About the editors

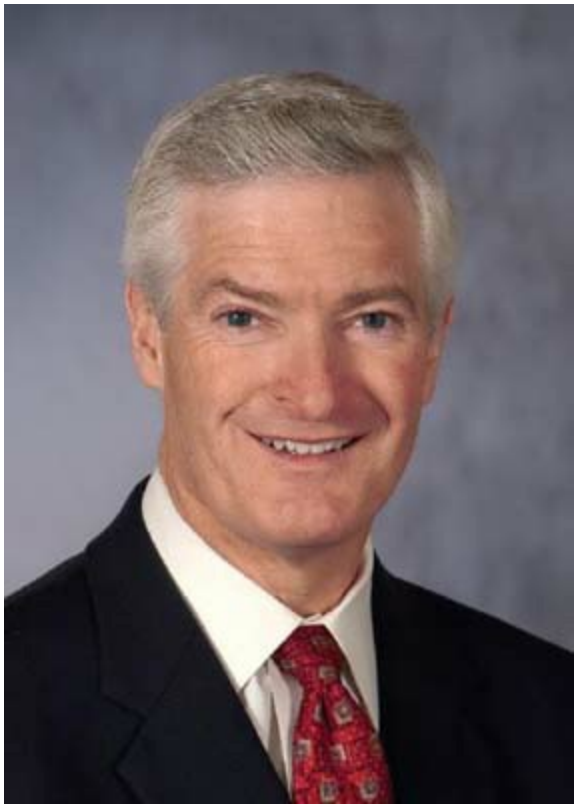
Louis H. Berman

Dr. Berman received his dental degree from the University of Maryland School of Dentistry and his Certificate in Endodontics from the Albert Einstein Medical Center. He is Clinical Associate Professor of Endodontics at the University of Maryland School of Dentistry and a Clinical Instructor and Guest Lecturer at the Albert Einstein Medical Center. He has lectured internationally in the field of endodontics and has published in several peer-reviewed international dental journals as well as co-authoring textbook

Telegram: @dental_k

www.konkur.in

chapters on numerous topics in various endodontic textbooks. He is past president of the Maryland State Association of Endodontics and is a member of the Journal of Endodontics Scientific Advisory Board. A Diplomate of the American Board of Endodontics and Fellow of the American College of Dentistry, Dr. Berman has been in full-time private practice in Annapolis, Maryland since 1983.



Kenneth M. Hargreaves

Dr. Hargreaves is Professor and Chair of the Department of Endodontics at the University of Texas Health Science Center at San Antonio. He is a Diplomate of the American Board of Endodontics and maintains a private practice limited to endodontics. He is an active researcher, lecturer, and teacher and serves as the Editor-in-Chief of the *Journal of Endodontics.* He is principal investigator on several nationally funded grants that combine his interests in pain, pharmacology, and regenerative endodontics. He has

Telegram: @dental_k

www.konkur.in

received several awards, including a National Institutes of Health MERIT Award for pain research, the AAE Louis I. Grossman Award for cumulative publication of research studies, and two IADR Distinguished Scientist Awards.

Ilan Rotstein

Dr. Rotstein is Professor and Chair of Endodontics, Orthodontics, and General Practice Residency and Associate Dean at the Herman Ostrow School of Dentistry of the University of Southern California in Los Angeles. He is on the Executive Leadership Team of the School of Dentistry and an ambassador member of the University of Southern California.

He has served in leadership roles for various dental organizations, including Chair of the International Federation of Endodontic Associations' Research Committee; as a committee member of the American Association of Endodontists and European Society of Endodontology; and as a scientific

Telegram: @dental_k

www.konkur.in

reviewer for international endodontic and dental journals. He has also served as President of the Southern California Academy of Endodontists, Israel Endodontic Society, and International Association for Dental Research—Israel Division and as Chair of the Israel National Board of Diplomates in Endodontics.

Dr. Rotstein has published more than 150 scientific papers and research abstracts in the dental literature as well as chapters in international endodontic textbooks, including *Pathways of the Pulp, Ingle's Endodontics*, *Endodontics: Principles and Practice*, *Seltzer and Bender's Dental Pulp*, and *Harty's Endodontics in Clinical Practice*. He has lectured extensively in more than 25 countries throughout 5 continents.

Dedication

Dr. John Ingle

The development of every edition of *Cohen's Pathways of the Pulp*, for all of its editors and contributors, is a journey into both the future and the past of endodontics. What we as clinicians know today and the care that knowledge enables us to provide to our patients are the result of the curiosity, dedication, and commitment of the teachers, researchers, and clinicians who have come before us. Dr. John Ingle, who contributed to the science, practice, and teaching of endodontics for more than 7 decades, is one of those extraordinary pioneers.

Dr. Ingle began his career as an educator at the University of Washington

Telegram: @dental_k

www.konkur.in

in Seattle, where he taught periodontics. While teaching, he became interested in the new field of endodontics and, perhaps drawing on the example of his pioneer great-grandfather, Daniel Boone, he entered a specialty program in endodontics at the University of Michigan to explore this new discipline, earning graduate degrees in endodontics and periodontics.

As an educator and clinician, Dr. Ingle knew the importance of evidence in establishing the efficacy of endodontic treatment as a new specialty. To meet this need, he evaluated the results of endodontic treatment in 3000 patients and presented his findings to the annual session of the American Association of Endodontists in 1953. The *Washington Study* established proof of outcome for endodontic treatment and remains a seminal work in the literature for our field.

New fields offer many new challenges to their pioneers, and Dr. Ingle soon turned his attention to the development of standardization of endodontic instruments. His work resulted in the metric measurements and the 0.2 taper of endodontics files that were established in 1957.

In 1965, Dr. Ingle brought together his experience as both a clinician and an educator in the publication of his foundational textbook *Ingle's Endodontics.* Now in its sixth edition, *Ingle's Endodontics* has provided an essential evidence-based reference to students and clinicians for more than 50 years.

While Dr. Ingle's many accomplishments are known and admired, the attributes of his character are equally revered. Dr. Ingle was modest about his many contributions to endodontics and was unfailingly generous in his support and encouragement of others. The compassion and empathy that motivated his work were experienced by all those he touched throughout his long and exemplary career and life.

It is with profound gratitude and appreciation that we dedicate this twelfth edition of *Cohen's Pathways of the Pulp* to Dr. John Ingle, a scholar, a leader, and a gentleman.

New to this edition

The radiographic interpretation of odontogenic and nonodontogenic lesions is exactly that: an “interpretation.” This new twelfth edition boasts a completely new chapter entitled Lesions That Mimic Endodontic Pathosis that elucidates and differentiates lesions that may appear as endodontic origin. This is a perfect adjunct to the chapters on Diagnosis and Radiographic Interpretation.

The chapter on Managing Iatrogenic Events has been completely rewritten to include an expansive section on injury to the inferior alveolar nerve.

Damage to the inferior alveolar nerve secondary to endodontic treatment is an avoidable dilemma. There is now specific content elaborating on the avoidance and management of these types of injuries.

Root resorption and root fractures can be some of the most difficult defects to clinically manage. The Root Resorption chapter on these subjects has been completely updated and will prove beneficial to the clinician and academician.

This edition updates all of the previous chapters to reflect the changes in the literature since the last edition.

New chapter organization

Chapters have been reorganized and grouped into three parts: Part I: The Core Science of Endodontics, Part II: Advanced Science Topics, and Part III: Advanced Clinical Topics. The twelve chapters in Part 1 focus on the core clinical concepts for dental students, while the chapters in Parts II and III provide the information that advanced students and endodontic residents and clinicians need to know. In addition, three additional chapters are included in the online version.

The new organization better reflects the chronology of endodontic treatment.

www.konkur.in

Introduction

Louis H. Berman, Kenneth M. Hargreaves

The foundation of the specialty of endodontics is a gift from the generations of great endodontists and researchers before us. They guided us with the goals of treatment, the benefits of their advancements, and the frailties of their deficiencies. From volumes of research, we have collectively built a virtual library of knowledge that leads us to the evidence we need for mastering our clinical procedures and benefiting our patients. As we look into our future, we should be directed toward developing the necessary tools for maximizing our outcomes with consistency, longevity, and, above all, patient well-being.

Over the past several decades, we have gone from arsenic to sodium hypochlorite, from bird droppings to gutta-percha, from hand files to motor-driven files, from culturing to one-visit appointments, from 2D to 3D radiography, and from pulp removal to pulpal regeneration. Yet still, the clinical and academic controversies are pervasive.

With patients living longer and with the inescapable comparison of endodontics to endosseous implants, the demand for endodontic excellence has greatly increased. Surprisingly, we still base our diagnosis on a presumed and almost subjective pulpal status. Imagine a future in which endodontic diagnosis could be made more objective by noninvasively scanning the pulp tissue. Imagine algorithms built into all digital radiography for interpreting and extrapolating disease processes. CBCT has made a huge impact on endodontic diagnosis, but can we enhance these digital captures with a resolution that would approach microcomputed tomography, and with less radiation? Will these 3D scans guide us not just with diagnostic objectivity,

Telegram: @dental_k

www.konkur.in

but also with direct treatment facilitation to guide us during surgical and nonsurgical treatment? Truly, we are now on the cusp of gaining the knowledge and technology for accomplishing this. As for clinical visualization, will 3D visualization and monitor-based observation change the way we visualize and implement our procedures? Will our procedures still be done with the fine motor skills of the clinician, or with the augmented reality of digital microsurgical devices? In the years to come, will we be able to truly eliminate all of the canal microorganisms, biofilms, and pulpal tissue? Will we be facilitating our canal cleaning with less toxic and more directed irrigants? Once we are finally able to totally clean and disinfect the canals to a microscopic level, will we have an obturation material that finally satisfies ALL the material requirements that Dr. Louis Grossman enumerated at the inception of our specialty? Will this obturating material be newly regenerated vital pulp?

Clearly, our endodontic future lies in out-of-the-box thinking, with the next generation of transformations coming with collaborations not just from within the biological sciences, but also in conjunction with physicists, chemists, engineers, and a multitude of other great innovative minds. The predictability of endodontics must be incontestable, not just with better technology to guide us toward greater success, but also to better elucidate exactly when endodontic treatment cannot be successful. Our future needs to focus on predictability and consistency, which will only be achieved with disruptive technologies, rather than persisting with variations and modifications of our current convictions. As a specialty, we have advanced by leaps and bounds since our inception; but we are still in our infancy with a brilliant future ahead of us. Since 1976, and now with 12 editions, *Cohen's Pathways of the Pulp* has always been about the art and science of endodontics, with an emphasis on evidenced-based direction rather than anecdotal guidance. The dedicated contributing authors have generously given their time to meticulously describe what is considered the state of the art of our specialty. We are hopeful that future editions will guide us toward enhanced endodontic outcomes, with the never-ending pursuit of endodontic excellence.

