records. The occurrence of the same aberration on the contralateral tooth varied according to the type of anomaly. In four of 501 patients, who were found to have three-rooted maxillary first premolars, all were bilateral. Their study found that the more rare the anomaly, the greater the incidence of the anomaly occurring bilaterally. Anomalies occurring <1% were found to occur bilaterally up to 90% of the time.

Canal System

The majority of maxillary first premolars were found to have two canals, whether the tooth had a single- or double-root morphology (Table 1-12). In 21 anatomical reports assessed, over 80% of the teeth had two canals.[5,7,8,11,31,54,69,76,78,88,89,94,103,109,113,135,167,185,408–410] Ethnicity was a factor affecting the canal number. The incidence of a Vertucci Type I single canal was significantly higher in Asian populations compared to mixed non-Asian populations.[54,69] The Vertucci and Weine classification systems are useful in exploring any canal systems with double canals in single roots for endodontic therapy.[14,122]

All the three-rooted first premolars in the anatomical studies were found to have a single canal in each root. The incidence of three canal maxillary premolar teeth ranged from 0%[54,69,409,410] to 6%.[135] This finding is a rare occurrence in Asian populations.[54,69]

Regardless of the number of roots, the majority of maxillary first premolars (80.8%) had two separate canals and 73.6% had two separate foramina at the apex.

TABLE 1-13 Variations and Anomalies Associated with the Maxillary First Premolar

2 roots and 3 canals[426]	1	1
Gemination[427]	1	1
Total number of case report references and cases	27	20

Variations and Anomalies

The most common variation reported for the maxillary first premolar was three roots and three canals (Table 1-13). Ethnic differences were found (Table 1-11). The study by Loh[69] reported a much lower incidence (50.6%) of the two-rooted maxillary first premolars in a Singaporean population compared to Sabala et al.'s study[22] (98.4%) based in the United States. Tratman[53] reported that the two-rooted first premolar was very uncommon in Asian stock as did

Petersen[51] in his study of the East Greenland Eskimo dentition. A more recent large anatomical study of 3202 maxillary first premolars in Japan by Aoki,[138] found that 65.7% of the specimens were single rooted.

Three-rooted forms were reported to be rare variations in Asian populations.[418,419,423] Mattuella et al.[426] reported a variation of the maxillary first premolar with a longitudinal sulcus on the buccal surface of the buccal root. This variation resulted in a two-canal system in the buccal root as the root canal system narrowed with age and thus, three canals in teeth with two roots. Gemination of the maxillary first premolar is rarely reported.[427]

Taurodontism is another rare anomaly in premolars, as a group, and less common in the maxillary premolars compared to their mandibular counterparts. Taurodontism of roots and canal systems is explained in greater detail in the section on maxillary first molars. Llamas et al.[428] found only three taurodont-like maxillary premolars in a sample of 379 extracted maxillary and mandibular premolars. Of the 16 cases of taurodontism in Shifman et al.'s review of radiographs, over a five-year period, none were maxillary first premolars.[429] Madeira et al.[430] studied 4459 premolars and found a total of 11 taurodont mandibular premolars (seven mandibular first premolars and four mandibular second premolars), but none in the maxillary premolars. Llamas et al.[428] reported three taurodont maxillary first premolars of the 379 teeth.

The Weine Type IV root canal system (Vertucci's Type V), with a wide buccolingual canal that branches into two apical canals and foramina in the apical third, may sometimes be confused as taurodont-like root canal anatomy, when it occurs in single rooted maxillary premolar teeth.

MAXILLARY SECOND PREMOLAR

External Root Morphology

The cross-sectional root anatomy of the maxillary second premolar in the mid-root area is described as oval or kidney shaped.[1,3,4,6,13,15–17] Developmental depressions are often present on the mesial and distal aspects of the root, but generally less pronounced than on the maxillary first premolar. The typical single root trunk is broad buccolingually and is narrower mesiodistally (Figure 1-15). The root tip usually ends as a single blunt apex, but may be fine and divide into two or more, rarely three, apices. Curvature in the apical third is also not uncommon. The overall average length of the maxillary second premolar is 22.5 mm with an average crown length of 8.5 mm and an average root length of 14 mm.[4]

Root Number and Form

All of the anatomical studies cited found that the most common form of the maxillary second premolar is a single root (Figure 1-15). The mean for data from eight anatomical studies of 9033 teeth is summarized in Table 1-14, resulting in a 91.5% incidence of single-rooted teeth. The incidence of two-rooted maxillary second premolars ranged from 1.6%[410] to 20.4%,[408] while the three-rooted form was a rare finding and ranged from 0%[5,87,410,431,432] to 1%.[408] Bilateral

symmetry of the three-rooted form may be expected in many patients, as well as this anomaly occurs in both first and second premolar teeth.[22]

Canal System

The maxillary second premolar has a single canal in ~51.8% of the 4829 teeth examined in 16 anatomical studies (Table 1-15).[7,11,14,31,78,80,87,89,167,185,408–410,431,433] Therefore, even though over 90% of these teeth have a single root, a high proportion will have two canals present. Canal exploration of maxillary second premolar teeth should be done with fine curved files, keeping in mind many types of the Vertucci's[14] or Weine's[122] classification of "two canals in one root" that may not always be apparent on the radiograph. The incidence of three canals was low in each of the anatomical studies. The majority of the teeth studied (63.6%) had a single canal and foramen at the apex.

Variations and Anomalies

Relatively few case reports of variations and anomalies in the maxillary second premolar have been published (Table 1-16). The most common variation reported is the maxillary second premolar with three roots and three canals.[419,433–440] These case reports also include examples of dens invaginatus,[441] a deep distal root concavity,[442] dens evaginatus,[443,425] taurodontism,[429] two roots, and three canals.[6]

Three-rooted maxillary second premolar teeth do not seem to be as common as in first premolars. This anomaly is often bilateral and should be considered by exposing radiographs taken at different angles. Both first and second premolar triple-canal system anomalies do occur, but rarely.[419]

TABLE 1-16 Variations and Anomalies Associated with the Maxillary Second Premolar

MAXILLARY FIRST MOLAR

External Root Morphology

The maxillary first molar normally has three roots (Figure 1-16). The mesiobuccal root is broad buccolingually and has prominent depressions or flutings on its mesial and distal surfaces.[1,3,4,6,15–17] The internal canal morphology is highly variable but the majority of the mesiobuccal roots contain two canals. The distobuccal root is generally rounded or ovoid in cross-section and usually contains a single canal. The palatal root is more broad mesiodistally than buccolingually and ovoidal in shape but normally contains only a single large canal. Although the palatal root generally appears straight on radiographs, there is usually a buccal curvature in the apical third.[445] Depressions on the

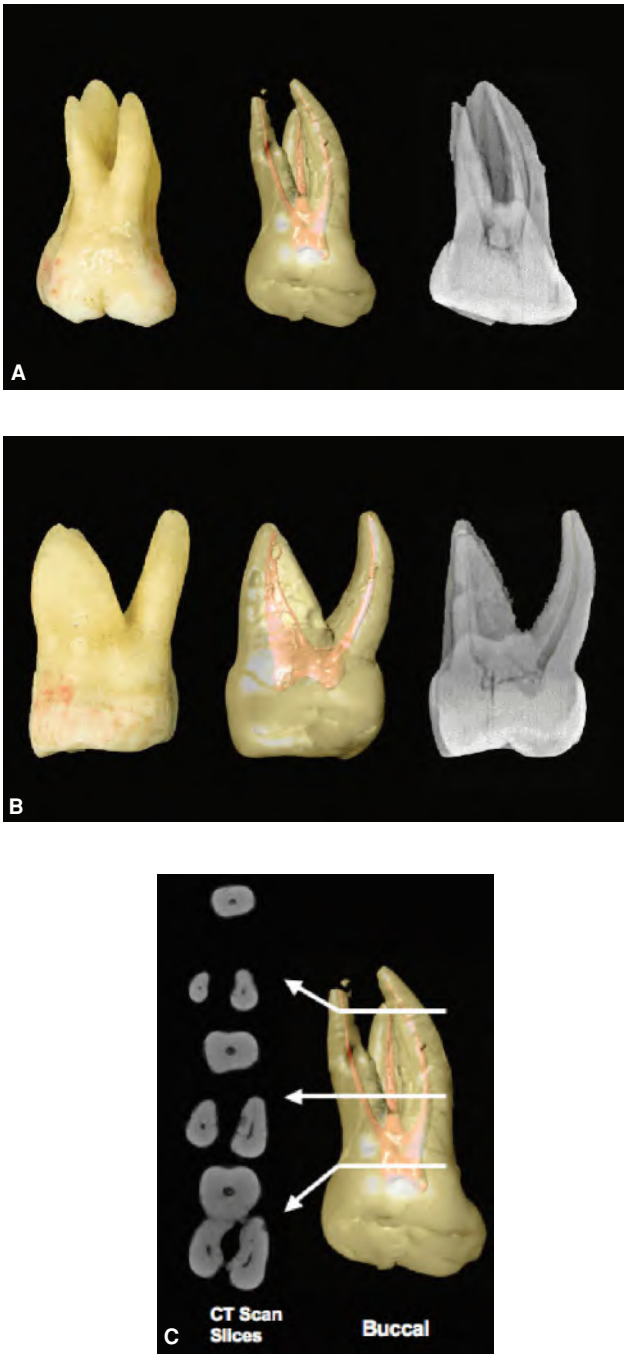

FIGURE 1-16 Maxillary right first molar. ***A.*** Buccal view. ***B.*** Mesial view. ***C.*** Root cross-sections. (Reprinted with permission from Brown P, Herbranson E. Dental Anatomy and 3-D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary First Molar- Rotations & Slices.)

buccal and palatal surfaces of the palatal root can be present but are generally shallow. Gher and Vernino[403] found prominent depressions not only on the mesial aspect but also on the distal aspect of the mesiobuccal roots. Shallow depressions could also be found on the furcal side of the distobuccal and palatal roots.

The overall average length of the maxillary first molar is 20.5 mm with an average crown length of 7.5 mm and an average root length of 13 mm.[4]

Root Number and Form

The maxillary first molar root anatomy is predominantly a three-rooted form, as shown in all anatomic studies of this tooth (Table 1-17). The two-rooted form is rarely reported, and may be due to fusion of the distobuccal root with palatal root or the distobuccal root with the mesiobuccal root. The single root or conical form of root anatomy in the first maxillary molar is very rarely reported.[5] Over 97.7% of maxillary first molars had three roots and 2.1% had two roots in 12 studies that included 2744 teeth. The four-rooted anatomy in its various forms is also very rare in the maxillary first molar and is more likely to occur in the second or third maxillary molars.[446,447]

The incidence of fusion (Table 1-18) of any two or three roots was ~5.9%.[18–23,182,448,449] The "C" shape canal morphology in the maxillary first molar is also a rare anomaly with an incidence varying from 0.09% to 0.3%.[449,450]

Canal System

Internal root canal system morphology reflects the external root anatomy. The mesiobuccal root of the maxillary first molar contains a double root canal system more often than a single canal according to most of the anatomical studies. This review contains data on the canal morphology of the mesiobuccal root that included a total of 14,346 teeth from 71 studies (Table 1-19). The incidence of two canals in the mesiobuccal root was 59.4% and of one canal was 40.6%. The incidence of two canals in the mesiobuccal root was somewhat higher in laboratory studies (64.0%) compared to clinical studies (56.8%).[11,30,132,139,143,148,183,451–454] Less variation was found in the distobuccal and palatal roots (Table 1-19). One canal was found in the distobuccal root in 98.8% of teeth, whereas the palatal root had only one canal in 99.3% of the teeth studied.[62]

Earlier *in vitro* studies of the mesiobuccal root canal system were slightly more likely to report two canals in the maxillary first molar than the *in vivo* clinical studies, but the incidence of location of a two-canal system in both clinical

and laboratory studies appears to be increasing with the routine use of the SOM and other aids during the modified endodontic access opening procedure.[12,459] The diagnostic tool that has had the greatest impact in both clinical and laboratory studies is CBCT. The Clearing Technique has been the "gold standard" in laboratory studies, and the CBCT is rapidly becoming the "gold standard" in clinical studies as well as in laboratory studies.[198–201,203–207,462–464] However, it should be noted that nine of the *in vitro* laboratory studies reported an incidence of second mesiobuccal canal (MB-2) in 80% to 96% of the time.[11,132,139,143,148,451–454] Four were clearing studies,[11,139,451,454] two utilized CT,[143,148] and three used either an SOM or surgical telescopes.[132,452,453] Two of the *in vivo* clinical studies reported an incidence of MB-2 of >80%.[30,183] One study was a clinical RCT study[30] and the other utilized CBCT.[183]

The two-canal system of the mesiobuccal root of the maxillary first molar has a single apical foramen ~59.7% of the time (Table 1-19).

The single-canal system and single apical foramen in the distobuccal and palatal root of the maxillary first molar is the most predominant form, as reported in all studies, but

multiple canals and more than one apical foramen variation does exist in ~1% of these roots in the studies reported (Table 1-19).

Variations and Anomalies

The root and canal morphology of molar teeth varies greatly. Many studies provided no information on ethnic background, age or gender, or possible explanations for variation observed. Walker[54,55,79] reported on the ethnic differences in the root anatomy of maxillary first premolars, mandibular first premolars, and the high incidence of three-rooted mandibular first molars in Asian patients. However, he did not report on the incidence of a MB-2 in the maxillary first molar. A study by Weine et al.[58] determined that the incidence of MB-2 in a Japanese population was similar to the incidence reported for other ethnic backgrounds.

Age was found to have an effect on the reported incidence of MB-2. Fewer canals were found in the MB root due to increasing age and calcification.[28,30,139]

Sert and Bayirli[11] conducted a clearing study that identified gender in a sample of 2800 teeth from Turkish patients. Although only 100 of each type of tooth for each gender was included in their study, a single Vertucci's Type I canal was present in the mesiobuccal root in only 3% of men compared to 10% of women. There are conflicting results with respect to gender and the number of canals in other studies.[7,11,28,30]

Some studies[27,64] compared *in vivo* versus *in vitro* techniques. Seidberg et al.,[27] in an *in vivo* study, reported 33.3% of the 201 teeth studied had an MB-2 canal. This increased to 62% in their *in vitro* study of 100 teeth. Similar results were reported in a study by Pomeranz and Fishelberg.[64] Only 31% of 100 teeth studied had an MB-2 canal in their *in vivo* study compared to 69% of 100 teeth in their *in vitro* study. The *in vitro* portion of this study described the samples as extracted maxillary molars and may represent pooled data instead of maxillary first molar data alone. The definition of a canal as a treatable canal used in clinical studies[12,28] versus the more complex canal configurations visible through clearing studies[7,11,14,18,63] can also lead to different results.

The more common use of SOM or loupes in recent clinical studies has resulted in an increased prevalence of the clinical detection of the MB-2 canal on the floor of the pulp chamber.[12,25,132,197] The effect of magnification on the incidence of clinical location of MB-2 was assessed in a clinical study by Buhrley et al.[197] The MB-2 canal was found in 71.1% of teeth when using SOM. The group using loupes found MB-2 in 62.5%. The lowest incidence of MB-2 was in the group performing RCT without any magnification. MB-2 was found in only 17.2%. A study by Sempira and Hartwell[25] found that use of an SOM did increase the incidence of finding MB-2. They attributed relatively low incidence in their study due to their characterization of a canal as one that must be negotiated and obturated to within 4 mm of the apex.

CBCT is being utilized more frequently now in both clinical and laboratory studies as well as in clinical practice to assist in identifying both root and root canal morphology.[107,148,173–175,182–184,188,189,193,198,207,465–488] As a result, the incidence of MB-2 as well as other canals detected is increasing. Eder et al.[143] reported an incidence of 94.1% of MB-2 in an *in vitro* study, while Reis et al.[183] reported an incidence of 88.5% in a recent clinical study using CBCT.

The incidence of many of the anomalies cannot be determined due to the lack of data collection and population size. However, although rare, these anomalies can and do occur. Ninety-six case reports were reviewed and the most common anomalies associated with the maxillary first molar were two palatal canals in three-rooted teeth, taurodontism (Figure 1-17), and various forms of root fusion (Table 1-20).

Of all the canals in the maxillary first molar, the MB-2 can be the most difficult to find and negotiate in a clinical situation. Knowledge from laboratory studies is essential to provide insight into the complex root canal anatomy. A study by Davis et al.[536] compared the post debridement anatomy of the canals of 217 teeth. Injection of silicone impression material into the instrumented canals revealed that standard instrumentation left a significant portion of the canal walls untouched. Fins, webbing, and portions of the canal were sometimes found not fully instrumented. Clinical instrumentation of this tooth, especially with respect to the mesiobuccal root, can be complicated. Failure to detect and treat the second MB-2 canal system will result in a decreased long-term prognosis.[170] Stropko[12] observed that by scheduling adequate clinical time, by using the recent magnification and detection instrumentation aids, and by having thorough knowledge of how and where to search for MB-2, the rate of location can approach 93% in maxillary first molars.

Taurodontism or "bull-like" teeth was first described by Keith.[537] Initially, it was considered to be a primitive trait found mainly in Neanderthal skulls from Krapina and other archaeological sites. Shaw et al.[495,538,539] classified the "modern" molar form as cynodont and classified taurodontism into hypo-, meso- and hypertaurodontism. There are several case reports that have described successful endodontic treatment on taurodont-like teeth.[540–545] Other case reports linked

taurodontism to certain inherited genetic syndromes.[543,546] (For more details, see Chapter 26, "Endodontic retreatment and management of mishaps.")

MAXILLARY SECOND MOLAR

External Root Morphology

The maxillary second molar normally has three roots (Figure 1-18 and Table 1-21). The relative shape of each of the roots is similar to the maxillary first molar but the roots tend to be closer and there is a higher tendency toward fusion of two or three roots.[16] There is usually more of a distal inclination to the root or roots of this tooth compared to the maxillary first molar.[16] There is also a general reduction

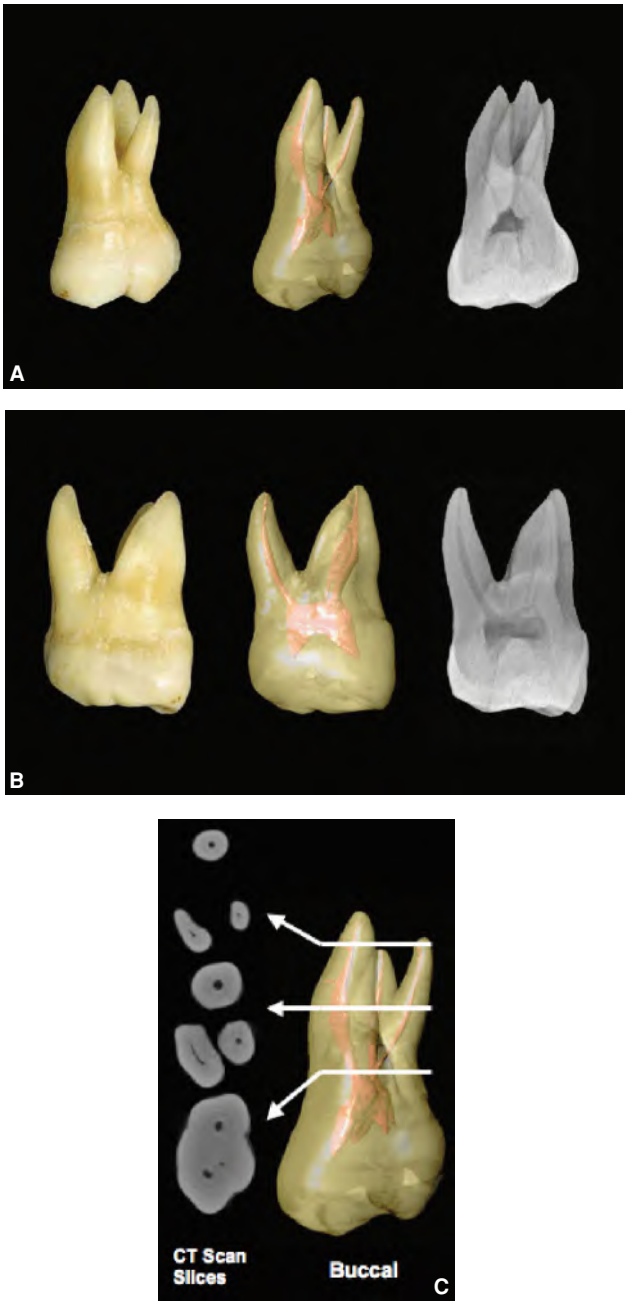

FIGURE 1-18 Maxillary left second molar. ***A.*** Buccal view. ***B.*** Mesial view. ***C.*** Root cross-sections. (Reprinted with permission from Brown P, Herbranson E. Dental Anatomy and 3-D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary Second Molar- Rotations & Slices.)

in crown and root size in the posterior arch consistent with the reduction in facial profile of modern *Homo sapiens*.[406]

The mesiobuccal root is broad buccolingually and has prominent depressions or flutings on its mesial and distal surfaces.[1,3,4,6,15–17] The internal canal morphology is variable and anatomical studies indicate that the mesiobuccal root has almost an equal incidence of one or two canals. The distobuccal root is generally rounded or ovoid in cross-section and usually contains a single canal. The palatal root is more broad mesiodistally than buccolingually and ovoidal in shape but normally contains only a single canal. Depressions on its buccal and palatal surfaces can be present but are usually shallow. Gher and Vernino[403] found prominent depressions on the distal aspect of the mesiobuccal roots. Lesser depressions could also be found on the furcal side of the distobuccal and palatal roots. The overall average length of the maxillary second molar is 19 mm with an average crown length of 7 mm and an average root length of 12 mm.[4]

Root Number and Form

The majority of maxillary second molars (85.8%) were three-rooted (Table 1-21). However, this is a lower incidence than that found in the maxillary first molar. The closer proximity of the roots results in a higher incidence of root fusion (26.4%) (Table 1-22) and C-shaped canals (4.9%) when compared to the maxillary first molar.[449]

Canal System

Mesiobuccal Canal System

In the most common three-rooted maxillary molar form, the shape of the root provides an indication of the shape of the internal canal morphology.[14] The broad buccolingual and narrow mesiodistal dimension of the mesiobuccal root of the maxillary second molar may have one or two canals (Table 1-23). A wide range of canal incidence in the mesiobuccal root exists. Kulild and Peters[132] reported that the norm would be a double-canal system and a low incidence of a single canal of 5.3%, while Hartwell and Bellizzi[460] found a single canal in 81.8% of their specimens. It should be noted that the former paper was a laboratory study while the latter was a clinical finding.

The single canal is usually described as being kidney or ribbon-shaped. Eskoz and Weine[74] suggested that age and continued deposition of secondary dentin in the isthmus can cause narrowing and possible occlusion in the mid portion resulting in two canals. There was a single apical foramen found in the mesiobuccal root over 64.7% of the time.

The Palatal and Distobuccal Canal Systems

The distobuccal and palatal roots exhibit a single canal over 99% of the time (Table 1-23). Both these roots are rounder in cross-section and a single-canal system is the expected normal finding. In a retrospective clinical treatment paper by Peikoff et al.[165] on the different forms of canal anatomy found in maxillary second molar teeth, six variants were described. In a random selection of 520 clinical treatments in a specialist office, Variants 1 to 6 reported and depicted second molar anatomy types from; single canal in a fused root to four canals in four roots (Figures 1-19 and 1-20).

Variations and Anomalies

Fifty case reports of anomalies associated with the maxillary second molar were reviewed (Table 1-24). The most common anomaly cited for this tooth is the four-rooted variation with two palatal roots. Other variations such as two canals within one large palatal root have been reported, but with a much lower frequency.[549,550]

A review article on the double palatal root by Christie et al.[446] studied a retrospective collection of 16 clinical cases from their practice and eight teeth from six published case reports[445,447,461,494,547,551] during a 25-year period. The highest occurrence of two palatal canals in double palatal roots (21/24 teeth) was found in the maxillary second molar tooth. The anomaly seemed to be grouped as three-root anatomy types; first, Type I, the two palatal roots being long and divergent; second, Type II, the two palatal roots being shorter, nearly parallel and comparable in shape and size to the two buccal roots (Figure 1-20); and third, Type III and IV were variations of root fusion that included a two-canal system, one entering the root from the palatal aspect. Subsequent case reports have tended to support this observation.[493,505,552–557]

FIGURE 1-19 Maxillary right second molar (buccal view) with bifurcated double palatal root Type I. (Courtesy of Dr. William H. Christie, Winnipeg, MB, Canada.)

In a study of 2636 posterior teeth in 875 Jordanian patients, a 4.4% incidence of taurodontism was found in the maxillary or mandibular molar teeth.[558] The maxillary second molar had the highest incidence of taurodontism. Of the 116 teeth identified in the study, 31% were permanent maxillary second molars. Treatment of hypertaurodont teeth was described in two case reports.[497,559] The ethnicity, if any, has not been established in this relatively rare root anomaly but it is no longer considered an exclusive primitive dental trait of *Homo Neanderthal* teeth.[538] (For more details, see Chapter 26, "Endodontic retreatment and management of mishaps.")

MANDIBULAR CENTRAL INCISOR

External Root Morphology

The mandibular central incisor is single rooted (Figure 1-21). The external form of the root is broad labiolingually and narrow mesiodistally. Longitudinal depressions are present on both the mesial and distal surfaces of the root. A cross-section of the root is ovoid to hourglass in shape due

to the developmental depressions on each side.[1,3,4,6,13,15,17]. The overall average length of the mandibular central incisor is 21.5 mm with an average crown length of 9 mm and an average root length of 12.5 mm.[4] In general, the mandibular central incisor is just slightly smaller than the mandibular lateral incisor in all dimensions.

Root Number and Form

The anatomical studies reviewed here reported that 100% of the mandibular central incisors were single-rooted teeth (Table 1-25). Variations from this form have either not been reported or not found in a review of the literature. An early study of the anatomy of the mandibular anterior teeth by Rankine-Wilson and Henry[585] established that even with a single root, these teeth may contain a "bifurcated" or double-canal system.

Canal System

The shape of the canal system is either rounded or ribbon sha ped.[1,3,4,6,13,15,17,589] The majority of mandibular central incisors have a single canal. Table 1-26 shows that out of 7455 pooled incisor teeth, a single canal is found in 81.1%. Two separate canals were found in 18.8%, which is less frequent than that found in the mandibular lateral incisor. The incidence of three or more canals was quite rare (0.2%).

A single apical foramen was found in 96.5% of the teeth. Therefore, even when two separate canals have been found, the majority of these canals will join and exit near or at a single foramen (Figure 1-22). Even the single canal system in all lower anterior teeth is wide in a labiolingual direction and narrow mesiodistally, matching the external root outline.[1,3,4,6,13,15,17] Fluting of the mesial and distal surfaces produces a figure eight shape single canal in cross section. As secondary dentin forms with age, the canal system takes on the shape of a double canal with a connecting isthmus, and should be treated as if it was a double canal when the root canal treatment is performed.[589] (Figure 1-23). Clements and Gilboe[590] and others have even recommended an incisal edge access opening for a straight-line approach to the apical foramen, when incisal edge wear is present or when a restorative crown is planned.

Green[213] found that the average diameter of the major foramen in 200 pooled mandibular incisors was 0.3 mm while the accessory foramina were 0.2 mm or less in diameter. Approximately 12% of the pooled mandibular incisors exhibited accessory foramina. The average distance of the apical foramen from the anatomical root apex was 0.2 mm.

Variations and Anomalies

Few anomalies are reported for this tooth (Table 1-27). Of the 15 case reports reviewed, the most frequently reported anomaly was dens evaginatus (talon cusp).

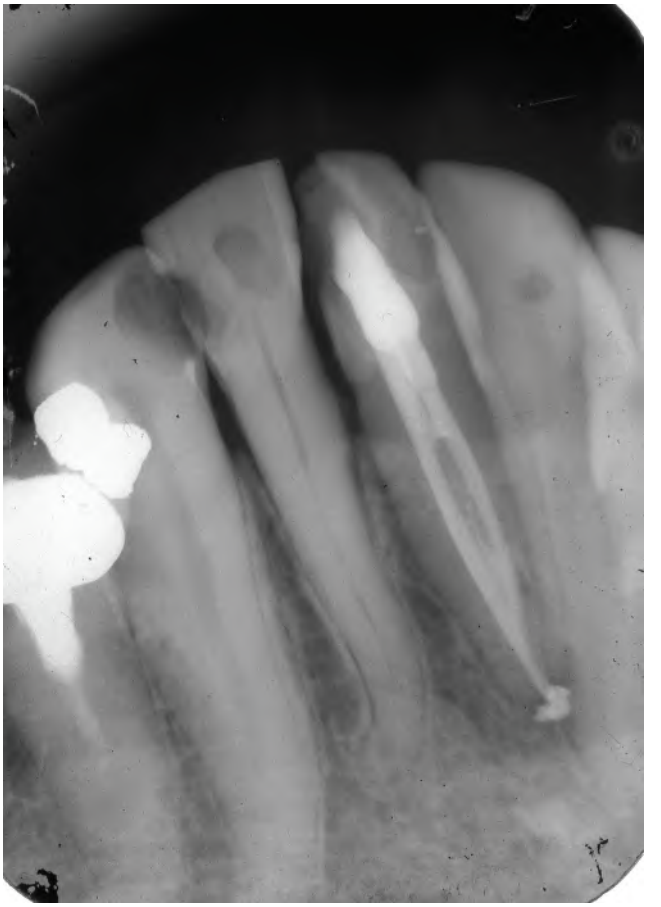

FIGURE 1-22 Mandibular left central with two canals and one apex. (Courtesy of Dr. Marshall D. Peikoff, Winnipeg, MB, Canada.)

MANDIBULAR LATERAL INCISOR

External Root Morphology

The mandibular lateral incisor is single rooted (Figure 1-24) and comparable in form and shape to the mandibular central incisor. The external form of the root is broad labiolingually and narrow mesiodistally. Longitudinal depressions are present on both the mesial and distal midroot surfaces.

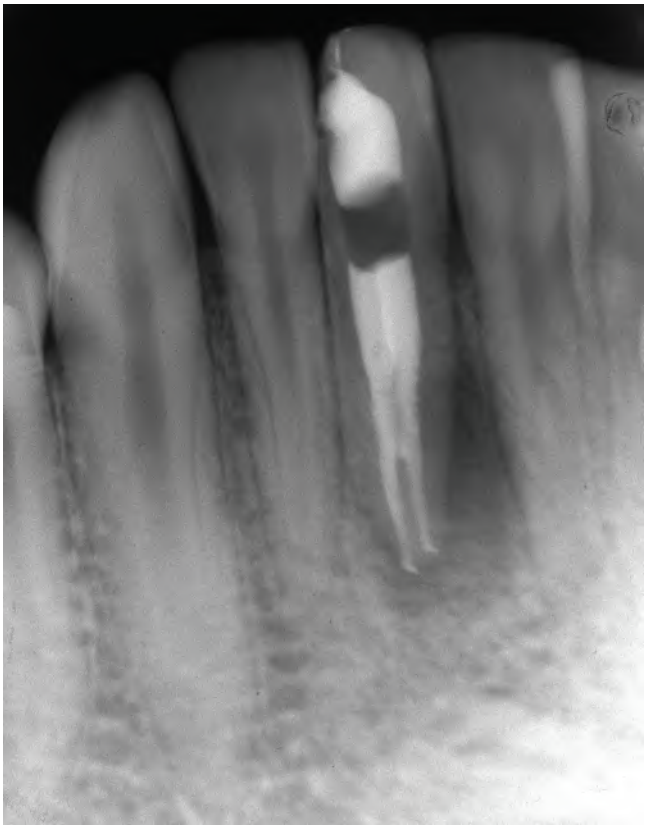

FIGURE 1-23 Mandibular left central incisor with two canals and two separate apical foramina. (Courtesy of Dr. Marshall D. Peikoff, Winnipeg, MB, Canada.)

A cross-section of the root is ovoid or hourglass in shape due to the developmental depressions on each side.[1,3,4,6,13,15,17] The overall length of the average mandibular lateral incisor is 23.5 mm with an average crown length of 9.5 mm and an average root length of 14 mm.[4]

In addition to being slightly larger in all dimensions, the major difference in tooth anatomy, compared with the mandibular central incisor, is at the incisal edge coronal anatomy. Slight angulation to the distolingual and mesiolabial of the mandibular incisor's incisal edge should be compensated for when preparing an endodontic access opening

and searching for the more frequently encountered, broader labiolingual canal system.

Root Number and Form

All eight studies reviewing a pooled average of 3266 teeth, reported that 100% of the mandibular lateral incisors were single-rooted teeth (Table 1-28). Variations in root number from this form have either not been reported or not found in a review of the literature, except that reported by Slowey.[445]

Canal System

The shape of the canal system is comparable to the mandibular central incisor and is either rounded or ribbon shaped.[1,3,4,6,13,15,17,589] The majority of mandibular lateral incisors have a single canal, which is less than the percentage found in the average mandibular central incisor (81.1%) (Table 1-29). Two canals were found in 24.6% of the specimens (Figure 1-25). The incidence of more than two canals was quite rare (0.04%). A single apical foramen was found in 95.8% of teeth. Therefore, similar to the mandibular central incisors, even when two separate canals have been found, the majority of the canals will join and exit through a single foramen.

Variations and Anomalies

Very few anomalies have been reported for this tooth (Table 1-30). Dens evaginatus (talon cusp), dens invaginatus, and fusion were the main anomalies. Slowey[445] described a radiograph of a rare mandibular lateral incisor with two distinct root tips.

FIGURE 1-25 Mandibular right lateral incisor with two canals and one apical foramen. (Courtesy of Dr. William H. Christie, Winnipeg, MB, Canada.)

MANDIBULAR CANINE

External Root Morphology

The root of the mandibular canine is wider labiolingually and narrower mesiodistally in cross-section, which is larger and longer than, but similar to the shape, the other mandibular anterior teeth (Figure 1-26). The projecting cusp tip of the mandibular canine is usually lingual to the long axis of the tooth length, while the cusp tip of a maxillary canine is labial to its long axis. Both canine roots are usually straight but may occasionally have fine and curved tips.

Developmental depressions are normally present on both the mesial and distal surfaces of the mid-root. The depressions can be relatively deep. Normally a single-rooted tooth,

one variation of root morphology is a bifurcated root that may resemble a premolar root.[1,3,4,6,13,15,17] At other times, when this bifurcation occurs, the furcation dividing the labial and lingual roots can be at any level on the root trunk and usually results in a smaller lingual rootlet at the apical third region. In rare occasions, even two separated roots can be found (Figure 1-27).

The overall average length of the mandibular canine is 27 mm with an average crown length of 11 mm and an average root length of 16 mm[4] that is comparable to the overall length of the maxillary canine.

Root Number and Form

The most common form of the mandibular canine is one with a single root (95.4%) (Table 1-31). The studies cited found an incidence of two roots ranging from 1.3%[586] to 6.2%.[5] A recent paper by Lee and Scott[617] suggested that this trait is largely a European ethnicity trait (5.7%–9.2%), found most frequently in Basque, Spain, and is rarely found in Asian or sub-Sahara African populations. An earlier article by Scott and Alexandersen[618] estimated the incidence of two-rooted mandibular canines in European samples to be ~5% to 10% and very rare in Asian and African populations.

Canal System

The mandibular canine usually presents with a single root canal system[5,7,14,22,31,83,85,168,409,594,596] (Table 1-32). The incidence of a single canal is 90.5%. However, even in a single canal system, the root trunk is broad in a labiolingual direction and therefore very ovoid or figure-eight shaped in cross-section.[620] In the single-canal system, 97.9% have a single apical foramen.[7,11,14,31,85,131,141,586] Therefore, when two canals are present (9.5%) in a single-rooted mandibular canine, the most common configuration is the joining of the two canals before

exiting at the apex [Vertucci Type II (2-1) or Vertucci Type III (1-2-1)].

Green[213] found that the average diameter of the major foramen was 0.3 mm, while the accessory foramina were 0.2 mm or less. The average distance of the major apical foramen from the anatomical root apex was found to be 0.35 mm. Approximately 10% of the mandibular canines exhibited accessory foramina.

VARIATIONS AND ANOMALIES

The most frequent variation found in the mandibular canine is the presence of two roots and two canals (Table 1-33).[13] A report by Alexandersen[401] showed a high incidence (5.6%) of two-rooted mandibular canine teeth in an Iron-Age Danish population.

Although, the data from anatomical studies varies greatly with respect to the incidence of two roots, the mandibular canine has the highest incidence of all of the anterior teeth at 4.5%. The human primary canine teeth are more likely to exhibit two separate (bifurcated) roots.[621] Other variations reported in the literature include two canals and two roots, two canals with a single apical foramen, three canals, dens invaginatus, and gemination.

MANDIBULAR FIRST PREMOLAR

External Root Morphology

The mandibular first premolar is typically a single-rooted tooth that is wider buccolingually and narrower mesiodistally, although two-rooted varieties do occur fairly frequently (Figure 1-28).[1,3,4,6,15–17] Developmental depressions or grooves are frequently found on both the mesial and distal surfaces of the root resulting in an ovoid or slight hourglass-shaped root that tapers to the lingual. The depression on the distal root surface has been described as being deeper than the mesial root depression.[634]

The overall average length of the mandibular first premolar is 22.5 mm with an average crown length of 8.5 mm and an average root length of 14 mm.[4]

Root Number and Form

The mandibular first premolar is normally a single-rooted tooth (Table 1-34); however, studies revealed an incidence of ~2.7% of bifurcated teeth.[5,7,11,14,408,635–637] Three-rooted mandibular first premolars are extremely rare with an incidence of 0.2%.

Trope et al.[638] found significant ethnic variations in root anatomy when comparing African American and Caucasian patients. Their study found an incidence of two root canals in 5.5% in Caucasian and 16.2% in the African American group of patients. Three-rooted mandibular first premolars are rare but are occasionally found in case reports (Figure 1-29).[435,639–642]

Scott and Turner[406] described the accessory root as "Tome's root." Their anthropological review of ethnic differences indicates that aboriginal Australians and sub-Sahara African populations have the highest incidence (>25%) of accessory roots. The lowest incidence (0%–10%) of Tome's

root occurred in American Arctic, New Guinea, Jomon, and Western Eurasian populations.

The complexity of the root and root canal system is related to the presence and severity of radicular grooves.[151,154,155] Tome's root ranges from a shallow concavity to a deep groove, to complete furcation(s) of the root(s). The deeper the concavity, the more likely the presence of a C-shaped canal system within.[151,154,155] Chen et al. studied the relationship of radicular grooves and root canal morphology in the mandibular first premolars using Micro-CT and found that 40.9% of the teeth in their study sample had radicular grooves. These grooves were primarily located on the mesial root surface (69.5%) and were more frequently associated with those teeth that had more complex root canal morphology.[156]

Canal System

Slowey[445] suggested that the mandibular premolars may present with the greatest difficulty of all teeth to treat endodontically. A University of Washington study assessed the failure rate of non-surgical root canal treatment in all teeth. It was highest for the mandibular first premolar at 11.45%.[643] Possible reasons for a high failure rate are the numerous variations in root canal morphology and difficult access, cleaning and sealing of a second canal. There is usually straight-line access to the buccal canal while the lingual canal branches below the chamber at a sharp angle, potentially resulting in a missed canal. Kartal and Yanikoglu,[644] using pooled data that included first and second premolars, reported a 27.8% incidence of mandibular premolars with more than one canal. Serman and Hasselgren[645] found that 15.7% of patients had at least one mandibular first premolar with either a divided canal or root. The second premolars had a lower but still notable incidence of 7% of the teeth with a double-canal system in this study.

The data from 29 anatomical studies of the canal system that included only mandibular first premolars but no ethnic attribute resulted in an average of a single canal in 77.3% of cases (Table 1-35). Two or more canals were found in 22.7% of the teeth. A single canal at the apex is found 76.7% of the time. Almost 25% of teeth had more than one foramen.

Trope et al.[638] found significant ethnic differences between African American and Caucasian patients. The African American group had an incidence of two or more canals in 32.8%, while the incidence in the Caucasian group was 13.7%. A study of 1000 full mouth radiographic surveys also found ethnic differences between African American and

Caucasian patients.[647] Although the number of patients in each ethnic group was not identified, the study reported that 16% of the Caucasian patients had bifurcated canals compared to 21.6% of the African American patients. Sert and Bayirli[11] found an incidence of two or more canals in 35% of men and 44% of women of Turkish descent, further reinforcing the importance of ethnic differences as well as possible gender differences.

Variations and Anomalies

Twenty-five case reports of anomalies or variations of the mandibular first premolar were identified in a review of the literature (Table 1-36). The most common variation associated with the mandibular first premolar was the three-rooted variation with three canals (Figure 1-29). However, only five case reports in total were identified.[435,639–642] Other reported developmental anomalies included "C"-shaped root canals in premolars,[151,154–156] three canals in a single root,[648–650] and three canals and two roots.[649]. Discussion of dens evaginatus, particularly in premolar teeth of patients of Asian ethnicity is also found under mandibular second premolar tooth anomalies.

A study of 45,X chromosome women (and 45,X/46,XX chromosome) found more than one canal in one or more of the mandibular premolars in almost half of the 87 patients studied who had the genetic syndrome. Separate canals were found in 23% of the mandibular first premolars and 25% of the mandibular second premolars.[666] The study concluded that X-chromosomes might have a gene or genes with a regulatory function for root development.

MANDIBULAR SECOND PREMOLAR

External Root Morphology

The mandibular second premolar is normally a single-rooted tooth (Figure 1-30) like the mandibular first premolar.[1,3,4,6,15–17] The root is described as flat or convex on its mesial surface while the distal surface often (73%) has a longitudinal developmental depression.[634] A cross-section of the root is usually ovoid in shape, generally tapering to the lingual.[16]

The overall average length of the mandibular second premolar is 22.5 mm with an average crown length of 8 mm and an average root length of 14.5 mm.[4]

Root Number and Form

The mandibular second premolar is normally a single-rooted tooth. Trope et al.[638] compared root and canal morphology in Caucasian and African American patients and found 1.5% incidence of two roots in mandibular second premolar teeth in Caucasian patients and 4.8% in African American patients. These differences were lower and not statistically significant in contrast to the differences (as high as one in six) found between these two groups in the mandibular first premolars.

Studies found multi-rooted mandibular second premolars to be quite rare (Table 1-37). Two-rooted varieties comprised 0.5% of the teeth. Three-rooted forms were rarely found and comprised 0.1% of teeth.

Canal System

Studies found a single canal in 91.3% of mandibular second premolars (Table 1-38). When a second canal system is located, it is usually fine and branches toward the lingual surface in the middle or apical third of the main canal. The incidence of two or more canals was 8.7%. The characteristic appearance of such a tooth on a periapical radiograph is of a clearly visible coronal canal that seems to abruptly fade-out in the apical region beyond the branching canal system.

Total number of canal apices studies	14	3123					90.6	2828	9.4	295

There was a single apical foramen 90.6% of the time. Serman and Hasselgren[645] found that second mandibular premolars had a 7% incidence of having a divided canal or root. Trope et al.[638] found ethnic differences between African American and Caucasian patients. African American group had a higher incidence (7.8%) of mandibular second premolars with two or more canals, while the incidence in the Caucasian group was lower (2.8%). These differences were not numerically significant in contrast to the results found with the mandibular first premolar canal systems.

Sert and Bayirli[11] study of Turkish patients found an incidence of two or more canals in 43% of men and 15% of the women. The gender differences in this population were significant and this ethnic group, as a whole, demonstrated a higher incidence of multiple canals than the averages of the remaining anatomical studies reported.

Variations and Anomalies

The most common anomaly reported was the variation with three canals in one or more roots (Table 1-39). The next most common anomaly was two canals in one or two roots

TABLE 1-39 Variations and Anomalies Associated with the Mandibular Second Premolar

(Figure 1-31), although this could be considered a variant from the one canal in one root.

Another anomaly includes mandibular second premolars with dens evaginatus (odontome) (Figure 1-32). Dens evaginatus is a fairly common occurrence in Asian populations and is usually found in the mandibular premolars, although not exclusively.[159,668,669] Merrill[670] reported a high incidence (4.5%) of this anomaly in Alaskan Eskimos (Inuit) and American Indians, an observation serving to illustrate Alaskan natives' ties to their more recent Asian heritage.

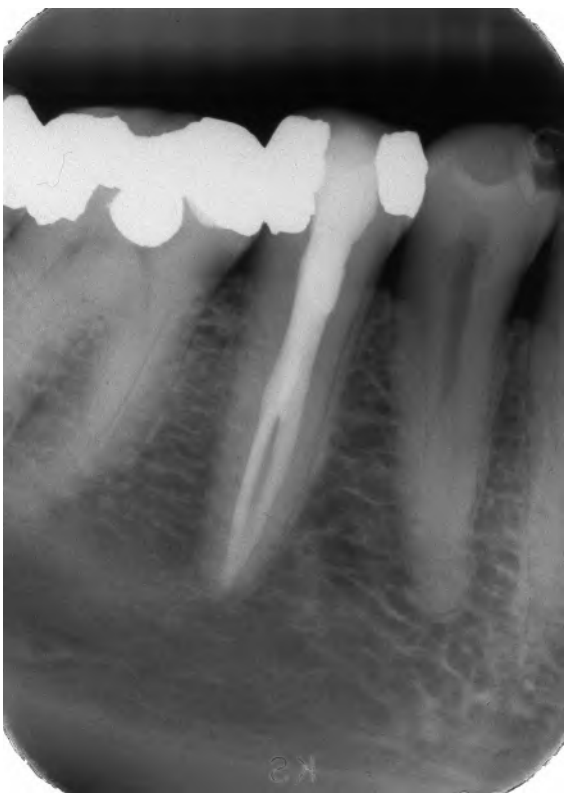

FIGURE 1-31 Mandibular right second premolar with two canals and one apical foramen. Complex canal anatomy can also be seen in the first premolar. (Courtesy of Dr. William H. Christie, Winnipeg, MB, Canada.)

Very often, when these teeth, with an occlusal enamel projection, erupt into occlusion, the pulp is exposed by attrition of the tubercle and it becomes nonvital. Root development at this age usually presents with a large or blunderbuss apex. Various prophylactic treatments have been suggested over the decades.[671–673] However, endodontic therapy and/or apexogenesis is the most frequent outcome of this coronal anomaly.[674]

C-shaped canal is a rare occurrence.[675,676] The hypotaurodont-like canal system may also appear in the mandibular second premolar tooth.[677]

MANDIBULAR FIRST MOLAR

External Root Morphology

The mandibular first molar is typically a two-rooted, three-canal tooth (Figure 1-33).[1,3,4,6,15–17] The mesial and distal roots are normally widely separated, with a furcation level at ~3 mm buccally and lingually and 4 mm apical to the cementoenamel junction, respectively.[4] Both roots are broader buccolingually than mesiodistally, with the mesial root wider buccolingually than the distal root. The mesial root has concavities on both its mesial and distal surfaces and is angled slightly mesially before curving to the distal approximately mid-root. The mesial root is slightly rotated and tapers distally from buccal to lingual. The distal root is generally more ovoid in its cross-sectional shape, although a mesial concavity in the mid-root may make it appear "kidney-bean" shaped in cross-section.[4]

The overall average length of the mandibular first molar is 21.5 mm with an average crown length of 7.5 mm and an average root length of 14 mm.[4] Root length may vary considerably in some individuals, with overall tooth length in excess of 25 mm in both first- and second-mandibular molar teeth.

Root Number and Form

The mandibular first molar is typically a two-rooted form with a mesial and a distal root (Table 1-40).[5,55,84,91,92,134,137,160,161,408,710–717] This anatomic form has an overall incidence of 85.6%. However, there are significant root anatomy differences when comparing Asian[55,91,92,137,160,710-712,714,717] to non-Asian

populations.[5,84,134,161,408,710,713,715–717] Non-Asian populations have a higher incidence of two roots (96.1%) while the Asian populations have a lesser incidence (77.7%). Therefore, three roots may occur in ~20% to 25% of Asian populations. Anatomical studies found that the three-rooted variety, with a bifurcated mesial or distal root or an additional supplementary root, had an overall incidence of 14.1%. Single-rooted forms, fused and four-rooted forms, were extremely rare and occurred in <1% of teeth.

There is a higher incidence of three roots (DLi supplementary) occurring in Asian populations, that includes North American Aboriginal peoples (Mongoloid groups). Thirteen of the 36 anatomical studies that specifically included Asian-ethnicity populations, showed a variation in incidence even within these population groups. The incidence of three-rooted mandibular first molars ranged from 10.1% in the Burmese[92] to 29.3% in the Chinese.[176] Non-Asian groups ranged from 0%[5,716] to 13.3%.[72] *Radix entomolaris* (as well as the single-rooted maxillary first premolar) may be used as one of the markers in following Asian origins in both ancient and modern individuals or groups.[405,710,716,718] The incidence of single, fused, or C-shaped roots increases in the mandibular molar teeth from first to third molars.[1,3,4,6,15–17]

Canal System

The mandibular first molar typically has two mesial and one distal canals (Table 1-41). The two-rooted forms have two canals in the mesial root 95.6% of the time. The mesial root canals may have a common exit foramen 1:3 (35.6%) or can exit separately as two or more apical foramina 2:3 (64.4%).

Slowey[461] indicated that the mesiobuccal canal usually has a distinct buccal curvature at the floor of the chamber while the mesiolingual canal is straighter in the long axis to the root. The distal root usually has a single, broad, oval or kidney

bean-shaped canal, but a two-canal system can occur in nearly one third of the distal roots, resulting in a four-canal system.

The three-rooted forms had two canals in the mesial root 97.8% of the time in an average of the three anatomical studies reported (Table 1-42). However, there was a single apical foramen 29.9% of the time. The distobuccal root had one canal 98.6% of the time and the distolingual or third root had a single canal 100% of the time.

Variations and Anomalies

Eighty-six case reports are included in Table 1-43. The most frequent reported anomalies relate to additional canals in one or more of the roots. However, the most frequently reported variation in root form is *radix entomolaris* (an anthropologic term for third root distolingually positioned). The additional reports of extra canals, supernumerary roots and canals, and taurodontism were not included in Table 6-43 (see Mandibular second molar and Chapter 26 for additional reports of taurodontism).

The mid-mesial canal is a concept that was described by Weine.[719] It is a term that is gaining acceptance with numerous case reports from the more frequent use of CBCT examination and increased use of microscope and guide-path probing techniques in endodontic treatments.[196,720–742] Table 1-41 shows that it was recorded in 1.1% of the mesial roots of the 5824 teeth in all studies.

MANDIBULAR SECOND MOLAR

External Root Morphology

The mandibular second molar normally has two roots (Figure 1-34).[1,3,4,6,15–17] The mesial and distal roots are usually closer or have a longer root trunk and slightly shorter radicular root ends, and are more frequently fused, compared to the mandibular first molar. The roots are broader buccolingually than mesiodistally. Root concavities are usually present on the mesial surfaces of both the mesial and distal roots and the distal surface of the mesial root.[16]

The overall average length of the mandibular second molar is 20 mm with an average crown length of 7 mm and an average root length of 13 mm.[4] Therefore, the overall dimensions of the second molar are smaller than the first molar.

Root Number and Form

The mandibular second molar is two rooted ~67% of the time (Table 1-44).[5,79,84,91,92,408,712,770,771] Root fusion, that becomes a single-root, conical or "C-shape" form, has an incidence of ~31.3%.

The incidence of a third root, usually the distolingual root, in mandibular second molars (1.3%) is not as high as in first mandibular molars (14.1%) (Table 1-44). However, patient of Asian ethnicity seemed to have a higher incidence of single or conical root.

Canal System

The mandibular second molar typically has two mesial and one distal canal (Tables 1-45 and 1-46). The mesial root of the mandibular second molar has a higher incidence of one canal (18.1%) than does the mesial root of the mandibular first molar (3.2%). Therefore, the two-rooted form may have only a two-canal system. On the other hand, since a distal root may have a double-canal system about 15% of the time, a four-canal system is not uncommon.

Mesial root canals may have a common foramen or may exit separately as two or more foramina, but the joining of the two canals is the most common form (Vertucci Type II).

Variations and Anomalies

Due to the higher incidence of root fusion in the mandibular second molar, C-shaped canals are not infrequent (Table 1-47). An extensive literature review by Fernandes et al.[45] found that the incidence of C-shaped canals ranged from 0.6% to 41.3% in the Chinese population and from 31.3% to 45.5% in the Korean population. The incidence of root fusion is generally higher in studies of Asian patients with Hou and Tsai,[448] reporting an incidence of fusion of 51.6% in the mandibular second molars in a Chinese population. In the same study, the maxillary second molar was found to have the highest incidence of fused roots (60.3%).

As would be expected, the incidence of C-shaped canals is often higher in Asian patients as well.[53] Seo and Park[777] reported an incidence of C-shaped canals in 32.7% of Korean patients and Gulabivala et al.[92] reported an incidence of 22.4% in the Burmese. Manning[49] reported a lower incidence of C-shaped canals at 12.7 but Caucasian ethnicity formed the majority of the patients. Studies in the United States by Weine et al.[771,772] and Sabala et al.[22] reported incidences of single root or C-shape of <10%. Ethnicity was not identified in either of these studies but it is likely that non-Asian patients formed the majority of

the patients in both the studies. The data from the studies that differentiated single conical and C-shaped roots indicate that the incidence of these two canal systems is approximately equal (8.3% and 8.5%, respectively).[49,91,92,408,712,771]

A variation in canal and root morphology was first termed as "C-shaped canal" by Cooke and Cox.[38] This canal shape results from fusion of the mesial and distal roots on either buccal or lingual root surface. A deep radicular groove is formed by Hertwig's root sheath that extends to the apical root end. The pulp canal system is of a "C" shape, which may vary in size with age of the patient.

Melton et al.[778] described three categories of C-shaped canals and Haddad et al.[775] added to the initial description. Category I is described as a continuous C-shaped canal from the pulp chamber to the apex. Category II is described as a "semi-colon" where one canal was separated by dentin from the C-shaped canal. The Category III, C-shaped anatomy, is described as having a C-shaped orifice with two or more distinct and separate canals. Although there have been reported cases of C-shaped canals in other teeth such as the maxillary lateral incisor, maxillary first molar,[450,498–501] maxillary second molar,[779,780] maxillary third molar,[82] mandibular first premolar,[126,781] mandibular first molar,[499,757,759] and the mandibular third molar,[38,82,782] with the most case reports are of the C-shaped mandibular second molar (Table 1-46). The incidence of C-shaped canals is the highest in mandibular second molars[36,38,45,57,60,61,79,783] ranging from 2%[119] to 44.5%.[776]

Other reported anomalies of mandibular second molars include fused or single roots, additional canals in one or more of the roots and two canals.

Munir et al.[807] found 12% incidence of taurodontism in 500 patients of a Punjab Dental Hospital. Two-thirds of the cases were meso-taurodontism (Figure 1-35) and <2% were considered hypertaurodont.

Just as in the other maxillary or mandibular molar teeth, hyper-taurodontism may occur in single instance in mandibular second molar teeth, which require endodontic treatment.[808]

SUMMARY

Maxillary Teeth

The preceding data aims to bring together the available knowledge of the anatomy of teeth in the human dentition in the dental literature. Because it comes from studies done with somewhat different methodologies and sources, it may not be amenable to meta-analysis, as such. However, some general observations and conclusions may be drawn about root and root canal anatomy of each tooth. Just as it is imperative to know what is the normal anatomy of a tooth, the range of variation and anomalous forms that a human tooth may take is equally

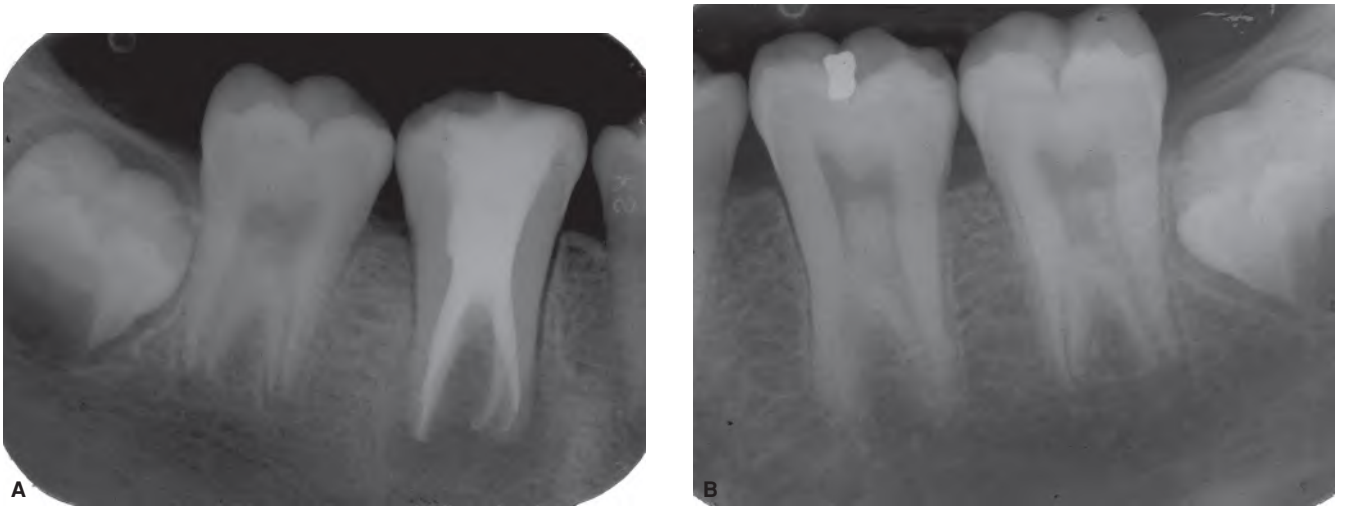

FIGURE 1-35 Bilateral mesotaurodont of mandibular second molars in the same patient. ***A.*** Right side. ***B.*** Left side. (Courtesy of Dr. William H. Christie, Winnipeg, MB, Canada.)

important. The tooth bud and eventually the developing tooth come from genes of each parent. Therefore, each patient may present with a dentition that is unique and individual.

The maxillary incisor and the maxillary canine teeth are all represented as a single-rooted tooth when data from all studies are combined for analysis. Despite this superficial similarity in anatomy, there are some distinctive differences in the morphology and variations in these anterior teeth.

After compensating for access alignment on the lingual side of midline, a root canal system of a *maxillary central incisor* is usually the largest and straightest of all human teeth. Even the palatal root of a first maxillary molar generally has a curvature to the buccal in the apical region. Lateral canals and apical delta canal branches are common. Nonetheless, gemination and fusion in the incisors occurred at the highest rate of all the teeth in one study. Developmental anomalies may include talon cusps or dens evaginatus, dens invaginatus, and fusions, which produced "double teeth." These and other anomalies outside the normal appearance of the maxillary central incisor are found in individual case reports.

The *maxillary lateral incisor* has a root canal system that is finer and oval in size and may curve in its apical portion to the distal, lingual, or both. Uncommon two rooted forms are reported up to 4% of the teeth, often a result of fusion of root forms with a root groove resulting. A lingual groove anomaly may be associated with both pulpal and periodontal pathology as first reported by Simon et al.[221] The developmental lingual groove anomaly may occur in maxillary central incisor and maxillary canine teeth, but are much rarer.

The lateral incisor may show anomalies such as dens invaginatus, followed by dens evaginatus (talon cusp), palatogingival grooves, and two roots and two canals fusion with peg-laterals and rarely three or four canals.

The *maxillary canine* was formerly known simply as the "cuspid." It has been shrinking in size in the human dentition since the times of the late Miocene hominids,[809] with closure of the canine diastema, as well. The canine is oval with a taper to the lingual as seen in cross-section, and a single-rooted tooth unless afflicted with developmental anomalies such as dens invaginatus or gemination. Dens evaginatus or "talon cusps," usually located on the lingual, may also occur. There may be two canals within one root in <5% of teeth, but the canal usually exits as a single foramen. Double-rooted maxillary canines occur rarely, compared to the mandibular canine teeth.

The *maxillary first premolar* tooth in its classic form is a "bicuspid" with two cusps and two roots of approximately equal size when viewed in standard dental anatomy and endodontic texts. Thus, the root trunk is wider in a buccolingual dimension. Both a double-rooted form and a single-rooted morphology occur, but the triple-rooted variant occurs with a frequency of 0.6% in Asian ethnicity and 2.3% in Caucasian populations.

Regardless of root number and ethnicity, the majority of maxillary first premolar teeth (80%) had a two-canal system. Anomalies such as taurodontism and dens evaginatus are relatively rare in maxillary premolar teeth.

The *maxillary second premolar* at times may resemble the first premolar in a slightly diminished size, and with similar ethnicity differences in root and canal numbers. It has a single root form over 90% of the time. The two-rooted form comprises a range of 1.6% to 20% of the time. Although three-rooted forms exist, it is found in lesser numbers but often concurrent with a three-rooted first premolar. All studies showed the majority of maxillary second premolars that had one root with either one- or two-canal system, terminated in one foramen ~64% of the time. Taurodontism or multi-foramen Vertucci Type IV–VIII and so forth canals were also noted in case reports.

Nearly 98% of *maxillary first molar* teeth have three roots. Only 2% are found as two-rooted varieties and single or conical root anatomy is rare. The palatal root is larger in diameter as is the internal root canal, often curving in the buccal direction that is rarely noted in periapical radiographs. Fusion may occur with any of the two roots, but is more likely encountered in the second maxillary molar, and more so with the third molar tooth.

The mesiobuccal root has two canals in >60% of the teeth. The incidence of conical C-shaped roots in a maxillary first molar is relatively low at 0.1% to 0.3%. Other anomalies may include two canals in the palatal root, taurodont molar (both genetic syndromes and otherwise), and multiple canal systems beyond four canals at five-, six-, and even seven-canal molars.

The *maxillary second molar* will still most likely be a three-rooted tooth, but only 86% of the time. Incidence of fusion of roots into a two-rooted form may occur in 10% of the teeth, and interestingly the single-rooted form is at 4% and a four-rooted tooth may occur just <1% of the time. The incidence of double palatal roots is rare. Other anomalies include teeth with five or more than six canals, fusions and C-shape canals, and taurodontism in its hypo-, meso-, and hyper-taurodont forms. Taurodont teeth are no longer considered a trait specific to *Homo neanderthalensis* in Ice Age Europe, but genetic syndromes, recessive familial inheritance and no specific ethnicity have been implicated.

MANDIBULAR TEETH

Just as the maxillary teeth of the human dentition have their own range of variation of crown, root, and root canal systems, the mandibular arch has its own unique characteristics. The opposing tooth and its antimere may be within the normal range or may be an anomaly in root number or canal number. The genetic characteristics of size and root shape of the mandibular teeth also have evolved to fit the occlusion of the upper arch. The reduction in the size of teeth and profile of both alveolar processes seem to be happening more quickly in human evolution than the base of the lower mandible, thus leaving the protruding chin and jaw that is not found in other

hominids. The roots of the mandibular teeth may also exhibit some interesting evolutionary characteristics.

The *mandibular central incisor* is typically a single-rooted tooth with a smaller incisal ridge to fit inside the smaller mandibular arch. The incisor roots in cross-section are far from circular, being most often a wide, ovoid shape like in the maxilla with concavities on the mesial and distal surfaces. It may present a double or bifurcated root canal system about 1:5 times. Despite the double canal internally, only about 4% of the canals existed in more than one foramen. Developmental anomalies are relatively rare and include "talon cusp" or dens evaginatus, dens invaginatus, and some fusions with supernumerary teeth.

The *mandibular lateral incisor* is a slightly larger, but very similar in root morphology to the central incisor. It also contains a double-root canal system slightly more often at a 1:4 ratio, and most often ends in a single foramen (~96%). Root anomalies are rare.

The *mandibular canine* is usually, but not always, a single-rooted tooth with a unique blend of mandibular incisor root morphology and characteristic canine tooth size and function. Deep developmental grooves on both sides of the root may sometimes be visible in a buccolingual radiograph. Even though the incidence of a single canal may be 90%, it would be prudent to treat the canal system as a wide, buccolingual double-canal shape. The tooth bud may form only a single, long cusp during the development of the canine crown, but the prominence of mid-root grooves may contribute to a two-rooted apical formation. Developmental anomalies of the mandibular canine, other than double canals and two-rooted forms are rare.

The *mandibular first premolar* is mainly a single-rooted tooth (Vertucci type I), but may have two roots with a 3% incidence and even a triple-root or canal with <0.2% incidence. However, this extra root on the lingual aspect, known as "Tome's Root" may occur much more frequently if ethnicity of the patient is considered. The missed canal and complex anatomy may be a reason for many attempts at retreatment of a failing initial treatment that assumed only one canal is present.

The *mandibular second premolar* root morphology may resemble the first premolar as a single-rooted tooth, but ethnicity differences in incidence have been reported. Vertucci Type I single canal in a single root is predominant. The two-root and two-canal morphology was rare at 0.5%, and triple-root forms at <0.1%. Even in the single-root morphology, a single canal compared to two or more canals ratio was about 9:1.

A coronal anomaly that may afflict premolar teeth is the dens evaginatus, or dental tubercle on the mid-occlusal surface. Since this delicate enamel projection often includes a fine pulp horn, occlusal attrition may create a pulp exposure at a young age. This developmental anomaly may be present predominantly in patients of Asian ethnicity. Preventive restorative measures or apexogenesis treatment may be required as a consequence to retain the tooth or teeth.

The *mandibular first molar* is usually a two-rooted tooth with three canals, two mesial and one distal. However, many more complex canal numbers and shapes can exist. The morphology of the two-rooted form may also vary from long, well-developed, and recurved roots that may resemble a "cow-horn," to short and parallel, almost fused double roots. Genetics play a role in root anatomy as studies show, with Asian populations having 78% of mandibular first molar teeth being two-rooted and up to 22% may have a third, or distolingual root. Other studies show that 96% of non-Asian populations are likely to be two-rooted and a three-rooted variant occurs <4% of the time. In average, two roots were observed in 86% of cases. The mesial root anatomy is of great interest. A single Vertucci Type I canal may occur >3% of the time, any of the two-canal types may occur 96% of the time, and a three-canal system in one root has about 1% incidence. The "mid-mesial canal" is now more routinely recognized if the SOM and ultrasonic trough techniques are used.

The *mandibular second molar* is usually a two-rooted tooth (2:3 ratio) with the roots usually smaller and developing closer together, to the point where they may appear fused externally, but retaining molar-like or three-canal root canal anatomy inside. Conical root, single canal form (Figure 1-36) and "C-shaped" root and canal system are found more frequently. Taurodontism, or the "bull-shaped" root trunk and pulpal anatomy may be occasionally found.

Tables 1-48 to 1-51 summarize the most relevant data on root number and root canal number of each tooth in the maxillary and mandibular arch.

Chapter 2

Structure and Function of the Pulp–Dentin Complex

Sivakami R. Haug, Syngcuk Kim, Karin J. Heyeraas

The dental pulp is a connective tissue. It consists of nerves, blood vessels, interstitial fluid, odontoblasts, fibroblasts, and other cellular components. As late Dr. I.B. Bender said, "The pulp is a small tissue with a big issue." The dental pulp resides in a rigid capsule consisting of enamel and dentin layers. The uniqueness of the pulp can be appreciated only when provoked. Unlike other connective tissues, this encasement creates a low-compliant environment in which a small increase in tissue volume, due to inflammation, has serious consequences. Moreover, the pulp receives its blood supply from end arteries, and the main blood supply goes through the apex such that there is no collateral blood circulation. Another uniqueness of the pulp is that it is densely innervated by sensory and sympathetic nerve fibers.

Despite its confinement by enamel and dentin, the pulp–dentin complex functions as an exquisitely responsive sensory system, using unusual mechanisms to defend itself from insults. Sensory fibers together with its microcirculatory vasculature make the dental pulp a unique organ to study the neurovascular interactions during various stages of inflammation. When the dental pulp is involved, dentists face diagnostic dilemmas, especially when presented with thermal sensitivity, sensitivity to osmotic pressure, and various grades of non-localized pain. Therefore, it is important that clinicians have a sound biological and physiological knowledge for diagnosis and treatment planning. As such, one must understand the very tissue frequently eliminated by endodontic therapy.

This chapter discusses the available information on the development, structure, and function of the dentin–pulp complex, with the aim that this knowledge provides a firm biological basis for clinical decision-making.

EMBRYOLOGY

Human tooth development begins as early as the fifth week of gestation for primary dentition. Mineralization of the primary dentition begins during the 14th week of gestation at the same time the permanent teeth start to develop. The first primary teeth erupt at the age of 6 months and the first permanent teeth at 5–6 years. The third molars are the last teeth to be formed with the completion of crown development between 12 and 16 years. Thus, tooth development starts from the embryonic stage and continues into early adulthood. Recent findings have revealed multiple growth and transcription factors, from several signaling families, acting as critical regulators at the initiation, and subsequently throughout all stages of tooth development. Gene-targeting experiments have demonstrated the biological function of transcription facts in regulating tooth morphogenesis. Today, over 200 genes have been demonstrated to be active in the developing tooth. This chapter overviews the topic of tooth development while referring to excellent reviews in this field.[1–4]

Teeth derive from two principal cell types: the ectoderm and the cranial neural crest-derived ectomesenchyme. The ectodermal component gives rise to the ameloblasts that form the enamel of the tooth crown while the ectomesenchyme gives rise to the dentin, pulp, and periodontal tissue. The neural crest cells migrate from the crest of neural ectoderm. Only neural crest-derived mesenchyme has the ability to respond to the initial signals from the dental epithelium and contribute to tooth formation.[5–7] Initiation of tooth development begins with the formation of dental lamina, a thickening of the oral epithelium. Localized proliferation within the dental lamina leads to the formation of a series of epithelial outgrowths or buds at sites where the tooth should be, thus marking the time and position of tooth development. The underlying mesenchyme underneath, called the dental papilla, forms the future dentin and pulp. The dental follicle, or sac, surrounds both the dental papilla and the enamel organ and gives rise to the supporting tissue.

There are three stages in the early tooth development: the bud, the cap, and the bell stage. During the bud stage, the mesenchyme underneath condenses and begins to appear like a cap on the dental papilla, thus leading to the stage known as the cap stage. The dental epithelium comes to be known as the enamel organ from the cap stage. The enamel organ, the dental papilla, and the dental follicle constitute the dental organ, or the tooth germ (Figure 2-1). Transition from the bud to the cap stage is a critical step in tooth morphogenesis involving multiple signaling molecules within the enamel organ epithelium. These have been implicated to regulate the expression of various transcription factors in the surrounding mesenchyme.[4,8,9] During the cap stage, a critical signaling center, the enamel knot, is formed within the enamel organ epithelium.

The enamel knot is a dense population of epithelial cells, without any proliferative activity, and is marked by the expression of multiple signaling molecules for the proper development of the tooth organ. The enamel knot serves as a transient signaling center and is removed by programmed

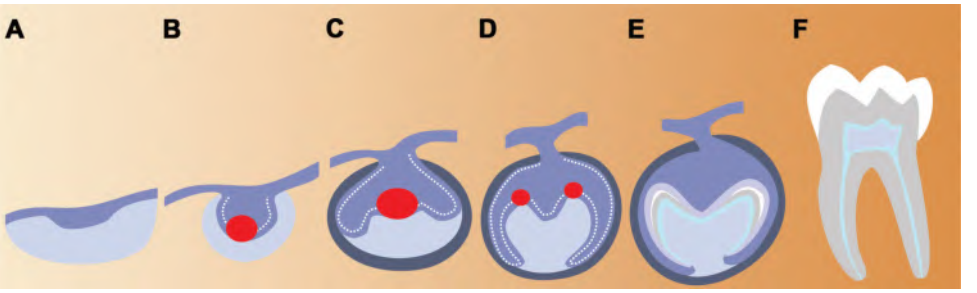

FIGURE 2-1 Schematic presentation of the embryonic molar tooth development and the adult tooth. ***A.*** Due to localized proliferation of the oral epithelium, thickening of the dental epithelium is formed at the beginning of tooth development. ***B.*** The ingrowth of dental epithelium into the condensed dental mesenchyme occurs and the dental bud is formed. At this bud stage, the primary enamel knot (PEK) (red dot), the signaling center, appears in the tip of the epithelial bud. ***C.*** The dental epithelium on the lingual and buccal sides of the PEK grows and cervical loop is forming at the cap stage. Dental mesenchyme becomes the dental papilla and dental follicle. ***D.*** The secondary enamel knots (SEK) (red dots) appear at the sites of the future cusp tips at the early bell stage. The epithelial cervical loop grows and surrounds the dental pulp. ***E.*** Tooth specific cells, odontoblasts and ameloblasts differentiate and secrete dentin (light grey) and enamel (white), respectively, at the late bell stage. cell death. In molar teeth, this primary enamel knot is replaced by secondary enamel knots that are responsible for inducing cusp development. The enamel knot is involved in the patterning process such as cusp shape and size during tooth morphogenesis.[4]

Determination of tooth identity depends on the expression of certain homeobox genes in the mesenchyme.[10,11] Continuous growth of the tooth germ leads to the bell stage during which the crown assumes its final shape (morphodifferentiation) and the cells that will be making the hard tissue (ameloblasts and odontoblasts) acquire their distinctive phenotype (histodifferentiation). Cranial neural crest-derived odontogenic mesenchyme and its adjacent inner enamel organ epithelium differentiate into preodontoblast and preameloblast, respectively. Dentin and enamel will begin to form at the junction between odontoblasts and ameloblasts to complete the tooth-forming process.

Blood supply to the developing tooth is via the dental follicle during the cap stage. The enamel organ is avascular, although there are numerous blood vessels in the adjacent follicle. These blood vessels ramify around the tooth germ. Their number in the dental papilla increases, reaching a maximum when matrix deposition begins. The vessels in the papilla are arranged in groups that coincide with the future root-forming site.

The first trigeminal nerve fibers are present in the vicinity of the tooth at the bud stage and around the tooth organ in the dental follicle during the cap and bell stages.[12–16] In the bell stage, sensory nerve fibers are present in the dental follicle but not in the dental papilla and enamel organ. In the advanced bell stage, after initiation of dentin and enamel formation, sensory nerve fibers enter the dental papilla. Sympathetic innervation appears later at the beginning of the root formation.[17] With the start of root development, a subodontoblastic nerve plexus gradually forms. Also with the start of root formation, nerves begin to appear in the developing periodontal ligament (PDL), although a mature distribution pattern does not occur until root formation is nearly completed.[17] The expression of growth factors such as nerve growth factor, brain-derived neurotrophic factors, gondotropin neurotrophic factor, neurotrophin 3, and neurotrophin has been shown at specific locations during various developing stages of the tooth.[18–20] Recent studies have shown that enamel and dentin formation is under circadian control. Clock genes may be involved in the regulation of ameloblast and odontoblast functions, such as enamel and dentin matrix protein secretion and biomineralization expressing incremental lines and cross-striations. Clock genes, such as Bmal1, Clock, Per 1, and Per 2, which are known to control circadian rhythms and related functions in many tissues, are expressed in teeth as well. Clock protein expression has been found preferentially in matrix secreting cells such as ameloblasts, odontoblasts, and osteoblasts and not in cementoblasts.[21,22]

STRUCTURES AND FUNCTIONS

Dental–Pulp Complex

As long as dentin is covered peripherally by enamel on coronal surfaces and cementum on radicular surfaces, the dental pulp will generally remain healthy for life, unless the apical blood supply is disrupted (e.g., severe impact trauma, surgical procedures, or excessive orthodontic forces). Most pathological pulp conditions begin with the removal of one or both these protective barriers via caries, fractures, or abrasion. The result is the communication of the pulp soft tissue with the oral cavity via dentinal tubules. A classic work by Pashley et al.,[23] using radioactive I^{131} in dog teeth, clearly demonstrated that once dentin tubules are opened, molecules can easily permeate to the pulp (Figure 2-2). This dentin permeability has a significant impact on the pathogenesis of the pulp in many clinical situations. This will be discussed later in this chapter.

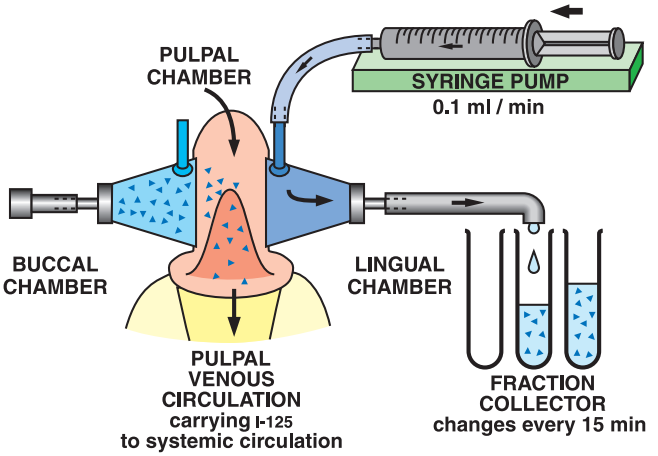

FIGURE 2-2 Pashley's experimental setup for the study of dentin permeability. ^{131}I, as the marker, was diffused through the buccal chamber attached to the naked dentin of the tooth. Blood was drawn from the venous system and checked for ^{131}I radioactivity. The appearance of ^{131}I in the blood demonstrates the degree of permeability of the dentin. (Reproduced with permission from Pashley DH, et al.[23])

It is apparent that substances easily permeate dentin, permitting thermal, osmotic, and chemical insults to act on the pulpal constituents. The initial stages involve stimulation or irritation of odontoblasts and may proceed to inflammation and often to tissue destruction. First, one must examine the dentin structure.

Dentin Structure

Dentin is a calcified connective tissue consisting of ~70% inorganic material and 10% water. Organic matrix accounts for 20% of dentin, of which about 91% is collagen. Most of the collagen is type I, but there is minor amount of component of type V. Noncollagenous matrix components include phosphoproteins, proteoglycans, γ-carboxyglutamaten-containing proteins, acidic glycoproteins, growth factors, and lipids. Dentin is penetrated by millions of tubules; their density varies from 40,000 to 70,000 tubules per square millimeter (Figure 2-3).[24] Tubules range in diameter from 1 μm at the dentinoenamel junction to 3 μm at their pulpal surface. These variations in the size of the tubules, in the dentin surface area, and in the surface area covered by the tubules are important in the pathogenesis of pulpal inflammation. For instance, permeation of toxic substances to the pulp created by caries or restorative procedures from the dentinoenamel junction is less likely compared to permeation from the middle of the dentin due to the degree of surface area covered by the tubules.

From a purely anatomical standpoint, possible pulpal damage increases exponentially the deeper toxins reach into the dentin. Dental tubules contain a fluid that has a composition similar to extracellular fluid.[25] If the fluid becomes contaminated with carious bacterial endotoxins and exotoxins, it becomes a reservoir of injurious agents that can permeate through dentin into the pulp to initiate inflammation.[26] It is useful to understand the important variables that control dentin permeability.

Dentin Permeability

Dentinal tubules in the coronal dentin converge from the dentinoenamel junction to the pulp chamber.[27] This tends to concentrate permeating substances into a smaller area at their terminus in the pulp. The surface area occupied by tubules, at different levels, indicates the effect of tubule density and diameter. One can calculate from Garberoglio and Brännström's[24] observations that the area of dentin occupied by tubules is only 1% at the dentinoenamel junction and it increases to 45% at the pulp chamber (Figure 2-3). Its clinical

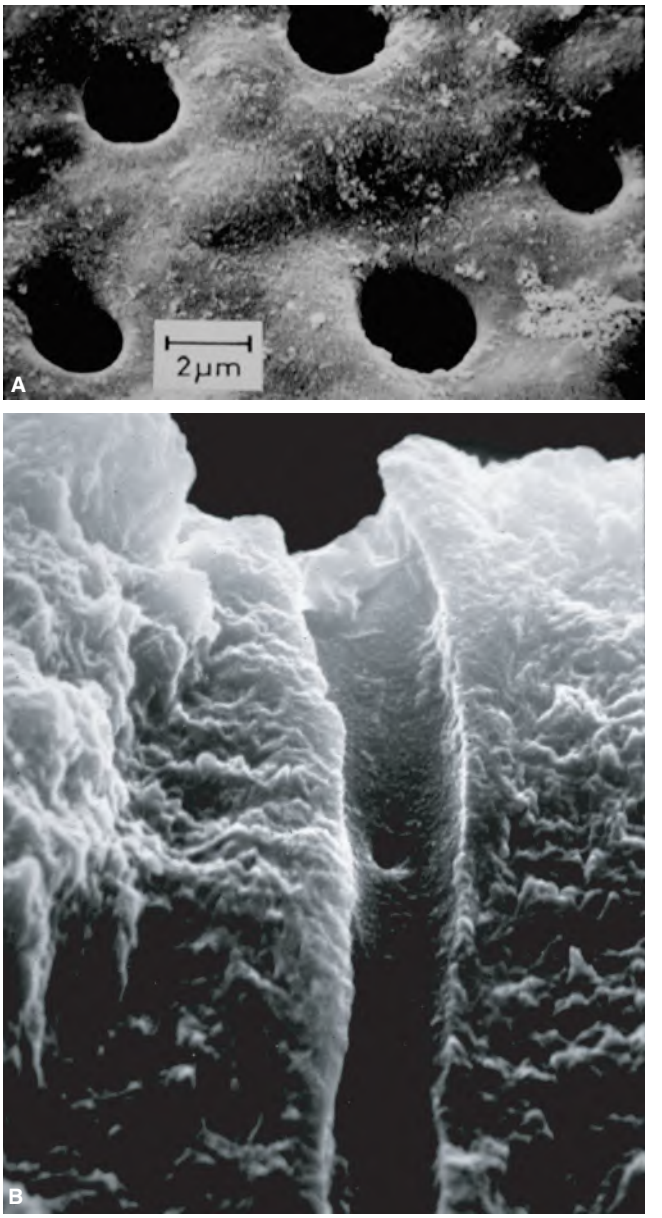

FIGURE 2-3 ***A.*** Heterogenous nature of the dentin tubular diameters along the dentin length and dentin surface. The tubular diameter increases (up to 4 μm) and the dentin surface area occupied by the tubules increases logarithmically as it approaches the pulp. ***B.*** Scanning electron micrograph (SEM) of a crosssection of tubules. (Courtesy of Dr. Henry Trowbridge, Philadelphia, PA, U.S.A. and Dr. David H. Pashley, Augusta, GA, U.S.A.)

implications are significant. As dentin is exposed to increasing depths, by restorative procedures, attrition, or disease, the remaining dentin becomes increasingly permeable.[28,29] Thus, dentin removal renders the pulp more susceptible to chemical or microbial irritation. This functional consequence of tubule area is also responsible for the decrease in dentin microhardness closer to the pulp.[30,31] As tubule density increases, the amount of calcified matrix between the tubules decreases. This relative softness of the dentin lining the pulp chamber facilitates canal enlargement during endodontic treatment.[32]

Overall dentin permeability is directly proportional to the total surface area of exposed dentin. Obviously, a leaking restoration over a full crown preparation provides more surface for diffusion of microbial products than a small occlusal restoration.[33] Restorations requiring extensive and deep removal of dentin (i.e., preparation for a full crown) would open more tubules and increase the rate of injurious substances diffusing from the surface to the pulp; thus, the importance of "remaining dentin thickness."[34,35]

The permeability of the root is 10 to 20 times less than that of a similar thickness of coronal dentin.[36] This may account for the lack of pulpal reactions to periodontal therapy that removes cementum and exposes root dentin to the oral cavity. Recent evidence indicates that dentin permeability is not constant after cavity preparation. In dogs, dentin permeability decreased over 75% in the first 6 hours following cavity preparation.[37] Although there were no histological correlates of the decreased permeability, dogs depleted of their plasma fibrinogen did not decrease their dentin permeability following cavity preparation.[38] These authors speculated that irritation to pulpal blood vessels caused by cavity preparation increased the leakage of plasma proteins from pulpal vessels into the dentinal tubules, where they absorb to the dentin, decreasing permeability. Future study of this phenomenon is required to determine if it occurs in humans.

The character of the dentin surface can also modify dentin permeability. Two extremes are possible: tubules that are completely open, as seen in freshly fractured[39] or acid-etched dentin,[40] and tubules that are closed, either anatomically or with microcrystalline debris.[41] This debris creates the "smear layer" that forms on dentin surfaces whenever they are cut with hand or rotary instruments.[42] The smear layer slows microbial penetration,[43,44] but permits a wide range of molecules to readily permeate dentin. Small molecules permeate much faster than large molecules. Smear layers are often slowly dissolved over months to years as oral fluids percolate around microleakage channels between restorative materials and the tooth. The removal of the "smear layer" by acid etching, or chelation, increases dentin permeability because the microcrystalline debris no longer restricts diffusion of irritants and also permits microorganisms to penetrate into dentin.[45,46] There is considerable debate as to whether smear layers created in the root canal during biomechanical preparation should be removed.[47] Its removal may increase the quality of the seal between endodontic filling materials and root dentin. It may also increase the bond strength of resin posts.[48]

Pulp Reaction to Permeating Substances

What happens when permeating substances reach the pulp chamber? Although microorganisms may not actually pass through dentin, their toxic by-products have been shown to cause severe pulp reaction.[49–51] The broad spectrum of pulp reaction, from no inflammation to abscess formation, may be related to the concentration of these injurious substances in the pulp. Although exposed dentin may permit substances to permeate, their concentrations may not reach levels high enough to trigger the cascade of events associated with inflammation. This would indicate that the interstitial fluid concentration of these substances can be maintained at low concentrations. As long as the rate of pulpal blood flow is normal, the microcirculation is very efficient at removing substances diffusing across dentin to the pulp chamber. This delicate balance between the dentin and the pulp is illustrated in Figure 2-4.

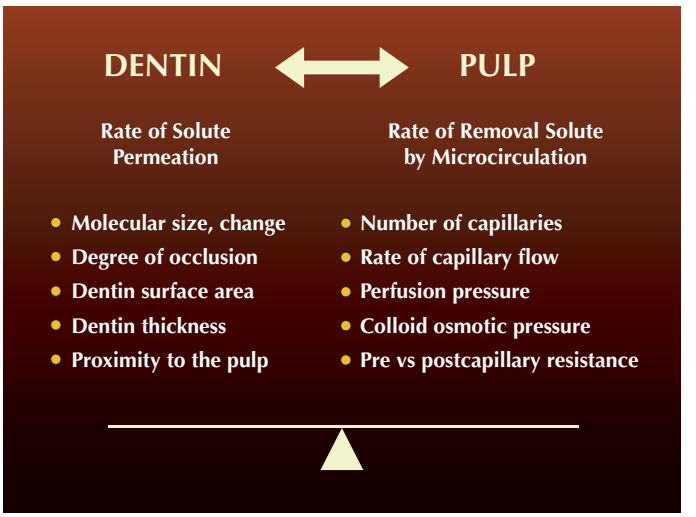

FIGURE 2-4 Diagram showing the delicate balance between dentin and the pulp. On the left side of the balancing beam are factors governing the dentin and on the right side are factors that govern the pulp.

Dentin Sensitivity

Clinicians recognize that dentin is exquisitely sensitive to certain stimuli. It is unlikely that this sensitivity results from direct stimulation of nerves in dentin (Figure 2-5). As previously stated, nerves have not been shown in peripheral dentin.[52,53] Another speculation is that the odontoblastic process may serve as excitable "nerve endings" that would, in turn, excite nerve fibers shown to exist in deeper dentin, closer to the pulp.[52–54]

The experiments by Anderson et al.[54] and Brännström[55] suggested that neither odontoblastic processes nor excitable nerves exist within dentin. They proposed the "hydrodynamic theory" of dentin sensitivity that sets forth that fluid movement through dentinal tubules, moving in either direction, stimulates sensory nerves in dentin or the pulp.[55,56]

Further support for the hydrodynamic theory came from electron microscopic examination of animal[57–59] and human dentin,[55,59–61] demonstrating that odontoblastic processes seldom extend more than one-third the distance of the dentinal tubules. A work by La Fleche et al.[62] suggested that the process may retract from the periphery during extraction or processing. Obviously, more investigation will be required before any definitive statement can be made regarding the distribution of the process. The tubules are filled with dentinal fluid, similar in composition to interstitial fluid.[25] The hydrodynamic theory satisfies numerous experimental observations. Although it cannot yet be regarded as fact, it has provided and will continue to provide a very useful perspective for the design of future experiments.[25]

Pulpal Microvasculatures

The arterial supply of the dental pulp has its origin from the posterior superior alveolar arteries and the infraorbital and the inferior alveolar branch of the internal maxillary arteries. Because the dental pulp itself is small, pulp blood vessels do not reach a large size. As such, the terms artery and vein cannot be used. Rather they are called arterioles (diameter in the range of 100 μm) and corresponding venules (diameter in the range of 200 to 300 μm).[63] Arterioles pass through the root pulp to supply the coronal pulp. As the arterioles travel straight to the coronal area, branching patterns develop. These branching vessels have very thin smooth muscle coating at the juncture and lose the coating as they reach toward the dentin, forming a capillary network. Near the dentin, around the odontoblastic area, they form a dense terminal capillary network in the subodontoblastic region[64] Figures 2-6 to 2-11 illustrate the basic microvascular units in the pulp. Terminal capillary networks are the key vessels in the pulp and are involved in transporting nutrients and O2 to the cells and removing waste products and CO_2 from the cells to maintain pulp homeostasis.

Corrosion cast studies have shown that numerous arterioles and venules pass through the apex of the root.[65] Vessels also enter and leave the pulp via accessory lateral canals that may be located anywhere on the root, but most commonly in the apical region.[66,67] The tooth lacks a collateral or alternative blood supply that makes the apical region a critical point. Thus, increased tooth movement in the apical area due to trauma, periodontitis, or excessive and uncontrolled

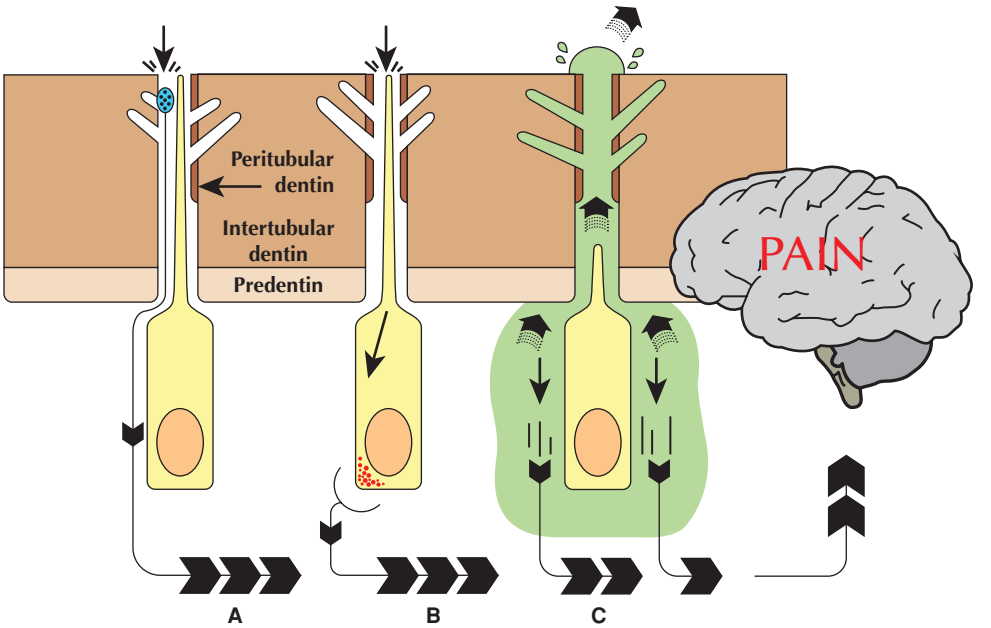

FIGURE 2-5 Diagram of essentials of three theories of dentin sensitivity. ***A.*** Classical theory proposed that stimuli applied to dentin caused direct simulation of nerves in dentin. ***B.*** Modified theory proposed that stimuli applied to the odontoblastic process would be transmitted along the odontoblast and passed to the sensory nerves via some sort of synapse. ***C.*** Hydrodynamic theory proposed that fluid movement within tubules transmits peripheral stimuli to highly sensitive pulpal nerves. (Modified with permission from Dr. Calvin D. Torneck, Toronto, Ontario, Canada.)

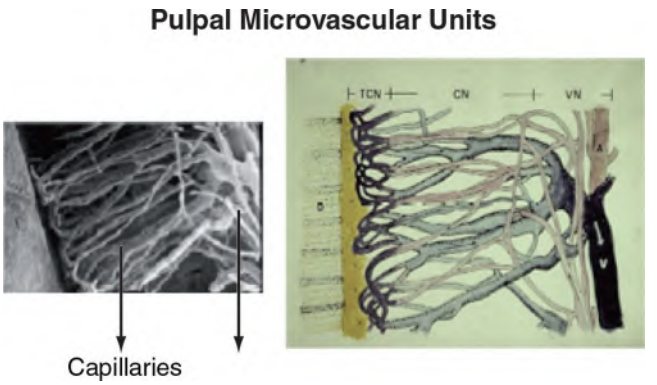

FIGURE 2-6 Pulpal microvascular units. Scanning electron micrograph (SEM) and a diagram based on the SEM are presented on the right side. The basic unit shows arterioles running parallel with venules in the center of the pulp. The small arterioles branch off almost 90° from the main arterioles. These small arterioles get smaller in diameter as they come near the dentin. These small arterioles also lose their smooth muscle coating and become capillaries forming the capillary network (CN). When they reach the odontoblastic layer, they become the terminal capillary network (TCN). They drain into the venular network (VN). (Courtesy of Drs. Kazuto Takahashi and Yoshiaki Kishi, Kanagawa, Japan.)

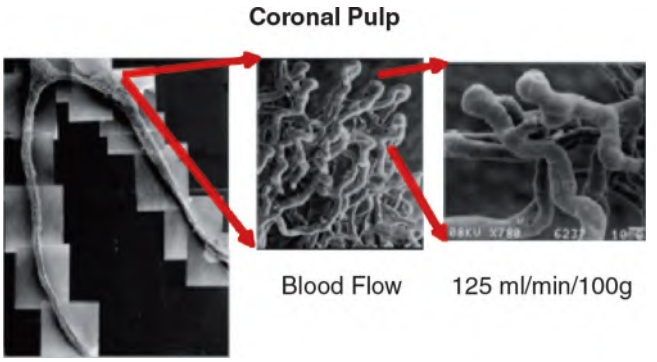

FIGURE 2-7 Corrosion resin casts of the pulp vessels of a dog premolar. These scanning electron micrographs (SEMs) clearly show heterogeneity of the pulpal microvascular architecture. Higher magnification of the coronal pulp region (arrows) reveals many hairpin capillary loops within the pulp horn. Higher magnification of the area (left) shows an individual loop with a diameter just over 10 mm. The blood flow per unit volume per minute is 125 mL/min/100 g tissue. Higher magnification of the root canal lesion in the apical pulp shows a very different architecture than the coronal pulp. Here, the microvessels show a net-type architecture surrounding the main arteriole and venules. The blood flow in this lesion is 22 mL/min/100 g, significantly less than that in the coronal pulp. (Courtesy of Drs. Kazuto Takahashi and Yoshiaki Kishi, Kanagawa, Japan, and Syngcuk Kim, Philadelphia, PA, U.S.A.)

orthodontic tooth movement may damage the pulpal blood supply. There is evidence that vessels have been identified connecting the pulp to the PDL (Figure 2-8). The degree to which these vessels play a role in pathogenesis remains to be investigated.

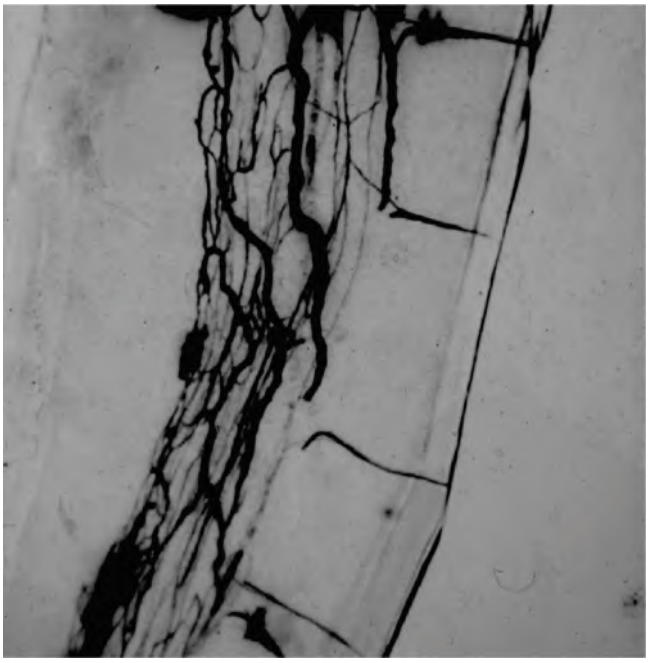

FIGURE 2-8 Vessel architecture in the pulp visualized by the India ink suction technique. Lateral canal vessels connecting the pulp and the PDL are observed.

Arteriovenous Anastomosis and "U"-Turn Loops

Before the arterioles break up into capillary beds, arteriovenous anastomosis (AVA) often arise to connect the arteriole directly to a venule.[68] The AVAs are relatively small vessels, having a diameter ~10 μm.[69] Their presence is more frequent in the radicular area of the pulp. The functional role of these vascular structures is not completely known. However, one can speculate that AVAs play a role in the regulation of blood flow. Theoretically, they could provide a mechanism for shunting blood away from the area of injury or inflammation, where damage to the microcirculation may result in thrombosis and hemorrhage. An interesting observation to support this view is during an intravital microscopic study, using the live rat incisor teeth. When the pulp is approached during tooth preparation, one sees a sudden appearance of AVA shunts and "U"-turn loops filled with streaming blood.[63] This might indicate that AVA shunts participate in temperature regulation within the pulp, as tooth preparation probably increases the pulp temperature and the AVA shunts will transport the heat out of the pulp. "U"-turn loops are frequently found in the pulp vascular network, and it is believed that their functions are similar to that of AVA's (Figures 2-9 and 2-10). Capillary density is highest in the subodontoblastic region with loops passing between odontoblasts (Figures 2-6, 2-10 and 2-11).[63,68,70] In the subodontoblastic region, capillaries with fenestrations occur frequently in both primary and permanent teeth.[68] However, the function of this fenestration is still disputed. Capillaries and the smallest postcapillary venules are the site of exchange between blood and the interstitial fluid. The terminal capillary network in the coronal area exhibits numerous short hairpin loops (Figures 2-6 and 2-7),[67] while the capillary network in

FIGURE 2-9 Corrosion resin casts of the AVA (A) and a "U"-turn loop (B). These unique features seem to play an important role in blood flow regulation, especially during the initial stages of inflammation. (Courtesy of Drs. Kazuto Takahashi and Yoshiaki Kishi, Kanagawa, Japan.)

the root area is similar to capillaries in the connective tissue elsewhere. Capillaries empty into small venules that connect with fewer and successively larger venules. At the apex, multiple venules exit the pulp. These venules connect with vessels that drain the PDL and adjacent alveolar bone. Vessels of the dental pulp have thinner muscular walls (tunica media) than vessels of comparable diameter in other parts of the body.[71] This is probably an adaptation to the surrounding protective and unyielding walls.

The vascular architecture can be divided into different vascular segments based on the morphology of periendothelial cells, such as smooth muscle cells and pericytes. These segments are muscular arterioles, terminal arterioles, precapillary arterioles, capillaries, postcapillary venules, and collecting or muscular venules. In most arterioles and in some venules, smooth muscle cells maintain a state of partial vasoconstriction at all times, and a variety of substances such as neurotransmitters, hormones, and local factors influence this muscle tone and, ultimately, the blood flow.[72] Nerve fibers have intimate association with the blood vessels, with arterioles being the most densely innervated. Compared with other connective tissues, the dental pulp has a high resting blood flow that is in the same range as blood flow in cerebral white matter, and four times as high as in resting skeletal muscles.[73] This is nearly as high as blood flow in the brain (Figure 2-12); however, the metabolic or functional requirements of this high resting blood flow in the pulp remains partly unexplained. Sometimes it is called a luxury perfusion. Figure 2-12 shows the comparison of blood flows among various tissues and organs, adjusted according to weight. Pulpal blood flow is intermediate between muscle and heart blood flow per unit weight.

Regulation of Pulpal Blood Flow

Pulpal blood flow is regulated by sympathetic α-adrenergic and neuropeptide Y (NPY) vasoconstriction,[74] β-adrenergic vasodilation,[75] sympathetic cholinergic vasoactive system, and an antidromic vasodilation, that is, a sensory axon reflex. A parasympathetic vasodilator mechanism is not shown in cat dental pulp.[76] The walls of arterioles and venules are coated with smooth muscles, innervated by unmyelinated sympathetic vasoconstrictor fibers as well as sensory fibers containing vasodilating neuropeptides substances such as calcitonin gene-related peptide (CGRP) and substance P (SP). When the sympathetic nerve fibers are stimulated, the muscle fibers contract, decreasing the diameter of the blood vessel and reducing blood flow. This phenomenon is called vasoconstriction. It has been shown experimentally that electrical stimulation of sympathetic fibers leading to the pulp results in a marked decrease in pulpal blood flow.[74,75] The sympathetic nerve-induced vasoconstriction of pulpal vessels is accomplished by the release of the α-adrenergic agonist noradrenalin, and NPY from sympathetic nerve endings. Activation of α-adrenergic receptors by the administration of an α-agonist norepinephrine results in a marked decrease in pulpal blood flow. This reduction in pulpal blood flow is blocked by pretreatment of the pulpal vessels with α-antagonist. These experiments clearly demonstrate that pulpal vessels are heavily equipped with sympathetic adrenergic receptors and their activation causes vasoconstriction. Activation of sensory nerves in the pulp cause increased blood flow, so-called vasodilation.

Blood circulation in an inflamed pulp involves very complex pathophysiological reactions that have not been fully elucidated, in spite of numerous studies.[77, 78]

A unique feature of the dental pulp is that it is rigidly encased within dentin. This places it in a low-compliant environment, much like the brain, bone marrow, and nail bed. Thus, the dental pulp tissue has limited ability to expand, so vasodilation and increased vascular permeability, evoked during an inflammatory reaction, result in an increase in pulpal hydrostatic

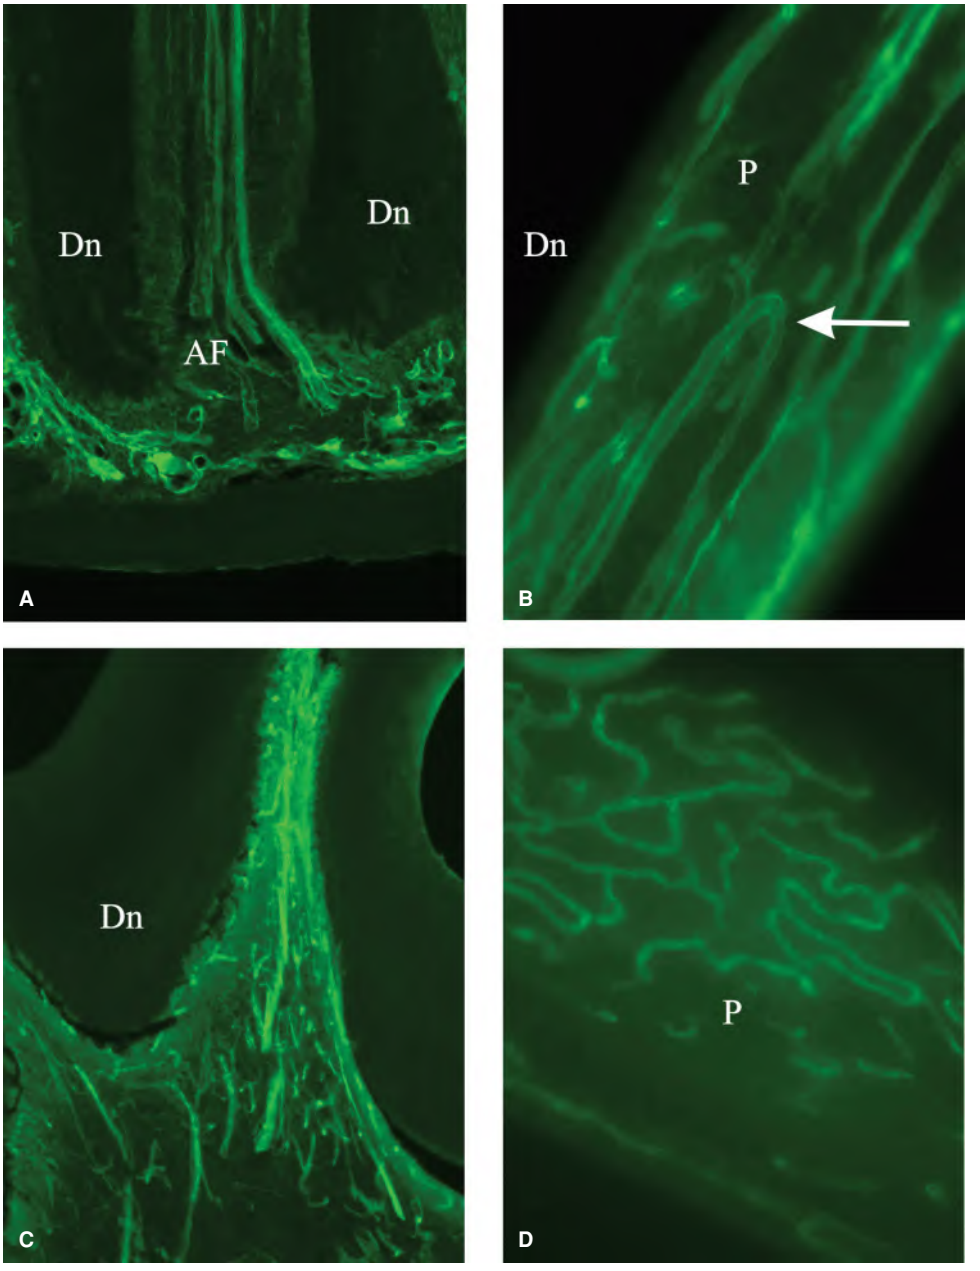

FIGURE 2-10 Immunohistochemical staining of dental pulp stained with fluorescence (green) antibody for laminin that stains mainly blood vessels. ***A.*** Large vessels enter the dental pulp via the apical foramen. ***B.*** Blood vessels in the root dental pulp showing U-turn loops (arrow). ***C.*** Numerous blood vessels in pulp horn region. ***D.*** Cross-section of the odontoblast layers showing capillary network. pressure.[79,80] Presumably, any sudden increase in intrapulpal pressure would be distributed equally within the area of pressure increase, including the blood vessels. Theoretically, if tissue pressure increases to the point that it equals the blood pressure, the thin-walled venules would be compressed, thereby increasing the vascular resistance and reducing the pulpal blood flow.[72] This could explain why injection of vasodilators such as bradykinin into an artery leading to the pulp results in a reduction rather than an increase in pulpal blood flow.[72,75,79] However, Heyeraas[79] observed that an increase in intrapulpal tissue pressure promoted absorption of tissue fluid back into the blood and lymphatic vessels, thereby reducing the pressure. Thus, it appears that blood flow can increase, in spite of an elevation in tissue pressure as long as the permeability of the pulpal vessels is not increased. By normal vessel permeability, the increased pressure causes fluid absorption according to "the Starling forces" that lowers the tissue pressure.

Obviously, a combined multidisciplinary approach is needed to understand the intricate circulatory changes occurring during the development of pulpal inflammation. Using the laser Doppler technique to study pulpal blood flow in dogs, Sasano et al.[81] suggested that an increase or a decrease in pulpal blood flow is more dependent on systemic blood pressure than on local vasoconstriction or vasodilation.

The Stealing Theory

The dental pulp receives its blood supply through the so-called end arteries. These arterioles, entering the apical pulp, have a relatively low blood pressure. The pressure difference from the arterioles entering the pulp to the venules leaving is only about one-fourth of the total arteriovenous pressure difference (Figure 2-13).[80] Accordingly, a considerable part of the vascular resistance that regulates the pulpal blood circulation is located in the venules and also outside the pulp.[82] This implies that changes in circulation in the neighboring adjacent tissues, such as the gingiva, alveolar bone, and PDL, will change the blood flow to the pulp because it will affect the feeding pulpal arterial blood pressure. Any vasodilation in tissues that receive their blood supply through side branches of the end arterioles feeding the pulp will, according to the Poisseuille law, "steal" blood pressure from the pulp (Figure 2-14).[80] Therefore, it should be borne in mind that clinical treatment causing vasodilatation in adjacent tissues, may decrease the circulation to the dental pulp. Thus, the mere application of a matrix may affect the pulpal circulation and cause a fall in pulpal blood flow. The dental pulp may become ischemic.

Low-Compliance System Theory

As stated earlier, the dental pulp is encased in rigid structures, namely dentin, enamel, and cementum, creating a low-compliance system. In this system, any increase in blood flow or vasodilation has a limit, depending on the degree of increase in tissue pressure. In normal conditions, venular blood pressure is higher than the tissue pressure in the pulp. However, introduction of a known vasodilator, such as isoproterenol, causes an initial increase in pulpal blood flow that in turn causes a sudden increase in tissue pressure.[83] When the tissue pressure exceeds that of the venular pressure, a passive compression can cause a decrease in pulpal blood flow (Figure 2-15). Injection of various vasodilators caused a biphasic flow response, an increase followed by a decrease using the radioisotope microsphere injection technique.[84] In clinical situations, the effects of vasodilators produced by the initiation of inflammatory process on pulpal blood flow seem to be based on the low-compliance system theory. Thus, outpouring of inflammatory mediators, mostly vasodilators that

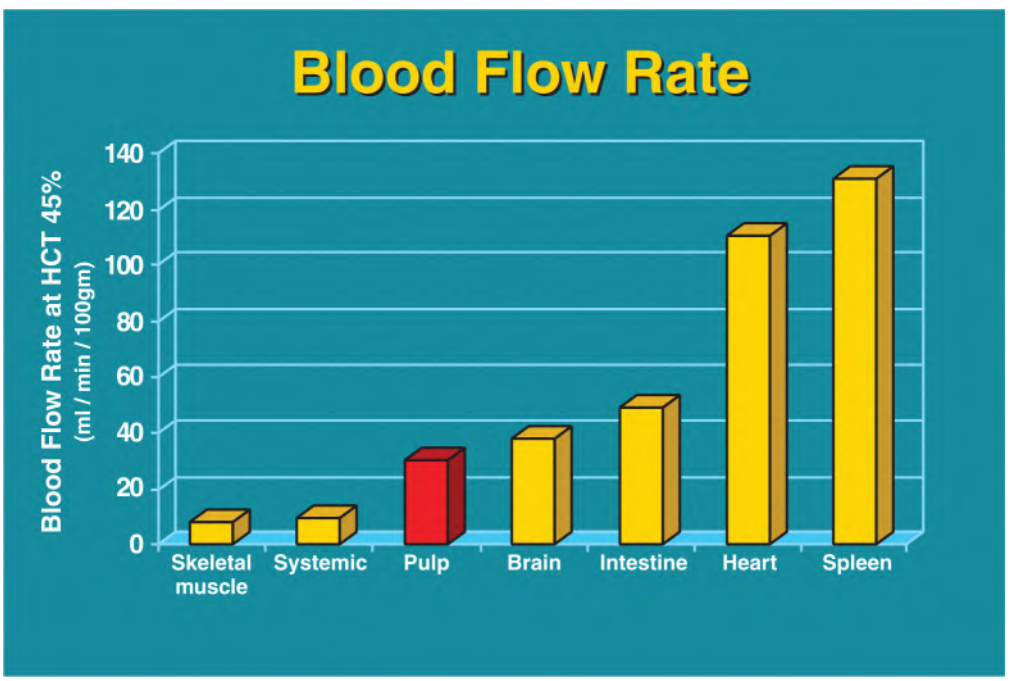

FIGURE 2-12 Blood flow rate in milliliters per minute per 100 g tissue of several important tissues and organs in a dog determined with a radioisotope-labeled microsphere technique. The pulpal blood flow is similar to that of the brain, but far less than in the major organs like the heart or the spleen. (Courtesy of Dr. Syngcuk Kim, Philadelphia, PA, U.S.A.)

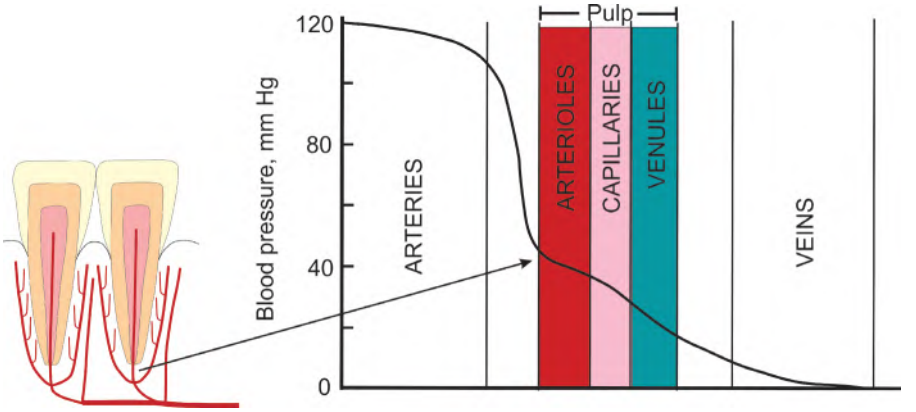

FIGURE 2-13 Fall in blood pressure along extra-pulpal and intra-pulpal blood vessels. Blood pressure in the small arteries entering the dental pulp is relatively low, about half of the aortic pressure. A considerable part of the vascular resistance that regulates pulpal blood flow is located in vessels outside the pulp (bone, gingiva, PDL). (Courtesy of Dr. Karin J. Heyeraas, Bergen, Norway.)

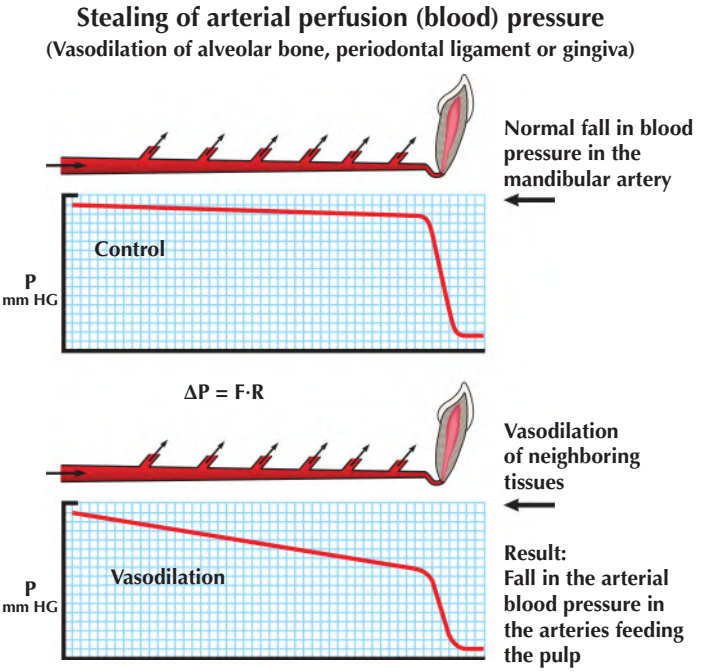

FIGURE 2-14 Stealing of arterial perfusion pressure during vasodilation in adjacent tissues. (P:blood pressure, F:blood flow, R:vascular resistance). (Courtesy of Dr. Karin J. Heyeraas, Bergen, Norway.)

also increases the vessel permeability, has grave consequences for pulpal survival due to passive compression of the low-pressure venules by a high tissue pressure (Figure 2-15).

Transcapillary Fluid Flow

At the same time as the exchange of substances occurs across capillaries, another completely distinct process also takes place, that is, the bulk flow of fluid across the capillary wall. The function of this bulk flow of fluid is not the exchange of nutrients and waste products, but the distribution of the extracellular fluid. This distribution is governed by the hydrostatic pressure difference and the colloid osmotic pressure difference across the capillary wall. These pressures determine the amount of the extracellular fluid located within the vessels as blood plasma and as interstitial fluid in the tissues. The difference in protein concentration between plasma and interstitial fluid is important because it creates a higher colloid osmotic pressure in plasma than in the interstitial fluid, thus favoring bulk fluid movement back into the capillary.

The hydrostatic pressure outside the vessels is normally considerably lower than the blood pressure inside the capillaries. Usually, this difference in hydrostatic pressure favors filtration, or bulk flow of fluid out of the vessels. However, in the low-compliant dental pulp, where a small increase in volume increases the tissue pressure, absorption may take place during vasodilation. In the low-compliant pulp, a nearly simultaneous increase in blood volume and tissue pressure, as a result of vasodilation and/or venous stasis,[78] has been

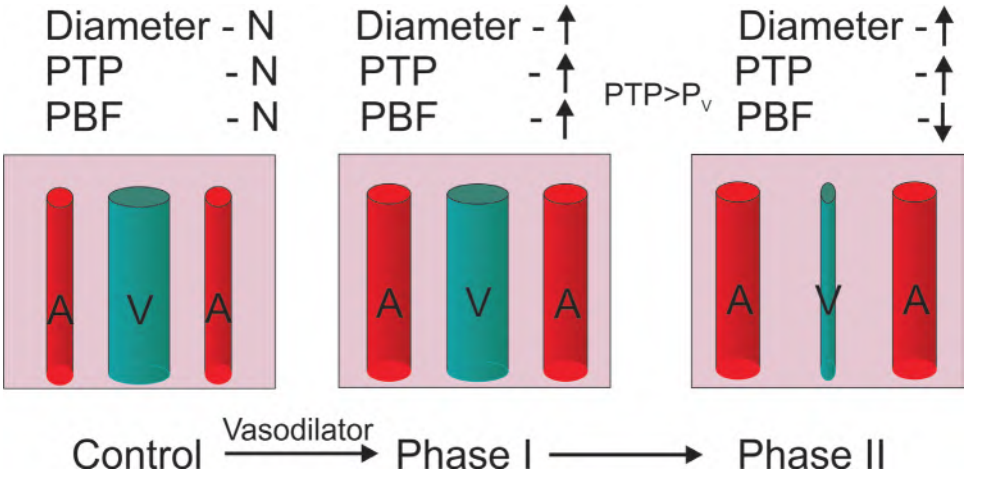

FIGURE 2-15 Diagram illustrating the low-compliance system during vasodilation (Phase I). The non-inflamed dental pulp has normal vessel permeability. Therefore, only a transient increased in pulpal tissue pressure (PTP) and fall in pulpal blood flow (PBF) will occur by vasodilation (Phase II). In non-inflamed pulp, the increased tissue pressure will cause absorption of interstitial fluid back into the vessels, and thus relatively quickly lower the tissue pressure and restore blood flow. On the contrary, in the inflamed dental pulp, the increased vessel permeability will prevent fluid absorption and a fall in PBF (Phase II) will prevail due to compression of veins. (Courtesy of Dr. Syngcuk Kim, Philadelphia, PA, U.S.A.)

recorded, showing that vascular distension with an increase in blood volume compresses the pulpal tissue and raises the tissue pressure. Thus, a rapidly responding hydrostatic counter pressure develops that lowers the transmural hydrostatic pressure difference. Consequently, capillary filtration is reduced and absorption occurs, and the tissue pressure is rapidly normalized, according to the Starling forces.[85]

The interstitial fluid in the pulp reaches out in dentinal tubules and forms a continuum that extends out to the dentinoenamel and cementoenamel junctions. The mere cutting of dentin, as it occurs during cavity and crown preparation, may, therefore, affect the dental pulp.[85] Furthermore, sensory nerve fibers are located in the subodontoblastic space and in ~50% of tubules in the crown. Research during the last decades has shown that sensory nerves have a strong impact on the blood circulation in the dental pulp, due to liberation of vasodilating neuropeptides. In the cat pulp, most of the sensory nerve fibers contain these neuropeptides. The majority of sensory nerve fibers containing the vasodilating neuropeptides in the main pulp seem to be located in the walls of the blood vessels, a finding that implicates a role for these neuropeptides in blood flow regulation.

Lymph Vessels

The only known mechanism for the removal of proteins and macromolecules that may leak out from the blood vessels in any tissue is the lymphatics. The existence of lymph vessels in the dental pulp is well established.[86, 87] Recovery of inflammation depends on the removal of macromolecules and plasma proteins from the tissue, thus a reversible pulpitis is dependent on functional lymph vessels.[88] Most lymphatic vessels are located in the root pulp, whereas in the coronal area, lymph vessels are observed in the more central part. Some studies conclude that in the coronal part, real lymph vessels are lacking and that lymph is collected in interstitial clefts and drains toward lymphatic vessels in the apical region of the pulp.[89] The lymphatics in the peripheral pulp zone join to form larger collecting vessels.[90] These vessels unite with progressively larger lymphatic vessels that pass through the apex together with the blood vessels.

Numerous authors, using both histological and functional methods, have described extensive anastomoses between lymph vessels of the dental pulp, the PDL, and alveolar bone.[91–94] The structural identification of lymph vessels[86, 91] complements the functional studies, demonstrating that substances placed in the pulp chamber can be found in regional lymph nodes. The open endothelial margins and incomplete basal lamina permit the entry of large molecules and even microorganisms into the lymphatics. The fact that materials placed in the dental pulp can migrate to lymph nodes[95] indicates the possibility of the spread of microorganisms or their products from the pulp.[96] The anastomoses of pulpal, periodontal, and alveolar lymphatics may be important routes for the spread of pulpal inflammation into adjacent tissues.

The architecture of the initial lymphatics, the so-called lymph capillaries, in different tissues varies considerably. Although in general they are wider than the blood capillaries, their number is much smaller. The wall of the initial lymphatics consists of a single layer of thin endothelial cells, often with overlapping margins. Open gaps between the cells, up to 2–5 μm, are frequent in many tissues. The initial lymphatics dilate and the number of open junctions increases during edema formation. It has been proposed that interstitial fluid pressure is the main determinant of lymph flow, and that lymph flow increases consistently with the tissue pressure.[97] In the low-compliant pulp, this would imply that the increased local tissue pressure, as measured during pulpitis, induces increased lymph flow that will normalize the pressure and also drain off microorganisms and their byproducts, promoting healing of the pulp.

An enhanced lymph flow during inflammation has also been suggested by Feiglin and Reade.[98] They deposited radioactive microspheres in rat pulps and found more microspheres in the submandibular lymph nodes in those rats whose pulps had been exposed for 5 days in comparison with those with acute pulp exposure.[98] The relationship of teeth to the cardiovascular and lymphatic systems is intimate and absolute. Clinicians should remember this when performing dental procedures, because placement of materials on dentin or the pulp may result in widespread distribution of that material or medicament.

Interstitial Fluid

The rigid encasement allows the tissue-limited possibilities to expand and keeps the extracellular fluid volume, that is, blood plasma and interstitial fluid, relatively constant. The extracellular fluid volume in the dental pulp is normally relatively high of ~63%.[99] Due to the low compliance, a small increase in the pulpal volume, caused by an increase in blood or interstitial fluid, will raise the hydrostatic pressure inside the tooth. This is shown to happen normally by any increase in blood flow and thus blood volume.[100] However, as long as there are no noxious stimuli that increase the vessel permeability, any change in tissue pressure caused by blood volume changes will be transitory, because interstitial fluid is absorbed back to the blood vessels, and no harm will happen to the pulp (Figure 2-15).[80]

The hydrostatic pressure in this fluid is the interstitial fluid pressure, or the so-called tissue pressure (Figure 2-16). The interstitial fluid is similar to blood plasma, except for a lower concentration of plasma proteins (albumin and globulin). In a healthy dental pulp, plasma proteins do not permeate through the capillary wall and the concentration in the interstitial fluid is normally low. However, a study in rat incisors, surprisingly high protein concentration in the pulp interstitial fluid during physiological conditions was reported.[99]

The main function of the interstitial fluid is to act as a transport medium for nutrients and waste products between cells and capillary blood. Accordingly, the interstitial fluid acts as a middleman between cells and blood, or as an extension of the plasma. Every cell must have nutrition plus the means to rid itself of waste products. These metabolic requirements are taken care by the blood and the interstitial fluid. Blood is brought to the tissues by the smallest blood vessels, the capillaries. Substances are transported between the blood and the interstitial fluid mainly by diffusion through the capillary wall (Figure 2-16). These capillaries are so widely distributed that no cells are >50–100 μm from the blood vessels. Due to this short distance, the exchange of substances between blood and interstitial fluid may take place rapidly by simple diffusion. Diffusion depends on the concentration differences. Accordingly, increased blood flow creates higher concentration difference between plasma and interstitial fluid and faster exchange of substances.

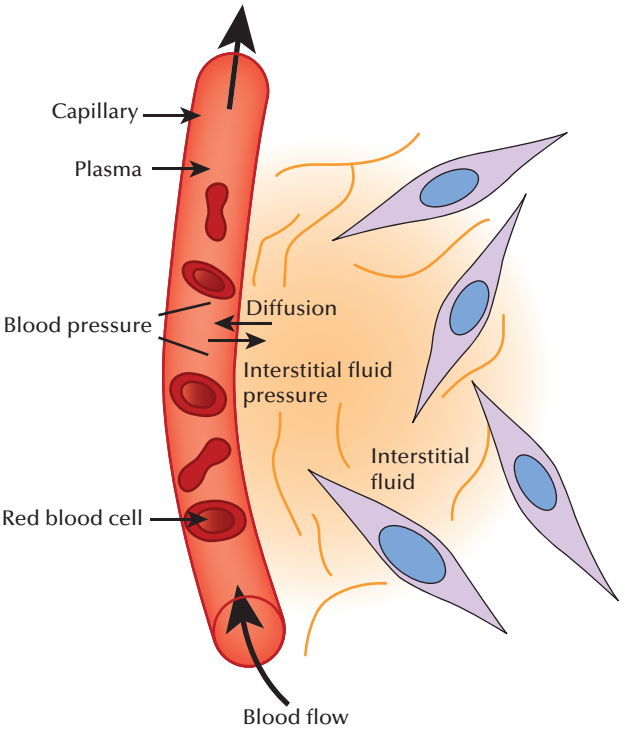

FIGURE 2-16 Schematic illustration of dental pulp tissue. The interstitial fluid is the fluid that surrounds cells and the hydrostatic pressure in this fluid is tissue pressure. (Courtesy of Dr. Karin J. Heyeraas, Bergen, Norway.)

Nerves in the Pulp

Classification of Nerves

The dental pulp has an abundant supply of both sensory and sympathetic nerves. The majority of these nerves are sensory. The trigeminal ganglion supplies sensory innervation to the pulp via the maxillary and mandibular nerves. Sympathetic nerves are less numerous with its source from the superior cervical ganglion. Postganglionic sympathetic nerves travel with the internal carotid nerve, reach the trigeminal ganglion, and supply teeth and supporting structures via the maxillary and the inferior alveolar nerve.[101–103] A small portion of sympathetic nerve fibers enter the dental pulp surrounding blood vessels. The proportion of sympathetic fibers in the dental pulp has been shown to be relatively small.[104, 105] Sympathetic fibers in fully developed teeth have been reported to make up no more than ~10% of the nerve fibers.[106] Parasympathetic fibers have been suggested to exist in the pulp.[107, 108] Anatomical and electrophysiological studies have classified nerves according to their diameter and conduction velocity (Table 2-1). The pulp contains two types of sensory nerve fibers: A fibers that are myelinated and C fibers that are unmyelinated. A fibers include both A-β and A-δ with A-δ amounting to ~90% of the total A fibers.[109] For more details, see Chapter 7.

Neuropeptides

Nerve fibers release biologically active peptides, known as neuropeptides that influence neural activity and

TABLE 2-1 Classification of Nerves in the Pulp

Type of Fiber	Function	Diameter (μm)	Conduction Velocity (m/sec)
A β	Pressure, Touch	5–12	30–70
A δ	Pain, Temperature, Touch	2–5	12–30
C	Pain	0.4–1.2	0.5–2
Sympathetic	Postganglionic sympathetic	0.3–1.3	0.7–2.3

functioning.[110–112] Neuropeptides are synthesized on ribosomes in the neuron cell body, processed through the endoplasmic reticulum and Golgi complex, transported in vesicles by axoplasmatic flow to the nerve terminals (Figure 2-17), and released from the peripheral terminals of mainly A-δ and C fibers.[113]

There are numerous neuropeptides in the dental pulp that are commonly classified as sensory, sympathetic, or parasympathetic neuropeptides according to the origin of nerve fibers. Sensory neuropeptides reported in the dental pulp are CGRP, SP, and neurokinin A (NKA). CGRP, a 37-amino acid peptide, is a member of the calcitonin family of peptides. It is synthesized in the trigeminal ganglion and transported to the dental pulp via maxillary and mandibular branches. CGRP is a potent vasodilator and can function in the transmission of pain.[114,115] In the dental pulp, CGRP seems to be mainly responsible for the increase in blood flow and interstitial fluid pressure during tooth stimulation.[116] SP belongs to the tachykinin neuropeptide family, a 11 amino acid peptide, closely related to NKA. Similar to CGRP, SP is also synthesized in the trigeminal ganglion and often co-localized with CGRP. The SP is found in small-diameter, predominantly unmyelinated sensory axons.[117,118] It is a vasodilator, increases vessel permeability and other aspects of inflammatory process, and is important in pain perception. The CGRP with SP has a synergistic effect on edema formation during inflammatory reactions.[119] When injected in the blood stream in experimental studies, CGRP, SP, and NKA produce vasodilation in the dental pulp.[120] Activation of nerve fibers by electrical stimulation, or electrical impulses on the tooth, produces long lasting vasodilation in the pulp.[77,121,122] Sensory denervation performed by axotomy of the inferior alveolar nerve decreases pulpal blood flow and interstitial fluid pressure indicating a basal release of vasoactive sensory neuropeptides.[116]

NPY, a neuropeptide released from sympathetic nerve terminals, is a 36 amino acid peptide that acts as a neurotransmitter and neuromodulator.[123,124] It is synthesized in the sympathetic ganglion and co-released with norepinephrine via anterograde axonal transport from the peripheral terminals.[125–127] It has been reported that NPY can also be found in sensory neurons and nerves when there has been neuronal injury such as axotomy.[128,129] Release of NPY causes vasoconstriction.[126] NPY has also been reported to be a modulator of the immune function in the dental pulp and surrounding structures.[130] Vasoactive intestinal peptide (VIP), a peptide containing 28 amino acid peptide, has been shown to be released from parasympathetic nerves.[131]

Distribution

Immunohistochemical staining methods have made it possible to identify the location and distribution of peptidergic nerves in the dental pulp. The figures from immunohistochemistry, shown in this chapter, are from experimental animals unless otherwise stated. Due to the staining procedures, animals are first perfused to remove red blood cells and then post-fixed, decalcified, sectioned, and stained with specific antigen-antibody (immunohistochemical) reactions.

Sensory nerves fibers containing CGRP or CGRP-immunoreactive (-IR) nerve fibers (Figure 2-18) enter the

pulp via the apical foramen in bundles either surrounding the blood vessels or individually, and ramify into a network of fine fibers in the coronal pulp.[132–134] Coronally, individual fibers penetrate the odontoblast layer and predentin to terminate in the inner 100 μm of the dentinal tubules. Nerve fibers have been found in >50% of tubules in inner cuspal dentin.[53,109,135,136] Radicular pulp fibers run parallel to the long axis of the tooth with little arborization and limited penetration of the odontoblast layer.

CGRP is the most abundant neuropeptide in the dental pulp (Figure 2-18). It is three to four times more abundant than SP.[132] SP is commonly found in C fibers with distribution patterns similar to CGRP-IR nerve fibers.[117,118,132] NKA-IR nerve fibers have distribution pattern similar to SP-IR nerve fibers.[137] CGRP, SP, and NKA neuropeptides have been shown to coexist in the same nerve fibers in the dental pulp. Neuropeptide containing nerve fibers are found in close contact with immune cells suggesting important neuroimmune interactions (Figure 2-19).

Sympathetic nerve fibers containing NPY or NPY-IR fibers are thin with varicosities. In a normal healthy dental pulp, thin varicose fibers enter the dental pulp via the apical foramen in close approximation to blood vessels. In the root pulp, NPY containing fibers exhibit a network arrangement surrounding blood vessels. These NPY containing fibers terminate in the floor or the mid-coronal part of the pulp chamber (Figure 2-20). They do not extend to the pulp horn region nor penetrate the odontoblast layer. NPY containing fibers are more in number in the radicular than in the coronal pulp.[108,132,138–140] VIP-IR nerve fibers in the dental pulp are associated with blood vessels,[141] or occur as free and interlacing nerves in the central pulp and the subodontoblastic plexus.[141,142]

Neurogenic Inflammation

Sensory neuropeptides have been shown to cause neurogenic inflammation. A classical demonstration of neuropeptide activity is the flare component of the "triple response" in the human skin: wheal (edema formation), local reddening (increased blood flow), and flare.[143] The flare component of the triple reflex is a consequence of the sensory nerve-mediated axon reflex release of SP and CGRP causing increase in blood flow (vasodilation) and vessel permeability.

During inflammation, neuropeptide containing nerve fibers exhibit changes in number, density, and architecture. This observation was first made by Byers et al. where sensory nerves fibers containing neuropeptides CGRP and SP showed sprouting during pulpal injury.[144–147] In experimental pulp exposure studies, sprouting occurs as early as one day after pulp exposure and stays high until healing or pulp necrosis occurs.[133,146] Nerve fibers also change in quantity and architecture when inflamed (Figure 2-21). Sympathetic fibers containing NPY, unlike sensory nerve fibers, do not sprout immediately after injury in experimental studies but a few weeks later[139,148,149] (Figure 2-22). In clinical situations, neuropeptide levels are increased in dental pulp diagnosed as irreversible pulpitis.[150,151]

External root resorption originating from the periodontium, however, does not display any nerve sprouting in the dental pulp or PDL, unlike caries and experimental pulp exposure.[152] A complete root resportion from the periodontium to the dental pulp creates very little damage to the dental pulp (Figure 2-23). This has been concluded to be mainly due to the lack of infection when a root resorption originates from the periodontium.[152]

Sectioning of the inferior alveolar nerve removes almost all sensory neuropeptide containing nerves in the dental pulp.[153] Removal of the superior cervical ganglion, eliminates almost all NPY containing nerve fibers in the dental pulp.[154] Electrical stimulation of teeth causes release of neuropeptides, creating a local neurogenic inflammation such as increased blood flow, transendothelial migration of inflammatory cells. When nerve fibers have been removed from the pulp, via axotomy of inferior alveolar nerve, no recruitment of immune cells was observed, thus confirming the importance of nerve fibers for neurogenic inflammation.[155,156] When sympathectomy was performed, granulocytes were not recruited after electrical stimulation.[157] It has been reported that while sensory neuropeptides have a pro-inflammatory role in the dental pulp, sympathetic neuropeptide, NPY, may have an anti-inflammatory role on the immune system.[130,150,157–159]

Sensory neuropeptides increase vascular permeability during inflammation, and stimulate the production of other inflammatory cytokines such as interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor-alpha (TNFα) (Figure 2-24). Sympathetic nerves inhibit the production of proinflammatory cytokines, while stimulating the production of anti-inflammatory cytokines.[130,160] Teeth lacking sympathetic nerves also tend to undergo

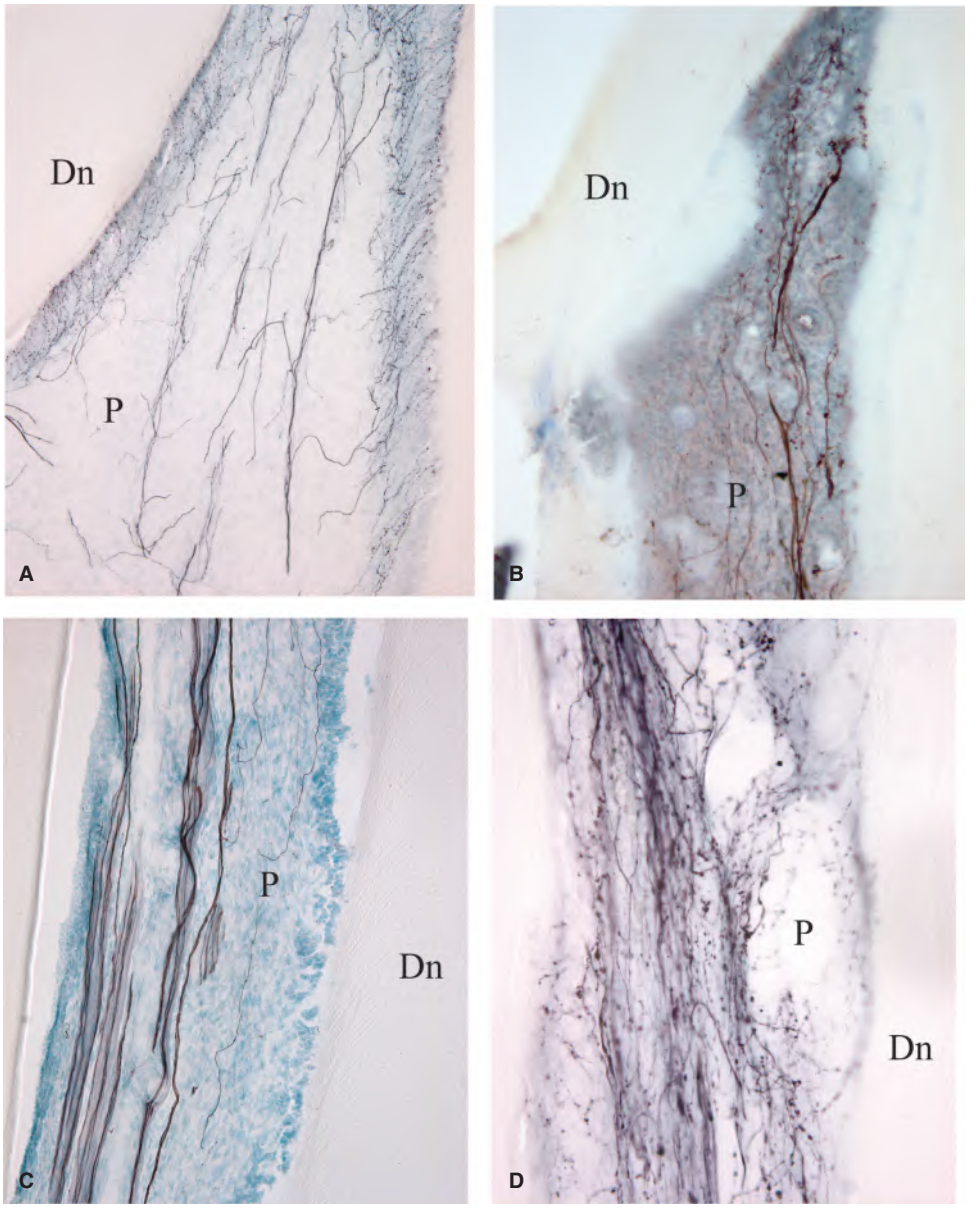

FIGURE 2-21 Calcitonin gene-related peptide-immunoreactive (CGRP-IR) nerve fibers in the normal dental pulp (A and C) and inflamed dental pulp (B and D). ***A & C.*** Normal architecture of nerve fibers in the root, coronal and pulp horn region. ***B & D.*** An inflamed dental pulp after 20-day pulp exposure injury shows extensive spouting of CGRP-IR nerve fibers. necrosis more frequently indicating the anti-inflammatory role of the sympathetic nervous system.[138]

Sympathetic nerves have been shown to be important in the recruitment of granulocytes during electrical stimulation of teeth and experimental tooth movement.[157,161] Sympathetic imbalance results in the recruitment of plasma cells in an intact tooth, suggesting an immune dysfunction.[162] Sympathetic nerves have also been shown to have an inhibitory effect on osteoclast resorption activity and on the cytokine IL-1α.[139,160,161] NPY, co-released in the sympathetic nerve terminal, has recently been reported to modulate immune function in a wide range of inflammatory conditions.[130]

Receptors

Neuropeptides cannot cross the cell membrane and, therefore, their action is dependent on the existence of specific receptors (Table 2-2). Without the existence of a particular receptor, release of neurotransmitters, or neuropeptides, will have no effect. Therefore, identifying the location and distribution of these receptors is important for understanding the functionality of a neuropeptide in a given location. NK1 receptors, specific for SP, are present in the blood vessels in the root pulp and smaller vessels along the odontoblast layer.[163,164] Fibroblasts express NK1 receptors during mechanical orthodontic stress.[161] NPY receptors are located in blood vessels, nerve fibers, fibroblasts, and immune cells.[165,166] Antagonists

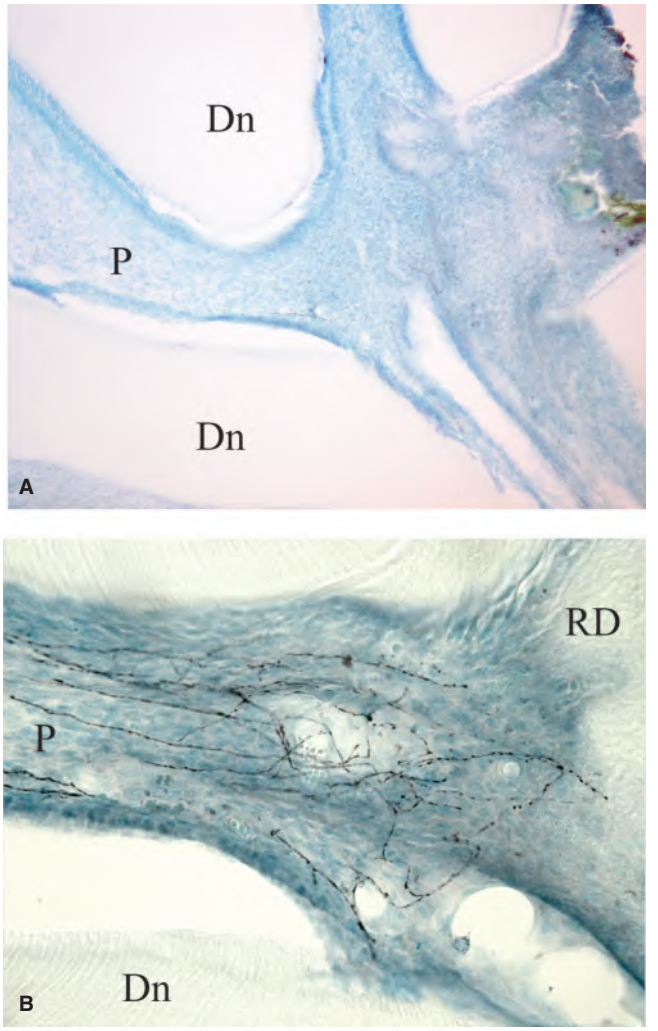

FIGURE 2-22 Neuropeptide Y-immunoreactive (NPY-IR) fibers in the inflamed dental pulp. ***A.*** After 6 days of pulp exposure injury, molar pulp shows no sprouting of nerve fibers. ***B.*** After 20 days of pulp exposure, there is extensive reparative dentin formation and increased number of NPY-IR nerve fibers penetrating the region of the reparative dentin.[140] (Dn: dentin, P: pulp, RD: reparative dentin). to these receptors are now being widely studied as therapeutic agents against inflammatory diseases, or diseases involving overexpression of neuropeptides.

Extracellular Matrix

Extracellular matrix (ECM), or ground substance, is a structureless mass making up the bulk of the pulp tissue. It consists primarily of complexes of proteins, carbohydrates, and water. These complexes are composed of combinations of glycosaminoglycans, namely hyaluronic acid, chondroitin sulfate, and other glycoproteins.

Proteoglycans are a large group of extracellular and cell surface-associated molecules that consist of a protein core, to which glycosaminoglycan chains are attached, which binds them to water. Hyaluronic acid, a large glycosaminoglycan, forms a viscous hydrated gel. Proteins, glycoproteins, and

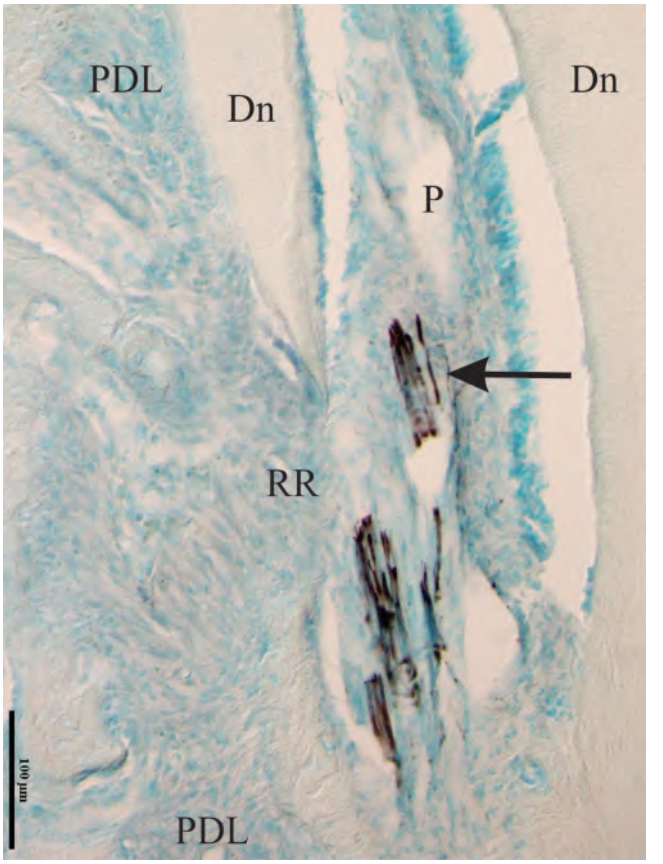

FIGURE 2-23 Immunohistochemical staining of PGP 9.5 immunoreactive nerve fibers in a tooth with experimental root resorption. Arrows pointing towards region of root resorption (RR) where whole dentin is resorbed. There is no sprouting of nerve fibers in the dental pulp or PDL.[153] (Dn: dentin, P: pulp, PDL: periodontal ligament). (Courtesy of Dr. Sivakami R. Haug, Bergen, Norway.)

proteoglycans of the ECM function in cell–matrix adhesion and signaling; regulate diffusion of nutrients, waste products, and soluble signaling molecules.

Cytokines, growth factors, and other inflammatory mediators are released by fibroblasts, endothelial cells, and immune cells in the dental pulp. Normal dental pulp contains cytokines such as IL-1α and TNFα[160]; however, during inflammation, orthodontic tooth movement, and other stimulation, IL-1α, IL-1β, IL-8, TNFα, prostaglandin E2, platelet-derived growth factor, insulin-like growth factor-1, transforming growth factor-b (TGFb1), vascular endothelial growth factor, basic fibroblast growth factor (FGF-2), hepatocyte growth factor, and keratinocyte growth factor levels are increased.[167–173] These molecules mainly act locally and play important roles during development, inflammation, and wound healing.

Fibers

Collagen is the major organic component in the dental pulp. The morphology of collagen fibers, a principal constituent in the pulp, has been described at the level of both light and electron microscopy.[174] Collagen is synthesized and secreted

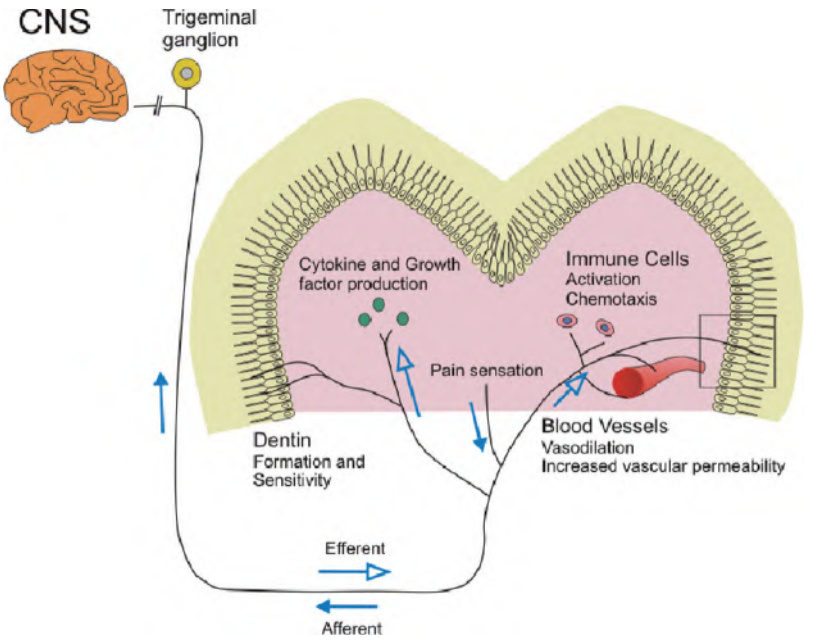

FIGURE 2-24 Schematic illustration summarizing some of the effects of neuropeptides (calcitonin gene-related protein, CGRP; substance P, SP) released from sensory nerves. Sensory nerves conduct afferent sensory information (e.g., pain sensations/dentin sensitivity) to the central nervous system. In addition, they have efferent functions, such as vasodilation and increased vessel permeability, due to liberation of neuropeptides at the nerve endings. It also affects various aspects of immune function such as activation and chemotaxis of immune cells, and release of cytokine and growth factors from various cellular structures in the dental pulp. Sensory nerves have also been shown to be involved in the formation of dentin. (Courtesy of Dr. Sivakami R. Haug, Bergen, Norway.)

TABLE 2-2 Neuropeptides and Their Origins Including Some of Their Main Actions and Specific Receptors

Neuropeptides	Released from	Actions	Receptors
Substance P	Sensory	Vasodilation, Increase vascular permeability	NK1
Neurokinin A	Sensory	Increase vascular permeability	NK2
Calcitonin Gene-Related Peptide	Sensory	Vasodilation	CGRP1 and CGRP2
Neuropeptide Y	Sympathetic	Vasoconstriction, pain modulation, immune function	NPY Y1-6
Vasoactive Intestinal Peptide	Parasympathetic	Vasodilation, immune function	VIP 1 & 2

by both odontoblasts and fibroblasts. However, the type of collagen secreted by odontoblasts to subsequently mineralize differs from the collagen produced by pulpal fibroblasts that normally does not calcify. They also differ not only in the basic structure but also in the degree of cross-linking and in slight variation in hydroxylysine content.

Tropocollagen is an immature collagen fiber that remains thin and stains black with silver nitrate, described as argyrophilic or reticular fibrils under light microscopy. If tropocollagen molecules aggregate into larger fibers, they no longer stain with silver and are then termed "collagen fibers." If several collagen fibers aggregate (cross-link) and grow denser, they are termed "collagen bundles." Collagen generally becomes more coarse (i.e., develops more bundles) as the patient ages. Collagen fibers are inelastic but have great tensile strength, giving its consistency and strength to the tissue.

Collagen type I and III make up the bulk of the tissue collagen. Collagen type IV is found in basement membranes. In the pulp, type III collagen appears as fine-branched filaments, whose distribution is similar to reticular fibers. Fibronectin is insoluble and the fibrils form part of the ECM. It acts as a mediator for cell–cell and cell–matrix adhesion. In the odontoblast layer, fibronectin is the fibrous structure between odontoblasts and probably corresponds to von Korff fibers, as they appear as corkscrew fibers passing from the pulp into predentin parallel to the long axis of the odontoblasts.[175] In the dental pulp, fibronectin forms a reticular network of fibrils, with an increased encasement around blood vessels. Integrins are transmembrane receptors that link intracellular actin network with ECM.

Cellular Structures

Odontoblasts

Odontoblast, the principal cell of the dentin-forming layer, is the first cell type encountered as the pulp is approached from the dentin (Figures 2-25, 2-26, and 2-27). These cells arise from peripheral mesenchymal cells of the dental papilla during tooth development and differentiate by acquiring the characteristic morphology of glycoprotein synthesis and secretion.[176] Glycoprotein forms the predentin matrix that is rendered mineralizable by the odontoblast, a unique

FIGURE 2-25 Pseudostratified appearance of odontoblasts. Dark horizontal line (arrow) delineates the cell body from the odontoblastic processes and predentin (once termed "pulpodentinal membrane"). Ultrastructural examination has shown this to be a terminal cell web that forms a support and attachment area between adjoining cells. (Reproduced with permission from Walton R, Leonard L, Sharawy M, Gangarosa L. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 1979;48:545-7.)

cell producing a unique tissue, dentin. Synthesis and secretory activities render the odontoblast highly polarized, with synthesis occurring in the cell body and secretion from the odontoblastic process. The cell body contains organelles that represent different stages of secretion of collagen, glycoproteins, and calcium salts.[177] Matrix secretion precedes mineralization, with these two events separated in time and space by the predentin. The initial mineral seeding of predentin at the dentinoenamel junction is by the formation of "matrix vesicles, similar to bone mineralization."[178,179] Classic studies by Weinstock and Leblond,[180,181] using an autoradiographic technique, have demonstrated the functional sequence of matrix production and secretion.

In histological sections viewed under a light microscope, odontoblasts appear to vary from tall, pseudostratified columnar cells in the coronal pulp, to a single row of cuboidal cells in the radicular pulp to a flattened, almost squamous

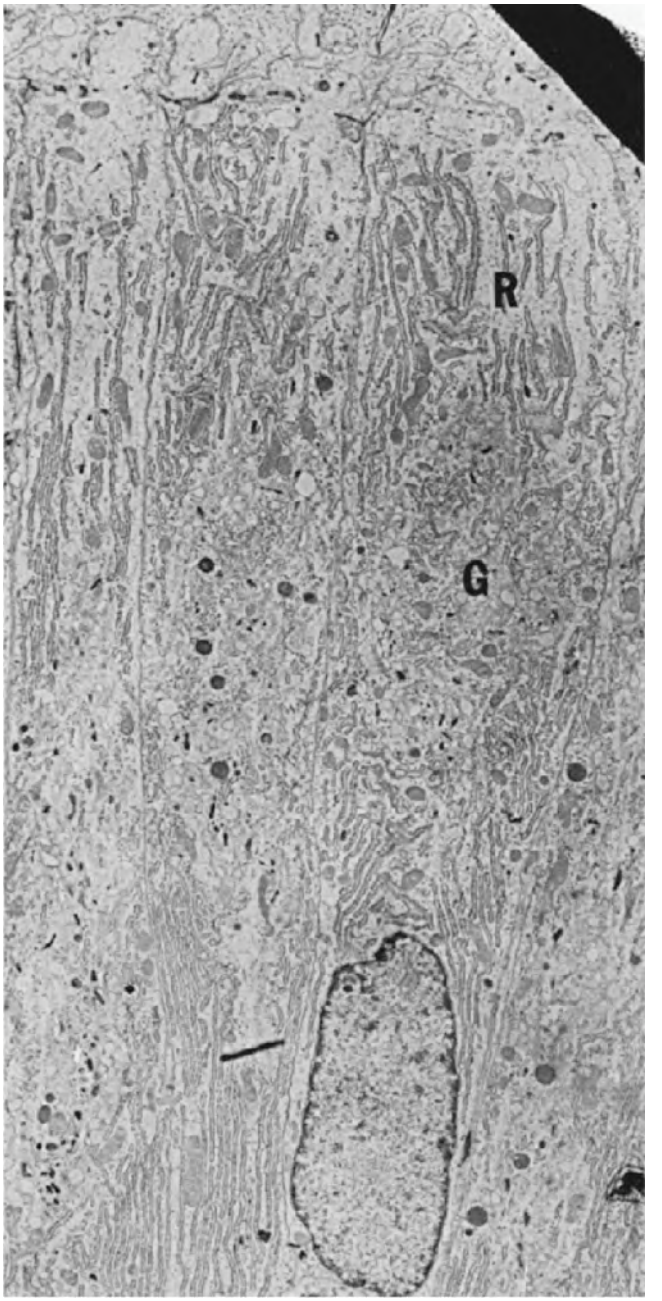

FIGURE 2-26 Odontoblasts, as viewed under the electron microscope, show organelles essential for protein synthesis; a plump nucleus filled with euchromatin, cytoplasm rich in rough endoplasmic reticulum (R), and a well-developed Golgi apparatus (G). (Courtesy of Dr. Dale R. Eisenmann, Chicago, IL, U.S.A.)

shape near the apex.[182,183] These squamous-shaped cells often form an irregular, atubular dentin. The large nucleus is located in the base of the cell, giving it a pear-shaped appearance.[184] From an exquisite scanning electron microscopic study, investigators have demonstrated that odontoblast cell bodies "appear tightly packed in the pulp horn and successively pear-shaped, spindle-shaped, club-shaped, or globular from the crown to the apex."[61]

During dentin formation in the crown, the odontoblasts are pushed inward to form the periphery of a pulp chamber,

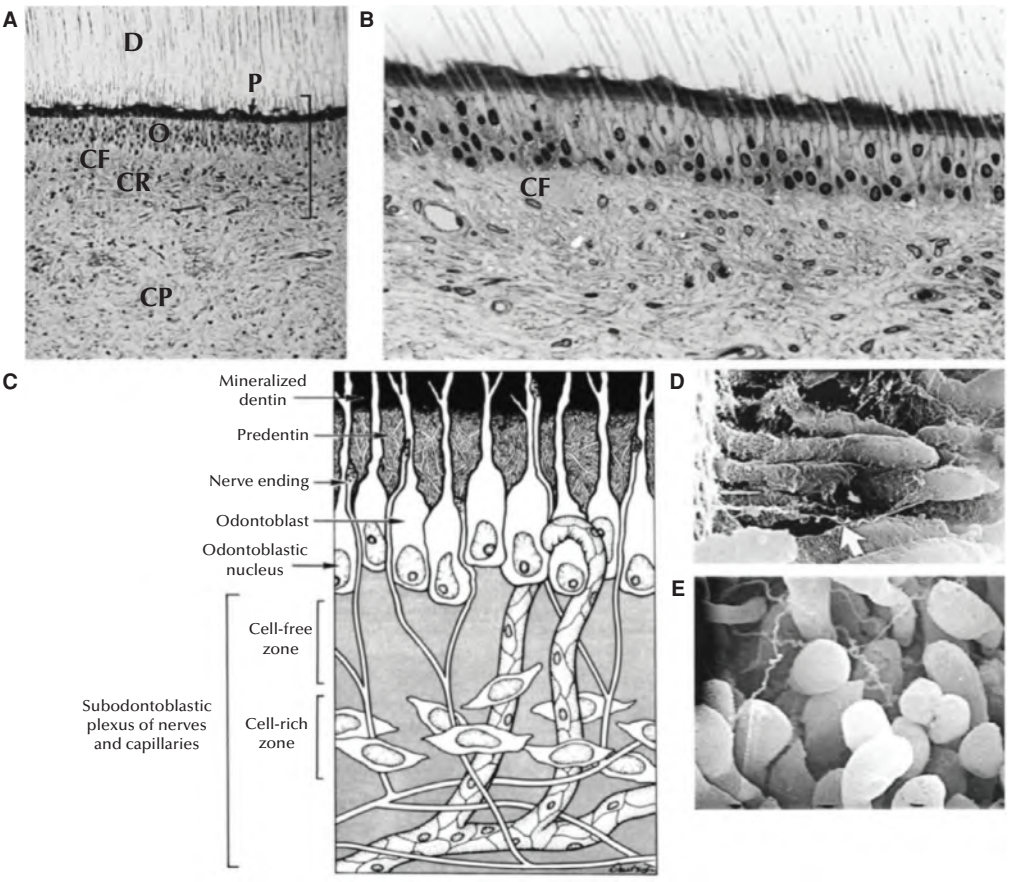

FIGURE 2-27 ***A.*** Medium-power photomicrograph of a human pulp specimen showing dentin (D), predentin (P), odontoblast layer (O), cell-free zone (CF), cell-rich zone (CR), and central pulp (CP). ***B.*** Region similar to the area bracketed in A. CF zone contains large numbers of small nerves and capillaries, not visible at this magnification. Underlying CR does not have high concentration of cells but contains more cells than the central pulp. (Courtesy of Drs. Dennis F. Weber and Michael K. Gaynor, Chicago, IL, U.S.A.) ***C.*** Diagram of peripheral pulp and its principal elements. ***D.*** Scanning electron micrograph (SEM) of the dentin–pulp junction. Note corkscrew fibers between odontoblasts (arrow). Reproduced with permission from Jean A, Kerebel JB, Kerebel LM. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 1986;61:392-8. ***E.*** SEM of the pulpal surface of the odontoblast layer. Thread-like structures are probably terminal raveling of nerves. (Courtesy of Drs. Robert R. White and Melvin Goldman, Boston, MA, U.S.A.)

a circumference that is increasingly smaller than the original circumference at the dentinoenamel junction. This explains why the cells are packed and palisaded into a pseudostratified appearance of coronal odontoblasts. Conversely, because the space is not so compressed in the radicular pulp, the odontoblasts maintain a columnar, cuboidal, or (in the apical region) squamous shape. Also, the resulting cell and tubule density are much higher in the pulp chamber than in the root pulp.[185] This increased tubule density in the chamber may explain the greater sensitivity and permeability of the dentin of the crown.

The cell body manufactures the matrix material; the material is transported to and secreted from the odontoblastic process. Classically, the odontoblastic process has been described as extending from the cell body to the dentinoenamel junction, a distance of 2–3 mm. This concept was based on the observations of many light microscopists using a variety of special procedures and stains.[41] When dentin was examined by electron microscopy, the odontoblastic process was determined to be limited to the inner third of dentin, with the outer two thirds of the tubule devoid of processes or of nerves, but filled with extracellular fluid.[59,186–188] Some investigations indicate that odontoblastic processes may indeed extend to the dentinoenamel junction.[189] However, tubular structures in dentinal tubules are not necessarily odontoblastic processes.[190,191] Unequivocal identification can be done only by identifying a trilaminar plasma membrane around the putative process, using transmission electron microscopy.[192,193] The extent of the odontoblastic process remains controversial.[62] Therefore, modern interpretations of pulpal injury following conservative cavity preparation may not be attributable to amputation of odontoblastic processes but to desiccation, heat, and osmotic effects. Furthermore, dentin sensitivity may not be related to direct stimulation of odontoblastic processes or nerves in the peripheral dentin since the tubules may be devoid of such structures in the periphery of dentin.

After initial dentin formation, the odontoblast, via its process, can still modify the dentin structure by producing

peritubular dentin. This is a hypermineralized cuff with little organic matrix within the tubule, decreasing the diameter of the tubule.[194–196] When stimulated, the odontoblast can accelerate peritubular dentin formation to the point of complete occlusion of the tubule.[197–199] When tubule occlusions extend over a large area, it is referred to as sclerotic dentin, commonly found in teeth with cervical erosion. Alternatively, irritated odontoblasts can secrete collagen, amorphous material, or large crystals into the tubule lumen; these occlusions decrease dentin permeability to irritating substances.[197–199] Although these secretions have been described as a defensive reaction by the odontoblast to protect itself and the underlying pulp, this "protection" has never been proved.

Fibroblast

Fibroblasts originate from the mesenchymal tissue and are the predominant cells of the connective tissue. It is the most abundant cell in the dental pulp. Fibroblasts are elongated with little cytoplasm and nucleus-containing condensed chromatin. They are responsible for the formation and maintenance of the fibrous components and ground substances of the connective tissue. Fibroblasts can synthesize and secrete a wide variety of extracellular molecules that include fibrous elements of ECM such as collagen, elastin, proteoglycans, glycoproteins, cytokines, growth factors, and proteinases. They are also involved in the remodeling of connective tissue through the degradation of collagen and other ECM molecules and their replacement by newly synthesized molecules.

Fibroblasts release proteolytic enzymes such as the matrix metalloproteinase (MMP) family. MMPs are secreted as inactive precursors and cleave to become active. Extracellular degradation often occurs in inflammatory lesions. Inhibitors to MMPs, called tissue inhibitors of metalloproteinases, are also secreted by fibroblasts to regulate extracellular degradation. Intracellular degradation is for the normal physiological turnover and remodeling of collagenous connective tissue.

Immune Cells

A normal dental pulp has a large number and a variety of indigenous immune cells that play a crucial role to maintain homeostasis.[200, 201] Dendritic cells expressing Class II major histocompatibility complex (MHC) molecule are considered to participate in immunosurveillance. These cells have distinctive cytoplasmic extensions, have a high surface area for capturing antigens, while lacking intracellular lysosomes and phagocytic vacuoles.[200] MHC class II antigen presenting dendritic cells are predominantly located in the paraodontoblastic area and along the pulp–dentin border and in the central portion of the pulp (Figure 2-28). Macrophages also express MHC molecules, and these cells are present in the central portion of the dental pulp. In the healthy dental pulp, resident macrophages act as scavengers, eliminating dead odontoblasts and apoptotic bodies.[202,203] Class II MHC-expressing cells increase in number shortly after tooth eruption and continue to increase even after the completion of tooth formation.[204]

Other immune cells in the dental pulp are T lymphocytes that are largely present in the normal dental pulp with both cytotoxic and helper subtypes.[200, 205] Granulocytes are not uncommon in the healthy dental pulp. However, granulocyte numbers are much lower in the dental pulp than gingiva.[161] B lymphocytes have not been clearly demonstrated in the normal dental pulp. Plasma cells are not common in the dental pulp. It is however increased after sympathectomy.[162]

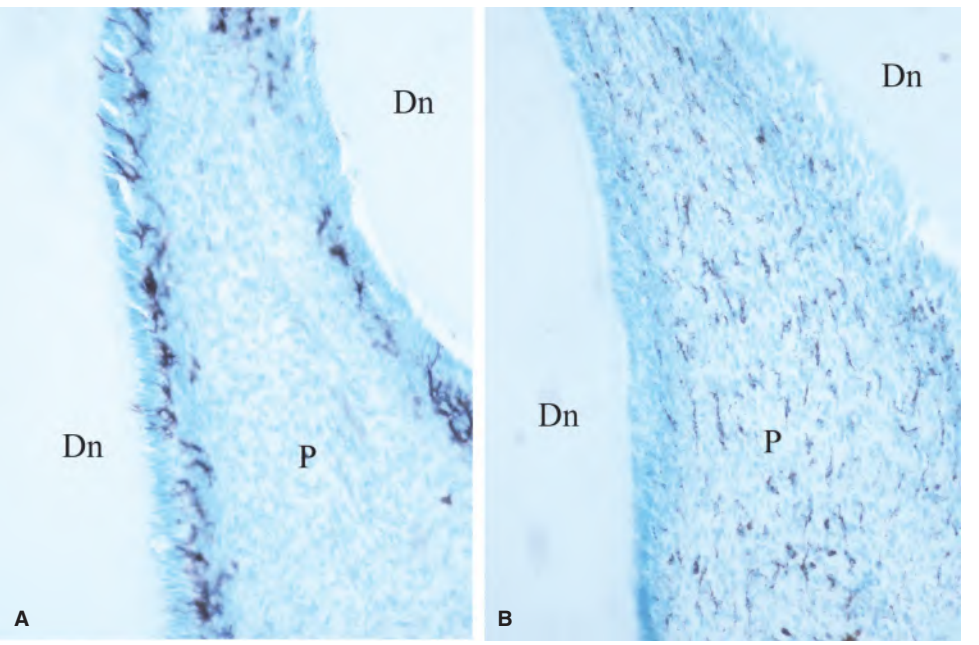

FIGURE 2-28 Immunohistochemical image from healthy coronal dental pulp with pulp horn region. Immune cells are from two different cell lines. ***A.*** MHC class II antigen presenting cells located within the odontoblast layer. ***B.*** Resident macrophages in the dental pulp proper. (Courtesy of Dr. Sivakami R. Haug, Bergen, Norway.)

Eosinophils are not common in a healthy dental pulp. Mast cells have not been shown to exist in the uninflamed dental pulp.[201,206–209] During an inflammatory process, all immune cell numbers are increased.[210,211] Inflammation of the dental pulp is discussed in another chapter.

Stem Cells

Dental pulp stem cells (DPSC) are highly proliferative, have the capacity for self-renewal, and have the ability to differentiate in response to injury. These cells were shown to produce sporadic and densely calcified nodules.[212,213] These cells were previously described as undifferentiated mesenchymal cells and are possibly the source of replacement odontoblasts that produce reparative dentin.[212] In addition to DPSC, stem cells are also present in the apical papilla of developing teeth.[212] For more details, see Chapter 29.

Chapter 3

Microbial and Nonmicrobial Etiologies of Endodontic Diseases

José F. Siqueira, Jr, Isabela N. Rôças, Domenico Ricucci

Apical periodontitis is an inflammatory disease of microbial etiology, primarily caused by infection of the root canal system.[1] This disease may be associated with untreated (primary apical periodontitis) or treated teeth (posttreatment apical periodontitis) and can be asymptomatic (or chronic) or symptomatic (or acute). Chemical and physical factors can induce periradicular inflammation, but a large body of evidence indicates that infection is essential to the progression and perpetuation of the different forms of apical periodontitis.[2–5] Endodontic infection develops in root canals devoid of host defenses, either as a consequence of pulp necrosis or pulp removal for treatment.

Bacteria are the main microorganisms involved in endodontic infections. Other microorganisms such as fungi, archaea, and viruses have been occasionally found in association with endodontic infections,[6–10] but bacteria are virtually always present and are regarded as the major microorganisms implicated in the pathogenesis of apical periodontitis. In the root canal, most bacteria are usually found organized in biofilms adhering to the canal walls.[11–14] As a consequence, apical periodontitis has been included in the roll of biofilm-related oral diseases (Figure 3-1).[15,16]

Endodontics is ultimately concerned with prevention and treatment of apical periodontitis. Because it is an infectious disease, the rationale for endodontic treatment is to prevent or eradicate infection of the root canal system and the periradicular tissues. The cardinal principle of any healthcare profession is the thorough understanding of disease etiology and pathogenesis that provides a framework for effective treatment. In this context, understanding the microbiologic and non-microbiologic aspects of apical periodontitis is essential for an endodontic practice of excellence and founded on solid scientific bases.

APICAL PERIODONTITIS IS AN INFECTIOUS DISEASE

The Dutch amateur microscope builder Antony van Leeuwenhoek (1632–1723) was probably the first one to report the occurrence of microorganisms (called by him as "animalcules") in the root canals of a decayed tooth.[17] However, the role of Leeuwenhoek's "animalcules" in disease causation was largely unknown at that time. The microbial etiology of apical periodontitis was only suggested ~200 years later, when

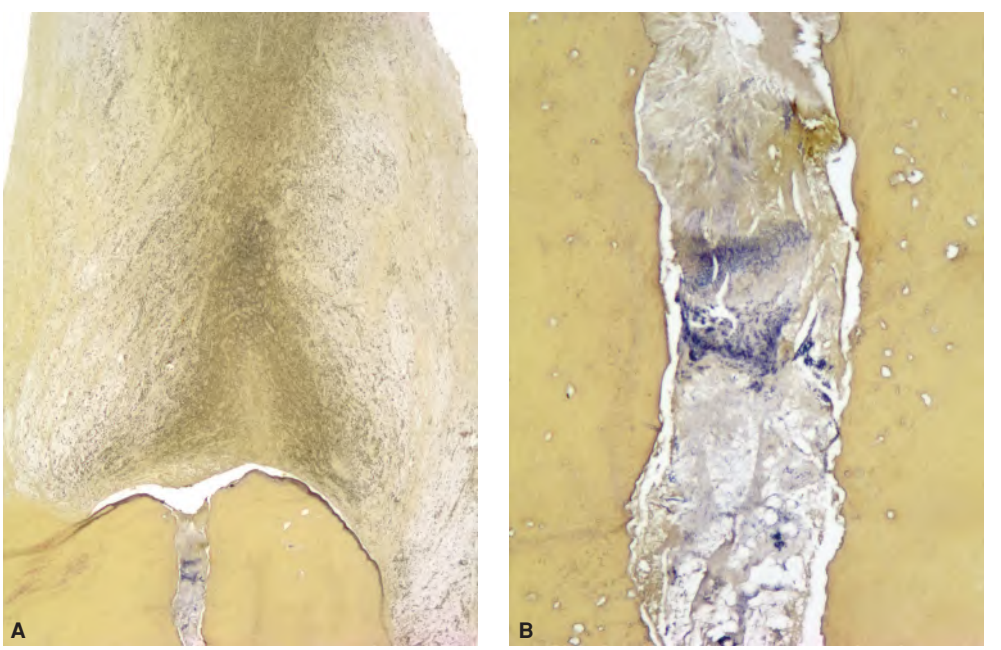

FIGURE 3-1 ***A***. Maxillary canine extracted with a large periapical lesion attached. Longitudinal section cut at the center of the foramen (Taylor's modified Brown & Brenn, original magnification ×16). ***B***. Detail of the apical canal showing its lumen clogged with necrotic debris and bacteria arranged in biofilm structures (original magnification ×100).

Willoughby Dayton Miller, an American dentist, working at the laboratory of Robert Koch in Berlin, Germany, reported the association between bacteria and apical periodontitis after the analysis of samples collected from root canals.[18] Miller observed that the bacterial diversity (as inferred by optical microscopy) was clearly different in the coronal, middle, and apical parts of the root canal. Spirochetes were found in high prevalence in acute apical abscesses, and an etiologic role was suspected for these bacteria. Miller also reported that most of the bacteria seen under microscopy could not be grown in culture. Those were conceivably anaerobic bacteria, which were only successfully cultivated ~50 to 100 years later with advanced technologies. It is important to point out that even today a large number of bacterial species living in diverse environments still remain to be cultivated.[19,20]

Miller reported association between bacteria and endodontic disease, but the cause-and-effect relationship was revealed only ~70 years later by Kakehashi et al.[2] These authors exposed the pulps of conventional and germ-free rats to their own oral cavities and observed by histology that although pulp necrosis and apical periodontitis lesions developed in all conventional rats, the pulps of germ-free rats not only remained vital but also repaired themselves by deposition of a dentin-like tissue that isolated them again from the oral cavity.

Other classic studies confirmed the important role of bacteria in the etiology of apical periodontitis. Sundqvist[3] used advanced anaerobic culturing techniques to evaluate the bacteriological conditions of pulps that became necrotic after trauma to the teeth. Bacteria were found only in the root canals of teeth with apical periodontitis. Most of them were obligate anaerobes, which corresponded to >90% of the isolates. In a study in monkeys, Möller et al.[4] demonstrated that only devitalized pulps that were infected induced apical periodontitis lesions, whereas devitalized and noninfected pulps did not cause significant pathologic changes in the periradicular tissues. These studies also revealed that the necrotic pulp per se is unable to induce and maintain an apical periodontitis lesion in the absence of infection.

Bacteria in root canals are primarily arranged in biofilm structures. Nair[11] was apparently the first one to observe intracanal bacterial organizations adhered to the root canal walls, resembling biofilms. Several other morphologic studies found similar structures,[12,13,21] but it was not until the study of Ricucci and Siqueira[14] that the high prevalence of bacterial biofilms and their association with primary and posttreatment apical periodontitis were consistently revealed.

PATHWAYS OF ENDODONTIC INFECTION

The pulpodentin complex is normally well isolated from oral bacteria by an intact hard tissue encasement and by a healthy periodontium. Loss of enamel or cementum integrity results in exposure of the pulpodentin complex to the oral environment and consequently to microorganisms present in saliva, caries lesions, or dental plaque formed on the exposed area. Conditions that may expose the pulpodentin complex include caries, trauma-induced fractures and cracks, leaking restorations, scaling and root planning procedures, attrition, and abrasion. Microorganisms from subgingival biofilms associated with periodontal disease may have access to the pulp via dentinal tubules at the cervical region of the tooth and lateral and apical foramina. (For more details, see Chapter 36.) Microorganisms may also have access to the root canal any time during or after root canal treatment.

Caries is by far the most common source of bacterial exposure to the pulp and is especially threatening when the lesion reaches the vicinity of the pulp (Figure 3-2). Whenever dentin is exposed, the pulp is put at the risk of infection as a consequence of the permeability of normal dentin dictated by its tubular structure.[22] The smallest diameter of the dentinal tubules is observed at the periphery, near the enamel, or cementum (mean, 0.9 μm),[23] and it is still compatible with the diameter of most oral bacteria, which usually ranges from 0.2 to 0.7 μm. However, frank invasion of the vital pulp by bacteria does not usually occur until a small width of dentin remains between the caries lesion and the pulp, and dentin permeability is significantly increased (Figure 3-3). However, bacterial invasion of dentinal tubules occurs more rapidly in nonvital teeth,[24] which helps explain the bacterial invasion of traumatized teeth that developed pulp necrosis. In vital teeth, the outward movement of dentinal fluid, the tubular contents, dentinal sclerosis, tertiary dentin, smear layer, intratubular deposition of fibrinogen, and host defense molecules also counterattack bacterial invasion.[25–28]

In contrast, direct exposure of the pulp to the oral environment is the most obvious route of endodontic infection as oral bacteria may now gain frank access to the tissue. Even a minuscule exposure can be critical. The most common causes of pulp exposure are caries, crown fracture due to trauma, and iatrogenic restorative procedures. Almost invariably, the exposed pulp will undergo inflammation and necrosis and subsequently becomes infected (Figure 3-4). The time elapsed between pulp exposure and infection of the entire canal is unpredictable, but it is usually a slow process.[29]

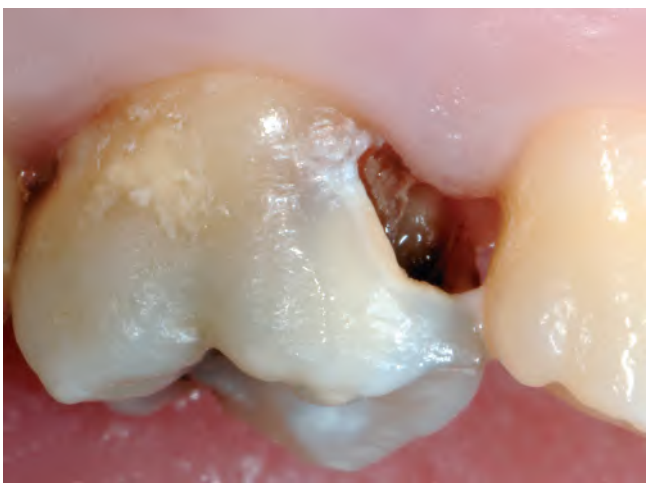

FIGURE 3-2 Maxillary first molar of a 20-year-old woman with a deep mesial caries lesion. The patient complained of sensitivity to cold and sweet stimuli.

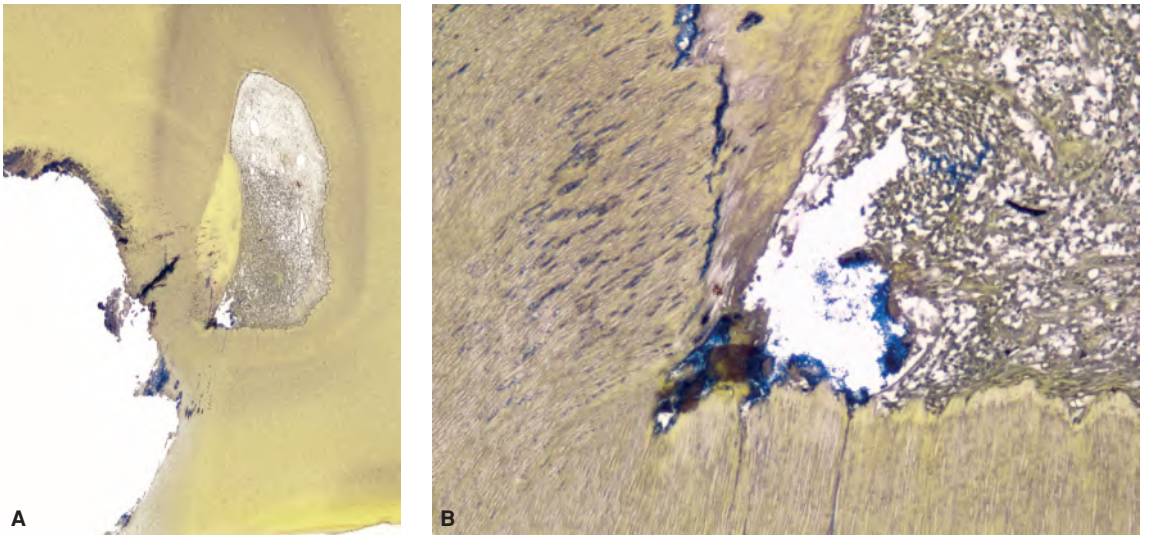

FIGURE 3-3 Symptomatic maxillary third molar with deep mesial caries. ***A***. The thin residual dentin layer is heavily infiltrated by bacteria owing to necrosis and infection localized in the subjacent pulp horn. Histologic serial sections could not demonstrate a perforation of the pulp chamber (Taylor's modified Brown & Brenn, original magnification ×16). ***B***. Detail from the pulp horn showing bacterial colonization (original magnification ×100).

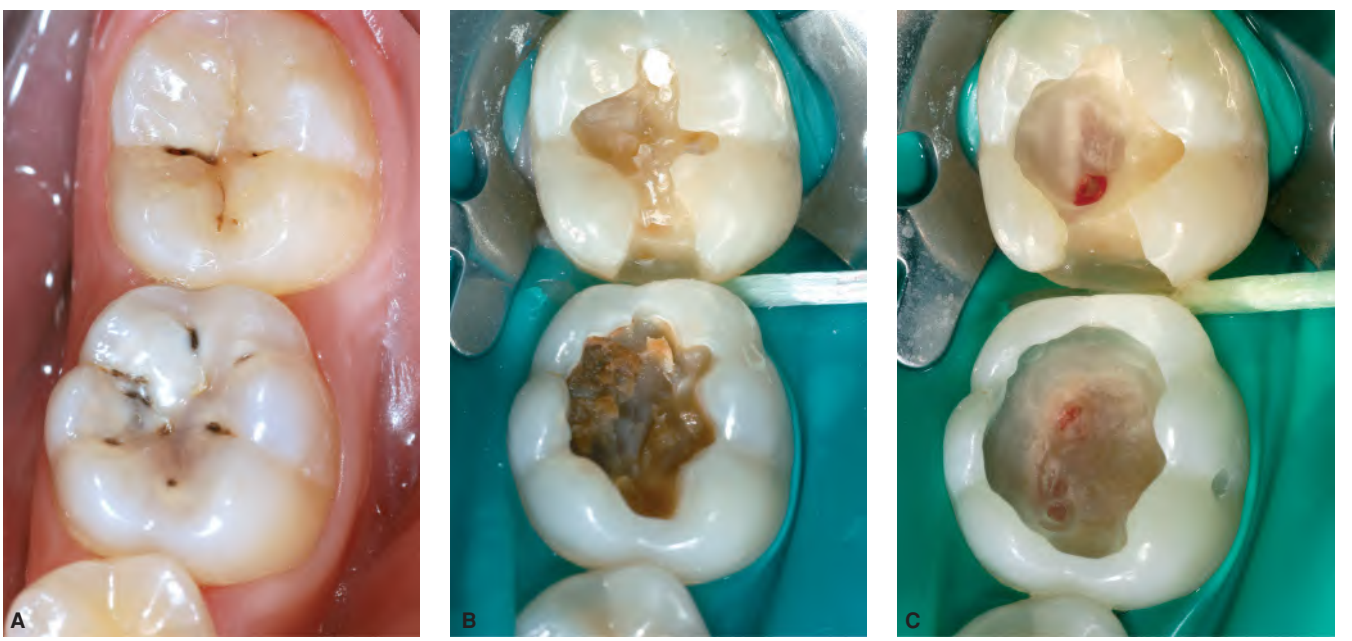

FIGURE 3-4 ***A***. A 17-year-old girl with carious lesions involving mandibular first and second molars. Apparently there are only small occlusal cavities in the enamel. ***B***. After removal of the occlusal enamel, a large amount of decayed dentin appears. ***C***. Careful excavation revealed perforations in the pulp horn areas.

Microorganisms in subgingival plaque biofilms associated with periodontal disease may reach the pulp by the same pathways intracanal microorganisms reach the periodontium. However, it has been shown that although degenerative and inflammatory changes of different degrees may occur in the pulp of teeth with associated periodontal disease, pulpal necrosis usually develops only when the periodontal biofilm reaches the main apical foramen, leading to irreversible damage to the main blood vessels that enter this foramen to irrigate the pulp (Figure 3-5).[30] Therefore, periodontal disease is usually a source of bacteria infecting the pulp once the disease reaches the root apex and causes pulp necrosis.

Although it has been suggested that microorganisms could reach the pulp via bloodstream in a phenomenon called anachoresis,[31–33] there is no solid evidence for it. A study showed that bacteria could not be recovered from unfilled root canals when the bloodstream was experimentally infected, unless the root canals were overinstrumented during the period of bacteremia, resulting blood seepage into the canal.[34]

In the past, anachoresis was used to explain why traumatized teeth, which were apparently intact, could have their root canals infected.[31] How did bacteria gain access to the canal? First, it is salient to point out that endodontic infection only develops after the pulp becomes necrotic or removed. Trauma, including concussion, subluxation, and various forms of tooth displacement, may cause rupture of the neurovascular supply at the root apex, a major internal bleeding and ischemia, leading to complete pulp necrosis. Because regeneration of the necrotic pulp is highly unlikely in mature teeth,[35] the pulp tissue is now devoid of a defense apparatus against microbial invasion. The origin of infecting microorganisms in these cases is the oral cavity, specifically via cracks in the enamel and dentin.[36–38] Macro- and microcracks are expected in traumatized teeth, as well as in teeth with caries and large restorations, and do not necessarily end at the enamel–dentin junction, but extend deep into the dentin and even reach the pulp (Figure 3-6).[36,38]

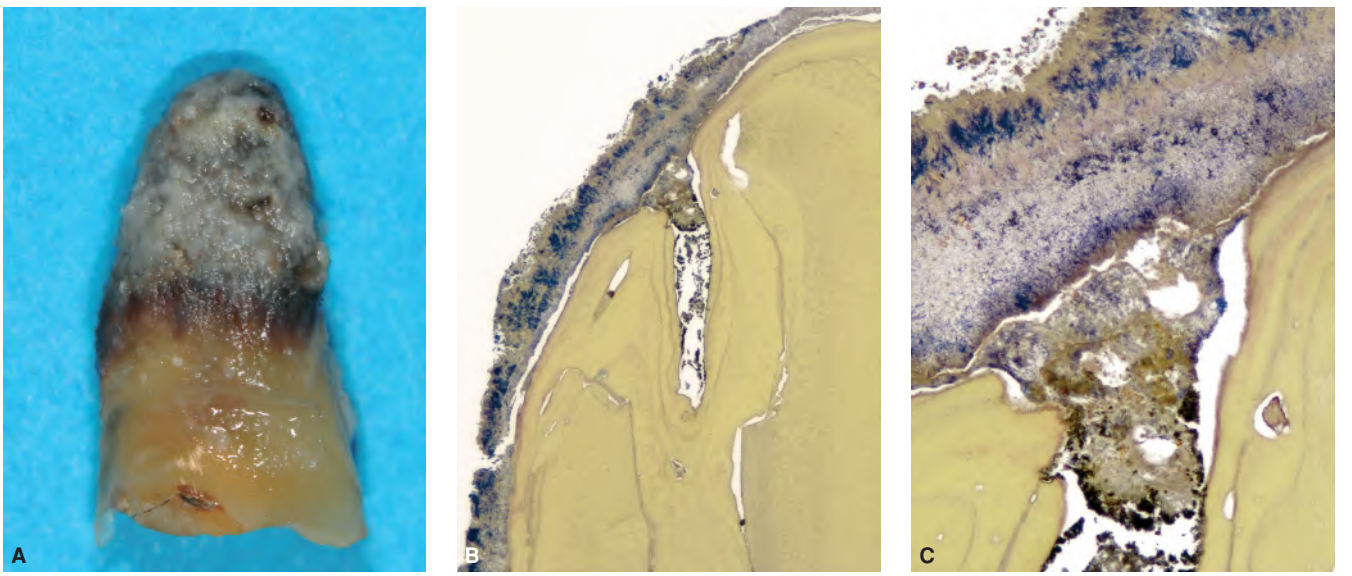

FIGURE 3-5 ***A***. Palatal root from a rizectomized maxillary first molar. Note that the apical half of the root is totally covered by calculus. ***B***. Section cut through the apical foramen emerging laterally to the root apex. A bacterial biofilm has engulfed the apical foramen, cutting the circulation and invading the apical root canal retrogradely (Taylor's modified Brown & Brenn, original magnification ×16). ***C***. Higher magnification of the foraminal area (original magnification ×100).

FIGURE 3-6 Mandibular molar with an extensive MOD amalgam restoration in a 55-year old man. The patient complained of pain upon chewing. ***A***. After anesthesia and removal of the old restoration, a mesio-distal crack crossing the entire cavity floor was evident. The tooth was extracted since the crack extended to the distal aspect of the root. ***B***. Section cut on a buccolingual plane. The crack appears close to the pulp chamber and is clogged with bacteria. Note the large pulp stone occupying the subjacent pulp horn (Taylor's modified Brown & Brenn, original magnification ×16).

Although the endodontic treatment is directed to prevention or control of the endodontic infection, there is a risk of secondary infection because the pulp is removed and the root canal is exposed and manipulated by the clinician. The source of microorganisms for a secondary infection includes a breach in the aseptic chain (during treatment), coronal leakage, fracture of the tooth or restorative material (between appointments and after treatment).[39]

PATTERNS OF MICROBIAL COLONIZATION OF THE ROOT CANAL SYSTEM

Spatial Distribution of Bacteria in Infected Canals

Understanding how microorganisms colonize the root canal system is of crucial therapeutic importance. With this knowledge in mind, researchers and clinicians can envision and develop enhanced strategies to eliminate infection from the entire system and improve outcome.

Morphologic studies of teeth with necrotic pulps and primary apical periodontitis lesions have demonstrated that although planktonic bacterial cells suspended in a fluid phase and enmeshed in the necrotic pulp tissue can be observed in the main root canal (Figure 3-7), the majority of bacteria colonizing the root canal system are organized in sessile biofilm communities adhering to the canal walls (Figure 3-8).[11–15] Bacterial cells from the bottom of the biofilm structures are often seen penetrating the subjacent dentinal tubules to varying depths (Figure 3-9). Dentinal tubule infection can occur in about 70% to 80% of the teeth associated with apical periodontitis lesions.[40,41] A shallow penetration is more common, but bacterial cells can be observed reaching ~300 µm in some teeth.[12] Infection can also spread to lateral canals, apical ramifications, isthmuses, and other areas in the root canal system (Figures 3-10 and 3-11).[42,43]

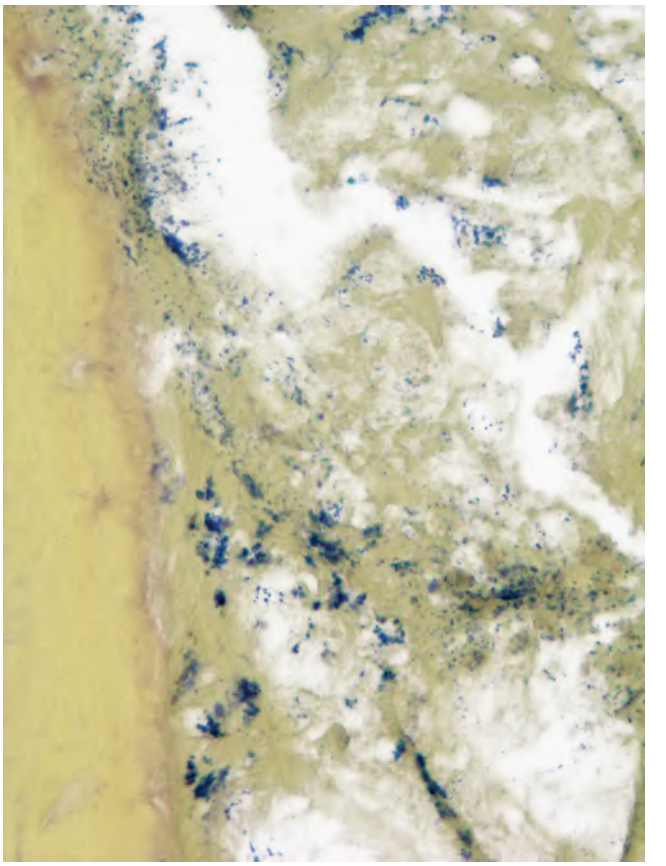

FIGURE 3-7 Necrotic root canal. Bacteria enmeshed in the necrotic pulp tissue, apparently in the planktonic state (Taylor's modified Brown & Brenn, original magnification ×400).

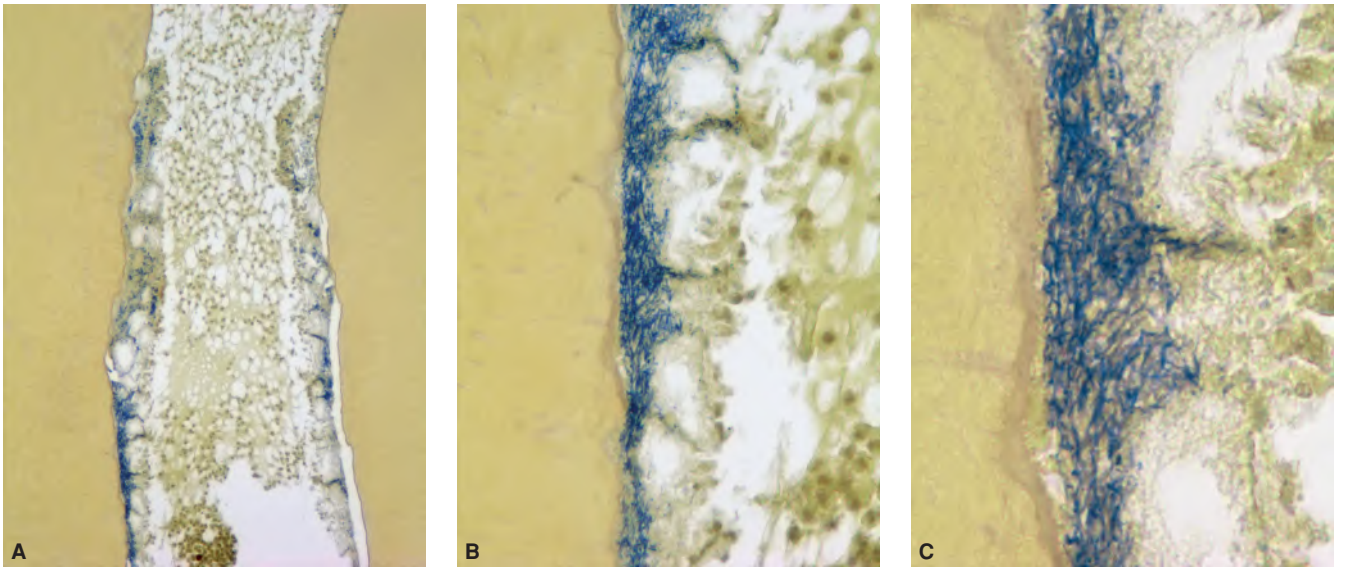

FIGURE 3-8 ***A***. Necrotic root canal. Biofilms adhering to the canal walls (Taylor's modified Brown & Brenn, original magnification ×100). ***B & C***. Progressive magnifications of the area of the left wall indicated by the arrow in A (original magnification ×400 and ×1000).

Bacteria found as planktonic cells in the main root canal are conceivably easy to eliminate by instruments and irrigants during preparation. Nevertheless, bacterial arrangements in biofilms, especially those located in difficult-to-reach areas, are definitely more difficult to access and eliminate.[42,44]

COMMUNITY-BASED PATHOGENESIS

Bacterial community refers to a unified assemblage of microcolonies or populations that coexist and interact at a given habitat. These populations perform functions that contribute to the physiology and pathogenicity of the overall community. Highly structured and spatially organized communities may exhibit properties that are greater than the sum of the component populations. Therefore, the interplay of the different parts composing the community will ultimately determine its properties. The community-forming ability can be regarded as essential for microbial survival in virtually all environments. The vast majority of microorganisms in nature invariably grow and function as members of metabolically integrated communities—the so-called biofilms (see below).[45,46]

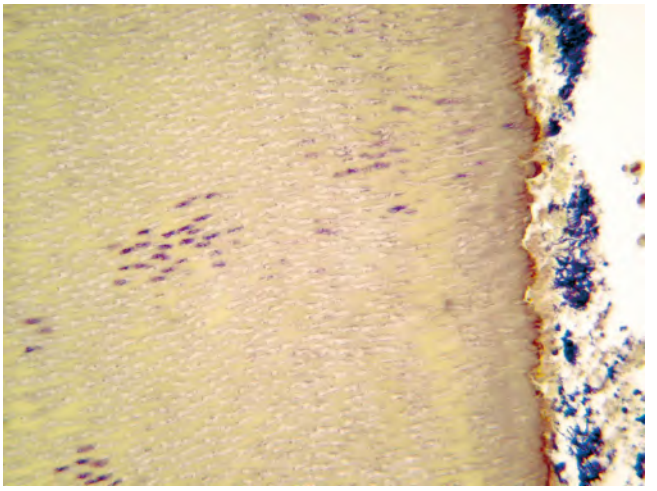

FIGURE 3-9 Bacteria penetrating dentinal tubules to a considerable depth from the bottom of the biofilm covering the canal wall (Taylor's modified Brown & Brenn, original magnification ×100).