Fig. 1.8 Swelling of the submental space associated with periradicular disease from the mandibular incisors.
Fig. 1.9 **A,** Extraoral drainage associated with periradicular disease from the mandibular right canine. Note the parulis on the right anterior side of the face. **B,** Initial scar associated with the extraoral drainage incision after the parulis was drained and root canal therapy performed on the canine. **C,** Three-month follow-up shows healing of the incision area. Note the slight inversion of the scar tissue.
Fig. 1.10 **A,** Extraoral sinus tract opening onto the skin in the central chin area. **B,** Radiograph showing large radiolucency associated with the mandibular incisors. **C,** A culture is obtained from the drainage of the extraoral sinus tract. **D,** The healed opening of the extraoral sinus tract 1 month after root canal therapy was completed. Note the slight skin concavity in the area of the healed sinus tract.
Fig. 1.11 Fluctuant swelling in the anterior palate associated with periradicular disease from the palatal root of the maxillary first premolar.
Fig. 1.12 Fluctuant swelling in the posterior palate associated with periradicular disease from the palatal root of the maxillary first molar.
Fig. 1.13 Fluctuant swelling in the mucobuccal fold associated with periradicular disease from the maxillary central incisor.
Fig. 1.14 **A,** To locate the source of an infection, the sinus tract can be traced by threading the stoma with a gutta-percha point. **B,** Radiograph of the area shows an old root canal in a maxillary second premolar and a questionable radiolucent area associated with the first premolar, with no clear indication of the etiology of the sinus tract. **C,** After tracing the sinus tract, the gutta-percha is seen to be directed to the source of pathosis, the apex of the maxillary first premolar.
Fig. 1.15 Percussion testing of a tooth, using the back end of a mirror handle.
Fig. 1.16 Mobility testing of a tooth, using the back ends of two mirror handles.
Fig. 1.17 **A,** Carbon dioxide tank with apparatus attached to form solid CO_2 stick/pencil. **B,** CO_2 gas being transformed into a solid stick/pencil. **C,** CO_2 stick/pencil extruded from end of a plastic carrier and ready for use.
Fig. 1.18 **A,** Refrigerant spray container. **B,** A large cotton pellet made of a cotton roll, or a ready-made size #2 (large) cotton pellet, can be used to apply

Telegram: @dental_k

www.konkur.in

the refrigerant spray to the tooth surface. The small #4 cotton pellet does not provide as much surface area as the #2 cotton pellet, and therefore should not be used to deliver the refrigerant to the tooth surface. **C,** A large cotton pellet sprayed with the refrigerant and ready to be applied to the tooth surface.

Fig. 1.19 Irreversible pulpitis associated with the mandibular right second molar. Patient has found that the only way to alleviate the pain is to place a jar filled with ice water against the right side of his face.

Fig. 1.20 **A,** Electric pulp tester with probe. The probe tip will be coated with a conducive medium, such as toothpaste, and placed in contact with the tooth surface. The patient will activate the unit by placing a finger on the metal shaft of the probe. **B,** View of the electric pulp tester control panel; the knob on the front right of the unit controls the rate at which the electric current is delivered to the tooth. The plastic panel on the left front displays the digital numerical reading obtained from the pulp test. The digital scale runs from 0 to 80.

Fig. 1.21 Nellcor OxiMax N-600x pulse oximeter.

Fig. 1.22 To determine which tooth, or tooth part, is sensitive to mastication, having the patient bite on a specially designed bite stick is often helpful.

Fig. 1.23 Sometimes there is no clear indication of why a tooth is symptomatic. This radiograph shows a mandibular second molar with a moderately deep restoration **(A);** the pulp tests nonvital. Without any transillumination, a fracture cannot be detected **(B).** However, by placing a high-intensity light source on the tooth surface, a root fracture can be observed on the buccal surface **(C)** and the distal-lingual surface **(D).**

Fig. 1.24 Radiograph showing what appears to be a mandibular lateral incisor associated with periapical lesion of a nonvital tooth. Although pulp necrosis can be suspected, the tooth tested vital. In this case, the appearance of apical bone loss is secondary to a cementoma.

Fig. 1.25 Radiographic images are only two-dimensional, and often it is difficult to discriminate the relative location of overlapping objects. **A,** When the source of radiation is directly perpendicular to overlapping objects, the image is captured without much separation of the objects. However, when the radiation source is at an angle to offset the overlapping objects, the image is captured with the objects being viewed as separated. **B,** The object that is closest to the film (or sensor) will move the least, with the object closest to the radiation source appearing farthest away.

Telegram: @dental_k

www.konkur.in

Fig. 1.26 Digital radiography has an advantage over conventional film in that the image can be enhanced and colorized—a useful tool for patient education.
Fig. 1.27 Cone-beam volumetric tomography, using the 3D Accuitomo 80.
Fig. 1.28 Cone-beam volumetric tomography has the ability to capture, store, and present radiographic images in various horizontal and vertical planes.
Fig. 1.29 Cone-beam volumetric tomography has the advantage of being able to detect pathosis in the bone or associated with the teeth without the obstruction of anatomic structures. The planes of vision may be axial, sagittal, or coronal.
Fig. 1.30 The radiation source in cone-beam volumetric tomography is conical. The receiving sensor captures the image as "voxels," or three-dimensional pixels of information, allowing digital interpretation.
Fig. 1.31 **A,** This standard two-dimensional radiographic image reveals recurrent caries under the mesial margin of the maxillary first molar. However, the patient localized pain to mastication on the maxillary second molar. **B,** Cone-beam volumetric tomography revealed an apical radiolucency associated with the maxillary second molar. The bone loss was obscured on the two-dimensional radiograph by the maxillary sinus, zygoma, and cortical bone.
Fig. 1.32 **A,** Periapical radiograph showing a large apical radiolucency associated with the mandibular second molar. Apical pathosis should be ruled out. **B,** Cone-beam volumetric tomography revealed salivary indentation of the mandible in the area apical and lingual to the mandibular second molar, consistent with a Stafne defect. **C,** Enlargement of coronal section in the area of the mandibular second molar and the Stafne defect located on the lingual aspect of the mandible.
Fig. 1.33 Poorly fitting intracoronal restorations can place stresses within the tooth that can cause a vertical root fracture. **A,** This radiograph of a mandibular second premolar (with a gold inlay) reveals extensive periapical and periradicular bone loss, especially on the distal aspect. **B,** The tooth pulp tested nonvital, and there was an associated 12-mm-deep, narrow, isolated periodontal pocket on the buccal aspect of the tooth. After the tooth was extracted, the distal aspect was examined. **C,** On magnification (×16) the distal aspect of the root revealed an oblique vertical root fracture. Similarly, the placement of an ill-fitting post may exert intraradicular stresses on a root that can cause a fracture to occur vertically. **D,** This radiograph depicts a

Telegram: @dental_k

www.konkur.in

symmetrical space between the obturation and the canal wall, suggesting a vertical root fracture. **E,** After the tooth is extracted, the root fracture can be easily observed.

Fig. 1.34 Physical trauma from sports-related injuries or seizure-induced trauma, if directed accordingly, may cause a vertical root fracture in a tooth. This fracture occurred in a 7-year-old child secondary to trauma from a grand mal seizure.

Fig. 1.35 Dentinal tubules are filled with fluid that, when stimulated, will cause sensation. Temperature changes, air, and osmotic changes can provoke the odontoblastic process to induce the stimulation of underlying A-delta fibers.

Fig. 2.1 **A,** A well-angulated periapical radiograph of the maxillary right first molar taken during a diagnostic appointment for endodontic evaluation of the maxillary right quadrant. At first glance, there is little radiographic evidence of significant or periradicular change. **B,** Contemporaneous CBCT image of same tooth gives an entirely different perspective; periapical changes are visible on all three roots in all three anatomic planes of section.

Fig. 2.2 **A** and **B,** High-resolution complementary metal oxide semiconductor (CMOS) sensors are available from many manufacturers. Note that Figure In **B,** wireless CMOS sensors transmit images to the chairside workstation by 2.4 GHz radiofrequency.

Fig. 2.3 **A,** Certain regions of interest (ROI) can be highlighted with a preset contrast tool that can be moved around the image. **B,** Preprogramed filters that enhance sharpness and contrast can be selected to optimize the image acquired.

Fig. 2.4 This case demonstrates the difficulty in assessing lesions in the mandibular posterior region when there is a dense cortex. **A,** This well-angulated periapical radiograph shows a normal periapical region associated with the mandibular left second molar, for which the patient has presented for evaluation and possible retreatment. **B,** The CBCT corrected sagittal, coronal, and axial reconstructed multiplanar views, (*left to right*, sagittal, coronal, and axial views) show previous endodontic treatment, with a 6 mm diameter radiolucency with a well-defined, mildly corticated border, centered over a point on the buccal aspect of the root, 2 mm coronal to the apex; these are features consistent with an apical rarefying osteitis. **C,** The ray sum images of the sagittal view, where the image is “thinned” by decreasing the number of

Telegram: @dental_k

www.konkur.in

adjacent voxels using postprocessing software, simulates a curvilinear projection, showing diminishing superimposition (*left to right,* image layer of 10 mm, 5 mm, 2 mm, and 0.076 mm).
Fig. 2.5 i-CAT unit.

Fig. 2.8 **A,** *Left,* Drawing represents a *pixel* (picture element), the image capture and display element of any traditional digital image displayed on the computer. Shades of gray or color are displayed in these pixels to represent a 2D image. *Right,* Drawing represents a *voxel* (volume element). Voxels in CBCT are isometric and have the same dimension or length on all sides. They are very small (from 0.076 to 0.6 millimeters) and are the capture elements for cone beam imaging devices. Principles of conventional fan beam and cone beam computed tomography are presented in **B** and **C**, respectively.
Fig. 2.9 Multiplanar and 3D color reconstructed views of the mandibular quadrant taken on a CBCT machine with a volume size of 37 × 50 mm.
Fig. 2.10 Image of entire head (17 × 23 cm) from a large FOV unit.
Fig. 2.11 **A,** Panoramic 2D image exposed with the JMorita Veraviewepocs 3D for evaluation of the mandibular left central incisor. Other radiographic findings also were revealed, including the horizontal bony impaction of the mandibular right third molar and a possible lesion of endodontic origin associated with the endodontically treated maxillary left second molar. Data available from the scan allowed a 3D reconstruction to be made for areas of concern. **B,** Periapical radiograph of the maxillary left second molar on the same patient revealed a periapical area of low attenuation in the region of the periapex of the mesiobuccal root. In this case, also, changes could be evaluated in greater detail with CBCT imaging. **C,** CBCT of the maxillary left second molar revealed detailed periapical and periradicular changes in all three orthogonal planes of the section, specifically illustrating the lesion of endodontic origin associated with the mesiobuccal root. Examination of the width of the mesiobuccal root in both the axial and coronal views (buccolingually) showed that the mesiobuccal root possibly had two canals and that only a single canal was treated during the initial endodontic therapy.
Fig. 2.12 **A,** This reconstructed panoramic image from CBCT data

www.konkur.in

approximates the view one would see with a conventional panoramic radiograph. It is somewhat difficult to see the lesion on the maxillary left first molar. **B,** This thin-slice pseudopanoramic image (0.01 mm) shows the lesion without most of the anatomic superimposition. These slices of the maxillary left first molar show the lesion in sagittal **(C)** and coronal **(D)** views, confirming the features seen in the pseudopanoramic view.

Fig. 2.15 CS 8100-3D.

Fig. 2.16 **A,** Axial slice from data obtained with a 0.4 mm voxel size. **B,** Compare the trabecular pattern and outline of the mental foramina to the same location in an axial slice from data obtained with a 0.16 mm voxel size.

Fig 2.17 Lateral periodontal cyst. A 12-year-old male presented for orthodontic consultation with an elevated lesion in the maxillary right anterior region that was fluctuant under pressure; the patient was referred for endodontic evaluation and radiographic assessment. The pulp vitality was normal for the maxillary anterior dentition. A preoperative CBCT of the anterior maxilla was exposed (**A,** pseudopanoramic reformation; **B,** 3D surface reformation; **C,** cross-sectional reformation of the maxillary right lateral incisor) showing a unilocular/ovoid area of uniform low density that measured approximately 18.0 mm × 15.0 mm. **D,** Axial reformation showing a partially well-defined, noncorticated border mesial to the canine and a poorly defined border between the distal of the right lateral and central incisor. Surrounding tissues showed locally destroyed buccal and palatal cortical plates of the right anterior side of the maxilla with 6 mm of expansion of the buccal and palatal plates in the area between the canine and lateral incisor. Roots of the canine and lateral incisor are displaced mesially and distally, respectively. There was a 3 to 5 mm thickening of the sinus membrane of the overlying floor of the maxillary sinus. Seven months after surgical intervention, the patient was asymptomatic and a follow-up CBCT study was acquired, showing normal healing. **E,** 3D surface. **F,** Cross-sectional. **G,** Axial reformation.

Fig. 2.18 A 62-year-old female was referred for evaluation and possible treatment for persistent dentoalveolar pain (PDAP) in the maxillary left region. The patient could alleviate this condition by placing a moist cotton roll in the adjacent vestibule to prevent the buccal mucosa from contacting

Telegram: @dental_k

www.konkur.in

the alveolus supporting the maxillary teeth in this area. This condition began after a history of local anesthetic administration, persisted for 1 year, and led to three successive new crowns and endodontic treatment on the "offending tooth," in an effort to remedy the condition without improvement. The response to endodontic tests, TMJ, and myofascial evaluations were normal. Application of topical xylocaine resulted in cessation of pain for 15 minutes. **A,** A PA radiograph showed a root-treated, maxillary left first molar with no apparent radiographic lesion. **B,** A limited FOV CBCT of the maxillary left posterior was acquired. The corrected sagittal view showed an approximately 4 mm, well-defined, ovoid, mildly corticated area of low attenuation (radiolucent) centered over the apex of the mesiobuccal root and extending to the junction of the middle and apical third of the mesiobuccal root *(yellow arrow)*. There was mild mucositis *(green arrow)*. **C,** There was a previously untreated mesioaccessory canal *(yellow arrow)* and mild mucositis. A diagnosis of neuropathic pain and a chronic apical periodontitis was made. Daily application of topical ketamine, gabapentin, and clonidine was prescribed. Endodontic revision of the maxillary left first molar was performed 3 months after the patient was stabilized with the topical medications.

Fig. 2.19 This patient was referred for evaluation and possible treatment after emergency pulp extirpation performed by others. **A,** This PA radiograph shows that the location of the physiologic terminus *(yellow arrow)* and radiographic apex *(blue arrow)* did not appear to coincide within the normal range. **B,** Contemporaneous CBCT sagittal reformation shows the anomalous location of the physiologic terminus *(yellow arrow)* and radiographic apex *(blue arrow)*. **C,** Presence of a mesioaccessory canal with isthmus *(blue arrow)* and **(D)** an oval-shaped canal *(yellow arrow)* is apparent.

Fig. 2.20 **A,** Dens en dente of the mandibular left second bicuspid; coronal slice. **B,** Coronal view. **C,** Panoramic reconstruction from CBCT. **D,** Sagittal view.

Fig. 2.21 **A,** Mandibular left second molar referred for endodontic evaluation and possible treatment. This 2D radiograph reveals significant pulp stones and canal calcification developing not only in the coronal aspect of the root canal system, but also extending down the visible distal canal. The apical third of the canal system appears unusual and dilacerated. Cone-beam computed tomography (CBCT) would be beneficial in visualizing the root

Telegram: @dental_k

www.konkur.in

canal anatomy, to create the ideal endodontic access. **B,** Single slice of the CBCT image for the same tooth. Information about the direction of the root canal anatomy is provided in all three planes of the section: axial, coronal, and sagittal. Interestingly, the axial slice shows that the mesial lingual root actually traverses buccally as it approaches its terminal extent. This is valuable information for the clinician before the entire root canal system is cleaned and shaped; it may also establish a higher degree of treatment predictability.

Fig. 2.22 This 38-year-old female patient presented for evaluation and treatment of a symptomatic mandibular right second molar, which had been endodontically treated more than 10 years previously. This tooth was sensitive to percussion and biting forces; periodontal findings were normal. Microscopic examination of the exposed dentin was negative for a vertical fracture. **A,** The PA radiograph showed the previous endodontic treatment; a post present in the distal canal; and an approximately 5 mm diameter, unilocular, well-defined area of uniform low density centered at the periapex of the distal root—features consistent with an apical periodontitis. Contemporaneous **(B)** CBCT sagittal and **(C)** axial reformations revealed a previously untreated distobuccal canal *(yellow arrow)*.

Fig. 2.23 Root fracture in an endodontically obturated maxillary right central incisor. **A,** Axial view with artifacts from a highly attenuating (opaque) obturant. **B,** View without artifacts from obturant. **C,** Oblique parasagittal view. **D,** Paracoronal view.

Fig. 2.24 This 64-year-old male patient presented with sensitivity when biting on the mandibular left second molar. The history included endodontic revision more than 6 months earlier and subsequent transient paresthesia and dysesthesia along the distribution of the inferior alveolar nerve, which persisted for 1 week after the retreatment. Epicritic and protopathic sensibility was normal. The results of periodontal probing, staining and microscopic examination of the exposed root surface at the sulcus were normal. **A,** Initial PA radiograph showed the approximate location of excess radiopaque material, a feature consistent with extruded root canal sealer *(yellow arrow)*. **B,** Contemporaneous CBCT corrected sagittal reformation shows approximate length of extruded material, measuring 3.4 mm *(yellow arrow)*. **C and D,** Corrected cross-sectional reformation shows the foreign material interior to the inferior alveolar canal *(yellow arrow)*, an area of low

Telegram: @dental_k

www.konkur.in

attenuation extending from the apex superiorly to an area near the alveolar crest *(blue arrow)*, and erosion of the lingual endosseous surface. **E,** The same feature was shown in the corrected axial view *(yellow arrow)*, bisected by a dark line extending from the obturant to the surface of the root—features suggestive of a vertical fracture. Examination of the extracted tooth revealed a vertical fracture at the lingual aspect of the distal root.

Fig. 2.25 Unexpected torsional and flexural failure of endodontic instruments can occur during instrumentation. **A,** PA radiograph shows a separated file *(yellow arrow)* located at the midroot of the mandibular left lateral incisor in a patient referred for revision treatment. **B,** To aid development of a retreatment strategy, CBCT was used to localize the instrument *(yellow arrow)* in the lingual canal, with identification of the buccal canal *(green arrow)* to facilitate bypassing the instrument and **(C),** subsequent removal. **D,** Obturation was completed without complication.

Fig. 2.26 **A** to **W,** Anatomic landmarks on CBCT images acquired using CS 9000, CS 9300, and iCAT units.

Fig. 2.27 After a traumatic injury to the maxillary right and left central incisors, crown fractures were noted. The PA radiograph showed an extrusive luxation injury in the maxillary left central incisor **(A).** The alveolar fracture (**B,** *yellow arrow*) and true extent of the displacement (**C,** *yellow arrow*) became evident with CBCT.

Fig. 2.28 **A,** Horizontal root fractures resulting from trauma were evident in this 22-year-old male patient, who was referred with a contemporaneous film–based PA radiograph **(B)** for evaluation and possible treatment 9 months after trauma to his maxillary lateral and central incisors. Since the trauma, the teeth had been stabilized with a ribbon-type splint on the palatal surface; they were of normal color and responded normally to all sensibility tests. There was slight mobility of the traumatized teeth. **C,** The true nature of the root fractures are shown in the 3D segmented reformation and the corrected cross-sectional views of the **(D)** maxillary right lateral and **(E)** central incisors, the **(F)** maxillary left central and **(G)** lateral incisors, and the 3D surface-rendered reformation **(H).** Temporal reevaluation at 7 years showed minimal changes when compared to the initial presentation *(left to right in each group)*. Task-specific exposure parameters allowed each successive CBCT image volume to be exposed with lower mA, resulting in a 20% radiation dose reduction.

Telegram: @dental_k

www.konkur.in

Fig. 2.29 **A,** External cervical resorption was evaluated in this patient after PA radiographic image, and **(B)** visual examination showed pathognomonic signs of this lesion *(yellow arrow)*. A CBCT image was exposed to determine the true extent of resorption and restorability. **C,** The lesion showed a perforative defect at the CEJ on the facial *(yellow arrow)* and **(D)** palatal aspects *(yellow arrow)*. **D,** The presence of an intact layer of mineralized dentin, the "pericanalar resorption-resistant sheet" *(blue arrow)*, is a hallmark of this condition.

Fig. 2.30 The problem of superimposition of unrelated structures onto the features of interest is reduced when tomographic slices are used instead of images in which an entire volume of data is compressed into a planar image. **A,** This PA radiographic image of the maxillary left second molar shows no radiographic indicators of pathosis. A contemporaneously exposed CBCT image (**B,** corrected sagittal view) shows a 4.3 × 1.9 mm, well-defined unilocular, noncorticated area of low attenuation centered over the apex of the mesiobuccal root, consistent with a periradicular periodontitis *(yellow arrow)*. There is a moderate mucositis in the region of the maxillary sinus adjacent to this tooth *(blue arrow)*. Experimental semiautomated segmentation of this image using active contour methods (ITK-SNAP) allowed for measurement of the true volume of the lesion **(C)** and for future temporal comparisons based on volumetric measurements **(D).** This lesion measured 85,112 voxels and 38.1044 cubic mm.

Fig. 2.31 Radiographic interval change is shown by comparing two volumetric datasets exposed at different times. **A,** Initial CBCT corrected sagittal reformation of maxillary right second molar, distobuccal root and **(B)** corrected sagittal reformation of same root at 13-month checkup. **C** and **D,** ITK-SNAP segmented sagittal reformation of same root. Alignment and overlap of the 3D models: tooth-blue, initial lesion is red, lesion at 13-month check-up is yellow, respectively. **E,** Voxel counting, volumetric measurement (mm) and mean intensity of the periapical lesion. **F,** Models were exported to the .stl format and then viewed with MeshLab software. **G,** 3D Mesh Metric Qualitative (color-coded map) and quantitative (point value) assessments of the lesions before (translucent), and after (colored). The color map shows changes with green color in the mesial region (0.28 mm) and changes with dark red color in the distal region (1.30 mm).

block of 2 molars. **B,** Volumetric rendering of the teeth. **C,** Lateral view of the teeth with virtual files in position. **D,** Printed guide. **E,** Representative occlusal view of an accessed tooth.

Fig. 2.33 Guided endodontic surgery. **A,** 3D printed guide. **B,** Guide placed in position prior to endodontic surgery. **C,** Surgical access with printed guide in position.

Fig. 3.1 A well-defined radiolucency near the apex of the maxillary first premolar and canine. Although the premolar did not respond to pulp testing, the location of the lesion and clinical presentation were suspicious and a biopsy revealed an odontogenic keratocyst.

Fig. 3.2 **A,** Deep caries in the mandibular second premolar, but the patient was asymptomatic with no history of pain. **B,** Tooth #29 responded normally to both cold and electric pulp testing, but nonsurgical root canal treatment was completed for restorative reasons.

Fig. 3.3 A limited field CBCT is a useful adjunct when the findings on a periapical image are not conclusive. **A,** A subtle radiolucent area is present at the mesial root apex of the mandibular first molar. **B,** Sagittal, **(C)** axial and **(D)** coronal CBCT images reveal a more prominent loss of density at this root apex.

Fig. 3.4 Periapical inflammatory disease presents with a wide spectrum of radiographic changes. **A,** Preoperative periapical image of a mandibular first molar with a necrotic pulp and asymptomatic apical periodontitis. There is a widened PDL space and subtle radiolucency at the mesial root apex. **B,** Nonsurgical root canal treatment was completed. **C,** Evidence of bone healing at 6-month recall. **D,** Preoperative periapical image of a mandibular first molar with a necrotic pulp and asymptomatic apical periodontitis. This lesion is considerably larger than in image **A** and involves the mesial and distal root apices with coronal extension along the distal aspect. **E,** Nonsurgical root canal treatment was completed and a lateral canal is present in the apical half of the root. **F,** Evidence of bone healing at 6-month recall.