The ability of forming organized biofilm communities also influences pathogenicity of involved microorganisms. The concept of the community as the unit of pathogenicity is based on the principle that teamwork is what eventually counts. The community behavior and the outcome of the host/bacterial community interaction will depend on the types and numbers of species present in the community biofilm and the network of resulting associations among them.[47]

Community-profiling molecular studies have provided insights into the endodontic bacterial community structure, offering new perspectives on the etiology and pathogenesis of apical periodontitis.[48] These studies moved the focus from the "single-pathogen," which was very popular in classic medical microbiology, to the "community-as-pathogen" concept that has arisen to explain the pathogenesis of polymicrobial infections, such as apical periodontitis. The fact that the bacterial community structure (composition and abundance of members) in endodontic infections varies from individual to individual indicates that apical periodontitis has a heterogeneous etiology and is the result of the

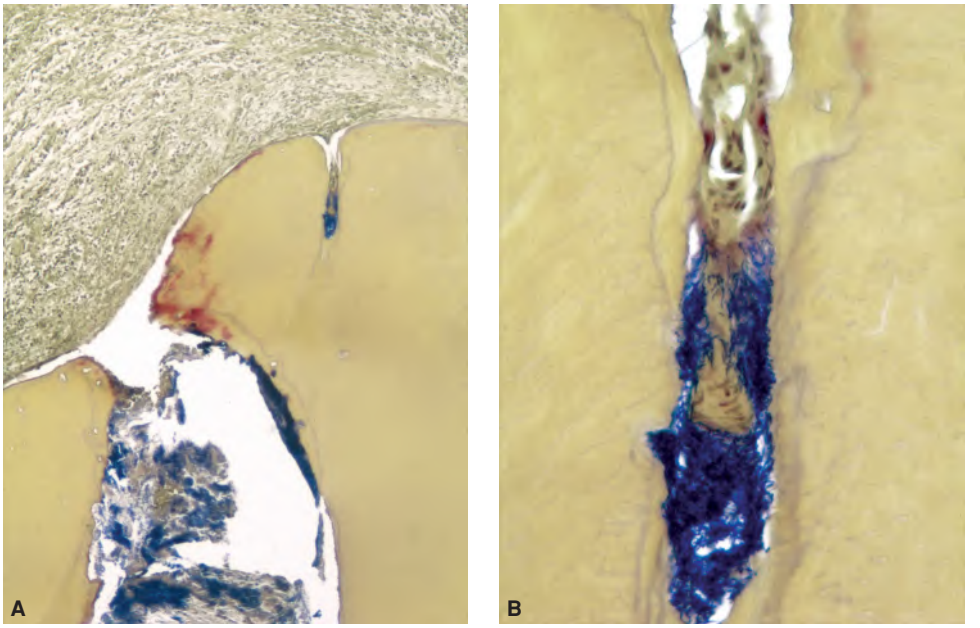

FIGURE 3-10 ***A***. Root canal with longstanding pulp necrosis. The main apical foramen is located laterally to the root apex. The canal is filled with a bacterial biofilm. The exit of a tiny apical ramification (arrow) can be seen at the geometrical top of the root (Taylor's modified Brown & Brenn, original magnification ×50). ***B***. High power view of the ramification reveals its lumen filled with bacterial biofilm, faced with inflammatory cells apically (original magnification ×400).

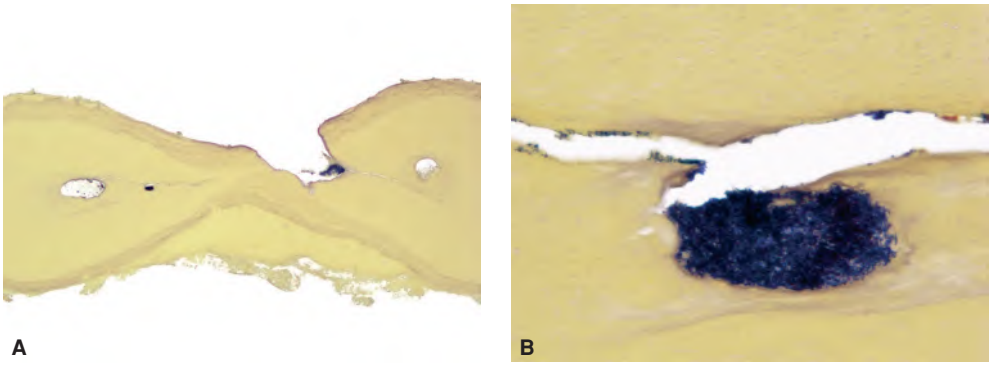

FIGURE 3-11 ***A***. Mesial root of a mandibular first molar with necrotic pulp and a large apical periodontitis lesion. Transversal section cut at about 2 mm from the apex. Two main canals can be seen. A narrow and long isthmus is departing from both canals (Taylor's modified Brown & Brenn, original magnification ×16). ***B***. High power view of the area of the isthmus indicated by the arrow in A. A dilation of the isthmus appears completely clogged by a thick bacterial biofilm. Biofilms can also be appreciated on the walls of the isthmus (original magnification ×400).

collective pathogenicity of the bacterial species composing and interacting in the endodontic biofilm.

Biofilm Infections

Biofilm can be defined as a sessile multicellular microbial community characterized by cells that are firmly attached to a hard or soft surface and enmeshed in a self-produced matrix of extracellular polymeric substance (EPS), usually polysaccharide. However, it can contain proteins and nucleic acids (Figure 3-8).[45,49,50] Bacterial cells in biofilms form microcolonies (~15% by volume) embedded and nonrandomly distributed in the EPS matrix (~85% by volume) and separated by water channels.[50–53] Dental biofilms can reach up to 300 or more cell layers in thickness.[53] Individual microcolonies may consist of a single bacterial species but more frequently are composed of several different species in a mixed community. The EPS matrix plays a role in bacterial adhesion to the surfaces, serves as a scaffold that determines the biofilm structure; retains nutrients, water, and essential enzymes; and provides protection against exogenous threats, such as antimicrobials and host defense cells and molecules.[54,55] The water channels permit circulation of fluid that carries nutrients, waste products of bacterial metabolism, and signal molecules involved in bacterial intercommunication systems.[56]

The biofilm community lifestyle affords a number of advantages to colonizing bacteria, including establishment of a broad habitat range for growth, increased metabolic diversity and efficiency, enhanced possibilities for genetic exchanges and bacterial intercommunications as well as protection from external threats.[57] Biofilm organizations can also result in enhanced and collective pathogenicity. In multispecies communities, a broad spectrum of relationships may arise between the component species, and in some circumstances interactions may result in synergistic pathogenic effects.

Bacteria in biofilms exhibit increased resistance to antimicrobial agents when compared to their counterparts growing in planktonic state. For instance, the antibiotic concentration required to kill bacteria in a biofilm can be ~100 to 1000 times higher than that needed to kill the same species in planktonic state.[58] The possible reasons for increased biofilm resistance include restricted penetration of antimicrobial agents in the biofilm, the altered growth rate of biofilm bacteria and the presence of a subpopulation of specialized survivor cells with altered phenotypes (so-called "persisters").[49,59]

Apical Periodontitis as a Biofilm-associated Disease

Although bacterial organization in biofilms had been revealed by isolated morphological studies, the prevalence of biofilms and their association with diverse presentations of apical periodontitis were only recently disclosed in a study by Ricucci and Siqueira.[14] Histobacteriological analysis of the apical root canal system of teeth with primary or posttreatment apical periodontitis yielded some important findings:

a. Bacteria were present in all root canals but biofilms occurred in ~80% of the root canals of teeth with primary or posttreatment apical periodontitis.
b. Biofilms had varied morphologies in terms of thickness, morphotypes, and bacterial cells/extracellular matrix ratio.
c. Biofilms were seen not only in the main root canal, but also in apical ramifications, lateral canals, and isthmuses (Figures 3-10 and 3-11).
d. Biofilms were more frequent in root canals of teeth with large apical periodontitis lesions as shown in radiographs and lesions histopathologically diagnosed as cysts. Large lesions (most of them were cysts) represent a longstanding pathologic process caused by an even "older" intraradicular infection. In longstanding infectious processes, involved bacteria may have had enough time and conditions to adapt themselves to the environment and set a mature and organized biofilm community.
e. Biofilms adhered to the outer root surfaces (extraradicular biofilms) were present in only 6% of the teeth and usually associated with intraradicular biofilms and clinical symptoms (Figure 3-12).

FIGURE 3-12 Mesiobuccal root of a maxillary second molar with longstanding pulp necrosis. The section, cut at the center of the foramen, discloses a bacterial biofilm extending from the root canal walls onto the external apical surface. Note the large area of resorption (Taylor's modified Brown & Brenn, original magnification ×16).

f. Flocs, which are different forms of biofilms (planktonic large colonies), were seen in some teeth in the main canal lumen.

Apical periodontitis seems to fulfill most of the established criteria used to determine whether a given infectious disease can be classified as a disease caused by biofilm communities.[14,60,61] Nonetheless, because biofilms are detected in the majority but not in all cases of apical periodontitis, it remains to be determined if biofilm formation is required for apical periodontitis development. For time being, it seems prudent to state that apical periodontitis is a disease strongly associated with bacterial biofilms.[62]

TYPES OF ENDODONTIC INFECTIONS

Endodontic infections can be classified according to the anatomic location as intraradicular or extraradicular infection. *Intraradicular infection* is caused by microorganisms colonizing the root canal system and can be subdivided into three categories based on the time infecting microorganisms gained entry into the root canal system: *primary infection,* caused by microorganisms that invade and colonize the necrotic pulp tissue; *secondary infection,* caused by microorganisms not present in the primary infection, but introduced in the root canal at some time during or after professional intervention; and *persistent infection,* caused by microorganisms that were members of a primary infection and in some way resisted intracanal antimicrobial procedures and were able to endure periods of nutrient deprivation in treated canals.

Primary infections are the cause of primary apical periodontitis. Persistent infections and less frequently secondary infections are the main cause of posttreatment apical periodontitis. *Extraradicular infection* in turn is characterized by microbial invasion of the inflamed periradicular tissues and is a sequel to the intraradicular infection. Extraradicular infections occur in abscessed cases and have been suggested as a possible cause of posttreatment apical periodontitis.

Endodontic infections develop in a previously sterile place that does not contain a normal microbiota. Any species found has the potential to be an endodontic pathogen or at least play a role in the ecology of the endodontic microbial community. Because all the studies of the endodontic microbiota are cross-sectional in nature, data are restricted to prevalence of species and associated with disease; consequently, causation cannot be proven. Thus, any species that has a pathogenic potential (as inferred by animal studies or participation in other diseases) and have been found in high prevalence in endodontic infections are regarded as candidate or putative endodontic pathogens.

ETIOLOGY OF PRIMARY APICAL PERIODONTITIS

Primary Intraradicular Infection

Primary infections are characterized by a mixed (multispecies) community conspicuously dominated by anaerobic bacteria. The number of bacterial cells may vary from 10^3 to 10^8 per root canal.[3,63–66] Molecular studies have disclosed a mean of 10 to 20 species/phylotypes per infected canal.[67–71] Canals of teeth with sinus tracts may exhibit a number of species close to the top of this range.[70] The more complex the infection, the larger the apical periodontitis lesion; in other words, the size of periradicular bone destruction is proportional to the number of bacterial species (diversity) and cells (density) in the root canal.[3,70,72]

Bacterial species/phylotypes detected in primary infections fall into 9 of the 13 phyla that have oral representatives, namely *Firmicutes*, *Bacteroidetes*, *Fusobacteria*, *Actinobacteria*, *Proteobacteria*, *Spirochaetes*, *Synergistetes*, TM7, and SR1.[64,67,70,73–75] However, there may be representatives of at least nine other phyla in endodontic infections as revealed by pyrosequencing.[76–81] Figure 3-13 depicts a phylogenetic tree with the species/phylotypes more commonly detected in endodontic infections. The following is an overview of the major bacterial groups and species regarded as candidate endodontic pathogens.

Gram-Negative Bacterial Species

Fusobacterium species, especially *Fusobacterium nucleatum*, are common members of the endodontic microbiota in primary infections, including acute apical abscesses.[79,82–90] PCR-based microbial typing approaches have revealed that different clonal types of *F. nucleatum* can be isolated from the same infected canal.[91]

Black-pigmented gram-negative anaerobic rods include species formerly known as *Bacteroides melaninogenicus*. These bacteria have been reclassified into two genera—the saccharolytic species were transferred to the genus *Prevotella* and the asaccharolytic species to the genus *Porphyromonas*.[92,93]

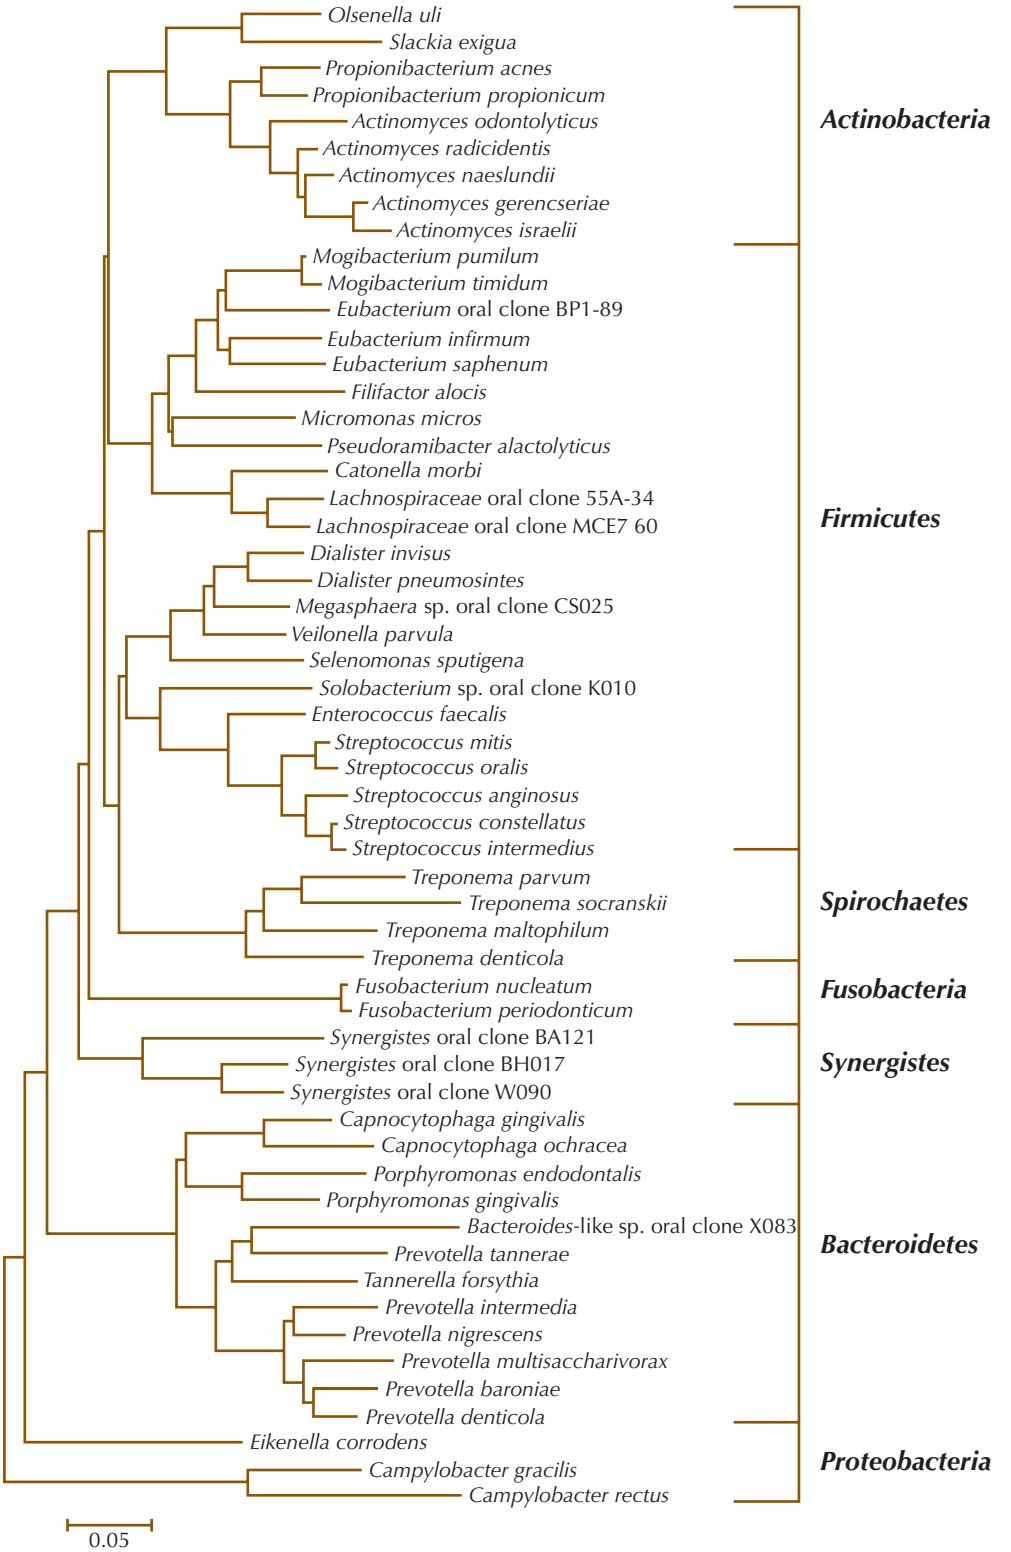

FIGURE 3-13 Phylogenetic tree of the most prevalent bacterial species and phylotypes found in endodontic infections. Note that the major endodontic pathogens fall into seven major phyla. Other phyla have been identified, but they do not contain species that are frequently detected.

Some bile-sensitive nonpigmented *Bacteroides* species were also transferred to the genus *Prevotella*.[94] *Prevotella* species frequently detected in primary endodontic infections include *Prevotella intermedia*, *Prevotella nigrescens*, *Prevotella multissacharivorax*, *Prevotella baroniae*, and *Prevotella denticola*.[74,87,95–106] *Prevotella tannerae*, which has also been found in endodontic infections,[107,108] has been transferred to the new genus *Alloprevotella*.[109] Of the *Porphyromonas* species, only *Porphyromonas endodontalis* and *Porphyromonas gingivalis* have been consistently found in endodontic infections

and they seem to play an important role in the etiology of different forms of apical periodontitis lesions, including acute apical abscesses.[90,95,96,104,110–114]

Dialister species are asaccharolytic obligate anaerobic gram-negative coccobacilli that represent another example of bacteria that have been consistently detected in endodontic infections only after the advent of molecular microbiology techniques. *Dialister invisus* and *Dialister pneumosintes* are among the most frequently detected species in asymptomatic and symptomatic primary endodontic infections in several molecular studies.[67,71,73–75,89,115–119]

Spirochetes are highly motile spiral-shaped Gram-negative bacteria that have been linked to several oral diseases.[120–122] For many years, spirochetes have been observed in samples from endodontic infections by microscopy, but they have never been reliably identified to the species level.[11,18,123] Culture-independent molecular microbiology methods allowed speciation of spirochetes in endodontic infections and revealed that all of the hitherto named oral treponemes can be found in primary endodontic infections.[124–137] The most prevalent treponemes in infections of endodontic origin are *Treponema denticola* and *Treponema socranskii*.[124,125,129,132,136,137] The species *Treponema parvum, Treponema maltophilum,* and *Treponema lecithinolyticum* have been moderately prevalent.[125,126,131,132,137]

Tannerella forsythia (formerly *Bacteroides forsythus*) is a recognized periodontal pathogen and another example of species that has been detected in endodontic infections only by molecular methods, usually in relatively high prevalence.[70,71,84,86,112,133,138–141]

Gram-Positive Bacterial Species

Gram-positive anaerobic rods have also been found as common members of the microbiota associated with primary infections. Of these, *Pseudoramibacter alactolyticus* has been detected by culture-dependent and culture-independent studies in frequencies as high as the most prevalent Gram-negative species,[71,82,142] including the very apical part of the root canal.[143,144] *Filifactor alocis* is an obligate anaerobic rod that had been only occasionally isolated from root canal infections by culture,[82] but molecular studies detected this species in several cases of primary endodontic infections.[145–147] Other Gram-positive rods, including *Actinomyces* species, *Propionibacterium propionicum*, *Olsenella* species, have also been reported to occur in relatively high prevalence in infected root canals.[67,70,82,86,148–153]

Some Gram-positive cocci are frequently present in primary endodontic infections. *Parvimonas micra* (formerly *Peptostreptococcus micros*) have been among the most commonly detected species in several studies, including high prevalence in symptomatic infections.[70,82,83,89,102,103,154,155] Members of the *Streptococcus anginosus* group have been reported to be the most prevalent streptococci, but other species of this group can also be often recovered/detected.[82,89,90,149] *Enterococcus faecalis*, which has been closely found in association with root-filled teeth, is not so frequent in primary infections.[149,156]

Many other Gram-positive and Gram-negative bacterial species have been detected in endodontic infections, but in lower prevalence than the ones discussed here. For a comprehensive review of the bacteria already detected in endodontic infections, the reader is referred to a review article by Siqueira and Rôças.[157]

As-Yet-Uncultivated Phylotypes

Molecular studies have demonstrated that as-yet-uncultivated bacteria comprise ~40% to 60% of the species-level taxa found in primary infections.[64,67,71,74,158] Uncultivated phylotypes from several genera have been identified, including *Dialister*, *Treponema, Prevotella*, *Solobacterium*, *Olsenella*, *Fusobacterium*, *Eubacterium*, *Megasphaera*, *Veillonella*, and *Selenomonas* as well as phylotypes related to the family *Lachnospiraceae* or the *Synergistetes* and TM7 phyla.[67,73–75,115,137,159–161] One of the most prevalent as-yet-uncultivated phylotypes found in endodontic infections is *Bacteroidaceae* sp. HOT-272 (synonym, *Bacteroidetes* oral clone X083).[70,106] Some members of the *Synergistetes* phylum that had been previously regarded as uncultivated and detected in endodontic infections in relatively high prevalence[75,115,162,163] have been recently cultivated, characterized, and formally named as *Pyramidobacter piscolens*[164] and *Fretibacterium fastidiosum*.[165]

The Complex Etiology of Symptoms

Symptomatic apical periodontitis and acute apical abscesses are the typical examples of endodontic infections causing severe symptoms. In these cases, infection is located within the canal system, but it has also advanced to the periradicular tissues. In acute apical abscesses, an extraradicular infection is established and results in purulent inflammation. Clinically, the disease leads to pain and/or swelling and has the potential to diffuse to sinuses and other fascial spaces of the head and neck to form a cellulitis or other complications. For more details, see Chapter 30.

A matter of great interest in endodontic microbiology is to find an explanation as to why only some infected teeth develop acute symptoms and complications. The desire to find a single or at least a group of major species that is associated with acute symptoms is an ever recurrent topic in the field of endodontic microbiology. In his milestone study, Miller[18] was the first one to suggest the involvement of a specific group of bacteria with endodontic symptoms—spirochetes were associated with acute abscesses. However, Sundqvist[3] was the first one to consistently report on the association of a given species with endodontic symptoms—dark-pigmented bacteria (formerly *B. melaninogenicus*) was found only in teeth with acute symptoms. Further culture and molecular studies reported on the association with symptoms of several species, the most frequent being *Porphyromonas* and *Prevotella* species, *F. nucleatum, P. micra,* and *S. anginosus* group.[3,79,96,149,166–169] Nevertheless, these findings have not been consistently confirmed by other studies, because basically the same species can also be found in the root canals

of teeth with asymptomatic apical periodontitis in similar prevalences.[68,70,84,86,95,101,112,141]

Animal studies have given some support to the potential role of some endodontic pathogens in causing abscesses. The ability to cause purulent infections in animal models strengthens the possible causative role of certain species clinically associated with symptomatic disease. Many candidate endodontic pathogens, alone or in combinations, have been shown to cause abscesses in animals.[170–174] One of the main problems with the animal model is that only cultivable bacteria have been tested, either in single culture or in combinations of two or a few species. Thus, any speculation about extrapolation of these results to a clinical condition where there is a network of interacting species (10 or more), including as-yet-uncultivated phylotypes, may lead to oversimplification.

Based on this discussion, one may assume that the etiology of acute endodontic infections is characterized by low specificity. The species that have been more frequently detected than others and either cause abscess in animals or are involved with diseases in other sites are suspected to play a role in making the community more virulent.[175,176] However, in addition to the presence of these pathogenic species, a multitude of other factors can be regarded as influential to the development of acute endodontic infections,[175] including (a) differences in the virulence ability among clonal types of the same species; (b) bacterial interactions resulting in collective pathogenicity; (c) overall and specific bacterial load; (d) environment-regulated expression of virulence factors; and (e) host resistance and disease modifiers.

Microbial Ecology in Endodontic Infections

The root canal system, containing necrotic pulp tissue, provides a space for bacterial colonization and affords bacteria a moist, warm, nutritious, and anaerobic environment that is by and large protected from the host defenses because of lack of active blood circulation in the necrotic pulp. In addition, the root canal walls are nonshedding surfaces conducive to persistent colonization and formation of complex biofilm communities. Although a large number of bacterial species (~100–200) can be found in the oral cavity of a particular individual,[177] only a limited assortment of these species (~10–20) is consistently selected for growth and survival within a root canal containing necrotic pulp tissue. This indicates that ecological determinants operate in the necrotic canal and dictate which species will succeed in colonizing this previously sterile environment. The major ecological factors that determine the composition of the root canal microbiota include oxygen tension, type, and amount of available nutrients, and bacterial interactions.

Oxygen Tension

Root canal infection is a dynamic process, and different bacterial species apparently dominate at different stages.[178] Shifts in the composition of the microbiota are largely due to changes in the environmental conditions, particularly in regard to oxygen tension and nutrient availability. In the very initial phases of the pulpal infectious process, facultative bacteria predominate.[179] After a few days or weeks, oxygen is depleted within the root canal as a result of pulp necrosis and consumption by facultative bacteria. Further oxygen supply is interrupted with loss of blood circulation in the necrotic pulp. At this point, an anaerobic milieu develops; highly conducive to survival and growth of obligate anaerobic bacteria. With the passage of time, anaerobic conditions become even more pronounced, particularly in the apical third of the root canal; as a consequence, anaerobes will dominate the microbiota, outnumbering facultative bacteria.

Type and Amount of Nutrients

Bacteria colonizing the necrotic root canal utilizes as the main source of nutrients (1) the necrotic pulp tissue itself; (2) proteins and glycoproteins from tissue fluids and exudate that seep into the root canal system via apical and lateral foramina; (3) components of saliva that may coronally penetrate into the root canal; and (4) end-products of the metabolism of other bacteria. Because the largest amount of nutrients is supposedly available in the main canal that is the largest area of the whole system, most of the infecting bacteria are expected to concentrate in this region.

Shifts in the composition of the microbiota colonizing the root canal system can also be dependent on the dynamics of nutrient utilization. Saccharolytic species dominate the very early stages of the infectious process but are soon outnumbered by asaccharolytic species, which will dominate later stages.[180] The necrotic pulp tissue is a finite source of nutrients to bacteria. However, once inflammation is established at the periradicular tissues, a sustainable source of nutrients to bacteria in the apical root canal is maintained in the form of proteins and glycoproteins present in the exudate that seep into the canal. At this point, proteolytic and asaccharolytic bacteria start to dominate. Therefore, as the infectious process reaches the stage of induction of periradicular inflammation, proteins become the principal nutrient source, particularly in the apical part of the canal, favoring the establishment of anaerobic species that utilize peptides and/or amino acids in their metabolism.

Bacterial Interactions

Multispecies biofilms are the major form of bacterial organization in infected root canals. In these structures, different bacterial species are in close proximity with one another, and interactions become inevitable. Thus, establishment of certain species in the root canal is also influenced by interactions with other species. Interactions can be positive or negative. Positive interactions enhance the survival capacity of the interacting bacteria and enable different species to coexist in habitats where neither could exist alone. They include the following:

a. interbacterial nutritional interactions (food chains/webs, and concerted action to break down complex substrates);
b. local environment modification;

c. collective protection against external threats;
d. intrageneric and intergeneric coaggregations;
e. cell–cell signaling (quorum-sensing systems); and
f. horizontal gene transfer.

For instance, interbacterial nutritional interactions are of special interest as they represent important ecological determinants leading to a high metabolic diversity and efficiency of the whole community. Nutritional interactions are mainly represented by food chain/webs, including utilization of metabolic end-products from one species by another, and bacterial cooperation for the breakdown of complex host-derived substrates.

In addition, one species can provide growth conditions favorable to another, for example, by reducing the oxygen tension in the environment and favoring the establishment of anaerobes (environment modification) or by releasing some proteinases or antibiotic-inactivating enzymes that can provide protection to the entire community from host defenses and antibiotics, respectively.

Many species adhere directly to host surfaces, while other species adhere to other bacteria already attached to the surface. The latter is called coaggregation and is a highly specific phenomenon with regard to the partners involved.[181] Coaggregation can favor colonization of host surfaces and also facilitate metabolic interactions between the partners. Coaggregation has been demonstrated for several pairs of endodontic bacteria.[182]

Negative interactions in turn act as feedback mechanisms that limit population densities. Examples include competition (for nutrients and space) and amensalism (when one species produces a substance that inhibits another species).

Other Microorganisms in Endodontic Infections

Fungi

Fungi are chemoorganotroph eukaryotic microorganisms that may be found in two basic forms: molds and yeasts. They constitute a small part of the oral microbiota, with members of the *Candida* genus as the most common fungal species. Fungi have been only occasionally detected in primary intraradicular infections.[85,183–185] This suggests that bacteria colonizing the root canal may inhibit the establishment of fungi. However, a molecular study[186] reported the occurrence of *C. albicans* in 21% of samples from primarily infected canals. Fungi are more frequently detected in canals of teeth with posttreatment apical periodontitis (see below).

Archaea

Archaea comprise a highly diverse group of prokaryotes distinct from bacteria. Members of the Archaea domain have been traditionally recognized as extremophiles, but some species have also been found to survive in nonextreme environments, such as the human body.[187] Some studies have failed to detect archaea in samples from primary endodontic infections,[188,189] others detected a *Methanobrevibacter oralis*-like phylotype in some primarily infected canals.[7,158] A study evaluating the exoproteome of endodontic infections detected one protein of archaeal origin linked to methane production.[190] Because archaea have not been consistently detected in infected root canals, their role, if any, in the ecology of the endodontic bacterial community and pathogenesis of apical periodontitis remains to be elucidated.

Virus

Viruses are particles structurally composed of a nucleic acid molecule (DNA or RNA) and a protein coat that require viable host cells to infect and replicate its genome. Thus, viruses cannot thrive in a root canal containing necrotic pulp tissue. The presence of viruses in the root canal has been reported only in teeth with vital pulps. For instance, the human immunodeficiency virus (HIV) has been detected in vital pulps of HIV-seropositive patients[191] and some herpesviruses have been identified in both noninflamed and inflamed vital pulps.[192]

On the other hand, viruses have been detected in apical periodontitis lesions, where living host cells abound. Herpesviruses, especially human cytomegalovirus (HCMV), Epstein-Barr virus (EBV), and Human Herpesvirus-8 (HHV-8), have been the most commonly detected viruses in apical periodontitis specimens. Suggestive evidence of herpesvirus infection has been observed in symptomatic apical periodontitis lesions,[193,194] abscesses,[10,114,195] and large lesions.[194,196] Papillomavirus has also been found in abscesses.[10]

It has been hypothesized that herpesviruses may be implicated in the pathogenesis of apical periodontitis as a direct result of virus infection and replication or as a result of virally induced impairment of local host defenses that might give rise to an overgrowth of pathogenic bacteria in the very apical part of the root canal.[9] The arrival of herpesviruses at the periradicular tissues seems to be related to the influx of virus-infected inflammatory cells in response to bacterial infection in the apical canal. Reactivation of herpesviruses by tissue injury induced by bacteria may evoke impairment of host immune response in the periradicular microenvironment, changing the potential of local defense cells to mount an adequate response against infectious agents. Moreover, herpesvirus-infected inflammatory cells are stimulated to release pro-inflammatory cytokines.[197,198]

The mere presence of virus in clinical samples does not necessarily imply a role in the pathogenesis of apical periodontitis. Several herpesviruses can be chronically present in the body infecting leukocytes and as these cells are attracted and accumulate in inflamed areas, these viruses will also be present. The role of herpesviruses in the pathogenesis of apical periodontitis, if any, has still to be clarified.

BACTERIAL CAUSES OF FLARE-UPS

Flare-up is "an acute exacerbation of an asymptomatic pulpal and/or periapical pathosis after the initiation or continuation of root canal treatment."[199] It is a true emergence,

characterized by severe pain and/or swelling that develops a few hours or the next day following professional intervention.[200] The periradicular tissues are acutely inflamed and the condition is diagnosed as an acute apical periodontitis or acute apical abscess secondary to treatment. Flare-ups are caused either by bacteria or iatrogenic approaches (e.g., overinstrumentation, apical extrusion of irrigants) or both.[200–204] There are numerous studies evaluating the influence of diverse factors in the incidence of flare-ups. The two most significant risk factors seem to be presence of pre-operative pain and intervention in the infected root canals (necrotic pulps and retreatment cases).[205–209] The prevalence of flare-ups ranges from 2.5% to 16%.[210]

Because of the low incidence and the unexpected/unpredictable nature of flare-ups, no study has so far consistently evaluated the bacterial species associated with this condition. It has been suggested that combinations of *F. nucleatum* and *Porphyromonas* and *Prevotella* species may lead to exacerbations.[211]

Flare-ups are caused by bacteria in the following situations: (a) apical extrusion of infected debris, (b) incomplete root canal instrumentation, and (c) secondary intraradicular infections. For more details, see Chapter 30.

Apical Extrusion of Infected Debris

Apical extrusion of infected debris during chemomechanical preparation is allegedly the major cause of postoperative pain.[201,203,204] In teeth with asymptomatic apical periodontitis, a balance is established between bacterial aggression from the infected canal and the host defenses at the periradicular tissues. If during chemomechanical preparation bacteria are forced to the periradicular tissues, the host will face a situation that is now challenged by a larger number of irrigants than before. Consequently, there will be a transient disruption in the balance between aggression and defense, in such a way that an acute inflammatory response is mounted in an attempt to re-establish the equilibrium.

Exacerbation of inflammation in response to extruded bacteria depends on their numbers and virulence. Thus, quantitative and qualitative factors are decisive in causing interappointment pain associated with apical extrusion of debris. The quantitative factor comprises the number of bacterial cells extruded, while the qualitative factor encompasses the virulence of the extruded bacteria. Virtually all instrumentation techniques promote apical extrusion of debris.[212–214] However, techniques significantly diverge as to the amount of extruded debris. Some techniques extrude less than the others. Such differences in the amount of extruded debris may be crucial for the development of postoperative pain. Techniques that extrude more debris conceivably increase the risk for exacerbations.

In the event of overinstrumentation during preparation of infected canals, the risk of flare-ups is increased. In addition to the mechanical injury to the periradicular tissues, overinstrumentation usually promotes extrusion of a large amount of infected debris.

Retreatment of teeth with posttreatment disease has been found to be a risk factor for postoperative pain.[206,209,215] During removal of the root canal filling material and further instrumentation, filling remnants and infected debris tend to be pushed ahead of the instruments and forced into the periradicular tissues, exacerbating inflammation and causing pain.[209,215] Solvents used during filling removal are also cytotoxic and may contribute to exacerbation of the periradicular inflammation.[216]

Incomplete Root Canal Preparation

Ideally, chemomechanical procedures should be planned to be completed in a single visit. The microbiota associated with endodontic infections are usually established as a multispecies community, and abrupt changes imposed to this consortium by instruments and antimicrobial irrigants have the potential to drastically affect the ecology of the microbiota. However, complete preparation is not always possible. The clinician should be aware that incomplete chemomechanical preparation can disrupt the community balance by eliminating some inhibitory species, leaving behind other previously inhibited species that can then overgrow.[217] If overgrown species are virulent and reach sufficient numbers, damage to the periradicular tissues can be intensified and result in exacerbation of inflammation.

Another form of environmental change induced by endodontic intervention refers to the entry of oxygen into the root canal. It has been suggested that this would alter the oxidation–reduction potential (Eh) in the root canal and, as a consequence, acute exacerbation might occur because of overgrowth of facultative bacteria.[218] However, this mechanism remains speculative and there is no scientific evidence indicating that it is valid.

Secondary Intraradicular Infections

Secondary infections are a contamination problem and can be a cause of flare-ups when it develops following a breach in the aseptic chain or coronal leakage. If the microorganisms that gained access to the root canal are successful in surviving and colonizing this new environment, a secondary infection is established and may be one of the causes of postoperative pain, providing the newly established species are virulent and reach sufficient numbers to induce acute periradicular inflammation.

ETIOLOGY OF POSTTREATMENT APICAL PERIODONTITIS

Microbial Factors

Persistent and Secondary Endodontic Infections

Persistent and secondary infections are two different conditions—the former is caused by bacteria that were in primary infections that persisted after treatment, while the latter is caused by bacteria introduced in the canal during

or after treatment. For the most part, these infections are clinically indistinguishable. Exceptions include infectious complications (e.g., acute apical abscess) arising after the treatment of noninfected vital pulps or cases in which apical periodontitis was absent at the time of treatment but present on the follow-up radiograph. Both situations are typical examples of secondary infections. Persistent and secondary infections are responsible for several clinical problems, including persistent exudation, persistent symptoms, interappointment flare-ups, and failure of the endodontic treatment, characterized by a posttreatment apical periodontitis lesion (Figure 3-14).

Although there is evidence in the literature that extraradicular infection or nonmicrobial factors may be involved,[219,220] intraradicular infections (persistent or secondary) are the major causes of endodontic treatment failure (Figure 3-15). This statement is supported by two strong evidence-based arguments. First, it has been demonstrated that there is an increased risk of adverse treatment outcome when bacteria are present in the canal at the time of filling.[221–223] Second, studies have detected microorganisms in the canals of virtually all teeth with posttreatment apical periodontitis.[224–231]

Studies have been conducted to identify the species persisting after treatment that have the potential to influence the treatment outcome, and the species present in teeth with posttreatment apical periodontitis that may be the cause of this disease and consequently the cause of failure.

Bacteria Persisting After Treatment Procedures

In some cases, even diligent antimicrobial treatment may fail to properly control the root canal infection. This is because persisting bacteria can be located in areas that are inaccessible to instruments, irrigants, and medications. Inherent resistance to treatment procedures or substances might also be a cause of persistence, but it is difficult to assume that bacteria may resist to both mechanical debridement and the strong antimicrobial effects of sodium hypochlorite. Thus, bacteria usually persist because they are not reached by antimicrobial procedures. Following antimicrobial endodontic treatment, the intracanal bacterial diversity and density are substantially reduced. In cases where persisting bacteria are detected, one to five bacterial species are usually found per canal, with counts usually varying from 10^2 to 10^5 cells per sample.[64,66,222,232,233]

No single species has been significantly found to persist after treatment procedures. Gram-negative bacteria that are common members of primary infections, are usually eliminated. Exceptions include some anaerobic rods, such as *F. nucleatum, Prevotella* species, and *Campylobacter rectus,* which are among the species found in postinstrumentation or postmedication samples.[64,65,222,232,234,235] Most studies have demonstrated that persisting species are generally Gram-positive bacteria, including streptococci, *P. micra, Propionibacterium* species, *P. alactolyticus, Actinomyces* species, lactobacilli, *E. faecalis,* and *Olsenella uli* [64,189,222,232–244]. As-yet-uncultivated bacteria have also been detected in posttreatment samples.[64,163,245]

Persisting bacteria will not always induce or maintain an infectious process. Some apical periodontitis lesions can heal even in cases where bacteria were detected in the canal at the time of filling.[221,222] There are some possible explanations for this finding[246]:

- Residual bacteria died after filling, because of the toxic effects of the filling material, access denied to nutrients, or disruption of bacterial ecology;
- Residual bacteria were present in quantities and virulence subcritical to sustaining periradicular inflammation;
- Residual bacteria remained in locations where access to the periradicular tissues was denied.

Bacteria resisting the effects of intracanal procedures and present in the canal at the time of filling can influence the outcome of the endodontic treatment when[246]

- they managed to withstand periods of nutrient scarcity, scavenging for low traces of nutrients or assuming a state of low metabolic activity, to prosper again when the nutrient source is reestablished;
- they endured treatment-induced disturbances in the ecology of the bacterial community, including disruption of quorum-sensing systems, food webs, genetic exchanges, and disorganization of protective biofilm structures;
- they reached critical counts necessary to inflict damage to the host;
- they had unrestrained access to the periradicular tissues through apical/lateral foramina or iatrogenic root perforations;
- they were sufficiently virulent and antigenic to directly or indirectly induce damage to the periradicular tissues.

Microbiota in Root Canal-Treated Teeth

The root canal microbiota of teeth with posttreatment apical periodontitis exhibits decreased diversity in comparison to primary infections. Canals apparently well treated harbor one to five species, but the number of species in canals with inadequate treatment can reach up to 10 to 20 species that is very similar to untreated canals.[226–230,247] Bacterial density in root canal-treated teeth ranges from 10^3 to 10^7 cells per canal.[63,236,248,249]

E. faecalis has been the most frequently detected species in association with posttreatment disease, with prevalence values reaching up to 90%.[156,226–229,248–251] Because *E. faecalis* is not so common in primary infections[156] and has been commonly recovered from teeth treated at multiple visits and/or left open for drainage,[252] the possibility exists that this species is a component of secondary intraradicular infection.

E. faecalis has some characteristics that help explain its high prevalence in retreatment cases. Its ability to invade dentinal tubules can enable it to escape the action of endodontic instruments and irrigants used during chemomechanical preparation.[253,254] Its ability to form biofilms on

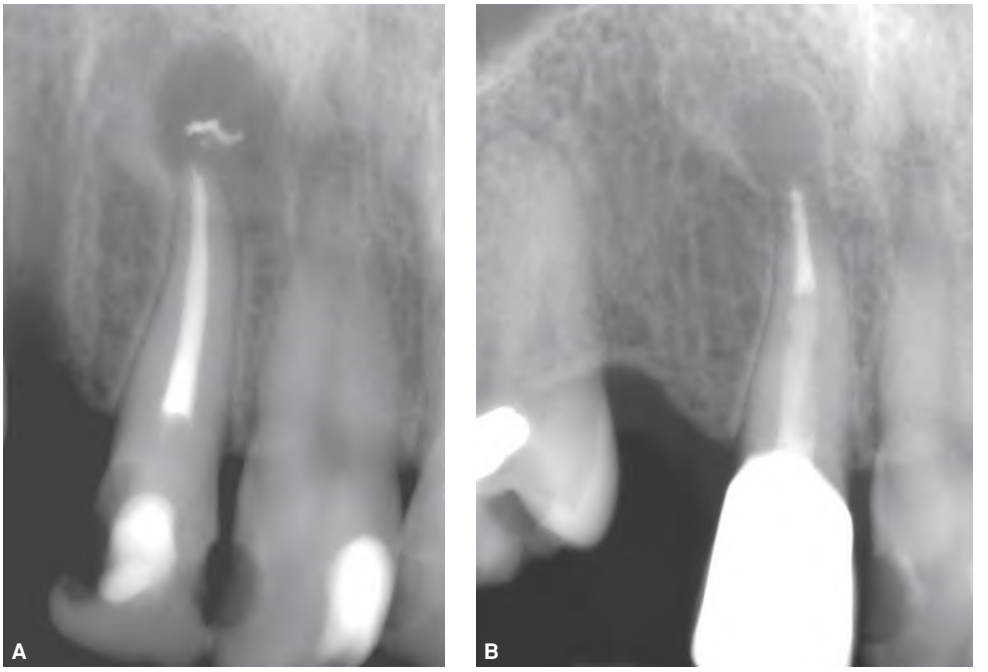

FIGURE 3-14 Lateral incisor with necrotic pulp and a large radiolucency. ***A***. Post-obturation radiograph. ***B***. Five-year recall. The lesion has slightly decreased in size. However, the residual radiolucency after a long observation period indicates root canal treatment failure.

the canal walls may be important for resistance to intracanal antimicrobial procedures.[255] *E. faecalis* shows resistance to calcium hydroxide,[256] possibly related to a functioning proton pump that, in an alkaline environment, drives protons into the cell to acidify the cytoplasm and allow survival.[257] Unlike most anaerobic bacteria frequently found in primary infections, *E. faecalis* may colonize the root canal in single infection.[228] Finally, this species can enter a so-called viable but non-cultivable (VBNC) state[258] that is a survival mechanism adopted by several bacteria when exposed to unfavorable environmental conditions.[259] This may be the case in treated canals. By the way, *E. faecalis* has been shown to survive in conditions of nutrient scarcity and then flourish again when nutrients are reintroduced.[260]

Its high prevalence and attributes do not suffice to prove a causative role for *E. faecalis* in posttreatment apical periodontitis. Its status as the main pathogen in failed cases has been questioned because of the following findings:

- *E. faecalis* is not detected in all studies evaluating the microbiota of root canal treated teeth with posttreatment disease.[159,261]
- If present, *E. faecalis* is rarely one of the most dominant species in the community associated with posttreatment disease.[230,247,249,262]
- *E. faecalis* is as prevalent in root canal treated teeth with lesion as it is in treated teeth with no lesion.[251,263]

Many other species have been detected in root canal-treated teeth with apical periodontitis, including *Streptococcus* species, *P. alactolyticus, Propionibacterium* species, *F. alocis, Dialister* species, *T. forsythia, P. micra, Prevotella* species, and *T. denticola.*[75,227–230,247,249,250,262,264,265] Uncultivated phylotypes can also be found and may correspond to 55% of the taxa.[230] Occurrence of uncultivated phylotypes may help explain the occurrence of negative cultures in studies evaluating the microbiota of teeth with posttreatment disease.

Fungi are only occasionally found in primary infections, but *Candida* species have been detected in root canal–treated teeth in up to 18% of the cases.[183,184,227–229,236,250,261] *Candida albicans* is the most commonly detected fungal species in root canal-treated teeth. This species has several properties that can be involved in persistence following treatment, including its ability to colonize and invade dentin[266–268] and resistance to calcium hydroxide.[269,270]

EXTRARADICULAR INFECTIONS

In response to root canal infection, the host mounts an inflammatory response at the periradicular tissues to curb the advance of infection to the bone and other areas of the body. In some specific circumstances, bacteria egressing from the canal can overcome this defense barrier and establish an extraradicular infection. The acute apical abscess is the best and most common example of extraradicular infection. Other forms of extraradicular infection have been proposed as one of the possible etiologies of posttreatment apical periodontitis.[271–275]

An extraradicular infection can develop in the following situations[276]:

- As a result of direct advance of bacteria into the periradicular tissues due to an extension of the intraradicular infectious process. Sometimes, it can occur in the

form of a biofilm advancing along the outer root surface. Alternatively, advancing bacteria may penetrate the lumen of a pocket cyst that is in direct communication with the apical foramen, resulting in an infected cyst (Figure 3-16).

- As a result of bacterial persistence in the apical periodontitis lesion after remission of an acute apical abscess. In these cases, an actively draining sinus tract can be observed in a condition now recognized as a chronic abscess.
- As a sequel to apical extrusion of infected debris during root canal instrumentation (particularly after overinstrumentation) (Figure 3-17). Bacteria embedded in dentinal chips can be physically protected from the host defense cells and persist in the periradicular tissues to sustain periradicular inflammation.
- As a result of bacteria in the very apical part of the canal that are left outside after inflammatory apical root resorption associated with apical periodontitis.

Conceivably, the extraradicular infection can be dependent on or independent of the intraradicular infection.[272] Independent extraradicular infections are those no longer fostered by the intraradicular infection and can persist even after successful eradication of the latter. So far, it has been suggested that the main bacterial species implicated in independent extraradicular infections are *Actinomyces* species and *Propionibacterium propionicum,* in a pathologic entity named *apical actinomycosis.*[275,277–279] These bacteria may form cohesive colonies that are collectively resistant to phagocytosis.[280] However, existence of apical actinomycosis as a self-sustained

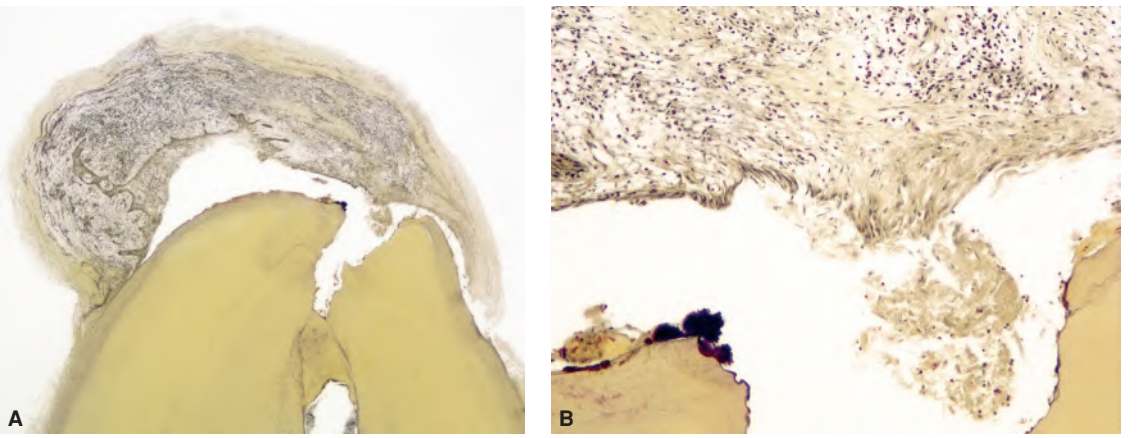

FIGURE 3-16 ***A***. The lesion remaining attached to this maxillary canine at extraction exhibits the characteristics of a "pocket cyst" (Taylor's modified Brown & Brenn, original magnification ×16). ***B***. Magnification of the foramen reveals that a bacterial biofilm is forming on the external surface of the root. This condition may sustain infection of the cyst cavity (original magnification ×100).

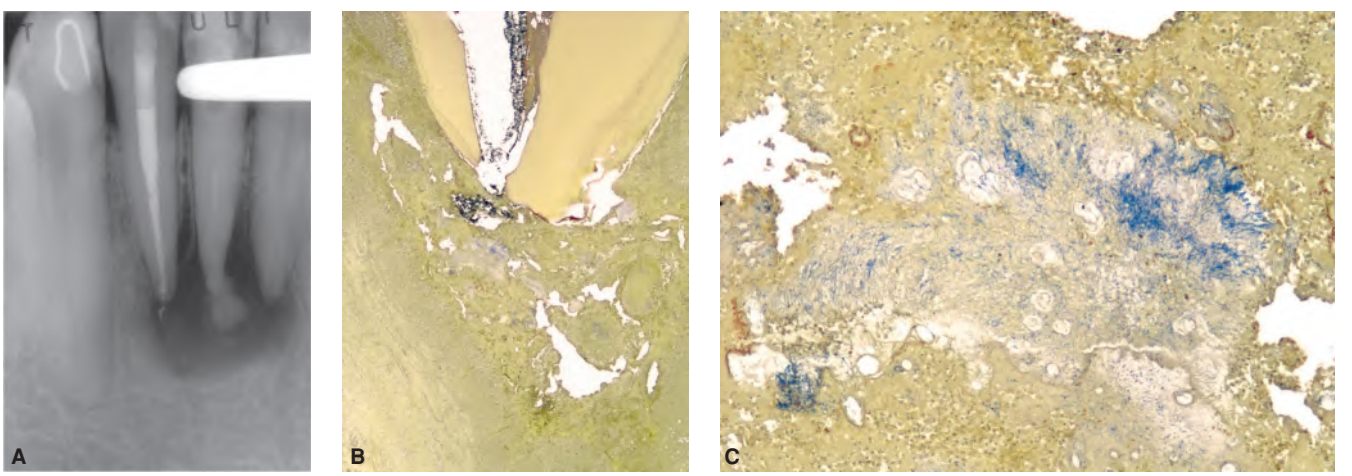

FIGURE 3-17 Mandibular incisor with necrotic pulp. ***A***. Radiograph taken after medication with calcium hydroxide revealed a considerable amount of the medicament inadvertently forced into the periradicular tissues. This may be an indication of overinstrumentation. Despite several sessions of instrumentation and intracanal medication, signs of persisting infection were constantly present. Permanent canal obturation was done and followed by perirapical surgery. ***B***. Longitudinal section cut through the foramen (Taylor's modified Brown & Brenn, original magnification ×16). ***C***. It is highly likely that this condition was caused by apical extrusion of infected debris as a consequence of overinstrumentation.

pathologic entity, no longer sustained by the intraradicular infection, and its involvement as an exclusive cause of treatment failure remains to be proven.[43,281]

It is still controversial whether extraradicular bacteria can establish themselves in an asymptomatic (chronic) apical periodontitis lesions for very long beyond initial tissue invasion.[282] Culture-dependent[219,283,284] or culture-independent molecular microbiology studies,[285–289] have reported the extraradicular occurrence of a complex microbiota associated with apical periodontitis lesions that did not respond favorably to the root canal treatment. Apart from a discussion about whether or not contamination can be effectively precluded during surgical sampling of periradicular lesions, these studies did not evaluate the bacteriologic conditions of the apical part of the root canal. This makes it difficult to ascertain whether those extraradicular infections were dependent on or independent of an intraradicular infection. Findings from a study evaluating both the resected root ends and the apical periodontitis lesions from treated teeth indicated that the large majority of cases of extraradicular infections are associated with concomitant infection of the apical root canal.[290]

NON-MICROBIAL FACTORS

As discussed above, numerous studies have demonstrated that the majority of teeth with posttreatment apical periodontitis are associated with intraradicular or extraradicular infections.[14,224,226,227,230,231,249,264,291] Because some studies failed to observe a possible microbial cause for this disease, it was suggested that endogenous or exogenous non-microbial factors may cause some lesions not to heal.[220] Endogenous causes purportedly include cholesterol crystals and true cysts, while exogenous causes encompass foreign body reactions caused by extruded endodontic filling materials[231,292,293] or cellulose-containing particles from paper points or food.[294,295]

Exogenous Factors

Some authors suggested that a foreign body reaction to the cellulose component of paper points, cotton wool, and some food material of vegetable origin may be the cause of persisting periradicular inflammation.[294,295] Cellulose is a stable polysaccharide of plant cell walls that is not degraded by the host defense cells. Once introduced into the tissues, cellulose may remain therein for long periods and elicit a foreign body reaction. Paper points or particles thereof can be dislodged or pushed into the periradicular tissues, inducing a foreign body giant cell response or sustaining an already existing inflammatory lesion. Cellulose-containing food particles may be impacted in the canals of teeth with grossly damaged crowns that have been left open for drainage, and be inadvertently pushed into the periradicular tissues during root canal treatment. It is salient to point out that in all these circumstances, it is virtually impossible to rule out the occurrence of concomitant infection (see Chapter 6), making it difficult to establish the cause of persisting inflammation. In the event of overfilling, the components of some filling materials may elicit a foreign-body reaction that has been claimed to sustain periradicular inflammation.[231,292]

Endogenous Factors

It has been suggested that cholesterol crystals can evoke a foreign body reaction and lead to persisting inflammation.[296] In areas of chronic inflammation associated with cysts and granulomas, cholesterol crystals can precipitate and accumulate as they are released from disintegrating host cells (see Chapter 6). They can also originate from circulating plasma lipids. If multinucleated giant cells are ineffective in removing these crystals, they continue to accumulate and may maintain chronic inflammation. Again, there is no consistent evidence indicating that cholesterol crystals are the cause of posttreatment apical periodontitis in the absence of concomitant infection.

"True" cysts that contain cavities completely enclosed by epithelial lining and not communicating with root canal, have been suggested to be self-sustaining entities that may not heal after root canal treatment.[297] However, it has never been proven that all apical cysts can be sustained without concomitant infection. Actually, some cysts are expected to heal after the cause of epithelial proliferation, that is, the root canal infection, is properly controlled.[298–300] The cyst epithelium loses the source of cytokines and growth factors that stimulate proliferation and serve as survival factors, leading to apoptosis of epithelial cells and resolution of the cyst.[300]

Pocket cysts are different from true cysts in the sense that the epithelial-lined cavity is open to the root canals. As a consequence of this direct contact between the lumina of the canal and the cyst, pocket cysts are more prone to be infected (Figure 3-16). Within the cyst cavity, bacteria egressing from the root canal are combated by host defense molecules and polymorphonuclear neutrophils that transmigrate through the epithelium into the cyst lumen. Because of the physicochemical conditions within the cyst cavity, the host defense mechanisms may not be effective in eliminating bacteria. Thus, persisting bacteria and their products within the cyst lumen may sustain periradicular inflammation in treated root canals.

Association of cholesterol crystals or true cysts with posttreatment apical periodontitis has not been observed in a study evaluating several cases of endodontic treatment failure.[231] In most studies that suggested a role for non-microbial agents, the microbiological conditions of the apical root canal was not assessed. Therefore, there is no consistent evidence regarding the role of cholesterol crystals as the sole cause of posttreatment apical periodontitis.

It is important to point out that endodontic infections and apical periodontitis are effectively treated by nonsurgical endodontic treatment with a very high success rate and the few failed cases can be managed by retreatment of periradicular surgery and converted to success in 80–90% of the cases. Therefore, endodontic treatment is an important and predictable approach to save teeth and promote oral health.

Chapter 4

Inflammation and Immunological Responses

Ashraf F. Fouad, George T.-J. Huang

Endodontic pathosis is primarily caused by infectious agents that mediate a series of inflammatory and immunological responses in the dental pulp and periapical tissues. This chapter describes some of the fundamental immune reactions that take place in these tissues, as well as other connective tissues, and outlines the basic mechanisms involved in disease initiation and progression.

The science of immunology is constantly changing and remarkable discoveries are constantly being made about the unique molecules, cells, tissues, and pathways that take place in response to external and autogenic stimulation. While an attempt has been made to address most of the critical and well-understood immunological data, it is virtually impossible to fully cover this topic in a comprehensive manner in this chapter. Many immunological reactions have not been adequately emphasized in the endodontic literature, or may exceed the scope of this textbook. These include neoplastic changes, autoimmune reactions, and some congenital and post-natal abnormalities in gene expression. Indeed, the reason why neoplastic changes are not common in the dental pulp may be of fundamental importance in understanding the pathogenesis of neoplasia in general, and may have relevance in the growing field of regenerative endodontics, particularly in gene therapy. However, given the paucity of data in some of these areas, and the speculative nature of the data that is available, this material may not be suitable for publication in clinical textbooks at this time. Therefore, these topics will not be addressed in this chapter, and the reader is referred to specialized textbooks or journals for more information on these topics.

The reactions and mechanisms that will be covered here are those that primarily deal with the inflammatory response, and that have been described to some degree in pulpal and periapical tissues or are widely recognized in other tissues and presumed to be in operation in endodontic tissues. In fact, wherever relevant, specific literature that have addressed these questions will be cited in the text, to bring the basic concepts closer to the mind of the reader, who is assumed to be primarily a clinician or a researcher in the endodontic field.

The material described in this chapter will be presented under discrete topics, for example, the individual cells and molecular mediators encountered in immunological reactions. However, the reader should always be cognizant of two fundamental concepts in immunology. The first is that there are many interrelationships between the pathways and mechanisms that will be presented, and much overlap among the functions of the cells is to be described. This creates a large amount of redundancy that assures a competent and robust response. Indeed, it is commonly stated that the main purpose of treatment of various disease processes is to remove the source of irritation and provide a suitable environment for the body to cure itself, through the effective healing mechanisms. The second concept is that there is a substantial degree of variability among different individuals in their response to a particular irritant. While some of this difference in response is quite extreme, and explained by the various hypersensitivity reactions, most of the variation is more subtle, and is mediated by systemic conditions and diseases, or individual genetic polymorphism of different patients. The concept of genetic polymorphism commonly refers to differences in expression of certain inflammatory mediators, cellular activation, or other immunological reactions. This variation may indeed render certain individuals more prone to a more dramatic expression of the disease process or delay in healing mechanisms. Genetic polymorphism may be explained by minor, perhaps a single nucleotides variation in the genetic make-up of particular genes. Thus, it is commonly referred as a single nucleotide polymorphism or SNP. It has been described with respect to the expression of a number of proteins, such as interleukin (IL) 1, and may explain why some inflammatory reactions to seemingly similar irritants, undergo different clinical presentations and response to treatment in different patients.

CELLS OF THE IMMUNE SYSTEM

The immune system represents a complex system of cells, tissues, organs, as well as molecular mediators that act in synchrony to assure the maintenance of health and the defense against disease. Cells interact with microbial irritants as well as with each other via a large number of molecular mediators and cell surface receptors that together result in the various phenotypic reactions. The various host reactions will be discussed in the context of a description of the main cells of the immune response, as these cells play a critical role in mobilizing the immune response. It is appropriate initially to present the ontogeny of immune cells from hematopoietic stem cells (Figure 4-1).[1–3] A description of the mature inflammatory cells and their activities is given below, starting with the innate immune system.

Innate Immune System

The innate immune system is composed of a number of natural barriers, as well as cellular and molecular elements that represent the initial nonspecific reactions of the immune response. The barriers are epithelial or generally ectodermal

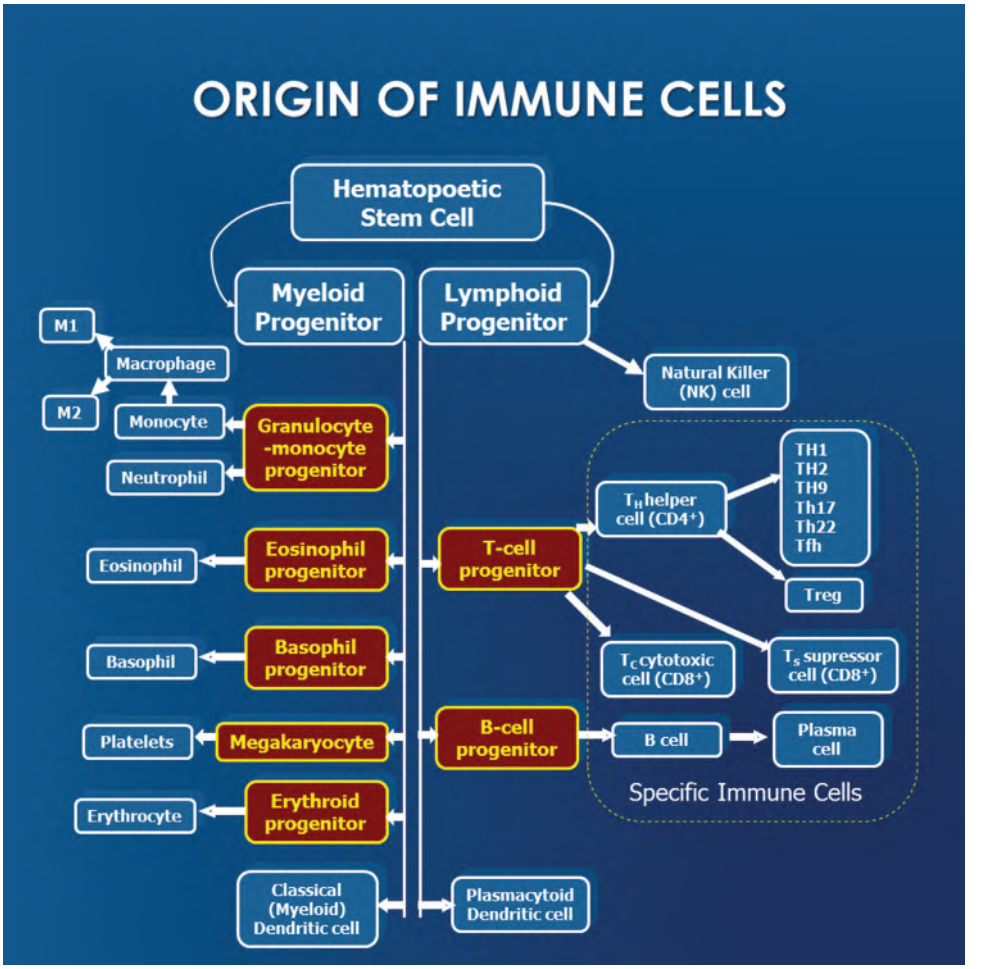

FIGURE 4-1 Hematopoiesis of principal immune cells. Note that dendritic cells may develop from both myeloid and lymphoid progenitor cells. Cells of the specific immune system develop memory clones for future interactions with the similar antigens.

TABLE 4-1 Normal Blood White Cell Counts[3]

	Mean count per microliter	Normal range
Total leukocytes	7400	4500–11,000
Neutrophils	4400	1800–7700
Eosinophils	200	0–450
Basophils	40	0–200
Lymphocytes	2500	1000–4800
Monocytes	300	0–800

or ectomesenchymal in origin. Examples include the skin, oral mucosa, junctional, and sulcular epithelium, as well as intact enamel and dentin. These barriers prevent the dissemination of microorganisms and their byproducts into the subjacent connective tissue that would result in disease. Dental caries, fractures of teeth, or congenital anomalies that expose the dental pulp create a break in this barrier, resulting in inflammation of the pulp, and ultimate necrosis. Once the pulp is necrotic and the pulp space is occupied by microorganisms, there is no natural barrier to the dissemination of these irritants into the periapical region and/or systemically through the apical, lateral, or accessory foramina. In fact, junctional complexes between odontoblasts in the vital pulp have been shown to play a role in preventing the leakage of microbial irritants into the pulp.[4,5]

Phagocytosis is another important component of innate immunity. Similarly, the presence of certain non specific proteins such as, lysozyme or complement, or pattern-recognition receptors, such as Toll-like receptors (TLRs) (see later), on the surface of immune cells are also constituents of the innate immune system. Inflammation is associated with a number of vascular changes such as vasodilatation, increased capillary permeability, and extravasation of blood cells and inflammatory mediators, together with reduced pain threshold. Many of these non specific changes are caused by neurogenic elements, such as neuropeptides. These concepts will be addressed later in the chapter. Therefore, innate immunity does not involve sensitization or priming, has a uniform response to all irritants that are detected, lacks memory, and aims to rapidly eliminate irritants and degenerated host tissues.

Cells of Innate Immunity

Neutrophils Neutorophils, also known as polymorphonuclear leukocytes or PMNs, are the most numerous white blood cells (Table 4-1), representing ~54%–63% of peripheral blood leukocytes. They have a short half-life, generally functioning

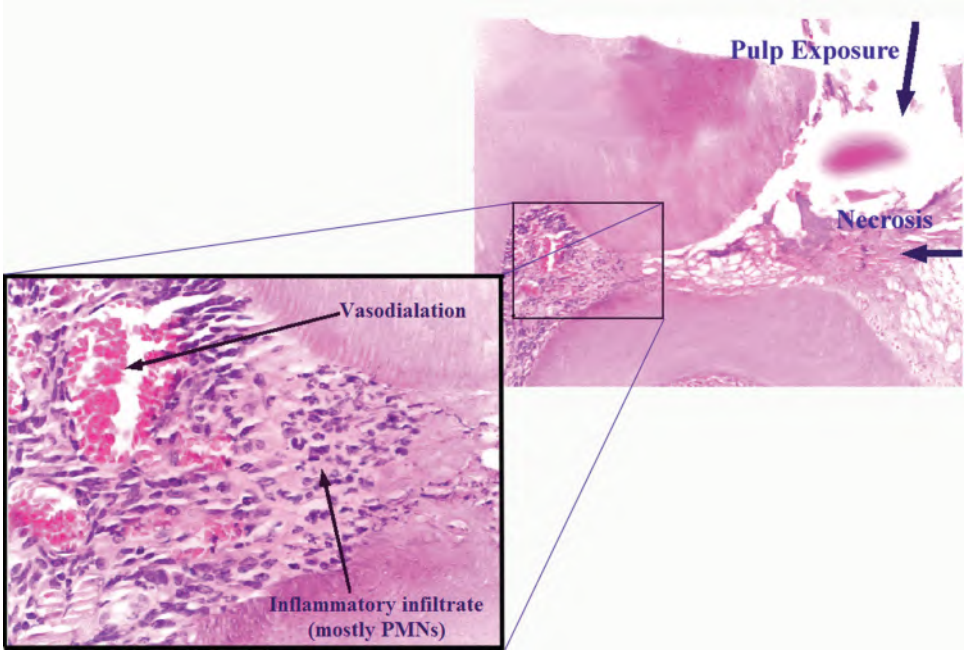

FIGURE 4-2 Experimental pulp exposure in a rodent molar showing pulp necrosis, acute and chronic inflammation, and vasodilatation.

for 1–2 days, and if not recruited to a site of inflammation, they undergo apoptosis. PMNs represent the first defense line against microbial irritants, being mobilized in what is traditionally known as acute inflammation (Figure 4-2). PMNs utilize a large number of defense mechanisms to eliminate invading pathogens and inactivate their toxins. These include the production of lysosomal enzymes, cytokines, oxygen-derived free radicals, as well as phagocytosis.

Within PMNs, defense proteins are contained within two types of granules that do not stain acidic or basic, that differentiate these cells from basophils and eosinophils. The first granule is azurophilic (large) granuales (lysosomes) (~0.5 μm in diameter) that contain lysozyme, myeloperoxidase, defensins, acid hydrolases, and neutral hydrolases such as collagenases, elastase, cathepsin G, and other proteinases. The second type is specific (small) granules (~0.2 μm in diameter) that contain lactoferrin, lysozyme, collagenases, plasminogen activator, histaminase, alkaline phosphatase, and membrane-bound cytochrome b_{558}. Production of neutrophils is stimulated by granulocyte colony-stimulating factor (G-CSF). An adult human produces >1011 neutrophils every day.[3] The cell also has abundant glycogen stores, that enable the cell to utilize glycolysis to produce energy in anaerobic conditions,[6] such as during an abscess formation.

Monocytes/Macrophages Monocytes are circulating leukocytes that represent 4%–8% of blood leukocytes. Macrophages reside within connective tissues. Certain macrophages become especially adapted for immunological functions in certain tissues. These cells are collectively referred to as members of the mononuclear phagocyte system. Examples of these cells are Kupffer cells in the liver, microglia in the central nervous system, or alveolar macrophages in the lungs. It is generally accepted now that both macrophages and osteoclasts have a common lineage. Likewise, a number of other cells commonly seen in inflammatory reaction or granulomatous disease, such as foam cells, epithelioid cells, or giant cells, may have a common lineage.

Macrophages have a relatively long half-life in tissues, commonly measured in months. They are considered among the principal inflammatory cells, commonly mobilized in areas of chronic inflammation. They possess major histocompatibility complex (MHC)-II receptor, have antigen-presenting capabilities, and are involved in phagocytosis. They are also among the principal producers of pro-inflammatory cytokines such as IL-1, IL-6, TNF-α, and IL-12.

Macrophages may be activated by activated Th1 cells of the specific arm of the immune response, or nonspecifically, such as by natural killer (NK) cells (Figure 4-3). There are two types of macrophages: M1 and M2. M1 macrophages express surface receptors, known as pattern-recognition receptors (PRRs). These receptors identify pathogen-associated molecular patterns (PAMPs) such as lipopolysaccharide (LPS) of Gram-negative bacteria, or peptidoglycan (PG) and lipoteichoic acid (LTA) of Gram-positive bacteria. PRRs generally belong to the TLRs, or nucleotide binding oligomerization domain (NOD)-like receptors (see later), and have intracytoplasmic component (homologous with the IL-1 receptor molecule) that transmits the signal through transduction proteins like myeloid differentiation factor 88 (MyD88) and transcription factors such as nuclear factor kappa-B (NF-κB) and other mitogen-activation protein (MAP) kinases. Eventually, messenger RNA is translocated into the nucleus in order to produce certain pro-inflammatory

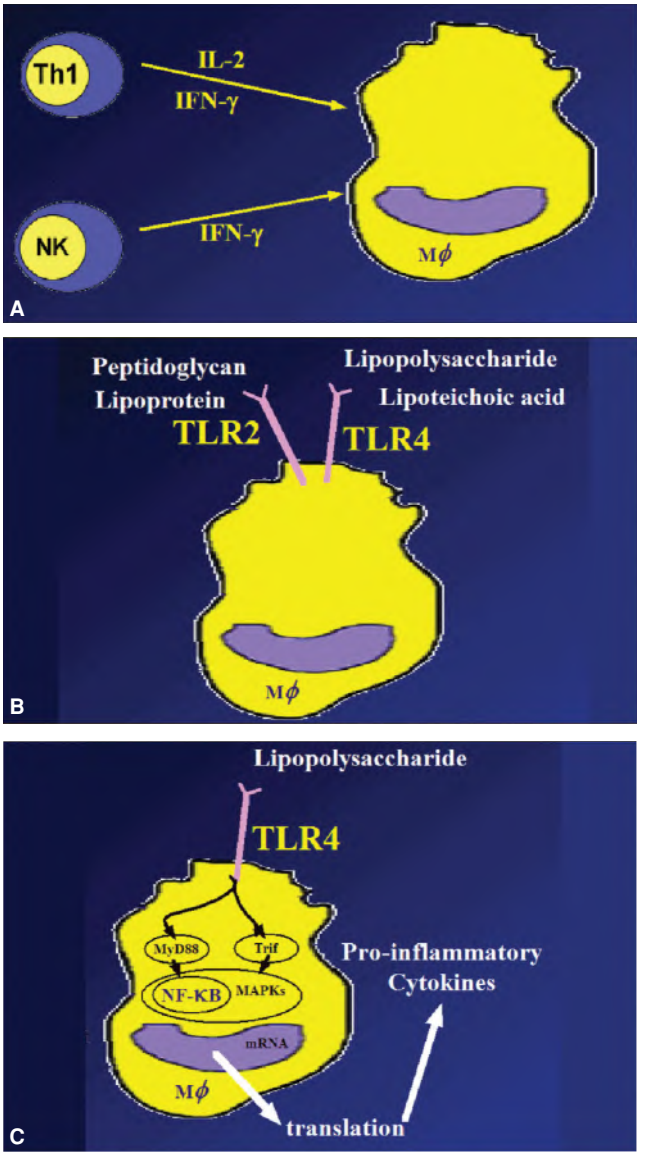

FIGURE 4-3 Macrophage activation and function. ***A.*** Cell is activated by cytokines from specific and non-specific immune cells. ***B.*** Cell expresses various pattern recognition receptors to microbial molecules. ***C.*** Signal transduction through myeloid differentiation factor 88 (MyD88) or other intermediaries, transcription through nuclear factor kappa-B (NF-κB) and mitogen-activated protein (MAP) kinases, that result in translation of mRNA and production of pro-inflammatory cytokines.

proteins, such as the cytokines, IL-1, IL-6, and TNF-alpha. The importance of these factors in inflammatory periapical lesions is demonstrated by the fact that all lesions (but not controls) were shown to have NF-κB.[7] More recently, periapical lesions were induced in MyD88-knock out mouse models and controls. Lesions in the knock out mice had much larger size, extensive neutrophils and monocyte counts, and tissue degradation, indicating a more extensive infection due to the down regulation of the inflammatory response.[8]

Molecules such as LPS are very potent biological toxins, capable of causing septic shock and killing the host. Therefore, in addition to the membrane-bound TLRs, a number of circulating molecules such as CD14 are available, that can bind to LPS in the blood rendering it less biologically active. This reaction is mediated by a plasma protein called LPS-binding protein (LBP). CD14 is also available in a membrane-bound form to the surface of macrophages and can bind LBP in this location; however, unlike TLRs, CD14 has no intracytoplasmic component, and thus is not capable of initiating the signal transduction pathway to initiate the production of cytokines. M2 macrophages are generally activated by IL-4 and IL-13, and are involved in tissue repair and control of the inflammatory response.[9] Recently, they have been shown to play a role in pulpal repair following vital pulp therapy.[10,11]

Phagocytosis The PMNs and macrophages are the main cells involved in phagocytosis. The surface of phagocytes can bind to the pathogen surface pattern molecules by lectin, through complement C3b or C5b, or by binding to the Fc portion of an opsonizing antibody through the FcγR receptors, which bind the carboxyl-terminal constant region of IgG molecules (Figure 4-4). These receptors include the high-affinity FcγRI receptor present in macrophages and PMNs, a low-affinity FcγRIIB that transduces inhibitory signals in B-cells and a low-affinity FcγRIIIA that mediates targeting activation of NK cells.[9] Studies in the endodontic literature have shown that healing following endodontic treatment was associated with genetic polymorphism in some alleles for the genes of FcγR receptors, such as FcγRIIA and FcγRIIIB,[12] but not FcγRIIIA.[13] After the initial binding of pathogen, which is significantly enhanced by opsonins, pseudopodia develop to surround and engulf the pathogenic organism, leading to the formation of a phagosome. The final stage of phagocytosis involves lysosomal enzymes that are released into the phagosome for degrading the microorganism or other foreign particles.

Microbial killing within the phagosome is effected through a series of oxidative reactions that require glycolysis, glycogenolysis, and the generation of reactive oxidative free radicals (Figure 4-5).[14] The fusion of the membranes of a phagosome and the lysosomal granules of the cells (such as the azurophilic granules of PMNs) results in an oxidative burst mediated by cytoplasmic- and membrane-bound oxidases. Through the action of NADPH oxidase, superoxide ions and hydroxyl radicals are generated. While these are sufficiently antimicrobial, lysosomes of PMNs contain myeloperoxidase, which through a halide intermediate can result in the generation of hypochlorous radicals (HOCl•). As is the case with exposure to sodium hypochlorite (NaOCl), HOCl• is a powerful oxidant and antimicrobial agent that kills bacteria by halogenation, or by protein or lipid peroxidation. Within the phagosome, other mechanisms of bacterial killing include lysozyme, which causes degradation of bacterial coat oligosaccharides, and defensins, which are peptides that kill bacteria by forming holes through their membranes.[14]

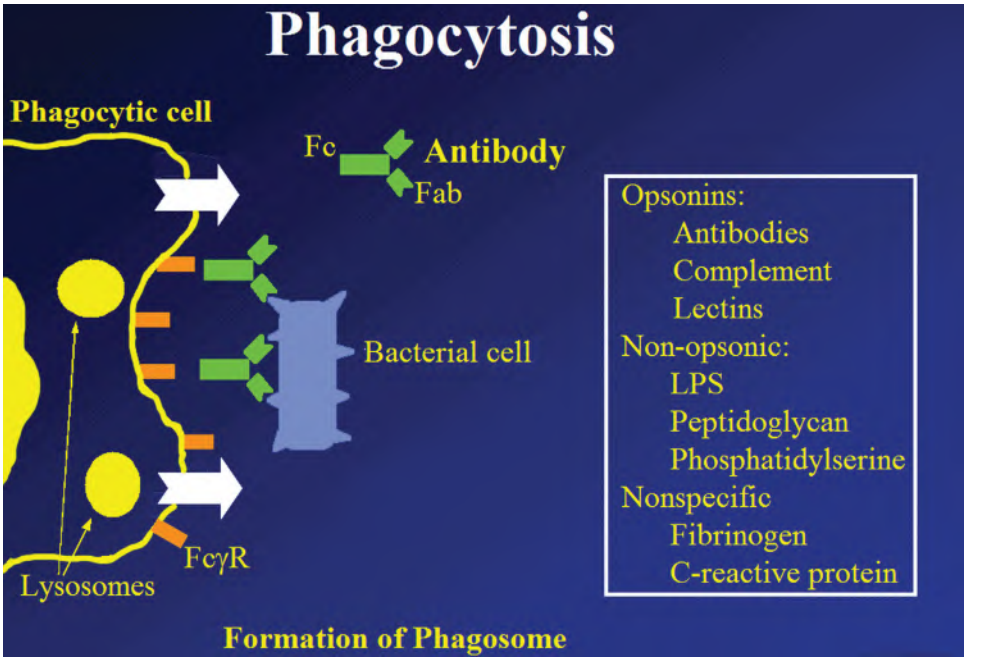

FIGURE 4-4 Phagocytic cell recognizes an opsonized bacterial cell, and starts to form a phagosome (white arrows) to engulf it. Eventually, lysosomal enzymes open into the phagosome to digest the material.

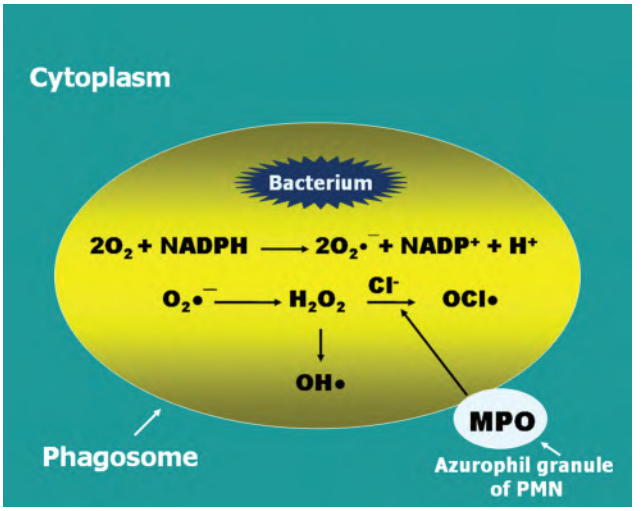

FIGURE 4-5 Oxidative burst reactions within a phagosome that result in destruction of a pathogen. MPO: myeloperoxidase; NADPH: reduced nicotinamide adenine dinucleotide phosphate; O2•⁻: Superoxide radical, OH•: hydroxyl radical; OCl•: hypochlorous radical.

While phagocytosis is quite effective in eliminating microbial irritants, when they are isolated or individualized, it frequently cannot deal with a microbial biofilm. A microbial biofilm has a large number of microorganisms embedded in a polysaccharide matrix. An example that is relevant to endodontics is a periapical infection with *Actinomyces* spp. that is generally thought to occur in the form of microbial colonies within the lesions. Inflammatory cells usually surround these colonies and attempt to eliminate them by forming phagosomes, but instead result in the release of oxygen radicals and lysosomal enzymes into the periapical tissues, causing tissue degradation.

Eosinophils Like neutrophils, eosinophils are segmented leukocytes, however, they stain red with hematoxylin and eosin stains (thus the name). They are much less prevalent than PMNs, constituting only ~1%–3% of circulating leukocytes. They are involved in allergic and some parasitic reactions. Their actions are primarily mediated by a low-affinity surface receptor for the Fc portion of the IgE molecule called FcεRII. Eosinophils express a number of inflammatory and healing mediators, most notably transforming growth factors (TGF) alpha and beta-1.[15–17] Eosinophils in human periapical cysts were shown to express TGF-α, and those in both cysts and granulomas also had TGF-β1, at the mRNA and protein levels.[18]

Basophils Basophils share some similarities in shape, size, and life-span with neutrophils and eosinophils; however, they are more intimately involved in the mediation of allergic reactions. In this regard, they share some features with connective tissue mast cells (Table 4-2).

TABLE 4-2 Comparison of Mast Cells and Basophils

	Mast Cells	Basophils
Size	10–15 μm	5–7 μm
Location	Connective tissue	Blood
Life span	Weeks or months	Days
Terminally differentiated	No	Yes
Granule content	Histamine, heparin, PAF	Histamine, heparin, PAF
High-affinity FcεRI	Yes	Yes

Mast Cells As noted in Table 4-1, mast cells reside in connective tissues for weeks to months. They are generally dormant with little activity, until they are stimulated by IgE activity in type 1 hypersensitivity reactions (see below). Complement activation also results in the production of C3a and C5a that are both described as anaphylatoxins as they initiate the acute responses effected by mast cell degranulation. Mast cell degranulation results in local (atopic) or systemic (anaphylactic) reactions. The primary outcomes of these reactions are vasodilation and broncho-constriction. Anaphylactic reactions can be life threatening, because of the resulting apnea and reduction in peripheral circulatory tone that dramatically reduces the blood pressure. These reactions are mediated by the release of granule contents, namely, histamine, arachidonic acid metabolites (especially prostaglandins: PGE2 and PGI1, and leukotrienes: LTB4 and LTD4), platelet activating factor (PAF), eosinophil chemotactic factor A, and a number of other enzymes that cause tissue damage.

Dendritic Cells Dendritic cells are the most important antigen presenting cells for activating naïve T-cells, thereby playing a critical role in linking innate and adaptive immunity.[3] Dendritic cells are stellate-shaped and reside in a variety of tissues including blood, lymph, epidermis, dermis, and secondary lymphoid organs.[19] They lack long-term adherence to immune cells or molecules and are not involved in phagocytosis. Like other antigen-presenting cells (APCs), namely macrophages, Langerhans cells (a subset of dendritic cells [DCs] present in the epidermis), B cells, and endothelial cells, they express MHC II. They have a variety of phenotypes, as determined by their morphology, surface markers, and the tissue where they reside. Circulating blood DCs have two different origins: classical (myeloid) and plasmacytoid. The former is characterized by the CD11c+ marker, while the latter lack CD11c, but have the CD123+ marker.[19] Classical CD11c+ DCs, such as macrophages, express a large number of TLRs, to both bacterial and viral molecules. In contrast, plasmacytoid DCs do not express TLR-2 and -4, and thus do not respond to bacterial molecules.[20]

They are also present in the dental pulp, where they are prevalent among the odontoblastic cell layer and around blood vessels,[21,22] in periodontal ligament[23] and in periapical lesions.[23,24] In mouse models, pulpal CD11b (the equivalent of human CD11c) DCs have been shown to migrate to regional lymph nodes in response to dentinal irritation, to present detected antigens to T-cells.[25]

NK Cells NK cells are lymphocytes that do not require activation like CD4 or CD8 lymphocytes. Therefore, they are members of the innate immune response. They represent ~4%–20% of circulating mononuclear cells. They produce interferon (IFN)-γ and are thus capable of activating macrophages to produce pro-inflammatory cytokines, without the need for activated T-lymphocytes. NK cells are particularly effective in killing host cells infected with viruses or other intracellular microorganisms.

Odontoblasts and Innate Immunity Odontoblasts are the first line of cells encountering foreign antigens after enamel and dentin breakdown, these resemble epithelial cells in this concept. Epithelial cells have been considered as an integrate part of innate immunity for being capable of producing pro-inflammatory cytokines and expressing antimicrobial peptides β-defensins.[26,27] Similarly, human odontoblasts have also been observed to express chemokines such as IL-8 and CCL20, chemokine receptor CCR6, as well as antimicrobial peptides β-defensins 1, 2, and 3.[28-31] Furthermore, odontoblasts express TLR including TLR2, TLR4, and virus recognizing TRLs 3, 7, 8, and 9,[30,32-34] indicating that odontoblasts plays a significant role in the pulp innate immunity.

Cells of Adaptive Immunity

The adaptive immunity involves the development of specific receptor molecules made by lymphocytes that recognize and bind to foreign or self-antigens. These specific receptor molecules on T cells are called T-cell antigen receptors (TCRs) and on B cells are B-cell antigen receptor (BCRs) or immunoglobulins. TCRs on T cells interact with antigens presented by MHC molecules along with other accessory molecules, whereas BCRs on B cells or as secreted form, generally known as antibodies, interact with antigens directly. The variable regions of both TCR and BCR are rearranged at the genomic level via V(D)J segment recombination. The estimated total diversity after this recombination for TCR is ~10^{18}, and for BCR is ~10^{14} that generates the repertoire of different individual T and B cell clones.[3,35]

Innate Lymphoid Cells Innate lymphoid cell (ILCs) not only play important roles in the development of lymphoid tissues and the initiation of inflammation in response to infection at the barrier surface, they also play complex roles throughout the duration of immune responses, participating in the transition from innate to adaptive immunity and contributing to chronic inflammation.[36] ILC family includes three groups, each predominantly express certain cytokines. ILC1s: IFN-γ; ILC2s: IL-5, IL-9, and IL-13; and ILC3s: IL-22 and/or IL-17. ILC2s are important in driving type 2 immune responses (Th2), while other members of the ILC family play roles in type 1 (Th1) and Th17 cell-mediated immunity and disease. Together they play roles in protective immunity against microbes, autoimmune disorders, and allergic diseases.[36]

T Cells T cells are found in normal pulp and constitute ~30% of the $CD45^+$ cells present in the pulp.[37,38] They play a pivotal role in adaptive immunity and their development goes through a rather intricate process. Originated from bone marrow hematopoietic stem cells, the precursor T cells migrate to the thymus to undergo maturation in which they express different cell surface markers (e.g., CD44, CD3, CD4, CD8, and CD25) at various stages and are screened via positive and negative selection processes. About 97% of T cells undergo apoptosis and only a small percentage of these cells are exported to the periphery

as mature T cells. During the positive selection, double-positive $CD4^+CD8^+$ T cells bearing TCRs that can interact with self-peptide: self-MHC on thymic epithelial cells are rescued from apoptosis. In the negative selection, these $CD4^+CD8^+$ T cells recognizing self-peptide: self-MHC too well are deleted via apoptosis. The positive selection ensures that mature T cells can recognize foreign antigen in the context of self MHC molecules that present the antigen, whereas the negative selection eliminates potentially self-reactive T cell clones. Before exiting the thymus, these cells become single-positive either $CD4^+$ or $CD8^+$ along with other surface markers such as CD25. These naive T cells then circulate back and forth between the lymphatic system and blood until they encounter foreign antigens presented by antigen presenting cells.

The interactions between TCR and antigen peptide: MHC and between co-stimulators CD28 and B7 activate signal transduction pathways in T cells leading to the synthesis of T cell growth factor IL-2 and its receptor and T cell clonal expansion/proliferation. Subsequently, T cells differentiate into armed effector T cells and some become memory cells. There are a number of T cell subpopulations categorized by their functions and some, can be distinguished by their cell surface markers, cytokine profiles, or transcriptional factors. Four main subpopulations are described below: T-helper cells, T-regulatory cells (Treg), T-suppressor, and T-cytotoxic (cytolytic) cells.

T-helper Cells (Th Cells) Naïve CD4 T cells upon antigen stimulation proliferate and differentiate into subsets of Th1, Th2, Th9, Th17, Th22, T-follicular helper cells and different subsets of regulatory T cells.[39] Th0, that subsequently commit into Th1 or Th2 cells. Classical (myeloid) DCs induce T-helper (Th) 1-type responses, and plasmacytoid DCs selectively induce Th2 responses. Each subset has distinct functions and cytokine profiles as depicted in Table 4-3. A Th1-specific T box transcription factor, T-bet, suppresses early Th2 cytokine production and induces Th1 T cell development via up-regulation of *IFN-γ* gene transcription and IL-12Rb2 chain expression. The differentiation of Th2 is dependent on the induction of transcription factors STAT6, c-maf, and GATA-3.[40] Th1 cells mainly produce IL-2 and IFN-γ; activate macrophages and induce B cells to produce opsonizing antibody. Th2 cells produce IL-4, -5, -10, and -13; activate B cells to make neutralizing antibody; have various effects on macrophages. Overall, Th1 and Th2 have mutually modulatory effect.[40]

Th9 Cells Th9 cells are a recently described new helper T-cell subset; the signature cytokine for Th9 cells is IL-9 (without IL-4).[41] Th9 cells are closely associated with Th2 cells, which co-express both IL-4 and IL-9 in the early phase of Th2 differentiation, and IL-4 is a key signal for Th9 induction.[41] Th9 cells play a role in allergic lung inflammation and certain autoimmune diseases.[41]

Th17 and Th22 Cells Th17 and Th22 cells are two emerging Th cell subsets that link the immune response to tissue inflammation; IL-17A, IL-17F, and IL-22 are their respective prototype cytokines.[39] Th17 cells are closely associated with Th1 in diseased tissues and may be directly derived from naïve CD4+ T cells.[42-44] Th17 produces IL-17 and its development can be induced by IL-23, which also stimulates Th1 production of IL-17-a cytokine that is linked to autoimmune and inflammatory diseases including rheumatoid arthritis and lupus. Th22 cells are characterized by particularly high IL-22 production. As a member of the IL-10 family, IL22 has 22.8% identity to IL-10.[39] Although both cytokines play roles in immune defense to extracellular bacteria, IL-17 augments inflammation, whereas IL-22 plays a role in recovery and regeneration.[39]

T follicular Helper Cells Generation of T follicular helper (Tfh) cells is similar to other CD4+ T cell lineages (e.g., Th1, Th2, Th17, and Treg cells) requiring signaling pathways. Tfh cells express a unique combination of effector molecules including high levels of the surface receptors ICOS, CD40 ligand (CD40L), OX40, PD-1, BTLA and CD84, the cytokine IL-21, the cytoplasmic adaptor protein

TABLE 4-3 Subpopulations of T Cells

Subtype	Main CD	Key cytokine profile	Transcriptional factors*	Main function
Th0	CD4			Challenged naive T cells
Th1	CD4	IFN-γ, IL-2	T-bet	Pro-inflammatory
Th2	CD4	IL-4, 5, 10, 13	GATA-3	Anti-inflammatory
Th9	CD4	IL-9	PU.1, IRF4	Allergy
Th17	CD4	IL-17	PORC2	Pro-inflammatory
Th22	CD4	IL-22	–	Promote healing
Tfh	CD4	IL-21	Bcl-6, c-Maf	Helper to B cells
Tr	CD4, CD25	IL-10	Foxp3	Anti-inflammatory
Tr-1	CD4, CD25	TGF, IL-10	–	Anti-inflammatory
Th3	CD4, CD25	TGF	–	Anti-inflammatory
Ts	CD8		–	Anti-inflammatory
Tc	CD8		–	Kill virus-infected cells

*Transcriptional factors are identified as important markers for the respective T cell subsets.

SLAM-associated protein (SAP), and the transcription factors Bcl-6 and c-Maf. These molecules play critical roles in promoting activation, differentiation, and survival of B cells and/or CD4+ T cells.[45]

T-regulatory Cells Treg cells have the cell surface markers CD4 and CD25 and therefore are generally named $CD4^+CD25^+$ Treg. They play an essential role in mediating immunosuppression and maintenance of tolerance. These T-cell clones that may react to self-antigens but are not deleted via negative selection in the thymus are considered to be suppressed by Treg cells in the periphery. Therefore, dysregulation of Treg function may elicit autoimmune diseases. There are subtypes of Treg cells based on their origin and the mechanisms of action and function.

Treg Cells or Natural Occurring (Tr) Natural occurring $CD4^+CD25^+$ Tr cells arise either in the thymus and reside in the blood and peripheral lymphoid tissues, or they can also arise in the periphery induced by antigen (Ag). Human Tr potently suppress the proliferation and effector functions in a cell contact-dependent manner or by acting on antigen presenting cells.[46,47] The transcriptional factor FoxP3 is important to their development and a marker. Human Tr can be further divided into two subsets with distinct functions based on differential expression of integrins. α4β7 integrin expressing Tr cells induce *de novo* differentiation of IL-10-producing Tr1 cells. α4β1 expressing Tr cells induce the differentiation of TGF-β-producing Th3 cells. The ratio of Th17 (pro-inflammatory) to Foxp3+ Treg (immunosuppressive) T-cells was found to increase during initial induction of periapical lesions, and decrease at later stages, indicating the importance that these two cell populations play in regulating periapical lesions.[48] Furthermore, the gene methylation (epigenetic changes that do not relate to the gene sequence) of the Foxp3 gene promoter were recently found to correlate with reduced activity in human periapical lesions.[49]

Tr1 Cells ($CD4^+$ Type-1 Treg) Tr1 cells arise in the periphery upon encountering antigen (Ag) presented by tolerogenic DCs, which requires IL-10. Tr1 cells produce high levels of IL-10 themselves, and mediate IL-10-dependent suppression of T cell response. In contrast, Tr cells do not produce IL-10. Defining Tre1 phenotype currently is solely based on cytokine production—IL-10, but not IL-4 and they express variable CD25. Tr1 cells regulate the response of naïve and memory T cells in vitro and in vivo and can suppress both Th1 and Th2 cell-mediated pathologies. Tr1-cell clones suppress the production of immunoglobulin by B cells. The major function of Tr1 cells is to control homeostasis of the response to foreign antigens in the periphery.[47]

Th3 Cells Although Th3 cells are named under T helper cells, they are grouped with Tr cells due to their close functionality to Tr-1 cells. They are $CD4^+$ T cells, which produce TGF-β. Similar to Tr1 cells, these T cells are generated in the periphery induced by oral antigen in the mesenteric lymph nodes. They express variable CD25 and produce TGF-β and varying amounts of IL-4 and IL-10. They also inhibit Th1- and Th2-mediated adaptive immune responses. It is speculated that Tr1 and Th3 cells derive from the same population and perhaps represent adaptive Tregs, as they have a similar phenotype and usually mediate their suppressive activities via the release of IL-10 and/or TGF-β (Figure 4-6).[50,51]

T Suppressor ($CD8^+$ T Suppressor Cells or Ts) There is a controversy regarding the recognition of $CD8^+$ T suppressor cells as a distinct subset of $CD8^+$ T cells. There is also a disputable hypothesis that $CD8^+$ Ts cells are merely cytotoxic T lymphocytes ($CD8^+$ CTLs) based on the finding that both $CD8^+$ Ts and CTL play roles in immunosuppressive activities and maintenance of tolerance. Evidence has suggested that $CD8^+$ Ts and $CD8^+$ CTLs represent distinct subpopulations of $CD8^+$ T cells. Human $CD8^+CD28^-$ T cells have also considered another subtype of Ts cells. These cells are MHC-class I-restricted $CD8^+CD28^-$ Ts cells that act on APCs in a contact-dependent manner, rendering them tolerogenic to Th cells. They inhibit the proliferation of Th by blocking the activation of APC and preventing the upregulation of co-stimulatory molecules required for efficient help. CD8+CD28– Tregs can block the upregulation of co-stimulatory molecules on APCs such as CD80, CD86, CD54, and CD58. Suppressor function could not be abrogated using neutralizing antibodies against IL-4, IL-10, TGF-β, and CTLA-4. In contrast to the suppression of co-stimulatory molecules, CD8+CD28+ Treg have been demonstrated to upregulate the inhibitory immunoglobulin-like transcript 3 (ILT3) and ILT4 receptors on DCs. Taken together, these results suggest that CD8+CD28– Tregs suppress immune responses by directly interacting with DCs and rendering these cells tolerogenic.[52]

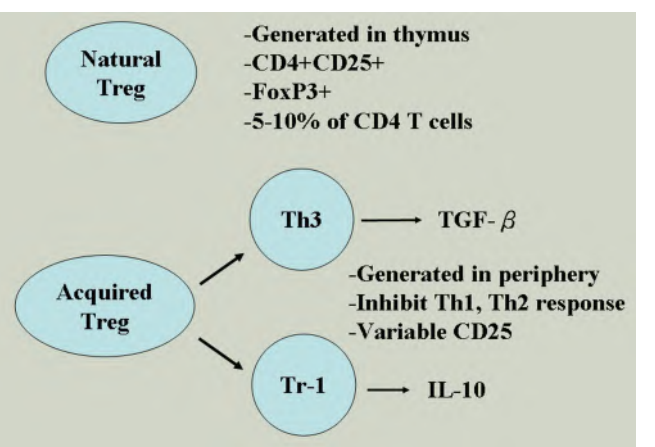

FIGURE 4-6 Regulatory T-lymphocytes. Redrawn with permission from van Ooosterhout and Bloksma, *Eur Respir J.*, 2005;26:918-32.

T Cytotoxic Cells (CD8⁺ T Cytotoxic Cells or Tc) A subset of T cells that kill target cells expressing MHC-associated peptide antigens are also known as cytolytic T lymphocytes (CTLs). The majority of Tc expresses CD8 and recognizes antigens degraded in the cytosol and expressed on the class I MHC molecules of the target cells. Tc develops from "pre-Tc" that lack cytolytic functions. Two separate kinds of signals are needed for pre-Tc to differentiate from functional Tc. One is specific recognition of antigen on a target cells and the other may be provided either by co-stimulators expressed on professional APCs or by cytokines produced by Th cells. Functional Tc acquires specific membrane-bound cytoplasmic granules including a membrane pore-forming protein called perforin or cytolysin and enzymes called granzymes. Tc also expresses FasL that can deliver apoptosis-inducing signals to target cells expressing Fas protein. The killing of target cells require cell contact and is antigen specific, that is, killing of the target cells bearing the same class I MHC-associated antigen that triggered the pre-Tc differentiation.[3,35]

B Cells B cells are rarely found in normal pulps.[37] Their role in adaptive immunity mainly lies in the production of antibodies that constitute the host humoral immune response. The rise and development of B cells take place in bone marrow where the progenitor B cells rearrange their immunoglobulin (Ig) genes and turn into immature B cells with assembled antigen receptors (BCRs) in the form of cell surface IgM. The commitment to B-cell lineage occurs prior to Ig gene rearrangement. This commitment is controlled by the expression of Pax5 transcriptional factor. The bone marrow stromal cells interact with progenitor B cells and provide signals and growth factors (e.g., IL-7) important for B-cell development.

The productive and sequential rearrangement of heavy- and light-chain gene dictates the survival of B cells-positive selection. Those cells that failed to rearrange their Ig gene segments to form functional heavy- and light-chain pairs will be lost. The V(D)J gene recombination occurs in both heavy- and light (κ and λ)-chains. A recombinase system, which is an enzymatic complex consisted of several enzymes including recombination activating gene 1 and 2 (RAG-1, RAG-2), terminal deoxynucleotidyl transferase (TdT), DNA ligase IV, Ku proteins, and XRCC4, is essential to the recombination process. This recombinase system is also used for TCR recombination.

Similar to T-cell selection, B cells also undergo negative selection. Developing B cells expressing BCRs that recognize self-cell-surface molecule are deleted via apoptosis. Immature B cells that bind soluble self-antigens are rendered unresponsive to the antigen-anergic. Only those B cells that do not interact with self-antigens mature normally and enter the peripheral lymphoid tissues bearing both IgM and IgD on their surface. Mature IgM/IgD co-expressing B cells undergo isotype switching via a process called switch recombination after encountering antigen. The rearranged V(D)J gene segment recombines with a downstream C region gene (γ, ε, or α) and the intervening DNA sequence is deleted. This gives rise to other classes of Ig, such as IgG, IgE, and IgA besides IgM. In addition to isotype switching, activated B cells undergo somatic mutation in V region gene leading to affinity maturation of antibodies and alternative splicing of VDJ RNA to membrane or secreted Ig mRNA. A large quantity of antibody is secreted when B cells terminally differentiate into plasma cells.

B-regulatory Cells (Breg) Specific regulatory B cell subsets also exist that downregulate adaptive and innate immunity, inflammation, and autoimmunity.[53] These rare, but specific, subset of regulatory B cells produce IL-10, referred as B10 cells, are capable of downregulating immune responses and inflammatory disease. No phenotypic, transcription factor, or lineage markers are unique to B10 cells, and they are functionally defined and enumerated by their competence to express measurable IL-10.[53]

MHC and Antigen Presenting Cells

Multistep antigen-processing pathways within the APCs are involved in the generation of cell surface antigen: MHC. Distinct subcellular pathways take place to generate complexes of peptides with class I versus class II.

Class I MHC and CD8+ T Cells Class I MHC molecule consists of α (heavy) chain and β chain (β2 microglobulin that is located only extracellularly). Almost all cells express class I MHC that display peptide antigens presented to CD8+ TCRs. Endogenously synthesized foreign proteins (e.g., viral proteins) or products of mutated genes in tumor cells are degraded into peptides by proteosome in the cytosol and transported via Transporter associated with antigen processing (TAP) peptide transporter into the endoplasmic reticulum (ER) in which the peptides are bound onto assembled class I MHC. Subsequently, this peptide:MHC is transported onto cells surface. CD8+ T cells (mostly CTLs) recognize peptide antigen associated with class I MHC.[3,35]

The molecules involved in the interactions between peptide antigen: class I MHC and TCR include CD8, CD3/ζ, CD2, CD28 and LFA-1 (on T cells) and ICAM-1, LFA-3, and B7-1/B7-2 on APC (Figure 4-7).

Class II MHC and CD4+ T Cells Class II MHC molecules composed of two noncovalently associated polypeptide chains-α and β chains, both of which have peptide-binding, immunoglobulin-like, transmembrane, and cytoplasmic domains. Unlike MHC class I, only restricted group of cells normally express class II MHC. They are APCs: 1) DCs, 2) macrophages, 3) B cells, 4) vascular endothelial cells, and 5) epithelial cells. The former three are considered professional APCs. The latter two nonprofessional APCs are induced by IFN-γ to express class II MHC.

DCs and macrophages phagocytose antigens, while B cells utilize the membrane immunoglobulin to bind and internalize antigens. Other nonprofessional APCs endocytose antigens into cytoplasm for antigen processing. These

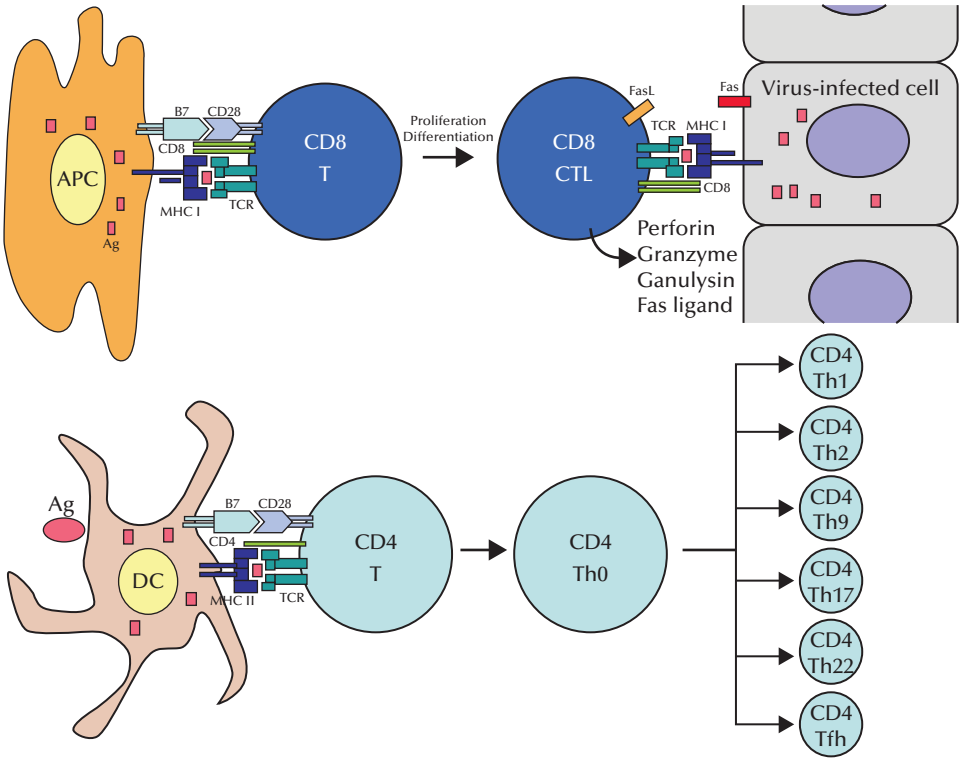

FIGURE 4-7 Cells and molecules involved in the interaction of APCs and CD4/CD8 T lymphocytes.

internalized antigens are localized in endosomes in which the antigens are degraded and then further processed in lysosomes. The processed antigens turn into small peptides and many of which are 10–30 amino acid long capable of binding onto the newly synthesized class II MHC molecules within intracellular vesicles before this antigen:class II MHC is transported to the surface of cells and presented to TCRs of CD4+ T cells (Figure 4-7).[3,35]

MOLECULAR MEDIATORS OF PRO-INFLAMMATORY RESPONSE

Chemokines

Chemokines are a group of ~50 chemoattractant cytokines. There are two main types of chemokines: (1) CC Chemokines: Macrophage/monocyte chemoattractant proteins (MCP-1-4); Macrophage Inflammatory Protein (MIP)-1α, MIP-1β, Eotaxin, RANTES; and (2) CXC Chemokines: IFN inducible protein 10 (IP-10); Monokine inducible IFN-γ (MIG); IL-8/CXCL8. These chemokines have currently been renamed to include CXCL1-16; XCL1, 2; CX3CL1; and CCL1-28. Table 4-4 contains different names of the commonly studied chemokines. The chemokines are primarily involved in trafficking/homing of cells of the innate immune system toward the site of an inflammatory response or during lymphoid organ development and angiogenesis.[6] They may also be involved in recruitment of stem cells to the site of tissue regeneration, such as with pulp regeneration.[54] For more details, see Chapter 29. IL-8 (CXCL8) is among the first recognized and most studied chemokines, which has also been most studied in endodontic pathosis.[28,55–58] There is some redundancy with respect to the cells that express chemokine receptors, and receptor specificity for the various chemokines (Table 4-5).

Adhesion Molecules

There are a variety of adhesion molecule classes that are expressed at the site of an inflammatory process. Adhesion molecules serve a critical role with respect to halting the inflammatory cells that are circulating in the capillaries at high speed, and which, through the function of chemokines, are directed to the site of inflammation. This process is achieved stepwise: the cells initially slow down, roll on the endothelial wall, and then start to bind to the endothelial cells. Eventually, through diapedesis they become extravasated and migrate to the area of inflammation. The slowing down of circulating leukocytes is mediated by Selectins, and then Integrins and Ig superfamily proteins mediate the binding of the cells to endothelial cells. The expression of these adhesion molecules is mediated by a number of inflammatory mediators, most notably IL-1 and TNF-α.

Platelet Activating Factor

PAF is a ubiquitous factor that is secreted by many different cells and plays a role in a number of immune mechanisms. It is secreted by platelets, basophils, monocytes/macrophages, PMNs, and endothelial cells. It is primarily involved in leukocyte adhesion to endothelial cells, production of prostaglandins and thromboxane, and in chemotaxis. In low doses,

TABLE 4-4 Common Chemokines, Their Receptors, and the Cells That They Target[3,6,59,60]

Chemokine	Other name	Cell for Chemotaxis	Receptor
CXCL8	IL-8	Neutrophils	CXCR1, CXCR2
CXCL9	Mig	T cells (T), NK cells (NK)	CXCR3-A, CXCR3-B
CXCL10	IP-10	T, NK	CXCR3-A, CXCR3-B
CXCL1	GROα	Neutrophils	CXCR1
CXCL2	GROβ	Neutrophils	CXCR2
CX_3CL1	Fraktalkine	T cell, NK cell, monocyte	CX_3CR1
CXCL12	SDF-1αβ	Mixed leukocyte; HIV co-receptor	CXCR4
CCL1	I-309	Monocyte, endothelial cells	CCR8
CCL2	MCP-1/ MCAF	T, NK, dendritic cells (DC), monocytes (Mono), basophils (Baso)	CCR2
CCL3	MIP-1α	T, NK, DC, Mono, eosinophils (Eosino)	CCR1, CCR5
CCL4	MIP-1β	T, NK, DC, Mono	CCR5
CCL5	RANTES	T, NK, DC, Mono, Eosino, Baso	CCR1, CCR3, CCR5
CCL7	MCP-3	T, NK, DC, Mono, Eosino, Baso	CCR1, CCR2, CCR3
CCL8	MCP-2	T, NK, DC, Mono, Baso	CCR3
CCL11	Eotaxin-1	T, DC, Eosino, Baso	CCR3
CCL13	MCP-4	T, NK, DC, Mono, Eosino, Baso	CCR2, CCR3
CCL20	MIP-3 α	Th17, DC	CCR6
CCL24	Eotaxin-2	T, DC, Eosino, Baso	CCR3
CCL26	Eotaxin-3	T	CCR3

*For a full list of all 50 chemokines see reference #3.

TABLE 4-5 Important Adhesion Molecules, Their Tissue Distribution and Ligands[3,35]

	Name	Tissue Distribution	Ligand
Selectins	P-selectin (CD62P)	Activated endothelium and platelets	Sialyl-Lewis X on glycoproteins; neutrophils, monocytes, T cells
Bind carbohydrates. Initiate leukocyte-endothelial interaction	E-selectin (CD62E)	Activated endothelium	Sialyl-Lewis X on glycoproteins; neutrophils, monocytes, T cells
	L-selectin (CD62L)	Neutrophils, monocytes, T cells, B cells	Sialyl-Lewis X on glycoproteins; neutrophils, monocytes, T cells
Integrins	$\alpha_L : \beta_2$ (LFA-1, CD11a/CD18)	Monocytes, T cells, macrophages, neutrophils, dendritic cells	ICAMs
Bind to cell-adhesion molecules and extracellular matrix. Strong adhesion	$\alpha_M : \beta_2$ (Mac-1, CD11b/CD18)	Neutrophils, monocytes, macrophages	ICAM-1, iC3b, fibrinogen
	$\alpha_X : \beta_2$ (CR4, p150.95, CD11c/CD18)	Dendritic cells, macrophages, neutrophils	iC3b
	$\alpha_5 : \beta_1$ (VLA-1, CD49d/CD29)	Monocytes, macrophages	Fibronectin
	VLA-4 (CD49aCd29)	Monocytes, T cells	VCAM-1 (CD106)
Immunoglobulin superfamily	ICAM-1 (CD54)	Activated endothelium	LFA-1, Mac-1
Various roles in cell adhesion. Ligand for integrins	ICAM-2 (CD102)	Resting endothelium, dendritic cells	LFA-1
	VCAM-1 (CD106)	Activated endothelium	VLA-4
	PECAM (CD31)	Activated leukocytes, endothelial cell-cell junctions	CD31

PAF may cause vasodilatation; however, in regular doses, it is involved in vasoconstriction.

Plasma Proteases

There are a large number of enzymatic changes that take place during an immune response, and that aim to remove antigenic or foreign material, kill microbial cells, control hemorrhage, as well as initiate and promote the healing process that takes place following the elimination of irritants. These enzymatic processes are closely regulated so that the response is proportionate to the irritation; however, they frequently result in side effects causing break down of host tissues that frequently accompanies an inflammatory response. The main pathways that are involved in these reactions will be described below. The principal mediators and interactions of these pathways are summarized in Figure 4-8.

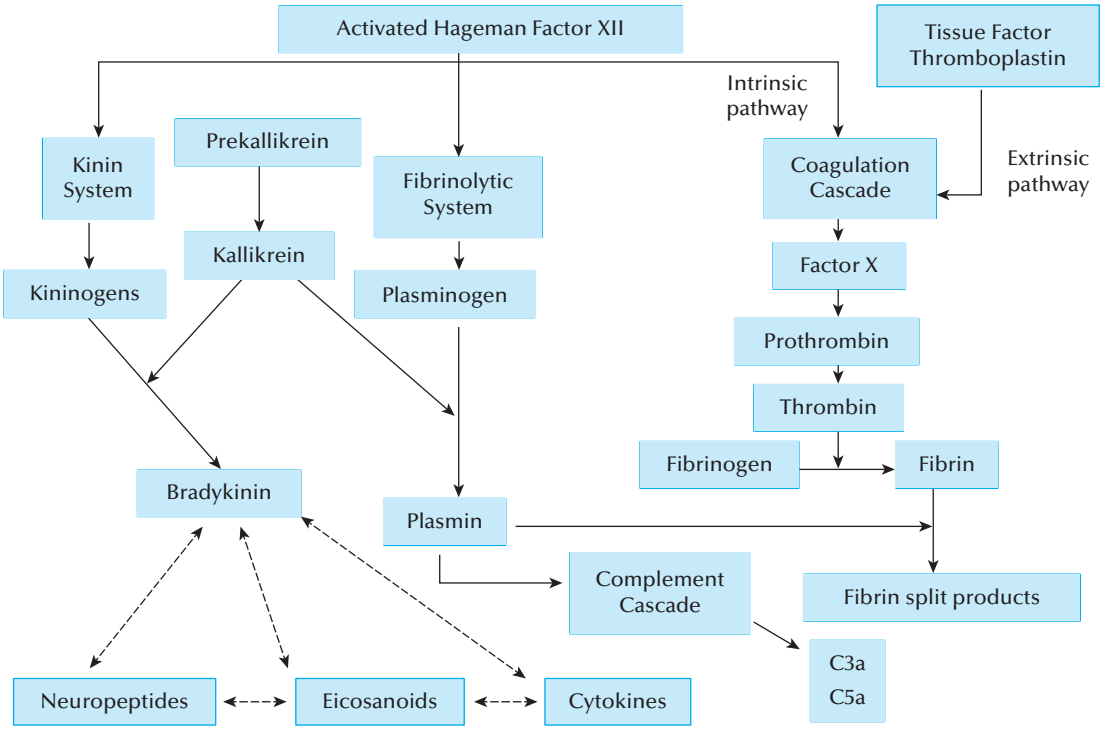

FIGURE 4-8 Diagram showing various pathways that are activated during an inflammatory response. Dotted lines indicate a synergistic or co-stimulatory function.

Kinin System: Bradykinin

As shown in Figure 4-8, the activated Hageman factor causes the formation of kinins from kininogen, a reaction that is mediated by kallikrein. The most important of the kinins is bradykinin. This protein causes vasodilatation, extravasation of plasma proteins, and reduction of pain threshold.[61] Bradykinin performs its actions through binding with two receptors, B1 and B2. B1 is primarily associated with chronic pain syndromes, while B2 is constitutively present in tissues and is overexpressed in acute pain situations,[62] including pulpal pain.[63] It has been shown that bradykinin can act synergistically with neuropeptides, thrombin, and other factors to enhances the production of a number of eicosanoids such as PGE2, and cytokines, such as IL-1 and TNF-α.[64–67] Once released, bradykinin levels are controlled by a number of kininases, and its effects on pain are controlled by endogenous opiates and steroids. Nonsteroidal anti-inflammatory drugs have also been shown to reduce bradykinin levels.[68] It has been shown that sex steroids such as estrogen enhance bradykinin activity in peripheral nerves of the female host.[69]

The Coagulation Cascade and Fibrinolytic Systems

Tissue injury and severe inflammation frequently result in hemorrhage, at macroscopic or microscopic levels. Therefore, one of the principal initial mechanisms of healing is the coagulation cascade. Traditionally, the coagulation cascade has been divided into intrinsic and extrinsic pathways (Figure 4-8). This was due to the fact that the intrinsic pathway could occur in vitro by the Hageman factor, in the absence of thromboplastin. However, there are many interactions between both pathways, and the distinction is now less critical.[14] Through a series of localized enzymatic activations, the Hageman factor/thromboplastin result in the formation of factor X, this in turn results in the formation of thrombin from prothrombin. Thrombin (activated Factor II) has a number of critical functions, including positive feedback activation of a number of other factors such as factors VIII and V, but essentially forms the insoluble fibrin clot from the soluble protein fibrinogen. In order to limit the size of the clot, and prevent disseminated coagulation, the fibrinolytic system is activated and results in the formation of plasmin.

Complement System

The complement system consists of a series of ~45 proteins that play a number of critical roles in the immune system (Figure 4-9). Complement is activated through one of the three main pathways. The classical pathway involves antigen-antibody reaction and results in activation of C1 to form a molecule commonly referred to as C3 convertase. Certain microbial cell wall molecules such as LPS or antigen antibody complexes can activate the alternate pathway, in which C3 through co-enzymatic interaction from Factors B and D, and a protein called properdin, result in the formation of another C3 convertase of a different structure. The lectin pathway is activated by mannose-binding lectin (MBL), which together with ficolin 1, 2, or 3, form the ficolin-associated serine proteases (MASPs). Collectin 11 is also thought to activate the lectin pathway.[70] The enzyme C3 convertase, in whichever formulation, mediates the formation of C3b from C3, with C3a as a by-product. Together

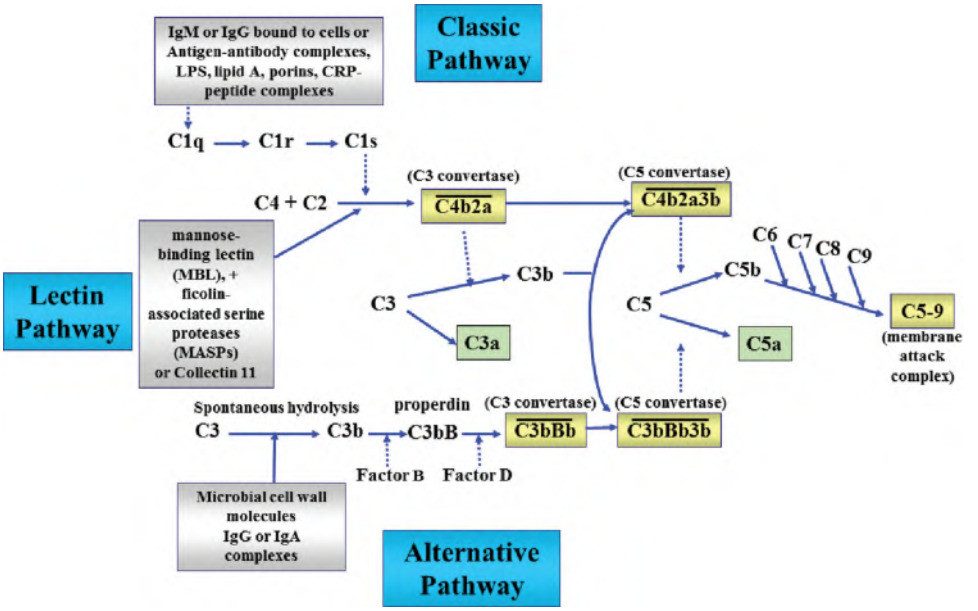

FIGURE 4-9 Complement cascade.

with C5 convertases, C3b activates C5 to C5b, with C5a as a by-product. C5b combines with C6, C7, C8, and C9 to form a membrane attack complex that forms holes through the bacterial cell membrane resulting in death of the cell. Complement molecules may also act as an opsonins for phagocytosis, as discussed previously. C3a and C5a are known as anaphylatoxins because they cause degranulation of mast cells with the release of histamine, which causes vasodilatation and increased vascular permeability. C5a activates the lipoxygenase pathway of arachidonic acid in neutrophils and monocytes, and is itself a potent chemotactic agent for these cells.

It has recently been revealed that some microbial virulence factors exploit the complement cascade to promote inflammation. This process creates an environment conducive to the formation of dysbiotic microbiota, such as that which characterizes periodontal disease.[70] For example, *Porphyromonas gingivalis* produces protein esterase virulence factors called gingipains that act as an agonist to the C5aR (the receptor for C5a).[71] In small amounts, gingipains activate complement and induce an inflammatory process, that is conducive to dysbiotic microbial proliferation. In addition, it was recently shown in two different animal models that C3 is required for induction of periodontal disease with bone loss.[72]

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) are a number of endopeptidases (Table 4-6) that are responsible for tissue remodeling during structural development, and tissue break down during pathological states such as the inflammatory and neoplastic changes, and caries. In addition to soft tissues, they are present in dentin, and their release during acid etching procedures may degrade collagenous matrix, which would degrade the bond to restorative materials with time. Occasionally some of these enzymes, such as collagenase, may be of microbial origin. Host MMPs are typically modulated by levels of cytokines and growth factors in various tissues. They are upregulated by IL-1β and TNF-α, and growth factors such as platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and nerve growth factor (NGF). They are abrogated by IFN-γ and TGF-β.[61] MMP levels may allow the differentiation for levels of inflammation or correlate with certain histopathological diagnoses. For example, MMP-9 and MMP-13 were shown to be more prevalent in periapical granulomas than cysts.[73] MMP-9 levels may aid in the diagnosis of irreversible pulpitis, or correlate with symptomatic apical periodontitis.[74–76] Finally, MMP-1 gene polymorphism was shown to be associated with the risk for periodontal disease.[77]

MMPs are inactivated by a group of molecules collectively known as tissue inhibitors of metalloproteinases (TIMPs), and by α_2-macroglobulin (that inhibits neutrophil elastase, see below). MMPs and TIMPs have been identified in the dental tissues during health and disease.[78–82] It is noteworthy though, that in the oral cavity MMPs can be released in saliva, and so the sources of MMPs that degrades dentin matrix in caries may be salivary rather than pulpal. Recently,

TABLE 4-6 Commonly Identified Matrix Metalloproteinases That Are Zinc-dependent Endopeptidases

Common Name	MMP
Collagenases	1, 8, 13,18
Gelatinases	2, 9
Stromelysins	3, 10, 11
Membrane Type MMPs (MT MMPs)	14, 15, 16, 17, 24, 25
Minimal domain MMPs	7, 26
Others MMPs	12, 19, 20, 21, 22, 23, 27, 28

TABLE 4-7 Summary of the Origin and Actions of the Commonly Investigated Cytokines[1,3,6,35]

Cytokine	Special function*	Secreted by Interleukins	Effector Function
IL-1α, IL-1β	Pro-inflammatory; bone resorptive	Mono, MΦ, DC, NK, B, Endo	Co-stimulates T activation by enhancing production of cytokines including IL-2 and its receptor; enhances B proliferation and maturation; NK cytotoxicity; induces IL-1, 6, -8, TNF, GM-CSF and PGE_2 by MΦ; pro-inflammatory by inducing chemokines and ICAM-1 and VCAM-1 on endothelium; induces fever, APP, bone resorption by osteoclasts.
IL-1 receptoran-tagonist (IL-1Ra)	Anti-inflammatory	MΦ	Competitive antagonist of IL-1
IL-2	Pro-inflammatory	Th1	Induces proliferation of activated T- and B-cells; enhances NK cytotoxicity and killing of tumor cells and bacteria by monocytes and MΦ.
IL-3		T, NK, MC	Growth and differentiation of hematopoietic precursors; MC growth
IL-4	Anti-inflammatory; bone modulatory	Th2, Tc2, NK, T, MC	Induces Th2 cells; stimulates proliferation of activated B, T, MC; upregulates MHC class II on B and MΦ, and CD23 on B; downregulates IL-12 production and thereby inhibits Th1 differentiation, increases MΦ phagocytosis; induces switch to lgG1 and lgE.
IL-5	Anti-inflammatory	Th2, MC	Induces proliferation of eosino and activated B; induces switch to lgA.
IL-6	Pro-inflammatory; bone modula-tory, systemic inflammation	Th2, Mono, MΦ, DC, BM stroma	Liver: Synthesis of acute phase proteins. Differentiation of myeloid stem cells and of B into plasma cells; enhances T proliferation.
IL-7		BM and thymic stroma	Induces differentiation of lymphoid stem cells into progenitor T and B; activates mature T.
IL-8		Neutro; Mono, MΦ, Endo	Chemokine:mediates chemotaxis and activation of neutrophils.
IL-9		CD4+ T cells	Induces proliferation of thymocytes; enhances MC growth; synergizes with IL-4 in switch to lgG1 and lgE.
IL-10	Anti-inflammatory; bone modulatory	MΦ, T cells (mainly regulatory T cells)	Inhibits IFNγ, IL-2, Th1 cells; downregulates MHC class II and cytokine (including IL-12) production by mono, MΦ and DC, thereby inhibiting Th1. differentiation; inhibits T proliferation; enhances B differentiation.
IL-11	Bone-resorptive	BM stroma	Promotes differentiation of pro-B and megakaryocytes; induces APP, production of platelets.
IL-12	Pro-inflammatory	Mono, MΦ, DC, B	Critical cytokine for Th1 differentiation; induces proliferation and IFNγ production by Th1, $CD8^+$and NK; enhances NK and $CD8^+$ T cytotoxicity.
IL-13	Anti-inflammatory	Th2, MC	Inhibits activation and cytokine secretion by MΦ; co-activates B proliferation; upregulates MHC class II and CD23 on B and mono; induces switch to lgG1 and lgE; induces VCAM-1 on Endo.
IL-15		T, NK, Mono, MΦ, DC, B	Induces proliferation of T-, NK an deactivated B and Cytokine production and cytotoxicity in NK and $CD8^+$ T; chemotactic for T; stimulates growth of intestinal epithelium.
IL-16		Th, Tc	Chemoattractant for CD4+ T, mono and eosino; induces MHC class II.
IL-17	Pro-inflammatory	Th17, innate lym-phoid cells	Pro-inflammatory; stimulates production of cytokines including TNF, IL-1β, -6, G-CSF, and chemokines.
IL-18	Bone-resorptive	Mono, MΦ, DC, keratinocytes, osteoblasts	Induces IFNγ production by T; enhances NK cytotoxicity. Mono: enhances GM-CSF, TNF, IL-1β.
IL-19		Mono, MΦ	Modulation of Th1 activity
IL-20		Mono, Keratinocytes	Regulation of inflammatory responses to skin
IL-21		Th2 cells, Th17 cells, Tfh cells	Regulation of hematopoiesis; NK differentiation; B cell activation, differentiation; T co-stimulation
IL-22		Th17 cells	Inhibits IL-4 production by Th2; epithelial cells to produce defensins.
IL-23		DC, MΦ	Induces proliferation and IFNγ production by Th1; induces proliferation of Th17 and memory cells.
IL-24		Th2, Mono, MΦ	Induction of TNF, IL-1, IL-6, anti-tumor activity
IL-25		Th1, MΦ, MC	Induction of IL-4, IL-5, IL-13 and Th2-associated pathologies
IL-26		T, NK	Enhanced production of IL-8 and IL-10 by epithelium
IL-27		DC, Mono	Induction of TH1 responses, enhanced IFN-γ production

(*Continued on facing page*)

TABLE 4-7 (*Continued*) Summary of the Origin and Actions of the Commonly Investigated Cytokines

Cytokine	Special function*	Secreted by Interleukins	Effector Function
IL-28		Mono, DC	Type 1 IFN-like activity, inhibition of viral replication
IL-29		Mono, DC	Type 1 IFN-like activity, inhibition of viral replication
IL-31		Th2 cells	Promotes inflammatory responses in skin
IL-32		NK, T	Promotes inflammation. Role in activation-induced
IL-33		Endothelial cells, smooth muscle cells, keratinocytes, fibroblasts	Th2 development;induction of IL-4, IL-5, IL-13, activation of innate lymphocyte cells.
		Tumor Necrosis Factors	
TNF-α	Pro-inflammatory; bone resorptive	Th1, Mono, MΦ, DC, MC, NK, B	Tumor cytotoxicity; cachexia (weight loss due to muscle fat catabolism); induces cytokine secretion; induces E-selectin on endo; activates MΦ; antiviral, hypothalamus: fever.
Lymphotoxin (LTα, TNF-β, TNFSf1)	Pro-inflammatory	Th1, Tc	Tumor cytotoxicity; enhances phagocytosis by neutro and MΦ; involved in lymphoid organ development, antiviral
Lymphotoxin-αβ (LTαβ)		T, NK, follicular B, lymphoid inducer cells.	Lymphoid organogenesis, chemokines
		Interferons	
IFNα		Leukocytes	Inhibits viral replication; enhances MHC class I
IFNβ		Fibroblasts	Inhibits viral replication, enhances MHC class I
IFNγ	Pro-inflammatory	Th1, Tc1, NK	Inhibits viral replication, enhances MHC class I and II; activates MΦ; induces switch to lgG2a; Th1 differentiation, increases antigen presentation and processing by T cells; antagonizes several IL-4 actions; inhibits proliferation of Th2.
		Colony stimulating factors	
GM-CSF	Pro-inflammatory	Th, MΦ, Fibro, MC, Endo	Stimulates growth of progenitors of mono, neutro, eosino and baso; activates MΦ.
G-CSF	Pro-inflammatory	Fibro, Endo	Stimulates growth of neutro progenitors.
M-CSF	Pro-inflammatory	Fibro, Endo, Epith	Stimulates growth of mono progenitors.
Stem cell factor (SLF)		BM stromal cells	Stimulates stem cell division (c-kit ligand).
		Others	
TGFβ		Treg cells, B, MΦ	Inhibition of proliferation and effector functions of T cells; differentiation of Th17 and Treg B cells, chemo attraction of mono and MΦ but also anti-inflammatory; promotes tissue repair and angiogenic factors.
LIF		Thymic epith, BM stromal cells	Stem cells: block in differentiation
Osteoprotegrin (OPG)		osteoblasts	Inhibits osteoclast differentiation
Oncostatin M	Bone marrow stromal cells	T, MΦ	Regulation of hematopoietic cytokines in endothelial cells; inhibits cancer cell proliferation.

APP, acute-phase proteins; B, B-cell; baso, basophil; BM, bone marrow; Endo, Endothelium; eosino, eosinophil; Epith, epithelium; Fibro, fibroblast; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; LIF, leukemia inhibitory factor; MΦ, macrophage; MC, mast cell ; Mono, monocyte; neutro, neutrophil; NK, natural killer; SLF, steel locus factor; T, T-cell; TGFβ, transforming growth factor-β. IL-8 is a member of the chemokine family.

1,10-phenanthroline-5,6-dione (Phendione), a metal chelator and an inactivator of MMPs, was shown to have antimicrobial agent against *Enterococcus faecalis* and to be an inhibitor of human MMP-2 in the root canal.[83]

It has been documented through a significant body of evidence that tetracyclines, and some tetracycline analogues and chemically-modified tetracyclines may degrade MMPs at subantibiotic levels.[84,85] This is thought to be one of a number of anti-inflammatory properties that are exhibited by some antibiotics.[61]

Neutrophil and Macrophage Elastases

During pulpal and periapical tissue inflammation, a number of other proteases may contribute to the tissue destruction frequently encountered. Among these protolytic enzymes are neutrophil elastases that are neutral serine proteases,

released from PMNs or macrophages during activation of these cells. Neutrophil elastase can cleave a wide variety of structurally important proteins and glycoproteins, such as elastin, type III and IV collagen, fibronectin, and core proteins of proteoglycan molecules. It has been reported that neutrophil elastase was increased in periapical lesions that were symptomatic,[86] and that its levels although correlated with prostaglandin E2, did not change following root canal instrumentation.[87] Differential expression of neutrophil and macrophage elastases showed the latter to increase earlier in periapical lesion induction, but both appeared to be expressed in high levels.[88]

Nitric Oxide

Nitric oxide (NO) is a gaseous free radical that has been described to have several pro-inflammatory and modulatory effects in tissues. It is produced through a reaction that involves the enzyme NO synthase (NOS) and several cofactors including NADPH. Several NOS isoforms are present, including inducible (iNOS), neuronal (nNOS), and endothelial (eNOS). The nNOS and eNOS are constitutively expressed in the respective tissues and are calcium dependent, whereas the iNOS is induced in macrophages and a number of other cells, primarily by cytokines such as IL-1 and TNF-α or microbial products such as LPS, and are calcium independent.[61] Because it is relatively volatile and short lived, the detection of NO is frequently assessed through the presence of NOS, particularly iNOS.

Under normal conditions, NO is primarily involved in vasodilatation through the relaxation of smooth muscles and prevention of adhesion of leukocytes to endothelial wall, which is considered as an anti-inflammatory function. However, during inflammation, including that of the pulp and periapical tissues, and due to the action of cytokines, large amounts of NO are released.[89–94] NO contributes to the killing of microbial cells and tumor cells by macrophages through its interaction with super-oxide free radical[14] as follows:

$$NO + O_2^{\cdot -} \rightarrow OH^{\cdot} + NO_2$$

NO is also an antagonist for platelet activation, adhesion, and degranulation. Moreover, it was shown that NO can regulate the proliferation, growth, and apoptosis of pulp cells *in vitro*.[95]

Oxygen-Derived Free Radicals

These are highly reactive, short-lived molecules produced by macrophages and neutrophils in normal and pathological states. The most important molecules are the superoxide anion ($O2^{\bullet -}$), which eventually is converted to hydrogen peroxide (H_2O_2), and the hydroxyl radical ($OH^{\bullet}$) and toxic NO derivatives.[14]

The main role that these molecules play is to increase the inflammatory response by increasing cytokines, chemokines, and adhesion molecules. However, in large amounts they cause thrombosis and tissue damage. The antioxidant activity is mediated through enzymes such as catalase, glutathione peroxidases, and superoxide dismutase (SOD). There are two main forms of SODs: copper–zinc (Cu, Zn-SOD) found primarily in cytoplasm and manganese (Mn-SOD) found primarily in mitochondria. While the presence of SOD in normal pulp has been described several decades ago,[96,97] the effect of inflammation on the levels of both isoforms of this enzyme has been controversial. Several studies have shown an increase of SOD,[96,98] or Cu, Zn-SOD and Mn-SOD[99] in pulpal inflammation. In fact, one study showed an anti-inflammatory effect that Cu, Zn-SOD has pulpal inflammation in an animal model.[100] However, a more recent study showed that there is a reduction of Cu, Zn-SOD in human pulpitis, possibly due to depletion.[101] Using quantitative real-time reverse transcriptase polymerase chain reaction, that is more sensitive than traditional protein assays, it has been reported that the expression of mRNA for both enzymes does increase in pulpitis in patients and that the elevation of Mn-SOD is significantly higher than that of Cu, Zn-SOD.[102] It was also shown that TLR-2 is involved in the induction of reactive oxygen species (ROS) production by macrophages in response to several root canal bacteria, while only *Fusobacterium nucleatum*-induced ROS production by TLR-4-competent macrophages.[103]

Cytokines

Cytokines are low-molecular-weight proteins that stimulate or inhibit proliferation, differentiation, or function of immune cells. Over 40 cytokines have been described with various functions that mediate or modulate the immune system and bone resorption. Cytokines may exert their actions through autocrine (acting on receptors of the same cell that produced them), paracrine (acting on other cells in the local vicinity), and endocrine (acting systemically) modes. Because of the involvement of cytokines in several areas of interest in endodontics, their various roles and functions have been and will be described in various sections of this chapter and in other chapters dealing with pulpal and periapical pathosis. In order to avoid redundancy, a brief description of the main features of some cytokines will be described here, with other information provided elsewhere in the chapter. Table 4-7 presents a summary of the role, sources, and main actions of common cytokines.

Pro-inflammatory Cytokines

Pro-inflammatory cytokines include IL-2, IFN-γ, IL-1α, IL-1β, TNF-α, IL-6, IL-12, IL-17, and CSFs such as GM-CSF and M-CSF (Table 4-7). These cytokines are produced by a variety of cells in response to antigens, microbial cells and molecules, autoimmune factors, and neoplastic triggers, or as part of homeostatic function, and represent the effector arm of the immune response. Their effects include cell differentiation, proliferation, activation, bone resorption, chemokine production, and a number of other important functions to respond to and degrade the irritants.

TNF-α is the principal mediator of the response to gram-negative bacteria. LPS stimulate the functions of mononuclear phagocytes and act as a polyclonal activator of B cells, thus contribute to elimination of the invading bacteria. The major cellular source of TNF is the LPS-activated mononuclear phagocyte. Other sources include antigen-stimulated T cells, activated NK cells, and activated mast cells. IL-1 derived from mononuclear phagocytes, and its principal function, similar to TNF, is to mediate host inflammatory response in innate immunity. T cells are more effective than LPS at eliciting IL-1 synthesis by monocytes. IL-1 is made by a diverse cell types, including epithelium and endothelium, providing local sources of IL-1 in the absence of macrophage-rich infiltrates.

The effect of IL-1 is similar to TNF. At low quantity, it acts on endothelium to increase the expression of adhesion molecules and on monocytes to secrete chemokines. It shares many features of TNF but is also different, for example, it potentiates rather than suppresses the actions of CSFs on bone marrow cells (Table 4-7). The actions of IL-6 induce IL-1 production, causing hepatocytes to synthesize plasma proteins, such as fibrinogen, C-reactive protein, and serum amyloid proteins, which contributes to the acute phase response. It serves as a growth factor for activated B cells.[104,105]

One of the principle pro-inflammatory (also known as Type 1) cytokines is IL-2. This cytokine is produced by the activated CD4+ cells and activates monocytes and macrophages leading to the initiation of the immune response. Other important Type 1 cytokines include IFN-γ, IL-12, and IL-17 (Table 4-7). All these cytokines are clearly critical for the initiation of pulpal and periapical inflammation. However, it has been shown that the main cytokines involved in bone resorption and mediating pulp necrosis and periapical inflammatory response are IL-1 and TNF-α, and that these reactions fundamentally rely on the innate rather than the adaptive immune response.[106] (For Anti-inflammatory cytokines, see later sections in this chapter.)

Neuropeptides

Neuropeptides are proteins produced by neural tissues and are released at the sites of nerve endings. Under normal conditions, they function to maintain the vascular tone of blood vessels; thus, modulating the vascularity and regulating the innervation of the tissue. During an inflammatory response, there is vasodilatation, extravasation of plasma proteins, and sprouting of nerve endings within the inflamed tissue. These changes result in an increase in the levels of certain neuropeptides. It is now recognized that certain neuropeptides such as Substance P (SP) have decidedly pro-inflammatory actions, whereas a number of other neuropeptides such as vasoactive intestinal peptide (VIP), a-melanocyte-stimulating hormone, neuropeptide Y (NPY), and somatostatin are members of an anti-inflammatory repertoire of immune modulators.[107–109] The newly discovered neuropeptides, such as urocortin, adrenomedullin, and cortistatin, also appear to have anti-inflammatory actions in that they inhibit T-cell proliferation, Th1 response, and IL-2 production.[108] Calcitonin gene-related peptide (CGRP) may have pro-inflammatory as well as anti-inflammatory actions.[108] SP was the first neuropeptide described around 1931. It is localized in sensory nerves, is related to neurokinins A and B, and its receptors are NK1, NK2, and NK3.[110] CGRP (described in 1983) binds to CGRP1, CGRP2, and AM2, whereas NPY (discovered in 1982) is localized in sympathetic, cholinergic, sensory, enteric, and central neurons, and binds to Y1, Y2, Y4, and Y5 receptors.

With respect to pulpal and periapical region, denervation experiments have shown that, in the pulp, SP-, neurokinin A-, and CGRP-containing nerve fibers originate from the trigeminal ganglion and that NPY-containing nerve fibers come from the superior cervical ganglion. The origin of VIP-containing fibers may be parasympathetic nerve fibers since it has been associated with acetylcholine in other tissues.[61,111]

Since the dental pulp is highly innervated, neuropeptides play a significant role in mediating and modulating the inflammatory response in it. The neuropeptides that have been studied the most in endodontic pathosis are SP and CGRP, and VIP and NPY are studied to a lesser degree. In the normal rat molar pulp, SP and CGRP were shown to be present in close proximity to macrophages, an association that was more prevalent in the odontoblastic layer than in the central pulp.[112] During inflammation, sprouting of pulpal nerve fibers was shown to be associated with an increased expression of SP and CGRP closely surrounding the areas of irritation.[113,114] However, severe irritation by experimental pulp exposures caused a drop in the overall pulpal levels of SP and CGRP, possibly due to the depletion of neuropeptide stores in the nerve endings.[115] CGRP addition to human pulp cells *in vitro* caused a two-fold increase in the levels of bone morphogenetic protein 2 (BMP-2), a member of TGFβ superfamily, which has the capacity to induce dentin regeneration.[116] Clearly, these findings suggest that neurogenic inflammation effected by neuropeptides plays an active and dynamic role in modulating pulpal inflammation.

Neuropeptides are thought to contribute to the inflammatory process in a number of ways. SP and CGRP,[117] together with VIP, are potent vasodilators; however, NPY is a vasoconstrictor.[111] SP also causes increased vascular permeability and plasma extravasation.[118]

Neuropeptides may reduce the threshold of pain in the pulp, accounting for symptoms associated with certain cases of pulpitis. The association of SP with the extent of caries and pain from caries was investigated in permanent molars of children.[119] The percentage of neuronal areas that positively stained for SP was found to be significantly more in gross carious lesions than in moderate or no lesions and significantly more in painful lesions. These findings were true at all levels of coronal pulp studied that included the pulp horn, subodontoblastic nerve plexus, and mid-coronal pulp. The fact that not all cases of irreversible pulpitis are associated

with pain may be explained by the actions of inhibitors of neurotransmitters such as γ-aminobutyric acid (GABA) or gastrin-releasing peptide (GRP). GABA-like and GRP-like immunoreactivity has been identified in the dental pulp.[120] It was also recently shown that NPY is capable of inhibiting capsaicin-sensitive afferent neurons at the spinal level, perhaps explaining the mechanisms for spinal NPY-induced anti-nociception.[121] Local opioid receptors in the pulp may also play a role in suppressing pulpal pain.[122,123] On the other hand, it was recently shown that dental pulp nociceptors, collected from patients with caries, express TLR-4 and CD-14,[124] that TNFα enhances the sensitivity of trigeminal neurons,[125] and that LPS senstizesTRPV1 receptors via action onTLR-4.[126] Collectively, these findings indicate a direct mechanism for bacteria and bacterial LPS to activate these nociceptors.

Neuropeptides may contribute to the inflammatory process by a number of other mechanisms. These include the release of inflammatory mediators, such as histamine, PGE2, collagenase, IL-1, IL-6, and TNFα, the enhancement of chemotaxis, phagocytosis, and the expression of adhesion molecules, and lymphocyte proliferation and IL-2 production.[127] The interactions between eicosanoids, bradykinin, and various neuropeptides suggest synergistic action with CGRP[128] or modulatory action with NPY[107] and illustrate the complex interplay between various elements of the immune response. The neuropeptides, SP, CGRP, VIP, and NPY, may also modulate the expression of angiogenic growth factors.[129] It is interesting to note that animal studies have shown a reduction of the neuropeptides SP and CGRP with age.[130]

Toll-like Receptors

Innate immunity has a considerable specificity achieved through the recognition of multiple microbe-specific surface molecules by PRR[131] present on host cells, such as TLRs and the receptors for complement. The PRR-recognized molecules on the microbes include surface proteins, nucleic acids, and carbohydrates (e.g., lipopolysaccharide, PG, LTAs). This is known as microbe-associated molecular patterns.[131,132]

TLRs, as pattern-recognition receptors, are a family of 12 members identified in mammals so far and are further divided into several subfamilies (Table 4-8). The subfamily of TLR1, TLR2, and TLR6 recognizes lipids, whereas the highly related TLR7, TLR8, and TLR9 recognize nucleic acids. TLR4 recognizes ligands such as lipopolysaccharide (LPS), fibronectin, and heat-shock proteins, all of which have different structures. TLRs are expressed on various immune cells, including macrophages, DCs, B cells, specific types of T cells, and on nonimmune cells, such as fibroblasts and epithelial cells. Expression of TLRs is modulated rapidly in response to pathogens, a variety of cytokines, and environmental stresses. TLRs may be expressed extracellularly or intracellularly. For example, TLRs 1, 2, 4, 5, and 6 are expressed on the cell surface, others (TLRs 3, 7, 8, and 9) are found almost exclusively in intracellular compartments such as endosomes.[131,132]

TABLE 4-8 Examples of TLR Recognition of Microbial Components

Molecule	Microorganism type/species	TLR
LPS	G(–) bacteria	TLR4
LTA (lipoteichoic acid)	Group B *Streptococcus*	TLR6/2
Peptidoglycan	G(+) bacteria	TLR2
Flagellin	Flagellated bacteria	TLR5
CpG-DNA	Bacteria and mycobacteria	TLR9
Not determined	Uropathogenic bacteria	TLR11
Zymosan	*Saccharomyces cerevisiae*	TLR6/2
Mannan	*Candida albicans*	TLR4
Viral DNA	Virus	TLR9

NOD-like Receptors

Similar to TLR family, NOD-like receptors or NLRs are cytoplasmic PRRs, together with retinoic acid-inducible gene 1-like receptor and TLR, make up the innate pathogen pattern-recognition system.[133] There are 22 members of NLRs in humans. They respond to intracellular pathogens as well as play important roles in distinct biological processes ranging from regulation of antigen presentation, sensing metabolic changes in the cell, modulation of inflammation, embryo development, cell death, and differentiation of the adaptive immune response.[133]

NLRPs are a subgroup of NLRs constituted by proteins such as NLRP1, 3, 4, 6, 7, and 12 that are involved in the formation of multi-protein complexes termed inflammasomes. These complexes consist of one or two NLR proteins, the adapter molecule apoptosis-associated speck-like containing a Caspase activation and recruitment domains (CARD) and pro-caspase-1. These inflammasomes might sense microbial products and a variety of stress and damage associated-endogenous signals.[134]

AGE/RAGE

Advanced glycation end products (AGE) are a group of heterogenous compounds formed in the hyperglycemic environment of patients with diabetes mellitus. The receptor for these compounds has the acronym RAGE. Diabetes mellitus (DM) affects an estimated 350 million cases worldwide,[135] and 29.1 million people or 9.3% of the U.S. population, of whom 8.1 million are undiagnosed <http://www.cdc.gov/diabetes/pubs/statsreport14/national-diabetes-report-web.pdf>. AGEs are thought to be involved in the pathogenesis of types 1 and 2 DM, and may also be oxidative derivatives resulting from diabetic hyperglycemia.[136] Glucose exhibits a slow glycation rate, and glucose-6-phosphate or glyceraldehyde-3-phosphate, which are intracellularly present at small levels, can form AGEs at a faster rate. The chemical transformation of amine-containing molecules by reducing sugars (glycation)—whether on proteins, lipids or nucleotides,

results in AGEs or the so-called: Maillard products.[136] Several molecules such as carboxymethyllysine (CML), pentosidine, or derivatives of methylglyoxal (MG), such as MG-H1, are well-studied AGE compounds, and serve as AGE markers. AGEs could also be introduced through food processing, dry heat cooking, and cigarette smoking.

In addition to mediating pancreatic β-cell toxicity, AGEs can promote recruitment and activation of T cells and macrophages.[137] At least two types of cellular AGE receptors have been characterized: RAGE and AGER1. AGER1 binds, degrades AGEs, and protects against oxidant injury. However, in excess of external AGEs, AGER1 is depleted.[136] Furthermore, the consequence of AGE-RAGE interaction is the development of cellular oxidant stress, a means by which cell signaling pathways may be activated, thereby resulting in altered cellular phenotype and cellular dysfunction.[137] AGE-RAGE axis in endothelial cells could induce the expression of genes for vascular endothelial growth factor, enhance vascular permeability, angiogenesis, and local inflammation. The production of several cytokines, such as TNF-α, IL-1β, IL-6, and monocyte chemotactic protein-1, is induced by the AGE–RAGE in monocytes and macrophage. RAGE promoter assays showed that AGE-RAGE signaling promotes the transcriptional upregulation of the RAGE gene through the activation of NF-κB.[138]

Defensins

Human β-defensins (hBDs or DEFB) is a potent antimicrobial peptide effective against a broad spectrum of bacteria, including Gram-positive bacteria, Gram-negative bacteria, and fungi. Among these microbes, *Streptococcus mutans* and *Lactobacillus acidophilus* that are associated with dental caries, and certain strains of periodontal bacteria such as *Aggregatibacter actinomycetemcomitans* and *P. gingivalis* have been shown to be sensitive to hBD-2.[139,140] hBDs are expressed mostly in epithelia.[27,141–144] Besides the cloned, sequenced, and well-characterized hBD-1, -2, -3, and -4, there appears to be at least 28 more hBDs existing based on the genomic surveys.[145] Fourteen hBDs or DEFB gene transcripts (DEFB-1, -4, and DEFB-103 to -114) have been detected in gingival keratinocytes.[146] Periodontal bacteria *F. nucleatum* and *A. actinomycetemcomitans* induce hBD-2 and hBD-3, respectively, in oral epithelial cells.[147]

Growth Factors

Growth factors are peptide molecules that transmit signals between cells and tissue, which may result in differentiation, proliferation, or activation of cells or inhibition of these functions. In general, growth factors promote and accelerate the structural development or the healing of tissues following injury. Some growth factors, such as angiogenic growth factors, have also been implicated in the pathogenesis of neoplastic changes within tissues. Most growth factors are named after the original tissue in which they were identified, a fact that could be misleading because the growth factors typically are ubiquitous in that they perform their actions in a wide range of tissues. As mentioned for cytokines, growth factors can perform their actions in an autocrine, paracrine, or endocrine manner. Table 4-9 lists a classification and nomenclature of some of the main classes of growth factors.

Many growth factors are not only mediators of hard tissue matrix deposition but also become entrapped within the matrix as it becomes calcified. This has led to a great

TABLE 4-9 Classification of the More Commonly Recognized and Studied Growth Factors

Superfamily	Family	Abbreviated Name
Transforming growth factor-β	Transforming growth factor-β	TGF-β
	Inhibins	Inhibin/Activin
	Bone morphogenetic proteins	BMP
	Vg-1	Vg-1, GDF-1, DPP
Platelet-derived growth factor	Platelet-derived growth factors	PDGF
	Vascular endothelial growth factors	VEGF
	Connective tissue growth factors	CTGF
Epidermal growth factor	Epidermal growth factor	EGF
	Transforming growth factor-*a*	TGF-*a*
Enamel matrix derivatives	Amelogenin	Collectively known as EMD
	Enamelin (Enam)	
	Tuftelin	
Other large peptide growth factor families	Fibroblast growth factors	FGF
	Insulin-like growth factors	IGF
	Nerve growth factor	NGF
	Hepatocyte growth factor	HGF
	Tumor necrosis factors*	TNF

*As noted before, TNF-α and TNF-β are usually classified as pro-inflammatory cytokines, but sometimes considered within growth factor Classifications.[148]

interest in osteoinductive growth factors such as the bone morphogenetic proteins BMP-2 or BMP-7, enamel matrix derivatives (EMDs), PDGF, and insulin-like growth factor (IGF). These proteins have been extensively investigated with respect to their ability to induce, potentiate, and accelerate bone regeneration, whether as purified proteins or as components of demineralized freeze-dried bones.[18,149–154]

There have been considerable interest in whether BMPs,[155–159] TGF-β,[160–163] EMD[164–166] or other growth factors may enhance the formation of reparative dentin following pulp exposure. *In vivo* trials in animal models have initially been conducted via protein deposition directly on experimentally exposed pulp.[156,159,167] However, more recently, gene transfer strategies have been employed to assure prolonged effect of the induced protein,[157,163] or transplantation of cells in which the growth factor genes have been induced *in vitro* to a polyglycolic acid scaffold in the pulp.[168] However, it was later realized that in the presence of inflammation, as induced by applying LPS to the model, these strategies fail to produce the desired outcome.[155]

Within a pathological pulpal or periapical tissue, or even during an orthodontic movement, growth factors are frequently expressed and are thought to modulate the inflammatory process and aid in the healing that ensues after the removal of irritants.[18,169–174] For example, it has been shown that TGF-β1 down-regulates the expression of matrix metalloprotein-8 (MMP-8) in human odontoblasts and dental pulp cells *in vitro*.[79]

Vascular endothelial growth factor (VEGF) has also been identified as a critical growth factor for the pathogenesis and sustenance of periapical lesions.[175–177] This growth factor most likely also plays an important role in healing of lesions following treatment, although this has not been adequately described.

MOLECULAR MEDIATORS OF ANTI-INFLAMMATORY REACTIONS

Membrane Phospholipids/Arachidonic Acid Metabolic Pathways

Inflammatory process is fine-tuned by pro-inflammatory and anti-inflammatory mediators. There is more information known about pro-inflammatory mediators, whereas less is known regarding anti-inflammatory factors. In fact, in the pathways leading to the production of pro-inflammatory mediators such as prostaglandins and leukotrienes, there is also production of anti-inflammatory mediators such as lipoxins (Figure 4-10). In the host defense mechanism, acute inflammation executed by neutrophils is resolved by proceeding to chronic inflammation in which pro-inflammatory mediators are produced, or to resolution in which protective mediators are released.[178–180]

This pro-resolution against acute inflammation is an active process that involves the activation of specific biochemical and cellular programs of resolution. Lipoxins are potent counter-regulatory signals for endogenous pro-inflammatory mediators, including lipids (e.g., leukotrienes) and cytokines (TNF-α, IL-6), resulting in inhibition of leukocyte-dependent inflammation. Lipoxins are rapidly biosynthesized in response to stimuli, act locally, and then are rapidly enzymatically inactivated.[179,181–183] Another important group of lipid mediators that possess anti-inflammatory and pro-solution action is resolvin, which protects healthy tissue during immune-inflammatory responses to infection or injury, promoting inflammation resolution and tissue healing.[184] Resolvins are derived from omega-3 (ω-3) fatty acids, docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA), and have subtypes including the E series (RvE1-3, from EPA), the D series (RvD1 and RvD2, from DHA), and aspirin-triggered (AT) forms (AT-RvD1-6).[179,184]

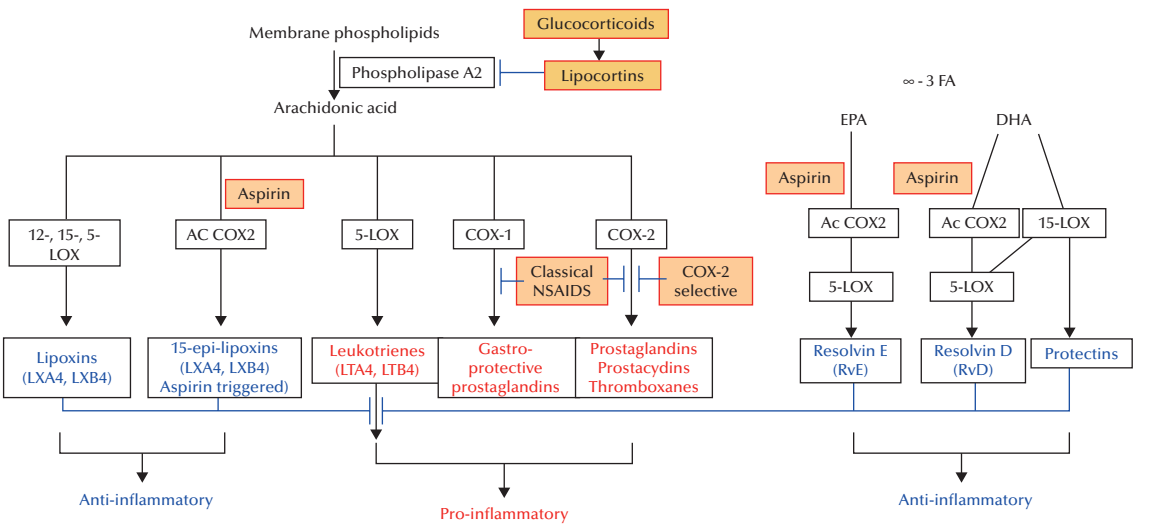

FIGURE 4-10 Pathways of lipid mediator production from membrane phospholipids and pathways of omega-3 (ω-3) fatty acids metabolism. LOX: lipoxygenase; COX: cyclooxygenase; NSAIDS: nonsteroidal anti-inflammatory drugs; LX: lipoxin; DHA: docosahexaenoic acid; EPA: eicosapentaenoic acid.

They are generated via COX2-/LOX-mediated pathways in which another molecule belonging to a new family of mediators named protectins are also produced that possess similar anti-inflammatory functions as resolvins (Figure 4-10).[185]

Anti-inflammatory Cytokines (IL-10, TGF-β, and Regulatory T Cells)

Several cytokines have predominantly anti-inflammatory effects including IL-1Ra, TGF-β, and IL-10 (Table 4-7). Monocytes and B cells are the major sources of IL-10 in human subjects. The primary T-cell source for IL-10 is regulatory T lymphocytes (Treg), as mentioned above. IL-10 inhibits production of many pro-inflammatory cytokines such as IL-1β, IL-6, IL-8, IL-12, IFN-γ, and TNF-α. In addition, IL-10 inhibits MHC class II, CD23, intercellular adhesion molecule 1, and CD80/CD86 expression by DCs and other APCs. IL-10 plays an important role in human allergic disease. Asthma and allergic rhinitis are associated with diminished IL-10 expression in the allergic airway by both alveolar macrophages and DCs. Newer members of the IL-10 family include IL-19, IL-20, IL-22, IL-24, and IL-26; however, none of these cytokines significantly inhibits cytokine synthesis, an activity that remains unique for IL-10.[186] Treg populations can be classified into naturally occurring Foxp3+/CD4+/CD25+ Treg subset (CD4+CD25+ Treg) and antigen-driven Treg producing IL-10 (IL-10-Treg) and TGF-β (TGF-β-Treg). The production and action of these two cytokines are inter-related and likely involve a positive feedback loop, in which IL-10 enhances the expression of TGF-β and vice versa.[186–188]

INTRACELLULAR SIGNALING PATHWAYS OF INFLAMMATORY MEDIATORS

TLR Signal Transduction Pathways

Upon binding the ligands, TLRs activate the same signaling molecules that are used for IL-1R signaling,[189] triggering downstream signaling cascades that leads to the activation of pro-inflammatory cytokine and chemokine genes. Stimulation of most TLRs leads to Th1 rather than Th2 differentiation. Thus, innate immunity is a key element in the inflammatory response as well as the immune response against pathogens. Microbial cell-wall components stimulate immune cells and serve as PAMPs, recognized by individual TLRs. LPS, also known as an endotoxin, is generally the most potent immune-stimulant among these cell-wall components. Earlier studies have shown that endotoxin plays an important role in initiating and perpetuating of periapical inflammation and bone resorption.[190-193] LPS liberated from Gram-negative bacteria binds LPS binding proteins (LBP) that present in the bloodstream, and then binds to CD14 expressed on the cell surface of phagocytes. Subsequently, LPS is transferred to MD-2, which associates with the extracellular portion of TLR4, followed by oligomerization of TLR4, a key molecule of LPS signaling.[194,195] LPS does not have a direct apoptotic effect on osteoblasts or PDL cells, but can activate macrophages to induce apoptosis in osteoblasts and PDL cells via released TNF-α.[196]

NF-κB and NF-κB-Activating Pathways

The transcription factor NF-κB plays a pivotal role in a series of cellular processes, particularly those involved in inflammation, immunity, cell proliferation, and apoptosis. It consists of homo- or heterodimers of a group of five proteins, NF-κB1 (p50), NFκB2 (p52), p65/RelA, c-Rel, and RelB. In resting, NF-κB is in the cytoplasm and bound by the inhibitory proteins IkBs. Upon cell stimulation, IκBs are rapidly phosphorylated and degraded, freeing the NF-κB to translocate into the nucleus and bind onto the transcriptional regulatory sequence motifs of multiple target genes. NF-κB activation is divided into two main pathways: the classical and the alternative pathways of NF-kB activation. The classical pathway is induced by a variety of innate and adaptive immunity mediators including pro-inflammatory cytokines (TNFα, IL-1β), TLRs, and antigen receptors (TCR, BCR) ligation. While these NF-κB inducers signal through different receptors and adaptor proteins, all converge to the activation of IκB-kinase (IKK) complex, which phosphorylates IκBa leading to its degradation. The freed NF-κB then translocates into the nucleus where it activates the transcription of target genes such as cytokines, chemokines, adhesion molecules, and inhibitors of apoptosis (Figure 4-3). The alternative pathway of NF-κB activation is important for secondary lymphoid organ development, homeostasis, and adaptive immunity. It is induced by B-cell activating factor, lymphotoxin-β, CD40 ligand, and human T cell leukemia (HTLV) and Epstein-Barr (EBV) virus. It enhances NF-κB inducing kinase (NIK)- and IKKa-dependent processing of p100 into p52, that binds DNA in association with its partners, such as RelB. These stimuli also activate the classical pathway.

NF-κB-inducers trigger the formation of ROS, this may be the reason why such a diversity of inducers activate NF-κB via the same IKK-dependent pathway. Both IL-β and TNF-α activation of NF-κB involves ROS.

INFLAMMATION-INDUCED BONE RESORPTION

Formation of periapical lesion as the result of pulpal infection involves features that are somewhat different from a typical microbial infection of other tissues. Pulp tissue ends and transits into the periodontal ligament tissue at the apical cemento-dentinal junction. Apical periodontal ligament begins to be affected as the pulpal inflammation spread toward it. Inflamed apical portion of the pulp and the periodontal ligament releases factors that induce bone resorption to build and maintain a defense line against the incoming microbial invasion. The resorbed bone space is replaced with abscesses and/or granulomatous tissue rife

with inflammatory cells and fibroblasts. Proliferation of epithelial cell rest of Malassez leads to scattered epithelial cell clusters within the inflamed periapical lesion. With time, these epithelial cell clusters may form a cyst.[197–203] A true periapical cyst occurs in 15% of the periapical lesions examined based on the findings by Nair et al.,[203] who also found that 52% (133/256) of these lesions demonstrated epithelial proliferation. For more details, see Chapter 6.

The epithelial cells in the PDL are involved not only in the formation of cysts, but may also be in the regulation of cementum and bone metabolism as they express osteopontin and osteoprotegerin that are not expressed in gingival epithelial cells.[204] Based on animal studies, periapical lesions expand in the early phase of the lesion formation and become self-limited at later stage.

Microbial Role in the Pathogenesis of Periapical Lesion

Although inflammation is generally associated with infection, inflammation can be the mere result of an aseptic trauma or a deregulated immune reaction. The classical study by Kakehashi et al.[205] verified this notion that without the presence of microbes, exposed pulp tissue will heal after a transient inflammatory response without the development of periapical lesions. Endodontic infection is characterized as a polymicrobial infection with predominately anaerobes, many of which are gram negative. The damage of host tissues from infection is the result of 1) direct infliction from microbial products such as collagenase, trypsin-like enzymes, and fibronectin-degrading enzymes; and 2) host immune response that leads to destruction of tissue such as periapical bone.

As mentioned above, host innate immunity exerts certain extent of specificity to the microbial components via PRRs such as TLRs. TLR4-mutated C3H/HeJ mice (LPS hyporesponsive) have reduced response to Gram-negative bacteria and are highly susceptible to infection by *Salmonella typhimurium* or *Neisseria meningitis*. There is a reduced expression of IL-1 and IL-12 and decreased periapical bone destruction at 21 days, in TLR-4 deficient mice when subjected to pulpal exposure and infection with a mixture of four anaerobic pathogens, *Prevotella intermedia, F. nucleatum, Streptococcus intermedius* (G+), and *Peptostreptococcus micros* (G+). Also, no dissemination of infection occurs in the TLR-4 deficient mice.[206]

However, if the pulp is exposed to the microorganisms in the oral environment, these LPS hyporesponsive mice do not show significant difference in the level of cytokine production or periapical bone destruction from the normal controls.[207] Studies have indicated that the variations of microflora obtained from molar surfaces of mouse within a same experimental group are as great as the variation between mice in the different groups[208] that could contribute to the discrepancies of findings by different investigators.

Components such as LTA of Gram-positive bacterial cell walls can also stimulate innate immunity in a similar manner as LPS. TLR2 plays a major role in detecting Gram-positive bacteria and is involved in the recognition of a variety of microbial components, including LTA, lipoproteins, and PG. The importance of TLR2 in the host defense against gram-positive bacteria has been demonstrated using TLR2-deficient (TLR2–/–) mice that were found to be highly susceptible to challenge with microbes,[209–211] and developed significantly larger periapical lesions with more osteoclasts than controls.[211]

LTA can cause apoptotic cell damage including that of *E. faecalis* that induces apoptosis in osteoblasts, osteoclasts, periodontal ligament fibroblasts, macrophages, and neutrophils. It also stimulates leukocytes to release mediators that are known to play a role in various phases of the inflammatory response including TNF-α, IL-1β, IL-6,[212] IL-8,[213] and PGE2. These factors have all been detected in periapical samples, and each has well-known tissue-damaging effects.[214]

Role of Immune Cells in Periapical Lesion Formation

Immune cells present in human periapical lesion consist of lymphocytes, macrophages, plasma cells, neutrophils, and natural killer (NK) cells with the former two types as the majority.[215,216] Within lymphocytes, T cells are in greater number or equal to B cells.[217] APCs and T suppressor/cytotoxic cells are associated with both pre-existing and newly formed epithelium.[216]

Using rodents as study models, the dynamics of periapical lesion development in rodents are characterized by having an active bone resorption phase within 15 days after pulp exposure followed by a chronic phase with little lesion expansion.[218–221] Th cells dominate during the active phase, whereas increased numbers of Ts cells are associated with chronicity. The subpopulations of specific Th cells involved in the periapical lesion development remain unclear.

The role of lymphocyte subpopulations in the formation of periapical lesions was studies using lymphocyte-deficient rodents. T cell-deficient rodents develop periapical lesion in a similar manner compared to the normal counter animals except some minor differences. Wallstom et al.[222] used athymic rat model (T cell-deficient) and found no significant difference between periapical tissue responses of the conventional and athymic groups. Tani et al.[223] used nude mice (T cell-deficient) and immunostaining to study the involvement of lymphocytes in the kinetics of periapical lesion development. They found that at 2 weeks after pulp exposure, nude mice develop larger periapical lesion than normal mice, but the lesion sizes are similar between the two experimental groups at 4 and 6 weeks after pulp exposure. At 8 week, however, normal mice have slightly larger lesion size. No T cells and reduced number of B cells are present in the lesions of nude mice. T cells (more Th than Ts) begin to emerge in lesions after 4 weeks in normal mice.[223] Fouad[106] employed severe combined immunodeficiency (SCID, T and B cell-deficient) mice as a study model and found that the SCID mice lesions are significantly smaller than the controls

at only the 3-week period. In these studies, pulp was exposed to oral microbes.

By using RAG-2 SCID mice (both T and B cell-deficient) and an infection protocol—equalized bacterial challenge of the exposed pulp with mixed microbes *Prevotella intermedia, F. nucleatum, P. micros,* and *S. intermedius* and the access sealed, Teles et al.[224] found that approximately one-third of the RAG-2 mice develop endodontic abscesses, while no immunocompetent controls have abscesses. In another study, specific knock-out (k/o) mice RAG 2, Igh-6 (B cell-deficient, Ig heavy chain k/o), Tcrb Tcrd (T cell-deficient, β & δ chain TCR k/o), and Hc^0 (C5 deficient) were used to determine which immune element is important for the defense mechanism in endodontic infection. Their results demonstrate that B cells, not T cells or C5, play a pivotal role preventing dissemination of endodontic infection.[225]

CD4+CD25hiFoxp3+ Treg cells are present in human periapical lesions expressing IL-10 and TGF-β. Tregs in the periapical lesions inhibit the proliferation of T-cells, at least in part, by the production of IL-10.[226] Various T cell subsets including Th1, Th2, Th9, Th17, Th22, Thf, Tr1, and Tregs have been examined in human periapical lesions by detecting the cytokines/markers expression. TNF-α, IFN-γ, IL-17A, and IL-21 levels are significantly higher in active lesions, while levels of IL-4, IL-9, IL-10, IL-22, and FOXp3 are higher than those in active lesions.[227] In a rat model, the presence of Th17 and Treg cells during development of periapical lesion was studied. IL-17–positive cells (Th17) markedly increased during early and mid-phase of active lesion expansion; whereas Foxp3-positive cells (Treg) remained at low levels until late phase and then dramatically increased thereafter.[48]

Mechanisms of Bone Resorption—Regulation of Osteoclast Formation and Activation

Under normal conditions, osteoclastogenesis mainly occurs within the bone marrow as a continuing process of bone modeling and remodeling. Compared to the generalized bone loss seen in osteoporosis, localized bone loss in jawbones resulting from endodontic infection is a combination of a focal inflammatory immune reaction and localized osteoclastogenesis. Inflammatory cells, including lymphocytes and macrophages, produce cytokines, such as tumor necrosis factor (TNF) and IL-1, and chemokines to recruit and activate more inflammatory cells. Lymphocytes, monocytes, and DCs found in periapical granulomas synthesize receptor activator of nuclear factor-κB ligand (RANKL). There is a significantly higher RANKL gene expression in the granulomas compared with the control tissues both in humans and rats.[7,228,229]

Macrophage CSF (M-CSF) and nuclear factor-κB ligand (RANKL) are two cytokines essential for promoting the differentiation of osteoclast precursors (OCPs) into mature osteoclasts. OCPs, generated in the bone marrow from hematopoietic stem cells, mobilize to diseased sites through

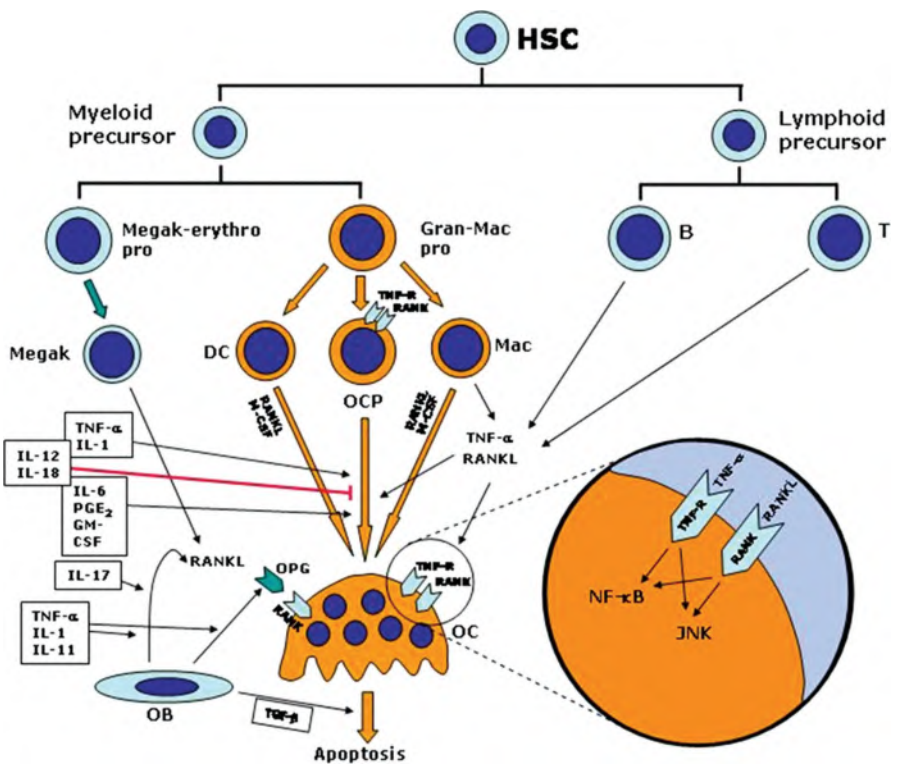

FIGURE 4-11 Regulations of osteoclast differentiation and the involved key cytokines. HSC: hematopoietic stem cells; OCP: osteoclast precursor; OC: osteoclast; OB: osteoblast; DC: dendritic cells; GC: granulocyte; Mac: macrophage; E: erythrocyte; OPG: osteoprotegerin.

the blood stream and differentiate into osteoclasts to resorb bone. OCPs migrate along chemokine gradients.

The RANKL/RANK system is essential for mature osteoclast formation, a critical player in T-lymphocyte-mediated osteoclastogenesis, and induces OCPs to produce pro-inflammatory cytokines and chemokines.[230–232] Mature B and T cells do not form osteoclasts but affect osteoclastogenesis indirectly by producing RANKL or osteoprotegerin (OPG), a soluble decoy RANKL receptor (Figure 4-11). OPG binds RANKL thereby preventing RANKL activity. OPG is expressed in human pulp of healthy and inflamed tissues[233]; however, its role in pulp tissue is unclear. The number of RANKL-positive cells and the ratio of RANKL/OPG in chronic apical lesion are significantly higher than those in healthy periapical tissues. The number of RANKL-positive cells is higher in lesions with severe inflammatory infiltration than in those with light inflammatory infiltration.[234] The influence of immune cells on osteoclastogenesis becomes significant when they accelerate osteoclast formation, and then both cell types contribute to the pathogenesis of the disease, as seen in inflammatory arthritis or periodontal disease.

The RANKL/RANK system is essential for osteoclast formation. RANKL not only delivers a final differentiation signal, but also activates osteoclasts and promotes their survival. RANKL is expressed by almost all cell types in the body. In the immune system, RANKL is expressed by activated T cells, B cells, and DCs. OPG is produced by cells of mesenchymal origin. RANKL and OPG expression is regulated by many factors, and the ratio of RANKL/OPG controls osteoclastogenesis. Periodontal ligament cells produce both RANKL and OPG.[235] In contrast to broad expression of RANKL, RANK, the receptor for RANKL, is only identified on mature osteoclasts, DCs, and OCPs, that are therefore the major target cells for RANKL and OPG. TNF is overproduced by many cell types at inflammatory foci, including macrophages, T cells, DCs, osteoclasts, and OCPs.[236]

Inhibition of Bone Resorption by Bisphosphonates

Bisphosphonates (BPs) have a unique high-affinity binding property to hydroxyapatite mineral, generating high local concentrations of drug on bone surfaces where these agents can preferentially interfere with osteoclast-mediated bone resorption. BPs comprise amino- and non-amino-containing compounds. Aminobisphosphonates such as pamidronate, alendronate, risedronate, and zoledronate exert their inhibitory effects on osteoclast function by inhibiting farnesyl pyrophosphate synthase, an enzyme in the mevalonate pathway necessary for lipid modification (prenylation) of small GTP binding proteins. Interference with the activity of the binding proteins alters cytoskeletal organization and intracellular trafficking in osteoclasts, resulting in inhibition of osteoclast function. Ruffled border formation is a process that is highly dependent on cytoskeletal function, strongly regulated by geranylgeranylated GTP binding proteins, such as Rac, Rho, and so on. Non-aminobisphosphonates such as etidronate and clodronate are metabolized to non-hydrolyzable analogues of ATP and act as inhibitors of ATP-dependent enzymes, leading to enhanced osteoclast apoptosis (Figure 4-12).[237]

The pathophysiological mechanism underlying ONJ may be multifactorial including altered bone remodeling, oversuppression of bone resorption, angiogenesis inhibition, soft tissue BPs toxicity, occurrence of constant microtrauma, inflammation or infection, and dento-alveolar surgery.[238–241] Precipitating factors of ONJ: severe periodontitis, spontaneous exposure, periodontal surgery, dental implants, and root canal surgery (in the order of prevalence).[242–244]

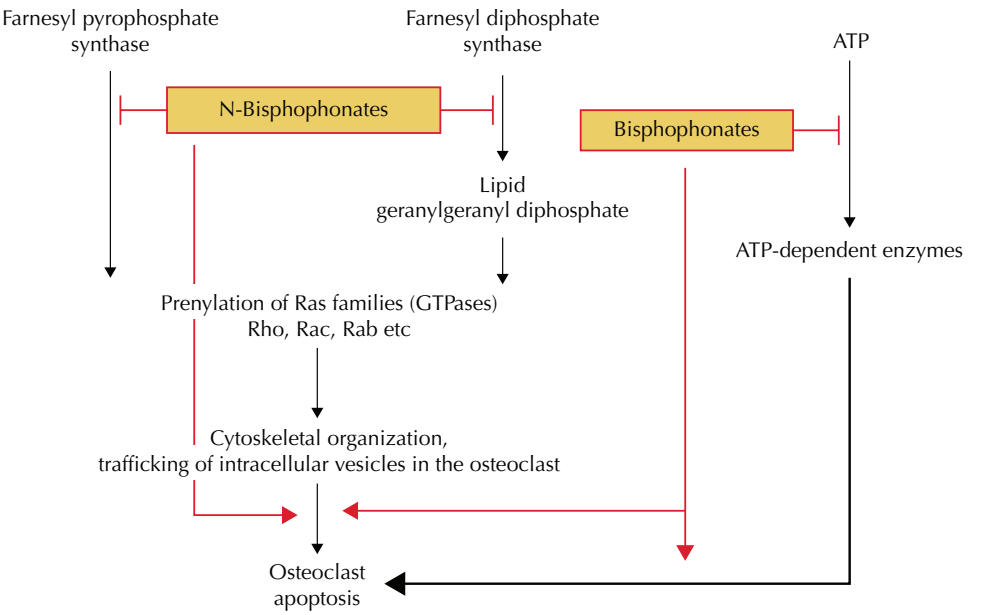

FIGURE 4-12 Metabolism of bisphosphonate (BP)-induced osteoclast apoptosis.

Roles of Cytokines in Periapical Bone Resorption

Many cytokines are involved in the initiation and maintenance of inflammation, some of which are also responsible directly or indirectly for the induction of bone resorption. Periapical bone resorption induced by cytokines is a destructive and an undesirable process indicative of the magnitude of endodontic infection. On the other hand, cytokines are also important for the establishment of local immune defense mechanism. The role of specific cytokines in a variety of immune and inflammatory diseases, including endodontic pathoses, is difficult to elucidate due to the intricate and overlapping functions of these inflammatory cytokines and mediators.

Cytokines TNFα, IL-1, IL-6, and IL-11 are involved in promoting bone resorption and mediating inflammation both systemically and locally. However, IFN-γ, IL-12, and IL-18 that may otherwise have pro-inflammatory actions, do not appear to augment periapical lesion development.[245] In human dental granulomas, there is a correlation between the intensity of inflammatory infiltrate and the percentage of mononuclear cells positive for IL-4, suggesting a predominant Th2 response. There is also a correlation between the frequency of cells expressing IL-6 and LT-alpha, suggesting a synergistic activities IL-6 and LT-alpha in granulomas. The numbers of inflammatory cells expressing the anti-inflammatory molecules far outnumbered the cells that expressed pro-inflammatory cytokines.[246,247]

In mice, TNFα and IL-1α are highly expressed in areas that contain a mixed inflammatory infiltrate or fibroblasts in periapical lesions. The number of cells expressing these two cytokines is proportional to the lesion size.[106] The expression of IL-11 was not modulated by pulp exposure. Most of the Th1-type cytokines, including IL-2, IL-12, and IFN-γ, showed an increase in mRNA and/or protein expression in periapical lesions after pulpal exposure; the expression of Th2-type cytokines (IL-4, IL-6, IL-10, IL-13) was similarly increased, but had declined at the latest time-point (day 28). There was a lack of correlation between IL-1a and Th2-type anti-inflammatory mediators, including IL-4, -6, and -10. These results indicate that a cytokine network is activated in the periapex in response to bacterial infection, and that Th1-modulated pro-inflammatory pathways may predominate during periapical bone destruction.[248–253]

The role of specific cytokines in the development of periapical lesions has been studies using mice with gene knock-outs of different cytokines or their receptors, such as IL-1, IL-6, and TNF.[208,254,255] Mice with functional deletions of receptors to IL-1 (IL-1RI(−/−)), TNF (TNFRp55(−/−)-p75(−/−)), or both (TNFRp55(−/−)-IL-1RI(−/−)) infected with multiple anaerobic pathogens after pulp exposure lead to increased polymorphonuclear and mononuclear phagocyte recruitment in the periracicular lesions and bacterial penetration into host tissue. Osteolytic lesion formation is also greater in animals lacking TNF and/or IL-1 receptors than in control mice indicating that IL-1 or TNF receptor signaling is not required for bacteria-induced osteoclastogenesis and bone loss, but does play a critical role in protecting the host against mixed anaerobic infections. Although TNFα enhances osteoclastogenesis and mediates lipopolysaccharide-induced bone loss, deletions of TNFRp55(−/−) does not reduce bacteria-induced bone resorption.[254] Between IL-1 and TNFα, IL-1 receptor signaling is more important than TNF receptor signaling in preventing the spread of infection into surrounding fascial planes.[256]

TABLE 4-10 Mediators That Promote or Inhibit Bone Resorption

Promote bone resorption	IL-1, TNF-α, PGE2, IL-6, IL-11, RANK/RANKL, M-CSF, IGF-I
Inhibit bone resorption	IL12, IL-18, IFN-γ, IL-4, OPG[258]
Dual functions	PGs, TGF-β, glucocorticoids

IL-6 production in mouse periapical lesions reaches its peak (~2-fold higher than base-line) on day 14 after pulpal exposure and then decreases to the basal level after 28 days.[250] Depleting IL-6 negatively affects the host defense mechanism against local infection in the periapical area.[208,255] In IL-$6^{-/-}$ mice, periapical lesions rapidly develop in week 2, whereas development of the lesion is one week slower in the IL-$6^{+/+}$ mice.[208] The increased bone resorption in IL-6-deficient animals correlated with increases in osteoclast numbers, as well as with elevated expression of bone-resorptive cytokines IL-1alpha and IL-1beta, in periapical lesions and with decreased expression of the anti-inflammatory cytokine IL-10. These data demonstrate that endogenous IL-6 expression has significant anti-inflammatory effects in modulating infection-stimulated bone destruction *in vivo*.[255]

The functional role of the Th2-type cytokines IL-4 and IL-10 in infection-stimulated bone resorption *in vivo* has been assessed using gene knock-out mice. IL-10(−/−) mice have significantly greater infection-stimulated bone resorption compared with wild-type mice, while IL-4(−/−) have no increased resorption. IL-10(−/−) mice show markedly elevated IL-1α production within periapical inflammatory tissues (>tenfold), whereas IL-4(−/−) exhibit decreased IL-1α production. These findings suggests that IL-10, but not IL-4, is an important endogenous suppressor of infection-stimulated bone resorption *in vivo*, likely acting via inhibition of IL-1α.[257]

The functional roles of the Th1 cytokine IFN-γ and IFN-γ-inducing cytokines IL-12 and IL-18 has also been determined with a similar approach using IL-12−/−, IL-18−/−, and IFN-γ−/− mice.[245] Although *in vitro* evidence has demonstrated that IL-12 and IL-18 have inhibitory effects on osteoclast formation,[258] no difference was found in the infection-stimulated periapical bone resorption between knock-out and wild-type control mice.[245] Therefore, it appears that there is a functional redundancy in pro-inflammatory pathways. A summary of bone-resorption related factors is presented in Table 4-10.

HYPERSENSITIVITY REACTIONS

Hypersensitivity reactions represent a group of immunological responses where the reaction observed by the host far exceeds that normally triggered in the immune response described before. This results in excessive tissue damage and even death in certain cases. There are four general types of immunological hypersensitivity reactions. They vary in their severity and extent from a mild subclinical response to a life-threatening reaction. It is important for the clinician to understand the underlying mechanisms of these conditions in order to recognize and manage these reactions in their patients effectively.

Type I: IgE-mediated degranulation of mast cells and basophils, with release of histamine. This may be either systemic (anaphylaxis) or local (atopy). Type I hypersensitivity is fundamentally caused by the initial sensitization of the patient to a particular allergen. Some of the common allergens here include penicillin, certain foods, pollen, and insect bite. Upon exposure to a second challenge to this allergen, cross-linking of IgE on the surface of mast cells occurs, and release of C3a and C5a complement molecules cause degranulation of mast cells and release of inflammatory mediators. The most important of these mediators is histamine; however, other mediators including eicosanoids, Th2 cytokines, and chemokines are released. The patient experiences vasodilatation, which may be local or systemic, as well as bronchoconstriction, which causes wheezing and may cause asphyxia. The patient is considered to have a medical emergency that should be immediately managed with subcutaneous injection of epinephrine. A proportion of patients with chronic exposure to allergens develop asthma.

Type II: Antibody-dependent cytotoxic hypersensitivity. Antigens on the cell surface can cause cell damage through the interaction with inflammatory cells that have FcγR or C3b receptors. Recall from the discussion of phagocytosis that this reaction primes the microbial surface by opsonins that aid in phagocytosis. In this case, however, phagocytosis does not occur, occasionally because the target is too large for phagocytosis such as for large target cells or in parasitic infections. Examples of type II reactions include blood factor (ABO) or rhesus (Rh) factor incompatibility and autoimmune hemolytic anemia.

Type III: Immune complex-mediated hypersensitivity. Excessive accumulation of antigen–antibody complexes in tissues, such as when there is excessive chronic accumulation of antigen, can stimulate an immune response through phagocyte-, complement-, and/or cytokine-mediated reactions. Frequently, neutrophils and macrophages attempt to perform phagocytosis, but due to the large amount of antigen, such as a microbial colony, they spill their proteases and oxygen- and nitrogen-reactive intermediates in the tissue causing tissue damage. Examples of this reaction include arthus reactions, serum sickness, systemic lupus erythematosus, and immune complex glomerulonephritis.

Type IV: Cell-mediated (delayed-type) hypersensitivity. This reaction is mediated by Th1, CD4+, or CD8+ cells, causing cytokine-mediated tissue damage. Examples of this reaction include allergic reactions to bacteria, viruses and fungi, contact dermatitis reactions, chronic granulomas, such as tuberculosis and leprosy. In the skin tuberculin test (Mantoux reaction), the subcutaneous administration of antigen causes accumulation of mononuclear inflammatory cells within 24 to 48 hours.

Other Types of Hypersensitivity

Stimulatory Hypersensitivity

The prime example of this reaction is Graves' disease, in which plasma cells continue to produce a self-antibody against the thyroid-stimulating hormone (TSH) receptor in the thyroid gland, which itself stimulates the gland to keep producing thyroxine, and does not respond to negative feedback mechanisms.

Innate Hypersensitivity Reactions

The severe disseminated reaction to LPS in Gram-negative bacteria is known as septic shock syndrome. In this reaction, LPS causes the release of systemic cytokines IL-1, TNF-α, and IL-6, which in excessive amounts activate compliment, cause respiratory distress by excess circulating neutrophils, and disseminated intravascular coagulation. Gram-positive septic shock has also been recognized due to enterotoxins of streptococci or staphylococci.

SYSTEMIC INFLAMMATION AS A CONSEQUENCE OF ENDODONTIC INFECTION

As noted before, during an acute infection or after tissue injury, there is an increase in the concentration of pro-inflammatory cytokines in the blood, primarily IL-1, TNFα, and IL-6. IL-1 and TNFα cause fever through their action on the thermoregulatory center in the hypothalamus due to the release of local eicosanoids.[14] IL-1 causes an increase in IL-6 that acts on hepatocytes to synthesize a number of plasma proteins called acute phase proteins, and the reaction is known as acute phase reaction. Among the most intensely secreted proteins are C-reactive protein (CRP), mannose-binding lectin (MBL), serum amyloid P component (SAP), and a1-acid glycoprotein. CRP and MBL are important in fixing complement and deposit C3b, that is opsonins, on the microbial cell.[6] SAP can, together with chondroitin sulfate, bind to lysosomal enzymes such as cathepsin B released in inflammation. This complex becomes a component of the amyloid fibrillar deposits that accompany chronic infections.[6] Other proteins that are released in moderate amounts in an acute phase reaction include fibrinogen, fibronectin, haptoglobin, angiotensin, ceruloplasmin, complement proteins C3, C9, and factor B, a1-proteinase inhibitors and a1-antichymotrypsin. Finally, cytokines may also act on bone marrow to cause the increased

production of white cells causing leukocytosis, where white cells may reach 15,000 to 20,000/mL rather than the 4,000 to 10,000/mL normal count.[9]

Acute endodontic infection can cause systemic inflammation with elevation of CRP and SAA.[259–261] These factors appear to subside shortly after the acute infection resolves.[259,260] Chronic periapical lesions in humans or animal models do not appear to be associated with CRP or SAA.[262,263] However, a number of other factors, including markers of inflammation, have been shown to increase with the presence of periapical lesions. Recently, a systematic review and meta-analysis in which the changes in 31 different systemic molecular markers were analyzed in both acute and chronic periapical infections.[264] The results showed that CRP, IL-1, IL-2, IL-6, asymmetrical dimethylarginine (ADMA), IgA, IgG, and IgM were increased in patients with apical periodontitis compared to controls. The meta-analyses further showed that: serum IgA, IgG, and IgM increased in humans with AP compared to healthy controls and that serum CRP, IgA, IgE, IgG, and IgM were not significantly different before and after treatment.

Chapter 5

Pulpal Pathosis

Graham R. Holland, Tatiana M. Botero, Stephen B. Davis

The pulp may be subjected to a number of insults: microbial, chemical, physical, trauma, and iatrogenic.

Most pulps being treated are already damaged. It should be assumed that every tooth that is being restored due to caries or leakage has an inflamed pulp, and its treatment should be undertaken cautiously.

Microorganisms are responsible for most pulpal disease. The classic study by Kakehashi et al.[1] proved that exposed pulps in gnotobiotic (germ free) rats did not become inflamed, whereas similarly exposed pulps in rats with a full oral flora became inflamed. Dental caries and the pulpal inflammation beneath it are clearly microbial in origin. Pulpal injury beneath restorations is mostly microbial and not due to cytotoxicity of the materials. Microorganisms and their byproducts enter between the restoration and the dentin as a result of microleakage.[2–4] The toxins from the carious lesion reach and affect the pulp well ahead of the microbes themselves.

Antigen-recognition cells and antigen-presenting cells initiate the immune response either the innate (nonspecific), in naïve tissue, or the specific in tissue that has been previously exposed to the antigen. Vascular changes are an essential part of the response but these changes have to take place within hard tissue walls with the blood vessels entering from only one end.

DENTAL CARIES ARE THE MOST COMMON SOURCE OF BACTERIA AND THEIR BY-PRODUCTS AFFECTING THE PULP

Dental caries begins beneath a biofilm of dental plaque when environmental factors favor the growth and metabolism of acidogenic bacteria. The population of bacteria that are present in carious lesions is mixed and variable. Chhour et al.[5] demonstrated the presence of 75 species in 10 samples of carious dentin. Up to 31 taxa were represented in each sample. A diverse collection of lactobacilli were found to comprise 50% of the species, with prevotellae also being abundant, comprising 15% of the species. In another study, significant positive associations were found between *Micromonas micros* and *Porphyromonas endodontalis* detection and inflammatory changes in the pulp.[6] These anaerobes have been strongly implicated in endodontic infections that occur as sequelae to carious pulpitis. Accordingly, the data suggest that the presence of high levels of these bacteria in carious lesions may be indicative of irreversible pulpal pathosis. In a clinical setting, however, it is very difficult to estimate the nature and size of the tissue injury.

Diverse groups and different proportions of species are found in carious lesions. Thus, it has not been possible to produce an antibiotic to inhibit the progress of caries or a vaccine to prevent it. The bacteria inhabiting the margins between restorations and dentin are similarly highly variable. A variety of products are released or formed on the death of the bacteria. These include acids and proteinases that dissolve and digest the enamel and dentin, as well as toxins including lipopolysaccharide (LPS) and lipotechoic acid (LTA). LPS results from the breakdown of the walls of gram-negative bacteria and LTA from the breakdown of gram-positive bacteria. As gram-negative bacteria predominate in the plaque over carious lesions, it may be assumed that LPS is the primary toxin. LPS is a generic term and there are many variations of its molecular structure, and differing virulence, depending on the species of bacteria producing it. The speed of progress of both dental caries and pulpal inflammation is variable, perhaps as a result of variations in the quantity, nature, and combination of toxins.

Although bacteria can themselves readily travel within dentinal tubules (Figure 5-1), toxins pass through dentin and enamel well ahead of them. Thus, the inflammatory response of pulp is to the toxins rather than to the bacteria themselves. Bacteria only invade the pulp at a late stage of the caries process that clinically would present as a carious exposure. For more details, see Chapter 3.

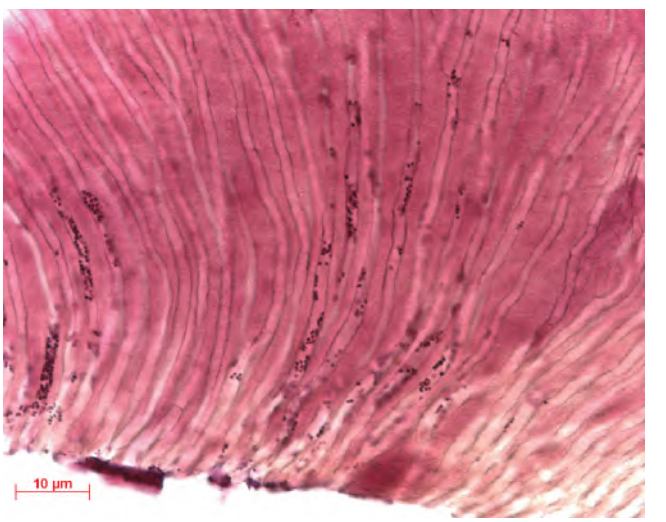

FIGURE 5-1 Bacteria in dentinal tubules in vitro. (Brown and Brenn[197]). (With permission from Dr. Christine M. Sedgley, Portland, OR, U.S.A.)

BACTERIA AND THEIR BY-PRODUCTS CAN REACH THE PULP BY MICROLEAKAGE AROUND RESTORATIONS AND FROM OTHER SOURCES

Anomalous Crown Morphology, Fractures, and Cracks

Any feature that allows the accumulation of bacteria will increase the likelihood of pulpal inflammation. In most cases, the inflammation will be secondary to caries. In cracked teeth, if they are symptomatic, the cracks will be lined with bacteria that have easy direct access to the pulp (Figure 5-2).[7]

Periodontal Disease

Biofilms form on the root surface of periodontal pockets. Their flora is similar to dental caries and would, presumably, release similar toxins. The presence of caries itself is not commonly found in this situation, but toxins may enter the pulp via lateral canals or by diffusing along dentinal tubules. For more details, see Chapter 36, "Endodontic–Periodontal Interrelationship." The outward flow of dentinal fluid would oppose this, and the relative impermeability of radicular dentin would prevent or reduce it. It has been demonstrated by the examination of extracted teeth with periodontal disease, but no caries, that pathologic changes do occur in the pulp when periodontal disease is present.[8]

On removing the cementum layer, periodontal scaling might be thought to allow greater ingress of microorganisms and toxins. This has not been supported experimentally.[9] The fact that the pulp has considerable powers to oppose invasion via the dentinal tubules has been clearly demonstrated by observations showing bacteria invading dentinal tubules of devitalized teeth much more readily than the tubules of vital control teeth.[10] Teeth with periodontal disease reaching the apex often remain vital. The consensus seems to be that periodontal diseases may lead to some pulpal changes but they rarely, if ever, lead to necrosis unless there is apical involvement.

FIGURE 5-2 Bacteria within a crack in dentine extending from the crack into dentinal tubules (Brown and Brenn). (With permission from Dr. Henry Trowbridge, San Francisco, CA, U.S.A.)

Blood Stream (Anachoresis)

Bacteria in circulating blood may be deposited in the pulp. An experimental study on dogs, in which some pulps were exposed and capped and then bacteria released into the blood stream, showed accumulations of bacteria in the capped pulps but not in normal pulps.[11] Whether this phenomenon is of clinical significance is unknown.