Fig. 3.5 Although most odontogenic keratocysts occur as multilocular radiolucencies at the angle of the mandible, they can be located at any position in either jaw. A cropped panoramic radiograph reveals a corticated odontogenic keratocyst in the mandibular right premolar region.

Fig. 3.6 **A,** A cropped panoramic radiograph shows a well-defined unilocular odontogenic keratocyst at the right angle of the mandible and distal root of

Telegram: @dental_k

www.konkur.in

second molar. The lesion was surgically removed and good bone healing was evident at a 3-year recall with no indication of recurrence **(B)**.

Fig. 3.7 **A,** A panoramic radiograph of a 10-year-old female with a mixed dentition. **B,** Serial panoramic images were obtained for orthodontic reasons and a well-defined expansile lesion developed in the mandibular right premolar region over 9 months. This type of radiolucency should not be confused with an inflammatory etiology due to its location around the crown of an unerupted tooth. This odontogenic keratocyst was treated by unroofing the cyst without removal of the entire lesion. **C,** Panoramic image with no evidence of recurrence at 2 years. **D,** Periapical image with no evidence of recurrence at 6 years.

Fig. 3.8 **A,** 3D volumetric rendering of an ameloblastoma between roots of mandibular canine and mandibular lateral incisor with destruction of the buccal cortical plate. **B,** Sagittal CBCT image reveals a low-density lesion with numerous septae displacing the roots of teeth #22 and #23. **C,** Axial CBCT image exhibiting a perforation of the buccal cortical plate and buccal-lingual expansion that is common with ameloblastomas. This lesion would be characterized as a multilocular radiolucency on a periapical image.

Fig. 3.9 **A,** Central giant cell lesion extending from left mandibular premolar region across the midline in a 17-year-old female. This radiolucency cannot be differentiated from other multilocular lesions without a biopsy (see Box 3.1). **B,** The left mandibular premolars and canine had nonsurgical endodontic treatment prior to removal of the central giant cell lesion and the mandibular incisors had nonsurgical endodontic treatment after removal of the lesion, when it was determined intraoperatively the blood supply to these teeth had been compromised. **C,** Eighteen-month recall with evidence of increased bone density, but incomplete healing.

Fig. 3.10 Axial view of CT showing the extent of the central giant cell lesion of the same patient from Fig. 3.9. This plane reveals a multilocular growth pattern with thinning of both the buccal and lingual cortical plates.

Fig. 3.11 **A,** Cropped panoramic image of condensing osteitis exhibiting a widened PDL space with a radiodense rim at the apex of a carious tooth #29. **B,** Sagittal CBCT image of maxillary premolar with previous endodontic treatment. A homogeneous high-density lesion is present with circumferential loss of density at the root apex suggesting an inflammatory etiology.

Fig. 3.12 **A,** Periapical image of #14 demonstrating cervical resorption and

Telegram: @dental_k

www.konkur.in

superimposition of the maxillary sinus over the palatal root apex. There is no way to determine the presence of inflammatory changes in the sinus based on this image. **B,** Sagittal CBCT image obtained because of resorption in first molar. Teeth in the field of view were asymptomatic and responded normally to pulp testing. There is no indication of mucosal thickening in the sinus. **C,** Periapical image of necrotic #3 with well-defined radiolucencies at the apices. **D,** Sagittal CBCT image confirms areas of low density at the root apices and reveals resorption of the maxillary sinus floor with localized mucosal thickening. **E,** Coronal CBCT image illustrates collateral edema into the sinus with a perforation of the sinus floor near the palatal root apex.

Fig. 3.13 **A,** Periapical image of #2. This tooth is nonresponsive to thermal testing and painful to percussion. Radiographically there is a slightly increased density in the maxillary sinus near the palatal root apex, but superimposition of normal anatomical structures limits the diagnostic accuracy of the image. **B,** Sagittal CBCT image reveals a homogeneous dome-shaped elevation into the maxillary sinus.

Fig. 3.14 Axial CBCT image of mandibular arch demonstrates irregular medullary bone destruction and cortical defects from tooth #25 to tooth #31. There is new bone formation along the inferior facial cortex consistent with osteomyelitis and proliferative periostitis.

Fig. 3.15 Idiopathic osteosclerosis. **A,** A cropped panoramic image with a well-defined alteration in the trabecular pattern apical to teeth #20 to 22 in a 15-year-old female. Peripherally there is slight cortication with no evidence of root resorption. **B,** Sagittal CBCT image showing a homogeneous area of hyperdensity near the canine and premolar root apices. The lesion has an irregular outline, but there is no indication of root resorption.

Fig. 3.16 **A,** Periapical image of a compound odontoma in a 35-year-old female. Multiple radiopacities resembling teeth are located interproximal to the maxillary central and lateral incisors. **B**, CBCT image demonstrating multiple high-density toothlike structures in association with a corticated low-density zone resembling dental follicle.

Fig. 3.17 Complex odontoma. Sagittal CBCT image with a high-density globular mass near the crown of a maxillary first molar. The mass exhibits the density of dentin.

Fig. 3.18 Panoramic radiograph demonstrating Paget disease of bone. A multifocal presentation involving both right and left mandibular molar areas.

Telegram: @dental_k

www.konkur.in

The coarse trabecular pattern and mixed radiolucency is common to Paget disease. There is significant root resorption, but the typical hypercementosis is absent.

Fig. 3.19 **A,** A radiodense ridge superimposed over the coronal portion of the roots extending from the implant in the #19 position to the mesial of tooth #30. This represents a prominent lingual exostosis and should not impact endodontic diagnosis but could interfere with visualization of the canals radiographically. This panoramic image also demonstrates well-defined uniform radiopacities inferior to tooth #21 and tooth #27 consistent with idiopathic osteosclerosis. **B,** Axial CBCT image of a maxillary torus characterized by a well-defined high-density area in the midline.

Fig. 3.20 **A,** Multiple periapical radiolucencies suggest the possibility of a noninflammatory etiology. However, teeth #12 and #13 did not respond to cold testing and both teeth were tender to percussion and palpation. The diagnosis for tooth #12 and tooth #13 was pulpal necrosis and symptomatic apical periodontitis. Nonsurgical root canal treatment was completed in both teeth. **B,** A 6-month recall demonstrated bone healing at the root ends of both teeth.

Fig. 3.21 Multiple well-defined radiolucencies in the anterior mandible. The patient reported no history of trauma and was asymptomatic. These teeth had no significant dental history and responded to both cold and electric pulp testing. Based on this clinical presentation, a diagnosis of periapical cemento-osseous dysplasia was made and no treatment was indicated.

Fig. 3.22 **A,** A 55-year-old female presented with pain, a sinus tract facial to #24, and a history of biopsy in the area several years prior. Teeth #23, #24, and #25 did not respond to cold or electric pulp testing. Radiographically the mixed radiolucent and radiopaque lesions were consistent with periapical cemento-osseous dysplasia, but the sinus tract and pulp testing indicated pulpal necrosis in teeth #23, #24, and #25. Pulpal necrosis was likely due to a disruption of the pulpal blood supply at the time of the biopsy. **B,** Nonsurgical root canal treatment was completed and there was no indication of vital pulp tissue in the canals. The previous biopsy report was obtained prior to root canal treatment, and the diagnosis of periapical cemento-osseous dysplasia was confirmed. **C,** At the 6-month recall the sinus tract had healed and the patient was asymptomatic. Because the radiographic lesions were not the result of a bacterial etiology, there was no expectation to see a significant

Telegram: @dental_k

www.konkur.in

change in the bone at the 6-month recall.

Fig. 3.23 Florid cemento-osseous dysplasia. A mixed radiolucent and radiopaque presentation with multiquadrant involvement. These teeth should respond normally to pulp testing unless there is a history of previous endodontic treatment. If a radiolucent area is present near the root apex of a previous root canal, it may be impossible to determine if the bone loss is due to a bacterial etiology or a manifestation of florid cemento-osseous dysplasia.

Fig. 3.24 Hyperparathyroidism. **A,** Sagittal CBCT image with multiple low-density lesions and changes in mandibular bone density. **B,** Axial CBCT image showing a thinning of the cortical plates in association with the low-density lesions.

Fig. 3.25 Langerhans cell histiocytosis. **A,** Reformatted panoramic image with destructive radiolucent area in mandibular molar region demonstrating "floating" teeth in the #17 and #18 area. **B,** Sagittal CBCT image confirming the aggressive nature of the lesion. **C,** Axial CBCT image revealing destruction of both buccal and lingual cortical plates.

Fig. 3.26 **A,** 50-year-old male with a complaint of increasing pain and swelling from the maxillary left canine region over the last year. Examination revealed a palatal swelling and radiographically there was an ill-defined radiolucent lesion near teeth #11 and #12. **B,** A periapical image with a mixed radiolucent and radiopaque lesion is present, but the margins are more well-defined than on the panoramic image. A biopsy was done to rule out a salivary gland neoplasm due to the palatal swelling and destructive nature of the radiolucency. The biopsy revealed both acute and chronic inflammation with sequestrum formation and bacterial colonies consistent with a diagnosis of osteomyelitis.

Fig. 3.27 **A,** Nonsurgical root canal treatment completed in tooth #30 due to pulpal necrosis. **B,** A 1-year recall due to increasing pain in the area. Radiographs revealed an ill-defined radiolucency associated with teeth #28, #29, and #30. These teeth exhibited abnormal mobility and there was significant soft-tissue inflammation, gingival bleeding, and exposed bone. The destructive nature of the bone loss and clinical presentation suggested malignancy, but a biopsy revealed sheets of chronic inflammatory cells and necrotic bone consistent with osteomyelitis. **C,** A panoramic image reveals complete osseous healing at 4-year recall.

Fig. 3.28 Medication-related osteonecrosis of the jaw. A cropped panoramic

Telegram: @dental_k

www.konkur.in

radiograph shows a sclerotic rim of bone over the mesial buccal root of tooth #3 and the root apex of tooth #4. There is a well-defined radiolucent area over the midroot of tooth #4 suggesting localized periodontal disease. Purulent discharge and exposed bone were present from teeth #2 to #5.

Fig. 3.29 A 29-year-old female with a history of numbness and swelling. These teeth responded normally to pulp testing, but there was a firm and tender buccal swelling from tooth #2 to #6. A diffuse radiolucency was present in the area of the buccal swelling with well-defined radiolucencies at the root apices. Teeth #3 and #4 had limited restorative histories and #2 and #5 were unrestored. Given this clinical presentation a noninflammatory etiology was suspected and biopsy revealed a lymphoma.

Fig. 3.30 A periapical image demonstrating multiple areas of radiolucency in a 42-year-old female with a chief complaint of achiness and loose teeth in the maxillary right quadrant. These teeth responded to both cold and electric pulp testing. A CBCT revealed an irregular and ill-defined loss of density that perforated the buccal and palatal cortical plates and the maxillary sinus. There was resorption of several root ends. The overall presentation suggested malignancy, and biopsy revealed metastatic breast cancer.

Fig. 3.31 **A,** Volumetric rendering reveals multiple osseous defects throughout the mandible consistent with multiple myeloma. **B,** Sagittal CBCT image showing a well-defined and destructive low-density lesion. **C,** Axial CBCT image exhibiting destruction of the trabecular bone and marked thinning of both buccal and lingual cortical plates.

Fig. 3.32 **A,** Well-defined radiolucency at the root apex of tooth #8. The previous root canal filling is short of the apex and exhibits numerous voids. A tissue sample obtained during apical surgery revealed a periapical granuloma. **B,** Well-defined radiolucency at the root apex of tooth #10. Apical surgery was completed, and the biopsy confirmed a periapical cyst. There is no way to differentiate periapical cysts from periapical granulomas using conventional imaging.

Fig. 3.33 CBCT images of the periapical granuloma from Fig. 3.32, *A*. It is not possible to differentiate periapical cysts from periapical granulomas using CBCT, and biopsy remains the best method to definitively make this distinction. **A,** Sagittal CBCT image of periapical granuloma. **B,** Axial CBCT image of periapical granuloma. **C,** Coronal CBCT image of periapical granuloma.

Fig. 3.34 **A,** Periapical image of tooth #30 with a previous root canal and a well-defined radiolucency at the mesial root apex. **B,** Angled periapical image of the same tooth, further demonstrating the extent of the lesion. **C,** Sagittal CBCT demonstrating a loss of density at the mesial root apex of tooth #30. This well-defined lesion was sampled during an apical surgery, and the biopsy showed a periapical cyst.

Fig. 3.35 **A,** Biopsy revealed a periapical cyst at the apex of tooth #7. There is a loss of trabeculation at the apex blending into normal bone resulting in an ill-defined radiolucency. **B,** Well-defined periapical granuloma at the root apex of tooth #27 was confirmed with a biopsy when bone loss and symptoms persisted following nonsurgical root canal treatment. Size and radiographic definition of periapical cysts and periapical granulomas are highly variable.

Fig. 3.36 Lateral radicular cyst. **A,** Preoperative image with gutta-percha tracing a draining sinus tract. Patient has a history of biopsy in the area that was diagnosed as a dentigerous cyst. Tooth #20 responds to both cold and electric pulp testing. Options included root canal treatment, extraction, or a second biopsy. The sinus tract suggests a necrotic pulp and the potential for a false-negative pulp test. Also, the diagnosis of dentigerous cyst is not accurate because the tooth has erupted. Nonsurgical root canal treatment was completed. **B,** Several lateral canals can be seen opposite the radiolucent areas and the sinus tract resolved within 1 week. **C,** Healing of bone is evident at 18-month recall.

Fig. 3.37 Lateral periodontal cyst. **A,** Periapical image of a well-defined radiolucency near the root apex of mandibular premolar and canine. The periapical image suggests a multilocular presentation that would not be consistent with periapical inflammatory disease from a bacterial etiology. **B,** Sagittal CBCT image revealing the loss of density between the canine and premolar teeth with a normal PDL space at the apex of tooth #21.

Fig. 3.38 **A,** Pulp testing indicated irreversible pulpitis symptoms from tooth #20 and a well-defined radiolucent area was identified between teeth #20 and #21. **B,** Nonsurgical root canal treatment was completed to address the thermal symptoms, and referral was made for a biopsy that identified an odontogenic keratocyst. Lateral radicular cysts, unicystic ameloblastomas, odontogenic keratocysts, and lateral periodontal cysts can exhibit identical radiographic appearances in the mandibular canine and premolar areas.

Fig. 3.39 Focal cemento-osseous dysplasia. **A,** Sagittal CBCT image demonstrating a mixed-density lesion with a low-density periphery between the mandibular second premolar and first molar. A second high-density lesion is present near the distal root apex of the first molar. **B,** Axial CBCT image exhibiting an expanded and thinned cortex from a mixed-density central globular mass with a hypodense periphery.
Fig. 3.40 **A,** Periapical image with a well-defined unilocular radiolucency at the root apex of tooth #8. Asymptomatic and no history of trauma. Tooth #8 responded to both cold and electric pulp testing. A biopsy revealed a nasopalatine duct cyst. **B,** The more classic presentation of nasopalatine duct cyst with a rounded radiolucency in the midline.
Fig. 3.41 Stafne defect. **A,** Sagittal CBCT image showing a well-defined loss of density inferior to the mandibular canal. **B,** Axial CBCT image demonstrating a lingual concavity. **C,** Coronal CBCT image also exhibiting a lingual concavity inferior to the mandibular canal with no involvement of the root ends.
Fig. 3.42 Anterior Stafne defect. **A,** Periapical image exhibiting a well-defined radiolucency near, but not at, the root apex of tooth #23. The lack of restorative history and location of the lesion suggest a noninflammatory etiology and these teeth respond to pulp testing. **B,** Reformatted panoramic image showing a loss of density near the apex of tooth #23. **C,** Coronal CBCT images reveal a concavity in the lingual cortex of bone with no involvement of the root ends.
Fig. 4.1 Pantomogram of a patient who has undergone several endodontic procedures without resolution of her chief complaint.
Fig. 4.2 A graphic depiction of the trigeminal nerve entering the brainstem. The primary afferent neuron synapses with a second-order neuron in the trigeminal nucleus. The second-order neuron carries pain information to the thalamus, from which it is sent to the cerebral cortex for interpretation.
Fig. 4.3 Illustration of pain that is referred from an area innervated by one nerve *(C2)* to an area innervated by a different nerve *(V2)*. Note that this phenomenon occurs secondary to the convergence of different neurons onto the same second-order neuron in the trigeminal nucleus. The sensory cortex perceives two locations of pain. One area is the trapezius region that represents the source of pain. The second area of perceived pain is felt in the temporomandibular joint area, which is only a site of pain, not a source of

Telegram: @dental_k

www.konkur.in

pain. This pain is heterotopic (referred).

Fig. 4.4 Illustration of the laminated pattern of innervation from orofacial structures into the trigeminal nucleus. These laminated patterns commonly reflect the patterns of referred pains felt in the orofacial structures.

Fig. 4.5 Herpes zoster involving the maxillary division of the left trigeminal nerve of the palate of a 45-year-old male. He complained of a deep, diffuse dull ache of his maxillary left quadrant for 1 week before this vesicular outbreak.

Fig. 4.6 Extrusion of the filling material from the distal canal of tooth #30 of a 36-year-old female. Her complaint was of extreme pain after completion of the root canal treatment followed by sharp, burning continuous pain that could be made worse by a light touch of the tooth.

www.konkur.in

Fig. 5.4 Two years after endodontic therapy of tooth #8, the patient returned with pain and swelling. A clinician mistakenly began endodontic access on tooth #7, without confirming the apparent radiographic diagnosis by sensibility testing. Tooth #7 was vital, and tooth #8 was successfully retreated after removal of the post.

Fig. 5.5 Many years after endodontic treatment of tooth #19, the patient returned with a chief complaint of pain and an inability to chew with the tooth. Despite the radiographic appearance of excellent endodontic treatment, the tooth was retreated and the patient's pain disappeared. Note the unusual distal root anatomy, which was not apparent during the initial procedure. **A,** Initial radiograph. **B,** Completion of initial endodontic therapy. **C,** Retreatment.

Fig. 5.6 Initial radiograph was misleading and implicated tooth #23 and tooth #24. Pulp testing indicated a vital pulp in tooth #24, and it was not treated. Retreatment of #23 resulted in healing of the periradicular lesion.

Fig. 5.7 Nonsurgical retreatment of tooth #30. An additional root was located and treated. **A,** Note inadequate endodontic treatment and large periapical lesion. **B,** Bitewing radiograph. **C,** Retreatment after post removal. **D,** Eighteen-month recall radiograph indicates periapical healing.

Fig. 5.8 Despite several exacerbations during endodontic retreatment, this case responded rapidly after the completion of therapy. Radiographic evaluation indicates a good periapical response after only 4 months. **A,** Radiograph taken 2 years after initial root canal therapy. **B,** Retreatment of the mesial root. **C,** Radiograph taken 4 months following retreatment.

Fig. 5.9 Four years after endodontic therapy, the patient complained of pain and swelling associated with tooth #6. The initial impression was that apical surgery was indicated. However, further radiographs revealed the true cause of the endodontic failure. The initial endodontic access through the crown or caries damaged the coronal seal and recurrent decay followed.

Fig. 5.10 **A,** Inflamed, edematous interproximal tissue *(arrow)* caused by acute endodontic pathosis. **B,** Soft-tissue healing *(arrow)* 3 days after initiation of endodontic treatment. **C,** Periradicular pathosis. **D,** Completed endodontic therapy. **E,** Periradicular healing at 1-year recall.

Fig. 5.11 A large, bony defect associated with tooth #20 healed after endodontic therapy. The tooth was nonvital, and no significant periodontal probing depth indicated pulpal disease.

Telegram: @dental_k

www.konkur.in

Fig. 5.12 Tooth #30 has a poor prognosis. Periodontal probing reached the apex of the distal root. Extraction is indicated and should be done as soon as possible to prevent further damage to the mesial bone associated with tooth #31. Implant site preservation is another consideration in treatment planning for this case.

Fig. 5.13 Resorptive defects can be successfully treated. Early intervention, before there is perforation of the root, increases the chance of success.

Fig. 5.14 **A,** Invasive cervical resorption of tooth #8 was detected on a periapical radiograph. **B,** A radiograph taken 9 years prior to the current examination. **C,** CBCT provided an accurate view of the location and the extent of the lesion. **D,** During surgery, following root canal therapy, the resorptive defect was excavated. **E,** The surgical site after restoration with Geristore. **F,** A 2-year follow-up CBCT shows that the lesion has not continued to extend.

Fig. 5.15 The presence of curved roots and multiple canals is a complicating factor.

Fig. 6.1 A cold refrigerant may be used to test for pulpal anesthesia before the start of a clinical procedure.

Fig. 6.2 An electric pulp tester also may be used to test for pulpal anesthesia before a clinical procedure is started.

Fig. 7.11 Common variant of a C-shaped canal anatomy found in Native Americans and Asian populations.
Fig. 7.12 μCT scans of mandibular premolars reflect a wide variation in canal morphology, moving from coronal to apical sections. The red color indicates a non–C-shaped canal space; green indicates a semilunar canal shape; and yellow indicates a continuous C-shaped configuration.
Fig. 7.13 An oval orifice must be explored with apically curved small instruments. When trying to locate the buccal canal, the clinician should place the file tip in the orifice with the tip curved to the buccal side. To explore for the palatal canal, a curved file tip is placed toward the palate. *B,* Buccal; *P,* palatal.
Fig. 7.14 **A,** In a mandibular second molar with two canals, both orifices are in the mesiodistal midline. **B,** If two orifices are not directly in the mesiodistal midline, a search should be made for another canal on the opposite side in the area of "X." *D,* Distal; *M,* mesial.
Fig. 7.15 Schematic representation of isthmus classifications described by Kim and colleagues. Type I is an incomplete isthmus; it is a faint communication between two canals. Type II is characterized by two canals

Telegram: @dental_k

www.konkur.in

with a definite connection between them (complete isthmus). Type III is a very short, complete isthmus between two canals. Type IV is a complete or incomplete isthmus between three or more canals. Type V is marked by two or three canal openings without visible connections.

Fig. 7.16 A, Mesial view of a mandibular premolar with a type V canal configuration. The lingual canal separates from the main canal at nearly a right angle. **B,** This anatomy requires widening of access in a lingual direction to achieve straight-line access to the lingual canal. This should be done with a DOM.

Fig. 7.17 A, Morphology of the root apex. From its orifice the canal tapers to the apical constriction, or minor apical diameter, which generally is considered the narrowest part of the canal. From this point the canal widens as it exits the root at the apical foramen, or major apical diameter. The space between the minor and major apical diameters is funnel shaped. **B,** Clinical view of major apical foramen. **C,** Histologic view of the apical constriction *(arrow)* and apical foramen *(yellow line)*. *P,* Pulp. (**B** and **C,** From Gutmann JL, Lovdahl PE: *Problem solving in endodontics,* ed 5, St. Louis, 2011, Elsevier.)