THE IMMUNE RESPONSE IN THE DENTAL PULP IS THE SAME BASIC PROCESS THAT OCCURS ELSEWHERE BUT IN A UNIQUE ENVIRONMENT

All connective tissues are capable of mounting an immune response that will follow the same basic pattern but is affected by local factors. The pulp's response differs from that in some other tissues. Because bacteria enter the tissue only at a very late stage, the pulp's blood supply is limited and the tissue is within a low-compliance chamber. If the tissue is presented with a new antigen, the innate immune response is initiated and is followed by the specific response a few days later. If the tissue is presented with an antigen it has met before, the specific response will be initiated immediately.

The tissue response to foreign antigens was described in molecular terms in Chapter 4, "Inflammation and Immunological Responses." The current chapter relates these processes to histologic and physiologic changes in the pulp and to the tissue's attempts at repair.

ANTIGEN RECOGNITION IN THE DENTAL PULP

All three antigen-presenting cell types expressing the type II major histocompatibility complex (MHC) surface proteins, macrophages, dendritic cells, and B lymphocytes are present and active in pulp's response to bacteria and toxins. In addition, it is now becoming clear that odontoblasts, being in the ideal position to detect antigens via Toll-like receptors (TLRs), produce a variety of cytokines and chemokines.[12]

In a normal healthy pulp, *macrophages* (Figure 5-3)[13] are present in a resting form, as monocytes. Macrophages require stimulation by microorganisms or cytokines before they express type II MHC molecules.[14] At rest, they are found predominantly around blood vessels,[15] although a few are distributed throughout the tissue.

Dendritic cells (Figure 5-4) are characterized by the shape that provides their name. They form a network throughout the pulp concentrating around blood vessels (Figure 5-5)[15,16] and the odontoblast layer. Some of the dendritic cells in the odontoblast layer extend their processes into the dentinal tubules (Figure 5-6).[17] They constantly express the MHC molecules on their surface without provocation. Recent studies[18] indicate that there are two populations of dendritic cells in the dental pulp, one beneath the odontoblast layer and the other around the blood vessels (Figure 5-7). The number

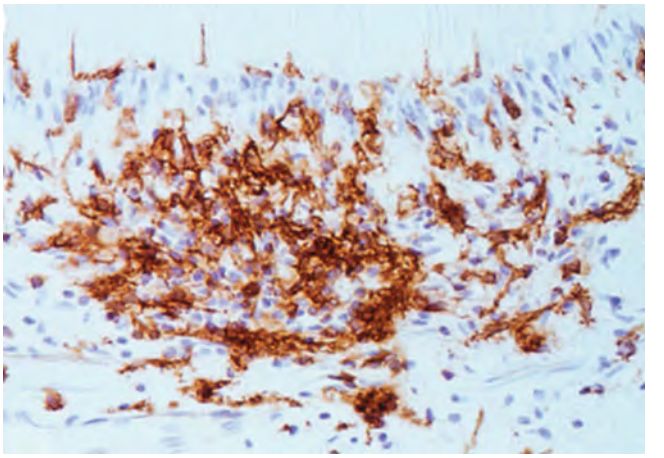

FIGURE 5-6 Dendritic cells (brown) congregating in an area of inflammation. (Reproduced with permission from Yoshiba et al.[17])

of dendritic cells increases in the pulp when it becomes inflamed and they accumulate beneath the carious lesion (Figure 5-6).[17]

B cells are specialized lymphocytes that will become plasma cells. They secrete antibodies during the specific immune response and express the MHC molecules. They have also been reported in the normal pulp but are rather rare.[19,20] Their role in the initial stages of antigen recognition and presentation in the pulp is unclear. Occasional T cells are found in normal pulp (Figure 5-8) and may be activated by antigen-presenting cells locally.

In the pulp, there is a close anatomic relationship between nerve fibers and dendritic cells (Figure 5-9), and both increase in parallel when the pulp is inflamed.[17,21] The sympathetic nervous system has recently been shown to have a modulating influence on pulpal inflammation.[22–24] The sympathetic system inhibits the production of proinflammatory cytokines, although stimulating the production of antiinflammatory cytokines.[22] In addition, T lymphocytes and other leukocytes produce antinociceptive molecules such as β-endorphin and somatostatin during inflammation (Figure 5-10), which reduce the excitability of pain fibers.[25]

Odontoblasts are the first cells to encounter an antigen diffusing along the dentinal tubules. Veerayutthwilai et al.[12] described how several markers of innate immunity have been demonstrated on odontoblasts and that their processes include chemokines and TLRs. Odontoblasts respond differentially to the toxins produced by gram-positive and gram-negative bacteria. A gram-negative toxin activating TLR-4 up-regulates mRNAs for interleukin-1β, interleukin- 8, tumor necrosis factor-α, and chemokines and TLRs. A synthetic peptide mimicking a toxin from gram-positive bacteria activating TLR-2 downregulates these mRNAs. Interleukin-1β, tumor necrosis factor-α, and chemokine (C-C motif) ligand 20 were also up-regulated from sixfold to 30-fold in odontoblast preparations from decayed teeth. These data show that odontoblasts express microbial pattern recognition receptors in situ, allowing differential responses to gram-positive and gram-negative bacteria. They also suggest that pro-inflammatory cytokines and innate immune

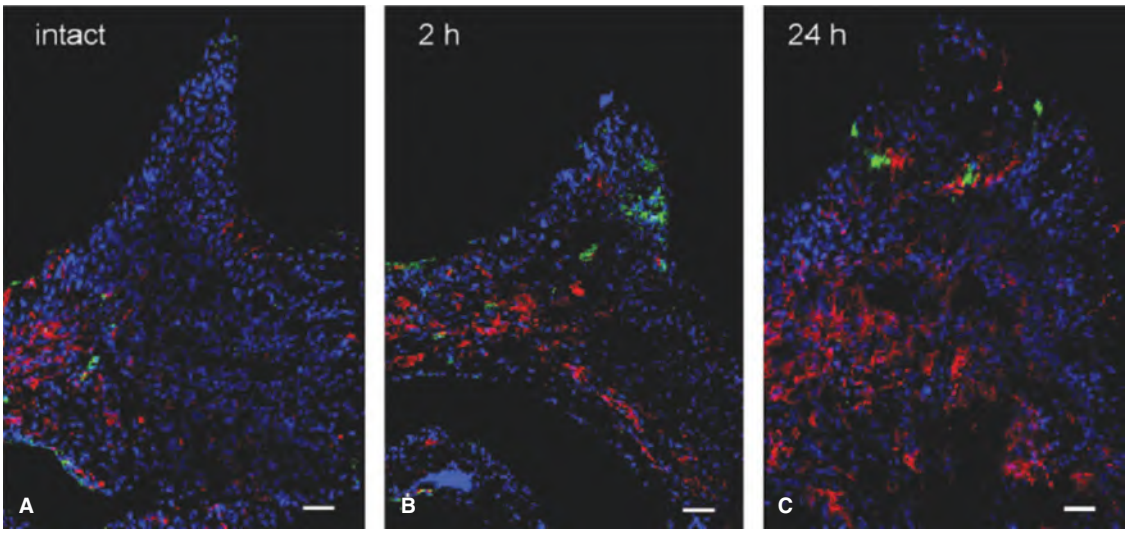

FIGURE 5-7 Two different types of dendritic cells (here stained red or green) differentiated by immunohistochemistry. The nuclei of odontoblasts and fibroblasts are stained blue. FIGURE 5-9 Confocal microscope image of a dendritic cell (red) and a nerve fiber (green). Where they are close together is yellow. (Reproduced with permission from Okiji et al.[15])

responses in decayed teeth may result from TLR signaling (Figure 5-11).[12] Other studies on odontoblasts *in vitro* suggest that in response to a bacterial toxin they produce chemokines that attract dendritic cells.[26]

Process of Antigen Recognition

Dendritic cells and macrophages bind to phagocyte antigen that is then processed intracellularly, bound to MHC molecules, and moved to the cell membrane for recognition by T cells. B cells bind antigen to specific cell surface receptors. All the antigen-presenting cell types enter the blood stream and carry the surface molecules to the lymph nodes where T cell activation takes place, although some may occur locally (Figure 5-8).[16] Each type of antigen-presenting cell carries different types of antigen. The T cells respond not only to the antigen but also to the modified complex in the cell membrane of the antigen-presenting cells. Being stationary, the odontoblast does not participate directly in the activation of T cells but, presumably, activates dendritic cells.

HISTOLOGIC CHANGES IN THE EARLY STAGES OF CARIOUS ATTACK DURING THE NONSPECIFIC IMMUNE RESPONSE ("ACUTE INFLAMMATION")

The classic description of the histology of the inflamed dental pulp beneath caries was published by Seltzer et al. in 1963.[27] They attempted, with limited success, to find a relationship between the clinical presentation of the patient and the histology of the pulp. In doing so, they looked at many examples of pulpitis at many different stages. This and other studies[19,20] have made it possible to put together a hypothetical description of pulpal changes during the progression of dental caries.

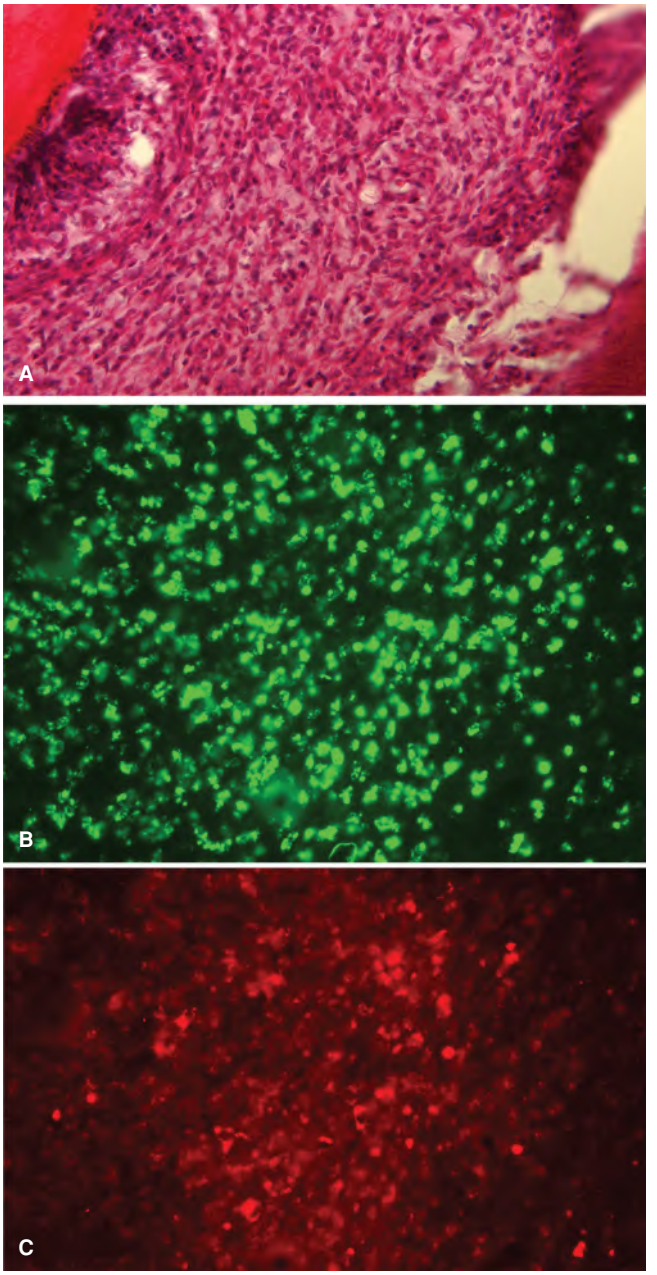

FIGURE 5-10 ***A.*** Area of inflammation in a pulp exposed 1 week earlier and left untreated (hematoxylin and eosin). ***B & C.*** Same section of the pulp photographed through different color filters after immunofluorescent staining. In ***B,*** the staining for β-endorphin is seen and in ***C,*** the staining for T lymphocytes. Some cells are labeled by both stains indicating that T lymphocytes produce β-endorphin. (Reproduced with permission from Mudie and Holland.[25])

The description is very much hypothetical as dental caries is a highly variable disease and its progress has never been followed continuously in a single tooth. This description was obtained largely by examining paraffin-embedded sections stained with hematoxylin and eosin under the light microscope. More recently, other approaches have been used, particularly immunohistochemistry, electron microscopy, and molecular techniques. However, the original microscopic description provides a framework on which newer data may be hung.

Cariogenic bacteria in the dental plaque produce a mixture of acids and enzymes that dissolve the mineral elements of enamel and dentin and then digest the organic matrix. The initial removal of mineral makes the enamel more permeable and the bacterial toxins will diffuse well ahead of cavitation. Once the dentin is reached, the toxins and, much later, the bacteria themselves will travel along the dentinal tubules (Figure 5-1). Clearly, variations in the composition and thickness of enamel and dentin, and particularly the patency of the dentinal tubules, will determine the rate at which these toxins reach the pulp. In vital teeth, this movement will be opposed by the outward flow of dentinal fluid. However, toxins reach the pulp at a very early stage relative to surface changes. Brannstrom and Lind[28] looked at a large number of extracted teeth and found that in ~50% of teeth with white spot lesions and no cavitation, there was histologic evidence of inflammation in the underlying pulp (Figure 5-12).

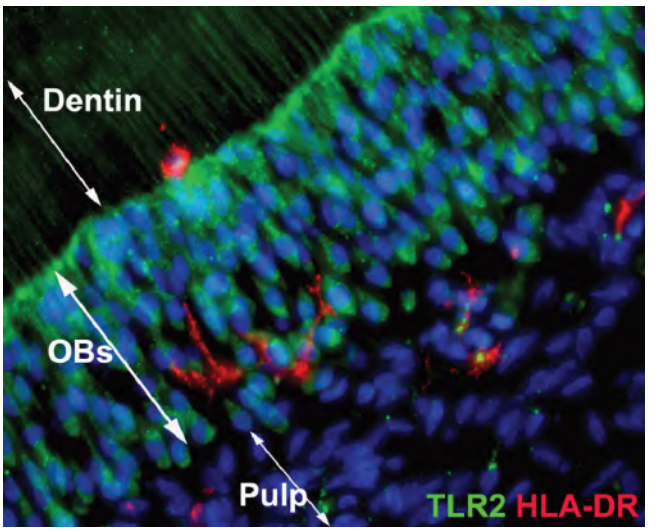

FIGURE 5-11 Immunohistochemistry showing TLRs (green) for bacterial components on odontoblasts (blue nuclei). Some dendritic cells are also stained (red). TLRs when activated by bacterial components lead to the release of chemokines that participate in the immune response. (Reproduced with permission from Zhang et al.[18])

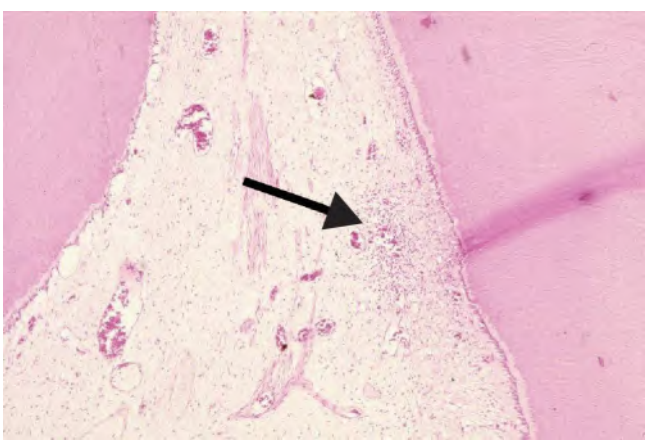

FIGURE 5-12 Early inflammatory response (arrow) beneath a non-cavitated carious lesion (hematoxylin and eosin).

The first cells contacted by the toxic bacterial broth, diffusing down the dentinal tubules, will be the odontoblasts. Some studies describe structural changes in the odontoblast layer even at an early stage. This may not be truly happening when seen in hematoxylin and eosin-stained sections. All histologic procedures are subject to artifacts, and man-made changes are not linked to any biologic change. Teeth that have been examined in this way have probably been extracted with forceps and compressed in the process, causing aspiration and damage to the odontoblast layer. Teeth are then fixed, usually in formaldehyde, which often causes the pulp to shrink away from the dentin. The later stages of preparation, demineralization, embedding in wax, and sectioning may also cause damage (Figure 5-13). From studies using other techniques, we now know that odontoblasts respond to toxins and can create a reactionary dentin barrier. It is more than likely that the morphologic changes reported in the odontoblast layer early in the carious process are artifactual.

With hematoxylin and eosin-stained sections, dendritic cells cannot be distinguished, but macrophages and neutrophils can be distinguished. The macrophages (and dendritic cells) will recognize a foreign antigen and carry its details to the lymph nodes, although this is a histologically invisible process. Resting macrophages (monocytes) enlarge and become active. Neutrophils leave the blood stream by diapedesis and migrate to the scene of action (Figure 5-14). This accumulation of phagocytic cells is dominated numerically by neutrophils, recognizable by their lobed nuclei, and is the key morphologic feature in the early response to caries. Mast cells may also be present,[29,30] but they are difficult to detect in routine preparations due to their extreme fragility. They are most common in surface tissues in response to inhaled or ingested antigens. At the same time, vascular and then neural changes (described elsewhere in this chapter) occur. Nerves are not well visualized in hematoxylin and eosin-stained sections, and observations of changes in them during inflammation require other techniques. Sometimes an apparent dilation of local blood vessels may be seen.

HISTOLOGIC CHANGES IN THE LATER STAGES OF CARIOUS ATTACK DURING THE SPECIFIC IMMUNE RESPONSE ("CHRONIC INFLAMMATION")

The immediate "inflammatory" phase of the immune response begins very shortly after the antigen arrives in the tissue. If the body has been exposed to the antigen on a previous occasion, then the record of that exposure will have been maintained by the memory T cells. The production of lymphocytes synthesizing specific antibodies will begin very quickly (within a few hours). If the antigen has not been encountered before, new clonal lines of lymphocytes will be developed, which takes several days. In either case, the production of specific lymphocytes will take place in the lymph nodes. With a known antigen, however, there may also be a second challenge, a local interaction between antigen-presenting cells and resident T lymphocytes.[16]

Whether the antigen is new or returning, the histologic appearance of the tissue will be the same, only the time scale will be different. At this stage, the appearance of the pulpal response is characterized by the dominating presence of lymphocytes (Figure 5-15). The numbers of lymphocytes present increases with the severity of clinical symptoms.[21]

A commonly used definition of chronic inflammation, often called a granuloma, is "inflammation of slow progress marked chiefly by the presence of lymphocytes and the formation of reparative tissue" (Figure 5-15). This is commonly seen in the dental pulp of extracted carious teeth, some of which may have been asymptomatic.

The pulp is a remarkably robust tissue and can, by the production of tertiary dentin, protect itself from persistent

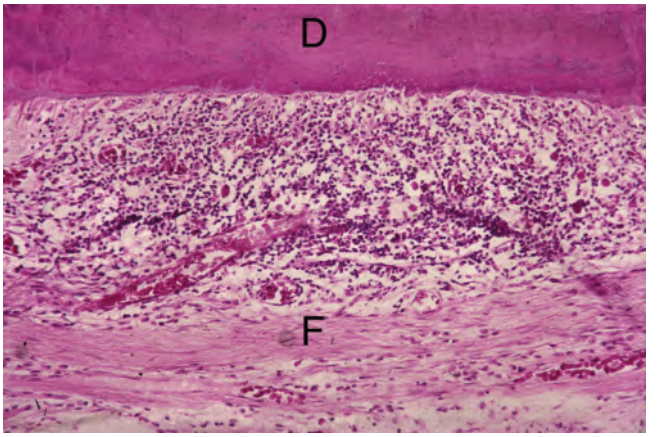

FIGURE 5-15 Chronic inflammation (D = dentin). An attempt at fibrous repair (F) is made at the same time as inflammation. The inflammatory cells are predominantly lymphocytes (hematoxylin and eosin). (With permission from Dr. Henry Trowbridge, San Francisco, CA, U.S.A.)

carious attacks. If the carious lesion is not treated, however, the increasing quantity of irritants will eventually cause irreversible changes. These are at first limited in size and may even form a "pulpal abscess." The bulk of the tissue around it appears healthy (Figure 5-16). This local necrosis, unless checked, will progress gradually throughout the tissue and into the periradicular tissues. The progress of tissue damage in the pulp is determined by the presence and spread of microbial toxins and is not due to the "strangulation" of blood vessels.

HEMODYNAMIC CHANGES IN THE PULP DURING CARIES

An understanding of the vascular component of the immune response in the dental pulp is critical to planning or executing vital pulp therapy. Unfortunately, there are relatively few studies on pulpal vascular changes under carious lesions in humans.[31–36] Several investigators have looked at the effect of experimentally induced inflammation in animal models.[37–41] There are some excellent reviews of the vascular physiology of the dental pulp[40] as well as the description given in Chapter 2, "Structure and Function of the Pulp–Dentin Complex."

Blood Flow

Measuring blood flow in the dental pulp, even in experimental animals, is a difficult procedure, and data generated are a challenge to interpret. Using plaque extract to initiate inflammation in a rat incisor model, Kim et al.[42] reported a 40% increase in blood flow in a "moderately inflamed" pulp but a 35% reduction in a "partially necrotic" pulp. Another study by Bletsa et al.,[41] in a similar model, showed that the application of LPS to the pulp resulted, after 10 minutes, in a reduction in blood flow that continued for the 3-hour duration of the experiments. This was interpreted as a limited ability of the pulp to respond.

Interstitial Fluid Pressure

The healthy dental pulp has an interstitial pressure of 5 to 10 mm Hg.[37,43] One of the key changes during inflammation is the movement of fluid from within the capillaries into the interstitial space. By the laws of physics, increasing the amount of fluid in a rigid chamber leads to an increase in pressure. It was assumed, for a long time, that there was such a pressure rise in the pulp and that it would cause compression of the blood vessels leading to vascular stasis and necrosis. It was even suggested that this pressure change could lead to strangulation of the vessels at the apex causing necrosis in areas of the pulp not directly affected by the bacterial toxins.

Experimental work by Tonder and Kvinnsland[37] (later Heyeraas) and Van Hassel[43] measured interstitial fluid pressure in the pulps of experimental animals and showed that although the pressure increased in the area immediately beneath an injury a short distance (2 mm) away, the pressure stayed within normal limits. Even within areas of raised interstitial fluid pressure, capillaries remain patent because of a balancing increase in intra-luminal pressure. The increased interstitial fluid pressure may be beneficial as, when combined with increased capillary permeability, it would lead to an accelerated rate of fluid exchange across the capillary membrane.[40] Any net increase in tissue fluid, especially macromolecules, will be removed by the lymphatics. The presence of lymphatics in the dental pulp has been controversial, but studies using ultrastructural and histochemical techniques

have established their existence.[44–46] Necrosis occurs beneath persisting carious lesions only when bacterial toxins poison cells directly, spreading throughout the pulp.

Changes in blood flow and pressure are an integral part of the immune/inflammatory response and thus a component of the normal process of limiting the extent of damage and initiating repair. The detailed physiology of the microcirculation is complex and varies considerably between tissues (e.g., brain, kidney).[41] In the dental pulp, it is particularly difficult to study. This contributes to the difficulties of precise diagnosis. Although there have been many attempts to measure pulpal blood flow clinically, none has been validated as completely accurate.

NEURAL CHANGES DURING PULPAL INFLAMMATION

Sympathetic nerves control blood flow by constricting precapillary sphincters[47–49] and by interacting with other elements of inflammation. In other sites, sympathetic activity inhibits the production of proinflammatory cytokines although stimulating the production of anti-inflammatory cytokines[50] and is involved in the recruitment of inflammatory cells to the area.[23,51,52] Sympathetic nerves have an inhibitory effect on odontoclasts and stimulate reparative dentin production, although they have no apparent effect on the degree of inflammation induced by mustard oil.[53] There is less abscess formation 4 days after deep cavity preparation in normal teeth when compared with sympathectomized teeth.[51] Nor are there differences in the extent or severity of inflammation after pulp exposure injury in sympathectomized rat molars after a waiting period of >20 days.[51]

Afferent sensory fibers from the trigeminal system also play an important role in response to toxins and injury. The afferent fibers release two important neuropeptides, substance P and calcitonin gene-related peptide (CGRP). Both cause vasodilatation and increased capillary permeability. Sympathetic activity causes vasoconstriction and also reduces the release of peptides from afferents. Thus, the sympathetics and the afferents seem to act in opposing directions.

In injured pulps, there is an increased expression of nerve growth factor (NGF) and its receptors.[54,55] A concomitant sprouting of the afferent terminals and increased presence of substance P and CGRP[55–60] also takes place. Sprouting of sensory nerve fibers occurs as early as 1 day after dental injury[61] and decreases 3 to 4 weeks after pulp exposure injury, a time when sympathetic nerve sprouting occurs.[62–65]

Pulpal injury and inflammation are also associated with neural changes outside the pulp itself. In the trigeminal ganglion after pulpal injury, the expression of various neuropeptides increases,[66,67] Trk-B receptors (associated with pain) increase,[68] and nitric oxide synthesis is enhanced.[69] There are also detectable changes in the supporting cells of the ganglion.[70] In the trigeminal nucleus (pars caudalis has been the most studied), pulpal injury and inflammation lead to degenerative changes[71] and to cFos expression, an indication of possible changes in the pain system.[72] Perhaps, most significantly from a clinical point of view are changes in the nucleus related to central sensitization.[73–77] This may help explain the variable presentation of pulpitis in terms of pain. For more details, see Chapter 7, "Dental Innervations and Pain of Pulpal Origin."

ANTI-INFLAMMATORY AND ANTINOCICEPTIVE MECHANISMS IN THE DENTAL PULP

During inflammation, there are important interactions between the nervous and immune systems.[78] Neuroimmune interactions control pain through the activation of opioid receptors on sensory nerves by immuno-derived opioid peptides.[79] Opioid-containing leukocytes migrate to peripheral sites of inflammation. On exposure to stress, opioid peptides are released, bind to opioid receptors on peripheral sensory neurons, and induce endogenous antinociception. Although much of the research in this area has been done on skin and joints (in relation to arthritis), the efficacy of adding as little as 1 mg of morphine to the local anesthetic used in oral surgery has been demonstrated.[80] Although no published studies focus directly on the effect of local opioids on pulpalgia, the underlying elements have been demonstrated. Opioid receptors are present on pulpal nerves[22,81] and β-endorphin has been shown to be present in, at least, lymphocytes in the inflamed pulp (Figure 5-10).[25] For more details, see Chapters 2 and 7. It is important to see this as a part of the pulpal response to injury. The extent of this antinociceptive mechanism may be variable depending on, for one possibility, the exact nature of the antigen presented. This may, in part, explain the wide variation in the pain experienced as a result of pulpal inflammation.

LESS COMMON PULPAL RESPONSES: CALCIFICATION AND RESORPTION

Calcification of the pulp takes a variety of forms. Discrete pulp stones occur in a large proportion of the population. In a study of young adults (dental students), 46% of the group had radiographic evidence of pulp stones in at least one tooth. Ten percent of all the teeth included in that study contained a pulp stone.[82]

The vast majority of pulp stones are found in molars (Figure 5-17). Pulp stones can be classified as true or false as they can resemble tubular regular dentin or bone with cells embedded in it. They are also classified as free, adherent, or embedded when they become part of the dentinal walls (Table 5-1).[83] Although the etiology of pulp stone formation is unknown, there is evidence that pulp stones are more common in patients with atheromatous cardiovascular disease (74%) than in those without (39%).[84] Pulp stones are not considered pathological, but act as an obstacle in locating and instrumenting root canals.

A higher incidence of pulpal mineralization is associated with some genetic disorders, such as Ehlers–Danlos syndrome[85] and amelogenesis imperfecta.[86] A generalized, more

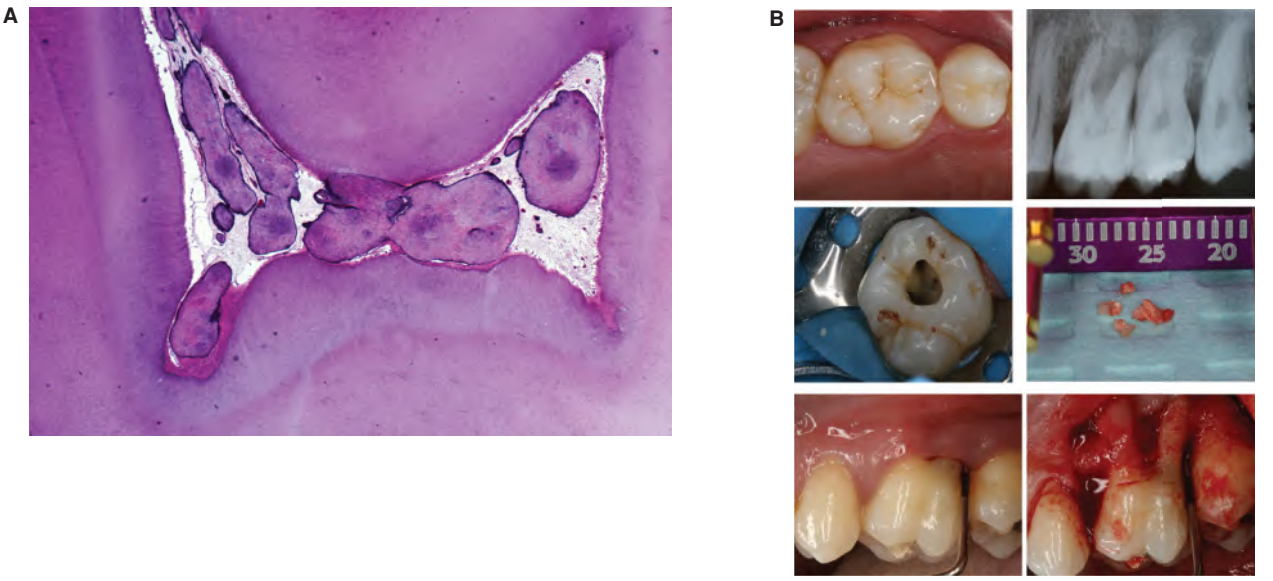

FIGURE 5-17 ***A.*** Multiple pulp stones in the pulp chamber of a molar (hematoxylin and eosin). With permission from Dr. Henrry Trowbridge, San Francisco, CA, UA. ***B***. Pulp stones from a periodontally involved maxillary molar of a healthy 28-year-old patient. Tooth responded normal to cold and electric pulp tests. Root canal treatment was done since the distal root was planned for amputation. Multiple calcifications were found during access opening. No pulp stones could be detected in the adjacent teeth. (With permission from Dr. Hector Rios and Dr. Tatiana Botero, Ann Arbor, MI, U.S.A.)

TABLE 5-1 Terminology

Pulp stone	True	Made of dentine and lined by odontoblasts.
	False	Formed from degenerating cells which mineralize.
	Free	Stone not related to pulp space wall, surrounded by soft tissue.
	Adherent	Stone attached to wall of pulp space, not fully enclosed by dentine.
	Embedded	Stone enclosed within canal wall, less attached than the above.
Denticle		An alternative term for pulp stone, more usually a calcification filled with epithelial remnants surrounded by odontoblasts.
Fibrodentine		Material produced by fibroblast-like cells against dentine prior to differentiation of a new generation of odontoblast-like cells.
Dystrophic calcification		Inappropriate biomineralization of the pulp in the absence of mineral imbalance.

Classification for dental pulp stones. Reproduced with permission from Goga R et al.[83]

diffuse dystrophic mineralization of the pulp may occur after trauma[87,88] and is one of several good reasons for follow-up radiographs. In these patients, a characteristic color change is noticeable as they become more yellow while the pulp chamber and canal space are filled by reactionary and reparative dentin. The majority of these teeth will not require endodontic therapy. Only <10% might become necrotic and develop a periapical lesion.[89,90]

Internal resorption has been considered an alternative sequela to trauma although most of the literature on this condition consists of case reports (Figure 5-18). The difficulty in establishing a correlation with trauma is probably related to the length of time between the traumatic incident and the diagnosis.

The internal root resorption is asymptomatic but progressive. This lesion may eventually perforate the root or crown. This type of resorption can be extensive and may

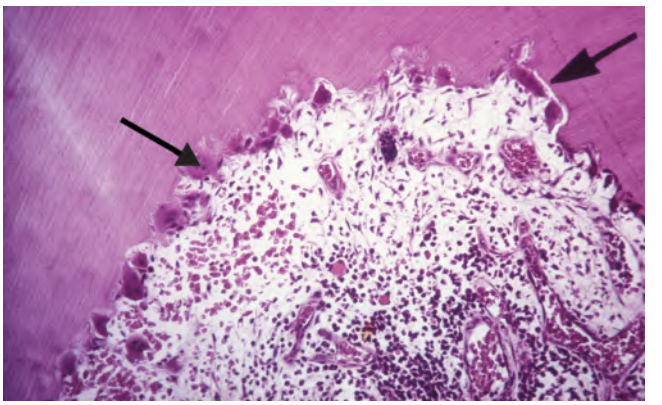

FIGURE 5-18 Internal resorption. Multinuclear odontoclasts can be seen within lacunae in the dentin (arrows) (hematoxylin and eosin). (With permission from Dr. Henrry Trowbridge, San Francisco, CA, U.S.A.)

become a coronal pink discoloration that is often misdiagnosed as caries. Internal resorption has also been found as microscopically small lesions in teeth with pulpitis and necrosis.[91] Damage to the predentin layer leads to a direct contact of the inflamed tissue and the exposed dentin. The odontoclast (differentiated from circulating monocytes) would start resorbing dentin and replacing it with granulation tissue. Although internal irresorption can be transient or progressive. When internal resorption is diagnosed, the pulp should be extirpated to stop this irreversible process.[92,93] For more details, see Chapter 15, "Pathologic Tooth Resorption."

WHEN THE PULPAL RESPONSE SUCCEEDS: REPAIR AND REGENERATION

The immune response, including inflammation, is only one part of the pulp's total response to toxins or injury. When effective, this response neutralizes and removes any foreign material and allows recovery, repair, and regeneration. The repair process can take several forms. The most obvious distinctions relate to the severity of the injury. When no cells are killed, the original odontoblasts can form reactionary (tertiary) dentin (Figure 5-19). When the odontoblasts are killed, new dentin-forming cells develop from stem cells and form reparative (tertiary) dentin (Figure 5-20).[94,95] The repair of larger areas of damage is more variable and depends on the nature of any clinical intervention. It seems that normally organized pulp tissue does not re-form. An example of extensive tissue damage from which the pulp recovers is the pulp polyp (Figure 5-21). Rapidly advancing caries in young molars can result in collapse of the crown with a large but self-cleansing pulp exposure. Epithelial cells from the oral mucosa settle on the exposed pulp and form an epidermis (Figure 5-22). This phenomenon attests to the pulp's ability to respond to injury but is futile as the molars involved are often not restorable.

Sometimes, the progress of caries and the defensive response can reach a stalemate. The irritant continues but is contained. This, by one definition, is chronic inflammation with injury and repair occurring at the same time. Many inflammatory cells, largely lymphocytes, are present as well as areas of fibrous tissue representing an attempt to "wall off" the diseased tissue.

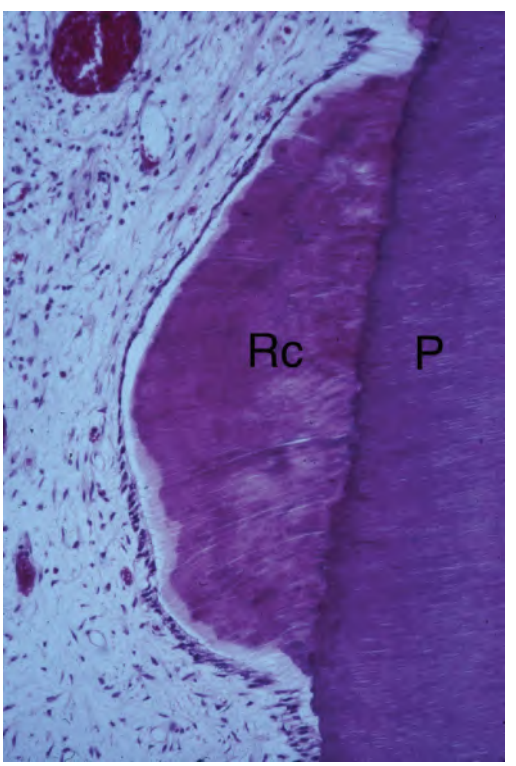

FIGURE 5-19 Reactionary (tertiary) dentin (Rc) developed beneath a deep cavity preparation. The tubules in the reactionary dentin are continuous with those of the primary dentin (P) (hematoxylin and eosin). (With permission from Dr. Henry Trowbridge, San Francisco, CA, U.S.A.)

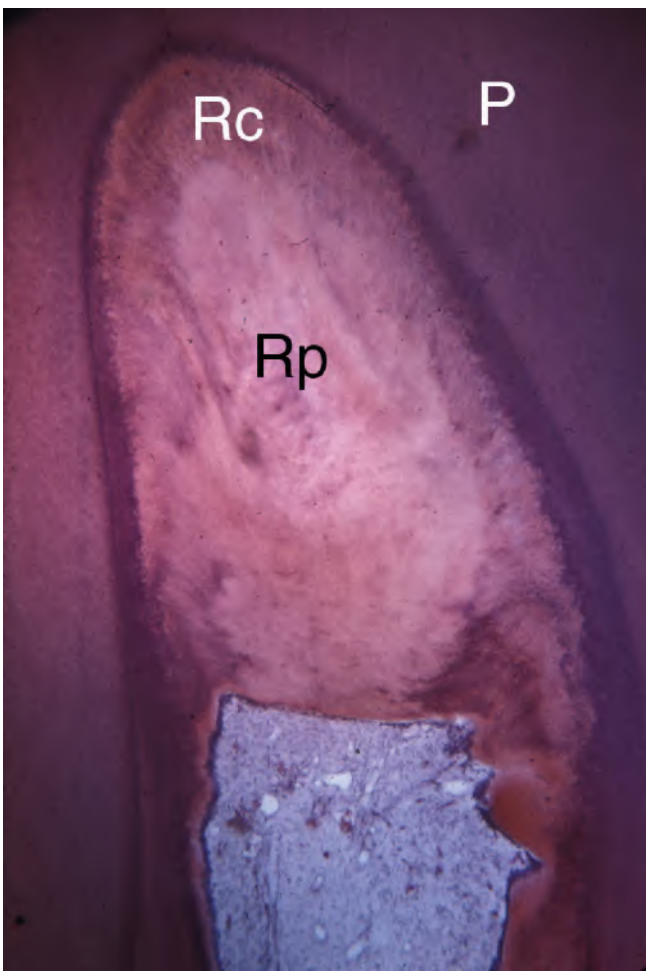

FIGURE 5-20 A layer of reactionary (tertiary) dentin (Rc) formed beneath an injury has then become severe enough to kill the original odontoblasts. It resulted in the formation of atubular reparative (tertiary) dentin (Rp), which has been formed by new odontoblasts (P = primary dentin) (hematoxylin and eosin). (With permission from Dr. Henrry Trowbridge, San Francisco, CA, U.S.A.)

FIGURE 5-21 Pulp polyp, also known as hyperplastic pulpitis (arrows). Caries of the mandibular first permanent molars in a young patient has proceeded so quickly that the walls of the cavity collapsed, leaving a largely self-cleansing area. The pulp survives and its surface colonized by epithelial cells shed from the buccal mucosa. (With permission from Dr. Henry Trowbridge, San Francisco, CA, U.S.A.)

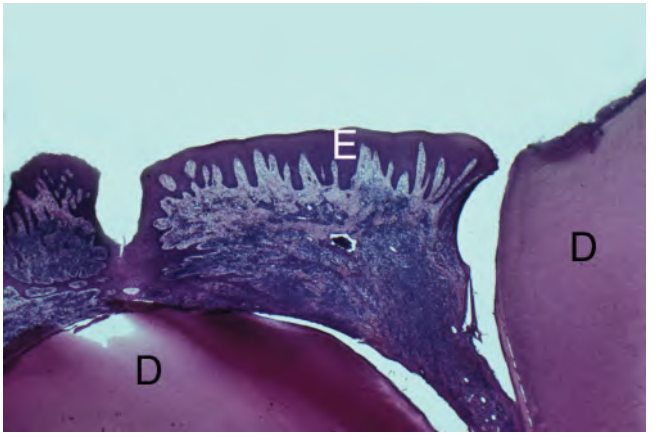

FIGURE 5-22 Structure of a pulp polyp. The epithelial cells shed from the buccal mucosa form an epithelium (E) that is normal in appearance. Dentin (D) is present on each side of the polyp that has a dense infiltrate of inflammatory leukocytes (hematoxylin and eosin). (With permission from Dr. Henry Trowbridge, San Francisco, CA, U.S.A.)

ENCOURAGING A SUCCESSFUL RESPONSE

From a clinical standpoint, it is important to recognize that the pulp has a strong innate ability to respond and repair. Most of our strategies for encouraging pulpal repair involve removal of the irritant and diseased tissue and prevention of further injury. Calcium hydroxide, for example, probably does nothing directly to stimulate reparative dentin formation but is permissive of the pulp's inherent activity. For >50 years, calcium hydroxide has been considered the standard of care for direct and indirect pulp capping. The advent of new materials derived from mineral trioxide aggregate (MTA) classified as bioceramics or tricalcium silicate cements set by a hydration reaction forming calcium silicate hydrate and calcium hydroxide ($CaOH_2$). Bioceramic cements have stimulatory activity, but their main property are due to the high level of biocompatibility and their success in preventing recontamination.[96] With the discovery of biologically active molecules such as growth factors and matrix proteins, there are now more possibilities of stimulating repair.[97,98] The development of cultures of pulpal stem cells from human permanent teeth (DPSC)[99] or deciduous teeth (SHED)[100] and supporting scaffolds may allow tissue regeneration. Neither of these approaches is, at present, ready for clinical adoption.[101]

FACTORS LIMITING THE PULP'S RESPONSE

The only significant factor that limits the pulp's ability to respond to injury is age. The older pulp has a reduced number of cells,[102] innervation,[103] and vascularity,[104,105] but the immune response remains active.[94,95]

CLINICAL PROCEDURES

Local Anesthetics

Local anesthetics reduce pulpal blood flow by approximately half when they contain vasoconstrictors.[106,107] This effect is almost due to the vasoconstrictor. It is important to remember that when preparing a cavity in an anesthetized tooth, the pulp is in a suboptimal condition to respond. Much of what we know about the pulp's response to cavity preparation and materials has been from animal experiments in which general, rather than local, anesthetics were used.

Heat During Cavity and Crown Preparation

Experimental Observations

The basic effect of heat on mineralized tissue has been best documented on bone.[108–111] From this work, a value of 10°C above body temperature is frequently cited as the threshold to cause irreversible damage to vital tissues.[108] Higher temperatures and increased application times lead to greater damage. An increase of surface temperature to 47°C held for only 1 minute, resulted in minor reversible injury. Increasing the duration to 5 minutes caused irreversible damage to calcified bone and marrow. Raising the temperature to 50°C but reducing the duration back to 1 minute produced injury similar to the injury caused by raising the temperature to 47°C at 5 minutes. Temperatures of 60°C and higher, will result in bone necrosis.[108] Severe cold will also damage tissue. The formation of water crystals

within cytoplasm will kill a cell. This occurs at a temperature of ~2°C below zero,[112] a temperature never likely to be experienced in the mouth.

Moderate elevation of temperature on the external surface of a tooth can raise the internal temperature of the pulp to the point that injury occurs. A temperature increase of 5.5°C above body temperature, as observed by Zach and Cohen,[113] is frequently cited as the threshold for damage to the pulp. This observation was made after applying a soldering iron preheated to 275°C to the teeth of monkeys for a limited time. When the same temperature was applied for a longer period of time, generating an 11.1°C increase in pulp temperature, 60% of pulps became necrotic. However, this very abrupt application of high heat may not translate directly to clinical situations.

Baldissara et al.[114] applied a gradually increasing heat stimulus until the patient indicated sensitivity then sustained it for 30 seconds. The temperature change across the dentin was measured after extraction. The maximum temperature increase was 14.7°C reaching a measured temperature of 50.9°C. Histologic examination of the heated pulp revealed neither necrosis nor alteration of the odontoblast layer. All the patients remained symptom free throughout the duration of the study, and all teeth responded to cold testing just before extraction.[114] These *in vivo* experimental observations were made on un-restored, noncarious human teeth, scheduled for extraction for orthodontic treatment. As these patients are of young age, their pulps will have a good blood supply and will not have been affected by previous injury. This model may not be fully revealing the effects of heat on the mature pulp.

The more moderate pulp responses observed by Baldissara et al.[114] are derived from earlier studies. Pulps from human subjects that were examined immediately and 1 month after a 30-second application of 150°C to 0.5-mm-thick dentin were found to have localized areas of injury although no pulps were completely necrotic.[115] The most common histologic observation was a breakdown of the odontoblast layer. Some of the pulps had localized areas of necrosis. The affected areas were not surrounded by inflammatory cells. None of these injuries was symptomatic. Other studies have reported similar results.[116,117] It appears that the dental pulp has some capacity to adapt to a moderate, gradually increase in temperature.

Cutting Dentin

The amount of heat produced during cutting of dentin is determined by the sharpness of the bur, the amount of pressure exerted on the bur, and the length of time the cutting instrument contacts tooth structure. The temperature on the surface of a rotating dental bur in contact with dentin has been reported to be as high as 417°C.[116] High-speed air-driven handpieces require an effective method of cooling the tooth in order to safely use these handpieces. The two cooling methods most frequently applied are air cooling and water cooling. Pulp temperatures with air cooling alone rise to 60°C, whereas with water cooling, it falls to 26°C (11°C below body temperature).[118]

Damage has been observed in the pulps of teeth cut with air cooling only.[119] Odontoblasts were dislocated into dentinal tubules and there were vacuoles throughout the odontoblast layer. By contrast, with water-cooling, displacement of odontoblasts occurred in less than half of the teeth and was less marked when it did occur. Fifteen days after cavity preparation, inflammation was noted in all the pulps under cavities prepared with air-cooling only. On the other hand, inflammation occurred in only 25% of water-cooled group. In both groups, recovery occurred within 200 days with the formation of tertiary reparative dentin. Dentin is a good insulator and thus careful cutting is not likely to damage the pulp unless the thickness of dentin between preparation and pulp is <1.0 mm.[119] Even then, the response should be mild.

The "blushing" of dentin during crown preparation is thought to be due to frictional heat resulting in vascular injury (hemorrhage) in the pulp.[115] The dentin takes on an underlying pinkish hue soon after the operative procedure. The most intense level of frictional heat is generated with a large diamond bur when teeth are prepared for a full crown. Crown preparation performed without the use of a coolant leads to a marked reduction in pulpal blood flow, presumably because of vascular stasis and thrombosis.[120]

The safest way to prepare tooth structure is to use ultra-high speeds of rotation (100,000–250,000 rpm), with an efficient water-cooling system, light pressure, and intermittent cutting. During cutting at high speeds, the revolving bur creates an area of turbulence that tends to deflect a stream of water. Therefore, an air-water spray with sufficient volume and pressure must be used if the coolant is to overcome the rotary turbulence. The bur–dentin interface should be constantly wet. Cavity preparation with a low-speed handpiece, sharp bur, and light, intermittent pressure is only slightly more injurious than cutting at high speeds. Hand instruments and low-speed cutting are relatively safe ways to finish a cavity preparation, rather than using a high-speed handpiece with the water coolant shut off.[116,117]

Lasers

The use of laser beams to fuse enamel and reduce the likelihood of carious invasion has been suggested.[117] Different lasers with different energy levels may also be used to remove caries. Certain types of lasers can generate a marked increase in temperature within dentin and pulp tissue.[121] Proper power setting, time of application, and use of water spray will moderate the temperature increase to levels below the heat threshold of pulp damage.[122,123]

Pins

Pulp damage may result from pinhole preparation or pin placement. Coolants do not reach the depth of the pin preparation. During pinhole preparation, there is always the risk

of pulp exposure. Furthermore, friction-locked pins often produce micro-fractures that may extend to the pulp, subjecting the pulp to irritation and the effects of microleakage. The use of pins should be discouraged and, with the introduction of newer adhesive materials, their use is no longer necessary.[124,125]

Cavity Cleansing

A prolonged blast of compressed air, aimed onto freshly exposed vital dentin, will cause a rapid outward movement of fluid in patent dentinal tubules.[126] Tubule diameter midway between the pulp and the dentin-enamel junction (DEJ) is only 1.5 μm. Therefore, the removal of fluid from the tubules by a blast of air activates strong capillary forces. These, in turn, lead to a rapid outward flow of dentinal fluid.[127] Fluid removed from the tubules at the dentin surface is replaced by fluid from the pulp.

The rapid outward flow of fluid in the dentinal tubules stimulates nociceptors in the dental pulp producing pain. Rapid outward fluid movement may also result in odontoblast displacement.[127] Odontoblasts are dislodged from the odontoblast layer and drawn outward into the tubules. Within a short time, the displaced cells undergo autolysis and disappear. When the pulp has not been severely injured either by caries or by other factors, displaced odontoblasts are replaced by new cells derived from stem cells deeper in the pulp. In this way, the odontoblast layer is reconstituted by "replacement" odontoblasts capable of producing tertiary dentin. Even vigorous drying of dentin alone does not result in severe injury to the underlying pulp.

Drying agents containing lipid solvents, such as acetone and ether, have been used to clean cavity floors. Because of their rapid rate of evaporation, application of these agents to exposed dentin produces strong hydrodynamic forces in the tubules causing odontoblast displacement. Cavities should be dried with cotton pellets and short "soft" blasts of air rather than harsh chemicals. Disinfectants have, in the past, been used in cavity cleansing. There seems to be no particular benefit to this, and they are now rarely used as they are potentially toxic to the pulp.

Etching Dentin/Smear Layer

Cutting dentin results in a smear layer on the cut surface consisting of fragments of microscopic mineral crystals and organic matrix.[128–134] This layer may interfere with the adhesion of restorative materials although some newer bonding agents bond well to the smear layer. Acidic cavity-cleansing products and chelating agents have been used to remove the smear layer, but the use of these depends on the nature of the restorative material. The smear layer does have one desirable property. By blocking the orifices of dentinal tubules, the smear plugs greatly decrease the permeability of dentin. While the smear layer is semipermeable, it is not a barrier to microorganisms or their products.

Complete dissolution of the smear layer opens the dentinal tubules thereby increasing the permeability of dentin. If the dentin is left unsealed, the diffusion of irritants to the pulp may intensify and prolong the severity of pulpal reactions. Available experimental evidence is contradictory. Some evidence indicates that etching, as a step in restoration, may reduce microleakage.[135] Other evidences suggest that etching causes pulpal damage, when the thickness of the remaining dentin is <300 μm (RDT).[136]

In the absence of microleakage, acid etching of dentin does not appear to produce injury to the pulp because calcium and phosphate ions are released, producing a buffering action. Even when placed in deep cavities, acid etchants produce only a small increase in hydrogen ion concentration in the pulp.[137]

Impressions, Temporary Crowns, and Crown Cementation

Temperatures of up to 52°C have been recorded in the pulp during impression taking with modeling compound. Modeling compound may be damaging because of the combination of heat and pressure.[138–141] Fortunately, this technique is no longer used. Rubber base and hydrocolloid materials do not injure the pulp. The heat generated during the exothermic polymerization of autopolymerizing resins may injure the pulp. Cooling is strongly recommended when provisional crowns are fabricated directly. Before cementing provisional crowns, the crown preparation should be carefully lined with temporary cement to minimize microleakage. The cemented temporary crown should be in place for a short period of time; temporary cements are not stable and will eventually wash out. Microleakage around temporary crowns is a common cause of postoperative sensitivity. During the cementation of crowns, inlays, and bridges, strong hydraulic forces may be exerted on the pulp as cement compresses the fluid in the dentinal tubules.[142] In deep preparations, this can result in a separation of the odontoblast layer from the predentin. Vents in the casting will allow cement to escape and facilitate seating. The pulps of heavily restored teeth that have overcome all these procedures are at risk of developing necrosis.[143]

DENTAL MATERIALS

Microleakage

The most important characteristic of any restorative material, related to its effect on the pulp, is its ability to form a seal that prevents the leakage of microorganisms and their byproducts onto dentin and then into the pulp.[2,136,144]

Cytotoxicity

Certain restorative materials are composed of chemicals having the potential to irritate the pulp. However, when placed in a cavity, the intervening dentin usually neutralizes or prevents leachable ingredients from reaching the pulp in a high enough concentration to cause injury. For example, eugenol in zinc oxide-eugenol (ZnOE) is potentially irritating but

very little can reach the pulp. Phosphoric acid is a component of silicate and zinc orthophosphate (ZnOP) cements and was thought to be highly injurious to the pulp. However, the buffering capacity of dentin greatly limits its penetration. It is now clear that the problems reported following use of these materials were due to their high degree of shrinkage and subsequent microleakage.[4]

Clearly, the thickness and permeability of dentin between a material and the pulp affect the response to the material. In addition, the penetration of some materials through dentin may be limited by the outward flow of fluid through the tubules that will be increased if the pulp is inflamed.[145] This is a factor that has been overlooked in many *in vitro* studies focusing on the passage of materials through dentin.

Many studies on cytotoxicity focus on isolated cell types in culture and do not take into account the immunocompetent cells present in the intact pulp. Materials may have a differential effect on these cells by either stimulating or inhibiting their activity.[146] Cytotoxicity tests can be used as an initial screening but they are not conclusive in determining their biocompatibily.[147]

Materials are more toxic when they are placed directly on an exposed pulp. Cytotoxicity tests carried out on materials *in vitro*, or in soft tissues, may not predict the effect these materials have on the dental pulp. The toxicity of the individual components of a material may vary.[148,149] A set material may differ in toxicity from an unset material. The immediate pulpal response to a material is much less significant than the long-term response. Upon examination a few days after placement, there may be a strong inflammatory response. After a few months, the inflammatory response may have receded and repair has taken over. The best measure of long-term response is the thickness of tertiary dentin laid down by the affected pulp.

Heat Upon Setting

Many restorative materials have exothermic setting reactions. Temperature increase during setting may be over 10°C[150] but can be limited to 2°C to 3°C.[141,151] Cooling includes the use of both well directed air and water spray.

Some luting cements generate heat during setting; it has been suggested that this might cause pulpal injury. The most exothermic luting material is ZnOP cement. However, during setting, an intrapulpal temperature increase of only 2°C was recorded.[152] Heat of this magnitude is not sufficient to injure the pulp.

Desiccation by Hygroscopy

Some hygroscopic materials may potentially cause injury by withdrawing fluid from dentin. However, little relationship exists between the hydrophilic properties of materials and their effect on the pulp. Moisture absorbed by materials is probably much less than that removed from dentin during cavity drying.[151]

SPECIFIC MATERIALS

Zinc Oxide–Eugenol

ZnOE has many uses in dentistry, with a long history as a temporary filling material, cavity liner, cement base, and luting agent for provisional cementation of castings. Before the introduction of calcium hydroxide, ZnOE was the material of choice for direct pulp capping.[136,153–155]

Eugenol, the most active ingredient in ZnOE, is a phenol derivative and is toxic when placed in direct contact with tissue.[156] It also possesses antibacterial properties.[157] The use of Eugenol in pain control is attributed to its ability to block the transmission of nerve impulses.[158] A thin mixture of ZnOE significantly reduces intradental nerve activity when placed in a deep cavity preparation in cat's teeth; a dry mix of ZnOE has no effect.[159]

When included in cements to temporize crown preparation, some eugenol does reach the pulp, but the amounts are small and unrelated to RDT. In *in vitro* studies, "desensitizing" agents do not seem to reduce the penetration of eugenol, although time does.[160] The movement of eugenol is by a hydrolytic mechanism that is dependent on the presence of fluid. With little fluid available, release is low.[153,154]

The most important property of ZnOE is that it provides a tight marginal seal preventing microleakage. Its superiority as a temporary restorative material is enhanced by its antimicrobial properties.[161]

Zinc Phosphate Cement

ZnOP was a popular luting and base agent. It has a high modulus of elasticity and therefore, was commonly used beneath amalgam restorations before glass ionomer cements were available. The phosphoric acid liquid phase was formerly thought to injure the pulp. Recent studies have shown that this is not the case. Cementation of castings with ZnOP is well tolerated. ZnOP is more likely than glass ionomer to produce pulpal sensitivity at the time of cementation and up to 2 weeks after cementation. However, 3 months after cementation, there is no difference in sensitivity.[162–165]

Polycarboxylate Cement

When placed in cavities or used as a luting cement, zinc polycarboxylate does not irritate the pulp. In cementing well-fitting crowns and inlays, neither polycarboxylate nor ZnOP cements contract enough to permit the ingress of bacteria. Consequently, it is unnecessary to apply a varnish or liner to cavity walls; doing so reduces cement adhesion.[165–167]

Glass Ionomer Cements

The original use of the glass ionomer cement was as an esthetic restorative material, but now it has also found use as liners, luting agents, and pulp-capping materials (sometimes in conjunction with calcium hydroxide). When placed on exposed pulps in non-carious teeth, glass ionomer cement shows a degree of bacterial microleakage similar to that of

composite resins but less than half of the calcium hydroxide cement.[168,169] The incidence of severe pulpal inflammation or necrosis caused by glass ionomer cement on exposed healthy pulps is similar to that for calcium hydroxide but greater than that for composite resins.[169] When placed in cavities in which the pulp is not exposed, and where there is a narrow RDT (0.5–0.25 μm), both calcium hydroxide and composite resin show faster deposition of tertiary dentin than glass ionomer cements.[170]

When used as a luting agent, the pulpal response to glass ionomer cements is similar to that of polycarboxylate and ZnOP cements.[163] For some time after their introduction as luting agents, glass ionomer cements were associated with post-cementation sensitivity. With the use of appropriate technique, the incidence of sensitivity using these agents is not greater than that with other commonly used luting agents.[164]

Calcium Hydroxide

Since its introduction in dentistry by Herman in 1927, calcium hydroxide has been the most widely used material for direct and indirect pulp capping procedures. Calcium hydroxide ($CaOH_2$) has high pH (12.5) and dissociates into Ca^{2+} and OH^{2-} that not only gives antibacterial properties[171,172] to the formulation but also provides a stimulus to induce tertiary reactionary or reparative dentin secretion.[173] When in contact with the pulp, a zone of necrosis is formed and a mild inflammatory reaction occurs. Cells from the core zones migrate, proliferate, and differentiate as odontoblast-like cells to form reparative dentin and gradually forms a dentinal bridge.[174,175] Coronal seal is a priority for success as calcium hydroxide lacks sealing properties.

Mineral Trioxide Agregate and Calcium Silicate Cements

Ideally, materials use to fill root-end preparations should be hydrophilic, which can set in the presence of water. MTA was the first hydrophilic cement developed 20 years ago from a Portland cement formulation. MTA contains tricalcium silicate, dicalcium silicates, and bismuth oxide as radiopacifier.[176,177] The hydration reaction with water or water-containing liquids generates a calcium silicate gel that gets harder after 4 hours or longer. Calcium hydroxide is also released for as long as the reaction is active. After setting, MTA creates a good seal to dentin and materials such as glass ionomer cements, copolymers, and composites. The composition, constant high pH, and the property to release calcium provides MTA several advantages over other materials as a biocompatible pulp capping material.[178,179]

The exposure of MTA to lights can lead to discoloration in the dentin due to the presence of several metals in its original formulation (gray-colored MTA). The long setting time, the sandy consistency, and the possible discoloration of MTA-derived cements have forced the development of newer materials. Some new materials are now available including Endo-Sequence (Brasseler, Savannah, GA, USA), Biodentine, (Septodont, Lancaster, PA, USA), white-colored MTA plus (Denstply, Tulsa, OK, USA), and Theracal (Bisco, Schaumburg, IL, USA) among others.[96,180,181] Most of these new formulations have improved the original MTA cement although more research is needed.

Amalgam

Amalgam alloy has been widely used for restoring posterior teeth. There is shrinkage during setting, which results in microleakage.[182] This decreases as corrosion products accumulate between the restoration and the cavity walls and can be further reduced by the use of liners.[183] Amalgam is the only restorative material in which the marginal seal improves with time. Esthetics and public concern with the mercury content of amalgams have lead to an accelerated use of composite resins as posterior restorative materials instead of amalgam. Their use, however, is more technique sensitive. In deep cavities in posterior teeth, composites have been associated with more pulpal injury than amalgams because of microleakage.[184]

Restorative Resins

The first adhesive-bonded resin composite systems that were developed contracted during polymerization resulting in gross microleakage and bacterial contamination of the cavity. Bacteria on cavity walls and within axial dentin are associated with moderate pulpal inflammation. Over a period of time, some composites absorb water and expand; this tends to compensate for initial contraction. To limit microleakage and improve retention, enamel margins are beveled and acid etched. When compared with unfilled resins, the newer resin composites present a coefficient of thermal expansion similar to that of dentin. With the development of hydrophilic adhesive bonding systems, the problem of marginal leakage appears to have diminished.[184–186]

Although restorative resins themselves do not release substantial heat upon setting, the heat of photo-curing lights can be transmitted through the resin and affect dentin. Time of exposure, thickness of dentin, and type of photo-curing light are factors to consider. Temperatures at the surface of the tips of various light curing units can increase from 49.6°C to 100°C above the temperature before activation.[187] In spite of these very high temperatures, *in vitro* and *in vivo* investigations have consistently demonstrated pulp temperatures below the level that will cause pulp damage.[188–191]

Pulp Capping Materials

Indirect or direct pulp capping is a very common procedure in operative dentistry and requires knowing the status of the pulp, the history of previous injuries, the status of root formation, the periapical condition, and future restoration plans. Calcium hydroxide was the first material introduced as a capping agent. It was considered as the material of choice for many years due to its impressive antimicrobial action as

well as its potential to induce dentinal bridge formation.[171] Many other capping materials have been explored such as hydroxyapatite, dentin chips, growth factors (BMP-1, -7, TFG-B-1,-3, FGF, IGF[192–202] glass ionomers, and composite resins.[197–200] The release of bioactive molecules is a key factor for the reparative dentinogenesis induced by any of these capping agents.[200] As previously described new tricalcium silicate-based materials such as Biodentine and Theracal have shown successful results for patients and clinicians.[201,202] For more details, see Chapter 27, "Vital Pulp Therapy."

POLISHING RESTORATIONS

Polishing glass ionomer and composite restorations does not cause an increased temperature at the pulp-dentin interface.[198] Polishing amalgam restorations, however, can produce temperatures that may be damaging. With high contact pressure, high speed, and no coolant, *in vitro* temperature increases of >20°C have been recorded within 30 seconds.[122] However, a handpiece rotating at 2,500 rpm that was held for 60 seconds with a relatively light (55 gm) force generated a maximum temperature increase of only 6.2°C.[136] This occurred when a Burlew disk without coolant was used as the polishing agent. With air cooling, the increase was 2.0°C. When polishing an amalgam restoration with continuous pressure and no water coolant, it is recommended to not exceed 4,000 rpm.[203] With use of coolant, light pressure, and intermittent contact during polishing, there is a low likelihood of heat-generated pulp damage.

POST-RESTORATIVE HYPERSENSITIVITY

Many patients complain of hypersensitivity after a restorative procedure.[150,164] This may be due to any one or an accumulation of the factors listed above. Discomfort is usually of short duration. If pain is prolonged, a pre-existing pulpitis may have been exacerbated. If delayed in onset by days, the cause may be microleakage of microbial toxins under a poorly sealed temporary restoration. The absence of postoperative sensitivity after restoration with modern composites of both class I and II preparations has been demonstrated in clinical studies, suggesting that variations in technique may be responsible for the anecdotal reports of sensitivity.[199,205] The use of hydroxymethacrylate and glutaraldehyde "desensitizer" does not reduce the incidence of sensitivity.[204] Self-etching, self-priming dentin-bonding systems reduce the incidence of sensitivity following the restoration of deep carious cavities.[130] If pain is evoked by biting on a recently restored tooth, an intracoronal restoration may be exerting a strong shearing force on the dentin walls of the preparation. It is more likely to be due to injury to the periodontal ligament resulting from hyperocclusion. Hyperocclusion from an extracoronal restoration is not injurious to the pulp but may cause a transient hypersensitivity.

VITAL TOOTH BLEACHING

Overnight external bleaching of anterior teeth with 10% carbamide peroxide causes mild pulpitis that is reversed within 2 weeks.[206] In vitro studies show that the principle bleaching agent, hydrogen peroxide, can reach the pulp after application to the enamel.[207] Whether this occurs *in vivo* is unknown. Outward fluid flow in dentinal tubules and other factors would reduce the effect. Both short-term and long-term (9–12 years) clinical observations on bleached teeth reported no significant pulpal changes.[208] Heat-activated bleaching agents can cause intrapulpal temperatures to rise by 5–8°C when measured *in vitro*.[209]

THERMAL SENSIBILITY TESTING

Thermal sensibility testing utilizes media at temperatures that certainly have the potential to damage tissues. Heated gutta-percha reaches a temperature of ~200°C just before the smoke point, and a cold-test substance such as carbon dioxide snow has an inherent temperature of –78°C. A heat-testing device such as the System B (SybronEndo, Orange, CA, USA) with the appropriate tip is recommended to be set at a temperature of 200°C. The question must be asked whether these extreme temperatures are transmitted to the dental pulp during clinical testing and whether there is any likelihood that the tissue may be damaged.

Rickoff et al.[210] reported combined *in vivo* and *in vitro* findings with no damage to pulp tissue following use of flame-heated gutta-percha and carbon dioxide snow. Gutta-percha was heated to the smoke point and then applied to a tooth surface *in vivo*. The gutta-percha remained in contact for 1–10 seconds. For cold testing, a carbon dioxide pencil of 3.5 mm diameter was held to the tooth for 5 seconds to 5 minutes. The teeth were extracted and examined histologically. To measure the temperatures generated at the pulpal–dentin junction (PDJ), a thermistor was placed onto the dentin surface of an extracted tooth and the temperature protocol repeated. Internal temperature was recorded as the external surface was heated to different temperatures. The maximum PDJ temperature reached with heat testing was 39.9°C (10-second application) and for cold was 9.5°C (5-minute application). These temperatures do not reach the thresholds at which tissue damage will occur. The time of heating falls within the range of likely clinical application.[210]

Augsburger et al.[211] observed similar temperature decreases. The greatest temperature drop in their *in vitro* evaluation was 6.3°C. This fall in temperature occurred in a tooth with a full gold crown that received a 5-second application of carbon dioxide snow. The greatest temperature drop in noncarious teeth was 2.5°C (also with carbon dioxide). They also tested water and skin refrigerant that had maximum temperature drops at the PDJ of 2.8°C and 1.8°C, respectively. The greatest temperature transference between adjacent teeth with metallic restorations was a decrease of 1.7°C between a tooth with a gold crown and one with an amalgam. Rickoff et al.[171] observed a similar, very small

temperature drop of 0.9°C, after applying carbon dioxide to four premolar teeth *in vitro*. *In vivo* histologic analysis revealed no alteration from normal tissue appearance after a 2-minute[212] or a 5-minute[213] application of carbon dioxide. When carbon dioxide was held to a tooth for 20 minutes, the pulp showed necrosis of odontoblasts.[213] It is, therefore, safe to conclude that heat and cold testing within normal clinical parameters will not damage the dental pulp.

TOOTH MOVEMENT

Orthodontic tooth movement of a routine nature does not cause clinically significant changes in the dental pulp. For more details, see Chapter 39, "Interrelationships of Endodontics and Orthodontics in Treatment Planning and Patient Treatment."

Responses to pulp testing, especially electrical, may be unreliable.[214] The heavy forces used to reposition impacted canines frequently lead to pulp necrosis or calcific metamorphosis.[215] Intrusion but not extrusion reduces pulpal blood flow for a few minutes as the pressure is applied.[211] Capillaries proliferate in the pulps of moving teeth.[216] A variety of growth factors are produced including vascular endothelial growth factor (VEGF) that may explain this increase in vascularity.[217–219]

REMOVAL OF ORTHODONTIC BRACKETS

Some of the methods of removing brackets at completion of orthodontic treatment have the potential to cause injury to the pulp.[210–224] Brackets may be simply ground off, or pincher-type pliers may be used to mechanically remove the bracket. A third method of bracket removal is use of an electrothermal device (ETD) that heat-softens the bonding composite expediting removal of the bracket. Heat transferred from the ETD has been measured as high as 45.6°C[225] on the pulpal side of dentin in *in vitro* experiments, though most reports have been in a lower range.[220,226–228] When residual composite is removed by grinding, pulp-side temperature actually decreased below ambient temperature when water coolant was used.[220] Metal brackets have a greater capacity to transmit heat to inner dentinal surfaces than ceramic brackets.[217]

In vivo evaluation has recorded much lower temperatures and has reported limited pulpal damage. Jost-Brinkman et al.[229] observed no pulpal inflammation 4 weeks after electrothermally debonding brackets from human teeth. The maximum temperature recorded was 6.9°C over a period of 43 seconds. There has been consensus that electrothermal debonding does not cause gross damage or necrosis of dental pulp. However, there may be limited peripheral disruption of odontoblasts with slight inflammation.[220,223,224]

Periodontal Disease

There is continuing controversy about the effect of periodontal disease on the dental pulp. The majority of evidence shows that, as long as the periodontal involvement does not reach the apical foramen of the tooth, there is minimal pulpal involvement. A histological study on 60 caries-free teeth with different degree of periodontitis demonstrated that the cumulative effect of periodontal disease on the pulp were mainly calcification, reactionary dentin formation and mild pulpal inflammation. These pulpal changes were found mostly when microorganisms were present in the dentinal tubules or lateral canals. Necrosis or total disintegration of the pulp was found only when the main apical foramen was involved.[229,230] The flushing action of the dentinal fluid is the primary protective mechanism of the healthy vital pulp to counter microorganisms and their toxins.[231] For more details, see Chapter 36.

Ultrasonic Scaling

Activation of ultrasonic instruments generates large amounts of heat. Although dentin is not a particularly good thermal conductor, this heat can still transfer through dentin to affect pulp tissue. Ultrasonic scaling of roots requires prolonged contact of an ultrasonic device and the potential for pulp damage exists. As with other heat-generating dental procedures, proper cooling with water prevents gross pulpal damage. In live dogs, ultrasonic scaling did not create heat-induced pulpal damage when water coolant was used. Interestingly, histologic examination did reveal acute pulpitis, but it was attributed to the vibratory effects of the ultrasonic device rather than the temperature.

An interesting phenomenon of ultrasonic dental scalers is that the load of force with which the ultrasonic tip is held against the tooth has a much greater effect (×4) on the heat generated in the dentin substrate than the power setting.[232,233] One investigation found greater heat generation with diamond sonic tips versus smooth surface tips and greater heat production with heavy versus light force (1N and 0.3N).[234] A diamond tip with heavy pressure resulted with in vitro measurement of 36°C increase. When water coolant was used, all measurements were below 4.2°C increase. Proper water-cooling of both ultrasonic and sonic scalers will prevent excessive heat production in the pulp.

Systemic Disease

Although rare systemic disease may affect the pulp, more likely are that pulpal changes are coincidental with the presence of pulpal disease. One relationship that has been postulated is that between cardiovascular disease and pulpal mineralization. An extensive study of 1,432 teeth reported significantly, higher numbers of pulp stones in patients with cardiovascular disorders (15.86%) than other groups (9.35%).[235] Other studies, however, provide very different data. One[236] found that 74% of patients with reported cardiovascular disease had detectable pulp stones, while only 39% of patients without a history of cardiovascular disease had pulp stones.

In patients with diabetes or autoimmune disorders there was no difference in the incidence of pulp stones between

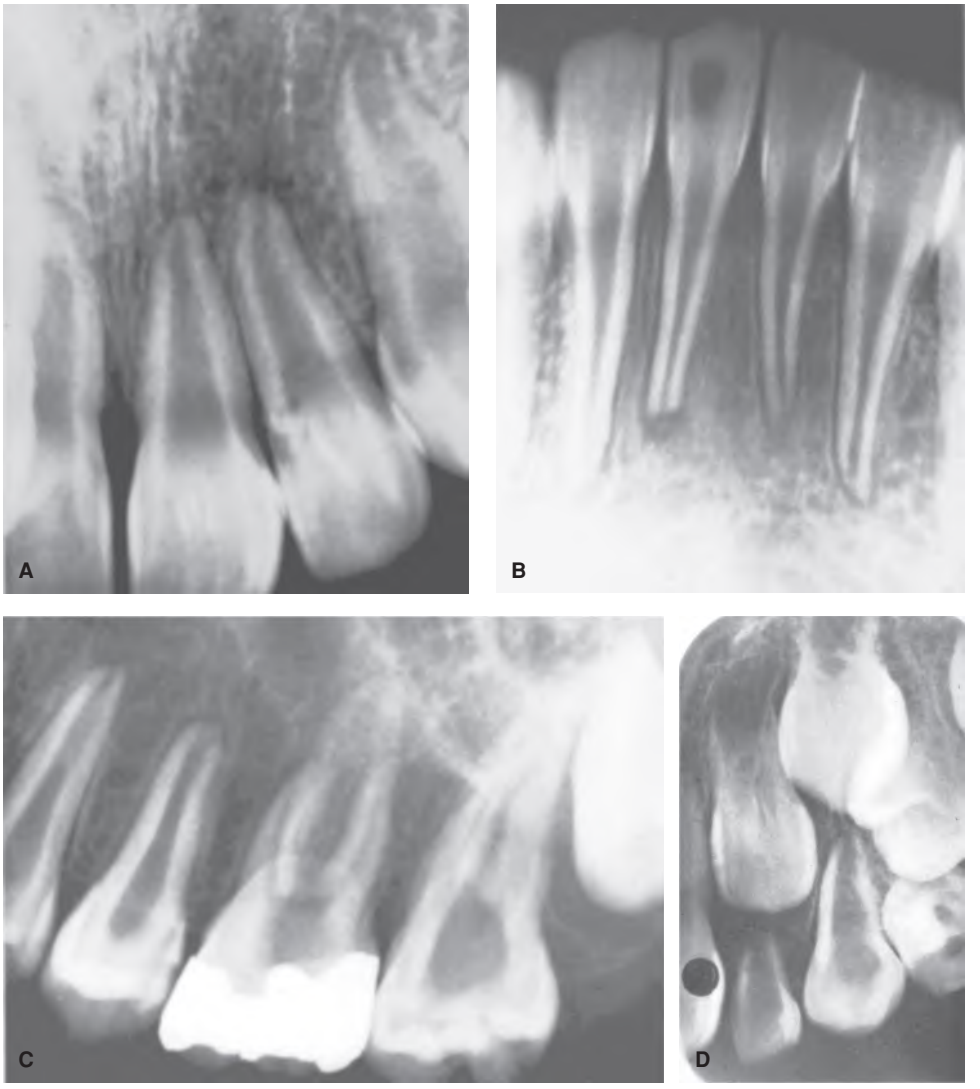

FIGURE 5-23 Unusual pulp dystrophy in *hereditary hypophosphatemia*. Incomplete calcification of dentin and large pulps leave these teeth vulnerable to infection and necrosis. ***A.*** Maxillary incisors at the age of 13. Note large pulp spaces. ***B.*** Mandibular incisors have been traumatized and pulp necrosis has developed. ***C.*** Large pulps can be seen in molar and premolar teeth. The pulp in the first molar later became necrotic. ***D.*** Large pulp size and shape are also apparent in the deciduous dentition. On the basis of these childhood radiographs, diagnosis can be made early about the patient's condition. Timely vitamin D therapy may prevent dwarfing.

patients suffering from diabetes or autoimmune disease and controls.[235] Pulp stones have also been noted in patients with genetic disorders such as dentin dysplasia and dentinogenesis imperfecta.[237]

An unusual and rare cause of pulpal dystrophy and necrosis is found in individuals afflicted with hereditary hypophosphatemia. This disease, which results in dwarfism and "tackle deformity" of the legs, was formerly called refractory rickets, renal rickets, or vitamin D-resistant rickets. Its involvement in dentistry was first reported by Everett and Ingle.[238] It is characterized dentally by the abnormally large pulps and incomplete calcification of the dentin (Figure 5-23). The pulps in these teeth appear to be fragile and succumb to minor irritating stimuli. In one report, the patient had 11 pulpless teeth requiring endodontic treatment.[239,240]

Chapter 6

Periradicular Disease

Domenico Ricucci, Isabela N. Rôças, José F. Siqueira, Jr.

Endodontics is the specialty ultimately involved with the prevention and treatment of periradicular diseases. These diseases are pathologic processes essentially inflammatory in nature. They develop initially in the periodontal ligament (PDL) to affect bone and cementum, and are caused by microbial infection of the root canal space. For more details, see Chapter 3, "Microbial and Nonmicrobial Etiologies of Endodontic Diseases."

Because periradicular lesions usually occur around the root apex, they are also referred to as periapical lesions or apical periodontitis; the latter denomination was recommended by many authors and international endodontic associations. Apical periodontitis is the term preferentially used throughout this chapter. The reader should be aware that periradicular lesions of endodontic origin may sometimes develop laterally to the root, in association with large lateral canals, or in the furcal region, in association with furcal accessory canals. Periradicular diseases are related to the host innate and adaptive immune responses to intra-radicular bacteria in an attempt to contain the spread of the infection to the bone and other body sites.[1–3]

ETIOPATHOGENESIS

Periradicular Tissues Respond Promptly to Bacterial Invasion of the Pulp

The dental pulp is protected from oral bacteria by its natural encasement in mineralized tissues, including dentin, enamel, and cementum. Immediately after tooth eruption, homeostasis of the pulp is constantly at risk during one's lifetime by the loss of the hard tissues. Dental caries is by far the most common cause of pulp breakdown, followed by periodontal disease. However, other causes may threaten the pulp tissue, such as attrition, trauma, cracks, fractures, and restorative procedures. It is important to remember that microorganisms can easily colonize the tubules of exposed dentin[4] and sometimes reach the pulp via tubules, even before a direct pulp exposure is established. This is true for teeth with deep caries lesions[5,6] as well as for teeth with dentin cracks or attrition.[7,8]

The pulp responds to microbial infection of the dentin tubules by mounting an inflammatory response. This involves both innate and adaptive immune responses, triggering the tertiary dentinogenesis process and reducing the permeability of dentin to microbial cells and their metabolic products. Inflammatory changes, including vasodilation (hyperemia), increase vascular permeability, and migration of inflammatory cells can remain reversible for a long period of time.[9] Reversibility of pulpal inflammation can often be achieved after intervention, consisting of complete removal of the diseased tissues followed by placement of an adequate restoration.

Once microorganisms have invaded the pulp, via tubules from a thin residual layer of dentin or pulp exposure, a focus of necrosis usually develops. Initially, this is limited to a small portion of the pulp adjacent to the forefront of the bacterial infection. This area is typically surrounded by severe acute inflammation, then an area of chronic inflammation and finally, at some distance, a histologically normal tissue.[10] From a histologic point of view, the occurrence of a focus of necrosis, even of limited extension, constitutes the point of transition from a reversible to an irreversible inflammatory state.[6,9,10] This process may happen interchangeably with or without clinical symptoms.

Progression of Pulp Degeneration Process

The initial area of necrosis slowly expands to involve increasing areas of the coronal pulp; however, the layers necrosis—acute inflammation—chronic inflammation—uninflamed tissue are always observed. Tertiary dentin and dystrophic calcifications are commonly seen. Radiographic changes in the periapical area are not normally visible in the radiograph during initial stages of pulp tissue degeneration. However, histologic observation allows recognition of early reactions in the apical PDL in some cases with only partial necrosis in the pulp chamber.

The case shown in Figure 6-1 illustrates the condition in which early periapical disturbances are observed with only partial necrosis in the pulp chamber. It is the maxillary third molar of a 70-year-old woman seeking treatment for severe spontaneous pain originating from the upper left jaw and radiating to the ear. A radiograph (Figure 6-1A) revealed an extruded maxillary third molar, due to missing mandibular third molar. It had deep mesial carious lesion originating at the cemento-enamel junction (CEJ), very close to the pulp chamber. Radiographically, thickening of the apical periodontal ligament (PDL) space was present. Diagnosis of irreversible pulpitis was made. The tooth was extracted upon patient´s request. Some soft tissue remained attached to the root apex (Figure 6-1B and C). The root was separated from the crown and the two portions were processed for histology. Histologic sections of the crown, cut on a mesio-distal plan confirmed that the carious lesion was very close to the pulp chamber (Figure 6-1D), although a direct pulp exposure could not be seen in any of

the serial sections. A partly empty space was present in the pulp horn subjacent to the caries with amorphous debris heavily colonized by bacteria, surrounded by a severe concentration of inflammatory cells (Figure 6-1D-F). Bacteria were shown to enter the pulp horn through dentinal tubules (Figure 6-1G).

At a short distance away from the pulp horn, at the root canal orifice, a completely different picture could be observed, with intact odontoblast layers on opposite walls and absence of inflammation (Figure 6-1H). Longitudinal sections of the single conical root cut through the main foramen showed vital tissues in the foraminal area, connected to the periapical soft tissue (Figure 6-1I and L). Early resorption of the apical canal walls could be observed (Figure 6-1L and M). The soft tissue attached to the apical surface was thicker than a normal PDL, and showed abundance of collagen fibers, hyperemic vessels, and scattered chronic inflammatory cells (Figure 6-1J and K). Pulp stones (free and embedded) were present in the apical canal, together with hyperemic vessels (Figure 6-1N-P).

This case clearly confirms that when necrosis and bacterial colonization occur in a limited portion of the pulp chamber, periradicular inflammatory changes may already be observed. The occurrence of these inflammatory reactions

at a considerable distance from the necrotic area colonized by bacteria is possibly explained by the diffusion of bacterial virulence factors and/or chemical mediators of inflammation through the vital connective tissue up to the periradicular region. In other words the inflammatory response is not only restricted to the narrow area immediately in contact with the most advanced bacteria, but bacterial products and inflammatory mediators may involve a large tissue area, although with less intense reaction because of the dilution in tissue fluids.[9-12]

In later stages, increasing portions of the coronal pulp are affected by degeneration, and necrosis reaches the root pulp, moving slowly in an apical direction. The clinical consequence can be periapical radiolucency as in the case illustrated in Figure 6-2. This is the left mandibular first molar of a 19-year-old woman with destructive caries. The pulp did not respond to thermal and electric pulp tests, and the radiograph showed periapical radiolucencies on both roots (Figure 6-2A). The diagnosis of necrotic pulp was made. The patient did not accept any treatment aimed at conservation and the tooth was extracted and processed for light microscopy. Sections, cut on a mesio-distal plane, revealed necrotic in the coronal third in the mesial root the tissue. However, toward the middle third, there was a transition between necrotic and viable pulp tissue, characterized by the typical gradient of tissue reaction: infected/necrotic tissue—acute inflammation—chronic inflammation—uninflamed tissue (Figure 6-2B-G).[10] It is important to point out that this vital tissue lacks odontoblasts and predentin, which is replaced by a less tubular or atubular calcified tissue resembling cementum (Figure 6-2G). For this reason, this tissue cannot be properly referred to as "pulp tissue." The periapical pathologic tissue appears comprised a severe concentration of acute and chronic inflammatory cells and absence of bacteria (Figure 6-2H and I). In conclusion, an apparently illogical condition is observed, characterized by a portion of relatively uninflamed tissue between two areas of severe inflammation.

The histologic features observed in this case confirm that it is not necessary for the entire pulp to be necrotic and for the frontline of infection, established at the apical foramen, to develop apical periodontitis.[9–13] Lin et al.[14] conducted a clinical and histological study on 75 carious teeth with radiographic evidence of apical periodontitis. After access preparation, they carefully extirpated the pulp tissue with barbed broaches, and performed histologic and histobacteriologic analyses of the tissue fragments. They observed that in most cases, pulp necrosis was only partial, with inflamed connective tissue and intact nerve fibers. This observation was later confirmed by Ricucci et al.[12] in a histologic study of 50 extracted teeth with an apical periodontitis lesion attached. Vital tissue, with varying degree of inflammation, was observed in the apical canal in 18 teeth, which represents approximately one third of the cases.

The possible presence of structured tissue between the bacterial front and the apical foramen in teeth with apical periodontitis lesions was also observed in a scanning electron microscopy study.[15] Therefore, in some teeth with apical periodontitis, microbial infection has not reached the very apical portion of the canal. This condition is referred to as "partial necrosis" and helps explain why an unanesthetized patient may feel a sharp pain when a file is inserted in the canal of a tooth with apical periodontitis even before the instrument reaches the apical canal. This also helps to explain the high rate of success in the treatment of teeth with apical periodontitis with instrumentation limited to 1 mm short of the apex,[16] in which apical patency files were not used.

With time, additional tissue becomes involved with necrosis in an apical direction, with or without concomitant clinical symptoms. Microabscesses can be observed in the apical pulp, while the most apical canal may still harbor structured connective tissue in direct continuation with the apical periodontitis lesion (Figure 6-3). Bacterial biofilms are located at the borderline between infection and inflamed tissue (Figure 6-3D and G). In more advanced stages, necrosis can reach the apical foramina. It is not uncommon to observe ingrowth of granulation tissue into the foramen, in an extreme attempt to halt the advance of the frontline of bacterial infection (Figures 6-4 and 6-5). Figure 6-6 illustrates the condition in which microbial infection has finally reached the end of the canal that appears clogged with a thick biofilm. It is evident that this was a condition of longstanding pulp necrosis, where microorganisms had time to organize in a complex biofilm structure that occupied the entire apical canal. At this point, host defenses are generally located outside the root canal in the apical PDL.

In cases with severe carious breakdown of the crown and direct exposure of the root canal space to the oral environment, food or other foreign bodies may gain access to the canals and be packed in an apical direction by mastication forces. Figure 6-7 illustrates a maxillary central incisor whose apical canal appeared to be clogged with various food remnants (including meat fibers), hair, and a toothpick fragment protruding through the foramen into the periapical area. These structures were enmeshed with amorphous debris heavily colonized by microorganisms (Figure 6-7G-L). Note that biofilms are formed on the external surface of hair (Figure 6-7H) and microorganisms also filled the large cellulose cells of the wood fragment (Figure 6-7J and K).

Intensity of Periradicular Tissue Response

The intensity of PDL response to the canal infection is directly proportional to the intensity of microbial aggression. The host-pathogen relationship will result in an acute inflammatory response (symptomatic apical periodontitis or

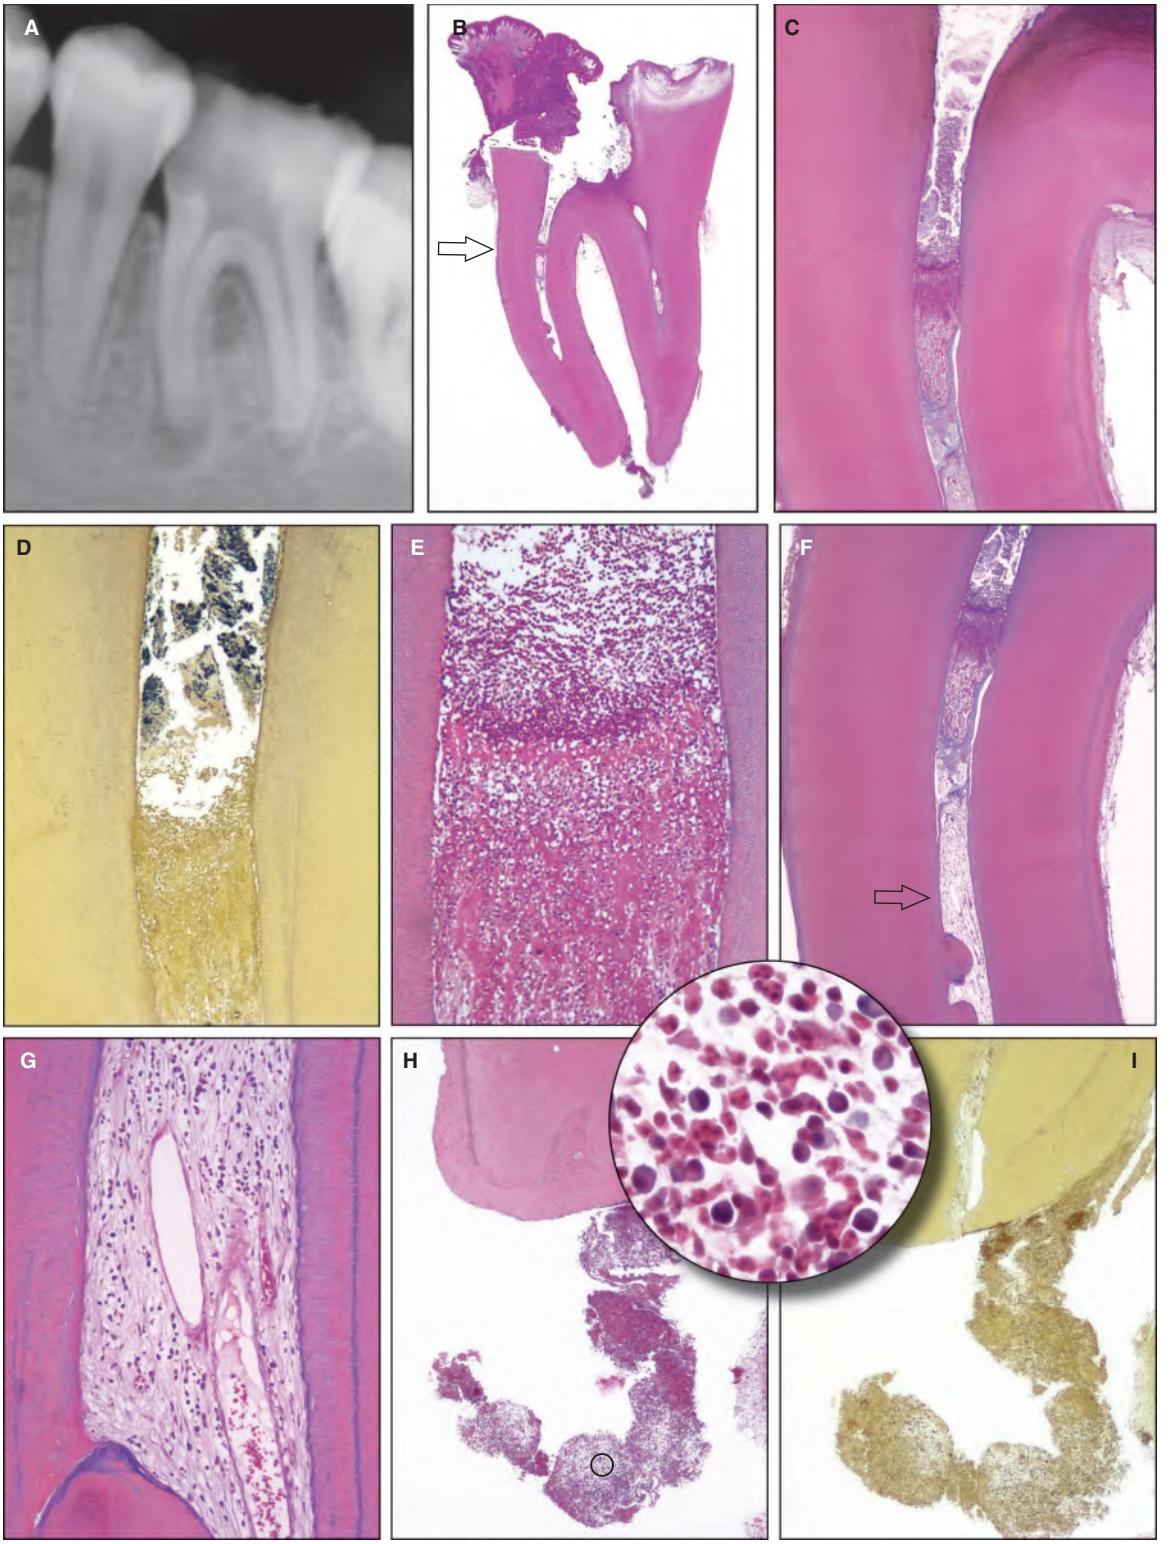

FIGURE 6-2 ***A***. Diagnostic radiograph. Apical periodontitis lesions are present on both roots. ***B***. Note that the tissue in the most apical part of the left ramification is not necrotic. The apparently empty space between the pathologic tissue and the apex is a surgical artifact (Taylor's modified Brown and Brenn, original magnification ×16). ***E***. Magnification of the area demarcated by the upper rectangle in D. A microabscess is present in a disintegrated tissue (×100). ***F***. Magnification of the area demarcated by the lower rectangle in D. Non-infected vital tissue is present in the ramification (×100). ***G***. High power view of the area indicated by the arrow in D. Necrotic tissue heavily infected (×400).

acute apical abscess) or a chronic response (asymptomatic apical periodontitis or chronic apical abscess), resulting in bone destruction. Inflammation is by and large effective in confining the infection to the root canal space, but cannot eliminate the infection therein. Therefore, microorganisms are located in a strategic position within the necrotic root canal, because the lack of an active circulation in the necrotic tissue prevents phagocytes to have a direct access to the source of infection. Additionally, the presence of biofilm structures protects bacteria from the host defense attacks. For more details, see Chapter 3.

Although the source of infection is not effectively eliminated, an equilibrium between aggression and defense is usually achieved. This equilibrium is often characterized by chronic inflammation, clinically referred to as asymptomatic (or chronic) apical periodontitis. As the tooth remains untreated and infection persists in the root canal system, the chronic process gives rise to bone resorption to the point of being radiographically detected. By adequately treating the root canal, the clinician promotes an imbalance favoring the host. Consequently, healing of the periradicular tissues is initiated. If the microbial aggression is significant, due to high bacterial counts and/or virulence, the host can mount an acute inflammatory response to curb the advance of infection and re-establish equilibrium. This gives rise to a condition clinically characterized as symptomatic (or acute) apical

periodontitis. The inflammatory response can become exacerbated, resulting in purulent exudate formation that characterizes an *acute apical abscess*.

Extraradicular Extension of Root Canal Infection

Infection is usually confined to the root canal, but occasionally can advance to the periradicular tissues. For more details, see Chapter 3. Acute apical abscess is the most common form of extraradicular infection. There is, however, another form of extraradicular infection that, unlike acute abscess, is usually characterized by absence of overt symptoms. This condition encompasses the establishment of infection in the periradicular tissues, either by forming cohesive actinomycotic colonies within the body of the inflammatory lesion (a condition referred to as apical actinomycosis),[17] or adhering to the apical external root surface in the form of biofilms.[18,19]

The diagnosis of apical actinomycosis by light microscopy is possible only in the presence of the typical structure of a "ray fungus" or actinomycotic rosettes in tissue sections.[20] An actinomycotic colony typically consists of a central area more or less intensely stained, containing intertwining and branching filaments, held together by an extracellular matrix with peripheral filaments in the form of clubs or rods.[20-22] The colony is usually surrounded by several layers of polymorphonuclear neutrophils (PMNs).

Another form of extraradicular infection is the spread of bacterial biofilms from the apical canal to the outer root surface, around the apical foramen/foramina. Biofilm-like structures have been observed on the external surface of the apical portion of teeth with infected canals. Tronstad et al.[18] reported that in some teeth with posttreatment disease, the external apical surface was covered by a continuous and smooth layer, without a defined structure, containing various bacterial morphotypes. Bacteria held together by extracellular material were present in resorption lacunae and other irregularities of the root surface. Lomçali et al.[23] observed chains or layers of bacteria enclosed in a dense matrix on the surface of teeth with asymptomatic apical periodontitis lesions. In 26 similar biopsies from untreated teeth, Siqueira and Lopes[24] reported one case in which dense bacterial deposits were seen beyond the apical foramen, including forming a corncob-like structure.

Extraradicular infection is a rare phenomenon. Based on the few cases described in the literature, it is possible to infer that extraradicular infections occur in teeth with massive infection of the root canal space. Such massive infection may result from prolonged exposure of the canal to the oral environment due to gross caries, inadequately restored teeth or sinus tracts.

The early phases of biofilm formation and adhesion to the external apical surface are illustrated in Figure 6-8. It is a maxillary second premolar of a 58-year-old patient with the crown destroyed by caries, and the canals exposed to the oral environment for a long period. The tooth was extracted with an apical periodontitis lesion attached, and bacterial staining demonstrated some small aggregates of filamentous bacteria just outside the buccal canal (Figure 6-8E,F). The cementum

layer was detached from dentin. The presence of debris in these spaces indicates that this condition is not histological artifact (Figure 6-8E). The clinical relevance of this observation is clear, as these spaces can be colonized by microorganisms consequently not responding to nonsurgical root canal treatment procedures.[25]

Sometimes, parts of the biofilm structure may even become mineralized and calculus formation is observed. This may be associated with a longstanding sinus tract. Ricucci et al.[26] described two cases in which calculi were present on the external root surface of teeth with posttreatment apical periodontitis.

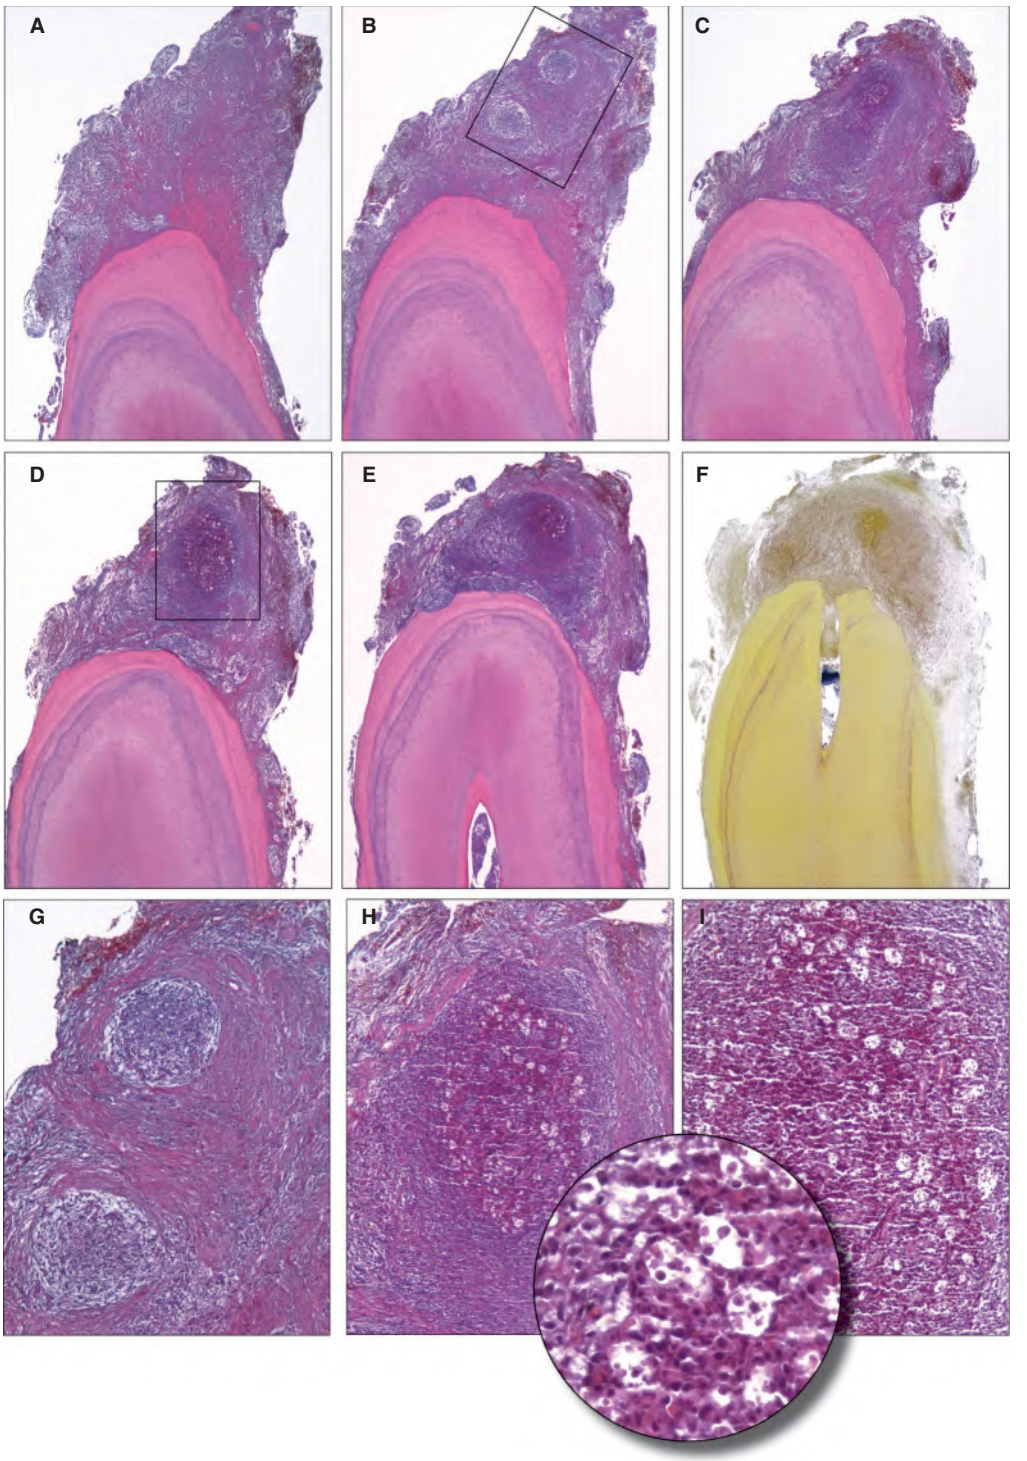

FIGURE 6-5 (*Continued on facing page*)

A dense microbial biofilm filling the canal lumen, faced with inflammatory tissue (×100). Inset. High power view from the interface between the bacterial biofilm and the inflammatory tissue. PMNs engaged in an intense phagocytic activity. Microbial fragments can be seen in their cytoplasms (×1000). ***K***. Magnification of the apical canal in F. The inflammatory tissue filling the apical canal is in direct continuation with the periapical pathologic tissue. Resorption of the apex can be appreciated (×100). ***L***. Magnification from the periphery of the lesion in F. The inflammatory tissue is limited externally by dense collagen bundles with few scattered inflammatory cells (×400).

Figure 6-9 shows an advanced condition in which the apical third of the mesial root of a mandibular first molar of a 35-year-old man is completely covered by calculus. The patient stated that the tooth had been treated endodontically 4 years previously and abscess symptoms had been occasionally present. No sinus tracts were present at the time of visit. A radiograph could not disclose the root tips, but showed inadequate endodontic treatment and a large radiolucency (Figure 6-9A). The patient was in pain and requested tooth extraction. The tooth was sectioned and the roots were extracted separately. The mesial root showed apical resorption and the apex was completely enveloped by a dark calculus (Figure 6-9B, C). Cross-cut sections showed that the untreated apical canals were filled with necrotic debris, dentin spicules, and bacteria (Figure 6-9D and E). Calculus exhibited masses of bacteria interspersed in an abundant extracellular matrix (Figure 6-9F).

The calculus deposits are conceivably originating from mineralization of an extraradicular biofilm of endodontic origin, present on the external surface of the root. Saliva is the main source of mineralization of supragingival calculus, whereas serum transudate of gingival crevicular or pocket fluid provides the minerals for subgingival calculus development.[27] As for periradicular diseases, a longstanding sinus tract may function as a possible route of communication between the periradicular area and the external environment. In addition to minerals available from tissue fluids, the passage of minerals and salts from the oral fluids into the apical periodontitis lesion, via sinus tract, may help explain calcification of the biofilm present on the apical root surface. However, an extraradicular bacterial biofilm can become mineralized even in the absence of a sinus tract, and the source may be the inflammatory exudate and periradicular tissue fluids saturated with calcium and phosphate from the solubilization of both bone and tooth.

CLINICAL CLASSIFICATION OF PERIRADICULAR DISEASES

Periradicular diseases of endodontic origin have been classified in many ways. In this chapter, terminology for clinical classification of these diseases follows the reports of the American Association of Endodontists Consensus Conference on diagnostic terminology.[28] Accordingly, periradicular lesions are basically divided into three main clinical groups: asymptomatic and symptomatic apical periodontitis; acute and chronic apical abscesses; and condensing osteitis.

Normal Periradicular Tissues

A tooth with normal healthy periradicular tissues shows no sensitivity to periradicular (percussion or palpation) tests. Radiographically, it presents with intact lamina dura surrounding the root and a uniform PDL space.

Asymptomatic Apical Periodontitis

Asymptomatic apical periodontitis is characterized by inflammation and destruction of the apical periradicular tissues and appears as a radiolucent area that is in the large majority of cases located around the root apex, but may occasionally develop laterally to the root or in the furcal region.

As the name implies, it presents with no symptoms, but the patient may report a previous painful episode. On clinical examination, the cause of pulp necrosis is evident, including the presence of extensive caries or coronal restoration. The tooth crown may be darkened due to pulp necrosis.

The results of pulp sensitivity tests are negative because the pulp is necrotic. Periradicular tests (percussion and palpation) yield negative results. In some cases, the lesion may cause bone fenestration at the level of the apical part of the root, so that palpation may reveal a slight increase in volume, as the inflammatory proliferative lesion is located in the submucosal tissue.

In the initial phase of asymptomatic apical periodontitis, radiographs show a thickened PDL space. In more advanced stages, a radiolucent area around the root apex (or sometimes laterally to it) is seen. The lesion usually has well-defined borders and exhibits loss of the integrity of the lamina dura.

Asymptomatic apical periodontitis is classified histopathologically as granuloma or cyst (see next section). These two histopathologic entities are radiographically indistinguishable. Attempts have been made to differentiate between the two conditions by means other than biopsy, including electrophoresis of the fluid sampled from the lesion,[29,30] computerized tomography,[31] cone-beam computed tomography,[32] ultrasound,[33] and ultrasound real-time imaging technique (echography).[34-36] However, the results were

inconclusive. In addition, the need for distinguishing the two conditions is questionable, as the treatment for both is the same. Although controversial, it seems that the outcome of the treatment for both conditions is also the same.

Symptomatic Apical Periodontitis

Symptomatic apical periodontitis is characterized by acute inflammation in the PDL, generating clinical symptoms. The patient usually complains of intense, pounding, and localized pain. The tooth is also tender to percussion. The patient may report that the tooth seems to have "grown or pushed out" of the alveolus. This is because the tooth is slightly extruded to accommodate the edema formed in the apical PDL. Chewing usually provokes or exacerbates pain.

This condition develops when the aggression caused by microorganisms and their byproducts leaching via the apical foramen is of high intensity. Pain is a result of the increase in vascular permeability associated with acute inflammation, producing an increase in tissue hydrostatic pressure and compression of sensory nerve fibers. Bacterial products, such as lipopolysaccharides (LPS), and chemical mediators of inflammation, such as bradykinin, can also cause pain by directly affecting the nerve fibers. However, because there is limited room for expansion of the PDL during acute inflammation, compression of nerve endings seems to be more significant in causing pain than the direct effects of mediators.

The results of pulp sensitivity tests are negative, because symptomatic apical periodontitis is most often associated with pulp necrosis. Percussion test is always positive and is often exquisitely painful to the patient. Therefore, it is strongly recommended that whenever symptomatic apical periodontitis is suspected, the percussion test should be performed by gently percussing the tooth with the tip of the index finger instead of using the handle of a mirror, just to confirm the involved tooth. In case the patient cannot even touch the tooth, the percussion test should be avoided. Palpation test is usually positive.

A tooth with symptomatic apical periodontitis may exhibit a normal or thickened apical PDL space. The latter

is due to the slight extrusion of the tooth in the socket to house the edema. However, there are cases in which a frank apical bone resorption is observed; this means that the symptomatic apical periodontitis developed from exacerbation of an asymptomatic lesion.

Acute Apical Abscess

Acute apical abscess is characterized by a severe inflammatory reaction to root canal infection. It has a rapid onset and is associated with pain, pus formation, and swelling of the associated soft tissues. Pain is usually spontaneous, throbbing and localized, exacerbated by chewing. Systemic involvement may occur, including fever, malaise, and regional lymphadenitis. Pain becomes severe when the purulent collection is still intraosseous or has reached the subperiosteal space. A dramatic relief in pain occurs as the purulent exudate breaks through the periosteum and reaches the supraperiosteal soft tissues.

The acute abscess is a sequel to symptomatic apical periodontitis, and is characterized by formation of a purulent inflammatory exudate in response to bacteria egressing from the apical foramen. An extraradicular infection is established in these cases. Bacterial proteolytic enzymes, especially lysosomal enzymes and oxygen radicals released by PMNs, promote tissue liquefaction and pus formation. In some cases, the host defenses do not succeed in confining the infection to the periradicular tissues and the abscess can spread to anatomical spaces of the head and neck and even give rise to life-threatening conditions. For more details, see Chapter 30.

Depending on the stage of the abscess process, intra-oral or extra-oral swelling, fluctuating or not, can be observed. Swelling is usually localized, but in some cases can become diffuse and spread to other head and neck sites to form a cellulitis. Localization of the swelling is determined by the relationship of the root apex to muscle attachments. In initial phases, no swelling is present and the clinical features resemble those of symptomatic apical periodontitis.

The results of pulp sensitivity tests are negative. Percussion yields positive results and, similar to symptomatic apical periodontitis, should be performed with caution or even avoided, as it can cause extreme pain.

If the abscess develops as an exacerbation of a longstanding asymptomatic apical periodontitis (the so-called "phoenix" abscess), radiographs reveal a radiolucent area around the root apex. If the abscess develops as a direct extension of pulp necrosis and infection, the PDL space may appear only thickened.

Chronic Apical Abscess

Chronic apical abscess is characterized by a mixed inflammatory reaction to root canal infection, with gradual onset, and associated with little or no discomfort. It may be related either with areas of exacerbation in an asymptomatic lesion or with a chronicization of an acute apical abscess.

Clinically, this condition is very similar to asymptomatic apical periodontitis, except for the presence of a sinus tract that promotes an intermittent or continuous discharge of pus. The sinus tract is usually located intra-orally, but in some cases, it can be found extraorally and even be confused with other facial skin lesions. The tract can be traced by introducing a gutta-percha point via its trajectory and then taking a radiograph, in order to determine the source of the sinus tract.

Pulp and periradicular tests yield negative results. A few cases, however, may present a mild sensitivity to percussion or palpation.

Radiographic findings for chronic apical abscess are very similar to asymptomatic apical periodontitis. However, the borders of the radiolucent lesion may not be so well defined.

Condensing Osteitis

Condensing osteitis is a diffuse radiopaque lesion, usually surrounding the root apex, and characterized by a localized reaction of the bone to low-grade inflammatory stimuli egressing from the root canal. In contrast to the other periradicular lesions, condensing osteitis is associated with a predominant active bone formation. The reason why the periradicular response is different in these cases is unknown. This condition appears radiopaque because the localized excessive production of bone around the root apex results in narrowing of the medullar bone spaces (and not an increase in calcification). Condensing osteitis is more commonly found in association with mandibular molars with pulp necrosis or asymptomatic pulpitis. Bone can be remodeled and return to radiographic normalcy following successful root canal treatment.

HISTOPATHOLOGIC CLASSIFICATION OF PERIRADICULAR LESIONS

The study of periradicular lesions using conventional light microscopy, according to contemporary agreed directives and defined criteria,[10] provides valuable information on the overall morphology of the periradicular pathologic tissue and its relationship with the root apex and apical root canal system. The presence and prevalence of the various types of inflammatory cells, identified by their classical morphology, as well as the occurrence of epithelium and collagen bundles can be ascertained, together with the structures originated from the interaction between these different tissues. This information is of great value because it provides spatial location, for example, of the epithelial structures and bacteria. However, this approach does not allow the study of the immunobiology of the periradicular host response. Consequently, immunohistochemical techniques have been employed to characterize the various immunocompetent cells present (T and B lymphocytes, macrophages, dendritic cells, plasma cells, and their subsets) and inflammatory mediators in periradicular lesions.[37-45]

When dealing with the histomorphological aspects of apical periodontitis lesions, one should have in mind the cross-sectional nature of the analysis, that is, we are observing a

specific moment of the lesion evolution. Depending on the microbial challenge and other factors, periradicular lesions may exhibit different cellular and molecular composition. This may change over time, in a dynamic host-pathogen interaction.

The methodology adopted in histological studies of periradicular lesions deserves special consideration. Many studies published in the past were based on inadequate biopsies and less than ideal histologic methodologies.[46,47] It is currently recognized that the correct histopathologic diagnosis of periradicular lesions can only be made when two conditions are met: *(1)* the biopsy sample includes the lesion and the root apex in their original spatial relationship and *(2)* a serial sectioning approach is undertaken.[11-12,48]

This may imply that adequate biopsies are only obtained from tooth extraction, in which the lesion remained attached to the root apex, or from periradicular surgery, in which block sections containing the apex, lesion, and possibly the surrounding bone are available. Fragments of periradicular pathologic tissue or even the entire lesion, removed by curettage from the alveolus, are not considered appropriate for a precise diagnosis of the type of apical periodontitis. Moreover, sections taken randomly through the biopsy specimen are not acceptable. The specimen should be sectioned completely from pole to pole. Serial sectioning approach is currently considered essential for proper histopathologic diagnosis.[10,48] This is because sections taken at different points of the lesion may differ considerably in terms of histologic patterns. For example, the section shown in Figure 6-5A would lead to a diagnosis of granuloma, while the sections taken at some distance and shown in Figure 6-5C and D show an abscess with microcavities and a massive concentration of PMNs in the center of the lesion (Figure 6-5H and I).

In one of the first reports on extracted teeth with periradicular lesions attached, Thoma[49] studied the microscopic appearance of periradicular lesions and described the possible presence of epithelium (including cyst formation), and suppuration in dental granulomas. His classification has not changed significantly over the years. The histopathologic classification used in this chapter is based on the presence or absence of epithelial cells and the distribution and type of inflammatory cells in the periradicular lesion.

Apical Abscess

Abscess is a collection of pus in a cavity formed by tissue liquefaction. Acute apical abscess can develop without previous chronic inflammation or may result from exacerbation of a previously chronic asymptomatic lesion. Abscess lesions are formed by an accumulation of PMNs, usually delimited by a granulomatous tissue composed mainly of lymphocytes, plasma cells, and macrophages. This pattern is mainly observed when the abscess develops as an exacerbation of granuloma (Figure 6-5A-I). Based on the presence or absence of epithelial strands, abscesses can further be categorized as epithelialized (Figure 6-10) or non-epithelialized (Figures 6-5 and 6-7). The epithelialized abscess could have originated from an exacerbation of an epithelialized granuloma (described below). In cases with severe clinical symptoms, histomicrobial analysis usually reveals microbial cells in the periradicular tissues that can be present both in the extracellular compartment and engulfed by PMNs (Figure 6-7F). The latter represents frank phagocytic activity. Several microcavities containing cellular debris and PMNs can be observed throughout the lesion body (Figures 6-5H, I and 6-7D-F), sometimes affecting the epithelial strands (Figure 6-10D, E). The peripheral area of the lesion may be composed of bundles of collagen fibers, indicating exacerbation of a previously chronic lesion (Figures 6-5E, H, L and 6-7D).

Apical Granuloma

Granuloma is characterized by chronic inflammation, and consists of elements of granulation tissue infiltrated by immune defense cells. Chronic inflammatory cells are observed in varying numbers and distribution throughout the granuloma tissue. They include macrophages, lymphocytes, plasma cells, foam cells, and multinucleated foreign-body cells (Figure 6-4I). At the periphery of the lesion, the inflammatory tissue usually gives way to a fibrous tissue, formed essentially by collagen, with few, if any, inflammatory cells (Figure 6-4I).

Apical granuloma can be epithelialized (Figure 6-8) and non-epithelialized (Figures 6-4 and 6-6). When present, epithelial cells can form strands that are randomly scattered (Figure 6-8C & D) and may be infiltrated by PMNs and chronic inflammatory cells (Figures 6-10E and 6-11A-C). This is a peculiarity of the apical granuloma, as other granulomas elsewhere in the body rarely contains PMNs in the extravascular location. The epithelium may exhibit extensive proliferation at the area adjacent to the apical foramen and even invaginate into the apical canal (Figures 6-8B & C and 6-10D). The epithelium may also form ramified structures that enclose islands of granulomatous tissue containing lymphocytes, plasma cells, and a rich circulatory network (Figures 6-11A-C and 6-12A, B).

Granuloma is the most common histopathologic form of apical periodontitis. Bhaskar[50] examined 2,308 specimens of periradicular lesions and found that 48% were classified as granuloma, 42% as cyst, and 10% represented other pathologic forms. Nair et al.[48] evaluated 256 apical periodontitis lesions and reported that 50% were granulomas, 35% abscesses, and 15% cysts.

Apical Cyst

Apical cyst is an inflammatory lesion of endodontic origin that is characterized by the presence of a cavity lined by epithelial cells. The epithelial lining is usually of the stratified squamous type, but in a few cases, a ciliated columnar epithelium can be observed (see below). According to the

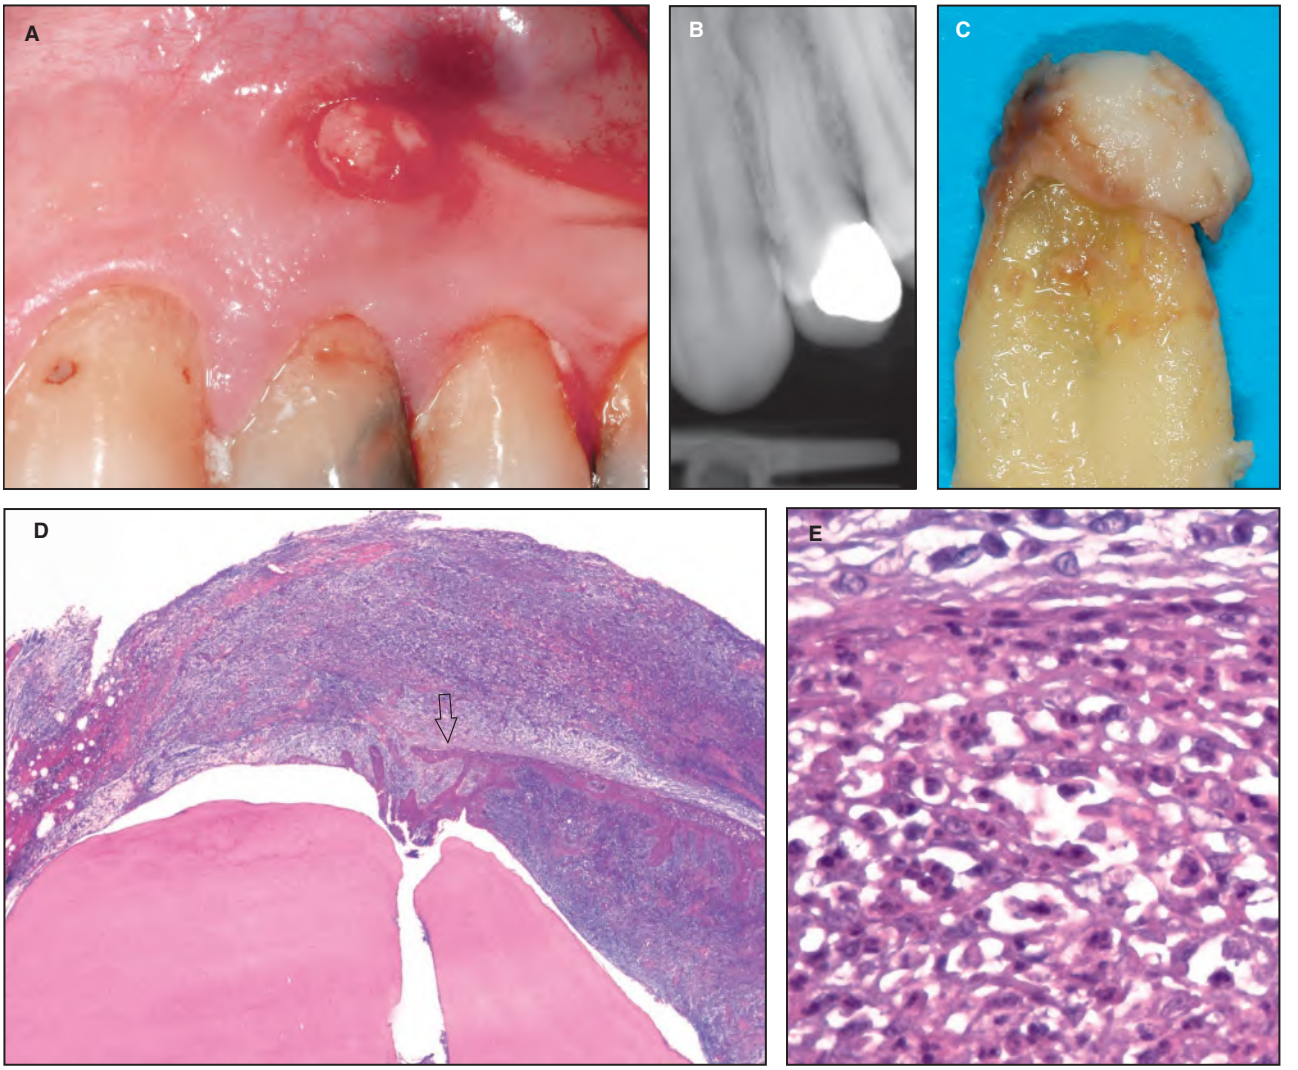

FIGURE 6-10 ***A***. Sinus tract in the buccal gingiva apically to the maxillary first premolar. ***B***. Radiograph of the tooth showing apical radiolucency. ***C***. High power view from the area of the epithelium indicated by arrow in D. The epithelial tissue is heavily infiltrated by PMNs (×400). The histologic diagnosis was "epithelialized abscess."

spatial location of the cavity, the cyst can be classified as true or pocket (bay).[48,51]

The true apical cyst is a periradicular lesion with a distinct pathologic cavity completely enclosed by the epithelial lining, without any communication with the root canal system (Figures 6-13 and 6-14). The pocket apical cyst is a sack-shaped apical inflammatory lesion, with the epithelium-lined cystic cavity in direct contact with the root canal system via apical foramen or lateral foramina. For a precise classification of a cyst as true or pocket, serial sectioning analysis of the lesion attached to the root apex is mandatory. For instance, according to the cavity morphology in Figure 6-15A, the lesion would have been diagnosed as a true cyst. However, hundreds of sections away revealed a clear communication between the cyst lumen and the root canal (Figure 6-15D) that is compatible with diagnosis of pocket cyst.

Histologically, the true cyst presents an epithelium-lined cavity separated from the root canal system. The cavity appears half-empty or containing necrotic tissue and clusters of cells in various stages of degradation (Figure 6-13A-D). In some instances, cholesterol crystals are detected (Figure 6-14). These crystals are usually dissolved by chemicals used in histologic processing. Therefore, they appear as void spaces with a typical pointed appearance of "broken glass" or "pine needles" (Figure 6-14A, B). Cholesterol crystals are often surrounded by a dense accumulation of PMNs (Figure 6-14C, D). Varying portions of the cyst lumen may be occupied by macrophages with foamy cytoplasm (foam cells) intermixed with PMNs (Figure 6-14E). Depending on the location, the epithelial lining of the cyst cavity may vary significantly in thickness and is often infiltrated by PMNs (Figure 6-13C, D). The epithelial lining may show signs of

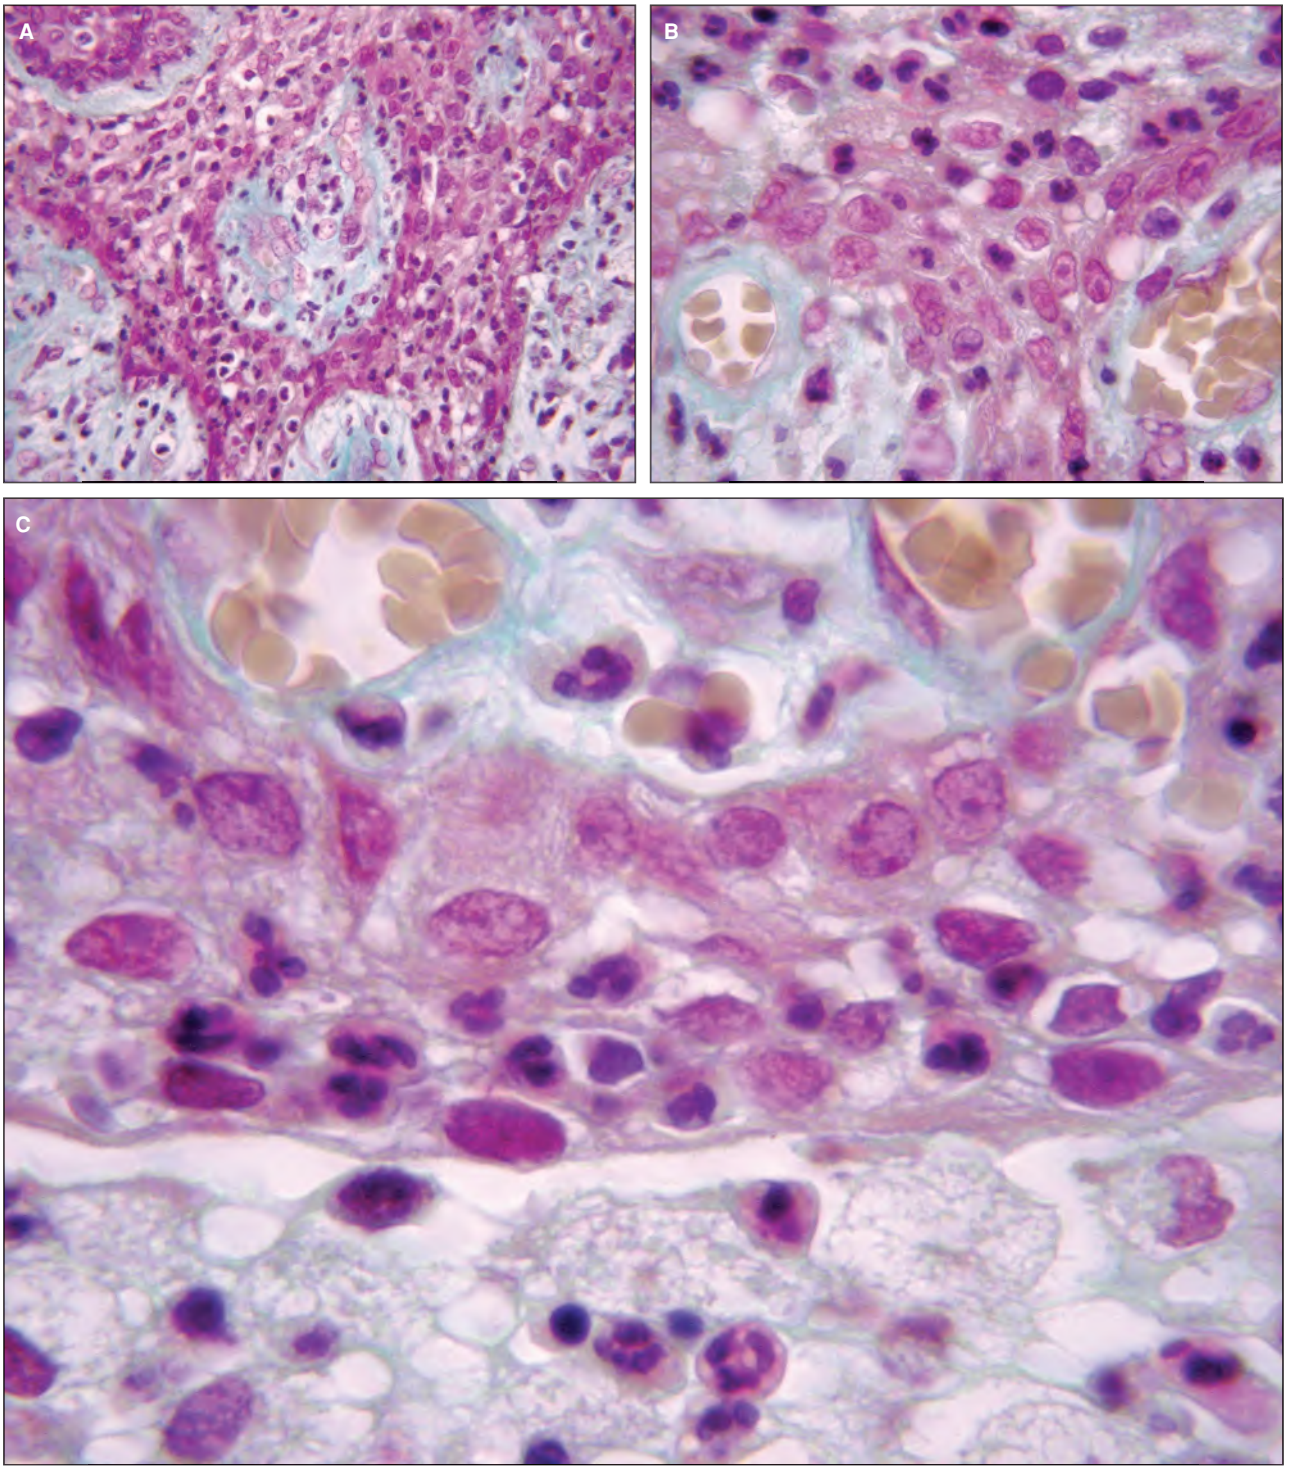

FIGURE 6-11 High power views of epithelial strands present in an epithelialized granuloma. ***A***. The epithelium surrounds cores of connective tissue infiltrated with inflammatory cells (Masson trichrome, original magnification ×400). ***B*** and ***C***. The strands appear infiltrated by PMNs. Note the hyperaemic cross cut vessels in the adjacent connective tissue (×1000).

exfoliation near the cyst lumen, with cells assuming a blurred appearance and indistinct nuclei. In the periphery of the true cyst, bundles of collagen fibers form a pseudo-capsular structure, separating the lesion from bone (Figure 6-13A). Chronic inflammatory cells may be observed, in moderate concentrations, between the bundles of collagen fibers. More than one cyst cavity may be present in the same lesion.[12]

The lesions classified as pocket cysts show a cystic cavity lined by epithelial cells forming a sac-like structure, separating the foramen from the remainder of the lesion

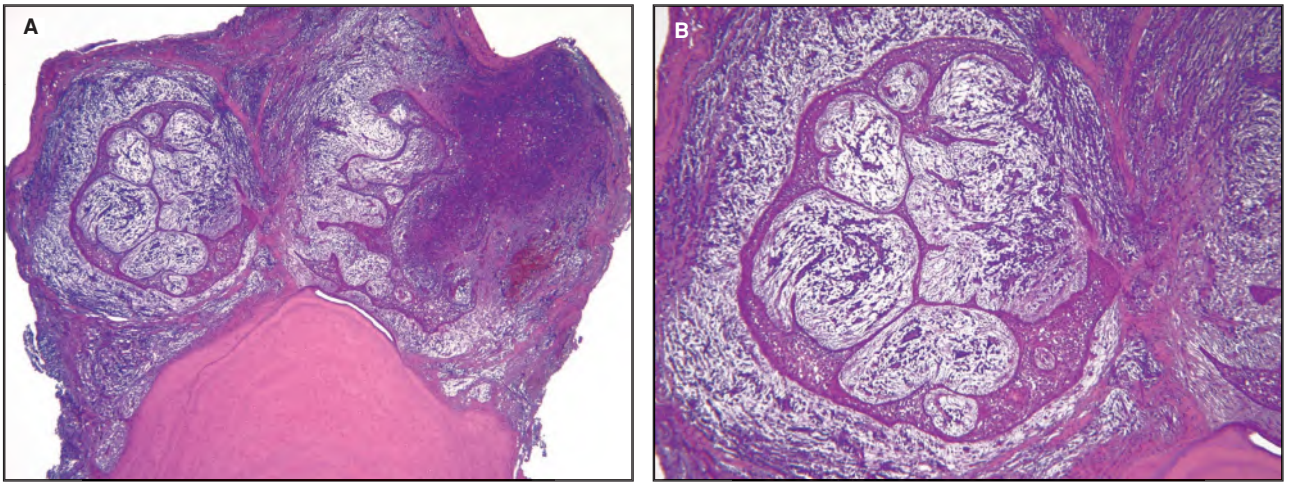

FIGURE 6-12 Maxillary premolar extracted with a large apical periodontitis lesion attached. ***A***. The lesion appears composed of two portions, separated by connective tissue. Both parts show epithelial strands surrounding islands of inflamed connective tissue, but no cavities can be seen. Despite the advanced proliferation of the epithelium, in the absence of cavities, the diagnosis is "epithelialized granuloma" (Hematoxylin and eosin, original magnification ×16). ***B***. Magnification of the left portion of the lesion (×50).

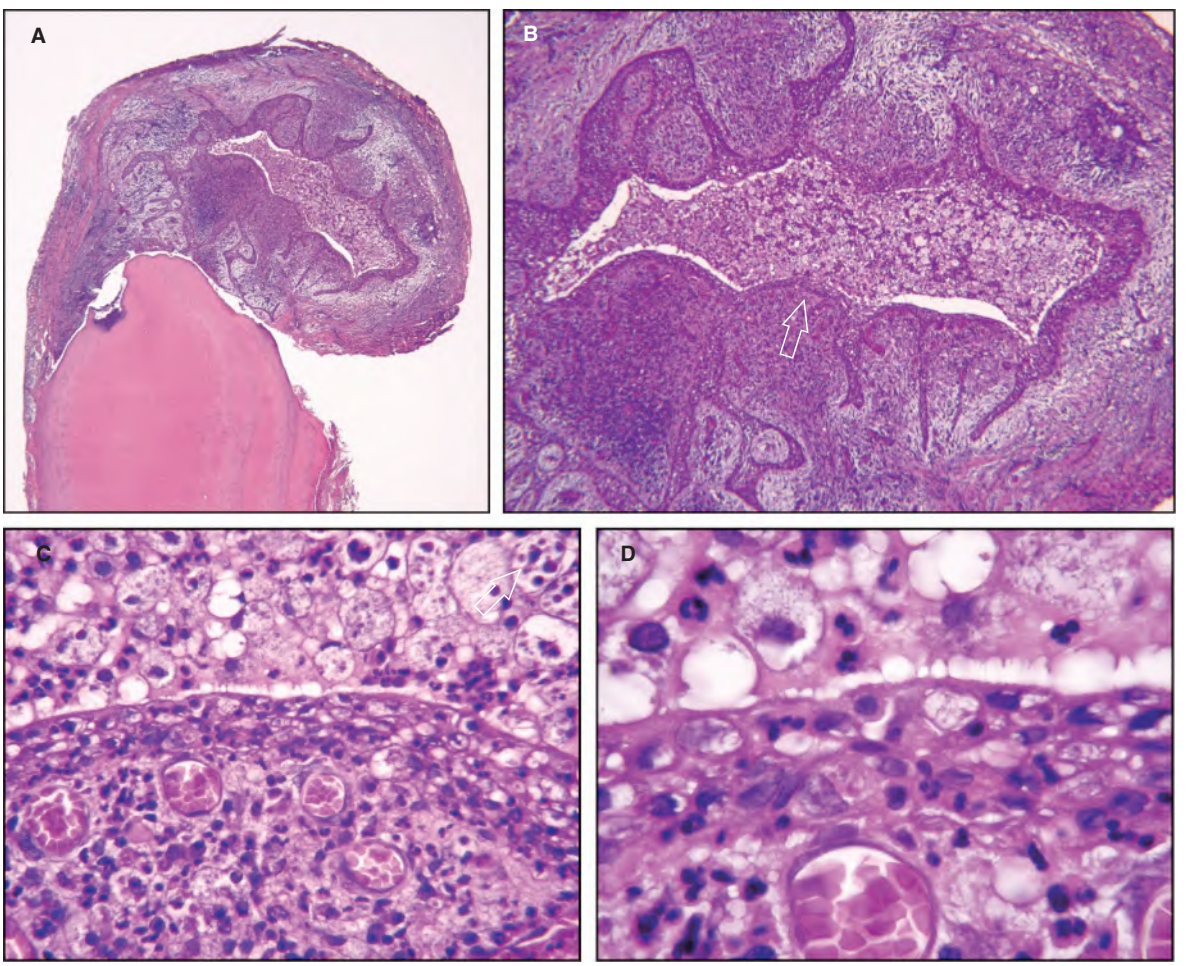

FIGURE 6-13 Distobuccal root of a maxillary molar. ***A***. The lesion shows a central cavity completely lined by epithelium, not in communication with the apical foramen. Serial sections confirmed the absence of communication between the cyst lumen and the root canal space, leading to the diagnosis of "true cyst" (Hematoxylin and eosin, original magnification ×25). ***B***. Magnification of the cyst cavity. Its lumen contains necrotic debris, with microcavities, foam cells, and PMNs (×50). ***C*** and ***D***. Progressive magnifications of the area of the cyst wall indicated by arrow in B. Necrotic debris, foam cells and PMNs in the lumen; hyperaemic vessels and PMNs in the underlying connective tissue (×400 and ×1000).

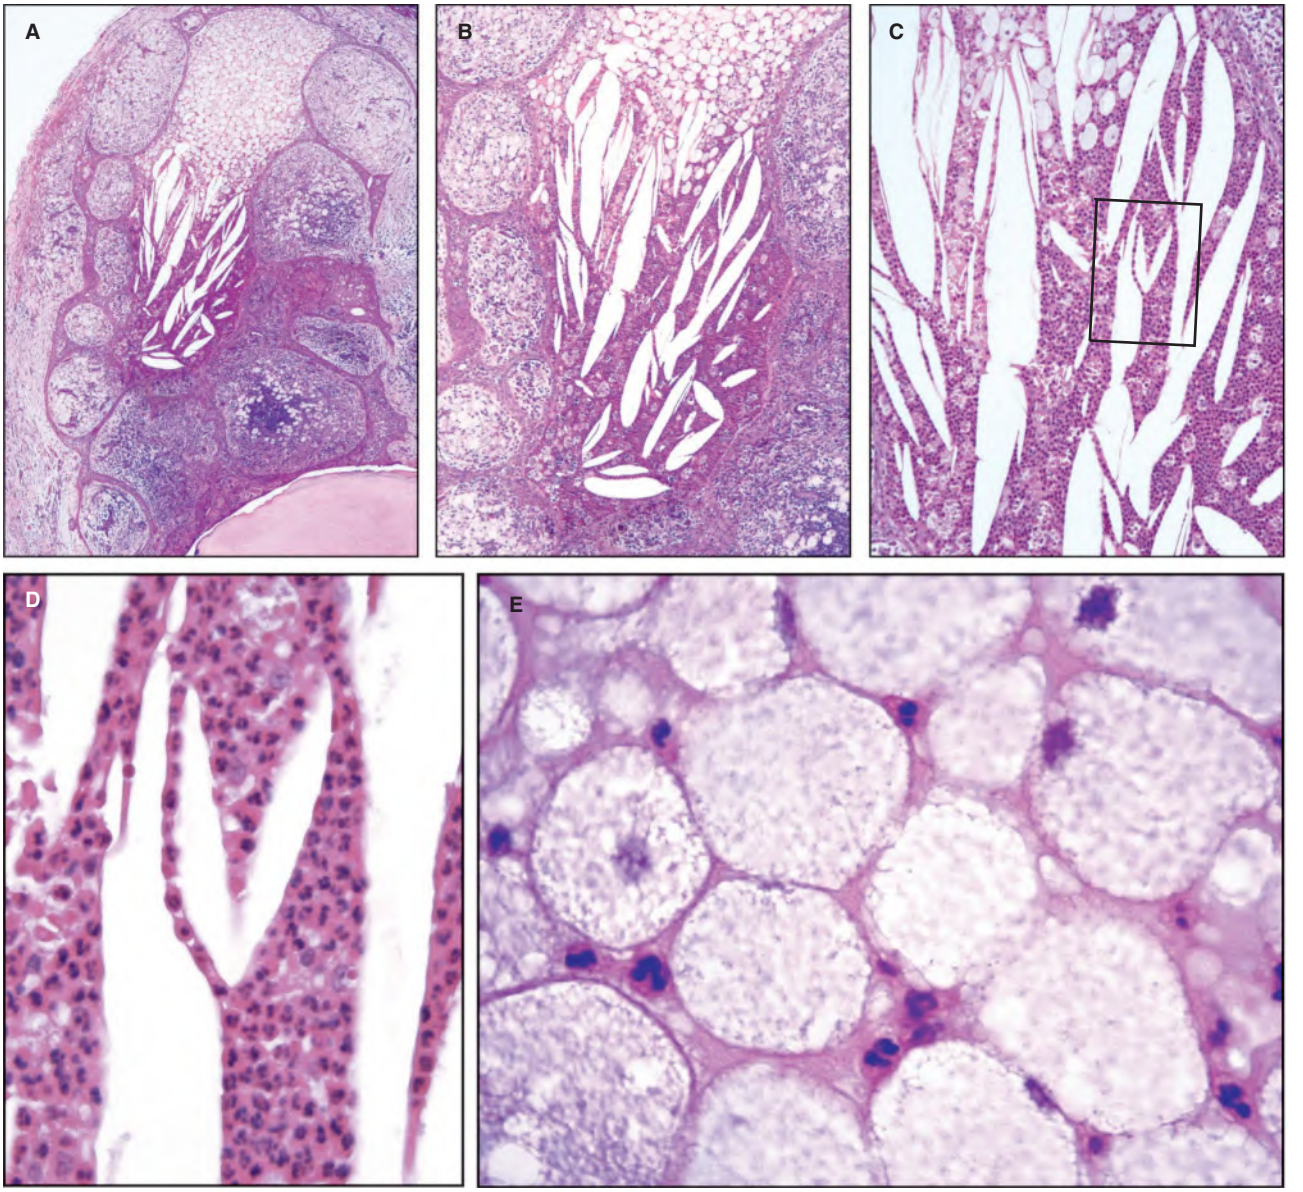

FIGURE 6-14 Maxillary premolar extracted with a lesion attached. ***A***. Serial sections demonstrated that the lesion was a "true cyst." In the upper portion, the cyst cavity appears filled with foam cells, while empty spaces with the appearance of "broken glasses," typical of cholesterol crystals, are present in the lower part (Hematoxylin and eosin, original magnification ×25). ***B***. Detail from the lower part of the cyst content (×100). ***C*** and ***D***. Progressive magnifications show empty spaces surrounded by a severe concentration of PMNs (×100 and ×400). E. High power view from the upper portion of the cyst cavity. Dead or dying lipid-filled foamy macrophages and PMNs (×1000).

(Figure 6-15). The epithelium forming the cystic wall may show signs of desquamation and is infiltrated by PMNs. Abundant debris are commonly seen in the cyst lumen. Similar to other chronic lesions, collagen bundles are seen at the periphery.

Hypothetical Mechanisms to Explain Cyst Formation

The epithelium forming cysts of endodontic origin is believed to be derived from the Hertwig's epithelial root sheath.[52] This sheath originates from the fusion of the external and internal dental epithelium to form the cervical loop that invaginates into the underlying connective tissue of the dental organ. The Hertwig's root sheath guides the deposition of root dentin, after which it disintegrates, leaving behind nests of epithelial cells in the PDL. These are known as epithelial cell rests of Malassez (ERM), and considered to remain in a resting stage.[53,54] The exact function of ERM in normal PDL is unknown.[55] However, if stimulated by specific extracellular signals, they have the potential to undergo cell division. In apical periodontitis lesions, epithelial cell rests proliferate in three dimensions and forming strands that have the tendency to form a three-dimensional network.

Structurally, ERM are surrounded by the basal lamina and appear as small agglomerates of cells with large nuclei and distinct nucleoli, closer to the cementum than to the bone

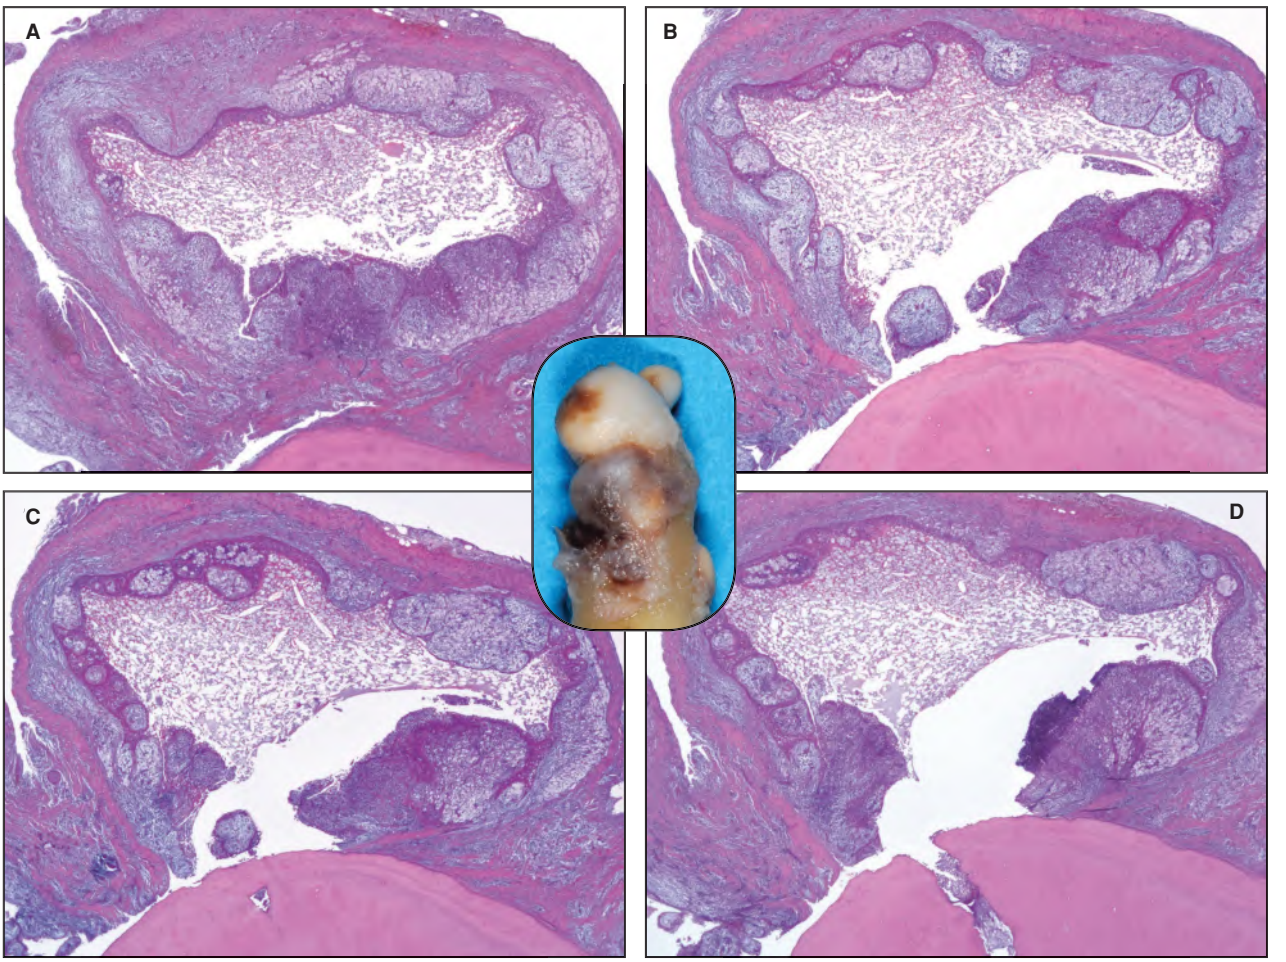

FIGURE 6-15 Series of sections taken from a maxillary third molar extracted with an apical periodontitis lesion attached. Section were distant approximately 50 sections from each other. ***A***. A cavity, completely surrounded by epithelium, may lead to a histologic diagnosis of a "true cyst." ***B–D***. Serial section procedure demonstrates a clear relationship between the cyst lumen and the root canal space, confirming a diagnosis of a "pocket cyst" (Hematoxylin and eosin, original magnification ×16).

surface (Figure 6-16A–C). Sometimes, they can be seen as large agglomerates of cells (Figure 6-17A, B).

The development of apical cysts can be regarded as a late stage of the host defense against root canal infection. Every apical cyst is supposed to have its origin in an apical granuloma, but there are no supporting data that every granuloma will invariably be transformed into a cyst. One might think of the epithelialized granuloma as an intermediary stage in the granuloma-to-cyst. However, there is no evidence that epithelial strands proliferating in the inflamed periradicular tissues will always form an apical cyst. Nair et al.[48] found that 52% of the periradicular lesions examined showed epithelial proliferation, but only 15% of them were classified as cysts.

Several theories have been suggested to explain cyst formation[55]:

1. ***Breakdown theory***. This theory states that epithelial islands continue to grow in a three-dimensional spherical mass, responding to inflammatory stimuli. The central cells of the epithelial mass will then drift away from their original source of nutrients and undergo necrosis and liquefaction degeneration. The microcavities would coalesce to form a cystic cavity.[52] This theory has been questioned because the epithelial cells form strands in the apical granuloma that are frequently surrounded by a vascularized connective tissue.
2. ***Abscess theory***. According to this theory, a cyst is formed after epithelial cells started to proliferate to cover a preexisting abscess cavity formed in the connective tissue.[56,57] This is due to the intrinsic tendency of epithelial cells to cover exposed surfaces of connective tissue.[58,59] To test the hypothesis that radicular cysts develop via the "abscess pathway," Nair et al.[60] attempted to experimentally induce inflammatory cysts in rats. Inoculations of epithelial cells, followed by a *Fusobacterium nucleatum* injection into tissue cages implanted in rats' backs, 7 days later, resulted in development of inflammatory cysts in two of the 16 cages. These two cages contained a total of four cystic sites. They concluded that inflammatory cysts were induced by acute inflammatory foci initiated by bacterial injection that were further enclosed by a proliferating epithelium.

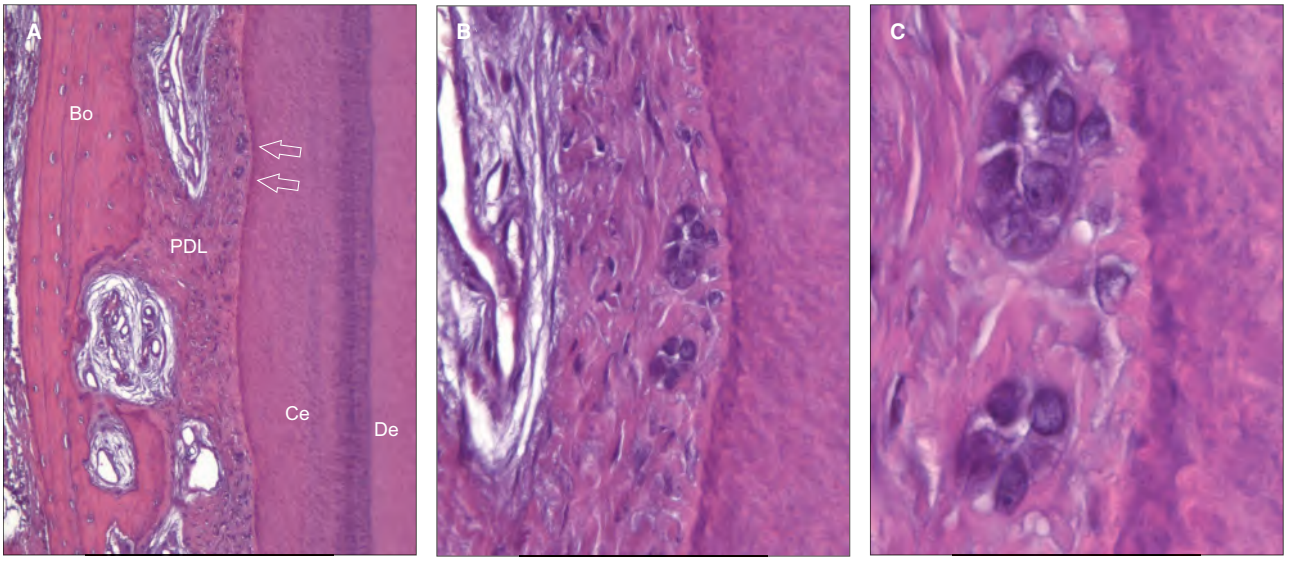

FIGURE 6-16 Histology of normal periodontal ligament. ***A***. From right to left are dentin (De), cementum (Ce), periodontal ligament (PDL), and alveolar bone (Bo). Arrows indicate two small groups of cells in the PDL, close to cementum (Hematoxylin and eosin, original magnification ×100). ***B*** and ***C***. Progressive magnifications show that these structures are nests of epithelial cell rests of Malassez surrounded by basement membrane (×400 and ×1000).

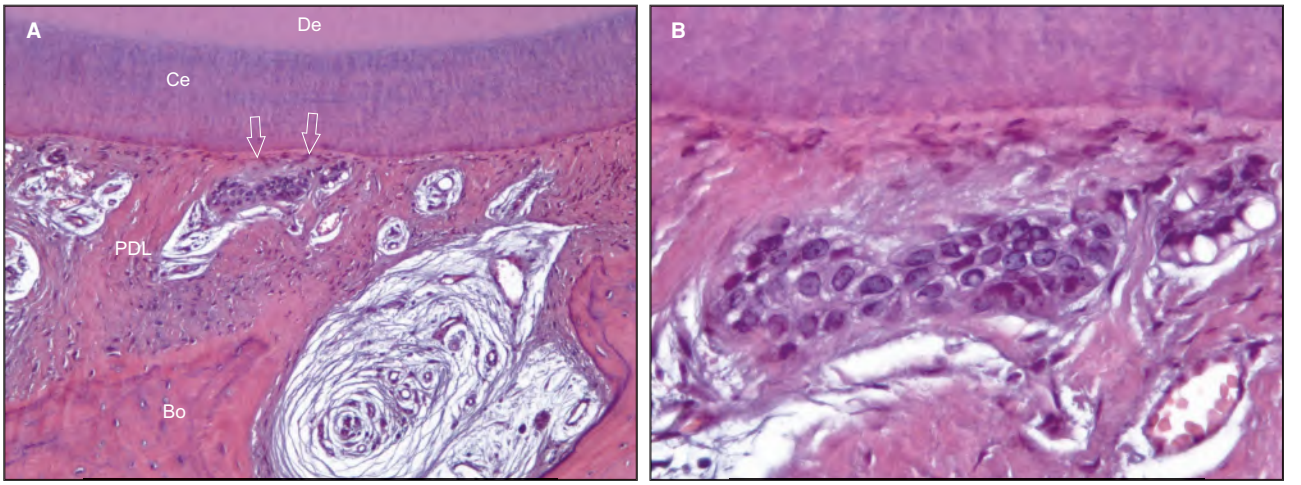

FIGURE 6-17 ***A*** and ***B***. Histology of normal periodontal ligament displaying a large aggregate of epithelial cells of Malassez (De, dentin; Ce, cementum; PDL, periodontal ligament; Bo, alveolar bone) (Hematoxylin and eosin, original magnification ×100 and ×400).

3. ***Immunologic theory***. This theory assumes that the development of cystic cavities in the proliferating epithelium is mediated by an immune response against activated epithelial cell rests of Malassez that become antigenic as a result of the abnormal growth.[61]
4. ***Fusion theory***. This theory[55] suggests that formation of the inflammatory apical cyst is caused by fusion of proliferating epithelial strands in all directions, to form a three-dimensional ball mass. The connective tissue trapped in the epithelial mass would undergo gradual degeneration as a result of the decrease in vascular support, giving rise to a cystic cavity.

Whatever be the process leading to development of cyst cavities, the phases for apical cyst formation are chronologically divided into three stages[62]:

1. Stage 1: The "dormant" cell-rests of Malassez start to proliferate stimulated by chemical inflammatory mediators produced and released in the lesion.
2. Stage 2: The cavity covered by epithelium is formed via one of the mechanisms discussed above.
3. Stage 3: The cyst expands at the expense of bone. Expansion of the cystic lesion may be related to an increase in the osmotic pressure generated by the decomposition of

inflammatory cells accumulating in the cyst lumen. This would substantially increase the number of macromolecules within the cyst lumen. Supporting this hypothesis is the fact that decompression (marsupialization) procedures usually succeed in reducing the lesion size. On the other hand, the observation that pocket cysts opened to the canal lumen also show a tendency to increase in volume might question the possibility that increase in osmotic pressure is responsible for lesion growth. Production of pro-resorptive inflammatory mediators in the periradicular tissues is the main cause of formation and growth of periradicular lesions, including granulomas. Therefore, it could be the main factor involved in cyst expansion.

Can Cystic Lesions Heal after Conventional Root Canal Treatment?

Some clinicians claim that cysts do not heal following root canal treatment. Based on morphological observations, some authors[63-65] speculated that true cysts are refractory to treatment because they may behave like a self-sustaining pathologic entity, independent of the influence of endodontic infection.

Lin et al.[66] argued against this notion. Inflammatory cells are always seen in the epithelium lining and/or fibrous connective tissue capsule of apical true cysts (Figures 6-8D, 6-10E, 6-11A-C, 6-13C, D).[12,48] This is a strong indication that irritants are present either in the root canal system or in the cyst lumen. It is also highly unlikely that the epithelial cells of true cysts, but not pocket cysts, can suddenly change the patterns of gene expression and start behaving like self-sustaining neoplastic cells.[66] However, this issue has not been fully elucidated yet.

To prove this theory, one should be able to distinguish between the types of cysts before nonsurgical endodontic treatment is performed. So far, no clinical or imaging diagnostic method can reliably differentiate granulomas from cysts, let alone true cysts from pocket cysts. The gold standard for diagnosis of periradicular lesions is still histologic examination, and this can only be performed in a cross-sectional approach.

A disease that persists, after cessation of stimuli that evoked its development, is regarded as a neoplasm.[67] Common examples are tobacco chewing and oral cancer, and smoking and lung cancer. Neoplasm is related to genetic damage of cells, including mutation of proto-oncogenes or loss of tumor suppressor genes to restrain cell growth and proliferation.[68,69] Neoplastic cells undergo spontaneous division, usually supported by autocrine secretion of growth factors, and are self-sustaining and immortal.[68,69] There is no evidence that epithelial cells, initially stimulated to grow by inflammatory stimuli in apical true cysts, become immortal and self-sustaining.

A disease caused by microbial infection, including true and/or pocket cysts, is expected to heal as long as the causative agents are eliminated or controlled. Exceptions include cases of chronic bacterial infections contributing to the development of malignancies, such as *Helicobacter pylori* infection and gastric cancer.[70-72] However, endodontic bacteria have not been shown to make epithelial cells behave like self-sustaining neoplastic cells.

Considering that epithelial cells from pocket cysts can undergo apoptosis in response to removal of the growth and survival stimuli following proper root canal treatment,[55] there is no reason to believe that the epithelial cells from true cysts would behave differently. One study[72] reported results of root canal treatment done in 42 teeth with large periradicular lesions regarded as cysts on radiographic basis. The canals were instrumented, dressed with calcium hydroxide, and filled. Complete healing was observed in about 75% of the cases. It must be pointed out that the examined cases may not have necessarily represented cystic lesions, since the study design does not permit histologic examination to confirm the diagnosis. Considering that all lesions were indeed cysts, one can conclude that most cysts heal after treatment. Non-healing lesions, irrespective of their histologic diagnosis, are virtually always a result of persistent intraradicular infection or extraradicular infection. For more details, see Chapter 3.

Based on current knowledge, there is no reason to believe that the two morphological varieties of cysts respond differently to root canal treatment. If one has a greater potential to present a significant problem, it will be the pocket cyst. Because the lumen of pocket cysts is in direct contact with the root canal system, it is possible that these cysts are more prone to become infected after direct advance of microorganisms from the root canal to the cyst cavity. Therein, microorganisms are beyond the effects of non-surgical root canal treatment and may be difficult to eliminate by the host defenses.[25] Thus, pocket cysts would have more plausible reasons to become recalcitrant than true cysts, because bacteria in the cyst lumen may provide continuous stimuli for growth and survival of epithelial cells.

Another problem related with pocket cysts is that the fluid present in the cyst lumen may seep into the canal after access opening, or during instrumentation, rendering conclusion of treatment difficult. In some cases with persistent drainage of the cyst fluid into the canal, application of a calcium hydroxide dressing or an apical plug of calcium hydroxide may help achieve a dry canal.

In addition to true cysts, cholesterol crystals have been suggested as another possible non-microbial cause of post-treatment apical periodontitis.[65,73,74] Cholesterol crystals can be formed locally in areas of tissue damage or necrosis caused by release of cholesterol from disintegrated cell membranes.[68] Because cholesterol is insoluble in water, it crystallizes into thin, flat rhomboid plates.[75] Cholesterol crystals occur in the cyst lumen, lining epithelium, and/or fibrous connective tissue capsule. Histologically, macrophages and giant cells are always found in association with cholesterol crystals in apical periodontitis lesions.

A study in guinea pigs evaluated the subcutaneous tissue response to implantation of pure cholesterol crystals and reported that macrophages and multinucleated giant

cells were unable to eliminate the cholesterol crystals over a period of 8 months.[74] It was extrapolated that accumulation of cholesterol crystals in periradicular lesions may prevent healing following endodontic treatment, and given the extraradicular location of the crystals, even retreatment would not succeed. However, it is unknown whether the same response occurs in humans. Actually, the medical literature provides evidence that activated macrophages can deal with cholesterol crystals.[66] Similar to true cysts, there is no evidence showing that cholesterol crystals can prevent periradicular wound healing after nonsurgical root canal therapy. Because the prevalence of cholesterol crystals in periradicular lesions has been shown to range from 18% to 44%,[75,76] some might infer that the same proportion of lesions would not heal following root canal treatment, if the cholesterol crystals had the ability to sustain inflammation by themselves. However, this does not match the high success rate of endodontic treatment[77] and the reported frequent causes of treatment failure.[78] Nevertheless, cholesterol crystals are the product and not the cause of apical periodontitis. However, it is conceivable that the occurrence of these crystals may delay the healing process following nonsurgical endodontic treatment.

Ciliated Epithelium in Apical Cyst Lesions

The epithelium commonly present in apical cysts is of the stratified squamous type. However, in some cases, a ciliated pluriserial (or pseudostratified) columnar epithelium, with features of the epithelium covering the respiratory airways, is observed.[79-84] The term "pseudostratified" indicates an epithelium consisting of a single layer of cells of varying heights and disposition; these epithelial cells rest on the basal membrane, but only some of them reach the free surface. This epithelium type presents with cilia that are moving filaments covering the cell surface. In the respiratory system, the cilia move regularly and rhythmically to induce currents in the fluid that bathes the cell surfaces, facilitating the removal of mucus and harmful particles.

The presence of the goblet cell is another feature of the respiratory epithelium. This cell is the only example of single-cell gland in the human body and is found inserted between the epithelial cells. Its main function is to secrete mucin, a protein-polysaccharide that, along with water, forming the mucus.

Occurrence of respiratory epithelium in apical cysts is not rare. Nair et al.[83] observed three ciliated epithelium-lined cysts among 39 cysts. These three cases were associated with maxillary premolars. Ricucci et al.[84] found four ciliated epithelium-lined cysts among 49 cysts. These four cases were all associated with maxillary molars. The proximity of the affected roots to the maxillary sinus floor was radiographically evident in three of them. These studies indicated that approximately 8% of the apical cysts exhibited ciliated epithelium.

Although this type of epithelium has been reported to occur also in cysts of the mandible,[79,82] findings from these two studies indicate that ciliated epithelium is most frequently associated with cysts affecting maxillary posterior teeth. In the posterior maxilla, presence of ciliated epithelium may be due to pathologic exposure of the maxillary sinus by the apical cyst. Radiographically, the apical cyst is seen in close proximity to, or extending into, the sinus. In some cases, a sinus tract may establish a contact between the cyst lumen and the maxillary sinus. This may cause the ciliated epithelium to merge with the squamous epithelial lining of the cyst. Indeed, an evident sinus tract crossing the cyst wall and connecting the cyst lumen with the external surface of the lesion (likely the maxillary sinus) was shown by Ricucci et al.[84] To our knowledge, evidence for this had been previously provided only by Kronfeld in 1939.[85]

An example of ciliated epithelium in an apical cyst is illustrated in Figure 6-18. It is a maxillary right first molar of a 50-year-old woman with the diagnosis of necrotic pulp. A radiolucency with indistinct margins was present around the mesiobuccal root apex proximal to the maxillary sinus floor (Figure 6-18A). To the patient's request, the tooth was extracted and the lesion remained attached to the mesiobuccal root. Histologic analysis revealed a cavity in the tissue mass and an apical extension with a sinus tract completely lined by ciliated epithelium (Figure 6-18B–E).

Prosoplasia is a pathologic phenomenon that can take place in the cyst lining epithelium and may help explain the rare occurrence of ciliated epithelium in cysts of the mandible and in maxillary teeth not in close proximity to the sinus. Prosoplasia is a progressive transformation of cells to either a higher level of function or organization. Accordingly, a simple epithelium would upgrade its differentiation from simple and non-functional epithelium to a higher or functional epithelium, such as those that contain secretory "mucus-cells."[86] Therefore, the presence of ciliated epithelium in apical cysts can be explained by either sinus involvement (in the posterior maxilla) or prosoplasia (other regions).

MORPHOLOGIC CHANGES OF THE APICAL ROOT STRUCTURE IN APICAL PERIODONTITIS LESIONS

Morphologic changes of the apical root structure may be associated with pulp and periradicular inflammation. The most common phenomenon is resorption. Although much less frequent, hypercementosis can also be observed.

Root Resorption in Apical Periodontitis

Root resorption can be defined as the process of removal of cementum and dentin by multinucleated clastic cells often referred to as odontoclasts.[87] This process is considered physiologic in shedding of deciduous teeth, but it is pathologic when it manifests as a sequel to microbial infection of the root canal space and consequent periapical inflammation. Pathologic root resorption is also caused by traumatic injuries to the teeth, neoplastic processes in the jaws and dental

Progressive magnifications of the periapical pathologic tissue that remained adhered to the apex of the mesiobuccal root at extraction. A cavity is present in the tissue mass (Hematoxylin and eosin, original magnification ×16 and ×25). ***D***. Detail of the apical extension of the lesion in C. A sinus tract completely lined by ciliated epithelium, containing debris and blood cells, can be observed (×100). ***E***. Detail of the area of the cyst cavity demarcated by the square in C. The epithelial lining consists of ciliated columnar epithelium with goblet cells, and stratified squamous epithelium in some parts. The cyst cavity is partly occupied by debris and inflammatory cells (original magnification ×100, inset ×400). Reprinted with permission from Ricucci D, Loghin S, Siqueira JF Jr, Abdelsayed RA. Prevalence of ciliated epithelium in apical periodontitis lesions. *J Endod*. 2014;40:476–483.

treatment procedures, among which orthodontic forces and intentional replantation are most common. For more details, see Chapter 15.

Depending on the amount of calcified tissue lost, root resorption can be detected by periapical radiographs. However, in many cases, the condition can be disclosed only by histologic sections. Laux et al.,[87] examined histologically 114 teeth and found that only 19% were diagnosed as having apical resorption on the basis of radiographs, whereas histologically, 81% of the teeth exhibited inflammatory apical root resorption. Vier and Figueiredo[88] examined 74 root apices associated with apical periodontitis lesions using light microscopy and scanning electron microscopy (SEM); 75% of the roots showed internal apical resorption.

Odontoclasts are the cells that resorb dental hard tissues. They are morphologically similar to osteoclasts[89]; the main difference is their smaller size and fewer nuclei. Osteoclasts and odontoclasts possess similar enzymatic properties[90] and resorb their target tissues in a similar manner. Both create resorption depressions termed Howship's lacunae on the surface of the mineralized tissues (Figure 6-19A–D).[91] These cells attach to their substratum via binding of integrins in the clear zone of the clastic cell to the amino acid motif Arg-Gly-Asp (RGD), present in proteins of the bone or tooth matrix.[92] After binding of the clastic cell to the bone/tooth, an intracellular signal cascade is generated that promotes re-organization of the clastic cell cytoskeleton and induces acidic vesicles to migrate to the region of the ruffled border. The ruffled border, also called brush border, corresponds to a number of cytoplasmic folds. These originate a network of channels that establish a communication between the attacked surface of the target mineralized tissue and the cell cytoplasm (Figure 6-19D). After adhesion, the bone surface beneath the clastic cell becomes segregated from the environment. Consequently, acids and enzymes released by the clastic cell concentrate on the surface of the subjacent mineralized tissue, leading to resorption.

Similar to what happens in the control of clastic functions during bone remodelling,[93] the OPG/RANKL/RANK system seems to be implicated in root resorption (see next section).[94] This system is responsible for the differentiation of clastic cells from their precursors via complex cell–cell interactions with osteoblasts and marrow stromal cells.

The precise events involved in triggering apical root resorption have not been completely elucidated, but it is evident that pulpal/periradicular inflammation and infection are responsible for the onset and the advancement of the resorptive process. Microbial stimulation, direct or indirect, of clastic cells is necessary for hard tissue resorption.[95]

Odontoclasts do not normally adhere to nonmineralized layers of the precementum covering the apical root surface. Similar to what happens in internal root resorption, where a breach in integrity of the predentin and odontoblast layer is necessary for resorption to occur, the precementum and

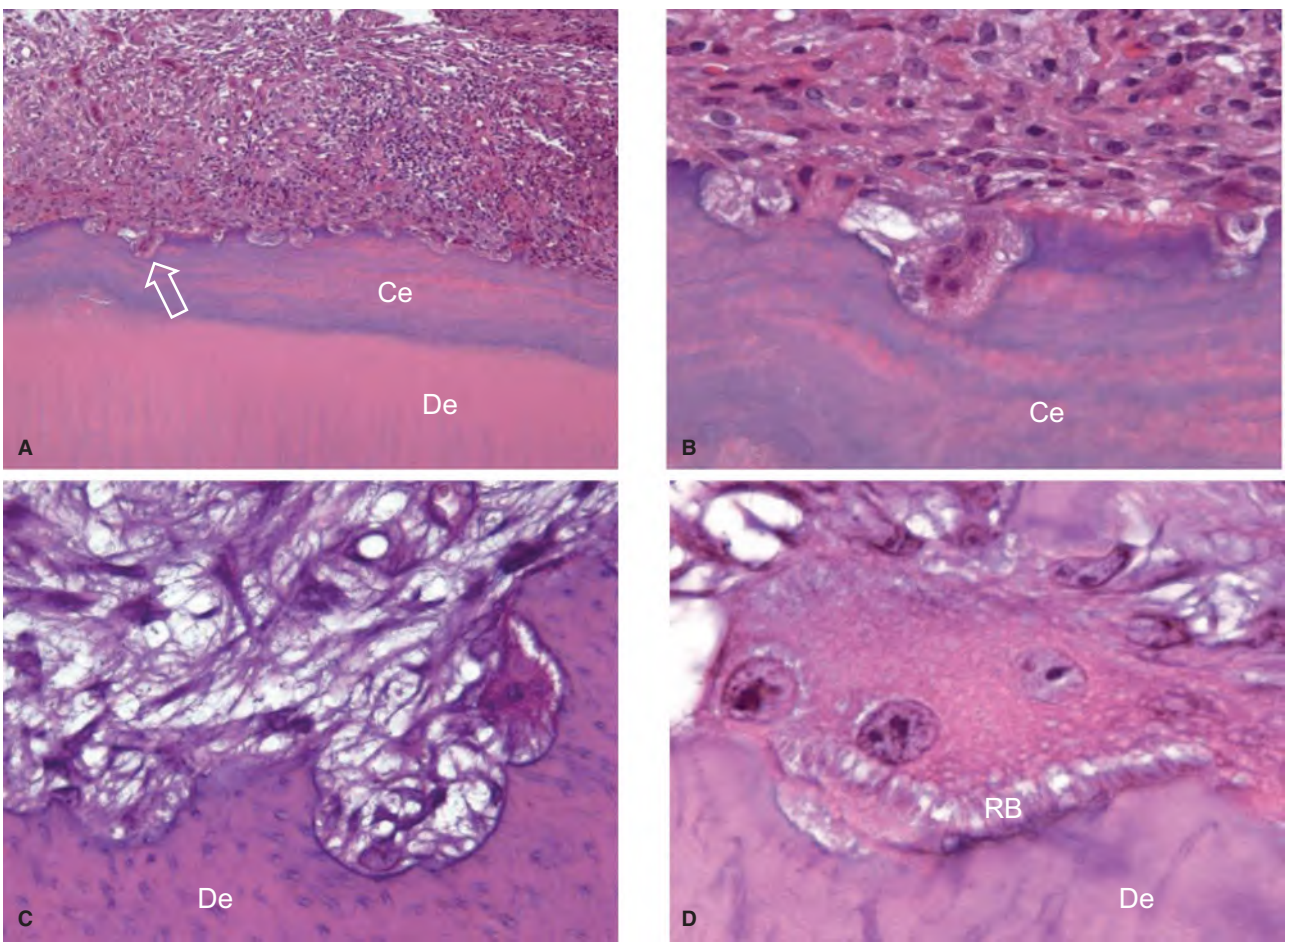

FIGURE 6-19 Apical external root surface of a tooth with periradicular inflammatory disease. ***A***. Cementum resorption is evident, as demonstrated by the presence of numerous Howship´s lacunae (Hematoxylin and eosin, original magnification ×100). ***B***. Magnification of the lacuna indicated by arrow in A showing an odontoclast (×400). ***C***. Another root in which dentin is denuded from cementum. Resorption lacunae are present. An odontoclast can be discerned in the major lacuna, adhered to dentin (×400). ***D***. The ruffled border can be seen all along the cell/dentin interface (×1000) (De, dentin. Ce, cementum. RB, ruffled border).

cementoblast layers need to be lost in order to stimulate cementum resorption.[95,96] Other than traumatic dental injuries or orthodontic forces, periradicular inflammatory changes due to endodontic infection may be responsible for the damage to precementum and cementoblast layer.

Microbial infection of dentinal tubules contributes significantly to maintain root resorption. Dentinal tubules, underneath endodontic biofilm communities, are usually invaded by bacterial cells from the bottom of the biofilm structure.[97,98] If the cementum layer is lost for any reason (e.g., superficial root resorption due to apical periodontitis lesion or trauma), dentinal tubule infection or bacterial mediators passing through tubules may sustain inflammation and the root resorption process.[99–101]

One example of extensive apical resorption caused by periradicular inflammation leading to considerable shortening of the apical structure is illustrated in Figure 6-20. It is a mandibular second premolar of a 58-year-old man extracted with an apical periodontitis lesion firmly attached to the root tip by a sleeve of dense collagen bundles (Figure 6-20C). The resorptive process destroyed the apical constriction and an embedded pulp stone was formed on the apical right wall (Figure 6-20C). The clinical relevance of these morphologic changes is evident.

Another example of apical root resorption associated with periradicular inflammation that altered considerably the apical structure is shown in Figure 6-21. It is a palatal root of a maxillary molar of a 45-year-old woman. It is interesting to note that, other than the apical top and the foraminal area, resorption affected the periforaminal root surfaces, with resorption lacunae in the cementum layer (Figure 6-21A, B).

Hypercementosis

Less frequent than resorption, the pathologic deposition of several layers of cementum around the apical structure can be observed in association with some periradicular lesions. One example is illustrated in Figure 6-22. In histologic sections, dentin appears surrounded by several layers of alternating cellular and acellular cementum, giving the appearance of the so-called "mixed stratified cementum."

IMMUNOLOGICAL ASPECTS OF PERIRADICULAR DISEASES

In response to irritants (usually microbial) egressing from the root canal system via apical, lateral, and furcal foramina, the host mobilizes its immune defense apparatus and concentrate cells and molecules in the tissue compartment near these foramina in an attempt to confine the infection to the canal. The immune response to tissue injury is a double-edged sword. On one hand, it has a protective function against infection, preventing dissemination to other areas, and preparing the injured area for repair. On the other hand, the immune reaction itself can lead to undesirable effects, such as tissue destruction resulting in pain, liquefaction, and bone resorption.

According to the intensity of aggression and host susceptibility state, the response may be acute or chronic.

Acute Periradicular Response

Microorganisms reaching the periradicular tissues from root canals are initially combated by local host defenses represented by resident macrophages and the complement system. Microbial antigens and virulence factors accumulate in the intraradicular biofilm and diffuse through tissues to reach the periradicular tissues and activate the immune defenses. For instance, bacterial cell structural constituents can activate macrophages as well as the complement system via the alternative[102] and lectin pathways.[103] Bacterial structural components and metabolic end-products are cytotoxic and can induce release of pro-inflammatory cytokines.[104,105] Bacterial peptides and metabolites are chemoattractants to PMNs.[106]

Macrophages and other defense cells possess surface receptors that recognize microbial substances and give rise

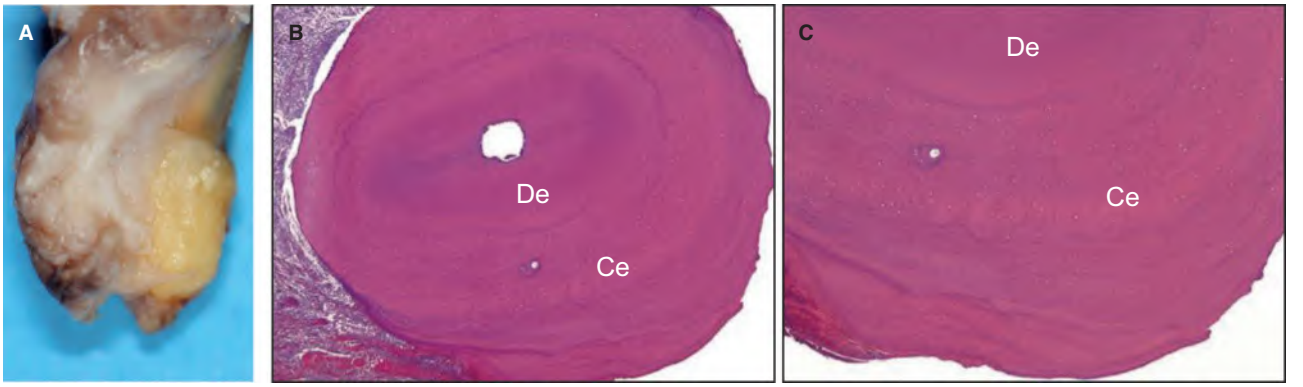

FIGURE 6-22 Distal root from the mandibular molar in Figure 6-9A. ***A***. Hypercementosis is associated with the periapical pathologic tissue. ***B*** and ***C***. Cross-cut section taken at the level of the line in A. Dentin (De) is surrounded by overgrowing layers of cementum with different morphologic characteristics, the so-called "mixed stratified cementum" (Hematoxylin and eosin, original magnification ×16 and ×25).

to signals that activate antimicrobial and pro-inflammatory functions. Once activated by microbial structural components, macrophages exhibit stronger phagocytic and antigen-presenting capabilities. Activated macrophages increase the production of pro-inflammatory mediators, including interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF)-a the chemokine IL-8/CXCL8, prostaglandins, leukotrienes, lisosomal enzymes, oxygen metabolites, nitric oxide, and platelet-activating factor.[107-111]

Activation of the complement system leads to increased antimicrobial activity of the serum by inducing cytolysis of microbial cells and promotes opsonization for improved performance of phagocytes. Some products of complement activation, such as C3a and C5a, can stimulate mast cells to degranulate and release histamine,[112,113] an important mediator of acute inflammation, by causing arteriolar dilation and increased venular permeability.[114] C5a is also a powerful chemotactic agent for phagocytes.

Activation of macrophages and the complement system results in the production and release of several molecules that stimulate the next step in host defense against infection (acute inflammation). It involves several vascular and cellular changes in the affected tissues. Increased vascular permeability is the hallmark of acute inflammation. The fluid that leaves the vessels (exudate) accumulates in the extravascular space to form edema that causes an increase in tissue hydrostatic pressure, with consequent swelling and pain.

Because microbial infection in the root canal cannot be eliminated by the host defenses alone, more phagocytic cells are recruited to the injury area. Consequently, the host ability to cope with the infection is increased, but excessive recruitment of PMNs coupled with intense damage to the periradicular tissues can result in abscess formation.

Cytokines, such as IL-1 and TNF, released by macrophages in response to microorganisms, stimulate endothelial cells to sequentially express different molecules that mediate the preferential attachment of different types of leukocytes.[115] Microbial structural components may also act directly on endothelial cells to promote the same effects.[116] Slowing of blood flow, as a result of increase in vascular permeability and activation of endothelial cells by mediators such as IL-1, TNF, and LPS, generates conditions that are conducive to leukocyte margination, rolling and adhesion to the endothelium. As the leukocyte rolls on the surface and then adheres to the endothelium, it may be activated by chemokines displayed on endothelial cells. In response to chemokines, leukocytes rearrange their cytoskeletons and become more motile.[117] Afterward, they leave the vessel by crossing the endothelial lining and, once in the extravascular space, they are attracted to the site of injury by chemotaxis induced by microbial products and host-derived factors (particularly chemokines, C5a, and LTB4).[115,118]

PMNs are the first leukocytes to migrate to the injured area. Once exposed to IL-8 and TNF-α, PMNs are activated and increase the production of oxygen radicals and release of granule contents, improving the bacterial killing ability. However, as a side effect, activated PMNs can also cause damage to the host tissues due to release of oxygen radicals and lisosomal enzymes. Abscess formation is the extreme form of tissue injury caused by PMNs in response to bacterial infection.

CHRONIC PERIRADICULAR RESPONSE

Microbes have numerous distinct antigens. Since endodontic infections are characterized by multispecies microbial colonies, one can realize the myriad of antigens that accumulate in a biofilm mass. Ingredients from this "antigenic soup" constantly diffuse and contact the periradicular tissues. Asymptomatic apical periodontitis develops as an adaptive immune response to the chronic antigenic stimulation egressing from the infected root canal.

The adaptive immune response develops in a host already sensitized to the antigens that induced the response. Sensitization occurs following the first contact with the antigen and at the level of draining regional lymph nodes. Recirculating naive B and T cells have more chances to

encounter the antigen to which they are specific and then undergo all the processes necessary to become activated.

The initial acute inflammatory response to infection generates a large number of antigenic fragments as a result of microbial killing. These fragments accumulate in the inflammatory exudate and are captured by dendritic cells that direct them to the local lymph nodes via lymphatics. Lymphocytes are constantly circulating through the lymph nodes. Consequently, these cells have more chances to encounter the antigen to which they are specific, rather than in the periradicular tissues. After antigen recognition, lymphocytes are activated to proliferate and differentiate in effector cells. Immune cells rarely proliferate in the periradicular area.[119] Thus, for the initiation of the adaptive immune response against endodontic pathogens, antigens must be taken to regional lymph nodes where recognition and lymphocyte activation can occur.[120]

Effector immune cells include plasma cells, originated from B cells, which secrete antibodies, and effector T cells that can activate other immune cells (CD4+ T lymphocytes) or destroy target cells infected by virus (CD8+ cytolytic lymphocytes). Some cells do not enter the differentiation process and give rise to memory cells.

Effector cells leave the lymph node, enter the circulation, and are attracted by chemokines to the source of antigens, that is, the injury site (the periradicular area). Effector immune cells then become established and accumulate in the periradicular tissues to eliminate the source of antigens or at least curb the spread of infection.

In sensitized individuals, a secondary immune response is faster against microbial species involved in the root canal infection. Sensitization may have occurred after previous contact with antigens from the same bacterial species present in caries, gingivitis, periodontal disease, or apical periodontitis in another tooth. Memory T cells predominate over naive T cells in periradicular lesions.[121]

A chronic inflammatory response can start from the onset or be resultant of chronicization of a previous acute episode. In response to microbial infection, chemical mediators are released into the periradicular tissues by macrophages, T cells, and other cell types and may reach critical concentrations to stimulate osteoblasts and bone stromal cells to express mediators that activate osteoclasts and bone resorption.[122,123] Bone is resorbed and replaced by a granulomatous tissue basically composed of immunocompetent cells such as lymphocytes, plasma cells, macrophages, and PMNs, as well as components of granulation tissue, including fibroblasts and newly formed nerves and blood vessels. The bone resorptive process creates enough space to accommodate a large number of defense cells in the area adjacent to the apical foramen in an attempt to confine the infection in the root canal. In the periphery of the granulomatous tissue, collagen fibers encapsulate the lesion. At a certain point, bone resorption is sufficient to produce a radiolucent lesion that is discernible radiographically. A granuloma is formed.

The predominant inflammatory cells in chronic periradicular lesions are lymphocytes and plasma cells, followed by mononuclear phagocytes (macrophages and dendritic cells) and neutrophils.[44,121,124,125] Mast cells and Natural Killer (NK) cells can also be found.[37,121,126,127] Even though PMNs are typical of acute inflammation, long-lasting chronic inflammatory response to root canal infection can exhibit large numbers of PMNs.[115] These defense cells accumulate particularly in areas adjacent to where microorganisms are located (e.g., near the apical or lateral foramina and around actinomycotic colonies).[10]

A variety of chemical mediators are produced in the inflamed periradicular tissues in response to bacterial infection of the root canal. Cytokines, such as IL-1α and β, TNF-α, IL-6, and macrophage colony-stimulating factor (M-CSF), chemokines, and prostaglandins are all bioactive molecules with great relevance in inducing inflammation and bone resorption.[106,128-130] These proinflammatory and proresorptive mediators can play an important role in pathological bone resorption associated with apical periodontitis.[1,131]

Chemical mediators primarily involved in regulation of osteoclastogenesis and bone resorption include receptor activator of NF-κB ligand (RANKL), M-CSF, and osteoprotegerin (OPG).[132] Differentiation of the precursors into osteoclasts requires the presence of osteoblasts/marrow stromal cells, which produce both RANKL and M-CSF.[92,133] M-CSF provides essential signals for survival and proliferation of osteoclast precursors.[136] RANKL is a surface molecule that is essential for differentiation of precursors into osteoclasts through interaction with RANK expressed on the osteoclast precursor.[134] RANKL can also occur in soluble form. To summarize, RANKL binds to RANK to activate osteoclastogenesis in the presence of survival factor M-CSF.

OPG is also produced by osteoblasts/marrow stromal cells and serves as a soluble "decoy" receptor that competes with RANK for RANKL to inhibit osteoclastogenesis and osteoclast activation.[135] The balance between RANKL (stimulator) and OPG (inhibitor) expression determines the amount of bone to be resorbed. Inflammation influences this balance, so that excessive bone resorption may ensue. Pathologic bone resorption typical of apical periodontitis is associated with increased RANKL/OPG ratio.[136,137] Upregulation of RANKL expression in apical periodontitis lesions correlates with the phase of lesion expansion.[136,137] A higher expression of RANKL than OPG has been reported in granulomas in comparison with cysts, resulting in a greater RANKL/OPG ratio and consequent increased bone resorption activity in granulomas.[138]

Immune cells participate in the differentiation and activation of osteoclasts in chronic inflammatory processes through the release of proinflammatory cytokines, chemokines, and other chemical mediators. These mediators can reach critical concentrations that indirectly stimulate

osteoclastogenesis by inducing osteoblasts/stromal cells to express RANKL and decrease OPG production.[122,123] Direct effects on osteoclastogenesis may also be induced by immune cells, since some cell types other than osteoblasts/stromal cells, including fibroblasts and T and B cells, can also produce RANKL.

Proinflammatory mechanisms must be tightly controlled in order to prevent excessive tissue destruction. The balance between proinflammatory and anti-inflammatory mediators controls the extent of host responses to antigen stimulation within chronic inflammatory processes. It has been suggested that T_H1 immune response, mostly mediated by proinflammatory cytokines such as IL-1, TNF-α and IL-6, is involved in the phases of lesion expansion as a result of bone destruction. Conversely, T_H2 response, mostly mediated by cytokines IL-4, IL-5, IL-5, IL-10, and transforming growth factor (TGF)-β, exert an important role in the healing process and restriction of the immune response.[139,140] T_H2 response can also exert an important protective role given its participation in the humoral response.[141] Colić et al.[121] proposed that T_H1 immune response is important for all stages of apical periodontitis development, while T_H2 and immunoregulatory cytokines are more significant in the process of stabilization of the lesion size.

T-regulatory cells (Tregs) can also be involved in regulation of destructive immune responses. These cells have been detected in apical periodontitis lesions.[142] Both T_H1 and T_H2 responses can be suppressed by Treg cells.[142] Treg infiltration in apical periodontitis may be delayed in comparison with other innate or adaptive immune cells, possibly to control excessive lesion expansion.[143]

T_H17 is a subset of T_H cells that seem to play a dominant role in exacerbating inflammation.[144] These cells produce IL-17, which stimulate IL-8/CXCL8 production and attraction of PMNs to the site. T_H17 cells and IL-17 have been detected in apical periodontitis lesions.[38-39,45,145]

Factors that may stimulate epithelial proliferation include the epidermal growth factor and the keratinocyte growth factor produced by macrophages and fibroblasts, respectively. Both factors have been detected in apical periodontitis lesions.[146,147] Other mediators produced by cells in the granuloma can also stimulate epithelial proliferation, including TNF, IL-1, IL-6, prostaglandins, and insulin-like growth factor.[55] Microbial components, such as LPS, can also stimulate the epithelial proliferation.[148]

Chapter 7

Dental Innervations and Pain of Pulpal Origin

Nikita B. Ruparel, Asma A. Khan

The dental pulp is a highly innervated tissue in the body. It primarily consists of two types of innervations: sensory and autonomic. While sensory nerves are the primary conductors of noxious information within the dental pulp, sympathetic and parasympathetic nerves play a role in regulating the vasculature, with both types serving to maintain pulpal homeostasis. Evidence of parasympathetic fibers in the dental pulp is controversial.

Sensory innervation in the entire orofacial region, including teeth, comes primarily from the trigeminal system with cell bodies in the trigeminal ganglion. The maxillary component of the dental sensory innervation is derived from V2 (maxillary division), while the mandibular component is derived from V3 (mandibular division). On the other hand, the autonomic innervation comes from the superior cervical ganglion.

CLASSIFICATION

Anatomical and electrophysiologic studies have demonstrated the presence of A-type and C-type fibers within the dental pulp. The subtypes of A-fiber type are Aα, Aβ, Aγ, and Aδ. Each subtype has distinct functions (Table 7-1) with Aδ functioning to detect noxious stimuli. Based on the conduction velocity, all fiber types are classified as either fast-conducting A-fibers or slow-conducting C-fibers. A-fibers are myelinated fibers, whereas C-fibers are unmyelinated; the presence or absence of the myelin sheath accounts for the conduction velocities of these fiber types by forming the nodes of Ranvier. Moreover, the thicker the myelin sheath, the larger is the fiber diameter and the greater is the distance between adjacent nodes (i.e., conferring faster conduction velocity). Conceivably, C-fibers are only 0.4–1.2 μm in diameter, whereas Aδ are 2–5 μm in diameter.

Primate studies have demonstrated that ~70%–80% of the pulpal terminals are unmyelinated.[1] These include postganglionic sympathetic fibers and sensory nerve fibers. Labeling studies[2–5] and some immunohistochemical studies,[6] evaluating sensory nerve terminals, indicate that despite most sensory fibers being unmyelinated within the dental pulp, the majority have a myelinated origin (Figure 7-1). Large diameter myelinated fibers lose some, or all, of their myelin sheath at the port of entry into the tooth and appear as unmyelinated or thinly myelinated. Therefore, the dull aching pain, which is popularly attributed solely to the slow conducting C-fibers, may also actually be due to the slower conducting Aδ-fibers that have now lost their myelin sheath. Of course, the sharp shooting pain is still primarily attributed to the relatively faster conducting Aδ-fibers, as their C-fiber counterparts completely lack any myelination. Moreover, high-threshold electrical stimulation is also mediated by Aδ-fibers. Other types of pain sensations, such as prepain, are mediated by Aβ-fibers.[7–9]

Interestingly, another school of thought attributes dentinal pain to low-threshold mechanoreceptors (LTMs).[10] Stimuli such as air-puffs and water spray, when applied to gingival tissues, evoked a sensation of touch but the same stimuli evoked a sensation of pain when applied to exposed dentin.[10] Both air-puffs and water spray do not evoke sufficient mechanical force within the dental tubules to activate high-threshold nociceptors. Therefore, LTMs (or "algoneurons"[10]) may be the ones mediating the painful sensation when activated by low-threshold stimuli within a tooth. Possible mechanisms contributing to LTM-induced dentinal pain may be the projection of Aβ-fibers onto the same second-order neurons as nociceptors[10,11] as well as release neurotransmitter content that is typically present in nociceptor population, such as calcitonin-gene related peptide (CGRP), thereby activating projection neurons in the trigeminal brainstem complex.[10] Moreover, neonatal capsaicin treatment in rats that cause ablation of C-fiber nociceptors in the hindlimb do not show any loss in pulpal afferents,[10,12,13] suggesting that the dental pulp may primarily be innervated with A-fiber LTMs.

TABLE 7-1 Classification of Nerve Fibers in the Dental Pulp

Type of Fiber	Function	Diameter (μm)	Conduction Velocity (m/s)
Aα	Motor, proprioception	12–22	70–120
Aβ	Pressure, touch	5–12	30–70
Aγ	Motor	3–6	15–30
Aδ	Pain, temperature, touch	2–5	12–30
C	Pain	0.4–1.2	0.5–2
Sympathetic	Postganglionic sympathetic	0.3–1.3	0.7–2.3
Parasympathetic	Postganglionic parasympathetic	Unknown	Unknown

Some of the nerve fibers extend into the dentin ***C.*** (Courtesy of Dr. Michael A. Henry, San Antonio, TX, U.S.A.)

Collectively, the dental pulp consists of some unique nerve fiber phenotypes that make it an intriguing tissue to study and understand pain mechanisms.

DISTRIBUTION

All primary afferent fibers make their entry into the pulp primarily via the major apical foramen. They are organized into bundles located in the center of the pulp. While many unmyelinated fibers terminate freely in the stromal of the pulp, some sensory fibers continue their path toward the subodontoblastic layer, forming the Plexus of Rashkow. From here, some even continue sending extensions into the dentinal tubules. This organization is key to understand the quick response of these nerve endings to various noxious stimuli and dentinal hypersensitivity.

The pattern of sensory innervation within the pulp follows a gradient in which regions, such as the pulp horn, are densely innervated with Aβ- and Aδ-fibers. However, the number of these fibers at the cervical region is low and is even lower in root dentin. Moreover, in the pulp proper, the primary fiber types found are the unmyelinated C-fibers. This distribution has implications on sensibility tests such as electric pulp tests (EPTs). According to many studies,

the optimal site for placement of the EPT electrode is the incisal, or incisal third, of an anterior tooth[14,15] or mesiobuccal cusp of a molar tooth,[16] both of which are regions with prominent pulp horns.

The pattern of distribution is attributed to the concentration and dependence of different nerve fibers on different neurotrophins.[17,18] A study using semaphorin3a knockout mice (Sema3a) has demonstrated that sema3a regulates the timing of navigation and the pattern of the terminals within the developing dental pulp.[19] Moreover, glial cell line-derived neurotrophic factor has been seen close to the coronal pulp with large diameter mechanosensitive A-fibers,[18] whereas nerve growth factor (NGF) is associated with the remainder of the fiber types.[17] Overall, the role of neurotrophins is critical for the spatial and temporal distribution of different nerve fibers in the dental pulp. This is not only prevalent during development but also during adulthood (see subsequently) and plays a strategic role in defending the pulp from tissue injury.

NEUROPEPTIDES

Nerve fibers innervating the dental pulp are classified as peptidergic or nonpeptidergic, based on the presence or absence of neuropeptides, such as CGRP[20–25] and Substance P (SP).[24–30] Aδ- and C-fibers are classically known to contain these two neuropeptides in their cell bodies. Under conditions of inflammation, they are able to package these peptides into vesicles, transport them to the terminals, and release them.[31]

Other neuropeptides present in the dental pulp and released by pulpal axons include neurokinin A (NKA),[24,30] neuropeptide Y (NPY),[32–35] vasoactive peptide (VIP),[25] cholecystokinin, somatostatin,[36,37] galanin,[38] cholecystokinin,[37] β-endorphin, and enkaphain.[37,39] Table 7-2 lists the commonly known neuropeptides, their source, and functions in the dental pulp.

Function

The dense innervation of the dental pulp with sympathetic and sensory nerve fibers indicates a potential role of these fibers in maintaining pulpal homeostasis and repair. The following subsections discuss three major functions of these fibers under normal and conditions of tissue injury.

Role in Regulation of Pulpal Blood Flow

In absence of tissue injury, the pulpal blood flow is maintained so that the pulp tissue is adequately perfused, delivering appropriate amounts of nutrients and oxygen to the cells residing within the pulp. Pulpal blood flow also maintains tissue pressure by keeping the capillary as well as colloidal tissue pressure and balance of proteins inside the capillaries and in the interstitium. On the other hand, under conditions of tissue injury and inflammation, two categories of nerve fibers are activated; sympathetic and sensory nerve fibers. The initial response of the pulp is reduction in pulpal blood flow. This effect is primarily mediated by neurotransmitters/peptides such as norepinephrine and NPY that are locally produced by sympathetic nerve fibers. Norepinephrine, in turn, activates α-adrenergic receptors expressed in smooth muscle cells of nearby arterioles to cause vasoconstriction.[40,41] Thus, the pulp undergoes a period of reduced blood flow upon sympathetic activation. Indeed, this effect is mimicked upon infiltration injection of local anesthetics containing "vasoconstrictors." Upon injury, however, primary afferent sensory nerve terminals are also activated.