Fig. 7.18 Root apex following root canal filling *(RCF)* short of the actual root length. Histologic evidence shows that hard tissue *(black arrows)* has formed from the cells of the periodontal ligament *(PDL)* adjacent to the root filling material. Cementum formation on the internal aspect of the apical foramen is indicated by the yellow arrows. These findings accentuate the variable nature of the apical tissues.

Fig. 7.19 A, Straight-line access to a canal. The instrument should not be deflected until it reaches the initial canal curvature. In some cases coronal tooth structure must be sacrificed to obtain direct access to the pulp chamber. **B,** Diagrammatic representation of centrality and concentricity of symmetry and location of canal orifices. *D,* Distal; *M,* mesial.

A, Pretreatment radiograph of tooth #19 shows an interradicular lesion. **B–C,** Posttreatment radiographs after root canal preparation and obturation. Note the lateral canal in the coronal third of the root canal. **D–E,** Two-month recall radiograph suggests rapid healing.

Fig. 8.3 Root canal therapy as part of a comprehensive treatment plan. The patient, who was recovering from intravenous drug addiction, requested restorative dental treatment. Because of extensive decay, several teeth had to be extracted, and nine teeth were treated endodontically. Root canal treatment was aided by nickel-titanium rotary instruments, and obturation was done with lateral compaction of gutta-percha and AH26 as the sealer. Microsurgical retrograde therapy was performed on tooth #8, and the distobuccal root of #14 had to be resected. Metal-free adhesively luted restorations were placed, and missing mandibular teeth were replaced by implants. **A,** Pretreatment intraoral status, showing oral neglect. **B,** Posttreatment intraoral status at 4-year follow-up, showing fully functional, metal-free, tooth-colored reconstructions. **C,** Panoramic radiograph at 4-year recall shows sound periradicular tissues in relation to endodontically treated teeth.

Fig. 8.4 Example of a desired shape, with the original root canal fully incorporated into the prepared outline. **A–B,** Micro–computed tomography reconstructions in clinical and mesiodistal views of a maxillary molar prepared with a NiTi rotary system. The *green area* indicates the pretreatment shape, and the *red area* indicates the posttreatment shape. Areas of *mixed red and green* indicate no change (i.e., no removal of radicular dentin). **C–E**, Cross sections of the coronal, middle, and apical thirds; the pretreatment cross sections *(green)* are encircled by the posttreatment outlines *(red)* in most areas.

Fig. 8.5 Example of excessive thinning of dental structure during root canal treatment. **A–B**, Micro–computed tomography reconstructions show pretreatment and posttreatment root canal geometry of a maxillary molar. **C–E**, Cross sections of the coronal, middle, and apical thirds with pretreatment canal cross sections. Note the transportation and thinning, in particular, in the main mesiobuccal canal.

Fig. 8.6 Presence of microorganisms inside the main root canal and dentinal tubules. **A,** Scanning electron micrograph of a root canal surface shows a confluent layer of rod-shaped microbes (×3000). **B,** Scanning electron

electronically controlled second-generation motor with sensitive torque limiter. **C,** Frequently used simple torque-controlled motor. **D,** Newer-generation motor with built-in apex locator and torque control.

Fig. 8.31 Diagram comparing fracture loads at D_3 *(upper section of graph)* to torques occurring during preparation of root canals *(lower section of graph)*. Filled columns represent the largest file in each set, and open columns show the scores of the most fragile file (see text and Box 8.3 for details).

Fig. 8.32 Sequence of instruments used for optimal preparation of an access cavity (e.g., in an incisor). A parallel-sided diamond or steel bur is used to remove overlying enamel in a 90-degree angle toward the enamel surface *(1)*. The bur is then tilted vertically to allow straight-line access to the root canal *(arrow)*. A bur with a noncutting tip (e.g., Endo-Z bur or ball-tipped diamond bur) is then used to refine access *(2)*. Overhangs or pulp horns filled with soft tissue are finally cleared with a round bur used in a brushing or pulling motion *(3)*.

Fig. 8.33 Clinical views of an access cavity in a mandibular molar as seen through an operating microscope (×20). **A,** Modification with an ultrasonically activated tip (**B**).

Fig. 8.34 Diagram of coronal enlargement in a more complicated maxillary posterior tooth. This maxillary molar presents several difficulties, including a narrow mesiobuccal canal that exits the pulp cavity at an angle. A possible approach in a case involving difficult entry into the root canal system is to use a small orifice shaper *(OS1)* after ensuring a coronal glide path with a K-file. Use of a sequence of orifice shapers *(OS3 to OS1)* then allows penetration into the middle third of the root canal. Wider canals can accept a second sequence of orifice shapers. Copious irrigation and securing a glide path with a size #10 K-file are prerequisites for use of NiTi rotary instruments.

Fig. 8.35 Various precurved, stainless steel hand files for path finding and gauging. Compare the curves in the instruments to the ones in a plastic training block (gradation of ruler is 0.5 mm).

Fig. 8.36 Root ZX apex locator with lip clip and file holder.

0.5 mm apart.

Fig. 8.38 Presence of dentin dust as a possible source of microbial irritation. Tooth #18 underwent root canal therapy. The clinician noted an apical blockage but was unable to bypass it. Unfortunately, intense pain persisted and at the patient's request, the tooth was extracted a week later. **A,** Mesial root of tooth #18; mesial dentin has been removed. **B,** Magnified view (×125) of rectangle in **A** shows an apical block (gradation of ruler is 0.5 mm).

Fig. 8.39 Schematic diagrams showing the most common preparation errors. **A,** Apical zip. **B,** Ledge. **C,** Apical zip with perforation. **D,** Ledge with perforation.

Fig. 8.40 Diagram of handle movements during balanced force hand preparation. STEP 1: After pressureless insertion of a Flex-R or NiTiFlex K-file, the instrument is rotated clockwise 90 degrees, using only light apical pressure. STEP 2: The instrument is rotated counterclockwise 180 to 270 degrees; sufficient apical pressure is used to keep the file at the same insertion depth during this step. Dentin shavings are removed with a characteristic clicking sound. STEP 3: This step is similar to step 1 and advances the instrument more apically. STEP 4: After two or three cycles, the file is loaded with dentin shavings and is removed from the canal with a prolonged clockwise rotation.

Fig. 8.41 Instrumentation of root canals with the single length technique, in this example using the ProTaper instruments. After irrigation and scouting (*1* and *2*), the coronal thirds are enlarged with shaping files *S1* and *S2*. Hand files then are used to determine the WL and to secure a glide path. Apical preparation is completed with S1 and S2. Finishing files are used to the desired apical width.

Fig. 8.42 Stepwise enlargement of mesial root canal systems in an extracted mandibular molar demonstrated with micro–computed tomography (μCT) reconstructions. The buccal canal *(left)* was prepared with a LightSpeed (LS) instrument, and the lingual canal *(right)* was shaped with a ProTaper (PT) instrument. **A,** Pretreatment view from the mesial aspect. Note the additional middle canal branching from the lingual canal into the coronal third. **B,** Initial preparation and opening of the orifices, aided by ultrasonically powered instruments. **C,** First step of root canal preparation, up to LightSpeed size #20 and ProTaper shaping file S1. **D,** Further enlargement to LS size #30 and PT shaping file S2. **E,** Apical preparation to LS size #40 and PT finishing file F1.

www.konkur.in

F, Additional enlargement to LS size #50 and PT finishing file F2. **G,** Superimposed μCT reconstructions comparing the initial canal geometry *(in green)* with the shape reached after use of the instruments shown in **F**. **H,** Final shape after step-back with LS instruments and PT finishing file F3. **I,** Superimposed μCT reconstructions comparing initial geometry and final shape. Note the slight ledge in the buccal canal after LS preparation and some straightening in the lingual canal after PT preparation.

Fig. 8.43 Remaining potentially infected tissue in fins and isthmus configuration after preparation with rotary instruments. **A,** Cross section through a mesial root of a mandibular molar, middle to coronal third of the root. Both canals have been shaped; the left one is transported mesially (×10). **B,** Magnified view of rectangle in **A**. Note the presence of soft tissue in the isthmus area (×63).

Fig. 8.44 Effect of a hybrid technique on root canal anatomy studied in a Bramante model. **A1–A4,** Both mesial canals of an extracted mandibular molar have been instrumented. Canal cross sections are shown before instrumentation **(B1–D1). B2–D2**, Cross sections after preenlargement with a ProTaper F3 file *(left canal)* and a size #45, .02 taper instrument *(right canal)*. The final apical sizes were LightSpeed (LS) #50 and size #50, .02 taper in the left and the right canal, respectively.

Fig. 8.45 Irrigation and movement of irrigants depends on canal shape. Sequential enlargement of a canal in clear plastic block was performed with a sequence of ProFile instruments in accordance with the manufacturer's recommendations. Alternating irrigation with blue and red fluid was done after each preparation step. Note the apical presence of irrigant after sufficient shape has been provided. Note the distribution of fluid immediately after irrigation with a 30-gauge needle.

Fig. 8.46 A, Various types of needles for root canal irrigation. Shown are examples with open end and closed end, side vented. These are manufactured from plastic and stainless steel. **B,** SEM image of 30 gauge safety needle.

Fig. 8.47 Schematic diagram of the mechanism of action of NaOCl with the main interactions and properties highlighted. This diagram shows the chemical reaction of NaOCl when in contact with organic matter. The solution produces glycerol and soap (saponification reaction) and acts as a fat solvent degrading fatty acids. Moreover, hypochlorous acid is formed with a reduction of the pH and formation of chloramines (chloramination reaction).

www.konkur.in

trephine bur that was needed to bond the tube.
Fig. 10.67 Close-up view of the Roydent Extractor tip. The tip is placed over the separated instrument and tightened to grasp the obstruction.
Fig. 10.68 **A,** Preoperative radiograph showing two separated instruments in one tooth. **B,** IRS instrument with a removed file. **C,** Note that large size files are difficult to push through the cutout window. **D,** Postoperative radiograph.
Fig. 10.69 The Terauchi File Retrieval Kit. This kit was designed to distill down all the techniques mentioned in the text into a simple to use system for separated file removal.
Fig. 10.70 Separated file removal using the GentleWave System. **A,** A small fragment of file is lodged at the apical extent of the canal. **B,** After one irrigation cycle of the GentleWave device, a check radiograph shows that the separated instrument has been removed. **C,** Postobturation image.
Fig. 10.71 **A,** Diagrammatic representation of a canal block. Fibrotic and/or calcified pulp and debris that is potentially infected remains in the apical segment of the canal when the canal is instrumented short of the apical constriction. **B,** Preoperative radiograph showing obturation short of ideal length. The patient was symptomatic and the canals were blocked. **C,** Three months posttreatment. Treatment took a total of 3.5 hours over three appointments due to the time-consuming nature of bypassing blocked canals.
Fig. 10.72 **A,** Diagrammatic representation of a ledged canal. Potentially infected debris remaining in the apical segment can result in posttreatment disease. **B,** Attempting to bypass the ledge with a small file having a 45-degree bend in the tip. Note that the opening to the apical canal segment is on the inside of the canal curvature and coronal to the level of the ledge.
Fig. 10.73 **A,** Preoperative radiograph showing a distal canal ledge with a small amount of sealer that has entered the apical segment. The ledge prevented proper cleaning and sealing of the canal system resulting in posttreatment disease. **B,** The ledge has been bypassed. The attempt is made to blend the ledge into the contour of the prepared canal wall. **C,** Final obturation showing the filled ledge and apical segment. **D,** Thirteen-month recall showing healing. The patient was then directed to have a definitive coronal restoration placed.
Fig. 10.74 **A,** Endobender Pliers (Kerr Corporation) used to overbend a nickel-titanium hand GT file. **B,** GT hand file can hold a bend to allow it to bypass ledges.

Fig. 10.75 **A,** Preoperative radiograph showing mesial canal blockages and potential distal root ledging with accompanying posttreatment disease. **B,** Final film showing mesial blockages bypassed but inability to negotiate beyond the distal ledge. The patient elected to pursue no further treatment at this time. **C,** One-year recall. Despite not achieving all the aims of conventional endodontic therapy, periradicular healing is apparent. The patient is asymptomatic and will now begin the final restoration with the knowledge that apical surgery may be needed in the future.

Fig. 10.76 Frequently missed canals that may result in posttreatment disease. **A,** Missed second mesiobuccal canal (MB2) in an upper molar. **B,** Final obturation showing cleaned, shaped, and filled MB2 canal. **C,** Missed lingual canal on a lower incisor results in posttreatment disease. **D,** Immediate postoperative film showing management of the missed canal.

Fig. 10.77 Furcal post perforation resulting in persistent infection and furcal bone loss.

Fig. 10.78 **A,** Mesially angulated preoperative radiograph showing a palatally oriented post perforation in an upper incisor. **B,** An 8 mm narrow-based probing defect on the mesiopalatal corner of the tooth. **C,** Following coronal disassembly, the true canal can be seen lying in a facial direction relative to the palatal post preparation. **D,** The perforation was repaired with an external matrix of Colla-Cote and MTA. Subsequently, in conjunction with a periodontist, periodontal flap surgery was used to remove periodontal disease etiology from the long-standing pocket, and guided tissue regeneration procedures were instituted. **E,** Three-year reevaluation. The tooth is asymptomatic and mesiopalatal probing depth is 4 mm.

Fig. 10.79 Bioceramics are the materials of choice for perforation repair. **A,** ProRoot MTA (Dentsply Endodontics) is a medical grade of Portland cement that has had the arsenic removed so that it can be used in the human body. **B,** Brasseler Endosequence Root Repair Material (Brasseler USA). This material has better handling characteristics than MTA and minimizes discoloration of the tooth. **C**, Biodentine (Septodont) is another bioceramic that minimizes tooth discoloration.

Fig. 10.80 Geristore Kit. This and other resin-ionomers have been advocated for cervical perforation repair due to good biocompatibility and the shorter more controlled setting times that make them useful for transgingival root fillings.

Fig. 10.81 **A,** Large furcal perforation created during an attempt at endodontic access. **B,** Colla-Cote (Integra Life Sciences, Plainsboro, NJ) to be used as an external matrix material to recreate the external root contour. **C,** Canals have been found, preliminarily instrumented, and the external matrix has been placed. **D,** Canals are protected from being blocked using large endodontic files cut off above the orifice. MTA has been placed into the defect. **E,** Radiograph showing the initial repair with MTA recreating the vault of the furcation. **F,** On the second appointment, the blocking files are removed with difficulty since the MTA has flowed into the flutes and set. At this time, endodontic therapy is completed as normal. **G,** Postobturation radiograph. Note the radiolucency in the furcal vault, which represents the Colla-Cote external matrix material. **H,** Nineteen-month reevaluation. The patient is asymptomatic and there is evidence of healing in the furcal vault area.

Fig. 10.82 Mid-root level perforation repair. **A,** Preoperative film showing mesial strip perforation with bone loss. **B,** Nonsurgical internal repair with inability to negotiate canals to the apical terminus and MTA overextension into the furca. **C,** Apical and perforation repair surgery performed. **D,** One-year follow-up showing complete healing.

Fig. 10.83 **A,** This patient was in extreme pain following initial endodontic instrumentation by her dentist. Mid-root level perforation found on access. **B,** The original canal was found and protected with an endodontic file. MTA was vibrated using ultrasonic energy applied to the file and it flowed into the defect. Then the file is moved in a push-pull manner to dislodge it from the MTA prior to closure. Note that the defect was intentionally enlarged to allow for more predictable application of the MTA. **C,** On the second appointment, the file is withdrawn easily since it was detached from the MTA repair material. Now the endodontic therapy is concluded as normal. The patient has been asymptomatic since the end of the first appointment. **D,** Twenty-seven–month follow-up showing complete healing.

Fig. 10.84 **A,** Preoperative radiograph showing mid-root level post perforation and associated periradicular periodontitis. **B,** The crown was removed and ultrasonic energy was applied to the post. **C,** Using the trephine bur from the Ruddle Post Removal kit to mill the end of the post. **D,** The screw post is removed using the wrench from the Ruddle kit. **E,** After removal of the post and gutta-percha, a plastic solid core carrier is found in

Telegram: @dental_k

www.konkur.in

the canal and removed using the techniques described in this chapter. **F,** Postoperative radiograph showing MTA perforation repair, canal seal with gutta-percha, and post and core fabrication. **G,** Thirteen-month recall showing healing around the perforation repair site.

Fig. 10.85 **A** and **B,** Preoperative images showing posttreatment disease in the upper left central incisor and a large custom cast post. The patient elected to leave the post and perform surgery rather than risk damage to his new crown. **C,** Submarginal rectangular flap design. **D,** Three-week follow-up showing excellent soft-tissue healing. **E,** Eighteen-month follow-up showing excellent healing of the periradicular tissues.

Fig. 10.86 **A,** This lower second molar became symptomatic many years after nonsurgical treatment. Nonsurgical retreatment had a guarded prognosis due to the large multiroot cast custom post and core. Surgery was precluded by the poor access and proximity of the inferior alveolar canal. **B,** Ultrasonic root end preparation is made in the extracted tooth. **C,** A white MTA retrograde filling was placed. Note the C-shape. **D,** Immediate post-implantation radiograph. **E,** Seven-month reevaluation showing apical healing. The patient was asymptomatic.

Fig. 11.1 Previously treated maxillary lateral incisor with persistent periradicular disease. Nonsurgical retreatment is possible but would involve disassembly of an otherwise adequate coronal restoration. Periradicular surgery is a reasonable option.

Fig. 11.2 **A,** Previously treated maxillary first molar with persistent periradicular disease and obvious transportation of the main mesiobuccal (MB-1) canal. Nonsurgical retreatment is unlikely to correct this iatrogenic condition, and surgery is the preferred choice. **B,** Immediate postsurgery radiograph. The root-end preparation and fill was extended from the MB-1 canal in a palatal direction to include the isthmus area and the second (MB-2) canal. **C,** One-year follow-up examination: the tooth is asymptomatic, and periradicular healing is apparent radiographically. Although surgery was the first-choice treatment in this case and the outcome was favorable, a good argument could be made for nonsurgical retreatment before surgery to ensure disinfection of the canal and to attempt to locate a MB-2 canal.

Fig. 11.3 **A,** Indication for surgery (biopsy): large radiolucent lesion in the area of the maxillary left central and lateral incisors was detected on routine radiographic examination. All anterior teeth responded within normal limits

Telegram: @dental_k

www.konkur.in

to pulp vitality testing. **B,** After administration of a local anesthetic but before surgery, the lesion was aspirated with a large-gauge needle to rule out a vascular lesion. **C,** Buccal and palatal flaps were reflected. The lesion was directly accessible from the palate. An excisional biopsy was performed, and the sample was submitted for evaluation. **D,** Light microscopic section of the biopsy specimen; the lesion was diagnosed as a nasopalatine duct cyst (×400).

Fig. 11.4 Exploratory surgery was indicated to rule out or confirm a root fracture. Magnification and staining with methylene blue dye confirmed the presence of multiple root fractures. The tooth was subsequently extracted.

Fig. 11.5 Lateral view of the skull showing the anterior nasal spine and the proximity of the maxillary anterior root apices to the floor of the nose *(red arrow)*, as well as the typical location of the mental foramen *(black arrow)*.

Fig. 11.6 Preoperative evaluation of a mandibular left second premolar included a panoramic radiograph to help locate the mental foramen *(white arrow)*, which was not visible on a standard periapical radiograph.

Fig. 11.7 Palatal view showing the position of the greater palatine foramen *(arrows)*. The approximate location of the anterior palatine artery is marked in *red*.

Fig. 11.8 **A,** Radiograph demonstrating periradicular radiolucency associated with previously treated tooth #9. **B–C,** After full-thickness flap reflection, the nasopalatine neurovascular bundle was identified (**B**), protected, and isolated (*arrow* in **C**) during curettage of cystic lesion.

Fig. 11.9 **A,** Periapical radiograph with gutta-percha tracing the sinus tract to tooth #5. Periodontal probings were within normal limits. This tooth was initially referred for exploratory surgery to rule out root fracture. CBCT confirmed root fracture and the treatment plan was changed to extraction with possible bone graft and guided tissue regeneration for ridge augmentation prior to implant placement. **B,** Axial CBCT view demonstrating extent of lesion. **C,** Coronal CBCT view demonstrating root fracture *(red arrow)* and perforation of buccal cortical plate in area of root fracture but intact bone in the cervical area.

Fig. 11.10 **A,** Preoperative periapical radiograph showing large radiolucency associated with teeth #4, 5, and 6. **B,** CBCT reconstruction *(lateral view)*. Rotation of the 3D volume on a computer monitor demonstrated that intact bone was present around the apex of tooth #6 and the lesion was associated

Telegram: @dental_k

www.konkur.in

only with #4 and 5 (this could not be detected with multiple angled periapical radiographs). **C,** Axial CBCT view demonstrating facial-palatal extent of the lesion. **D,** Coronal CBCT view showing displacement of the sinus membrane (a finding that suggests a sinus membrane perforation will be detected during surgery). **E,** Clinical image after surgical access removal of granulation tissue, and root-end resection (note sinus perforation [*arrow*]). **F,** Placement of bone graft and Capset. **G,** Immediate postoperative radiograph. **H,** Two-year follow-up radiograph demonstrating good healing.

Fig. 11.11 **A,** Periapical radiograph demonstrating persistent periradicular pathosis following nonsurgical retreatment of tooth #19. The extension of the lesion in the vicinity of the mandibular canal and possible involvement of tooth #20 was uncertain based on interpretation of periapical and panoramic radiographs. Tooth #20 responded WNL to pulp vitality test. **B,** Coronal CBCT demonstrates that the periradicular lesion does not extend apical or lingual to the mandibular canal. **C,** Axial CBCT view demonstrating perforation of the buccal cortical plate and extension into, but not through, the furcation of #19 and presence of intact bone around #20.