External stimuli such as bacterial toxins, for example, lipopolysaccharides (LPSs) or inflammatory mediators, released by neighboring cells, act via respective receptors on these fibers and trigger vesicular release of many neuropeptides.[42–44] The two most extensively studied peptides are SP and CGRP. These peptides play a key role in mediating vasodilation and vascular permeability,[26] two essential components of "*neurogenic inflammation*." The effect of these neuropeptides is mediated via both Aδ- and C-fibers.

The neural regulation of pulpal blood flow is evident from anatomical studies showing the close proximity of peptidergic nerve fibers with pulpal microvasculature (Figure 7-2).[6] Moreover, sprouting of nerve fibers is also evident upon inflammation, suggesting an increase in the overall number and activation of fibers leading to neurogenic inflammation.[45] Immunohistochemical analysis demonstrates an increase in levels of SP, CGRP NPY, and NKA after irreversible pulpitis.[24,25,31,46,47] Transient changes in the pulpal vasculature are well tolerated by the pulp. However, under conditions of persistent injury or inflammation, the pulpal defenses are overwhelmed and unable to be sustained. For more details, see Chapter II.

TABLE 7-2 Tabulation of Dental Pulp Neuropeptides, Their Sources, and Functions

Neuropeptides	Source	Function
Substance P (SP)	Sensory nerve terminals	Vasodilation
Calcitonin-gene related peptide (CGRP)	Sensory nerve terminals	Vasodilation
Neurokinin A (NKA)	Sympathetic nerve terminals	Vasoconstriction
Vasoactive peptide (VIP)	Parasympathetic nerve terminals	Vasoconstriction
Neuropeptide Y (NPY)	Sensory nerve terminals	Vasoconstriction
β-endorphin	Sensory nerve terminals	Inhibition of SP release
Enkaphalin	Sensory nerve terminals	Inhibition of SP release
Somatostatin	Unknown	Inhibition of SP release
Galanin	Unknown	Unknown
Cholecystokinin	Unknown	Unknown

Role in Immune Regulation

Neuropeptides released from terminal nerve fibers are known to regulate the immune response. Studies evaluating SP have demonstrated several effects of this peptide in mediating proinflammatory effects in pulp tissue. These include recruitment and enhancement of macrophage-induced phagocytosis,[48,49] release of proinflammatory cytokines by macrophages,[50,51] and proliferation of T lymphocytes.[52,53] Similar effects on macrophage activation are also demonstrated by the neuropeptide, NKA.[54] CGRP, on the other hand, inhibits some of these effect while continuing to participate in neurogenic inflammation by triggering release of histamine from mast cells.[55]

In addition to their role in the dental pulp, neuropeptides have also been implicated in regulating periapical disease. Increased levels of VIP have been shown to limit the size of a periapical lesion.[54,56] This effect may be mediated by inhibition of macrophage-induced cytokine production thereby inhibiting osteoclastogenesis[57,58] and/or by $CD8^{+}$ lymphocyte apoptosis.[59] Similar effects have been observed with CGRP as well. Moreover, expression of SP on immune cells and endothelial cells indicates its potential key role in regulating the periapical response to infections from the root canal system.

Role in Transmission of Pain

The involvement of sensory nerve fibers or nociceptors in pain mechanisms is well studied. The pathway for pain transmission in the dental pulp starts with detection of noxious chemical, thermal, or mechanical stimuli by primary afferent nerve fibers (Figure 7-3). These belong to the trigeminal system, where the first-order neurons project their central terminals to the sensory nucleus, located in the brainstem. Three different regions of this nuclei namely, nucleus oralis, interpolaris, and caudalis receive projections from these terminals. However, the preponderance of evidence points to nucleus caudalis as being the primary nucleus receiving majority of the nociceptive input (Figure 7-4).[60,61] The signal is then relayed by second-order projection neurons to the thalamus that finally sends inputs to the somatosensory cortex. Therefore, the initiation of dental pain transmission occurs peripherally within the dental pulp for pulpal pain, such as pulpitis, and from the periodontium when periapical inflammation in ensued as in cases of symptomatic apical periodontitis or acute apical abscess.

Specialized fibers that can detect a variety of stimuli such as thermal, mechanical, and chemical stimuli are called polymodal nociceptors. These include both Aδ- and C-fibers. Detection of these noxious stimuli occurs via stimuli-sensing receptors located at peripheral termini. These include G-protein-coupled receptors (GPCRs) that upon activation couple/bind to one of three G proteins, namely $G\alpha_{s}$, $G\alpha_{i/o}$, $G\alpha_{q/11}$.[62] Depending on which G protein is bound, different cellular events occur. Several inflammatory mediators activate specific GPCRs. For example, prostaglandins are known to activate $G\alpha_{s}$; activation of a stimulatory G protein leads to activation of adenylate cyclase, that causes an increase in cyclic adenosine monophosphate (cAMP) and ultimately leading to cellular activation.[62] On the other hand, activation of $G\alpha_{i/o}$ by opioid and cannabinoid agonists leads to

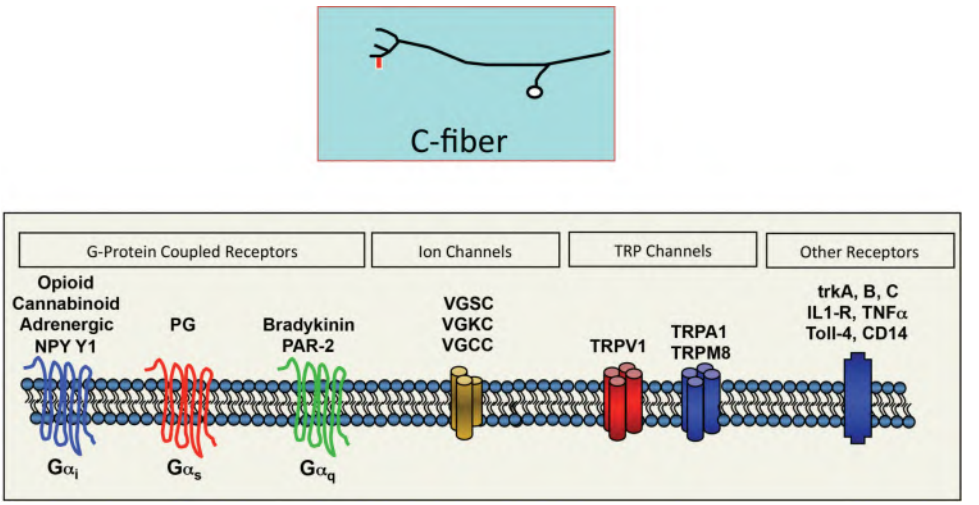

FIGURE 7-3 Cartoon depicting major classes of receptor or ion channels proposed to be present on peripheral terminals of sensory neurons that serve to transduce external stimuli into altered neuronal function. Not all receptors or ion channels are present on all neurons, and several have been shown to be altered during inflammation or nerve injury. PAR-2, protease-activated receptor subtype 2; PG, prostaglandin; TRPA1, transient receptor potential A1; TRPM8, transient receptor potential M8; TRPV1, transient receptor potential V1 (aka the capsaicin receptor); VGCC, voltage-gated calcium channel; VGKC, voltage-gated potassium channel; VGSC, voltage-gated sodium channel. FIGURE 7-4 Dental afferents project broadly throughout the entire trigeminal sensory nuclear complex. Darkfield photomicrographs show the central projection of dental afferents (arrows) to oralis and caudalis following the transganglionic transport of horseradish peroxidase from the feline mandibular canine pulp to primary afferent terminals, located throughout the trigeminal sensory nuclei. Labeled fibers exit the trigeminal tract and terminate in rostral (oralis; arrowhead) and caudal levels of the complex including the superficial laminae of caudalis (arrow). (Courtesy of Dr. Michael A. Henry, San Antonio, TX, U.S.A.)

decease in cAMP levels leading to nociceptor inhibition.[62–64] Nociceptors also respond to inflammatory mediators by activating $G\alpha_{q/11}$; bradykinin and leukotriene receptors that activate their respective GPCRs bind to $G\alpha_{q/11}$ that activate a different signaling cascade involving phospholipase C ultimately leading to sensitization of nociceptors.[62,65,66]

Apart from metabotrophic GPCRs, ionotrophic receptors are also equally, if not more critical in nociceptor activation. One of the most extensively studied receptors is transient receptor potential vanilloid 1 (TRPV1) receptor.[62] It belongs to the ion channel family of receptors and is extensively studied for inflammatory pain. TRPV1 is capable of detecting chemical stimuli, such as capsaicin, the primary component in chili peppers, and temperatures >43°C.[67] Moreover, under conditions of inflammation, a variety of inflammatory mediators can reduce its threshold of activation by sensitizing the receptor, leading to a hyperalgesic state.[66,68] Interestingly, TRPV1 expression is evident in the dental pulp[3,69] and is increased in symptomatic and asymptomatic teeth, suggesting the critical role of TRPV1 in pain and inflammation.[70]

Other TRP channels such as TRP ankyrin 1 (TRPA1)[71–74] and TRP melastatin 8 (TRPM8)[72,75] have roles in detecting cold or cooling temperatures as well as inflammatory mediators. Overall, TRPs play a major role in being one of the first targets that detect external stimuli and mediate the transmission of pain.

Other types of receptors expressed on sensory nerve terminals include pattern recognition receptors, such as Toll-like receptors (TLRs). These recognize structurally conserved antigens produced by microorganisms, such as LPS from gram-negative and lipotechoic acid (LTA) from gram-positive microbes. Activation of TLR on nociceptors causes sensitization of receptors, such as TRPV1.[42,43] This in turn reduces the threshold of nociceptor activation and

therefore, promotes the process of spontaneous pain or lingering pain. Similar to LPS and LTA responses, local release of inflammatory meditators such as prostaglandins[76] and bradykinin[77,78] also sensitize the effects of nociceptors under conditions of inflammation.

Key to dental pain mechanisms are voltage-gated sodium channels (Na_v) that aid in the propagation of the signal through the length of the nerve. These channels have isoforms that are specially expressed on terminal nerve endings of sensory fibers.[79] The isoforms within the pulp are $Na_v1.7$ and $Na_v1.8$.[80] These isoforms are seen to be upregulated in painful teeth compared to normal pulps (Figure 7-5).[81] Their location along the nerve axon promotes faster conduction of an impulse from the termini to the central terminals thus sometimes mediating spontaneous and sharp shooting pain characteristic of pulpitis. Na_v can form clusters in the unmyelinated segments of myelinated axons, suggesting a possible role of these channels in mediating pain characteristic of irreversible pulpitis.[6] Moreover, inflammation-induced sensitization of Na_v channels by prostaglandins has also been implicated in pain from irreversible pulpitis as sensitization can allow for depolarization of nerve fibers at lower stimulus strengths than usual.[82]

Neural plasticity has been implicated in dental injury. Nerve fibers not only react by modifying gene expression but also change their cytochemical phenotype. Upon low intensity injury, primary afferent fibers increase in number within the dental pulp. This phenomenon has been termed a "sprouting."[83,84] The role of NGF in mediating this process has been implicated, as increase in pulpal NGF is seen following pulpal injury.[85] These effects appear to last as long as the stimulus is present. The neuronal architecture returns to normal soon after the stimulus is removed. However, under conditions of persistent inflammation or infection, sprouting can continue over long periods of time and may contribute to nociceptor sensitization. While this is conceivable, it is arguable. Wood et al.[86] showed preliminary data indicating that pulps collected from normal and cariously involved nonpainful teeth present significant differences in nerve density (Figure 7-6). Cariously involved nonpainful teeth

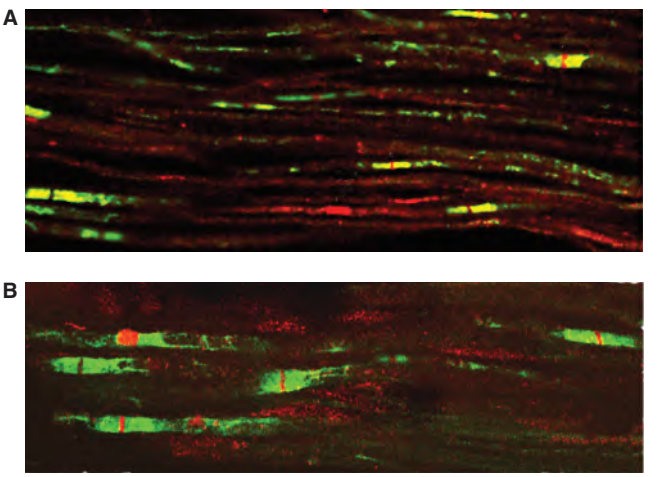

FIGURE 7-5 ***A*** and ***B.*** The $Na_v1.7$ and $Na_v1.8$ sodium channel isoforms (red) are prominently expressed within nerve fibers, located in the painful human dental pulp at both non-nodal and nodal locations. Nodes of Ranvier are identified by the paranodal staining of Caspr (green). (Courtesy of Dr. Michael A. Henry, San Antonio, TX, U.S.A.)

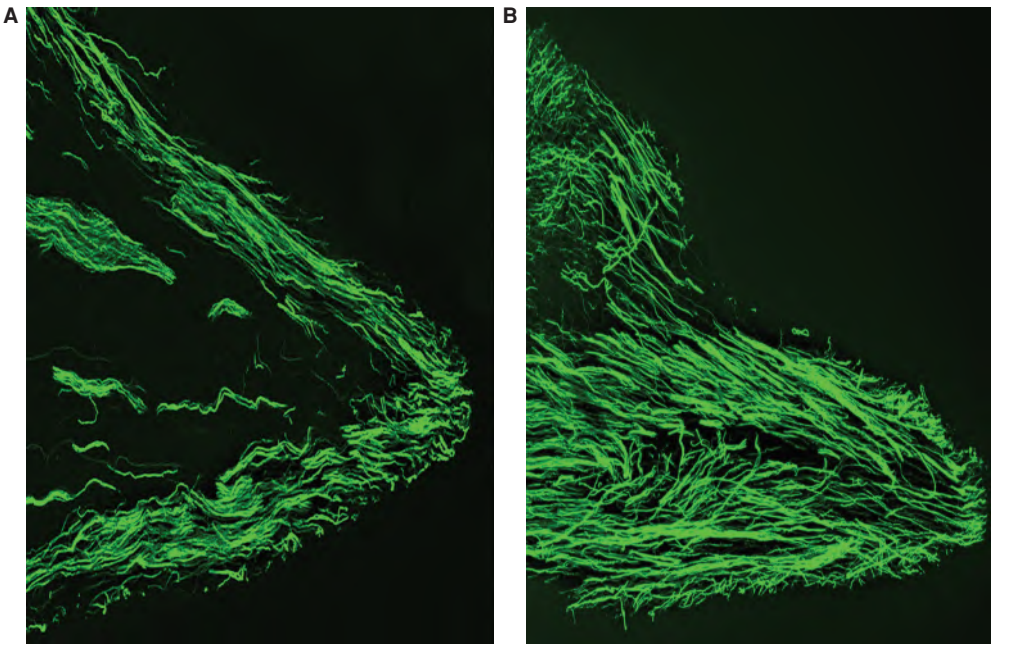

FIGURE 7-6 Nerve sprouting in carious nonpainful teeth. Confocal micrographs of nerve labeling (identified with N52/GAP43) within two different pulp horns, from the same human molar tooth, show a normal nerve distribution in the pulp horn lacking a carious lesion ***A.*** while extensive nerve sprouting is seen in the other pulp horn that was associated with an early carious lesion ***B.*** (Courtesy of Dr. Michael A. Henry, San Antonio, TX, U.S.A.)

have higher amounts of nerve sprouting compared to normal pulp, suggesting that sprouting may not directly correlate to increased pain. Nevertheless, sprouting may contribute to change in pulpal homeostasis, repair, and healing.

Central terminals of primary afferents, located in the dental pulp, are key in relaying peripherally detected stimuli to second-order neurons located within the medullary dorsal horn. Although the majority of peripheral tooth terminals terminate in nucleus caudalis, some also make connections on neurons located in nucleus oralis and interpolaris.[87–90] This may explain the inability of patients to localize pain originating from a tooth with symptomatic pulpitis. These second-order neurons or projection neurons are the primary centers of the majority of pain processing that occurs following peripheral injury.

Apart from the primary afferents, projection neurons also receive input from neighboring cells, such as interneurons, descending neurons, and glia. Upon peripheral tissue injury, central terminals of primary afferents release excitatory neurotransmitters, such as SP and glutamate. Glutamate has been studied extensively for its role in generation of hyperalgesia. Activation of NK1 for SP and NMDA and AMPA for glutamate on projection neurons causes excitation of these neurons that then send this signal via the trigeminothalamic tract to the thalamus from where the signal travels via the thalamocortical tract to the somatosensory cortex.

Although seemingly simple, the integration of input at the projection neuronal level, under conditions of inflammation, is quite complicated. Inflammation-evoked persistent activation of C-fiber input leads to sufficient intensity that renders the projection neurons in a state of constant activation. This establishes an area of synaptic plasticity. Other inputs from neighboring cells such as interneurons and glia can also modify this signal depending on the neurotransmitter they release. Moreover, larger fibers such as Aβ-fibers, which typically deliver information such as touch and proprioception from the periphery, are now primed under conditions of inflammation and contribute to amplification of this signal. Overall, these cellular pathways increase the receptive field, contribute to response mediated by non-noxious stimuli (allodynia), increase response to painful stimuli (hyperalgesia), and promote spontaneous pain. Together, the sensitization of the central projection neuron establishes the phenomenon of central sensitization.

Central sensitization is key to understanding some of the pain experienced by patients post treatment. Approximately 11% of patients continue to have pain seven days after endodontic treatment,[91] while 1.9% continue to have pain that remains unresolved for three to five years.[92] This suggests that despite achieving successful endodontic treatment as seen by clinical measures, persistent pain may exist. This may partly be explained by central sensitization that persists long after removal of the peripheral component. It is therefore conceivable that preoperative pain can be a strong predictor for possible postoperative pain.[93]

Taken together, dental pain mechanisms depend largely on the extent of pulpal injury and therefore on the severity of inflammation. Target receptors present on nociceptors, which show changes in their physical and molecular expression as well as central mechanisms leading to maintenance of a hyperalgesic state, contribute significantly to the overall symptoms of pain.

PAIN OF PULPAL ORIGIN

Activation of sensory neurons that innervate the pulp and periapical tissues commonly evokes a sensation of pain. The perception of "toothache" may result from activation of neurons innervating the pulp and periapical tissues as well as from central mechanisms of hyperalgesia. Experienced clinicians also find that, in some cases, the noxious input may not originate from the tooth the patient perceives to be associated with the pain. Instead, the pain may be referred from a distant site.

DENTIN HYPERSENSITIVITY

Dentin sensitivity is a common form of odontogenic pain and is described as a short, sharp pain from exposed dentin in response to thermal, tactile, osmotic, evaporative, or chemical stimuli, and that cannot be ascribed to any other pathosis or any form of dental defect.[94] The reported prevalence of dentinal hypersensitivity ranges from 3% to 98%.[95–99] The discrepancy in reported prevalence rates may be due to selection bias in the recruitment of study subjects, the use of different diagnostic criteria, and cultural factors.

Risk factors for dentin hypersensitivity include age, gingival recession, bleaching, periodontal treatment, abrasion, attrition, and anatomic defects.[100,101] Some studies report that the incidence of dentin hypersensitivity peaks in the third and fourth decades.[102] Gingival recession, erosion, and abfraction expose dentin tubules are likely to result in dentinal hypersensitivity. A recent study reported that the prevalence rate of dentin hypersensitivity was higher in subjects with gingival recession (PR 5.5; 95% CI 3.0–10.1).[103] The decrease in dentin hypersensitivity after the fourth decade may be due to the formation of tertiary dentin or loss of pulp vitality.

Several mechanisms have been proposed to explain dentinal hypersensitivity (see Chapter II, Figure 2-5). The neural theory proposes that neurons innervating the dentinal tubules are directly activated by stimuli. The hydrodynamic theory, the most widely accepted theory, proposes that movement of fluid in the dentinal microtubules generated by mechanical, thermal, or chemical forces activates nerve fibers, resulting in pain.[104] Movement of dentinal fluid induces shear stress that may, in turn, activate mechanosensitive ion channels, such as TREK1, TREK2, and ASICS3.[73] The direction of movement of dentinal fluid can be both inward (toward the pulp) and outward (away from the pulp). Cold stimuli elicit an outward flow and more rapid transient pain sensations, while hot stimuli elicit an inward flow.

The odontoblast transduction theory proposes that odontoblasts function as sensory receptors that transduce external stimuli and then transmit them to nerves terminals in the dentin or pulp. Odontoblasts are known to express cell surface receptors and ion channels, including TRPV1, TRPV2, TRPV4, TRPA1, TPRM3, and Ca and K channels,

thus suggesting that these cells can potentially function as sensory receptors.[105–111]

MANAGEMENT OF DENTIN HYPERSENSITIVITY

Treatment of dentin hypersensitivity usually takes one of the two approaches; reduction in dentinal fluid flow or reduction in activity of neurons innervating the dentinal neurons. Agents such as sodium fluoride, stannous fluoride, strontium chloride, potassium oxalate, calcium phosphate, calcium carbonate, and bioactive glasses reduce fluid flow by plugging dentinal tubules. Dentin adhesive sealers, including fluoride varnishes, oxalic acid and resin, glass ionomer cements, composites, and dentin bonding agents, occlude the tubules, resulting in attenuation of dentin hypersensitivity.

Neural modulating agents such as potassium nitrate are thought to act by depolarizing the nerves and preventing repolarization. A meta-analysis compared the effect of potassium containing tooth pastes to that of nonpotassium-containing tooth pastes on dentin hypersensitivity ($N = 390$).[111] The results showed that the use of potassium-containing tooth pastes results in a significant decrease in mean sensitivity to tactile, air blast, and thermal stimulation but not in subjective assessment.

PULPITIS

Inflammation of the pulp (and periapical tissues) is commonly associated with pain constituting ~90% of emergency visits with tooth pain as the chief complaint. This pain is attributed to activation of pulpal or periapical nociceptors.[112] Microbial infections of the pulp trigger an immune response designed to limit infection, signal injury, and promote repair. A plethora of immune mediators are released that trigger pain, inflammation, and, in advanced stages, pulpal necrosis. As the pulp becomes inflamed and transitions from a stage of normal to reversible pulpitis to irreversible pulpitis, patients often experience spontaneous or evoked pain.

Some patients with irreversible pulpitis present spontaneous pain. Descriptors used by patients to describe the quality of their pain are important clues that help differentiate odontogenic pain from pain referred from other sites. For more details, see Chapter XVII.

A study comparing the quality of pain in patient with odontalgia ($n = 359$) to those with craniofacial pain referred from cardiac origin ($n = 115$) showed that the quality descriptors, such as aching, burning, pressure, and throbbing, have high validity ($P = 0.53$) for differentiating between odontogenic and cardiac pain.[113]

While the descriptor "throbbing pain" is commonly associated with odontogenic pain, the underlying mechanisms are yet to be understood. It was previously thought that the sensation of throbbing was caused by the rhythmic activation of pain sensory neurons in close approximation to blood vessels. An elegant study on the relationship between throbbing pain and arterial pulsations in odontogenic pain patients showed that the throbbing rate (44 bpm ± 3 standard error of mean [SEM]) was much slower than the arterial pulsation rate (73 bpm ± 2 SEM) and, that there was no synchronicity between the two rhythms ($P < 0.001$) (Figure 7-7).[114] Therefore, it appears that the physiological mechanisms underlying these two rhythmic events are distinct.

Thermal hyperalgesia is considered a hallmark of symptomatic irreversible pulpitis pain. Several studies have examined the expression of thermoreceptors and ion channels in the dental pulp in order to better understand the mechanisms underlying thermal hyperalgesia in pulpitis. For example, studies on TRP receptors show that odontoblasts express TRPV1–3, TRPA1, and TRPM8[108,115]; dental pulp fibroblasts express TRPA1, TRPM2, and TRPM8[46]; and axons innervating the dental pulp express TRPA1, TRPM2, TRPM8, and TRPV1. Preclinical studies and *ex vivo* studies clearly show that these receptors are functional and that they are sensitized in the presence of infection (such as LPS) and inflammatory mediators.[43,69,116] However, data generated from clinical studies comparing pulps collected from patients with symptomatic pulpitis and normal pulps have yielded conflicting results. TRPM2

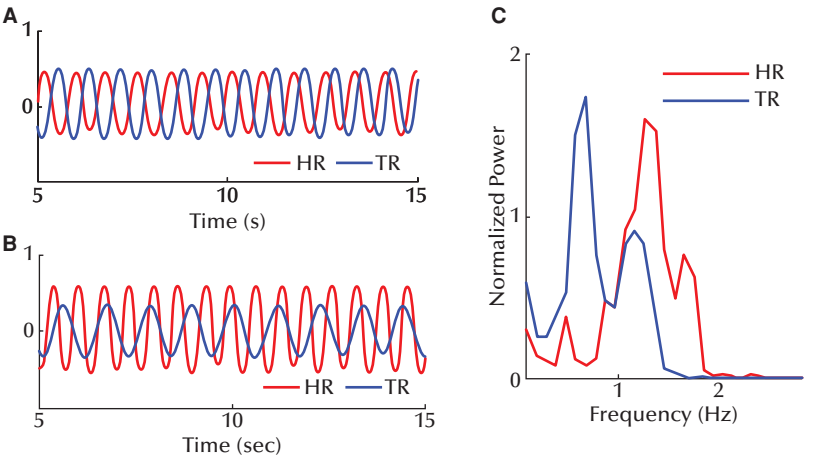

FIGURE 7-7 Spectral analysis of the rate of throbbing rhythm (TR) and the arterial pulse rate (HR) in odontogenic pain patients. ***A*** and ***B.*** show the superimposed and smoothed waveforms of TR and HR from two representative subjects. ***C.*** Shows the average normalized power spectral from all subjects. (Reproduced with permission from Mirza et al.[126])

expression is increased in fibroblasts but not in axons innervating symptomatic human dental pulps.[117] Axonal expression of TRPM8 is decreased (not as expected) in inflamed cold-sensitive pulpitis samples as compared to normal pulps.[118]

Mechanical Allodynia is a common finding in patients presenting with signs and symptoms consistent with irreversible pulpitis.[119] Several hypotheses have been proposed to explain the concurrent presentation of mechanical allodynia with irreversible pulpitis (Figure 7-8). One hypothesis is that mechanical allodynia is mediated by mechanoreceptive neurons innervating the pulp. This is supported by the findings that odontoblasts express the mechanoreceptors

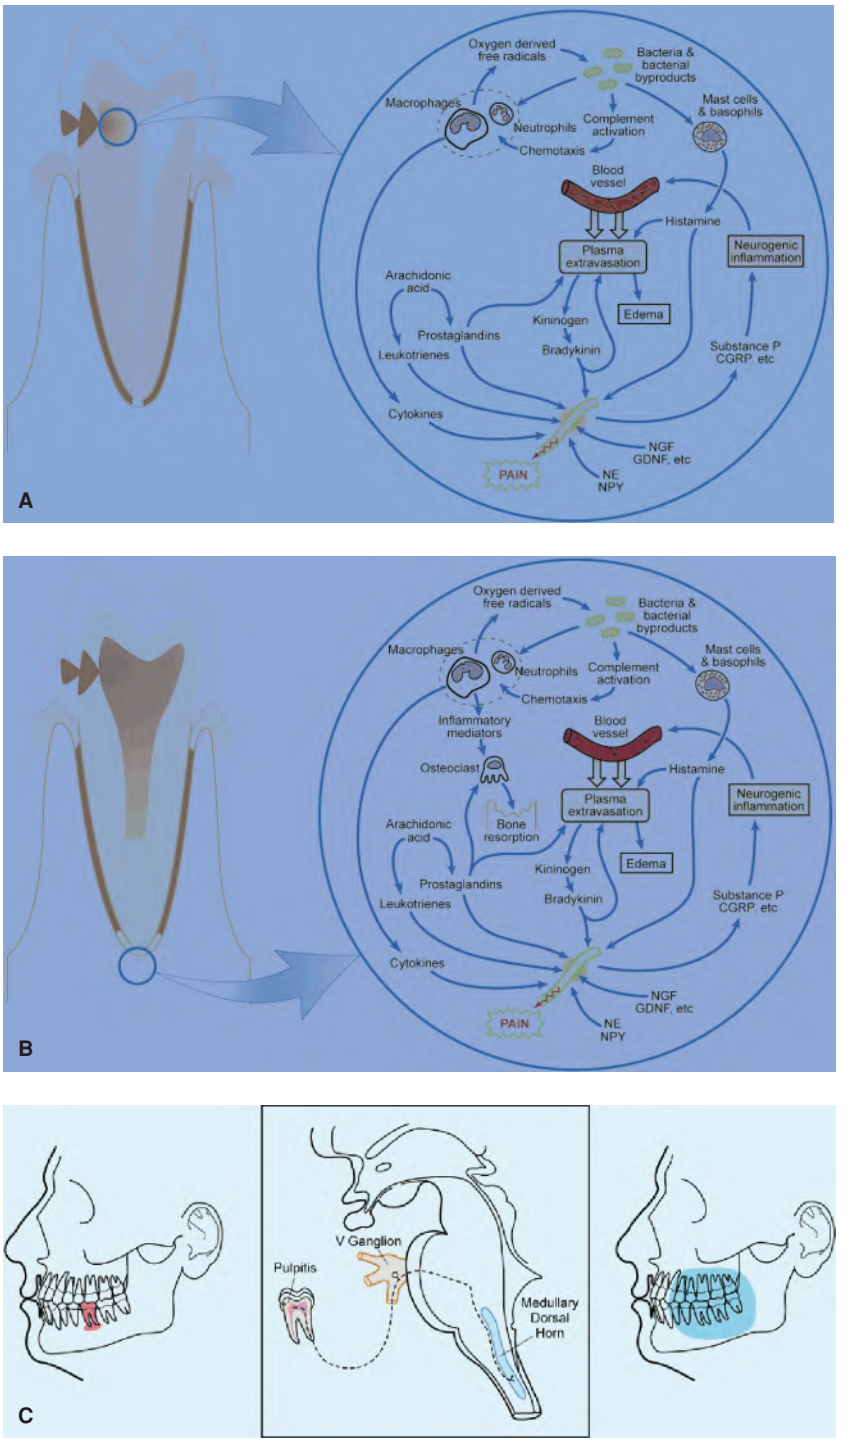

FIGURE 7-8 Diagrammatic representation of three hypotheses proposed to explain the incidence of mechanical allodynia is teeth with inflamed pulps. ***A.*** Microbial byproducts and inflammatory mediators in the pulp activate mechanoreceptors. ***B.*** Microbial byproducts and inflammatory mediators from the pulp diffuse into the periapical tissues and activate periradicular mechanoreceptors. ***C.*** Afferent barrage from pulpal nociceptors induces central sensitization resulting in expansion of receptor fields and mechanical allodynia. (Reproduced with permission from Owatz et al.[119])

TRPV4 and TRPM3 and that pulpal afferent A-fibers respond to mechanical stimulation.[70] Given that not all patients with symptomatic irreversible pulpitis present with mechanical allodynia, it is unlikely that the mechanical allodynia in odontogenic pain patients is activated via sensitization of pulpal mechanoreceptors.

A second theory is that inflammatory mediators and microbial byproducts from inflamed pulps diffuse into the periradicular space and activate or sensitize mechanoreceptors in the periodontal ligament. A recent study, comparing cone beam computerized tomography (CBCT) and periapical radiographs, detected periapical radiolucencies ≥1 mm in diameter in the CBCT images of almost 20% of teeth with vital pulps and no detectable radiolucencies in the periapical radiographs.[120] Another study found that 13.7% of teeth diagnosed with irreversible pulpitis had periapical lesions visible on CBCT as compared to only 3.3% on periapical radiographs.[121] This, coupled with histologic findings that periapical changes occur in teeth with vital pulps (prior to complete pulpal necrosis), support the hypothesis that the mechanical allodynia is teeth with irreversible pulpitis is due to activation of mechanoreceptors in the periodontal ligament.

A third hypothesis is that the mechanical allodynia results from central sensitization following activation of pulpal nociceptors. This is supported by preclinical studies showing that acute sensitization of TRPA1, expressing pulpal nociceptors, induces mechanical allodynia at distant sites.[122] A clinical study found that patients diagnosed with irreversible pulpitis and mechanical allodynia reported higher spontaneous pain as compared to those with irreversible pulpitis and normal periapical tissues.[119] Interestingly, the mechanical pain thresholds of the normal contralateral teeth in patients with irreversible pulpitis were lower than those in asymptomatic patients. Thus, there is both clinical and preclinical evidence supporting central sensitization in patients with irreversible pulpitis and mechanical allodynia.

REFERRED PAIN

Referred pain is a sensation felt in a site innervated by a nerve different from the one innervating the area from which the pain originates. Referred pain in the orofacial tissues is not uncommon. A systematic review and meta-analysis of nonodontogenic pain after endodontic therapy found that nonodontogenic factors accounted for 56% of dentoalveolar pain, present for ≥6 months after endodontic therapy.[123] A nested case series of patients (n = 19) with persistent tooth pain for >6 months after endodontic therapy found that nonodontogenic pain accounted for 42% of all cases.[123] The most common nonodontogenic reason was myofascial temporomandibular disorders with involvement of the masseter, temporalis, and lateral pterygoid muscles.

Pain referral commonly occurs in a laminated manner that reflects the order in which the nociceptors enter the spinal trigeminal tract. For more details, see Chapter XVII. Referred pain may present a diagnostic dilemma. The source of pain is usually identified by taking two approaches. The first is to elicit the pain (i.e., reproduce the chief complaint). Stimulation at the source elicits the pain while stimulation at the site of perception does not. The other approach is to block the pain using local anesthetics.[124] The prudent clinician appreciates the importance of listening to the patients' pain history, using appropriate diagnostic tests and replicating the chief complaint in order to arrive at the right diagnosis.

Chapter 8

Examination and Diagnosis of Pulp, Root Canal, and Periapical/Periradicular Conditions

Paul V. Abbott

The first, and the most important, step in managing any condition is to determine what the condition is, that is, it must be diagnosed. In addition, the causes of the problem must be identified. Once this information has been gathered, the appropriate options for managing the problem will become obvious. This applies as much to diseases and conditions involving the dental pulp, the root canal system, and the periradicular tissues as it does to any other disease or condition of the human body. Hence, the importance of diagnosis must not be forgotten or downplayed at any time. However, unfortunately, many clinicians do not take enough time to establish a meaningful or correct diagnosis and they often proceed immediately to providing some form of treatment. This approach may work in some cases, but it is akin to a guess and inevitably some guesses will be incorrect, which in turn can lead to inappropriate management or treatment with potentially adverse outcomes for the patient. This chapter outlines the various pulp, root canal, and periradicular conditions and provides a detailed, yet simplified, approach to the diagnosis of these conditions. In most situations, the term *"condition"* is used rather than *"disease"* since not every state of these tissues is a disease process or an indication of pathosis of the tooth and surrounding tissues. The term *"disease"* will be used where there is clearly a disease process occurring.

THE IMPORTANCE OF DIAGNOSIS

When assessing any disease or condition, it is essential for the clinician to know

- What the condition is,
- Whether it should be treated,
- When it should be treated,
- Why it should be treated, and
- How it should be treated.

Diagnosing the condition, in conjunction with having a thorough understanding of the disease processes, will provide the abovementioned information. In particular, the diagnosis will indicate the management options available for the condition as it can be considered that "*Diagnosis Drives Dentistry*." The diagnosis will also determine the details of the treatment required.

There are several management options for each of the various pulp, root canal, and periradicular conditions that affect teeth. The option chosen needs to be carefully considered and for each particular case and situation. The possible endodontic management options for teeth with pulp, root canal, and periapical/periradicular conditions usually include one or more of the following, depending on the diagnosis of the specific presenting problem:

- No treatment—but review and reassess.
- Restoration of the tooth (or replacement of the existing restoration).
- Conservative pulp treatment—such as indirect or direct pulp capping, partial pulpotomy, pulpotomy, or partial pulpectomy.
- Pulpectomy and root canal treatment.
- Root canal treatment of pulpless teeth.
- Root canal retreatment.
- Periapical surgery—or other surgical procedure(s).
- Systemic medications—such as nonsteroidal anti-inflammatory drugs (NSAID's), analgesics, antibiotics, and so forth.

The procedure most often performed in the practice of Endodontics is commonly called "root canal treatment." However, such treatment should not be the same for all cases, and it should vary according to the diagnosis. The mechanical processes (root canal instrumentation, root canal filling, etc.) are similar for all cases BUT the treatment needs and the biological objectives will vary depending on the diagnosis. Therefore, the management must vary. The typical variations include

- The cause of the disease and how it is removed.
- Some cases have a pulp to remove while others do not have a pulp.
- In some cases, the primary aim of the irrigants is to dissolve pulp tissue while in others it is to disinfect the root canal system.
- The medicament regime varies according to whether the aim is to reduce inflammation, destroy bacteria and/or encourage hard tissue repair.
- Some cases require drainage of pus while others have no pus to be drained.

BOX 8-1 Examples of how the diagnosis affects the details of how teeth with different pulp, root canal, and periapical/periradicular conditions are managed

Example 1

Diagnosis—Chronic reversible pulpitis as a result of toothbrush abrasion (often referred to as "sensitive dentin")

- Typical management—desensitisation of the dentin.

Example 2

Diagnosis—Acute reversible pulpitis as a result of caries

- Options for management—with the actual procedure chosen depending on clinical findings once the caries has been removed:
  - ◊ Indirect pulp cap
  - ◊ Direct pulp cap
  - ◊ Partial pulpotomy
  - ◊ Pulpotomy.

Example 3

Diagnosis—acute irreversible pulpitis as a result of caries

- Options for management:
  - ◊ Extraction
  - ◊ Pulpectomy and root canal treatment—with the following considerations/variations:
    - » Pulp tissue is present and needs to be removed
    - » Sodium hypochlorite is used to dissolve pulp tissue remnants
    - » Anti-inflammatory medicament should be used to reduce periapical nerve sprouting and neuropathic pain, e.g., a corticosteroid/antibiotic compound
    - » If the tooth also has acute apical periodontitis—consider postoperative systemic NSAID's and analgesics.

Example 4

Diagnosis—a pulpless and infected root canal system

- Options for management:
  - ◊ Extraction
  - ◊ Root canal treatment—with the following considerations/variations:
    - » There is no pulp tissue present
    - » Sodium hypochlorite is used as an antibacterial agent (i.e., tissue dissolution less important)
    - » Antibacterial medicament is required, e.g., calcium hydroxide
    - » If the tooth also has acute apical periodontitis—consider using a corticosteroid/antibiotic compound in conjunction with the calcium hydroxide to reduce periapical inflammation and pain.
    - » If the tooth also has an acute apical abscess—consider drainage; consider systemic antibiotics.

Some typical examples of the variations in management as a result of different diagnoses are outlined in Box 8-1.

In order to be able to diagnose any condition or disease, it is essential that the clinician has a good understanding of the condition itself. The discipline of Endodontics is concerned with the diagnosis and management of conditions and diseases of the dental pulp, the root canal system and the periapical/periradicular tissues. Hence, clinicians must have a thorough understanding of these tissues, their various conditions and the disease processes that occur within them.

The clinician must also recognize and understand that conditions and especially diseases of the dental pulp, the root canal system and the periapical/periradicular tissues are not static and that they progress through various stages of the overall disease processes. For example, when the dental pulp is irritated by microorganisms, it will progress though the various stages of inflammation (reversible pulpitis, irreversible pulpitis) and then necrosis if the microorganisms are not removed. Within a few months, the necrotic pulp tissue will be removed by the microorganisms so the root canal system then becomes pulpless and infected.[1] None of these conditions occur instantaneously; they will always progress from one to the next over a period of time (Figure 8-1). Similarly, the periapical tissues progress through various stages of inflammation (apical periodontitis), infections (abscess, cellulitis) and possibly cyst formation if the source of irritation is not removed.[2] The periapical disease process is a dynamic one and the tissues may alternate between various conditions on a regular basis (Figure 8-2), depending on the overall local environment and the patient's general health.[3] Hence, the symptoms that any particular patient will describe will depend on the current stage of the condition or disease processes when the patient presents to a dentist for assessment.

The pulp, root canal, and periapical/periradicular tissues are all inter-related and the conditions within the pulp or root canal have a direct effect on the periapical and periradicular tissues.

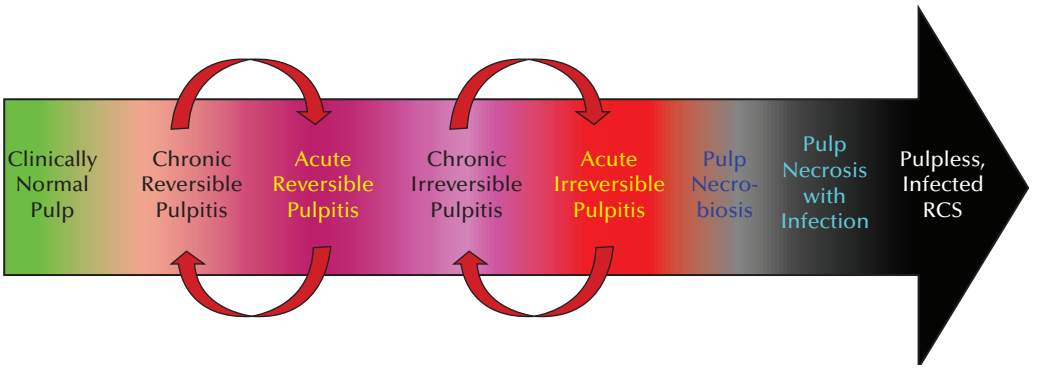

FIGURE 8-1 Schematic representation of the progression of pulp and root canal conditions through the various stages of the disease process.

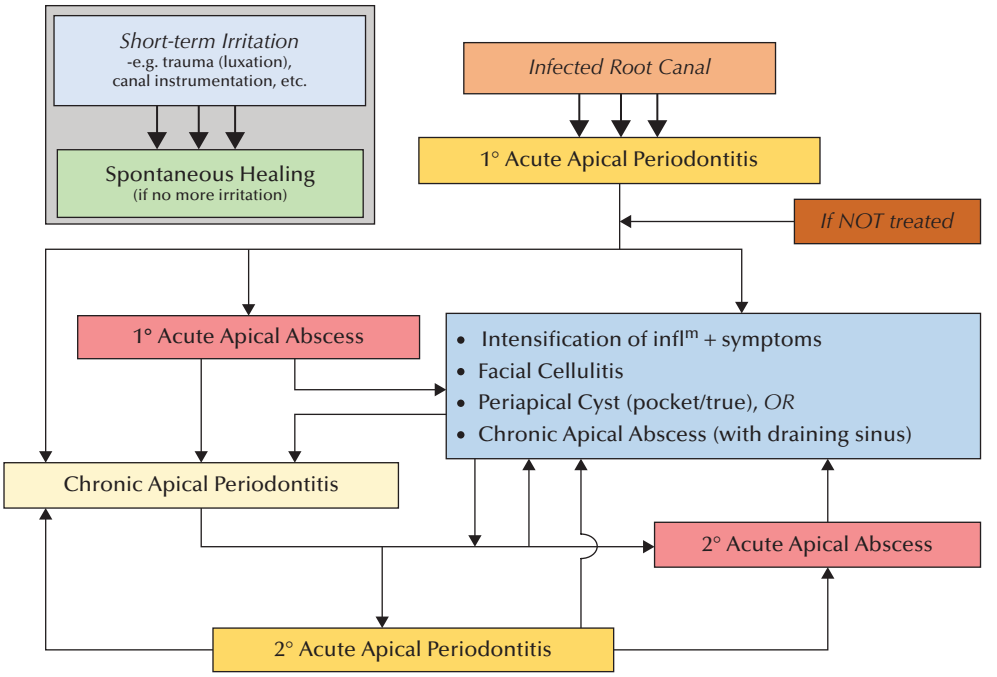

FIGURE 8-2 Schematic representation of the progression of periapical/periradicular conditions through the various stages of the disease process (adapted from Abbott[3]).

Hence, a thorough understanding of the interactions is also required. It is also essential to assess and diagnose the state of all tissues involved. When diagnosing endodontic conditions, there are four essential elements that must be determined.[4,5] These are the tooth involved, the state of the pulp (if present, otherwise the state of the root canal system), the state of the periapical/periradicular tissues, and the cause of the disease(s). If the condition of any tissue is missing, then the diagnosis is incomplete. Diagnosis is as much about assessing disease and abnormal conditions as it is about assessing the health of tissues. Hence, if one of the tissues is normal or healthy, then this should be stated as part of the diagnoses (see examples subsequently).

As mentioned earlier, not all teeth will have a pulp and therefore, these teeth cannot have the pulp assessed. Teeth that have become necrotic as a result of microbial invasion in the tooth will rapidly become pulpless and infected.[1] The tendency among many clinicians is to describe these teeth as having a "necrotic pulp" but this is inaccurate since there is no necrotic pulp tissue left in the root canal system. In any case, a necrotic pulp in itself does not cause apical periodontitis and therefore does not require root canal treatment. It is only when the necrotic pulp becomes infected that apical periodontitis occurs, and then root canal treatment is indicated.[6–10]

CLASSIFICATION OF CONDITIONS/DISEASES

The act of making a diagnosis is to determine what condition is present—in other words, to determine whether the tissues being assessed are normal or affected by a disease process. In essence, the final step of allocating a name (i.e., "the diagnosis") to any condition is one of summarising a

set of symptoms, clinical signs, test results, and radiographic observations into a few words. Hence, the words or terminology used must actually be possible to use in a clinical setting, meaningful with respect to what is happening in the tissues, and useful by leading to the management options. They should also be clear to all clinicians, and ideally used universally.[11] Unfortunately, this is not the case in the endodontic or dental literature when referring to pulp, root canal, and periapical/periradicular conditions. Many different classifications have been suggested over the years with virtually every textbook and many journal papers having their own classification. Likewise, many professional organizations and teaching institutions have their own classifications. Abbott and Yu[11] summarised 13 different classifications of pulp and root canal conditions used by various organizations and in textbooks. It is clear that there is no consistency between these classifications or the terminology used. Most of the classifications are either too simple (and miss many conditions) or too complex (and cannot be easily used in a clinical setting), and most of the classifications do not include all of the conditions that can occur. The end result is that there is no standardisation in terminology and this ultimately leads to confusion among clinicians. When the requirements for a clinical classification of diseases are considered, it is clear that most classifications of pulp, root canal, and periapical/periradicular conditions in the dental literature are inadequate, as they do not meet these criteria.

Another confounding factor in the diagnosis of pulp conditions has been the long-held belief by clinicians and researchers that there is no correlation between histological findings and the clinical presentation of pulp conditions. This belief was based on studies reported in the 1960s and 1970s[11–16] and it has led to confusion among clinicians and the subsequent use of many poor and inappropriate terms for the diagnosis of pulp conditions. However, Ricucci et al.[17] have reported that there is good correlation between the histological and clinical diagnoses as 96.6% of cases clinically diagnosed with either a normal pulp or reversible pulpitis had the same histologic diagnosis, and 84.4% of teeth clinically diagnosed with irreversible pulpitis had the same histologic diagnosis. In light of these findings, the old beliefs need to be reconsidered.

It is standard practice in medicine and dentistry to use the terms "acute" and "chronic" in a clinical sense without implying the histological response that may be occurring in the tissues.[11] For example, medical practitioners may diagnose "acute appendicitis" or "chronic appendicitis," depending on the severity of the presenting condition and the time that it has been present. Likewise, the dental profession uses terms such as chronic periodontal disease, acute ulcerative gingivitis, acute pericoronitis, and so forth. In endodontics, these terms have been used for many years but in more recent times, there has been a tendency toward not using them and instead to use "asymptomatic" and "symptomatic" even though they are inappropriate. As stated by Gutmann et al.,[18] there is "little, if any, support in the historic or contemporary peer-reviewed literature for the use of these terms," and they "have slowly crept into usage with little scientific basis for their applications or meanings."

Medical and dental dictionaries define "acute" and "chronic" for clinical use as follows:

- **Acute**—of or relating to a disease or a condition with a rapid onset and a short, severe course.[19] The pain is usually moderate to severe and the patient is typically seeking relief of the symptoms.
- **Chronic**—of long duration, used for a disease of slow progress and long continuance.[20] The pain associated with chronic conditions is usually mild and only occasionally present (i.e., "comes and goes"). The patient may only mention the problem in passing at a routine examination.

Hence, it is possible to use "acute" and "chronic" as clinical terms as long as the appropriate definitions are applied. These terms are appropriate for conditions of the pulp, root canal, and periapical/periradicular tissues. Hence, they will be used throughout this chapter and clinicians are encouraged to use them in their clinical practice in order to be consistent with other fields of dentistry and medicine.

Each pulp, root canal, and periapical/periradicular condition will have its own typical symptoms, clinical findings, and radiographic appearance that lead to the diagnosis. In addition, each pulp and root canal condition will have one or more typical associated periapical/periradicular conditions, and vice versa. Some conditions may appear to be similar to other conditions but there are key findings from the examination that allow clinicians to differentiate between them.

Abbott and Yu[11] and Abbott[5] have developed clinical classifications (Tables 8-1 and 8-2) for pulp, root canal, and periapical/periradicular conditions that meet the criteria for classifications, that is, they are possible to use in a clinical setting, meaningful with respect to what is happening in the tissues, and useful by leading to the management options. These classifications and each condition are outlined subsequently.

PULP AND ROOT CANAL CONDITIONS

This section describes each pulp and root canal condition listed in Table 8-1 to guide clinicians in the diagnostic process with a brief description of the typical symptoms reported by the patient, the typical clinical findings found on examination and testing of the tooth, the typical radiographic observations seen on periapical radiographs, the typical periapical/periradicular conditions associated with each pulp/root canal condition, the key findings that lead to the particular diagnosis, and the findings that distinguish each condition from other similar conditions.

The various forms of internal resorption will not be discussed in this chapter as they are discussed in detail elsewhere in this book.

TABLE 8-1 Classification of the Conditions of the Pulp and Root Canal System—See Text for a Description of the Typical Symptoms, Signs, and So Forth of Each Condition

No signs of disease:
- **Clinically normal pulp** *(based on history, clinical examination, tests, radiographs, etc.)*

Pulpitis:
- **Reversible pulpitis - acute***
  - chronic*
- **Irreversible pulpitis - acute***
  - chronic*

** Notes:*
- **Acute**—rapid onset and a short, severe course; moderate to severe pain; patient is seeking urgent relief of the symptoms.
- **Chronic**—long-standing; no pain or only mild and occasional pain; patient not seeking urgent relief.

Pulp necrosis:
- **Pulp necrobiosis** *(part of pulp is necrotic and infected; the rest is irreversibly inflamed)*
- **Pulp necrosis with NO signs of infection**
- **Necrotic and infected pulp**

Pulpless teeth:
- **Pulpless and infected root canal system**
- **Teeth with previous root canal treatment**
  - ◊ **Root-filled with NO signs of infection**
  - ◊ **Root-filled and infected root canal system**
  - ◊ **Incomplete endodontic treatment**** *(e.g., treatment started elsewhere)*
    *** Note: Must also specify whether the root canal system is infected or not*
  - ◊ **Technical standard** *(based on the radiographic appearance)*
    - » **Adequate**
    - » **Inadequate**
  - ◊ **Other problems**—*specify the problem: e.g., perforation, untreated canal(s), fractured instrument, silver point, etc.)*

Degenerative changes:
- **Pulp canal calcification**** *(based on radiographic appearance)*
  *** Note: Must also specify the diagnosis/condition of the pulp or root canal system*
- **Pulp hyperplasia** *(note: a form of irreversible pulpitis; specify whether acute or chronic)*

Note: the various forms of internal resorption are not included as these are discussed elsewhere in this book. (Adapted from Abbott[3] and Abbott and Yu.[11])

TABLE 8-2 Classification of the Conditions of the Periapical/Periradicular Tissues—See Text for a Description of the Typical Symptoms, Signs, and So Forth of Each Condition

No signs of disease:
- **Clinically normal periapical/periradicular tissues** *(based on the history, clinical examination, tests, radiographs, etc.)*

Inflammatory conditions:
- **Apical periodontitis - Acute: Primary** *(i.e., NO p-ap. radiolucency)*
  Secondary *(i.e., has a p-ap. radiolucency)*
  - Chronic *(i.e., has a radiolucency)*
  - Condensing osteitis *(i.e., radiopacity)*
  (Note: a form of chronic apical periodontitis)
- **Foreign body reaction**

Infections:
- **Apical abscess - Acute: Primary** *(i.e., NO p-ap. radiolucency)*
  Secondary *(i.e., has a p-ap. radiolucency)*
  - Chronic *(i.e., has a draining sinus)*
- **Facial cellulitis**
- **Extra-radicular infection**

Cysts:
- **Periapical pocket cyst**
- **Periapical true cyst**

Scar:
- **Periapical scar**

Notes: Definitions for acute and chronic are included in Table 1. The various forms of external resorption are not included as these are discussed elsewhere in this book. (Adapted from Abbott.[3,5])

Clinically Normal Pulp

The term "clinically normal pulp" is used for a pulp that has no signs or symptoms to suggest that any form of disease is occurring. The term "clinically" is used since such a pulp may not be histologically normal and/or may have some mild inflammation, fibrosis (scarring) as a result of previous injury or stimuli such as caries, restorations, trauma, and so forth. However, for all intents and purposes, the tooth does not have any pulp pathosis that requires treatment.

Typical symptoms—no symptoms.

Clinical findings—normal reaction to cold and electric pulp sensibility tests as long as there has been no calcification of the coronal pulp space; will not respond to heat; percussion and palpation are normal.

Radiographic findings—no radiographic signs of pathosis; normal periodontal ligament (PDL) space and lamina dura.

Associated periradicular conditions—clinically normal periapical tissues.

Key findings for diagnosis—no symptoms and no abnormal findings.

Pulpitis

Pulpitis can take several forms—it can be reversible or irreversible, and both of these stages of the disease process can

be chronic or acute in nature. Chronic reversible and chronic irreversible pulpitis are conditions that have been present for a reasonable length of time (typically weeks, months, or years) while acute reversible and acute irreversible pulpitis are recent conditions (typically only present for a few hours or days). The acute conditions have more intense pain than the corresponding chronic conditions. Patients with pulpitis typically complain of pain associated with temperature changes brought on by having hot or cold foods and drinks. It is most likely that pulps have chronic pulpitis for some time before the condition exacerbates and becomes acute.

Reversible pulpitis implies that the pulp is capable of healing following conservative management. Clinically, this cannot be accurately assessed but the diagnosis is based on the symptoms being relatively mild and requiring greater temperature change to stimulate the pain compared to irreversible pulpitis. Reversible pulpitis is effectively a provisional diagnosis that can only be confirmed following treatment and resolution of the symptoms with the pulp returning to a clinically normal state, as shown by a review examination and pulp sensibility tests.

Irreversible pulpitis implies that the pulp is not capable of healing following conservative management and therefore the pulp or the tooth needs to be removed. Clinically, it is not possible to determine how advanced the inflammation is, nor is it possible to determine whether the entire pulp is inflamed. In some cases, the inflammation may be limited to just part of the pulp but the pain is quite intense and suggests irreversible pulpitis. Despite the uncertainty at times, Ricucci et al.[17] have shown good correlation between the clinical and histological diagnoses of pulp conditions, as discussed previously.

Chronic Reversible Pulpitis

Typical symptoms—the pain has been present for a long time (e.g., months); occasional sensitivity to heat, cold and/or biting; pain only occurs with extreme temperature changes (e.g., ice cream and cold drink from the fridge); pain is sharp but mild; pain is of short duration (e.g., a few seconds); tooth may have had a restoration prior to the onset of symptoms.

Typical clinical findings—there may be caries, a restoration breaking down or a crack; thermal pulp sensibility tests can reproduce the pain associated with heat and/or cold stimuli; the pain with thermal testing will be sharp and of short duration; there may be pain on biting or tenderness to percussion on a specific cusp if a crack undermines the cusp; caries may be seen if extensive enough or the restoration may have signs of marginal breakdown.

Radiographic findings—normal PDL space and lamina dura; occasionally may be condensing osteitis; rarely, a slightly widened PDL space.

Associated periapical/periradicular conditions—usually clinically normal periapical tissues; occasionally may have primary acute apical periodontitis or occasionally condensing osteitis indicating chronic reversible pulpitis and chronic apical periodontitis for some time.

Key findings for diagnosis—the nature of the pain (thermal sensitivity, sharp pain, short duration).

Distinguish from acute reversible pulpitis by the length of time the problem has been present and the occasional nature of the symptoms.

Distinguish from acute and chronic irreversible pulpitis by the short duration of the symptoms and the extreme temperature changes required to cause the pain.

Acute Reversible Pulpitis

Typical symptoms—the pain has only been present for a short time (e.g., a few hours or days); the pain is present every time the stimulus is applied to the tooth; there is sensitivity to heat, cold and/or biting; pain only occurs with extreme temperature changes (e.g., ice cream and cold drink from the fridge); pain is sharp but mild and of short duration (e.g., a few seconds); may have had a restoration prior to onset of symptoms.

Clinical findings—may be caries, a restoration breaking down or a crack; thermal pulp sensibility tests can reproduce the pain associated with heat and/or cold stimuli; pain with thermal testing will be sharp, and of short duration; may be pain on biting or tenderness to percussion on a specific cusp if a crack undermines the cusp; caries may be seen if extensive enough or restoration may have signs of marginal breakdown.

Radiographic findings—normal PDL space and lamina dura; occasionally may have condensing osteitis; rarely, a slightly widened PDL space may be evident.

Associated periapical/periradicular conditions—usually clinically normal periapical tissues; occasionally may have primary acute apical periodontitis; occasionally condensing osteitis indicating chronic reversible pulpitis and apical periodontitis for some time before acute presentation.

Key findings for diagnosis—the nature of the pain (thermal sensitivity, sharp pain, short duration).

Distinguish from chronic reversible pulpitis by the length of time the problem has been present and the regular nature of the symptoms.

Distinguish from acute irreversible pulpitis by the short duration of the symptoms and the extreme temperature changes required to cause pain.

Chronic Irreversible Pulpitis

Typical symptoms—the pain has been present for a long time (e.g., months); occasionally pain to heat, cold and/or biting; pain occurs with minor temperature changes (e.g., tap water); pain is sharp and severe, then becomes a dull ache; pain lingers (e.g., more than five minutes); may have had a restoration prior to onset of symptoms.

Clinical findings—may be caries, a restoration breaking down or a crack; thermal pulp sensibility tests can reproduce the pain associated with heat and/or cold stimuli; pain with thermal testing will be sharp, painful and lingers; may be pain on biting or tenderness to percussion on a specific cusp if a crack undermines the cusp.

Radiographic findings—caries may be seen if extensive enough; normal PDL space and lamina dura; occasionally condensing osteitis; a slightly widened PDL space may be evident.

Associated periapical/periradicular conditions—usually clinically normal periapical tissues; occasionally may have primary acute apical periodontitis; occasionally condensing osteitis indicating chronic reversible or irreversible pulpitis and apical periodontitis for some time.

Key findings for diagnosis—the nature of the pain (thermal sensitivity, sharp pain, then a dull ache that lingers).

Distinguish from acute irreversible pulpitis by the long time that the pain has been present and the occasional nature of the symptoms.

Distinguish from acute reversible pulpitis and *chronic reversible pulpitis* by the lingering pain, and only minor temperature changes required to cause the pain.

Acute Irreversible Pulpitis

Typical symptoms—the pain has only been present for a short time (e.g., a few days or less); pain to heat, cold and/or biting; pain occurs with minor temperature changes (e.g., tap water); pain is sharp and severe, then becomes a dull ache; pain lingers (e.g., more than five minutes); pain may be spontaneous; pain may occur when lying down; pain may wake the patient at night; may have had a recent restoration.

Clinical findings—may be caries, a restoration breaking down or a crack; thermal pulp sensibility tests can reproduce the pain associated with heat and/or cold stimuli; pain with thermal testing will be sharp, very painful and lingers; may be pain on biting or tenderness to percussion on a specific cusp if a crack undermines the cusp.

Radiographic findings—caries may be seen if extensive enough; normal PDL space and lamina dura; occasionally condensing osteitis; a slightly widened PDL space may be evident.

Associated periapical/periradicular conditions—often have primary acute apical periodontitis; occasionally condensing osteitis indicating chronic apical periodontitis for some time prior to the acute presentation; sometimes clinically normal periapical tissues (e.g., if no tenderness to percussion).

Key findings for diagnosis—the nature of the pain (thermal sensitivity, sharp and severe pain, then a dull ache that lingers). Spontaneous pain, waking at night, and worse lying down are positive signs of acute irreversible pulpitis.

Distinguish from chronic irreversible pulpitis by the short time that the pain has been present and the regular nature of the symptoms.

Distinguish from acute and chronic reversible pulpitis by the severity and lingering pain, and only minor temperature changes required to cause pain.

Pulp Necrobiosis

A tooth with necrobiosis has both inflamed (acute irreversible pulpitis) and necrotic (usually infected) pulp tissue.[21] Many dentists use "partial necrosis" for this stage of the disease process. However, Grossman[21] suggested the term "necrobiosis" because it more accurately indicates the condition with *"necro-"* indicating necrosis and *"-bio-"* indicating live tissue. The necrotic tissue may be in the pulp chamber with the inflamed tissue in the root canal(s), or the different conditions may exist in different canals of a multicanal tooth. Teeth with this condition are difficult to diagnose since they often present with a mixture of the symptoms and signs of both pulpitis and necrosis with infection.[11] Typically, this stage of the disease process is only present for a short time—perhaps a few hours only or up to a few days.

Typical symptoms—the pain has only been present for a short time (e.g., a few days or less); typically history of very recent pain heat, cold and/or biting; if temperature changes cause pain then usually only minor temperature changes required (e.g., tap water); pain may be sharp and severe, then may become a dull ache; pain lingers for a long time; pain may be spontaneous; patient typically reports a mixture of symptoms suggesting pulpitis or an infected root canal system; pain can be quite distressing for the patient; may have had a recent restoration.

Clinical findings—may be caries, a restoration breaking down or a crack; pulp sensibility test results are mixed and frequently inconclusive or inconsistent with the patient's description of symptoms; often tenderness to percussion; may be pain on biting. Pain may be severe and may be relieved by "swishing" iced water around the tooth; relief lasts for seconds to a minute and may require constant application of cold water; a "bead" of pus may emerge when the pulp chamber is opened and this relieves the pain.

Radiographic findings—caries may be seen if extensive enough; usually have normal PDL space and lamina dura; sometimes a slightly widened PDL space may be evident.

Associated periapical/periradicular conditions—usually clinically normal periapical tissues (e.g., if no tenderness to percussion); sometimes have primary acute apical periodontitis (e.g., if tender to percussion).

Key findings for diagnosis—the patient's symptoms are often mixed (i.e., symptoms of pulpitis and an infected root canal system at the same time). The pulp sensibility tests usually do not correlate with the patient's symptoms, and the pain is often severe and distressing.

Distinguish from acute irreversible pulpitis by the mixed symptoms and inconsistency between symptoms and pulp sensibility tests.
Distinguish from acute and *chronic reversible pulpitis* by the nature of the pain and its severity, plus the pulp sensibility tests results.
Distinguish from necrotic and *infected pulp* by the nature of the pain and inconsistent symptoms.
Distinguish from a pulpless and *infected root canal system* as there is no periapical radiolucency.

Pulp Necrosis with No Signs of Infection

The dental pulp may undergo necrosis for several reasons. The most common reason is due to the bacterial invasion through caries, cracks or restoration breakdown that will ultimately lead to the pulp necrosing and becoming infected. However, some pulps may necrose as a result of trauma when the tooth is luxated or displaced sufficiently to sever the apical blood vessels. If the pulp cannot revascularize, then it necroses but does not necessarily become infected unless there is a coronal pathway of entry for bacteria. In cases of necrosis without infection, there will be no periapical tissue response[6–10]; that is, there will be no apical periodontitis (Figure 8-3).

The term used for this condition includes *"no sign of necrosis"* because it is not possible to categorically state that the tooth is *"not infected,"* based on the information obtained from a clinical and radiographic examination. It is known that radiographic signs of apical periodontitis (i.e., a radiolucency) take at least several months to be visible once a pulp becomes infected,[1] hence, the lack of a radiolucency does not necessarily indicate the lack of an infection. It merely means there was no sign of apical periodontitis (and hence no sign of root canal infection) at the time the radiograph was exposed.

Typical symptoms—no pulp-related symptoms (i.e., no thermal sensitivity); may have a history of trauma to the tooth.
Clinical findings—the tooth does not respond to pulp sensibility tests; may be some tooth discolouration; tooth may have a crack or fracture (e.g., if history of trauma), caries or a restoration.
Radiographic findings—no abnormal observations of the tooth unless trauma has caused a fracture; normal PDL space and lamina dura.
Associated periapical/periradicular conditions—clinically normal periapical tissues.
Key findings for diagnosis—no symptoms, no response to pulp sensibility tests but no other abnormal findings.
Distinguish from pulp necrobiosis as there are no symptoms and no signs of apical periodontitis.
Distinguish from a necrotic and infected pulp as there are no signs of apical periodontitis.

Necrotic and Infected Pulp

When a pulp necroses as a result of bacterial invasion of the tooth, it will become infected over time. The bacteria will remove the necrotic tissue quite rapidly (within one to two months, depending on whether or not the pulp is exposed to the mouth)[1] so the root canal system becomes "pulpless and infected." During the first few months following pulp necrosis, a periapical radiolucency will not be evident (Figure 8-4) as this takes several months more to manifest. Within these first few months, the pulp is still considered necrotic but there are signs that it is infected, as outlined subsequently. This stage of the disease process (i.e., necrotic and infected pulp) is only present for a very short period of time.

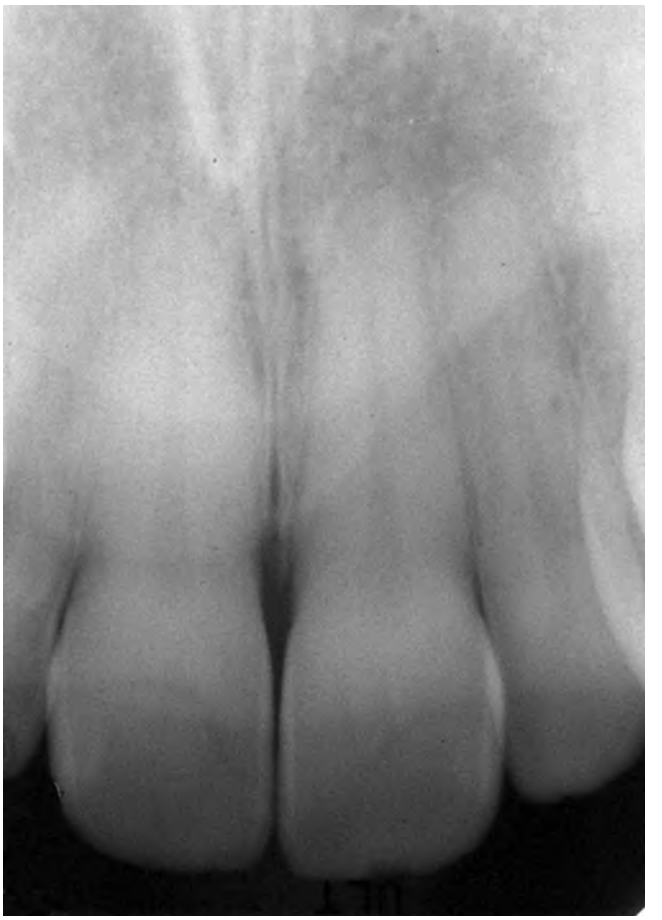

FIGURE 8-3 The maxillary left central incisor is likely to have pulp necrosis but there are no clear signs of the canal being infected since there are no periapical changes evident radiographically. This tooth had a history of trauma (extrusion) four years previously and the tooth was repositioned orthodontically after one week of being in the extruded position. The tooth does not respond to cold and electric pulp sensibility testing. It did not show any signs of blood flow when tested with a laser Dopplerflowmeter.

Typical symptoms—no pulp-related symptoms (i.e., no thermal sensitivity); may be no symptoms at all; any symptoms will be from the periapical tissues—hence, symptoms depend on the periapical status; may have pain associated with biting or pressure (depends on the periapical status); occasionally pain with heat that is temporarily relieved by applying very cold water/ice to the tooth.
Clinical findings—may be caries, a restoration breaking down or a crack; tooth does not respond to pulp sensibility tests; may be tender to percussion

FIGURE 8-4 The maxillary left central incisor was laterally luxated and now has a necrotic and infected pulp with primary acute apical periodontitis.

FIGURE 8-5 The maxillary right lateral incisor has a pulpless and infected root canal system with chronic apical periodontitis as a result of lateral luxation seven years previously. Note, there is also apical inflammatory resorption of the lateral incisor.

(depends on the periapical status); may be some tooth discolouration.

Radiographic findings—caries may be seen if extensive enough; usually have normal PDL space and lamina dura; sometimes a slightly widened PDL space and loss of lamina dura may be evident periapically.

Associated periapical/periradicular conditions—may have clinically normal periapical tissues (in the early stages); may have primary acute apical periodontitis (if pain and tender to percussion); may have a primary acute apical abscess (if pain, tender to percussion, swelling, and localized collection of pus).

Key findings for diagnosis—no response to pulp sensibility tests and no periapical changes seen radiographically.

Distinguish from pulp necrosis with no signs of infection by the symptoms and the apical periodontitis.

Distinguish from a pulpless and infected root canal system as there is no periapical radiolucency.

Pulpless and Infected Root Canal System

A root canal system that has a necrotic and infected pulp will rapidly (within one to two months) become pulpless and infected.[1] A periapical radiolucency will then develop over the next few months (Figure 8-5). Hence, once a periapical radiolucency is present, it is safe to assume that the root canal system is pulpless and infected—at this stage, it should no longer should be called a necrotic and infected pulp.

This condition should not be confused with a tooth that has had previous root canal treatment as specific terminology is used for those teeth (see subsequently). The term "pulpless and infected" is used to demonstrate that the tooth has no pulp because of the bacteria in the canal.

Typical symptoms—no pulp-related symptoms (i.e., no thermal sensitivity); may be no symptoms at all; any symptoms will be from the periapical tissues—hence, symptoms depend on the periapical status; may be an occasional dull ache or "awareness of tooth" if chronic apical periodontitis or a chronic apical abscess is present; will have pain associated with biting or pressure if secondary acute apical periodontitis or a secondary acute apical abscess is present.

Clinical findings—may be caries, a restoration breaking down or a crack; the tooth does not respond to pulp sensibility tests; may feel "different" on percussion if chronic periapical condition present; will be tender to

percussion if acute periapical condition present; may have increased mobility if acute periapical condition present; may be some tooth discolouration.

Radiographic findings—caries may be seen if extensive enough; a periapical radiolucency will be present.

Associated periapical/periradicular conditions—may have any of the following—depending on the symptoms, clinical and radiographic findings: chronic apical periodontitis (no symptoms or only occasional ache); a chronic apical abscess (if draining sinus present); secondary acute apical periodontitis (if pain and tenderness to percussion); a secondary acute apical abscess (if pain tender to percussion, swelling, and localized collection of pus), or facial cellulitis (if facial swelling due to spreading infection).

Key findings for diagnosis—no response to pulp sensibility tests and there will be a periapical radiolucency.

Distinguish from a necrotic and infected pulp by the presence of a periapical radiolucency.

Distinguish from pulp necrosis with no signs of infection as there is a periapical radiolucency.

Distinguish from a tooth with *previous endodontic treatment* as there is no history or radiographic evidence of previous treatment.

Previous Endodontic Treatment with No Signs of Infection

There are various procedures that can be grouped as "endodontic treatment"—essentially any procedure that involves treatment of the pulp or root canal system. These include direct pulp capping, partial pulpotomy, pulpotomy, partial pulpectomy, root canal filling, root canal retreatment, and the commencement of root canal treatment (i.e., commenced but not completed). Separate diagnostic categories for each type of treatment are not required but when assessing teeth with previous endodontic treatment, the nature of that treatment should be included in the diagnosis.

The term "no signs of infection" is used because it is not possible to categorically state that the tooth is "*not infected*," based on the information obtained from a clinical and radiographic examination. It is known that radiographic signs of apical periodontitis (i.e., a radiolucency) take at least several months to be visible once a pulp or root canal system becomes infected[1]—hence, the lack of a radiolucency does not necessarily indicate the lack of an intracanal infection. It merely means that there were no signs of apical periodontitis (and hence no sign of root canal infection) at the time the radiograph was exposed (Figure 8-6).

Typical symptoms—no symptoms; will have a history of some form of previous pulp/root canal treatment, such as: pulp capping, partial pulpotomy, pulpotomy, partial pulpectomy, root canal filling (on one or more occasions), or incomplete root canal treatment (e.g., if started as an emergency but not yet completed).

Clinical findings—the coronal restoration is intact and "clinically satisfactory"; no caries, no cracks or fractures of tooth; no abnormal findings except the tooth may or may not respond to pulp sensibility tests (depends on type of previous pulp treatment, e.g., may respond if previous pulp cap, partial pulpotomy, or pulpotomy) and there may be some tooth discolouration.

Radiographic findings—no caries evident; restoration appears satisfactory; no abnormal observations of tooth; normal PDL space and lamina dura; evidence of previous pulp treatment or root canal filling; if root canal filling present, it may or may not be technically satisfactory; other deficiencies or procedural errors may be evident in some cases but without associated radiolucency—for example: perforation, untreated canal, blocked canal, fractured file, incomplete root canal treatment, and so forth.

Associated periapical/periradicular conditions—clinically normal periapical tissues.

Key findings for diagnosis—history and/or radiographic evidence of previous pulp/root canal treatment, plus no symptoms, and no other abnormal findings.

Distinguish from previous endodontic treatment with an infected root canal system as there is no periapical radiolucency and no signs indicating apical periodontitis.

Distinguish from a pulpless, infected root canal system as there is a history or radiographic evidence of previous endodontic treatment.

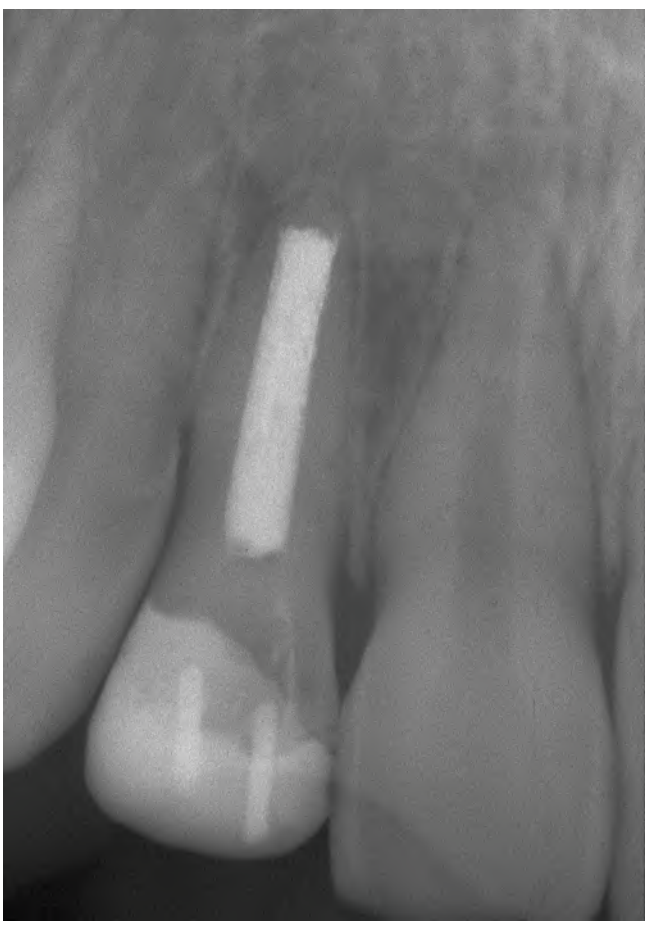

FIGURE 8-6 The maxillary right lateral incisor is a root-filled tooth following apexification with no signs of infection.

Previous Endodontic Treatment with an Infected Root Canal System

Once a tooth with previous endodontic treatment develops a periapical radiolucency, then the root canal system should be considered to be infected (Figure 8-7). The endodontic treatment could be any procedure that involves treatment of the pulp or root canal—these include direct pulp capping, partial pulpotomy, pulpotomy, partial pulpectomy, root canal filling, root canal retreatment, and the commencement of root canal treatment (i.e., commenced but not completed). Separate diagnostic categories for each type of treatment are not required but when assessing teeth with previous endodontic treatment, the nature of that treatment should be included in the diagnosis.

A tooth that has had root canal treatment commenced, but not completed, may still have a periapical radiolucency. This may represent a continuation of chronic apical periodontitis or the periapical tissues may be healing (but not completely healed). It is not possible to differentiate between these scenarios and hence it is safer to assume the root canal system may still be infected and to continue treating the tooth accordingly.

FIGURE 8-7 The mandibular right central incisor has a root-filled and infected root canal system with secondary acute apical periodontitis as a result of breakdown of the composite restoration and an unsatisfactory root canal filling. The patient had a continuous dull ache and the tooth was very sore to bite on. The radiolucency extends over the apex of the adjacent tooth root that has a normal PDL space and normal responses to pulp testing.

Typical symptoms—any symptoms will be from the periapical tissues—hence, symptoms depend on the periapical status; may be an occasional dull ache or "awareness of tooth" if chronic apical periodontitis or a chronic apical abscess is present; will have pain associated with biting or pressure if secondary acute apical periodontitis or a secondary acute apical abscess is present; will have a history of some form of previous pulp/root canal treatment, such as pulp capping, partial pulpotomy, pulpotomy, partial pulpectomy, root canal filling (on one or more occasions), or incomplete root canal treatment (e.g., if started as an emergency but not yet completed).

Clinical findings—may be caries, a restoration breaking down or a crack; the tooth does not respond to pulp sensibility tests; may feel "different" on percussion if chronic periapical condition present; will be tender to percussion if acute periapical condition present; may have increased mobility if acute periapical condition present; may be some tooth discolouration.

Radiographic findings—caries may be seen if extensive enough; a periapical radiolucency will be present; evidence of previous pulp treatment or root canal filling; if root canal filling present, it may or may not be technically satisfactory; other deficiencies or procedural errors may be evident in some cases and may have an associated radiolucency (e.g., perforation, untreated canal, blocked canal, fractured file, incomplete root canal treatment, etc.).

Associated periapical/periradicular conditions—may have any of the following depending on the symptoms, clinical and radiographic findings: chronic apical periodontitis (no symptoms or only occasional ache), a chronic apical abscess (if draining sinus present), secondary acute apical periodontitis (if pain and tenderness to percussion), a secondary acute apical abscess (if pain, tender to percussion, swelling, and localized collection of pus), or facial cellulitis (if facial swelling due to spreading infection).

Key findings for diagnosis—history and/or radiographic evidence of previous pulp/root canal treatment, plus the presence of a periapical radiolucency.

Distinguish from previous endodontic treatment without signs of infection as there is a periapical radiolucency.

Distinguish from a pulpless and infected root canal system as there is a history and/or radiographic evidence of previous endodontic treatment.

Pulp Atrophy

Atrophy of the pulp is a normal physiologic process that occurs with age. Clinically, it is difficult to distinguish whether this is present but it is likely in older patients. This condition does not require any specific treatment but it is important for clinicians to recognize that it does occur as it can affect the ability to diagnose the pulp status of some teeth.

Typical symptoms—no symptoms.
Clinical findings—usually no abnormal findings but the tooth may have a restoration; the tooth may or may not respond to pulp sensibility tests; the patient is usually elderly.
Radiographic findings—usually no abnormal observations of the tooth but it may have a restoration; some pulp canal calcification (PCC) may be evident; normal PDL space and lamina dura.
Associated periapical/periradicular conditions—clinically normal periapical tissues.
Key findings for diagnosis—no symptoms and no abnormal findings.

Pulp Canal Calcification

PCC could be considered as a radiographic observation of the appearance (especially the width) of the root canal(s) rather than as a distinct condition of the pulp or root canal system. It is not necessarily indicative of a disease process or pathological state of the tooth and therefore it is included as a "condition" rather than as a "disease." It is included in this classification of root canal conditions as its presence affects the management of the tooth—since it may affect the diagnostic process (e.g., pulp tests are less reliable) as well as the treatment (e.g., difficulty locating and negotiating the root canal). Clinicians should recognize that the pulp contained within a calcified canal can be normal or diseased, or the canal may be pulpless and infected, and so forth[11]—that is, all pulp and root canal conditions could be associated with PCC (Figure 8-8). Hence, the complete diagnosis of a tooth with PCC must include the diagnosis of the pulp or root canal condition as well as the PCC.[11]

The term "PCC" is the preferred term.[11] Some clinicians and authors use the term "pulp canal obliteration" but this is not accurate and hence not appropriate. The word "obliterate" is defined as "complete removal or destroying all traces of."[22] When a pulp undergoes calcification (defined as deposition of calcific material), it is not possible for the root canal to be completely removed or destroyed. There will always be a very small, narrow canal present even when the canal cannot be seen radiographically. The remaining canal may only be a few microns in width that is enough for several cells and it may or may not be possible to negotiate it with a root canal file; however, the canal still exists.[11] Hence, it is more appropriate to refer to the process as "PCC" as this accurately describes what is truly happening inside the tooth.

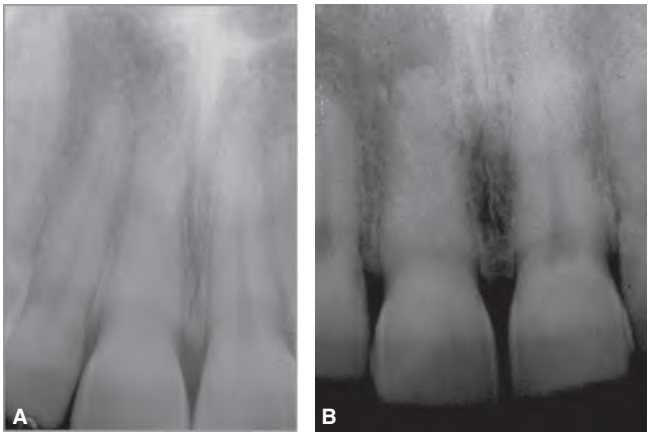

FIGURE 8-8 ***A.*** The maxillary right central incisor has pulp canal calcification. There was no response to CO_2 and electric pulp testing but there are no radiographic signs of any periapical changes; hence, there are no signs of the root canal system being infected and no treatment is required. ***B.*** The maxillary right central incisor has pulp canal calcification with a pulpless and infected root canal system and chronic apical periodontitis as a result of trauma 22 years previously.

Typical symptoms—symptoms will depend on the pulp or root canal condition—any of the following may be present with the typical symptoms as outlined earlier: clinically normal pulp, chronic reversible pulpitis, acute reversible pulpitis, chronic irreversible pulpitis, acute irreversible pulpitis, pulp necrobiosis, pulp necrosis with no signs of infection, necrotic and infected pulp, pulpless and infected root canal system, previous endodontic treatment with no signs of infection, previous endodontic treatment with an infected root canal system, pulp atrophy.
Clinical findings—clinical findings will depend on the pulp or root canal condition—with the typical clinical findings for each condition as outlined earlier; if a clinically normal pulp, then response to pulp sensibility testing may be variable, as follows: usually no response to a cold test, may or may not respond to an electric pulp test; if any form of pulpitis present, then the tooth should respond to cold pulp sensibility testing but some cases do not respond; the tooth should respond to an electric pulp test; if pulp necrosis, pulpless and infected or previous endodontic treatment, then there will be no response to pulp sensibility tests.
Radiographic findings—PCC is evident—this may be partial (vertically and/or horizontally) or it may involve the entire pulp space; other radiographic observations will depend on the pulp or root canal condition—with the typical radiographic observations for each condition as outlined earlier.
Associated periapical/periradicular conditions—this will depend on the pulp or root canal condition with the various possible periapical/periradicular condition(s) as outlined earlier for each particular pulp/root canal condition.
Key findings for diagnosis—radiographic evidence of PCC.
Distinguish from ***other conditions*** that do not respond to pulp sensibility tests by the symptoms, other clinical and radiographic findings, plus the associated periapical/periradicular condition(s).

Pulp Hyperplasia

Pulp hyperplasia almost exclusively occurs in young teeth with an abundant blood supply and a large carious lesion.[11]

It is essentially an overgrowth of granulation tissue and it appears as a polyp arising from the pulp. In some cases, it may appear to be connected to the gingival tissues.

Typical symptoms—often no symptoms; some cases may have pain when eating if the hyperplastic tissue is contacted by food, drinks, and so forth; some cases may bleed when the hyperplastic tissue is touched, brushed, and so forth; some cases will have the typical symptoms of pulpitis, as outlined earlier—the pulpitis can be chronic reversible pulpitis, acute reversible pulpitis, chronic irreversible pulpitis, or acute irreversible pulpitis.

Clinical findings—a "pulp polyp" is evident, within a large carious cavity where the pulp has been exposed by the caries; the pulp polyp may bleed on probing; the pulp polyp may or may not be sensitive to probing; the tooth will respond to pulp sensibility tests with the nature of the response depending on the type of pulpitis present, as outlined earlier; the pulp polyp will sometimes appear to be continuous with the gingival tissues if the cavity extends to the gingivae.

Radiographic findings—large carious lesion evident; other radiographic observations will depend on the pulp or root canal condition—with the typical radiographic observations for each condition as outlined earlier; as pulp hyperplasia is usually a long-standing problem, there is likely to be some minor widening of the PDL space or condensing osteitis, with both appearances indicating chronic apical periodontitis.

Associated periapical/periradicular conditions—the associated periapical/periradicular condition(s) will depend on the type of pulpitis present, as outlined earlier; typically there will be chronic apical periodontitis.

Key findings for diagnosis—clinical appearance of a "pulp polyp."

Distinguish from the ***various forms of pulpitis*** without hyperplasia by the presence of the pulp polyp.

Distinguish from ***all types of infected root canal systems*** by the symptoms, the clinical appearance of a pulp polyp and the response to pulp sensibility tests.

PERIAPICAL/PERIRADICULAR CONDITIONS

This section will describe each periapical/periradicular condition listed in Table 8-2 to guide clinicians in the diagnostic process with a brief description of the typical symptoms reported by the patient, the typical clinical findings found on examination and testing of the tooth, the typical radiographic observations seen on periapical radiographs, the typical pulp/root canal conditions associated with each periapical/periradicular condition, the key findings that lead to the particular diagnosis, and the findings that distinguish each condition from other similar conditions.

The term "periapical" is commonly used by most practitioners although "periradicular" is more accurate. Most periradicular conditions manifest in the periapical tissues because these tissues are adjacent to the apical foramen of the root canal(s). However, the same responses can manifest in the PDL and adjacent bone anywhere along the length of the root surface. Lateral canals are the same as the main canal in that they are part of the root canal system and they can contain inflamed pulp tissue that may become necrotic and eventually the lateral canals become pulpless and infected. In addition, pulp and root canal conditions can cause other periradicular conditions such as various forms of external root resorption. Hence, the term "periradicular" is more comprehensive, more accurate and more appropriate when discussing conditions caused by pulp and root canal conditions.

The various forms of external resorption will not be discussed in this chapter as they are discussed in detail in Chapter 15.

Clinically Normal Periapical/Periradicular Tissues

The term "clinically normal" is used when there are no signs or symptoms to suggest that any form of disease is occurring. The term "clinically" is used since the periapical/periradicular tissues may not be histologically normal and/or may have some degree of inflammation or fibrosis (scarring) as a result of previous injury or stimuli (such as some form of apical periodontitis, etc.). However, for all intents and purposes, the tooth does not have any periapical/periradicular pathosis that requires treatment.

Typical symptoms—no symptoms from the periapical or periradicular tissues; if there are any symptoms, these will be from the pulp—hence, symptoms depend on the status of the pulp.

Clinical findings—no abnormal findings; no tenderness to percussion; no tenderness to palpation; no increased mobility; various pulp and/or root canal conditions may be present—any clinical findings will depend on what condition is present; the tooth may or may not respond to pulp sensibility tests—this depends on the state of the pulp/root canal system.

Radiographic findings—no abnormal observations of the tooth; normal PDL space and lamina dura; some cases may have evidence of previous endodontic treatment.

Associated pulp/root canal conditions—may have any of the following—depends on the symptoms, clinical and radiographic findings: clinically normal pulp, reversible pulpitis—chronic or acute, irreversible pulpitis—chronic or acute, pulp necrobiosis, necrosis with no signs of infection, necrotic and infected pulp, previous endodontic treatment with no signs of infection, pulp atrophy, PCC, pulp hyperplasia, internal surface resorption, internal inflammatory resorption, or internal replacement resorption.

Key findings for diagnosis—no symptoms from the periapical/periradicular tissues and no abnormal findings.

Primary Acute Apical Periodontitis

The term *"apical periodontitis"* implies inflammation of the periapical tissues. When this first commences, there will not be a radiolucency as it takes some time for the bone (and possibly some of the tooth) to be resorbed to the extent where it is visible radiographically. The first stage of apical periodontitis is called "primary acute apical periodontitis"[2,5] and its key feature is the lack of a radiolucency (Figure 8-4), yet there is considerable pain. The pain occurs, and is usually intense, because the inflammation is confined within the hard bony tissues and the PDL where there is no space for the swelling, exudate, and so forth to expand.

- *Typical symptoms*—the pain has only been present for a short time (e.g., a few days or less); the pain is usually quite severe; pain to biting and pressure on the tooth; pain to touch the tooth—even with light pressure; may be pain due to acute irreversible pulpitis if present; occasionally may have pain due to acute reversible pulpitis.
- *Clinical findings*—may be caries, a restoration breaking down or a crack; severe pain to percussion; pain when pushing on the tooth; usually no response to pulp sensibility tests—unless acute reversible pulpitis or acute irreversible pulpitis in which case the tooth will respond to cold pulp testing which reproduces the thermal sensitivity pain that the patient will also complain of; sometimes the tooth is in traumatic occlusion due to being extruded from its normal position as a result of the periapical inflammation being constrained by the hard bone structure that has not yet resorbed to create space.
- *Radiographic findings*—caries may be seen if extensive enough; normal PDL space and lamina dura; a slightly widened PDL space may be evident if the tooth is extruded from its normal position; some cases may have evidence of previous endodontic treatment; occasionally may see a radiolucency within the tooth root indicating internal inflammatory resorption.
- *Associated pulp/root canal conditions*—usually due to an infected root canal system—may have any of the following depending on symptoms, clinical and radiographic findings: pulp necrobiosis, a necrotic and infected pulp, previous endodontic treatment with an infected root canal system, or internal inflammatory resorption; may be associated with acute irreversible pulpitis; rarely associated with acute reversible pulpitis.
- *Key findings for diagnosis*—there are no radiographic periapical changes, the pain is recent and severe; there is pain when touching the tooth, with pressure and on percussion.
- *Distinguish from* ***secondary acute apical periodontitis*** by the lack of radiographic signs of any periapical changes.
- *Distinguish from* ***chronic apical periodontitis*** by the lack of radiographic signs of any periapical changes, plus the presence of pain and the tenderness to percussion.
- *Distinguish from a* ***primary acute apical abscess*** by the lack of swelling.
- *Distinguish from a* ***secondary acute apical abscess*** by the lack of swelling.
- *Distinguish from a* ***chronic apical abscess*** by the lack of a draining sinus.

Secondary Acute Apical Periodontitis

Secondary acute apical periodontitis occurs when there has been chronic apical periodontitis or a chronic apical abscess present for some time so there is also a periapical radiolucency (Figure 8-7). Secondary acute apical periodontitis is usually a result of an imbalance occurring between the intra-canal infection and the host defence system whereby some bacteria and/or their endotoxins escape through the apical foramen and cause an acute exacerbation of the chronic inflammatory response that has been present for some time. The patient then becomes aware of symptoms. This process may occur on numerous occasions (e.g., patient reports that the pain "comes and goes") so in effect it is not necessarily just the second time that an acute inflammatory reaction occurs but every time that it changes from chronic to acute inflammation. The process is dynamic and the secondary acute apical periodontitis can return to being chronic apical periodontitis if the environmental conditions are suitable and the host defence response is adequate.

- *Typical symptoms*—the pain has only been present for a short time (e.g., a few days or less); the pain is usually quite severe; pain to biting or pressure on the tooth; no thermal sensitivity.
- *Clinical findings*—may be caries, a restoration breaking down or a crack; very tender to percussion; no response to pulp sensibility tests; may be tender to palpation.
- *Radiographic findings*—caries may be seen if extensive enough; a periapical radiolucency is present—this indicates chronic apical periodontitis has been present for some time; some cases may have evidence of previous endodontic treatment; occasionally may see a radiolucency within the tooth root indicating internal inflammatory resorption.
- *Associated pulp/root canal conditions*—will be due to an infected root canal system, hence, may have any of the following depending on the symptoms, clinical and radiographic findings: pulpless and infected root canal system, previous endodontic treatment with an infected root canal system, or internal inflammatory resorption.
- *Key findings for diagnosis*—there is a periapical radiolucency, the pain is recent and severe; pain with pressure and on percussion.
- *Distinguish from* ***primary acute apical periodontitis*** by the presence of a periapical radiolucency.

Distinguish from ***chronic apical periodontitis*** by the pain and the tenderness to percussion.
Distinguish from a ***primary acute apical abscess*** by the lack of swelling.
Distinguish from a ***secondary acute apical abscess*** by the lack of swelling.
Distinguish from a ***chronic apical abscess*** by the lack of a draining sinus.

Chronic Apical Periodontitis

After an initial period of primary acute apical periodontitis, and if the tooth has not been treated, the periapical inflammation can become chronic. After several months, this usually manifests as a periapical radiolucency (Figure 8-5). Bone is resorbed to create space for the inflammatory reaction to occur so there are usually no, or only occasional mild symptoms or an occasional "awareness" of the tooth feeling different to the other teeth.

Typical symptoms—usually no symptoms; the patient may report a history of occasional "awareness" of the tooth feeling different; the patient may report a history of previous pulp-related symptoms some time ago; the patient may report a history of previous endodontic treatment.
Clinical findings—may be caries, a restoration breaking down or a crack; the tooth is not tender to percussion but will sometimes feel "different" to percussion; no response to pulp sensibility tests.
Radiographic findings—caries may be seen if extensive enough; a periapical radiolucency will be present; some cases may have evidence of previous endodontic treatment; occasionally may see a radiolucency within the tooth root indicating internal inflammatory resorption.
Associated pulp/root canal conditions—will be due to an infected root canal system—may have any of the following depending on the symptoms, clinical and radiographic findings: a pulpless and infected root canal system, previous endodontic treatment with an infected root canal system, or internal inflammatory resorption.
Key findings for diagnosis—there is a periapical radiolucency and no pain or only occasional "awareness" of the tooth.
Distinguish from ***primary acute apical periodontitis*** by the presence of a periapical radiolucency.
Distinguish from ***secondary acute apical periodontitis*** by the lack of symptoms.
Distinguish from a ***primary acute apical abscess*** by the lack of swelling and lack of symptoms.
Distinguish from a ***secondary acute apical abscess*** by the lack of swelling and lack of symptoms.
Distinguish from a ***chronic apical abscess*** by the lack of a draining sinus.

Condensing Osteitis

Condensing osteitis is a form of chronic apical periodontitis but it manifests as a radiopacity instead of a radiolucency (Figure 8-9). It is most commonly associated with teeth that have long-standing pulpitis—usually, or at least initially, chronic reversible pulpitis.[5] Hence, it is essentially an extension of the inflammatory response that began in the pulp or it is an indication that the periapical tissues have been irritated for some time with the result that more bone is laid down rather than being resorbed. The chronic reversible pulpitis may have episodes of acute reversible pulpitis that may be the time when the patient presents for treatment. Alternatively, the chronic reversible pulpitis may develop into chronic irreversible pulpitis, acute irreversible pulpitis or pulp necrosis with infection. Also, the root canal system may become pulpless and infected. The state of the pulp/root canal will depend on when the patient presents for treatment whereas the increased bone density that is evident radiographically may take many years to resolve and may not resolve at all. When the root canal system becomes infected, a radiolucency will typically develop immediately adjacent to the root apex and this may be surrounded by the sclerotic bone of the condensing osteitis, thus appearing as both radiopacity and radiolucency.

Typical symptoms—no symptoms from the periapical or periradicular tissues; no tenderness to percussion; any symptoms will be from the pulp—hence, symptoms depend on the status of the pulp; usually associated with long-standing chronic reversible pulpitis—hence symptoms will be typical of this condition (see earlier); the chronic reversible pulpitis may progress to acute reversible pulpitis, chronic irreversible pulpitis or acute irreversible pulpitis by the time the patient presents for treatment—hence the symptoms vary according to the stage of pulp disease.
Clinical findings—may be caries, a restoration breaking down or a crack; the tooth is not tender to percussion but may occasionally feel "different" to percussion; the tooth will usually respond to pulp sensibility tests (the nature of the

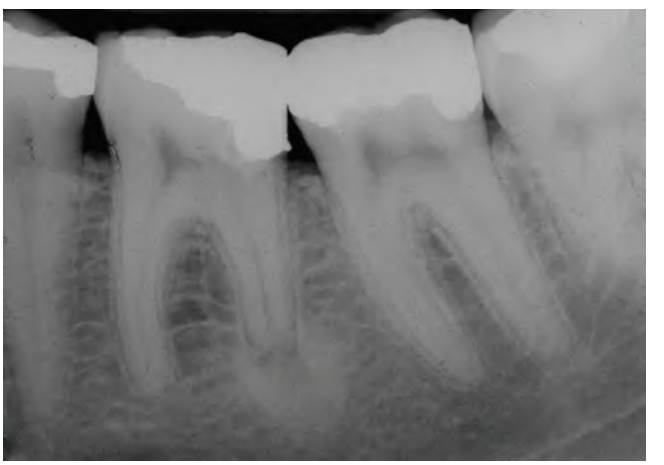

FIGURE 8-9 Condensing osteitis associated with the distal root of a mandibular first molar that had a long-standing history of chronic reversible pulpitis that subsequently became acute irreversible pulpitis two days prior to the patient presenting for treatment. The pulpitis developed as a result of breakdown of the 30-year old amalgam restoration. Note there is also evidence of slight apical inflammatory resorption of the distal root.

response depends on the state of the pulp) unless the pulp state has progressed to pulp necrosis, and so forth.

Radiographic findings—caries may be seen if extensive enough; the periapical region appears more radiopaque than the surrounding bone due to increased bone deposition (i.e., condensing osteitis); some cases may present later after the pulp has necrosed and the root canal system has become infected with various forms of apical periodontitis or apical abscesses—in these cases, some condensing osteitis may still be evident radiographically and there may be a widened PDL space or a radiolucency surrounded by the denser bone of condensing osteitis.

Associated pulp/root canal conditions—will be long-standing chronic reversible pulpitis initially; the chronic reversible pulpitis may progress to any of the following depending on the symptoms, clinical and radiographic findings: acute reversible pulpitis, chronic irreversible pulpitis or acute irreversible pulpitis; some cases may present later after the pulp has necrosed and the root canal system has become pulpless and infected with various forms of apical periodontitis or apical abscesses—in these cases, some condensing osteitis may still be evident radiographically but the process has changed to bone resorption instead of increased bone deposition.

Key findings for diagnosis—there is a radiopacity indicating denser bone (i.e., condensing osteitis) present in the periapical region.

Distinguish from ***primary acute apical periodontitis*** by the presence of the radiopacity and lack of symptoms.

Distinguish from ***secondary acute apical periodontitis*** by the presence of the radiopacity and lack of symptoms.

Distinguish from ***chronic apical periodontitis*** by the presence of the radiopacity (although it should be noted that condensing osteitis is essentially a form of chronic apical periodontitis).

Distinguish from a ***primary acute apical abscess*** by the lack of swelling and lack of symptoms, and the presence of the radiopacity.

Distinguish from a ***secondary acute apical abscess*** by the lack of swelling and lack of symptoms, and the presence of the radiopacity.

Distinguish from a ***chronic apical abscess*** by the lack of a draining sinus and the presence of the radiopacity.

Primary Acute Apical Abscess

An abscess is defined as a *"localized collection of pus."* When this occurs in the early stages of the periapical disease process, there will not be a radiolucency as it takes some time for the bone (and possibly some of the tooth) to be resorbed to the extent where it is visible radiographically (Figure 8-10). Hence, an abscess in its early stages is called "primary acute apical abscess"[2,5] and its key feature is the lack of a radiolucency, yet there is considerable pain. The pain occurs, and is usually intense, because the inflammation and the pus are confined within the hard bony tissues and the PDL where there is no space for the pus and swelling to expand.

Typical symptoms—the pain has only been present for a short time (e.g., a few days or less); the swelling has had rapid onset (e.g., hours, or less than one day); pus will be present; the pain is severe; pain to biting and pressure on the tooth; pain to touch the tooth—even with light pressure; occasionally the patient may complain of feeling unwell and having fever.

Clinical findings—may be caries, a restoration breaking down or a crack; swelling associated with the tooth;

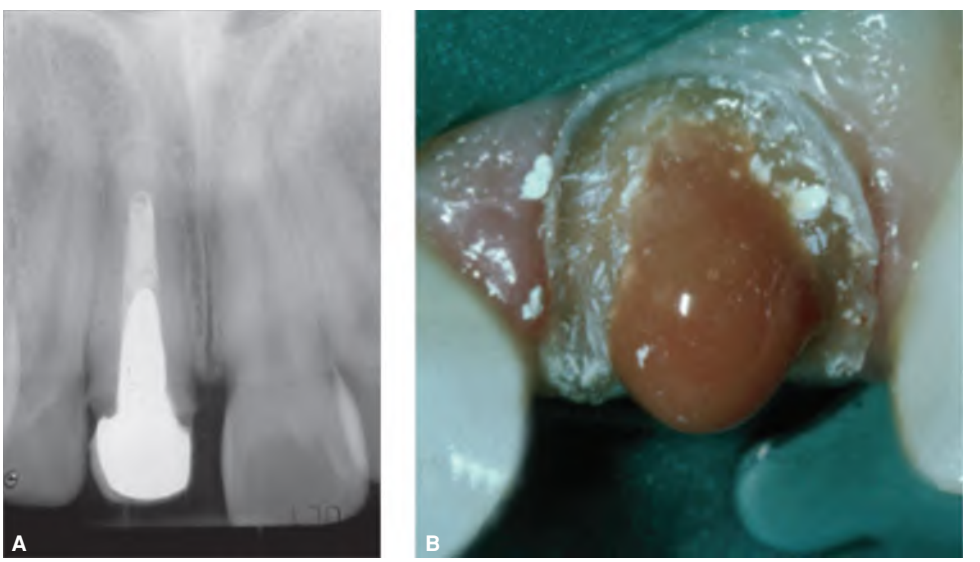

FIGURE 8-10 The maxillary right central incisor has a root-filled and infected root canal system and a primary acute apical abscess as a result of breakdown of the crown restoration. ***A.*** Periapical radiograph showing no periapical changes. ***B.*** Pus draining as soon as the existing root canal filling was removed.

severe pain to percussion; pain when pushing on the tooth; pain on palpation; no response to pulp sensibility tests; usually the tooth is in traumatic occlusion due to being extruded from its normal position; occasionally the patient may have fever, malaise and lymphadenopathy.

Radiographic findings—caries may be seen if extensive enough; normal PDL space and lamina dura; a slightly widened PDL space may be evident if the tooth is extruded from its normal position; some cases may have evidence of previous endodontic treatment; occasionally may see a radiolucency within the tooth root indicating internal inflammatory resorption.

Associated pulp/root canal conditions—will be due to an infected root canal system—hence, may have any of the following depending on the symptoms, clinical and radiographic findings: a necrotic and infected pulp, previous endodontic treatment with an infected root canal system, or internal inflammatory resorption.

Key findings for diagnosis—there are no radiographic periapical changes, there is swelling present, the pain is recent and severe, and there is pain when touching the tooth, with pressure and on percussion.

Distinguish from ***primary acute apical periodontitis*** by the presence of the swelling and pus.

Distinguish from ***secondary acute apical periodontitis*** by the lack of periapical radiolucency, and the presence of the swelling and pus.

Distinguish from ***chronic apical periodontitis*** by the lack of periapical radiolucency, and the presence of pain, swelling tenderness to percussion, and pus.

Distinguish from a ***secondary acute apical abscess*** by the lack of periapical radiolucency.

Distinguish from a ***chronic apical abscess*** by the lack of a draining sinus and no periapical radiolucency.

Secondary Acute Apical Abscess

A secondary acute apical abscess occurs when there has been chronic apical periodontitis or a chronic apical abscess present for some time so there is also a radiolucency (Figure 8-11). A secondary acute apical abscess is usually a result of an imbalance occurring between the intra-canal infection and the host defense system whereby some bacteria and/or their endotoxins (or both) escape through the apical foramen and cause an acute exacerbation of the chronic inflammatory response that has been present for some time. The acute exacerbation will be in the form of a localized collection of pus (i.e., an abscess). It may also occur when the draining sinus of a chronic apical abscess closes or becomes blocked so the pus cannot drain.

Typical symptoms—the pain has only been present for a short time (e.g., a few days or less); the swelling has had rapid onset (e.g., hours, or less than one day); pus will be present; the pain is usually quite severe; pain to biting or pressure on the tooth; no thermal sensitivity; occasionally the patient may complain of feeling unwell and having fever.

Clinical findings—may be caries, a restoration breaking down or a crack; the tooth is very tender to percussion; no response to pulp sensibility tests; tender to palpation; occasionally the patient may have fever, malaise and lymphadenopathy.

Radiographic findings—caries may be seen if extensive enough; there will be a periapical radiolucency present—indicates chronic apical periodontitis has been present for some time before the abscess developed; some cases may have evidence of previous endodontic treatment; occasionally may see a radiolucency within the tooth root indicating internal inflammatory resorption.

Associated pulp/root canal conditions—will be due to an infected root canal system—hence, may have any of

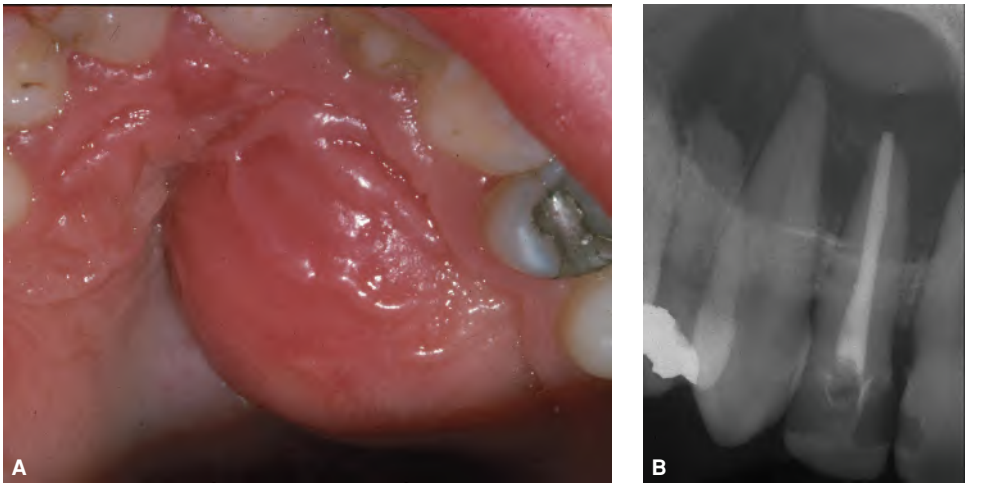

FIGURE 8-11 The maxillary right lateral incisor has a root-filled and infected root canal system with a secondary acute apical abscess. ***A.*** A large swelling on the palate that was full of pus and required drainage via an incision. ***B.*** The preoperative periapical radiograph shows a large periapical radiolucency.

the following depending on the symptoms, clinical and radiographic findings: a pulpless and infected root canal system, previous endodontic treatment with an infected root canal system, or internal inflammatory resorption.

Key findings for diagnosis—there is a periapical radiolucency, swelling is present, the pain is recent and severe, and there is pain when touching the tooth, with pressure and on percussion.

Distinguish from ***primary acute apical periodontitis*** by the presence of a periapical radiolucency and the swelling.

Distinguish from ***secondary acute apical periodontitis*** by the presence of the swelling and if the patient has fever, malaise, and so forth.

Distinguish from ***chronic apical periodontitis*** by the presence of swelling, pain, fever, and so forth.

Distinguish from a ***primary acute apical abscess*** by the presence of a periapical radiolucency.

Distinguish from a ***chronic apical abscess*** by the lack of a draining sinus and the presence of swelling and symptoms.

Chronic Apical Abscess

A chronic apical abscess is characterized by the presence of a draining sinus[5]—either intra-orally or extra-orally on the face (Figure 8-12). The draining sinus may "come and go" and this will be dependent on whether there is pus to drain.

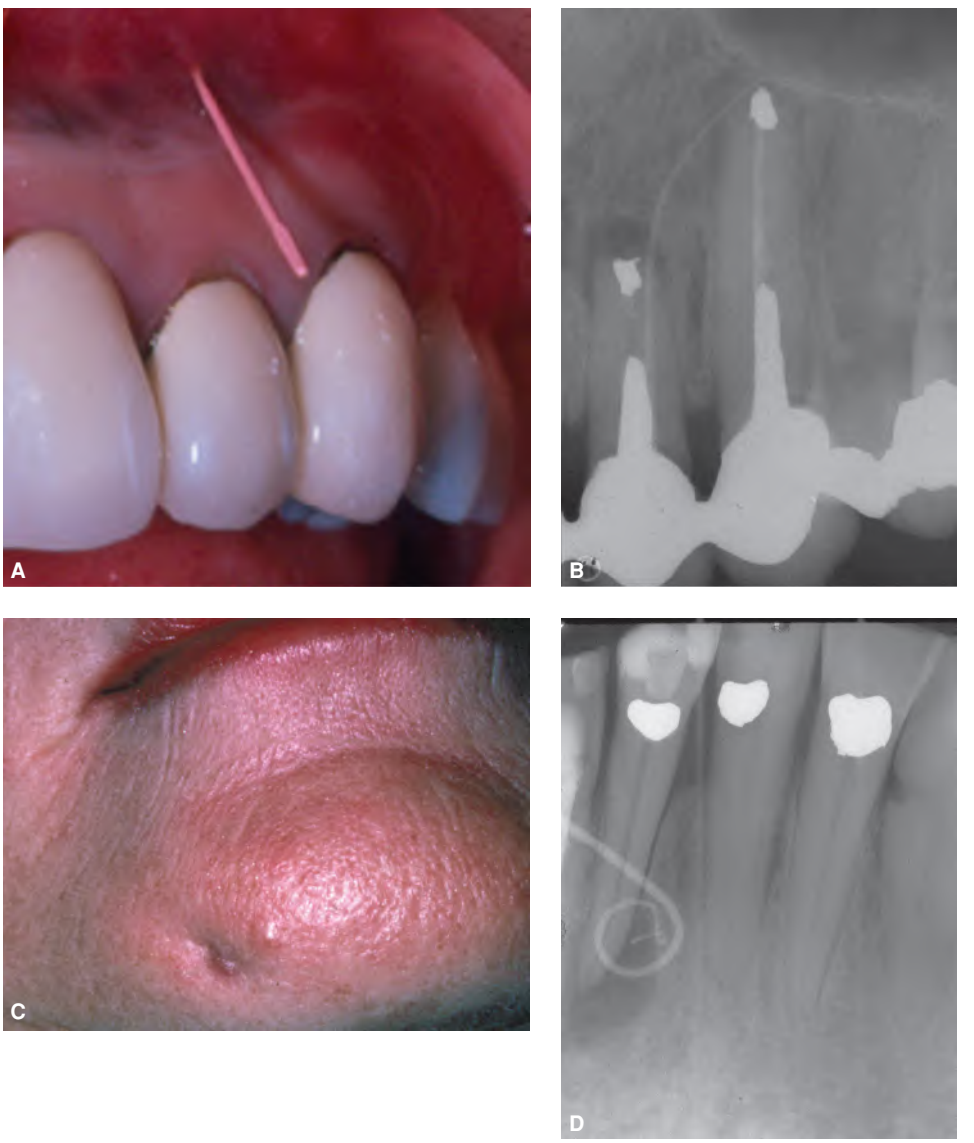

FIGURE 8-12 Examples of two chronic apical abscesses. ***A***. An intra-oral draining sinus that was tracked by inserting a gutta-percha point into the sinus and taking a radiograph. ***B.*** The periapical radiograph shows the gutta-percha point tracing the draining sinus to the periapical radiolucency associated with the maxillary left canine. The tooth has a root-filled and infected root canal system, previous periapical surgery with a root-end amalgam filling and a chronic apical abscess as a result of breakdown of the crown restoration. ***C.*** An extra-oral draining sinus (on the face) tracks to the mandibular right lateral incisor. ***D.*** The periapical radiograph shows the gutta-percha point tracing the draining sinus track. The tooth has incomplete root canal treatment, an infected root canal system and a chronic apical abscess as a result of breakdown of the composite resin restorations.

Hence, the condition may oscillate between being chronic apical periodontitis and a chronic apical abscess.

Typical symptoms—usually there are no symptoms; some patients may be aware of the presence of a draining sinus (they may refer to it as a "gum boil," "lump," "ulcer," etc.); the draining sinus is usually intra-oral (on the oral mucosa) but may be extra-oral (on the face); the patient may report a history of occasional "awareness" of the tooth feeling different; the patient may report a history of previous pulp-related symptoms some time ago; may have history of previous endodontic treatment.

Clinical findings—may be caries, a restoration breaking down or a crack; the tooth is not tender to percussion; may feel "different" to percussion; no response to pulp sensibility tests; draining sinus evident—intra-oral or extra-oral; palpation or pressure on the tissues overlying the periapical region may cause pus to exude from the draining sinus; can often insert a gutta-percha point into the draining sinus to trace it radiographically.

Radiographic findings—caries may be seen if extensive enough; there is a periapical radiolucency present; a gutta-percha point inserted into the draining sinus can trace its origin to the infected tooth; some cases may have evidence of previous endodontic treatment; occasionally may see a radiolucency within the tooth root indicating internal inflammatory resorption.

Associated pulp/root canal conditions—will be due to an infected root canal system—hence, may have any of the following depending on the symptoms, clinical and radiographic findings: a pulpless and infected root canal system, previous endodontic treatment with an infected root canal system, or internal inflammatory resorption.

Key findings for diagnosis—there is a draining sinus, a periapical radiolucency and no pain or only occasional "awareness."

Distinguish from ***secondary acute apical periodontitis*** by the presence of the draining sinus and lack of symptoms.

Distinguish from ***chronic apical periodontitis*** by the presence of the draining sinus.

Distinguish from a ***secondary acute apical abscess*** by the presence of the draining sinus, and the lack of swelling and symptoms.

Distinguish from a ***foreign body reaction*** by the presence of the draining sinus and the lack of radiographic evidence of a foreign body (but some foreign bodies may not be radiopaque and therefore may not be evident radiographically).

Facial Cellulitis

Facial cellulitis occurs when an infected root canal system develops a periapical abscess (usually a secondary acute apical abscess, although it could be a primary acute apical abscess) and the infection spreads between the fascial planes of the muscles of the face, head, and/or neck (Figure 8-13). It is a spreading infection and it can be superficial or deep. In either case, it can be life-threatening if the resultant swelling restricts the airway. Patients with facial cellulitis require immediate and aggressive treatment—that is, not just oral antibiotic therapy but active dental treatment to remove the source of the bacteria. They often require hospitalisation and even management in an intensive care unit to protect the airway and provide life support in severe cases. For more details, see Chapter 30.

Typical symptoms—facial swelling that is increasing in size—often rapidly; the swelling has had rapid onset (e.g., hours); the patient has considerable pain and discomfort; the pain has only been present for a short time (usually less than 24 hours); there is pain to biting or pressure on the tooth; no thermal sensitivity; the patient has fever and feels unwell.

Clinical findings—facial swelling is evident; may be caries, a restoration breaking down or a crack; very tender to percussion; no response to pulp sensibility tests; tender to palpation; the patient has fever, malaise and lymphadenopathy; severe cases may have airway involvement; typically also have localized signs of a secondary acute apical abscess as the abscess usually occurs before the infection spreads to become facial cellulitis.

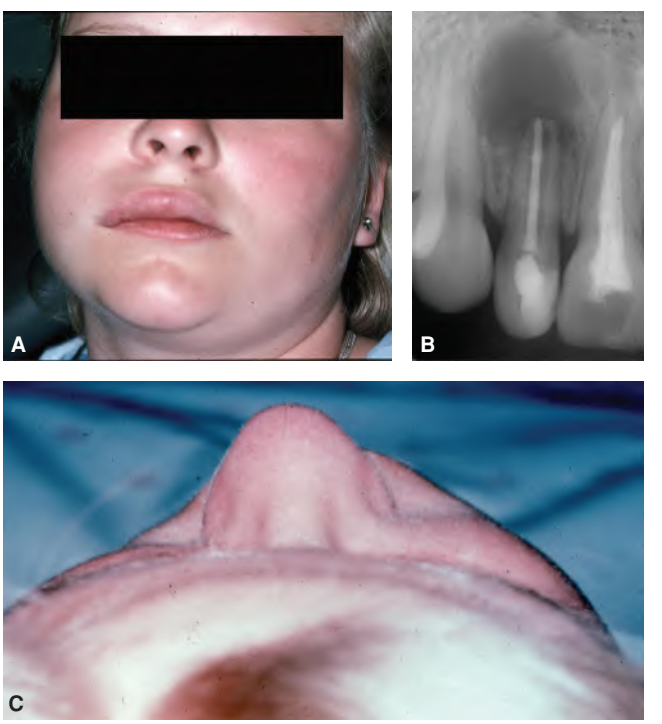

FIGURE 8-13 Facial cellulitis originating from a poorly root-filled and infected root canal system in the maxillary right lateral incisor as a result of breakdown of the composite restoration. ***A.*** Facial view showing considerable swelling and evidence of a spreading infection. ***B.*** Viewing the patient from above and behind demonstrates the extent of the swelling. ***C.*** Periapical radiograph showing a large periapical radiolucency and an inadequate root canal filling.

Radiographic findings—caries may be seen if extensive enough; there is a periapical radiolucency present—indicates chronic apical periodontitis has been present for some time before the abscess and facial cellulitis developed; some cases may have evidence of previous endodontic treatment; occasionally may see a radiolucency within the tooth root indicating internal inflammatory resorption.

Associated pulp/root canal conditions—will be due to an infected root canal system, hence, may have any of the following depending on the symptoms, clinical and radiographic findings: a pulpless and infected root canal system, previous endodontic treatment with an infected root canal system, or internal inflammatory resorption.

Key findings for diagnosis—there is facial swelling of rapid onset, the swelling is spreading, the patient has fever, feels unwell, has a periapical radiolucency, and pain with pressure and percussion.

Distinguish from ***primary acute apical periodontitis*** by the presence of a periapical radiolucency, facial swelling, fever, and malaise.

Distinguish from ***secondary acute apical periodontitis*** by the presence of facial swelling, fever, and malaise.

Distinguish from ***chronic apical periodontitis*** by the pain, facial swelling and the tenderness to percussion.

Distinguish from a ***primary acute apical abscess*** by the presence of a periapical radiolucency, facial swelling, fever, and malaise.

Distinguish from a ***secondary acute apical abscess*** by the swelling spreading throughout the face, and so forth.

Distinguish from a ***chronic apical abscess*** by the lack of a draining sinus and the presence of pain and facial swelling.

Extra-Radicular Infection

An extra-radicular infection occurs when bacteria establish colonies on the external root surface within the periapical region. It is usually a sequel to an infected root canal system and the extra-radicular bacteria are similar to those found in infected root canals.[2,23–25] Actinomyces species are often found in these cases (Figure 8-14).

Extra-radicular infections cannot be diagnosed clinically and they can only be diagnosed histologically. However, clinicians should recognize that this condition does occur and it should be part of the differential diagnosis of a persistent radiolucency following endodontic treatment.

Typical symptoms—may have no symptoms; may be associated with persistent swelling and/or draining sinus; patient may report a history of occasional "awareness" of the tooth feeling different; history of recent or current root canal treatment that is not resolving the problem.

Clinical findings—may be caries, a restoration breaking down or a crack; tooth has signs of recent root canal treatment (e.g., access cavity restoration); not tender to percussion or may feel "different" to percussion; no response to pulp sensibility tests; some cases will have a persistent draining sinus despite recent or ongoing root canal treatment—the draining sinus may be intra-oral or extra-oral; palpation or pressure on the tissues overlying the periapical region may cause pus to exude from the draining sinus, if present; can insert a gutta percha point into the draining sinus, if present, to trace it radiographically.

Radiographic findings—caries may be seen if extensive enough; a periapical radiolucency is present; the radiolucency is persisting or may be increasing in size despite recent root canal treatment; root canal filling or intracanal dressing evident; gutta percha point inserted into the draining sinus, if present, can trace its origin to the affected tooth.

Associated pulp/root canal conditions—usually considered as part of the differential diagnosis of a persistent radiolucency despite recent or ongoing endodontic

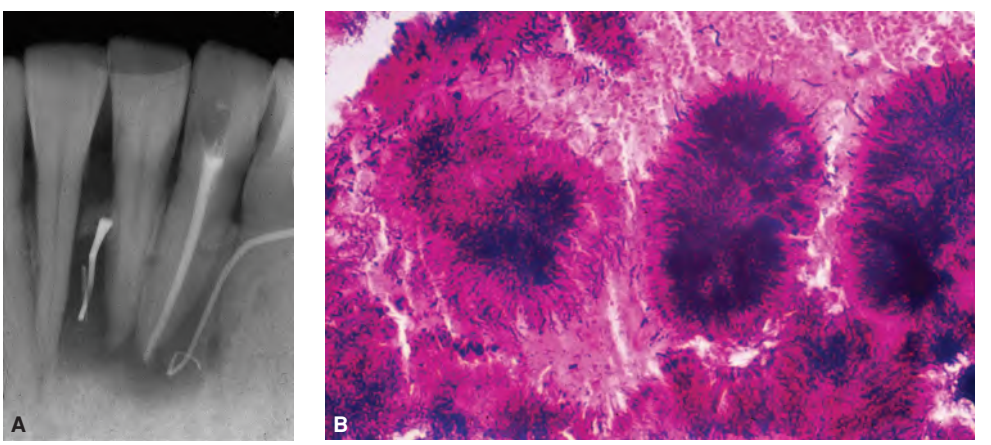

FIGURE 8-14 An extra-radicular infection associated with the mandibular left central and lateral incisors. ***A.*** The central incisor had a pulpless, infected root canal system while the lateral incisor had a root-filled and infected root canal system. Despite root canal treatment of the central incisor and root canal retreatment of the lateral incisor, the two draining sinuses persisted. Hence, a periapical curettage was done immediately after the root canals were filled. ***B.*** The histological diagnosis was "periapical actinomycosis."

treatment—hence, it will initially be associated with an infected root canal system; may be associated with previous endodontic treatment with an infected root canal system—treatment may be incomplete with an intracanal medicament in place; or treatment may be complete with a root canal filling evident.

Key findings for diagnosis—a periapical radiolucency and no pain, typically has had recent root canal treatment without resolution of the periapical radiolucency.

Distinguish from a foreign body reaction, a periapical pocket cyst, a periapical true cyst, and a periapical scar by histological examination of a biopsy specimen.

Foreign Body Reaction

A foreign body reaction is an inflammatory response to a foreign material within the periapical tissues.[2,26,27] The most common foreign material is excess root filling material, such as gutta percha or root canal cement that has been extruded through the apical foramen.[28,29] Radiographically, foreign body reactions usually appear as a periapical radiolucency surrounding some radiopaque material (Figure 8-15) but there have been reports of other materials that are not radiopaque—such as talcum powder and food.[29]

Foreign body reactions cannot be diagnosed clinically and they can only be diagnosed histologically. However, clinicians should recognize that this condition does occur and it should be part of the differential diagnosis of a persistent radiolucency following endodontic treatment.

Typical symptoms—usually no symptoms; the patient may report a history of occasional "awareness" of the tooth feeling different; history of recent or current endodontic treatment without resolution of the periapical radiolucency and/or symptoms.

Clinical findings—the tooth has signs of recent root canal treatment (e.g., access cavity restoration); the tooth is not tender to percussion or may feel "different" to percussion; no response to pulp sensibility tests.

Radiographic findings—a periapical radiolucency is present; the radiolucency is persisting or may be increasing in size despite recent root canal treatment; root canal filling or intracanal dressing evident; radiopaque material may be seen in the periapical tissues; some cases may be due to materials that are not radiopaque and therefore not evident radiographically.

Associated pulp/root canal conditions—usually considered as part of the differential diagnosis of a persistent radiolucency despite recent or ongoing endodontic treatment—hence, it will initially be associated with an infected root canal system; may be associated with previous endodontic treatment with an infected root canal system—treatment may be incomplete with an intracanal medicament in place; or the treatment may be complete with a root canal filling evident.

Key findings for diagnosis—there is a periapical radiolucency; usually no pain; typically has had root canal treatment without resolution of the periapical radiolucency; many cases have radiopaque material present within the periapical radiolucency.

Distinguish from an extra-radicular infection, a periapical pocket cyst, a periapical true cyst, and a periapical scar by histological examination of a biopsy specimen.

FIGURE 8-15 A foreign body reaction may occur in the periapical tissues of all three roots of this maxillary right first molar as a result of extrusion of root filling materials into the periapical tissues. However, further observation is necessary and a surgical biopsy may be required if the symptoms and signs continue.

Periapical Pocket Cyst

A cyst is a sac-like structure lined by epithelium and containing fluid or semisolid material. Nair[2,30,31] has reported and defined two types of periapical cysts—pocket cyst and true cyst. Both are essentially forms of chronic apical periodontitis that develop as a sequel to an infected root canal system but they have different histological appearances. A pocket cyst has an opening that communicates with the root canal system (Figure 8-16), hence it is not a true cyst according to the definition. It is believed that pocket cysts are likely to heal after the root canal system has been treated, but if no treatment is provided a pocket cyst may "break away" from the root canal and the tooth apex, and the opening closes to become a "true cyst."

Periapical pocket cysts and periapical true cysts cannot be differentiated clinically or radiographically from other periapical conditions that manifest as radiolucencies. In the past, many practitioners have erroneously thought that well-defined borders of the radiolucency indicated a cyst but this is only indicative of a slowly developing lesion. A diffuse border is more likely to indicate a rapidly developing lesion. Likewise, the size of the radiolucency is not indicative of a cyst if it is large—since apical periodontitis, abscesses and cysts can be small or large. A large radiolucency is more likely to indicate a long-standing problem. For more details, see Chapter 6.

Periapical pocket cysts cannot be diagnosed clinically and can only be diagnosed histologically. However, clinicians should recognize that this condition does occur and it should be part of the differential diagnosis of a persistent radiolucency following endodontic treatment.

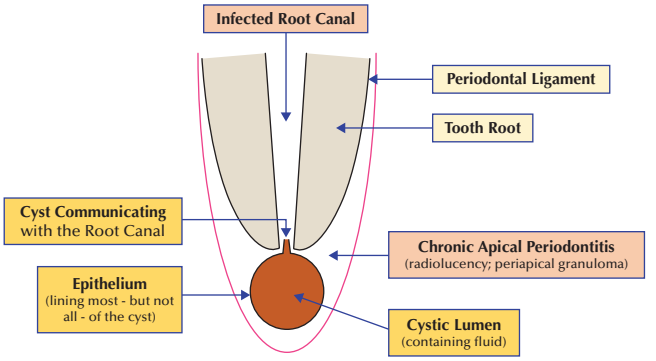

FIGURE 8-16 Schematic representation of a periapical pocket cyst showing communication of the lumen of the cyst with the root canal system (adapted from Abbott[3]).

Typical symptoms—usually no symptoms; may have symptoms if the cyst has become infected (e.g., becomes an acute apical abscess, chronic apical abscess or extra-radicular infection); the patient may report a history of occasional "awareness" of the tooth feeling different; usually a history of recent or current endodontic treatment without resolution of the periapical radiolucency and/or symptoms.

Clinical findings—may be caries, a restoration breaking down or a crack; the tooth has signs of recent root canal treatment (e.g., access cavity restoration); the tooth is not tender to percussion or palpation (unless it has become infected) or it may feel slightly "different" to percussion; no response to pulp sensibility tests.

Radiographic findings—caries may be seen if extensive enough; a periapical radiolucency is present; the radiolucency is persisting or may be increasing in size despite recent endodontic treatment; root canal filling or intracanal dressing evident.

Associated pulp/root canal conditions—usually considered as part of the differential diagnosis of a persistent radiolucency despite recent or ongoing endodontic treatment—hence, it will initially be associated with an infected root canal system; may be associated with previous endodontic treatment with an infected root canal system—treatment may be incomplete with an intracanal medicament in place; or the treatment may be complete with a root canal filling evident.

Key findings for diagnosis—no symptoms and no abnormal findings; there is a periapical radiolucency and no pain, typically has had root canal treatment without resolution of the periapical radiolucency.

Distinguish from an extra-radicular infection, a foreign body reaction, a periapical true cyst and a periapical scar by histological examination of a biopsy specimen.

Periapical True Cyst

As discussed earlier, Nair[2,30,31] has reported and defined two types of periapical cysts—pocket cyst and true cyst. A true cyst has a complete epithelial lining (Figure 8-17) and contains fluid and often cholesterol crystals. It is a self-propagating lesion that is no longer dependent on the root canal system being infected.

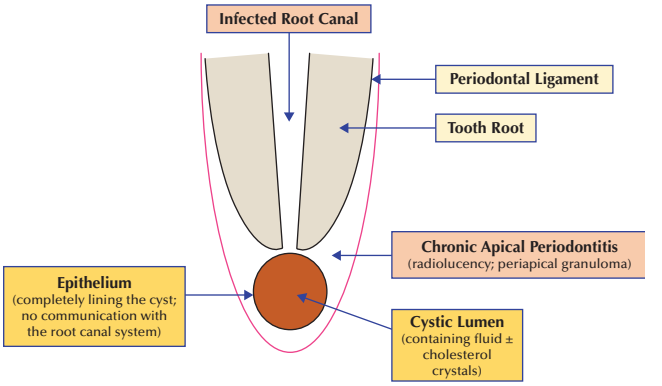

FIGURE 8-17 Schematic representation of a periapical true cyst. There is no communication between the cyst lumen and the root canal system (adapted from Abbott[3]).

Hence, root canal treatment alone will not resolve a periapical true cysts and surgical removal will be necessary.

As also discussed earlier, periapical pocket cysts and periapical true cysts cannot be differentiated clinically or radiographically from other periapical conditions that manifest as radiolucencies. The size of the radiolucency and the appearance of the borders are not specific diagnostic signs that can be used to diagnose a true cyst.

Periapical true cysts cannot be diagnosed clinically and can only be diagnosed histologically. However, clinicians should recognize that this condition does occur and it should be part of the differential diagnosis of a persistent radiolucency following endodontic treatment.

Typical symptoms—usually no symptoms; may have symptoms if the cyst has become infected (e.g., becomes an acute apical abscess, chronic apical abscess or extra-radicular infection); the patient may report a history of occasional "awareness" of the tooth feeling different; usually a history of recent or current endodontic treatment without resolution of the periapical radiolucency and/or symptoms.

Clinical findings—may be caries, a restoration breaking down or a crack; the tooth has signs of recent root canal treatment (e.g., access cavity restoration); not tender to percussion or palpation (unless it has become infected) or it may feel slightly "different" to percussion; no response to pulp sensibility tests.

Radiographic findings—caries may be seen if extensive enough; a periapical radiolucency is present; the radiolucency is persisting or may be increasing in size despite recent endodontic treatment; root canal filling or intracanal dressing evident.

Associated pulp/root canal conditions—usually considered as part of the differential diagnosis of a persistent radiolucency despite recent or ongoing endodontic treatment—hence, it will initially be associated with an infected root canal system; may be associated with previous endodontic treatment with an infected root canal system—treatment may be incomplete with an intracanal medicament in place; or the treatment may be complete with a root canal filling evident.

Key findings for diagnosis—no symptoms and no abnormal findings; there is a periapical radiolucency and no pain; typically has had root canal treatment without resolution of the periapical radiolucency.

Distinguish from an ***extra-radicular infection***, *a* ***foreign body reaction***, *a* ***periapical pocket cyst*** and a ***periapical scar*** by histological examination of a biopsy specimen.

Periapical Scar

A periapical scar is not a disease or a pathological condition. It is a healing response where fibrous, connective tissue forms instead of bone and/or PDL. Typically the radiolucency reduces in size over time but it does not completely disappear (Figure 8-18). Scar tissue may form following either treatment of an inflammatory condition with bone resorption (i.e., any form of apical periodontitis) or following surgical endodontic treatment.[31]

Periapical scars cannot be definitively diagnosed clinically; they can only be diagnosed histologically but surgery in order to biopsy a suspected periapical scar is not justified or indicated. Clinicians should recognize that this condition does occur and it should be part of the differential diagnosis of a persistent radiolucency following endodontic treatment.

Typical symptoms—no symptoms; history of root canal treatment or a surgical endodontic procedure.

Clinical findings—the tooth will have a restoration; the tooth has signs of root canal treatment (e.g., access cavity restoration); there are normal responses to percussion and palpation; no response to pulp sensibility tests.

Radiographic findings—the tooth has a restoration; the periapical radiolucency is smaller than it was preoperatively and immediately postoperatively but it is persisting following root canal treatment or endodontic surgery; a root canal filling is evident; a root-end root canal filling may be evident if there is a history of previous endodontic surgery.

Associated pulp/root canal conditions—usually considered as part of the differential diagnosis of a reduced but persistent radiolucency following root canal treatment or endodontic surgery; history of previous endodontic treatment with no signs of infection.

Key findings for diagnosis—no symptoms and no abnormal findings; there is a periapical radiolucency and no pain; typically the tooth has had root canal treatment with some, but not complete, resolution of the periapical radiolucency.

Distinguish from an ***extra-radicular infection***, *a* ***foreign body reaction***, *and a* ***periapical pocket cyst*** by histological examination of a biopsy specimen (however, a biopsy is not indicated if the clinical assessment is indicative of a periapical scar—simply observe and reassess over time).

THE DIAGNOSTIC PROCESS

Formulating a diagnosis is part of a sequence of steps or procedures which can be referred to as the "diagnostic process." The 11 stages of this process are outlined in Box 8-2. A summary of the consultation and examination procedures used in the diagnostic process is provided in Table 8-3.[11]

Each step is an essential part of the diagnostic process. If one step is omitted, or if insufficient information is obtained, then the clinician may not have the required details to make an accurate diagnosis. This process can be likened to a jigsaw puzzle where a missing piece may mean the puzzle cannot be solved although it may be possible to guess the answer—which may or may not be correct. Likewise, when diagnosing a patient's presenting condition, it may be possible in some cases to "guess" the diagnosis correctly but there is always a risk of an incorrect diagnosis that may then lead to incorrect treatment.

The diagnosis will be much stronger and more reliable if there are several conforming or corroborative findings rather than just one or two. As an example, if a patient has no response to pulp sensibility tests, a different sensation on percussion of the tooth and a periapical radiolucency, then a diagnosis of a pulpless, infected root canal system with chronic apical periodontitis is likely to be a very strong or reliable diagnosis compared to a patient who only has no response to pulp tests. The latter may be a result of PCC or a false-negative test result.

Recommended Consultation Procedure

Many patients presenting to a dentist will be apprehensive about the situation. The level of apprehension is generally

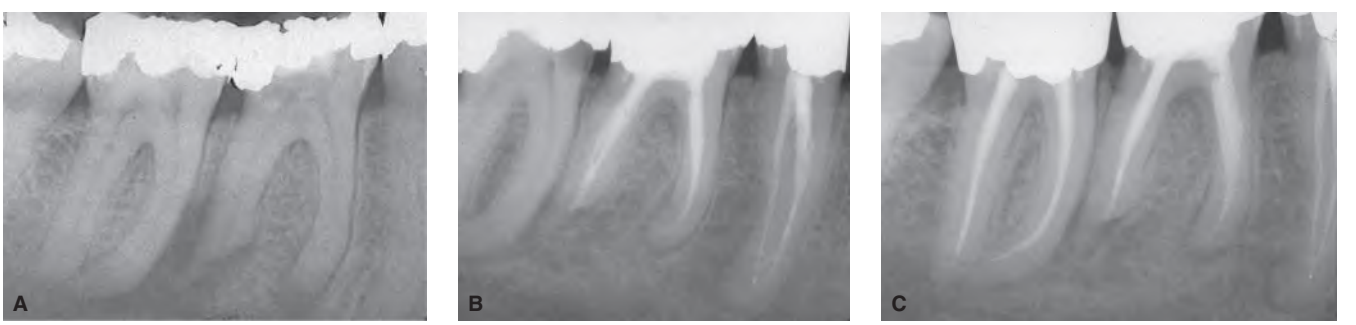

FIGURE 8-18 The mandibular right first molar is very likely to have a periapical scar, based on the radiographic follow-up. ***A.*** Preoperative radiograph shows a large radiolucency. ***B.*** One year after root canal treatment, the radiolucency is much smaller. ***C.*** The radiolucency has remained of a similar size when reviewed after three more years.

higher when the patient sees a particular dentist for the first time because the patient will not be familiar with the dentist and his/her approach, abilities, communication style, and overall office procedures. The apprehension can be even further heightened when the patient is experiencing pain, with greater levels of pain usually meaning greater apprehension. Clinicians must be sensitive to this and approach the patient with a calming and confident manner.

BOX 8-2 The 11 stages of the "diagnostic process"

1. History taking—medical, dental, and the presenting complaint
2. Clinical examination
3. Clinical tests
4. Taking and interpretation of radiographs and/or other images
5. Formulating the diagnosis/diagnoses
6. Identifying the cause(s) of the disease(s)
7. Assessing the management options
8. Discussion with the patient
9. Finalizing the management plan with the patient's consent
10. Tooth investigation—suitability for restoration/case selection
11. Records—note all findings and discussions in the patient's clinical record

Most dentists' offices consist of a dental chair and various other equipment surrounding it—such as the dental light, the dental unit with various handpieces, X-ray machines, sometimes an operating microscope, and possibly various other devices. This creates an overwhelming sight for a patient entering the room for the first time or when already apprehensive. Some patients may even feel intimidated and their level of anxiety may increase on seeing all these things surrounding them when they sit in the dental chair. Then, many dentists sit behind or to the side of the patient that does not create an ideal situation for communication with the patient to discuss their problems. This can be further exacerbated by the dentist and the assistant staff wearing face masks, safety glasses, and so forth.

Patients are usually quite familiar with consulting medical practitioners where they are more likely to sit at a desk facing the practitioner who will proceed to ask them various questions about their presenting condition before they undergo a physical examination. Dentists should ideally adopt this approach, as it is more likely that the patient will be more relaxed and will then communicate more effectively. The act of taking detailed medical and dental histories and obtaining details about the patient's presenting complaint requires effective communication. This is more readily achieved in a nonthreatening environment with the practitioner demonstrating empathy and concern for the patient.

Once sufficient information has been obtained from the patient through this communication process, the clinician

TABLE 8-3 Summary of the Examination Procedures That Should Be Performed as Part of Any Routine Dental Examination and Diagnosis but Particularly Whenever Pulp, Root Canal, and Periapical/Periradicular Pathosis Is Suspected

General medical history	As required for all dental procedures
Presenting complaint	Long- and short-term history Past and current symptoms Past and recent treatment Medications being used (prescribed, self-prescribed, alternative) Description of PAIN: location, onset, nature, duration, stimuli, relief, referred
Clinical examination	Visually examine tissues for puckering, indentation, draining sinus, facial asymmetry, swelling, etc. Probe pits, fissures, grooves and tooth surfaces for caries Assess restorations and probe all margins Transillumination of the tooth with a fibre-optic light (re cracks) Periodontal probing Mobility Biting on individual cusps (e.g., with a 'Tooth Slooth', 'FracFinder')
Clinical tests	
Pulp sensibility tests	Cold (e.g., CO_2—dry ice) Electric Heat (if required, e.g., when only complaint is sensitivity to heat)
Periradicular tests	Percussion Palpation
Radiographic examination	Periapical radiographs (all cases) Other images may be required for some cases (e.g., tube shift periapical radiographs, bitewing radiographs, occlusal radiograph, panoramic radiograph, CT scans, etc.)
Tooth investigation	Remove all restorations, caries, cracks Transillumination of the cavity, cusps, marginal ridges, etc. Assess whether, and how, the tooth can be restored again Assess the need for any other treatment (e.g., periodontal) Assess the long term prognosis of the tooth (consider endodontic, periodontal and restorative aspects)

(Adapted from Abbott[3] and Abbott and Yu.[11])

should be able to form the provisional diagnoses that can then direct the clinical examination and tests that need to be performed. The nature of the examination can be explained to the patient along with informing the patient that radiographs need to be taken. It is at this stage that the patient can be invited to move to the dental chair for the examination.

When a patient presents with pain suggesting pulp, root canal or periapical/periradicular disease, a systematic approach to diagnosis should be followed. Specific symptoms and signs will aid the diagnosis as shown in Figure 8-19. The first decision is whether the pain is a result of pulpitis or an infected root canal system (implying periapical symptoms)—this can initially be established from the history and symptoms. If the pain is originating from the pulp, then the operator must decide whether the pulpitis is reversible, irreversible and whether acute or chronic, plus whether apical periodontitis (acute or chronic) is also present. If the pain is a result of an infected root canal system, then the patient can present in various ways that can be distinguished via the history, pulp tests and radiographs. The periapical tissues must then be assessed to determine whether the problem is a result of apical periodontitis, an abscess or cellulitis, and whether the condition is acute (primary or secondary) or chronic in nature.

The clinical examination should be performed in a systematic manner as outlined subsequently. The clinical examination allows the clinician to:

- Establish the definitive diagnoses—note that when dealing with pulp, root canal, and periradicular conditions, there should always be at least two diagnoses—that is, the condition of the pulp (or the root canal system) and the condition of the periapical/periradicular tissues (as earlier),
- Identify the cause(s) of the condition(s)/disease(s),
- Assess the overall oral condition, and
- Determine the appropriate management for the presenting problem.

Once the clinical examination has been completed, the patient should be invited back to the consultation area/desk in order to discuss the findings, the diagnoses and the options for managing the problem(s). Other issues such as costs and further restoration of the tooth should also be discussed at this stage so that fully informed consent for treatment can be given by the patient.

Once the patient has consented to treatment, the patient can return to the dental chair for the commencement of the treatment, or further appointments can be arranged, as appropriate.

History

Medical History

The medical condition of the patient is an important aspect that should be assessed as part of all dental examinations. Typically, this begins with the patient filling in a written questionnaire and there are many examples of such questionnaires. Most dental institutions (e.g., schools, hospitals) will have their own versions and many professional dental organizations have developed medical history forms for use by their dentist members. The purpose of a medical history is to identify any risks that the patient may be exposed to during dental treatment and to alert the clinician to any precautions that need to be taken. The history may also alert the dentist to any risks posed to the clinician and staff. Since root canal treatment and other endodontic procedures do not carry any significantly different risks than other dental treatment, a routine medical history form can be used. The history should include questions about any medications being taken by the patient—this should include prescribed, over-the-counter, and alternate medications. The topic of medical history taking and medical conditions affecting dental treatment is well discussed in various texts and will not be elaborated here.

Particular medications of concern when managing pulp, root canal, and periradicular conditions are antibiotics, analgesics and anti-inflammatory agents. Some patients may have been prescribed, or may self-prescribe, these drugs prior to seeking dental treatment. Antibiotics are not commonly indicated and their over-use is problematic in many ways. In particular, patients may develop resistant strains of bacteria that may compromise the root canal treatment that is necessary. Inappropriate use of antibiotics is common even with conditions such as pulpitis—patients should be advised to cease taking antibiotics if they are not truly indicated. If they are required, then the clinician may need to change the antibiotic medication if the current one is not being effective.

If a patient has been using analgesics and/or anti-inflammatory agents prior to the consultation then this may provide some insight into the severity of the pain, as well as the patient's perceptions of pain and their pain-coping mechanisms. Some drugs may also affect the results of pulp testing procedures that may then affect the clinician's ability to form a diagnosis.

For more details, see Chapter 31.

Dental History

The patient should be questioned about their general dental history so the clinician can gauge the patient's general attitude to, and use of, dental services. Details such as when the patient last saw a dentist, what treatment was done, why the treatment was done, the preoperative symptoms, how often the patient seeks a dental check-up, whether they only attend when they have problems, their oral hygiene habits (regularity, bushing method, use of floss), and so forth all provide valuable information to the clinician which can be used when formulating a management plan for the presenting problem.

The Presenting Complaint

The patient should be questioned about why they have attended for dental treatment. If the patient is presenting for a general or regular check-up, then there may not be a particular problem that needs special assessment. However, if the presenting problem is pain or a "toothache," then further details are required.

General (or open-ended) questions should be used initially to encourage the patient to describe the pain or presenting problem in his/her own words. While listening to this description, the clinician should be listening for key symptoms or events that will help to diagnose the problem.

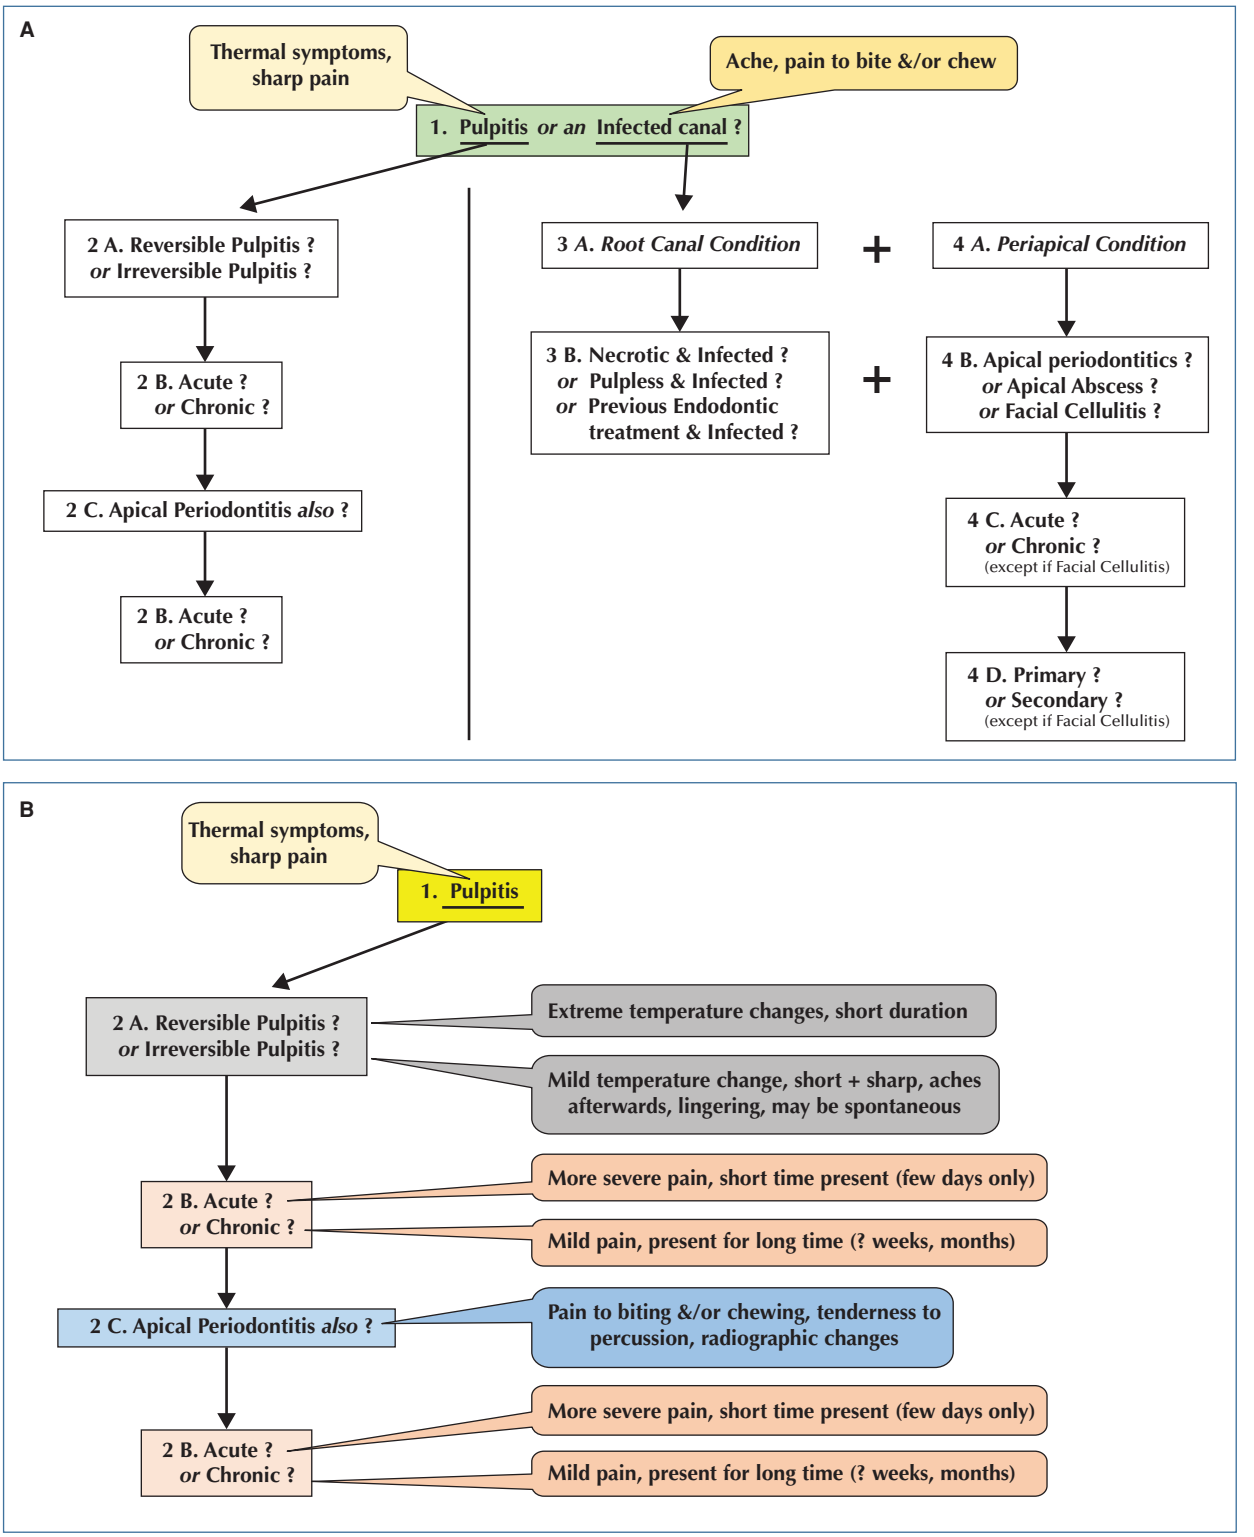

FIGURE 8-19 When a patient presents with pain suggesting pulp, root canal or periapical/periradicular disease, a systematic approach to diagnosis should be followed. Specific symptoms and signs will aid the diagnosis as shown. ***A***. The first decision is whether the pain is a result of pulpitis or an infected root canal system (that implies periapical symptoms). ***B***. If the pain is originating from the pulp, then the clinician must decide whether the pulpitis is reversible, irreversible and whether acute or chronic, plus whether apical periodontitis (acute or chronic) is also present. (*Continued on facing page*)

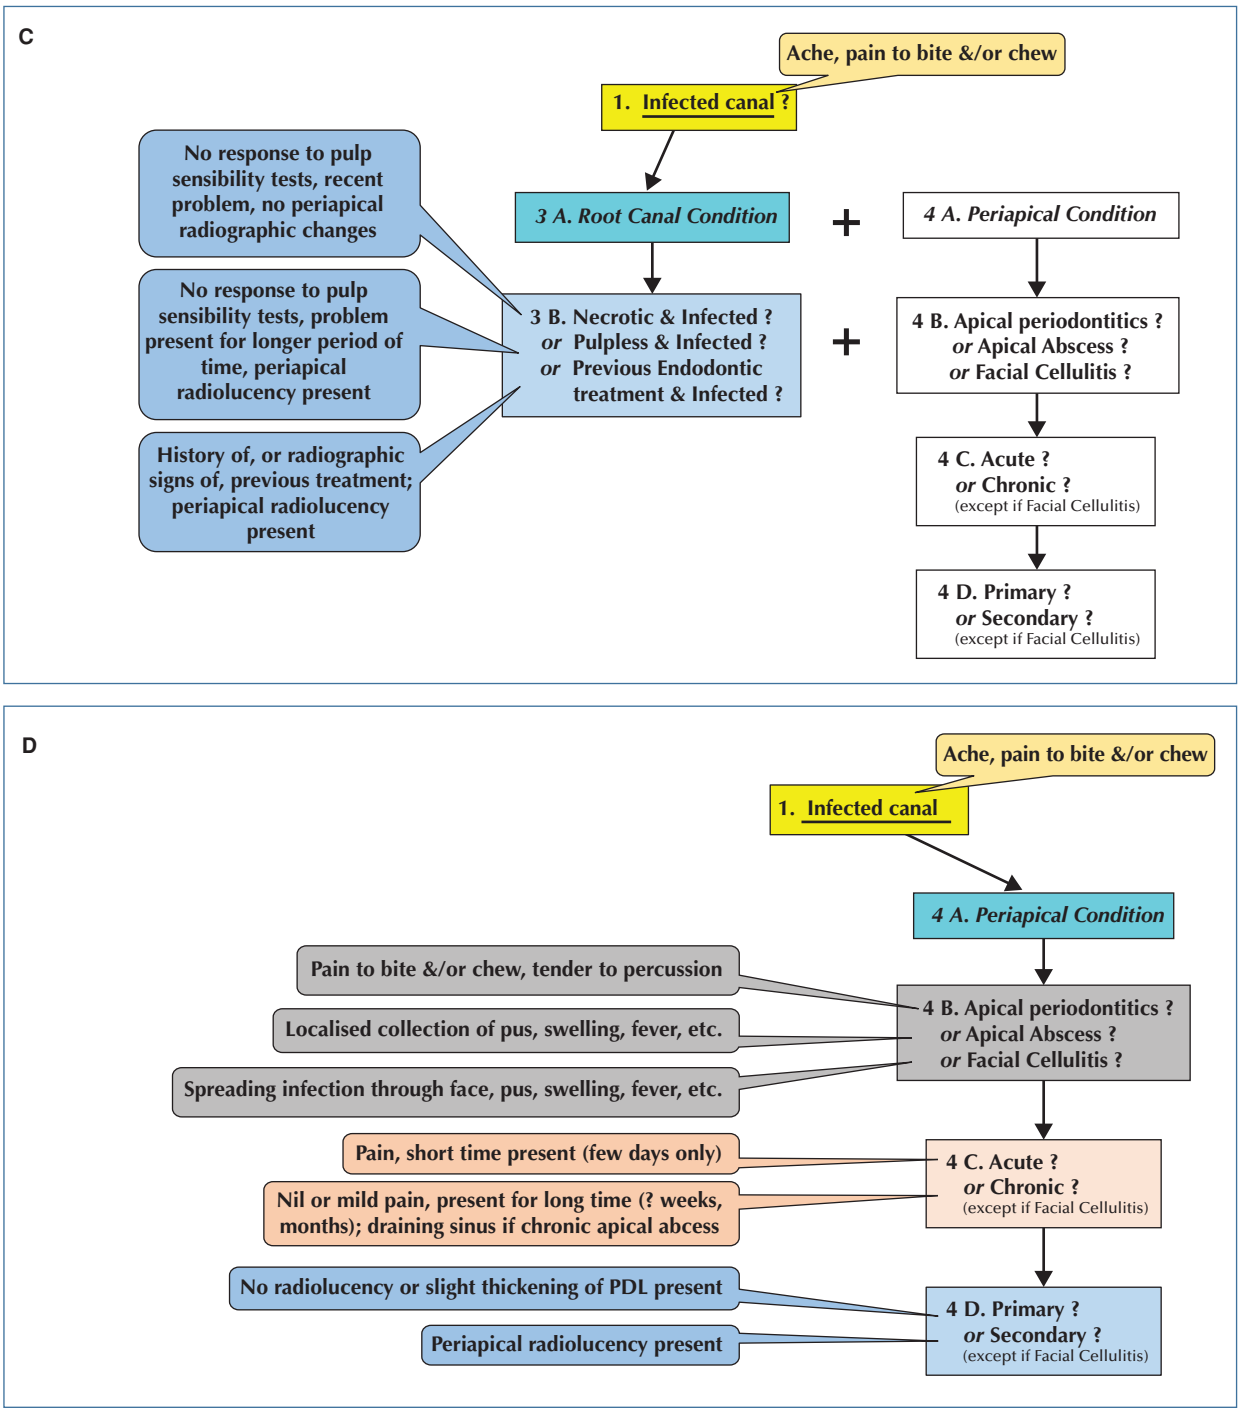

FIGURE 8-19 (*Continued*) ***C***. An infected root canal system can present in various ways that can be distinguished by the history, pulp tests and radiographs. ***D***. The periapical tissues must then be assessed to determine whether the problem is apical periodontitis or an abscess/cellulitis and whether acute (primary or secondary) or chronic.

Leading questions should be avoided wherever possible since many patients will respond in the way that they think the dentist wants them to respond, whereas allowing the patient to outline their problem without direct prompting is generally more reliable. As an example, ask the patient to describe the pain rather than asking whether it is a sharp pain. Another example is to ask the patient what stimulates the pain rather than asking if a cold drink causes the pain.

It is essential to ask the patient about the pain they are experiencing, if they present with a pain problem. This includes the stimulus required to produce the pain, the nature of the pain (sharp, dull, etc.) and how long the pain lasts. There are many dental and oral conditions that can cause pain. Each has some typical characteristics although some may be common. Hence, the more information obtained, the more reliable the diagnostic process will be.

Patients will often use the word *"sensitivity"* but this could have several meanings and could indicate different conditions. For example, sensitivity to cold or heat usually indicates pulpitis (reversible or irreversible), sweet sensitivity usually indicates a restoration is breaking down (causing reversible pulpitis), sensitivity to biting may indicate a crack undermining a cusp (causing pulpitis) or sensitivity to biting may indicate acute apical periodontitis. Hence, the patient should be asked *"what do you mean by 'sensitive'?"* in order to gather more detailed information. This also avoids the dentist being misled by what he/she perceives as *"sensitivity."*

The history should include questions about any recent dental treatment, especially in the region of the presenting problem. For example, if a restoration was done recently by another dentist, then this tooth may have pulpitis. Knowing the reasons why the restoration was done and any symptoms prior to the restoration are important when assessing what has happened since the restoration. In many cases, these patients will provide an almost textbook-like answer that describes the progression of pulp disease, thus facilitating the diagnosis.

Once the clinician has obtained a detailed history of the presenting problem, the provisional diagnoses should be made. There should be at least two provisional diagnoses at this stage—one for the pulp (if a pulp is present, otherwise for the root canal system) and the other for the periapical/periradicular tissues. The provisional diagnoses should be based on what the patient tells the clinician—hence, the value of the history should not be under-estimated. Once the clinician has the provisional diagnoses in mind, the clinical examination can be performed and the provisional diagnoses will help to target this examination with the appropriate tests and procedures.

The Clinical Examination

The clinical examination should ideally include an extra-oral examination and a detailed examination of all the soft tissues in the mouth, the lips, and the teeth. However, in an emergency or pain situation, a limited examination is acceptable in order to diagnose and manage the presenting problem. In this scenario, the patient should be advised to return for a comprehensive examination of the entire mouth at a later date.

The limited dental examination should include a screening of the soft tissues in order to eliminate any problems such as oral cancer or ulcerations that may be present and causing the pain. A screen of all teeth should also be performed in order to identify any major and/or urgent problems that require attention. This screening of the mouth and teeth also provides the clinician with a general overview of the patient's oral conditions that will help with planning how to manage the presenting problem(s).

The limited examination can then focus on the area of interest with the provisional diagnoses in mind. The provisional diagnoses will help to determine which clinical tests will be the most appropriate to lead to definitive diagnoses. For example, if the provisional diagnosis is acute irreversible pulpitis, then a cold pulp sensibility test is the most appropriate and reliable test, whereas a pulpless, infected root canal system with chronic apical periodontitis will be more reliably assessed through radiographic examination. This does not mean that all tests are not required; rather they should all be performed but the relative weight of the information obtained from each test will vary with the different conditions.

The overall aims of diagnostic testing are two-fold. The first aim is to gain objective data from the patient's symptoms and clinical signs as well as from the results of diagnostic tests. The second aim is to reproduce the patient's chief complaint if the patient has been experiencing pain. If the patient has been experiencing pain and this pain cannot be reproduced during the examination, then the practitioner should be wary of providing any treatment that may be well-intentioned but might result in a poor outcome, since that treatment may not be related to the chief complaint and may not actually have been necessary.

In order to diagnose teeth with pulp, root canal or periradicular conditions, the following procedures and tests should be carried out:

Extra-oral Examination

The face should first be observed while taking the medical and dental histories. Swellings are usually obvious but occasionally they may be only slight and not so obvious. When the patient sits in the dental chair, the clinician should observe the patient from behind and above the head to see if there is any asymmetry between the two sides of the face. Any swellings that are identified should be palpated to determine whether they are hard or soft, fluctuant, painful, hot to touch, red or have a different colour. The lymph nodes in the head and neck should also be palpated for any patient presenting with an infection or inflammatory condition. The jaw opening should also be assessed to determine if there is trismus that may impede treatment, particularly when there is swelling associated with an apical abscess or facial cellulitis.

The face should also be examined for the presence of an extra-oral draining sinus, or signs of a scar that may indicate a previous draining sinus that has temporarily healed. An extra-oral draining sinus may be indicative of a chronic apical abscess associated with an infected root canal system. The extra-oral draining sinus should be traced by placing a gutta-percha point into the draining sinus and exposing a periapical radiograph to trace its origin.

Intra-oral Examination

As mentioned earlier, the mouth should be screened for any soft tissue lesions, that is, visually inspect the gingivae, lips, tongue, cheeks and look for any abnormalities such as ulcerations, swellings or other signs. In particular, if the history suggests an infected root canal system, then check carefully for the presence of a draining sinus, or evidence of a draining sinus that may no longer be active.

The teeth should then be checked for the presence of caries, restorations, cracks, fractures, discolorations, developmental defects or any other abnormalities. The first stage of assessing teeth is to visually examine them using a good light source. The teeth should be probed to assess pits, fissures, grooves, restoration margins and any other defects. Cracks and fractures are best identified by transilluminating the tooth using an intense light source, as described subsequently.

Many text books and teachers refer to one or more of the following procedures as *"special tests."* However, except where mentioned subsequently, they should all be considered as ***routine and mandatory tests*** that are required for all cases where pulp, root canal, and periradicular diseases are suspected. As discussed earlier, as much information as possible should be obtained before the diagnoses are finalized. If these tests are only considered to be "special tests," then the tendency will be to only use them in special circumstances rather than routinely. All dentists should be encouraged to undertake these tests for every "new patient examination" and prior to doing any restorative dental treatment to a tooth. If the tests are not done, then chronic conditions without any symptoms or obvious clinical manifestations will remain undetected and will progress to more serious problems over time. As an example, not performing pulp sensibility tests prior to restoring a tooth is akin to not doing periodontal probing. It is well known that periodontal disease is often undetected because clinicians do not routinely do periodontal probing. Medical examples of undetected conditions as a result of not undertaking appropriate, regular and simple tests are hypertension (if blood pressure is not checked) and diabetes (if not blood tests). Likewise, pulp disease often goes undetected because clinicians do not do pulp tests routinely and they only use them if the patient reports a problem. Many teeth have pulps that progress through the various stages of the pulp/root canal disease process to become pulpless and infected root canal systems with chronic apical periodontitis for a long time before secondary acute apical periodontitis develops and the patient then seeks dental care. A study undertaken at the University of Michigan[32] reported that about 40% of teeth with infected root canal systems and periapical radiolucencies had not had any symptoms of pulpitis prior to their presentation to the University clinic. The presence of periapical radiolucencies associated with these teeth indicates that the disease process had been present for a considerable time.

Pulp Sensibility Tests

It is essential to understand the concepts of pulp sensibility testing. These tests are performed to help with the diagnosis of the condition of the pulp. Traditionally, these tests have been called "vitality" tests but this is an incorrect term to use. The use of this incorrect term over many years has resulted in many clinicians mis-diagnosing the pulp condition and not understanding the test process. The nature of the tests and the information they provide should be understood by clinicians so they can be applied correctly.

"Sensibility" is defined as "the ability to respond to a stimulus"[33] whereas "vitality" is defined as "the capacity to live, grow, or develop."[34] In dental settings, "vitality" is taken to imply that there is a viable blood supply to the pulp.[11] The typical tests used to assess pulps are either thermal (cold, heat) or electric pulp tests—these all test whether the pulp responds to the applied stimulus and hence they are "sensibility tests."[11] They do not assess the pulp's blood supply or whether it has the "capacity to live, grow or develop."[11] Specific tests are available for testing the pulp's blood supply (e.g., Laser Doppler flowmetry, pulse oximetry) but these tests have not been developed to the point where they are clinically useful on a day-to-day basis. They have been used for research but the costs and the time taken, plus the difficulties and limitations in using them, render them unsuitable for routine clinical use. In addition, they do not reproduce the symptoms reported by the patient for pulpitis cases so their application is limited.

If the tests are considered to be testing the "vitality" of the pulp, then the result can only be "vital" or "nonvital." However, these terms do not truly indicate the state of the pulp or the root canal system. In addition, these terms do not meet the criteria outlined earlier for a possible, useful and meaningful classification of diseases/conditions. In particular, they do not distinguish between many conditions with 12 of the above pulp/root canal conditions that could be called "vital" and 10 that could be called "nonvital"—the treatment for these conditions varies and therefore these terms do not help to decide the management or treatment required. Hence, these terms are inappropriate and should no longer be used in modern dentistry.

Some clinicians erroneously use the term "sensitivity tests" instead of sensibility tests. "Sensitivity" is the state of being "easily irritated or annoyed." A pulp that responds to a stimulus is displaying "sensibility" but the response may be exaggerated or painful, as when there is inflammation present (i.e., pulpitis), in which case it is then responding in a "sensitive" manner. It is the response that differs but the test is still the same (i.e., a pulp sensibility test).

Pulp sensibility tests can be used in different ways and for different reasons—their use and interpretation will be determined by the history provided by the patient and the situation being assessed. In general, pulp sensibility tests are used to:

- Assess the health status of the pulp:
  - ◊ Prior to restorative, endodontic, orthodontic, periodontal or surgical procedures,
- Locate and diagnose a tooth with pulpitis (reversible or irreversible) when the history suggests such a condition exists:
  - ◊ In such a situation, the pulp sensibility tests can reproduce the pulpitis pain (especially when associated with cold stimuli) and

◊ These tests can also be used to differentiate between reversible and irreversible pulpitis by observing the patient's response to the test stimulus,

- Locate and diagnose a tooth that has a necrotic pulp or one that has become pulpless and infected where the history suggests such a condition exists,
- As a follow-up, and to monitor, the pulp after trauma to the teeth, or
- As part of a differential diagnostic process (such as to exclude periapical pathosis of pulp origin).

There are two aspects to consider—the first is whether the pulp responds to the stimulus, while the second is the nature of the response. If a tooth does not respond to the stimulus, then this suggests that the pulp is necrotic or the root canal system has become pulpless and infected. In contrast, if a tooth does respond to the stimulus, then the pulp is either "clinically normal" or it has some form of pulpitis. The nature of the response will then determine the diagnosis—if the response is "normal" (compared to other teeth in that same patient's mouth), then the pulp is likely to be "clinically normal." However, if the response is exaggerated and the test reproduces the pain that the patient has been experiencing, then the general diagnosis will be pulpitis. The clinician must then determine what type of pulpitis—this is based on the history, the duration and the nature of the pain. The latter two aspects can be reproduced by the pulp sensibility test (especially a cold test) that then leads to the diagnosis.

There are three types of pulp sensibility tests commonly used in dental practice. They are cold, heat and electric tests. It is important to note that all pulp tests should be performed and interpreted in conjunction with all other clinical findings and periapical radiographs. If other information and radiographs are not available, then the pulp tests may not be meaningful—for example, a tooth may not respond to a cold pulp test because it has PCC that can only be determined radiographically. Another example is a tooth that does not respond to both cold and electric pulp tests because it has had previous root canal treatment—the presence of the root canal filling can only be noted radiographically or sometimes by clinically observing a typical endodontic access cavity restoration in the tooth.

Cold Pulp Sensibility Tests

There are several methods for performing cold pulp sensibility tests. These include the use of dry ice sticks (carbon dioxide, CO_2) (Figure 8-20), refrigerant sprays (Figure 8-21) and ice. The principle of using these tests is to apply the cold stimulus to the enamel of the tooth or on the restoration so the temperature of the tooth is reduced. The nerve fibres within the pulp will feel this change in temperature if they are functioning normally or if they are inflamed. In the inflamed situation

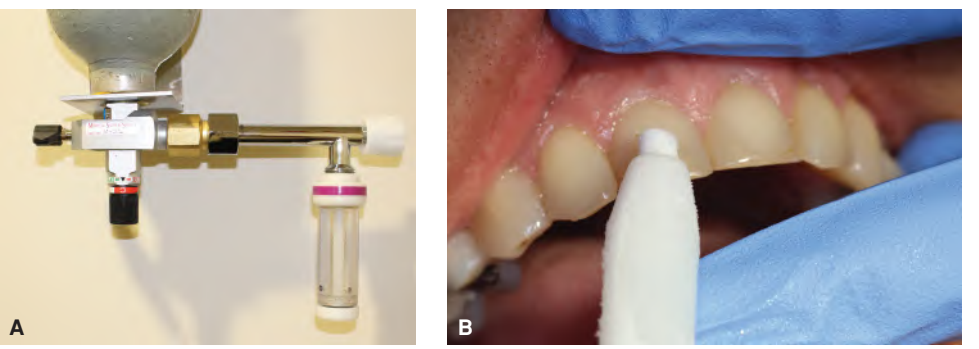

FIGURE 8-20 ***A.*** The Odontotest carbon dioxide pulp-testing device. ***B.*** The Odontotest being used to test the anterior teeth of a patient.

FIGURE 8-21 ***A.*** An example of a cold spray used for pulp testing. ***B.*** A cotton pellet held by tweezers and sprayed with the cold spray gas being used to pulp test a tooth.

(i.e., pulpitis), the sensation will be greater and typically reproduces the pain that the patient has been experiencing.

Chen and Abbott[35] have reported that dry ice sticks were the most reliable cold test to use in most diagnostic situations. It is also the cheapest and quickest method of testing the pulp's reaction to a cold stimulus. The dry ice is formed in a device known as the Odontotest (Fricar A.G., Zurich, Switzerland). This device uses pressurized liquid carbon dioxide that is forced through a small orifice. It becomes dry ice when it comes under atmospheric pressure. The device produces a "stick" of dry ice inside a thin plexiglass tube. A plunger is used to compress the dry ice and to extrude a small amount from the tube so it can be applied to the tooth surface. The temperature of the dry ice is approximately −78°C when it exits the cylinder with an effective temperature of about −56°C when applied to the teeth.[36] The dry ice stick is applied directly to the tooth surface or to a restoration if present. It will not stick to the tooth or restoration and will not damage them.

There are several manufacturers who produce refrigerant (cold) sprays. The original gas used was ethyl chloride which was largely replaced by dichlorodifluoromethane until environmental concerns arose. Now typically tetrafluoroethane or a mixture of gases (e.g., propane/butane/isobutane) is used. Tetrafluoroethane has a temperature of about −26°C when first sprayed from the pressurized can but this reduces to about −18.5°C in the mouth while the propane/butane/isobutane mixture temperature is approximately −50°C and reduces to about −28°C in the mouth.[36] These sprays are somewhat effective for pulp sensibility testing but not ideal or reliable since they also have the disadvantage of becoming liquid quite rapidly in the warm environment of the mouth. The liquid can then flow on to the gingivae or adjacent tooth where it may be felt and misinterpreted as being from the pulp of the tooth being tested. They are generally less effective than dry ice, especially when testing teeth with porcelain crowns. These cold gases must be sprayed on to a cotton pellet that is then applied to the tooth or restoration surface. As they are gases, they will evaporate as their temperature increases, especially in the mouth. Hence, the cotton pellet must be resprayed with the gas for every tooth, or at least every second tooth, in order to maintain a reasonably constant temperature. If the pellet is not cold enough, then false responses will be obtained and this will complicate the diagnosis.

Ice has been used by freezing water in local anaesthetic cartridges and then applying the extruded portion to the tooth. This is considered to be an ineffective and unreliable test, as well as being largely impractical to use in the mouth since the ice melts very quickly and the cold water may be felt by the gingivae or an adjacent tooth, and thus misinterpreted as being from the pulp of the tooth being tested.

Heat Pulp Sensibility Tests

Pulp sensibility testing with heat is not a particularly useful or common test.[37] This is largely because it is difficult to test teeth with hot devices and there is a high risk of burning the tooth surface or the patient's lip, cheek, or tongue. Hence, there is a degree of danger associated with them. Fortunately, most patients that have sensitivity associated with hot stimuli also have pain associated with cold stimuli and therefore a cold test can be more easily performed. Heat tests are only useful if sensitivity to hot stimuli is the only symptom reported by the patient. In such a case, a cold test is usually still useful and may provide the required information anyway. In addition, teeth with clinically normal pulps do not respond to heat—they only respond to heat when they are inflamed. Hence, the heat test cannot be used to differentiate a normal pulp from a necrotic pulp or a tooth with a pulpless and infected root canal system.

Various methods have been proposed for heat testing—these include the use of a heated ball burnisher, a rotating rubber polishing cup, a heated gutta-percha stick, an electronic device (e.g., System B; Sybron Endo, Orange, CA, USA), or the application of hot water.[37] However, none of these methods are ideal and some can be dangerous.

If a heated ball burnisher is used, it needs to be heated over a Bunsen burner flame until the metal is glowing "red hot." The instrument is then held about 1–2 mm away from the labial or buccal surface of the tooth so the heat can radiate from the instrument to the tooth (Figure 8-22). It is important to avoid touching the tooth surface as the hot instrument will burn the enamel and leave a black spot. The amount of heat that effectively reaches the pulp is unpredictable and therefore this test must be used and interpreted with caution. The lips and cheeks must be carefully protected to avoid burning them.

If a rubber polishing cup is rotated as fast as possible in a low speed handpiece while in contact with the tooth surface, heat will be generated by friction. However, the amount of heat is unpredictable and may vary from one tooth to another. The vibration produced by this method may be misinterpreted by the patient as pain, especially if there is any apical periodontitis present. Hence, this method is not recommended.

Gutta-percha sticks can be heated over a Bunsen burner flame until they are almost molten at which stage they can

FIGURE 8-22 A ball heated burnisher being used to test a tooth with heat. Note that the instrument must not touch the tooth. It should be held 1–2 mm away from the tooth so the heat can radiate onto the tooth.

be applied to the tooth surface. However, this method is also unreliable as the temperature varies and the gutta percha cools rapidly. It is a dangerous method as the gutta-percha may drip on to the patient's lip and cause a burn. The tooth surface should be coated with a lubricant (e.g., Vaseline) to prevent the gutta-percha from sticking to it.

Electronic devices such as the System B (Sybron Endo, Orange, CA, USA) have been advocated by some clinicians. Special tips are required and the temperature can be set so it is consistent. A temperature of 65°C is recommended as this is similar to warm water that is tolerable in the mouth. This type of device is relatively safe as the surrounding tissues are unlikely to be affected.

Bathing the tooth with hot water can be a useful test at times, particularly when all other tests have not led to a conclusive diagnosis and the patient has been experiencing pain with hot stimuli. In order to do this test, the clinician needs to isolate one tooth at a time with rubber dam. Heavy body rubber dam is recommended as the thicker sheet of rubber insulates the adjacent teeth and soft tissues more effectively. The rubber dam needs to be applied carefully so the tooth is completely sealed from the mouth by the rubber dam. Water should be heated in a kettle so it is quite hot—but not boiling. It is then loaded into a syringe so it can be syringed onto the tooth to bathe it. If the tooth has pulpitis, it will usually react with pain quite quickly so the dental assistant should be ready to evacuate the hot water as soon as the patient feels the pain. Ideally one or two teeth that are expected to have normal pulps should be tested first with the suspect tooth being tested last so the patient does not become overly apprehensive. The first tooth to be tested should be the most distal tooth in the region. This procedure is a slow process since the rubber dam must be applied to one tooth at a time and then removed before being applied to the next tooth. Hence, this test is not often perfumed but it can be useful in some cases.

Electric Pulp Sensibility Tests

The first reported use of an electric pulp test dates back to 1921 when Raper[38] outlined 22 circumstances for using an electric pulp test. The majority of these reasons are still valid today. The concept of an electric pulp test is to apply a low level electric current to the tooth to assess whether the patient can feel a "tingling sensation" in the tooth. The assumption is that if the patient feels this sensation, then the pulp has viable nerve fibres although many dentists have erroneously interpreted this as meaning the pulp is "vital" (see earlier). Electric pulp tests are sensibility tests that demonstrate the pulp's ability to respond to an electric stimulus.

There are various electric pulp testers (EPTs) available. Some of these are "benchtop" devices (Figure 8-23) while some are hand held devices. They are usually battery-powered and require an electric circuit to be completed. The circuit usually includes the pulp testing device itself, the tooth, the patient and sometimes the operator all making contact to provide a complete circuit for current flow. Several methods have been proposed, depending on the device being used (Figure 8-24). Most devices have a metal

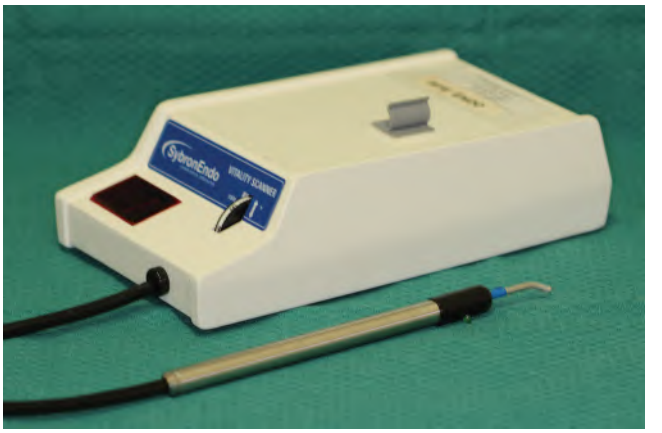

FIGURE 8-23 A "benchtop" style of electric pulp tester.

component to the probe which can be held or touched by the patient or the operator. If the patient touches the metal component, then this provides the electric circuit. If the operator holds the device, then the operator needs to remove the glove from one hand and touch the patient's skin, such as on the face, to complete the circuit. Alternatively, some devices have a metal "lip clip" which can be placed over the patient's lip and is attached to the probe. The method chosen by the operator depends on their personal preference but the operator using an un-gloved hand to touch the patient's face and hold the device is the simplest as it does not require the patient's involvement that can be cumbersome.

Some EPTs automatically increase the amount of electric current being applied to the tooth once the circuit is complete while other devices require the operator to manually increase the current—typically by turning a dial on the device. The latter is more difficult and somewhat cumbersome to use compared to the automatic devices. The automatic devices usually have a digital display to indicate the level of current being applied whereas the manual devices may have a numbers on the dial or there may be a digital display.

Most EPTs provide a scale of responses. The scale varies between the various devices that are commercially available. Some have a scale ranging from 0 to 80, while others are from 0 to 4 or 0 to 5. The scales used are not indicative of any particular amount of electric current being applied apart from indicating an increase from the lowest to the highest level.

The level at which a response is felt by the patient (or in other words, the amount of current applied to the tooth) is not critical and cannot be used to assess the health or state of the pulp tissue. That is, a tooth with pulpitis does not necessarily respond at a lower level of current than a tooth with a clinically normal pulp. Electric pulp tests do not induce pain and therefore they cannot be used to reproduce the symptoms reported by a patient. Hence, the results of electric pulp tests should only be considered as either "a response" or "no response"—in the same manner as thermal pulp tests.

Other Pulp Tests

Other pulp tests are available—such as the laser Doppler flowmeter[35] or pulse oximetry.[39,40] Both of these are truly "vitality" tests as they do test for the presence of blood within

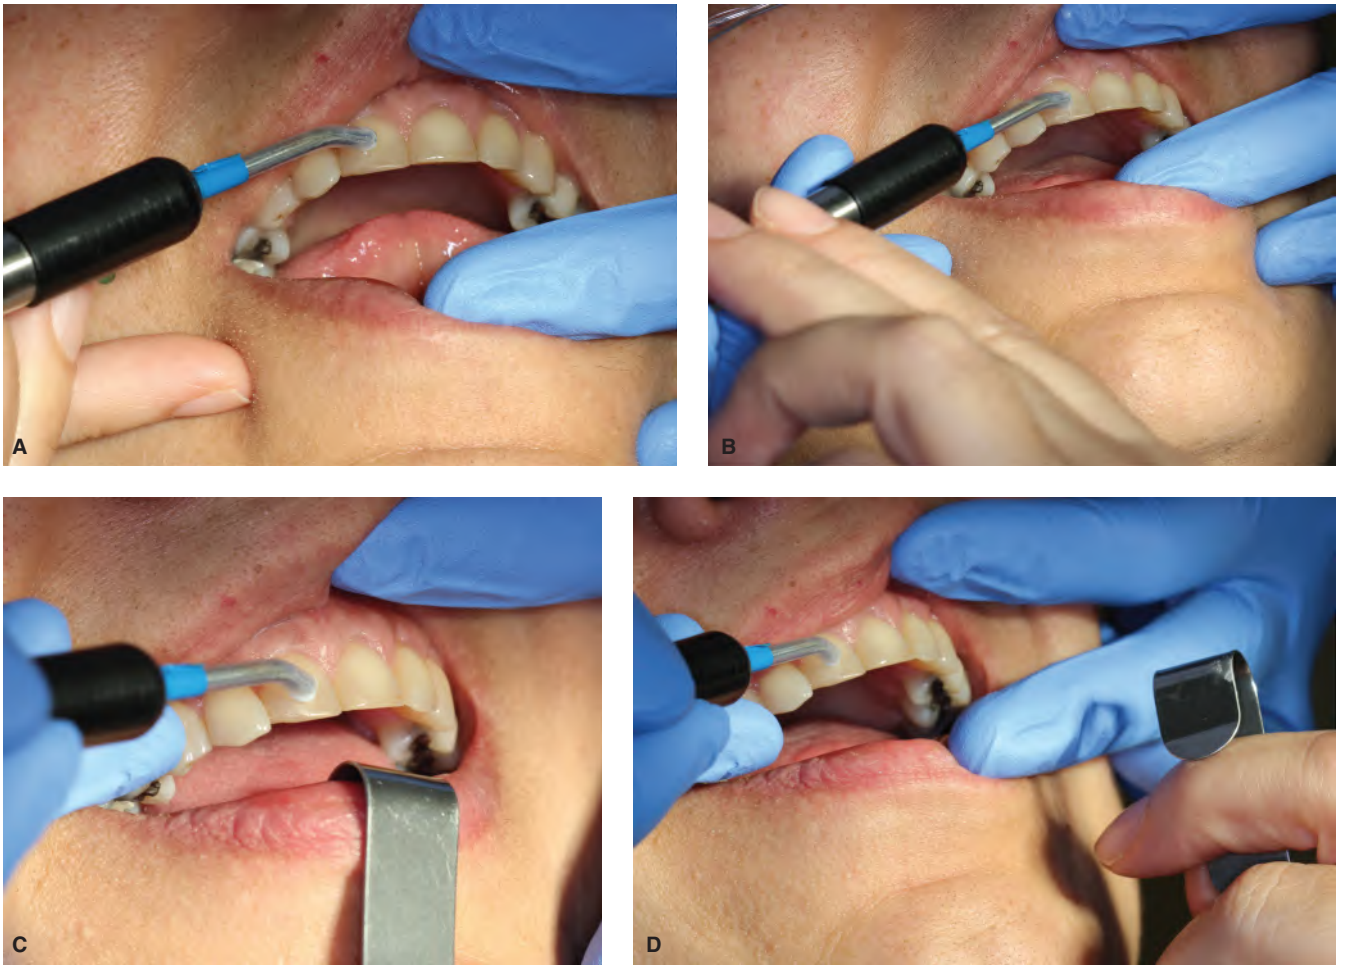

FIGURE 8-24 The electric pulp tester being used on a patient; four different methods for completing the circuit. ***A.*** The operator using one finger to touch the patient's face. ***B.*** The patient touching the metal handle of the pulp tester probe. ***C.*** The lip clip placed over the patient's lip. ***D.*** The patient holding the lip clip in her hand.

the pulp. Specifically, they test blood flow. However, studies have not been conclusive with respect to their usefulness in day-to-day clinical practice although they are useful tools for research purposes.

Laser Doppler flowmeters are expensive to purchase and very time consuming to use. They require the construction of a stent using a rubber-based impression material or acrylic in order to block out the effects of blood flow in the surrounding tissues (e.g., gingiva, adjacent tooth) as well as to provide a stable method for applying the probe to the tooth. Pulse oximetry tests the tissues for oxygen saturation.[39,40] When testing pulps with this method, the assumption is that higher oxygen saturation implies more blood flow. However, this method still has some clinical limitations such as lack of specifically designed proves and inaccurate reading in the presence of restorations.

Which Pulp Sensibility Test Is Best?

Many studies have been conducted to compare the various pulp sensibility and vitality tests under different circumstances. However, it is difficult to compare the results as different methods and statistical analyses have been used. The following is a brief summary of the most relevant and useful findings. They mainly concern pulp sensibility tests, as vitality tests are not clinically useful at present (as discussed earlier).

Chen and Abbott[35] compared CO_2, electric, cold spray (EndoFrost), ice tests and laser Doppler flowmetry. They reported that pulp sensibility testing of teeth with clinically normal pulps can be reliably performed with CO_2, electric and the cold spray tests. However, when testing teeth with diseased pulps, the CO_2 test was the most likely test to identify pulp disease and this was particularly the case when the teeth had restorations. Teeth with nonmetallic restorations were more difficult to pulp test accurately, especially when the pulp was diseased. Although the electric pulp test was accurate when there was no disease, it was not reliable when pulp disease was present. The cold spray was less reliable and less accurate than CO_2 and electric pulp tests. Ice was of little value and unreliable, as well as difficult to use. Laser Doppler flowmetry was suitable for unrestored teeth but less reliable than CO_2 and electric tests, as well as being difficult to use in restored teeth, expensive, and time consuming.

Clinically normal teeth were tested in a study by Fuss et al.[42] They reported that CO_2 and electric tests were the most reliable. Ice and ethyl chloride spray were unreliable.

When they tested immature teeth, electric pulp tests were less reliable than in fully developed teeth while the reliability of CO_2 was similar in both groups. The CO_2 test also had a greater rate of temperature decrease than ice and ethyl chloride that probably contributed to its reliability.

Peters et al.[43] used CO_2 and electric pulp tests on 1488 diseased and clinically normal pulps in 60 adults. They reported that no response to both tests (and with no history of trauma to the tooth) almost certainly indicated a diseased pulp. When there was no response to CO_2 but there was a response to the electric test, then pulp disease was possible but further clinical and radiographic investigations were required in order to make a diagnosis. If the tooth responded to CO_2 but not the electric test, then the electric test was more likely to be a false response.

Ethyl chloride, hot gutta-percha and an electric pulp test were compared in a study of 75 teeth with either clinically normal or diseased pulps.[44] Ethyl chloride was more sensitive and slightly more accurate than the electric test but their specificity and positive predictive value were the same. The heat test was the least accurate and the least specific plus it had the lowest positive and negative predictive values. Hence, heat is not a very useful test in most cases.

Jones et al.[45] compared CO_2 and a cold spray (Endo-Ice). There was no difference in producing a pulp response with these two tests but two teeth had a false-positive response. These two teeth had metal crowns and the false responses were with the cold spray—this may have been a result of gingival stimulation as the cold spray became liquid and flowed over the surface of the crown. They also reported that CO_2 was cheaper in the long term and this is consistent with the findings of Chen and Abbott.[35]

Many dentists have the perception that teeth with crowns cannot be pulp tested. However, this is not entirely true. Electric pulp tests cannot be performed when crowns are present unless there is some exposed tooth structure on which the probe can be placed. However, cold pulp tests can be used on all types of crowns, as shown by Miller et al.[46] They tested the conductivity of CO_2, a cold spray (Endo-Ice) and ice through extracted teeth with full gold crowns, porcelain-fused-to-metal (PFM) crowns, all-ceramic crowns and controls with no restorations by measuring temperature change at the pulp-dentin junction. All crown types had similar temperature reduction compared to that of intact teeth without crowns. Ice was the least effective and the temperature change associated with CO_2 lasted the longest. This study showed that PFM and ceramic crowns do not "insulate" the pulps. Hence, teeth with porcelain restorations can be effectively pulp tested with cold tests.

Weislader et al.[47] used CO_2, a cold spray (Endo-Ice) and an electric test on 150 teeth and compared their findings to the status of the pulp (bleeding or no bleeding) on gaining access to the pulp chamber. Of the teeth that responded to all three tests, 97% had bleeding on access. Of the teeth that did not respond to all three tests, 90% had no bleeding. Varying responses (i.e., responded to one or two but not all three tests) occurred in 25% of the teeth; of these, 54% had bleeding and 46 % had no bleeding. Overall, there was bleeding in 83% of the teeth that responded only to the electric pulp test, compared to 97% of teeth that responded to both a cold and electric test. These authors concluded that combinations of cold and electric pulp tests provided a more accurate assessment of the pulp condition.

Pulp testing in children is often not performed, as many practitioners believe the children cannot be relied upon to provide reliable responses, or the tests may affect their behaviour in the dental surgery. However, there is no conclusive evidence to support this belief and studies such as the one by Hori et al.[48] have demonstrated that electric, cold and heat tests can be reliably used in primary teeth. They tested teeth in children aged 6–8 years old and compared their findings to the state of the pulp on gaining access to the pulp chamber. They did not report any difficulties or behavioural issues with the children. Many practitioners regularly use pulp sensibility tests in children following trauma and there are no reports of problems with performing these tests. Hence, the age of the patient may not a barrier to the use of pulp sensibility tests.

Which Pulp Sensibility Test Should be Used and When?

There is not one single pulp test that can be recommended as a universal test. Different tests need to be applied to different clinical scenarios, based on the reason why the test is required (i.e., the provisional diagnosis obtained from the history) and the state of the tooth.

Pulp testing is performed for two main reasons—first to identify diseased pulps when a patient presents with pain or a potential pulp problem, and second, to assess the pulp status when performing a general dental examination which may be prior to restoration of the tooth, following trauma to the teeth, prior to orthodontic treatment, etc. The results of the studies discussed earlier have been combined to form recommendations (Table 8-4) for the typical clinical situations where pulp testing is required.

Practitioners should have BOTH a cold pulp test system and an EPT as the abovementioned studies have shown the value of having more than one test system. Of the various cold tests available, the CO_2 pulp tester has been shown to be more reliable, easier to use, faster, and cheaper than the cold sprays and ice.

Percussion

The percussion test is a simple means of assessing whether there is inflammation or other changes occurring in the periradicular tissues. It is an indirect test in that the periradicular tissues themselves are not directly contacted by the test. Instead, the tooth has a force applied to it via percussion and this force is transmitted through the tooth to the surrounding tissues. Percussion testing does not specifically indicate periapical changes in all cases as inflammation or changes anywhere along the entire length of the tooth root can produce different responses to the percussion test.

The simplest instrument to use for the percussion test is the handle of the dental mirror (Figure 8-25). The tooth does not need to be struck with great force—just a light tapping on the tooth is sufficient to determine whether there are

TABLE 8-4 Recommendations for the Use of Pulp Sensibility Tests in Different Clinical Situations. These Pulp Tests Should Be Performed and Interpreted in Conjunction with all Other Clinical Findings and Periapical Radiographs

Clinical Scenario	Recommended Pulp Test(s)	Reason(s) for Recommendation(s)	Comments
Routine clinical examination	Use both **CO_2** and **EPT**	• Two tests more reliable than a single test. • CO_2 and EPT are reliable for assessing clinically normal pulps.	• All teeth should be pulp tested at initial examination and regularly thereafter. • If no reason to suspect pulp disease (e.g., unrestored tooth with no caries and no history of trauma), then can use one test only—CO_2 is the easiest to perform.
Prerestoration assessment	Use both **CO_2** and **EPT**	• Two tests more reliable than a single test. • CO_2 and EPT are reliable for assessing clinically normal pulps but CO_2 is the best for diseased pulps.	• All teeth should be pulp tested prior to a new restoration being done in order to identify any pulp disease if present. • If only one test to be used—then use CO_2 as it is the most reliable (i.e., in case pulp disease is present).
Trauma follow-up	Use both **CO_2** and **EPT**	• Two tests more reliable than a single test	• Traumatized teeth will require regular follow-up. Some teeth may respond to one test but not the other.
Pulpitis (all forms of pulpitis—i.e., acute and chronic reversible pulpitis; acute and chronic irreversible pulpitis)	**CO_2**	• The most reliable test, plus • It reproduces the presenting symptom • Response can be assessed to confirm the diagnosis (e.g., severity, lingering, etc.) and to distinguish between reversible and irreversible pulpitis	• EPT has little value when testing for pulpitis as they do not differentiate between an inflamed pulp or a clinically normal pulp. • Heat tests are not reliable but can be used if the patient complains of heat sensitivity—especially if that is the only symptom.
Necrotic Pulp (with or without signs of infection)	Use both **CO_2** and **EPT**	• CO_2 is the most reliable test	• Use EPT also to confirm the CO_2 findings.
Pulpless, infected root canal system	Use both **CO_2** and **EPT**	• CO_2 is the most reliable test	• Use EPT also to confirm the CO_2 findings.
Pulp canal Calcification (PCC)	**EPT**	• EPT is the most reliable for PCC. • CO_2 and other cold tests are not reliable with PCC	• Calcification reduces conductivity of temperature changes throughout the tooth. • EPT results must be interpreted carefully as some teeth with PCC will not respond even though there is no pulp disease present. • Periapical radiographs are essential.
Crowns/Bridges	**CO_2**	• CO_2 is the most reliable test. • Temperature change lasts longer with CO_2 than cold sprays used on crowns	• Coldness is readily conducted through crowns. • Interpret carefully with bridges as difficult to know which tooth is responding (due to conduction of temperature through the bridge).
Concurrent endodontic and periodontal diseases	Use both **CO_2** and **EPT**	• Two tests more reliable than a single test.	
During orthodontic treatment	**CO_2**		• The arch wires will conduct electric current to other teeth—hence, EPT unreliable.
Children (for both primary and permanent teeth)	Use both **CO_2** and **EPT**	• Two tests more reliable than a single test.	

Note: CO_2 = carbon dioxide/dry ice pulp test; EPT = electric pulp test.

tissue changes. The greater the force used, the more likely it is that the patient will interpret the test as being painful, in which case the test results may not be meaningful.

The percussion test is performed by tapping on the crown of the tooth—usually on the incisal edge of anterior teeth and the occlusal surface of posterior teeth (Figure 8-25). Teeth can also be percussed from other directions (i.e., on other surfaces) that can be helpful in some cases of tooth fracture or periodontal disease. If the patient's history is suggestive of a crack undermining a cusp of a posterior tooth, then percussion of individual cusps from different directions may help to identify the problem cusp, although it should be noted that the lack of tenderness when doing this does not mean that there is no crack.

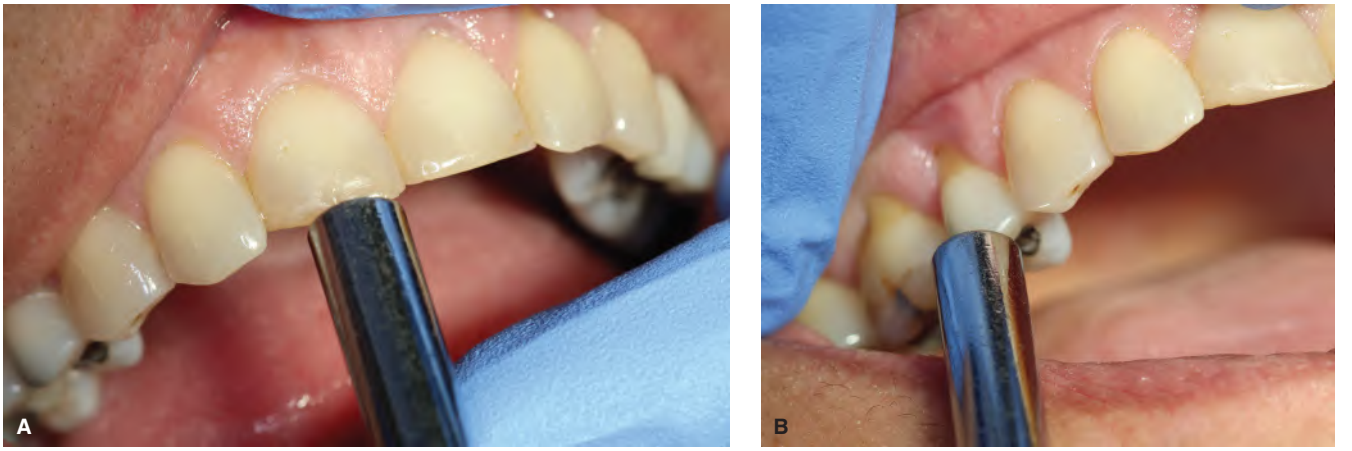

FIGURE 8-25 Performing a percussion test with the handle of a mirror. ***A.*** Percussing the incisal edge of an anterior tooth. ***B.*** Percussing the buccal cusp of a premolar tooth. All cusps of the teeth being examined should be tested in this manner.

As with all clinical tests for teeth, the tooth suspected as having apical periodontitis should not be the first tooth that is percussed. Other teeth in the same quadrant should be percussed first so the patient is aware of the nature of the test, and what is a normal response for their teeth, before the painful tooth is assessed. The clinician can also gauge how each individual patient reacts to the percussion test on normal teeth and compare this to the suspect tooth.

The results of percussion tests should be graded and noted as one of the following:

- **"Normal"**—the same feeling as that patient's other teeth, and with no tenderness or pain; this typically indicates clinically normal periradicular tissues (as long as there are no other signs or symptoms to suggest otherwise).
- **"Tender"**—a painful response when percussing the tooth; this typically indicates secondary acute apical periodontitis or a secondary acute apical abscess.
- **"Very tender"**—very painful response on percussion of the tooth; this typically indicates primary acute apical periodontitis or a primary acute apical abscess.
- **"Different sensation"**—the patient reports that the tooth feels "different" on percussion compared to how the adjacent teeth felt—it is not painful or tender; this typically indicates chronic apical periodontitis or a chronic apical abscess.
- **"Ankylosis sound"**—there is no pain but percussion produces a dull sound that is different from that produced when percussing the adjacent teeth—there is usually decreased mobility of the tooth also; this indicates the tooth has ankylosis and it may also have external replacement resorption (or possibly another form of resorption). A detailed history should help to determine why there is ankylosis.

All of these are "positive" responses. It is impossible to have a negative response to percussion. Hence, the test results for percussion should not be called "positive" or "negative." Instead, the earlier descriptors should be used when recording the results of a percussion test.

Palpation

Palpation of the soft and hard tissues overlying the tooth can provide information regarding the periradicular status of the tooth. In the normal, healthy situation, palpation does not cause any discomfort. However, if there is inflammation present, then palpation may produce discomfort or even pain. Pain is more likely when there is swelling of the mucosa overlying the tooth root.

Palpation is performed by gently feeling and pushing the mucosa overlying the teeth (Figure 8-26). It should be performed on both the labial/buccal and lingual/palatal aspects of the tooth. It should be performed over the periapical region as well as along the entire length of the tooth root (Figure 8-26). In most cases with apical periodontitis or an apical abscess, the labial/buccal aspect will have tenderness but this is not always the case and is dependent on the degree of inflammation and its spread toward the labial/buccal or lingual/palatal aspects. In addition to assessing whether palpation causes discomfort, the clinician should assess whether the region feels normal with respect to shape and size of any abnormality plus whether the region feels hard, soft, or fluctuant. The teeth and their surrounding tissues on the contralateral side of the mouth should also be visually examined and palpated as this can help to determine whether an unusual finding with palpation is a normal anatomical variation or not.

The absence of any discomfort during palpation does not necessarily mean that there is no disease present or that the tissues are healthy, for example, teeth with chronic apical periodontitis usually have no tenderness to palpation. Conversely, the presence of discomfort does not necessarily mean that a disease is present, for example, palpation over an anatomic structure such as the mental foramen may be uncomfortable for some patients.

The results of palpation tests should be graded and noted as one or more of the following:

- **"Normal"**—the same as the other teeth for that patient, with no tenderness or pain; this typically indicates clinically normal periradicular tissues (as long as there are no other signs or symptoms to suggest otherwise).

- **"Tender"**—painful response when palpating the mucosa overlying the tooth root and/or the periapical region; this typically indicates secondary acute apical periodontitis or a secondary acute apical abscess.
- **"Very tender"**—very painful response when palpating the mucosa overlying the tooth root and/or the periapical region; this typically indicates primary acute apical periodontitis or a primary acute apical abscess.
- **"Hard swelling or expansion"**—the tissues overlying the root and/or periapical region appear to be swollen or the cortical plate has expanded; the region feels hard on palpation.
- **"Soft swelling"**—the tissues overlying the root and/or periapical region are swollen; the region feels soft on palpation.
- **"Soft fluctuant swelling"**—the tissues overlying the root and/or periapical region are swollen and fluctuant; the region feels soft on palpation as though the swelling contains fluid.

Periodontal Probing

Periodontal probing is an essential part of the diagnostic process for pulp, root canal, and periradicular diseases. However, it is often not performed by clinicians especially if they do not think that the patient has generalized periodontal disease. However, the lack of periodontal probing may mean that an important piece of information is missed and this may in turn lead to misdiagnosis of the presenting complaint.

Periodontal probing is performed for two main reasons—first to assess the overall periodontal status of the dentition and in particular the individual tooth with the problem. The second reason is to check for the presence of a deep, narrow pocket that could be associated with an infected root canal system, a draining sinus, concurrent endodontic and periodontal diseases, or a crack in the tooth roots.

Since one of the main aims is to locate deep, narrow periodontal pockets, it is important to use a narrow periodontal probe. The ideal instrument for this is the WHO periodontal probe with a small ball-end (Figure 8-27). Such an instrument should be included in every examination kit.

When examining a tooth that is suspected as having pulp, root canal, or periradicular pathosis, that particular tooth plus several adjacent teeth should be periodontally probed as a minimum. Ideally the contralateral teeth should also be assessed as this will help to assess the overall periodontal

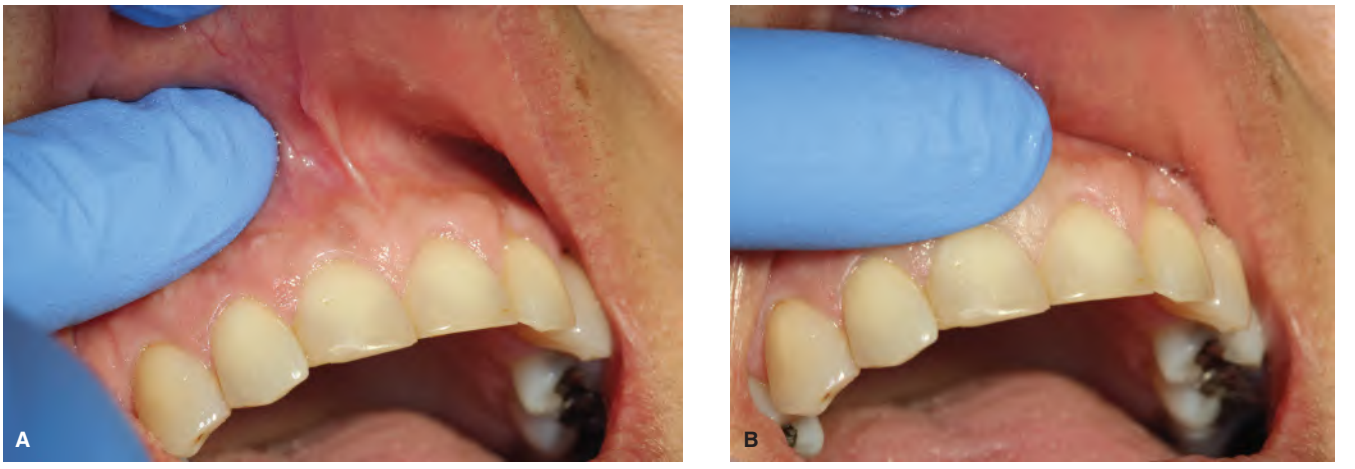

FIGURE 8-26 ***A.*** Palpating the periapical region of a tooth. ***B.*** Palpating the coronal third of the tooth root.

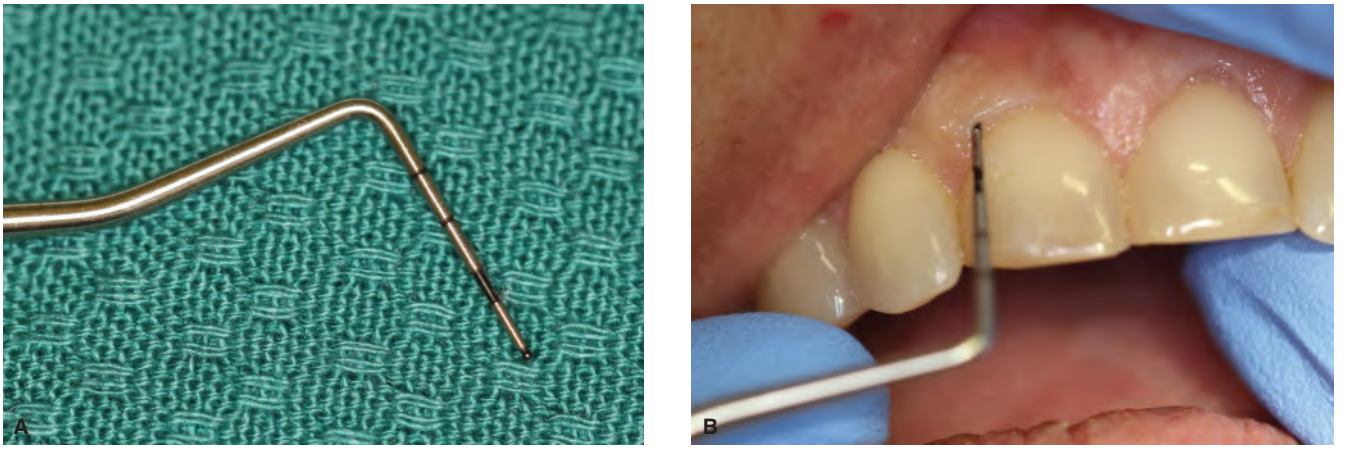

FIGURE 8-27 ***A.*** A WHO periodontal probe. ***B.*** Periodontal probing around a tooth; this should be performed in a step-wise manner around the entire circumference of the tooth.

status for that patient. Each tooth should be probed in a continuous, stepwise manner around the entire circumference of the tooth and not just at the typical six points (MB, B, DB, DLi, Li, and MLi) where pocket depths are recorded. If only these six points are probed, then a deep, narrow pocket situated between these points may be missed (Figure 8-27).

Care must be taken to probe the proximal surfaces (mesial, distal) of the teeth as these are the most common locations for deep, narrow pockets associated with cracks in teeth—since many cracks run in the mesiodistal direction. However, the proximal surfaces are particularly difficult to probe for deep, narrow pockets because of the presence of the adjacent teeth. This process can be further complicated by the presence of old restorations that may not be ideally contoured. Even in an ideal situation, the deep, narrow pockets associated with mesial or distal cracks are often in the centre of the proximal surface and it is usually impossible to angle a periodontal probe into such pockets when approaching from the buccal and lingual directions.

As a result of the difficulties associated with periodontal probing during a routine examination, teeth undergoing root canal treatment should have further periodontal probing done during the investigation phase of the treatment (see subsequently). In summary, investigation means removal of all restorations, caries and cracks from teeth. This is typically done under local anaesthesia and rubber dam isolation using a "cuff technique." Once the proximal aspects of the restorations have been removed, an ideal opportunity exists for re-evaluation of the proximal periodontal condition as the proximal surfaces can be directly probed without hindrance and also without causing discomfort for the patient as local anaesthetic has been administered.

The furcation of multirooted teeth should also be carefully probed from all directions since pocketing in these regions is sometimes a result of an infected root canal system where there are accessory canals running from the floor of the pulp chamber to the furcation region. Such teeth need to be distinguished from teeth with periodontal disease causing bone loss in the furcation.

The results of periodontal probing should be recorded to indicate that such probing was done and to provide information that can be compared with the findings of subsequent examinations after initial treatment, postoperatively, and when reviewing the treatment outcome.

The probing depths at the six points (MB, B, DB, DLi, Li, and MLi) assessed for periodontal disease should be recorded and a note made to indicate that no other pockets were found. Alternatively, if one or more pockets are found, then the exact location(s), the depth(s) and the nature of the pocket (narrow, broad) should be recorded in the patient's clinical record.

Mobility

The mobility of teeth should be assessed for two main reasons—first, it can provide information about the periodontal status of the tooth, and second, it indicates whether there has been bone loss which might be a result of an infected root canal system and involvement of the periradicular tissues. This information is required when assessing the prognosis of the tooth as well as when diagnosing the presenting condition.

Horizontal/lateral mobility implies movement in the buccolingual or mesiodistal direction. This can be assessed by using the handles of two instruments with one instrument on the labial/buccal surface and the other on the lingual/palatal surface (Figure 8-28); then push against the tooth with one instrument at a time. Movement can be detected by the instrument on the opposite side of the tooth. Repeat from the opposite direction and then do this several times to gauge how far the tooth moves in each direction.

Vertical mobility should also be tested and this is easily achieved by pushing the tooth from the occlusal or incisal direction using the end of the mirror handle. The depth of intrusion and subsequent extrusion of the tooth should be noted.

The Miller Index[49] is the most common system used to grade tooth mobility. There are various descriptions of this Index in the literature but the most common[50] is

- **Grade 0:** Normal (or physiological) mobility for the particular patient and when compared to that patient's other teeth.
- **Grade I:** Increased horizontal/lateral movement up to 1 mm.
- **Grade II:** Increased horizontal/lateral movement exceeding 1 mm.
- **Grade III:** Severe horizontal and vertical (depression) movement and/or rotation of the tooth.

Radiographs

Radiographic techniques and interpretation of the images will not be discussed in detail in this chapter. For more details, see Chapters 9 and 10. However, the following should be noted.

Radiography is an essential adjunct to, and should be an integral part of, every clinical examination when attempting

FIGURE 8-28 Testing the mobility of a tooth by concurrently using the handles of two instruments.

to assess the pulp, the root canal system and the periradicular tissues. Radiographs provide a wealth of information ranging from the causes of the various conditions, the anatomy of the involved tooth and its root canals, the periodontal status and the general state of the dentition in that region of the mouth (Figures 8-3 to 8-15, and 8-18). Radiographs are also essential when interpreting pulp sensibility test results since the lack of a response may be indicative of a tooth without a viable pulp (Figures 8-3 to 8-5, 8-8, 8-14, and 8-18), a tooth with PCC (Figure 8-8), a tooth with a root canal filling (Figures 8-6, 8-7, and 8-10 to 8-15) or a tooth that has had a pulpotomy performed in the past (Figure 8-12). These can only be determined by viewing a periapical radiograph of the tooth.

The most useful radiographic image for the diagnosis of pulp, root canal, and periradicular conditions is the periapical radiograph. Ideally, this should be taken using the modified parallel technique or the parallel technique (Figures 8-3 to 8-15, and 8-18). The former provides a more accurate image of the tooth since it reduces the inherent magnification (average 10%) associated with the parallel technique. The modified parallel technique involves using an increased vertical angle of approximately 15°, that is, the X-ray machine collimator is angled from a more apical direction by 15°.

Horizontal tube shift periapical radiographs are also useful at times to assess teeth with endodontic problems. The horizontal shift can be either from the mesial or distal direction, depending on which tooth is being assessed and what the possible problem is. A mesial shift is usually the best adjunct view for maxillary and mandibular central incisors and premolars, as well as for mandibular molars. Distal horizontal tube shifts are the most useful for maxillary and mandibular lateral incisors and canines, and for maxillary molars. Some teeth may even require both mesial and distal tube shifts; for example, maxillary molars, because of their typical anatomy with three divergent roots.

Bitewing radiographs are not sufficient on their own for the examination of teeth with pulp, root canal, and periradicular conditions since these radiographs do not show the entire tooth root and surrounding tissues. However, at times, bitewing radiographs are useful to assess whether a tooth has caries or open restoration margins, external invasive resorption, and bone loss due to periodontal disease. The angle from which bitewing radiographs are taken potentially provides a better view of the crown of the tooth and the most coronal part of the tooth root.

Panoramic radiographs do not provide sufficient "fine detail" for accurate assessment of pulp, root canal, and periradicular conditions. From an endodontic perspective, panoramic radiographs should only be considered as a screening method to provide an overview of the patient's oral and dental status. They may reveal areas of pathosis that were not evident prior to the radiograph being taken and they can also provide a better indication of the size of large lesions and their proximity to anatomical structures. A panoramic radiograph should be considered as a "screening radiograph" that can be used to direct the clinician to areas that require periapical radiographs for further assessment of the teeth.

Computed tomography (CT) scans can also be used as an adjunct to the assessment of teeth with pulp, root canal, and periradicular conditions. Such scans may be multislice CT or cone-beam CT (CBCT) scans. These provide a three-dimensional view of the teeth and surrounding tissues that may make them useful for some cases (e.g., where surgery is being considered). However, they are not required for the routine diagnosis of the vast majority of teeth with pulp, root canal, and periradicular conditions. Care also needs to be taken when assessing CBCT images as many teeth with clinically normal pulps may have widened PDL spaces or even periapical radiolucencies.[51] Such appearances may confuse the clinician and emphasizes the need for a thorough examination, and especially the use of pulp sensibility tests, before making a diagnosis.

Transillumination

Transillumination has been used as a diagnostic tool in medicine and dentistry for over 100 years. In 1916, Cameron[52] reported the use of the "Dentalamp," an instrument that he developed, to transilluminate teeth and surrounding structures to diagnose infection in the alveolar process and maxillary sinuses. He also advocated its use for the detection of subgingival calculus, caries in teeth (especially interproximal caries) and the extent of fillings in the crowns of teeth. Transillumination is also very useful during endodontic procedures, such as to help locate root canal orifices (especially where there has been calcification of the canals) and to observe the progress of root canal preparation. Transillumination is also an excellent and simple tool for assessing the progress and direction of a posthole preparation.

The concept of transillumination involves the use of an intense light source with concentrated white light rays projected as one beam of light. The intense light is deflected in different directions when the light rays reach tissues of different densities or of a different nature (e.g., fluid versus soft tissue, hard tissue versus soft tissue, etc.). Similarly, when a strong beam of light is shone through a tooth with a crack, the light will be deflected by the crack (Figure 8-29). This results in illumination of the ipsilateral side of the tooth only while the contralateral side remains dark. In addition, the crack becomes readily visible (Figure 8-30).

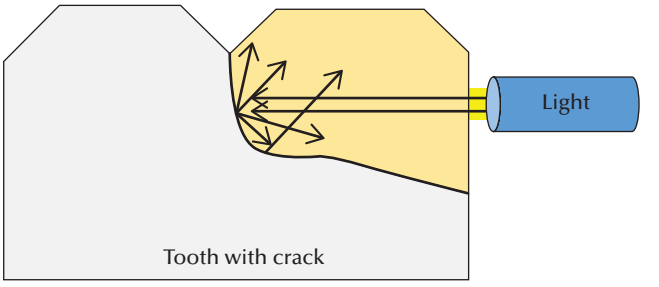

FIGURE 8-29 Diagrammatic representation of the effects of transillumination of a tooth with a crack. The light rays are deflected by the crack so the tooth structure on the other side of the tooth is not illuminated.

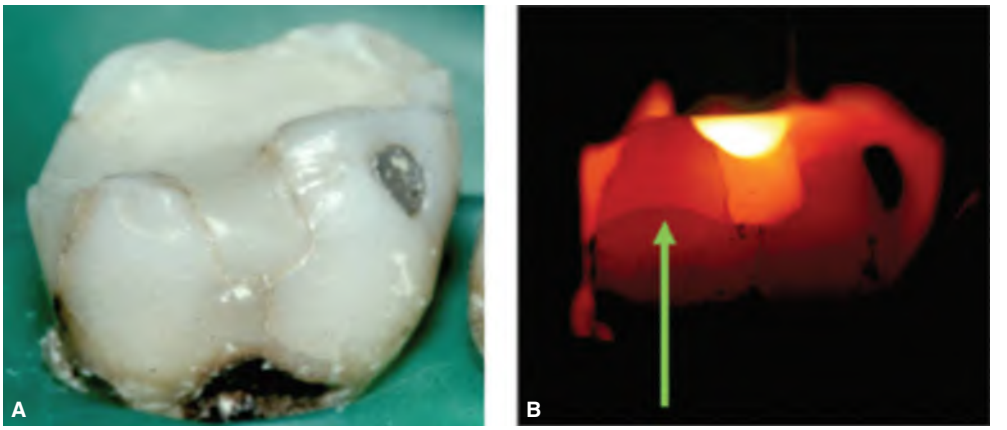

FIGURE 8-30 Transillumination. ***A.*** Visual examination under normal operating light. ***B.*** Examination of the same tooth using transillumination with a fibre-optic light source.

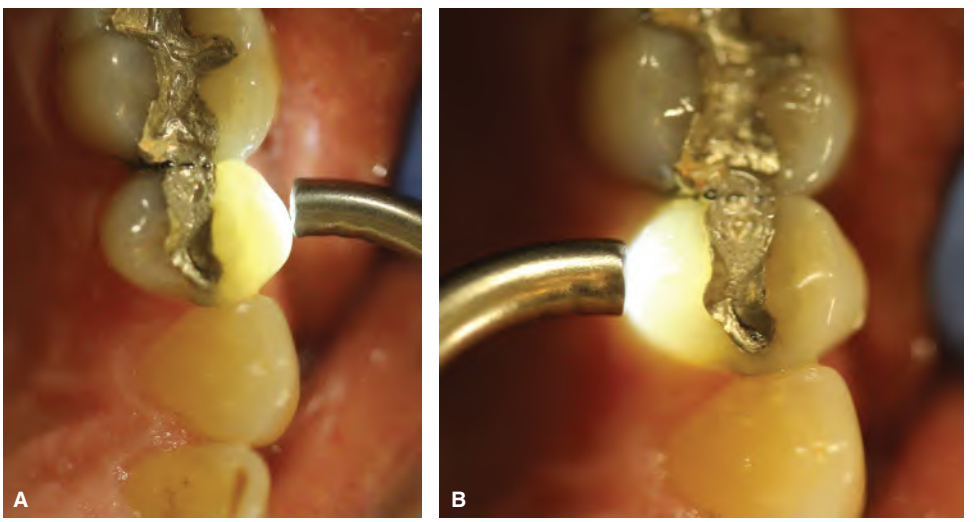

FIGURE 8-31 Transilluminating a maxillary first premolar tooth. ***A.*** Transilluminating from the buccal aspect. ***B.*** Transilluminating from the palatal aspect. The light should be moved around all surfaces and from different angles to fully assess the tooth for cracks in the enamel.

In the 1950s, the dental profession began to become aware of the effects of cracks in teeth.[53] Since then, many textbooks, especially older books,[54,55] and scientific articles[4,56–61] have advocated the use of transillumination to detect cracks. However, this technique has not been widely adopted or used regularly by most dentists despite being a very inexpensive, simple and reliable method for the detection of cracks, as well as for the other uses outlined earlier.

Several studies[62,63] have compared the use of transillumination to detect cracks in the apical third of teeth undergoing surgery or in an experimental model simulating the surgical treatment of root apices. Transillumination has been compared to other methods for detecting cracks such as the use of various dye solutions, magnification with microscopes and camera devices. Transillumination has consistently been reported to be the most reliable method with no added advantage from using a dye at the same time as transilluminating.

While these studies have assessed apical cracks, the results are consistent with a study by Jang[64] where cracks in enamel were assessed using transillumination, the normal dental operating light and a microscope. Transillumination revealed the highest number of cracks in the enamel of teeth. The normal operating light was better than the dental operating microscope which found the least number of cracks. The cracks found in these teeth using these methods were compared to the cracks seen on micro-CT scans of the same teeth. Transillumination had the highest sensitivity, the highest positive predictive value, the highest intra-observer reliability and the highest inter-observer reliability of the three techniques. Hence, transillumination is recommended as a routine examination procedure for all patients when assessing teeth for pulp, root canal, and periapical conditions as it can readily reveal cracks in teeth (Figure 8-31) and the cracks may be the pathway by which bacteria have entered the tooth to cause these conditions. Furthermore, transillumination should be performed when teeth are being investigated as the first stage of root canal treatment (see subsequently).

Several types of lights are commercially available. The most convenient light is the "diagnostic light probe" which is made by most companies that manufacture dental handpieces (Figure 8-32). These lights use the fiber-optic light systems within the dental unit or cart. A most convenient way to incorporate transillumination into everyday dental practice is to install an extra line/hose in the dental cart (Figure 8-32) so the light probe can be easily attached and used without having to remove a handpiece and swap with the light (especially when investigating teeth, as outlined subsequently). Other lights can also be purchased—some are battery operated (Figure 8-32) while others use the normal electrical power supply. The most ideal light has a small diameter tip (3.5–4 mm) as this concentrates the light on the tooth.

Biting Tests

The "biting test" can be a useful way to determine the tooth involved when a patient complains of pain associated with biting or chewing on a specific tooth. If the patient does not complain of such pain, then this test is not indicated. Percussion can also identify a tooth that is painful to biting or chewing but the biting test can sometimes identify a particular cusp that may be associated with the pain—such as when there is a crack undermining the cusp.

Pain associated with biting or chewing on a tooth can indicate several possible problems that vary in their management. Hence, it is important for the clinician to determine the nature of the pain caused by biting so the correct diagnosis can be established. In some cases, it can be difficult to distinguish between the different conditions that could cause pain to biting or chewing. The important criteria for each condition are:

- **Cusp flexure** (associated with a crack undermining the cusp)
  - ◊ The pain is usually sharp in nature and only momentary; it does not occur every time the patient bites on the tooth and typically only occurs when hard objects are bitten in a particular direction (with the direction of biting depending on the position and direction of the crack).
- **Apical periodontitis** (especially acute apical periodontitis)
  - ◊ The pain is not sharp although it can be severe (e.g., when primary acute apical periodontitis is present); the pain is present every time the patient bites or chews on the tooth.
- **Apical abscess** (especially an acute abscess)
  - ◊ The pain is not sharp although it can be severe (e.g., when a primary acute apical abscess is present); the pain is present every time the patient bites or chews on the tooth.
- **Lateral periodontitis** (associated with a crack, a fracture or a periodontal abscess).
  - ◊ The pain is not usually sharp but it can be sharp at times (e.g., when a root fracture is present); the pain is present every time the patient bites or chews on the tooth; the tooth will usually have a periodontal pocket and/or swelling on the lateral aspect of the tooth rather than apically; the tooth will have tenderness to palpation of the lateral aspect of the tooth rather than over the periapical region.

Many methods have been described for testing biting pain to identify a crack undermining a cusp but the most common, and generally considered to be the most useful, is the use of a specially-designed instrument such as the Tooth Slooth or the FracFinder (Figure 8-33). These instruments have a "pyramid-shape" on one side of the end of the instrument while the opposite side is flat (and may be serrated). The "pyramid" side has a concave tip which can be placed over one cusp at a time. The patient then bites on the flat or serrated surface with the opposing teeth (Figure 8-33). This allows the biting force to be placed on one cusp at a time in order to identify the cusp with the crack. The patient should be asked to bite down hard on the instrument and then to maintain pressure on it while the

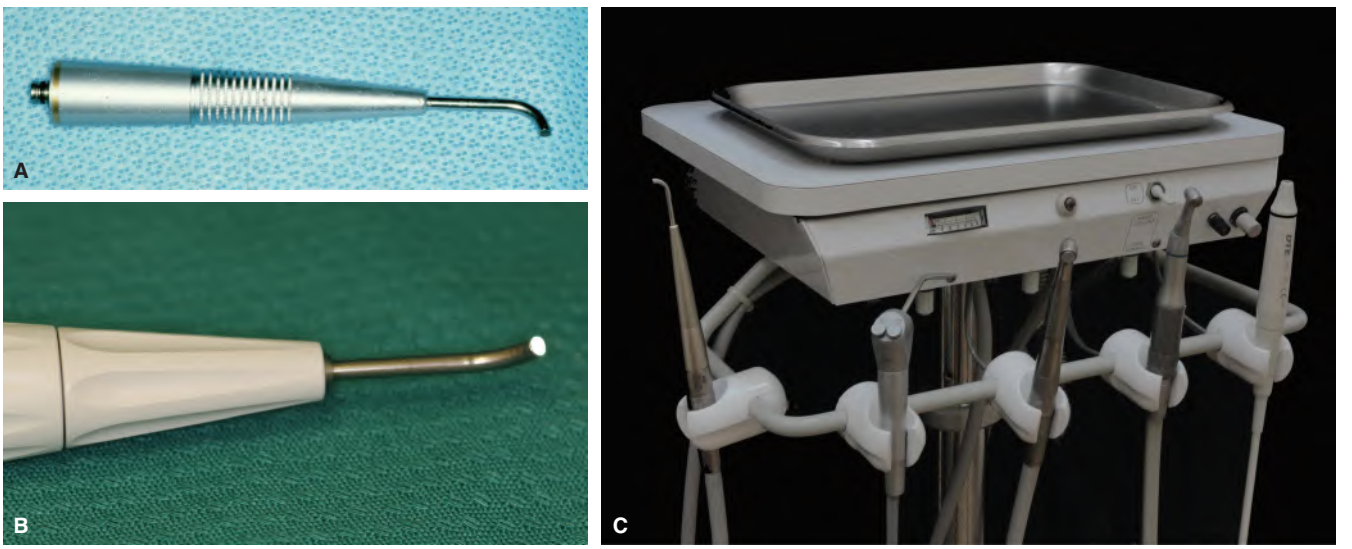

FIGURE 8-32 Examples of lights used to transilluminate teeth. ***A***. Light probe that attaches to the handpiece hose of a dental unit. ***B***. Battery-operated light. ***C***. A dental cart with an extra line/hose installed for the light probe.

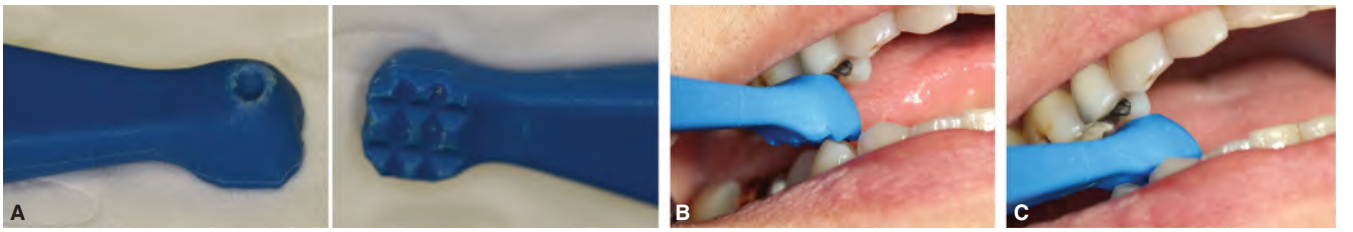

FIGURE 8-33 Performing a biting test with the FracFinder instrument. ***A.*** The left image shows "pyramid" side of the tip of the FracFinder instrument showing the concave depression that is placed over the cusp being tested; the right image shows the serrated surface on the opposite side of the tip onto which the patient bites with the opposing teeth. ***B.*** The FracFinder instrument being used on the buccal cusp. C. Testing the palatal cusp with the FracFinder instrument.

clinician manually moves it around in various directions to try and simulate the forces applied during chewing. The patient is then asked to stop biting on it by releasing the biting forces. Patients should be asked to identify whether they had any pain during the test procedure and, if so, when they felt the pain. The test is then repeated on each cusp (Figure 8-33) and on several teeth in the region of the patient's complaint. It can also be useful to repeat the test on any cusp(s) that gave an uncertain response or in order to confirm initial findings. The cusps of the teeth in the opposing arch should also be tested, as there may be referred pain.

In the past, much emphasis has been given to trying to identify teeth where the patient experiences pain on release of biting pressure with the belief that this was indicative of a crack undermining a cusp whereas pain on application of pressure did not indicate a crack. However, this concept is not supported by the literature as Abbott and Leow[65] reported that 68% of patients with cracks in teeth with reversible pulpitis had pain on application of pressure, 8% on release of pressure, 15% on both application and release of pressure and 9% did not have any pain on biting. Hence, pain on biting can occur any time and is not specific enough as a test on its own to indicate a crack in a tooth. It is just one of several symptoms that can occur and therefore the entire range of tests should be performed.

Biting pain associated with apical periodontitis and an apical abscess is easily reproduced and assessed by percussing on the tooth as this transmits the force of the percussion through the tooth to the PDL, and particularly the periapical PDL. Applying continuous pressure can also be useful at times and this is more indicative of pain associated with chewing rather than biting.

Biting pain associated with lateral periodontitis can be assessed through percussion in a vertical direction as well as from a lateral direction—such as from the labial/buccal or lingual/palatal. Palpation can also help locate the painful tissues. Lateral periodontitis is also likely to be associated with some increased mobility of the tooth.

Occlusal Analysis

The occlusion should be carefully checked to determine whether the affected tooth is in "traumatic occlusion." Excess occlusal forces or occlusal interferences can be either a cause of pulp inflammation[66,67] or they may be a result of periapical/periradicular conditions. They can also affect the healing of the periapical/periradicular tissues following trauma[68] to a tooth or after root canal treatment.[69]

Traumatic occlusion can cause either reversible or irreversible pulpitis in a tooth. Most cases will be reversible unless the traumatic occlusion has been present for a long time. A simple occlusal adjustment may be the only treatment required for many cases of reversible pulpitis. Hence, it is important to determine the cause of the pulpitis so appropriate treatment can be provided and to avoid unnecessarily removing pulps.

A tooth may be in traumatic occlusion as a result of apical periodontitis or an apical abscess. Primary acute apical periodontitis is an inflammatory condition with no space for the inflammatory cells and exudate since there has been no bone resorption—this in itself will lead to pain on biting but the inflammation may also cause the tooth to be extruded slightly from its normal position with the result that it may look longer than the adjacent teeth and it will be subjected to excess forces on biting and chewing. This can be quite painful for the patient. Likewise, a primary acute apical abscess has no space for the inflammatory reaction to occur and for the pus that is produced as part of the process of abscess formation. The resultant pain is usually very severe and often present even with just very light touching of the tooth (e.g., with the patient's tongue).

Chronic apical periodontitis, secondary acute apical periodontitis, a secondary acute apical abscess and other chronic periapical conditions are less likely to cause traumatic occlusion since bone has been resorbed to create space—this is evidenced by the presence of a periapical radiolucency. However, traumatic occlusion may be present in some cases or it may be result of periodontal disease and loss of bone support.

The occlusion should be carefully checked by examining the tooth for the presence of wear facets and by visually observing the tooth when the patient bites the teeth together. The patient should be asked to tap their teeth together several times in centric occlusion to see if there is any vertical movement of the affected tooth. If the tooth is depressed into its socket as the patient bites, then this indicates traumatic occlusion. The patient should then be asked to grind their teeth from side to side (lateral excursions)

and from front to back (protrusive movements)—if the tooth moves as the jaw moves, then this also indicates traumatic occlusion.

The occlusion can also be checked by placing a finger on the tooth while the patient taps and grinds the teeth in order to feel for fremitus or movement of the tooth. Finally, the occlusion should be checked for excessive contacts and "high spots" by using articulating paper (Figure 8-34) held in a pair of Miller's articulating forceps (Hu-Friedy Manufacturing Co., Chicago, IL, USA) while the patient bites and grinds the teeth laterally and protrusively.

FIGURE 8-34 Assessing the occlusion with articulating paper held in a pair of Miller's articulating paper forceps.

Other Tests

Local Anesthetic Test

The principle of the local anesthetic test is to use a series of local anesthetic injections to anesthetize one small area at a time in an effort to localize the source of the patient's pain. This test should only be done when all the other tests have been performed (ideally several times) and the diagnosis is still uncertain. There are several limitations to this test and it is relatively uncommon that clinicians would need to perform this test for pulp or periapical conditions. It is unlikely to be required for the diagnosis of acute conditions since the symptoms are present and can usually be readily reproduced via the various tests outlined earlier. In acute pain cases, it is easy to stimulate the pain or to increase it by applying the stimulating factor (e.g., cold, heat, percussion, biting, etc.) to the tooth. However, in some cases where the patient has chronic pain, the local anaesthesia test might be helpful.

If considering the use of a local anesthetic test, it is essential that all other tests have been performed first as they cannot be done once local anaesthetic has been administered. If the local anesthetic test is to be helpful, then the clinician initially determines the general region of origin of the pain. Then, a small amount of local anesthetic solution can be injected into that region to see if the pain subsides. If the pain does not change, then another injection can be given in an adjacent region, and so on until the pain abates.

The most mesial tooth in the region should be anaesthetized first and then move distally with each subsequent injection. This works best in the maxilla where infiltration injections can be given but a large factor that restricts the usefulness of this test is the spread of anesthetic through the bone to potentially anaesthetize several teeth. In the mandible, infiltration injections are unreliable and therefore the local anesthetic test is also unreliable. PDL injections have been advocated but these injections are essentially intraosseous injections and the solution is known to spread to adjacent teeth. Hence, the local anesthetic test is not an ideal tool for localising the source of pain.

A thorough history and the full range of noninvasive diagnostics tests outlined earlier will usually lead the clinician to a diagnosis without the need for invasive tests such as the local anesthetic test. If a diagnosis cannot be established once all the tests have been performed, then the clinician should not attempt any irreversible treatment; instead the patient should be referred to a specialist practitioner for further assessment. Fortunately, most pulp, root canal, and periradicular conditions are readily diagnosed if the clinician collects the relevant information and has a good understanding of the disease processes.

Test Cavity

The concept of doing a so-called "test cavity" involves cutting a cavity in a tooth without the use of local anesthetic. This is essentially just another a form of pulp sensibility test as all it can do is indicate whether the pulp of the tooth is able to respond to a stimulus. However, this is an invasive procedure that damages the tooth structure and/or existing restoration. It is also very likely to make the patient quite apprehensive which may result in the patient perceiving pain even if the pulp is necrotic or the tooth is pulpless and infected—that is, false responses are very likely in this situation. Patients are unlikely to feel relaxed about such a procedure even when clinicians believe they have fully informed a patent of the nature of the test.

The procedure is invasive in that it involves cutting an unnecessary cavity into the tooth. This particularly applies if the pulp does respond to the procedure since the tooth now has a cavity that requires restoration. All restorations have a finite life span and every restoration has the potential to break down and allow bacterial penetration with the potential of eventual pulp disease. This can be avoided by not doing a "test cavity" in the first place.

The only potential results of a "test cavity" are that the patient feels pain or the patient does not feel pain. Neither of these is indicative of the status of the pulp as they do not indicate whether the tooth has a clinically normal pulp, reversible pulpitis or irreversible pulpitis if pain is felt. Alternatively if no pain is felt, then this does not indicate whether the pulp is necrotic and infected, pulpless and infected or even root filled and infected. Hence, the test is not specific enough in its outcome to lead to a diagnosis.

A further problem exists with teeth that have PCC. These teeth are unlikely to respond to cold pulp sensibility tests and they may or may not respond to an electric pulp test. Likewise, they may or may not respond to the "test cavity." If there is no response to the cavity preparation, yet there

is a viable pulp in the calcified canal, then unnecessary root canal treatment will be performed. The diagnosis of the state of calcified canals should be based on whether there are any periapical changes evident radiographically—if no changes are evident, then the pulp is likely to be clinically normal but just does not respond to pulp sensibility tests. Such a tooth does not require root canal treatment. Hence, the "test cavity" can be very misleading.

In addition to the abovementioned problems, a "test cavity" provides no additional information than what can be obtained with standard pulp sensibility tests such as a cold test or an electric pulp test—that is, it only indicates the pulp's ability to respond to a stimulus. In essence, the cutting of such a cavity without anesthetic is a barbaric procedure that should *not* be considered as a "test" and it simply causes pain and apprehension for the patient. This procedure really has no place in modern dentistry as better, simpler, noninvasive, and more reliable tests are available.

FINALIZING THE DIAGNOSES

All of the information obtained from the diagnostic process will lead to the definitive diagnoses and management plan in a stepwise manner, as outlined in Table 8-5. Usually, the examination and tests confirm the provisional diagnoses that the operator had formulated (based on the patient's history) prior to the examination. However, in some cases, the final diagnoses may vary from this.

There should always be more than one diagnosis whenever teeth with pulp, root canal, and periapical/periradicular conditions are being assessed since these aspects are interrelated. Pulp and root canal conditions are part of the same disease process, but at different stages of the process, and they cause periapical/periradicular conditions. Hence, all cases should have the pulp assessed if it is present, otherwise the root canal system must be assessed, and all cases must also have the periapical/periradicular tissues assessed. The state of each should be recorded even in the absence of disease as diagnosis also includes the assessment of health.

The clinical examination should also have identified the cause(s) of the disease processes. Hence, the four aspects of a complete diagnosis listed above—that is, the tooth involved, the state of the pulp (if present, otherwise the state of the root canal system), the state of the periapical/periradicular tissues, and the cause of the disease(s)—must be recorded in the patient's record.

MANAGEMENT PLANNING, PATIENT DISCUSSION, AND CONSENT FOR TREATMENT

Once the definitive diagnoses and cause(s) have been identified, the management options usually become obvious. Teeth with clinically normal pulps will not require any treatment but will usually need to be monitored and reassessed to ensure the pulp remains normal. Teeth with reversible pulpitis will normally require some form of conservative pulp therapy such as a direct pulp cap, a partial pulpotomy, a pulpotomy or partial pulpectomy. The actual treatment chosen will depend on

TABLE 8-5 Summary of the Examination and Diagnostic Processes for the Assessment of Pulp, Root Canal, and Periradicular Conditions, and Their Outcomes

Stage	Procedure		Outcome
History	Medical history Dental history Description of presenting complaint Details of previous treatment of tooth involved	→	• Provisional diagnoses of presenting conditions
Clinical examination	Extra-oral signs Intra-oral signs Individual tooth assessment, *e.g., mobility, periodontal probing, etc.* Restoration assessment	→	• Identify possible cause(s) • Provisional assessment of tooth status
Clinical tests	Pulp sensibility tests, *e.g., CO_2, EPT*	→	• Provisional diagnosis of the status of the pulp or root canal system
	Periradicular tests, *e.g., percussion, palpation*	→	• Provisional diagnosis of the periapical/periradicular status
Radiographic examination	Periapical radiograph(s) Other radiographs/images (if needed, *e.g., Bitewings, panoramic, CT, etc.*)	→	• Provisional diagnosis of the periapical status • Assess/identify/confirm cause(s)
Correlation of all findings	Combine the history, clinical examination, clinical tests and radiographic examination results	→	• Definitive diagnoses—tooth, pulp, or root canal system, and periapical/periradicular tissues + Cause(s) of the condition(s)
Management plan	Tooth Investigation, *i.e., remove all restorations, caries, cracks, etc.*	→	• Confirm the definitive diagnoses and cause(s)
	Reassess amount of tooth structure and the overall prognosis/longevity of tooth + restoration	→	• Finalize management plan and continue treatment if the canals can be negotiated and tooth is suitable for further restoration

(Adapted from Abbott[3,5] and Abbott and Yu.[11])

the restorative dental requirements of the tooth. Some cases of reversible pulpitis may even require root canal treatment if they are found to need some form of intra-radicular retention to help retain the restoration but this can only be determined when the tooth has been investigated as described subsequently.

Root canal treatment (or retreatment) will generally be the first choice of treatment to manage irreversible pulpitis and most other root canal and periapical/periradicular diseases (Tables 8-6 and 8-7) although some cases may require, or be more suitably managed with, periapical surgery. Furthermore, some teeth will require extraction as they are not suitable for root canal treatment and/or further restoration of the tooth. In a study by Al-Dhufairi and Abbott,[70] 11.8% of 5775 teeth with pulp, root canal, and periapical/periradicular problems were recommended for extraction following a thorough examination. They were recommended for extraction because there was insufficient tooth structure (8.3%) or they had significant cracks (3.5%) that rendered them unsuitable for further restoration.

Extraction is always an option for teeth with irreversible pulpitis and most other root canal and periapical/periradicular diseases, even if the tooth is suitable for further treatment, as extraction will lead to predictable resolution of the symptoms and healing. Some patients may choose to have the tooth extracted for a variety of reasons. As with all clinical procedures, the advantages and disadvantages of retaining the tooth versus extracting it should be discussed with the patient so he/she can make an informed choice.

The examination findings and the diagnoses must be discussed with the patient along with an outline of the management options. The patient needs to understand what has happened to the tooth, why it has happened and what treatment can be done to rectify the problems. The best approach to discussing this is to advise the patient of the general nature of the problem—such as whether it is an

TABLE 8-6 Summary of Endodontic Treatment Strategies for the Various Pulp and Root Canal Conditions

Clinically normal pulp		NIL treatment required
Reversible pulpitis—acute or chronic		Conservative pulp therapy then reassess healing response
Irreversible pulpitis—acute or chronic		Routine root canal treatment with anti-inflammatory medications then reassess healing response, or extraction
Pulp necrobiosis		Routine root canal treatment with anti-inflammatory and antimicrobial medications then reassess healing response, or extraction
Pulp necrosis	No signs of infection	No treatment required—monitor and reassess periapical tissues for signs of inflammation (which would indicate an infected root canal)
	Infected	Routine root canal treatment with anti-inflammatory and antimicrobial medications then reassess healing response, or extraction
Pulpless, infected root canal system		Routine root canal treatment with anti-inflammatory and antimicrobial medications then reassess healing response, or extraction
Pulp atrophy		NIL treatment required
Pulpal canal calcification		Treatment will be determined by the condition of the pulp/root canal system (e.g., irreversible pulpitis; pulpless, infected root canal system; etc.)
Pulp hyperplasia		Routine root canal treatment with anti-inflammatory medications then reassess healing response, or extraction
Previous root canal treatment		
No signs of infection		No treatment but monitor and reassess unless restoration being replaced ➔ then do root canal retreatment and reassess healing response
Infected root canal system		Root canal retreatment with anti-inflammatory and antimicrobial medications then reassess the need for periapical surgery, or extraction, if the canal is still infected or if there are signs of on-going periapical pathosis
Technical standard	Inadequate	No treatment but monitor unless the restoration is being replaced or the root canal system is infected ➔ then root canal retreatment and reassess healing response
	Adequate	No treatment but monitor unless the restoration is being replaced or the root canal system is infected ➔ then root canal retreatment and reassess healing response
Other findings	Perforation	Root canal retreatment and repair the perforation from an internal approach if possible; then reassess the need for periapical or periodontal surgery, or extraction—if there are signs of on-going periapical and/or periodontal pathosis
	Missed canal	Root canal retreatment then reassess the need for periapical surgery, or extraction, if the root canal system is still infected or if there are signs of on-going periapical pathosis

Note: recommendations for endodontic treatment and retreatment are dependent on the tooth having sufficient tooth structure remaining to enable it to be adequately restored again. (Adapted from Abbott and Yu.[11])

TABLE 8-7 Summary of Endodontic Treatment Strategies for the Various Periapical/Periradicular Conditions

Clinically normal periapical/periradicular tissues	NIL treatment required
Apical periodontitis • Primary acute • Secondary acute • Chronic	Routine root canal treatment with anti-inflammatory and antimicrobial medications then reassess healing response, or extraction
Apical abscess • Primary acute • Secondary acute • Chronic	Routine root canal treatment with anti-inflammatory and antimicrobial medications then reassess healing response, or extraction
Facial cellulitis	Immediate systemic antibiotics (intra-venous, intra-muscular), plus routine root canal treatment with anti-inflammatory and antimicrobial medications then reassess healing response, or extraction
Extra-radicular infection	Root canal treatment or retreatment with anti-inflammatory and antimicrobial medications then reassess the need for periapical surgery, or extraction, if the canal is still infected or if there are signs of on-going periapical pathosis
Foreign body reaction	Root canal treatment or retreatment with anti-inflammatory and antimicrobial medications then reassess the need for periapical surgery, or extraction, if there are signs of on-going periapical pathosis
Periapical cyst • Pocket • True	Root canal treatment or retreatment with anti-inflammatory and antimicrobial medications then reassess the need for periapical surgery, or extraction, if there are signs of on-going periapical pathosis
Periapical scar	NIL treatment required but regular radiographic review essential to monitor and reassess

Note: recommendations for endodontic treatment and retreatment are dependent on the tooth having sufficient tooth structure remaining to enable it to be adequately restored again. (Adapted from Abbott.[3])

inflammatory condition (e.g., pulpitis) or an infection (e.g., pulpless and infected root canal system) that also has an inflammatory component (e.g., chronic apical periodontitis). Simple, although not too simplistic, and meaningful terms should be used. For example, the pulp should not be called the "nerve" of the tooth as this word conjures an image or expectation of pain in the patient's mind when advised that it needs to be removed. In many cases, there will be no pulp tissue to remove anyway (e.g., pulpless, infected teeth) and therefore the clinician should not mislead the patient by saying the pulp or "nerve" needs to be removed.

An important part of the discussion is to inform the patient of the reasons why the tooth has the problem. Typically pulp, root canal, and periradicular conditions develop as a result of bacteria entering the tooth. Hence, the patient should be advised about this and the specific way that the bacteria have entered the tooth in question. The majority of cases are a result of restorations breaking down, caries and/or cracks in the tooth even when these may not be visible or entirely evident during the investigation. If the patient understands this, then he/she will be more likely to realize that the existing restoration(s), caries and cracks will need to be removed while the tooth is being investigated, as outlined subsequently.

The discussion should also include an outline of the alternative treatments that may be available for the particular problem. This will typically include extraction and possible replacement with a prosthesis. Some cases may involve a discussion about reversible pulpitis and conservative pulp treatment, while others may involve discussions about root canal retreatment and/or periapical surgery. The exact nature of the discussions will depend on the diagnoses, the condition of the involved tooth, as well as the particular patient, their overall oral status and their interest in retaining their teeth. While a discussion of all possible options for managing the problem is necessary, the patient should not be misled or given false expectations about a procedure that is unlikely to have a good outcome or to provide a predictable long-term result for the patient. For example, periapical surgery should not be offered if the root canal system is infected and the coronal restoration is unsatisfactory.

Once the patient has had a full explanation of the problem and the proposed treatment, they can then provide informed consent so the treatment can commence. However, patients should understand that the initial stage of treatment (i.e., the tooth investigation—see subsequently) is also an important part of the diagnostic process as the tooth cannot be fully assessed until the restorations, caries and cracks have been removed. The overall treatment plan cannot be finalized until this procedure has been performed.

TOOTH INVESTIGATION

Tooth investigation is the procedure whereby all existing restorations, caries and cracks are removed from the tooth (Figures 8-35 and 8-36) as the initial stage of root canal treatment.[4] Despite seeming to be more a part of the treatment procedure, it should be first considered as part of the diagnostic process since it provides valuable information about the tooth, the conditions being treated and the prognosis of the tooth. This is not a new concept and it has been advocated by many authors for many years[55,71,72] but it has not been regularly practiced by the profession. In 1985,

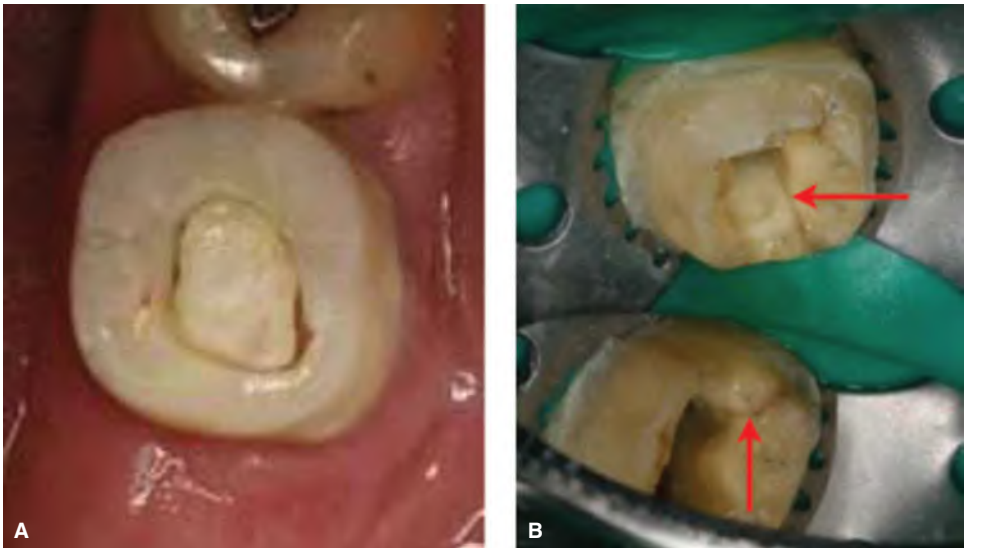

FIGURE 8-35 Investigation of a tooth. ***A.*** Preoperative view of the tooth with a full coverage crown restoration. A dentist had been attempting root canal treatment but the patient continued to have symptoms. ***B.*** After removing the crown restoration, a crack was evident (see arrows) This crack was allowing continual microbial entry into the tooth and therefore symptoms continued. The tooth was recommended for extraction due to the extent of the crack. (Courtesy of Dr. Edward Houston, Brisbane, Australia.)

Marshall et al.[55] stated that *"prior to any endodontic treatment, and after all coronal restorations and decay are removed, the remaining tooth structure should be ere-examined with a fiber-optic light for fractures and perforations. Teeth with vertical fractures and perforations may be untreatable."* Today, with better definitions, "fractures" could be interpreted to mean both cracks and fractures, and "untreatable" implies that they are not salvageable and require extraction. Marshall et al.[55] also stated that the suitability of a tooth for further restoration *"depends on the amount of sound tooth structure remaining"*—another concept that remains true today.

There are several aims of tooth investigation:

- To remove the cause(s) of the disease(s) that are present in the tooth and the surrounding tissues,
- To assess the remaining tooth structure to determine if the tooth is suitable for further restoration after the root canal treatment has been completed,
- To assess whether root canal treatment will be feasible (e.g., can the canals be located and negotiated, can the existing root filling material be removed in retreatment cases, etc.).
- To better assess the long-term prognosis of the tooth, and
- To allow construction of an interim restoration that will prevent bacterial penetration into the tooth during the root canal treatment and until a definitive restoration is placed.

It is well accepted that bacteria are the major cause of pulp, root canal, and periradicular conditions. However, the pathway of entry of the bacteria into the tooth is often ignored. In order to achieve the highest possible rate of favourable outcomes of the treatment of any disease, the first principle is to remove the cause(s) of the disease. This applies to root canal treatment as much as it does to any other treatment. Since the most common pathways of entry for bacteria are via caries, cracks and the breakdown of restoration margins, it is essential to first identify the cause(s) of the diseases and then to remove them as part of the treatment.

Abbott[4] has demonstrated that the standard visual clinical examination and periapical radiographs do not provide sufficient information to accurately assess the status of the teeth and the pathway(s) of bacterial penetration that commonly cause pulp, root canal, and periapical diseases. He examined a series of 245 teeth in 220 consecutive patients referred for endodontic treatment using the standard visual clinical examination procedures and tests plus periapical radiographs. In particular, evidence of restoration breakdown, caries, cracks, and fractures was noted. The examination procedure included a visual inspection with probing of restoration margins, pits, fissures and grooves, periodontal probing, percussion, palpation, and transillumination of the teeth with a fibre optic light shone from numerous different directions. The restorations were then removed from the teeth and the clinical examination was repeated with the same methods. Examination of the teeth without restorations in place revealed 2.5 times as many teeth with evidence of marginal breakdown of the restorations, 2.3 times as many teeth with caries and 2.6 times as many teeth with cracks than what could be seen preoperatively. Hence, the value of tooth investigation is clear in that it not only reveals the common cause(s) of the diseases but it removes them from the tooth.

Teeth with infected root canal systems must have a pathway of entry for the bacteria to invade the tooth. This same pathway is also a likely pathway of entry for nutrients from the oral cavity (food, drinks, etc.) to enter the tooth and help the bacteria to establish colonies so they can survive

FIGURE 8-36 Interim restorations placed following investigation of the teeth. ***A.*** A maxillary molar after tooth investigation, and ***B.*** following placement of a stainless steel band and Ketac Silver interim restoration. ***C.*** A maxillary premolar after tooth investigation and placement of an intracanal medicament and Cavit in the pulp chamber, and ***D.*** Following placement of a stainless steel band and Ketac Fil interim restoration. The Ketac Fil has overlaid the buccal aspect of the band as a veneer to provide an esthetic interim restoration. ***E.*** Ketac Silver without a band with subsequent access cavity in a mandibular molar tooth. ***F.*** Ketac Fil placed as an interim restoration to restore the fractured mesioincisal portion of the right maxillary incisor tooth while root canal treatment was performed.

within the root canal system. However, the pathway of entry may not always be clinically evident as demonstrated by Kwang and Abbott[73] who used scanning electron microscopy to examine the fitting surfaces of 30 restorations that had been removed from teeth with infected root canal systems. In order to be included in the study, the restorations had to be "clinically satisfactory"—that is, they had no visible signs of marginal breakdown when examined—and the teeth had no caries or cracks that could have allowed bacteria to enter and infect the root canal system. All 30 restorations were completely lined by bacterial biofilms that consisted of a wide range of bacterial morphological types—cocci, filamentous rods, spirochaetes, and so forth. The results clearly demonstrate that it is not possible to accurately assess restored and infected teeth for the presence of bacteria under the restorations. This study further supports the concept of tooth investigation and the need to remove all restorations prior to commencing root canal treatment so all possible pathways of bacterial entry are removed.

Tooth investigation is also a valuable process that leads to better case selection since the remaining tooth structure itself can be examined and assessed rather than trying to evaluate the tooth with the restoration in place (Figures 8-35 and 8-36). Al-Dhufairi[70] has reported that a higher proportion of teeth were referred for extraction at the tooth investigation stage than at the initial examination stage. Al-Dhufairi reviewed the decisions made by 13 operators (specialist endodontists and postgraduate endodontic students) regarding 5775 teeth. When these teeth were examined using the standard clinical procedures outlined earlier, 11.8% of the teeth were referred back to the referring dentist for extraction—8.3% were recommended for extraction due to an obvious lack of tooth structure and 3.5% were recommended for extraction due to the presence of cracks. Both of these findings rendered the teeth unsuitable for root canal treatment and further restoration. Then, 4218 of the original set of teeth were investigated by removing the restorations, caries and cracks—this revealed that 11.9% had insufficient tooth structure and 7.3% had cracks which made them unsuitable for root canal treatment and further restoration. Overall, extraction was recommended for 19.2% of the teeth that were investigated—that is, approximately one in every five teeth were not suitable for root canal treatment and further restoration. If these teeth had not been investigated then they would have had an unrecognized poor, or hopeless, prognosis and the patient would have had inappropriate treatment with subsequent loss of the tooth within a short period of time.

A systematic review by Ng et al.[74] involving 14 studies with over three million teeth that had undergone root canal treatment reported a mean survival rate of just 86% over two to three years. This meant that 14% of these teeth had been extracted within a very short period of time following the treatment. This study did not account for teeth that may have been extracted after four to five years (or longer) and it did not include teeth that required further root canal treatment due to persistent periapical disease which is likely to be a result of not removing the cause of the disease or not having sufficient tooth structure to enable an adequate restoration to be placed. While this figure of 14% is slightly less than the 19.2% reported by Al-Dhufairi,[70] it is reasonably similar and supports the concept that tooth investigation should be done in order to improve case selection and only treat those teeth that have a good prognosis.

A further study by Ng et al.[75] assessed the reasons for extraction following root canal treatment. This was a prospective analysis over two to four years of 759 teeth that had root canal treatment and 858 teeth that had root canal retreatment. In both groups, approximately half of the teeth that were extracted had a "tooth structure" problem which led to either fracture of the tooth (28.6% and 29.3%, respectively) or "failure" of the restoration (22.9% and 22%, respectively). The other major factor leading to extraction was an "endodontic problem" in 28.6% and 39.0%, respectively, of the teeth. Analysis of other studies[76–79] reveals similar findings that approximately half the teeth requiring extraction within just a few years of having root canal treatment have either fractured or the restoration has not been adequate, both of which are "tooth structure" problems. The results of these studies are also highly suggestive of the teeth not being adequately assessed prior to the root canal treatment. This is a very likely consequence of not removing existing restorations, caries, and cracks.

When the concept of tooth investigation was applied to a series of 432 teeth undergoing root canal retreatment of infected teeth, Abbott[80] reported that 423 teeth (97.9%) had a favourable outcome of the treatment when assessed for up to five years or until periapical healing was confirmed radiographically. While it is recognized that there are many factors that can affect the outcome of root canal treatment, the ability to select only those teeth that had sufficient tooth structure and no obvious cracks is likely to be a major contributor to this result which is a much higher rate of favourable outcomes than reported in most studies regarding root canal retreatment of infected teeth.

The abovementioned studies highlight the need to investigate teeth as part of the diagnostic process. This allows better case selection and avoids patients having inappropriate and expensive treatment for no long-term gain. When presenting the concept of tooth investigation to patients, they should initially be advised of the reasons why the tooth requires investigation (i.e., to remove the causes of the diseases and to assess the remaining tooth structure). They should then be advised that there are two possible outcomes of the investigation:

- The tooth *is* suitable for root canal treatment and further restoration (in which case the root canal treatment can be continued), or
- The tooth is *not* suitable for root canal treatment and further restoration (in which case the tooth will require extraction).

A patient fully informed and forewarned of these possible outcomes is more likely to understand and accept the need for the restorations, and so forth to be removed (i.e., tooth investigation). This essential part of the diagnostic process then becomes the first stage of the endodontic management of the tooth if the tooth is proven to be suitable for treatment.

Apart from the reasons and advantages outlined earlier, tooth investigation also markedly simplifies the initial root canal treatment since it allows uninhibited access to the pulp chamber and root canals. As stated by Ingle in 1965,[71] *"it is much easier to complete the radicular preparation through an open cavity than through the restored crown. As a matter of fact, the more of the crown that is missing, the easier the canal preparation becomes."* This is still true today. Furthermore, Ingle stated in 1985[72] *"complete caries excavation is imperative both to diagnose the condition and to plan proper treatment."* Again, this is still true today, particularly to *"plan proper treatment"* which should not just be planning of the endodontic treatment but it should also include planning of the restoration.

The two key aspects to consider about the restoration are first should the tooth be restored, and second, can it be restored adequately with a good long-term prognosis. These factors can only be determined by assessing the tooth structure that remains (Figures 8-35 and 8-36). Unfortunately, in general, the dental profession has not followed this concept and have tended to cut access cavities through existing restorations. However, this approach ignores the cause(s) of the disease(s) that are not removed—this in turn leads to continuation of the disease process as bacteria can continually enter the tooth and root canal system. This approach also hinders the ability of the operator to assess the long-term prognosis of the tooth as the amount and quality of remaining tooth structure cannot be seen and therefore cannot be assessed.

In summary, removal of all existing restorations, caries and cracks is essential since these are the most likely pathways of entry for the bacteria causing the pulp, root canal, and periapical conditions. This approach also allows the diagnoses to be confirmed, allows assessment of the amount and quality of the remaining tooth structure, allows assessment of the tooth's suitability for further restoration, and improves the prognosis for healing and longevity of the tooth. That is, better and appropriate case selection becomes possible when the tooth is investigated in this manner.

Once a tooth has been investigated, a comprehensive interim restoration will be required. This can usually be achieved with relatively simple techniques[81] such as by using glass ionomer cements with or without stainless steel bands to help retain the restorative material (Figure 8-36), especially at subsequent appointments when access is gained to the pulp chamber and root canals.

RECORD KEEPING

The final stage of the "Diagnostic Process" is to thoroughly record all the details of the history and clinical examination, the test results, a radiographic report, the definitive diagnoses, the cause(s) of the disease(s), the management options, the discussions with the patient, the patient's consent, the anesthetic used, the findings of the investigation procedure, the procedures provided during the investigation stage, the materials used (e.g., irrigants, medicaments, restoration, etc.), other relevant details (e.g., number and location of canals, files used, etc.), recommendations for further restoration,[4,5] final advice regarding retention or extraction of the tooth, any postoperative medications prescribed or advised, and the future treatment needs.[82] In summary, a through clinical record is required! This may be facilitated through the use of specifically designed paper forms or computerized screens that help to ensure that details are not omitted.

Chapter 9

Imaging Devices and Techniques

The success of endodontic treatment is dependent on the identification of teeth requiring such treatment, and then the recognition of the root canal system, so that it can be properly cleaned, shaped, and obturated. Endodontic treatment relies on a series of images made at different stages of the treatment: preoperatively, periodically during instrumentation and obturation, and postoperatively. These images provide important clues about hard and soft tissues of the teeth, including the pulp chamber and root canals. They also facilitate the estimation of root canal length and appropriateness of obturation. Furthermore, they aid in detecting pathoses, provide useful information of the periradicular region, and assist in evaluating posttreatment healing.

Imaging technology has gone through many advances in the past several years. This chapter describes the most pertinent imaging technologies related to endodontics, traditional, and advanced that have impacted the way endodontic treatment is being performed.

A. Analog Radiography

Richard E. Walton, Manuel R. Gomez

Radiographs are the "eyes" of the dentist when performing many procedures. They are essential for diagnosis and treatment planning, determining anatomy, managing treatments, and assessing outcome. Now considered essential, the use of the X-ray was not available to the dental profession until early in the last century.

No single scientific development has contributed as greatly to improved dental health as the discovery of the amazing properties of cathode rays by the German professor Wilhelm Konrad Roentgen in 1895. The significant possibilities of their application to dentistry were seized upon 14 days after Roentgen's announcement. Dr. Otto Walkoff took the first dental radiograph for himself.[1] In the United States, within five months, Dr. William James described Roentgen's apparatus and displayed several radiographs. Three months later, Dr. C. Edmund Kells gave the first clinic in the USA on the use of the X-ray for dental purposes. Three years later (1899), Kells was using the X-ray to determine tooth length during root canal therapy. "I was attempting to fill the root canal of an upper central incisor," Kells later said. "It occurred to me to place a lead wire in this root canal and then take a radiogram to see whether it extended to the end of the root or not. The lead wire was shown very plainly in the root canal."

One year later (1900), Dr. Weston A. Price "called attention to incomplete root canal fillings as evidenced in radiographs." By 1901, radiographs were used to check the adequacy of root canal fillings.[2] Price is credited with developing the bisecting angle technique, whereas Kells described what today is called the paralleling technique, made popular some 40 years later by Dr. Gordon Fitzgerald.

Although these early attempts were rarely of diagnostic quality, they were the beginning of a new era. For the first time, dentists could visualize hidden disease as well as see the accumulation of past dental treatment; therapy done without knowledge of what lay beneath the gingiva. Yet even today, with all of the technical refinements, the sleekness of operation, and the reduction of hazards, a discouraging segment of our profession continues to deprive their patients by failing to use radiography to its full potential. Dentists often under- or overuse, under- or overinterpret radiographs or fail to use careful and appropriate techniques.

EVOLUTION OF RADIOGRAPHY

Endodontics evolved and upgraded as a dental discipline throughout the 20th and into the 21st centuries. Much of the improvement was because of procedural advances as well as technical innovations. This section is focused on traditional (analog) radiography. Other sections that follow in the chapter will include newer imaging methodologies. These technologies have many advantages and also some shortcomings and limitations. In many parts of the world, including the United States, these newer techniques are neither practical nor available nor affordable.

Importantly, traditional analog techniques and procedures, utilized for decades, are still effective. In fact, in many dental offices and clinics this is the only technique utilized. Therefore, not only analog radiograph is useful but also most of the analog aspects are applicable to digital and somewhat to cone beam computed tomography (CBCT). Therefore, this section reviews these basic analog methods and applications.

APPLICATION OF RADIOGRAPHY TO ENDODONTICS

In endodontics, radiographs have the following several essential functions:

1. Aid in diagnosis of hard tissue alterations in the teeth and periapical structures and proximity of anatomic structures.
2. Determine the number, location, shape, size, and direction of roots and root canals.[3]
3. Assess anatomy, size, and alterations in the pulp chamber.
4. Detect procedural errors such as perforations, ledges, transportation, and instrument separation.
5. Locate root tips prior to surgery.
6. Estimate and confirm the length of canals.
7. Localize hard-to-find, or disclose unsuspected, pulp canals by examining the position of an instrument within the root (Figure 9A-1).
8. Aid in locating a pulp space markedly calcified and/or receded (Figure 9A-2).
9. Determine the relative position of structures in the facial–lingual dimension.
10. Confirm the position and adaptation of master cones.
11. Aid in the evaluation of obturation.
12. Facilitate the examination of soft tissues for tooth fragments and other foreign bodies following traumatic injuries.
13. Aid in localizing a hard-to-find apex during root-end surgery.
14. Confirm, following root-end surgery and before suturing, that all tooth fragments and excess filling material have been removed from the apical region and the surgical flap (Figure 9A-3).
15. Evaluate, in follow-up films, the outcome of treatment.

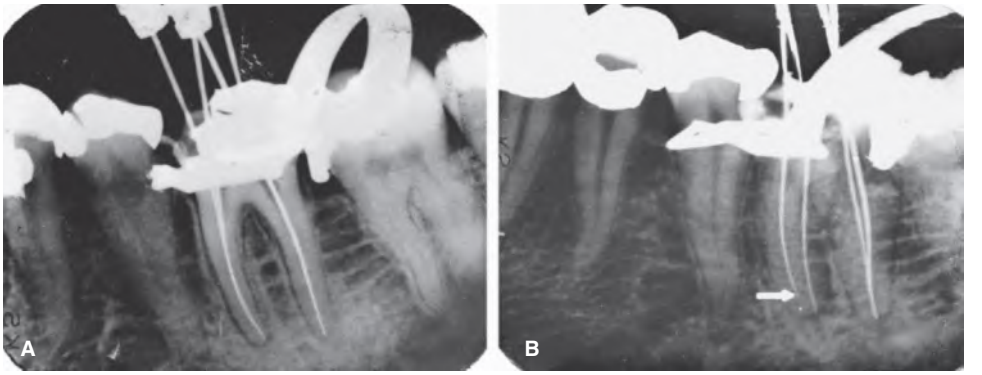

FIGURE 9A-1 Disclosing canals by radiography. ***A.*** Right angle horizontal projection reveals four superimposed files. ***B.*** Horizontal angulation varied 30° mesially reveals that there are three canals (two files in a broad distal canal). The file is short of working length in the mesiolingual canal (arrow).

FIGURE 9A-3 Radiograph taken after suturing and developed after patient left the office. The patient had to return to the office for removal of the root tip.

Limitations of Radiographs

Radiographs could be termed the "Great Pretender." They are obviously essential, but are frequently overused and/or misinterpreted. A radiograph is but a two-dimensional shadow. They are suggestive only and are not the singular final evidence in judging a clinical problem. There must be correlation with other subjective and objective findings. The greatest fault with the radiograph relates to its physical state. As with any shadow, these dimensions are easily distorted through improper technique, anatomic limitations, or processing errors. In addition, the buccal–lingual dimension is absent on a single film and is frequently overlooked, although techniques are available to define the third dimension. These techniques are later described in detail.

Radiographs are not infallible. Various states of pulpal pathosis are indistinguishable in an X-ray shadow.

This factor must be considered in evaluating teeth that become symptomatic but show no radiographic changes; thus, the lack of radiolucency should not be interpreted as an absence of a bone resorbing process. Neither healthy nor necrotic pulps cast an unusual image. Correspondingly, the status of infection in hard or soft tissue is not detectable other than by inference. Only microbial culture can determine this. Furthermore, periapical soft tissue lesions cannot be accurately diagnosed by radiographs; they require histologic verification.[4] Chronic inflammatory tissue cannot, for example, be differentiated from healed, fibrous, "scar" tissue, nor can a differential diagnosis of periapical radiolucencies be solely made on the basis of size, shape, and density of the adjacent bone.[3–7] A common misconception is that an inflammatory lesion is present only when there is at least a perceptible "thickening" of the periodontal ligament space. In fact, investigators have demonstrated that lesions of the *medullary bone* often go undetected unless there is marked resorption or until the resorption has eroded a portion of the *cortical plate*.[8–11]

The fallibilities and inherent errors in radiographic interpretation were clearly demonstrated by Goldman et al.,[12] who submitted recall radiographs of endodontic treatments, for clinical evaluation, to a group of radiologists and endodontists. They assessed success and failure by observation of radiodensities. There was *more disagreement than agreement* among the examiners.

Importantly, the radiograph is only an adjunctive tool and can be misleading. Information obtained from proper interpretation of the radiograph is not always absolute and must be always integrated with information gathered from a detailed medical and dental history, clinical examination, and pulp testing procedures. For more details, see Chapter 10.

The techniques outlined in the following sections have proved to be successful and predictable. If followed, they will greatly simplify difficulties in root canal treatment.

TECHNOLOGY SYSTEMS

Alternative imaging techniques have been introduced over the years to overcome the existing limitations of analog intraoral radiographs. CBCT has proved to be particularly useful for diagnosis, treatment planning, and anatomic surveys.[13,14] CBCT, magnetic resonance imaging and ultrasound will be discussed later in this chapter.

There are basically two radiographic approaches. The traditional is the X-ray exposure of film that is chemically processed to produce an image. The newer digital systems rely on an electronic detection of an X-ray-generated image that is then electronically processed and reproduced on a computer screen. Overall, the resulting image is similar in interpretative quality to the traditional radiograph.[15,16] Advantages of digital radiography include reduced radiation, speed of obtaining the image, enhancement of the image, computer storage, transmissibility, and a system that does not require chemical processing.[17] Disadvantages are cost and more difficulty in placing the sensor. However, the advantages outweigh the disadvantages. As costs decrease, sensor design improves and technology progresses, use of the digital system has increased considerably and is becoming the standard.

Either digital or film type receptors can be used to capture the image when exposing an intraoral radiograph. Both digital and film type receptors are available in American National Standard Institute sizes 0, 1, 2, and 4. The receptor size is selected considering the specific area of interest. Usually, the size 1 receptor is chosen for evaluation of anterior teeth, while the size 2 receptor is used in the posterior region, specifically from the distal of the canine posteriorly. The size 4 receptor is used exclusively for the occlusal radiograph. The size 0 receptor is indicated for pediatric patients or in situations where anatomic considerations limit the ability of adequate placement of a larger receptor. For full discussion on digital radiography, see Chapter 9-B.

Traditional Machines

Two basic types of X-ray machines are commonly used in dental offices. One type has a range of kilovoltage and two milliamperage settings with which the long (16-in) cone is frequently used. The other type offers only 1 kV and milliamperage setting and only the short (8-in) cone. Either type provides adequate radiographs. However, each has advantages that, under different circumstances, will yield a better result. The long-cone system is superior for diagnostic radiographs, whereas the flexible short-cone machine is more appropriate for treatment or "working" films. However, either the "long cone" or the "short cone" is satisfactory if used properly.

The long-cone machine is preferred for exposing diagnostic, final, and follow-up radiographs, because of the clarity and minimum distortion inherent in the long-cone parallel technique.[18,19]

The short-cone machine with a small, easily manipulated head, saves time, energy, and frustration, and may therefore be preferred when taking working radiographs.

Short Cone and Long Cone

The positioning-indicating device is sometimes referred to as the cone. Whether using digital or film, the length of the cone does affect the size of the image. A longer cone decreases magnification and gives better detail. The shorter cone has greater divergence of the X-ray beam causing excessive interproximal overlapping.

Increasing the focal spot distance from the object using a long cone, decreases the magnification and fuzziness of an image. There is also less divergence of the X-ray beam. The short cone has a greater divergence of the X-ray beam causing excessive overlapping and magnification, if there is any distance between the tooth and the film (Figure 9A-4). The length of the cone does not affect the amount of scatter radiation because the diameter of both cones is the same.

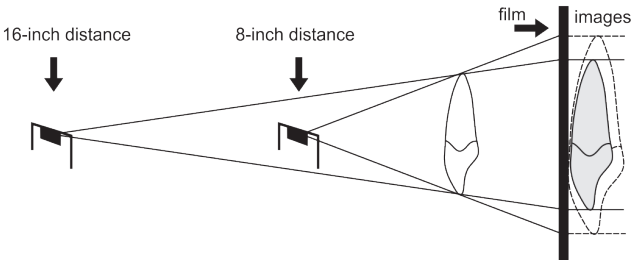

FIGURE 9A-4 Effect of changing the focal length. Increasing the focal spot distance from the object using a long cone decreases the magnification. It also decreases the fuzziness of the image. Another advantage is less divergence of the X-ray beam and therefore less magnification of the image.

Film Speed

Film speed is a term that refers to how efficiently the light-sensitive agents in a film emulsion react to energy (e.g., e-rays or light) exposure.

The American National Standards Institute and the International Organization for Standardization have established standards for film speed.[20] Film speeds available for dental radiography are D-speed, E-speed, and F-speed, with D-speed being the slowest and F-speed the fastest. The use of faster film speed can result in up to a 50% decrease in exposure to the patient without compromising diagnostic quality.[3,21] Film of a speed slower than E-speed should not be used for dental radiographs.[21,22]

The limited use of E or F-speed films compared with D-speed films is often due to misconceptions about price, clinical film quality, and processing. A comparison of one manufacturer's D-speed film to E-speed or F-speed film shows no significant clinical differences in quality between the films. Using E-speed or F-speed film for endodontic application provides a similar mean-correct diagnosis, comparable sensitometric properties (i.e., technical aspects of film imaging) and similar clarity of film compared to D-speed film. E-speed or F-speed film is processed without significant changes in processing practices to those that are used for D-speed film.[23,24] F-speed film is beginning to be more and more popular in dental offices.

The standard periapical-size film is used for most situations. In addition, every office should have 3 by 2 1/4-in *occlusal* film available for use when:

1. Periapical lesions are so extensive that they cannot be demonstrated in their entirety on one perirapical film;
2. there is interest in, or involvement of, the nasal cavity, sinuses, or roof or floor of the mouth;
3. trauma or inflammation prohibits normal jaw opening required to place and hold a periapical film;
4. a disabled person is unable to hold a periapical film by the usual means;
5. detection of fractures of the anterior portion of the maxilla or mandible is needed; and
6. very young children are being examined.

Intraoral Film Placement

Film placed parallel to the long axis of the teeth and exposed by cathode rays at a right angle to the surface of the film yields the most accurate images, with no foreshortening or elongation[25,26] (Figure 9A-5). If this principle is applied, it is unnecessary to memorize fixed cone angulations. Also, a patient need not be returned to an upright position for each exposure.

To achieve this parallel orientation it is often necessary to position the film away from the tooth, toward the middle of the oral cavity. This technique permits an accurate reproduction of the tooth's dimension and additionally reduces the possibility of superimposing the zygomatic process over the apices of maxillary molars that often occurs with distal-angulated films.

Because of the complicating presence of the dental dam, the methods for placement of *working* films differ somewhat from the methods for placement of diagnostic, final, and follow-up films.

Diagnostic Radiographs

These must be the best radiographs possible. The tooth should be centered on the film; this gives the least distortion. In addition, at least 3 mm of bone must be visible beyond the apex.

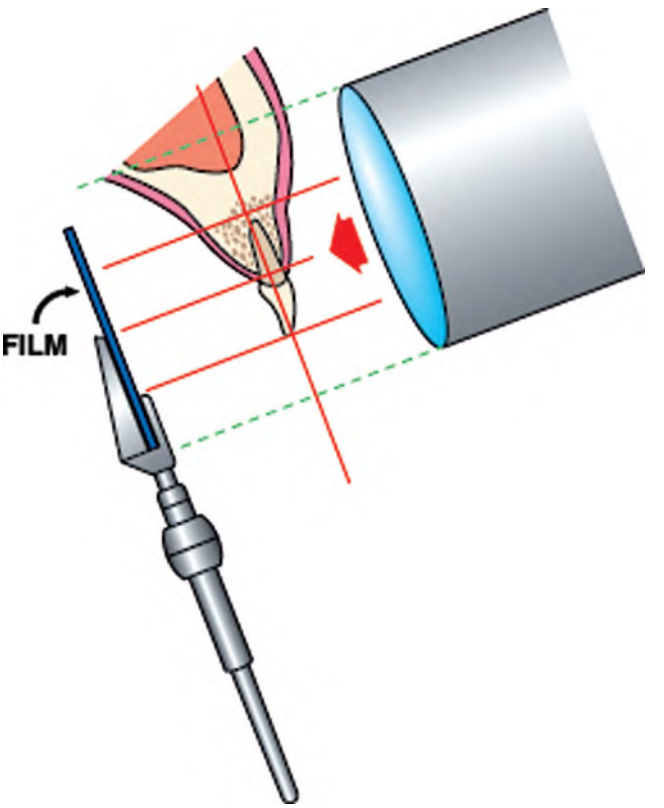

FIGURE 9A-5 Radiographic parallelism. The long axis of the film, the long axis of the tooth, and the leading edge of the cone are parallel and perpendicular to the X-ray central beam. (Reproduced with permission from Goerig AC. In: Besner E, Michanowicz A, Michanowicz J. editors. *Practical endodontics*. Mosby, St. Louis, MO, 1993; p. 56).

Failure to capture this area may result in misdiagnosis. There are advantages to parallelism; this permits more accurate visualization of structures as well as reproducibility. This facilitates comparison of follow-up radiographs.

The bitewing radiograph is often used as a supplement for diagnosis. It provides less image distortion because of its parallel placement. It is a single image depicting the maxillary and mandibular crowns, the interproximal contacts, the height of the bone crest, anatomy and size of the pulp chamber, presence of pulp stones, calcifications or resorptions, recurrent caries, and status of restorations. The bitewing is very helpful assessing restorability.

Bitewing radiographs are usually made with the size 2 receptor in a horizontal orientation. Horizontal bitewings may fail to reveal the alveolar crests when the crest has receded. Reorienting the receptor into a vertical position will then capture the alveolar crests. During treatment, a bitewing radiograph is useful to check the depth of access or the proximity of the furcation in cases with a receded pulp chamber. In this case, the dental dam should be removed temporarily to avoid overlapping of the clamp on the cervical area of the tooth. With large radiolucent lesions, an occlusal or a panoramic radiograph will assess the size and extent, as well as aiding in the planning of a proper treatment strategy.

There are a number of devices on the market that improve film placement and parallelism. The *Rinn XCP* (Dentsply/Rinn, Elgin, IL, USA) virtually guarantees distortion-free films but cannot be used with the dental dam in place. Special endodontic film holders are designed specifically to ensure parallelism yet avoid dental dam clamps while allowing space for files protruding from the tooth (Figure 9A-5). A disadvantage to this system is that the paralleling bar interferes with the cone when varying the horizontal cone angulations. Finger retention of the film should not be used, because the film is often bent and therefore, distorted. A *straight hemostat* is a good film holder and additionally serves as a cone-positioning device (Figure 9A-6).

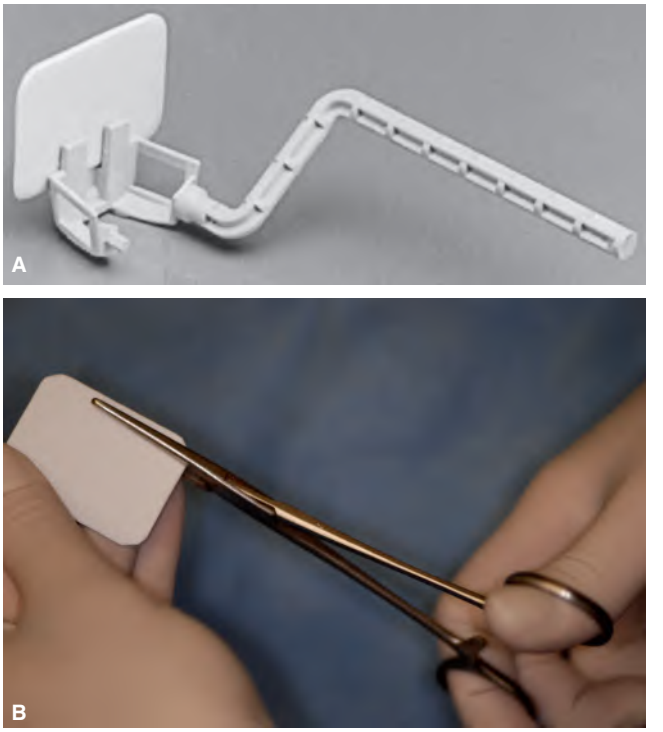

FIGURE 9A-6 Devices for holding "working" films. ***A.*** The Universal Rinn Endo Ray plastic film holder is designed for horizontal posterior films or anterior vertical films, maxilla or mandible, right or left. Here it is set for a maxillary posterior view. The "cupped out" area accommodates the tooth, clamp, and extruding endodontic files. (Photo courtesy of Rinn Corp., U.S.A.) ***B.*** A hemostat is used for grasping the film and as a cone positioning and orientation device.

Working Radiographs

One difficulty in root canal therapy is the clumsy, aggravating method of taking treatment radiographs with the dental dam in place. The dental dam frame should not be removed for access in film placement because doing so allows saliva entry to contaminate the operating field. A film-placement technique is used so that the *dental dam frame need not be removed*. Use of a radiolucent frame such as the *Star VisiFrame* (Dentaleze/Star, USA) will ensure that apices are not obscured.

With the dental dam in place, a *hemostat-held* film has the following significant advantages:

1. The film placement is easier when the opening is restricted by the denta dam and frame.
2. The patient may close somewhat with the film in place, a particular advantage in *mandibular posterior areas* where closing relaxes the mylohyoid muscle, permitting the film to be positioned farther apically.
3. The handle of the hemostat is a guide to align the cone in the proper vertical and horizontal angulation (Figure 9A-6).
4. There is less risk of distortion of the radiograph caused by too much finger pressure bending the film.
5. Patients can hold a hemostat handle more securely with less possibility of film displacement.
6. Any movement can be detected by the shift of the handles and corrected before exposure.

The *identifying dimple* is always placed at the incisal or occlusal edge to prevent its obscuring an important apical structure.

Cone Positioning

It is often a mistake to rely on only one film. Additional exposures taken from varied horizontal or vertical projections give better visualization of the third dimension (Figure 9A-7).

Vertical Angulation

Ordinarily, it is preferable to align the cone so the beam strikes the film at a right angle. This alignment ensures a fairly accurate vertical image. Elongation of an image, however, *may be corrected by increasing the vertical angle* of the

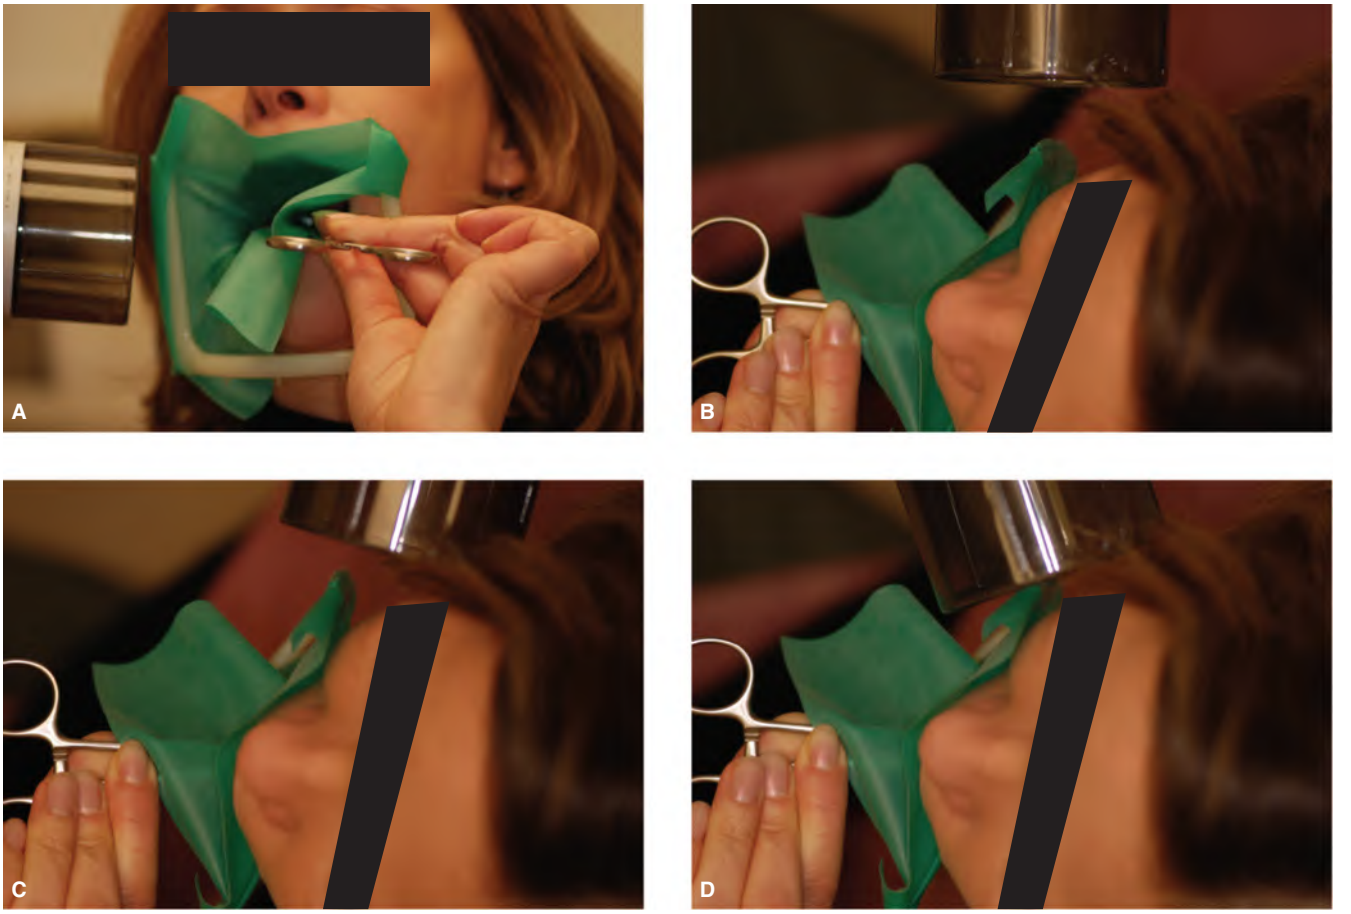

FIGURE 9A-7 "Working" film properly placed and held under dental dam with hemostat. ***A.*** Vertical angle. Cone is aligned so that central beam is parallel with the handle. ***B.*** Cone is aligned at right angle to handle and film. ***C.*** Varying horizontal angle to the distal 20–25°. Vertical angle is maintained. ***D.*** Cone is shifted 20–25° to the mesial.

central ray. Conversely, *foreshortening is corrected by decreasing* the vertical angle of the central ray.

Frequently, an impinging palatal vault prevents parallel alignment of the film and the teeth. However, if the film angle is no greater than 20° in relation to the long axis of the teeth, and the beam is directed at a right angle to the film, no distortion occurs, although there is a less effective orientation of structures.[26] The resulting radiograph is still adequate.

Vertical angulations are divided into positive (+) and negative (-) angles depending on the X-ray beam direction in reference to the horizontal plane. A positive (+) angle indicates the downward direction of the beam, while a negative angle (-) refers to an upward beam direction.

Horizontal Angulation

Walton[27] introduced an important refinement in dental radiography that has materially improved the endodontic interpretive film. He demonstrated a simple technique whereby the *third dimension* may be readily visualized. Specifically, the anatomy of superimposed structures, the roots and pulp canals, may be better defined. The horizontal plane of the buccal surfaces of the teeth determines the horizontal angulation.

The basic technique is to vary the *horizontal angulation* of the central ray of the X-ray beam. By this method, overlying canals may be separated, and by applying Clark's rule,[28] the separate canals may then be identified. Clark's rule states that "the most distant object from the cone (lingual/palatal) moves toward the direction of the cone." Stated in another way, using a helpful mnemonic, Clark's rule has been referred to as the Same Lingual, Opposite Buccal (SLOB) rule: the object that moves in the ***S***ame direction as the cone is located toward the Lingual. The object that moves in the Opposite direction from the cone is located toward the Buccal. The SLOB rule, simply stated, is "The lingual object follows the tube head." Goerig and Neaverth[29] applied the SLOB rule to determine, from a single film, from which direction a radiograph was taken: mesial, straight on, or distal. By knowing the direction, the lingual is differentiated from the buccal (Figure 9A-8). Stated more simply, Ingle's rule is *MBD*: If "shot" from the Mesial, the Buccal root will be to the Distal.

Horizontal Cone Angulations

For working and/or interpretive diagnostic radiographs, the following cone angles are preferred:

1. Maxillary anterior teeth (straight facial).
2. Maxillary premolars and molars (mesial angle).

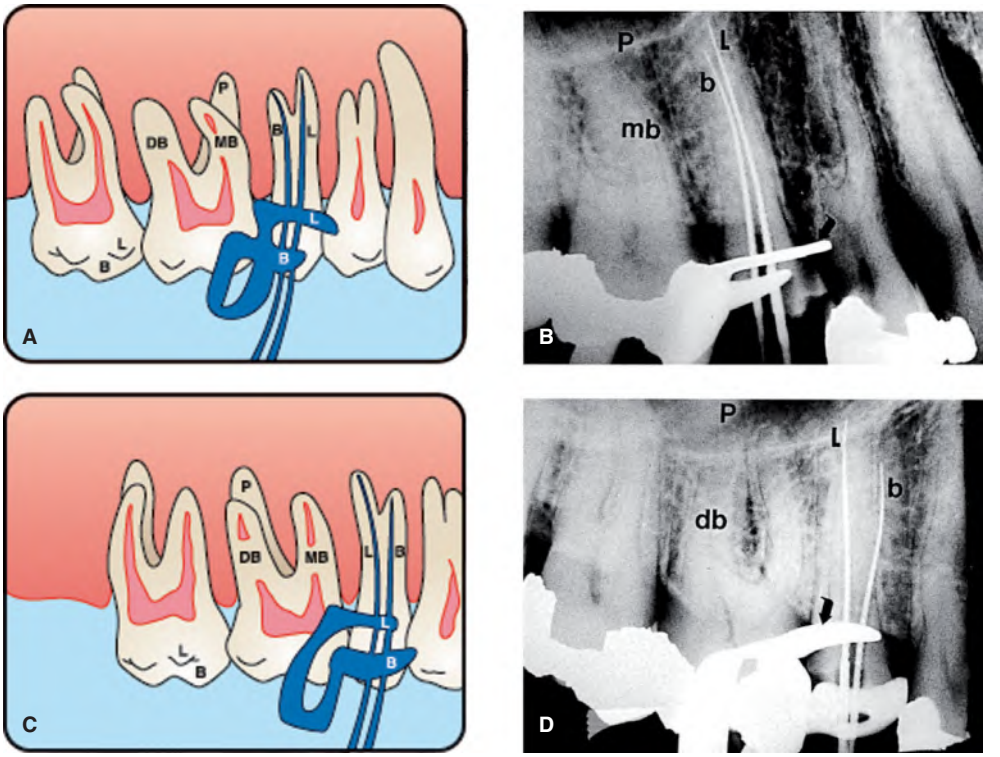

FIGURE 9A-8 Applying the Same Lingual, Opposite Buccal (SLOB) rule to determine the cone angle. ***A & B.*** Clues that the cone is oriented from the mesial. The mesial–buccal (MB) root lies over the palatal (P) root, that is, the lingual (palatal) root has moved mesially; the lingual arm of the dental dam clamp (arrow) has moved mesially. The canine is visible. Once it has been determined that the radiograph was taken from the mesial, the lingual root (toward the mesial) of the premolar is defined. ***C & D.*** Radiograph of the same teeth taken from the distal. Clues are reversed. The canine is not visible. The lingual premolar canal is now toward the distal. (Reproduced with permission from Goerig AC. In: Besner E, Michanowicz A, Michanowicz J. editors. *Practical Endodontics*. Mosby, St. Louis, MO, 1993; p. 54).

3. Mandibular incisor teeth (distal angle).
4. Mandibular canines (mesial angle).
5. Mandibular premolars (mesial).
6. Mandibular molars (distal).

A helpful mnemonic for the working mandibular angulations: MDDM.

All teeth require specific film placement and cone positioning for working films (Figure 9A-9).

Mandibular Molars

As previously emphasized, the film must be positioned parallel to the lower arch. The *standard* horizontal X-ray projection then is at a right angle to the film (perpendicular), as shown in Figure 9A-10. The two mesial canals are superimposed one upon the other and appear as a single line.

Through the *Walton projection (SLOB)*, however, the roots will "open up." This is done by directing the central beam 20° to 30° from either the distal or the mesial (Figure 9A-11A). In Figure 9A-11B (black arrows), the two canals in each root can now be readily discerned. The contrast gained by varying the horizontal projection is seen in a clinical case with four canals (Figure 9A-1). Figure 9A-1A taken at a right angle clearly shows the four instruments superimposed on one another. Figure 9A-1B, on the other hand, made from a 30° variance in horizontal projection, emphasizes the third dimension: the separation of the instruments in the canals. By applying Ingle's rule (MBD: project the central beam from the *mesial*), the *buccal* canals are toward the *distal*, the *lingual* canals toward the *mesial*.

Another point concerns a frequent mistake in "reading" periapical radiographs. It can best be illustrated by cross-sectional drawings of molar root structure (Figure 9A-12). Roots containing two canals are often hourglass shaped. When an X-ray beam passes directly through this structure (center image), the buccal and lingual portions of the root are in the same path (arrows). These will change with distal and mesial projection. Because a double thickness of tooth structure is penetrated by the X-rays, it is seen in the film as a radiopaque root outline in close contact with the *lamina dura*. This is readily apparent on the radiograph (Figure 9A-13).

By aiming the cone 20° from the mesial, however, the central beam passes through the hourglass-shaped root at an angle (Figure 9A-14). In this case, the two thicknesses of the root are projected separately onto the film. Because less tooth structure is penetrated by the X-ray, the image on the film is less dense. A radiolucent line is clearly seen (open arrow). This radiolucent line can be erroneously interpreted as a canal. By following up the length of the line, instead of

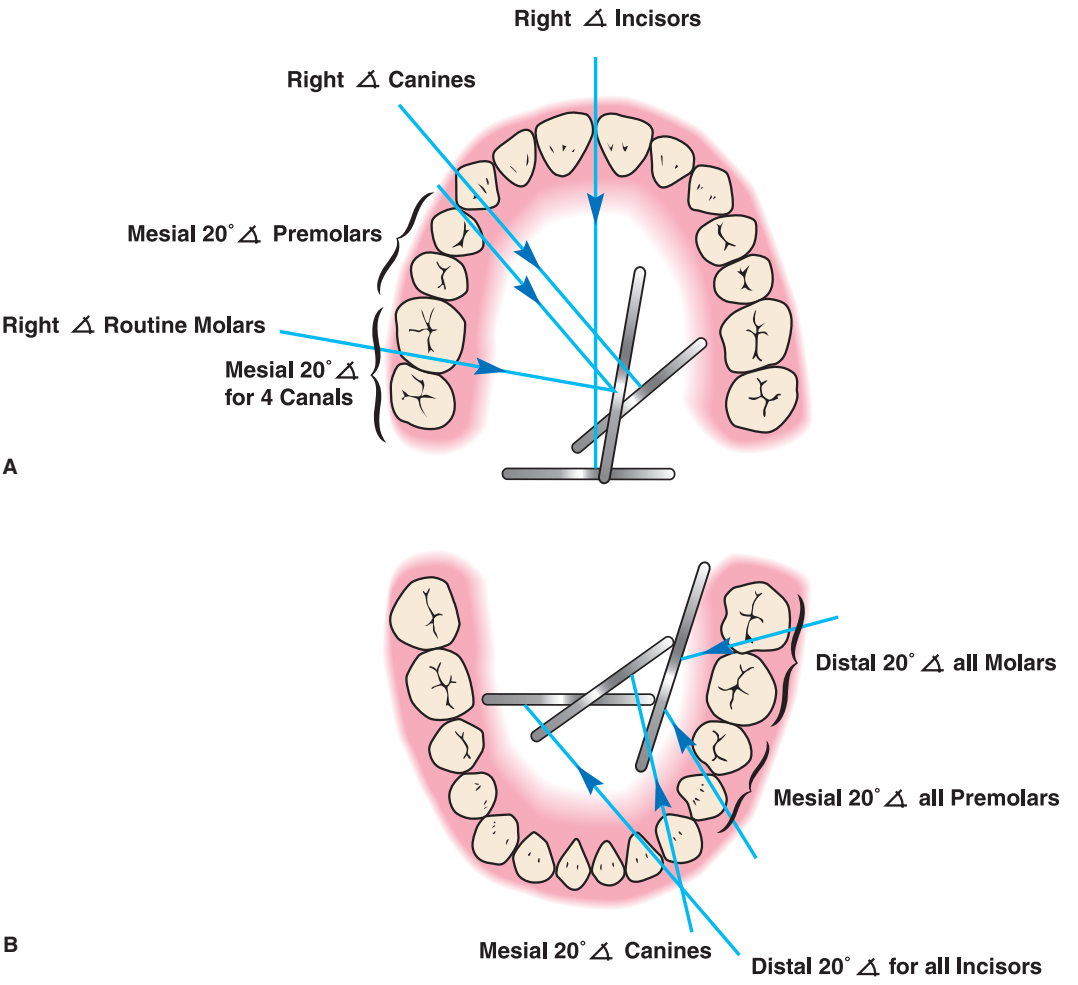

FIGURE 9A-9 ***A.*** Maxillary film/central beam (arrows) position. ***B.*** Mandibular film/central beam position (arrows). (Reproduced from Torabinejad M, Walton R. *Endodontics: Principles and Practice*, 5th ed. Philadelphia, PA: Saunders and Co., 2015, pp. 214–215).

entering the pulp chamber, the line can be traced to the gingival surface of the root; this is the PDL space. This simple interpretive error can easily lead to gross mistakes.

Mandibular Premolars

The importance of varying the horizontal angulation when radiographing mandibular premolars is demonstrated in Figure 9A-15A. The central beam is directed at a right angle to the film. What appears to be a single straight canal is discernible in each premolar (Figure 9A-15B). There is an indication, however, in the image of the first premolar that the canal might bifurcate at the point of the abrupt change ("fast break") in density (arrow).

Directing the central ray 20° from the mesial in the *first premolar* (Figure 9A-16A) causes the bifurcation to separate into two canals (Figure 9A-16B). The tapering outline of the tooth, seen in both projections, would indicate, on the other hand, that the two canals undoubtedly rejoin to form a common

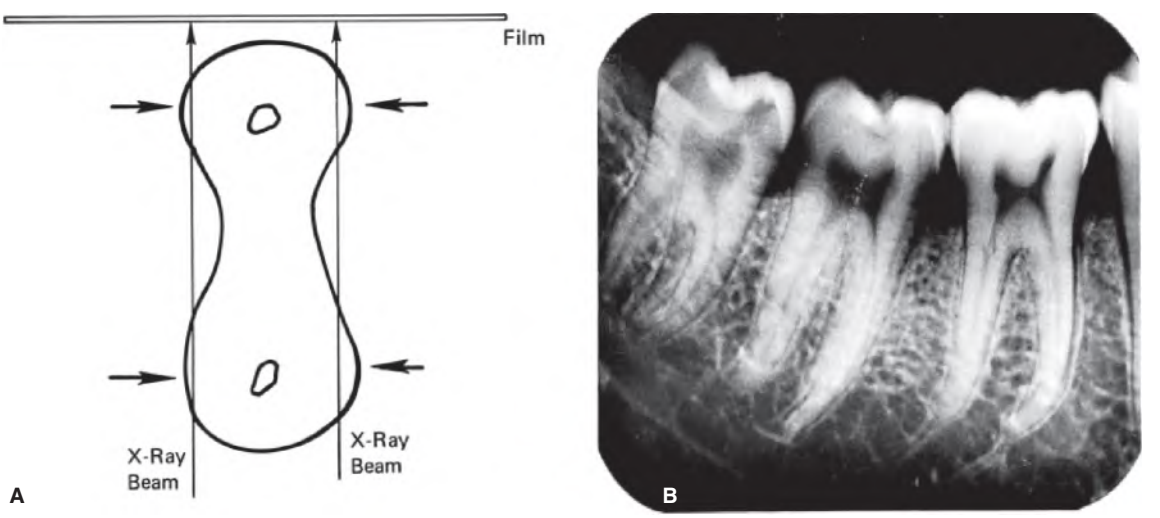

FIGURE 9A-13 X-ray beam passing directly through two thicknesses of root structure presents intensified image on film. Note radiopaque root outline inside lamina dura. (Reproduced with permission from Walton RE.[27])

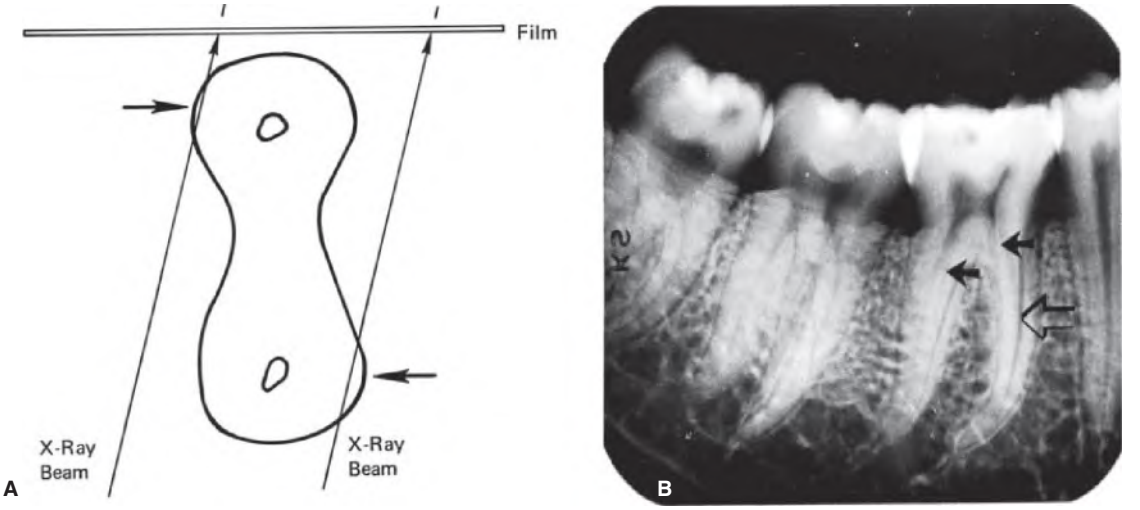

FIGURE 9A-14 X-ray beam aimed 20° passes through single thicknesses of hourglass root, leaving less dense impression on film. Radiolucent line is apparent (open arrow) and may be confused with root canal. Note that it emerges at gingival, not into pulp chamber. Black arrows indicate regular canals. (Reproduced with permission of Walton RE.[27])

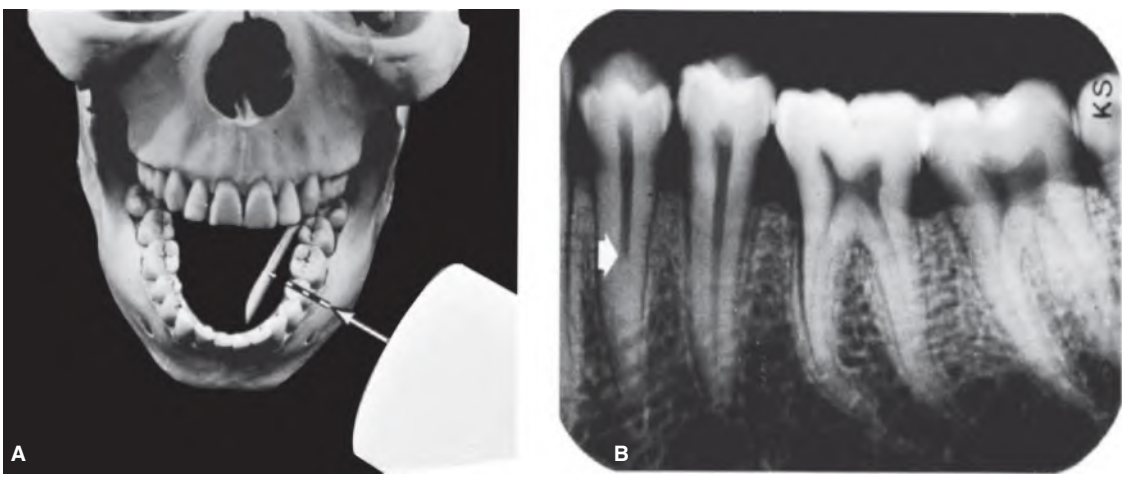

FIGURE 9A-15 Mandibular premolars. ***A.*** Central ray directed at right angle to film positioned parallel to arch. ***B.*** Radiograph reveals one canal in each premolar, although abrupt change in density (*arrow*) may indicate bifurcation. (Reproduced with permission from Walton RE.[27])

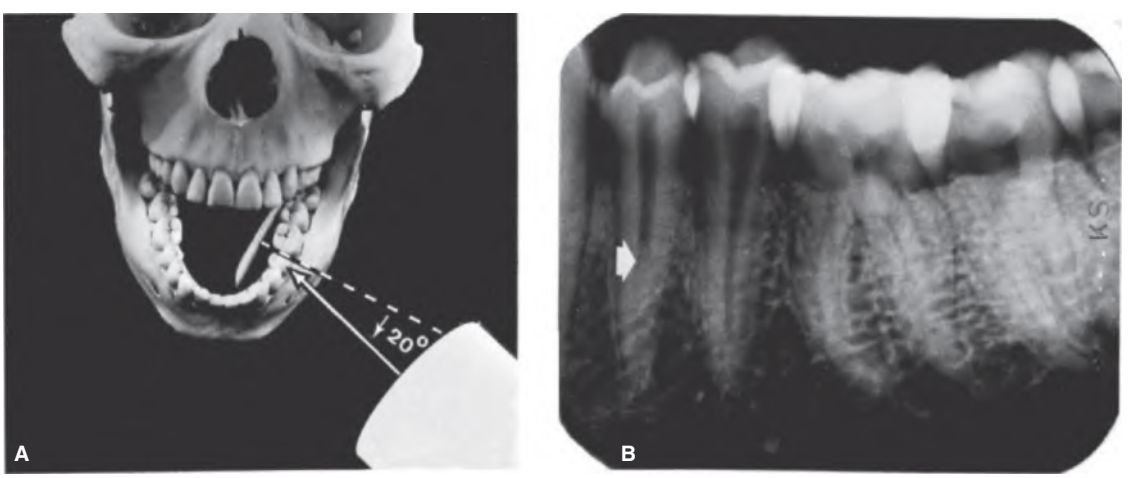

FIGURE 9A-16 Mandibular premolars. ***A.*** Central ray directed at 20° mesially to film, parallel to arch. ***B.*** In first premolar, two canals that are clearly visible (*arrow*) probably reunite, as indicated by sharply tapered root. (Reproduced with permission from Walton RE.[27])

canal at the apex. In both the right-angle and 20° variance projections, the *second premolar* appears as a single canal.

Maxillary Molars

Maxillary molars are consistently the most difficult to radiograph because of (1) their more complicated root and pulp anatomy, (2) the frequent superimposition of portions of the roots on each other, (3) the superimposition of bony structures (sinus floor, zygomatic process) on root structures, and (4) the shape and depth of the palate. Each of these, singly or in combination, can be a major impediment.

As is true of the mandible, the complex root anatomy and superimpositions may be dealt with *by varying the horizontal* angulations. Film placement must be parallel to the median raphe, not to the posterior maxillary arch.

The standard right-angle projection for a maxillary first molar, illustrated in Figure 9A-17A, produces the image seen in Figure 9A-17B, wherein the zygomatic process is superimposed on the apex of the palatal root (arrow) and the distobuccal root appears to overlie the palatal root. The sinus floor is also superimposed on the apices of both the first and second molars. When the horizontal angulation is varied by 20° to the mesial (Figure 9A-18A), the zygomatic process is "moved" to the distal of the first molar and the distobuccal root is cleared of the palatal root (Figure 9A-18B, arrows). The mesial projection also better "opens" the mesiobuccal root to demonstrate both canals.

The *opposite projection* can also be used to isolate the mesiobuccal root of the first molar, that is, the central ray may be projected from *20° distal* to the right angle (Figure 9A-19A). Although this projection distorts the shape of the mesiobuccal root, it also isolates it (Figure 9A-19B), so that the canal is readily discernible (arrow). In addition, the zygomatic process is moved completely away from any root structure, including the second molar. The same technique illustrated here for the maxillary first molar can be applied to

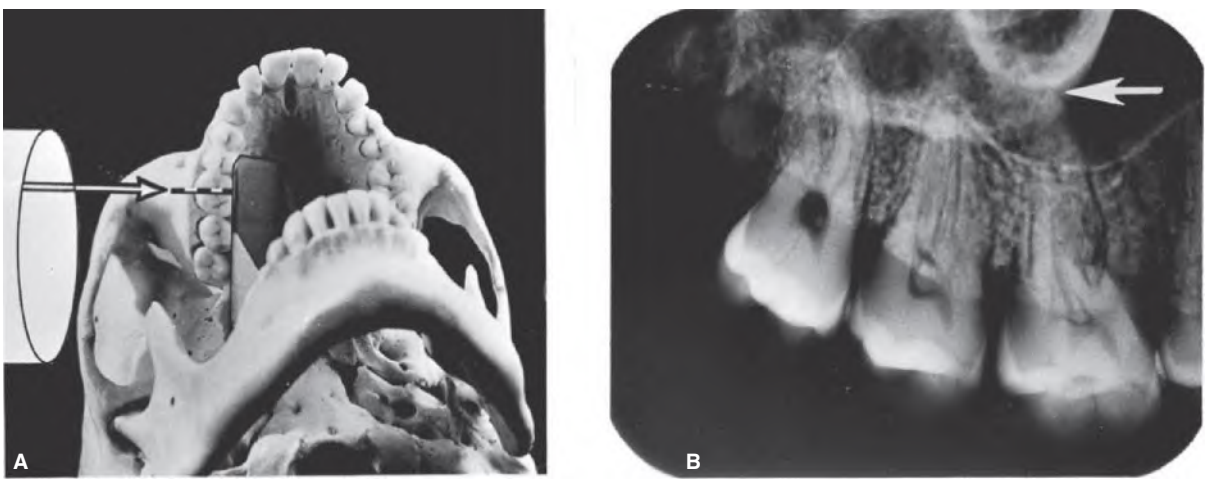

FIGURE 9A-17 Maxillary molars. ***A.*** Central ray is directed through maxillary molar at right angle to inferior border of film. Arrow and dotted line passing through malar process indicate it will superimpose over first molar. ***B.*** Superimposition of first molar roots, sinus floor, and malar process (white arrow) confuse the diagnosis. (Reproduced with permission from Walton RE.[27])

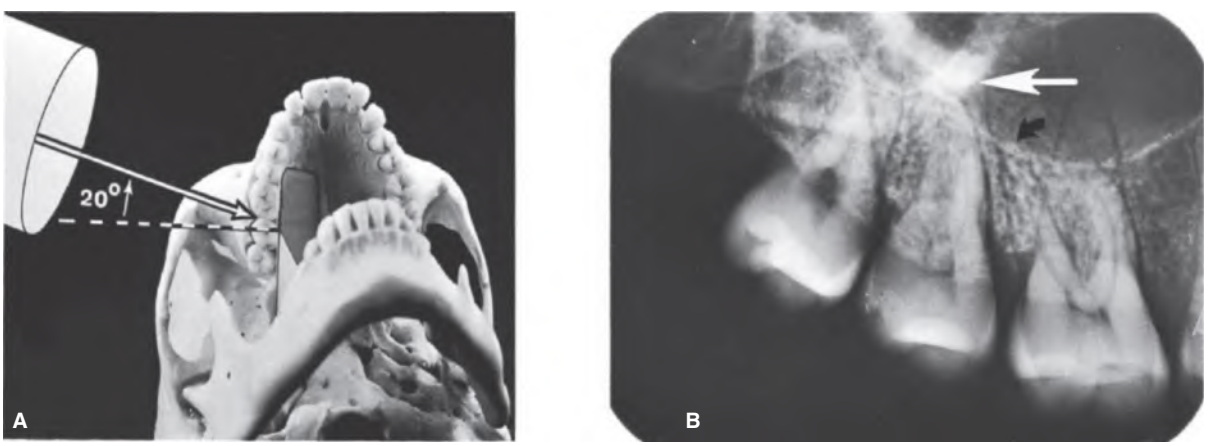

FIGURE 9A-18 Maxillary molars. ***A.*** Central ray directed at 20° mesially skirts malar process, projecting it distally. ***B.*** Distobuccal root is cleared of palatal root and malar process is projected far distally (white arrow). Between right angle and 20° projection, all three roots are clearly seen. (Reproduced with permission from Walton RE.[27])

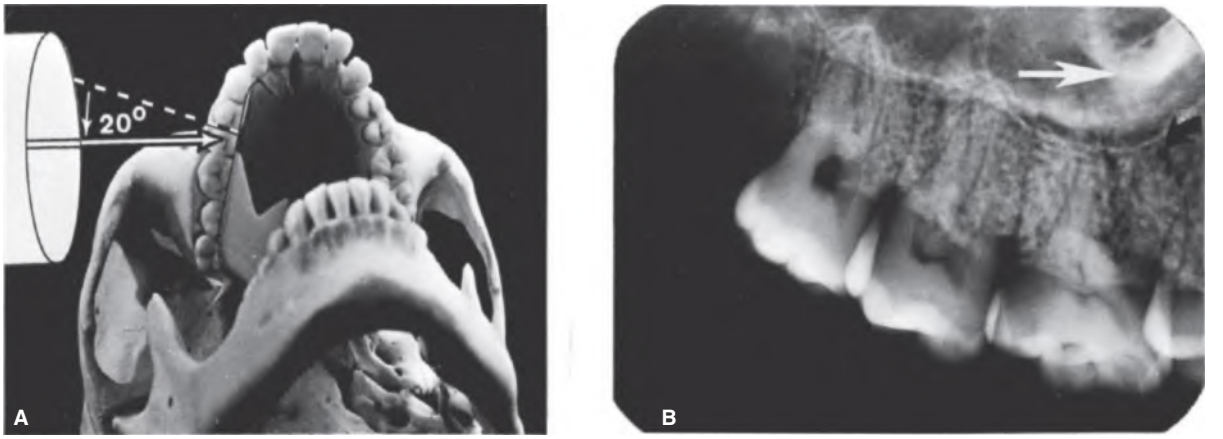

FIGURE 9A-19 Maxillary molars. ***A.*** Central beam projected 20° from the distal. ***B.*** Mesiobuccal root of the first molar is isolated (*black arrow*) and second and third molars are cleared of malar process, that is projected forward (*white arrow*). Sinus floor may be "lowered" or "raised" by changing vertical angulation. (Reproduced with permission from Walton RE.[27])

the second or third molars by directing the central beam at a horizontal variance through those teeth.

Maxillary Premolars

Variance in the horizontal projection has great value in maxillary premolar radiography, particularly for the *first* premolar, that generally has two roots and canals, but sometimes three. The clinical efficacy of the Walton (SLOB) technique is well illustrated in Figure 9A-20. The right-angle horizontal projection produces the single canal image seen in Figure 9A-20A. By varying the angulation by 20°, however, the two canals are separated (Figure 9A-20B), giving an unobstructed view of the obturation quality in both canals.

Mandibular Anterior Teeth

Aberrations in canal anatomy in the *mandibular* anterior teeth are not uncommon. Variance of the horizontal X-ray projections in this region will bring out the differences. Figure 9A-21A illustrates the standard X-ray projection bisecting the film held parallel to the arch. The incisor teeth appear to have single canals. However, a deep single canal is seen in the distorted canine image (Figure 9A-21B).

By varying the film placement and projecting directly through the canine, as seen in Figure 9A-22A (about 30° variance for the incisors), separate canals appear in the incisors (Figure 9A-22B, arrow); the canals join at the apex. This would be expected. However, when viewing the tapered incisor roots seen in both horizontal projections, the roots are far too narrow to support two separate canals and foramina. Once again, the abrupt change in canal radiodensity in the premolars (arrow) indicates a canal bifurcation.

Maxillary Anterior Teeth

Although canal or root aberrations appear less frequently in the maxillary anterior teeth, root curvature in the maxillary lateral incisors is a particularly vexing problem. Grady and Clausen[30] have shown, for example, how difficult it is to determine when foramina exit to the labial or lingual. Their radiographs of extracted teeth matched with photographs of instrument perforation short of the apex are a warning to all (Figure 9A-23).

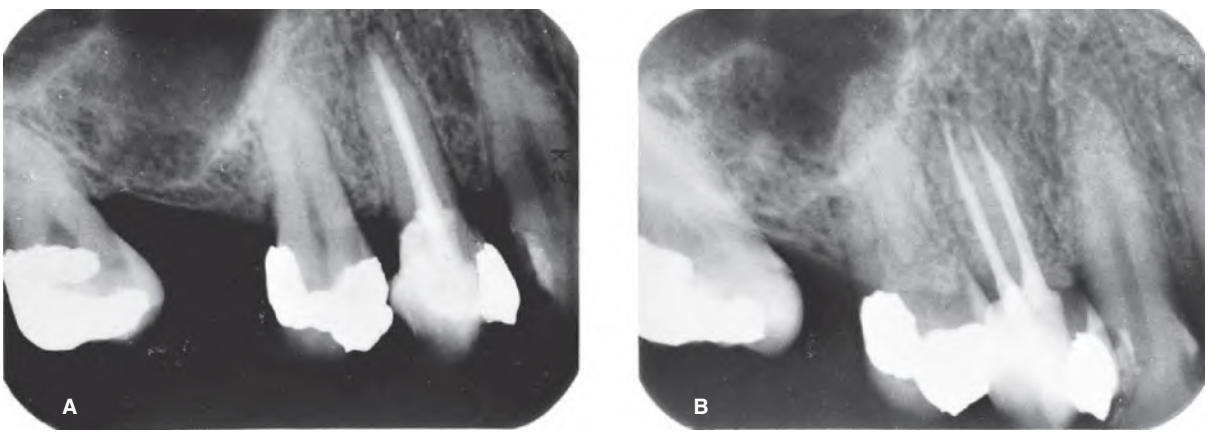

FIGURE 9A-20 Maxillary premolars. ***A.*** Horizontal right-angled projection produces illusion that that maxillary first premolar has only one canal. ***B.*** Varying horizontal projection by 20° from the mesial separates two canals. Buccal canal is distal (MBD). (Reproduced with permission from Walton RE.[27])

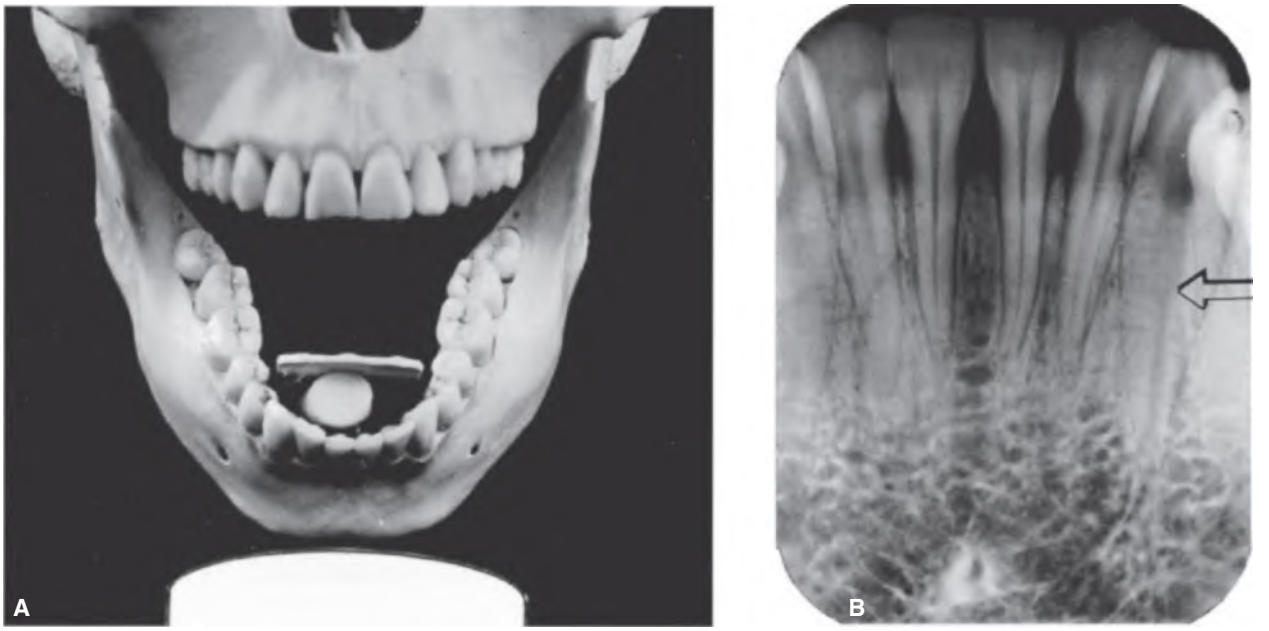

FIGURE 9A-21 Mandibular anterior teeth. ***A.*** Film placement for modified parallel technique. Horizontal central beam projection at right angle to film. ***B.*** Single canals seen in central incisors with only suggestion of two canals in lateral incisor. In distorted image of canine, note deep labiolingual canal dimension (arrow). (Reproduced with permission from Walton RE.[27])

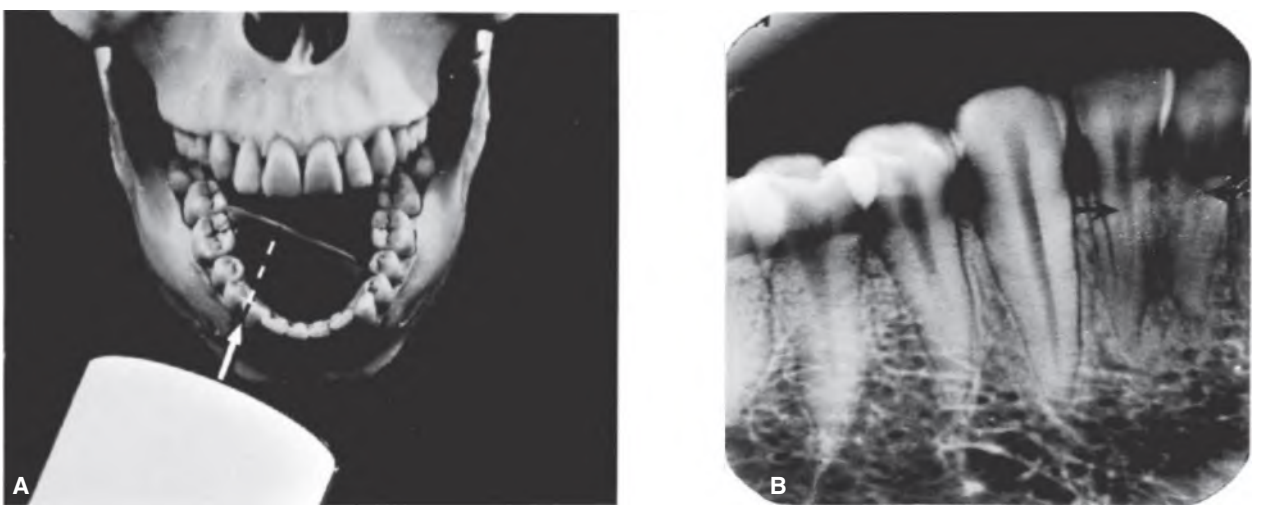

FIGURE 9A-22 Mandibular canine. ***A.*** Film is positioned for canine radiograph. Horizontally, central beam is projected at right angle to the film. ***B.*** Canine image is single straight canal, but incisor image reveals bifurcated canals that reunite in narrow tapered root (arrows). Note "bonus" image of bifurcated canals on first premolar. (Reproduced with permission from Walton RE.[27])

Extraoral Film Placement

This is useful for patients who cannot accommodate or tolerate intraoral film placement, usually because of gagging or trismus. Acceptable diagnostic and working films are possible.[31] This requires special positioning of cone and film (Figure 9A-24).

Processing

Another deterrent has been the length of time required to process films. Old, weakened solutions greatly increase the time required for processing. Moreover, adherence to the manufacturer's recommended temperature and time (68°F for five to seven minutes) for developing and clearing has hampered "on-the-spot" processing and viewing.

Ingle et al.[32] demonstrated, in a well-controlled blind study, the effects of varied processing temperatures. A processing temperature of 92°F yielded, in less than one minute, the most acceptable radiographs. At 92°F, using Kodak developer and fixer mixed to company specifications, *development required only 30 seconds* and fixation required 25 to 35 seconds, with no loss of quality. By comparison, at 70°F temperature, it required 5 minutes' developing time and 10 minutes' fixing time for Ultraspeed film. Ektaspeed is slightly better: 72 to 80°F for 2 1/2 to 4 minutes' developing and 2 to 4 minutes' fixing time. All films need to be *final washed* for at least 30 minutes.

For rapid processing, small quart-size tanks are adequate and economical. Frequent change in solutions is recommended.

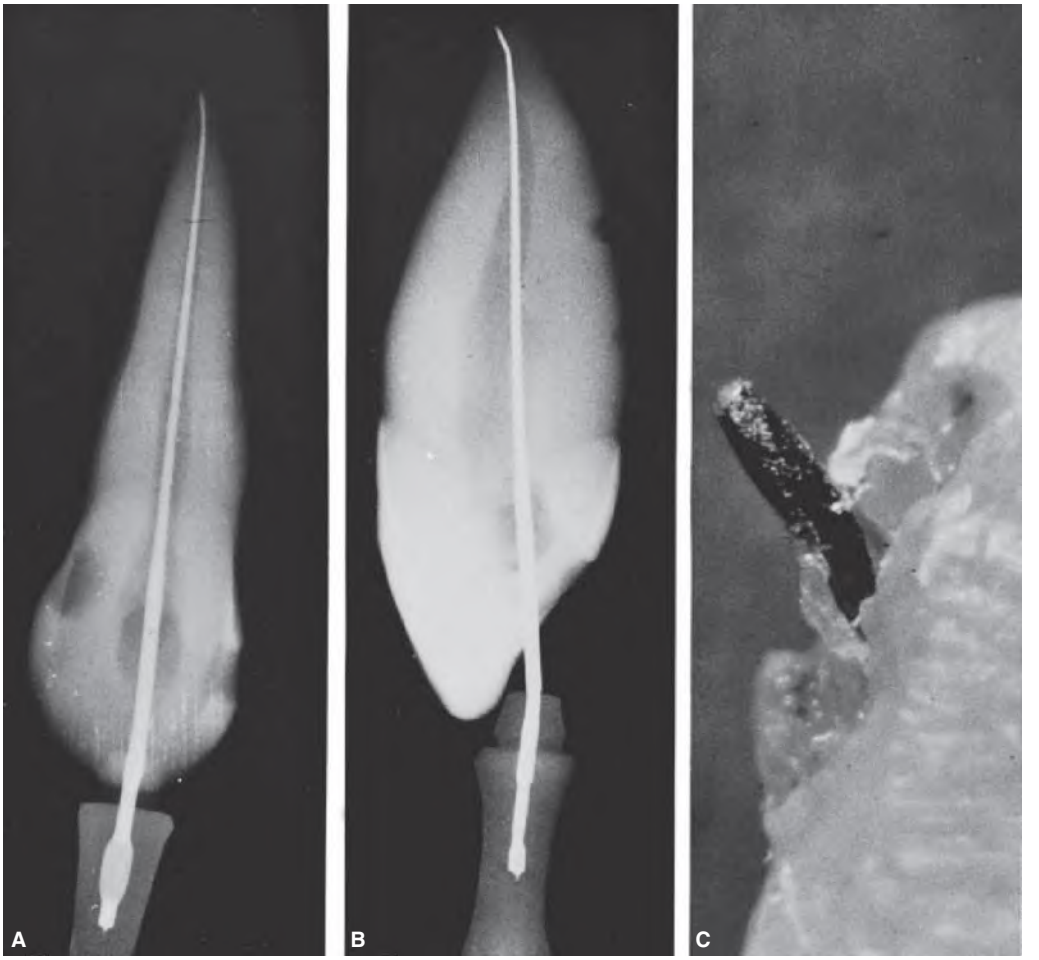

FIGURE 9A-23 ***A.*** Labiolingual projection through canine shows instrument apparently at apex with slight distal curvature. ***B.*** Mesiodistal projection reveals instrument actually emerging from the labial, short of apex. ***C.*** Instrument perforating foramen to labial well short of radiographic root end. FIGURE 9A-24 Extraoral film placement. Useful for patients who cannot accommodate or tolerate an intraoral film. The film or sensor is placed on the cheek. Increasing the exposure time is necessary—approximately double. ***A.*** Maxillary posterior: The cone is positioned a negative 45° to the occlusal plane. ***B.*** Mandibular posterior: The cone is positioned a negative 35°.

Rapid-Processing Solutions

Concentrated chemicals, such as *Kodak's Rapid Access* developing and fixing solutions, have become very popular in endodontic practice. Although more expensive, they save measurable time, requiring only 15 seconds' developing and 15 seconds' clearing time in the fixer at room temperature.[33] These rapidly processed films will fade or discolor with time.[34] This change can be prevented, after viewing, by returning the wet film for a few minutes of fixation, followed by washing for 30 minutes, and then drying. The films will then retain their quality indefinitely.

TABLE-TOP DEVELOPING

For quick turnaround and ease of processing, combining rapid-speed solutions with a *table-top processing hood* greatly improves radiographic reporting, particularly working films. These hoods are often used right in the operatory. The film is passed through light-proof cuffs; hand movement is seen through the red Plexiglas cover. The rapid solutions and rinse water can be in small cups.

Chapter 9B

Digital Radiography

Allan G. Farman, Martin D. Levin, Ramya Ramamurthy, Lars G. Hollender

Many acronyms have come about as a result of the development of technology in radiography and the need for terms to describe concepts. The following glossary of the acronyms used in this chapter will assist the reader in understanding these new concepts.

GLOSSARY OF ACRONYMS

AEC: Automatic Exposure Compensation is an enhancement feature that compensates for image variations due to exposure.

ALARA: Acronym for "As Low As Reasonably Achievable," an important principle in radiation protection.

CBCT: Cone-Beam Computed Tomography is a 3-D imaging device that integrates a series of transmission images generally taken over an arc of 180° or greater.

CBVCT: Cone-Beam Volumetric Computed Tomography (synonym of CBCT).

CCD: A Charge-Coupled Device is an image sensor consisting of an integrated circuit containing an array of linked or coupled, energy-sensitive capacitors.

CDR: Computed Dental Radiography. Digital intraoral sensor manufactured by Schick Technologies (A Division of Sirona AG).

CMOS: Complementary Metal–Oxide–Semiconductor. This represents a major class of integrated circuits including image sensors.

CMOS-APS: CMOS Active Pixel System.

DICOM: Digital Imaging and Communication in Medicine. The internationally referenced standard for improving the likelihood of interoperability of diagnostic images by setting file format standards and transmission protocols.

dpi: Dots per inch.

H&D: Hurter and Driffield. Descriptor applied to a curve relating optical density to exposure for film photography and radiography.

IP: Imaging Plate. The sensor plate used for photostimulable phosphor (PSP) imaging.

ISO: International Standards Organization.

MB2: For maxillary molar, mesiobuccal root second canal.

PSP: PhotoStimulable Phosphor. An imaging system using IPs that store energy from transmitted X-rays. The PSP IP is processed using laser scanning.

RVG: RadioVisioGraphy. Radiographic system proprietary to Kodak Dental Imaging: Term applied to the first commercial dental digital detector.

SNR: Signal-to-Noise Ratio.

TACT: Tuned Aperture Computed Tomography. A system developed by Richard Webber that integrates a series of transmission images taken from varying beam geometry to tomosynthesize a limited 3D perception.

Radiography is an important adjunct to endodontic diagnosis and image-guided treatment. The use of digital technologies can facilitate the process by speeding image acquisition and display. The invention of digital intraoral radiography has "endodontic roots." In the 1970s, Mouyen, then a dental student at the University of Toulouse, France, tells the story that because the distance between the endodontic clinic and the film processors several floors below spurred the idea of finding a way to create instant X-ray images for "operative" purposes. Mouyen realized that the chip in his video camera could detect light and that X-rays could be converted to light by scintillators such as the screens used in extraoral radiography cassettes. In other words, almost 90 years after the discovery of the X-ray, available technology could indeed permit the placement of a "fluoroscope" in the patient's mouth.

A few years following graduation as a dentist, Mouyen completed the DERSO, a French equivalent to the PhD in engineering, and went on to develop a prototype digital radiographic system that he named RadioVisioGraphy (RVG).[1] The RVG patent was licensed by a French Company, Trophy Radiologie, and digital imaging for operative radiology in dentistry was born (Figure 9B-1). In 1989, in a special issue of the "National Geographic" magazine, celebrating the bicentennial of the French Revolution, the RVG was included among 10 major French inventions, alongside such inventions as the Train Grand Vitesse (TVG), the Concorde, and the Arienne space rocket. Trophy Radiologie was acquired by Kodak Dental Imaging, and Kodak Dental Imaging was subsequently acquired by Carestream Dental.

Since 1989, there have been eight new generations of RVG, and there are now many alternate solid-state systems (Figure 9B-2) that can produce almost instant images electronically. Although these images are essentially "instant," most are not "direct" as the solid-state systems, for the most part, employ a scintillator to convert X-rays to light, and it is the analog light signal that is then converted to a digital image.

Furthermore, it is possible to replace silver halide film by photostimulable phosphor (PSP) plates that interact directly with X-rays but require the added step of subsequent processing by laser scanning to convert the latent image to one that can be viewed on a computer monitor screen.

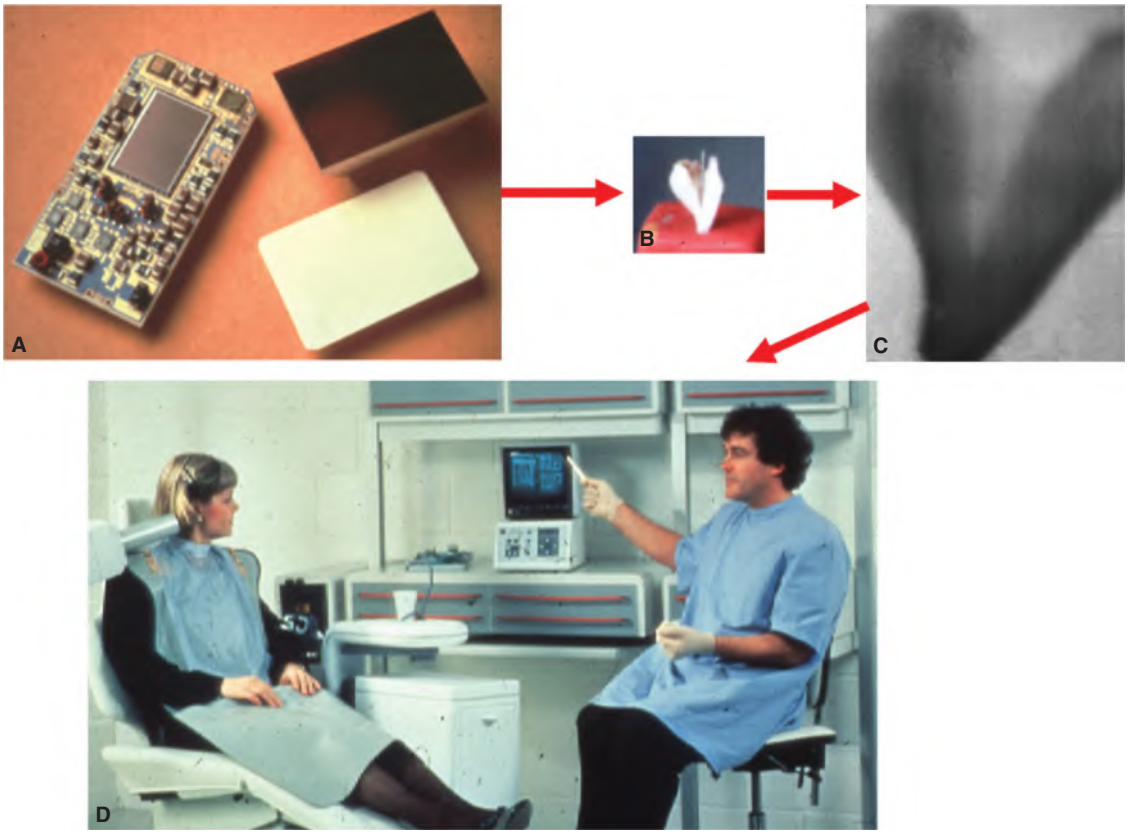

FIGURE 9B-1 ***A.*** components of the RadioVisioGraphy (RVG)-32000 showing the solid-state electronics board with charge-coupled device (CCD) chip, the scintillator, and the fiber-optic plate used to reduce the size of the image to the size of the CCD. The fiber optics were made of tungsten glass that protected the CCD from direct exposure to X-rays; ***B.*** Primary tooth of Mouyen's daughter; ***C.*** The first "clinical" RVG image achieved in Dr. Mouyen's living room of this tooth; ***D.*** Commercial version of the RVG with Mouyen himself in the blue gown.

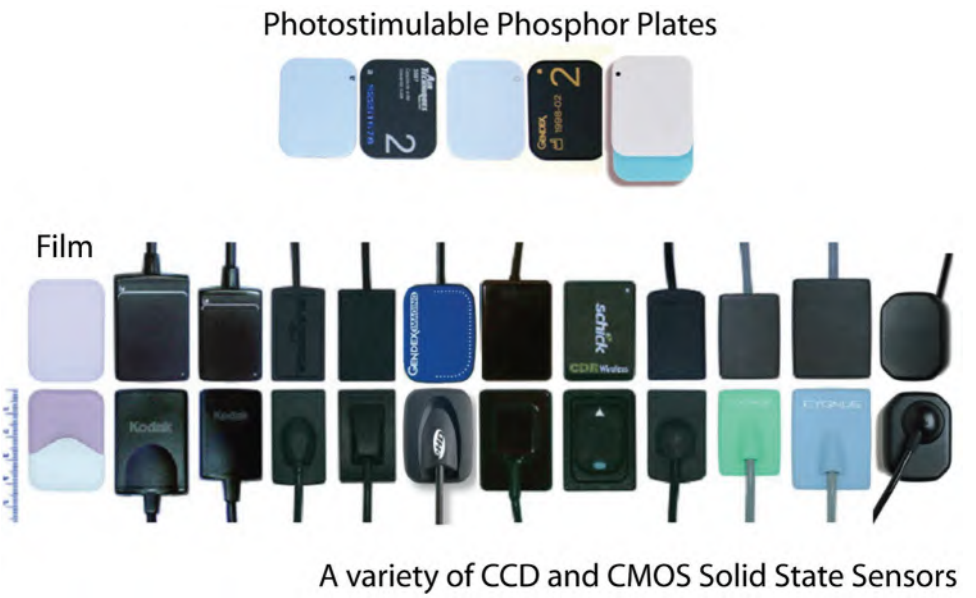

FIGURE 9B-2 Demonstration of the diversity of available intraoral X-ray sensors.

DIGITAL INTRAORAL X-RAY IMAGING OPTIONS

Digitization Using Secondary Capture of Analog Film Images

2-D Imaging

Conventional X-ray films consist of a polyester sheet covered on both sides by a thin layer of silver halide emulsion that absorbs X-ray photons resulting in a latent image. When the latent image is developed using developing chemicals, the silver halide crystals are converted into metallic silver (silver is not black but gives such an impression in granular from within the processed radiograph). The unexposed crystals are later removed from the emulsion during the fixing process. This procedure, including the unpacking of the film in a light safe environment, usually takes several minutes and can produce a visible image of high diagnostic quality even when automatic processing is utilized, as long as optimal procedures are employed. Unfortunately, optimal procedures are not always employed in dental practices. To digitize the analog film image adds another time-consuming step, and the extra step also leads to the possibility of impaired image quality. For more details, see Chapter 9A.

Once a visible film-based image has been produced, it is possible to use a flatbed scanner with a transparency adaptor to digitize the image by secondary capture. Flat bed scanners are preferred over cameras as the latter is more prone to optical distortion and added "noise" from light reflected from the surface of the radiograph film. For scanning, the parameters should be set at high-definition grayscale images and scanned at a minimum of 300 dots per inch (dpi) using a transparency adaptor and acquisition software parameters set to "transparency." Secondary capture images are dependent on the person making the input and associate such information as right versus left, patient name, procedure date, and so forth. This can be subject to "human error."

Conventional X-ray film has survived around 120 years in dental radiography. It obviously is capable of providing useful diagnostic information. However, disadvantages of analog X-ray film include the following:

1. Inefficiency as photon detectors, therefore requiring a relatively high radiation exposure.
2. Film packet is thin and can be felt by the patient to "cut into the tissues."
3. Film is not rigid and hence can bend resulting in a distorted radiographic image.
4. Produce static images with no availability of post-image treatments other than varying the brightness of the viewbox illumination.
5. Exposure errors and suboptimal processing conditions can result in poor image quality that is not immediately obvious.
6. Film processing is relatively time consuming.
7. Costs for maintaining a darkroom.
8. Silver in spent processing chemicals has the potential to cause environmental pollution.
9. Duplicate radiograph in a double film packet is of very slightly lower density compared with the top film. Physicochemical duplication of film radiographs results in copies of higher contrast and less detail.
10. Archiving radiographic film radiographs in physical patient files requires extra storage space in the office. Retrieving radiographs can take time.
11. Intraoral film radiographs not appropriately mounted and labeled cannot in themselves be associated for certainty with a given patient or time of exposure. Although one cannot exclude the possibility that digital radiographs may be attributed to the wrong patient, the use of a Digital Imaging and Communications in Medicine (DICOM) file format that is appropriately populated makes this less likely to occur.

DIGITAL RADIOGRAPHY

Figure 9B-2 represents some choices in intraoral digital X-ray systems for dentistry. Several of these systems may share an identical detector; however, they generally differ in electronics and the application software supplied. There is increasing acceptance of filmless X-ray alternatives in dentistry. As of 2015, at least half of the dentists in the United States were using digital X-ray detectors. This represented a fivefold increased penetration of the technology over the past few years. The adoption of digital imaging technologies by endodontists is undoubtedly much greater than is the case for general dental practice. With the continuous addition of improvements and sophistications in the already existing digital systems and introduction of new systems, the diagnostic quality of digital intraoral systems is now generally considered equal to conventional X-ray film even for tasks where film is known to do well such as in endodontic assessment and detection of proximal dental caries.[2]

Digital systems utilize computer technology in the capture, display, enhancement, and storage of radiographic images. Computers work on the binary number system consisting of two digits (0 and 1) to represent data. These two characters are called bits (binary digits), and they form "words" of eight or more bits in length called bytes. The total number of possible bytes for 8-bit language is $2^8 = 256$. The analog-to-digital converter transforms analog data to digital data based on binary number system. The strength of the output signal is measured and assigned a number from 0 (black or white depending on designation) to 255 (white or black—opposite of "0") according to the intensity of the electric signal. These numeric assignments translate into 256 shades of gray in an 8-bit system. A digital image consists of a number of pixels (picture elements), and each pixel is represented by a number corresponding to its gray level. The pixel is the smallest picture element of the image, and the resolution of an image is directly related to the pixel size among other factors. Images of 12, 14, or 16 bits will have a greater range of pixel values

and also consume greater memory space of the computer. For instance, a 12-bit image can have a range up to 4096 gray values, and window and level adjustments can permit selection of the gray levels to be displayed on the monitor as the latter is usually restricted to 256 gray levels at one time.

The two major technologies presently used in intraoral digital X-ray systems are as follows:

1. Solid-state detectors (Figures 9B-3 and 9B-4)
   a. Charge-coupled device (CCD)
   b. Complementary metal–oxide–semiconductor (CMOS)

Solid-state detectors, CCD and CMOS can be indirect detectors using a scintillating screen such as cesium iodide or gadolinium oxysulfide, or (less commonly) can use direct conversion of X-ray photons to electrons (e.g., Cadmium–Telluride technology).

2. Storage phosphor detectors (Figures 9B-5 and 9B-6)
   a. PSP

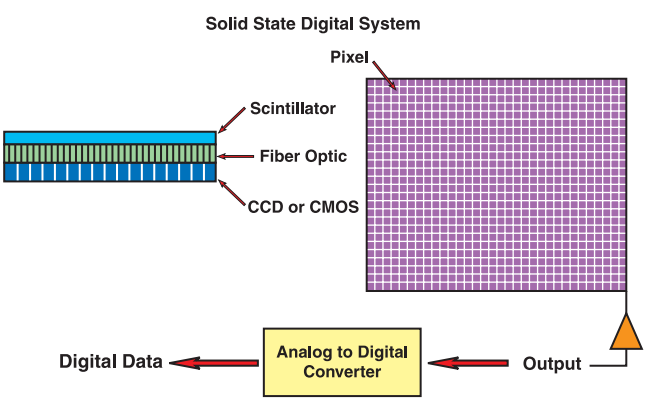

FIGURE 9B-4 Solid-state sensor process. With the charge-coupled device (CCD), the pixel wells are read out in sequence, whereas with the complementary metal–oxide–semiconductor (CMOS), each pixel can be read independently. CMOS sensors are employed more commonly than CCD technology.

FIGURE 9B-5 Example of a photostimulable phosphor (PSP) laser scanner (Scan-X; Air Techniques, Melville, NY, USA). Detail shows loading area for the individual PSPs. Scanners come in a variety of sizes and configurations from the various vendors of this technology.

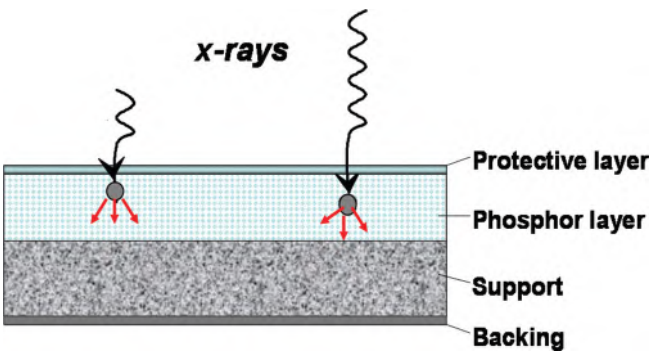

FIGURE 9B-6 The intraoral photostimulable phosphor (PSP) is composed of a phosphor layer, a thin protective layer, support, and backing. X-ray energy is stored during exposure and subsequently released as photoluminescence on application of energy from a scanning laser. The emitted light is photomultiplied and then converted to an electronic signal that is digitized. (Note that this figure is of the PSP during exposure only and represents only a small section of a PSP.)

WORKING PRINCIPLES OF DIGITAL INTRAORAL SYSTEMS[3]

Solid-State Systems

Complementary Metal–Oxide–Semiconductor Active Pixel Technology (CMOS-APS)

CMOS chips are commonly used in digital cameras, video cameras, and computers. Externally, CMOS detectors appear similar to CCDs, but the former use an active pixel technology, that is, each CMOS-APS has an active

transistor built into each pixel and provides a reduction by a factor of up to 100 in the system power (translating into electric voltage) required when compared with CCDs. This has permitted the introduction of wireless radio frequency (RF) transmission of the acquired image. Other advantages of the CMOS-APS include design integration and a potential for relatively low cost manufacture that, however, has not so far translated into cost savings for the consumer. In addition, the APS system eliminates the need for charge transfer between adjacent pixel wells extending the exposure latitude by suppressing "pixel blooming." Most intraoral solid-state digital X-ray sensors now employ CMOS technology. This technology is also used in some panoramic and CBCT systems.

Charge-Coupled Device

The CCD is composed of an electronic circuit embedded in several thin layers of silicon. The silicon chip usually is composed of an array of light sensitive pixels (picture elements), and each pixel consists of a small electron well into which the X-ray or light energy is deposited upon exposure. Each silicon atom in the detector chip is covalent with another silicon atom. When light photons strike the silicon and the energy exceeds the strength of the covalent bond, an electron hole pair is formed. Alternatively, electrons can be produced by a coating layer when direct technology is used instead of a scintillator layer. Either way, an electric charge is established by release of electrons. The electric charge in each "pixel" well is proportional to the incident X-ray or photon energy. Charge coupling is a process by which the electrons from one well are transferred to another in a sequential manner, and this transfer concept has been compared to a "bucket brigade." The charge of each pixel is converted from an analog electric signal representing the energy absorbed by the solid-state chip to a digital signal representing the discrete numeric pixel values for image display on a computer monitor. The CCD is still used in some digital solid-state intraoral and panoramic dental radiography systems, but less frequently now than CMOS technology.

STORAGE PHOSPHOR DETECTORS

Photostimulable Phosphor

The PSP imaging plate (IP) (Figure 9B-7) works on the principle of radiation-induced emission of photostimulated luminance. PSPs generally contain barium fluorohalide crystals with small amounts of bivalent europium atoms as an activator. When a storage phosphor IP is exposed to X-radiation, the europium atoms in the phosphor crystalline lattice are ionized liberating a valence electron. This results in the formation of electron vacancy. The valence electrons are exited to the level of conduction band where they travel freely until trapped by so-called Farbzentren centers present in halide crystals to form metastable electrons with an energy level slightly lower than the conduction band but greater than that of the valence band. These trapped metastable electrons constitute the latent image and their number is proportional to the number of incident X-rays. When the latent image is exposed to the red light of solid-state laser, the metastable electrons are again exited to reach high-energy conduction band where they recombine with Eu^{3+} atoms and return to low-energy valence bond ($Eu^{3+} + e^- = Eu^{2+}$). This results in the liberation of energy, emitted as blue light. The light is registered by a photo multiplier tube and converted into an analog electric output signal that is digitized, resulting in a digital image. Each pixel has a numeric value that is proportional to the amount of light emitted from the corresponding area of the PSP IP.

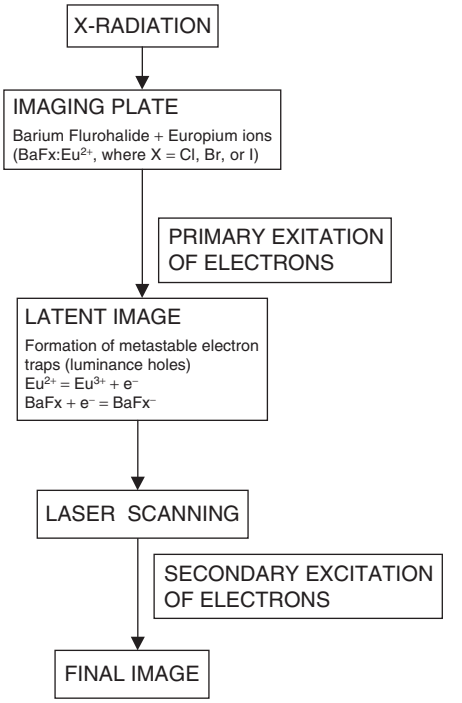

FIGURE 9B-7 Flow diagram to demonstrate the sequence involved in the formation of a photostimulable phosphor (PSP) image.

Advantages of Digital Intraoral X-Ray Imaging

Potential advantages of digital X-ray over analog film imaging include the following:

1. Reduced time between exposure and image formation when using solid-state detectors.
2. Reduced radiation dose per image sometimes possible.
3. Multiple exposures, from various angles, both vertical and horizontal, may be made without moving the sensor once positioned.
4. Elimination of chemical processing and disposal of spent chemicals.

5. Images can be duplicated any number of time without any loss of image quality (each is a perfect clone of the original).
6. Images can be stored and retrieved electronically.
7. Images can be transmitted electronically for referrals and other purposes.
8. Dynamic nature of the image with the ready option of post-imaging enhancements.
9. Digital systems also have measurement tools that, given a suitably positioned fiducial reference (e.g., an endodontic instrument of known length placed in a root canal), can accurately measure, for example, the root canal working length.
10. Reusable detector reduces expenditure on consumables.
11. With DICOM image file usage, digital images can provide greater security regarding radiographic image integrity and tags include such information as patient name, date of exposure, and laterality.
12. Wired detectors have an advantage when working on special needs patients as the wire makes swallowing or ingesting the detector unlikely.

Potential Disadvantages of Digital Intraoral Imaging over Analog Film

There are also some potentially negative issues that should be considered:

1. Relatively high initial investment cost if the practice has previously sunk costs in film-processing facilities.
2. Issues related to infection control as the intraoral detectors cannot be autoclaved.
3. Solid-state intraoral detectors are somewhat thicker and more rigid (however, this can also be an advantage in preventing disproportionate distortion from film bending).
4. Packaged PSP IPs are thinner than prepackaged analog intraoral X-ray films and may not be held firmly in position in film holders.
5. As most current versions of CCD and CMOS detectors are wired, this could create patient psychological discomfort. It might also be a drawback for the inexperienced operator, requiring adjustments in technique and patience through the learning curve of a new methodology.
6. Competency using software may take time to master. The learning curve may be longer or shorter depending on the computer literacy of the operator.
7. With PSPs, the intraoral (IPs) have been prone to mechanical degradation necessitating replacement of plates to sustain image quality.
8. Although unlikely to occur given reasonable diligence, mishandling can cause mechanical damage with high replacement costs for CCD and CMOS detectors.

Examples of Digital Intraoral Images Used in Endodontics

It is now appropriate to illustrate some examples of digital radiographic images used in the practice of endodontics so one might get a better appreciation of attainable image quality (Figures 9B-8 to 9B-10). It should, however, be remembered that the printed page is static and does not permit the modifications to image density and contrast that are available when the digital images are viewed on the computer monitor.

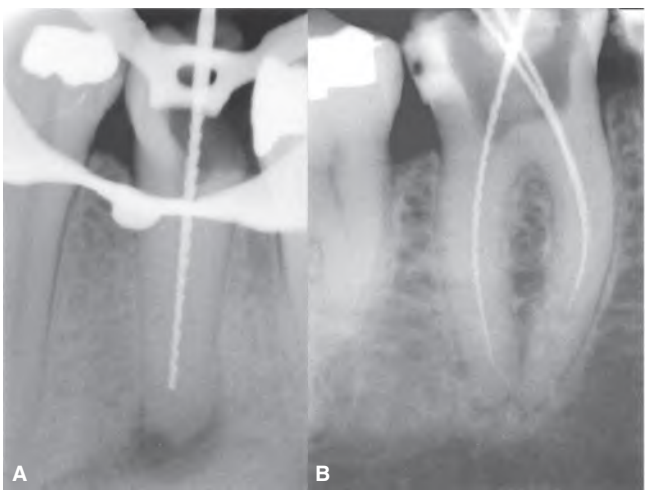

FIGURE 9B-8 ***A.*** endodontic instruments in a mandibular second premolar tooth with a radiolucent periapical pathosis; ***B.*** mandibular molar with slight widening of the apical periodontal ligament space of the distal root. These images were made using the DentX Eva (CMOS) system (AFP/DentX, Elmsford, NY, USA).

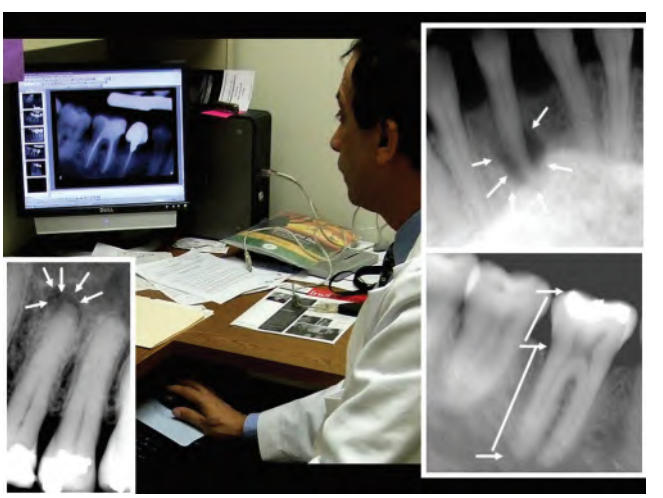

FIGURE 9B-9 Endodontic evaluations using the Kodak RVG-6000 (Kodak Dental Imaging, Marne-la-Vallée, France) CMOS system. These details clearly demonstrate the ability of solid-state sensors to demonstrate periapical lesions and tooth length (even with long root length in rhizodontia).

DIGITAL VERSUS CONVENTIONAL: WHICH IS BETTER?

With the introduction of digital imaging systems in dentistry, a question arises: "How effective are these systems when compared with film for specific diagnostic tasks in endodontic practice?" The reported studies are rather consistent and have shown that the diagnostic ability of the digital image is equivalent to film-based radiographs as referenced in the subsequent sections of this chapter. The following discussion concentrates on investigations concerning diagnostic tasks in endodontology.

DETECTION OF PERIAPICAL LESIONS

Accurate assessment of the periradicular status is crucial in diagnosis, treatment, and evaluation of healing in endodontic therapy. However, from some reported studies, it is believed that periapical lesion cannot be detected until a comparatively advanced bone destruction, that is, not until the lesion erodes the junction between cortical and cancellous bone.[4,5] Alternatively, it has been postulated that changes in the lamina dura are key to the detection of periapical lesions.[6,7] Several studies have evaluated the efficacy of digital images in detecting periradicular bone changes. Most of the studies, concluded that digital imaging did not increase the rate of detection of lesions.[6,8–11] Paurazas et al.[10] for instance, found no difference in diagnostic accuracy between film radiographs, CCD, and CMOS-APS systems in detecting periradicular lesions. However, the use of CMOS APS system has been supported because of perceived functional advantages over CCD systems such as "low cost," reduced electric power requirement, and suggested increased life time of the product. Digital imaging was preferred over film-based imaging as the former, according to one report, requires 50% less radiation than the latter.

Yokota et al.[8] studied mechanically created lesions in human cadaver specimens using film radiographs and an early vintage RVG CCD X-ray detector. It was concluded that (1) when no lesion exists, conventional radiograph was more accurate than the vintage RVG; (2) when the lesion is enlarged to involve lamina dura and medullary bone, the vintage RVG was superior; and (3) when the lesion involved the cortical bone, there was no difference between a conventional radiograph and vintage RVG. This study was in agreement with a similar study conducted by Tirrell et al.[12]

It has been reported that digital images have been found to be more accurate than conventional radiographs when image enhancements are performed.[13] In another study, image processing was found to be of limited value on diagnostic quality, but altering the basic functions such as contrast and brightness were preferred for the detection of periapical lesions.[14] However, Wallace et al.[15] concluded that enhanced digital images perform inferior to film-based images in periapical lesion detection. This was attributed to the observers' lack of familiarity with digital images and lack of experience with the image enhancement procedures.

Other image-processing functions such as color enhancement and reverse imaging have been found to be of limited diagnostic value in the detection of periapical lesions.[16] In this context, it should be noted that many times the enhancement leads to worse performance, although the subjective impression is that of improvement. It should be remembered that when enhancements are applied, they generally hide information, thereby making certain features stand out. Also many studies have used rather underexposed films or digital

detectors, before the enhancement of the digital images leading to improved performance of the digital system. One has to caution the readers about these inherent fallacies and also point out the great variation sometimes reported among observers in periapical radiographic diagnosis. When high variability between observers is present, one can predict that the studies concerned will result in no proven differences between the modalities compared. Woolhiser et al.[17] even reported great variation in the seemingly straightforward task of estimation of root length, with variations for the same observation being as great as 1.5 to 8 mm. Nevertheless, they did conclude that observers using enhanced digital images outperformed the same observers using analog film radiographs.

EVALUATION OF ASSESSMENT OF ROOT CANAL LENGTH

A too short working length can result in infected tissue being left in the root canal, and this can then continue to damage the periapical tissue. Hence, a correct estimation of working length is crucial for endodontic success. The radiographic apex does not always coincide with true apex (apical foramen). Even though, the International Standards Organization recommended smallest file size for a working length radiograph is #15, files smaller than #15 are required for initial instrumentation in fine, curved, and calcified canals to prevent root perforation or ledge formation within the canal. The problem encountered with small-sized files is that the instrument tip will not always be clearly visible on a radiograph. Comparative studies have been conducted between film radiographs and digital detectors to evaluate their accuracy in estimating endodontic length and perceived clarity in visualizing fine endodontic files. It has been reported that digital systems closely approximate film radiographs in the accuracy they provide for practitioners in estimating root length.[18,19] However, digital images were found to be inferior to film images when #10 rather than #15 files are used.[20,21]

Cederberg et al.[22] compared the difference in interpretation of the position of endodontic file tips between PSP imaging (Digora; Soredex, Helsinki, Finland) and intraoral radiographic film (Ektaspeed Plus; Kodak, Rochester, NY) for a limited number of patients (n = 13). Film radiographs were viewed using a 7× measuring magnifier. PSP was reported to outperform film radiographs in that a smaller difference was found between the file tip and root apex with digital imaging.

Eikenberg and Vandre[19] sectioned human skulls into 15 sextants. Teeth were then removed and 45 canals were instrumented to their apical foramina. Endodontic files were glued in place at random distances from the apical foramina. Image geometry was maintained by a custom-mounting jig. Images were captured with two types of analog film and a solid-state digital radiographic system (Dexis). Digital images were read on a conventional color monitor (cathode ray tube) and a laptop screen (active-matrix liquid crystal display). Fifteen dentists measured the distance from the file tip to the apical foramen of the tooth. Results showed that the measurement error was significantly less for the digital images than for the film radiographs.

Martinez-Lozano et al.[23] evaluated the diagnostic efficacy of an electronic system for the determination of working length, in comparison with two radiologic methods (conventional film and digital radiography). The study sample consisted of 28 root canals in 20 human mandibular teeth. A comparison was made between the working length measurements obtained by the radiologic methods and an apex locator, using as "gold standard" the observation of the actual file position within the root following selective grinding of the root tissue. It was concluded that none of the techniques was totally satisfactory in establishing the true working length. No statistical differences were proven comparing the techniques investigated.

DETECTION OF ROOT CANAL ANATOMY

Success of endodontic treatment depends on the identification of all the canals in the tooth that can then be cleaned, shaped, and obturated. The ability to locate all the canals is crucial in determining the eventual success of the therapy, and radiographs are considered one of the important tools apart from clinical examination. Reported studies are contradictory to one another. Naoum et al.[24] compared conventional with PSP images to visualize the root canal system contrasted with radiographic contrast medium. The image clarity on conventional radiographs was found to be better than with Digora PSP images.

Nance et al.[25] studied maxillary and mandibular molars using conventional D-speed film radiographs versus tuned aperture computed tomography (TACT) in the identification of root canals. TACT, using arrays of several digital images to tomosynthesize the third dimension, was reported to be superior to conventional film radiographs in the detection of root canal in molars. There was a reported 36% detection rate of the (elusive) second mesiobuccal canal (MB2) in maxillary molars and 80% detection rate of the mesiolingual canal in the mandibular molar using the TACT system. By contrast, with the film-based images, there was a somewhat unbelievable 0% detection of MB2 canals. This highly skewed result might be caused by using a standard paralleling technique for making conventional images, leading to overlap of canals. In a similar study by Barton et al.[26] parallax analog and parallax digital images were compared with TACT in the ability to detect MB2 canals in maxillary first molars. With TACT, there was 37.9% chance of locating the MB2 canal, which is consistent with the results

of Nance's study. However, in this study, the success rate of detecting MB2 canals using film-based images was approximately equal to that using TACT, and TACT did not significantly affect the rate of detection of MB2 canals. It was also observed that the distance between first mesiobuccal and the MB2 canal is quite small and perhaps too minute for current TACT applications.

Digital Subtraction Radiography

Given radiographs taken in precisely the same position and with the same beam geometry and exposure parameters, images can be subtracted to show changes over time. This technique has been largely conducted for research purposes in view of the difficulties experienced in practice in achieving images with reproducible projection geometry over time.

Digital subtraction has been performed for endodontic tasks, and digital detectors have been used for this purpose (Figure 9B-11).[27–29] Yoshioka et al.[27] evaluated the efficacy of digital subtraction radiography using an early version of the RVG system in a follow-up study of endodontically treated teeth. The intra-image variation of the original image caused by dark current and sensitivity variations among pixels in this vintage digital system was corrected pixel-to-pixel. The inter-image variation was further corrected using a copper step-wedge attached to the detector. Standardized images were obtained using the same beam geometry at patient follow-up. Pixel values at the regions of interest, positioned on the periapical lesion, increased after endodontic treatment, and this change continued during an observation period of up to 545 days. It was concluded that subtraction radiology is possible for the purpose of endodontic follow-up.

Nicopoulou-Karayianni et al.[28] also evaluated the effect of root canal treatment on periapical lesions by conventional and subtracted digital radiographic images of patients. Better observer agreement was achieved by digital subtraction radiography during the evaluation than without digital subtraction at follow-ups 3 to 12 months after treatment.

Mikrogeorgis et al.[29] evaluated the suitability of digital radiograph registration and subtraction in the assessment of the progress of chronic apical periodontitis. Ninety cases of teeth with chronic apical periodontitis were studied. In each case, a preoperative radiograph was made, root canals were prepared, and a calcium hydroxide paste was placed in the root canals. Radiographic control and replacement of calcium hydroxide paste took place at 15-day intervals before final obturation. The root canals were obturated 1.5 months after the first appointment, and recall radiographs were made 2 and 6 weeks, 3, 6, and 12 months after the obturation. Digital radiography using a solid-state detector was employed. Changes to the periapical tissue structure were detectable using digital subtraction, even during short time intervals.

Digital subtraction is effective but also time consuming. From 2014, the CDT procedure codes used in the United

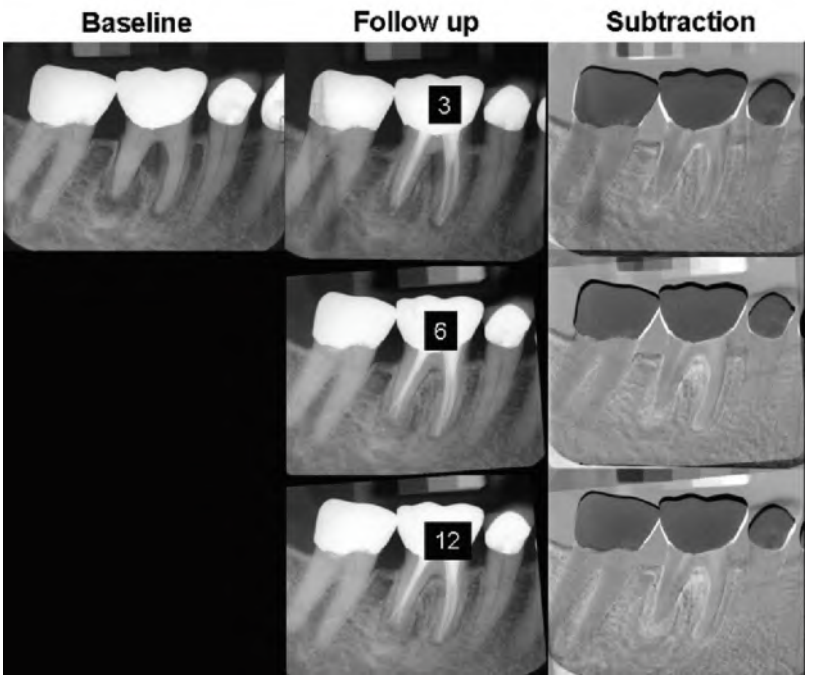

FIGURE 9B-11 Digital subtraction comparing baseline (column 1) to follow-up images made at 3, 6, and 12 months following endodontic therapy (column 2). Column 3 indicates subtraction of respective follow-up images from the baseline radiograph. Progressive remineralization of the radiolucency at the apex of the distal root of the first molar is evident.

States has included an image post-processing code for digital subtraction.

Radiation Dose for 2-D Imaging

The *A*s *L*ow *A*s *R*easonably *A*chievable (ALARA) principle advocates the use of the smallest possible radiation dose that can still produce an image without compromising diagnostic quality. Conventional direct exposure emulsion X-ray films are relatively poor detectors of radiation and can require relatively high radiation dosages to produce images of optimal diagnostic value.

By contrast, digital detectors can be more quantum efficient and, therefore, require lower radiation exposure. On the other hand, intraoral X-ray films are now available in higher speed than heretofore and this has greatly increased film's quantum efficiency to radiation. Hence, with the use of high-speed films, it is possible to obtain high-contrast images at relatively low exposure. Underexposing X-ray film still tends to increase radiographic "mottle" and graininess of the images, giving an impression of a lack of sharpness in the image.[30] This finding was supported by Sheaffer et al.[31] who found that underexposed radiographs, in an attempt to minimize radiation dosage, result in inferior images irrespective of film speed.

With the invention of increasingly more efficient digital X-ray detector technologies, with an added advantage of contrast enhancement as well as reported reduction in radiation dose, it might be possible to achieve diagnostically efficient images at lower exposures than with conventional film. Velders et al.[32] found that it was possible to achieve a dose reduction of approximately 95% compared with Ektaspeed film when digital systems were used for dental radiographic imaging. One should remember, however, that the use of such low dosages can impair image quality because of a reduced signal-to-noise ratio (SNR).

Although the possible dose reduction for thinner objects has, however, been questioned for a PSP detector, in a study by Huda et al.[33] the low-contrast discrimination of PSPs was found to be superior to that of X-ray films when using the same exposure time. By way of contrast, in a study by Berkhout et al.[34] it was found that the PSPs required 10 times more radiation than the minimally acceptable dose to produce images of preferred quality. Further, these authors state that PSPs require more radiation than E-speed films and that dose reduction with digital technology can be achieved only when using solid-state systems. PSP systems have a wide dynamic range, much larger than CCD systems and films. PSPs are said theoretically to have an exposure latitude ratio of approximately 10,000:1.[33] Hence, they should be capable of producing usable images over a wide range of exposures.[33–38] The actual exposure latitude for PSP systems is dependent on the acquisition software and scanning electronics. It does not exceed 25:1 for PSP intraoral radiography when the relative exposure latitude is determined using clear discrimination of the enamel–dentin junction as the lower limit and pixel blooming or unacceptable levels of cervical burnout as the upper limit.[39]

The effective latitude range for solid-state detectors can exceed 20:1 for some CMOS systems. However, intraoral X-ray systems using a CCD generally have narrower recording latitudes (<10:1), because high exposure results in pixel blooming.[39]

Dynamic range, also known as latitude, corresponds to the range of exposures that will produce images within the useful density range. Radiographic modalities, that produce diagnostic images over a wide range of exposures, are said to have a wide dynamic range and vice versa. The Hurter and Driffield (H&D) curve was invented to characterize photographic emulsion some 5 years before the discovery of the X-ray but was extended to include X-ray film radiographs (Figure 9B-12). Using pixel values rather than film density, the H&D curve concept can also be applied to digital imaging. The straight-line portion of the curve for film corresponds to the dynamic range. This curve demonstrates, for conventional film, the relationship between exposure (log number of X-rays) and the optical density (darkness) of an image detector. The scale of useful densities for film radiographs ranges approximately from 0.5, that produces low density or light images, to 3.0, that results in darker images of high density. However, outside this range, images tend to lose diagnostic detail. For films, this curve takes a form of stretched letter S appearance, with the top horizontal portion of the curve called "shoulder" that corresponds to higher exposure and the lower portion called "toe" that corresponds to lower exposure. Exposure changes in these portions of the curve have little effect on density. Even little changes in the straight-line and vertical portion of the curve significantly affect image density. Thus, the more vertical the straight-line portion of the curve, the smaller is the latitude. This explains the relatively wider dynamic range of digital receptors, especially storage phosphors. The curve can be linear and wider with no shoulder or toe when compared with film images (Figure 9B-12).

Many digital systems have an option of using an "image equalize" function, and this is commonly the automated default setting. Equalization is a method of enhancing the

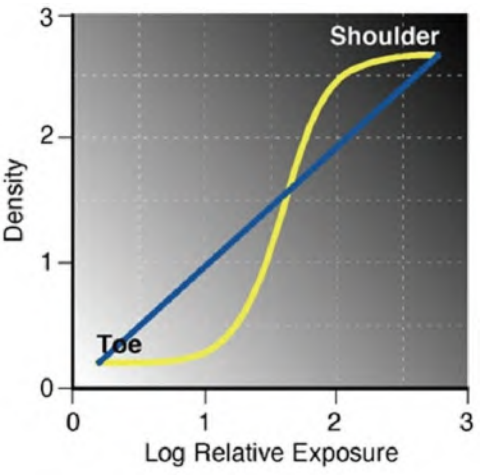

FIGURE 9B-12 Hurter and Driffield curve relating radiograph density to exposure.

contrast in a nonlinear fashion by stretching the pixel values disproportionately to obtain images of optimum image quality. In a study by Hayakawa et al.[40] equalization exposure compensation for computed dental radiography was found to be useful only for underexposed images but not for overexposed images. They also found that this compensation for underexposure did not significantly change the SNR. Furthermore, other studies have found that lower exposures, when severe, can in fact result in increased background noise and thus negatively affect the detection of small and low-contrast details within an object or tissue.[41]

Similar to equalize function in PSP images, the fourth generation RVG had an option of automatic exposure compensation (AEC) that compensated for exposure errors by stretching the pixel value range to increase the contrast of structures within the images. It was found that both under- and overexposed images can be compensated using this algorithm. Because it can compensate for overexposure, it might lead to the risk of practitioners overexposing their patients. Moreover, it was also found that AEC reduces the SNR and produces disproportionate pixel values relative to exposure.[40] Newer versions, such as the RVG-6200, have dose indicator that warns the dentist in cases of exposure errors.

There is evidence that dentists, particularly endodontists, routinely prefer and view high-contrast and relatively dense images when performing endodontic tasks.[31] Likewise, detection of occlusal caries was found to be more accurate when using darker radiographs.[42] This is probably because higher exposure allows easier discrimination between small and low-contrast objects. Moving the exposure difference up on the H&D curve increased contrast results. The smaller the change in structure, the greater the contrast required to differentiate between adjacent structures. One of the methods employed to achieve required contrast is increasing the exposure. Furthermore, if there is superimposition of structure by the images of other objects, the signal of the latter has to be handled as additional noise. Thus, the dose has to be increased in order to notice the structure in the image. This is proposed by Thoms,[43] who believes that attempting a dose reduction will result in images having a low SNR and thereby reducing the visibility of small structures. However, higher exposures also negatively affect the diagnostic accuracy. Whereas images with lower exposures resulted in more false negatives, overexposed images resulted in higher false-positive responses.[44] With these rather contrasting studies in the literature and unanswered questions, there is confusion regarding the exposure time that is actually required to produce images of diagnostic quality and more so in the detection of low-contrast objects. Questions that still need to be addressed are as follows: (1) What is the optimal exposure time or range of exposures required by each of the intraoral radiographic systems that are presently used? (2) Is high radiation exposure really necessary for endodontic tasks? (3) What are the effects of radiation dose on the detection of low-contrast objects such as fine root canals? Many of these questions have not yet been fully answered even for analog film radiography.

While endodontics is not frequently used on children, the American Association of Endodontists has joined the Image Gently Alliance that demands especial care when taking images on children using x-radiation. Children are thought to be especially affected by untoward effects of ionizing radiation due to the more rapid turnover of cells and the longer life expectancy. The aim is to child-size dose by appropriate selection of radiographs based upon inspection and professional judgment rather than routine, use of the fastest receptors consistent with diagnostic images, appropriately collimating the beam as much as possible, and use of a thyroid shield.[45,46]

SUMMARY

Digital imaging systems, using solid-state detectors, have definite advantages over analog film in terms of immediacy of image display and seem to be equal to film imaging for most tested diagnostic purposes. There is still a need, however, for further scientific validation of the best exposure strategies for imaging optimizing specific diagnostic tasks including those used for endodontics.

Chapter 9C

Cone Beam Computed Tomography

Martin D. Levin, Allan G. Farman

Cone beam computed tomography (CBCT) is a mature technology that has a definite place in endodontic evaluation under certain circumstances. CBCT allows for the undistorted three-dimensional visualization of the dentition and the maxillofacial skeleton without the compression of anatomic features. CBCT may be used if a patient's chief complaint, medical history, clinical examination, and intraoral radiographic assessment demonstrate the need for additional information.

Imaging is achieved by use of a rotating gantry to which an X-ray source and detector are fixed. A divergent pyramidal or cone-shaped beam of x-radiation is directed through the center of the area of interest onto an area X-ray detector on the opposite side. The X-ray source and detector rotate around a fulcrum fixed within the center of the region of interest. During the rotation, hundreds of sequential planar projection images of the field of view (FOV) are generally 180° or greater. (Figure 9C-1). This procedure varies from a multislice CT (MSCT) that uses a fan-shaped X-ray beam in a helical progression to acquire image slices of the FOV and then stacks the slices to obtain a 3-D representation. Each slice requires a separate scan and separate 2-D reconstruction (Figure 9C-2) Because CBCT exposure incorporates the entire FOV, only one rotational sequence of the gantry is necessary to acquire enough data for image reconstruction for most maxillofacial purposes.

CBCT was initially developed for angiography,[1] but more recent medical applications have included radiotherapy guidance and mammography.[2,3] CBCT is less expensive in components than MSCT and provides a reduction of image unsharpness that might be caused by the translation of the patient during MSCT. Additional advantages of CBCT are faster exposure time, reducing likelihood of patient movement, and a reduction in radiation dose. However, its main disadvantage is a limitation in image quality related to noise and contrast resolution because of increased scattered radiation resulting in lower signal strength relative to back ground noise. While CBCT is excellent for hard tissue (bone window) imaging, contrast between soft tissues is generally poor. Fortunately, hard tissue discrimination is paramount in endodontic assessments. Further, CBCT can achieve the high resolution needed for endodontics while using a relatively low radiation dose.

It has only been since the late 1990s that sufficiently inexpensive powerful computers and X-ray tubes capable of

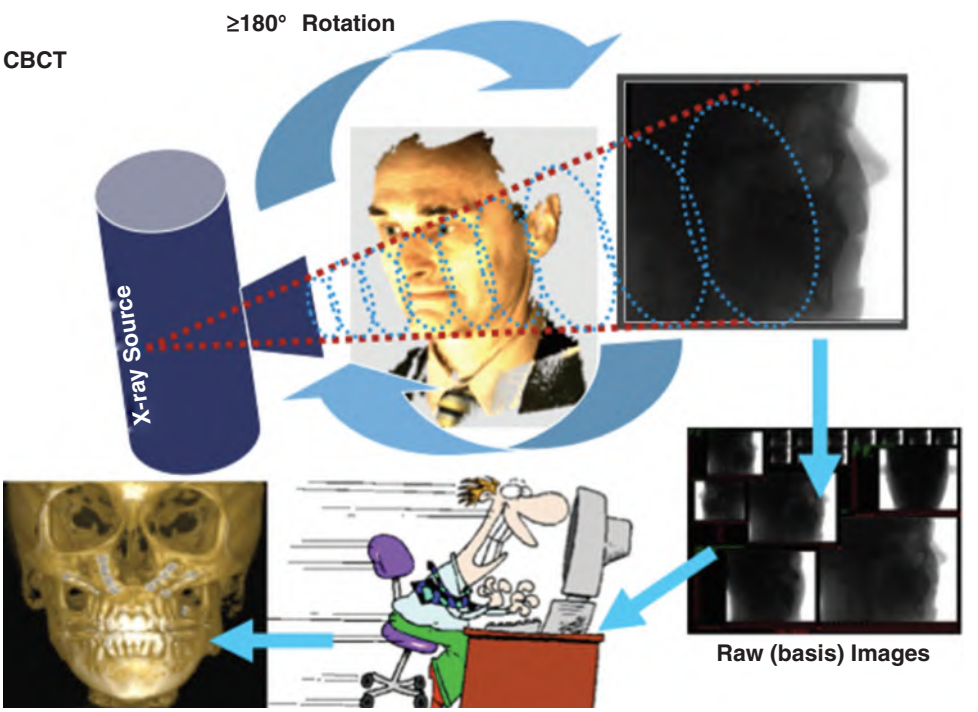

FIGURE 9C-1 Schematic illustration demonstrating CBCT operation. A collection of 2-D transmission images are integrated via back-projection filtering to provide image data that can be viewed in 3-D or as single slices in any plane.

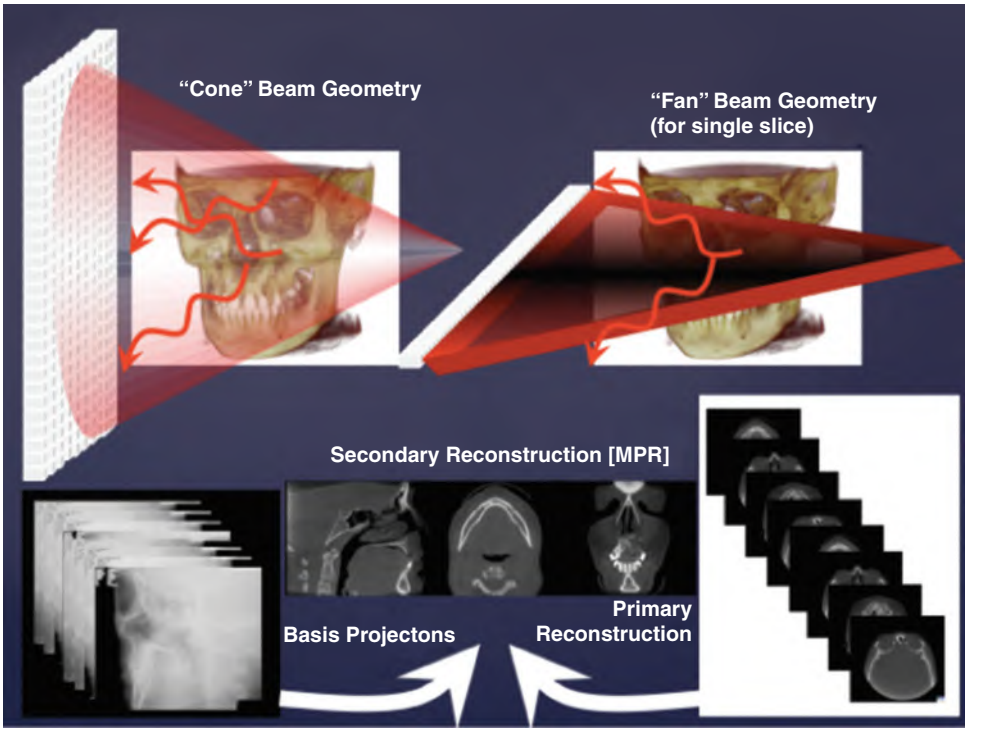

FIGURE 9C-2 Comparison of CBCT and fan beam CT.

continuous exposure have enabled clinical systems affordable for use in the dental office, to be manufactured. Additional critical components of the CBCT system include detectors capable of rapidly receiving and clearing multiple images without afterglow, plus the development of algorithms to convert the successive 2-D basis images into a 3-D image volume.

CBCT is a valuable technology when used wisely. Considerations for minimizing patients' exposure to radiation to as low as reasonably achievable include: (1) image selection based upon professional judgment of diagnostic or treatment guidance need rather than using ionizing radiation exposure as a "routine" without prior individualized patient assessment by the dentist; (2) minimizing the FOV by collimation, to reduce radiation exposure to tissues that need not be imaged; and (3) using the fastest exposure/lowest dose parameters consistent with adequacy in diagnostic image quality.

The restriction of radiation dose is particularly important for younger individuals. The International Commission on Radiological Protection (ICRP) has indicated that the effect of dose to children can be as much as three times that for young adults aged 20 to 25 years and as much as an order of magnitude more than for mature adults aged around 60 years.[4,5] Children are more susceptible to untoward effects of ionizing radiation than adults, due to the longer life ahead of them during which changes might occur, and also due to their faster turnover of cells compared to adults. CBCT should only be performed after clinical evaluation of the patient by the dentist, and a after a judgment is made that the benefits of this procedure will sufficiently outweigh the risks to the patient even though these risks are small. Additional guidance on the use of CBCT in endodontics can be found in the Joint Position Statement of the American Association of Endodontists and the American Academy of Oral and Maxillofacial Radiology on the Use of Cone Beam Computed Tomography in Endodontics. (Available online at http://aae.org or http://aaomr.org)

Many of the commercially available CBCT units (Figure 9C-3) have separate CBCT and panoramic detectors, allowing increased functionality. This multimodal design may allow a limited scan volume to be supplemented by a panoramic radiograph (Figure 9C-4) to assess the entire mandible and maxilla when necessary.

FIELD OF VIEW AND SPATIAL RESOLUTION

In endodontics, the region of interest (ROI) is generally small and predetermined. The extent of anatomy imaged in a CBCT scan is dependent on the scan volume or FOV selected, and is controlled by the detector size and shape, beam projection geometry and beam collimation. The FOV is generally divided into large, medium and limited sizes and is determined by the task at hand. The scan volume should only be slightly larger than the anatomy of interest, resulting in lower x-radiation exposure to the patient.

Additional benefits of limited field size are smaller volumes to be interpreted and increased resolution to allow for the detection of very small features, such as alterations of the periodontal ligament space that measures approximately

200 μm.[6] At this time, the nominal voxel resolution is reported to be 0.075 mm.

Bauman et al.[7] in examining the literature for detection of mesiobuccal canals in maxillary first molars found that as many as half of second canals could be missed using 2-D imaging, whether analog film or digital detectors were used. CBCT was successful in accurate detection of the number of mesiobuccal canals in 93.3% of cases when using 0.125 mm voxel resolution and the maximum number of basis images were employed. High resolution was essential for achieving this accuracy as with a setting of 0.4 mm voxel resolution (and half the number of basis images) the accuracy decreased to 60.1%. At 0.2 and 0.3 mm resolution settings the accuracies of detection were 77.7% and 88.8%, respectively. This study demonstrated the value of CBCT use in endodontics and also demonstrated that imaging parameters need to be selected carefully to assure resulting accuracy.

INTERPRETATION

All radiographs require careful and complete analysis by the ordering clinician because they may demonstrate findings that affect the health of the patient. A systematic

review and documentation of the findings is essential. Clinicians are responsible for evaluation of the entire image volume. Interpretation questions should be referred to an oral and maxillofacial radiologist.[8] For more details, see Chapter 10.

DETECTION OF APICAL PERIODONTITIS

Essential elements in endodontic assessment are patient chief complaint, history and clinical and radiographic examination. Intraoral radiographs should be used in the initial evaluation of the endodontic patient. Planar imaging modalities offer the possibility of accessible, relatively inexpensive and low radiation assessments of the teeth, supporting structures and the location of anatomic features. However, these *in vivo* imaging methods suffer from inherent limitations such as superimposition, magnification, geometric distortion, and misrepresentation of structures. Early studies showed that experimental bone lesions that did not affect the cortex eluded detection using periapical radiography.[9] The addition of cross-sectional imaging allows for the assessment of complex root canal morphology, the true extent of lesions and their spatial relationship to anatomic structures.[10] CBCT should be considered in the presence of a clinical condition that would likely benefit the patient if tomographic imaging is employed.

CBCT has been shown to be superior to conventional imaging in many endodontic applications. Lofhag-Hansen et al.[11] compared the accuracy of three calibrated oral radiologists using two paralleling intraoral radiographs with a 10° horizontal tube shift between exposures to assess 46 teeth. The same patients were scanned with a high-resolution, limited FOV CBCT that identified additional clinically relevant information in 69.5% of the teeth imaged. Although they showed that 10 teeth with small periapical radiolucencies were undetected using conventional imaging, 3 teeth with large lesions that perforated the cortex in the buccolingual direction were invisible to the observers. Low et al.[12] evaluated 156 roots of maxillary posterior teeth and found that CBCT identified 34% more lesions than periapical radiographs. Both studies showed that CBCT can detect apical radiolucencies in the cancellous and cortical bone that are normally hidden by the superimposition of unrelated structures onto the features of interest.[13]

Bone alterations associated with apical periodontitis may be undetectable on periapical projections because the lesions are small or are concealed by superimposition. Tsai et al.[14] determined that two CBCT units showed poor accuracy in detecting simulated lesions smaller than 0.8 mm, better accuracy if the lesion measured 0.8 to 1.4 mm and high accuracy when the lesion measured larger than 1.4 mm. Periapical radiography showed poor accuracy in all lesion sizes tested. Patel et al.[15] placed small and large synthetic lesions in the cancellous bone surrounding six human mandibular molar distal roots. CBCT images were 100% accurate in showing the presence (sensitivity 1.0) and absence (specificity 1.0) of periapical lesions. Periapical radiographs showed 24.8% of periapical lesions (sensitivity 0.248) but were accurate in showing the absence of lesions (specificity 1.0). They concluded that superimposition and poor geometric factors decreased lesion detection. CBCT resulted in improved lesion detection because the tooth could be viewed at any angle showing the true nature of the periapical bone destruction. Cortical bone lesions were detected with greater accuracy than in trabecular bone.

In a systematic review and meta-analysis regarding the diagnostic accuracy of conventional and digital intraoral radiography and CBCT imaging to detect apical periodontitis, Leonardi Dutra et al.[16] found only nine eligible studies, of which six qualified for meta-analysis. They found little or no data about inter- or intraobserver agreement. They also noted variation in sensitivity and that sensitivity while examining artificial apical periodontitis may have resulted from differences in bone lesion size, anatomic region studied, observer experience, and other factors. The study concluded that conventional and digital intraoral periapical radiography showed good accuracy, 0.73 and 0.72, respectively, in the discrimination of artificial apical periodontitis from no lesion; and CBCT showed excellent accuracy values (0.96). A reported limitation of this analysis was that all studies included were in vitro and involved skeletal tissues without diffuse borders associated with naturally occurring apical periodontitis.

Intraoral radiography compresses a three-dimensional object into a two-dimensional image. It requires an optimized geometric configuration of the X-ray generator, tooth, and detector to provide an accurate projection of the tooth.[17] Complex anatomy, where the superimposition of unrelated structures onto the features of interest may present challenges to lesion detection, are well documented in the literature. For example, imaging of the maxillary posterior teeth with a periapical radiograph in the presence of a low palatal vault may result in suboptimal geometry, causing superimposition of the zygomatic arch, sinus floor, palate, alveolar bone, and overlying teeth onto the roots. Radiolucencies in close proximity to the sinus floor are often missed with periapical radiography.[18] It can be difficult to interpret the status of each root, even if several angles are acquired. CBCT can accurately produce three-dimensional images of the teeth, supporting structures, and spatial relationship of anatomic features.[19] Using available tomographic slicing techniques, each root can be longitudinally aligned in parallel with the sagittal or coronal slicing tool, allowing undistorted examination of the axial slice.

ROOT CANAL TREATMENT OUTCOMES

Determination of the outcome of root canal treatment depends on the clinical signs and symptoms and radiographic assessment. Radiological assessment is important because many teeth with periapical lesions are asymptomatic (Figure 9C-5).

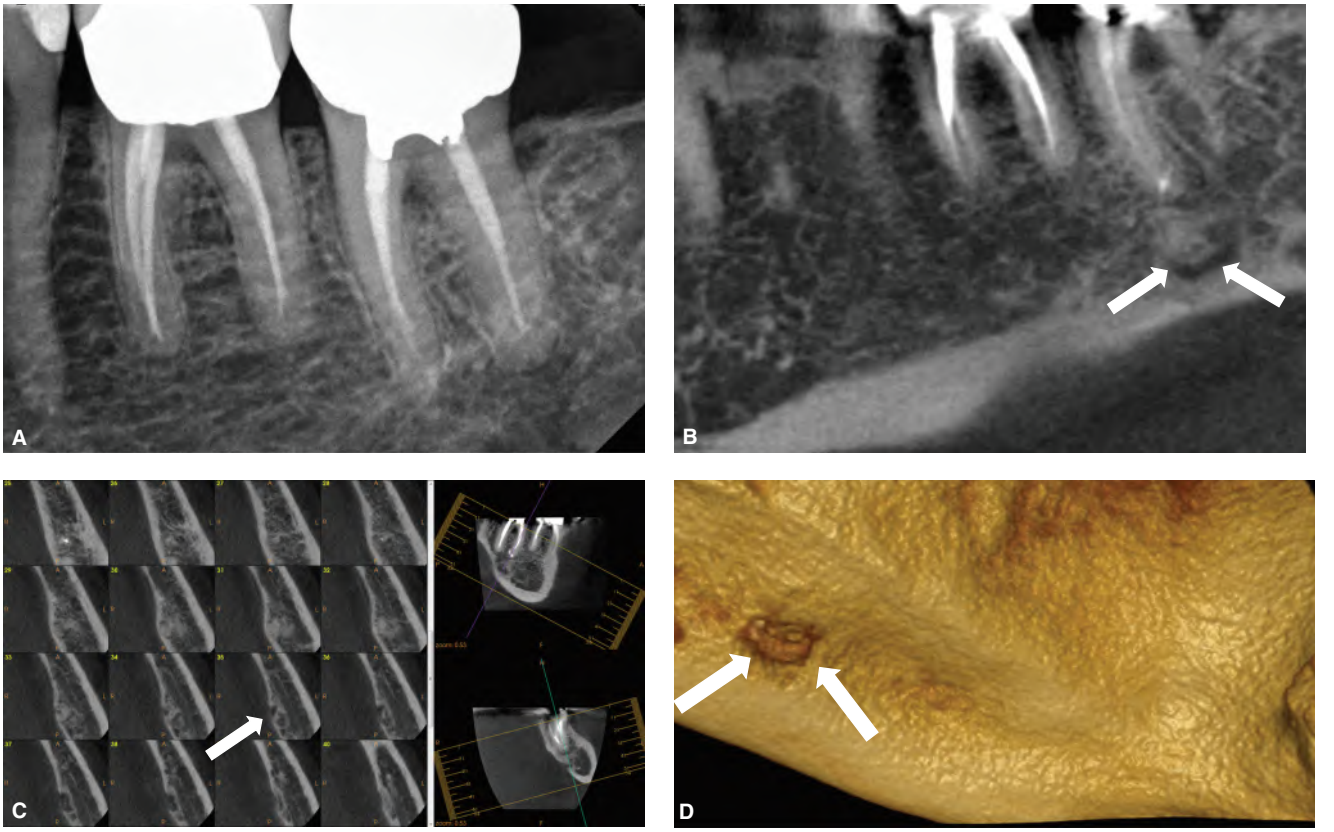

FIGURE 9C-5 Outcome predictors based on intraoral radiography and CBCT vary. ***A.*** Periapical radiograph shows previous incomplete endodontic treatment of an asymptomatic mandibular left second molar. There are short metal posts in the mesial and distal roots, and an area of low radiodensity at the furcation that extends to the distal aspect of the distal root. ***B.*** CBCT panoramic reformation shows a periapical discontinuity of the lamina dura and widening of the PDL space, with periapical osseous rarefaction that appears to track along the distal aspect of the mesial root in a narrow channel, to a large region of low radiodensity at the furcation, and also appears to track inferiorly to a 6-mm diameter somewhat well-defined serpiginous defect (solid arrows), causing erosion of the lingual cortex. ***C.*** CBCT-correlated multiple cross sections show two unilocular regions of low attenuation with well-defined, corticated borders constituting a multilocular lesion lying along the lingual cortical plate (solid arrow). ***D.*** 3-D reformation of the same area shows erosion of the cortex (solid arrows).

Outcome predictors using intraoral and tomographic imaging vary, and are further influenced by methodological rigor, such as inclusion and exclusion criteria. Wu et al.[20] reported that previously published systematic reviews of endodontic treatment outcomes showed a high percentage of cases confirmed as healthy by intraoral radiographs revealed apical periodontitis on CBCT and by histology. Furthermore, they stated that additional factors such as extractions, retreatments, low reevaluation rates, and the location of teeth evaluated limit the value of these studies. Patel et al.[21] compared the outcome of primary root canal treatment after 1 year in 123 teeth using periapical radiography and CBCT imaging. The absence of a radiolucency was 92.7% using periapical radiographs and 73.9% using CBCT scans. They concluded that periapical imaging showed a higher healing rate for primary endodontic treatment than CBCT.[21] The size of periapical rarefactions were underestimated when using two-dimensional projections because apical periodontitis confined within the cancellous bone or covered by a thick cortex was not visible using intraoral imaging.[22] Paula-Silva[23] compared endodontic treatment outcomes in dogs using periapical radiographs, CBCT, and histologic measurements after 180 days. CBCT closely corresponded with microscopic lesion measurements, whereas periapical radiographs consistently underestimated lesion size.[23] Temporal evaluations of healing using periapical radiography were adversely affected by the difficulty in achieving an exact geometric match.[24] In a retrospective study of 115 teeth, Liang et al.[25] reported that at the check-up visit, periapical radiographs and CBCT showed periapical areas of low density" on 12.6% and 25.9% of teeth evaluated, respectively. Outcome predictors using periapical radiographs were obturation length and density of root filling, whereas outcome predictors using CBCT were density of root filling and quality of coronal restoration. Periapical radiographs, which reliably show the mesiodistal direction only, underestimated the voids per root canal filling (16.1%) when compared with CBCT (46.2%).

CBCT can offer undistorted multiplanar imaging information that shows lesions hidden by superimposition that cannot be shown by periapical radiographs. (Figure 9C-6) The use of CBCT to assess the outcome of treatment should

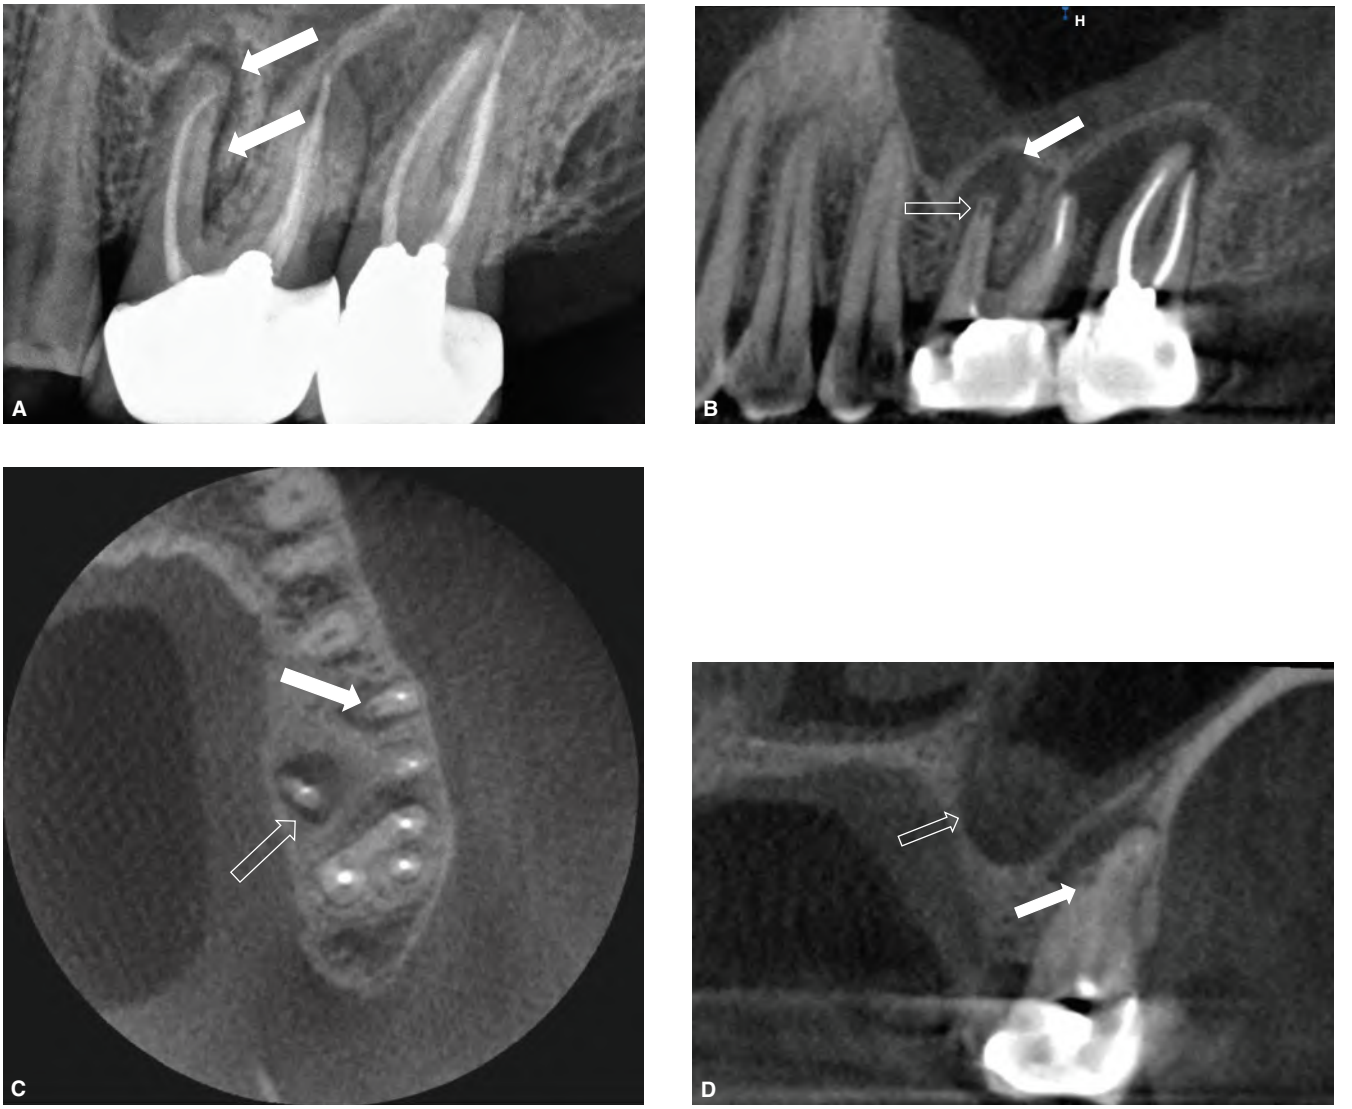

FIGURE 9C-6 Periapical radiographs can be suboptimal in representing complex anatomy compared with CBCT. ***A.*** Periapical radiograph of an endodontically treated maxillary molar is consistent with mesiobuccal root apical periodontitis continuous with a furcal defect (solid arrows). This first molar also evidences PDL widening distal to the distal root. The second molar has features consistent with apical periodontitis of the palatal root and widening of the PDL space anterior to the mesiobuccal root. ***B.*** CBCT sagittal reformation, left maxillary first molar shows features consistent with chronic periradicular abscess at the mesiobuccal root (solid arrow), continuous with a furcation defect. There is an untreated mesioaccessory canal and internal resorptive defect at the periapex not visible on the periapical radiograph (open arrow). The left maxillary second molar has features consistent with a large, periradicular abscess continuous with a furcation defect and periradicular periodontitis along the distal aspect of the distobuccal root extending to the distobuccal apex. The maxillary sinus within the CBCT image has features consistent with chronic sinusitis. ***C.*** CBCT axial reformation, left maxillary first molar has features consistent with a chronic periradicular abscess at the mesiobuccal root and also has an untreated mesioaccessory canal. Note internal resorptive defect at the periapex (solid arrow) and features consistent with chronic periradicular abscess at the palatal root (open arrow). There is a mucositis of the floor of the maxillary sinus overlying both the left maxillary first and second molars, and these teeth show radiographic features consistent with advanced periapical periodontitis along the mesial aspect of the mesiobuccal root and early periradicular periodontitis at the palatal root. ***D.*** CBCT corrected axial reformation shows radiographic features consistent with a chronic periradicular abscess at the palatal aspect of the mesiobuccal root. The subjacent floor of maxillary sinus shows radiographic features consistent with a mucositis (open arrow). There is an internal resorptive defect at the periapex of the mesioaccessory root (solid arrow).

be ordered on a case-by-case basis, predicated on the benefit and risk to the patient of increased radiation dose and cost. The use of tomographic technology in medically complex patients where the harm from apical periodontitis may pose a serious health risk should be considered. Medical conditions such as osteomalacia, common in elderly patients, may be apparent using CBCT assessments but not using conventional radiographics. Cases of osteometabolic diseases may be apparent using CBCT. The apparent rarefactions, thin cortex, hyperdense appearance of trabeculae, porosity in the jaws may be useful.

Conventional radiography has been shown to overestimate healing after endodontic surgery.[26] A recent study has proposed new CBCT-based healing criteria one year after apical surgery.[27] This novel approach presents three healing indices using buccolingual CBCT slicing: the cut root surface, apical area, and cortical plate. The apical area and cortical plate indices showed complete healing in only 34.3% of cases, suggesting that complete healing may require more than a one year follow-up.

PATIENTS WITH NONSPECIFIC OR CONTRADICTORY SIGNS AND SYMPTOMS

Nonlocalized pain or contradictory findings associated with an untreated or previously root-treated tooth or teeth is not uncommon. A major advantage of CBCT is that it can accurately show the true size and location of alterations involving the teeth and supporting structures[12] (Figure 9C-7).

Endodontic treatment may result in persistent pain lasting for more than 6 months, estimated at between 5.4% and 10.0%.[28] This pain may result from odontogenic or

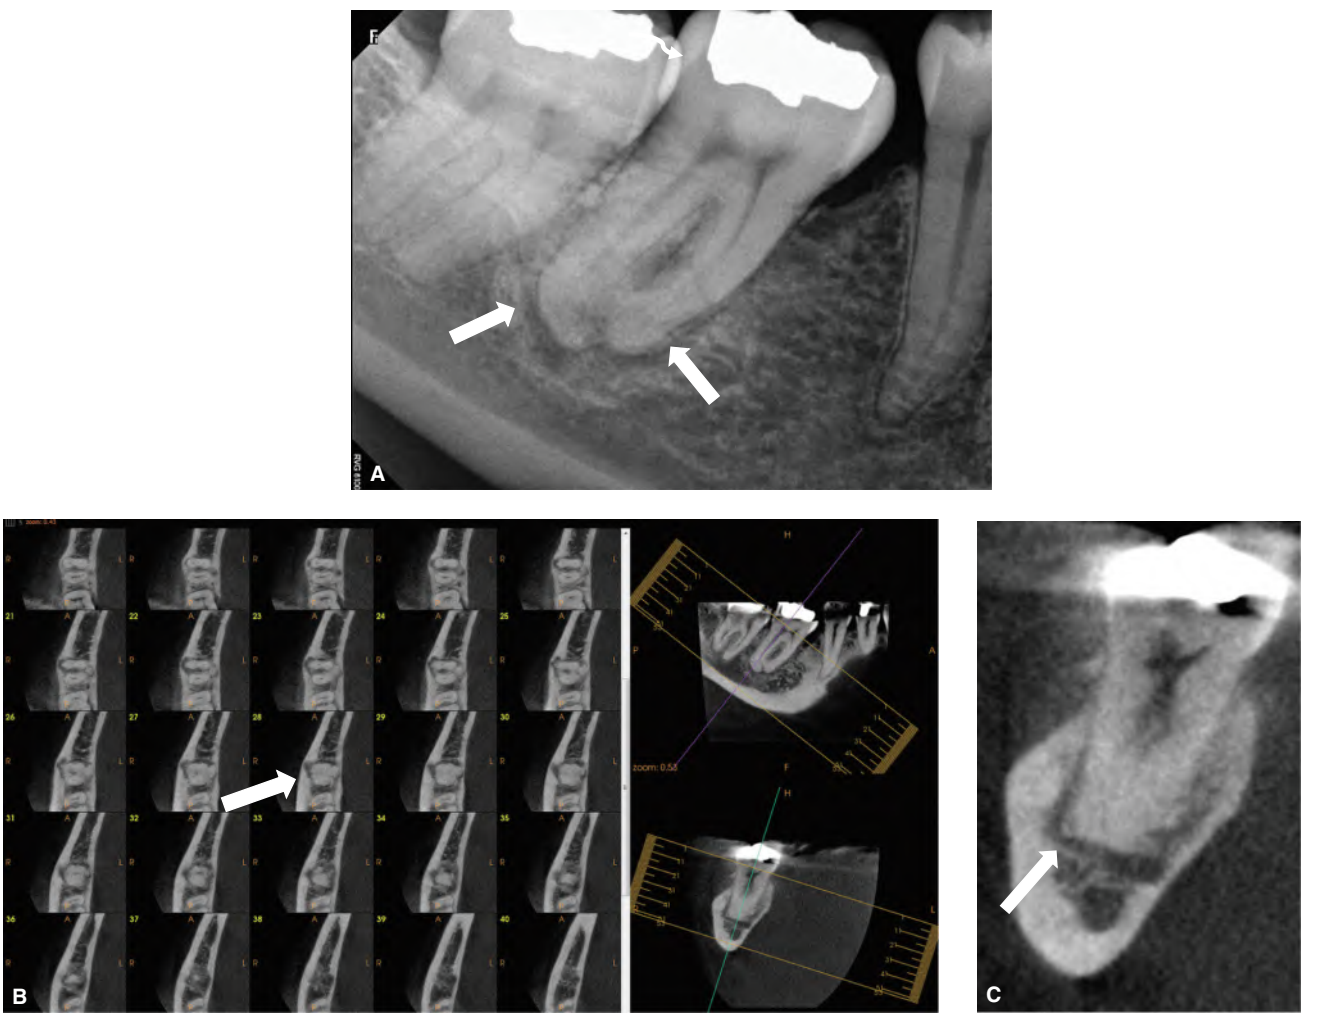

FIGURE 9C-7 ***A.*** Periapical radiograph of this 56-year-old African-American female shows the mandibular right second molar with small circular radiolucent bands surrounded by opaque bands approximately 2 mm wide, centered on a point around the apicies of the mesial and distal roots (solid arrows). The assessment of this lesion was confounded by a pulpal diagnosis of irreversible pulpitis. ***B.*** Correlated and corrected axial reformation showing erosion of the buccal cortex (solid arrow). ***C.*** Cross-sectional reformation of the same region showing multiple periapical areas of different densities and hypercementosis of the distal aspect of the distal root (solid arrow). These features were consistent with an irreversible pulpitis with cemento-osseous dysplasia.

nonodontogenic causes. The pathogenesis of the pain source is critical because treatment and outcomes are different for each individual. In patients who had odontogenic-related pain, such as from missed canals, over-instrumentation or overfilling, periapical radiographs and CBCT showed untoward findings in 57% and 100% of cases, respectively. Patients diagnosed with nonodontogenic pain had normal findings on their radiographs approximately 75% of the time, whereas approximately 25% had periapical radiolucencies. The ability of CBCT to show all of the odontogenic lesions was considered significant in the diagnosis of these patients. Some patients with a painful tooth 6 months after treatment may have nonodontogenic pain, with temporomandibular disorder the most frequent cause.[28]

The pathophysiology of this pain is uncertain, but hypothesized to involve deafferentiation of peripheral sensory neurons in predisposed patients. The diagnosis of atypical odontalgia (AO) or persistent dentoalveolar pain disorder (PDAP) is challenging, and depends on patient history, clinical examination, and the absence of radiographic findings. In some cases, the symptoms from apical periodontitis and AO are closely related. In a study of 20 patients with AO, with at least one tooth in the region of discomfort having had an invasive treatment including 21 of 30 teeth that underwent endodontic treatment, Pigg et al.[29] found that 60% had no periapical lesions and that CBCT showed 17% more periapical lesions than conventional radiography. This study demonstrated that CBCT may be a useful supplement to two-dimensional radiography.[29] In the majority of patients with PDAP, there were no signal changes in the painful region when examined by MRI. There was a high correlation between radiographic and MRI findings.[30] In a study that followed 46 patients previously diagnosed with PDAP over 7 years, approximately one-third showed significant temporal improvement, but for many patients, pain was persistent and treatment-resistant.[31]

COMPLEX ROOT CANAL MORPHOLOGY: ADDITONAL ROOTS, CANALS, ROOT CURVATUES, ANOMALIES, AND PROXIMAL ANATOMY

The success of endodontic treatment requires thorough cleaning and obturation of the root canal system. Endodontic treatment failures have been attributed to the inability to locate all of the root canals present. Anatomic variations are common and show certain morphologic characteristics among ethnic population groups.[32] CBCT has shown results that are comparable to *in vitro* histologic examination and provide images in different representations, such as multiplanar reformations and 3-D surface rendering.[33] Variations in root canal morphology may be categorized into additional roots, additional canals, root curvatures, and anomalies.

Additional Roots, Canals, and Root Curvatures

The operating microscope plays an important role in the intraoperative identification of root canal anatomy and can be supplemented by the use of CBCT when necessary. CBCT and the operating microscope result in an increased detection of canals and appreciation of roots curved in the buccolingual direction.[34] Blattner et al.[35] conducted an *in vitro* investigation comparing physically cut sections of extracted maxillary first and second molar teeth with CBCT assessments for the prevalence of mesio-accessory (MB2) canals. There was a positive correlation (79%) between the two techniques, showing that CBCT is a reliable method to detect MB2 canals. In a sample of 2575 Chinese subjects, CBCT showed the highest incidence of MB2 canals were in the second decade of life, and there was a high likelihood of MB2 canals in the contralateral tooth.

According to Matherne et al.[36] three endodontists evaluated 72 extracted human teeth with digital detectors and photostimulable phosphor plates. The same teeth were evaluated by an oral and maxillofacial radiologist using CBCT. When the two-dimensional images were compared with the CBCT scans, the evaluating endodontists failed to identify at least one root canal in 40% of the teeth examined.

The prevalence of additional roots and additional canals has been reported using various techniques, such as intraoral[37] and three-dimensional radiography, MRI, scanning electron microscopy, tooth sectioning, micro-CT, and magnification. The use of CBCT in combination with the operating microscope showed that the identification and localization of extra canals in maxillary first molars was significantly improved.[34] The ability to identify internal anatomy is affected by canal scarification and the spatial resolution of the CBCT employed. Bauman et al.[7] reported that the detection of the MB2 canal increased from 60.1% at 0.4-mm voxel size to 93.3% at 0.125-mm voxel size. Detection of the MB2 canal was also more accurate when viewed by more experienced observers.

Teeth with severe curves or dilacerations require an instrumentation strategy that will respect the natural form of the root canal.[38] Cyclic fatigue fracture of rotary instruments with the same radius decreases as the length of the arc increases.[39] In a study of 100 mandibular first and second molars, all teeth evaluated had curvatures in both the buccolingual and mesiodistal directions, with the highest incidence of secondary curves occurring in the mesiodistal view.[40] CBCT has been shown to aid in accurate measurement of the radius of root curvature, resulting in more precise instrumentation and a reduction in procedural errors.[41]

Anomalies

CBCT can aid in diagnosing anomalies such as developmental malformations. Taurodontism, for example, is a developmental malformation characterized by an apical extension of the pulp chamber and no constriction at the level of the cemento-enamel junction seen most frequently in multirooted teeth.[42] CBCT was successfully used in several cases

reported in the literature owing to the difficulty in understanding the location and size of the root canals.[43,44]

Dens invaginatus (DI), is a dental anomaly that may result from an infolding of the dental papilla during tooth development[45] in response to external forces on the tooth bud or genetic disorders.[46] DI may affect teeth in both arches, but maxillary lateral incisors, followed by maxillary central incisors are most often affected and bilateralism is not uncommon.[47] There are case reports demonstrating the value of CBCT in understanding the three-dimensional architecture of these teeth and allowing orthograde endodontic treatment with preservation of tooth structure and vital elements of the pulp.[48]

Dens evaginatus (DE), is characterized by the formation of an accessory cusp that contains pulp tissue that may extend up to and including the tubercle's dentin core.[49] Jaya et al.[50] reported that the use of CBCT was useful in understanding the complex anatomy in a rare case of DI coupled with DE in the same maxillary central incisor.

For more information about these anomalies, see Chapters 1 and 26.

Proximal Anatomy

Determining the proximity of neurovascular structures to root apicies, especially in the mandible prior to orthograde and surgical endodontic treatment, may be useful in establishing a margin of safety. Carruth et al.[51] found that the mental foramen is located approximately 2.8 mm inferior and 0.01 mm mesial to the apex of the mandibular second premolar. Kovisto et al.[52] determined the distance from the apicies of mandibular bicuspid and molar teeth to the superior border of the mandibular canal. They reported that the mesial roots of the mandibular second molar were the closest to the superior border of the mandibular canal in female patients compared to male patients. CBCT was an accurate method to localize the relative position of the mandibular canal and should be considered in cases where iatrogenic injury is a risk.[52]

INTRAOPERATIVE

Fractured Endodontic Instruments

Instrument fracture during endodontic treatment is a procedural mishap that may occur at any stage or any location in the root canal. In a graduate endodontic program over a 4 year period, fracture incidence of hand instruments were 0.25% and rotary instruments were 1.68% of cases treated.[53] The apical third of mandibular molar root canals are the most common location of instrument separation.[53] CBCT was successfully used in a case study reported by Ball et al.[44] to determine the space for further ultrasonic preparation, evaluate the proximity of the root apex from the mental foramen, and localize a resorptive defect in the root. CBCT was successfully used to localize a separated file in the middle third of a ribbon-shaped canal of a mandibular lateral incisor that was subsequently bypassed and removed.[54]

Elderly patients show many changes in their dentition, especially partial or nearly complete occlusion of root canal space by secondary and tertiary dentin formation. The United States will experience an expected growth of its aged 65 and over population from approximately 50 to 84 million between 2015 and 2050.[55] Root canals typically calcify coronally first, then show decreasing calcification apically. CBCT has been shown to reveal internal root canal anatomy not shown with conventional imaging projections. During endodontic treatment, using available multiplanar reformations, CBCT has been shown to improve the triangulation of calcified canals with the use of markers, such as instruments or other radiopaque materials, leading to improved access without removal of additional tooth structure.[6] CBCT scans may show radiographically complete calcification of the root canal system with no changes in the periodontal membrane, allowing for the preservation of dentin and elimination of the risks of further treatment.[44]

Assessment of Root Perforations

Root perforations are usually associated with iatrogenic events and account for approximately 10% of all nonhealed cases.[56] Root perforations can be caused by procedures such as a postperforation, interproximal instrumentation error resorption or separated instrument retrieval, and are difficult to assess with conventional imaging because no information is available in the buccolingual direction.[57] An *ex vivo* study of the diagnostic accuracy of CBCT and periapical radiography in the detection of furcal perforations was conducted by Kamburoglu et al.[58] They concluded that actual perforation width was accurately determined with CBCT imaging, and CBCT showed superior detection of perforative defects when compared with periapical radiography. In a case report, CBCT was successfully used intraoperatively to mark the exact location of a perforation and facilitate repair with the appropriate material.[44]

Materials Extending Beyond the Root Canal, Inferior Alveolar Neurovascular Bundle

Endodontic treatment complications, such as overextension of obturation materials, or over-instrumentation in close proximity to the inferior alveolar neurovascular (IAN) bundle, may result in significant morbidity, such as anesthesia, hypoesthesia, paresthesia, and dysesthesia.[59,60] The IAN bundle, consisting of the inferior alveolar vein(s), artery, and nerve,[61] resides within the cribiform bone-lined mandibular canal and courses obliquely through the ramus of the mandible, and horizontally through the mandible body, terminating in the mental and incisive foramina.[62] Numerous case reports have concluded that the mandibular second molar is most frequently involved, but cases involving first molars and bicuspids have been described.[63,64] CBCT allows the mapping of endodontic treatment complications by producing three-dimensional representations of the teeth, supporting structures and vital anatomic features.

Pogrel[64] presented a case series of injury to the IAN and recommended careful monitoring of patients when there is radiographic evidence of sealant expressed into the IAN. If neuropathic symptoms develop after the anesthetic period has elapsed, immediate referral to an oral and maxillofacial surgeon is indicated. Even patients with no immediate untoward symptoms should be monitored for the development of latent symptoms for a period of 72 hours. Surgical decompression and debridement of the nerve should be conducted within 48 hours to ensure the best outcome.[64] Damage to vital structures such as the IAN are well-known adverse events associated with endodontic treatment.[65] A case study of IAN injury, resulting from overextension of sealer into the IAN, treated with nonsurgical management, has also been reported.[66] Gambarini et al.[67] reported that limited FOV CBCT was an effective radiographic modality to assess endodontic-related IAN complications.

Materials Extending Beyond the Root Canal, Maxillary Sinus

Iatrogenic introduction of obturants, irrigants, and instruments into the maxillary sinus has been described in numerous case studies. Overextension of zinc oxide-eugenol containing sealers into the maxillary sinus may promote sinus aspergillosis.[68] Legent et al. evaluated 85 cases of aspergillomas and concluded that 85% of the cases resulted from endodontic treatment.[69] Hodez et al.[70] stated that CBCT is very effective for the assessment of sinusitis of dental origin, but lacks soft tissue discrimination necessary to explore tumoral processes. For more details, see Chapter 16. CBCT was also able to show fine calcifications, associated with aspergillus, around foreign bodies of dental origin.

VERTICAL ROOT FRACTURES

The detection of vertical root fractures is challenging. VRFs are complete or incomplete longitudinal fractures of the root, are usually directed buccolingually, may involve one or both proximal surfaces, are confined to the root, and may originate from the root at any level.[71] For more details, see Chapter 14.

The prevalence of VRF in extracted, root-treated teeth has been reported to range from 8.8 to 20%.[72,73] Teeth with VRFs have an unfavorable prognosis, may cause significant loss of supporting bone, and ultimately result in extraction.[74] VRFs are difficult to accurately diagnose because the clinical and radiographic signs are inconsistent, leading to the possibility of unwarranted extraction.[75] Root-filled mandibular posterior teeth show the highest incidence of fracture.[76] VRFs are difficult to visualize with intraoral radiographs unless the X-ray beam is parallel to the plane of the fracture.[77]

The accuracy of CBCT in the detection of VRF is controversial. In a review and meta-analysis of all *ex vivo* and *in vivo* studies published before November 2013, the use of CBCT in the detection of VRF showed a range of results.[73a] In the detection of VRF in unfilled teeth, *in vitro* studies showed significantly higher sensitivity and specificity using CBCT imaging with a voxel size of 0.2 mm or smaller when compared with periapical radiography. In root-filled teeth, CBCT imaging showed lower pooled sensitivity and specificity when compared with periapical radiographs. The low pooled sensitivity and specificity of CBCT in the assessment of VRF is thought to be related to beam-hardening and streak artifact. CBCT imaging may contribute other benefits to the diagnosis, such as the ability to see the true nature of the fracture, without tissue compression, magnification, and parallax error. Only two *in vivo* studies were considered in this meta-analysis, where CBCT showed high sensitivity and specificity in the detection of VRF, but more study was recommended.

The value of CBCT in the detection of VRF has been reported in *ex vivo* and clinical studies. VRF in root-filled teeth reduced the sensitivity and accuracy of periapical radiographs whereas it only reduced the specificity of CBCT.[78] In another *ex vivo* study, Brady et al.[74] concluded that the detection of simulated incomplete VRF in non-root-treated teeth was unreliable with either CBCT or periapical radiographs. Accuracy varied between the two CBCT scanners tested; however, both CBCT scanners showed better results than intraoral radiographs when the size of the VRF was ≥50 μm compared with VRFs of <50 μm. *Ex vivo* studies may show higher accuracy than clinical investigations, because patient-derived movement artifact is eliminated.[81,82] Additional study[83] showed that the results, determined for vertical root detection, were significantly different between different CBCT systems with the iCAT (ISI, Hatfield, PA), outperforming the other systems tested. The Galileos (Sirona, Bensheim, Germany) performed poorly, the NewTom 3G (VR Imaging, Verona, Italy) and Accuitomo xyz (J Morita Corporation, Osaka, Japan) provided fair results, the Scanora 3D (Soredex) moderate results, and the iCAT Next Generation (ISI, Hatfield, PA) provided good results. VRFs were better detected in molars than in premolars.

Successful detection of VRF requires high spatial resolution and benefits from the use of the axial view.[84] CBCT images suffer from artifacts generated by highly attenuating obturation materials and posts, resulting in reduced specificity.[85] Patel et al.[86] examined extracted teeth with synthetically generated incomplete fractures using a light microscope and optical coherence tomography. They reported that the maximum width of fractures ranged from 30 to 100 μm. The detection of VRF with all CBCT systems is influenced by the spatial resolution and contrast-to-noise ratio of the selected FOV,[82] size of the fracture, number of basis projections, technique factors, reconstruction algorithms, detector sensitivity, and imaging artifacts. Smaller voxel size and the application of sharpening high-pass filters improved sensitivity without affecting specificity for the detection of transverse root fractures.[87]

Numerous case series have been published to evaluate the usefulness of CBCT in the detection of VRF. While the resolution of 2-D digital detectors and CBCT detectors ranges from 16 to 25 lp/mm and 6 to 8 lp/mm, respectively, CBCT has been shown to have higher sensitivity and specificity where the detection of VRF was validated by surgery. Bias in these studies is difficult to control, however, because observations are

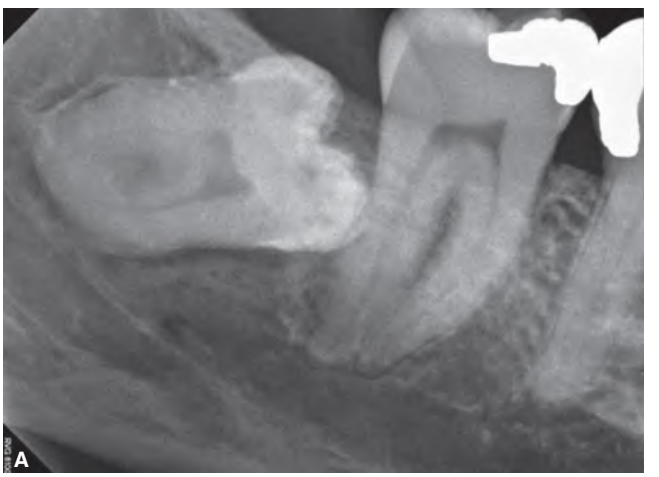
influenced by the presence of alterations in the tooth-supporting tissues and the selection of patients evaluated.[88]

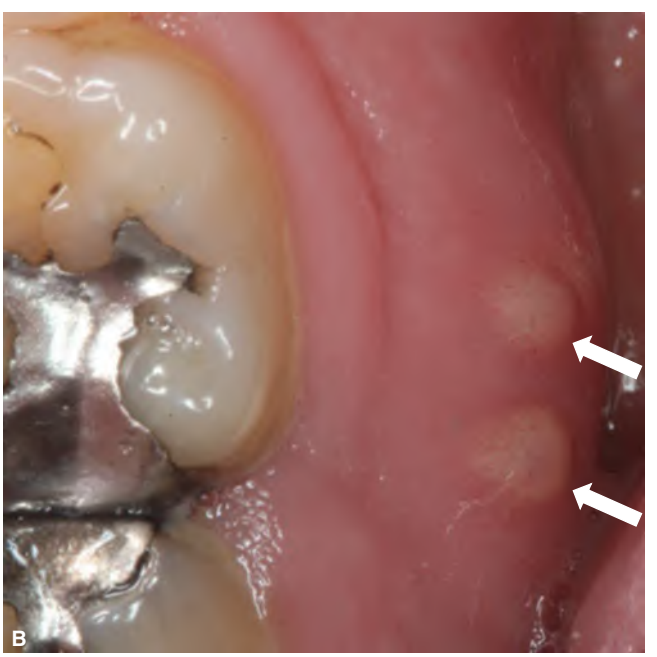
ROOT RESORPTION

Root resorption is a physiologic process that results in exfoliation of a primary tooth or a pathologic process that is usually associated with mechanical, thermal, or chemical injury to the supporting structures, cementum, or dentin.[89] For more details, see Chapter 15. This resorption may be inconsequential[90] or cause significant damage to the tooth and supporting structures if the resorptive process continues. Because of the inconsistent clinical presentation of resorptive lesions, detection of this condition is predicated on the appearance of radiographic alterations. The pathogenesis of external root resorption (ERR) and internal root resorption (IRR) are different, and the treatment protocols vary. However, several studies have reported that intraoral radiography may not show the full extent of resorptive lesions.[91] In an *ex vivo* study, Durack et al.[92] reported that the accuracy of CBCT was the same for 180° and 360° gantry rotation settings. The 180° scans resulted in a significant reduction in the x-radiation dose to the patient.

External Root Resorption

The use of serial cross-sectional CBCT to show the true size and location of ERR has been well documented[93] (Figure 9C-8). Additional *ex vivo* studies have shown that





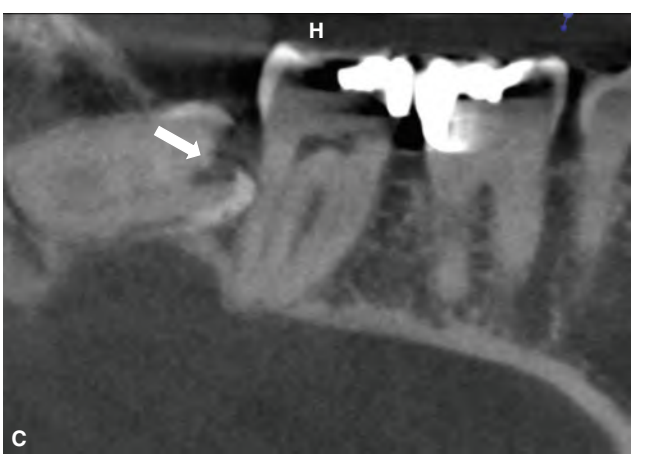


FIGURE 9C-8 Planar imaging is limited by superimposition of anatomic features. ***A.*** Initial periapical image of the mandibular right second molar and bony impacted-third molar shows no pathologic findings. ***B.*** A photograph of two nonproductive sinus tracts on the lingual of the mandibular right second molar that suggest a lesion in the supporting bone (solid arrows). ***C.*** CBCT of the same region shows a wedge-shaped resorptive lesion in the crown of the third molar (solid arrow) with erosion of the lingual aspect of the alveolar crest on the distal and mesial aspects of the mandibular second molar; features consistent with external resorption.

CBCT was more accurate than conventional imaging in the detection of simulated surface defects[94] and postorthodontic resorption in roots of lateral incisors as a result of impacted maxillary cuspids.[95] Patel et al.[96] compared the accuracy of intraoral radiography with CBCT in an *in vivo* study of 15 teeth. They found that CBCT showed a significantly higher prevalence for selection of the correct treatment option when measured against intraoral radiography. There was higher inter-examiner and intra-examiner agreement using CBCT, suggesting that less superimposition of structures and the ability to visualize the region in any plane assisted in the correct assessment. An *ex vivo* volumetric analysis has demonstrated improved quantification with high-resolution CBCT scans when compared with low resolutions scans and periapical radiography.[97] In an *ex vivo* comparison of CBCT and intraoral radiographs, Bernardes et al.[98] showed that CBCT provided significantly better detection values regardless of the simulated lesion size and tooth evaluated.

Invasive cervical resorption is a less common form of external root resorption.[99,100] CBCT can be relied upon to reveal the true extent of the lesion, allow for the identification of the portal of entry and to ensure that an appropriate treatment plan has considered[6] (Figure 9C-9).

Internal Root Resorption

Clinically detectible IRR is considered a rare occurrence. It is usually asymptomatic and appears as a round, radiolucent

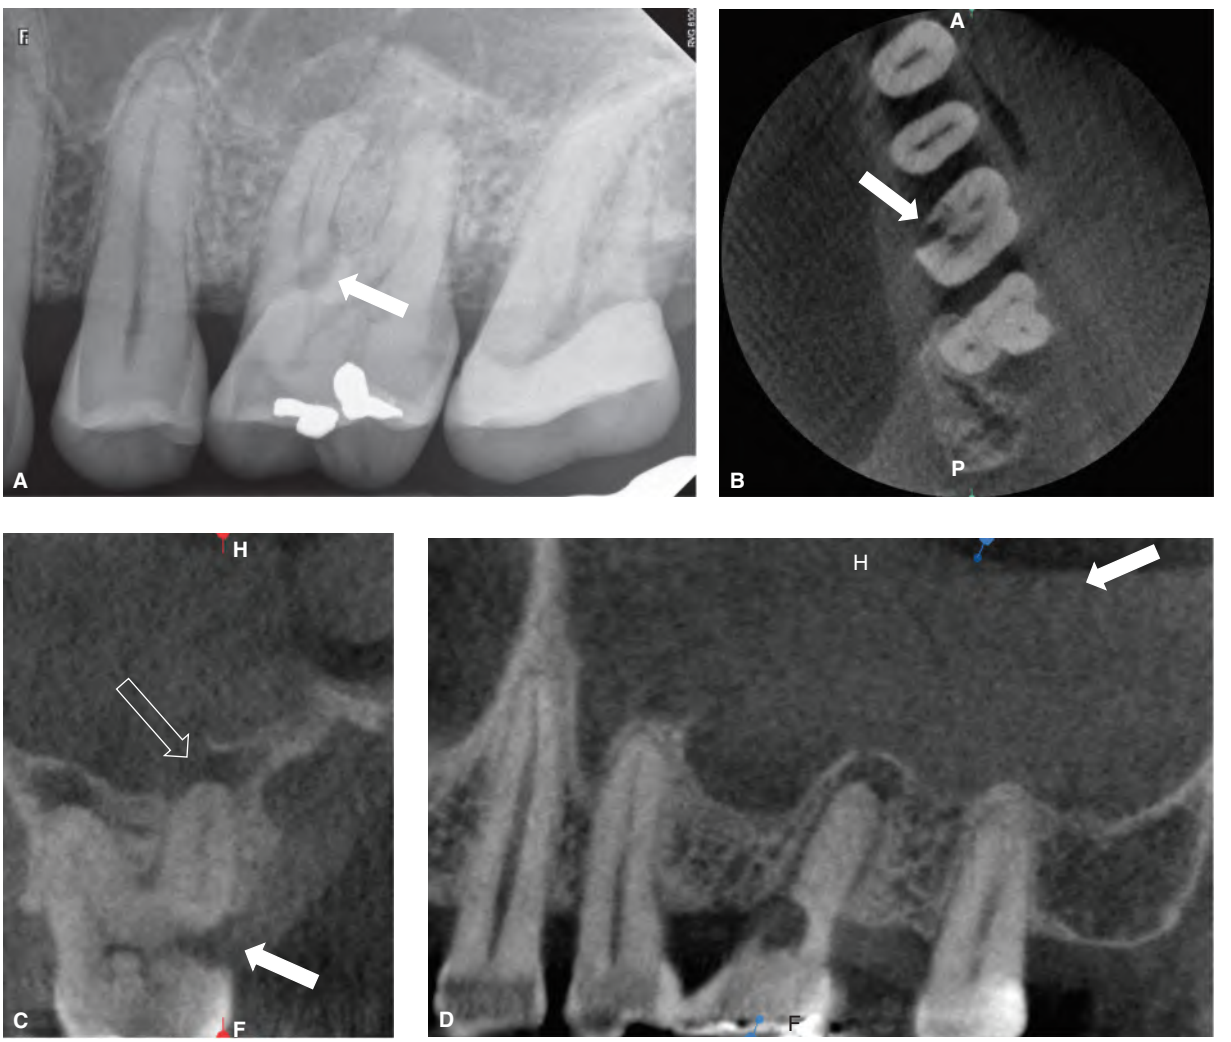

FIGURE 9C-9 CBCT has been shown to be more accurate than periapical radiography in the detection of invasive cervical resorption. ***A.*** Periapical radiograph shows the maxillary left first molar with an irregular region of medium attenuation at the junction of the mesiobuccal and palatal roots (solid arrow), rarefying osteitis at the periapicies of the of the mesiobuccal, distobuccal, and palatal roots and lifting the sinus floor. ***B.*** Axial reformation shows the true extent of an irregular region of low attenuation (solid arrow), a feature consistent with invasive cervical resorption. ***C.*** Cross-sectional reformation shows a wedge-shaped region of low attenuation of the palatal root (solid arrow), large pulp stone, rarefying osteitis of the mesiobuccal and palatal roots with erosion of the sinus floor (outline arrow) and mucositis of the portion of the sinus imaged. ***D.*** Panoramic reformation of the palatal root with osteoperiostitis and mucositis (solid arrow).

widening of the root canal space.[101] Several studies show that small resorptive lesions detected with scanning electron microscopy may be a common finding in teeth with pulpal inflammation or necrosis, but may not be radiographically visible.[102,103] CBCT has been shown to provide high sensitivity and specificity when serial cross-sectional views of external resorption were viewed.[104] A recent case study showing the assessment and subsequent repair of a massive internal resorptive lesion relied on CBCT to show the full extent of the lesion.[105] CBCT allows precise mapping of IRR lesions and allows for authoritative differentiation between IRR and ERR.[96]

DENTAL AND MAXILLOFACIAL TRAUMA

Approximately 5% of all injuries involve the oral region. Crown fractures and luxation injuries occur most frequently, affecting the maxillary central incisors in 80% of cases.[106] The prevalence of maxillofacial trauma and sequelae are generally underestimated. Systematic studies have suggested that facial injuries may frequently result in dental trauma.[107,108]

Root fractures occur in approximately 7% of traumatic dental injuries,[109] but are difficult to confidently diagnose and manage with conventional radiography alone[110] (Figure 9C-10). While intraoral radiography is essential to help identify the nature of the traumatic injury to the teeth, such as exposure of the pulp and stage of root development, these conventional projections may not show horizontal root fractures (HRFs), alveolar fractures and tooth displacement. Fractures in the apical, middle, and coronal thirds and the extent of dislocation of the coronal fragment are important in treatment planning. According to the International Association of Dental Traumatology's guidelines the exact nature of a HRF is difficult to assess with conventional imaging, even when several horizontal and lateral projections angles and an occlusal radiograph are acquired. Multiple intraoral projections and the discomfort to a child undergoing an intraoral radiographic examination in emergent conditions may favor a single periapical image and limited FOV CBCT examination. Limited FOV CBCT image volumes showed higher sensitivity, negative predictive value, and diagnostic accuracy in the detection of vertical fractures than multidetector helical CT at a slice thickness of 0.63 mm and intraoral radiographs.[111] Kamburoğlu et al.[112] compared the diagnostic accuracy of conventional radiographic images and CBCT in 36 teeth with simulated HRF. The sensitivity of CBCT was significantly higher than conventional imaging techniques. Bernardes et al.[113] compared conventional imaging with CBCT to detect HRFs in 20 patients. They found that CBCT was able to detect fractures in 90% of patients whereas periapical images could only detect fractures in 30% to 40% of cases.

PRESURGICAL TREATMENT PLANNING

Endodontic surgery is sometimes necessary if nonsurgical procedures are unsuccessful. For more details, see Chapter 24. CBCT provides undistorted multiplanar representations of the roots, supporting structures, and important anatomic features, allowing precise localization of pathologic alterations.[114] Individual roots can be assessed and the location and true size of endodontic pathoses can be determined. The value of CBCT in optimizing surgical procedures was first described by Rigolone et al.[115] in the planning for apical surgery on the palatal roots of maxillary first molars. They suggested that the distance between the palatal root and the vestibular cortex could be measured, possibly allowing trans-alveolar access instead of the more difficult palatal surgical approach. Using CBCT for successful localization of lesions and separated instruments prior to endodontic surgery have been reported by others.[116] Low et al.[12] compared intraoral radiographs with CBCT for the assessment of 37 maxillary bicuspids and 37 maxillary molars prior to apical surgery. They concluded that CBCT identified 34% more lesions than conventional radiography and that additional findings, such as sinus membrane thickening and missed canals, were only visible on CBCT image volumes. Missed canals, additional roots, dilacerations, and the true size of a periapical lesion may be visible with CBCT.[6]

Anterior teeth are not exempt from consideration of their proximity to important anatomic structures. Taschieri et al.[117] evaluated 57 maxillary central and lateral incisors with CBCT imaging. The maxillary central incisor measured 4.71 ± 1.26 mm from the anterior wall of the nasopalatine duct at 4 mm from the apex and 9.5 mm from the apex to the floor of the nasal cavity. CBCT has been shown to be useful in the pre-surgical assessment of the region of interest.

Studies support the use of CBCT in the treatment planning process. Ee et al.[118] examined preoperative intraoral radiographs and CBCT image volumes in 30 endodontic cases and concluded that 62% of the treatment plans were modified based on information provided by the volumetric images. The distance between the apex of mandibular molars and the roof of the mandibular neurovascular bundle could be determined in only 35.4% of cases studied.[119] CBCT can allow assessment of the full extent of lesions that are underrepresented by approximately 10%[120] and comorbidities in the maxillary sinus prior to surgery.[121]

MAXILLARY SINUSITIS OF ENDODONTIC ORIGIN

Maxillary sinusitis can result in dental pain because of shared innervation and the proximity of the antrum to the roots of the maxillary posterior teeth. Conversely, inflammation or infection of the maxillary posterior teeth can cause

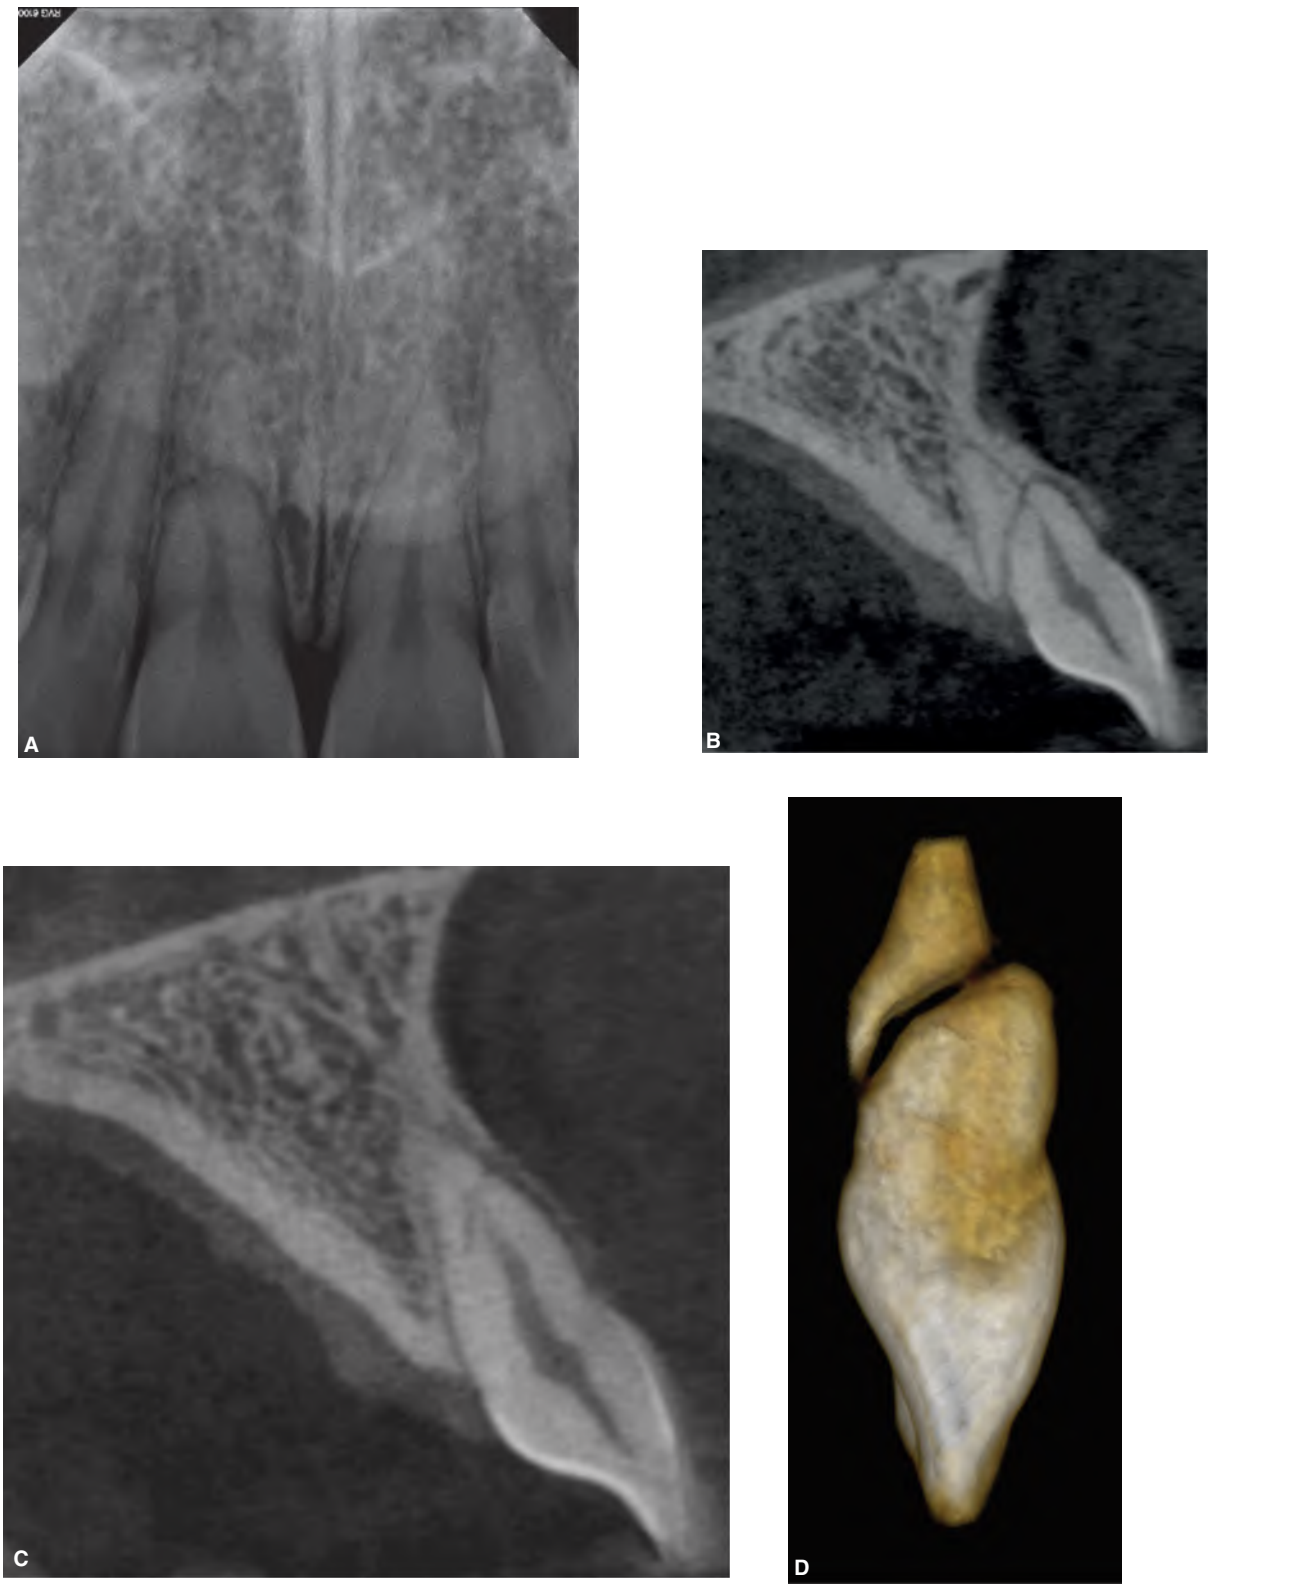

FIGURE 9C-10 The sensitivity of CBCT is significantly higher than conventional imaging techniques in the detection of horizontal root fractures. ***A.*** Periapical radiograph showing a horizontal fracture in the middle third of the maxillary right central incisor with dislocated apical fragment. ***B.*** Sagittal reformation of the same tooth showing the true nature of the dislocation of the apical third of the root. ***C.*** Sagittal reformation of the maxillary left central incisor showing nondislocated oblique fracture of the apical third not clearly visible with periapical radiograph. ***D.*** Segmented 3-D CBCT reformation of the maxillary right central incisor.

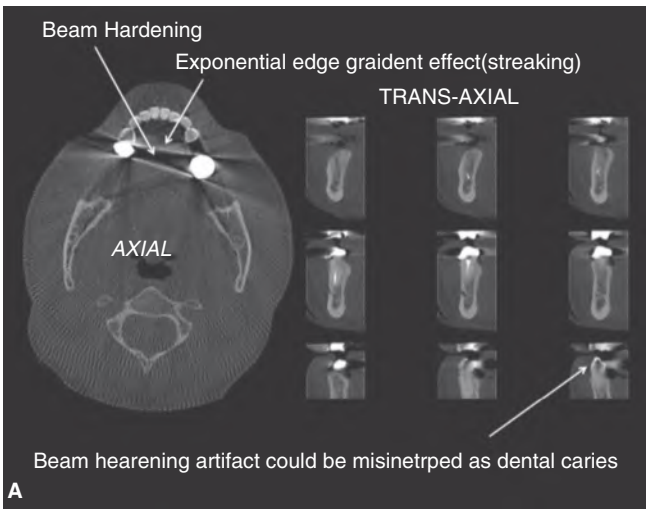
inflammatory changes in the sinus, possibly leading to sinusitis. For more details, see Chapter 16.

Maxillary sinusitis of dental origin may account for 10 to 12% of sinusopathy.[122] Teeth closest to the maxillary sinus have the highest incidence of maxillary sinusitis.[123] Numerous cadaver and clinical studies have suggested the importance of tomographic imaging, early intervention, and management in the event of maxillary sinusitis secondary to odontogenic causes. Nair et al.[124] reported a case series that showed lesions of endodontic origin with confounding clinical findings. CBCT showed involvement of the maxillary sinus, aiding with a presumptive diagnosis. They stated that an otolaryngology consultation may be indicated in these instances. In a case series, Cymerman et al.[125] reported that CBCT was useful in showing the etiology, extent of the lesions studied and aided in clinical management. In one of the cases, bronchitis of 1-year duration resulted from sinusopathy caused by a dental infection. Peri-implatitis is another possible cause of sinusopathy, and should be considered in the differential diagnosis, when indicated.[126] In a meta-analysis reported by Arias-Irimia et al.[127] maxillary first molars were the most frequently implicated. In a retrospective analysis of 143 patients with at least one maxillary posterior tooth showing a periapical area of low density, Nunes et al.[128] found that 64.3% of maxillary sinuses showed abnormalities in the presence of periapical areas of low density, without clinical correlation. Limited FOV CBCT should be considered as an adjunct to periapical imaging in cases where sinusitis of endodontic origin is suspected.

ARTIFACTS IN CBCT

CBCT is a valuable adjunct to endodontic practice; however, artifacts should be understood in order to reduce confusion that might otherwise lead to misdiagnosis. As with any imaging modality there is need to consider the possible artifacts that may either obscure real disease changes, or be mistaken for disease when no lesion is actually present. Understanding artifacts is important when selecting CBCT as an imaging method, in modifying exposure parameters or patient position, and in making correct assessments of the acquired image volume. An excellent review of CBCT artifacts in the maxillofacial region was made by Schulze et al.[129] Artifacts in CBCT include beam hardening, photon starvation, streaking through scatter, undersampling, ring artifact, aliasing, quantum noise, cone beam artifact, and motion.

Beam hardening artifact is produced by increased mean beam energy caused through absorption of low energy photons due to the presence of substances of high radio-density such as metallic dental coronal restorations, radiopaque endodontic filling materials, surgical plates, and dental implants. An extreme example of this is photon starvation with complete absorption of all photons along certain paths. Such features appear as dark areas or bands and can be accompanied by white streaks (streaking) from the exponential edge gradient effect due to scatter with X-ray deflection accompanied by faulty projection data. These phenomena can be readily interpreted in the axial view (Figure 9C-11A). However, in the last of the series of transaxial views, the premolar tooth has a dark area over the crown due to the beam that might easily be misinterpreted as dental caries. Narrow bands of beam hardening due to endodontic restorations could be misinterpreted as dental root fractures. A true vertical root fracture is compared to beam hardening artifact from endodontic fillings in Figure 9C-11B. Beam hardening and the exponential



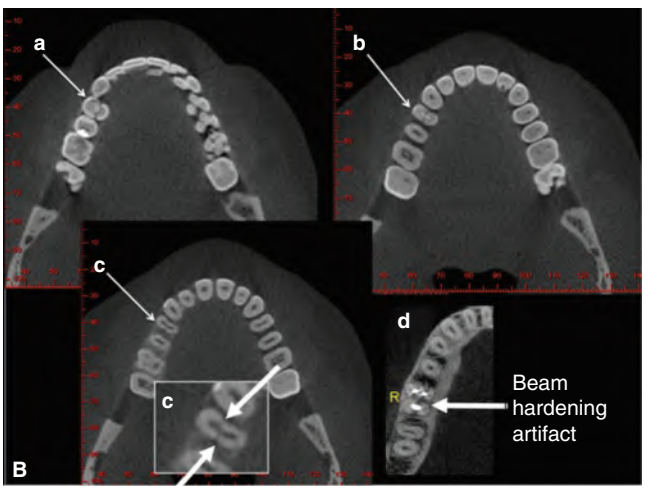


FIGURE 9C-11 ***A.*** Beam hardening and exponential gradient effect due to metallic restorations. Beam hardening artifact can be mistaken for dental caries when it projects over the crown of a tooth or teeth. When there are multiple metallic restorations, particularly in both jaws, the problem can be alleviated to some extent by having the head tilted at an angle to reduce superimposition of the restorations within the beam projection. ***B.*** Axial views of the same premolar tooth with a vertical fracture (a–c). Beam hardening artifact in an endodontically-treated molar tooth that does not have a root fracture (d).

gradient effect can create confusion (Figure 9C-12A). The initial axial view demonstrates that there are no teeth in the maxilla between the left central incisor and second premolar; however the transaxial view made at slice a-b appears to show an endodontically treated tooth in that region. Indeed, this apparent tooth was found throughout the gap between the left central. The apparent endodontic filling was streaking artifact and the apparent tooth dentin was a bite block positioned to stabilize the jaws during imaging (Figure 9C-12B).

Ring artifact (Figure 9C-13) is caused by the circular trajectory in CBCT and bad pixels at the periphery of the scan. The ROI should be kept central within the FOV rather than the extreme edge of the detector. Moire pattern (aliasing) is caused by undersampling often in a misguided attempt to excessively reduce dose and thereby diminish image quality to below diagnostic utility (Figure 9C-14). Overly minimizing dose by reduced milliamperage or kilovoltage can also lead to quantum noise and grainy and undiagnostic image

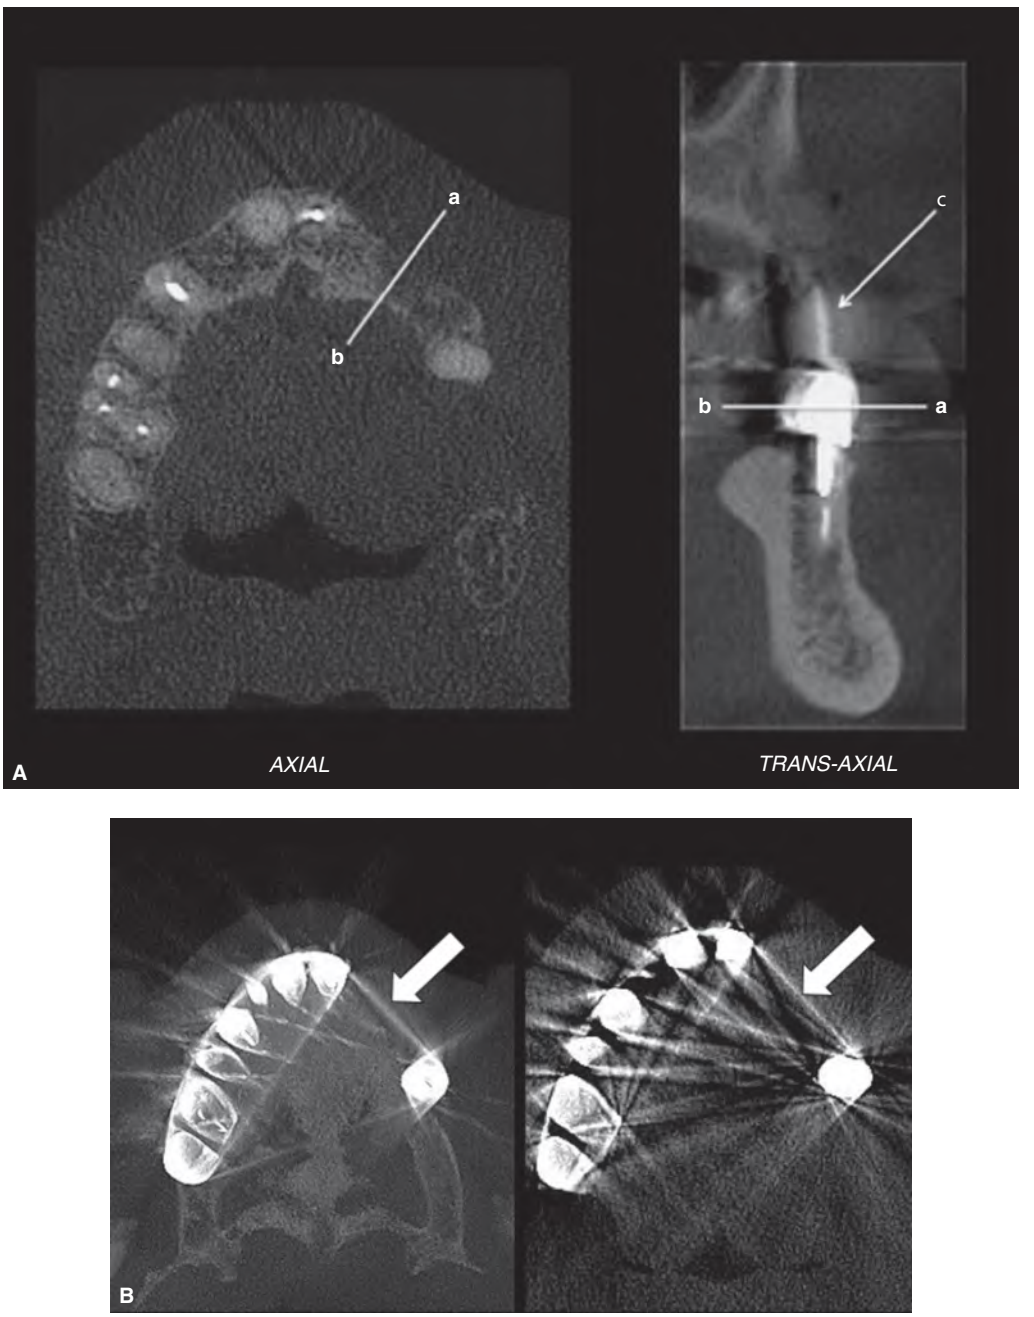

FIGURE 9C-12 ***A.*** The axial view demonstrated that the maxilla is edentulous between the endodontically treated left central incisor and the left second premolar. However, the transaxial view made from (a) to (b) shows what appears to be an endodontically treated tooth in this site in the maxilla. Transaxial and axial views made at different levels reveal the apparent endodontic filling in the figure to be due to streak artifact from exponential edge gradient effect. ***B.*** The apparent tooth dentin is a prop placed to stabilize the jaws during imaging.

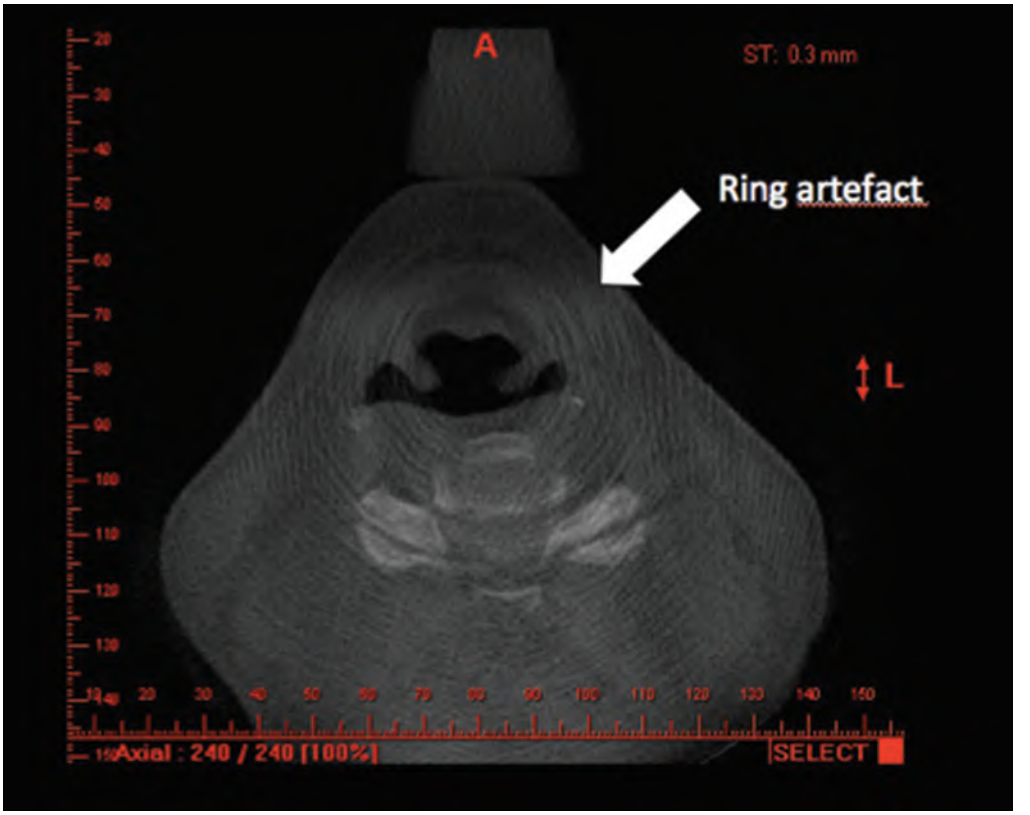

FIGURE 9C-13 Axial view showing ring artifact due to circular trajectory and bad pixels at the periphery of the detector.

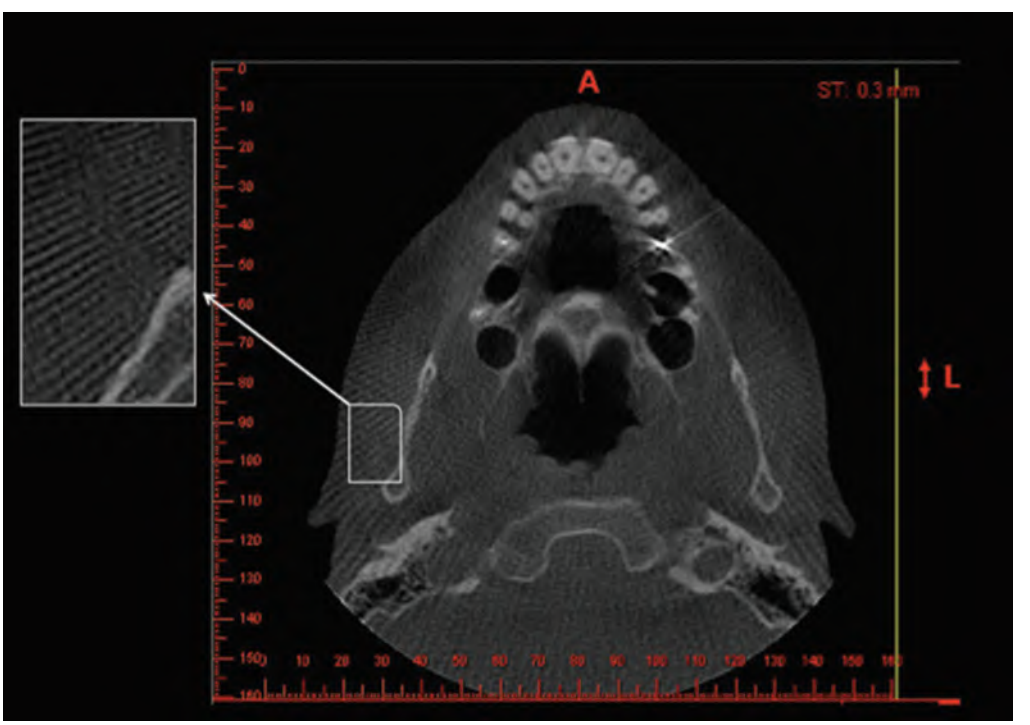

FIGURE 9C-14 Axial view: Moire ("cartwheel") pattern due to undersampling causing aliasing.

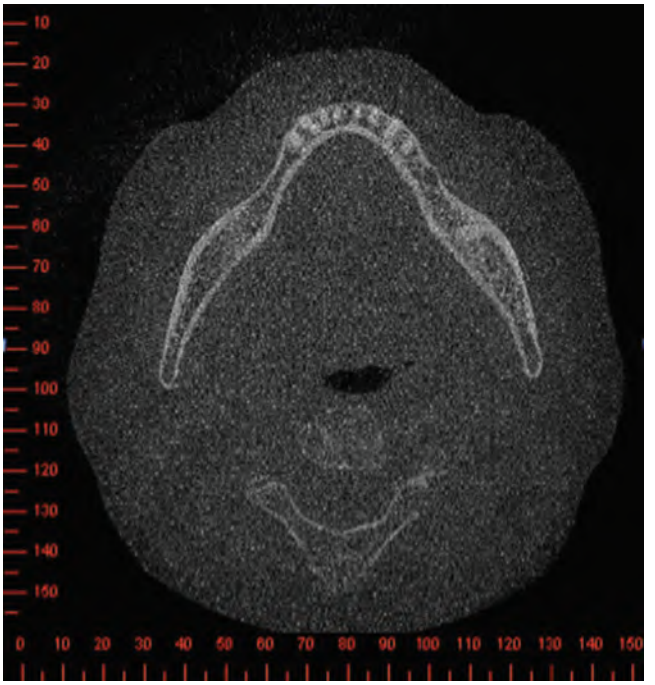

FIGURE 9C-15 Axial view: Quantum noise due to low exposure producing a grainy image suboptimal in diagnostic quality.

(Figure 9C-15). The diverging beam in CBCT and scattering of radiation mean that CBCT is not entirely consistent in pixel gray scale value across the image volume, hence unlike multislice CT, voxel Hounsfield Number determination should not be counted upon to be precise.

As with other imaging techniques, it is imperative that the patient remains motionless during CBCT exposure. The selected voxel resolution will not be realized in the final image volume should the patient move. For this reason, patient stabilization within the cephalostat is a must. It is recommended that patients close their eyes during the exposure to prevent movement while following the trajectory of the generator and detector.

SUMMARY

Intraoral and panoramic radiography delivers a cost-effective, high-resolution imaging modality that may be augmented by CBCT when necessary. CBCT has been shown to improve endodontic assessments by providing undistorted representations of the dentition and maxillofacial structures without compression of anatomical features. CBCT is an important, task specific imaging modality for the comprehensive treatment of endodontic disease.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of Dr. Elena Andronova for her technical assistance and Dr. Barry Pass for his contribution to the preparation of this chapter. CBCT data for figures 9C-5 through 9C-10 were acquired on a CS 9000 3D at 0.076 mm resolution and reformatted using Carestream Dental Imaging Software v.3.5.7 (Carestream Dental, Atlanta, GA).

Chapter 9D

Magnetic Resonance Imaging

Hatice Dogan-Buzoglu

Magnetic resonance imaging (MRI) is a well-established, noninvasive technique to create high-resolution images of internal structures of the body using strong magnets. It is accepted as one of the best imaging technique for soft tissues and vessels rather than hard tissues.[1–3]

OPERATING PRINCIPLE OF MRI

MRI utilizes nonionizing electromagnetic radiation to produce high quality cross-sectional images of the body, depending on the behavior of hydrogen protons inside the magnetic field. Normally, the patient's hydrogen protons spin on their axis. When the patient is placed into a strong magnetic field, the nuclei of many atoms in the body, including hydrogen, align with the effect of the magnetic field. A radiofrequency (RF) signal that is sent toward the body structures knocks the hydrogen protons and systematically alters the alignment of this magnetization moving from a longitudinal to a transverse plane. This produces a rotating magnetic field from the body that is detectable by a scanner ultimately creating the magnetic resonance (MR) image by a computer.

MRI is based on the natural magnetism of the human body. The strength of this magnetism depends on the proton density that is dependent on the number and type of hydrogen atoms in the tissue fluids and fats. Loosely bound hydrogen atoms, such as those present in soft tissues and liquids, can align themselves with the external magnetic field and produce a detectable signal. On the other hand, tightly bound hydrogen atoms of hard dental tissues fail to produce a usable signal as they cannot align themselves.[3–6]

As soon as the RF pulse is turned off, the return of the hydrogen protons to their original direction (longitudinal) occur at a lower energy. This process is called *relaxation*. There are two relaxation types: *spin-lattice* and *spin-spin*. Spin-lattice controls the re-growth of the magnetization along the *z*-axis and is known as the *longitudinal proton relaxation time* or *T1-weighted sequence*. A tissue with long T_1 produces a low intensity signal and appears dark in MR image. T_1 weighted images are also called *fat image* because fat has the shortest T_1 relaxation time and appears bright in the image. It shows the high anatomic detail due to excellent image contrast.

Spin-spin controls the loss of transverse magnetization in the *xy*- plane, and is known as *transverse proton relaxation time* or the *T2-weighted sequence*. It is also termed *pathology scans* or *water image* since collection of abnormal fluid in pathological tissues gives similar signal sequences like in water that has the longest T_2 relaxation time with bright image, as opposed to darker normal tissues with short T_2 sequences. These images are useful for detecting infection, hemorrhage, and neoplasm. In practice, images often must be acquired with both T1 and T2 weighting to separate the several tissues by contrast resolution.[5–7]

Most MRI machines are graded based on the strength of the magnet, measured in Tesla units (T); equivalent to 10,000 times the magnetic field strength of the Earth. MRI with scanners with the power of 0.5 to 4 T have been used in clinical practice. Higher T produces higher MR signal rates and offers advanced neuroimaging with suitable software. Although magnets as high as 11, 4 T were used in vitro for high quality image resolution, a safe magnet value is limited to 4 T in vivo.[4,8]

MRI IN DENTISTRY

In dentistry, alternative imaging techniques have been suggested as diagnostic aids and to overcome the limitations of intraoral radiographs such as transfer of three-dimensional anatomy into a two-dimensional image, geometric distortion, and anatomical noise. MR imaging attracted attention for potential use in dentistry during the 1980s, after first being used as a tool for medical diagnosis in humans in 1977 (Figure 9D-1).[8–10]

MRI is generally used in dentistry to diagnose disorders of the temporomandibular joint, inflammatory conditions of the facial skeleton, salivary glands, maxillary sinuses, and early bone changes such as neoplasms, osteomyelitis, fractures, and changes of mouth floor and tongue. MRI has an essential role in determining the extent of soft-tissue invasion of maxillofacial tumors. Some cases of squamous cell carcinoma of the tongue can only be visualized by MRI. It provides greater specificity than CT in distinguishing between odontogenic cysts and tumors by examination of signal characteristics.[11,12]

The potential use of MRI in dentistry has increased with the development of methods that allow imaging of hard dental tissues, such as enamel, dentin, cementum, and bone. The thickness of cortical bone, extent of periapical lesions, number of roots in multirooted teeth as well as smaller branches of the neurovascular bundle entering apical foramina can be successfully detected. It can also be useful for periapical surgery, dental implant planning, and periodontal structures. Furthermore, some researchers have successfully studied caries lesions and pulp vitality as well as pulp anatomy.[13–18]

USE OF MRI IN ENDODONTICS

Soft dental tissues have higher water content and much longer T_2 relaxation times. Therefore, MRI imaging of these tissues by standard MRI techniques, such as 2D or 3D gradient-echo is possible. Spin-echo offers echo times in the range of a few milliseconds and gradient-echo offers echo times as short as 1 ms. Both pulse sequence methods are considered as the "liquid" imaging. In the literature, detailed-MRI images of dental pulp anatomy were accurately demonstrated in vitro and in vivo by additional volumetric image program or high magnetic field.[1,11,19] Moreover, comparison of signal intensities before and after contrast agent administration showed a significant difference, with high sensitivity, between vital and nonvital teeth, depending on age.[16,20]

There are different clinically relevant MRI methods for obtaining images of densely calcified dental tissues. Dentin comprises up to 70% mineral hydroxyapatite, about 20%

organic material and only 10% water. In enamel, the mineral content can even get as high as 96%. Due to the high mineral content, the lack of free hydrogen protons causes weak magnetization. This results in extremely low T2 relaxation time and a scarcely detectable signal. In order to obtain images, it is important to reduce the echo, or detection time, to microseconds.[13,21,22]

Projection reconstruction, single point imaging or its improved version, SPRITE, with moderate spatial 3D resolution, turbo-spin echo (TSE), ultra-short echo time (UTE), zero-echo time (ZTE), FID-projection imagines and stray-field imaging (STRAFI) are useful for obtaining MR images of hard dental tissues. STRAFI produces suitable images by high resolution when the T2 time is very short, but is less appropriate when T2 time is long, as is typical for soft tissues.[22–26] Recently UTE and ZTE MR imaging were successfully used to detect lesions in enamel, dentin, and pulp tissue (Figure 9D-2).[26]

A new technology named SWIFT (sweep imaging with Fourier transform) has also been used in hard dental tissues. This system can visualize tissues in vitro using a 9.4 T, ranging from 100 seconds to 25 minutes scanning time with 100 µm resolution. The same technique can be used in vivo for imaging tissues with 4T, 10 min scanning time and 400 µm resolutions. It can simultaneously image both hard and soft dental tissues with high resolution in relatively short scanning times and thereby be useful to determine the extent of carious lesions and the status of the pulp tissue (Figure 9D-3).[8] Similar results were observed when pulp tissue response to caries was assessed by diffusion-weighted imaging technique that determines the apparent diffusion coefficient (ADC) of water in the tissue (Figure 9D-4). However, long scanning time necessary for this method prevents its use under in vivo conditions.[27] Present clinical diagnostic modalities do not provide accurate information on pulp inflammation as related to caries, except for visualizing the formation of reparative dentin against the insult. Therefore, additional techniques, using MRI, should be assessed as potential markers to accurately diagnose the pulp response.

In caries lesions, properties of hard dental tissues are significantly altered. Increase of porosity and water concentration due to a demineralization process in the carious lesions prolongs T_2 relaxation time of dentin. This makes caries detection possible using even standard MRI techniques, such as T_1-weighted MRI. Caries lesion is observed as brightly radiopaque-like pulp and periodontal ligament in MR imagines.[8,11,27]

Bone tissue fails to produce adequate MRI signal. However, bone marrow emits fat tissue signals. Therefore, MRI is the diagnostic method of choice in cases with an infection such as periapical abcess and osteomyelitis that spreads to the soft and bone tissues. It can detect cancellous bone marrow abnormality in acute osteomyelitis as well as the disruption of cortical bone in periapical lesions. The principal MR examination technique used for fat suppression is the short inversion time inversion recovery (STIR).

ADVANTAGES AND DISADVANTAGES OF MRI USE

MRI can produce very high spatial resolution images in any plane and provides images without exposure to ionizing radiation used in X-rays and CT scans. Conventional tooth radiographs cause superposition of pulp structures since it shows only 2-D projection of a tooth in the bucco-lingual direction. Therefore, the fourth canal of maxillary molars can be scarcely visualized. Using MR imaging, the anatomical variations in teeth including the size and shape of the pulp chamber and root canals are well demonstrated by MRI 3-D images that can be converted into a projection and give significantly more information than radiographic 2-D projections. MRI signals of soft tissues may also provide valuable information about the vitality of the pulp tissue. Therefore, it is considered as a convenient method for dental pulp imaging that cannot be directly assessed by radiographic imaging.[11,19,28]

Every object exposed to a magnetic field displays a certain amount of magnetism depending on composition of the material. Although fixed dental prostheses, amalgam restorations, and orthodontic appliances can produce image distortions on MRI scan of orofacial area, they exhibit minimal deflection in a static magnetic field that can be a major problem with CT technology and are, therefore, regarded safe for MRI.[3,6,29]

MRI has several disadvantages when compared to simple radiographs such as, poor resolution and long scanning times, reducing patient comfort and risking safety. Another aspect of the MRI technology is that it requires high financial resources for setup and operation of MRI units. Different types of hard tissues such as enamel and dentine cannot be differentiated from each other or from metallic objects; they all appear radiolucent. Specific absorption rate that leads to tissue heating may also limit the use of MRI. Although it was suggested that MRI can be used in children and even pregnant patients, claustrophobia (i.e., morbid fear of closed places) may affect the patient's motion. Additionally, contrast materials may cause allergic tissue reactions. Due to these reasons, MRI still has limited use for management of endodontic diseases.[6,11]

A strong magnetic field has the capability to pull heavy objects towards the scanner at a very high velocity.

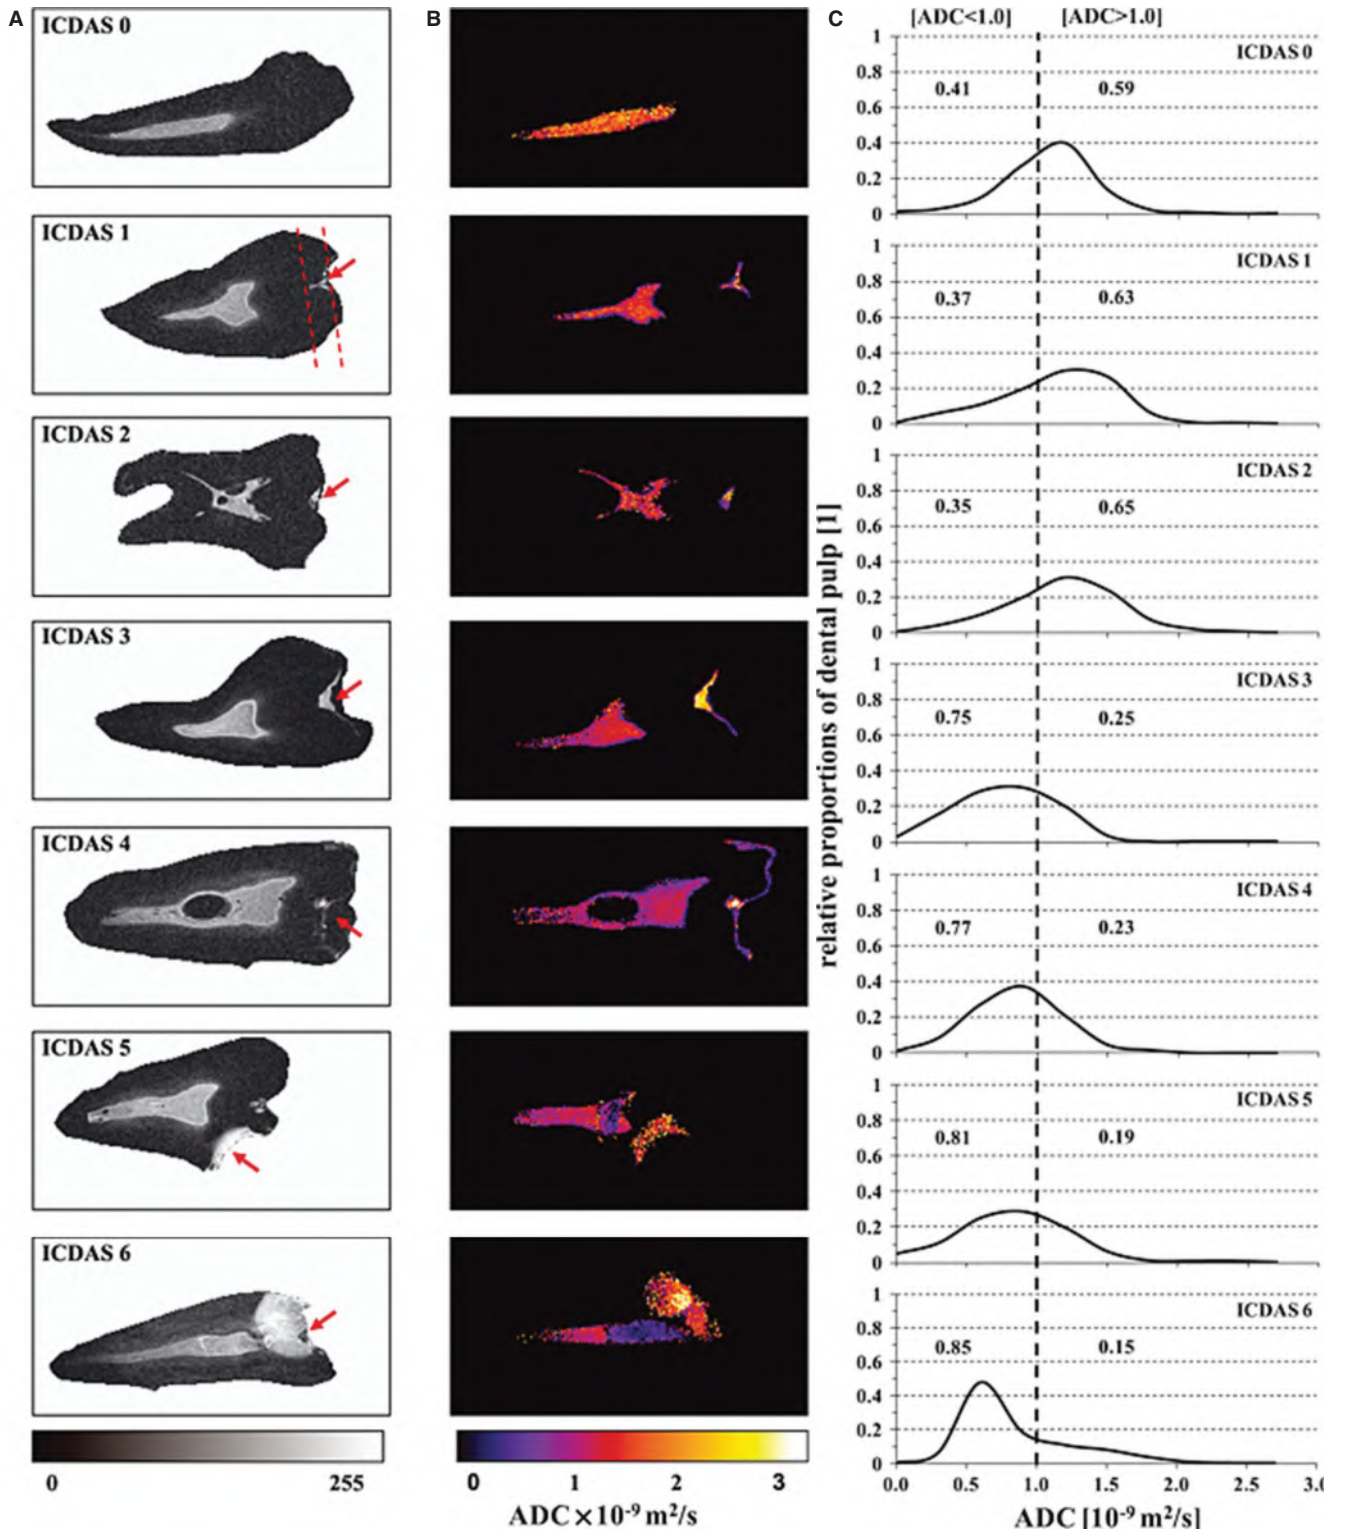

FIGURE 9D-4 T1-weighted MRI with ADC mapping for assessment of dentin–pulp complex response to caries at 2.35 T. ***A***, T1-weighted MR images of intact and decayed teeth. Detection of caries lesions were classified according to ICDAS (Caries detection and assessment system) scores. This is called a *projectile effect*. Patients with biomedical devices such as pacemakers, cochlear implants, neurostimulators, and infusion pumps are considered to be at high-risk. MRI's magnetic field can cause these devices to become nonfunctional, potentially generating life-threatening situations and dislocation.[3,6]

The signal-to-noise ratio and resolution are both significant parameters for high- quality dental MRI resolution. It is highly dependent on the configuration and performance of the RF coil that provides a limited magnetic field. In clinical practice, MR imaging for dental use is obtained mostly by a head and neck coil. Recently, Idiyatullin et al.[24] developed a new intraoral loop coil in the occlusal position. This device produces high nominal resolution images (0.3 mm^3) with stronger signal detection of teeth and associated structures, thereby increasing accuracy (Figures 9D-5). Additionally, contrast-enhanced dental MRI (covering the teeth with water-based contrast materials) may offer a better visualization and signaling of the different anatomical dental structures.[19,28]

Human teeth are relatively small. Therefore, the resolution needs to be high. It requires the use of a strong magnet with proper RF coil, specific for dental applications. Its magnetic field produces very stable and extremely homogeneous magnetic field. Therefore, these magnets are practically the only efficient solution for high-resolution MRI of teeth. Currently strong magnets (9, 4 or 11, and 4 T) are only available for in vitro use due to safety.[8,23,26] With advancements in clinical MRI hardware, those magnets may be applied to clinical imaging for new treatment modalities in regenerative endodontics and in other fields of dentistry.

Chapter 9E

Ultrasound

Elisabetta Cotti

Given the importance of imaging in the diagnosis, description, follow-up, and study of endodontic lesions in the mandible and maxilla, as well as the development of advanced diagnostic systems in traditional radiology, alternative imaging techniques are constantly being investigated.[1–4]

Osteolytic endodontic lesions in the jaws are a consequence of pulpal and periapical inflammation.[5–7] The clinical diagnosis of a tooth with a root-end radiolucency of endodontic origin is apical periodontitis. However, following biopsy and depending on the microscopic features of an apical lesion, it may receive a histopathologic diagnosis of either granuloma or cyst. The possibility of making a clinical differential diagnosis between a granuloma and a cyst may be important in the management of such lesions, especially in predicting the outcome of endodontic treatment or explaining a lack of healing.[6, 8–13] Traditional radiographs are not good guides for differentiating these types of lesions, because they allow the visualization of hard tissues only and not soft tissues.[1–4] Attempts to correlate the appearance of endodontic lesions on computed tomography (CT) scans, and later on cone beam computed tomography (CBCT), to their histopathologic features have not been fully successful. Trope et al.[10] suggested that a cyst could be differentiated form a granuloma because it exhibits a CT density similar to the background (darker than a granuloma), while a granuloma shows more density, similar to that of the surrounding soft tissues. Controversial results have been served when investigators identified the cut off point between different shades of gray as a way to differentially diagnose endodontic bone lesions on CBCT.[11–13]

In recent years, ultrasound real-time echotomography, a non-invasive and safer imaging technology not using ionizing radiation, has been successfully used to supplement traditional radiology, in the study of apical periodontitis.[2–4]

BASIC PRINCIPLES OF ULTRASOUND REAL-TIME IMAGING

Ultrasound real-time imaging, also called echography or real-time echotomography, has been a widely used diagnostic technique in many fields of medicine since its introduction in 1942.[14,15] The production of ultrasonic images is based on the generation and reflection of ultrasound waves.

Ultrasound (US) waves are generated as a result of the so called *piezoelectric effect*: when a quartz or a synthetic ceramic crystal is exposed to an alternating electric current, the electrons cause a change in the structure of its grid. This change emits mechanical energy in the form of US waves. The crystals distribute waves at a frequency that depends on the alternating current (AC) they are exposed to (i.e., crystals exposed to a 7 MHz AC create ultrasound waves oscillating to a frequency of 7 MHz). Ultrasound waves, generated for a diagnostic purpose, employ frequencies more often ranging from 1.6 to 20 MHz; US waves oscillating at the same frequency are bundled by means of an acoustic lens and directed toward the area of interest in the body via an ultrasonic probe (transducer) that contains the crystals (Figure 9E-1A).

Biologic tissues of the body possess different mechanical and acoustic properties. When the US waves encounter the interface between two biologic tissues, with different acoustic impedance, they undergo phenomena of reflection and refraction. The echo is the part of the US wave that is reflected back from the tissue interface toward the crystal (Figure 9E-1B).

The crystal is capable of transforming an incoming ultrasound wave (echo) of the same frequency back to an electromagnetic wave. The echo is then transformed into electric energy that in turn is transformed into a light spot, using a gray scale, into a computer monitor built into the ultrasound apparatus[15] (Figure 9E-2). The intensity of the echoes depends on the difference in acoustic properties between two adjacent tissue compartments; the greater the difference, the

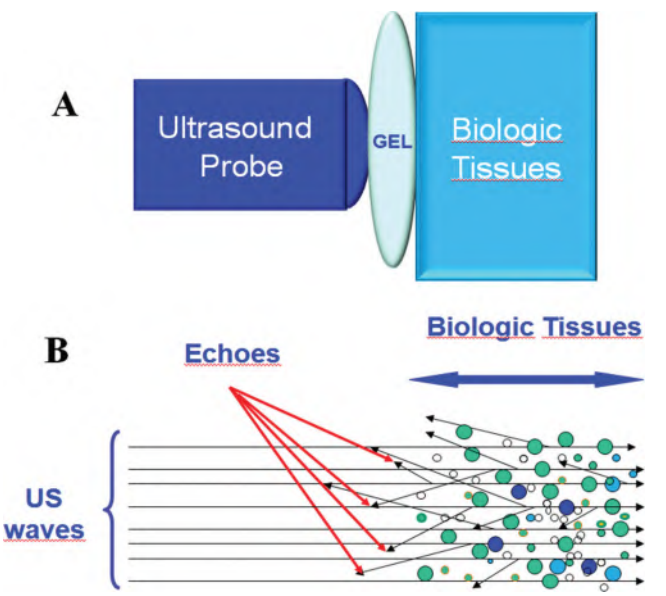

FIGURE 9E-1 ***A***. Schematic representation of sending ultrasound (US) waves into biologic tissue with a probe. ***B***. Production of echoes from ultrasound waves sent into biologic tissues and reflected back to the source.

FIGURE 9E-2 Ultrasound technical equipment. ***A.*** Ultrasound imaging apparatus with the transducers. ***B.*** Detail of three different transducers/probes (arrows).

greater the amount of reflected ultrasound energy, the higher the echo intensity. Low echo signals appear as dark spots whereas high echo signals appear as bright/white spots.

The point in the tissue where the echo originates is calculated by measuring the time delay from the beginning of the wave signal until the return of the echo. The ultrasound images seen on the monitor are produced by the automatic movement of the crystal over the tissue of interest. Because each movement of the crystal gives one image of the tissue (depending on its plane), and an average of 30 images per second are produced, the tissue being examined will appear on the monitor as a sequence of moving images. The movement of the probe by the operator, on the area of examination, creates a change on the sector plane, thus allowing the creation of a "real-time three-dimensional image" of that space.[14,15]

The latest US imaging systems use multi-frequency, wideband transducers with multiple, low-impedance linear crystals (up to 256) organized in 3 to 5 layers and electronically connected in a variable sequence. The resolution of the US image depends on the distance between the focus and the section of the tissue studied. The dynamic focalization gives a precise resolution in structures smaller than 2 mm by varying the frequencies within 5 to 10 MHz.[16] The interpretation of the gray values on the images is based on a comparison with those of normal tissues. When an area in a given tissue has high echo intensity, it is called "hyperechoic." When it displays low echo intensity, it is termed "hypoechoic"; if characterized by absence of echo intensity, it is called "anechoic" or "transonic."[15] In areas filled with fluids (i.e., cysts) reflection of US waves does not occur (anechoic); whereas in bone, total reflection occurs (hyperechoic). Areas that contain different types of tissues show a "dishomogeneous echo." The presence of air in the field of observation exhibits total reflection. It is, therefore, necessary to use a gel as an interface between the probe and the tissues while performing the exam (Figure 9E-1A).

The echographic features of the tissues may be described as follows:

- ***Solid tissue structures***: echogenic. They reflect the echoes in many different ways and can result in hypoechoic or hyperechoic effects. Within this group are: a) solid homogeneous structures; b) solid dishomogeneous structures; c) solid structures with "posterior shadows" (i.e., solid structures with calcific formations); and d) solid structures with colliquations (dissolved tissues)
- ***Liquid structures***: transonic. They may present "reinforced contours" and "lateral acoustic shadows." Liquid structures may also present themselves as: a) liquid with aggregates; b) liquid with septa; and c) liquid with parietal echogenic vegetations.

The ultrasound examination can be supplemented by use of Color Power Doppler (CPD) flowmetry to determine the perfusion of the tissue of interest. When applied to the ultrasound, examination with the CPD offers the opportunity to observe the presence and direction of the blood flow and the intensity of the Doppler signal with its changes in real time

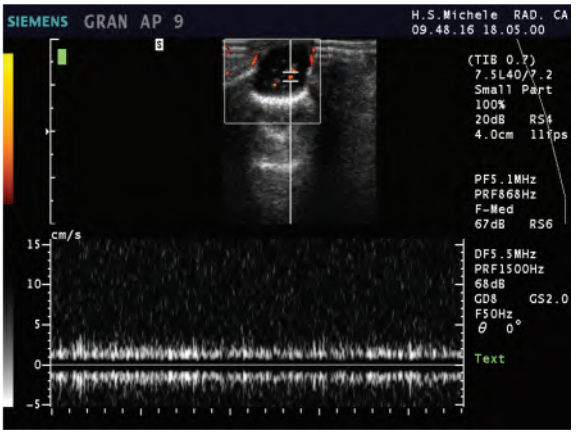

FIGURE 9E-3 Image representing the echo color power Doppler applied to the echographic examination of a periapical lesion. On the upper right, the ultrasound image of the lesion is showed (framed). The colored spots represent the presence and direction of the blood flow (color Doppler). The intensity of the Doppler signal with its modification in time (cm/s) is represented in the lower part of the figure.

(Doppler), in the format of color spots superimposed on the images of blood vessels (color), and with very high sensitivity (power).[15,17–20]

The Doppler ultrasound test uses sound waves transmitted to a vessel from a transducer in the probe. The part of the waves reflected back to the probe is processed by a computer that creates graphs or pictures representing the blood flow within that vessel. The movement of blood cells causes a change in pitch in the reflected sound waves (Doppler effect). The Doppler shift of the moving blood is monitored continuously to form the Doppler signal. Because the transmitted frequency is about 2 to 4 MHz, the Doppler shift of moving blood is in the audible range, and is represented on a graph with its changes in real time; the spectra obtained are plotted as a function of time (horizontal axis) and frequency shifts (vertical axis).

The CPD technique combines ultrasound real-time imaging with the color encoding of the Doppler frequency shift and is used to visualize the presence and velocity of blood flow within an image plane. The frequency shift is color-encoded depending on the velocity and direction of the blood flow relative to the transducer and is superimposed on the grayscale image. The way in which the frequency shifts is encoded and defined by the color bar located to the left of the image (Figure 9E-3).

Blood flow is assigned different hues that reflect the flow velocity and the insonation angle. Fast flow is assigned lighter hues, whereas slow flows appear with deeper hues[17–19] (Figure 9E-3). Positive Doppler shifts are caused by the blood moving toward the transducer and are encoded as red; negative Doppler shifts are caused by blood moving opposite to the transducer and are encoded as blue. Because color Doppler presents some shortcomings such as dependency on the insonation angle and the "aliasing," *power Doppler* is best associated with it to improve its sensitivity to low flow rates. The power Doppler is based on the integrated power spectrum, is angle independent, and is up to five times more sensitive in detecting blood flow than color Doppler.[17–19] CPD discloses the presence of the network of minor vessels and slower flows within the tissue of interest.[17–19] Intravenous injections of contrast media increase the echogenicity of the blood by enhancing the difference in acoustic impedance in the area of interest, thus rendering the CPD examination more sensitive.[15,20,21] The use of second-generation contrast media that reach the lumen of the smaller vessels allows the evaluation of the blood flow in its wash-in and wash-out phases and the study of the micro-vascular system.[19]

Three-dimensional (3-D) ultrasonic imaging can also be performed to obtain 3-D scanning and volumetric reconstructions of the US scatters. It can be obtained manually (optically tracked) or mechanically, either by moving a 1-D ultrasonic array, or by 2-D array technology.[22]

Ultrasound imaging is considered to be a relatively safe technique. Ultrasound waves targeted into biologic tissues are absorbed in the form of heat energy. This could be hazardous because it causes cavitation and vibration.[15] On the other hand, it is important to note that the crystal emits energy only during 0.1% of its activity, whereas the remainder of the time it is receiving echoes - it is "listening." Any potential adverse effects of the system depend on the length of application time of the sound energy. Safety, therefore, is achieved by limiting the number and the repetitions of the examinations. No adverse effects of ultrasound waves have been reported in experimental and clinical studies.[23–25] In any case, the risk entailed is much lower than that associated with radiographic investigations.[23–27]

To perform an echographic examination in the maxillary bones, the patient is in a clinostatic position or sitting or in an examination bed. The probe is protected with a latex/plastic cover and topped with the echographic gel and is moved by the radiologist inside the buccal area of the mandible or the maxilla that corresponds to the periapical area of the tooth that has been identified has having apical periodontitis. The same examination can also be performed extra-orally, by placing the probe on the external surface of the skin. The radiologist controls the progression of the exam in the computer monitor, while moving the probe around the area of interest to obtain an adequate number of scans to picture the lesion in real time. Each moving sequence or single image can be selected and stored in the computer.

The transducers (Figure 9E-2B) best suited for dentistry are linear probes, and allow the formation of a high frequency (7,5 MHz–15 MHz) rectangular or trapezoidal image that exhibit both optimal lateral resolution and optimal contrast of the superficial structures.[16] The transducers can also be in the format of intra-operatory probes (smaller probes useful for intraoral examination). To better evaluate bone lesions in the jaws, and especially to reduce the artifacts in fluid structures (cysts), these are simultaneously insonated with converging boundless of US waves sent from different directions (*compound technique*).[20]

To date, ultrasound real-time imaging has been applied to dentistry for the evaluation of maxillo-facial soft-tissue inflammatory lesions,[22,28] bone lesions,[29] fractures,[22,30] and

for the diagnosis of temporo-mandibular joint disorders[16,22,31] as a complement to clinical and radiographic examinations.

ULTRASOUND IMAGING IN ENDODONTICS

Ultrasound real-time imaging has been successfully applied to the endodontic field for the detection and description of apical periodontitis,[32] for differential diagnosis between cystic and solid lesions of endodontic origin,[4,33–37] for differential diagnosis between endodontic lesions and non-endodontic lesions,[29,36] and for evaluating the short-[38] and long-term[39–41] outcome of orthograde and surgical endodontic treatment.

Detection of Endodontic Lesions of Apical Periodontitis

In 2001, a pilot project was conducted at the University of Cagliari, Italy, to try ultrasound real-time examination in the study of periapical lesions of endodonticorigin. Several patients diagnosed with apical periodontitis, based on clinical signs and symptoms and intraoral and panoramic radiographs, were asked to participate. They signed an informed consent and had echographic examinations of the areas affected by the apical lesions. An endodontist, an oral surgeon, and a radiologist expert in echography were involved in the project.

After a few trials, it was possible to consistently trace the lesions within the mandible and maxilla and describe them by means of echography. Twelve patients diagnosed with endodontic periapical lesions were chosen to participate.[32] Intraoral and/or panoramic radiographs were used as a guide. An Elegra Siemens apparatus (Siemens, Erlangen, Germany) with a standard, high-definition multi-frequency ultrasound probe of 7 to 9 MHz was used for the examinations. The echographic probe was moved into the buccal area of the mandible or maxilla, corresponding to the area of tooth of interest. When the bony defect was identified, the probe was moved around the area to obtain an adequate number of transversal scans to define the lesion.

The data were accurately reported in a descriptive chart. It was noted that examinations were relatively easy to perform and that the patients reported no discomfort. In all the cases examined, it was possible to obtain an ultrasound real-time three-dimensional image of a given lesion, to measure its dimensions, and to evaluate its content (fluids, solid, or a combination of both). Following the application of CPD to echography, it was possible to see the presence of blood vessels within a lesion.

Based on these first data, application of US real-time echotomography,[2,4,32–41] the healthy and pathologic tissues within the maxillary bones appeared as follows in the echographic images:

1. Alveolar bone, if healthy, is hyperechoic because it exhibits a total reflecting surface that appears white in the image (Figure 9E-4A).
2. The roots of the teeth are also hyperechoic and appear as an even whiter shade than bone and can be seen in three dimensions (Figure 9E-4B).
3. Solid lesions in the bone are echogenic or hypoechoic presenting various intensities of echoes and appear as different shades of gray (Figure 9E-5).
4. A bone cavity filled with clear fluids (i.e., serous) is anechoic (or transonic) because it has no reflection and it appears dark (Figure 9E-6A).
5. A bone cavity filled with fluids containing inclusions is hypoechoic and exhibits various degrees of darkness, depending on the contents of the fluid (Figure 9E-6B)
6. The irregular bone (resorbed) around a lesion shows a dishomogeneous echo.
7. The reinforced bony contour of a lesion is usually very bright (hyperechoic) (Figure 9E-6).
8. By applying the CPD to the examination procedure, the presence and direction of blood vessels around and within the lesion can be detected (Figures 9E-3 and 9E-5B).

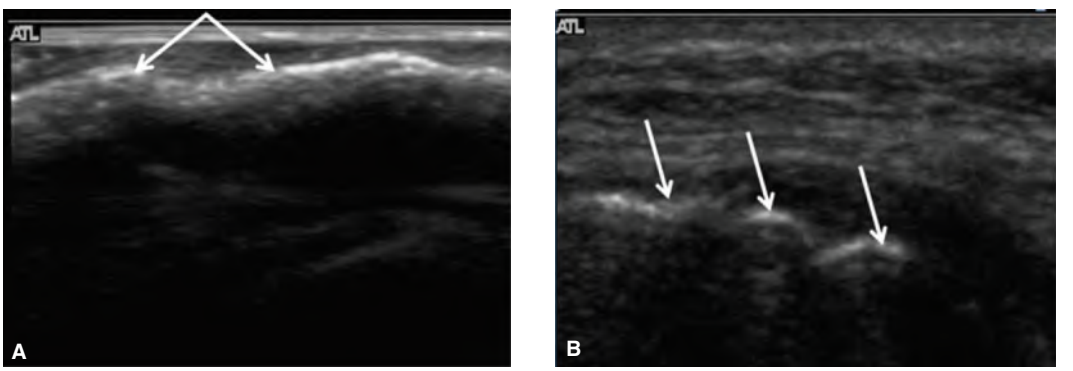

FIGURE 9E-4 ***A.*** Ultrasound image of the profile of the maxilla (arrows); the image shows a "hyperechoic" area (white) where total reflection occurs. ***B.*** Ultrasound image of the maxilla that shows the contours of three roots of teeth (arrows); the contours are hyperechoic (white).

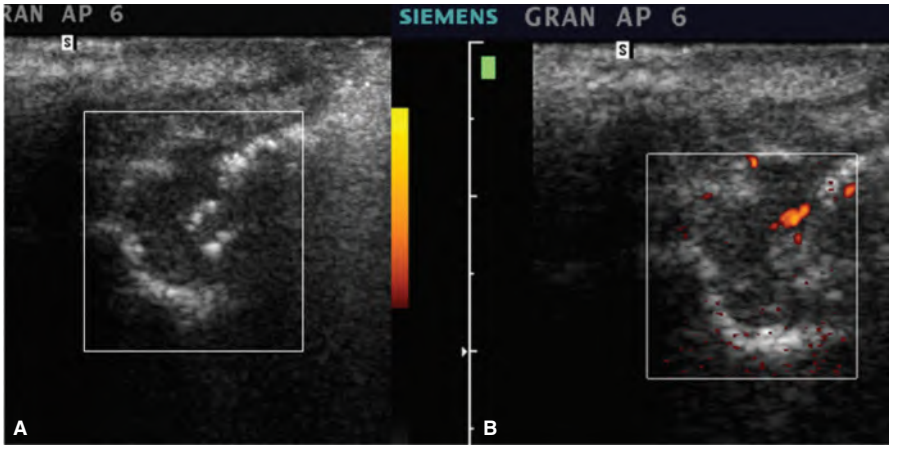

FIGURE 9E-5 Ultrasound real-time imaging of 2 different lesions in the jaws. ***A.*** Periapical lesion (granuloma) as seen in the ultrasound image (framed); it is an "echogenic," hypoechoic area where echoes are reflected at different intensities. ***B.*** The same lesion after the application of color power Doppler. The colored spots represent the vascularization within the lesion.

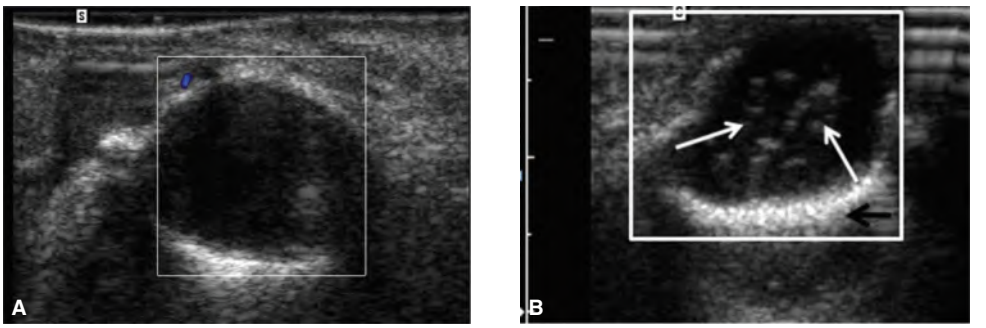

FIGURE 9E-6 Ultrasound image of two cystic lesions. ***A.*** This cyst presents an "anechoic"/ "transonic" cavity (framed) with reinforced, hyperechoic, bone contours. ***B.*** This cyst presents a transonic cavity filled with fluids and containing inclusions (arrows), with reinforced bone contour (arrow head).

9. The mandibular canal, the mental foramen, and the maxillary sinus can often be distinguished and appear mostly transonic.

Differential Diagnosis of Cysts and Granulomas

A study was done to differentiate between cystic lesions and granulomas based on the ultrasound examination complemented with the CPD procedure.[33] It included 11 patients with clinical diagnoses of apical periodontitis whose treatment plan included endodontic surgery with apicoectomy, root-end filling, and biopsy. The ultrasound examination with CPD was performed in each area of diagnostic interest in the maxilla. A representative echographic image was selected for each lesion, analyzed, and recorded. An attempt was made to differentiate a diagnosis between cystic lesions and granulomas based on the following principles:

1. Cystic lesion: a transonic, well-contoured cavity filled with fluid, surrounded by reinforced bony walls with no evidence of internal vascularization based on CPD (Figure 9E-7).
2. Granuloma: a distinct lesion that could be echogenic or mixed in content, with non-precisely defined contours and exhibiting the presence of blood vessels based on CPD (Figure 9E-8).

The results from the histopathologic examination confirmed the tentative echographic diagnosis. Six of 11 lesions that were described as transonic cavities were well contoured, and corresponding to the features of a cyst: a cavity lined with stratified squamous epithelium with necrotic debris and impressions from cholesterol crystals within its lumen. One lesion, whose transonic content showed also scattered echogenic particles, revealed a cystic lumen with areas of secretory epithelium. This case supports the specific sensitivity of this technique with respect to the content of bone pathosis. Four of the remaining lesions were echographically diagnosed as granulomas because of their echogenic appearance and the presence of internal blood vessels. Their reports described the typical appearance of granulomas: connective tissue with peripheral mononuclear (PMN) cells, lymphocytes, monocytes, and newly formed blood vessels. The only case that presented with both an echogenic appearance in the lower portion and a hypoechoic aspect toward the upper

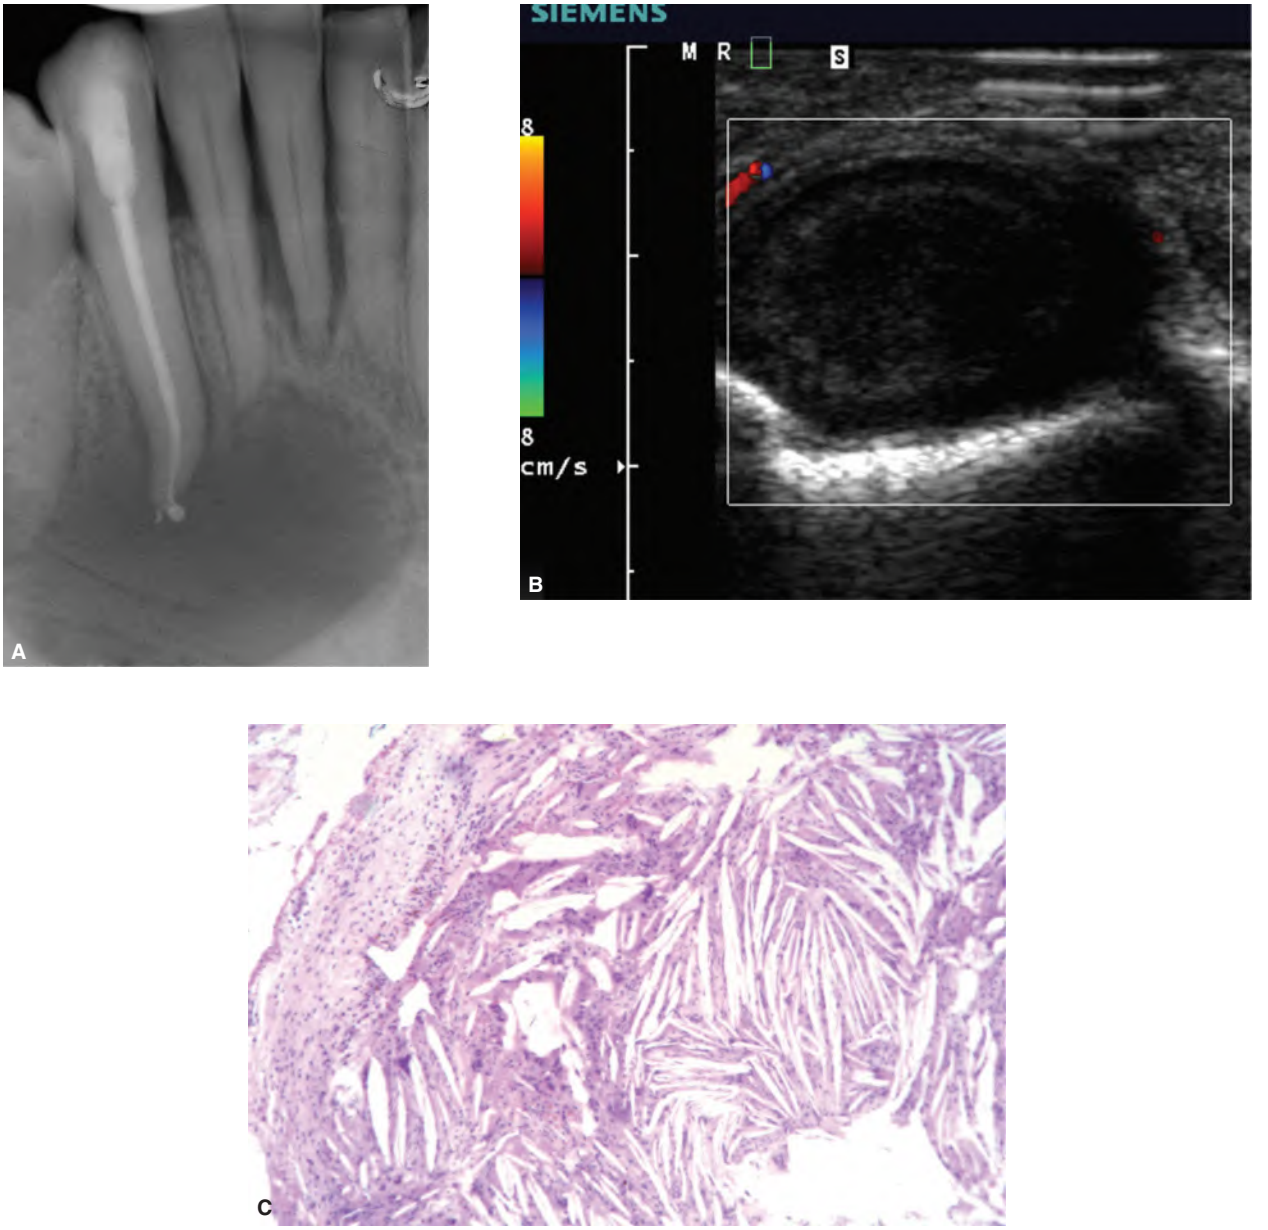

FIGURE 9E-7 Ultrasound real-time imaging of a lesion of endodontic origin in the mandible. ***A.*** Periapical lesion as seen in the intraoral radiograph; the lesion involves the periapical area of the mandibular right lateral incisor, canine, and first premolar. ***B.*** The same lesion as seen in the ultrasound image (framed): it is a "transonic" cavity with reinforced, hyperechoic bony contour. The vascular supply appearing at the CPD (red spots) is external to the lesion. ***C.*** Histopathologic features of the lesion confirmed the echographic diagnosis of cystic lesion.

end showed the histopathologic feature of a large granuloma containing a cyst. Based on these findings, ultrasound imaging showed enough potential sensitivity to allow the distinction between a cyst and a granuloma, to define a mixed type of lesion, and to evaluate the various degrees of turbidity of the fluid content in a bony lesion.[33–34]

Studies with similar designs have reported results consistent with our findings on lesions from endodontic origin.[35–37] According to Raghav et al.,[37] US examination exhibits a high sensitivity (0.95) and specificity (1.00) and is significantly more accurate than conventional and digital radiography for differential diagnosis of apical periodontitis.

Differential Diagnosis of Other Lesions in the Jaws

When lesions of a various nature in the jaws (keratocysts, dentigerous cysts, residual cysts, radicular cysts, periapical granulomas) are examined with US real-time imaging and CPD, the results are slightly less predictable.[29,36] While the diagnosis of periapical granuloma is always consistent with

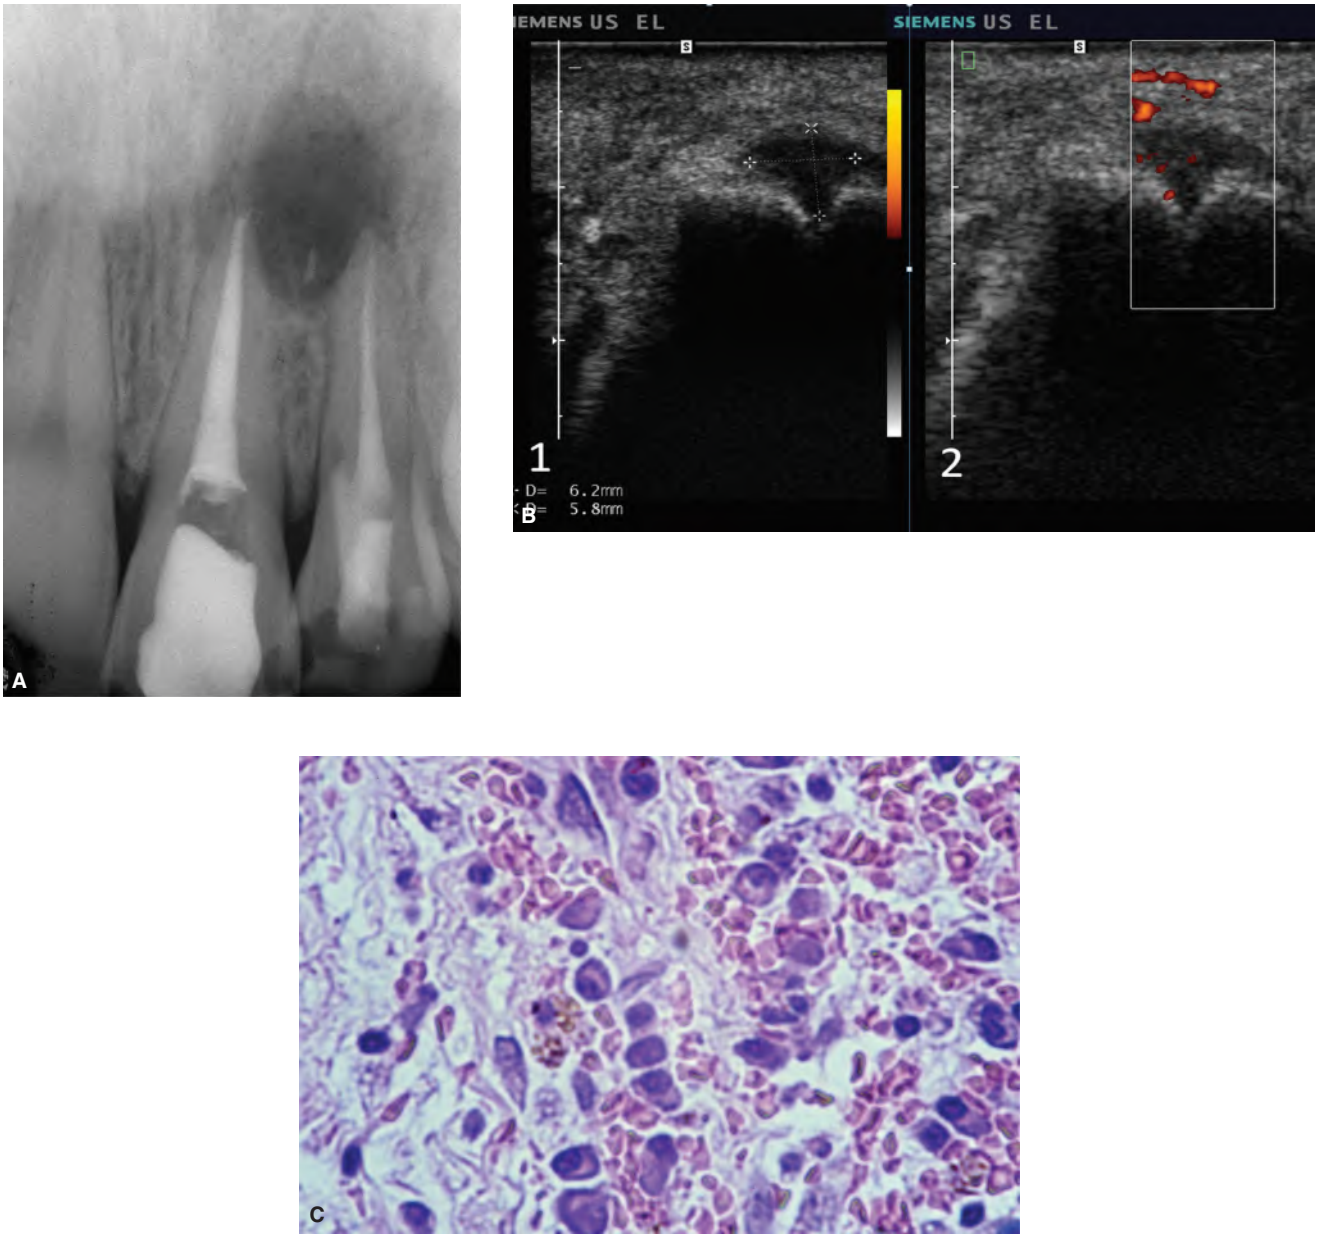

FIGURE 9E-8 Ultrasound real-time imaging of a lesion of endodontic origin in the maxilla. ***A.*** Intraoral radiograph showing a periapical lesion involving the maxillary left central and lateral incisors. ***B(1).*** Periapical lesion as seen in the ultrasound images. It is possible to distinguish an "echogenic" area with irregular contours; the dotted areas correspond to the diameters of the lesion. ***B(2).*** The same lesion with the CPD showing the presence of blood vessels within the lesion. The lesion was diagnosed as periapical granuloma. ***C.*** Histopathologic features of the previous lesion (granuloma) confirming the echographic diagnosis.

the biopsy reports, lesions presenting histopathologic features of different kinds of cysts sometimes exhibit a more composite ultrasound appearance. Infected cysts may disclose a mixed transonic and echogenic appearance because of the presence of dense secretion. In addition, when the perilesional capsule of a cystic lesion is very thick it may simulate a solid component and the presence of an internal vascular supply.

In conclusion, ultrasound diagnosis of periapical granuloma, specifically, and of solid lesions, generally, is reliable, whereas the diagnosis of cysts depends on the type of cyst, the thickness of its capsule, and its status of infection.[29,32,36,42]

Follow-up of Endodontic Treatment

By providing data on changes in echogenicity, size, and vascularity within the periapical lesion or at the surgical site, US examination associated with CPD allows for the assessment of postoperative short- and long-term healing response to endodontic treatment that is not feasible using conventional radiography alone.[4,38–41]

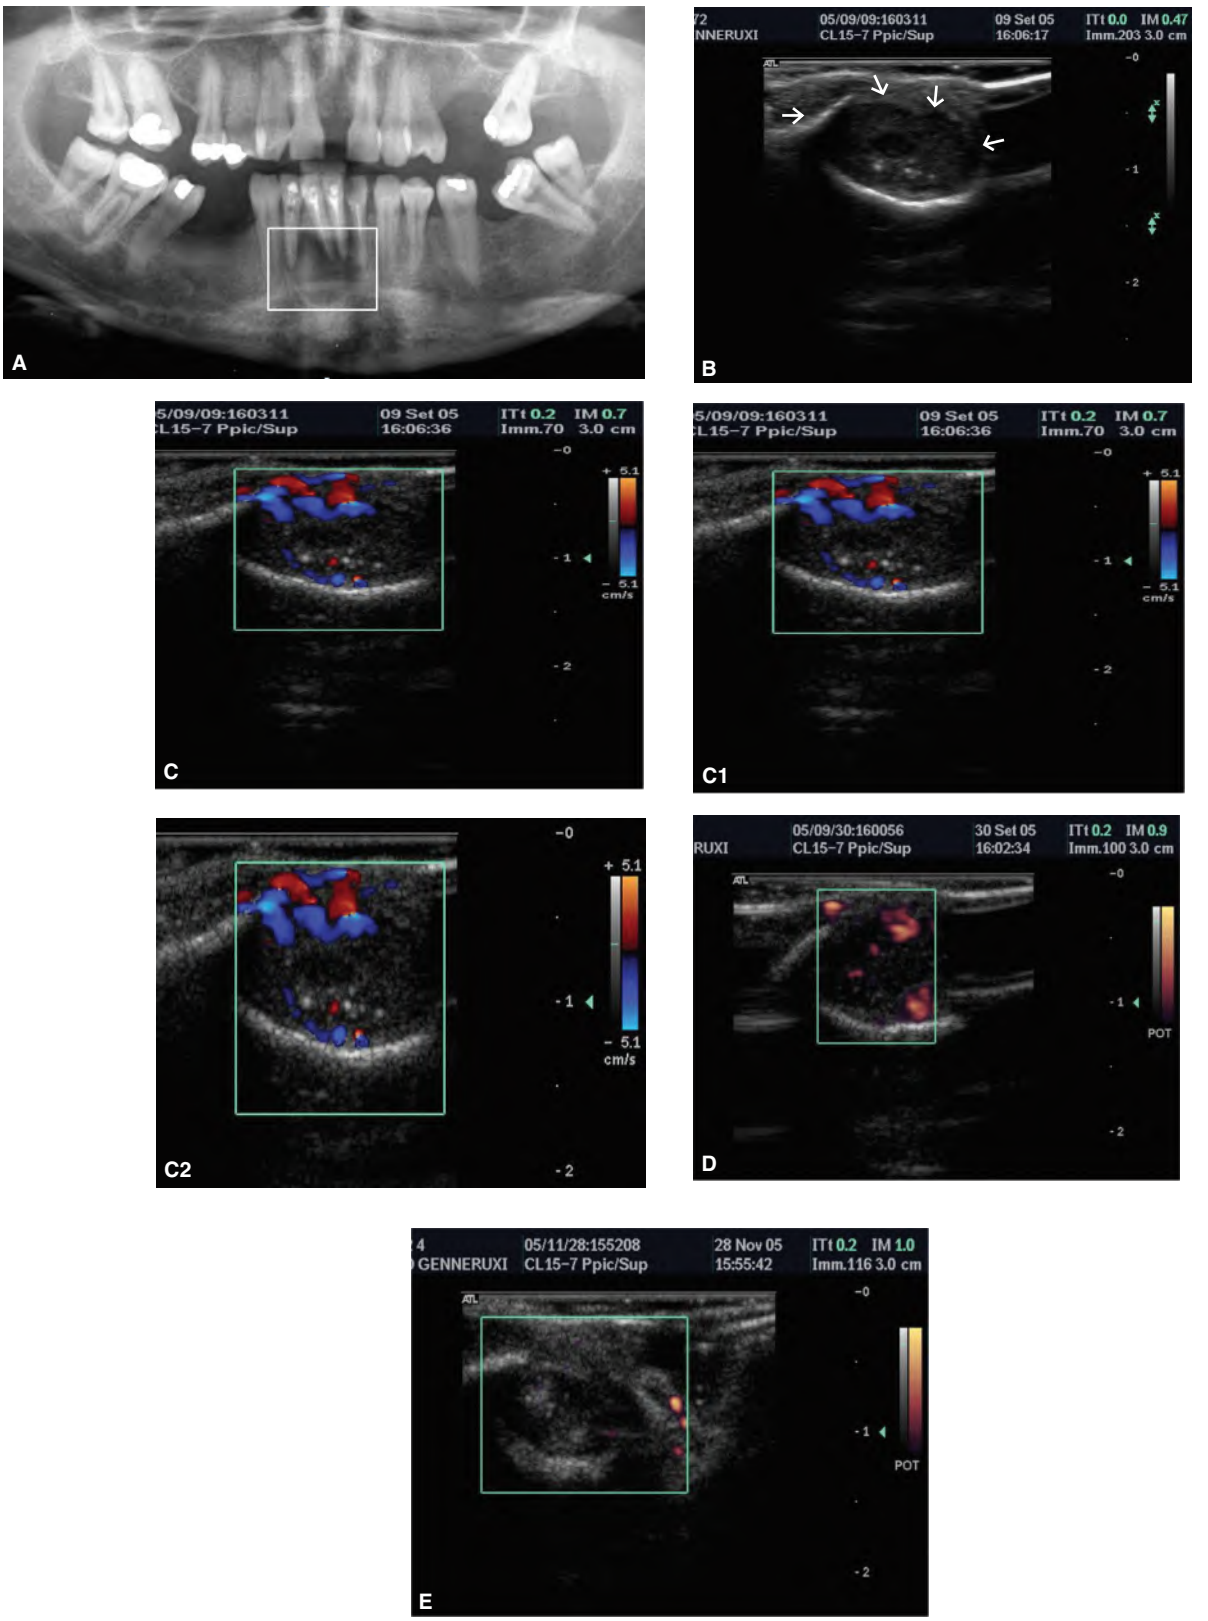

FIGURE 9E-9 Ultrasound real-time imaging follow-up of an endodontic treatment with application of CPD. ***A***. Panoramic radiograph showing an extensive periapical lesion involving all four mandibular incisors, before endodontic re-treatment (framed). ***B***. The same lesion seen in the ultrasound image (arrows): it is an "echogenic" image with solid content and well-defined contours. ***C***. The two echographic images of the same lesion after the application of the power Doppler (C1) and Color Doppler (C2) showing the presence of vascular supply. The diagnosis was periapical granuloma. ***D***. Echography of the lesion (framed) one week after endodontic re-treatment was initiated and an intracanal medication was placed. The CPD shows reduced vascularization. ***E***. Ultrasound image of the lesion (framed) one month after completion of retreatment on all four teeth. The CPD indicated that the vascular supply was greatly reduced.

Immediate Response to Treatment

The possibility of monitoring inflammatory changes in diseased bone, as an early response to endodontic treatment using the US examination associated with CPD, is the subject of an ongoing research. The rationale is that the various degrees of inflammation of a given lesion can be assumed by evaluating the diffusion of blood vessels within or/and around the lesion, and that the application of CPD has the sensitivity to detect the presence of newly formed vessels.

In a preliminary study,[38] 12 patients, presenting with apical periodontitis, whose treatment plan included endodontic orthograde treatment, have participated. A clinical protocol was established and it was decided to complete the treatment in two appointments using calcium hydroxide as an interappointment canal medication. Routine conventional periapical radiographs, and echographic examinations with CPD of each case, were carried out as follows: 1) before treatment; 2) 1 week after root canal cleaning, disinfection, and application of intermediate medication; and 3) 1 month after completion of root canal treatment.

Two independent observers evaluated the exams after obtaining a K value of 8.5. According to the data obtained, all lesions presented a vascular supply before treatment. In 9 cases, a progressive reduction of the vascularity within and around the lesion was documented during the one week and four weeks controls with the echography and the CPD, indicating a reduction in the inflammatory burden of the lesion as a consequence of cleaning, shaping and disinfection (Figure 9E-9). In 2 cases, there was an increase of vascularization at the one-week post-treatment control, and a decrease at four weeks, indicating a temporary increase in the inflammatory reaction following the initial treatment. In one case, the vascularization of the lesion remained stable during both controls indicating a failure of treatment in controlling the periapical inflammation. These data are still preliminary, but they open new horizons to the possibility of assessing the response of apical periodontitis to the different stages (and types) of treatment[38] (Figure 9E-8).

Long Term Follow-up

US examination with CPD has also been used to monitor the long-term response to endodontic treatment.[39–41] Rajendran[39] performed echography with CPD on 5 lesions treated with orthograde endodontic therapy by assessing the following parameters: a) changes in dimension and volume; b) variation in the echogenicity of the lesions; and c) presence, characteristics, and modifications of blood flow within the lesions. The patients were followed-up immediately after treatment and at 1, 3, and 6 months, with clinical and radiological examinations to monitor the healing process. A postoperative echography was then performed 6 months after treatment was completed. They reported that: a) the exam showed a gradual increase in echogenicity of the lesion throughout the healing phase; b) the Doppler signal was able to show the progressive formation of new vessels in bone during the initial healing process; c) as the bone was remodeled, the flow signal would progressively decrease to the point of disappearing when the lesion has completely healed; d) the presence of arterial flow and the increase in flow velocity were also a testimony of the healing process; and e) a lack of flow signals during the earlier stages, following treatment, was indicative of delayed or impaired bone healing.[39]

Later studies, based on US CPD, proved that initial signs of healing of apical periodontitis are evident as early as six weeks post operatively,[41] and that at six months follow-up, US CPD imaging is significantly more sensitive than conventional radiographs in detecting changes in healing of hard tissues at the site of endodontic surgery.[40] When monitoring the vascularity of apical periodontitis, it is advisable to use the ultrasonic probe intraorally, to avoid interferences of labial and skin blood flow.

CONCLUSIONS

Ultrasound real-time represents an advanced imaging technique that can be used in endodontics as a complement to radiographic examinations for the detection and dimensional measurement of apical periodontitis.[2,4,32–41] The most important advantage of ultrasound real-time imaging over other diagnostic imaging systems is that it is the only exam that possesses the sensitivity to assess the features of endodontic lesions (fluid versus mixed or solid content) and their internal and external blood supply, that can be used to address the differential diagnosis between solid lesions (granulomas) and cystic lesions of the jaws.[33–37] It also permits to evaluate the outcome of the treatment of apical periodontitis, based on the changes in echogencity and vascularity of the lesions.[38–41] Furthermore, the changes in the vascular supply, within a lesion of endodontic origin, observed with US and CPD, may be used to assess the immediate response of the periapical tissues to any given treatment.[38]

Ultrasound real-time examination is a non-invasive, painless method that entails lower biologic adverse effects than techniques using ionizing radiations.[23–27] A major drawback of US examination is that images interpretation is very critical and needs an expert eye, and that there are not landmarks to help distinguish the position of a lesion within a given area of the mouth, once the exam has been performed. High frequency transducers dedicated to dental use are currently being produced[43] and the 3-D volumetric reconstructions of the US scatters promise to provide better information for the study of apical periodontitis (Figure 9E-10). In the near future, the use of ultrasound looks promising for the diagnosis of caries, cracks, and fractures in teeth, periodontitis, and bone characterization for implant placement.[16,22]

Chapter 10

Imaging Interpretation

Parish P. Sedghizadeh, Rafael A. Roges, Jose-Maria Malfaz

Endodontics has long utilized imaging devices and techniques as indispensable tools for clinical, educational, and research applications. Imaging and imaging interpretation are essential to the contemporary practice of endodontics for diagnosis, therapeutics, and outcome assessment. In order to accurately interpret imaging studies and manage patients at an acceptable standard of care, the clinician must have knowledge of the normal imaging appearance of anatomy and morphology of maxillofacial structures such as teeth, jaws, articulation, and sinuses, as well as of common pathologic conditions affecting these structures.

Commonly used imaging modalities used in endodontic practice have included intraoral dental radiographs, panoramic radiography, and more recently cone-beam computed tomography (CBCT). Therefore, this chapter will focus on these modalities for clinical relevance.

Choice of imaging modality by the clinician should be predicated by multiple parameters related to individual clinicopathologic factors, and is, therefore, ideally a case-by-case decision-making process rather than a "one size fits all" approach. Certain principles of minimizing radiation exposure to patients, such as: "as low as reasonably achievable" (known by the acronym ALARA), also guide radiographic decision-making clinically.

It is important to recognize that there are advantages, disadvantages, and limitations to any imaging study; those can affect interpretation. One of the most important advantages of any of the aforementioned imaging techniques is that it provides the clinician with visualization of hard tissue anatomy, or pathology, not normally visible by clinical examination alone. For conventional dental intraoral radiographs, advantages include low cost, being readily available in the dental practice, high spatial resolution, and low radiation dose that is even further minimized with digital radiographs. As far as the disadvantages, intraoral X-rays have inherent limitations in that 3-dimensional (3-D) anatomy is represented in a 2-dimensional (2-D) image. This may result in geometric distortion and anatomic noise that can mask a region of interest.[1] Superimposition of anatomic structures when viewed in two dimensions can create a false representation of reality, suggesting normality when pathology exists, or suggesting pathology when normality exists (Figure 10-1). This case also highlights the importance of familiarity with normal anatomy and anatomic variations for accurate diagnosis. Some of the limitations of intraoral radiographs were already described decades ago by Seltzer and Bender in their classic experiments.[2,3] Panoramic radiography also represents a 2-D image of 3-D anatomy that again has some limitations. It also contains artifacts and unique distortions that can further complicate panoramic interpretation.

The overall purpose of this chapter is to provide an objective approach to radiographic diagnosis and interpretation for clinical applications in the endodontic practice. Radiographic interpretation inherently has subjectivity and observer bias in addition to having objectivity. For example, disagreement was found in the interpretation of radiographs by different evaluators regarding the presence of periapical radiolucencies,[4] as well as, the same evaluator interpreting the same image over time.[5] Limitations of radiographic interpretation have been minimized by exposing multiple radiographs, from different angulations, to improve visualization of changes in an area in question.[6]

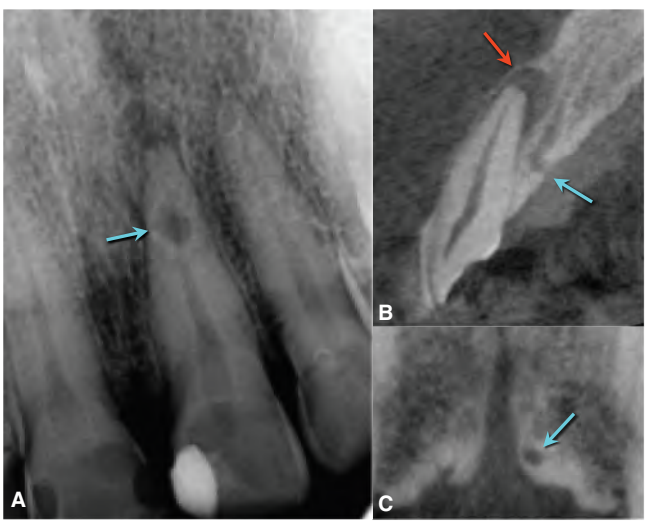

FIGURE 10-1 *Canalis Sinuosus* mimicking the appearance of root resorption. ***A.*** Periapical radiograph of a maxillary left central incisor with recurrent caries and pulpitis showing apical radiolucency, and what appears to be root resorption in the apical third of the root (blue arrow). ***B.*** CBCT sagittal reconstruction showing the same tooth with an apical lesion (red arrow), however, without evidence of the root resorption. Instead, *canalis sinuosus* was detected. *Canalis Sinuosus* is a normal anatomic variation of the anterior superior alveolar neurovascular bundle with rare manifestations in the anterior maxilla. ***C.*** CBCT coronal reconstruction showing the terminal region of the *canalis sinuosus* that is distinct from the incisive canal (blue arrow). Because of the nonmidline location, *canalis sinuosus* can mimic various pathologic lesions on conventional radiographs when superimposed on other anatomic structures, such as a tooth root in this case. (Courtesy of Dr. Daniel S. Schechter, Los Angeles, CA.)

Over the years, advancements in devices, hardware, software and modes of operation significantly improved the information obtained. Digital radiography has allowed for image enhancement with control of parameters such as brightness, contrast, magnification, inversion, color, and resolution. This is a clear advantage over traditional radiography. The introduction of digital radiography has improved the speed of image acquisition and potentially reduced patient exposure to radiation. Nevertheless, the overall limitations of conventional radiography and 2-D imaging remain inherently present.[7] For more details, see Chapters 9A and 9B.

THE ADVENT OF CBCT AND THE THIRD PLANE OF VISUALIZATON

CBCT has been optimized for dental applications. Smaller fields of view and higher resolution scans appear to be ideal for endodontic use and may impact the nature of endodontic practice and radiographic decision-making in the near future.[8–10] For more details, see Chapter 9C.

One of the disadvantages of CBCT use is cost and access to the technology. However, with time, costs should continue to decrease and access to increase. Other areas of controversy and concern are radiation exposure to patients, the training needed to operate and interpret the scans optimally, as well as the amount of time necessary to evaluate them. Like all radiographic studies, CBCT imaging and diagnostic accuracy rely heavily on parameters such as image quality, viewing conditions, and observer performance characteristics. Interpretation of the collected volumes, potentially affecting treatment planning, can be a challenge with respect to defining normal versus pathological conditions.[11] Hardware and software parameters also heavily influence image quality and resolution.[12]

CBCT, like other radiographic modalities, can also contain artifacts and noise that make evaluation and interpretation difficult in some cases. Common artifacts to be aware of include noise, aliasing, scatter and beam hardening, motion artifact, and finally streak artifact that usually results from metal or high density restorations in the oral cavity such as metal crowns, orthodontic appliances, amalgam fillings, separated instruments and tooth, and root canal filling materials.[13,14] (Figure 10-2).

A major advantage of CBCT is the visualization of anatomic structures in three planes, generally referred to as coronal, axial (transverse), and sagittal reconstructions. CBCT technology also allows for panoramic and oblique reconstructions in addition to anatomic-specific reformatting such as temporomandibular joint (TMJ) analysis. This 3-D evaluation as compared to 2-D evaluation allows for unprecedented applications in dentistry and endodontics, and in some instances has improved the sensitivity and specificity or positive predictive value of accurately detecting lesions or conditions affecting the jaws.

For endodontic applications, the future is the third plane of visualization (3-D), however, there is still some controversy regarding CBCT use over conventional dental radiography for routine cases. Some of this controversy may be due to lack of higher level evidence-based clinical studies comparing CBCT with conventional radiography in specific contexts. Nonetheless, endodontics has successfully utilized CBCT mainly in the following contexts:

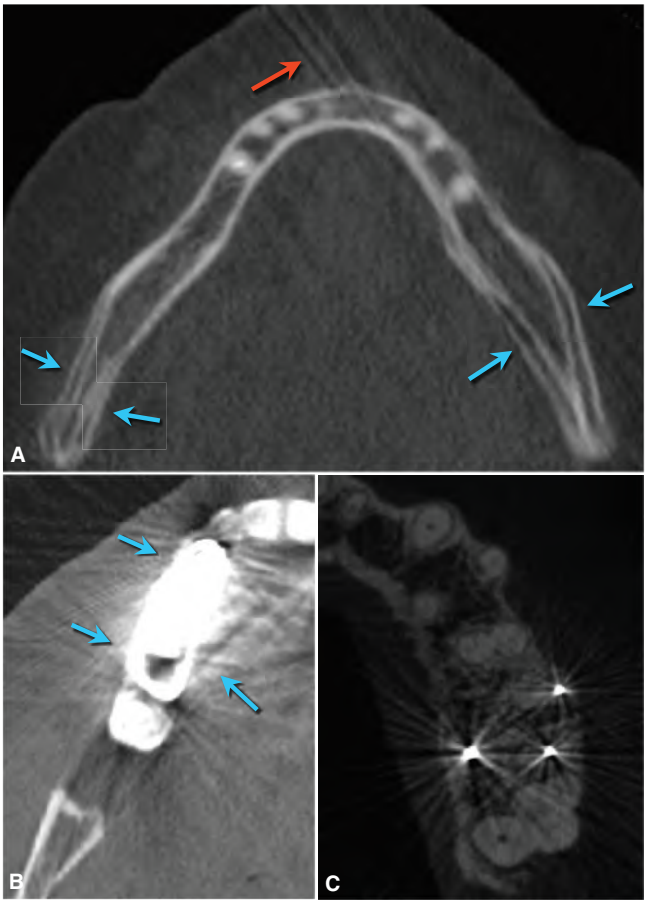

FIGURE 10-2 Common artifacts associated with CBCT. ***A.*** Motion artifact from patient head movement during image acquisition that produced a blurry or double-image of the mandible (blue arrows). Note the aliasing artifact (red arrow) presenting as linear radiolucent lines. ***B.*** Streak artifact (blue arrows) from metal restorations in the oral cavity. ***C.*** Streak artifact from silver points used for root canal obturation. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain (Figure 10-2A & B) and Dr. Parish P. Sedghizadeh, Los Angeles, CA. (Figure 10-2C).)

1. Evaluation of endodontic complications such as traumatic dental injuries, root fracture, resorption and perforation[15–21] (Figures 10-3 to 10-11)
2. Presurgical endodontic assessment and posttreatment evaluation[1, 22–25] (Figure 10-12)
3. Evaluation of root and canal morphology[26–29] (Figure 10-13)
4. Differential diagnosis of odontogenic, pulpal, and periapical pathology[30–35] (Figures 10-14 to 10-16)

Currently, CBCT imaging is generally recommended for endodontic cases in which conventional dental radiographs may not yield adequate information to allow

appropriatevmanagement of the endodontic problem.[36] It should also be noted that the dental specialty of oral and maxillofacial radiology is most ideally trained, in general, to comprehensively evaluate and interpret CBCT images for dental applications, particularly when it comes to the diagnosis of potential pathology. When a CBCT scan is obtained, the entire volume and all anatomic structures in the field of view or acquisition should be reviewed for potential pathology.

RADIOGRAPHIC IMAGES OF LESIONS

In general, the most common conditions or pathology an endodontist may encounter via radiographs can be classified into *odontogenic* or *nonodontogenic* lesions. This pathology can also be further categorized by etiology as *developmental, reactive,* or *neoplastic*. Examples of odontogenic and nonodontogenic conditions within these etiologic categories are provided in Table 10-1.

RADIOGRAPHIC INTERPRETATION

It is recommended to apply a systematic approach to radiographic diagnosis and interpretation for all endodontic cases. In this chapter, clinical cases are used to highlight the process of imaging interpretation, particularly with reference to conditions that have endodontic relevance, many of which are listed in Table 10-1. Importantly, radiographic interpretation requires at least a basic knowledge of radiation physics and anatomy. Diagnosis and management of endodontic conditions require clinical evaluation and correlation of imaging findings with clinical findings. In some cases, this may include biopsy for more definitive histopathologic diagnosis, whereas in other cases, radiographs and clinical findings alone are sufficient.

Once a clinical assessment is made and appropriate images are acquired (of satisfactory diagnostic quality and with minimal artifacts), image analysis can begin. The key to accurate imaging diagnosis is to have a systematic and thorough approach to interpreting any image as well as also

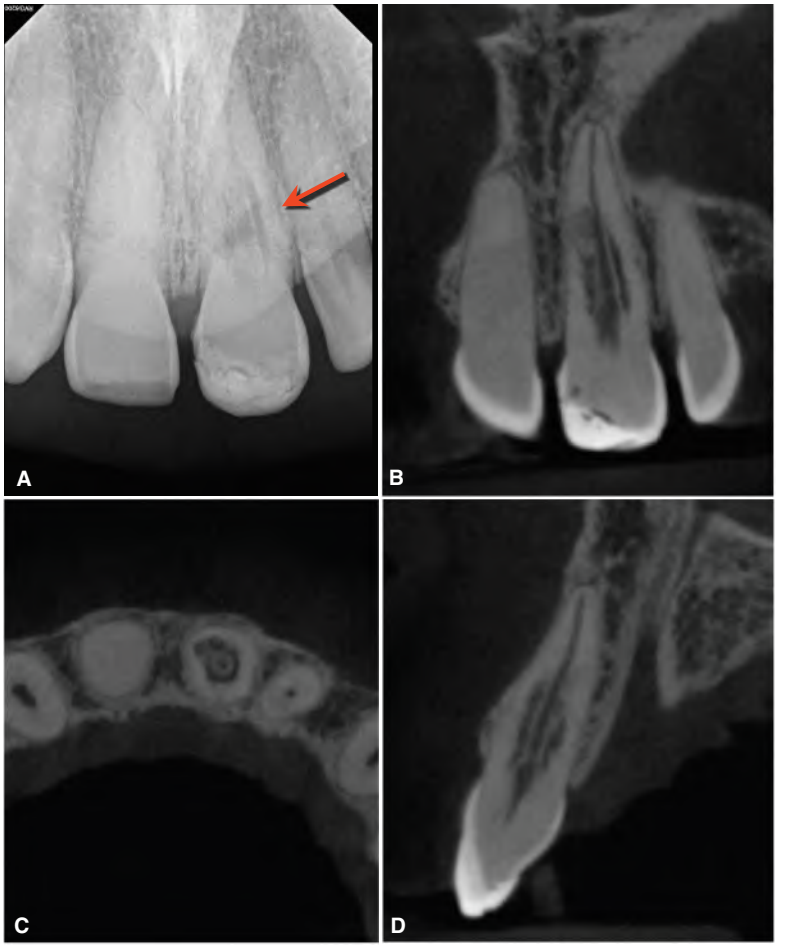

FIGURE 10-8 External root resorption in a maxillary left central incisor. ***A.*** Periapical radiograph. Red arrow points to the affected tooth. ***B.*** High resolution CBCT coronal view. ***C.*** CBCT axial view. ***D.*** CBCT sagittal view. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

appropriate viewing conditions. All visible anatomic structures should be evaluated to detect any potential abnormality. Since more than one abnormality may be present in a patient, all aspects of each image should be evaluated carefully in order to avoid missing important pathosis or failing to diagnose a significant condition. Improved imaging analysis and interpretation comes with practice and experience. The more normal radiographic anatomy one views, the more likely one may identify abnormalities (Figure 10-17). The exact approach recommended for accurate interpretation has been delineated in detail in textbooks on oral radiology.[37,38] In general, the steps involved include the following:

1. Systematic evaluation of normal anatomic structures on the radiograph or the entire CBCT volume, to look for lesions or abnormalities. When viewing conventional dental X-rays such as periapical or bitewing films, one should systematically observe each tooth in the image along with adjacent bone or other visible anatomic structures to look for changes suggestive of pathology. With a dental full mouth X-ray series there is even duplication of teeth in more than one image so one can observe from slightly different angles or representations the same tooth. This enables one to identify pathoses more accurately and avoid misinterpretation resulting from artifacts or superimposition of anatomic structures. When viewing new images, always start at the same place and then carefully trace each tooth's lamina dura for breaks or discontinuity in these structures.

   Conventional and digital dental radiography remain the imaging tools of choice for caries detection (Figure 10-18). In caries diagnosis, the endodontic challenge is to determine the spatial relationship between the carious lesion and the pulp.[39] On one hand, the notion is that proximal caries goes deeper than what can be seen in a conventional dental radiograph. On the other hand, caries located on the buccal or lingual aspect of the tooth may project over the pulp and give a false impression of pulpal involvement.[39] Additionally, interpretation of radiographic findings in restored teeth can present unique challenges.
2. When an abnormality, or pathosis, is suspected, there are specific parameters that should be evaluated in each case to achieve an accurate differential diagnosis (Table 10-2). These are the anatomic location and epicenter of the lesion, relative radiodensity (Figure 10-19), size

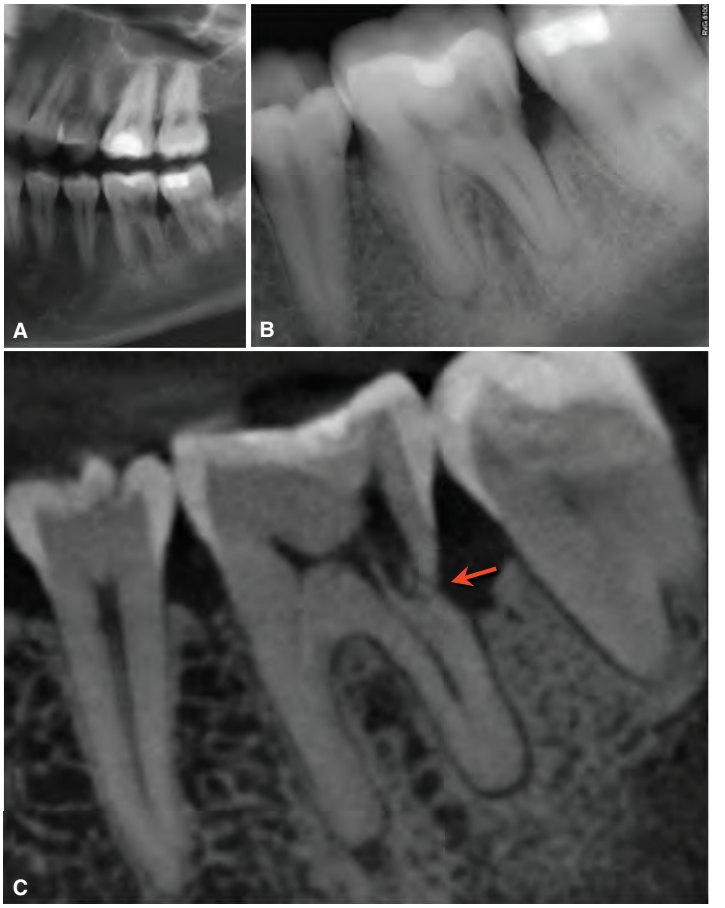

FIGURE 10-9 External resorption in a mandibular left first molar. ***A.*** Panoramic radiograph section displaying a lesion in the crown with the appearance of dental caries. ***B.*** Periapical radiograph. ***C.*** High resolution CBCT sagittal view of the entry point of the external resorption (red arrow). Note evidence of bony healing and remodeling. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

and shape or growth pattern, internal structure, border characteristics, and the effects of the lesion on adjacent structures. These parameters are important to evaluate because they provide insight into pathophysiologic processes occurring at the tissue level that may also be observed at the radiographic level. This process is similar to that used in clinical diagnosis or histopathologic diagnosis to some extent.

For example, Figure 10-20 shows two hyperdense or radiopaque-appearing lesions that are very different in nature and pathogenesis. Clinically, in the case of *idiopathic osteosclerosis* the patient was asymptomatic and didn't present any clinical signs such as expansion of bone or nerve paresthesia. Pulp sensibility tests in the associated teeth were normal. Conversely, in the case of *fibrous dysplasia*, the patient had significant maxillary and mandibular bone expansion and paresthesia of the left inferior alveolar nerve. Multiple associated teeth did not respond to pulp sensibility tests. Radiographically, if we evaluate the parameters for each lesion as shown

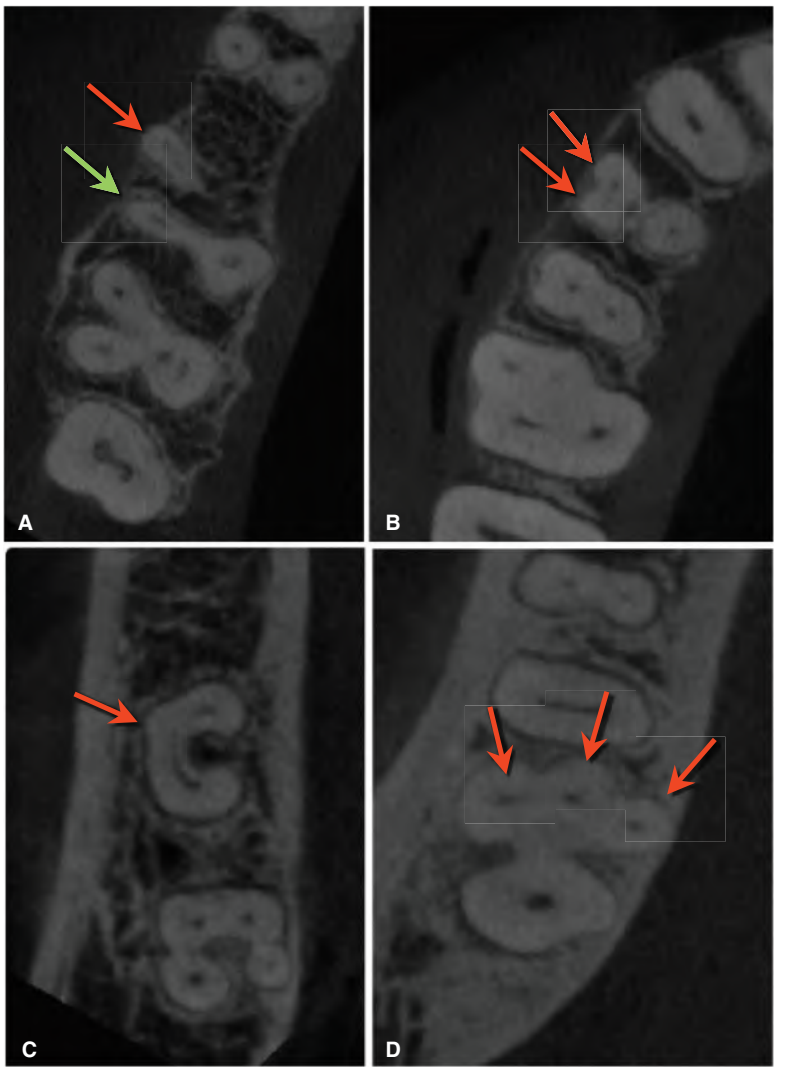

FIGURE 10-13 Axial (transverse) CBCT reconstructions are useful for characterizing root and canal morphology. ***A.*** A maxillary first molar with fused distobuccal and palatal roots; red arrow denotes mesial root, and green arrow denotes fused root. ***B.*** A maxillary first premolar with three separate canals; red arrows denote mesiobuccal and distobuccal roots. ***C.*** A mandibular second molar with "C" shape anatomy (red arrow). ***D.*** A mandibular third molar; red arrows denote fused mesial root with three separate canals. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

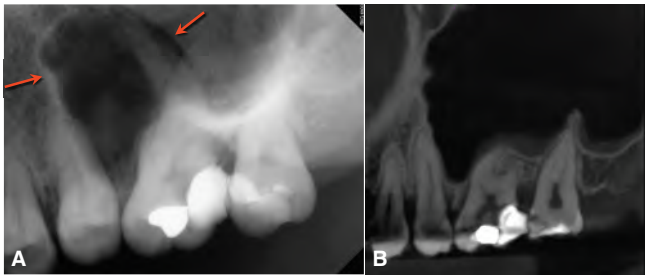

FIGURE 10-14 ***A.*** Periapical radiograph showing a radiolucency between the maxillary left second premolar and first molar (red arrows) mimicking a cyst-like process. ***B.*** High resolution CBCT sagittal view displaying the maxillary sinus between the maxillary left second premolar and first molar with no evidence of a lesion. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

in Table 10-2, in the case of *idiopathic* osteosclerosis the *anatomic location*, or epicenter, of the lesion is the mandibular bone near teeth apices, the *relative radiodensity* is that of dense cortical bone (see the inferior border of the same mandible for comparison), the *size* is smaller as compared to the other condition, the *shape, or growth pattern,* is relatively regular and uniform, the *internal structure* is homogenous and solid, the *borders* are relatively distinct with blending into adjacent tissue or bone, and there are *no effects on adjacent structures* such as teeth. In the case of *fibrous dysplasia*, radiographically, the *anatomic location*, or epicenter, of the lesion is bone in both jaws, the *relative radiodensity* is that of enamel compared to dense cortical bone, the *size* is much larger and multifocal as compared to *idiopathic osteosclerosis*, the *shape or growth pattern* is irregular, or nonuniform, the *internal*

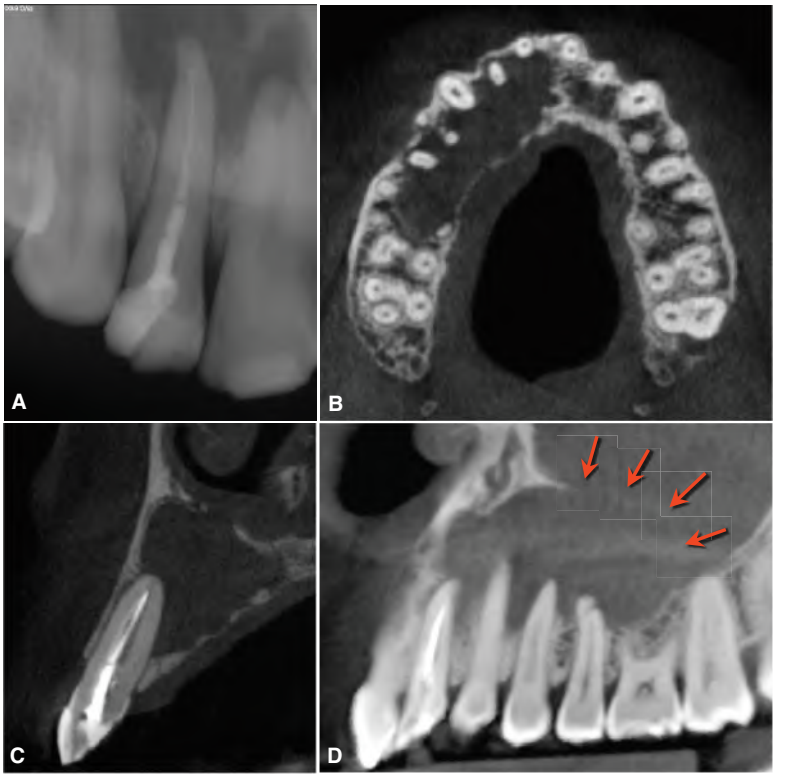

FIGURE 10-15 ***A.*** Periapical radiograph showing a periapical radiolucency associated with root-filled maxillary right lateral incisor. ***B.*** 180 µm voxel size CBCT axial view displaying the extensive bone damage extending from the lateral incisor to the second molar. ***C.*** 90 µm voxel size CBCT coronal view displaying obturation defect. ***D.*** 180 µm voxel size CBCT sagittal view displaying extension into the maxillary sinus (red arrows). (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

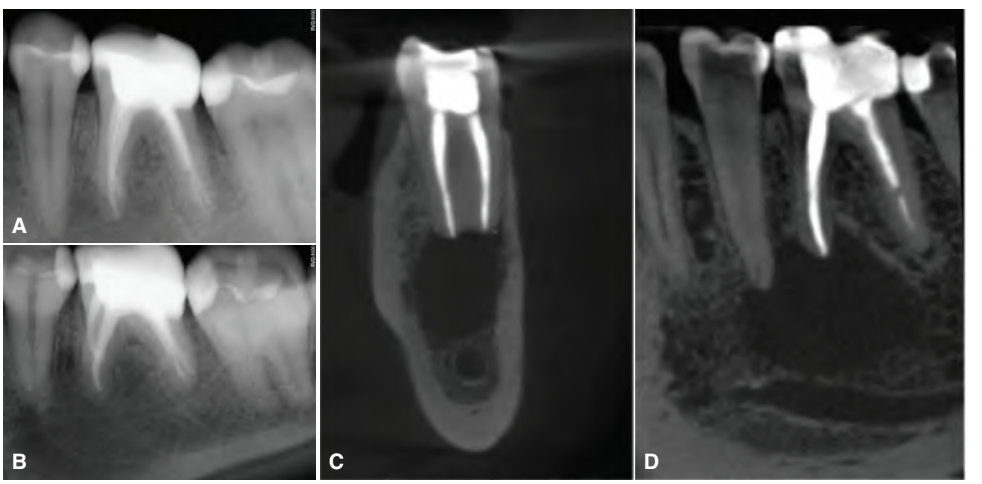

FIGURE 10-16 ***A & B.*** Periapical radiographs from two different angles do not overtly reveal the pathosis seen in the next image. ***C & D.*** Coronal and sagittal CBCT images of same tooth showing a well-defined periapical radiolucency, the anatomic extent of the lesion, relationship to the inferior alveolar canal and involvement of the adjacent premolar. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

structure is heterogeneous and solid with "cotton wool" appearance, the *borders* are also blending but indistinct, and there are major *effects on adjacent structures*.

Although these conditions are both in the spectrum of bone pathology, the differences in the evaluated parameters indicate that they are very different with respect to diagnosis and behavior (which is what we see clinically and radiographically with both conditions) and these findings, therefore, impact differential diagnosis and management in each case. In these specific cases, the *fibrous dysplasia* patient required more definitive diagnosis, including biopsy and systemic workup, to rule out other osseous involvement or a syndromic-related form of *fibrous dysplasia*. It also required more complex

TABLE 10-1 Odontogenic and Nonodontogenic Conditions That Can Be Encountered During Endodontic Imaging Interpretation

Pathology	Developmental	Reactive	Neoplastic
Odontogenic lesions	Amelogenesis imperfecta Dentin dysplasia Dentinogenesis imperfecta Dens in dente/invaginatus Dilaceration Enamel pearl Fusion Gemination Hypercementosis Mesiodens Supernumerary roots Systemic syndromes Tauradontism Turner's hypoplasia	Apical root resorption Apical scar Calcified root canal Caries Chronic apical periodontitis External resorption Internal resorption Pulpal calcification Pulpitis Periapical granuloma Periapical abscess Radicular cyst Root perforations Tooth/root fractures	Ameloblastoma Ameloblastic fibroma Calcifying odontogenic cyst Calcifying odontogenic tumors Cementoblastoma Cementoma Glandular odontogenic cyst Keratocystic odontogenic tumor Odontogenic fibroma Odontogenic myxoma Odontoma
Nonodontogenic lesions	Antral pseudocyst Canalis Sinuosus Dentigerous cyst Idiopathic osteosclerosis Incisive canal cyst Lateral periodontal cyst Pneumatized sinus Systemic syndromes Tori/exostoses	Ankylosis Antral Pseudocyst Metabolic bone pathology Osteomyelitis Osteonecrosis Periodontitis Periostitis Sinusitis Traumatic bone cavity	Fibro-osseous lesions Cemento-osseous dysplasia Florid osseous dysplasia Fibrous dysplasia Ossifying fibroma Central giant cell granuloma Hemangioma Primary malignancy Metastatic cancer

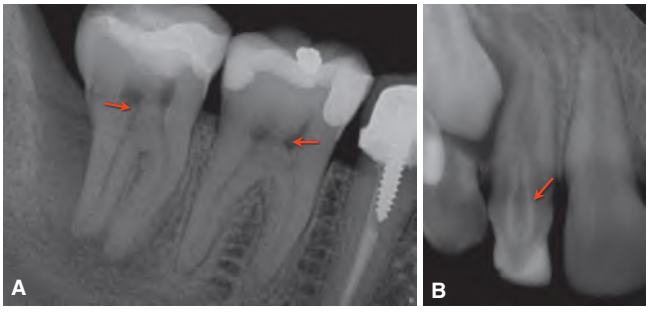

FIGURE 10-17 ***A.*** Identification of *pulpal calcification* (red arrows), or stones, in mandibular molars. ***B.*** Presence of a *dens invaginatus* (red arrow) can only be made with knowledge of normal tooth and pulpal anatomy as viewed on radiographs. Teeth affected by this developmental anomaly can present endodontic treatment challenges. (Courtesy of Dr. Reham Sharroufna, Los Angeles, CA. (Figure 10-17A) and Dr. Carl M. Allen, Columbus, OH. (Figure 10-17B).)

surgical management and long-term follow-up. The *idiopathic osteosclerosis* patient didn't require any treatment; only periodic reevaluation. This highlights the importance of clinico-radiographic findings for diagnosis, management, and outcome. Even with more subtle or challenging cases, the rules of imaging interpretation still apply and should be utilized.

3. Once lesion parameters (Table 10-2) have been characterized radiographically and correlated with clinical findings, it is important to identify the potential etiology of the lesion as *developmental*, *reactive*, or *neoplastic*. Most organic pathoses can be categorized into one (or more) of these three etiologic classifications.

Developmental conditions, in general, tend to be hereditary or acquired, usually manifest early in life, and have a symmetric and bilateral/diffuse distribution or a midline distribution based on head and neck embryologic patterns. Examples may include head and neck syndromes (Figure 10-21), tori (Figure 10-22), incisive canal cyst (Figure 10-23), dentinogenesis imperfecta (Figure 10-24), and dentinal dysplasia (Figure 10-25).

Reactive conditions are generally inflammatory in nature, where the body is reacting to either exogenous or endogenous irritants. This group may include infections, autoimmune conditions, trauma, and foreign body reactions. Clinically, one or more of the classic signs of inflammation such as redness, heat, swelling, pain, or loss of function may exist; although not in all cases. Examples may include acute or chronic apical periodontitis (Figure 10-26), inflamed radicular or periapical cyst (Figure 10-27), antral pseudocyst (Figure 10-28), traumatic bone cavity (Figure 10-29), and osteomyelitis (Figure 10-30).

Neoplastic conditions are generally benign or malignant in nature. Benign tumors are usually well-defined and slowly growing as compared to cancers that can grow more rapidly and present as ill-defined radiographic lesions. In the jaws and around teeth, examples of benign neoplasms encountered include odontogenic tumors such as odontoma (Figure 10-31), ameloblastoma (Figure 10-32) and odontogenic myxoma

TABLE 10-2 Parameters and Potential Pathologic Features That Should Be Evaluated When Making Endodontic Imaging Interpretation

Imaging Parameters	Potential Pathologic Features
Anatomic location and epicenter of lesion	Unifocal or multifocal; localized or generalized; unilateral or bilateral; association with anatomic structures such as teeth, nerve canals, and sinuses
Relative radiodensity of lesion	Lucent (lytic), opaque, or mixed; soft tissue or hard tissue density
Size, shape, and growth pattern	Regular or irregular shape; uniform or nonuniform; hydraulic/cystic appearance or solid; expansile or nonexpansile; permeating; infiltrative
Internal structure	Homogenous or heterogeneous; solid or cystic; scalloped or circular border; punched-out; septated; sequestrum formation; dystrophic calcifications; ground glass or cotton wool appearance
Border characteristics	Well-defined or poorly defined margins; distinct or indistinct margins; blending margins; sclerotic or corticated periphery; lobular; perforation
Effects on adjacent structures	Resorption of teeth or bone; lamina dura widening or destruction; reactive bone formation; periosteal reaction; space-occupying; displacing

FIGURE 10-18 ***A & B.*** Conventional dental radiographs show *caries* lesion (red arrows) and its relationship with the pulp. ***C.*** *Caries* lesion (red arrow) appears to extend toward the distal pulp horn of this mandibular second molar. (Courtesy of Dr. Jaydeep Talim, Los Angeles, CA.)

Blue arrows highlight the significant mandibular involvement and growth. ***D***. CBCT Sagittal view. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

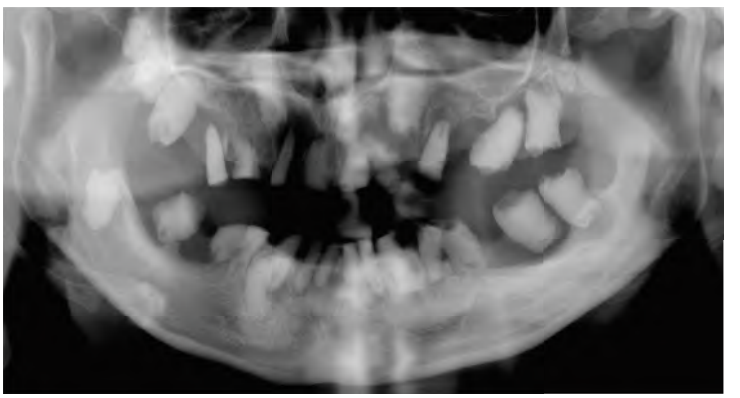

FIGURE 10-21 ***A.*** 14-year old boy with hereditary disease of *ectodermal dysplasia* who also had dermatologic and oral manifestations. Oral findings revealed abnormal tooth development including obliterated pulp canals, and secondary infections of the teeth and periodontium. Note the characteristic developmental presentation of diffuse and bilateral involvement of this condition. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

(Figure 10-33), and benign fibro-osseous tumors (Figure 10-34). Examples of malignant neoplasms include primary or metastatic cancers (Figure 10-35).

4. The final step, radiographically, is to formulate a *differential diagnosis* based on the anatomic and pathologic findings in correlation with clinical findings. Figures 10-36 and 10-37 demonstrate two clinical examples of this process. Avoid making a diagnosis based on any single finding, whether it is clinico-pathologic or radiographic. Accuracy in diagnosis increases when multiple factors are being considered instead of only one (Figures 10-38 and 10-39)

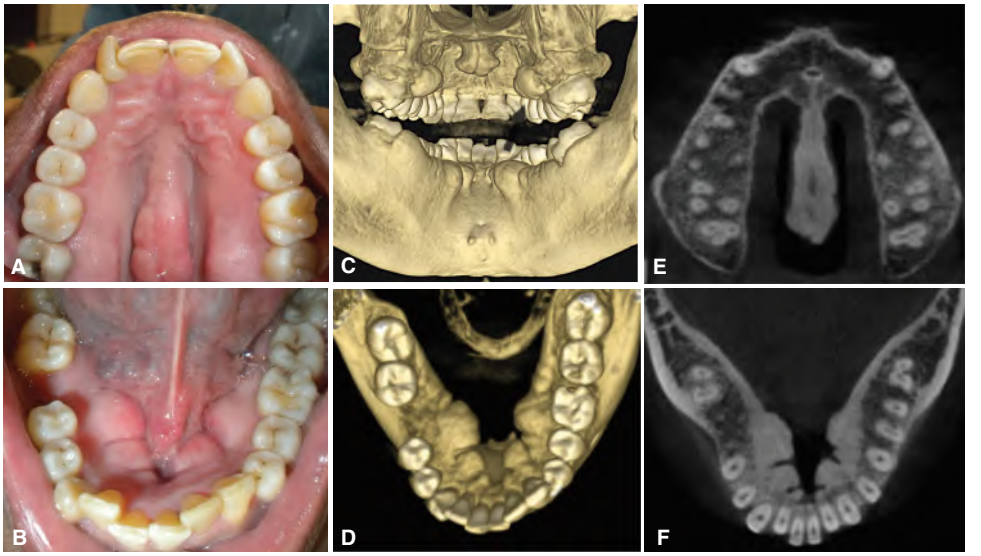

FIGURE 10-22 Developmental *tori*. ***A & B.*** Clinical images. ***C & D.*** volumetric 3-D reconstructions. ***E & F.*** Axial views. Note the midline and symmetric distribution of the palatal torus and the bilateral symmetric distribution of the mandibular tori that may be characteristic findings for developmental conditions. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

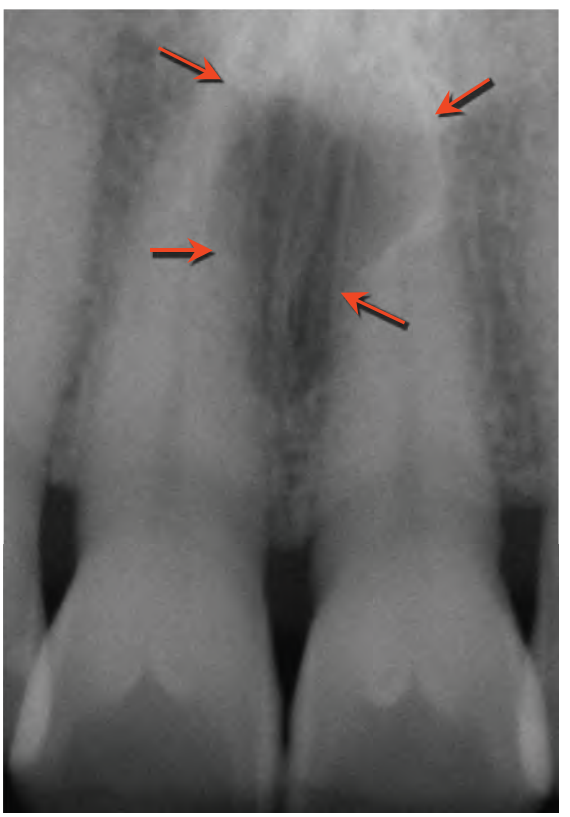

FIGURE 10-23 Periapical radiograph showing an *incisive canal cyst* (red arrows) also known as nasopalatine duct cyst. The midline location and relatively well-defined and symmetric appearance are highly suggestive of a developmental condition associated with normal anatomic structures in this region. These lesions are often described as "pear-shaped" or "heart-shaped" and are usually more than 6mm in diameter. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

FIGURE 10-24 Periapical radiograph of a patient with *dentinogenesis imperfecta* showing characteristic findings such as bulbous crowns, cervical constriction, and obliterated pulp canals and chambers. (Courtesy of Dr. Carl M. Allen, Columbus, OH.)

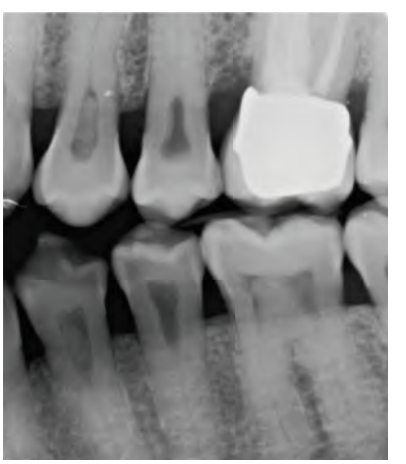

FIGURE 10-25 A bitewing radiograph of a patient with *dentinal dysplasia*, type II (coronal). Note the characteristic 'thistle-tube' appearance of the pulp chambers and presence of pulp stones in several teeth. (Courtesy of Dr. Carl M. Allen, Columbus, OH.)

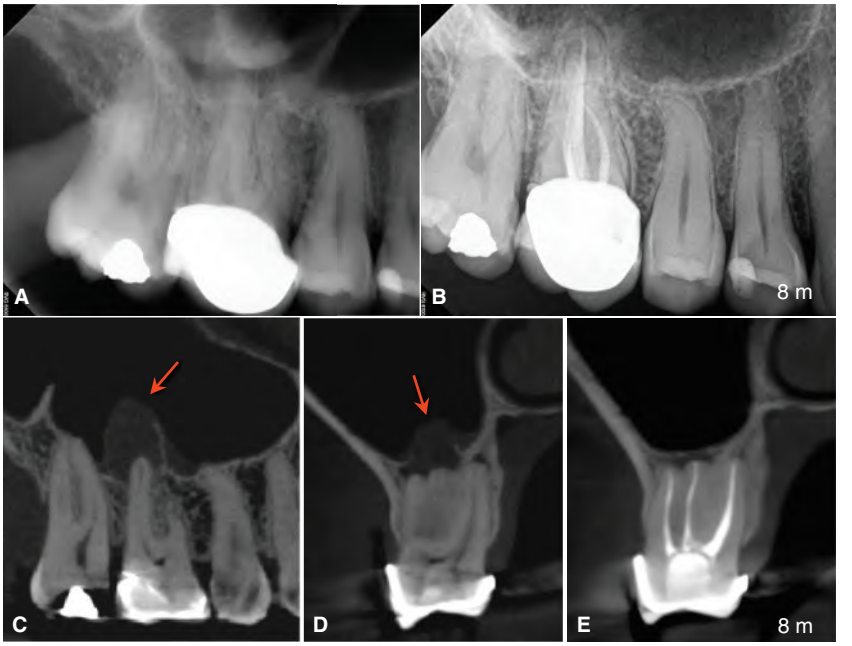

FIGURE 10-26 ***A.*** Periapical radiograph of the maxillary right first molar with asymptomatic *apical periodontitis*. Periapical radiolucency is not visible. The tooth underwent root canal treatment. ***B.*** Eight-month follow-up radiograph. ***C & D.*** 90 µm voxel size CBCT sagittal (C) and coronal (D) views, displaying periapical lesion invading the maxillary sinus (red arrows). ***E.*** Eight-month follow-up CBCT image showing evidence of healing of the lesion. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

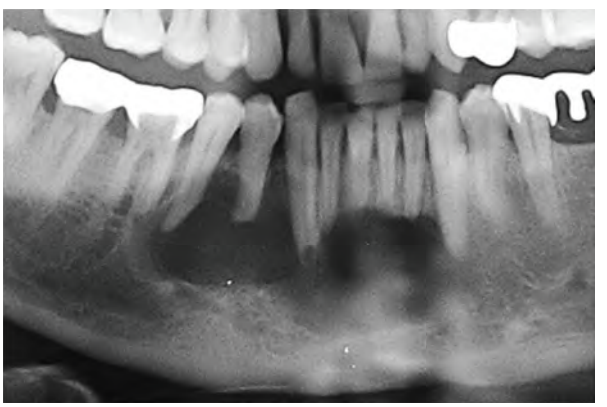

FIGURE 10-27 Panoramic radiographic section showing a large radiolucent lesion of the anterior mandible that was consistent with a large *periapical* (*radicular*) *cyst* diagnosed after surgical enucleation and histopathologic analysis. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

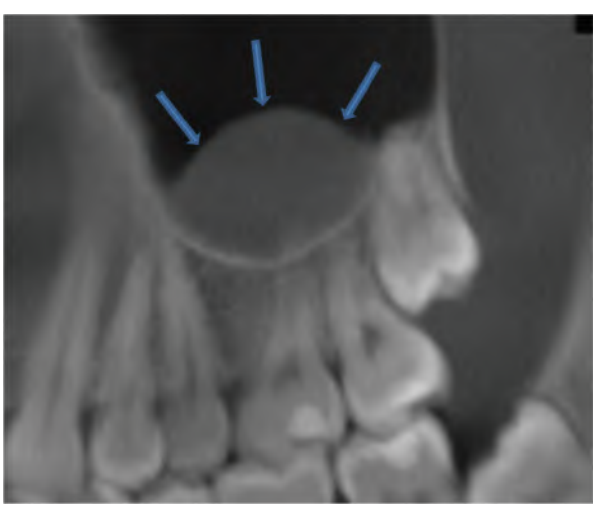

FIGURE 10-28 A section of a panoramic reconstruction from a CBCT scan showing a well-defined, dome-shaped, homogenous and faint radiopacity consistent with an *antral pseudocyst* (aka: sinus mucocele). This is a common radiographic finding in the sinus and is usually clinically inconsequential. Also, in this case, there were no signs or symptoms associated with this lesion and the teeth and pulps were normal. Lack of a corticated rim of bone (arrows) is highly suggestive that this does not represent a periapical cyst. Compare this image to the case of periapical cyst shown in Figure 10-26C & D where a thin rim of corticated bone can be seen at the periphery of the cyst lifting up from the floor of the sinus. Because antral pseudocysts arise from the lining of the sinus they do not alter or lift the antral bone as seen here. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

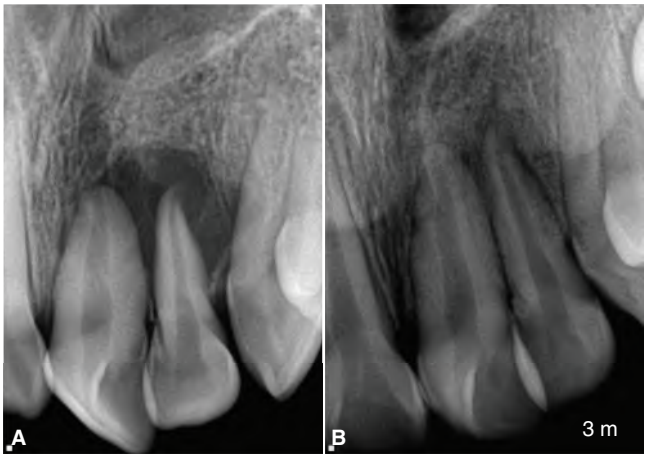

FIGURE 10-29 ***A.*** Periapical radiograph showing an apical radiolucency in a 12-year-old boy. Patient complained of pain and reported a history of trauma to the anterior maxilla. The associated apical radiolucency is most likely consistent with a *traumatic bone cavity* but could represent other conditions such as radicular cyst, periapical granuloma, or an odontogenic tumor (based on radiographic features alone without biopsy) All anterior teeth tested normal to pulp sensibility tests as compared to unaffected control teeth. ***B.*** Periapical radiograph, taken 3 months after initial presentation, showing bone-fill in the region following conservative treatment with antibiotics and close monitoring. The patient was asymptomatic within 2 weeks. On 1-year recall, the area remained healthy. (Courtesy of Dr. Diego Dalla-Bona, Los Angeles, CA.)

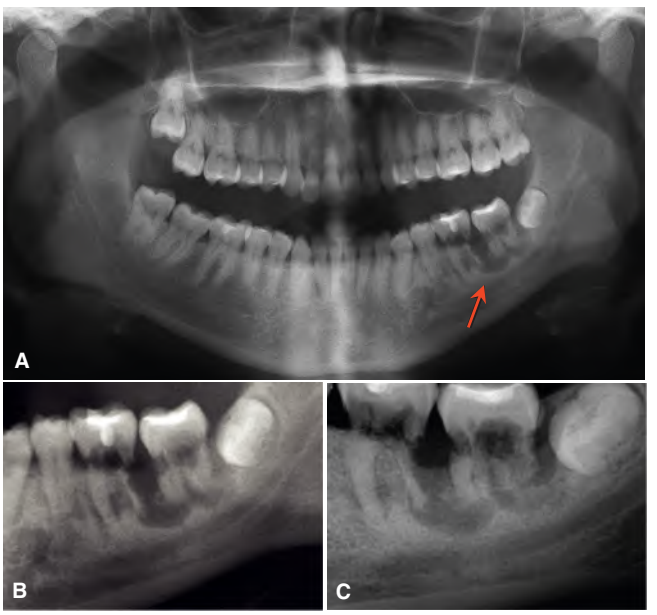

FIGURE 10-30 ***A.*** Panoramic radiograph showing an ill-defined lytic lesion (red arrow) of the left posterior mandible. A diagnosis of *osteomyelitis* (actinomycotic) was confirmed following extraction of the affected molars and histopathologic analysis. ***B & C.*** Higher magnification of the affected area reveals significant tooth and root resorption and irregular bone loss (often consistent with a diagnosis of infection, or sometimes even malignancy). (Courtesy of Dr. Tomoko Wada, Los Angeles, CA.)

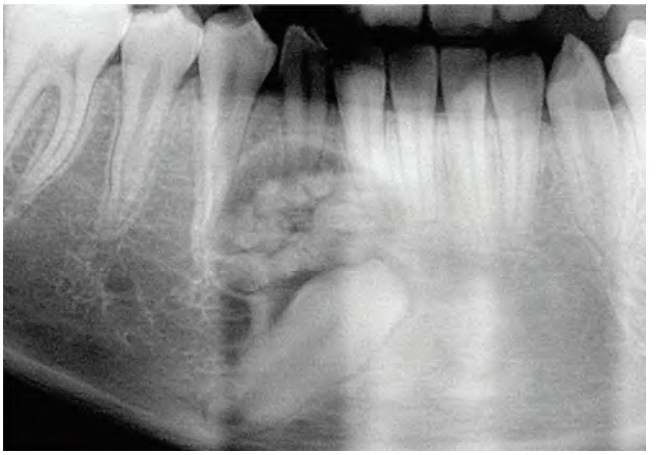

FIGURE 10-31 Panoramic radiographic section showing a well-defined mixed lesion with internal calcifications, circumferential radiolucency, and a thin sclerotic rim or periphery that is highly suggestive of a benign process. An impacted tooth is seen in association with this lesion. After surgical removal and histopathologic analysis, a diagnosis of *compound odontoma* was confirmed. (Courtesy of Dr. Saravanan Ram, Los Angeles, CA.)

FIGURE 10-32 Periapical radiograph showing a multilocular radiolucency confirmed as *ameloblastoma* following biopsy and histopathologic evaluation. Note loss of lamina dura and potential resorption of adjacent roots and the fine internal septations (red arrows) indicating a multilocular growth process. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

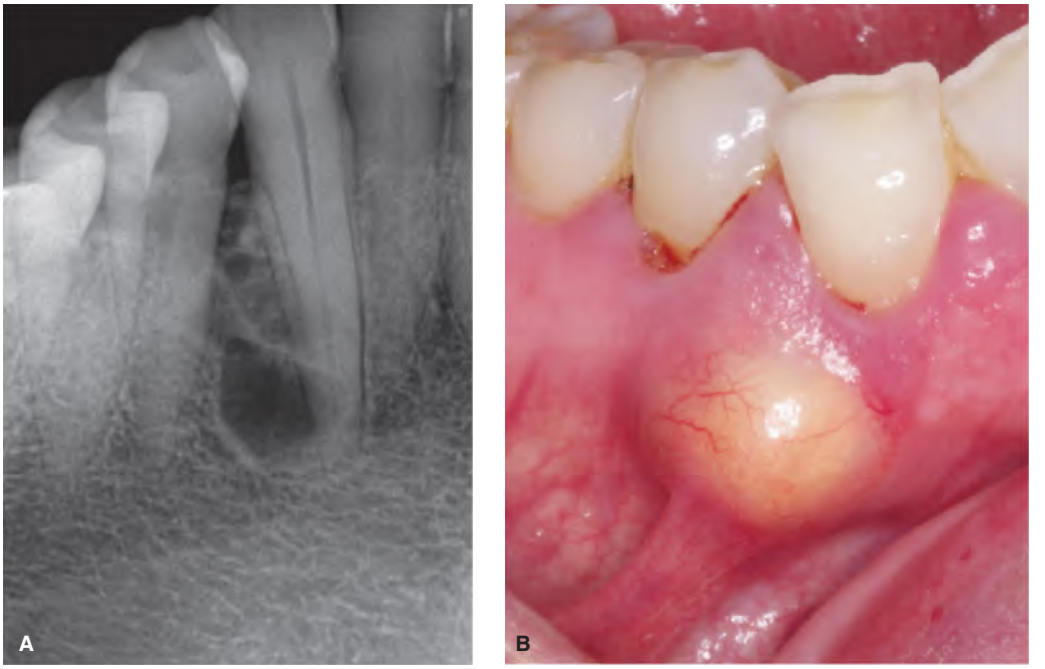

FIGURE 10-33 ***A.*** Periapical radiograph showing a multilocular radiolucency. ***B.*** Clinically, a buccal expansion associated with the intraosseous lesion is noted. Surgical enucleation and biopsy confirmed a diagnosis of *odontogenic myxoma*. Compare this case to the one described in Figure 10-32. The multilocular nature of the process can be suggestive of an odontogenic tumor in general. (Courtesy of Dr. Tomoko Wada, Los Angeles, CA.)

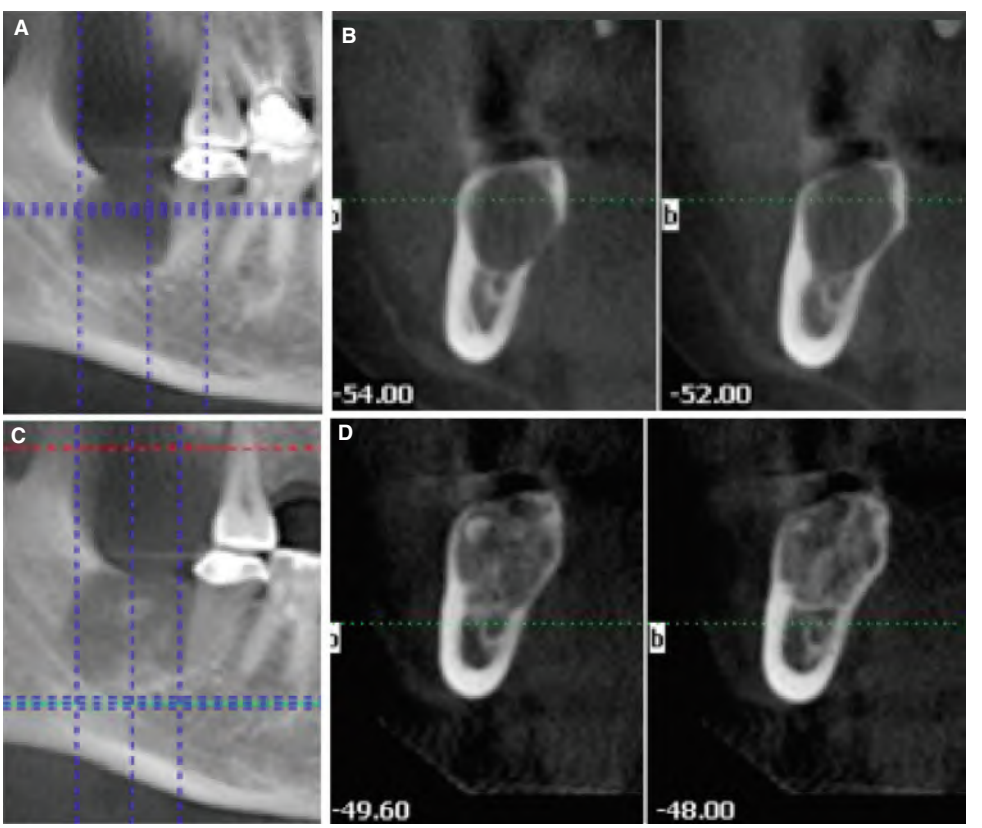

FIGURE 10-34 ***A.*** Panoramic reconstruction from a CBCT scan showing a well-defined radiolucency of the posterior mandible in an asymptomatic patient. ***B.*** Sagittal views reveal the expansile nature of the lesion and thinning of the cortical bone associated with this process. ***C & D.*** CBCT images taken 1 year later, showing internal calcification of the lesion and a more complex appearance than initial findings. Biopsy of the lesion confirmed a *benign fibro-osseous tumor* that explains the mixed radiographic appearance and well-defined nature of the process. (Courtesy of Dr. Yuan-Lung Hung, Los Angeles, CA.)

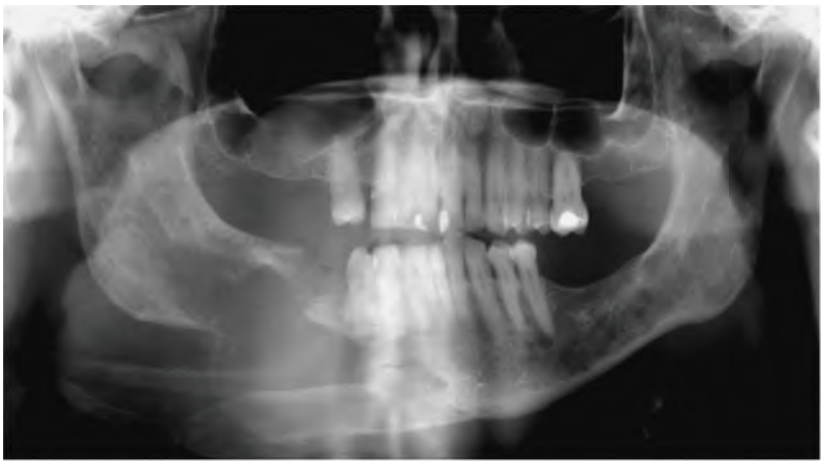

FIGURE 10-35 Panoramic radiograph of a healthy 67-year-old man complaining of pain on the right side of the mandible, presumably from odontogenic origin. The ill-defined radiolucency, or lytic nature of the lesion, and the presence of pathologic fracture is worrisome, warranting immediate biopsy and subsequent histopathologic evaluation that confirmed malignancy of *multiple myeloma*. Note the "punched-out" radiolucent lesions throughout the mandible that can be characteristic (but not pathognomonic) of multiple myeloma. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

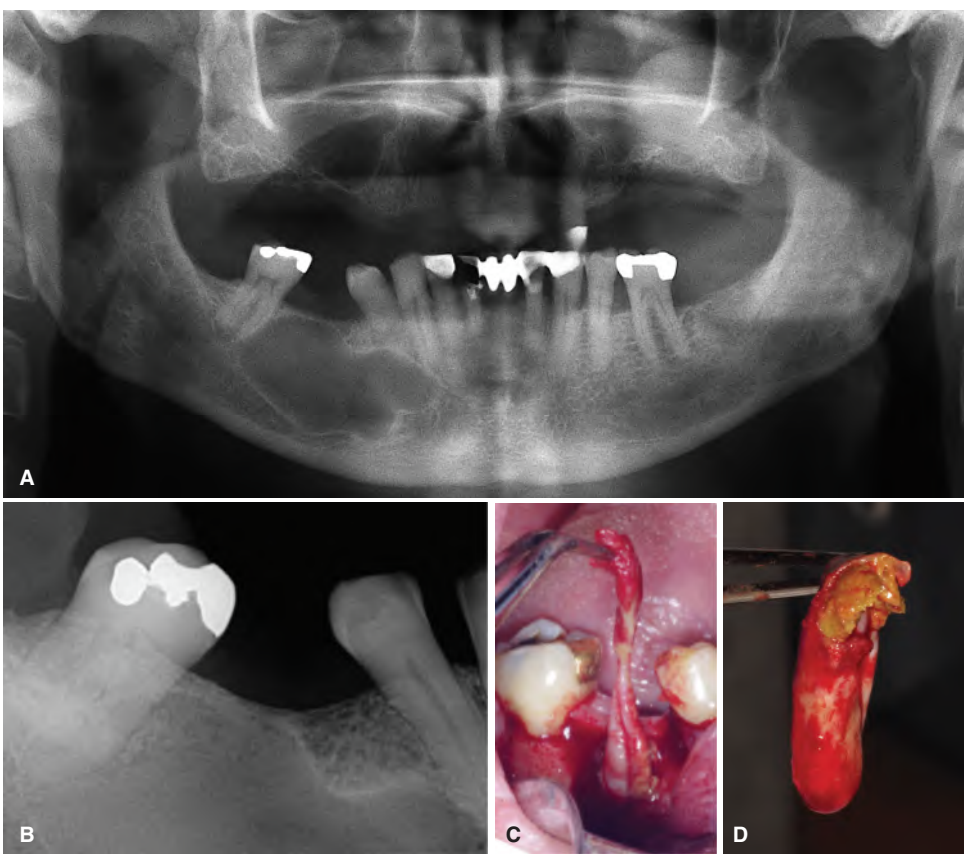

FIGURE 10-36 ***A.*** Panoramic radiograph showing a well-defined radiolucency of the right side of the mandible with a sclerotic rim, or border. The patient exhibited buccal expansion and complained of pain associated with the lesion. ***B.*** Conventional radiograph of the same lesion shows homogenous density in its internal part. ***C.*** Surgical removal of the lesion. Note, cystic appearance of the lesion. ***D.*** The surgical specimen has a sac-like appearance with keratinaceous debris oozing out superiorly. The clinical, surgical, and radiographic findings suggest a benign and cystic process that could include any number of odontogenic cysts or tumors as well as bony cysts or tumors. In this case, histopathologic diagnosis confirmed a *glandular odontogenic cyst*. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

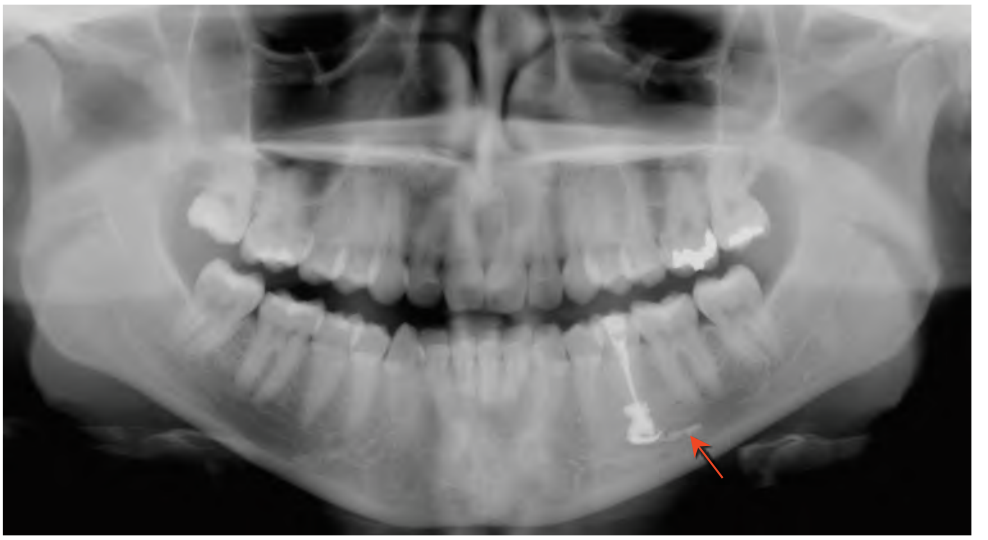

FIGURE 10-37 Panoramic radiograph of a patient complaining of pain and paresthesia/dysesthesia of the left side of the mandible and lower lip, shortly after root canal treatment. Note extrusion of radiopaque material into the inferior alveolar canal, extending several millimeters posteriorly (red arrow). This can explain the patient's chief complaint and neuropathic pain. Clinical symptoms correlated with radiographic findings. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

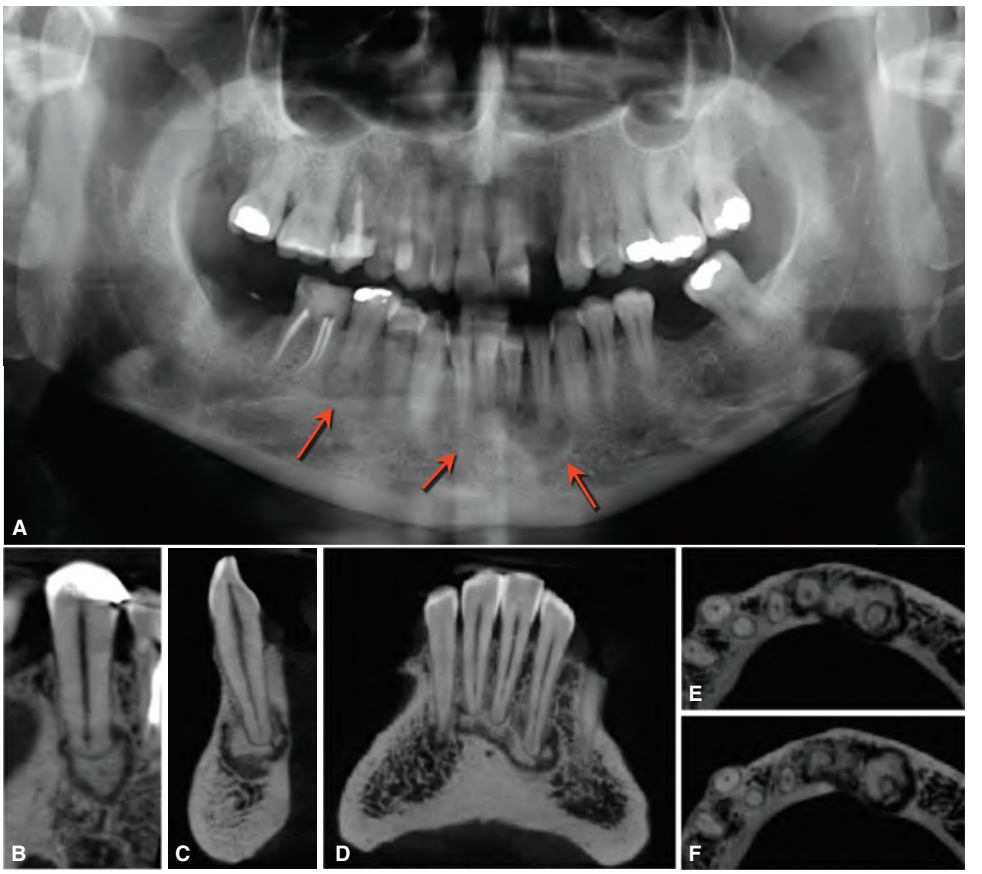

FIGURE 10-38 A case of *cemento-osseous dysplasia*. ***A.*** Panoramic radiograph displaying the radiolucent phase in several teeth (red arrows). All teeth tested normally to pulp sensibility tests. ***B.*** High resolution CBCT sagittal view of the mandibular right second premolar showing a characteristic radiopaque lesion surrounded by a rim of radiolucency. ***C.*** Sagittal view at the level of the mandibular right lateral incisor. ***D.*** Coronal view of the mandibular incisors. ***E & F.*** Axial view of the mandibular incisors displaying expansion of the cortical bone (red arrow). Accurate clinical diagnosis in such cases, requires thorough evaluation of any associated signs and symptoms as well as testing of pulpal responses. (Courtesy of Dr. Jose-Maria Malfaz, Valladolid, Spain.)

In summary, the algorithm for image interpretation involves a careful and systematic analysis (Figure 10-40). It is important to recognize, however, that any algorithm for diagnosis and interpretation may fail in some cases since not all lesions behave exactly as expected.[38]

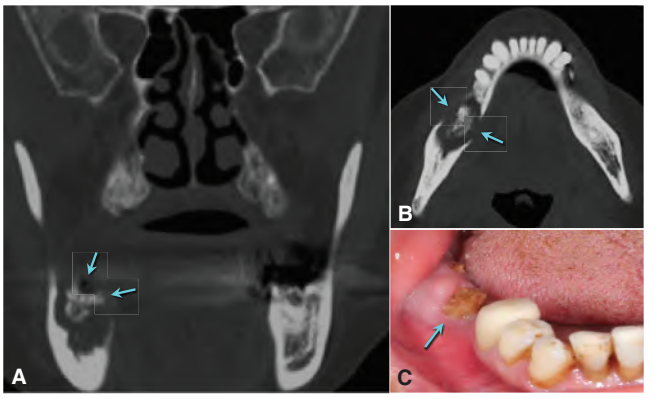

FIGURE 10-39 A case of *medication-related osteonecrosis of the jaw* in an 83-year-old woman who was taking a bisphosphonate drug for osteoporosis therapy for 6 years. ***A.*** Coronal CBCT view shows an ill-defined radiolucency of the right side of the mandible with internal opacity (blue arrows), characteristic of free-floating necrotic bone or "sequestrum." ***B.*** Axial view shows erosion or perforation of the buccal and lingual plates (blue arrows) along with the central sequestrum formation. Note contralateral uninvolved mandible. **C.** Clinical image of the same patient showing exposed necrotic bone (blue arrow) in the oral cavity. Diagnosis of such cases can only be made in conjunction with accurate medical history and clinical factors linked to bisphosphonate drug history. (Courtesy of Dr. Parish P. Sedghizadeh, Los Angeles, CA.)

Chapter 11

Treatment Planning and Case Selection

Paul A. Rosenberg, Matthew Malek, Katsushi Okazaki

Following the diagnosis of an endodontic problem, the clinician must establish a treatment plan that best meets the oral health needs of the patient. A central question is often whether or not the patient's best interests are served by a specific tooth's retention, or extraction and replacement.

The treatment plan is affected by an array of dental and nondental variables. The patient's health status, endodontic prognosis, motivation, and economic factors all play a role in determining the ultimate treatment plan. Periodontal status, restorability of the tooth, and prognosis of the proposed plan must all be considered.

A complex treatment plan with a questionable prognosis is not appropriate for a patient with limited motivation and a history of infrequent or inadequate dental care. The basic question for the clinician to resolve is, "How can I best serve the patients and meet their oral health needs?"

Today, clinicians have options that did not previously exist. The use of microscopy and improved lighting of the operative field enables clinicians to treat teeth that previously would have been thought to be hopeless. The use of ultrasonics has had a profound effect on post removal and nonsurgical retreatment of failed endodontics. When a tooth has a poor or hopeless endodontic prognosis, an implant can be considered as a replacement. However, retention of the natural dentition remains our primary goal.

This chapter reviews significant factors influencing development of a treatment plan for a patient with a diagnosis of a tooth requiring endodontic treatment. A decision concerning tooth retention, or extraction, can be resolved only after a complete review of the patient's medical, dental, and psychosocial status.

MEDICAL CONSIDERATIONS

Determining the medical status of the patient is a primary consideration before an endodontic treatment plan is established. Texts are available that provide detailed reviews of the impact of specific medical complications on the dental patient. For more details, see Chapter 31. Additionally, the American Academy of Oral Medicine (Edmonds, WA) has a website (www.aaom.com) that is a valuable resource for accessing information concerning medically compromised patients.

The American Society of Anesthesiologists (ASA, Park Ridge, IL) Physical Status Classification System (Table 11-1) is a widely used assessment method for preanesthetic patients. The clinician's responsibility is to go beyond the ASA classification and determine initially when the most recent visit of the patient to his or her physician was and what his or her compliance was with any prescribed medication.

In addition, basic questions to answer at the diagnostic visit include, but are not limited to:

- Date of the most recent medical examination, reason for the visit, and pertinent findings
- History of drug allergies
- History of pertinent information concerning drug interactions, and adverse effects
- Presence of prosthetic valves, joints, stents, and pacemakers
- History of required antibiotic premedication
- Bleeding disorders
- Reaction to local anesthesia with vasoconstrictor
- Assessment of the patient's level of anxiety
- Specific patient concerns

The use of only a written form to collect data about a patient's medical status is not sufficient. Frequently, a patient may not indicate important information on a written form but during a follow-up conversation with the dentist, reveal significant facts about their medical status. A prime example of this is a patient who has a history of a sexually transmitted disease and may not want to disclose that on a written form.

MEDICAL FINDINGS THAT MAY INFLUENCE ENDODONTIC TREATMENT PLANNING

There are several medical conditions that may influence the endodontic treatment planning. For a detailed discussion on this topic, see Chapter 31.

DEVELOPMENT OF THE ENDODONTIC TREATMENT PLAN

The strategic value of a tooth in question should be considered before initiating endodontic treatment. Some decisions may be straightforward, while others can be challenging as the clinician weighs multiple factors that will play a role in determining the ultimate success or failure of the case.

TABLE 11-1 American Society of Anesthesiologists Physical Status Classification System

ASA PS Classification	Definition	Examples, Including, But Not Limited to:
ASA I	A normal healthy patient	Healthy, nonsmoking, no or minimal alcohol use
ASA II	A patient with mild systemic disease	Mild diseases only without substantive functional limitations. Examples include (but not limited to): current smoker, social alcohol drinker, pregnancy, obesity (30 < BMI < 40), well-controlled DM/HTN, mild lung disease
ASA III	A patient with severe systemic disease	Substantive functional limitations; one or more moderate to severe diseases. Examples include (but not limited to): poorly controlled DM or HTN, COPD, morbid obesity (BMI ≥40), active hepatitis, alcohol dependence or abuse, implanted pacemaker, moderate reduction of ejection fraction, ESRD undergoing regularly scheduled dialysis, premature infant PCA < 60 weeks, history (>3 months) of MI, CVA, TIA, or CAD/stents.
ASA IV	A patient with severe systemic disease that is a constant threat to life	Examples include (but not limited to): recent (<3 months) MI, CVA, TIA, or CAD/stents, ongoing cardiac ischemia or severe valve dysfunction, severe reduction of ejection fraction, sepsis, DIC, ARD or ESRD not undergoing regularly scheduled dialysis
ASA V	A moribund patient who is not expected to survive without the operation	Examples include (but not limited to): ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel in the face of significant cardiac pathology or multiple organ/system dysfunction
ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes	

From https://www.asahq.org/resources/clinical-information/asa-physical-status-classification-system

Referral of the patient to a specialist should be considered when the complexity of a procedure is beyond the ability of a clinician. Factors that affect endodontic prognosis, including periodontal and restorative considerations, must be considered. The decision concerning endodontic therapy and tooth retention, or extraction and implant placement, should be based on the best available evidence. The patient is usually best served when the natural dentition can be preserved. However, if endodontic treatment has a poor prognosis, an extraction and replacement by an implant is an appropriate consideration.

ENDODONTIC PROGNOSIS

Studies concerning endodontic prognosis identified a number of preoperative factors affecting the outcome of primary endodontic treatment. In a systematic review, it was determined that the absence of a periapical radiolucency significantly improves the outcome of root canal treatment.[1] In the same study, it was found that tooth vitality does not have an impact on endodontic prognosis as long as the periapex is healthy.[1]

It has also been found that the size of the radiolucency may affect the outcome of treatment.[1,2] Another study determined that existence of a sinus tract, narrow but deep periodontal probing depth, pain and discharging sinus have a significant effect on outcome of nonsurgical root canal treatment.[3] Preoperative pain is not only one of the most important predictors for postoperative pain, it may also have an impact on tooth survival after endodontic treatment.[4,5]

These findings suggest that preexisting signs and symptoms may affect the prognosis of treatment. Endodontic prognostic factors and factors affecting other disciplines, such as periodontics, should be taken into consideration when developing a treatment plan. It is of utmost importance that the prognosis and risks and benefits of the treatment be explained to the patient before initiation of the treatment as well. For more details, see Chapters 33 and 34.

Endodontic Retreatment

There is a lack of agreement concerning the endodontic prognosis of retreatment cases. Differences in research methodology may explain the variation in research findings. In a systematic review, it was suggested that the outcome of retreatment cases should be similar to treatment cases as long as access to the apical infection can be re-established (Figure 11-1).[1] However, there is some evidence indicating that the incidence of postoperative pain and flare up is higher in retreatment cases in comparison to treatments.[6] The presence of a preoperative periapical lesion, apical extent of root filling, and quality of coronal restoration have been shown to significantly affect the outcome of retreatment cases.[7]

Important questions to be considered before initiating retreatment include the following:

- Why did the treatment fail?
- Can the point of bacterial entry to the canal space be identified?
- Are prior radiographs available for review?
- Is there an obvious procedural problem that can be corrected?
- Is the canal system readily accessible for reentry?

FIGURE 11-1 Potential for healing should not be underestimated. ***A.*** Preoperative radiograph. ***B.*** The mandibular right first molar was treated nonsurgically. ***C.*** Follow-up examination at 6 months indicates healing in progress.

- Are there additional factors (other than endodontic) that may have contributed to the failure?
- Is the tooth critical to the treatment plan?
- Does the patient understand the prognosis for the tooth and want to attempt retreatment?

A retreatment plan should be developed after the clinician has determined the cause of failure and weighed other factors that may affect the prognosis (e.g., root fracture, defective restoration) (Figure 11-2). Retreatment cases may require surgical endodontics in combination with nonsurgical retreatment. Referral to a specialist is often helpful when planning treatment for complex cases (Figure 11-3). If retreatment (with or without surgery) for a tooth with a new restoration is being considered, it must be weighed against the possibility of an implant. Many variables must be considered before a reasonable conclusion can be reached. For more details, see Chapter 23.

Evaluation of Endodontic Treatment Outcome

It is essential that teeth having had endodontic treatment receive periodic follow-up examinations. This is particularly important in teeth with apical periodontitis. Apical lesions may heal within months or take years to resolve. Only through periodic review of the case can the clinician determine the course of healing. Numerous possibilities exist. There may be complete healing, partial healing, or failure of the treatment. The ideal outcome is the absence of clinical signs or symptoms and complete radiographic healing of preoperative apical periodontitis. Following endodontic treatment no further treatment may be required or apical surgery with or without retreatment is necessary.

A number of variables affect the decision concerning how best to approach the case requiring further treatment. The variables include quality of the previous instrumentation and obturation, periodontal status, quality of the restoration, and the patient's systemic health. However, the central issue always comes down to preventing microbial microleakage from the canal(s) space into the periradicular tissues.

Guidelines published by the European Society of Endodontology, state that the first follow-up examination should be made after 1 year.[8] If the original lesion is only diminished it should be categorized as "questionable and should be followed for up to 4 years. The treatment plan must be modified if clinical symptoms develop, or if the lesion increases in size.[8]

Single-Visit Versus Multiple-Visit Treatment

There is an ongoing debate concerning single visit endodontics. Some clinicians take an extreme approach and treat all cases in a single visit, regardless of the patient's symptoms or complexity of the case. Others believe that many vital cases are suitable for single-visit treatment. The number of roots, time available, and the clinician's skills are factors to be considered.

Severity of the patient's symptoms is another important consideration. For example, a patient with a necrotic pulp and in severe pain, with or without swelling, is not a candidate for single visit therapy. Treatment in such cases should be directed at alleviating pain, with filling of the canal deferred for a subsequent visit. There are advantages in having a patient return for a second visit, after initially presenting with an endodontic emergency due to pain and/or swelling with or without a stoma. The second visit allows the clinician to determine the effect of the treatment on inflamed and infected tissues.

The best available evidence in considering a single- or multiple-visit approach is frequently contradictory. Although some studies have reported less posttreatment pain in single-visit cases, a systematic review found that the incidence of postobturation discomfort was similar in the single- and multiple-visit approaches.[9–12] In another systematic review, it was concluded that there was a lack of compelling evidence indicating a significantly different prevalence of post treatment pain/flare-up with either single- or multiple-visit root canal treatment.[13] Differences in research methodology may explain the conflict in their findings.

Regarding the healing rate of single- and multiple-visit cases, a systematic review found that there was no detectable difference in the effectiveness of root canal treatment in terms of "radiographic success" between single- and multiple-visits.[10] A more recent systematic review also found that the healing rate of single- and multiple-visit root canal treatment is similar for infected teeth.[12]

Teeth with nonvital pulps and apical periodontitis pose a microbiological problem for the clinician. There is no

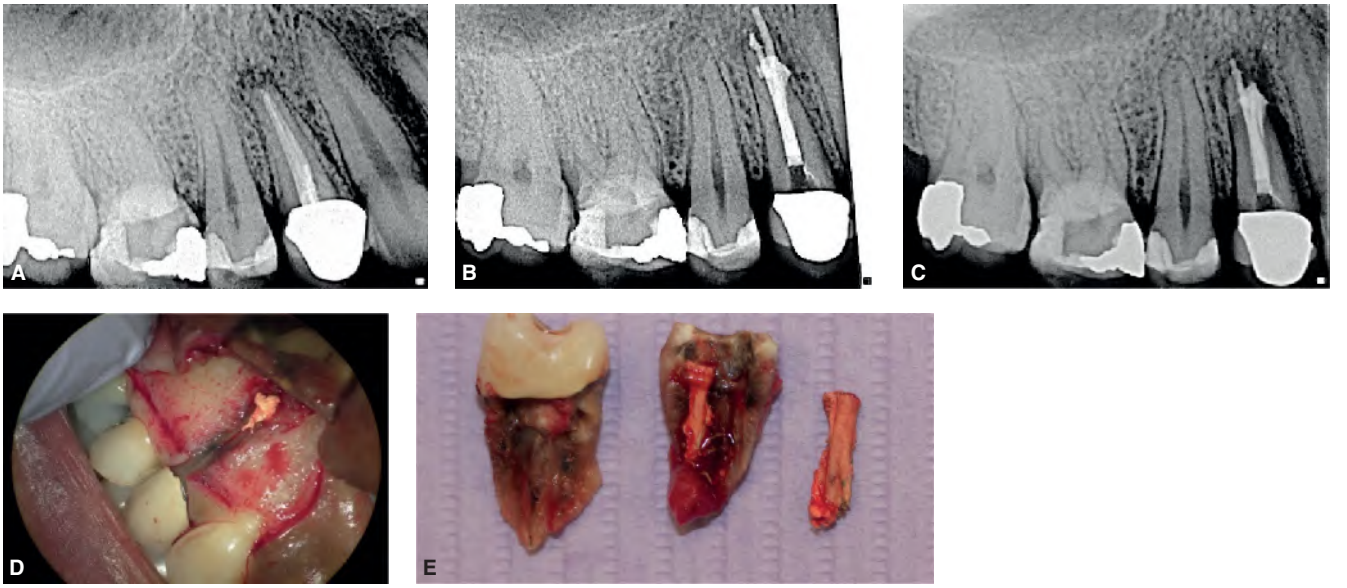

FIGURE 11-2 Retreatment without accurately determining the cause of failure. ***A.*** Preoperative radiograph showing periapical radiolucency associated with the maxillary right second premolar that is symptomatic to biting. A deep isolated pocket is present along the buccal root surface. ***B.*** Postoperative radiograph showing extensive overfilling. ***C.*** 6-month follow- up radiograph indicates that retreatment has failed. Since the cause of failure was not determined preoperatively, the clinician proceeded to periapical surgery. ***D.*** Intraoral image after flap reflection indicates a split in the root. The tooth is hopeless and requires extraction. ***E.*** The tooth following extraction.

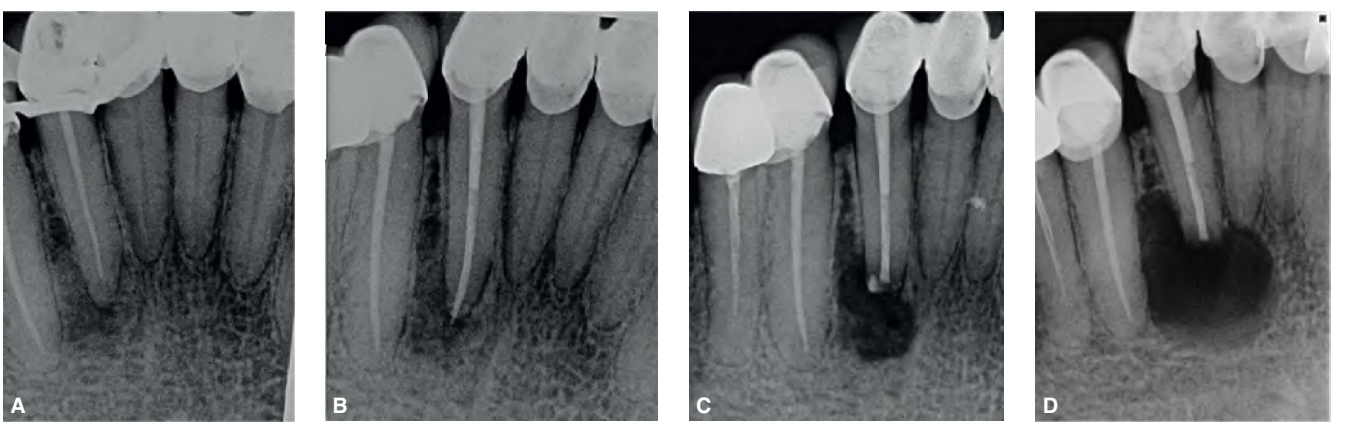

FIGURE 11-3 Treatment challenge in a mandibular lateral incisor. ***A.*** Preoperative radiograph. ***B.*** The tooth was retreated nonsurgically. ***C.*** At 12 months, treatment was deemed a failure. An apicoectomy was performed. ***D.*** One-year follow-up radiograph shows that the apicoectomy also failed. Possible reasons for failure include: absence of adequate seal, existence of a second canal, or vertical root fracture. Treatment options are retreatment (nonsurgically and surgically), or extraction. How would you treat this case?

consensus regarding the appropriateness of single-visit endodontics for treating these patients. Some have postulated that the intervisit use of an antimicrobial dressing is essential to thoroughly disinfect the root canal system.[14–16] In contrast, other researchers have not found any statistically significant difference in success when using the single-visit or multiple-visit approach to the nonvital tooth with apical periodontitis.[2,4,10,12,17–22].

A systematic review found that, single-visit root canal treatment appeared to be slightly more effective than multiple-visit treatment (6.3% higher healing rate). However, the difference between these two treatment regimens was not statistically significant.[21] This is a complicated issue because the inability to detect differences between groups might also be due to variations in research methodology, including sample size, duration of follow-up, and treatment methods.

It is possible that total elimination of microorganisms may not be absolutely necessary for healing. Perhaps maximal reduction of bacteria, effective root canal filling, and a timely satisfactory coronal restoration can result in a high level of clinical success. However, regardless of the number of appointments, effective disinfection of the root canal system is critical.[22] For more details, see Chapter 3.

Treatment planning for an endodontic case should be based on biologic considerations. Patients, who present with acute symptoms, present a different set of biologic issues than those with an asymptomatic tooth. Swelling and/or acute pain are signs of pathologic processes that must be addressed immediately if the tooth is to be retained. The ultimate treatment plan can be fully developed after the symptoms are under control.

Although in most cases, the clinical procedures required to complete endodontic treatment can be accomplished in a single-visit that does not mean it is the best approach. What *can be done* and what *should be do*ne represent two very different approaches to endodontic treatment planning. The patient's systemic health, level of anxiety, and symptoms, as well as the complexity of the root canal system, are among the factors that should be considered.

The author of a study, concerning outcome of initial endodontic treatment of apical periodontitis, commented that, "… treatment of this disease cannot be improved merely by changing treatment techniques. Because apical periodontitis results from interactions between microorganisms, their environment, and the host immune system, only use of effective modifiers of any of these three factors might significantly improve the outcome of treatment".[2]

INTERDISCIPLINARY TREATMENT PLANNING

Periodontal Considerations

Severe periodontal lesions may complicate endodontic prognosis. Lesions with combined endodontic and periodontal components may necessitate consultation with an endodontist and/or periodontist in order to gather more information about the tooth's prognosis.

In a 4-year-retrospective study, it was found that attachment loss and periodontal status affected endodontic prognosis of endodontically treated molars.[23] It is crucial that the dental practitioner be aware of the periodontal factors that may influence the prognosis of endodontic treatment, such as root perforations, bone loss (Figure 11-4) and clinical attachment loss.

When establishing the prognosis of a tooth with an endodontic/periodontal lesion, there are essential factors to be considered. Determination of pulp vitality and the extent of the periodontal defect are central to establishing the prognosis and treatment plan for a tooth with an endodontic/periodontal lesion.

In primary endodontic disease, the pulp is nonvital (Figure 11-5), whereas in primary periodontal disease the pulp retains vitality. True combined endodontic–periodontal disease occurs less frequently. The combined lesion is usually found when the endodontic disease process advances coronally, and joins with a periodontal pocket progressing apically. There is significant attachment loss with this type of lesion and the prognosis is questionable.[24] The radiographic appearance of combined endodontic–periodontal lesions may sometimes be similar to that of a vertically fractured tooth. Therapy for true combined lesions requires both endodontic and periodontal therapy.

The prognosis and treatment of each type of endodontic–periodontal disease vary. Primary endodontic disease should be treated solely by endodontic therapy and the prognosis is usually favorable. Primary periodontal disease should be treated only by periodontal therapy and the prognosis varies depending on the severity of the disease and patient's response to treatment.[24]

Pathogenesis of the lesion can be better understood after pulp sensibility testing, periodontal probing, radiographic assessment, and evaluation of dental history. When extensive prostheses are planned, the potential risk of including a tooth with a questionable prognosis must be considered. It is not prudent to incorporate a chronic problem into a new complex prosthesis. For more details, see Chapter 36.

Surgical Considerations

Biopsy is the definitive means of diagnosing osseous pathoses that may mimic a lesion of endodontic origin. When retreatment is being considered, the clinician must determine

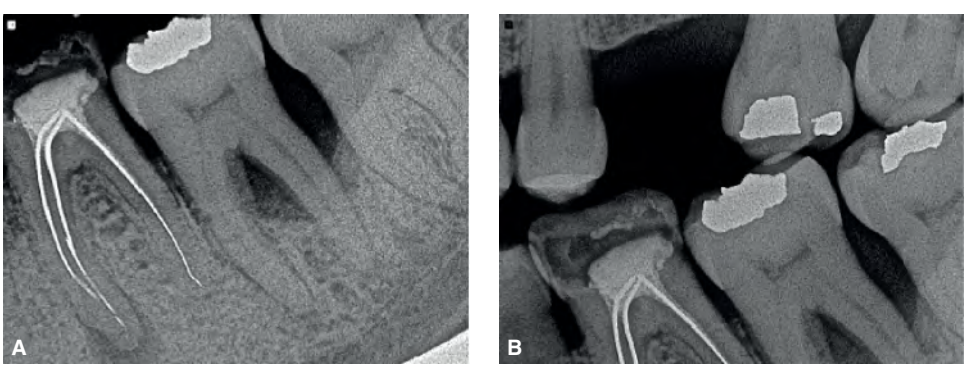

FIGURE 11-4 The pulp of the mandibular left second molar is nonvital, possibly due to root fracture. ***A***. Periapical radiograph ***B***. Bitewing radiograph. Severe destruction of intraproximal bone is indicative of primary periodontal involvement. Periodontal probing reached the apical third of the distal root. The prognosis is questionable. Extraction is indicated and should be done as soon as possible to prevent further damage to the bone associated with the adjacent teeth. Implant site preservation is another consideration in treatment planning for this case.

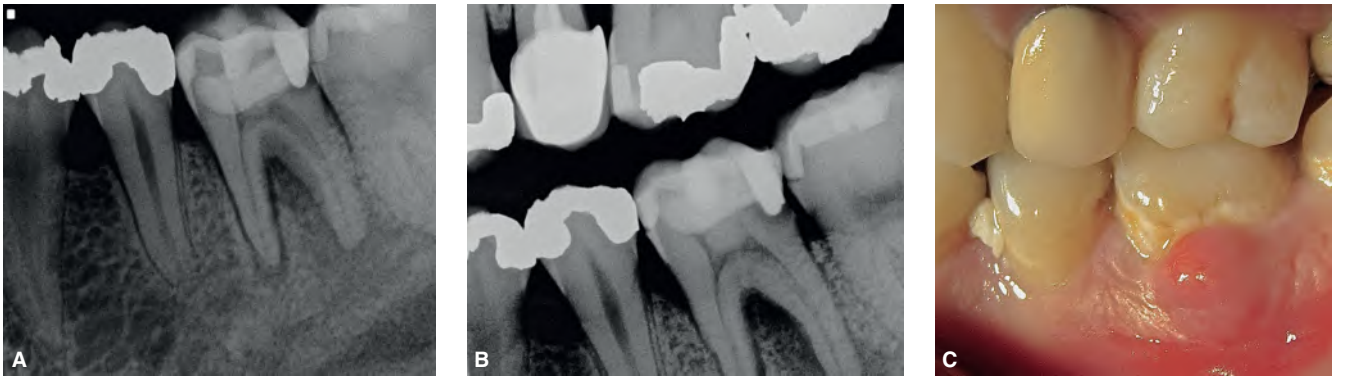

FIGURE 11-5 Primary endodontic lesion with secondary periodontal involvement in a mandibular left first molar. ***A.*** Periapical radiograph showing a deep coronal restoration with distal caries. ***B.*** Furcation bone loss is visible on bitewing radiograph. ***C.*** Clinically, a swelling is visible on the buccal attached gingiva of the affected tooth. Pulp sensibility test was negative. Periodontal probing reached the apical third of the distal root. The prognosis of endodontic treatment depends also on the healing of the periodontal lesion.

whether nonsurgical, surgical, or combined treatment is appropriate. This decision is influenced by the presence of complex restorations, posts, and radiographic assessment, including cone-beam computed tomography (CBCT) of prior endodontic therapy.

Endodontic surgery is most often performed in an attempt to improve the apical seal of unsuccessful nonsurgical treatment. Microbial leakage, due to an inadequate apical seal, is the primary cause of failure. Prior to surgery, it is important that the clinician determine the cause of microbial leakage. For example, a deficient restoration, or recurrent decay, will result in microleakage into the root canal space. Unless that issue is addressed, neither apical surgery nor retreatment will be successful. When a deficient restoration is identified it must be replaced in order to prevent continued microbial penetration.

Endodontic surgery may also be performed as a primary procedure when there are complications, such as calcific metamorphosis, preventing penetration of the canal. In those cases, by electing surgery as the initial treatment, the clinician can preserve the crown of the tooth.

The treatment plan for these cases is determined after reviewing multiple radiographs and considering the possibility of completing nonsurgical therapy without destroying an otherwise functional crown or natural tooth. Endodontic surgery without prior nonsurgical therapy should be a treatment of last resort and only when nonsurgical treatment is not possible.

Reviewing the best available evidence for alternative treatments is an important aspect of treatment planning for a tooth with failed endodontics. Evidence concerning healing potential after endodontic surgery is an important consideration in the management of post treatment disease.[25] Numerous studies have examined the outcome of apical surgery and the results vary considerably.[26–28] This variability may reflect actual outcome differences or variations in case selection techniques, recall periods, and methodology.

In a prospective study, it was found that there is an increased odds ratio for disease persistence in teeth with large pretreatment lesions and pretreatment root canal filling of adequate length.[27] In another study, it was found that patients presenting with pain at the initial examination, before surgery, had a significantly lower rate of healing at the 1-year follow-up compared with patients having no pain at the initial examination.[26]

It should also be noted that the periodontal condition of the tooth, including the interproximal bone levels and the amount of marginal bone loss, has been shown to significantly affect the long-term prognosis of periapical surgery.[29,30] Moreover, it has been reported that isolated endodontic lesions have much higher success rates (95.2%) at the 1- to 5-year follow-up, in comparison with endodontic–periodontal combined lesions (77.5%).[31]

Dramatic changes in surgical techniques and materials have occurred. The advent of microscopy, endoscopy, and ultrasonics, as well as improved root-end filling materials represents important modifications of surgical techniques. In an outcome study comparing traditional root-end surgery (TRS) and endodontic microsurgery (EMS), it was found that the probability of success for EMS was 1.58 times the probability of success for TRS.[23,32] In another study, comparing the EMS techniques with and without the use of higher magnification, it was found that the difference of probability of success between the groups was statistically significant for molars, but not for the premolar or anterior teeth.[33]

CBCT has proved to be of value diagnostically in surgical cases. It produces three-dimensional images of a tooth, lesions, and adjacent anatomical structures (Figure 11-6). It is beneficial in localizing the mandibular canal, mental foramen, maxillary sinus, and nasal cavity.[34–37] For more detials, see Chapter 24.

Restorative and Prosthodontic Considerations

A restoration may be jeopardized by a number of complications. Subosseous root caries (perhaps requiring crown lengthening), poor crown-to-root ratio, and extensive periodontal defects or misalignment of teeth may have serious effects on the final outcome. These complicating factors must

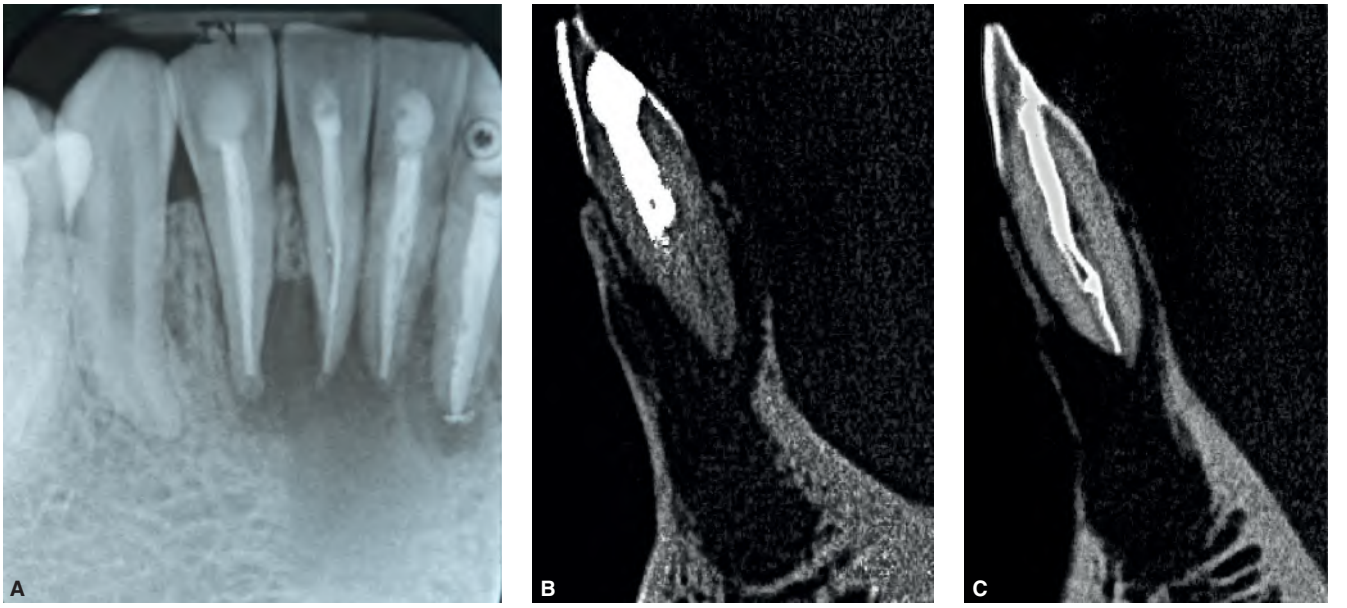

FIGURE 11-6 ***A.*** Periapical radiograph of the mandibular anterior region. ***B & C.*** CBCT reveals thin labial and lingual cortical bony plates that were not visible with conventional radiography. It also provides an accurate image of the extent of the periapical pathosis. This information is critical prior to endodontic surgery.

be recognized before endodontic treatment is initiated. For complex cases, a restorative treatment plan should be determined before initiating endodontic treatment. Some teeth may be endodontically treatable but nonrestorable without extensive additional treatment (Figure 11-7).

Reduced coronal tooth structure under a full-coverage restoration makes endodontic access more difficult because of reduced visibility and lack of radiographic information about the anatomy of the chamber. It is not unusual for full coverage restorations to be compromised during endodontic access. Whenever possible, restorations should be removed before endodontic treatment.

It is possible that the complexity of a treatment plan involving endodontics, periodontics, including crown lengthening, and a post and crown may not be financially prudent. A patient should never be "pushed" into a treatment plan. A treatment plan and its alternatives should always be discussed with the patient weighing the risks and rewards of retaining the tooth versus a replacement.

Full coverage restorations are usually suggested after endodontic treatment. In a systematic review on tooth survival following nonsurgical root canal treatment, four factors were found to be of significance in tooth survival[36]:

- A crown restoration after root canal treatment
- Tooth having both mesial and distal proximal contacts
- Tooth not functioning as an abutment for removable or fixed prosthesis
- Tooth type or specifically nonmolar teeth

In another systematic review, it was found that the odds for healing of apical periodontitis increase with both adequate root canal treatment and adequate restorative treatment.[37] However, poorer clinical outcomes may be expected with adequate root filling/inadequate coronal restoration and inadequate root filling/adequate coronal restoration, with no significant difference in the odds of healing between these two combinations.[37] These findings suggest that the quality of the coronal restoration is as important as the quality of the root canal treatment. Therefore, in order to increase the success of the treatment, it is strongly suggested to discuss the restorative plan of the tooth with both the patient and if it is a referred patient, with the referring dentists, before initiation of treatment.

Endodontic Treatment and Dental Implants

The successful evolution of dental implants as a predictable replacement for missing teeth has had a positive impact on patient care. A clinician now has an additional possibility to consider when developing a treatment plan for a patient with a missing tooth, or teeth. More challenging is the decision concerning whether or not to provide endodontic treatment for a tooth with a questionable prognosis or extract and use a single-tooth implant as a replacement. Numerous studies have evaluated both nonsurgical endodontic therapy and endosseous dental implants.[3,7,38–45]

It is not possible to compare endodontic/implant outcome studies because of variations in research methodologies, follow-up periods, and criteria associated with determining success or failure. A review of current outcome studies points to the need for randomized controlled trials with standardized, or similar, methodologies that could provide a higher level of evidence to use in answering important clinical prognostic questions.

A synthesis of available evidence indicates that both primary root canal treatment and single-tooth implants are highly predictable procedures when treatment is appropriately

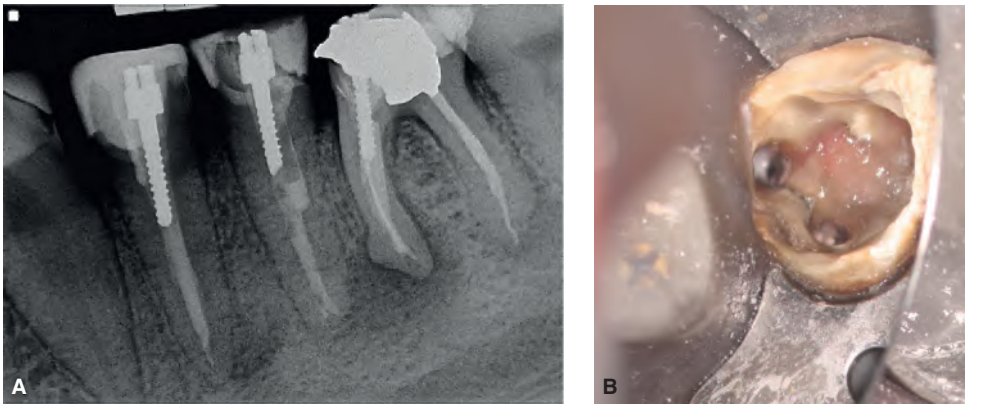

FIGURE 11-7 Restorability of teeth prior to initiating root canal therapy is an important consideration. ***A.*** The mandibular left second premolars and first molar were referred for evaluation and possible retreatment. Severe destruction of tooth structure in all three teeth is evident. This finding eventually leads the clinician to the conclusion that the patient would be better served by extraction and replacement with implants. ***B.*** Intraoral image after removal of the restoration and post on the mandibular molar. Note perforation on the floor of the pulp chamber.

planned and implemented. A study assessed clinical and radiographic success of initial endodontic therapy of 510 teeth over a period of 4 to 6 years. It was found that 86% of teeth healed and 95% remained asymptomatic and functional.[38] Another study considered the outcomes of endodontic treatment on 1,462,936 teeth. More than 97% of teeth were retained after 8 years.[46] In a similar study it was found that overall, 89% of the 4744 teeth were retained in the oral cavity 5 years after the endodontic retreatment.[39] A recent study, concerning the outcome of endodontic therapy on 1312 patients in general practice with a mean follow-up time of 3.9 years, found a combined failure rate of 19.1%, concluding that "failure rates for endodontic therapy are higher than previously reported in general practices, according to results of studies based on dental insurance claims data."[47] However, the number of patients included in this study were sustantially lower than those used in the other large epidimiological studies.

The American Dental Association's Council on Scientific Affairs has reported high survival rates for endosseous implants. An evaluation of 10 studies with more than 1400 implants demonstrated survival rates ranging from 94.4% to 99% with a mean survival rate of 96.7%.[42] With such high survival rates reported for endodontics and single-tooth implants a clinician must consider a multiplicity of factors within the context of the best available evidence. Most current studies indicate no significant difference in the long-term prognosis between restored endodontically treated teeth and single-tooth implants.[44]

A retrospective cross-sectional comparison of initial nonsurgical endodontic treatment and single-tooth implants suggested that restored endodontically treated teeth and single-tooth implant restorations have similar failure rates (Figure 11-8).[48]

A review summarized the best available evidence concerning factors influencing the preservation of a tooth with endodontic therapy or replacement by a single-tooth implant.[44] Factors considered included prosthetic restorability of the natural tooth, quality of bone, esthetic concerns, cost-to-benefit ratio, systemic factors, potential for adverse effects, and patient preferences. The authors concluded that "endodontic treatment of teeth represents a feasible, practical and economical way to preserve function in a vast array of cases and that dental implants serve as a good alternative in selected indications in which prognosis is poor."[44]

Aside from treatment outcome, there are other factors involved in any treatment that the practitioner has to consider when making a treatment planning decision. In a study evaluating the quality of life of endodontically treated versus implant treated patients, the results showed a high rate of satisfaction with both treatment modalities.[49] In a prospective comparative study, it was also found that patients perceive both nonsurgical root canal treatments and single-tooth implants with high degrees of satisfaction and with minimal pain and discomfort.[50] One study compared endodontic molar retreatment and fixed partial dentures to implant–supported restorations. Despite its high survival rate, an implant was found to be the least cost-effective treatment option.[51] In light of this finding, patient's demographic and socio-economic status (SES) should be considered in desiging a treatment plan. In a related study, it was found that older patients were six times more likely than younger patients to receive dental implants. Male patients were 1.3 times more likely than female patients. Insured patients were 1.6 times more likely to have received root canal treatment compared with uninsured patients. The odds of patients with higher SES receiving dental implants was 2.4 times greater than those from low SES.[52]

Another study found that "endodontically treated natural teeth may provide more effective occlusal contact during masticatory function compared with implant-supported restorations, leading to more efficient mastication."[53]

Implants require a surgical procedure that may not be adjustable due to the patient's medical status. Diabetes mellitus can be a complicating factor. However, it has been

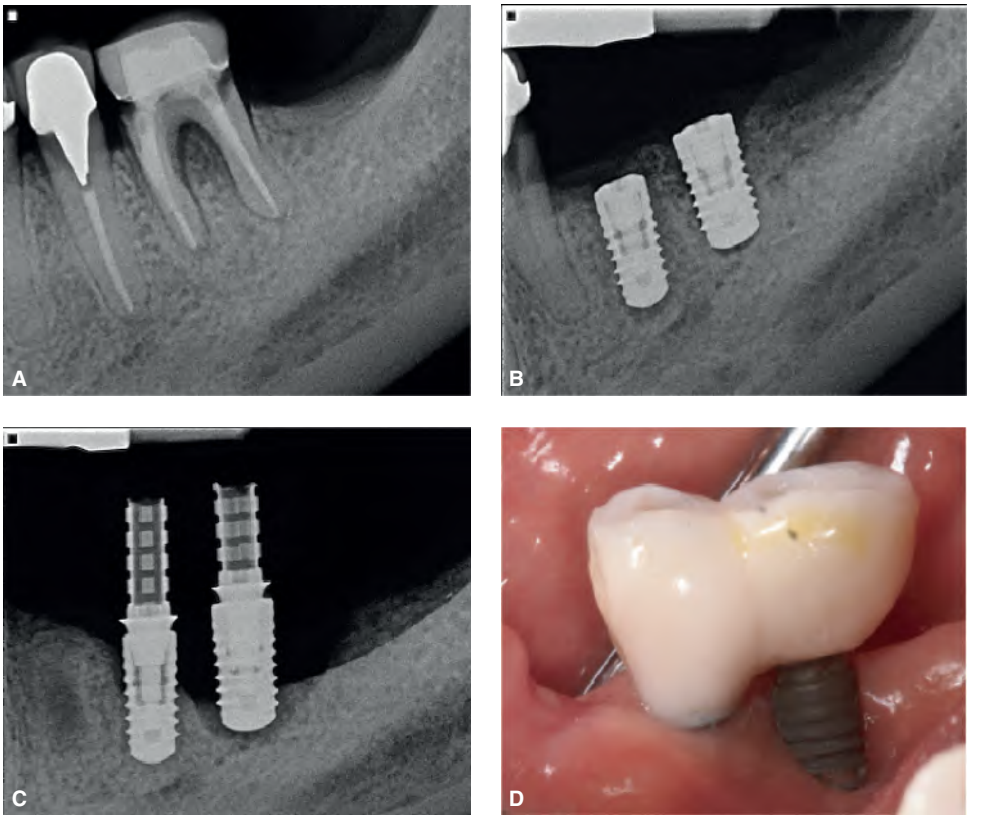

FIGURE 11-8 Implant placement may successfully address a problem if planned and executed appropriately. ***A.*** Periapical radiograph of the mandibular left second premolar and molar with questionable prognosis. ***B.*** The teeth were extracted and replaced with two implants. ***C & D.*** Eighteen months later, the implants are failing.

shown that dental implant osseointegration can be accomplished in these subjects as long as they have good glycemic control.[54]

It seems clear that the patient is best served by retaining their natural dentition as long as the prognosis for long-term retention is positive. It is not reasonable to extract a tooth if endodontics with a good prognosis can be completed. Similarly, it is also not reasonable for a patient to invest in root canal therapy, a post and crown if the prognosis is highly questionable and an implant with a good prognosis can be placed.

An important advantage of providing endodontic therapy is the rapid return of the patient's compromised dentition to full function and aesthetics. This is in marked contrast to the use of provisional restorations associated with dental implants while waiting for osseous integration.

The challenge is to weigh all pretreatment variables and reach a reasonable conclusion concerning tooth retention or implant replacement.

OTHER FACTORS THAT CAN INFLUENCE ENDODONTIC CASE SELECTION

A variety of factors may complicate proposed endodontic therapy. Calcifications (Figure 11-9), dilacerations, or resorptive (Figure 11-10) defects may compromise endodontic treatment of a tooth with potentially strategic value. The inability to isolate a tooth efficiently is also a problem and may result in microbial contamination of the root canal system. Additional roots and canals pose a particular anatomic challenge that conventional radiographs do not always reveal. A bitewing radiograph is useful in providing an accurate image of the pulp chambers of posterior teeth (Figure 11-11). A CBCT is of particular value in providing a three dimensional image of a tooth's anatomy and an associate lesion. For more details, see Chapter 9.

Another consideration is the stage of maturity of the tooth. Primary and immature permanent teeth may have pulpal pathosis caused by caries or trauma; preserving these young teeth is essential. Premature loss of an anterior tooth can lead to malocclusion, predispose the patient to tongue habits, impair aesthetics, and damage the self-esteem of the patient.

Some clinicians use a simple formula for determining those endodontic cases they treat and that they refer to a specialist. The number of roots may be the determining factor in a decision concerning referral, or the key factor may be the chronic or acute status of the case. Others consider the complexity of the ultimate prosthesis as a factor in considering an endodontic referral. The most important variables in determining whether to refer a patient to a specialist are the skills of the clinician and the complexity of the case.

The American Association of Endodontists (AAE) developed guidelines for assessing endodontic case difficulty (available at *www.aae.org*). The AAE Endodontic Case Difficulty Assessment Form enables a clinician to assign a level of difficulty to a particular case. The form describes cases with minimal, moderate, and high degrees of difficulty. This form

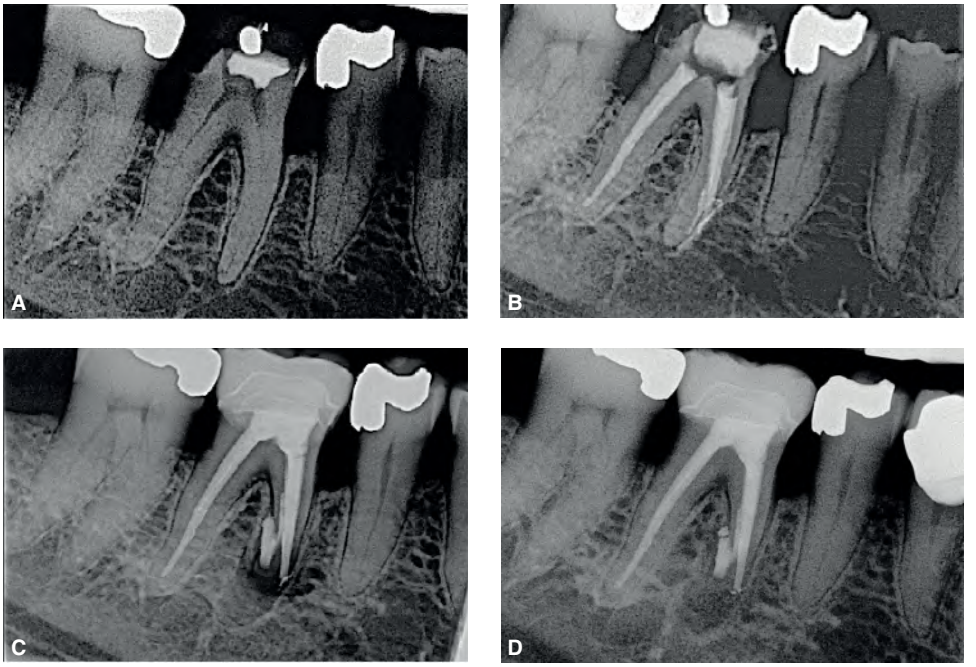

FIGURE 11-9 Calcification may complicate root canal treatment. ***A.*** Radiograph showing calcific metamorphosis in the coronal third of the root of the mandibular right first molar. The tooth is symptomatic to percussion. ***B.*** The clinician was not able to negotiate the mesial canals curvatures and perforated the distal side of the mesial root. The tooth is still symptomatic. ***C.*** Apical surgery was attempted to treat the defect. The retrograde filling is not optimum. ***D.*** Twelve-month follow-up radiograph showing signs of bony healing. The tooth is no longer symptomatic.

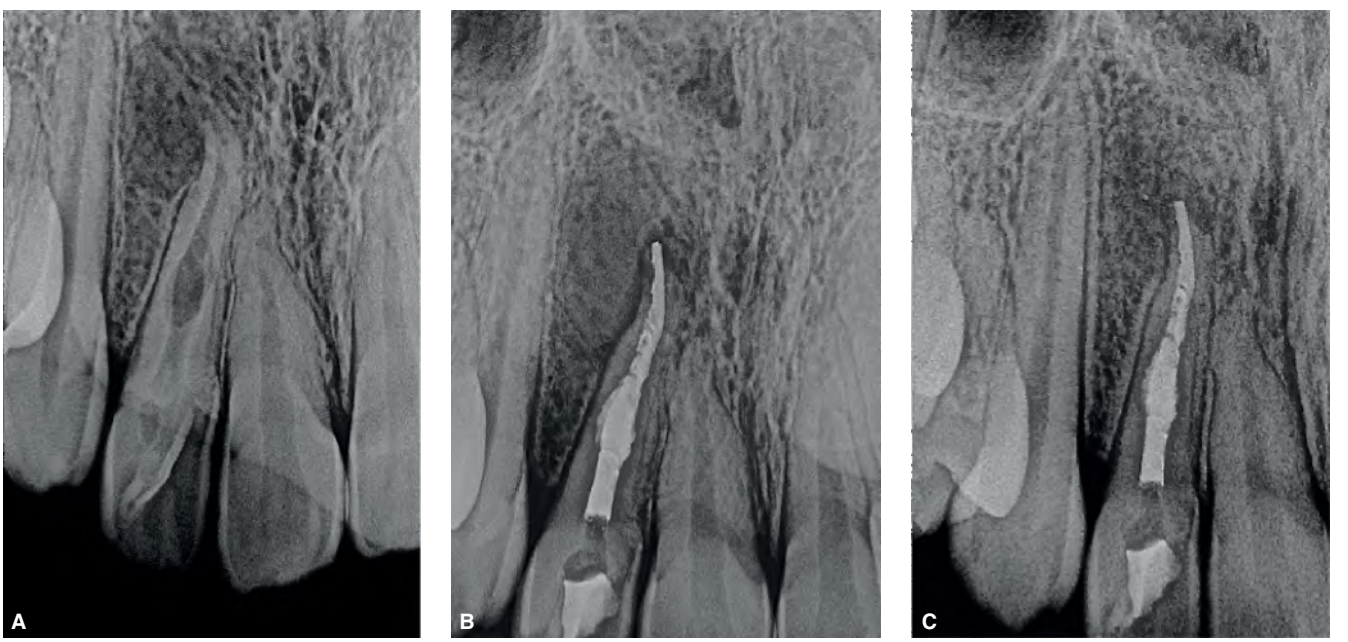

FIGURE 11-10 Some resorptive defects can be successfully treated endodontically. Early intervention, before perforation occurs, is essential. ***A.*** Preoperative radiograph showing a maxillary right lateral incisor with internal resorption and associated periapical rediolucency. ***B.*** Immediate postoperative radiograph. ***C.*** Twelve-months follow-up showing evidence of resolution of the periapical radiolucency. lists criteria that can be used to identify cases that should be referred to a specialist. The use of surgical operating microscopes (Figure 11-12), endoscopes (Figure 11-13), CBCT, and ultrasonics enables the clinician to predictably diagnose and treat teeth that would not have been treatable previously.

Anxiety

Anxiety presents a problem at many levels of dental care and often results in the avoidance of dental treatment. This avoidance appears to be associated with significant deterioration of oral and dental health.[55] Severe anxiety may cause confused diagnostic results.[56] For more details, see Chapters 18 and 31.

Scheduling considerations

Scheduling of visits during endodontic treatment is an important component of treatment planning. If a vital case is to be treated using a multiple-visit approach, it is suggested that the clinician waits 5 to 7 days between canal instrumentation and obturation in order to allow periradicular tissues to recover. This, often, prevents filling a case while tenderness

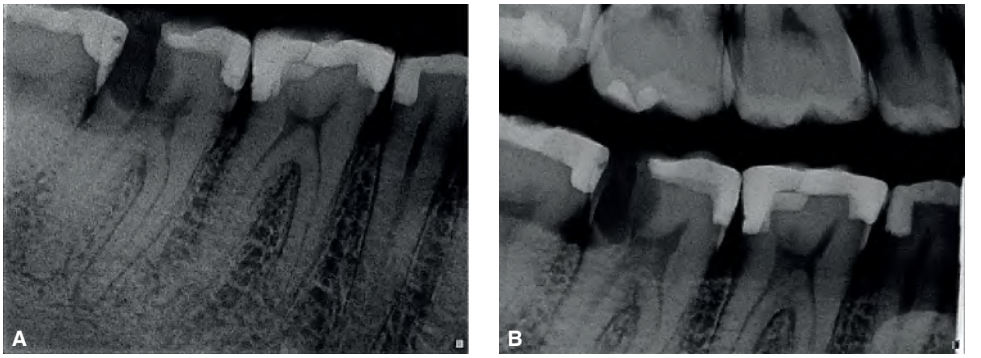

FIGURE 11-11 ***A.*** Periapical radiograph showing a madibular right second molar with large coronal destruction. ***B.*** A bitewing radiograph provides a clearer image of the pulp chamber and surrounding structures. It indicates that the tooth may require crown lengthening prior to restoration. This should be factored into the patient's treatment plan.

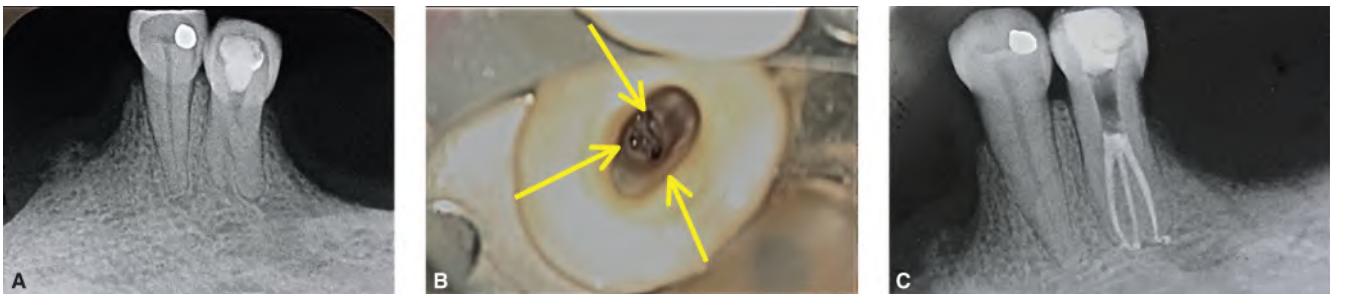

FIGURE 11-12 Enhanced visibility with use of the surgical microscope allows the clinician to accurately locate the third root of the mandibukar left first premolar. ***A.*** Preoperative radiograph. ***B.*** Three orifices are visible at their point of splitting from the main canal using 4.8× magnification (yellow arrows). ***C.*** Immediate postoperative radiograph.

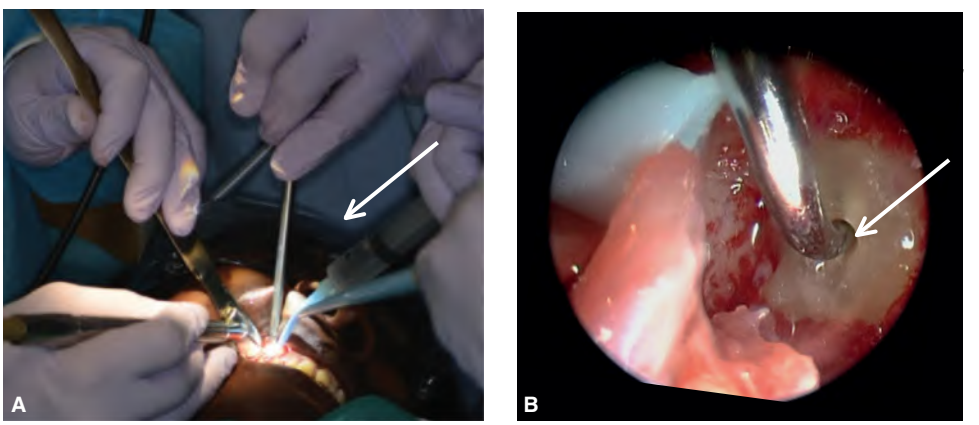

FIGURE 11-13 The endoscope provides high magnification images in areas that may be difficult to view with a microscope. ***A.*** Use of the endoscope during apical surgery. persists following instrumentation. When a vital case is to be treated in a single visit, adequate time must be scheduled so the clinician can comfortably complete the procedure. Since profound inferior alveolar nerve block anesthesia can require approximately 15 to 20 minutes, it is wise to include that time when scheduling a patient's appointment.

When indicated, appointments to obturate nonvital cases should be scheduled approximately 1 week after instrumentation in order to maximize the antimicrobial effect of intracanal medicaments and to allow time for the apical tissues to recover following instrumentation.[14,15]

Acute (pain and/or swelling) associated with nonvital cases should be seen every 24 to 48 hours in order to monitor the patient's progress and bring the acute symptoms under control. Further cleaning, shaping, and irrigation are important components of the treatment as the clinician seeks to eliminate persistent microorganisms from the canal system. Long delays between visits contribute to the development of resistant microbial strains and should be avoided.

Chapter 12

Endodontic Considerations in Dental Trauma

Martin Trope

Traumatic injuries to the teeth result in damage to many dental and periradicular structures. Therefore, the management and consequences of these injuries are multifactorial, and knowledge of the interrelating healing patterns of these tissues is essential.

The focus of this chapter is the dental pulp and how damage to the dentinopulpal complex can contribute to complications after a traumatic injury and how correct diagnosis and treatment can result in favorable healing after an injury. More information on management of dental trauma can be obtained from the Website of the International Association of Dental Traumatology: <http://www.iadt-dentaltrauma.org>.

ASPECTS UNIQUE TO DENTAL TRAUMA

Most dental trauma occurs in the 7- to 10-year-old age group owing to falls and accidents near home or school.[1,2] It occurs primarily in the anterior region of the mouth, affecting the maxilla more than the mandible.[3]

Thus, in many cases after a dental traumatic injury, endodontic therapy is provided to caries-free, single rooted, **young** permanent teeth. Therefore, maintenance of the tooth is particularly important in these young individuals. Luckily, the potential for a successful endodontic outcome is very good if timely and correct treatment is provided soon after the injury.

CROWN FRACTURES

The primary aim from an endodontic point of view is to **maintain pulp vitality** after fractures involving the crowns of teeth.

Crown infractions—"incomplete fracture or crack of enamel without loss of tooth structure"[4]—and **uncomplicated crown fractures**—"fractures of the enamel only or enamel and dentin without pulp exposure"[4]—are injuries that have little danger of resulting in pulp necrosis. In fact, the biggest danger to the health of the pulp is iatrogenic, caused during esthetic restoration of these teeth. Therefore, meticulous follow-up, over at least a 5-year period, is an important endodontic preventive measure. Endodontic intervention should be considered at any follow-up time, when reactions to sensibility tests change, apical periodontitis develops, the root appears to have stopped development, or the pulp is obliterating.

Complicated Crown Fractures

By definition, complicated crown fractures involve enamel, dentin, and pulp[4] and occur in 0.9% to 13% of all dental injuries.[5–7] A crown fracture involving the pulp, if left untreated, will always result in pulp necrosis.[8] However, the manner and time sequence in which the pulp becomes necrotic allow a great deal of potential for successful intervention in maintaining pulp vitality.

The first reaction after an injury is hemorrhage and local inflammation. Subsequent inflammatory changes are usually proliferative but can be destructive. A proliferative reaction is favored in traumatic injuries since the fractured surface is usually flat, allowing salivary rinsing with little chance of impaction of contaminated debris. Therefore, unless impaction of contaminated debris is obvious, it is expected that within the first 24 hours after the injury, a proliferative response with inflammation will extend no more than 2 mm into the pulp (Figure 12-1).[9–11] In time, however, microbial infection will result in local pulp necrosis and a slow apical spread of pulpal inflammation.

Treatment

Treatment options are (1) **vital pulp therapy** comprising pulp capping, partial pulpotomy, and full pulpotomy or (2) **pulpectomy**. The choice of treatment depends on the stage of development of the tooth, time between the accident and treatment, concomitant periodontal injury, and the restorative treatment plan.

Stage of Development of the Tooth

Loss of vitality in an immature tooth can have catastrophic consequences. Root canal treatment on a tooth with a "blunderbuss" canal is time consuming and difficult. Of more importance, however, is the fact that necrosis of an immature tooth leaves it with thin dentinal walls that are susceptible to fracture both during and after an apexification procedure.[12] Therefore, every effort must be made to keep the pulp vital at least until the apex and cervical root have completed development. Pulpectomy in a mature tooth has a high success rate,[13] but vital pulp therapy (rather than removal) on a mature tooth performed under optimal conditions can also be carried out successfully.[14,15] Therefore, vital pulp therapy can be an option under certain circumstances, even though a pulpectomy is the treatment affording the most predictable success. **In an immature tooth, vital pulp therapy should be attempted, if at all feasible, because of the tremendous advantages of maintaining the vital pulp.**

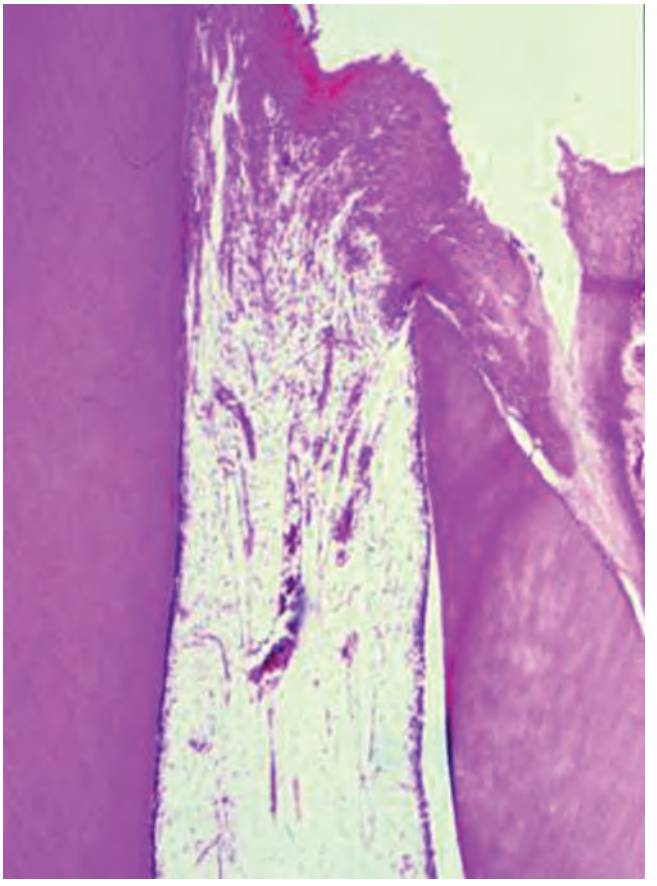

FIGURE 12-1 Histologic appearance of the pulp within 24 hours of a traumatic exposure. The pulp proliferates over the exposed dentinal tubules. There is approximately 1.5 mm of inflamed pulp below the surface of the fracture.

Time Between the Accident and Treatment

For 48 hours after a traumatic injury, the initial reaction of the pulp is proliferative, with a depth of no more than 2 mm of pulpal inflammation (Figure 12-1). After 48 hours, chances of direct microbial contamination of the pulp increase as the zone of inflammation progresses apically.[16] Thus, with time, the chance of success in maintaining a healthy pulp decreases.

Concomitant Attachment Damage

A concomitant periodontal injury will compromise the nutritional supply of the pulp. This fact is particularly important in mature teeth, in which the chance of pulp survival is not as good as for immature teeth.[17,18]

Restorative Treatment Plan

In a mature tooth, pulpectomy is a viable treatment option, unlike an immature tooth, in which the benefits of maintaining vitality of the pulp are great. However, if performed under optimal conditions, vital pulp therapy after traumatic exposures can be successful. Thus, if the restorative treatment plan is simple, and a composite resin restoration will suffice as the permanent restoration, this treatment option should be given serious consideration. If a more complex restoration is to be placed (e.g., a crown), pulpectomy would be the more predictable treatment method.

VITAL PULP THERAPY FOR TRAUMATIC DENTAL INJURIES

Requirements for Success

Vital pulp therapy in traumatically injured teeth has a very high success rate if the following requirements are adhered to:

1. **Treatment of a healthy pulp** has been shown to result in predictable success.[19,20] Vital pulp therapy of the inflamed pulp, affords a less predictable success rate.[19,20] Therefore, the optimal time for treatment is within the first 24 hours, when pulp inflammation is superficial. As time increases between the time of injury and therapy, pulp removal must be extended apically to attempt to reach a noninflamed pulp area.
2. **A microbial-tight seal** is the most critical factor for successful treatment.[20] Challenge by microorganisms during the healing phase will cause failure.[21] On the other hand, if the exposed pulp is effectively sealed from microbial access, successful healing of the pulp with a hard tissue barrier will occur, independent of the dressing placed on the pulp, and in some cases where the capped pulp is inflamed.
3. **A proper pulp dressing** is important, and, presently, calcium hydroxide dressing is commonly used for vital pulp therapy for traumatized teeth. Its advantages are that it is antibacterial[22,23] and will disinfect the superficial pulp. Pure calcium hydroxide (pH 12.5) will cause necrosis of about 1.5mm of the pulp tissue[24,25] involving the superficial layers of inflamed pulp if present (Figure 12-2). The toxicity of the calcium hydroxide appears to be neutralized as the deeper layers of pulp are affected, causing coagulative necrosis at the junction of the necrotic and vital pulp, resulting in only a mild irritation. This mild irritation will initiate an inflammatory response and in the absence of microrganisms[24] will heal with a hard tissue barrier (Figure 12-3).[25,26] Hard-setting calcium hydroxide does not cause necrosis to the superficial layers of pulp but has been shown to initiate healing with a hard tissue barrier as well.[27,28] A major disadvantage of calcium hydroxide is that it does not seal the fractured surface. Therefore, an additional material must be used to ensure that the pulp is not challenged by microorganisms, particularly during the critical healing phase.

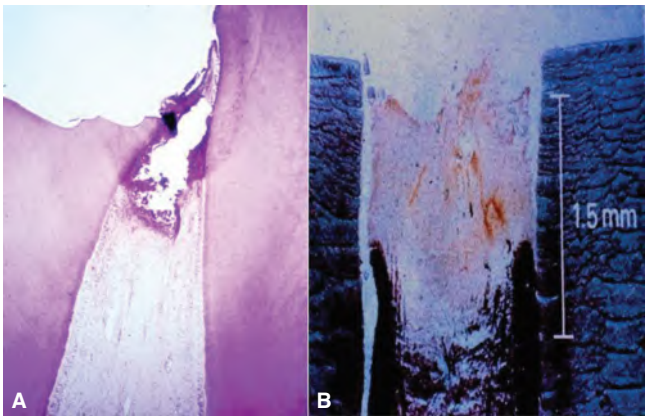

FIGURE 12-2 Pulp necrosis (1.5 mm) as a result of the high pH of calcium hydroxide.

FIGURE 12-3 Hard tissue barrier developed after calcium hydroxide partial pulpotomy. Histologic appearance of replacement odontoblasts and a hard tissue barrier.

Other materials, such as zinc oxide–eugenol,[20] tricalcium phosphate,[29] and composite resin,[30] have been proposed as materials for vital pulp therapy. They have not afforded the predictability of calcium hydroxide used in conjunction with a well-sealed coronal restoration.

Today bioceramic materials are considered the best materials for vital pulp therapy.[31,32] They have a high pH, similar to calcium hydroxide, when unset[32] and after setting will create an excellent bacteria-tight seal.[33] They also set hard enough to act as a base for a final restoration.[34] Mineral trioxide aggregate (MTA) was the first bioceramic used for this purpose. However, certain formulations may cause discoloration of the tooth which is a particular problem in traumatized teeth that are usually in the esthetic zone. Second generation bioceramics like premixed bioceramic putty (Endosequence, [Brasseler, Savannah, Georgia], or TotalFill [FKG Dentaire, La Chaux- De- Fonds, Switzerland]) do not have this disadvantage. For more details, see Chapter 27.

TREATMENT METHODS

Pulp Capping

Pulp capping implies placing a dressing directly onto the pulp exposure. As indicated by the success rate of this procedure (80%) compared with that of partial pulpotomy (95%),[35] it appears that a superficial pulp cap should not be considered after traumatic pulp exposures. The lower success rate is not difficult to understand since superficial inflammation develops soon after the traumatic exposure. Thus, if the treatment is at the superficial level, a number of inflamed (rather than healthy) pulps will be treated, lowering the potential for success. In addition, a microbial-tight coronal seal is much more difficult to achieve in superficial pulp capping since there is no cavity depth to create this microbial-tight seal, as there is with a partial pulpotomy.

It should be noted that the success rates mentioned previously are of studies performed in the 1970s[20] with calcium hydroxide as the pulp capping agent and a restoration above with a high probability of leakage. Recent case series studies[34] on capping the inflamed pulp suggest that the bioceramic materials offer a better success rate than previously thought. Studies particularly on vital pulp therapy on traumatized teeth with inflamed pulps are yet to be performed but there is a good chance these too will show an improved success rate if bioceramic base is used before the final restoration.

Partial Pulpotomy

Partial pulpotomy implies the removal of coronal pulp tissue to the level of healthy pulp tissue. In traumatic injuries, this level can be accurately determined owing to the knowledge of the reaction of the pulp after a traumatic injury. This procedure is commonly called the "Cvek pulpotomy." For more details, see Chapter 27.

Full Pulpotomy

This procedure involves removal of the entire coronal pulp to the level of root orifices. This level of pulp amputation is chosen arbitrarily because of its anatomic convenience. Therefore, since the inflamed pulp sometimes extends past the canal orifices into the root pulp, many "mistakes" are made, resulting in treatment of an inflamed rather than a noninflamed pulp. This procedure is indicated when it is predicted that the pulp is inflamed to deeper levels of the coronal pulp or with symptoms of irreversible pulpitis. Traumatic exposures after 72 hours and a carious exposure with symptoms of irreversible pulpitis are two examples in which this type of treatment may be indicated. While the more predictable procedure would be pulpectomy in mature teeth, the benefits outweigh the risks for this treatment in immature teeth with incompletely formed apices and thin dentinal walls. For more details, see Chapter 27.

Pulpectomy

Pulpectomy implies removal of the entire pulp to the level of the apical foramen. The indications are for complicated crown fracture of mature teeth (if conditions are not ideal for vital pulp therapy). This procedure is not different from root canal treatment of a vital, nontraumatized tooth.

TREATMENT OF NONVITAL PULPS

Immature Tooth: Apexification

Apexification is indicated for teeth with open apices and thin dentinal walls in which standard instrumentation techniques cannot create an apical stop to facilitate effective root canal filling (Figure 12-4). For more detail, see Chapter 28.

PULP REVASCULARIZATION

Regeneration of a necrotic pulp has been considered possible only after avulsion of an immature permanent tooth. The advantages of pulp revascularization are the possibility

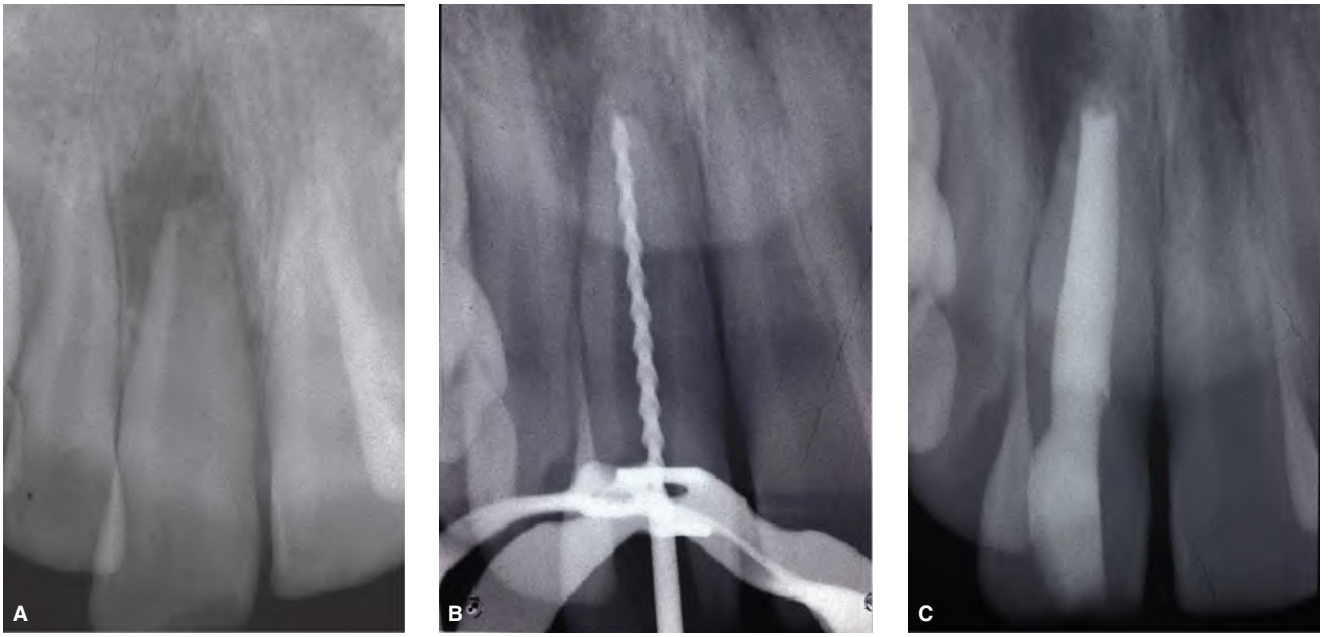

FIGURE 12-4 Apexification with calcium hydroxide. ***A.*** Maxillary central incisor with a history of crown fracture and subluxation. The pulp was infected and necrotic and there was an apical lesion of endodontic origin. The canal was cleaned and disinfected and a preparation of calcium hydroxide placed. ***B.*** Radiograph taken 3 months later showing a file used to test the presence of an apical barrier (apexification). ***C.*** The root canal was obturated with gutta-percha and sealer. The tooth was asymptomatic and the patient monitored for continued healing. (Courtesy of the Endodontic Clinic, Loma Linda University, School of Dentistry, CA.)

of further root development, reinforcement of dentinal walls by deposition of hard tissue, and thus strengthening the root against fracture. After replantation of an avulsed immature tooth, a unique set of circumstances exists that allows regeneration to take place. The young tooth has an open apex and is short, that allows new tissue to grow into the pulp space relatively quickly. The pulp is necrotic but usually not degenerated and infected, so it will act as a matrix into which the new tissue can grow. It has been experimentally shown that the apical part of a pulp may remain vital and after replantation proliferate coronally, replacing the necrotized portion of the pulp.[36–39] In addition, the fact that, in most cases, the crown of the tooth is intact and caries-free, ensures that bacterial penetration into the pulp space through cracks[40] and defects, will be a slow process. Thus, the race between the new tissue and infection of the pulp space favors the new tissue.

Regeneration of pulp tissue in a necrotic infected tooth with apical periodontitis has been thought until now to be impossible. However, if it were possible to create a similar environment as described previously for the avulsed tooth, regeneration should occur. Thus, if the canal is effectively disinfected, a matrix into which new tissue could grow is provided, and the coronal access is effectively sealed, regeneration should occur as in an avulsed immature tooth. A report by Banchs and Trope reproduced results in cases reported by others that indicate that it may be possible to replicate the unique circumstances of an avulsed tooth so as to revascularize the pulp in infected necrotic immature roots[41] (Figure 12-5). For more details, see Chapter 29.

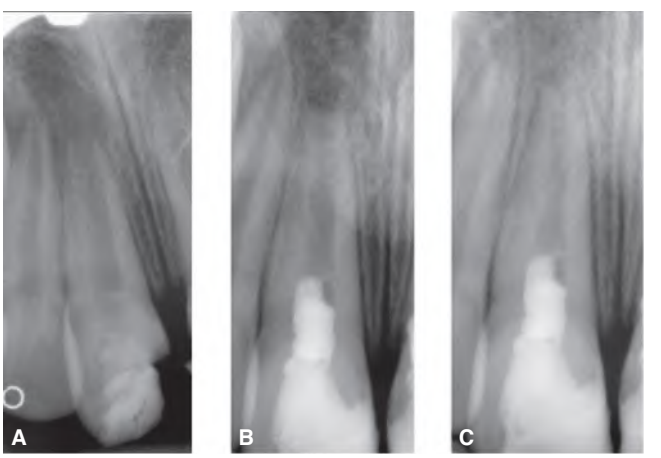

FIGURE 12-5 ***A.*** Immature tooth with a necrotic infected canal associated with apical periodontitis. The canal is disinfected with copious irrigation of sodium hypochlorite and a triantibiotic paste is placed. After 4 weeks, the triantibiotic paste is removed and a blood clot is created in the canal space. The access is filled with a mineral trioxide aggregate base and bonded resin above it. ***B.*** At 7 months, the patient is asymptomatic. The apex shows some signs of closure and healing of the apical periodontitis is noted. ***C.*** At 12 months, further apical healing is evident and root wall thickening has occurred, indicating that the root canal has been revascularized with vital tissue. Mature Teeth

Traumatized mature teeth are routinely treated endodontically in the same manner as nontraumatized teeth.

CROWN-ROOT FRACTURES

These fractures are first treated periodontally to ensure that a good margin for restoration is possible. If the tooth can be maintained from a periodontal point of view, the pulp is treated as a crown fracture.

HORIZONTAL ROOT FRACTURES

This injury implies fracture of the cementum, dentin, and pulp. They are relatively infrequent injuries, occurring in less than 3% of all dental injuries.[42] Incompletely formed roots with vital pulps rarely fracture horizontally.[42] When a root fractures horizontally, the coronal segment is displaced to a varying degree, but, generally, the apical segment is not displaced. Because the apical pulpal circulation is not disrupted, pulp necrosis in the apical segment is extremely rare. Pulp necrosis develops in the coronal segment owing to its displacement but occurs in only about 25% of cases.[43] The clinical presentation is similar to that of luxation injuries. The extent of displacement of the coronal segment is usually indicative of the location of the fracture and can vary from none, simulating a concussion injury (apical fracture), to severe, simulating extrusive luxation (cervical fracture). Radiographic examination for root fractures is extremely important. Since root fractures are usually oblique (facial to palatal), one periapical radiograph can easily miss its presence. It is imperative to take at least three angled radiographs (45, 90, and 110°) so that at least at one angulation the X-ray beam will pass directly through the fracture line to make it visible on the radiograph (Figure 12-6).

Today cone-beam tomography (CBCT) has made the diagnosis of horizontal root fractures less of a challenge and allowed a much better assessment in terms of treatment strategy and prognosis prediction. CBCT is still relatively rare in the armamentarium of the people who see these injuries, so the periapical radiographic strategies for diagnosis remain extremely important.

Treatment

Emergency treatment involves repositioning of the segments in as close a proximity as possible and splinting to adjacent teeth for 2 to 4 weeks with a functional splint.[44,45] This splinting protocol has recently changed from the 2 to 4 months of rigid splinting that had been recommended for many years.[44,45] If a long time has elapsed between the injury and treatment, it will likely not be possible to reposition the segments close to their original position, compromising the long-term prognosis of the tooth.

TREATMENT OF ROOT FRACTURE COMPLICATIONS

Coronal Root Fractures

Historically, it had been thought that fractures in the cervical segment had a poor prognosis, and extraction of the coronal segment was recommended. Research does not support such treatment, and, in fact, if the coronal segment is below the attachment level and adequately splinted, the chances of healing do not differ from those of midroot or apical fractures.[43]

Midroot and Apical Root Fractures

Pulp necrosis occurs in 25% of root fractures.[43–45] In the vast majority of cases, the necrosis occurs in the coronal segment only with the apical segment remaining vital. Therefore, endodontic treatment is indicated in the coronal root segment only unless a periapical lesion is seen in the apical

FIGURE 12-6 Radiographic technique for finding diagonal root fractures. ***A.*** Conventional 90° periapical radiograph of a maxillary central incisor with a diagonal root fracture that is easy to miss since the fracture does not show radiographically. ***B.*** A steep occlusal view (approximately 45°) clearly identifies the fracture because the X-ray beam can travel parallel to the fracture in the root. (Courtesy of the Endodontic Clinic, Loma Linda University, School of dentistry, California.)

segment. In most cases, the canal lumen is wide at the apical extent of the coronal segment, so long-term calcium hydroxide treatment or an Bioceramic apical plug is indicated. The coronal segment is root-filled after a hard tissue barrier has formed apically in the coronal segment and periapical healing has taken place (Figure 12-7). If Bioceramic is used, the root filling will be placed before healing is seen, making follow-up visits essential in these cases.

In rare cases, when both the coronal and apical pulp areas are necrotic, treatment is more complicated. Endodontic treatment through the fracture is extremely difficult and should be avoided. Endodontic manipulations, medicaments, and filling materials all have a detrimental effect on healing of the fracture site. In more apical root fractures, necrotic apical segments can be surgically removed. This is a viable treatment if the remaining root is long enough to provide adequate periodontal support. Removal of the apical segment in midroot fractures leaves the coronal segment with a compromised attachment, and the crown to root ratio must be assessed before the decision to maintain the tooth is made.

After the splinting period is completed, follow-up is conducted at the same intervals as all dental traumatic injuries: at 3, 6, and 12 months and yearly thereafter.

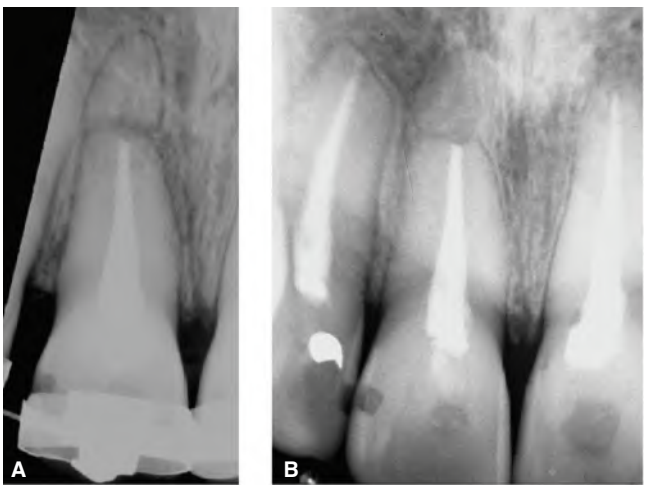

FIGURE 12-7 The coronal segment (only) is root-filled after a hard tissue barrier has formed at the most apical part of the coronal segment.

Factors Influencing Repair

1. The degree of dislocation and mobility of the coronal fragment are extremely important in determining outcome.[46,47] Increased dislocation and coronal fragment mobility result in a decreased prognosis.
2. Immature teeth are seldom involved in root fractures, but when they are, the prognosis is good.[48,49]
3. Quality of treatment: prognosis increases with early treatment, close reduction of the root segments, and semirigid splinting for 2 to 4 weeks.[44,45]

Complications are as follows: (1) pulp necrosis that can be treated successfully[48,50] by treating the coronal segment with adequate disinfection and long-term calcium hydroxide or Bioceramic and filling when a hard tissue barrier has formed; (2) root canal obliteration is not uncommon if the root segment (coronal or apical) remains vital (Figure 12-8).

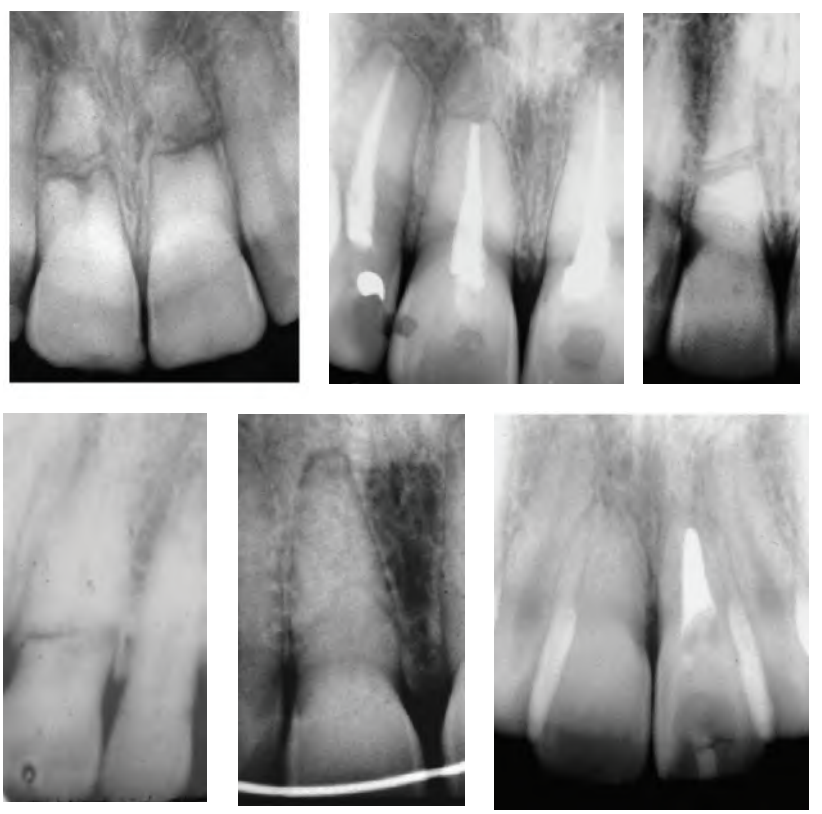

FIGURE 12-8 Examples of root canal obliteration in root-fractured teeth. It is common for the segments that maintain vitality to obliterate.

Endodontic Essentials

If the coronal segment is reduced quickly and a functional (nonrigid) splint is placed for 2 to 4 weeks, pulp necrosis is remarkably low. It will occur only 25% of the time, and in the vast majority of cases, the necrosis will occur only in the coronal segment. Root canal obliteration of both segments is very common. When necrosis does occur, disinfection of the coronal segment only should be initiated, followed by initiation of a physiologic barrier with long-term calcium hydroxide or a physical barrier with Bioceramic. Root canal obliteration is usually not treated endodontically.

LUXATION INJURIES

Definitions

1. **Concussion** implies no displacement, normal mobility, sensitivity to percussion.
2. **Subluxation** implies sensitivity to percussion, increased mobility, no displacement.
3. **Lateral luxation** implies displacement labially, lingually, distally, or incisally.
4. **Extrusive luxation** implies displacement in a coronal direction.
5. **Intrusive luxation** implies displacement apically into the alveolus.

Definitions 1 through 5 describe injuries of increasing magnitude in terms of the intensity of the injury and subsequent sequelae.

Luxation injuries result in damage to the attachment apparatus (periodontal ligament and cemental layer), the severity of which is dependent on the type of injury sustained (concussion least, intrusion most). The apical neurovascular supply to the pulp is also affected to varying degrees, resulting in altered or total loss of pulp vitality in the tooth. If the luxation injury is mild, the inflammatory response to the external root surface will be small and the pulp will maintain vitality. Inflammation owing to the trauma will thus be self-limiting, and cemental (favorable) healing will result.

If, on the other hand, the luxation injury is severe, the damage to the external root surface may be so diffuse that healing with new cementum alone may not be possible. If bone attaches directly to the root (ankylosis), the root will eventually be replaced by bone through physiologic resorption and apposition of the bone (osseous replacement). In addition and of special interest to the endodontist, with a severe luxation injury, the neurovasculature tissues of the pulp may be severed, resulting in a necrotic pulp. If this necrotic pulp becomes infected, the microbial toxins will pass through the tubules and the damaged cemental covering of the root, resulting in potentially catastrophic periradicular inflammation with bone and root resorption. For more details, see Chapter 15.

There are two types of trauma-related resorption in which the pulp plays an essential role:

1. In **external** inflammatory root resorption, the **necrotic, infected pulp** provides the stimulus for periodontal inflammation. If the cementum has been damaged and the intermediate cementum penetrated, as when the tooth undergoes a severe traumatic injury, the inflammatory stimulators in the pulp space are able to diffuse through the dentinal tubules and stimulate an inflammatory response over large areas of the periodontal ligament. Owing to the lack of cemental protection, periodontal inflammation will include root resorption and the expected bone resorption.
2. In **internal** inflammatory root resorption, the inflamed pulp is the tissue involved in resorbing the root structure. The pathogenesis of internal root resorption is not completely understood. It is believed that coronal necrotic infected pulp provides a stimulus for pulpal inflammation in the more apical parts of the pulp. If in "rare" cases, the inflamed pulp is adjacent to a root surface that has lost its predentin protection, internal root resorption will result. Thus, both the necrotic infected pulp and the inflamed pulp contribute to this type of root resorption.

CONSEQUENCES OF APICAL NEUROVASCULAR DAMAGE

Pulp Canal Obliteration

Pulp canal obliteration is common after luxation injuries, if not severe enough to sever the neurovascular supply apically. The frequency of pulp canal obliteration appears inversely proportional to that of pulp necrosis. The exact mechanism of pulp canal obliteration is not known. It is theorized that the sympathetic or parasympathetic control of blood flow to odontoblasts is altered, resulting in uncontrolled reparative dentin formation.[43,50] Another theory is that hemorrhage and blood clot formation in the pulp after injury are a nidus for subsequent calcification if the pulp remains vital.[43,50] Pulp canal obliteration can usually be diagnosed within the first year after injury[43,50] and was found to be more frequent in teeth with open apices (>0.7 mm radiographically), in teeth with extrusive and lateral luxation injuries, and in teeth that have been rigidly splinted.[51]

Pulp Necrosis

The factors most important for the development of pulp necrosis are the type of injury (concussion least, intrusion most) and the stage of root development (mature apex > immature apex).[52] Pulp necrosis can lead to infection of the root canal system, with external inflammatory root resorption as the consequence. To develop pulp space infection, the pulp must first become necrotic (either partially or totally). In trauma, necrosis is usually due to displacement of the tooth, resulting in severing of the apical blood vessels. In mature teeth, pulp regeneration cannot occur, and usually by 3 weeks, the necrotic pulp will become infected. For more details, see Chapter 3.

Because serious injury is required for pulp necrosis, it is usual that areas of cemental covering of the root are also affected, resulting in the loss of its protective (insulating) quality. Now microbial toxins can pass through the dentinal tubules and stimulate an inflammatory response in the corresponding periodontal ligament. The result is resorption of the root and bone. The periodontal infiltrate consists of granulation tissue with lymphocytes, plasma cells, and polymorphonuclear leukocytes. Multinucleated giant cells resorb the denuded root surface, and this continues until the stimulus (microorganisms in the pulp space) is removed (Figure 12-9).[53,54] Radiographically, the resorption is observed as progressive radiolucent areas of the root and adjacent bone (Figure 12-10). For more details, see Chapter 15.

Treatment

The attachment damage owing to the traumatic injury is often the focus of an emergency visit that, unfortunately, rarely involves the endodontist. The clinician's attention to pulp space infection should ideally be within 7 to 10 days after the injury.[55] Root canal therapy either removes the necrotic pulp as a nidus for microbes, or removes the stimulus (microbes already present) to the periapical inflammation. Without microbial stimulation, resorption will not occur or will heal.[55,56] In most cases, a new cemental attachment will form, but if a large area of root is affected, osseous replacement (ankylosis) can result by the mechanism already described. Treatment principles include prevention of pulp space infection or elimination of the microorganisms if they are present in the pulp space.

1. **Prevention of pulp space infection**
   a. ***Reestablish the vitality of the pulp.*** If the pulp stays vital, the canal will be free of microorganisms, and external inflammatory root resorption will not occur. In severe injuries in which vitality has been lost, it is possible under some circumstances to promote revascularization of the pulp. Revascularization is possible in young teeth with incompletely formed apices if the teeth are replaced in their original position within 60 minutes of the injury.[57,58] However, even under the best conditions, revascularization will fail to occur on many occasions. Thus, a diagnostic dilemma results. If the pulp revascularizes, external root resorption will not occur and the root will continue to develop and strengthen. However, if the pulp becomes necrotic and infected, the subsequent external inflammatory root resorption that develops could result in the loss of the tooth in a very short time.

      At present, the diagnostic tools available cannot detect a vital pulp in this situation before approximately 6 months after successful revascularization. This period of time is obviously unacceptable since by that time, the teeth not revascularized could be lost to the resorption process. The laser Doppler flowmeter has been shown to be an excellent diagnostic tool for the detection of revascularization in immature teeth. These devices appear to accurately detect the presence of vital tissue in the pulp space by 4 weeks after the traumatic injury.[58]

   b. ***Prevent root canal infection by root canal treatment at 7 to 10 days.*** In teeth with closed apices, revascularization cannot occur. These teeth should be endodontically treated within 7 to 10 days of the injury before the ischemically necrosed pulp becomes infected.[55,56] This is also a convenient time because this is the time

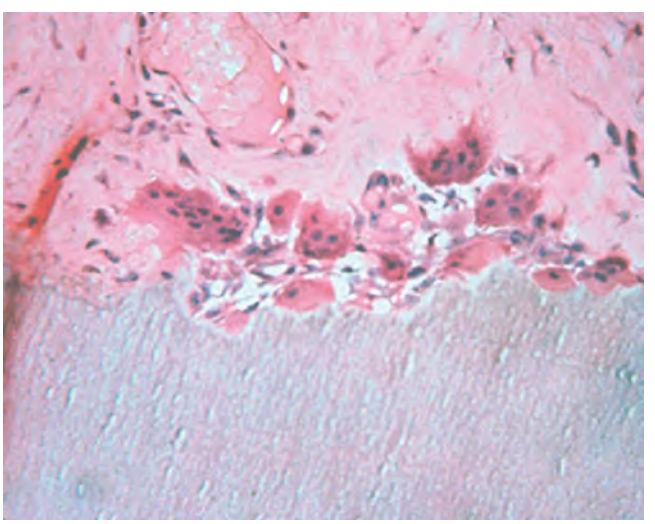

FIGURE 12-9 Histologic appearance of multinucleated osteoclasts (dentinoclasts) resorbing the radicular dentin.

period in which the functional splint is removed and chemotherapeutic medicaments to limit the initial inflammatory response are stopped.[79]

From a theoretical point of view, the teeth treated at this time can be considered equivalent to the treatment of a tooth with a vital pulp. Therefore, the endodontic treatment could be completed in one visit. However, efficient treatment is extremely difficult so soon after a serious traumatic injury, and it is beneficial to start the endodontic treatment with pulpectomy and canal preparation followed by an intracanal dressing with a creamy mix of calcium hydroxide.[55,56] The practitioner can now fill the canal at his or her convenience, after periodontal healing of the injury is complete, approximately 1 month after the instrumentation visit. There appears to be no necessity for long-term calcium hydroxide treatment in cases in which the endodontic treatment is started within 10 days of the injury. Notwithstanding, in a compliant patient, the calcium hydroxide can be applied for a longer term (up to 6 months).[56]

2. **Elimination of pulp space infection** When root canal treatment is initiated later than 10 days after the accident, or if active external inflammatory resorption is observed, the preferred antibacterial protocol consists of microbial control followed by a long-term dressing with densely packed calcium hydroxide.[56] Calcium hydroxide can affect an alkaline pH in the surrounding dentinal tubules, kill bacteria, and neutralize endotoxin, a potent inflammatory stimulator.

The first visit consists of the microbial control phase with instrumentation of the canal and placement with a lentulo-spiral of a creamy mix of calcium hydroxide as an intracanal antibacterial agent. The patient is seen in approximately 1 month, at which time, the canal is filled with a dense mix of calcium hydroxide. Once filled, the canal should appear radiographically to be calcified since the radiodensity of calcium hydroxide in the canal is usually similar to that of the surrounding dentin (Figure 12-11). A radiograph is then taken at 3-month intervals. At each visit, the tooth is tested for symptoms of periodontitis. In addition, healing of the resorptive process and the presence or absence of the calcium hydroxide (i.e., calcium hydroxide washout) are assessed. Since the root surface is so radiodense as to make the assessment of healing difficult, the adjacent bone healing is assessed. If the adjacent bone has healed, it is assumed that the resorptive process has stopped in the root as well, and the canal can be permanently root-filled (Figure 12-12). If it is determined that additional healing would be beneficial before root filling, the need for replacing the calcium hydroxide in the canal is assessed. If the canal still appears calcified radiographically, there is no need to replace the calcium hydroxide. If, on the other hand, the canal has regained its lucent appearance, the calcium hydroxide should be repacked and reassessed in another 3 months.

TREATMENT OF ESTABLISHED EXTERNAL ROOT RESOPTION IN A YOUNG PATIENT

Arresting external inflammatory root resorption owing to pulp space infection is achieved by disinfecting the pulp space. This is particularly difficult after a luxation injury since the cemental covering is also damaged. This results in the microbes and their by-products moving deeper into the dentinal tubules to stimulate and maintain the inflammation in the surrounding periapical tissues.

A triantibiotic paste introduced by Hoshino et al.[59] has been used in the revascularization process of necrotic teeth with open apices and apical periodontitis.[59] The antibiotic paste comprising metronidazole, ciprofloxacin, and minocycline has been shown to have an excellent antimicrobial spectrum for pulp space microbes and an excellent ability to penetrate the dentinal tubules. Since many cases of external inflammatory

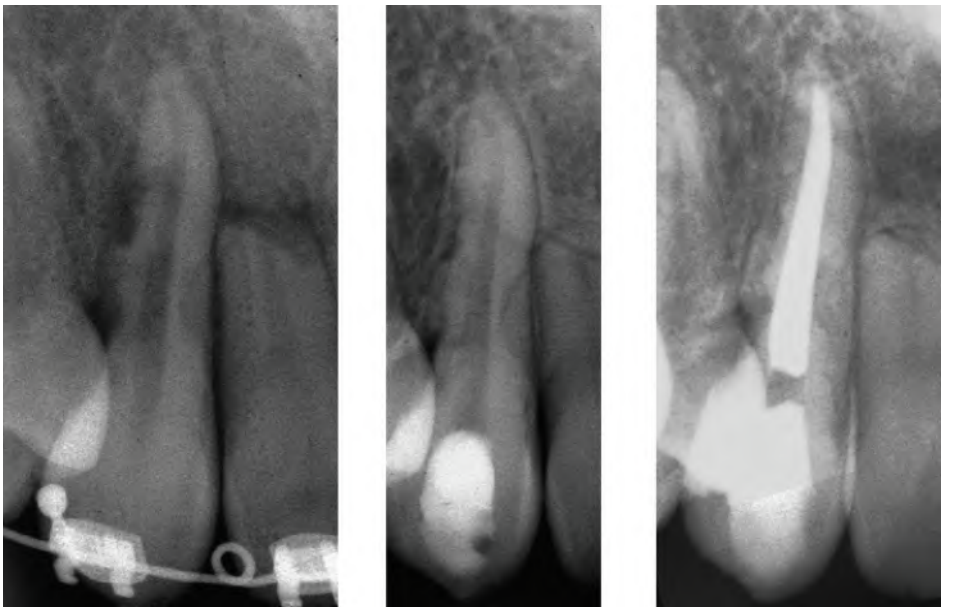

FIGURE 12-12 The root canal is filled when the adjacent bone has healed, indicating that root resorption has stopped. **Left.** Active root resorption with lucencies in the root and adjacent bone. **Middle.** After long-term calcium hydroxide treatment, the adjacent bone has healed. **Right.** The canal is now obturated.

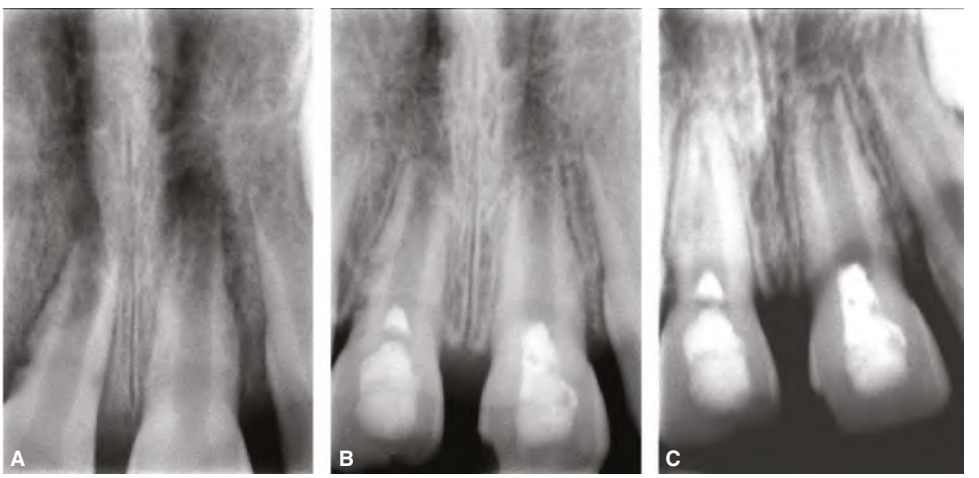

FIGURE 12-13 Immature tooth with a necrotic infected pulp, apical periodontitis, and external inflammatory root resorption. Treatment is as described in Figure 12-5. Note the healing of the external root resorption and the continued root development. (Courtesy of Dr. Linda Levin, Durham, NC.)

resorption owing to pulp space infection occur in immature teeth or teeth with apical resorption, the same procedure for the healing of external resorption and revascularization should work in these cases also. With this antimicrobial medicament, the potential exists to arrest the external inflammatory root resorption and revascularize the root canal (Figure 12-13).

The canal is disinfected without mechanical instrumentation but with copious irrigation with sodium hypochlorite and the use of a mixture of antibiotics for at least 4 weeks.[41,60] A blood clot is produced by mechanically irritating the periradicular tissues to the level of the cementoenamel junction to provide a matrix for the ingrowth of new tissue followed by a deep coronal restoration to provide a microbial-tight seal. The patient is followed every 3 months until evidence of healing of the external root resorption and thickening of the dentinal walls are seen (Figures 12-5 and 12-13).

An early study has confirmed the potent antibacterial properties of the triantibiotic paste used in this case,[61] and further studies are described in Chapter 29. The procedure described here can be attempted in most cases, and if after 3 months no signs of resorption repair and regeneration are present, the more traditional treatment methods may be initiated.

ENDODONTIC ESSENTIALS

Concussion and Subluxation

Since both of these injuries imply no noticeable displacement of the tooth in its socket, pulp consequences should not be expected. However, baseline and follow-up diagnostic tests are essential to pick up late complications such as pulp canal obliteration (most likely) or pulp necrosis.

Teeth that give a positive pulp test response at the initial examination cannot be assumed to be healthy and continue to give a positive response over time. Teeth that yield a negative response or no response, however, cannot be assumed to have necrotic pulps because they may give a positive response at later follow-up visits. It has been demonstrated that it may take as long as 9 months for normal blood flow to return to the coronal pulp of a traumatized fully formed tooth. As circulation is restored, the responsiveness to pulp testing returns.[62]

The transition from a negative to a positive response at a subsequent test may be considered a sign of a healthy pulp. The repetitious finding of positive responses may also be taken as a sign of a healthy pulp. The transition from a positive to a negative response may be taken as an indication that the pulp is probably undergoing degeneration. The persistence of a negative response would suggest that the pulp has been irreversibly damaged, but even this is not absolute.[62]

Thermal and electric pulp tests of all anterior teeth (canine to canine) of the maxillary and mandibular jaws should be performed at the time of the initial examination and carefully recorded to establish a baseline for comparison with subsequent repeated tests in later months. These tests should be repeated at 3 weeks; 3, 6, and 12 months; and yearly intervals following the accident. The purpose of the tests is to establish a trend as to the physiologic status of the pulps of these teeth. Particularly in traumatized teeth, carbon dioxide snow (–78°C) or dichlordifluoromethane (–40°C) placed on the incisal third of the facial surface gives more accurate responses than does a water ice pencil.[63,64] The intense cold seems to penetrate the tooth and splints or restorations and reach the deeper areas of the tooth. In addition, dry ice does not form ice water, that could disperse over adjacent teeth or gingiva to give a false-positive response. The electric pulp test relies on electric impulses directly stimulating the nerves of the pulp. These tests have limited value in young teeth but are useful in cases in which the dentinal tubules are closed and do not allow dentinal fluid to flow in them. This situation is typical of teeth in elderly patients or in traumatized teeth that are undergoing premature sclerosis. In these situations, the thermal tests that rely on fluid flow in the tubules cannot be used and the electric pulp test becomes important.

Lateral Luxation, Extrusive Luxation

The tooth should be repositioned as soon as possible and a functional splint placed. The endodontic focus takes place at 7 to 10 days after the emergency visit. The clinician must evaluate the potential for revascularization of the pulp and therefore not initiate root canal treatment, or if revascularization is not likely, root canal treatment should be initiated at this 7- to 10-day time period.

The potential for revascularization depends primarily on the width of the apical constriction at the time of repositioning. If the width is 1.0 mm or more, revascularization is considered a possibility. The wider the apical opening is, the higher the likelihood of revascularization.[65] If revascularization is considered possible, a regular follow-up regimen must be scheduled. Since pulp testing is so erratic in these types of teeth, radiographic follow-up at short intervals with similar angulations is undertaken.

A small amount of radiographically appearing root resorption should be expected owing to the initial inflammation. This should be self-limiting and not increase in size after 3 weeks. If the radiographic resorption increases or any other signs of pulp infection are present, root canal therapy should be quickly initiated. If the apical opening is < 1 mm, root canal treatment should be started immediately. If the patient does not present to the clinician within 7 to 10 days postinjury, or if radiographic evidence of active external resorption is present, long-term calcium hydroxide treatment or a triantibiotic regimen should be initiated.

Intrusive Luxation

Intrusive luxation is the most destructive traumatic injury. Attachment damage is diffuse, and pulp survival is considered impossible. It is possible that in immature roots, spontaneous re-erupt and revascularization may occur, but in mature teeth, pulp necrosis is a certainty.[4] Thus, at the first chance of accessing the pulp space, root treatment should be initiated.

THE AVULSED TOOTH

The conditions at the emergency visit will have an important effect on the steps taken at the second visit. Ideally, the tooth should be replanted as soon as possible after the avulsion and functionally splinted. If unable to replant the tooth, it should be placed in a physiologic storage solution to allow for an extended extraoral time with fewer resorption complications after reimplantation. At the emergency visit, the root is prepared depending on the maturity of the tooth (open vs. closed) and the extraoral **dry time**. A dry time of 60 minutes is considered the point at which survival is unlikely for periodontal ligament cells.

EXTRAORAL DRY TIME LESS THAN 60 MINUTES

Closed Apex

The root should be rinsed of debris with water or saline and replanted in as gentle a fashion as possible. If the tooth has a closed apex, revascularization is not possible,[65] but because the tooth was dry for less than 60 minutes (replanted or placed in appropriate medium), the chance for periodontal healing exists. Most importantly, the chance of a severe inflammatory response at the time of replantation is lessened. A dry time of less than 15 to 20 minutes is considered optimal where periodontal healing would be expected.[66–68]

A continuing challenge is the treatment of the tooth that has been dry for more than 20 minutes (periodontal cell survival is ensured) but less than 60 minutes (periodontal survival unlikely). In these cases, logic suggests that the root surface consist of some cells with the potential to regenerate and some that will act as inflammatory stimulators. Exciting new strategies are under investigation that may be extremely valuable in these cases. The use of Ledermix placed in the canal space at the emergency visit has been found to be valuable in cases that were considered hopeless in the past[69] (see the following), and this medicament may prove extremely valuable in the 20- to 60-minute dry time period.

Open Apex

Soak in doxycycline or cover with minocycline for 5 minutes, gently rinse off debris, and replant. In an open-apex tooth, revascularization of the pulp and continued root development are possible (Figure 12-14). Cvek et al.[70] found in monkeys that soaking the tooth in doxycycline (1 mg in approximately 20 mL of physiologic saline) for 5 minutes before replantation significantly enhanced revascularization. This result was confirmed in dogs by Yanpiset et al.[71] Ritter et al.[72] found that covering the root with minocycline that attaches to the root for approximately 15 days further increased the revascularization rate in dogs. Although these animal studies do not provide us with a prediction of the rate of revascularization in humans, it is reasonable to expect that the same enhancement of revascularization that occurred in two animal species will occur in humans as well. As with the tooth with the closed apex, the open-apex tooth is then gently rinsed and replanted.

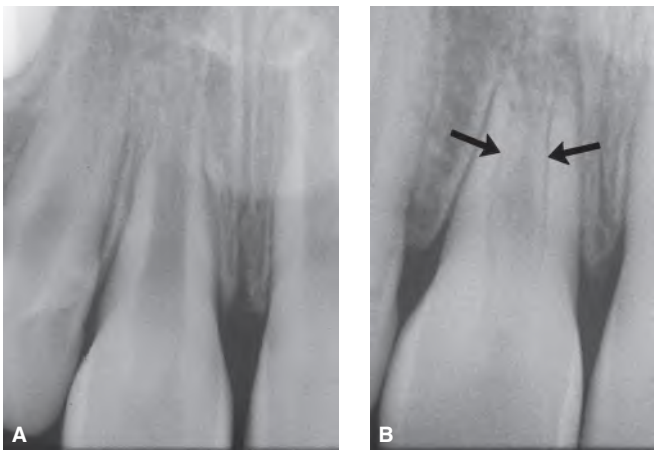

FIGURE 12-14 Revascularization of an immature root. A tooth with an open apex was replanted soon after the avulsion. A shows the radiographic picture immediately after replantation B. The follow up taken The follow-up radiograph 1 year later suggests that revascularization had taken place. In this case, it appears that new periodontal tissue has formed with a lamina dura and bone growth within the pulp canal (black arrows). (Courtesy of Dr. Cecilia Bourguignon, Paris, France.)

EXRAORAL DRY TIME MORE THAN 60 MINUTES

Closed Apex

Remove the periodontal ligament by placing it in etching acid for 5 minutes, soak it in fluoride, and replant. When the root has been dry for 60 minutes or more, survival of the periodontal ligament cells is not expected.[66,73] In these cases, the root should be prepared to be as resistant to resorption as possible (attempting to slow the ankylotic osseous replacement process). These teeth should be soaked in an acid for 5 minutes to remove all remaining periodontal ligament and thus remove the tissue that will initiate the inflammatory response on replantation. The tooth should then be soaked in 2% stannous fluoride for 5 minutes and replanted.[74,75] Alendronate was found to have resorption slowing effects similar to those of fluoride when used topically,[76] but further studies need to be carried out to evaluate whether its effectiveness is superior to fluoride and if this justifies its added cost. Some studies have found that Emdogain (enamel matrix protein) may be beneficial in teeth with extended extraoral dry times, not only to make the root more resistant to resorption but also possibly to stimulate the formation of new periodontal ligament from the socket.[77,78] Another study has not confirmed the beneficial effect of Emdogain.[79]

If the tooth has been dry for more than 60 minutes and no consideration is given to preserving the periodontal ligament, the endodontics may be performed extraorally. In the case of a tooth with a closed apex, no advantage exists to this additional step at the emergency visit. However, in a tooth with an open apex, the endodontic treatment, if performed after replantation, involves a long-term apexification procedure. In these cases, completing the root canal treatment extraorally, where a seal in the "blunderbuss" apex is easier to achieve, may be advantageous. When endodontic treatment is performed extraorally, it must be performed aseptically with the utmost care to achieve a root canal system free of bacteria.

Open Apex

Replant? If yes, treat as described with a closed-apex tooth. Endodontic treatment may be performed out of the mouth. Since these teeth are in young patients in whom facial development is usually incomplete, many pediatric dentists consider the prognosis to be so poor and the potential complications of an ankylosed tooth so severe as to recommend that these teeth not be replanted. However, considerable debate exists as to whether it would be beneficial to replant the root even though it will inevitably be lost owing to osseous replacement. If the patients are followed carefully and the root is submerged at the appropriate time,[80,81] the height and, more importantly, the width of the alveolar bone will be maintained. This allows for easier permanent restoration, when the facial development of the child is complete. Studies are ongoing to evaluate whether the present recommendations should be changed.

ADJUNCTIVE THERAPY

Systemic antibiotics given at the time of replantation and prior to endodontic treatment are effective in preventing microbial invasion of the necrotic pulp and therefore subsequent inflammatory resorption.[82] Tetracycline has the additional benefit of decreasing root resorption by affecting the motility of the osteoclasts and reducing the effectiveness of collagenase.[83] The administration of system antibiotics is recommended beginning at the emergency visit and continuing until the splint is removed.[84] For patients not susceptible to tetracycline dentin staining, doxycycline twice daily for 7 days at an appropriate dose for patient age and weight[83,84] is the antibiotic of choice. Penicillin V 1000 mg and 500 mg every 6 hours for 7 days has also been shown to be beneficial. The microbial content of the sulcus also should be controlled during the healing phase. In addition to stressing to the patient the need for adequate oral hygiene, chlorhexidine rinses for 7 to 10 days are useful.

Bryson et al.[69] found benefit in removal of the pulp contents at the emergency visit and placing Ledermix (not available in the United States) into the root canal. This product contains a tetracycline corticosteroid combination that has been shown to move through the dentinal tubules. Based on the results of the study, the use of the medicament was able to shut down the inflammatory response after replantation to allow for more favorable healing compared with those teeth that did not have the medicament.

It appears that any corticosteroid alone (without tetracycline) is equally effective in shutting down the inflammatory response and decreasing the incidence of osseous replacement.[85]

The need for analgesics should be assessed on an individual case basis. Mild analgesics are usually adequate, or a nonsteroidal anti-inflammatory drug may be recommended. The patient should be sent to a physician for consultation regarding a tetanus booster within 48 hours of the initial visit.

Second Visit

This visit should take place 7 to 10 days after the emergency visit. At the emergency visit, emphasis is placed on the preservation and healing of the attachment apparatus. The focus of this visit is the prevention or elimination of potential irritants from the root canal space. These irritants, if present, provide the stimulus for the progression of the inflammatory response and bone and root resorption. Also at this visit, the course of systemic antibiotics is completed, the chlorhexidine rinses can be stopped, and the splint is removed.

ENDODONTIC TREATMENT

Extraoral Time Less Than 60 Minutes

Closed Apex

Initiate endodontic treatment at 7 to 10 days. In cases in which endodontic treatment is delayed or signs of resorption are present, treat with calcium hydroxide until evidence of healing is present, such as redevelopment of the periodontal ligament space. The root canal can then be filled and the crown restored.

Open Apex

Avoid endodontic treatment and look for evidence of revascularization. At the first indication of an infected pulp, initiate the apexification procedure.

Extraoral Time More Than 60 Minutes

Closed Apex

These teeth are treated endodontically in the same way as those teeth that had an extraoral time of <60 minutes.

Open Apex

If endodontic treatment was not performed out of the mouth, initiate the apexification procedure. In these teeth, the chance of revascularization is extremely poor.[55,86] Therefore, no attempt is made to revitalize these teeth. An apexification procedure is initiated at the second visit if root canal treatment was not performed at the emergency visit. If a root canal filling was placed at the emergency visit, the second visit is a recall visit to assess initial healing only.

Temporary Restoration

Effectively sealing the coronal access is essential to prevent infection of the canal between visits. Recommended temporary restorations are reinforced zinc oxide–eugenol cement, acid-etch composite resin, or glass ionomer cement. The depth of the temporary restoration is critical to its sealing ability. A depth of at least 4 mm is recommended and a cotton pellet need not be placed; the temporary restoration is placed directly onto the calcium hydroxide in the access cavity. Calcium hydroxide should first be removed from the walls of the access cavity because it is soluble and will wash out when it comes in contact with saliva, leaving a defective temporary restoration.

After initiation of the root canal treatment, the splint is removed. If time does not permit complete removal of the splint at this visit, the resin tacks are smoothed so as not to irritate the soft tissues and the residual resin is removed at a later appointment. At this appointment, healing is usually sufficient to perform a detailed clinical examination on the teeth surrounding the avulsed tooth. The sensibility tests, reaction to percussion and palpation, and periodontal probing measurements should be carefully recorded for reference at follow-up visits.

ROOT FILLING VISIT

The root canal can be filled at the practitioner's convenience or, in the case of long-term calcium hydroxide therapy, when an intact lamina dura can be traced. If the endodontic treatment was initiated 7 to 10 days after the avulsion and clinical and radiographic examinations do not indicate pathosis,

filling of the root canal at this visit is acceptable, although the use of long-term calcium hydroxide is a proven option for these cases. On the other hand, if endodontic treatment was initiated more than 7 to 10 days after the avulsion or if active resorption is visible, the pulp space must first be disinfected before root filling. Traditionally, the reestablishment of a lamina dura (Figure 12-12) is a radiographic sign that the canal infection has been controlled. When an intact lamina dura can be traced, root filling can take place. The canal is cleaned, shaped, and irrigated under strict asepsis. After completion of the instrumentation, the canal can be filled by any acceptable technique, with special attention to an aseptic technique and the best possible seal of the filling material.

Permanent Restoration

Much evidence exists that coronal leakage caused by defective temporary and permanent restorations results in a clinically relevant amount of microbial contamination in the root canal after root filling. Therefore, the tooth should receive a permanent restoration at or soon after the time of filling of the root canal. As with the temporary restoration, the depth of restoration is important for its seal; therefore, the deepest restoration possible should be made. A post should be avoided if possible. Because most avulsions occur in the anterior region of the mouth, where esthetics is important, composite resins with the addition of dentin bonding agents are usually recommended in these cases. They have the additional advantage of internally strengthening the tooth against fracture if another traumatic event should occur.

Follow-up Care

Follow-up evaluations should take place at 3 months, at 6 months, and yearly for at least 5 years. If osseous replacement (ankylosis) is identified (Figure 12-15), timely revision of the long-term treatment plan is indicated. In the case of inflammatory root resorption (Figure 12-10), a new attempt at disinfection of the root canal space by standard retreatment can reverse the process. Teeth adjacent to and surrounding the avulsed tooth or teeth may show pathologic changes long after the initial accident. Therefore, these teeth should be tested at recall and the results compared with those collected soon after the accident.

INTERNAL ROOT RESORPTION

Internal root resorption is **rare** in permanent teeth. Internal resorption is characterized by an oval-shaped enlargement of the root canal space.[4] External resorption, that is much more common, is often misdiagnosed as internal resorption. Internal root resorption is characterized by resorption of the internal aspect of the root by multinucleated giant cells adjacent to granulation tissue in the pulp. For more details, see Chapter 15.

Internal root resorption is usually asymptomatic and is first recognized clinically through routine radiographs. Pain may be a presenting symptom if perforation of the crown occurs and the metaplastic tissue is exposed to the oral fluids.

FIGURE12-15 Radiographic appearance of osseous replacement. The root acquires the radiographic appearance of the surrounding bone (without a lamina dura). Note that radiolucencies typical of active inflammation are **not** present.

For internal resorption to be active, at least part of the pulp must be vital, so a positive response to pulp sensitivity testing is possible. The coronal portion of the pulp is often necrotic, whereas the apical pulp that includes the internal resorptive defect remains vital. Therefore, a negative sensitivity test result does not rule out active internal resorption. It is also possible that the pulp becomes nonvital after a period of active resorption, giving a negative sensitivity test, radiographic signs of internal resorption, and radiographic signs of apical inflammation. Traditionally, the pink tooth has been thought pathognomonic of internal root resorption. The pink color is due to the granulation tissue in the coronal dentin undermining the crown enamel (Figure 12-16). The pink tooth can also be a feature of cervical subepithelial external inflammatory root resorption that must be ruled out before a diagnosis of internal root resorption is made.

Radiographic Appearance

The usual radiographic presentation of internal root resorption is a fairly uniform radiolucent enlargement of the pulp canal (Figure 12-17A). Because the resorption is initiated in the root canal, the resorptive defect includes some part of the root canal space. Therefore, the original outline of the root canal is distorted. Only on rare occasions, when the internal resorptive defect penetrates the root and impacts the periodontal ligament, does the adjacent bone show radiographic changes.

Histologic Appearance

Similar to other inflammatory resorptive defects, the histologic picture of internal resorption is granulation tissue with multinucleated giant cells. An area of necrotic pulp is found coronal to the granulation tissue. Dentinal tubules

FIGURE 12-16 Pink spot associated with internal root resorption.

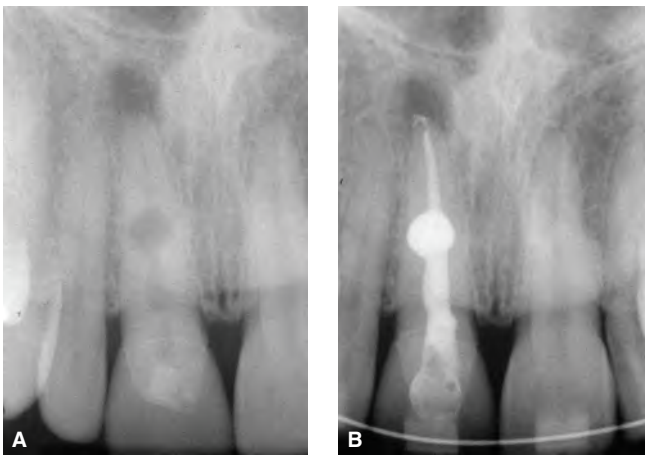

FIGURE 12-17 Internal root resorption. ***A.*** Radiograph showing the typical uniform radiolucency of internal resorption in the middle of the root of the left maxillary incisor. ***B.*** The area of internal resorption has been filled with softened gutta-percha and sealer. (Courtesy of Dr. Steven G. Morrow, Loma Linda, CA.)

containing microorganisms and communicating between the necrotic zone and the granulation tissue can sometimes be seen.[87,88] Unlike external root resorption, the adjacent bone is not affected with internal root resorption.

Endodontic Treatment

Treatment of internal root resorption is conceptually very easy. Since the resorptive defect is the result of the inflamed pulp and the blood supply to the tissue is through the apical foramina, endodontic treatment that effectively removes the blood supply to the resorbing cells is the treatment approach. After adequate anesthesia is obtained, the canal apical to the internal defect is explored and a working length short of the radiographic apex is used. The apical canal is thoroughly instrumented to ensure that the blood supply to the tissue resorbing the root is cut off. By completion of the root canal instrumentation, it should be possible to obtain a blood-free and dry canal with paper points. Calcium hydroxide is spun into the canal to facilitate the removal of the tissue in the irregular defect at the next visit. At the second visit, the tooth and defect are filled with a soft root filling technique (Figure 12-17B).

Chapter 13

Crown-Originating Dental Fractures

Leif K. Bakland

A confusing area in dental diagnosis and treatment planning is that involving teeth with various types of fractures. These conditions are associated with many different patient histories, complaints, symptoms, clinical and radiographic findings, treatment options and preferences, and treatment outcomes.

Efforts have been made to categorize the various dental fracture entities. An early effort by Talim and Gohil[1] was rather complex and Silvestri and Singh[2] simplified it to a system based on complete and incomplete fractures. This was followed by the American Association of Endodontists (AAE) identifying five types of cracks in teeth.[3] No system has yet gained universal acceptance.

With the current emphasis on practicing evidence-based dentistry, there is recognition of the need for evidence-based guidelines for diagnosis, prevention, and treatment of cracks in teeth.[4] To that end, developing a useful classification of dental fractures would be beneficial. Developing such a classification system may take time, but the effort to accomplish that is needed. For a step in that direction, one may consider using the term "*Dental Fractures*" as an umbrella term to cover all the various entities of fractures that can occur in a tooth. Under that umbrella one may then divide into three categories fracture situations that have commonalities with each other (Table 13-1): *Crown-originating fractures* (COFs), *vertical root fractures* (VRFs), and *trauma-related fractures.*

COFs often seem to occur spontaneously and their etiology can be difficult to establish. The fractures usually start in the tooth crowns and progress into the roots in an apical direction (Figure 13-1). This category will be described in more detail.

VRFs are primarily found in endodontically treated teeth (Figure 13-2);[5] reports of VRFs in teeth with vital pulps have been published, but seem to be limited to a specific Asian population with some unusual chewing habits.[6,7] When VRFs occur in endodontically treated teeth, they frequently appear to originate in the apical segment of the root and progress coronally; they may, however, also occasionally

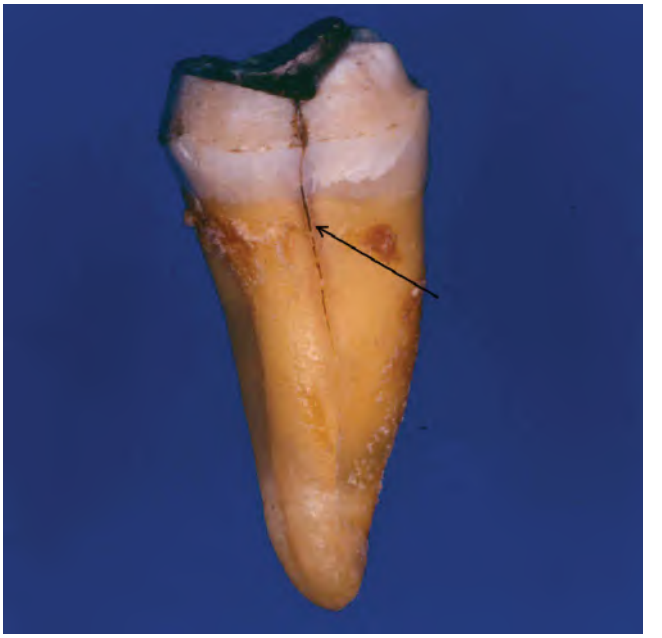

FIGURE 13-1 Extracted tooth shows common example of a crown-originating fracture (arrow). These fractures originate in the tooth crowns and propagate in an apical direction.

FIGURE 13-2 Radiograph showing a maxillary first premolar with a vertical root fracture. Characteristically, such fractures occur in endodontically treated teeth and the fracture orientation is bucco-palatally/lingually, thus they are usually readily apparent on radiographs.

TABLE 13-1 Three Subcategories of Dental Fractures. Each Subcategory Contains Clinical Situations That Have Commonalities With Each Other

Categories	Characteristics
Crown-originating fracture (COF)	Spontaneous fracture originating in the crown and progressing into the root in an apical direction.
Vertical root fracture (VRF)	A root-originating fracture that may begin anywhere in the root; it occurs primarily in endodontically treated teeth.
Trauma-related fracture	Tooth fracture of acute nature that may involve the crown or the root, or both.

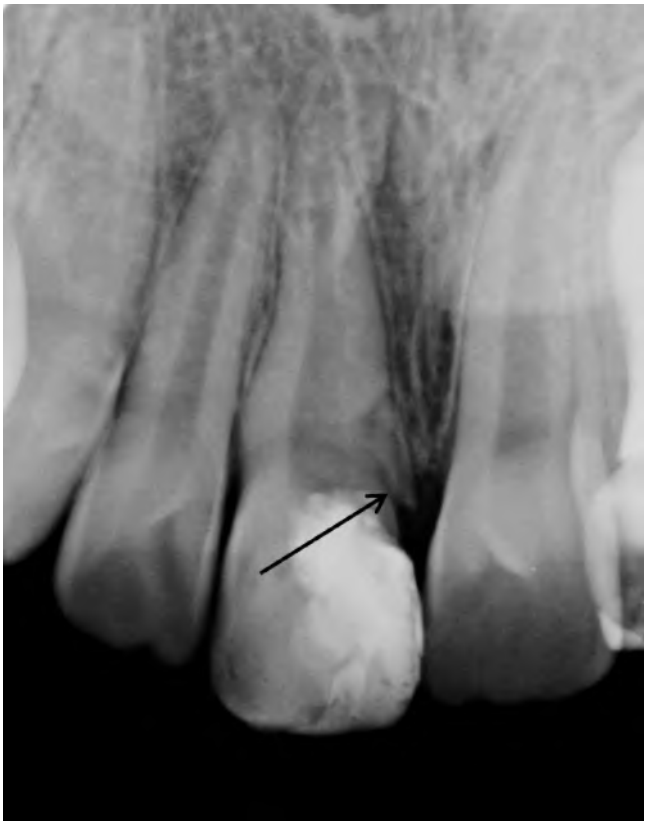

FIGURE 13-3 Radiograph showing a right central incisor with a cemental tear in the mesio-cervical area. The tooth had suffered a traumatic injury 2 years prior.

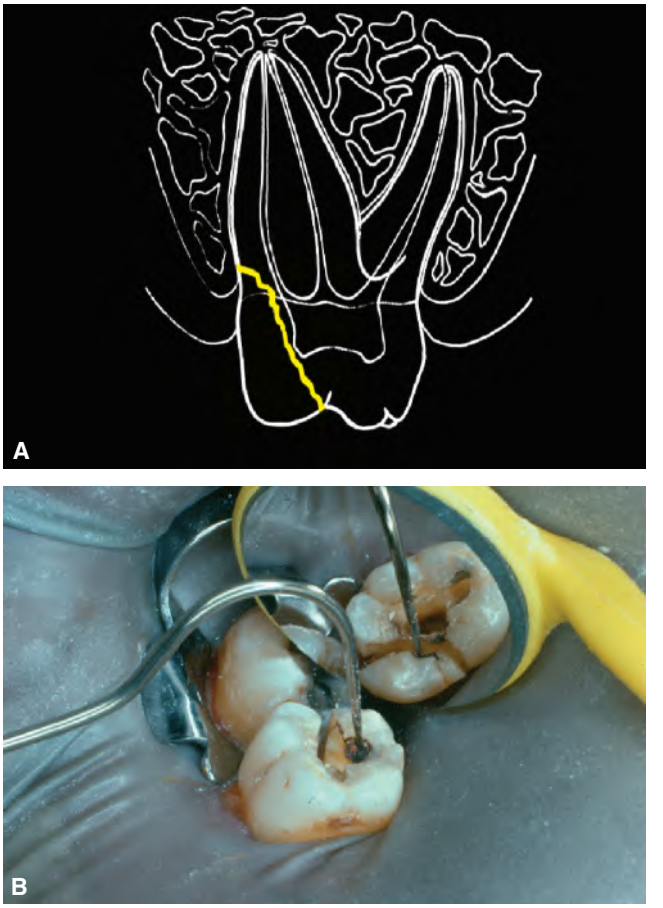

FIGURE 13-4 Cuspal fractures. ***A.*** Graphic illustration showing a common fracture orientation in cuspal fractures. The fracture line often skirts the pulp without invading it. ***B.*** Clinical example of a cuspal fracture; if the pulp is not directly involved, endodontic therapy may not be necessary.

develop in the cervical areas or mid-root and spread longitudinally.[5,8–10] Diagnosis is usually based on history (root canal treatment), radiographic appearance, and clinical findings. With few exceptions, treatment requires extraction. For more details, see Chapter 14.

Trauma-related fractures are, as the term implies, the result of acute traumatic events, such as may occur in sports, at work, during physical assault or in other accidental situations. These fractures are categorized as crown fractures, crown/root fractures, and root fractures. In addition a type of fracture not often addressed is what is referred to as cemental tears (Figure 13-3); they may have a traumatic etiology even if not always an acute traumatic event.[11]

CROWN-ORIGINATING FRACTURES

A possible term for fractures that typically originate in the crowns of teeth has been suggested.[12] The term COF could be considered a general term for the many others that have been used and would include both symptomatic and asymptomatic teeth. Many of the terms that have been used are fairly specific for certain fracture situations; it is however, often difficult to distinguish clinically among the various types of cracks.

Teeth have been subject to fractures for as long as humans have existed; a 6500 year old skull, recently discovered, was found to not only have a cracked tooth, but the crack had been filled with beeswax, probably to alleviate symptoms.[13] More recently, Gibbs[14] coined the term *cuspal fracture odontalgia* for those situations where teeth had become symptomatic and subsequently were found to have cracks extending under cusps and often resulting in the cusps fracturing off (Figure 13-4). The term *cracked tooth syndrome* (CTS) was suggested by Cameron[15] and it immediately became accepted by the profession for symptomatic teeth with the presence of fractures in the crowns. While generally accepted, using the term "syndrome" for such cases may be questionable. A syndrome is considered a combination of signs and symptoms that are indicative of a particular disease or disorder.[16] In teeth with CTS, there is a presumptive diagnosis based on the presence of consistent symptoms of pain to biting and cold temperature stimuli. Whether CTS qualifies as a "syndrome" is not certain, but it has become so well recognized over the past 50 years that it probably has to be accepted as a recognized term for symptomatic teeth with COFs.

Another term that has been used by many, including Brynjulfsen et al.[17] is *infraction*. This is a very descriptive term that indicates an incomplete fracture without

displacement of the fragments.[16] Similar terms are hairline fractures,[18] incomplete tooth fractures,[19,20] green stick fractures,[21,22] cracked teeth,[3] crown-root fractures,[23] and longitudinal tooth fractures.[3,24]

Two other terms represent the extremes of COFs. *Craze lines* are visible fractures that only involve enamel[4] (Figure 13-5). They may extend into subjacent dentin, but that is usually difficult to determine. They are not associated with symptoms and treatment is limited to esthetic concerns. The other extreme is the *split tooth*[3,21,23] that describes a fracture that extends through both marginal ridges usually in a mesio-distal direction, splitting the tooth completely into two separate segments (Figure 13-6). For convenience in this chapter, the term fracture will generally be used for these various COFs.

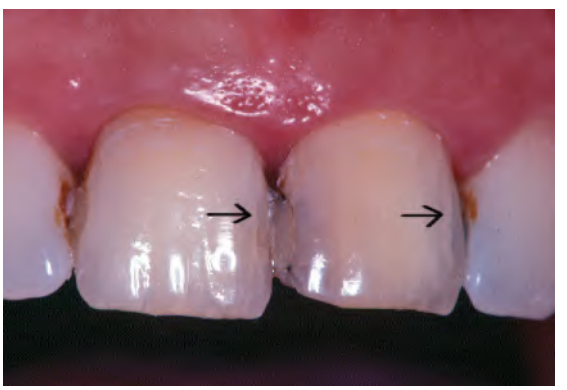

FIGURE 13-5 Maxillary central incisors with many craze lines (arrows).

FIGURE 13-6 Maxillary premolar with a mesio-distal split.

CHARACTERISTICS OF CROWN-ORIGINATING FRACTURES

COFs are progressive in nature and may be described as discontinuity in the integrity of a tooth's hard tissues. They originate in the tooth crown on the pulpal side and propagate toward the dentino-enamel junction, and then further apically in to the root[25–27] (Figure 13-7). Some COFs are the cause of cuspal fractures and these often do not directly involve the pulp. Fractures that more centrally located on the occlusal surface do involve the pulp.[17] Some fractures are associated with symptoms while others are not.[28] As pointed out by Ritchey et al.[19] even the symptomatic teeth are difficult to localize since the symptoms are vague—discomfort to chewing and elevated sensitivity to cold food and drinks. Also puzzling is the observation that teeth with infractions, even if sensitive to biting, are often not distinguishable by percussion.[29] Diagnosis will be covered later in this chapter.

Incidence

The incidence of tooth COFs has not been extensively reported. Two studies[30,31] indicate that 2% to 3% of dental patients have infractions in their molars and premolars; most are asymptomatic, so the incidence of symptomatic teeth may be less than 1%. Other studies[28,32] show a more ubiquitous presence of teeth with cracks, though most are asymptomatic. A reasonable estimate would be five fractured teeth per 100 adults per year.[28]

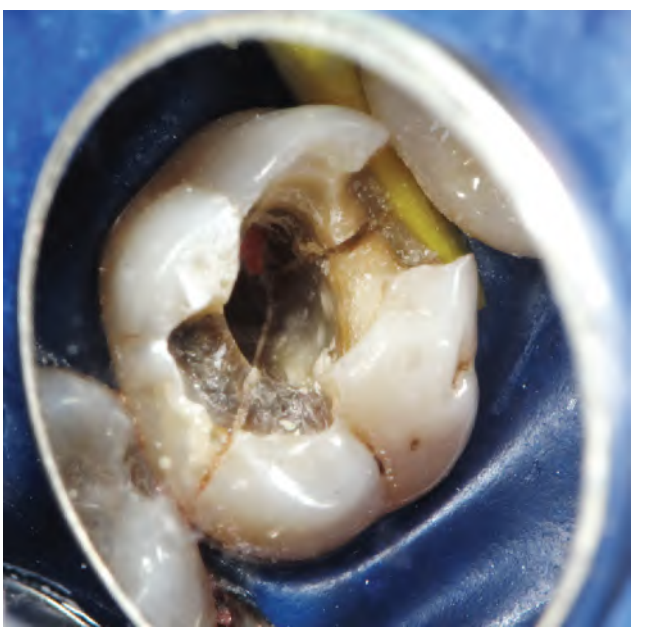

FIGURE 13-7 A molar with a very visible crown-originating fracture that has propagated from the pulpal aspect of the tooth to the external surfaces on both the mesial and distal sides of the tooth.

Molars and premolars appear to be the teeth most frequently involved in COFs.[15,17,31,33–35] The location of fractures is overwhelmingly in the mesio-distal direction (Figure 13-8), with only a few in the bucco-lingual direction (Figure 13-9), and some in a combination of both directions.[15,17,26,33,34] Brynjulfsen et al.[17] noted that 10% of the infractions were centrally located, indicating likely pulpal involvement. It is interesting that in their study, in maxillary teeth, the majority (70%) of fracture lines were situated toward the buccal tooth surface, while in the mandibular teeth they were inclined to be located toward the lingual surface, also at 70%.

Many reports appear to point to mandibular teeth, in particular the second molar as being most frequently involved,[15,33,36] but other studies identify maxillary molars more frequently.[17,35] Both of the latter studies involved specific groups of patients; the first group of patients had long histories of undiagnosed infractions and the second group was exclusively Korean. The influence of various factors on the incidence is not entirely understood. In a study where the findings of 12 previous studies were compiled, the following results emerged: 48% of cracked teeth were mandibular molars, 28% were maxillary molars, 16% were maxillary premolars, 6% were mandibular premolars, and about 2% were other teeth.[4]

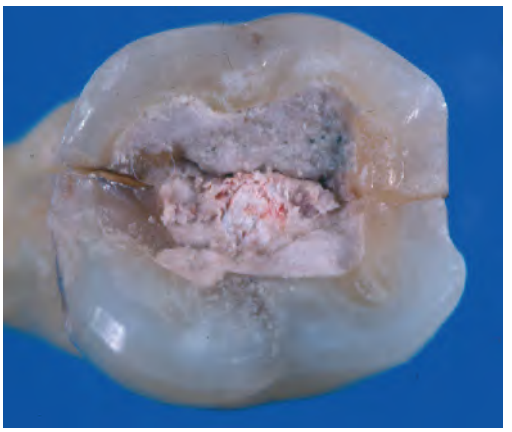

FIGURE 13-8 An extracted mandibular molar demonstrating the typical mesio-distal direction of crown-originating fractures. This is more common in mandibular teeth.

FIGURE 13-9 Maxillary molar with a crown-originating fracture running in a bucco-palatal direction; such fracture direction is seen more in maxillary teeth than mandibular ones.

In the rare case when an anterior tooth is involved with an infraction, it probably is the result of an injury from a sudden traumatic blow to the tooth.[37] (Figure 13-10)

One might intuitively expect teeth with restorations to be more prone to fracture than those without. The available evidence is not conclusive. Most investigators agree that teeth with restorations are more likely to develop infractions,[26,27,30,31,38–41] but there are also reports about nonrestored teeth with infractions.[21,34,35] Hiatt,[34] however, selectively chose teeth with no proximal restorations and Roh and Lee[35] studied a group of elderly Korean patients in which the majority of teeth were nonrestored. They speculated that diet and racial anatomical characteristics contribute, as well as restorative procedures, to the development of infractions. Age may also be a factor due to less elasticity and more brittleness in the teeth.[21]

An unusual type of COF has been described by Berman and Kuttler.[42] They used the term "fracture necrosis" for teeth with cracks that extended from the occlusal surface into the pulp and progressed to an external root surface. Pulp necrosis was found in the absence of restorations, caries, or luxation injuries, and was likely caused by longitudinal fractures extending from the occlusal surface and into the pulp.

When looking at the total picture of nontrauma related fractured teeth, COFs and VRFs, it appears that clinicians encounter VRFs more often than COFs.[6,43] However, because of the rather minimal epidemiological evidence, one cannot be certain about which type of fracture is more common.

FIGURE 13-10 Two central incisor teeth with crown-originating fractures, probably resulting from a traumatic injury to the teeth years earlier.

Pain Characteristics

Pain is generally a complaint that draws patients' attention to problem teeth. That is true with respect to COFs as well.[14,15,17,19,22,26,27,34,44–47] As these authors have pointed out, pain to chewing is the most common finding in symptomatic tooth fractures.

Brännström[45] proposed that masticatory pain is due to sudden movement of dentinal fluid when the fractured tooth portions move independently, activating myelinated A-delta fibers in the pulp and creating a rapid, acute pain response. Stimulation of the A-delta fibers does not require inflammation of pulp tissue that explains why chewing discomfort occurs in the very early stages of infraction and appears to be a symptom common to all fractures, both cuspal fractures and those directly involving the pulp. Sutton[22] similarly suggested that the occasional sharp, momentary lancinating masticatory pain was due to bending and rubbing of dentin along fracture lines.

A unique pain response to chewing, experienced by many patients, is the pain that occurs when patients release the pressure of biting, variously referred to as "rebound" or "relief" pain.[26,27,47] This can be used diagnostically as suggested by Ailor[26] by having the patient bite on a moist cotton roll, (Figure 13-11) and if "rebound" pain occurs on release, there is a higher likelihood that one of the two opposing teeth, maxillary or mandibular, has an infraction.

Pain that is generated by temperature changes, particularly with application of cold stimuli, is also a common feature of teeth with infractions, but less common than chewing discomfort.[15,19,26,27,29,33,34,45,48] Ritchey et al.[19] noted an elevated response to cold, a condition likely due to pulpal inflammation caused by the infractions that contain bacteria and which communicate with the pulp.[27,29,45,48,49] Brännström[45] proposed that the inflammation sensitizes the pulpal C-fiber-receptors that respond to temperature changes. While hot stimuli are not often mentioned as associating with symptoms, they, no doubt, can cause pain, particularly as pulpal inflammation increases, making C-fiber receptors more sensitive and lowering threshold levels to both cold and hot stimuli.

FIGURE 13-11 Biting test performed using a moist cotton roll. The patient bites as hard as possible until experiencing pain. If on release, the patient experiences a sudden, sharp pain that is what is described as "rebound" or "relief" pain, characteristic of crown-originating fractures.

It would be reasonable to expect teeth that are painful to mastication to also be hypersensitive to percussion stimuli. This does not appear to be the case with tooth infractions.[35] Swepson and Miller[46] have suggested that sensitivity to percussion occurs when the pulp becomes involved, which is not always the case in tooth infractions, at least not initially. Rosen[29] pointed out that until a fracture has propagated all the way from the pulp to the periodontal ligament (PDL), localization of an infracted tooth by percussion is very difficult. Thus, in cases of cuspal fractures in which the pulp is not directly involved, percussion may not produce a painful response.

It is well known that teeth with COFs may present with unusual pain conditions.[15,17,18,19,27,29] Ritchey[19] described the patients' chief complaint as vague discomfort to mastication, a description echoed by Cameron,[15] who included the observations that in addition to being vague, the pain complaint could mimic other conditions, such as trigeminal neuralgia. This was also reported by Caufield.[18] Further confounding the pain description in teeth with fractures is that the resultant pulpal inflammation can refer pain sensations to other areas served by the fifth cranial nerve with the result that pain can be experienced in other noninvolved teeth, and adjacent anatomical locations.[29] For more details, see Chapter 7.

Both Kahler et al.[27] and Brynjulfsen et al.[17] have made a point of the fact that tooth infraction pain can be associated with protracted histories of pain. The latter group reported a range of 3 months to 11 years in a group of 32 patients with undiagnosed long-standing orofacial pain from tooth infraction. They indicated that such protracted histories could lead to development of chronic orofacial pain with hyperalgesia. Another observation by Brynjulfsen et al.[17] was that, in some cases, the symptoms of pain were not provoked by chewing or application of cold stimuli, but rather were spontaneous pain experiences involving diffuse orofacial areas. Often, the pain would be felt anterior to the tooth responsible for the symptom when not referred to an anatomic area apart from teeth. The pattern of pain referral was that pain from mandibular teeth was frequently distributed to maxillary teeth, the neck, the ear, muscles of mastication, and temporomandibular joint (TMJ). Pain from maxillary teeth seldom projected to the mandible. An important observation was that the longer the duration of pain, the more diffuse it became and often led to headaches.[17]

Pain response to sweets in teeth with fractures has been reported[27,34,41,44]; this is probably related the presence of microorganisms located in the tooth fracture causing pulpal inflammation.[49] Since pain responses in teeth with COFs can mimic many other conditions, such as cariously affected teeth, it is prudent to maintain a high degree of suspicion when a general dental examination yields symptoms and examination findings that are contradictory.

Etiology

There are two primary factors predisposing teeth to cracks: natural predisposing features such as occlusal anatomy

and bruxism, and iatrogenic causes such as instruments used and cavity preparations.[4] Considering that restored teeth are often associated with COFs,[26,27,30,31,38–41] it has led many investigators to evaluate a number of restorative factors for clues to the etiology of tooth infractions. In fact several aspects of restorative dentistry have been identified as potential culprits. Most often-mentioned are excessively large and incorrectly designed restorations.[26,29,30,38,39–50] Seo et al.[24] showed that the use of nonbonded inlay restoration materials such as gold or amalgam increased the occurrence of longitudinal tooth fractures.

Another contributing factor has been the use of pins for supporting large restorations, especially self-threading and friction-lock pins.[29,38,50–52]

Abrasion, erosion and caries may also contribute to the development of fractures,[40] along with age changes in dentin,[26] oral habits,[26,29] and thermal cycling.[53,54] The latter is suspected of initiating infractions near the dentinoenamel junction and leading to a breakdown of the dentin-enamel bond. Resisting these damaging forces is the dentin's collagenous structure which prevents fractures from forming and propagating. As the dentin loses the ability for plastic deformation, it becomes more inclined to develop infractions, evidenced by the increase in infractions with age.[27]

In addition to cavity designs and size, the act of preparing a tooth for a restoration can also be hazardous. It is suspected that both the use of high-speed hand pieces[52] and course diamond burs[55] can lead to infractions. When course diamond burs are used, subsurface cracks develop from enamel into dentin. It is not clear if such infractions are more likely to progress further than the frequently observed enamel infractions. These craze lines can range from 1 to 20 μm in size and are usually filled with organic material that appears to stain quite readily.[54]

The act of chewing is also implicated in the development of fractures.[6,27,29,34,35,36,41,47,50] Masticatory forces from repeated occlusal loads and perhaps certain types of foods can contribute to this problem.[6,27,35,36,41,47,50] Certainly accidental biting on hard objects has resulted in tooth infraction and VRFs.[29,47] Bruxism and clenching often combined with a wedging effect of cusps in opposing fossae can be stressful on teeth.[6,34,35,36] Considering a biting force of up to 90 kg on first molars[41] it is obvious that these teeth are subjected to extensive stress. Yeh[36] coined the term "fatigue root fracture" to describe the stress on teeth combined with a course diet.

Acute trauma to teeth can also be responsible for tooth fractures.[29] Makkes and Folmer[37] described a situation in which injury to a central incisor in a child resulted in a VRF that was not discovered until years later.

Teeth are subjected to a variety of traumatic and stressful events, many resulting in damage such as COFs. In contrast to bone where repair of fractures can take place, repair in dentin and enamel fractures does not occur.

DIAGNOSIS OF CROWN-ORIGINATING FRACTURES

One of the difficulties in making a diagnosis of COF is that the cracks may be hidden below restorations;[17,24] (Figure 13-12) further, fractured teeth may not always be symptomatic or they may alternate between being symptomatic and asymptomatic.[24] Clinically, symptomatic tooth fractures are confusing because they often mimic symptoms from other conditions such as earache, sinusitis, temporomandibular joint dysfunction, and even trigeminal neuralgia and other neurological pain conditions.[17,18,30,33] When the problem is difficult to identify, it can lead to a long standing pain condition that becomes more diffuse, making localization of the offending tooth even more difficult.[17,27] Many reported cases of long standing histories of orofacial pain have been associated with the finding of cracks and infractions in teeth.[17,27,33,37]

Diagnosis of symptomatic tooth fractures is accomplished based on symptoms, clinical and radiographic findings, and history. A suspicion of COF should be considered when symptoms of a possible toothache are not readily connected to evidence of caries, periodontal disease, or recent trauma. The careful practitioner will proceed cautiously when a definitive diagnosis is difficult to establish to avoid acting on an incorrect diagnosis. Adding to these complications is the notion pointed out by Brynjulfsen et al.[17] that the longer it takes to make a diagnosis the more diffuse the pain becomes.

Symptoms

The most common symptoms associated with symptomatic tooth fractures are pain to chewing,[14,15,22,26,27,33,35,41] followed by pain to exposure to cold food and liquids,[15,19,26,27,35,41,48] and in some cases to sweets.[27,41,44] It is interesting to note the common absence of heat induced sensitivity.[21] This is probably related to early stages of pulpitis that may be present when teeth with COFs become symptomatic.

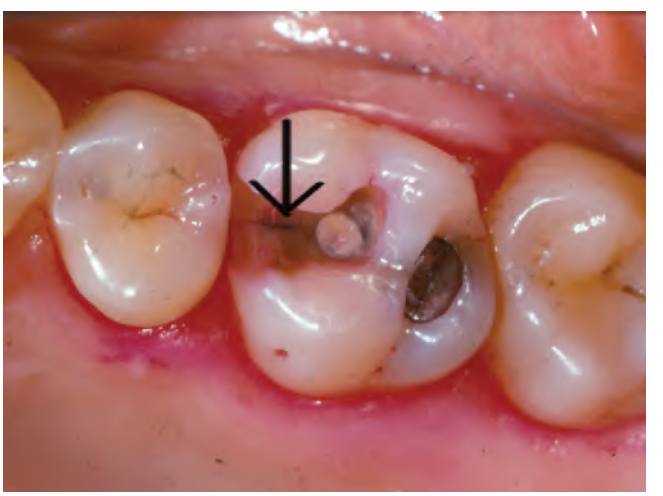

FIGURE 13-12 Maxillary molar with suspected crown-originating fracture. The mesio-occlusal amalgam had to be removed to identify the infraction (arrow) that has been highlighted by using red dye.

As has been noted, not all teeth with infractions are symptomatic.[31] Symptoms probably develop when fractures become populated with microorganisms that stimulate pulpal inflammation.[27,46,48,49] Localization may be possible when infractions reach the PDL, usually in the area of the crestal ligament where proprioceptive nerve fibers are present while not present in the pulp.[27,29]

Patients' histories of symptoms can be helpful in establishing a diagnosis of COF. Diffuse, protracted pain not associated with more easily diagnosed conditions of caries-induced pulpitis should at least attract a suspicion of tooth fracture.[17,27,29,30,33] Considering that symptomatic COF is in fact not a common dental condition, it should be considered when the more common conditions are ruled out.

Clinical Examination

Developing a definitive diagnosis of symptomatic COFs requires obtaining adequate information, both from the patient's history and from clinical examination. It usually begins with a chief complaint of pain to chewing, possibly elevated sensitivity to cold food and sweets. The absence of an obvious carious etiology should trigger a suspicion of a possible fracture and in most cases the following clinical examination procedures should help identify teeth with fractures.

Visual examination can reveal many instances of infractions, especially when aided by the use of transillumination[17,26] (Figure 13-13) and a dye such as methylene blue or red dye.[17,26,33,56] (Figure 13-12) The use of transillumination is dependant on the part of the tooth to be examined to be without restoration in order to allow the light beam to pass through the tooth; when it encounters a fracture line in the dentin, the light beam will bend and not pass through and the tooth structure opposite to the fracture line will be dark.[26] Additionally, to aid in visualization, the use of a microscope can be very valuable,[17,26] although magnification alone may not be a predictable way of detecting fractures.[57] However, in combination with the application of a dye, infractions become quite visible.[17]

Since existing restorations may hide infractions, it is often necessary to remove the filling to reveal the fracture lines.[17,26] (Figure 13-12) This becomes an important step in the clinical examination when the symptoms are vague and location of pain is diffuse and not localized. Brynjulfsen et al.[17] methodically removed restorations, one tooth at a time, to locate teeth with infractions in patients with long standing, undiagnosed orofacial pain.

An important step in the clinical examinations is the application of a **biting test.** Various techniques have been recommended, such as biting on Burlew wheels,[33] rubber wheels,[25] cotton tip applicators,[25] moist cotton rolls,[26] (Figure 13-11) and commercial biting applicators such as ToothSlooth (Professional Results Inc., Laguna Nigel, CA) and Fractfinder (Denbur, Oak Brook, IL). Ailor[26] has suggested that to differentiate between biting pain from restorations with microleakage and pain from tooth infraction, the ToothSlooth can be positioned so that pressure is placed on the filling and then the tooth cusps to determine the source of the symptoms (Figure 13-14).

A very significant response to biting is when pain is experienced on release of biting pressure[26,27,47] and referred to as either "rebound pain"[27] or "relief pain."[47] Kahler et al.[27] explain the pain associated with release of pressure results from fluid movement as the crack rapidly closes.

FIGURE 13-13 Example of transillumination highlighting a mesio-distal infraction (arrow) in a maxillary molar being prepared for a crown.

FIGURE 13-14 Illustration of the use of a ToothSlooth to attempt to differentiate between a fractured cusp versus a leaky restoration as the source of pain during mastication. The point of the ToothSlooth is being placed alternately on a cusp or on the surface of a restoration.

The moist cotton roll has been very effective for the author in stimulating rebound pain, providing a good clue to the tooth in question.

Cold stimulus application and ***electric pulp testing*** (EPT) will provide information about the status of the pulp and there is evidence that teeth with fractures respond at lower threshold levels to cold and EPT stimulation compared to nonfractured teeth.[19,48] Since any tooth with pulpal inflammation is likely to have lowered pain thresholds, it is not particularly significant that teeth with infractions also do. But it can add to the total information about the tooth.

Cameron[33] has suggested the use of a thin sharp **explorer** to probe around the cervical circumference of teeth suspected of having infractions, particularly in interproximal areas not readily visible if the tooth crown has a large or full coverage restoration (Figure 13-15). Both the "click" of the explorer tip encountering the fracture, and perhaps the patient's response, as in touching a sensitive spot on the root surface, can provide a clue. Another clue can be found by using a sharp explorer at margins of large restorations—a sharp pain may be elicited if a crack is present.[21]

Percussion sensitivity in teeth with infractions is not as common as biting sensitivity.[35] An explanation for this may be that in teeth with COFs the infractions typically originate internally and propagate peripherally,[27] so a tooth with infraction is not likely to be identified by percussion until the fracture extends to involve the PDL.[29]

Periodontal probing is recognized as an indispensable part of dental examinations in general and that also applies when examining teeth with potential fractures.[26,34] Hiatt[34] described periodontal probing to reveal narrow pockets adjacent to fracture lines, and Ailor[26] has suggested that if the probing extends below the alveolar crest, the tooth is not suitable for restoration (Figure 13-16). Since the pockets adjacent to infractions are extremely narrow, in contrast to those adjacent to VRFs in endodontically treated teeth, it is usually necessary to anesthetize the tissues surrounding the tooth prior to probing.

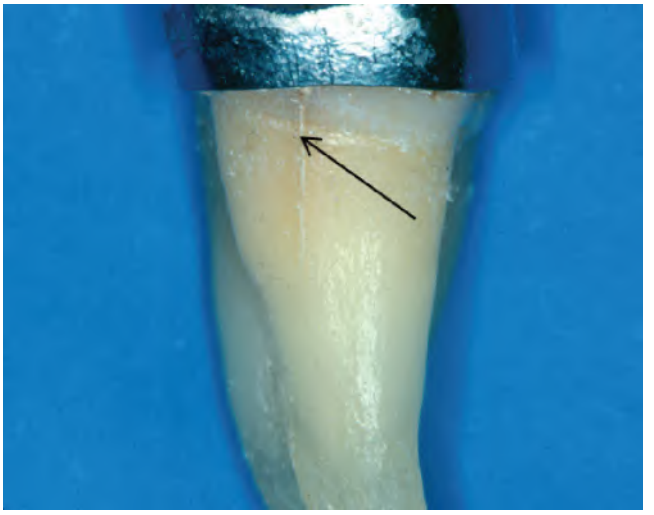

FIGURE 13-15 Infractions located below crown margins can be difficult to detect. Using a sharp explorer to probe around the cervical circumference of teeth suspected of having infractions, they may be identified by the "click" when the explorer encounters the fracture (arrow). Some patients may also feel a sharp, sudden pain at that time.

Radiographic Examination

It is generally recognized that radiographic examinations, while obviously necessary for a number of reasons, do not always provide diagnostic information with respect to COFs.[17,26,27] This is because the infraction lines usually run mesio-distally in the majority of cases[33] and the X-ray beam travels perpendicular to the fracture lines. If, however, the tooth infraction is located in a bucco-lingual direction, the X-ray beam will produce a clear image of the fracture line on the film or sensor (Figure 13-17).

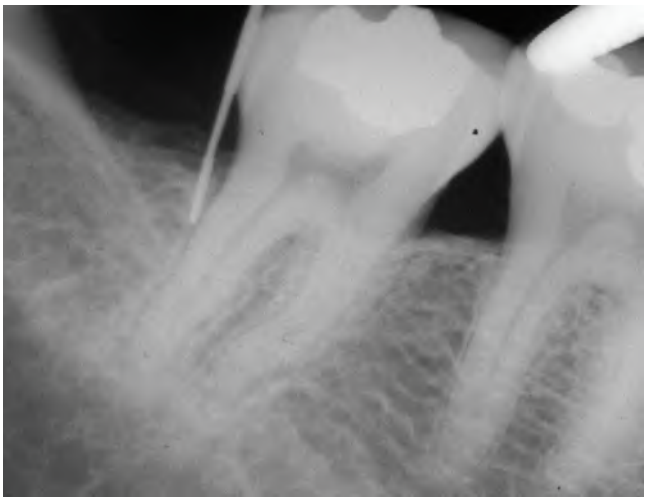

FIGURE 13-16 Illustration of periodontal probing in the narrow pocket adjacent to a crown-originating fracture. Such probing, that must be done using local anesthetic, can reveal approximate extent of the fracture's propagation down the root.

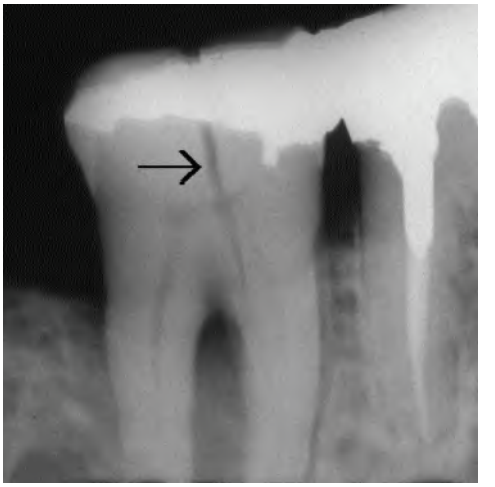

FIGURE 13-17 Radiograph of a mandibular molar showing a fracture (arrow) located in a bucco-lingual orientation. Because the X-ray beam runs parallel to the fracture, it becomes readily visible on the film.

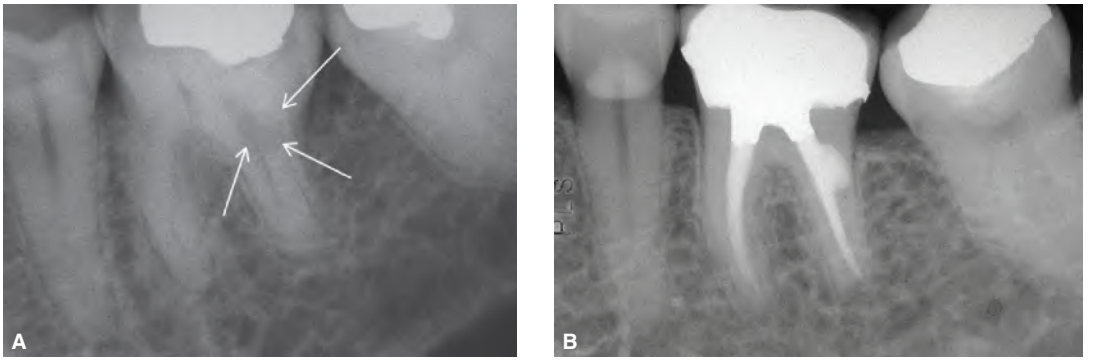

FIGURE 13-18 Illustration of infraction-related internal resorption. ***A.*** The mandibular molar had developed a symptomatic crown-originating fracture located on the distal aspect of the tooth. The radiograph shows the location of the resorptive lesion (arrows). ***B.*** Radiograph taken after endodontic treatment and placement of a full coverage crown. The resorptive lesion was connected to the still vital pulp at the point where the infraction entered the pulp; there was no external communication with the lesion.

Cone beam computed tomography (CBCT) has made radiographic examination of dental conditions of almost every type more easily visualized than ever before. Certainly VRFs in teeth are easily recognized on CBCT images.[7,58–60] This technology is less applicable to diagnosis of teeth with COFs. If an infraction is strongly suspected but the clinical examination lacks enough information for a diagnosis, CBCT may be indicated, selecting a 0.2 voxel system because of the small diameter of the infraction.[60] The use of CBCT for COF diagnosis should be very selective, as CBCT should not be used if other less risky avenues are available.[61]

One pathologic entity connected with COFs that can be detected radiographically, is the rare instance where bacteria in the fracture has stimulated clastic activity in the pulp, resulting in an internal resorptive lesion.[62] (Figure 13-18) This type of internal resorption is unique in many respects in that it appears to occur adjacent to the pulp space and may be mistaken for invasive external resorption. The presence of an infraction, associated with a resorption defect and with no communication of the resorptive defect with the periodontal tissues, confirms the diagnosis.

Future Diagnostic Options

While many tooth fractures can be diagnosed quite readily with just a few examination steps, others are often very difficult to detect and require extensive efforts.[17] There is a need for additional means to detect fractures in teeth; various avenues are being explored including the application of **ultrasound.** This modality may have potential for complementing radiography as an imaging technique by identifying physical discontinuances (infractions) in hard tissues such as enamel and dentin. The application of ultrasound is used in industry for a similar purpose and would, if developed in dentistry, be a great help in the detection of tooth fractures; it has been shown to be capable of imaging cracks in simulated tooth structure.[63]

Another ultrasonic technique is using ultrasonic power to heat the fracture line thus making it detectable by thermography.[64] For more information, see Chapter 9.

Differences Between COFs and VRFs

There are fairly distinct differences between teeth with COFs and those with VRFs. In the former the initial symptoms often are sudden, sharp pains on chewing, and occasionally "rebound" pain during chewing of certain foods. Patients with VRFs are more likely to complain of gradual onset soreness in the fractured teeth.

Another difference is the matter of localization; teeth with COFs are often difficult to identify while those with VRFs can be more readily identified. While chewing may produce responses in both situations, percussion sensitivity is more pronounced in teeth with COFs.

Radiographically, teeth with VRFs are often readily recognized while those with COFs are rarely identified on radiographic films or sensors; this is because the usual direction of fractures is in a mesio-distal direction in teeth with COFs while most often in a facio-lingual direction in teeth with VRFs. Thus in the latter situation, the X-ray beams travel parallel to the fracture lines and perpendicular to the fractures in the former.

TREATMENT

Any discussion of the treatment of teeth with COFs must include an acknowledgement that neither dentin nor enamel can be permanently reunited once a fracture line develops. Treatment efforts therefore are attempts (some better than others) to prevent separation of the hard tissue entities, and perhaps to keep bacteria from colonizing the fracture spaces, however that may be impossible.[49] The goal of treatment is to bind a tooth with infractions together, but one has to expect that in time this discontinuity in the integrity of the tooth structure will progress toward separation such as seen in split teeth and cuspal fractures. Further, root canal therapy, while reducing or eliminating symptoms, will not change the fact that a tooth with a fracture is a weakened tooth that likely will not last as long as a nonfractured tooth.[42,65]

The need for evidence-based treatment guidelines have been pointed out.[4] While these are not yet available,

endodontists appear to be in agreement that many teeth with fractures can be treated,[66] but it is not clear if all teeth with fractures need root canal therapy. The lack of clear understanding in this regard is probably related to the difficulty in determining if an infraction communicates directly with the pulp, in which case endodontic treatment would reasonably be a part of the overall treatment for the tooth, or the fracture is a cuspal fracture that may not communicate with the pulp and the pulp may not be involved.

Using the commonly accepted criteria for pulpal diagnosis, Krell and Rivera[67] reported the outcomes of symptomatic fractured teeth that were initially diagnosed with reversible pulpitis and treated with full coverage restorations. The outcomes suggest that, if an infraction is identified early and the diagnosis is reversible pulpitis and a crown is placed, root canal treatment will be necessary in about 20% of the cases.

One approach that can help in deciding if endodontic therapy for a tooth with COF is necessary is a method followed by some clinicians.[17,26] If the tentative diagnosis is *reversible pulpitis*, the tooth can be stabilized with an orthodontic band for about 2 weeks (Figure 13-19). If the initial pulpal diagnosis is *reversible pulpitis* (based on no lingering pain to cold and no spontaneous, severe pain) a 2-week waiting period will provide useful information. If the symptoms have subsided after placement of the orthodontic band, the patient may be offered the option of only placing a restoration that binds the tooth together, such as a full crown, with the understanding that the tooth may later need root canal therapy.[67] The reason for waiting a while after placement of the orthodontic band is because it takes some time before cold sensitivity subsides. For instance, Davis and Overton[25] found that it took 2 weeks for cold sensitivity to subside after restoring teeth with bonded amalgam restorations.

When fractured teeth have *irreversible pulpitis* or *pulp necrosis*, the need for root canal treatment is self-evident if they are to be retained. Root canal treatment will obviously eliminate pulpal pain and sensitivity to temperature changes and to sweets; one should not, however, expect all fractured teeth to be free of chewing pain after root canal therapy. Pain to mastication is associated with inflammation in the PDL. Such inflammation is generated by bacteria in the infractions that extend from the coronal area apically.[27,29,34,49] The problem of not being able to predict if pain to chewing will cease after root canal treatment and restoration, can be addressed again by the recommendation made previously to first place an orthodontic band to measure the response to binding the crown together, followed by root canal therapy. If the patient is comfortable with the tooth the treatment can be completed; if not, extraction becomes the alternative treatment.

Treatments designed to bind cracked teeth together include the use of adhesives,[20,68–70] amalgam with retention on both sides of the infractions[25] and full coverage crowns,[17,25,26,65,71] and bonded composite overlays.[72] Experimental approaches using lasers (CO_2, Nd:YAG) have not produced any promising results yet.[73]

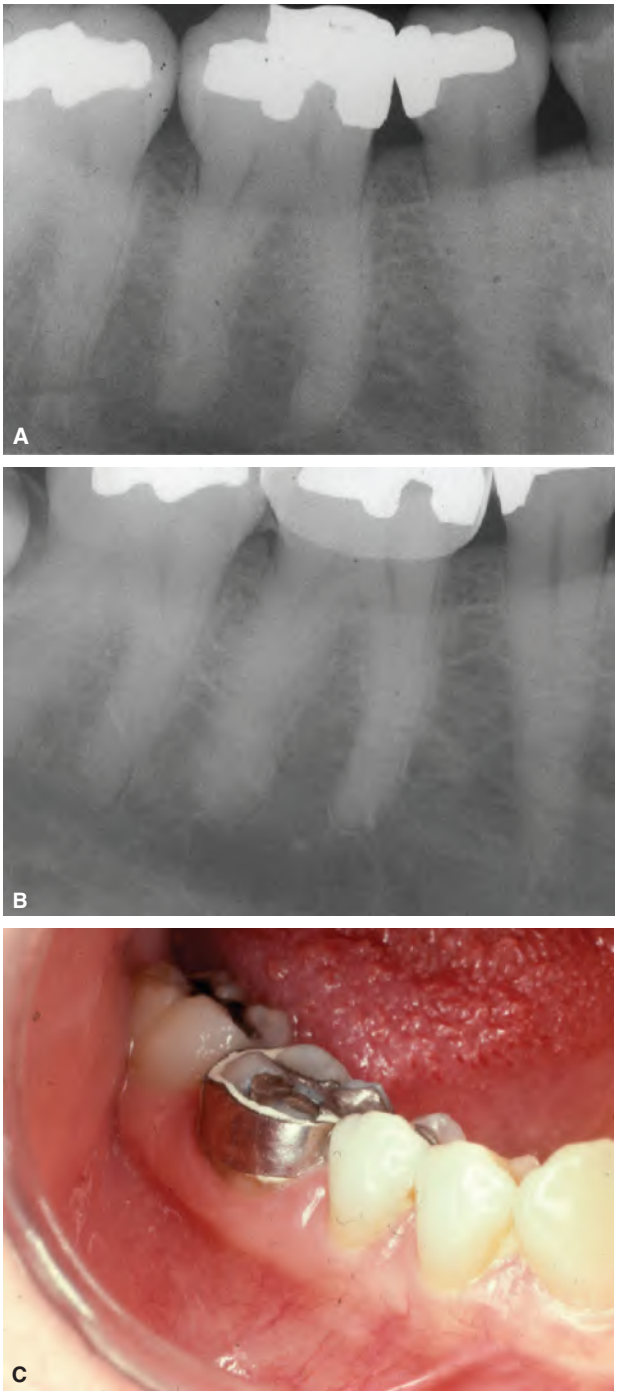

FIGURE 13-19 Diagnostic banding of a tooth with crown-originating fracture (COF). ***A.*** Radiograph of mandibular first molar with a symptomatic COF on the distal aspect of the tooth. Since the fracture line is in a mesio-distal orientation, it is not visible radiographically. ***B.*** With a pulpal diagnosis (based on symptoms and clinical findings) of reversible pulpitis, a band is cemented to bind the tooth together. ***C.*** Photograph taken 2 weeks later when the patient reports complete absence of symptoms. The patient can now be offered the option of a full coverage crown with the information that about 20% such teeth may need endodontic treatment later;[67] some patients may choose to have root canal treatment done prophylactically before crown placement.

Prognosis

The outcome of treatment for teeth with infractions has not been extensively reported. Cameron[33] reported a 75% success after 10 years following placement of crowns, and Guthrie and Di Fiore[71] found that 24 of 25 teeth restored with acrylic crowns were asymptomatic after 1 year. Brynjulfsen et al.[17] achieved pain relief in 90% of their patients after protective restorations were placed on teeth with infraction (endodontic therapy was included when indicated), and Tan et al.[65] had an 85% survival rate 2 years after protective crowns were placed. The available data is insufficient to use as a basis for giving individual patients odds on tooth survival for a specific number of years. Patients must be fully informed of the uncertainty based on lack of data. What one can recognize is that in certain situations the prognosis is poor: terminal teeth, teeth with periodontal involvement related to infractions, and teeth with multiple infractions.[65] Treatment recommendations and informed consent, based on best evidence, suggest that clinicians search what is available in the literature, include the clinician's own experience, and seek the patient's own preferences.

PREVENTION

A number of suggestions have been made toward reducing the incidence of tooth fractures. They include cavity design and size,[25,26,29,38,39,50] proper design of intra-coronal cast restorations,[39,50] avoiding use of self-threading and friction-lock pins, [29,38,50,51] avoiding extensive use of course diamond burs and vibrating high-speed hand pieces,[26,55] and restoring teeth with attention to occlusion to avoid interference from working premature contacts.[26,29] It may also be beneficial to advise patients about potential damage from oral habits (pipes, pencils, finger nails)[26,29] and the stress excessive repetitive heavy mastication can produce in teeth.[6,36,41]

Yeh[36] coined the term "fatigue root fracture" to describe the result of consuming a course diet over a long period of time in a group of Chinese patients. Many of them developed VRFs in often nonrestored teeth with no history of endodontic treatment. The biting force on first molars is up to 90 kg[41] and if there is sudden external trauma, such as biting unexpectedly on something hard in the food, an infraction may result. Kahler et al.[27] described how infraction can occur from "cyclic fatigue" and repeated occlusal loads. Similar to all body parts, teeth are not indestructible.

With respect to care of teeth, a question sometimes raised is, is it damaging to chew on ice? The dental literature is not very informative on this topic. Brown et al.[53] used thermal cycling, alternating exposure to very cold and very hot stimuli on extracted teeth, and reported extensive cracking in the teeth. It is not clear if that information can be applied to the question of ice-chewing, but until more information becomes available, it seems reasonable to advice against chewing on ice.

SUMMARY

The incidence of COF does not present a major problem in dentistry,[30,31] but diagnosis of COF can be difficult when symptoms and clinical findings are not definitive.[15,17,18,19,26,27,33,34] Infractions or cracks in teeth are incomplete fractures, most often originating in the crowns, and will, if untreated, lead to cuspal fractures or split teeth.[6,15,23,25–27,29,35] Cuspal fractures usually do not communicate directly with the pulp and such teeth may not need endodontic treatment. Infractions may, however, propagate from the pulp toward the dentin-enamel and dentin-cementum junctions. In such cases the pulps are usually irreversibly involved requiring endodontic treatment.[3,25,35,65] Restorative treatment involves procedures that provide a binding effect on the tooth infraction; this can be accomplished by using amalgam restorations that incorporates retention on both sides of the infractions,[25] amalgam in combination with bonding agents or full coverage cro wns,[17,25,26,65,74] or composite overlays.[72] Today, however, use of amalgam is less frequent.

Adequate data is not available to determine prognosis for symptomatic teeth with infractions; when such teeth have received treatment, either restorative alone or in combination with root canal therapy, they have been reported to survive for many years.[33,65,71] Patients however, need to be informed that long-term retention is questionable. However, in spite of unfavorable long-term outcome, retaining a tooth with COF may still be an excellent option for many patients.

Chapter 14

Vertical Root Fractures

Aviad Tamse, Louis H. Berman

Vertical root fracture (VRF) is a fracture originating in the root of a tooth that can present a serious treatment complication.[1,2] It occurs primarily in endodontically treated teeth, but has also been observed in intact nonendodontically treated mesial roots of mandibular molars, mostly in Chinese population.[3] According to the American Association of Endodontists' classification, VRFs are considered a subcategory of longitudinal root fractures since they are chronic in nature and progress longitudinally over time.[2,4,5] VRFs originate in the root at any level and progress either coronally or apically.[5] From a horizontal perspective, the fracture originates in the root canal wall, mostly on the buccal or lingual surface, and extends outwardly to the external root surface.[4] It can involve one root surface (incomplete VRF), or both root surfaces (complete VRF).[4,5] Complete VRF often becomes an eventual buccal-lingual fracture (Figure 14-1 A–D).

Because VRFs originate in the root of the tooth, they are different from other longitudinal fractures that occur subsequent to impact trauma, such as "craze lines," "fractured cusps," "cracked teeth," or "split roots."[4] These fractures originate in the crown of the tooth and progress longitudinally in an apical direction.

The clinician should be aware that when there is no obvious cause for a chronic symptomatic pulpitis or pulp necrosis, especially when there is an intact crown with either no caries or with a shallow restoration, one should suspect a fracture in the crown.[6] Enhanced magnification and illumination are imperative in such cases, and the patient should be informed of a possible decrease in prognosis. In cases whereby these fractures were not recognized prior to root canal therapy, the patient is likely to return with typical signs and/or symptoms of a VRF (Figure 14-2 A–C). Therefore, the clinician should meticulously evaluate the clinical and radiographic appearance of such of a tooth prior to initiating root canal therapy.

VRFs in endodontically treated teeth can present a frustrating diagnostic and treatment-planning dilemma both for the patient and clinician. The clinical signs and symptoms may be difficult to differentiate from nonhealing endodontic treatment or chronic periodontal disease.[4,7–9] Often, the definitive diagnosis is only made years after the endodontic and restorative procedures have been completed or when the tooth is extracted.[4,8,10,11] Prevention of VRFs is difficult since the etiology is multifactorial.[8,12,13]

Subjectively, there is a higher reported incidence of fractured crowns and VRFs in recent years.[14] This may be attributed to the increased awareness of clinicians that endodontically treated teeth may be more prone to fractures. It is also possible that restorative and orthodontic treatment may be directing an increase in occlusal prematurities. Alternatively, changes in dietary habits and ingredients may be altering the way teeth are developing, possibly making them more brittle or prone to fracture. However, presently there is no objective explanation for the possible increased incidence of VRFs. Seo et al.[14] evaluated 107 extracted endodontically treated teeth and found 13% incidence of VRFs. Fuss et al.[15] and Coppens et al.[16] showed an incidence of 11% and 20% VRFs, respectively. In teeth referred for extraction, the incidence was higher.[17,18]

CLINICAL DIAGNOSIS AND PATHOGENESIS

When present, it is imperative that a diagnosis of a VRF be made as soon as possible. A direct correlation was found between bone resorption around a VRF and time without treatment.[19] As bone resorption increases over time, it may compromise other roots of the same tooth or adjacent teeth. This bone loss may also compromise the subsequent placement of an endosseous implant in the area of the extracted tooth. When the diagnosis of a VRF is made, the tooth or offending root(s) should be extracted as soon as possible, assuming patient compliance.

Achieving an accurate and timely diagnosis of a VRF in an endodontically treated tooth can sometimes be challenging. Fractures may be obscured by obturation material or there may be no significant periodontal or radiographic findings to suggest a VRF.[20] In addition, typical signs and symptoms of a VRF, such as spontaneous dull pain, pain upon mastication, tooth mobility, presence of a sinus tract, deep periodontal probing defects, periodontal-type abscesses, and bony radiolucencies, are often similar to those observed in nonhealed endodontic treatment, reinfected root canals, and primary periodontal disease.[1,4,7–9,21]

According to the 2008 AAE Communiqué,[5] there is a specific combination of signs and symptoms that, when present in the endodontically treated tooth, are considered "pathognomonic" for the presence of a VRF. These parameters are:

1. Presence of a sinus tract.
2. Existence of a narrow and deep isolated periodontal defect.

However, this "pathognomonic combination" is not necessarily present in all VRF cases. According to Tamse et al.[7] this combination of clinical finding was only observed in 23.9% of diagnosed VRFs. In a recent study,[21] this "pathognomonic

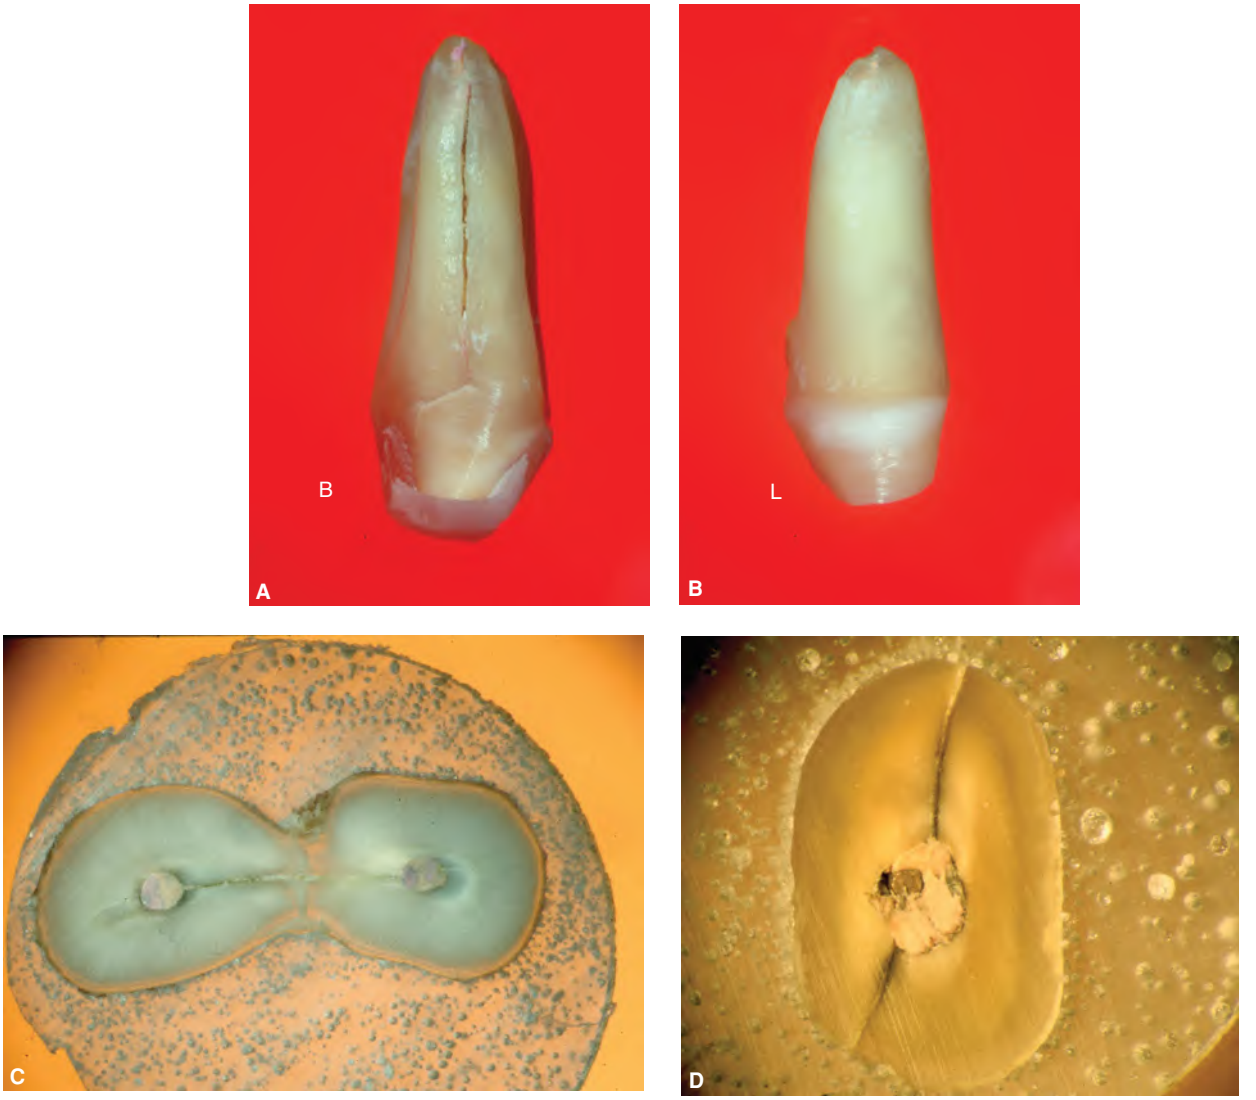

FIGURE 14-1 ***A***. Buccal aspect of incomplete VRF from apical to coronal in an extracted maxillary premolar. ***B***. Incomplete fracture does not involve the lingual aspect. ***C***. Incomplete fracture in a maxillary premolar. ***D***. Complete fracture in a mandibular premolar.

combination" was only observed in 43.8% of vertical root fractured cases. (Figure 14-3 A,B)

Although there are several radiographic features associated with VRF's,[22,23] they are not part of the AAE's "pathognomonic combination" but rather described by the AAE as "radiographic evidence varies."[5] The typical pattern of bone loss associated with a VRF is a dehiscence of the buccal plate adjacent to the fracture site, followed by loss of the interproximal bone of the affected root.[19] (Figure 14-4 A,B) This process continues unless the tooth, or root, is extracted. These radiographic changes are often observed on 2-D radiographs; however, 3-D radiography, that is, cone beam computed tomography (CBCT), is often necessary to better observe these bony changes.[24] For more details see Chapters 9C and 10.

Two typical clinical signs that can help the clinician make an accurate diagnosis of a VRF are

1. Deep and often narrow periodontal probing defect (Figure 14-5 A,B)
2. Sinus tract positioned more coronally in the attached gingiva (Figure 14-6 A,B)

In four retrospective clinical studies of teeth with VRFs, deep probing defects were found in 64% to 93% of cases; a more coronally positioned sinus tract was present in 13% to 35% of cases.[7,21,25–27]

This periodontal presentation and position of the sinus tract are expected considering the dynamics of the host response to the fracture. Once the fracture progresses to the outer surface of the root, the periodontal ligament (PDL) space becomes involved and local inflammation develops. This is due to bacterial invasion of the fracture from the oral cavity that extends into the PDL space.[10] The local inflammatory process results in development of vertical bone loss and formation of a narrow periodontal defect. Over time, an abscess develops that is similar to any other form of a chronic periodontitis.[7,25–27] An exploratory surgical procedure is highly recommended

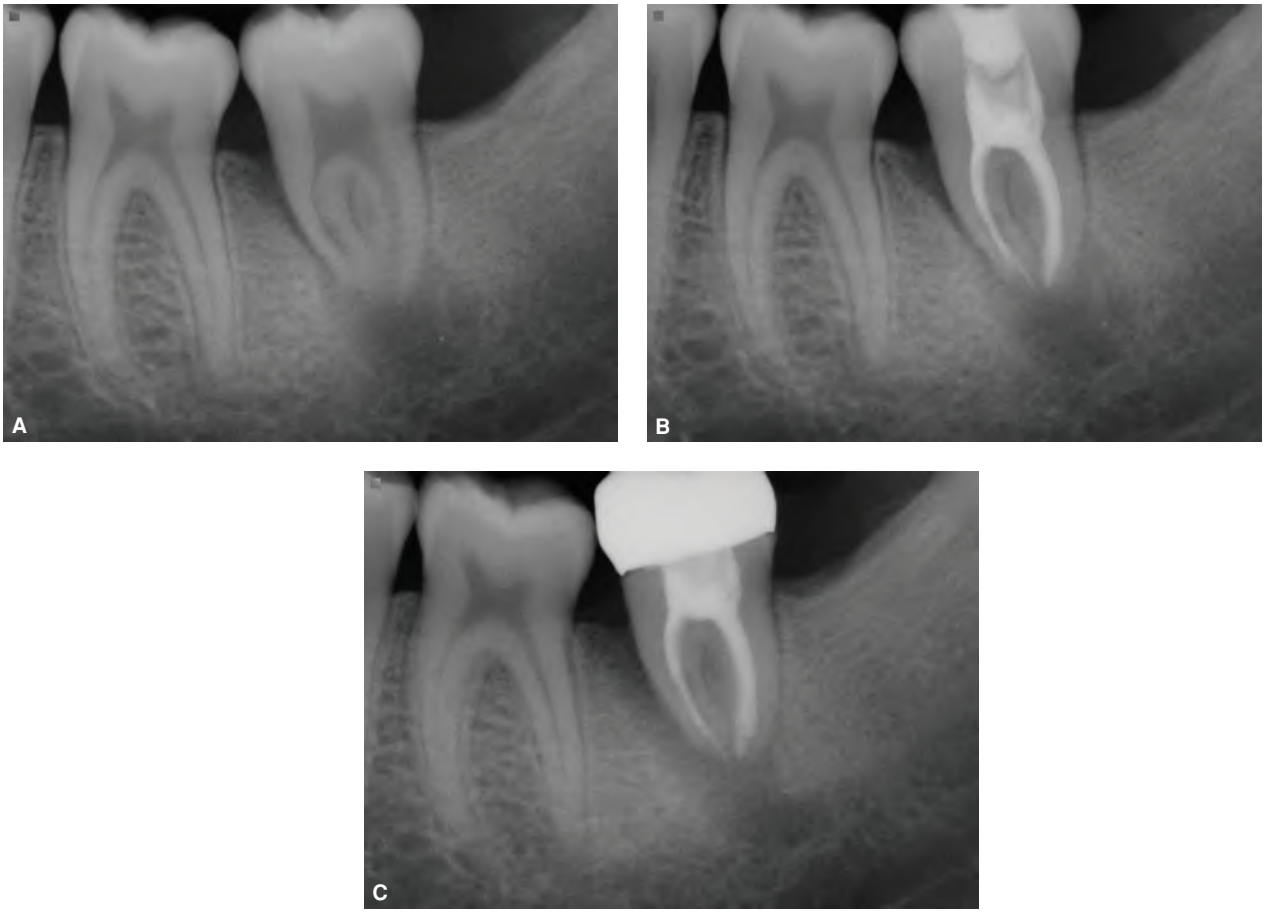

FIGURE 14-2 ***A***. Lower left second molar with nonvital pulp and no apparent reason for necrosis other than possible root fracture. for an immediate and definitive diagnosis and treatment plan[9,19,21] (Figure 14-7 A–D).

Lustig et al.[19] described the typical pattern of bone resorption associated with a tooth having a VRF. In 90% of cases wherein teeth were extracted due to a VRF, buccal bone dehiscence was observed along the entire length of the fractured root. In addition, a direct correlation was found between the amount of bone resorbed and time without treatment (Figure 14-8). A fenestration type of bone loss was found in only 10% of maxillary premolars and mesial roots of mandibular molars (Figure 14-7 C,D). Walton and Rivera et al[28] described this progression of bone loss when the fracture propagates in an apical-to-coronal direction. They observed that when the fracture extends to the gingival margin, bone resorption progresses rapidly in apical and lateral directions, into the interproximal area. However, even if the buccal plate is completely resorbed, with no interproximal involvement, a single periapical radiograph may often not reveal the entire extent of bone loss (Figure 14-9 A,B).

Typically, when bone resorption is present on the lingual aspect of a VRF, it appears as a shallow rounded U-shaped defect. This is due to the cancellous bone in this area being much thicker than on the buccal side; over time, the resorption continues to extend laterally. Surprisingly, only 10% of bony fenestrations, secondary to a VRF, appear as an abscess, similar to a typical abscess of endodontic origin without significant periodontal defects on the buccal aspect.[19]

When a bony dehiscence is present and associated with a visible fracture, as seen during an exploratory surgery,

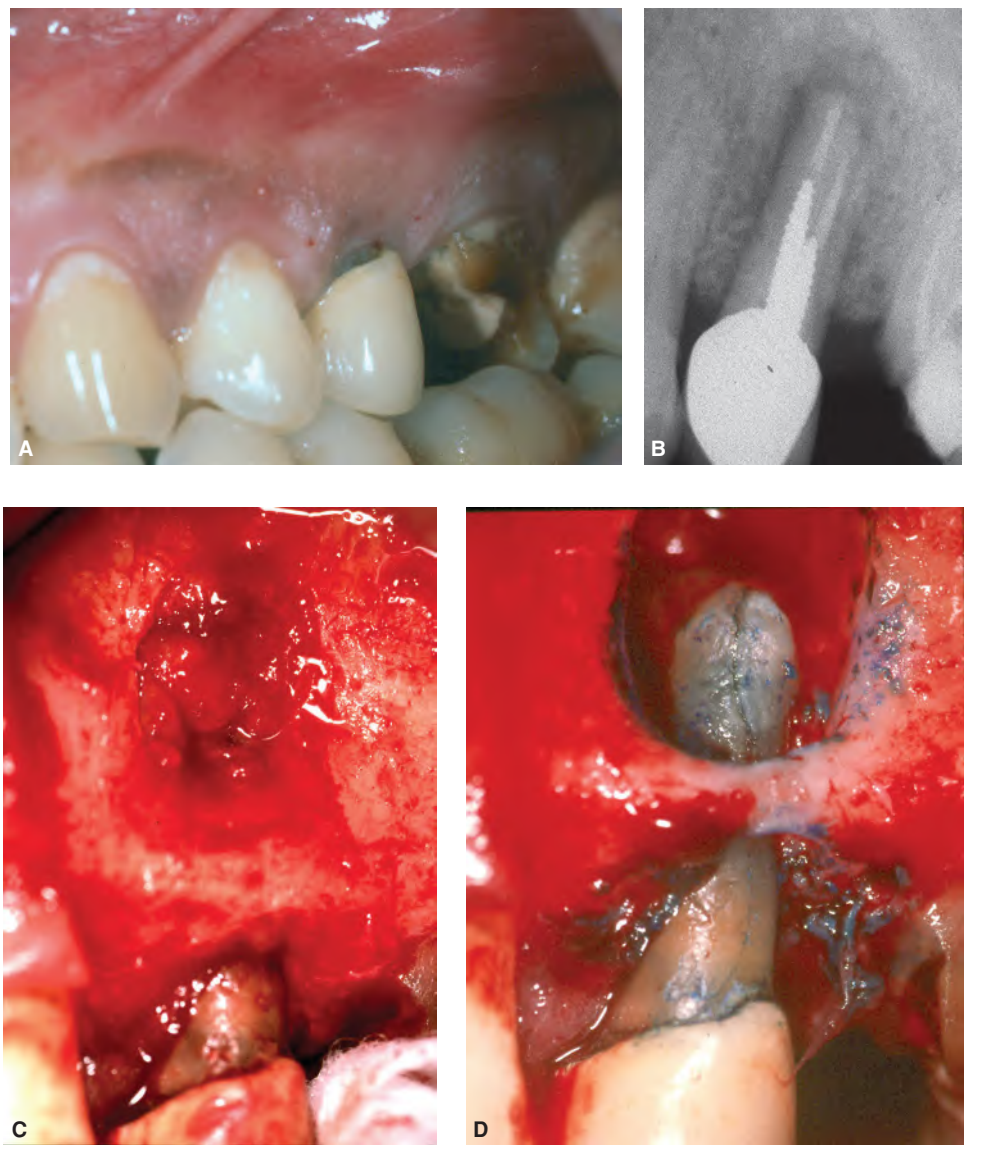

FIGURE 14-7 ***A***. VRF in a maxillary premolar. New restorative treatment was required for the posterior segment. ***B***. Periapical radiograph shows the "halo" radiolucency around the root. ***C***. Exploratory flap procedure reveals buccal fenestration filled with granulation tissue. ***D***. Removal of the soft tissue reveals fracture line from apical to cervical root area. Methylene blue dye helps to demonstrate the fracture.

(Figure 14-7) extraction of the root, or tooth, will prevent further bone loss.[19]

Sinus tracts associated with VRFs, unlike those that result from a typical chronic periapical abscess, are not usually located in the apical area, but rather several millimeters below the gingival margin[7,29] (Figure 14-6). This type of sinus tract was found in 14% to 42% of VRF cases.[7,8,21,27] Therefore, when a deep narrow periodontal probing defect is present with a coronally located sinus tract, and when a bony dehiscence is observed during exploratory surgery, the tooth with a VRF can be better diagnosed in a timely manner.

FIGURE 14-8 A late diagnosis of a VRF showing separated root segments of a mesial root of a mandibular molar. Large bony lesion can be seen surrounding the tooth from all aspects.

Radiographic Findings

Occasionally, direct radiographic detection of a VRF is possible. If there is separation of the root segments (Figure 14-10), especially when accompanied by a large radiolucent area between the roots, radiographic visualization is more likely. Note that the inflammatory tissue between the root segments may actually aid in facilitating the separation of the segments over time.[29,30] Also, sometimes a "hairline" fracture can create a radiolucency that can occasionally be detected on a periapical radiograph[9] (Figure 14-11). However, in clinical practice, radiographic detection of fractures does not seem to occur that often.[9,31] Hairline fractures are quite difficult to detect radiographically. When a root fracture is suspected, it is recommended that at least two periapical radiographs be taken, from different angulations (Figure 14-9).

The appearance of a radiolucency associated with a VRF is influenced by the extent of bone destruction, the direction and location of the fracture, and the time elapsed since the fracture developed.[29] To help distinguish between a radiolucency associated from a VRF and bone loss associated with periodontal disease, or nonhealing root canal treatment, certain characteristics of bone loss were suggested.[4,20,23,22,32] The most frequent radiographic presentation observed with VRFs, especially with maxillary premolars and the mesial roots of mandibular molars (that are among the

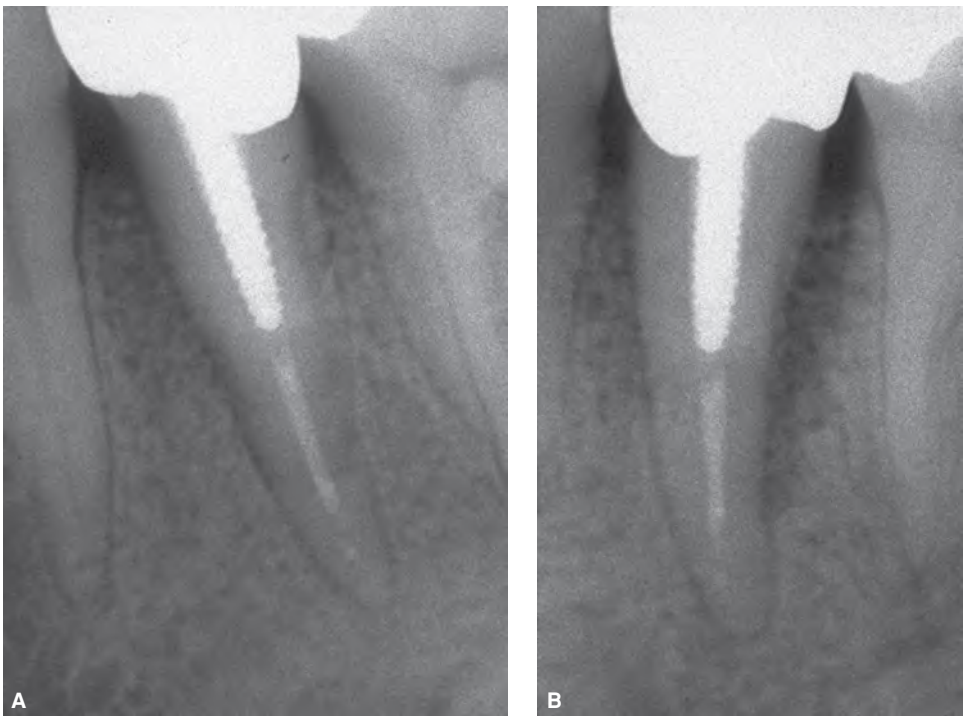

FIGURE 14-9 ***A***. Periapical radiograph of a mandibular premolar reveals widening of the periodontal ligament space on the mesial tooth aspect. ***B***. Change of horizontal angulation reveals radiolucency along most of the distal part of the root from the coronal aspect, not involving the periapical area (periodontal radiolucency).

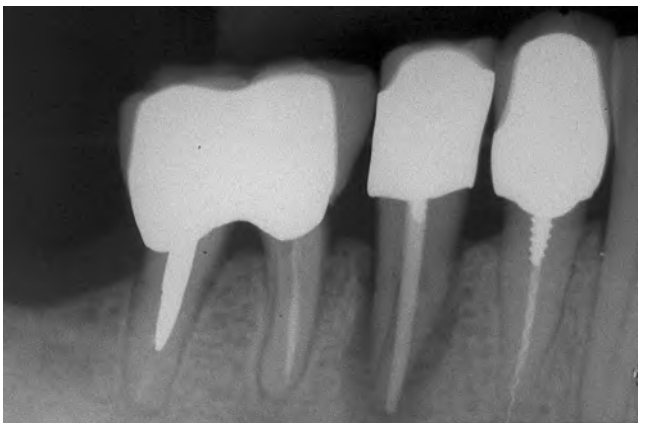

FIGURE 14-11 A "hairlike" radiolucent line can be seen at the distal aspect of a fractured mandibular incisor.

most susceptible teeth and roots to fracture), is a "halo" or "J-shaped" appearance of bone loss. These bony defects are a combined periapical and lateral root radiolucency, present on one or both sides of the involved root[1,22,23] (Figure 14-12 A–C). Also, in 63.3% of VRF cases involving the mesial roots of mandibular molars, the "halo" pattern of bone loss involves the furcation area between the mesial and distal roots[22] (Figure 14-13 A–D). Although this pattern of bone loss is not necessarily pathognomonic for a VRF, it is highly suggestive, especially when associated with other signs and symptoms as previously described.

In recent years, CBCT) has become popular due to its ability to accurately diagnose VRFs, especially as compared to periapical radiography.

Several publications in recent years claim that the CBCT is superior to periapical radiographs in the sensitivity, specificity, and accuracy, over periapical radiographs in detecting VRFs in endodontically treated teeth.[33–35] However, this has been disputed by a recent systematic review and meta-analysis study,[36] as well as two other clinical investigations.[37,38]

The primary challenge in diagnosing VRFs from CT scans is the difficulty observing incipient fractures. Additional issues include the presence of streak (radiopaque) artifacts secondary to the presence of gutta-percha or metal dowels, presence of beam hardening artifacts, increase in radiation dosage, and cost (Figure 14-14 A–F). According to the American Dental Association (ADA) statement,[39] CBCT should be used only when the clinician expects the diagnosis will yield a benefit to the patient. In a publication from the AAE,[40] it is stated that "Fine vertical cracks appear not to be revealed unless the radiolucency width is higher than 0.15 mm. What may be observed is the Specific patter of bone loss in one or more CBCT

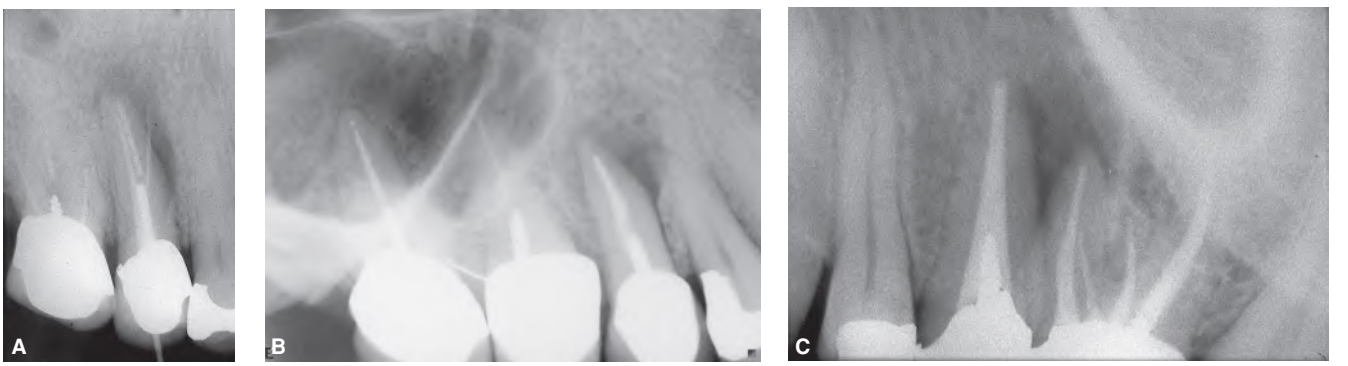

FIGURE 14-12 ***A***. "Halo" appearance radiolucency around the apical and mesial aspects of the root of a maxillary premolar. ***B***. scans." However, future generations of CBCT machines may yield better detection capabilities. For more details, see Chapter 9.

Unless an actual fracture of the root is seen on the radiograph, the pattern of bone loss can only be considered as highly suggestive of a VRF. It should be noted that the pattern of bone loss associated with VRFs is also similar to those seen in primary endodontic or periodontal lesions.[7,9,22,23,32] Therefore, with radiographic evidence alone, a final diagnosis cannot and should not be made. Unfortunately, with the lack of other clinical findings, there is typically a delay in making a diagnosis, resulting in subsequent increase of bone loss surrounding the tooth. When VRF is suspected, the clinician must inform the patient of a potentially reduced prognosis prior to considering any endodontic treatment.

ETIOLOGY

Although VRFs are typically associated more with endodontically treated teeth, they can, on rare occasions, also occur in nonendodontically treated molars. As stated before, this finding seems to be more prevalent in Chinese population[3]; the reason is not well understood.

The causes of VRFs in endodontically treated teeth are multifactorial. They can be divided into predisposing factors and contributing factors.[13,41]

Predisposing Factors

Changes in the quality and mechanical properties of root dentin of an endodontically treated tooth may predispose the root to fracture. In addition, the specific anatomy of a susceptible tooth may also be involved.[13,41] The amount of remaining tooth structure, as a result of caries and trauma, can also be a factor that increases the risk of future crack formation in dentin.[26]

The roots most susceptible to fracture are those in which the mesio-distal dimension is narrower than the bucco-lingual dimension (i.e., the root cross section is oval, triangular, kidney-shaped, ribbon-shaped or hourglass-shaped).[42] Examples of such teeth are maxillary and mandibular premolars, mesial

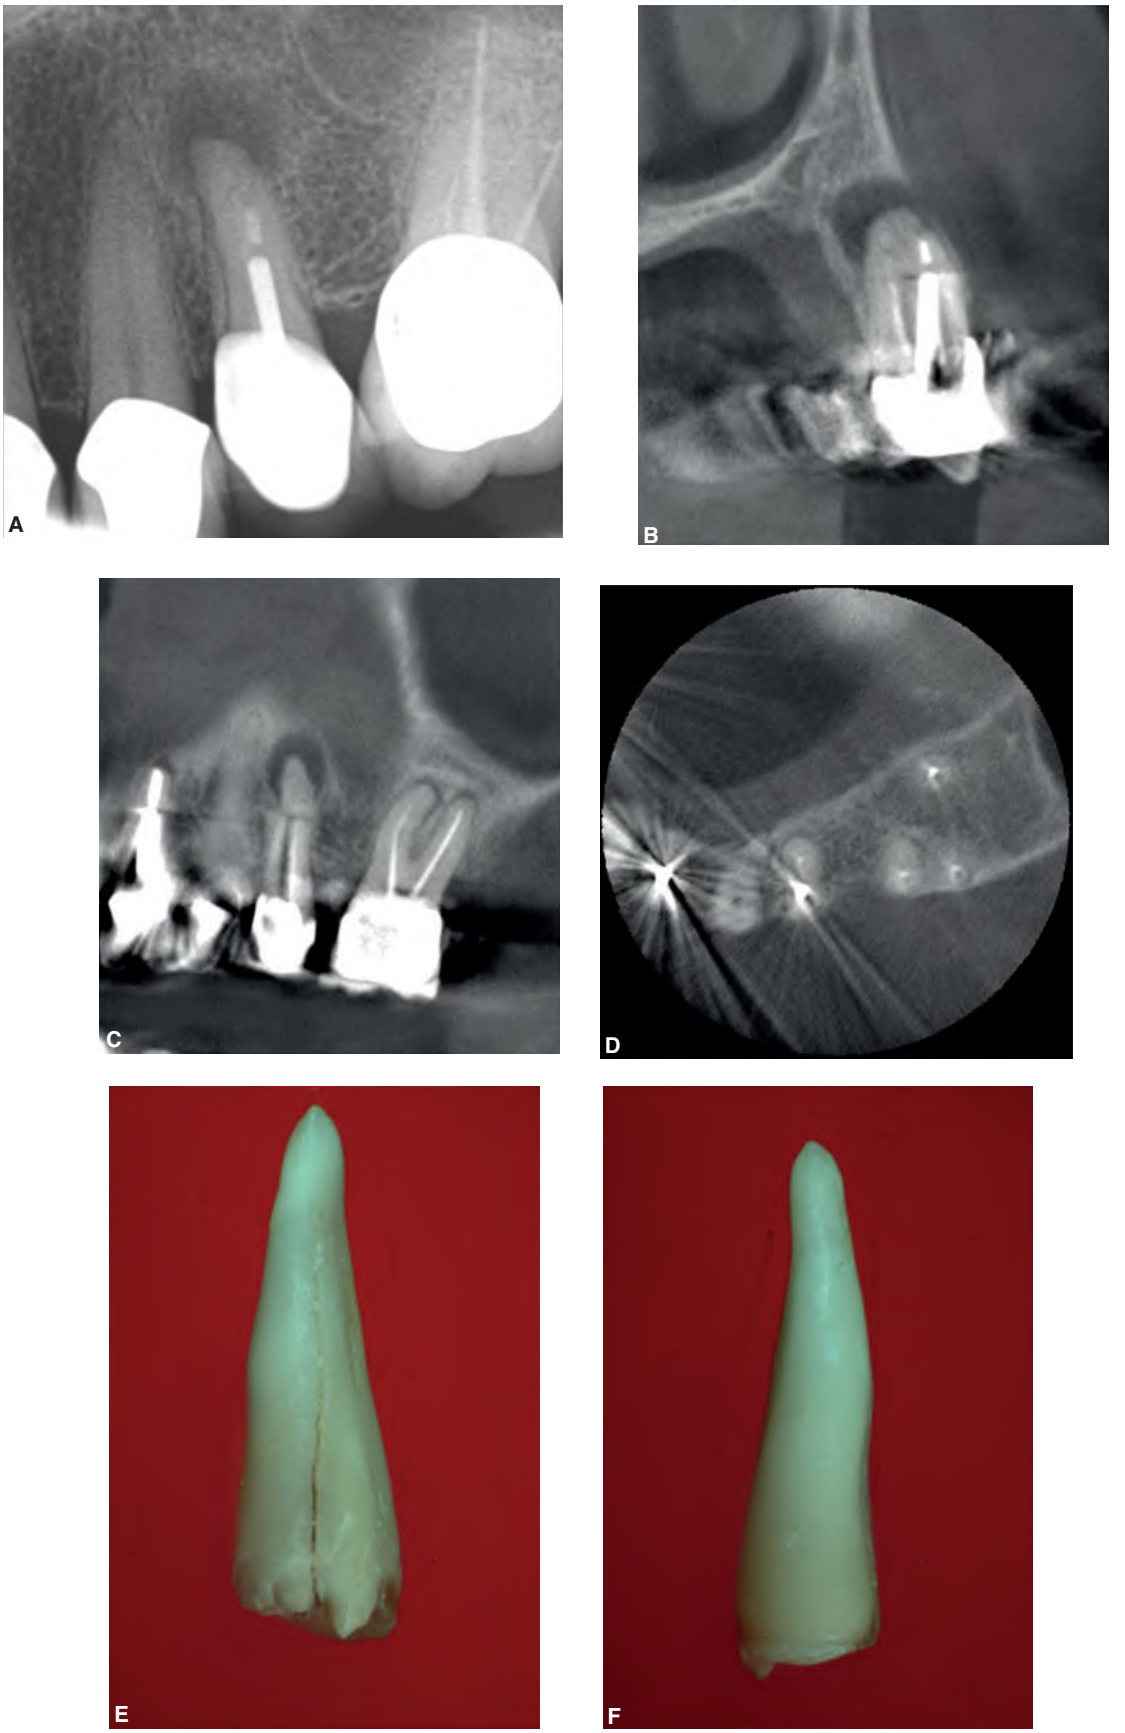

FIGURE 14-14 Restored, endodontically treated maxillary premolar. "Halo" radiolucency can be seen around the tip of the root (***A***). Despite deep probing defect in the midbuccal area, no evidence of fracture can be seen in CBCT coronal (***B***), sagittal (***C***) or in axial (***D***) views. After the tooth was extracted, the VRF can be seen clearly in the buccal aspect of the root (***E***) but not in the lingual one (***F***). (Courtesy of Dr. Ron Ganik, New York, NY.)

roots of mandibular molars, mandibular incisors, and mesiobuccal roots of maxillary molars.[43] In a retrospective study of fractured roots, Tamse et al.[7] found these root shapes to be the most frequently fractured (79%). To minimize the risk of VRFs and to increase the success rates of endodontic and restorative treatments, familiarity with root anatomy and morphology is essential.[42] For more details, see Chapter 1.

Root curvatures and depressions, like those present in the mesial root of mandibular molars and the buccal root of a bifurcated maxillary premolar, are anatomic entities that can predispose a tooth to fractures (also root perforations)[42,44,45] (Figure 14-15).

Canal and root shape, as well as dentin thickness, can affect the tensile stress distribution during intra-canal procedures.[46] Recognition of canal shape is paramount since the area of reduced curvature radius (the buccal and lingual areas) is strongly influenced by stress concentrations.[47] This is probably the reason why these roots have a predilection to fracture in a bucco-lingual direction as opposed to mesio-distally, even though more tooth structure is removed from the mesial and distal aspects during canal instrumentation and post space preparation.[48]

Another important predisposing factor for VRFs is the amount of pretreatment tooth structure missing; mainly due to caries or trauma. Coupled with reduced amount of radicular dentin resulting from various intra-canal procedures (i.e., initial root canal therapy, endodontic retreatment,[21] and post space preparation), sound tooth structure is directly correlated with the ability of the endodontically treated tooth to resist fractures[42,48,49] (Figure 14-16 AB).

Reduced moisture content of dentin has been reported in endodontically treated teeth.[50] The dehydration of dentin can induce cracks in the root canal wall, which can subsequently develop into a fracture. Dentin "age" is also considered a predisposing factor for tooth fracture in endodontically treated teeth.[51,52] Crack extension in older dentin has been shown to propagate at a faster rate than in younger dentin.[53] Also, aged dentin has an increased amount of translucent dentin, making it more susceptible to fracture.[54]

Small cracks are often present naturally in the dentin of intact teeth, appearing both parallel and/or perpendicular to the root canal space.[55] During intra-canal procedures when dentin is removed, especially in the mesio-distal areas, these cracks may be exposed and progress over time in a buccal and/or lingual direction, potentially creating incomplete or complete fractures.[56]

There are several factors that may directly or indirectly contribute to the formation of a VRF. These include endodontic access preparation, root canal preparation, various solutions and medicaments used during canal preparation, root canal obturation, post space preparation and placement, and appropriateness of the coronal restoration.[20,41,57,58]

Excessive removal of dentin during access preparation and enlargement of the coronal third of the root may result in unintentional thin dentin walls and a weakened root, predisposing it to a future fracture[41] (Figure 14-16 AB).

FIGURE 14-15 Complete VRF in buccal and lingual roots of a maxillary bifurcated premolar. Note the concavity on the bifurcation aspect of the buccal root.

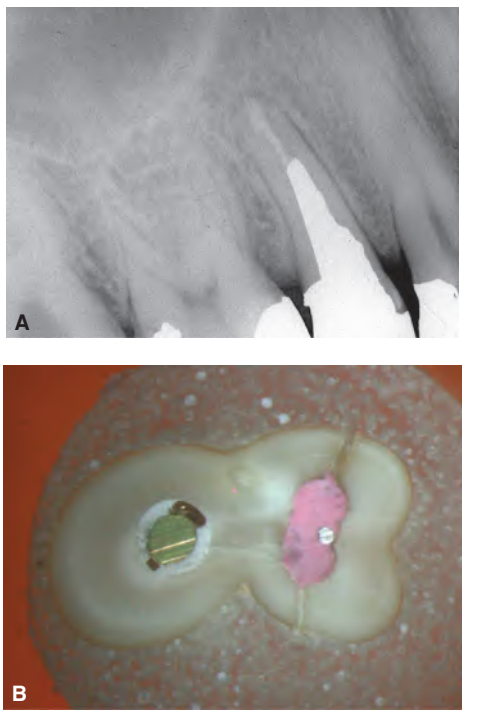

FIGURE 14-16 Thin dentin walls following excessive preparation for a post in a maxillary premolar.

Studies suggest a correlation between the type of canal preparation and susceptibility to fracture.[49,59] Therefore, the design of the NiTi instruments is an important factor when evaluating the ability of roots to resist fractures. Roots may be significantly weakened when instruments with larger tapers are used. In recent years, in vitro studies have shown that rotary NiTi endodontic instruments may create micro cracks in the dentin.[60,61,62] These small cracks produced in the canal wall, or at the root surface, coupled with preexisting cracks in the dentin (even in untreated teeth),[56,63] may be precursors to the development of incomplete and complete fractures at a later time. Dentinal cracks have also been associated with root-end preparation using ultrasonic root-end tips.[64] It is possible, these cracks could be an important cause for some failures after surgical endodontic treatment. When evaluating the stress–strain response of human dentin, Kishen,[41] found that dentinal cracks that originate from the inner walls of the root canal and placed under load, tend to progress to the outer surfaces in the buccal and lingual directions.

There are also some recent in vitro studies suggesting that excessive use of various root canal irrigation solutions and medicaments, such as sodium hypochlorite, chelating agents and calcium hydroxide, may change the quality of dentin, possibly causing an increase in dentinal wall erosion that makes the dentin more prone to cracks and fractures.[65–67]

During lateral compaction of gutta-percha, stress is generated through the dentin walls. This is due to the wedging effect of the spreader, either directly on the canal walls or indirectly through lateral compaction of the gutta-percha.[57] The design of the spreader and the metal used may also be a contributing factor to the initiation and propagation of a VRF.[68] Since the introduction of NiTi instruments for canal preparation, specially designed NiTi spreaders have been designed that are more elastic than earlier stainless steel spreaders, exerting less strain on the canal walls during lateral compaction.[69] On the other hand, any decrease in the initiation or exacerbation of a fracture is not known. Chai and Tamse[47] designed a model to analyze the fracture mechanics that occurs during the compaction of gutta-percha. After creating a dentinal crack in the root canal wall of oval and round root canals, it was shown that less load was required to propagate the preexisting crack to the outer surface of oval canals compared to round ones, confirming previous studies.[70,71]

Sathorn et al.[70,71] showed a significant correlation between root fractures and root canal anatomy related to other factors, such as stress distribution, residual dentin thickness, and types of canal preparation. Canal diameter, shape, and proximal concavity all have a significant influence on fracture susceptibility. Surprisingly, residual dentin thickness in itself does not appear to increase the susceptibility for fracture.

Restorative considerations after root canal therapy, such as post space preparation, post type and shape, hydrostatic pressure from traumatic cementation of a post, and the expansion of a post due to corrosion, are all possible additional iatrogenic factors contributing to the initiation of a VRF in endodontically treated teeth.[72] Post space preparation and post selection are of utmost importance, especially in teeth susceptible to VRFs because of specific cross-sectional contours and curvatures associated with certain roots.[42]

Recently, the use of fiber posts has been recommended because their modulus of elasticity is similar to that of dentin, allowing them to flex with the root once under stress.[73] It has been shown[74] that placement of fiber posts improved the survival rate of endodontically treated premolars. Other studies have shown a preference of fiber posts depending on the type of coronal coverage.[75,76] Fiber reinforced resin posts have also been shown to be superior to other types of posts.[77–79] Ferrari et al.[79] suggested to preserve at least one coronal wall during restoration of an endodontically treated tooth as a significant preventive measure in reducing fractures in maxillary premolars.

Endodontically treated teeth should have suitable coronal coverage after completion of treatment[13] (Figures 14-17 A,B). Proper type and design of coronal coverage with adequate ferrule may be more important than the post characteristics.[80]

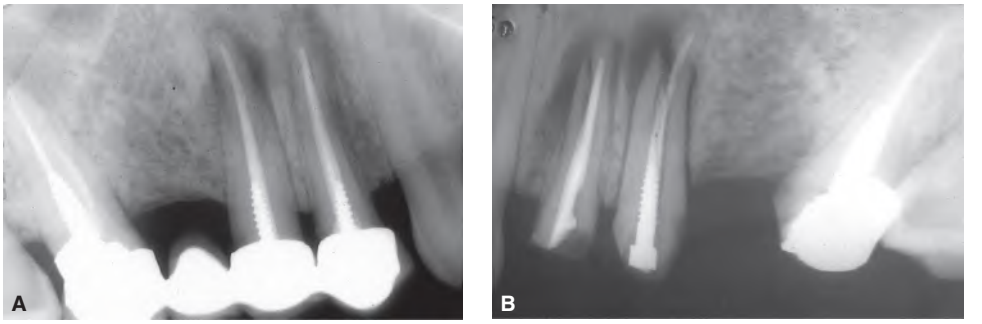

FIGURE 14-17 Endodontically treated maxillary premolars serving as abutments. ***A***. Typical periradicular radiolucencies around the two premolars. ***B***. Six months after diagnosis of VRF. Separation of root segments can be seen in both teeth.

CLINICAL MANAGEMENT

In the presence of a VRF, there is a constant ingress of bacteria from the oral cavity into the subjacent periodontal tissues and alveolar bone. Therefore, in order to prevent further breakdown of these supporting structures, extraction (or the removal of the affected root(s)) is the only option. If selective root amputation is planned, a new coronal restoration is often advised. Occasionally, the partial removal of a root can be accomplished if the VRF is limited to the apical part of the root[81,82] (Figures 14-18 and 14-19).

PREVENTION

Prevention of VRFs in endodontically treated teeth is essential; however, because of the multifactorial etiologies, this can be a difficult task. The following can reduce potential risks of VRFs:

1. Recognize the roots and teeth most susceptible to fracture.
2. During endodontic and restorative procedures preserve as much tooth structure as reasonably possible. It

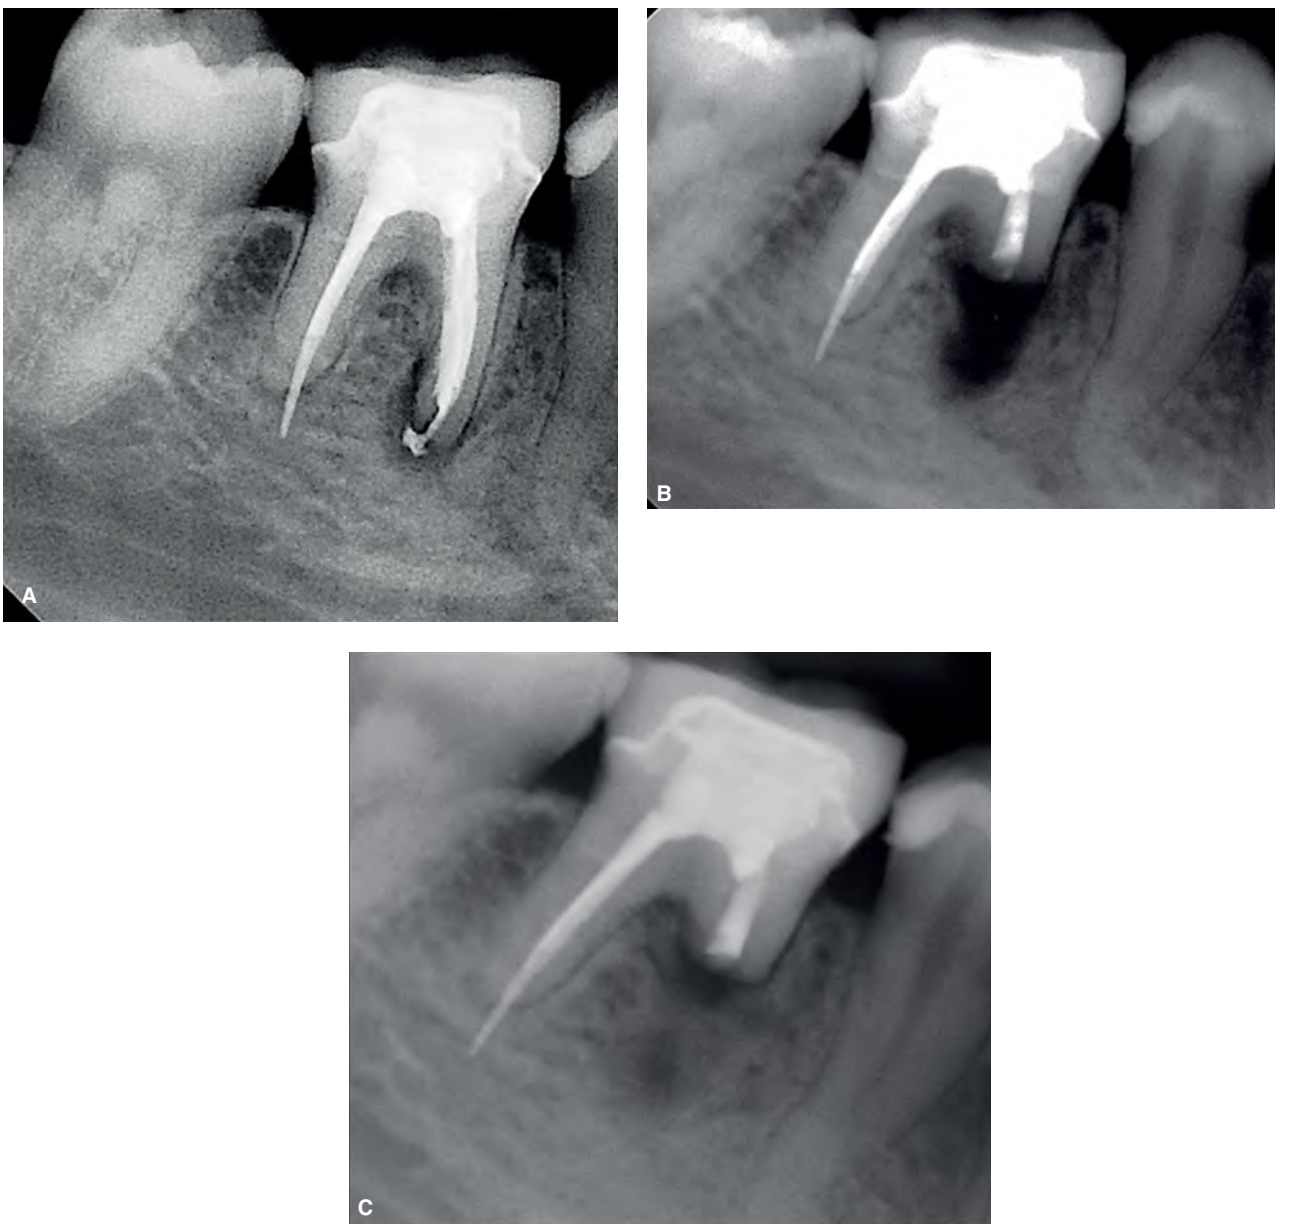

FIGURE 14-18 ***A***. Poor obturation in apical third of the mesial root in an endodontically treated mandibular molar. ***B***. During the surgery, a root fracture was noted in this region. The root was shaved until elimination of the fracture, leaving part of the root in the bone. ***C***. Twelve-month postoperative radiograph showing evidence of periapical healing. is recognized that there may be a challenging balance between the need to achieve a clean root canal system and removing only the amount of dentin necessary for the specific intra-canal procedure.

3. Compaction forces during canal obturation should be minimized. Future developments of root canal obturating methods and materials should focus on preventing excessive stresses on root dentin.
4. Posts should only be used when necessary for additional core support.
5. Metal posts should have parallel walls with passive fit and round edges.
6. Fiber reinforced resin based composite posts should be used when indicated.
7. Full coverage coronal restoration should have a ferrule margin with a vertical length of 1.5 to 2 mm on sound dentin.

SUMMARY

1. VRFs originate from the root and may progress coronally or apically. They differ from fractures in nonendodontically treated teeth tending to originate in the crown and remain either in the crown or progress apically.
2. When a combination of highly located sinus tract and a narrow deep periodontal defect is present, it is highly suggestive of a VRF.
3. There is no correlation between the location and the extent of a root fracture and their signs, symptoms, and radiographic features.
4. Evidence-based studies on the clinical and radiographic features of VRFs are lacking and difficult to perform.
5. VRFs are usually diagnosed after all endodontic and restorative procedures have been completed, and often not recognized until years later.

6. Most VRFs occur in cases where the endodontic and restorative procedures seem to have been done correctly.
7. When the diagnosis is made of a VRF, extraction should be done in a timely manner in order to minimize complications like periradicular bone loss. This bone loss may compromise subsequent implant placement. It is recognized that patient compliance can often be an issue, especially if the patient is asymptomatic.
8. Prevention of VRF is often difficult due to the multifactorial nature of the causes.

Chapter 15

Pathologic Tooth Resorption

Jens O. Andreasen, Geoffrey S. Heithersay, Leif K. Bakland

Resorption of permanent teeth has been considered an unfortunate and unpredictable phenomenon. In the past 30 years, new information about the nature of osteoclasts, and more specifically how they behave in the oral environment, has provided valuable insight into the previously mysterious osteoclastic attacks on the roots of teeth.[1] The sequence of traumatic and pathologic events that may lead to root resorption will be described; however, it may be of interest first to consider why permanent teeth normally survive without succumbing to root resorption.

THE HOMEOSTASIS PHENOMENON OF PULP AND PERIODONTAL LIGAMENT PREVENTING OSTEOCLASTIC ATTACKS

It is a surprising fact that a permanent tooth throughout life survives in an environment surrounded by alveolar bone with very active osteoblasts and osteoclasts, without being approached by any of these two cell lines, under normal conditions (Figure 15-1).[2] Several studies indicate that this immunity possibly relates to the presence of intact cementoblast and odontoblast cell layers, and perhaps also to adjacent cell layers.[2] In various animal experiments, it has been shown that physical and chemical insults to these cell layers can result in loss of protection, leading to active root resorption, both on the external root surface and in the root canal.[3,4]

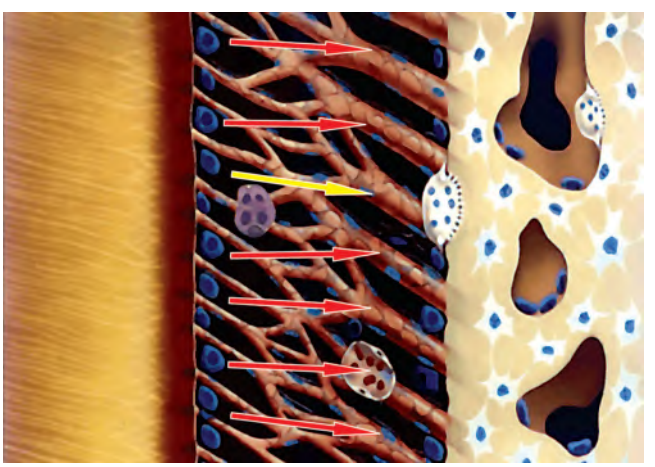

FIGURE 15-1 Antisorptive and antiosteogenesis signals released from cementoblasts, periodontal ligament cells, and Mallassez epithelial islands creating a periodontal ligament space homeostasis. (From Lindskog et al. 2007[1]; used with permission.)

To understand the full scope of tooth resorption it is necessary to understand the nature of osteoclasts, a cell with multipotential behavior that plays at least five significant roles during adolescence and adult life.

PHYSIOLOGY OF OSTEOCLASTS

Osteoclasts represent a syncytium of stimulated macrophage progenitor cells. This stimulation is under control of the Rank-Rankl/osteoprotegerin (OPG) system.[1] It serves as an on-off system for osteoclastic activity, where activation of the OPG system, and down-regulating of the RANKL system, may favor differentiation of new osteoclasts. Osteoclastic activity of the opposite OPG system may slow down or arrest the resorption (Figures 15-2 and 15-3).

MECHANISM OF HARD TISSUE DECONSTRUCTION

After an osteoclast has been formed, its role is to resorb hard tissue (i.e., cementum, dentin, enamel, or bone). The mechanism of hard tissue deconstruction is dissolution of inorganic materiel by acids associated with a breakdown of the organic structures (Figure 15-4).[1]

THE ROLE OF OSTEOCLASTS IN TOOTH ERUPTION

The osteoclast plays a key role in the shedding of primary teeth (**physiologic resorption**). At a certain stage in the development of a permanent successor and the eruption process, the coronal part of the follicle induces a rim of osteoclasts that, over a couple of years, resorb the roots of the primary predecessor and the adjacent bone.[5–7] In the case of ectopic position of a permanent tooth germ, **nonphysiologic root resorption** may affect adjacent permanent teeth.

Endodontic Implications

As to the physiologic resorption of primary teeth, it should be noted that chronic periapical inflammation from pulp necrosis in primary teeth accelerates shedding.[6,7] For example, with the ectopic eruption of a canine, resorption of the permanent lateral incisor may take place (Figure 15-5). If the lateral incisor has an intact pulp and if the ectopic eruption path changes to a normal path, or if the canine is removed,

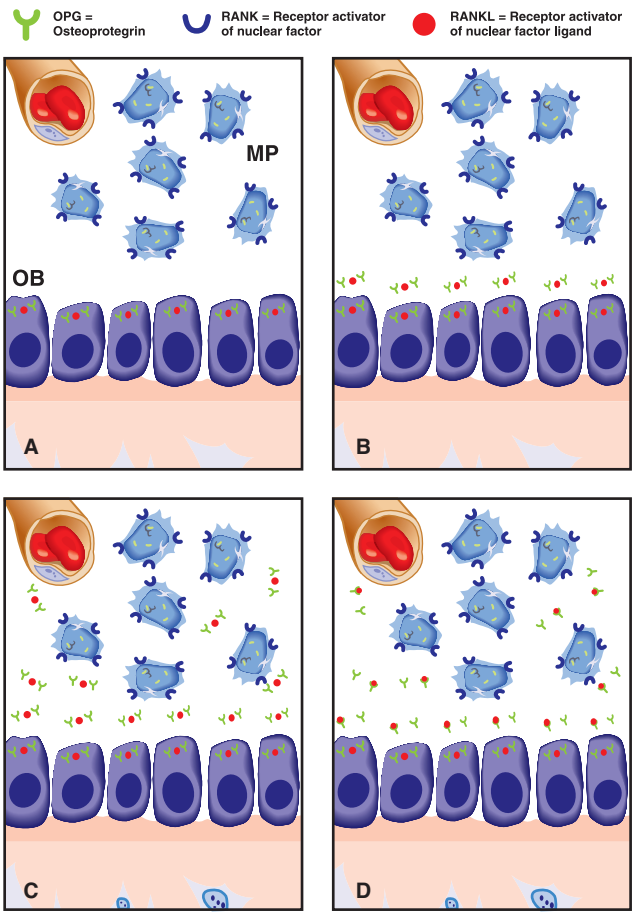

FIGURE 15-2 ***A & B.*** Activation of the OPG/RANK/RANKL system. Osteoclastogenesis is the result of differentiation of mononuclear/macrophage progenitor cells and fusion of these cells to become osteoclasts. The commitment of these cells to become osteoclasts depends on the activation of the RANK receptors on the surface of RANKL, that is produced by stroma cells and osteoblast. ***C.*** RANKL is liberated into the tissue and attaches to the receptors of the mononuclear/macrophage progenitor cells. ***D.*** Mononuclear/macrophage cells aggregate, fuse, and form osteoclasts. Proresorptive factors are hormones and cytokines such as PTH, $1,25(OH)_2D_3$, IL-1, IL-6, TNF, LIF and corticosteroids, that activate osteoblasts and stroma cells to produce RANKL and depress OPG. (From Lindskog et al. 2007[1]; used with permission.)

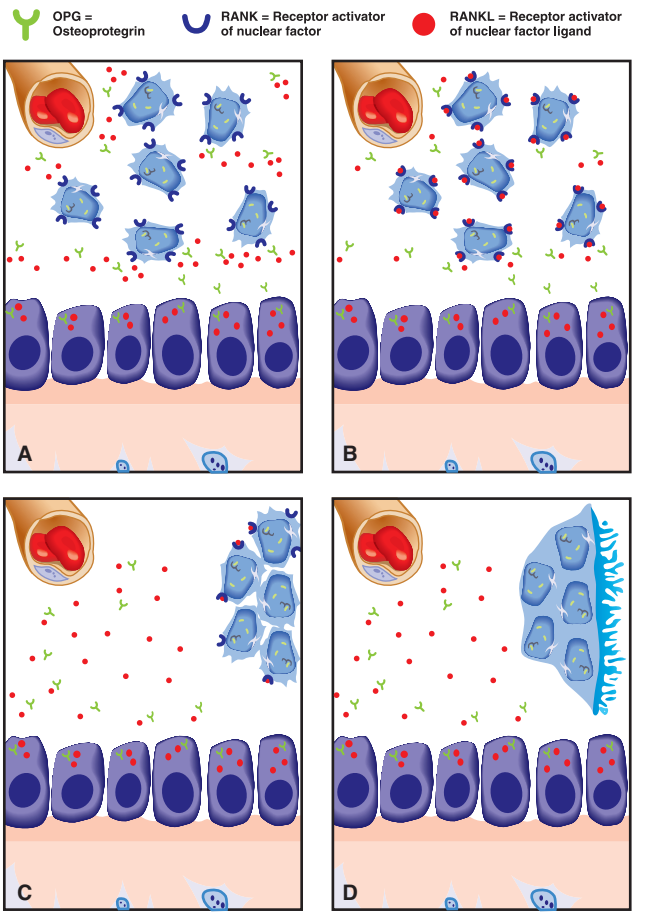

FIGURE 15-3 ***A–C.*** Inactivation of the OPG/RANK/RANKL system. Antiresorptive factors such as estrogens, calcitonin, BMP, TGF-β, IL-17, PDGF and calcium depress RANKL production by osteoblasts and stroma cells, and activate their OPG production. ***D.*** OPG binds and neutralizes RANKL, leading to a block in osteoclastogenesis and decreased survival of osteoclast. (From Lindskog et al. 2007[1]; used with permission.)

the resorption process of the lateral incisor will be arrested and the pulp can survive. Consequently, root canal treatment of such teeth is not necessary.

THE ROLE OF OSTEOCLASTS IN ALVEOLAR BONE GROWTH AND MAINTENANCE

The alveolar bone structure is entirely dependent on a controlled symbiosis between osteoblastic and osteoclastic activity, whereby a continuous turnover of bone takes place throughout life. Table 15-1 shows the stimulatory and inhibitory factors that are associated with osteoclastic activity. If there is a lack of equilibrium in the activities of these two cell types, either osteoporosis or osteosclerosis will occur.[1,6]

Endodontic Implications

In case of ankylosis-related (replacement) resorption of a tooth (external root surface or internal root canal), the tooth becomes a part of the general bone remodelling process and continuous replacement of the root with bone takes place. Internal (root canal) ankylosis-related resorption, leading to infraocclusion, can be arrested by pulp extirpation and root canal filling. In case of external (root surface) ankylosis-related resorption, the condition can, as a rule, not be successfully treated today, at least if the ankylosis has reached a nonreversible stage. Endodontic interventions and placement of calcium hydroxide may slow, but not arrest, the ankylosis process. Intervention also carries the risk of accelerating the process.[8]

OSTEOCLASTS AS MEMBERS OF THE REPAIR TEAM AFTER INJURY

In revascularization situations in bone and teeth, the osteoclast and ingrowing vessels work jointly together as part of the wound healing module; the osteoclast having the role

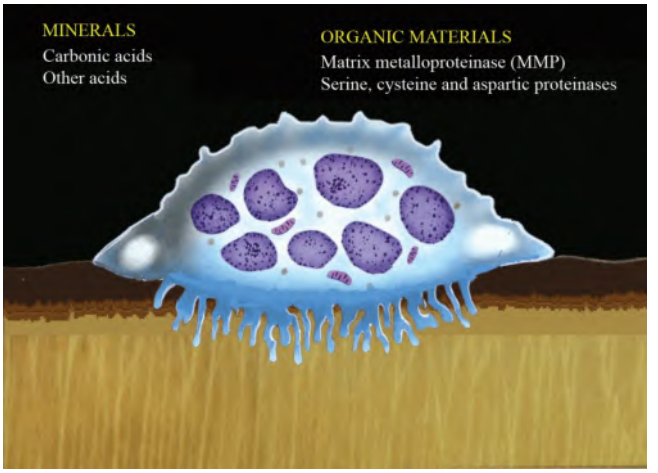

FIGURE 15-4 Physiology of an osteoclast: Removal of inorganic material, such as minerals, by acids (proton pump) and organic material by matrix metalloproteinases, such as MMPs, serine, cysteine, and aspartic proteases.

FIGURE 15-5 An example of root resorption on a maxillary lateral incisor from the ectopic eruption of the adjacent canine.

of creating space for the new vascular tissue to grow into narrow spaces (and the root canal).[2] This is later reversed by apposition of new hard tissue (cementum or bone). This phenomenon has been **termed transient apical breakdown, transient marginal breakdown, transient ankylosis, and transient internal surface resorption** according to the location of the process[2,9] (Figure 15-6). These events are frequently seen after luxation injuries and root fractures with coronal displacement, where avascular, but sterile, pulp tissue is replaced in conjunction with the revascularization process.

Endodontic Implications

It is very important to consider that the radiographic signs of osteoclastic activity are not always signs of ongoing infection, but may represent an actual healing process and therefore only requires monitoring.

OSTEOCLASTS AS DEFENSE CELLS AGAINST MICROBIAL INVASION

In the periodontal ligament (PDL) area, a constant battle takes place between microbial invasion in the cervical area, due to plaque accumulation and periodontal pocket formation, and in the apical area, due to microbial accumulation in the root canal. In both situations, a series of osteoclast-promoting signals are released by microorganisms and inflammatory cells, stimulating osteoclast generation and accelerating osteoclast activities[1,10] (Figure 15-7). This typically results, after some time, in marginal or periapical bone loss. Likewise, if a combined injury has happened to the root surface and the pulp space has become infected, the osteoclast may get a dual stimulation to resorb the root surface. In fact, the first tissue damage to the root surface initiates resorption, and after penetration of the

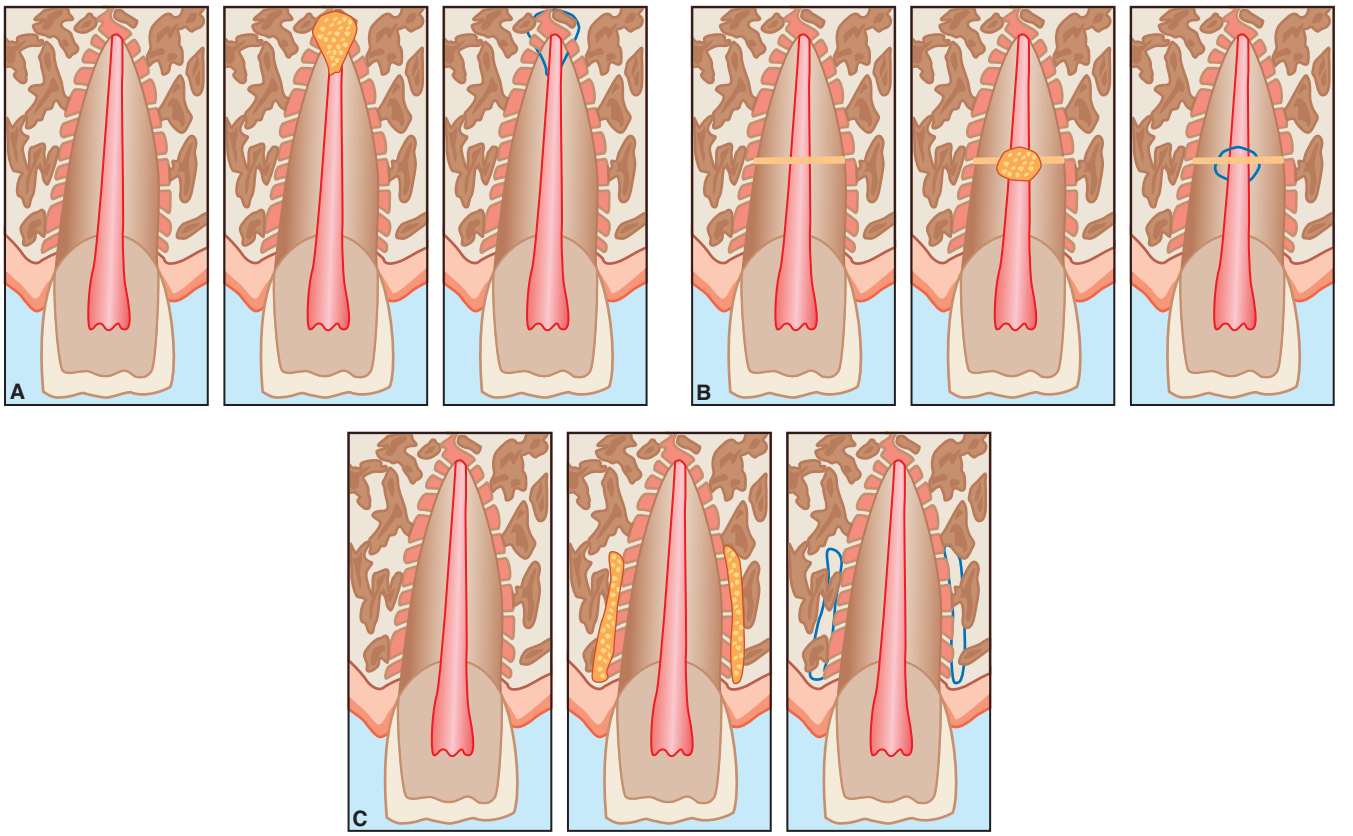

FIGURE 15-6 Examples of various transient healing events. ***A.*** Transient apical breakdown. ***B.*** Transient internal surface resorption. ***C.*** Transient marginal breakdown.

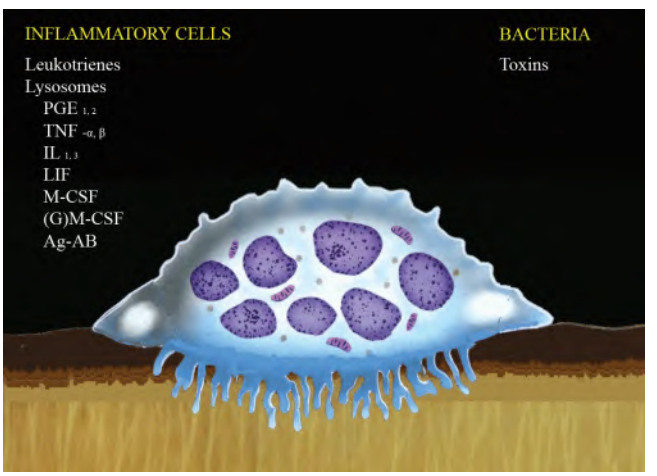

FIGURE 15-7 Osteoclast activators related to bacteria in the root canal and dentinal tubules.

cementum, the osteoclast can be triggered by microbial toxins from the root canal (if present in the canal), through the dentinal tubules, to continue to resorb dentin (see later).

Endodontic Implications

When radiographic evidence of apical or marginal breakdown, or external root resorption, is seen, infection-related root resorption caused by necrotic and infected pulp tissue should be suspected. Endodontic intervention in such cases is indicated and most beneficial.

METHODS FOR CONTROLLING OSTEOCLAST ACTIVITY

A series of osteoclast activators have been identified and all are capable of initiating and activating osteoclast activity.[10] In Figure 15-8, some of the agents that have been used to try to interfere with, or inactivate these triggers of, root resorption are shown.[2,11] These agents, whether administered systemically or topically (in the root canal or on the root surface), have had either no, or a very limited effect on the osteoclastic activity on resorption-prone replanted teeth.[11] The most promising medication appears to be tetracycline and cortisone combinations (e.g., Ledermix®, Lederle Pharmaceuticals, Wolfratshausen, Germany) topically applied in the root canal. In a detailed experimental study in dogs, it was found that the cortisone part of this combination (Ledermix®) had the most significant influence on reducing the extent of the osteoclast attack on the root[11] (Figure 15-9).

An alternative chemical way of arresting or preventing osteoclastic attack on the root surface is to change the dentin environment from a neutral pH to a basic pH. This may

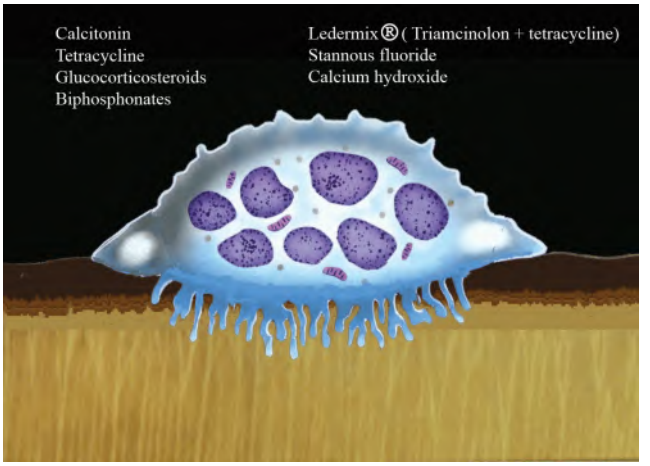

FIGURE 15-8 Example of various medicaments used to influence osteoclast activity.

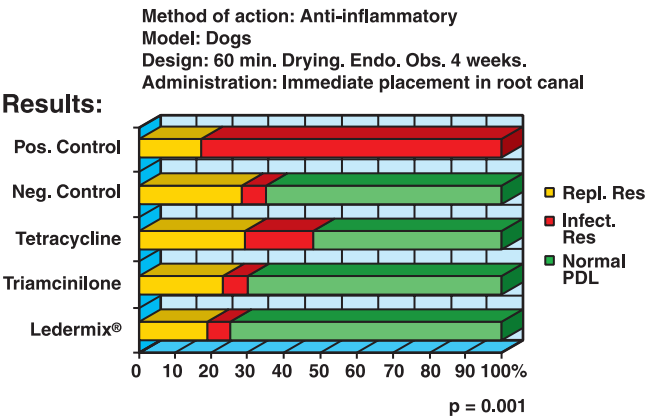

FIGURE 15-9 Effect of Ledermix® (triamcinilone and tetracycline) on PDL healing after replantation. (From Chen et al. 2008[11]; used with permission.)

interfere with the osteoclast's mineral dissolution.[1] Such a change has been shown in several in vitro and in vivo experiments to be possible by an intracanal dressing of calcium hydroxide.[8] In these cases, the pH of the external surface of the dentin reached a level of 9–10.[12,13] In one clinical study, there was a tendency for an elevated pH to result in a slightly higher likelihood of arresting external root resorption.[8]

Elimination of Microorganisms Responsible for Infection Related Resorption

Only one clinical study has investigated the use of antibiotics for infection-related resorption and it appears that short term use of antibiotics (a mixture of neomycin and bacitracin) has almost the same capacity as short term use of calcium hydroxide in reducing the extent of infection-related resorption in replanted human teeth[8] (Figure 15-10). Due to possible side-effects of antibiotics (e.g., allergy) it seems inappropriate today to use antibiotics for these purposes. There might be an indication for disinfection of the root

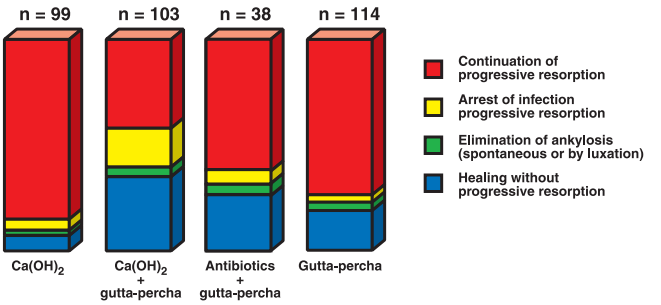

FIGURE 15-10 Periodontal ligament healing related to four types of endodontic treatment of 354 avulsed and replanted teeth. Efficacy of various endodontic procedures to reduce progressive root resorption after replantation in a clinical study of 354 replanted human teeth. (From Andreasen et al. 2015[8]; used with permission.)

canal and dentin with antibiotics in cases where pulp revascularization is intended. Calcium hydroxide, however, is not able in all cases to eliminate all microorganisms in the root canal that seems to be necessary for successful revascularization.

TYPES OF ROOT RESORPTION

The following short systematic synopsis will present the various root resorption types and how they relate to endodontic practice. The reader is also referred to a series of survey articles dealing with diagnosis and treatment of root resorption.[4,14–21]

REPAIR-RELATED RESORPTION (EXTERNAL SURFACE RESORPTION)

Etiology

Repair-related resorption is a part of the healing response to chronic and/or acute tissue injury in the PDL, and it affects the cells adjacent to the root surface. The typical situation where **acute transient** repair-related resorption occurs appears to be following luxation injuries such as concussion, subluxation, and lateral luxation. It can also occur following intrusion and replantation of avulsed teeth. In such cases, it may affect all parts of a root; in root fractures it is observed adjacent to the fracture lines. This type of resorption also occurs frequently after **chronic** injury affecting the PDL such as that associated with orthodontic treatment, traumatic occlusion and pressure from developing cysts/apical granulomas and ectopically erupting teeth. When the trauma and/or pressure is discontinued, spontaneous healing takes place, that is a typical feature of repair-related resorption.[2]

Pathogenesis

Injured tissues, adjacent to the root and surface cementum, are removed by macrophages and osteoclasts. These events

take 2–4 weeks. Repair is accomplished by progenitor cells from the adjacent PDL, that form new cementum and insertion of PDL fibers[2] (Figure 15-11A–C).

Radiographic Findings

After 2–4 weeks, a localized widening of the PDL space can be seen, due to loss of surface layers of the cementum and the bony alveolar socket. At this time, the radiographic images are similar to infection-related root surface resorption. Subsequently though, healing takes place with reformation of the PDL and deposition of hard tissues. Radiographically, slight cavitations may be seen on the root surface.[16,22,23] However, most repair-related root surface resorptions have such minimal size that they cannot be recognized radiographically.[24,25]

Endodontic Implications

Due to their nature (being primarily related to a periodontal injury), endodontic intervention is not indicated for teeth with this type of root resorption. However, a diagnostic problem may exist since the initial stage of infection-related root resorption has an identical beginning.

Treatment

If traumatic and/or pressure factors are eliminated, there is almost 100% repair. If the root apex has been resorbed, increased mobility may become a problem if the root is shorter than 9–10 mm.[26,27]

EXTERNAL INFECTION-RELATED RESORPTION (INFLAMMATORY ROOT RESORPTION)

Etiology

Infection-related resorption was described in 1965 in a clinical and histological study of avulsed, replanted teeth.[22,23] Such trauma represents a combined injury to the pulp and PDL, in which microorganisms, primarily located in the pulp spaces and in the dentinal tubules, trigger osteoclastic activity on the root surface and adjacent alveolar bone. It can affect all parts of the root and is typically diagnosed 2–4 weeks after injury. The resorption is a rapidly progressing process that may result in total resorption of the root within a few months. It is almost exclusively related to acute trauma and is especially common after intrusion injuries and replantation of avulsed teeth.[16]

Pathogenesis

In the event the initial resorption has penetrated cementum and exposed dentinal tubules, toxins from microorganisms present in the infected root canal and/or the dentinal tubules can diffuse via the exposed tubules to the PDL[2] (Figure 15-12A–C). This results in continuation of the osteoclastic process and associated inflammation in the PDL leading to resorption of adjacent alveolar bone. The process is progressive and root dentin is resorbed until the root canal is exposed. If however, microorganisms are eliminated from the root canal and dentinal tubules by endodontic therapy, the resorptive process will be arrested.[27–30] The resorption cavity will then be filled in with cementum or bone, according to the type of vital tissue found next to the resorption site (PDL or bone marrow-derived tissue).

Clinical Findings

A tooth undergoing infection-related root resorption will have increased mobility and a dull percussion tone. Sometimes the tooth may be extruded. Sensibility testing gives no response and sometimes a sinus tract develops.

Radiographic Findings

Infection-related resorption is typically diagnosed 2–4 weeks after injury and appears as progressive cavitations involving the root and adjacent alveolar bone. The resorption is a rapidly progressing event that may result in total loss of root

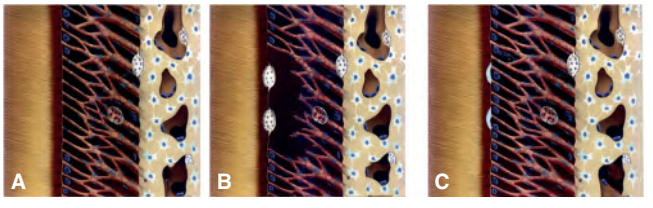

FIGURE 15-11 Pathogenesis of repair-related resorption (surface resorption): healing following minor injury to the periodontal ligament. The injury site is resorbed by macrophages and osteoclasts. The osteoclasts have exposed factors and other soluble molecules in dentin such as IGF-1, TGF-β, PDGF, BMPs, FGF-2, and A4 (amelogenin gene splice products). These molecules may serve as stimulators for cementoblasts. Subsequent repair takes place by the formation of new cementum and insertion of Sharpey's fibers. (From Andreasen and Lövschall, 2007[2]; used with permission.)

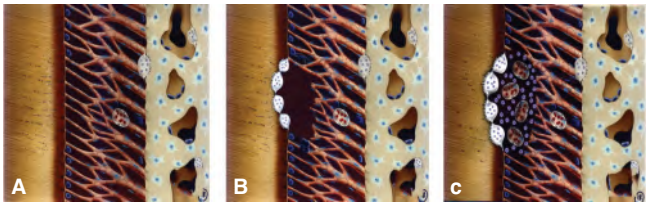

FIGURE 15-12 Pathogenesis of infection-related resorption (inflammatory resorption): Response to moderate or extensive injury to the periodontal ligament and associated infection in the pulp and/or dentinal tubules. The initial injury to the root surface triggers a macrophage and osteoclast attack on the root surface. Osteoclasts are exposed to toxins from microorganisms located in the root canal and dentinal tubules, such as LPS (lipopolysaccharide) MDP (muramyl dipeptide) and LTA (lipoteichoic acid). These toxins serve as direct activators of osteoclastic activity. The resorption process is accelerated and granulation tissue ultimately invades the root canal. (From Andreasen & Lövschall, 2007[2]; used with permission.)

structure after only a few months, particularly in young children (Figure 15-13A–D).

Endodontic Implications

This type of resorption represents a combined periodontal and pulpal injury and requires immediate endodontic treatment to control or remove the osteoclast promoting factors (microbial toxins from the root canal system).

Treatment

The treatment goal is to remove or destroy microorganisms in the root canal and dentinal tubules. This will allow healing to take place in the entire periradicular space (root surface, PDL, and adjacent alveolar bone). Microorganisms are effectively destroyed by using $Ca(OH)_2$ as an intracanal medicament. A side effect, however, of using $Ca(OH)_2$ for a long term (>30 days) is a weakening of the root structure in **immature** teeth that can lead to cervical root fracture. This is a risk that has been found to be as high as 66%–72% in two clinical studies.[30,31] In **mature** teeth, the problem apparently does not exist.[30] The endodontic technique, therefore, should be related to the maturity of the tooth.

Mature Teeth

Replantation of avulsed, fully developed, teeth needs to include prophylactic extirpation of the pulp to prevent infection-related resorption. Biomechanical canal preparation should include the use of sodium hypochlorite and $Ca(OH)_2$. The latter medication can be expected to accomplish its task of disinfection of the canal in 2–3 weeks.

Immature Teeth

In a tooth where the root is not fully developed, and where the pulp becomes infected, the apical opening is often large and thus, placing a root filling can be difficult. In such cases, apexification procedures, using calcium hydroxide, have been performed with good success. The disadvantage of using calcium hydroxide for apexification is that it takes many months to obtain enough of an apical barrier to allow placement of a root canal filling. Additionally, and as stated earlier, long-term use of $Ca(OH)_2$ may weaken dentin, possibly by dissolving its organic component, and thereby resulting in cervical root fracture from slight impacts or even normal use.[31,32] By using mineral trioxide aggregate (MTA) and similar materials as a physical barrier apically, a root canal filling can be placed immediately without waiting for a biological response (Figure 15-14A–H). Minimizing exposure of immature root dentin to calcium hydroxide, may result in less damage to the dentin.[33,34]

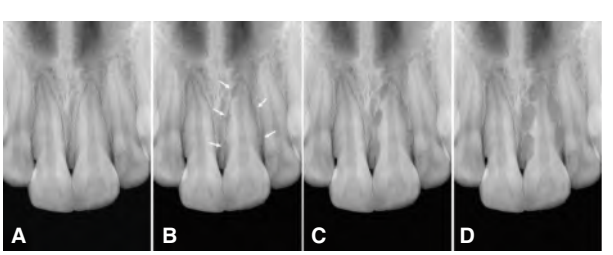

FIGURE 15-13 Progression of infection-related root resorption. If left untreated, the root will resorb rapidly, particularly in children. (From Andreasen et al. 2011[58]; used with permission.)

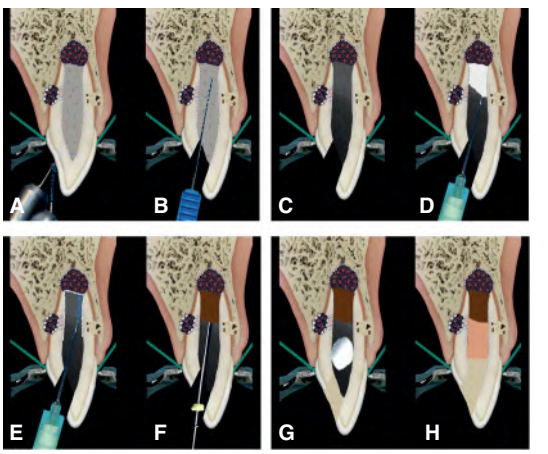

FIGURE 15-14 Combined calcium hydroxide and MTA treatment of a traumatized permanent tooth with immature root formation. ***A.*** The tooth is isolated with dental dam, the crown disinfected, and an access cavity to the root canal prepared. ***B.*** Extirpation of necrotic pulp tissue is done to a level apically, where fresh bleeding from healthy tissue is encountered. This can be anywhere from several millimeters from the apex to flush with the apical foramen. ***C.*** Root canal preparation in developing teeth requires a conservative approach, so as to preserve as much root dentin as possible. Hence minimal canal shaping is appropriate. ***D.*** Disinfection of the root canal with sodium hypochlorite is followed by short-term (approx. 2–4 weeks) interim dressing with calcium hydroxide. The use of calcium hydroxide allows acceptable disinfection of the root canal system and provides a dry root canal, free of seepage of apical exudates. The coronal access opening must be sealed with a dependable temporary restoration. ***E.*** At the next visit, the calcium hydroxide is removed and the canal is thoroughly irrigated with saline or sodium hypochlorite to obtain a debris-free canal. Small increments of the MTA-water mixture are introduced into the canal and gently condensed. Length can be controlled using a rubber stopper on a plugger. No harm is done, however, with slight overfilling. ***F.*** When properly condensed, the apical MTA plug should be at least 4 mm thick. The entire canal can be filled with MTA (to the cervical level), or the coronal part of the canal can later be filled with gutta-percha and sealer. ***G.*** To allow setting, a moistened (water) cotton pellet is placed in the access cavity that is then sealed with a temporary filling material. Once set (usually within 4–6 hours), the canal can be conventionally filled. ***H.*** The temporary material and cotton pellet are removed, the apical plug is checked for setting hardness; it should not be vigorously probed, as the material can break. The canal is then irrigated, dried, and filled, followed by a bonded coronal composite restoration. (From Andreasen et al. 2011[58]; used with permission.)

Prognosis

Dentin lost through resorption cannot be replaced with new dentin, at least with today's treatment approaches. Healing occurs after arresting the resorption process and with either a replacement layer of new cementum or bone and establishment of new PDL.[35–37]

EXTERNAL ANKYLOSIS-RELATED RESORPTION (REPLACEMENT RESORPTION)

Ankylosis-related PDL complications represent a sequel to a defect in, or injury to, the PDL cells, including the cell layer next to the cementum.[2] The most frequent cause appears to be acute trauma[2] (severe luxations such as lateral luxations, intrusions, and replantation of avulsed teeth). In those situations, the homeostasis of the PDL has been reduced. This leads to healing events taking place from the bony alveolus resulting in creation of a bony bridge between the socket wall and the root surface (Figure 15-15A–C).

In situations of moderately sized injuries (1–4 mm^2) an initial ankylosis forms that can be reversible. If the tooth is allowed functional mobility such as by the use of a nonrigid splint, or no splinting, small areas of resorption can later be replaced with new cementum and PDL attachment (transient ankylosis).[38–42] In more extensive injuries (>4 mm^2), a progressive ankylosis takes place. This implies that the tooth becomes an integral part of the bone remodeling system. The entire process includes osteoclastic resorption dependent upon bone remodeling processes, parathyroid hormone induced resorption, remodeling due to function, and resorption due to microorganisms present in the gingival area and/or the root canal.[2] All of these processes are very active in children and lead to gradual infraocclusion and arrested development of the alveolar process.[43] As a result, this combination of resorption processes leads to loss of ankylosed teeth within 1–5 years. In older individuals, ankylosis-related resorption is significantly slower and often allows a tooth to function for much longer periods of time (i.e., 5–20 years), and the position of the tooth in the arch remains the same (similar to a dental implant).[44]

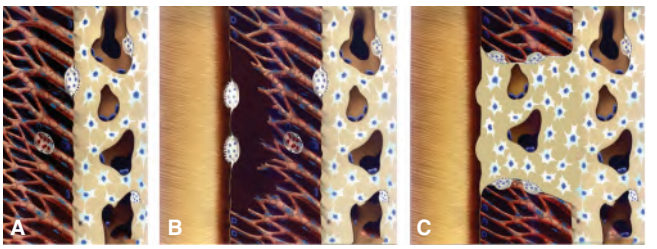

FIGURE 15-15 Pathogenesis of ankylosis-related resorption (replacement resorption): Response to extensive injury to the periodontal ligament. The osteoclasts have been exposed to stimulating factors and other soluble molecules in dentin such as IGF-1, TGF-β, PDGF, BMPs, FGF-2, and A4 (amelogenin gene splice products). These molecules may serve as stimulators for cementoblasts and/or osteoblasts. Ankylosis is formed because healing occurs almost exclusively by cells from the alveolar wall. (From Andreasen & Lövschall, 2007[2]; used with permission.)

Clinical Findings

A tooth undergoing ankylosis-related root resorption appears very firm in its socket, eliciting a high metallic sound on percussion. This can be demonstrated after 4–6 weeks post-trauma.[42,45]

Radiographic Findings

The ankylosis-related resorption process is in response to extensive damage to the layer of the PDL closest to the root surface. Because of the normal remodeling characteristic of bone, the root structure is gradually replaced by bone (Figure 15-16A–D). Ankylosis is a frequent occurrence after intrusion and replantation of avulsed teeth. It can usually be diagnosed radiographically within 2 months after injury and clinically, within 1 month by a high percussion sound.[42,45]

Endodontic Implications

Endodontic therapy cannot arrest progressive ankylosis-related resorption. If the pulp is vital, endodontic treatment is not indicated. In the case of an associated pulp necrosis, the treatment described for infection-related root resorption is applicable, but it will only address the related infection-related situation.[8]

Treatment

In children and adolescents, an ankylosed tooth will fail to erupt and will gradually be in infraposition with respect to the adjacent teeth. The younger the age, the more pronounced would be the infraposition (Figure 15-17A, B). Presently, the following are possible treatment options: (1) Decoronation (in order to maintain and augment the alveolar process); (2) luxation of the tooth (breaking of ankylosis sites if they are minimal); (3) extraction with ridge augmentation in preparation for later implant placement; (4) extraction and prosthetic bridge; (5) distraction osteogenesis; (6) prosthetic elongation; and (7) extraction and transplantation of a premolar tooth.

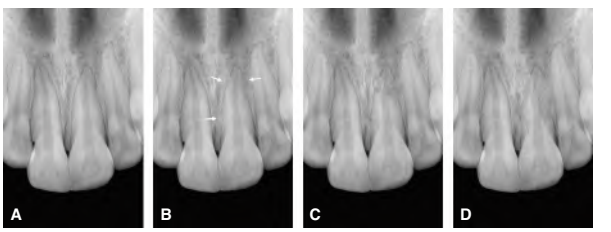

FIGURE 15-16 Progression of ankylosis-related resorption (replacement resorption). (From Andreasen et al. 2011[58]; used with permission.)

FIGURE 15-17 Infrapositioned maxillary central incisor initially intruded at the age of 9. ***A.*** Clinical photograph shows position of tooth at age 13. ***B.*** Radiograph shows extent of ankylosis-related resorption. The pulp retained vitality, that is not unusual in teeth with ankylosis-related resorption.

Decoronation treatment is very suitable in children and adolescence where significant remaining alveolar growth is expected. The procedure involves removal of the crown of the tooth (leaving what remains of the root) allowing continued vertical growth of the alveolus.[46–49] If the crown is surgically removed slightly below the cervical bone level and any root filling or pulp tissue removed, the reformation of the interdental fibers, dento-periosteal fibers and the periosteum will lead to a normalization of the bone level.[48] Due to the ankylosis-related resorption of the remaining root with bone replacement, the alveolar structure will be optimal for implants placed later when growth has been completed.[46–49]

EXTERNAL SPONTANEOUS ANKYLOSIS-RELATED RESORPTION

Etiology

This type of ankylosis may affect one or several primary or permanent teeth. The etiology is presently not known. It is suspected to be related to instability of the RANK-RANKL-OPG system[2] (Figure 15-18A, B).

Pathogenesis

This ankylosis-related resorption process leads to infraposition of the involved teeth in young individuals and in all cases leads to gradual substitution of the root substance with bone.

Clinical Findings

Primary dentition: This type of resorption especially affects primary molars and the mandibular second primary molar is most prone to be involved (20%). The ankylosis leads to gradual infraposition and tilting of neighboring teeth.[50]

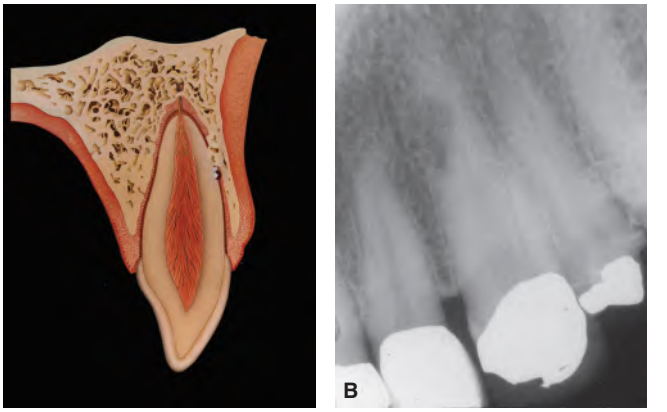

FIGURE 15-18 External spontaneous ankylosis resorption. ***A.*** Graphic illustration. ***B.*** Clinical example.

Permanent dentition: The first and second permanent molars are most prone to show this type of resorption. These molars will, in young individuals, show a gradual infraposition and the percussion tone is high and metallic.[6,7]

Radiographic Findings

Primary molars: The ankylosis process starts in the interdental area and gradually spreads to the remaining part of the root.

Permanent molars: The first molars will, in most cases, show replacement resorption starting in the intraradicular area. From this location it will gradually spread to the remaining part of the root (Figure 15-19). Semi-impacted or impacted third molars will, only in rare cases, show ankylosis.

Endodontic Implications

This is primarily a PDL problem and endodontic intervention may actually aggravate the aggressive nature of the ankylosis process.

Treatment

Primary dentition: If diagnosed early, decoronation is a reasonable option. If diagnosed late in adolescence, the crown may be rebuilt to prevent over-eruption of the antagonist.

Permanent dentition: If diagnosed in early adolescence, the ankylosed tooth should be extracted. At later stages, the crown may be rebuilt with a restoration to achieve a functional occlusal level.

Pathogenesis

Any permanent tooth may become involved and the process takes place over 10–20 years. It usually affects a single group of teeth (premolars, molars) and gradually affects other groups of teeth.

INVASIVE CERVICAL RESORPTION

Etiology

While the etiology of invasive cervical resorption remains obscure, a defect in the cementoblast layer seems to be a prerequisite, coupled with a breakdown of the RANK-RANKL-OPG system.[1] In a large clinical study of 222 patients (total of 257 teeth) with invasive cervical resorption, several potential predisposing factors were identified.[51] The most frequently identified single factor was orthodontic treatment (21.2%), followed by trauma (14%). Often there was a combination of factors, for example, trauma and bleaching (7.7%), whereas bleaching as a sole factor was found in 4.5% of the patients studied.[52]

Pathogenesis

Hyperplastic resorptive tissue, apparently derived from precursor PDL cells, invade the hard tissues of the tooth in a destructive, invasive, and apparently uncontrolled fashion akin to the nature of some fibro-osseous lesions. Initially, the resorptive tissue is fibrovascular in nature (Figure 15-20) but as the resorptive process extends more deeply into radicular root structure, it becomes fibro-osseous in character, as shown in Figure 15-21. Ectopic bone-like deposits can be observed both within the lesion itself and at the interface with resorbed dentin. In addition, the resorptive tissue creates a series of channels that encircle the root canal, infiltrate radicular dentin, and also interconnect with the PDL at other locations on the root surface.[53,54]

Clinical Findings

This relatively uncommon type of external root resorption may, on occasion, show no external signs, nor elicit any clinical symptoms, and may be diagnosed primarily as the result of a chance radiographic finding. An example is shown in Figure 15-22A,B. The initial clinically observable sign may be a slight reddish defect near the gingival margin of an affected tooth, or a pink discoloration of coronal tooth structure (Figure 15-23A). Ultimately, with extensive invasive cervical resorptions, there may be enamel cavitation (Figure 15-24A). The pulp remains intact until late in the process, apparently protected from the resorptive tissue by a layer of predentin and dentin

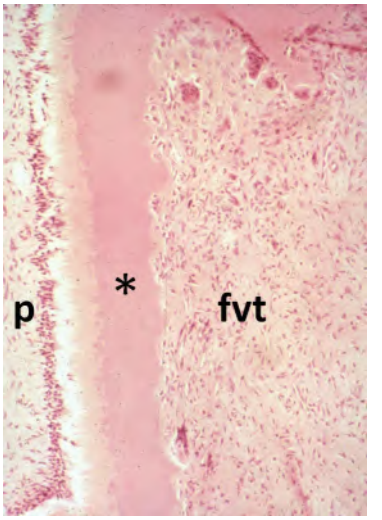

FIGURE 15-20 Histologic appearance of an incisor tooth with the first stage of invasive cervical resorption. An intact layer of predentin and dentin (*) separates the pulp (p) from the mass of fibro-vascular resorptive tissue (fvt) that contain both mononucleated and multinucleated clastic cells. (Reproduced from Heithersay GS. Quintessence Int. 1999;30:27–37 with permission, Quintessence Publishing.)

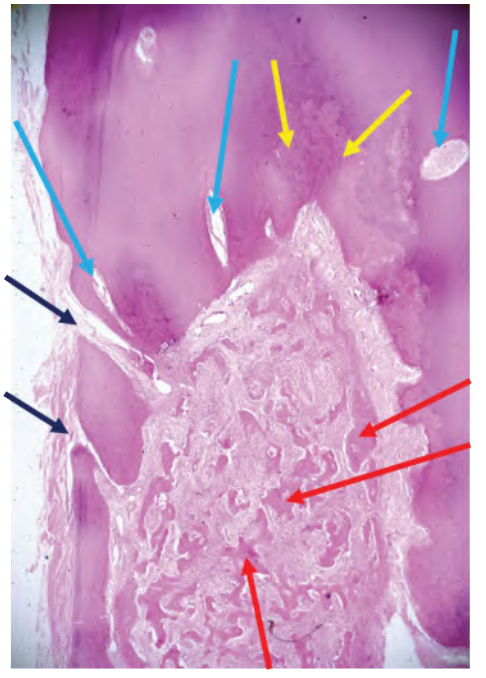

FIGURE 15-21 Histological appearance of an extensive invasive cervical resorption with radicular extensions. The resorptive tissue within the resorption cavity is fibro-osseous in character (red arrows) and there are bone like deposits at an interface with resorbed dentin, akin to replacement resorption (yellow arrows). There are also intercommunicating channels with the periodontal ligament (black arrows) and deeply penetrating small channels within the residual dentin (blue arrows). (Reproduced from Heithersay GS. Quintessence 1999;30:27–37, with permission, Quintessence Publishing.)

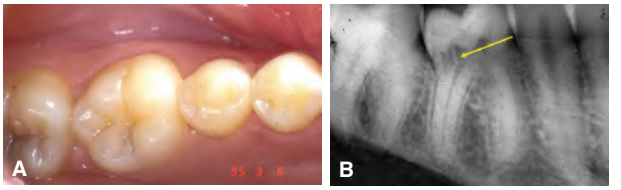

FIGURE 15-22 ***A.*** Crown of a mandibular first molar with no external signs of resorption. ***B.*** Radiograph of the tooth pictured in ***A*** showing an irregular radiolucency extending from the distal cervical region into the crown and adjacent to the pulp space but separated by a radiopaque line (yellow arrow).

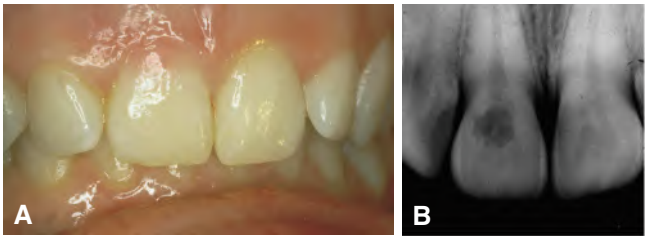

FIGURE 15-23 ***A.*** The maxillary right central incisor of a 21-year-old female shows a pink discoloration of the cervical third of the crown. ***B.*** A radiograph of the central incisor shows an irregular radiolucency overlying the root canal outline.

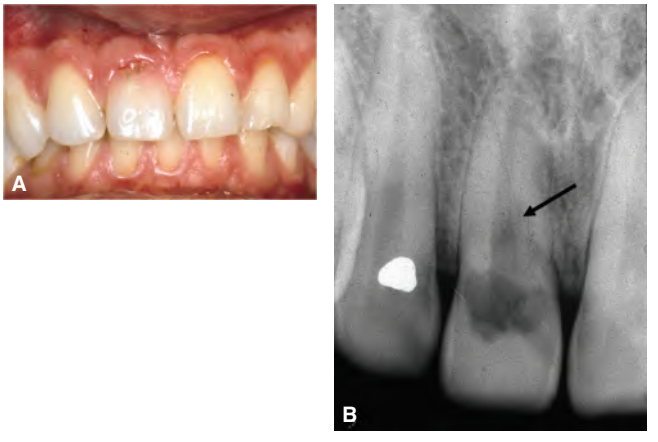

FIGURE 15-24 ***A.*** Cavitation of labial enamel with exposure of underlying resorptive tissue can be observed in the crown of the maxillary right central incisor, that also shows a pink discoloration. ***B.*** Radiograph of the tooth pictured in ***A*** shows an irregular radiolucency in the tooth crown and extending into the coronal third of the root (arrow). The pulp space is demarcated from the image of the resorptive lesion by a radio-opaque line. (Reproduced from Heithersay GS. Quintessence Int. 1999;30:27–37; used with permission from Quintessence Publishing.)

(Figure 15-20). Generally, the affected tooth remains asymptomatic unless there is superimposed infection late in the progression of the resorptive process, that will likely lead to pulpal or periodontal symptoms.[52,53]

Radiographic Findings

The periapical radiographic features will vary depending on the location and extent of the resorptive process. Initially, there may be a slight radiolucency at the cervical region but with invasion of the coronal tooth structure, the image may have an irregular appearance overlying the outline of the root canal (Figure 15-23B). A characteristic radio-opaque line in some radiographs demarcates the intact predentin–dentin protective layer from the irregular image of the invading resorptive tissue in an extensive process (Figure 15-24B) and in a mandibular molar with outwardly a normal clinical appearance[52,53] (Figure 15-22B,G,H).

Cone-beam computed tomography can be used to advantage in more extensive cases of invasive cervical resorption to identify the location of the main portal of entry of the resorptive tissue and the extent of the resorptive process (Figure 15-25A,B). This enhanced imaging can be important in treatment planning where alternative forms of management are to be considered (e.g., implant therapy). For more details, see Chapter 10, Imaging Interpretation. A clinical classification, largely based on radiographic evidence, developed in 1999 as an aid to diagnosis and treatment planning, is shown in Figure 15-26.[51]

Endodontic Implications

In class 1 and class 2 invasive cervical resorptions, the pulp is generally not involved in what is essentially a periodontally derived external resorptive process does not indicate endodontic therapy. It will only be indicated if the resorption has extended to the pulp. In the more extensive class 3 and class 4 invasive cervical resorptions, the pulp will ultimately be encroached and in the treatment of class 3 cases endodontic therapy is recommended as follows.

Treatment

Two treatment modalities have been reported.[54] The first and frequently employed method involves periodontal flap reflection, curettage of the resorptive tissue, and restoration of the defect with a composite resin or glass ionomer cement. An example of this approach is shown in Figure 15-27A–D.

The second treatment method involves the topical application of a 90% aqueous solution of trichloracetic acid (TCA) to affect a coagulation necrosis of the highly active and invasive resorptive tissue, followed by curettage, endodontic treatment, if indicated, and restoration.[54] An example of this treatment modality carried out in the class 2 invasive cervical resorption case illustrated previously in Figure 15-23A,B, is shown in Figure 15-28A,B. Five year clinical and radiographic follow-up images are shown in Figure 15-28C,D.

In class 3 cases, the coronal extension of the resorption is treated with the topical application of TCA as mentioned previously, followed by prophylactic endodontic therapy to facilitate access for treatment of the resorptive tissue encircling the root canal. The further careful topical use of TCA to this region followed by curettage should not only inactivate this encircling resorptive tissue but also aid in controlling further

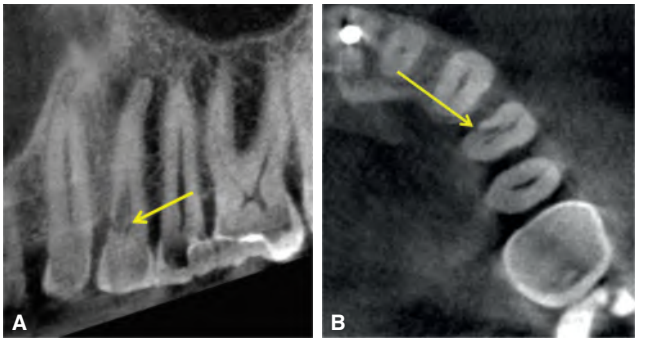

FIGURE 15-25 ***A.*** CBCT sagittal image showing radiographic evidence of an extensive invasive cervical resorption in a maxillary left first premolar. A characteristic radio-opaque line can be observed at the interface between the image of the resorptive tissue and the dental pulp (yellow arrow). ***B.*** CBCT axial view of the same tooth shows the mesio-palatal portal of entry of the resorptive defect (yellow arrow). (Courtesy of Drs. Randolf Todd and Paul Fletcher, New York, NY.)

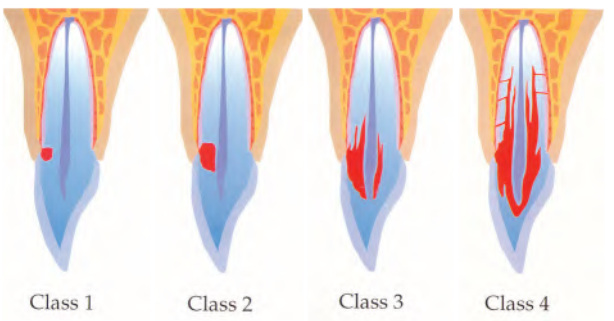

FIGURE 15-26 Clinical classification of invasive cervical resorption. Class 1 denotes a small invasive resorptive lesion near the cervical area with shallow penetration into dentin; Class 2 denotes a well-defined invasive resorptive lesion that has penetrated close to the coronal pulp chamber but shows little or no extension into the radicular dentin; Class 3 denotes a deeper invasion of dentine by resorbing tissue, not only involving the coronal dentin but also extending into the coronal third of the root; Class 4 denotes a large invasive resorptive process that has extended beyond the coronal third of the root. (Reproduced from Heithersay GS Quintessence Int. 1999;30:83–95; used with permission from Quintessence Publishing.)

progression of resorptive tissue contained in small deeply infiltrating channels (Figure 15-21). An illustrative case is shown in Figure 15-29A–H. Orthodontic extrusion can also be employed to advantage as an adjunctive therapy in some instances to render the repaired resorptive defect into a more harmonious position in respect to the gingival crevice.

The results of a prospective study of 101 teeth with varying degrees of invasive cervical resorption, using the second approach, have been reported.[53,54] The results judged by tooth survival and no radiographic evidence of

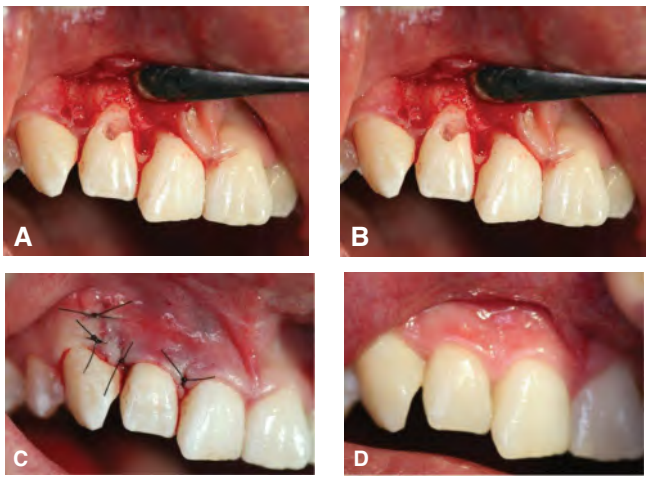

FIGURE 15-27 Management of a class 2 invasive cervical resorption by flap reflection, curettage of resorptive tissue, and restoration. ***A.*** Following periodontal flap refection and curettage of resorptive tissue, the extent of the resorption cavity is revealed showing no involvement of the dental pulp. ***B.*** Restoration of the resorptive cavity with composite resin. ***C.*** Flap repositioned and sutured. ***D.*** Excellent soft tissue healing response is evident. (Courtesy of Dr. Steve Soukoulis, Wayville, Australia.)

resorption, periradicular or periapical pathosis, showed that the treatment modality was entirely successful in class 1 and class 2 situations and acceptably successful in class 3 cases. However, as there was a low success rate for class 4 resorptions, no treatment can be generally recommended. While the progression of the resorption in class 4 cases may be slow, ultimately extraction and replacement with an implant or other prosthodontic means will be necessary.

Invasive Coronal Resorption

In rare instances, where there has been a defect in enamel integrity in an erupting tooth, an invasion of coronal tooth structure by hyperplastic resorptive tissue can occur (Figure 15-30A,B). The enamel defect is generally due to an area of hypomineralization, that can occur developmentally or as a result of intrusive luxation of a primary tooth impacting on the developing permanent successor. The same management principles apply as with invasive cervical resorption.

Invasive Radicular Resorption

When the invasion of resorptive tissue occurs in a more apical, rather than cervical location, the term invasive radicular resorption is applied. It generally occurs in patients who have had vertical bone loss due to periodontal disease so that their gingival attachment is more apically placed. This type of resorption follows a similar pattern to that of invasive cervical resorption but generally there are no extensions into coronal tooth structure.

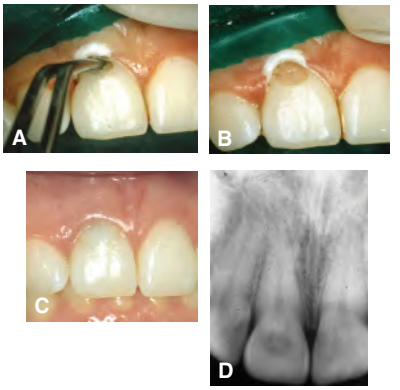

FIGURE 15-28 Management of the class 2 invasive cervical resorption shown in Figure 23-*A,B* by topical application of a 90% aqueous solution of trichloracetic acid (TCA), curettage, and restoration. ***A.*** After a protective application of glycerol to adjacent soft tissue, a dental dam "cuff" has been placed for protection and isolation. This has been supplemented with a glycerol impregnated cotton roll placed in the labial sulcus. TCA, on a small cotton pellet, has been applied to the resorptive defect with slowly increasing pressure, so that the resorptive tissue within the cavity undergoes coagulation necrosis. ***B.*** Following curettage of the avascular tissue from the resorption cavity, the glistening dentinal base of the cavity has been revealed. The incisal margin of the cavity was smoothed with high-speed bur under water spray and a glass-ionomer restoration was then placed in the cavity, and its surface protected with an unfilled resin. ***C.*** Clinical appearance of the tooth 5 years postoperatively. The original glass-ionomer cement has been faced with a composite resin restoration. ***D.*** 5-year follow-up radiograph of the maxillary right central incisor shows no evidence of periapical pathosis or extension of the treated resorptive lesion. (Reproduced from Heithersay GS, Quintessence Int. 1999; 30:96–110; used with permission from Quintessence Publishing.)

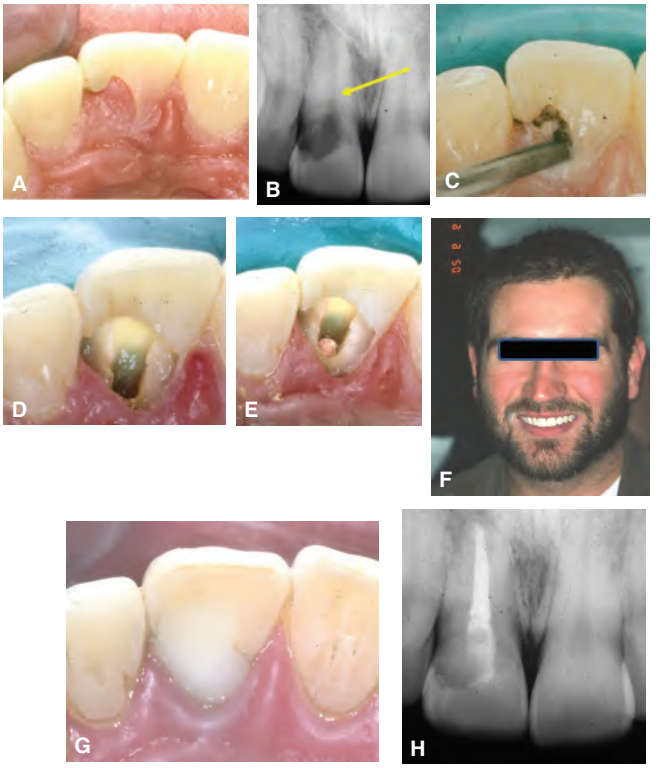

FIGURE 15-29 ***A.*** A mass of soft tissue is evident in a defect on the palatal aspect of the auxillary right central incisor of a 19-year-old male with a history of orthodontic treatment 6 years earlier. The labial surface of the patient's dentition showed a normal appearance. ***B.*** A radiograph of the tooth shows a large, irregular radiolucency extending both coronally and into the radicular tooth structure (yellow arrow). This hyperplastic invasive cervical resorption is classified as class 3. ***C.*** Topical application of TCA, on a small cotton pellet, has been carried out with slowly increasing pressure, to prevent hemorrhage and effect a coagulation necrosis of the resorptive tissue mass. ***D.*** Following curettage of the devitalized tissue in the coronal extent of the resorption, elective pulpectomy and canal enlargement with a Gates Glidden drill has been carried out to allow access to encircling resorptive tissue. Further resorptive tissue inactivation can be affected by the careful application of TCA to the area. Visualization with enhanced vision, or microscope, is important to confirm the removal of all resorptive tissue. ***E.*** Root canal filling with gutta-percha and sealer was done following initial root canal dressing with a corticosteroid antibiotic paste (Ledermix® paste) and temporization. The two stage procedure allowed a further visual check of the margins of the resorption cavity and the contents of the root canal. The cavity was then restored with glass-ionomer cement protected with an unfilled resin. ***F.*** Facial view of the patient at a 10-year recall. ***G.*** Palatal view of the treated central incisor. The original glass ionomer restoration has been refaced with composite resin due to some surface crazing. ***H.*** A 10-year follow-up radiograph shows no evidence of further resorption or periradicular pathosis. (Reproduced from Heithersay GS, Quintessence Int. 1999; 30:96–110; used with permission from Quintessence Publishing.)

MULTIPLE EXTERNAL INVASIVE CERVICAL RESORPTION, OR SITES OF ANKYLOSIS, OR INFECTION-RELATED RESORPTIONS

Etiology

These are very rare types of root resorptions; only a handful of new cases are reported each year in Denmark (6 million inhabitants). The etiology is suspected to be a defect in the RANK-RANKL-OPG system and a hereditary background is found in some cases.[2] A viral etiology acquired by contact with cats displaying feline invasive cervical resorption has also been reported.[55] The possibility of drug induction of these resorptions has been raised and a recently reported case series implicated bisphosphonate therapy.[56]

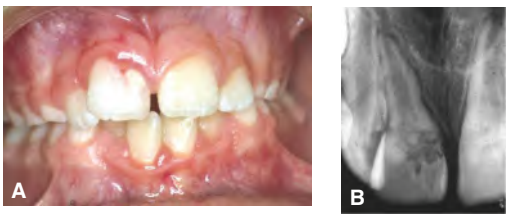

FIGURE 15-30 ***A.*** Hyperplastic invasive coronal resorption in the maxillary right central incisor of a 11-year-old male; the resorption is apparently associated with an area of hypomineralization of the crown. ***B.*** Radiograph of the maxillary right central incisor showing an extensive irregular radiolucency indicative of hyperplastic invasive coronal resorption. (Reproduced from Heithersay GS. *Aust Dent J* Suppl. 2007; 52(Suppl. 1):S105–S12; used with permission from Wiley Blackwell.)

Pathogenesis

As with the preceding section, hyperplastic resorbing tissue, apparently derived from precursor PDL cells, invade the hard tissues of multiple teeth in the cervical region in an extremely aggresive and destructive manner. Superimposed microbial invasion in advanced lesions will result in pulpal or periodontal pathosis that may assume the characteristics of ankylosis or infection-related resorptions.

Radiographic Findings

The radiographic images of multiple invasive cervical resorptions will vary from relatively small radiolucencies at the cemento-enamel junction to extensive radiolucencies indicative of tooth destruction due not only to invasive cervical resorption but may also be due to superimposed pulpal and periodontal pathosis.

Clinical Findings

The pattern of development of these multiple resorptions is unclear as it is often difficult to trace the date of the initiation of the lesions. However, it could be estimated that the process variously takes place over a matter of months to several years. Some cases indicate a spontaneous initiation in multiple teeth, while others indicate a spread of the resorptions from one tooth to another. Often the patient may be unaware of the resorptions as there may be no symptoms or external signs either in the tooth crowns or the gingival tissues. A spontaneous crown/root fracture may precipitate a dental examination where the full extent of the condition will be revealed (Figure 15-31A–D). Alternatively, some tooth crowns may show the typical pink coronal discoloration and symptoms with associated pulpal or periodontal pathosis may develop in advanced cases.

Endodontic and Periodontal Implications

Due to the extremely aggressive nature of the cells involved in these resorptions, the prognosis for successful management is poor.

Treatment

Heroic treatment could involve periodontal flap reflection, application of 90% aqueous TCA to the resorptive tissue

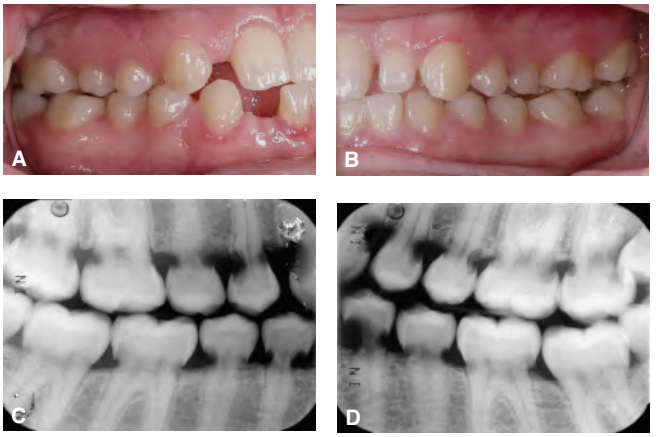

FIGURE 15-31 ***A & B***. Clinical appearance of the caries-free dentition of a 27-year-old female who sought dental advice after her mandibular right lateral incisor spontaneously fractured subgingivally Other than gingival inflammation associated with the mandibular right central incisor, the gingival soft tissues appear normal and in an apparently healthy state. ***C & D***. Radiographs of the right and left posterior segments show varying degrees of invasive cervical resorption in the entire dentition. The most severely affected teeth seen in these radiographs are the maxillary and mandibular premolars and canines. Similar gross destruction was evident in the mandibular anterior region and the retained root of the fractured mandibular right lateral incisor was still present. (Courtesy of Dr. Paul V. Abbott, Nedlands, Western Australia, Australia.)

followed by curettage, endodontic treatment (if there is pulp involvement), and finally restoration. Long term, these patients will sadly face prosthodontic replacement of the involved teeth.

INTERNAL SURFACE RESORPTION

Etiology

Internal surface resorption can be found in areas where revascularization occurs, such as in fracture lines of root fractures, and in the apical part of the root canal of a luxated tooth undergoing revascularization[57–59] (Figures 15-6B and 15-32).

Pathogenesis

Osteoclastic activity is part of the process along with the formation of granulation tissue.

Radiographic Findings

Radiographically, there appears to be a temporary widening of the root canal.

Endodontic Implications

It is very important to consider that this transient resorption process is a sign of progressing pulp healing and that any endodontic intervention may arrest this process.

Treatment

No treatment is recommended except to monitor for radiographic changes.

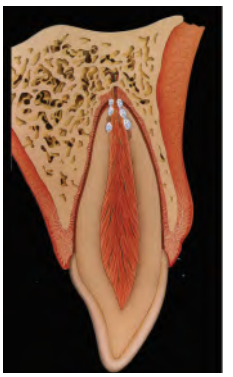

FIGURE 15-32 Internal (root canal) surface resorption.

FIGURE 15-33 Internal infection-related root resorption. The resorption site represents resorbing granulation tissue interposed between vital (apically) and diseased (coronally) pulp tissue.

INFECTION-RELATED INTERNAL RESORPTION

Etiology

Coronal to the resorption site in the pulp is found necrotic infected tissue (root canal and dentinal tubules or pulp tissue with chronic inflammation). The resorption site represents resorbing granulation tissue interposed between healthy and diseased pulp tissue[60] (Figure 15-33). This type of resorption can also be found associated with root fractures.

Pathogenesis

The resorptive process will gradually expand leading to perforation or fracture of the root.

Treatment

Endodontic treatment is appropriate and requires a technique that allows management of the resorbed area of the root canal (Figure 15-34A, B).

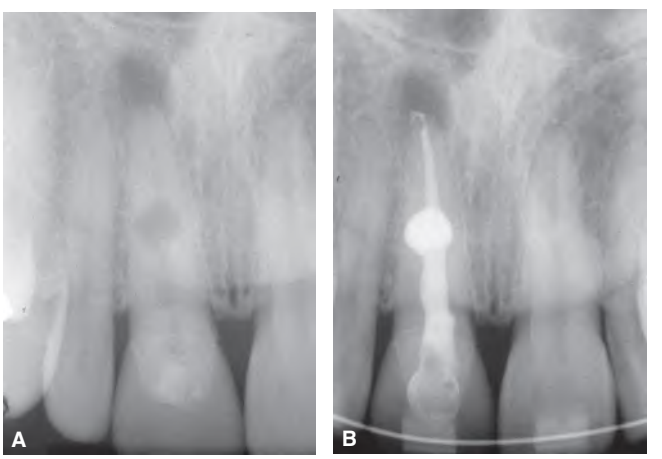

FIGURE 15-34 Teeth with internal root resorption can be treated successfully with any of the many endodontic techniques that allow filling material to be compacted into canal irregularities. ***A.*** Preoperative radiograph of a maxillary central incisor with internal resorption midroot. ***B.*** Radiograph after completion of the endodontic treatment procedure. (Courtesy of Dr. Steve Morrow, Loma Linda University, California.)

INTERNAL REPLACEMENT RESORPTION

Etiology

When damaged pulp tissue is replaced as part of a healing process, tissue metaplasia may take place leading to formation of bone tissue in the pulp canal. The damage to the pulp tissue is usually related to trauma and the damaged pulp tissue is replaced with an ingrowth of new tissue, which includes bone-derived cells.[57]

Pathogenesis

The root will gradually be replaced with bone. In some cases the bone replacement will spontaneously arrest.

Clinical Findings

The teeth are asymptomatic but if ankylosis occurs, the teeth will gradually develop infraocclusion in young patients.

Radiographic Findings

A dissecting resorptive area may be seen in the root canal; initially the root canal appears intact. Mesio-distal and ortho-radiographic exposures should verify the central location of the ankylosis site.

Endodontic Implications

Since the eventual outcome of allowing this type of condition to continue is the loss of the tooth, it may be advantageous to treat the tooth endodontically, in spite of the fact that that may lead to a poor prognosis due to the lack of root maturity.

SUMMARY

With few exceptions, pathologic tooth resorptions have endodontic implications that clinicians can address. It is

clear that most infection-related resorptions respond well to endodontic treatment. It is hoped that the future will provide avenues that currently are not available for successful management of ankylosis-related resorptions.

Chapter 16

Rhinosinusitis and Endodontic Disease

Roderick W. Tataryn

Rhinosinusitis is the single most common chronic medical condition in the United States affecting approximately 15% of the population.[1] Sinus pain, caused by inflammation, or infection, of the maxillary sinus, is often perceived by patients as odontogenic pain, and therefore deserves important consideration when developing a differential diagnosis for a maxillary toothache.[2] Despite its prevalence, differentiating pain caused by rhinosinusitis from that of dental etiology can be one of the more difficult diagnostic challenges facing clinicians. The result of a misdiagnosis in this area can lead to unnecessary endodontic therapy, periapical surgery, and even multiple tooth extractions, with no effective pain relief for the patient.

In order to effectively distinguish rhinosinusitis from odontalgia, it is imperative that clinicians understand the anatomy and functions of the paranasal sinuses both in healthy and diseased states, and recognize the signs and symptoms associated with sinus inflammation. It should be made clear that it is not expected of the endodontist, and is in fact outside the scope of dentistry, to definitively diagnose or provide treatment for a sinus condition. This diagnosis and treatment is best left to an otolaryngologist, or ear, nose, and throat physician (ENT). Nevertheless, it is essential that the endodontist have a thorough understanding of this system and its potential disease processes, in order to effectively diagnose or rule out pain of odontogenic origin, and to make an appropriate ENT referral if rhinosinusitis is suspected. Knowledge of sino-nasal structures and their function is also crucial to understanding the effects of periapical infection on the adjacent sinus tissues and the causative role that endodontic disease has in a significant percentage of sinus infections.

THE PARANASAL SINUSES: ANATOMY AND FUNCTION

Sinuses are hollow air spaces, or cavities, located within the skull surrounding the nasal cavity. There are four pairs of paranasal sinuses: the maxillary, the frontal, the ethmoid, and the sphenoid (Figure 16-1). The sinuses are lined with a membrane of ciliated and nonciliated pseudostratified columnar epithelium that is continuous with the nasal cavities. The columnar cells are interspersed with mucous producing goblet cells that constantly produce a thin layer of mucinous fluid. The mucous is rich with immune cells, antibodies, and antibacterial proteins that serve in immune defense and air filtration by trapping and filtering particles such as dust, spores, viruses, and bacteria. The cilia beat in a coordinated, rhythmic wavelike pattern moving the mucous toward and through a small (1–4 mm diameter) opening, or ostium, into the nasopharynx where it is ultimately swallowed and dissolved by digestive acids. In addition to air filtration, the paranasal sinuses serve to humidify and warm inspired air and are also important in giving the voice resonance, defining tonal quality and voice amplification, as well as reducing the weight of the skull.[3]

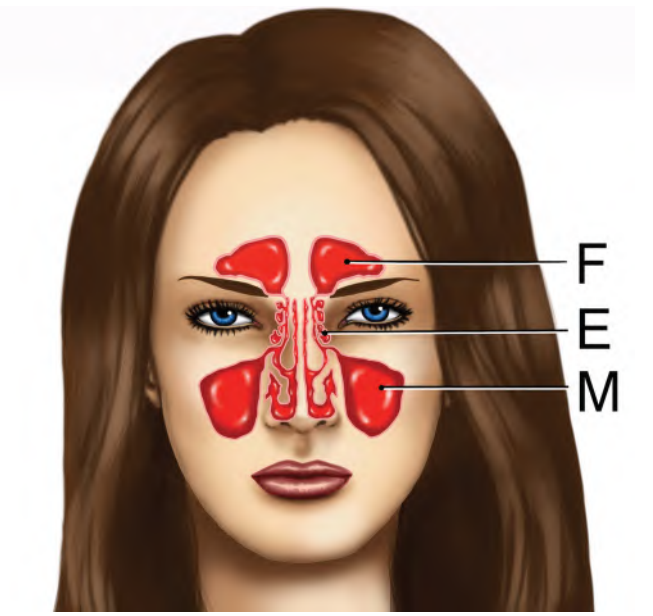

FIGURE 16-1 The paranasal sinuses: Maxillary (M), Ethmoid (E), and Frontal (F). The sphenoid sinuses are posterior to the ethmoids and are not shown.

The largest of the paranasal sinuses and most prone to infection are the maxillary sinuses. The maxillary sinus, also known as the antrum, is somewhat pyramidal in shape with the lateral wall of the nasal cavity forming the base and the apex extending into the zygoma. The floor of the maxillary sinus is the maxillary alveolar and palatine process, the roof is the floor of the orbit, and the posterior wall is adjacent to the infratemporal fossa. The maxillary sinus ostium is located near the top of the medial sinus wall and drains via the infundibulum into the semilunar hiatus of the middle meatus of the nasal cavity. Although the mucosa of the sinuses is rather insensitive to pain, the region of the ostia of the sinuses, also known as the osteomeatal complex, is the most sensitive of any of the nasal structures.[4] The osteomeatal region is highly innervated and is extremely sensitive when inflamed or stimulated during sinus-related pain episodes.[5]

RHINOSINUSITIS: ETIOLOGY, SYMPTOMS, DIAGNOSIS AND TREATMENT

The sinus ostia are considered to be the primary focal point for sinus disease, with obstruction being the major pathophysiologic factor in rhinosinusitis.[6] Sinus obstruction is commonly caused by inflammatory edema of the lining mucosa usually in response to a virus, allergen or bacteria. Ostial blockage can also occur from an anatomic obstruction such as a septal deviation or polyp, or a foreign body obstruction such as dried mucous. When a blockage occurs, mucous secretions, normally expelled through the ostia, accumulate within the sinus cavities where they begin to stagnate and thicken. The lack of sinus ventilation and stagnation of the secretions results in a lowered oxygen tension and a decrease in pH, providing an excellent environment for bacterial pathogens to colonize.[7] As the condition progresses, the cilia and epithelium become damaged, preventing fluid movement, and there is further mucosal thickening creating a more severe obstruction. The term *sinusitis* is used in the current literature interchangeably with *rhinosinusitis* due to the contiguous lining membrane of the paranasal and nasal cavities and its similar responses to therapy.[8]

Approximately one in five visits to primary care physicians in the United States result in a diagnosis of rhinosinusitis.[9] This condition is more prevalent in patients with congenital or acquired immunodeficiency, asthma, or allergic rhinitis. Symptoms may include nasal congestion, facial pain and pressure, purulent rhinorrhea, cough, headache, fever and fatigue, and pain in the maxillary posterior teeth.[10]

A diagnosis of rhinosinusitis is generally made through clinical examination and is based on the patient's history and physical signs and symptoms, with no single clinical finding being conclusively predictive of the condition.[11] In recurrent acute or chronic cases, endoscopy and CT scanning may be helpful in the diagnosis.[12] Coronally viewed sections of a sinus CT scan can reveal ostial patency or blockage, soft tissue changes, or any retained fluids that may be indicative of sinus disease (Figure 16-2). Although CT imaging has a high sensitivity, it has a low specificity for demonstrating rhinosinusitis. More than 40% of asymptomatic patients and 87% of patients with common colds show sinus abnormalities on a sinus CT.[13,14] It is also important to note that sinus inflammation and symptoms can occur in the absence of CT findings, thus the physician's overall clinical impression is superior to any single physical or radiological finding.[15]

Rhinosinusitis is classified as acute, subacute, recurrent acute, or chronic according to the temporal course of the disease.[10,12] Acute rhinosinusitis by definition lasts less than 4 weeks. Four or more episodes of acute rhinosinusitis within a 1-year period are defined as a recurrent acute rhinosinusitis. Subacute rhinosinusitis is a continuation of an acute form lasting between 4 and 12 weeks. Persistent signs and symptoms that continue unresolved for more than 12 weeks are classified as a chronic rhinosinusitis.[15] Acute

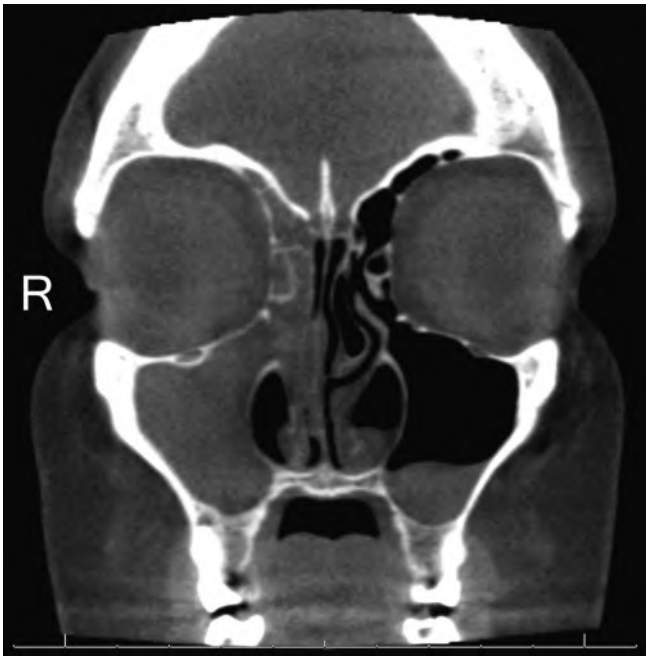

FIGURE 16-2 Rhinosinusitis. Coronal CT image shows fully obstructed right (R) maxillary, ethmoid, and frontal sinuses, as well as mucosal thickening on the floor of the left maxillary sinus.

rhinosinusitis usually has a sudden onset, usually with severe symptoms, but 40% to 50% of patients will recover spontaneously and the remainder will respond fairly well to antibiotic and/or adjunctive treatments. The predominant bacterial florae isolated in acute rhinosinusitis include *Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis*. Amoxicillin or trimethoprim-sulfamethoxazole is often prescribed as the preferred first-line antibiotic treatment although the role of antibiotics in uncomplicated rhinosinusitis has been questioned because of concern regarding its overuse.[16–19] Sinusitis accounts for 21% of all antibiotics prescribed for adults in the United States, and 9% of all antibiotics prescribed for children.[20] The bacterial species isolated from acute rhinosinusitis has not changed in the last 60 years; however, antibiotic resistance in these organisms is a growing problem due to a significant increase in production of beta-lactamase. It has been estimated up to 40% of *H. influenza* strains and more than 90% of *M. Catarrhalis* isolates are resistant to amoxicillin.[21]

Chronic rhinosinusitis usually has less severe symptoms, yet is more difficult to resolve. Because symptoms are poorly localized and mild, this condition may be extremely difficult to recognize. The microbial flora of chronic rhinosinusitis tends to be a more mixed infection with *Staphlococcus aureus* and anaerobes being the more frequent isolates.[22] Narrow spectrum antibiotic regimens are typically ineffective against chronic rhinosinusitis. Treatment of chronic sinus disease is centered on reestablishing and then maintaining adequate drainage. Current treatment guidelines include the use of broader spectrum antibiotics such as amoxycillin-clavulanate, clindamycin, or the combination of metronidazole and

penicillin. Other adjunctive treatments include the use of steroid nasal sprays, decongestants, or saline irrigation. If antibiotic therapy and adjunctive treatments prove ineffective, then endoscopic sinus surgery is currently the recommended procedure to surgically remove any diseased tissue or blockage and open the natural ostium in attempt to reestablish drainage.[23]

REFERRAL OF MAXILLARY SINUS PAIN TO THE TEETH

The referral of pain from the maxillary sinus to the maxillary dentition is primarily due to the close anatomic relationship between the floor of the maxillary sinus and the roots of the posterior maxillary teeth. In a highly pneumatized antrum, the sinus floor will extend below and between the individual roots of the adjacent maxillary molars (Figure 16-3). In a study of adults, Eberhardt[24] found the average thickness of the bony partition between the apices of the maxillary second molar teeth and the antral musosa to be only 0.83 mm. Occasionally, no bony partition exists at all, with the roots apices and the sinus separated only by the mucosal tissue.[5] With such an intimate relationship, increased sinus pressure during sinusitis can produce the sensation of pain and pressure in the maxillary alveolar process and the corresponding teeth. Percussion of these proximate teeth produces acute tenderness due to the direct transfer of shock pressure to the inflamed sinus and sensitive ostium. For some patients, the most sensitive trigger for their sinus pain is often caused by manipulation of the maxillary posterior teeth, leading them to believe, with near certainty, that teeth are the source of their pain.

Heterotropic or neurologically referred pain can also be responsible for patients mistaking rhinosinusitis for odontalgia.[25] It has been demonstrated that stimulation of the maxillary sinus ostium can induce dental pain in the maxillary posterior teeth.[26–28] It has also been demonstrated that local topical anesthetic applied to the maxillary sinus ostium can relieve perceived dental pain in the case of referred sinus pain.[29] Anesthetic nerve blocks, however, may not be reliable in differentiating maxillary rhinosinusitis from odontalgia due to mutual dental and antral innervations. Sensory innervation of the maxillary sinus is via the maxillary division of the trigeminal nerve with branches coming from the anterior, middle, and posterior superior alveolar nerves, the infraorbital nerve, and the anterior palatine nerve.[4] These nerves travel along the floor of the maxillary sinus innervating the related teeth.[30]

FIGURE 16-3 Periapical radiograph of a highly pneumatized left maxillary sinus in close approximation to the roots of the maxillary posterior teeth. The dense cortical bone defines the inferior border of the antrum (arrows).

DISTINGUISHING DIFFERENCES BETWEEN SYMPTOMS OF ODONTALGIA AND SINUS PAIN

Proper diagnosis always starts with a complete medical and dental history. An important question to ask the patient during the endodontic exam as well as on the medical history form is, "Do you have chronic allergies, a current cold, congestion, nasal drainage, or a history of sinus infections or problems?" Although many patients suffering from maxillary sinusitis may perceive dental pain, they usually complain of a dull aching pain that is difficult to pinpoint or localize to a single tooth. In addition, the patients often feel pressure in their cheeks and below their eyes that usually can be reproduced by external palpation of the cheeks. Erythema may also be evident. Positional changes can cause increased pain due to the movement of mucosal fluid over the sensitive sinus ostia as well as from increased intracranial pressure from blood flow.[31] The pain usually increases when patients are lying down, usually on one side more than the other, or if they bend over and place their head below their knees. In addition, patients with acute rhinosinusitis can have potentially severe symptoms, but then experience sudden and total relief if the sinus pressure is temporarily alleviated.

In contrast, pain of pulpal origin is more easily localized, unchanged with variations in position, and rarely intermittent in intensity. In cases of maxillary sinusitis, often all teeth proximate to the sinus floor test positive to percussion, whereas with odontalgia usually only the specific offending tooth is percussion-sensitive. The key diagnostic test for differentiating maxillary sinus etiology from pain of pulpal origin is thermal pulp sensibility response. If the teeth in question respond within normal limits to heat and cold stimuli when compared with other healthy teeth, then a pulpal etiology is effectively ruled out. Regardless of percussion sensitivity or the patient's complaint of spontaneous dental pain, endodontic treatment is not indicated as removal of a healthy pulp will surely not provide pain relief.

Although periapical radiographs are crucial to a thorough endodontic examination, the clinician must be careful not to establish the entire diagnosis on radiographic interpretation alone, particularly when evaluating the posterior maxillary region. The variation in bone density, presence of the maxillary

sinus and its bony septa as well as the zygomatic and palatal processes can impede important periradicular details necessary for accurate interpretation. Ambiguous radiographic conclusions are often the result. The increased availability of cone-beam computed tomography (CBCT) has vastly improved diagnostic ability in this region by eliminating superimposed structures and allowing for a much more accurate detection of periradicular lesions and sinus mucosal changes.[32,33]

MAXILLARY SINUSITIS OF DENTAL ORIGIN

The link between dental and sinus disease is widely recognized in both the dental and medical literature.[34–51] The pathological extension of dental disease into the maxillary sinus is a condition first referred to by Bauer in 1943 as *maxillary sinusitis of dental origin* (MSDO).[35] Bauer's classic study on cadavers showed histological evidence of the extension of periradicular infection causing destruction of the cortical bone, normally separating the teeth from the sinus floor, and pathological damage to the sinus tissues. Since then, other investigators have discovered that this is a prevalent and common occurrence with dental infections of posterior maxillary teeth. Abrahams et al.[44] have reported that infections of maxillary posterior teeth show maxillary sinus pathology in 60% of the cases, while Matilla[45] found sinus mucosal hyperplasia present in approximately 80% of teeth with periapical osteitis. Obayashi et al.[46] found maxillary sinus mucosal changes in 71.3% of patients with infections originating in the maxillary canines, premolars, and molars.

The increased availability of in-office CBCT has increased clinicians' recognition of MSDO. Low et al.[47] have shown that with the use of CBCT imaging, mucosal changes associated with dental infections was found with a prevalence of 77%, compared to only 19% using conventional radiographs. Lofthag-Hansen et al.[48] found that thickening of the mucous membrane of the maxillary sinus was identified more than four times as often with CBCT imaging than with periapical radiographs. If a sinus infection has a dental etiology, sinus healing cannot occur unless the source of the infection is removed. The dental literature provides numerous case reports of resolution of maxillary sinusitis following endodontic treatment or extraction.[49–54]

EFFECTS OF ENDODONTIC DISEASE ON THE MAXILLARY SINUS

Endodontic disease is characterized by pulpal microbial infection and the consequent inflammatory response in the adjacent periradicular tissues. Typically, throughout the dentition, the root apices are surrounded by alveolar bone, and thus classical assessment of endodontic inflammatory processes centers on the clinical, radiographic, and histopathologic effects of endodontic disease on osseous tissues. However, as previously discussed, in the maxillary posterior dentition the adjacent periapical tissues are typically respiratory mucosal, occasionally separated by only a very thin layer of cortical bone (Figure 16-4). Understanding the radiographic and clinical manifestations of periapical inflammation on the sinus cortical floor and respiratory tissues is critical to accurate endodontic diagnosis and treatment in this region. Endodontic pathosis

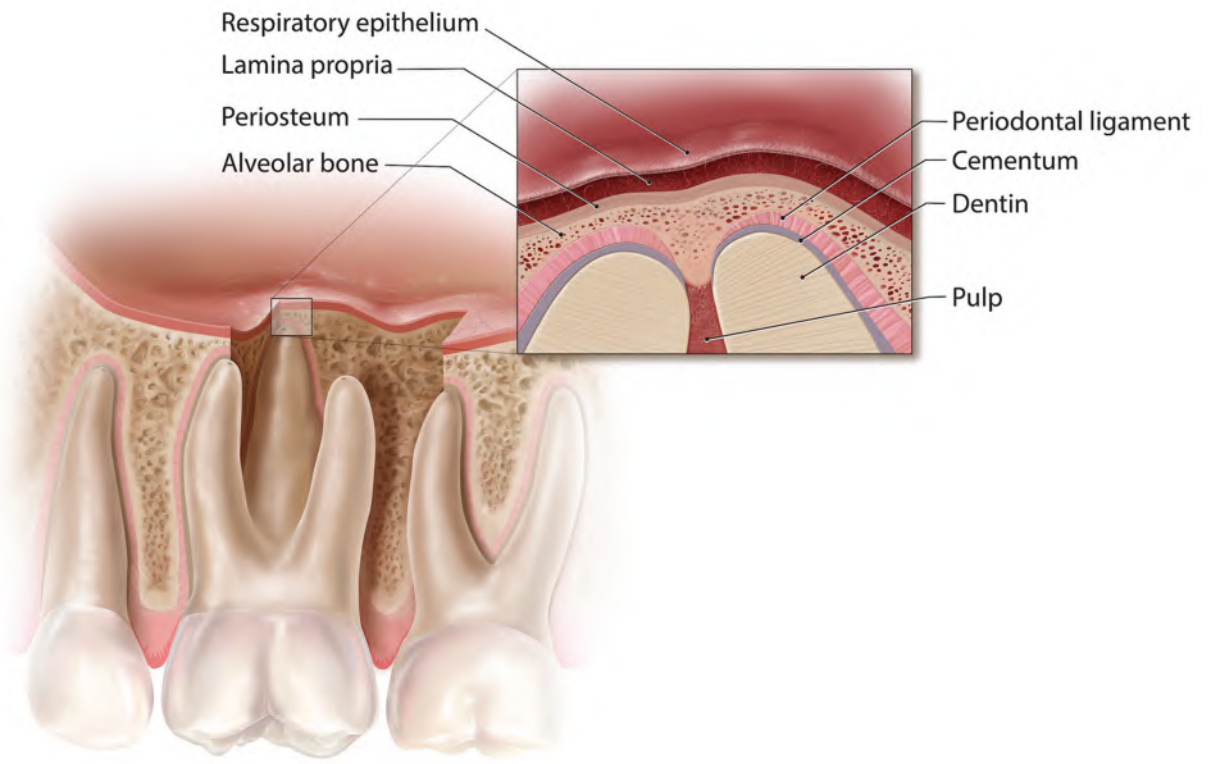

FIGURE 16-4 Illustration of the tissue layers separating the maxillary posterior root apices from the maxillary sinus in a healthy condition.

affects the maxillary sinus tissues in varying degrees: including periostitis, mucositis, and sinusitis.

PERIAPICAL OSTEOPERIOSTITIS

Inflammatory exudate from apical periodontitis, adjacent to the maxillary sinus, can penetrate the antral cortex and subsequently detach and lift the periosteum, displacing it into the sinus, and inducing periostitis (Figure 16-5). The periosteum is a dense connective tissue membrane, consisting of an outer fibrous layer and an inner cellular layer called the cambium. When irritated by inflammatory stimuli, the cambium layer contains progenitor cells that develop into osteoblasts and begin to produce new bone. This unique periosteal reaction, termed *periapical osteoperiostitis,* continues to deposit a thin layer of new bone on the inner periphery of the disease process as it expands, creating a cortical dome that produces a "halo" appearance radiographically (Figure 16-6).[55] In long-standing cases, the periosteum may continue displacing and remodeling the sinus cortical floor that, over time, can become thicker and expand deep into the maxillary sinus (Figure 16-7).

PERIAPICAL MUCOSITIS

If periradicular inflammation penetrates, or perforates, the antral cortex and associated periosteum, a localized mucosal tissue response can develop in the sinus. This localized inflammation and swelling of the sinus mucosal membrane presents as a radiopaque soft-tissue expansion called a *periapical mucositis* (Figures 16-8 and 16-9).[34,55] Mucositis can present overlying a periapical osteoperiostitis lesion (Figure 16-10), or can develop with no evident osseous changes, particularly in cases where no bony partition exists between the infected root apex and the sinus mucosa (Figure 16-11). Periapical inflammation has also been shown to be capable of affecting the sinus mucosa without perforation of the cortical bone. This is due to the extension of inflammatory mediators via bone marrow, blood vessels, and lymphatics.[35]

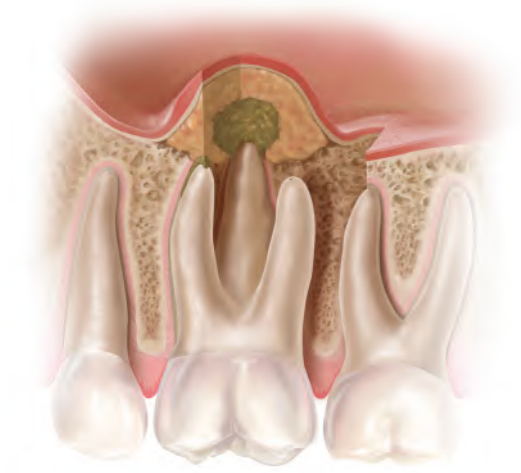

FIGURE 16-5 Illustration of periapical osteoperiostitis. Apical periodontitis displaces the periosteum into the floor of the maxillary sinus. The inflamed periosteum deposits a thin layer of newly formed cortical bone on the periphery as the lesion expands.

FIGURE 16-6 Periapical osteoperiostitis ("'halo" lesion). ***A***. Periapical radiograph of a failing root canal treatment of the maxillary right first molar. Apical periodontitis has displaced the periosteum into the sinus and new cortical bone has formed on the periphery of the disease process creating the appearance of a "halo" on the radiograph (arrows). ***B***. Sagittal CBCT image of the periapical osteoperiostitis lesion. Sinus mucosal edema, or fluid, is also evident on the sinus floor adjacent to the lesion.

It is important not to confuse a *periapical mucositis* with a *sinogenic mucosal hyperplasia*, a *mucocele*, or a *mucous retention cyst*. Mucosal thickening and mucous retention cysts are seen in approximately 10% of routine sinus CTs and are considered incidental findings. They can develop in all areas of the sinus and normally do not require treatment or surgical intervention by the ENT physician, unless

they are blocking the ostium.[10] If, however, sinus mucosal hyperplasia is seen adjacent to a dental root apex, on either routine periapical radiographs or CBCT imaging, it should raise the suspicion for a potential odontogenic etiology. Careful pulp testing is imperative in distinguishing a routine mucosal abnormality on the floor of the sinus from a periapical mucositis secondary to an odontogenic infection. Periapical mucositis should resolve within 3 to 6 months following endodontic treatment (Figure 16-11), however, long-term outcome studies of mucosal healing following endodontic treatment are lacking. Nurbaksh et al.[56] treated maxillary posterior teeth with apical periodontitis and found that 3 months after treatment there was full resolution of sinus mucositis in 30% of cases and partial resolution in an additional 30% of cases; 60% were considered healed after 6 months.

ODONTOGENIC RHINOSINUSITIS

Sinus inflammatory response to a dental infection may remain localized to the floor of the maxillary sinus in the form of an osteoperiostitis and/or mucositis, however, in progressed cases, a partial or full obstruction of the maxillary sinus can develop. This inflammatory process may extend even further, obstructing the nasal cavity, ethmoids, and frontal sinuses (Figure 16-12). This advanced pathological extension of dental disease, obstructing the maxillary sinus and potentially beyond, often termed *odontogenic rhinosinusitis,* is well documented. The reported frequency of odontogenic rhinosinusitis varies considerably, between 4.6% and 47% of all sinus infections.[57] This wide variation may be due to the difference in criteria and definitions as well as the inherent difficulty in establishing an exact causal relationship in maxillary

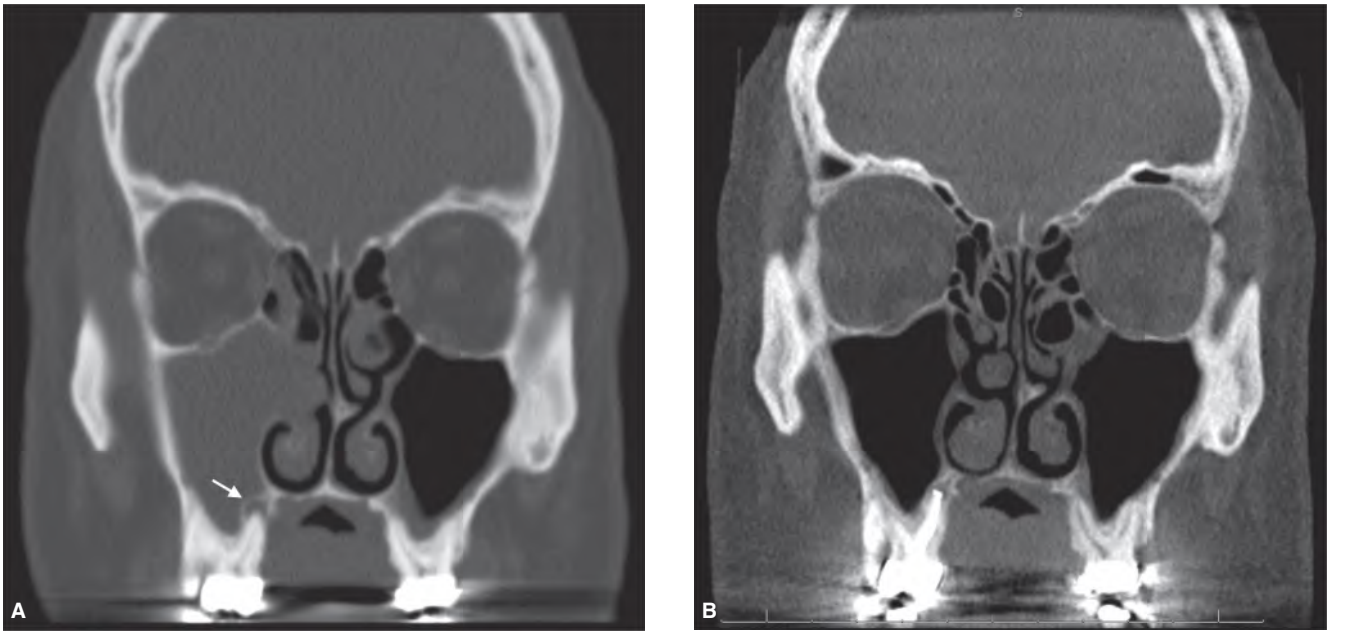

FIGURE 16-12 Odontogenic rhinosinusitis. ***A***. Coronal CT image of a fully obstructed right maxillary sinus. The patient had experienced recurrent right maxillary sinus infections and nasal obstruction for more than 4 years with no resolution, despite multiple antibiotic regimens and adjunctive sinus treatments. An associated periapical osteoperiostitis lesion is evident over the palatal root apex of the maxillary right first molar (arrow). ***B***. Three-month postoperative coronal CT image showing full resolution of the maxillary rhinosinusitis following endodontic treatment of the maxillary first molar. No other sinus treatment was performed nor antibiotics administered.

sinusitis.[58] It is often quoted and generally accepted that dental infections account for approximately 10% to 12% of all cases of maxillary sinusitis.[10,37,43,53,57] However, the primary source for this figure provides no epidemiological data to support it.[59] The actual incidence of odontogenic rhinosinusitis is likely much higher, particularly in chronic cases. Melen et al.[42], in a study of 198 patients with 244 cases of chronic bacterial maxillary sinusitis, found a dental etiology in 40.6% of the cases. Maillet et al.[60] reviewed 82 CBCT scans that had previously shown maxillary sinusitis for evidence of a dental pathology, and concluded that over 50% of these cases were of dental etiology. Bomeli et al.[61] found that the more severe the sinus disease, the more likely it was to be associated with dental pathology, such that up to 86% of severely affected maxillary sinuses were felt to have a dental etiology for the infection.

It is well documented that the predominant anaerobic bacterial isolates frequently found in chronic sinusitis are *Prevotella sp., Porphyromonas sp., Fusobacterium nucleatum, and Peptostreptococcus sp.*, the same bacterial species that are also found in endodontic infections.[22,62–64] It is unclear if the presence of these species is an indication of dental etiology or simply develops due to environmental changes within the sinus as the condition becomes more chronic.

One of the challenges in diagnosing odontogenic rhinosinusitis is that patients often have primary symptoms of maxillary sinusitis, yet are rarely able to localize pain to a specific tooth or sense any dental pain at all. These patients, typically, first seek care from their physicians or otolaryngologist who may diagnose and treat the condition as a primary sinus infection, since dental infections are easily overlooked during routine ENT examinations.[65] Otolaryngologists report that radiologists rarely comment on dental pathology on their sinus CT interpretation regardless of sinus pathology.[66] Regrettably, some patients have undergone multiple antibiotic regimens, and even one or more sinus surgeries, before a dental condition is finally diagnosed as the primary etiology (Figure 16-13).[67] This, unfortunately, occurs despite clear recommendations in the medical literature for careful dental examination and appropriate imaging in all patients with recurrent acute or chronic maxillary sinusitis.[42,61,64,65,68] The importance of properly diagnosing and treating odontogenic sinusitis is heightened with reports in the literature of dental infections spreading rapidly through the maxillary sinus causing orbital cellulitis, blindness, meningitis, subdural empyema, brain abscess, and life-threatening cavernous sinus thrombosis.[68–71] In spite of numerous medical publications emphasizing the need to rule out and treat any possible dental etiology for rhinosinusitis, to date none of the current medical guidelines for management of acute or chronic rhinosinusitis include recommendation for a clinical endodontic examination to rule out a possible odontogenic source. Longhini and Ferguson[72] reviewed 85 sinusitis guidelines published between 1998 and 2010 and found only 11 that mentioned a dental or odontogenic cause of maxillary sinusitis, and only three of these

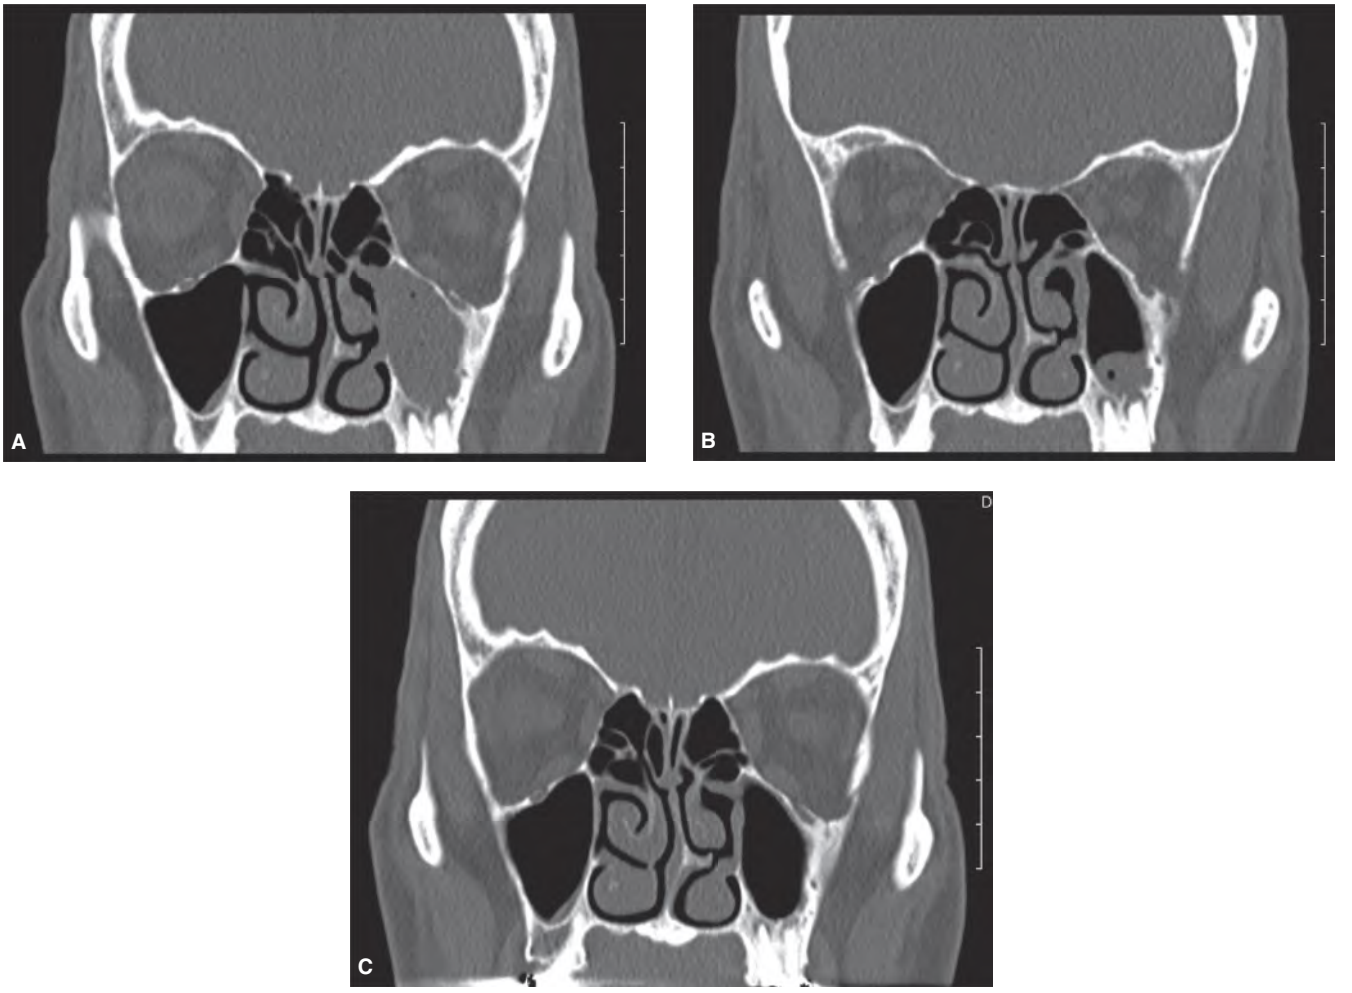

FIGURE 16-13 Odontogenic rhinosinusitis. ***A***. Coronal CT image of a fully obstructed left maxillary sinus. The patient had experienced severe maxillary sinus infections for over 7 years with no resolution, despite multiple antibiotic regimens. He was scheduled for endoscopic sinus surgery when a periapical osteoperiostitis lesion was noted over the apices of the maxillary left second molar. Endodontic treatment was recommended prior to proceeding with surgery. ***B***. 4-week postoperative coronal CT image showing significant improvement of the condition in the left maxillary sinus, with the air-fluid level less than 50%. ***C***. 10-week postoperative coronal CT image showing full resolution of the sinusitis in the left maxillary sinus. No other sinus treatment was performed nor antibiotics administered. All symptoms had resolved and the patient's sinus surgery was cancelled.

guidelines outlined diagnostic procedures for odontogenic sinusitis. The same authors also found that routine general dental examination, including dental radiographs, failed to diagnose odontogenic maxillary sinusitis in 86% of patients.[72] Melen et al.[42] similarly reported that 56 out of 99 (55%) odontogenic maxillary sinusitis cases are missed on routine dental examination and dental radiography. An improved communication between the ENT community and endodontic specialists is essential in providing improved patient care and resolving a greater number of cases of odontogenic sinusitis.

When diagnosing a possible dental etiology in a patient with rhinosinusitis, the clinician must confirm any pulpal necrosis and periapical disease, and carefully evaluate all previous endodontic treatment for possible failure in the suspected quadrant. In order for a periapical infection to occur, microorganisms must be present within the root canal system.[73] A vital pulp, whether healthy or inflamed, will not contribute to any significant periradicular or odontogenic sinus infection. Therefore, in order for odontogenic sinusitis to occur, the causative tooth must either have a necrotic pulp or a failing endodontic treatment. As discussed, periapical or panoramic radiographs may offer helpful, but limited, information regarding maxillary posterior periapical and sinus mucosal changes. Sinus CT or CBCT imaging is far more accurate and highly recommended whenever an odontogenic etiology for rhinosinusitis is suspected.[74] Other diagnostic findings that should raise the suspicion of odontogenic sinusitis are a history of unilateral maxillary sinus disease, particularly when associated with a patent sinus infundibulum or previously unsuccessful sinus surgery.[75]

If a sinus infection is determined to be caused by a periapical infection, endodontic therapy, or extraction, should provide full resolution of the disease. However, clinical and radiological follow-up is essential as concomitant management of the associated rhinosinusitis by an ENT and may be necessary in some advanced cases.[63]

Chapter 17

Non-Odontogenic Toothache and Chronic Head and Neck Pain

Bernadette Jaeger

Pain is perfect misery, the worst of evils; and excessive, overturns all patience.

–John Milton, Paradise Lost

Patients with orofacial pain, or headache, present a true diagnostic and therapeutic challenge to the practitioner. Many patients with orofacial pain have suffered mistreatment due to misdiagnosis, and stand as proof of the complex nature of head and neck pain. Attending to patients who have been unable to obtain resolution of their pain complaint, despite extensive evaluation and treatment, requires a compassionate reappraisal and fresh approach. Often the most important first step toward resolution of a patient's orofacial pain is to seriously consider that the pain is not of odontogenic origin. Therefore, appropriate treatment often requires a referral to an orofacial pain dentist or other medical specialist.

WHAT IS PAIN?

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1] The statement "actual or potential tissue damage" emphasizes the subjective nature of pain that distinguishes it from the mere stimulation of nociceptors.

> "Many people report pain in the absence of tissue damage or any likely pathophysiological cause; usually this happens for psychological reasons. There is no way to distinguish their experience from that due to tissue damage, if we take the subjective report. If they regard their experience as pain and if they report it in the same ways as pain caused by tissue damage, it should be accepted as pain. This definition avoids tying pain to a stimulus. Activity induced in the nociceptor and nociceptive pathways by a noxious stimulus is not pain, that is always a psychological state, even though we may well appreciate that pain most often has a proximate physical cause."[1]

The IASP definition of pain makes the point that *pain is pain even if a nociceptive source is not readily identified*. Pain due to psychological causes is as real as any pain associated with actual nociception and should be treated as such. Pain is what the patient says it is.

An individual's reaction to this perceived sensation can be considered as "pain behavior." This is any behavior, physical or emotional, that follows pain perception. Culture or environment often influences these behaviors, in particular behaviors associated with chronic pain. The suffering or emotional toll the pain has on any given individual is personal and must be quantified, evaluated, and treated if the patient's pain is to be understood.

Pain may also be classified into two broad categories; protective or maladaptive. Protective pain causes the sufferer to withdraw from a potential injury; for example, pulling the finger out of a flame. It protects the organism from further injury reflexively. This type of short-lasting pain, secondary to a local injury with minimal damage, is what is known as nociceptive pain.[2] The inflammation associated with an injury such as bone fracture or even sunburn sensitizes the nociceptive and non-nociceptive nerve endings in the area resulting in signaling in responses to otherwise non-noxious stimuli. This inflammatory pain protects a patient against further trauma. Once healed, inflammation resolves and pain subsides. Pain that continues after the injury or other cause of pain has resolved is known as maladaptive pain. This type of pain is complex and involves processes as such peripheral nociceptor activation and sensitization, "central sensitization" and changes in peripheral processes such that now a non-nociceptive stimuli evokes a pain sensation. Maladaptive pain typically takes a chronic course and no longer serves any protective function.

The fact that pain is difficult to define, quantify, and understand is reflected in the numerous ways in which it has been described throughout history. Modern definitions of pain began with Descartes who defined pain as the stimulation of, or the pulling on delicate threads that led to the brain resulting in pain.[2] This idea of a peripheral receptor resulting in a central pain response was accepted for nearly 500 years until it was expanded upon by more current discoveries in neuroscience.

Fields[3] defined pain as "an unpleasant sensation that is perceived as arising from a specific region of the body and is commonly produced by processes that damage or are capable of damaging bodily tissue." He emphasized the need to be able to localize the painful source in order to distinguish it from psychological pain and suffering, for example, the "pain" of a broken heart.

To understand the nuanced and complex topic of pain better, particularly in the orofacial region, the reader is referred to comprehensive literature in the field.[4]

NEUROPHYSIOLOGY OF PAIN

Acute Pain Pathways

The body has specialized neurons that respond only to a noxious or potentially noxious stimulus. These neurons are referred to as primary afferent nociceptors and are very complex in structure. Once stimulated, these primary afferent neurons synapse with neurons known as second-order pain transmission neurons in the substantia gelatinosa of the dorsal horn of the spinal cord or, in the head and neck region, the trigeminal nucleus caudalis. From here the signals are transmitted along specialized pathways to the thalamus and brain stem respectively (Figure 17-1) and then to the somatosensory cortex where the pain location and intensity are determined. Projections to the anterior cingulate gyrus and insular cortex produce emotional responses to the stimulus. It is important to note that there is no single brain area that processes pain.[5]

Arachidonic acid is released during tissue injury and is processed by two different enzyme systems into prostaglandins and leukotriene B4 respectively (Figure 17-2). Whereas prostaglandins stimulate the primary afferent nociceptor directly, the leukotrienes contribute indirectly by causing polymorphonuclear neutrophil leukocytes to release another chemical that, in turn, stimulates the nociceptor. Bradykinin contributes further by causing the *sympathetic* nerve terminal to release a prostaglandin that also stimulates the nociceptor.[6] Additionally, in an area of injury or inflammation, the *sympathetic nerve terminal* will release yet another prostaglandin in response to its own neurotransmitter, *norepinephrine*. The presence of such an ongoing inflammatory state causes physiological sensitization of the primary afferent nociceptors.[6] Sensitized nociceptors display ongoing discharge, a lowered activation threshold to *normally nonpainful stimuli* (*allodynia*), and an *exaggerated response* to noxious stimuli (*primary hyperalgesia*).[7]

Activation of cutaneous C fibers stimulates synthesis within their cell bodies, of the neuropeptides *substance P* and *CGRP*. These neuropeptides are then transported along axon branches back to the periphery where they induce further plasma extravasation and increase inflammation. The release of these algogenic substances at the peripheral axon injury site produces the flare (redness) commonly seen around the site of injury and is referred to as *neurogenic inflammation*,[8–11] or the *axon reflex*[7] (Figure 17-3).

The primary afferent nociceptor synapses with a second-order pain transmission neuron in the dorsal horn of the spinal cord where a new action potential heads toward higher brain structures (Figure 17-2). It is at this point that repeated or intense pain fiber activation facilitates and

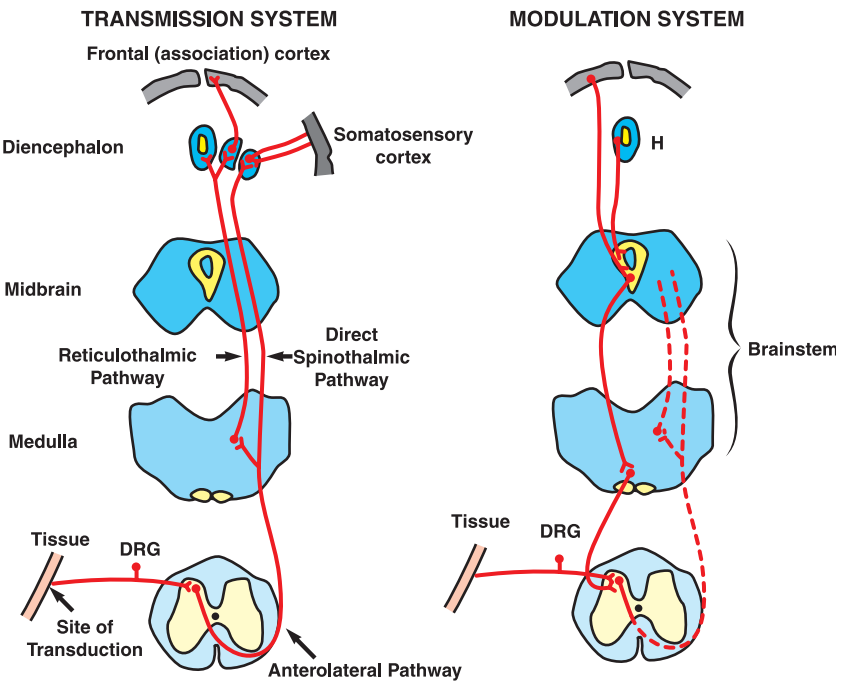

FIGURE 17-1 A diagrammatic outline of major neural structures relevant to pain. Perception of nociception begins with transduction (lower left), in which a noxious stimulus produces nerve impulses in the primary afferent nociceptor. These impulses are conducted to the spinal cord, where primary afferent nociceptors synapse with second-order pain transmission neurons that relay the message to the somatosensory cortex either directly via the spinothalamic tract or indirectly via the reticular formation and the spinoreticulothalamic pathway. From the thalamus, the message is relayed to the cerebral cortex and the hypothalamus (H). The pain modulation system depends on outflow from the cortex through the midbrain and medulla to the dorsal horn of the spinal cord, where it inhibits pain transmission cells, thereby reducing the intensity of the nociceptive signal. (Reproduced with permission from Committee on Pain, Disability, and Chronic Illness Behavior. Institute of Medicine. *Pain and Disability. Clinical, Behavioral, and Public Policy Perspectives*. M. Osterweis, A. Kleinman and D. Mechanic, eds. National Academy Press. Washington, DC, 1987.)

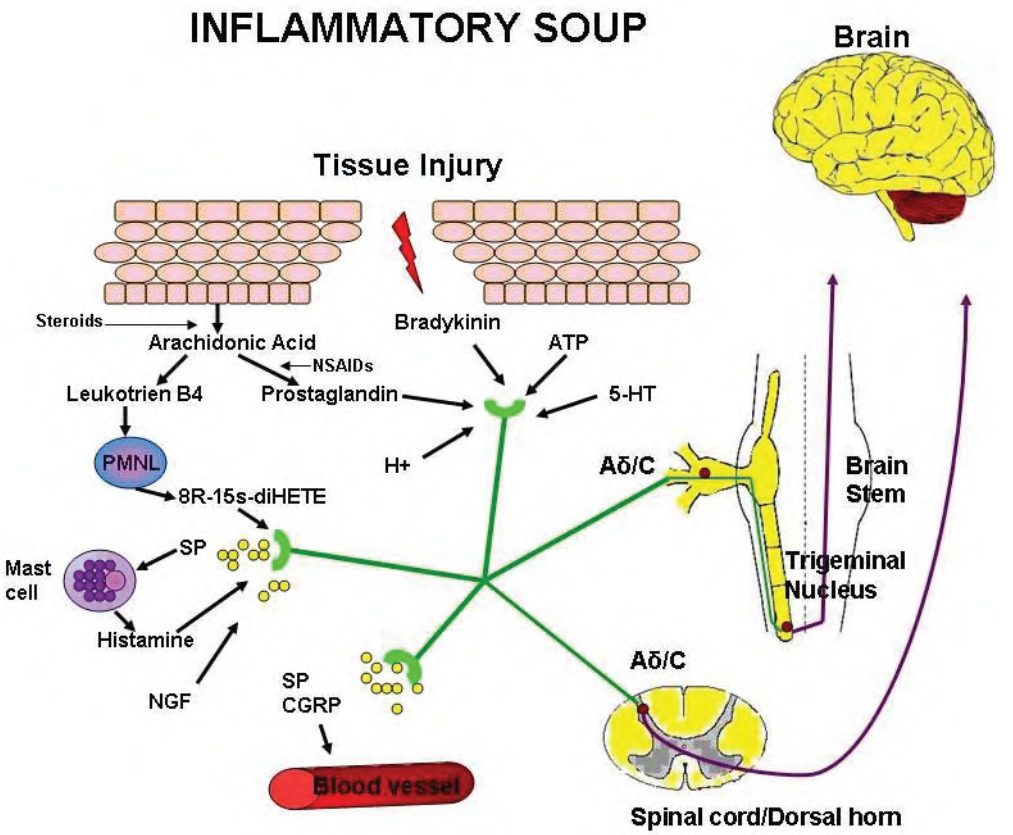

FIGURE 17-2 Arachidonic acid is produced by membrane lipids and is released with tissue injury. It is converted to prostaglandins and leukotriene B4 by two separate pathways. The cyclooxygenase pathway can be blocked by using nonsteroidal anti-inflammatory drugs (NSAIDs). Steroids prevent the synthesis of arachidonic acid altogether, thus inhibiting both pathways of prostaglandin production. Prostaglandins act directly on the primary afferent nociceptors to lower the firing threshold and therefore cause "sensitization." Leukotriene B4 causes polymorphonuclear neutrophil leukocytes to produce another leukotriene that, in turn, acts on the primary afferent nociceptor to cause sensitization.

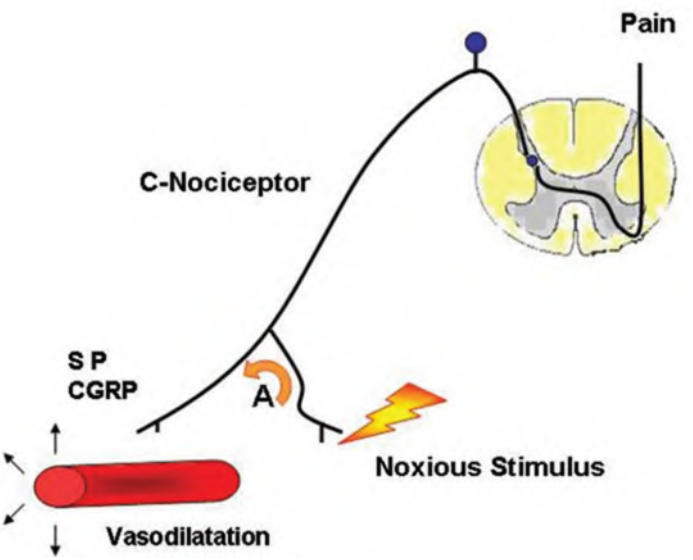

FIGURE 17-3 The axon reflex. Activation of cutaneous nociceptive C fibers elicits impulses that are conveyed centrally to induce pain and antidromically via axon branches (A). The antidromically excited peripheral C-fiber terminals release vasoactive substances, for example, calcitonin gene-related peptide (CGRP) and substance P (SP), causing cutaneous vasodilation, that produces the flare that develops around the site of noxious stimulation. (Reproduced with permission from Pain. Field HL, et al., *Neurobiol Dis*. 1998.[7])

increases responsiveness in the second-order pain transmission neuron, enhancing synaptic transmission and depressing inhibition in the dorsal horn.[12] This process further induces physiological, neurochemical, anatomical, and genetic changes,[10,13] resulting in *central sensitization*.[7,14]

The response of these spinal cord dorsal horn neurons increases progressively and is enhanced with repeated identical noxious cutaneous input from the periphery, a process called "windup."[15–17] In addition, the size of the receptive field of the second-order pain transmission neuron increases.[18] The subjective correlate of windup is "temporal summation," for which a slowly repeated noxious stimulus of the same intensity is associated with a progressive increase in perceived discomfort or pain.[7,19]

In addition, with central sensitization, stimulation of Aβ fibers (large-diameter low-threshold mechanoreceptors that normally respond only to painless tactile stimuli) will also establish connections with second-order nociceptive dorsal horn neurons, producing what is called a "secondary mechanical hyperalgesia"[7,20,21] (Figure 17-4). Aβ, when injured, gain the capacity to produce pain transmission neuropeptides not seen in unaffected Aβ fibers.[22] These plastic changes result in nonpainful stimuli causing pain. This can be observed in the hypersensitivity and allodynia present during a migraine headache or the pain to light touch of the skin after sunburn.[2] as well as in the ongoing persistent aching burning pain present in centralized trigeminal neuropathies such as painful posttraumatic trigeminal neuropathy.[23]

Modulation refers to mechanisms by which the transmission of noxious information to the brain is modified. Numerous *descending inhibitory* systems that originate supraspinally and influence spinal nociceptive transmission exist.[24] Activity in the pain modulation system results in decreased activity in the pain transmission pathway in response to noxious stimulation.

An endogenous opioid system for pain modulation also exists.[25] *Endogenous opioid peptides* are naturally occurring pain-dampening neurotransmitters and neuromodulators that are *implicated in pain suppression* and modulation because they are present in large quantities in the areas of the brain associated with these activities (subnucleus caudalis and the substantia gelatinosa of the spinal cord).[25–27] The presence of these natural opioid receptors for endogenous opiates is why morphine-like drugs work. However, evidence suggests that exogenous opioids, when used extensively, can paradoxically induce hyperalgesia.[28]

Finally, glial cells, considered the macrophages of the central nervous system, also contribute to central sensitization

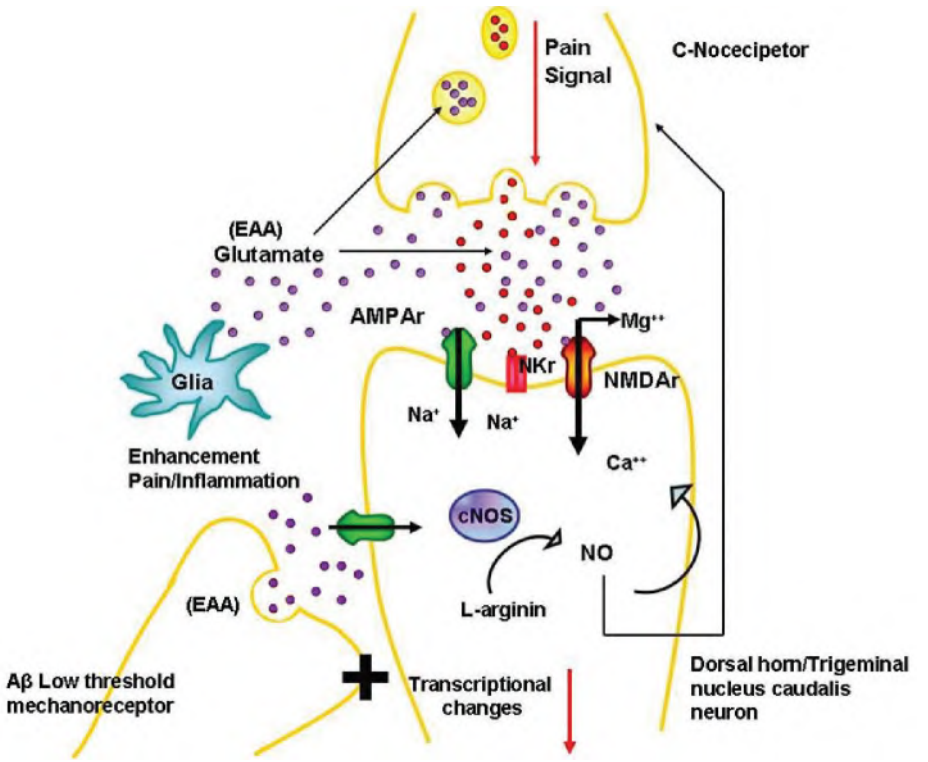

FIGURE 17-4 Central sensitization and allodynia. Input from C-nociceptors enhances the response of dorsal horn pain-signaling neurons to subsequent afferent inputs (central sensitization). This involves neuropeptides such as substance P (SP) acting at neurokinin receptors (NKR) and excitatory amino acids (EAA) acting at both the AMPA/KA and *N*-methyl-D-aspartate (NMDA) receptors, triggering secondary nitric oxide (NO) mechanisms. Large diameter low-threshold mechanoreceptive primary afferents (A fibers) respond maximally to innocuous tactile stimuli and normally produce tactile sensation. When central sensitization is present, A fibers become capable of activating central nervous system (CNS) pain-signaling neurons (+), leading to touch-evoked pain (allodynia). (Modified with permission from Fields HL et al., *Neurobiol Dis*. 1998.[7])

after physical injury to a peripheral nerve when they leave their usual homogenous distribution in the gray matter of the spinal cord to accumulate in the superficial dorsal horn of the injured peripheral nerves and even surround cell bodies of ventral horn motor neurons.[6] Glia release a variety of molecules that enhance central sensitization and persistent pain.[29]

The final step in the subjective experience of pain is *perception*. How and where the brain perceives pain is still under investigation. Part of the difficulty lies in the fact that the pain experience has at least two components: the sensory-discriminatory dimension and the affective (emotional) dimension. The affective dimension of pain is made up of feelings of expectations, unpleasantness, and emotions associated with future implications related to the pain.[30,31] Neuroimaging studies have demonstrated the involvement of the thalamus and multiple cortical areas in the perception of pain.[32]

Of significance is the fact that, with high levels of modulation or with damage in the pain transmission system, it is possible to have nociception without pain perception. Conversely, with certain types of damage to the nervous system, there may be an overreaction to pain stimuli or pain perception without nociception.[2]

Referred Pain

Pain arising from deep tissues, muscles, ligaments, joints, and viscera, is often perceived at a site distant from the actual nociceptive source. For example, cardiac problems may be perceived in the left arm or the jaw, and diaphragmatic pain is often perceived in the shoulder or the neck.[33,34] Cutaneous and mucogingival pain is sharp, burning, and clearly localized; referred pain from musculoskeletal and visceral sources is typically described as deep, dull, aching, and more diffuse. Referred pain is dependent on the primary pain source and will cease if this source is eliminated.

Referred pain presents a diagnostic dilemma. Unrecognized, it may result in ineffective treatments that, especially if invasive or irreversible, subject the patient to unnecessary risks, expense, and complications. When nothing else works, a misdiagnosis of psychogenic pain may be made.

The mechanism of referred pain is still enigmatic. The two most popular theories are convergence-projection and convergence-facilitation.

1. *Convergence-projection theory*. This is the most popular theory and was proposed by Ruch in 1965.[35] Primary afferent nociceptors from both visceral and cutaneous neurons often converge onto the same second-order pain transmission neuron in the spinal cord,[6,36] and convergence has been well documented in the trigeminal brain stem nuclear complex as well.[37] The trigeminal spinal tract nucleus also receives converging input from cranial nerves VII, IX, X, and the upper cervical nerves.[38] The brain, is programmed to interpret noxious signals as arising from cutaneous rather than visceral structures. Pain is perceived as arising from the most common source: the regions subserved by the cutaneous afferent fibers (Figure 17-5).

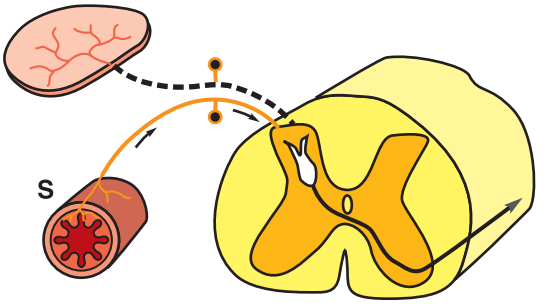

FIGURE 17-5 The convergence-projection hypothesis of referred pain. According to this hypothesis, visceral afferent nociceptors (S) converge on the same pain-projection neurons as the afferents from the somatic structures in which the pain is perceived. The brain has no way of knowing the actual source and mistakenly "projects" the sensation to the somatic structure. (Reproduced with permission from Fields HL, McGraw-Hill; 1987.[3])

2. *Convergence-facilitation theory*. This theory dates back to MacKenzie in 1920.[39] It is similar to the convergence-projection theory, except that the nociceptive input from the deeper structures causes the resting activity of the second-order pain transmission neuron in the spinal cord to increase or become "facilitated." The resting activity is normally created by impulses from the cutaneous afferents. "Facilitation" from the deeper nociceptive impulses causes a perception of pain associated with the normal, resting background activity. This theory tries to incorporate the clinical observation that blocking sensory input from the reference area, with either a local anesthetic or cold, can sometimes reduce the perceived pain.

Neither theory is considered complete, as changes in the reference zone and sympathetic involvement are not explained.[2] Spinal and supraspinal mechanisms may be involved.[2]

Trigeminal System

An appreciation of the arrangement of the trigeminal nociceptive system provides some insight into the interesting pain and referral patterns that are encountered in the head and neck region. The primary afferent nociceptors of the fifth cranial nerve synapse in the trigeminal nucleus caudalis of the brain stem.[37] The nucleus caudalis is the caudal portion of the trigeminal spinal tract nucleus and corresponds to the substantia gelatinosa of the rest of the spinal dorsal horn (Figure 17-6).

Of significance is the arrangement of the trigeminal nerve fibers within this nucleus and the fact that the nucleus descends as low as the third and fourth cervical vertebrae (C3-4) in the spinal cord. Fibers from all three trigeminal branches are found at all levels of the nucleus, arranged with the mandibular division highest and the ophthalmic division lowest.[40] In addition, they are arranged in such a manner that fibers closest to the midline of the face synapse in the most cephalad portion of the

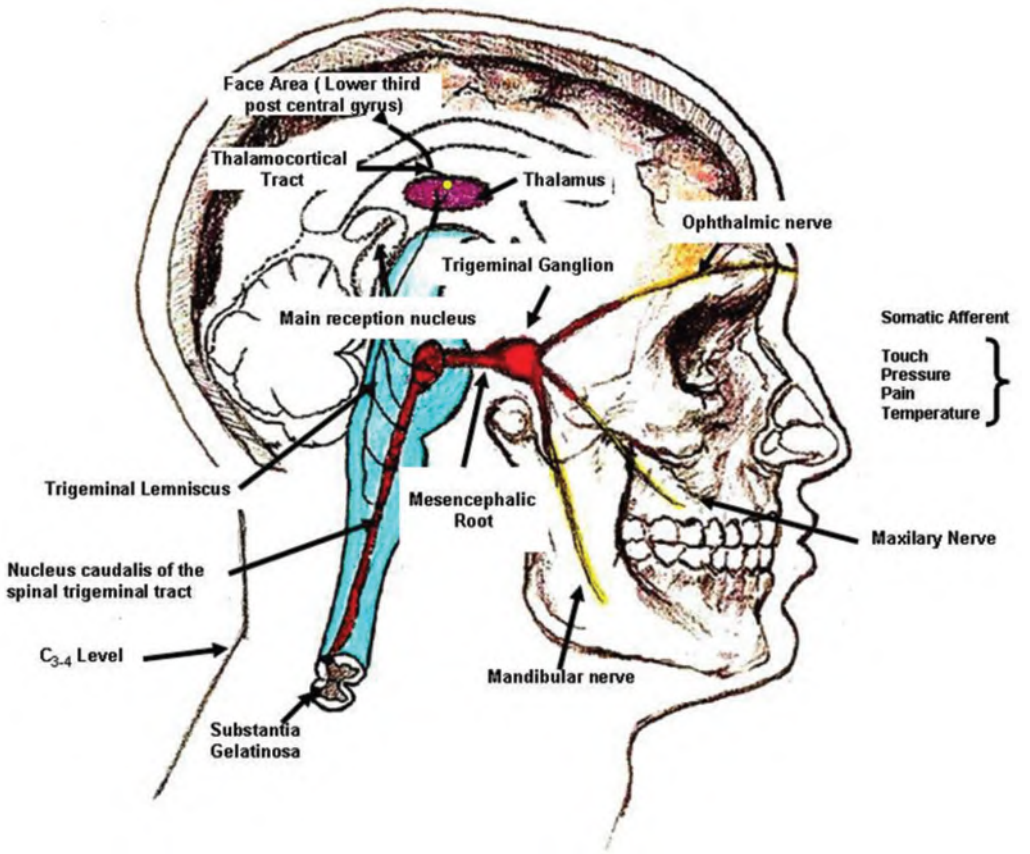

FIGURE 17-6 Primary afferent nociceptive fibers of the trigeminal nerve (cranial nerve V) synapse in the nucleus caudalis of the spinal trigeminal tract. The nucleus caudalis descends as low as C3-4 in the spinal cord. Many nociceptors from deep cervical structures synapse on the same second-order pain transmission neurons as the trigeminal nerve fibers do. This may explain why cervical pain disorders are often perceived as facial pain or headache.

tract. The more lateral the origin of the fibers on the face, the more caudal the synapse in the nucleus (Figure 17-7) Understanding this "laminated" arrangement helps to explain why a maxillary molar toothache may be perceived as pain in a mandibular molar on the same side (referred pain) but not in an incisor. Similarly, pain perceived in the ear may actually be due to (or referred from) an infected third molar.

Because the trigeminal nucleus descends to the C3-4 level in the spinal cord, primary afferent nociceptors from deep cervical structures synapse on the same second-order pain transmission neurons that subserve the fifth cranial nerve.[37] This convergence of primary afferent nociceptors from the trigeminal region and the cervical region provides a basis for understanding why *cervical pain* disorders may be perceived as pain in the head and face, particularly in the *forehead and temple*—the lateral ophthalmic trigeminal fibers synapse most caudally (Figure 17-7).

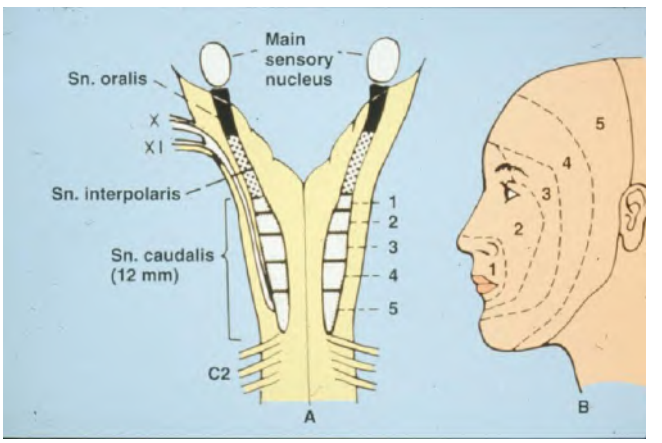

FIGURE 17-7 The arrangement of the trigeminal nociceptive fibers of the spinal trigeminal tract is significant. Fibers from all three trigeminal branches are found at all levels of the nucleus, arranged with the mandibular division highest and the ophthalmic division lowest. Fibers closest to the midline of the face synapse in the most cephalad portion of the tract. The more lateral the origin of the fibers on the face, the more caudal the synapse in the nucleus. Psychological Factors That Modify Pain

Psychological and social factors are inextricably linked with the perception of pain and illness.[41] The traditional dualistic view of mind and body as separate, independently

functioning entities has been successfully challenged with the revelation of brain function during pain functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scan imaging illustrate that various locations in the brain, not associated with pain perception, demonstrate increased activity in response to pain. Conversely, these same regions in the brain show increased activity when the subject is presented with a painful scenario or asked to view a disturbing photograph. Areas of the brain responsible for cognition, motivation, and emotions are activated during the experience of pain and play a significant role in pain modulation.[5]

In recognition of the need for a new approach to illness and pain, the biopsychosocial model for disease and illness has evolved. In this model, *disease* is defined as a "definite pathologic process with a characteristic set of signs and symptoms."[42] *Illness* refers to the subjective experience of that disease or the belief that disease is present.[43] An explosion of research in chronic pain has documented the complex interrelationship between genetics, neurophysiology, pain, and emotion.[44] For example, emotional distress may predispose a person to experience pain, amplify or inhibit the intensity of the pain, perpetuate the pain, or be a result of the pain. Anxiety and depression have long been studied with respect to their complexly intertwined relationship with chronic pain, but anger also plays an interesting role. These emotional concomitants to chronic pain are important to appreciate because they affect treatment motivation and compliance to treatment recommendations. For successful treatment, clinicians treating patients with pain, acute or chronic, must pay attention to their emotional/psychological states, as well as the somatically identified nociceptive cause.

Behavioral Factors

Suffering and pain are communicated through actions such as moaning, limping, grimacing, guarding, pill taking, or visiting the doctor. These actions are termed *pain behaviors*. Pain behaviors follow basic learning principles and tend to increase unconsciously if they are rewarded by positive consequences. Positive consequences may include attention from loved ones and/or the health care system and avoidance of various aversive tasks and responsibilities. Since chronic pain conditions, by definition, last a long time, they provide an opportunity for unconscious learning to occur. The pain behaviors observed in a patient with chronic pain may be the cumulative result of intermittent *positive reinforcement* over months or years. In addition, *well behaviors* are often totally ignored and non-reinforced, causing them to decrease. Thus, even when the nociceptive source has diminished or healed, pain perception and attendant disability may be maintained through *learned pain behaviors* along with physical, cognitive, and affective factors.[44]

MAKING A PAIN DIAGNOSIS

Diagnosing orofacial disease and headaches follows the same principles as any medical diagnosis. Of primary importance is a careful and exhaustive history. This alone will often point directly to a specific diagnosis or at least reveal a diagnostic category. The history is followed by a physical examination that should help to confirm or rule out the initial diagnostic impression. If necessary, further diagnostic studies such as pulp testing, nerve blocks, imaging, or blood tests may be ordered at this time. These may help rule out serious disorders and provide information complementing the history and physical examination. Finally, if doubt concerning the diagnosis persists, other medical specialists and health care providers may provide valuable consultation.

Classification

In evaluating orofacial pains and headaches, an easy-to-use, practical, and clinical classification of these pains will facilitate diagnosis (Table 17-1). In developing such a classification, it is important to remember that local disease of the extracranial or intracranial structures must be ruled out first. Most dentists are well trained to evaluate a patient for acute pathologic disease. Referred pains from disease in structures distant from the oral cavity must also be considered, although these disorders may be less well known to the dentist and will be reviewed.

There are other disorders, however, causing pain in the head and neck region that for the most part cannot be attributed to any obvious diseases. These disorders are less well appreciated and, for ease of clinical use, are best classified according to the apparent tissue origin of the pain (Table 17-1). For an exhaustive classification of headaches and facial pain that includes very specific diagnostic criteria, the reader is referred to the International Headache Society's Classification of Headache disorders.[45]

TABLE 17-1 Practical Clinical Classification of Craniofacial Pain

General classification	"Origin" of pain	Basic quality of pain
Local disease of extracranial structures	Craniofacial organs	Any
Intracranial disease	Brain and related structures	Any
Referred pain from remote sites	Distant structures	Aching, pressing
Neurovascular	Blood vessels	Throbbing
Neuropathic	Sensory nervous system	Shooting, sharp, burning
"Causalgic"	Sympathetic nervous system	Burning
Muscular	Muscles	Deep aching, tight
Idiopathic	Etiology as yet unknown	Deep aching, burning

The primary distinguishing feature of these practical clinical diagnostic categories is the quality of the pain. For example, neuro-*vascular* pain, such as migraine, generally has a throbbing, pulsing, or pounding quality; *neuropathic* pain, for example, trigeminal neuralgia or postherpetic neuropathy, is usually described with sharp, shooting, or burning qualities and is restricted to the peripheral distribution of the affected nerve branch; *muscle* pain is usually deep, steady, and aching or produces a sensation of tightness or pressure.

In contrast, *extracranial* or *intracranial* diseases may present with any quality of pain: a toothache may throb, a cracked tooth has sharp pain, a tumor in the mandibular canal may cause burning pain.

Once organic disease has been ruled out, a preliminary diagnostic category can be chosen based on the *quality* of the pain. Therefore, the first question to ask after location is the quality of the pain. This will help guide further questioning. For example, a constant dull ache in front of the ear along with a sharp shooting pain from the ear to the chin describes two qualities of pain. One points to a musculoskeletal diagnosis for the ear pain and the other to a paroxysmal neuralgia for the shooting pain. Further history, examination, and diagnostic tests will help establish a final or differential diagnosis.

History

The key elements of taking a pain history are delineated in Table 17-2. Chronic pain patients often have multiple pain complaints with different descriptions that may indicate multiple diagnoses. When this is the case, obtaining complete information on each complaint separately simplifies the diagnostic process.

Different pains have different *temporal patterns*. For example, a patient with a migraine would complain of unilateral throbbing head pain or toothache that lasts 4 hours to 3 days. The pain of trigeminal neuralgia is seconds in duration and may be triggered frequently throughout the day. The pain of a neuropathy is continuous.

TABLE 17-2 History of Pain

Chief complaint
Characteristics of pain
Location
Quality
Temporal patterns
Continuous or intermittent
Diurnal or nocturnal variation in intensity if continuous
Duration of each attack if intermittent
Pain intensity range (lowest, usual, and highest intensities)
Seasonal variation of symptoms if any
Associated symptoms
Precipitating factors if intermittent
Aggravating factors
Alleviating factors
Onset and history
Past and present medications or other treatments for pain
Past medical and dental history
Family history
Social history
Review of systems

Often there are *associated symptoms* such as nausea, vomiting, ptosis, tingling, or numbness. Visual changes may precede a migraine with aura. Nausea and vomiting often accompany severe headaches, especially migraine. Generalized malaise may accompany a temporal arteritis. Autonomic changes almost always accompany the trigeminal autonomic cephalalgias (TACs).

Unexplained neurological symptoms, however, such as cognitive or memory changes, transient sensory or motor loss, tinnitus, vertigo, or any of the previous symptoms not fitting an appropriate pain picture, may be signs of an intracranial lesion.

Precipitating, aggravating, and *alleviating factors* also add clues to the probable diagnosis. Withdrawal from alcohol or caffeine may trigger a migraine attack.[46] Light touch, shaving, or brushing teeth may precipitate trigeminal neuralgia. Cold weather, immobility, or over-exercise will aggravate myofascial pain (MFP).

Gathering information about the *onset* and *history* of the problem will provide further clues. What happened around the time the pain started, how has the pain changed, and what evaluations and treatments were tried? For example, a history of malaise and skin lesions (herpes zoster) typically precedes the pain of postherpetic neuropathy.

Knowing which specialists the patient has seen, which tests and radiographs were already completed, what the previous diagnostic impressions were, and which treatments were tried, helps the practitioner rule out various diagnoses and decide if other workups are needed. With acute pain, the history is usually quite short, but with chronic pain, the history may take hours to obtain, the patient having seen many different health care providers.

A *family history* should include information regarding the patient's parents and siblings. Does anyone in the immediate family suffer from a similar pain problem? For example, 70% of migraine patients have a relative who also has or had migraine. Does anyone in the family have a chronic illness? This person may provide a model for pain behavior and coping.

A *social history* should not only cover demographic information, marital status, household situation, and occupation but also seek to uncover any potential perpetuating factors. Look for potential stressors at work and at home and ask about postural habits, body mechanics with sleeping, driving, computer work, watching TV and reading, dietary habits, environmental factors, and drug and alcohol use.

The *past medical history* may reveal systemic illnesses such as lupus erythematosus or hypothyroidism that may predispose the patient to developing pain. Past surgeries and medications for other purposes, any psychiatric history, allergies, hospitalizations, and other illnesses must be included.

A *review of systems* screens the person's present state of health. It includes asking about any recent symptoms related to the head and neck; the skin; and the cardiovascular, respiratory, gastrointestinal, genitourinary, endocrine, neurological, and musculoskeletal systems.

The next step in diagnosis is a thorough physical examination.

Physical Examination

Disease of extracranial structures, particularly the oral cavity, must be sought and ruled out first. Intraoral examination that must include inspection of all intraoral tissues, teeth, and periodontium is discussed in detail in Chapter 8. Once acute disease has been ruled out, the physical examination must be augmented to include evaluation of the cranial nerves, temporomandibular joint (TMJ), cervical spine, and head and neck muscles. In specific cases, a more comprehensive neurological examination may be indicated.

General inspection can reveal a great deal about a patient to the alert clinician. A slouching posture can point to *depression*. Asymmetry, swelling, redness, and other signs may indicate inflammation, infection, or a neoplastic process. Closer inspection of the head and neck may reveal scars of past surgeries or traumas long forgotten by the patient.

The *stomatognathic examination* of the TMJs involves testing the range and quality of motion of the mandible, palpating and listening to joint noises, and palpating the lateral and dorsal joint capsules for tenderness. The normal range of jaw opening is 40–60 mm. Laterotrusive and protrusive movements should be 8–10 mm. The path of opening and laterotrusive and protrusive movements should be straight, without deflections or deviations. Joint capsule palpation anterior to the tragus of the ear for the lateral capsule and from the top of the condyle for the dorsal capsule may be "uncomfortable" but should not be painful.

A *cranial nerve examination* (Table 17-3) is indicated any time the history points to a non-odontogenic type of pain or when there are unusual complaints or symptoms. Detailed information on how to perform a cranial nerve examination is available in Bates's textbook on physical examination and history taking.[47] If intracranial disease is suspected, a complete *neurological examination* and referral to a competent neurologist is indicated.

Poor posture, especially anterior head positioning, is one of the most important contributing factors to TMJ dysfunction and MFP and also affects the occlusion.[48] The cervical spine is often the source of referred pain to the orofacial and TMJ regions. A discussion of the examination for posture and of the cervical spine is found in the section on Cervical Spine later in the chapter. For details on how and why this is important, the reader is referred to Chapter 5 in Travell and Simons' *Trigger Point Manual*, 2nd ed.[49]

Myofascial trigger point (TrP) examination requires a thorough, systematic palpation of all of the masticatory and cervical muscles, looking for tight muscle bands and the focal tenderness associated with myofascial TrPs. Myofascial TrPs are the most prevalent cause of chronic pain, both in the head and neck region and in general.[50–52] Also, it is frequently an accompanying diagnosis to other chronic pain conditions.

The next step involves choosing appropriate diagnostic studies to help rule out suspected disease or disorders and could include pulp testing; radiographs; more advanced imaging such as CT, CBCT, or magnetic resonance imaging (MRI); laboratory studies of blood or urine; and differential diagnostic analgesic blocking to name a few.

TABLE 17-3 Nerve Examination

I	Olfactory: test sense of smell of each nostril separately by using soap, tobacco, or coffee with patient's eyes closed
II	Optic: test visual acuity Examine fundi ophthalmoscopically Test visual fields
III, IV, VI	Oculomotor, trochlear, abducens: Test pupillary reactions to light and accommodation Test extraocular movements Check for ptosis or nystagmus
V	Trigeminal: Motor—palpate masseter and temporalis during contraction Sensory—Test discrimination of pinprick, V1, V2, V3 temperature, V1, V2, V3, and light touch, V1, V2, V3 Test corneal reflex
VII	Facial: Observe patient's face during rest and conversation Check for symmetry, tics Examine for symmetric smile, ability to wrinkle forehead, hold air in cheeks, and tense the platysma muscle
VIII	Acoustic: Whisper, rub fingers, or hold watch next to ear, use tuning fork for Rinne and Weber tests
IX, X	Glossopharyngeal and vagus are tested together: Check for symmetric movement of the soft palate and the uvula when patient says "Ah" Check gag reflex by touching back of throat. Note any hoarseness
XI	Spinal accessory: Have patient shrug shoulders against resistance (trapezius) (partially innervated by C4) Have patient turn head against resistance (SCM)
XII	Hypoglossal: Observe tongue in mouth: check for atrophy or asymmetry or fasciculation Check for deviation by having patient stick tongue out

A Word About Psychogenic Pain

Many clinicians use the term "psychogenic" as a diagnosis in patients in whom they cannot identify a disease process to explain the symptoms or in patients whose pain has caused a strong emotional component or in patients who have not responded well to somatic treatment. It must be emphasized, however, that while psychological factors are intimately involved in the expression of all pain, regardless of etiology or time course, it is *rare* for pain to be purely due to a psychological disorder. And whether or not the pain has an ongoing identifiable organic basis, it is still very real to the patient and can be as intense as any somatic pain. Also important

to remember is that referred pain from myofascial TrPs is frequently overlooked as an organic finding and is thus often mislabeled as psychogenic pain.[53]

"Psychogenic pain" or "somatoform disorders" are described in the DSM-V, the *Diagnostic and Statistical Manual of Mental Disorders*, and include physical complaints that, after appropriate medical workup and testing, either cannot be explained by a medical condition or substance (ab) use or, if due to an identifiable medical condition, cause physical, social, or occupational impairment greater than what would be expected given the objective findings. In addition, the complaints must have been present for over 6 months and cannot be explained by other psychological disorders such as depression or anxiety. Despite their inclusion in the *Diagnostic and Statistical Manual of Mental Disorders*, somatoform disorders have been the subject of continuing criticism by both professionals and patients[54] mostly because no empirical evidence exists to support these psychodynamic diagnoses and to date no psychodynamic treatment has been shown to be effective in treating these disorders. Thus the validity of these diagnoses is under debate.[55]

Finally, it is generally accepted that all chronic pain began at some point with a true pathological or nociceptive stimulus that elicited a "pain behavior." Most people live in an environment that systematically and positively reinforces pain behaviors while ignoring or punishing healthy behaviors.[56] In acute pain, these behaviors and their rewards subside quickly, but in chronic or persistent pain, pain behaviors and operant conditioning become more prominent and may persist even after the noxious stimulus is gone; it is this behavior that often leads some clinicians to doubt the patient's veracity or label them as having psychogenic pain.

Rather than falling into the trap of calling unidentified pain "psychogenic," the clinician should go back to the classification of pain to answer this question (Table 17-1).

SPECIFIC FOR EACH BROAD CATEGORY OF PAIN ORIGIN

The remainder of the chapter will be devoted to discussing several of the specific diagnoses that fall into each broad diagnostic category. This classification is by no means exhaustive. The disorders discussed are those with which dentists should be familiar. An exhaustive treatise of orofacial pains was published by Bell[57] and an official classification with diagnostic criteria by the International Headache Society.[45]

EXTRACRANIAL DISEASE

Local Disease of Extracranial Structures

Local disease of extracranial structures and referred pain from distant sites are listed in Tables 17-4 and 17-5. Acute pain arising from disease of the extracranial structures is commonly seen in dental practice. Most extracranial acute pain is well localized, easily identifiable, and straightforward to treat. However, some pains from local diseases are more elusive because they are referred from other head, neck, and thoracic structures.

TABLE 17-4 Local Disease of Extracranial Structures

Structures	Diseases
Tooth pulp, periradicular structures	Inflammation
Periodontium, gingival, mucosa	Infection
Salivary glands	Degeneration
Tongue	Neoplasm
Ears, nose, throat, sinuses	Obstruction
Eyes	
Temporomandibular joints	

TABLE 17-5 Referred Pain from Remote Sites

Structures	Diseases
Heart	Angina pectoris, myocardial infarction
Thyroid	Inflammation
Carotid artery	Inflammation, other obscure causation
Cervical spine	Inflammation, trauma, dysfunction
Muscles	Myofascial TrPs

Ear Pain

Patients may present themselves to the dentist with a primary pain complaint of toothache or temporomandibular joint pain, and ear pain is found to be an associated symptom. Similarly, when a medical workup for ear pain is negative, an astute physician will want to know whether the TMJ or dental infection is referring the symptoms.

Ear pain is typically seen with disorders such as otitis media, otitis externa, and mastoiditis and may be associated with headache.

Etiology. The ear is innervated by cranial nerves V, VII, VIII, IX, X, and XI and also branches of the upper cervical roots that supply the immediate adjacent scalp and muscles. Therefore, pain can be referred to the ear from inflammatory or neoplastic disease of the *teeth*, tonsils, larynx, nasopharynx, thyroid, *TMJ*, and cervical spine, as well as from inflammation or tumors in the posterior fossa of the brain.[58] Ear pains are also associated with pain from acute herpes zoster, glossopharyngeal neuralgia, and nervus intermedius neuralgia. These are discussed in the section "Neuropathic Pains."

Symptoms. Primary ear pains are usually described as a constant aching pressure. Their onset is usually recent. Inflammatory or infectious disorders may be associated with fever and malaise.

Patients with otitis externa (inflammation of the external auditory canal) may present themselves to the dentist first because *swallowing is an aggravating factor*. Otitis externa may be misdiagnosed as arthralgia of the TMJ if the condyle is palpated through the external auditory canal without first evaluating the ear. Glossopharyngeal neuralgia, also aggravated by swallowing, may need to be considered if ear and dental disease are absent.

Examination. The dentist must first rule out referred ear pain from oral or dental sources. Myofascial TrPs in the lateral and medial pterygoid, masseter, and sternocleidomastoid muscles frequently refer pain to the ear. Deep masseter and sternocleidomastoid muscle TrPs may also cause tinnitus.[49]

If primary ear pain is suspected, screening examination should include visual inspection of the ear and ear canal. Wiggling the auricle itself or tugging on the earlobe will aggravate otitis externa and will help distinguish an ear lesion from a TMJ problem. Pumping on the ear with the palm of the hand will exacerbate pain from otitis media. Hearing can be grossly evaluated by rubbing the fingers together in front of each ear.

Treatment. Primary ear pain should be diagnosed and managed by an ENT specialist.

Sinus and Paranasal Pain

The most common extraoral source of dental pain arises from the maxillary sinus and associated pain-sensitive nasal mucosa. Many teeth have been mistakenly extracted because of an incorrect diagnosis of this syndrome. For more details, see Chapter 16.

Temporomandibular Joint Articular Disorders

Table 17-6 provides a simple breakdown of TMJ disorders, the vast majority of which are non-painful. It is possible to have several of these diagnoses affecting one joint.