Fig. 11.12 **A,** Basic tray setup for initial surgical access. Surgical instruments shown are distributed by Hu-Friedy ([HF] Chicago), CK Dental Specialities ([CKDS] Orange, CA), EIE ([EIE]), and G. Hartzell & Son ([GHS]). *Left to right* (left section of tray): Small round micromirror (CKDS); medium oval micromirror (CKDS); handle for microscalpel (CKDS); scissors (S18 [HF]); surgical suction tip (GHS). *Top to bottom* (main section of tray): Carr #1 retractor (EIE); Carr #2 retractor (EIE); TRH-1 retractor (HF); periosteal elevator (HF); Ruddle R elevator (EIE); Ruddle L elevator (EIE); Jacquette curette (SJ 34/35 [HF]); spoon curette (CL 84 [HF]); scaler (7/8 [HF]); surgical forceps (TP 5061 [HF]); mouth mirror (HF); periodontal probe (HF). **B,** Instrument tray for root-end filling and suturing. *Left to right* (left section of tray): Two Castroviejo needle holders (Roydent Dental Products, Rochester Hills, MI); Castroviejo scissors (S31 [HF]); micro–tissue forceps (TP 5042 [HF]). *Top to bottom* (main section of tray): Cement spatula (HF); Feinstein super plugger (F1L); microexplorer (CX-1 [EIE]); endoexplorer (DG-16 [EIE]); right Super-EBA Placing & Plugging instrument (MRFR [HF]); left Super-EBA Placing & Plugging instrument (MRFL [HF]); small anterior microburnisher and plugger (HF); small left microburnisher and plugger (HF); small right microburnisher and plugger (HF); medium anterior

Fig. 11.28 Reflection of the triangular flap to expose the root-end area.
Fig. 11.29 Submarginal (Ochsenbein-Luebke) flap.
Fig. 11.30 Clinical case involving a submarginal incision and flap. **A,** Periodontal probing of the entire area was performed before this type of flap was selected and the incision started. A submarginal incision often is used in aesthetic anterior areas of the mouth where postoperative gingival recession might expose the crown margins. **B,** The incision should be at least 2 mm apical to the depth of the sulcus. **C,** With the flap reflected, osteotomy and root-end resection were performed. Methylene blue dye was placed to mark the outline of the root end and to help identify cracks or fractures before root-end cavity preparation and filling. **D,** The flap was repositioned and sutured with 5-0 Tevdek.
Fig. 11.31 Elevator placed in the vertical incision for the first step in undermining flap reflection.
Fig. 11.32 Continuation of reflection of full-thickness flap.

www.konkur.in

root-end filling. Although many teeth treated this way healed successfully, newer materials and techniques described in this chapter are currently recommended.

Fig. 11.38 Perpendicular or near perpendicular root-end resection *(green line)* can be achieved with the use of microsurgical instruments and enhanced magnification and illumination.

Fig. 11.39 Diagram of a perpendicular root-end preparation and 3-mm deep cavity preparation along the long axis of the root.

Fig. 11.40 Error in root-end cavity preparation: ultrasonic preparation did not follow the long axis of the mesial root and therefore did not allow for proper sealing of this root. Healing is unlikely.

Fig. 11.41 Ultrasonic tip in use. Preparation along the long axis of the root is possible using tips designed for each area of the mouth. In this case, the tip is properly positioned for root-end cavity preparation of a maxillary first premolar but is dangerously close to the lip because of improper retraction. Heat generated by an ultrasonic tip can cause a thermal burn, which may result in scar tissue formation.

Fig. 11.42 Scanning electron microscope image of a root end prepared in vitro with an ultrasonic device at high-power setting. A distinct fracture line can be seen *(red arrow).* Root-end preparation with ultrasonic devices should be done at low power and with water coolant.

Fig. 11.43 Ultrasonic tips (Obtura Spartan) are available in a wide variety of configurations for use in different areas of the mouth. Most new tips have a special coating (zirconium nitride or diamond) that improves cutting efficiency.

Fig. 11.44 Ultrasonic tip with diamond coating and irrigation port (DENTSPLY Tulsa Dental Specialties).

Fig. 11.45 **A,** Immediate postoperative radiograph of a bonded root-end filling in a maxillary first premolar. **B,** Follow-up radiograph at 20 months showing good periradicular healing.

Fig. 11.46 **A,** Stropko syringe used to dry a root-end preparation before placement of the root-end filling material. **B,** Clinical use of an MTA delivery system (Dentsply Tulsa Dental). The device is loaded with MTA and placed over the root-end preparation. **C,** Pressing the plugger into the sleeve delivers the filling material to the root-end cavity preparation. The filling material then is compacted with microcondensers, and additional filling material is

Telegram: @dental_k

www.konkur.in

placed as needed.

Fig. 11.47 **A,** Preoperative radiograph (mesial angle) of a left mandibular first molar. Periradicular disease and symptoms had persisted after nonsurgical retreatment by an endodontic resident. The mesial canals were completely obstructed at the midroot level. The preoperative evaluation included three periapical radiographs, two different horizontal angulations, and one vertically positioned radiograph. **B,** Straight view preoperative radiograph. **C,** Vertical periapical view preoperative radiograph. **D,** Osteotomy and root resection perpendicular to the long axis of the root were performed; a partial bony dehiscence over the mesial root can be seen. **E,** Racellets were packed into the bony crypt to establish hemostasis. **F,** The Racellets were removed (one usually is left in the deepest part of the crypt during root-end preparation and filling), and the root end was beveled perpendicular to the long axis of the root. Methylene blue dye can be useful for identifying the root outline and locating any cracks. Ultrasonic root-end preparation was completed to a depth of 3 mm, connecting the MB and ML canals. **G,** Mineral trioxide aggregate root-end filling was placed and inspected. The bony crypt was then gently curetted to initiate bleeding and to remove any remnants of hemostatic materials. The flap was repositioned, and a radiograph was taken. **H,** An immediate postoperative radiograph confirmed the depth and density of the root-end filling and the absence of any foreign objects. Note that calcium sulfate and bone grafting material was placed in the osseous defect and over the root because of the large buccal dehiscence, although this is not routinely required in these cases.

Fig. 11.48 **A,** Preoperative radiograph of a maxillary left central incisor showing evidence of previous surgery but no apparent root-end filling. Because of the short root length and inadequate band of keratinized gingiva, an intrasulcular incision and full-thickness triangular mucoperiosteal flap design were selected. **B,** The root was minimally resected, and the root-end cavity was prepared ultrasonically. **C,** Mineral trioxide aggregate was placed and condensed into the root-end cavity preparation. **D,** The root-end filling was inspected before the flap was repositioned and sutured. **E,** Immediate postoperative radiograph. **F,** The 6-month follow-up radiograph showed good initial periradicular healing.

Fig. 11.49 **A,** A maxillary right first molar that was sensitive to percussion and tender to palpation over the MB root. Periodontal probing revealed a

Telegram: @dental_k

www.konkur.in

deep, narrow bony defect on the facial aspect of the MB root. The presence of a vertical root fracture was confirmed visually using magnification and methylene blue dye. The maxillary right second premolar had been recently extracted because of a vertical root fracture. **B,** A bonded amalgam core buildup was placed in the DB and P canals, and Geristore was placed in the MB canal system. **C,** The MB root was resected, and methylene blue dye was used to help define the extent of the fracture. **D,** At the 3-year follow-up visit, a new crown had been fabricated for the molar, and the premolar had been replaced with an implant.

Fig. 11.50 Example of postoperative instructions. Written instructions provide an essential reference for the patient, because verbal instructions often are difficult to remember after surgery. The instructions may be modified as needed; it is important to provide instructions that the patient can understand. For example, the readability of these instructions is at approximately the eighth-grade level using the Flesch-Kincaid Grade Level scale.

Fig. 11.51 **A,** Preoperative periapical radiograph of tooth #19. **B,** Clinical image demonstrating periodontal defect along the facial aspect of the mesial root. **C,** Immediate postsurgical radiograph. The mesial root end was prepared with ultrasonics and filled with MTA. A mixture of DFDBA and Capse was placed for guided tissue regeneration. **D,** One-year follow-up radiograph demonstrating good healing. Periodontal probings were WNL.

Fig. 11.52 (Case 1): **A,** Periapical radiograph of tooth #3. Retreatment RCT was attempted, but MB1 and MB2 were blocked. **B,** Sagittal view demonstrating the extent of the periapical lesion. **C,** Clinical view of periodontal probing to the apex. **D,** Axial view of the apical one third demonstrating the close proximity of the periapical defect to the MB root of tooth #2 (#2 responded WNL to pulp vitality testing). **E** and **F,** Coronal views of the MB and DB/P roots, respectively.

Fig. 11.65 Postoperative ecchymosis can be alarming to the patient but resolves spontaneously within 7 to 14 days.

Fig. 12.1 Schematic drawing demonstrating the different stages of root development and the subsequent reduction of the apical papilla and Hertwig root sheath**.**

Fig. 12.2 Schematic drawing illustrating potential sources of postnatal stem cells in the oral environment. Cell types include tooth germ progenitor cells *(TGPCs)*, dental follicle stem cells *(DFSCs)*, salivary gland stem cells *(SGSCs)*, stem cells of the apical papilla *(SCAPs)*, dental pulp stem cells *(DPSCs)*, inflamed periapical progenitor cells *(iPAPCs)*, stem cells from human exfoliated deciduous teeth *(SHEDs)*, periodontal ligament stem cells *(PDLSCs)*, bone marrow stem cells *(BMSCs)*, and, as illustrated in the inset, oral epithelial stem cells *(OESCs)*, gingiva-derived mesenchymal stem cells *(GMSCs)*, and periosteal stem cells *(PSCs)*.

Fig. 12.3 Dissection of an immature permanent tooth indicating the extent of the apical papilla (**A–C**). Note that this structure is likely lacerated during the evoked bleeding step of revascularization cases and thus cells from this structure, including mesenchymal stem cells of the apical papilla (SCAPs), are likely to be delivered into the root canal space. *Arrow* in **C** denotes junction of apical papilla and dental pulp.

Fig. 12.4 Evoked-bleeding step in endodontic regenerative procedures in immature teeth with open apices leads to significant increase in expression of undifferentiated mesenchymal stem cell markers in the root canal space. Systemic blood, saline irrigation, and intracanal blood samples were collected during second visit of regenerative procedures. Real-time RT-PCR was performed by using RNA isolated from each sample as template, with validated specific primers for target genes and 18S ribosomal RNA endogenous control. Expression of mesenchymal stem cell markers CD73 and CD105 was upregulated after the evoked-bleeding step in regenerative procedures. Data were normalized to the housekeeping gene 18S levels and presented as mean ± standard deviation fold increase in relation to systemic blood levels for each gene and analyzed with one-way analysis of variance with Bonferroni post hoc test ($n = 8$; $*P < .05$; $**P < .01$; n.s., not statistically significant).

Fig. 12.5 Mesenchymal stem cells were delivered into root canal spaces during regenerative procedures in immature teeth with open apices. Cells

Fig. 12.9 Regeneration of pulp tissue after autologous transplantation of mobilized dental pulp stem cells (MDPSCs) with G-CSF in pulpectomized teeth of young dogs on day 14. (**A** and **B**) Regenerated pulp tissue. (**B**) Odontoblastic cells *(black arrows)* lining to newly formed osteodentin/tubular dentin *(TD)* along with the dentin. (**C**) Immunohistochemical staining of BS-1 lectin. (**D**) Immunohistochemical staining of PGP9.5.

Fig. 12.10 An 11-year-old female was referred for evaluation of tooth #19 diagnosed with pulp necrosis and chronic apical abscess traced with a gutta-percha cone as seen in the periapical (PA) radiograph (**A**). A small-volume CBCT revealed resorption in mesial and distal roots (**B**). The canals were disinfected and medicated with Vitapex (**C**). Four weeks later, the patient was asymptomatic and tooth #19 and the sinus tract healed. The tooth was reaccessed, irrigated with 1.5% NaOCl and 17% EDTA, and bleeding evoked in all canals precurved 25 K. MTA was placed over the blood clot followed by glass ionomer and composite restoration (**D**). After 24 months, the patient was asymptomatic, the tooth responded to electric pulp tester (EPT) demonstrated complete healing as seen in PA radiograph (**E**) and small-volume CBCT (**F**).

Fig. 12.11 TAP remains in dentin, whereas most $Ca(OH)_2$ is eliminated after endodontic irrigation. Radiolabeled TAP or $Ca(OH)_2$ was placed within canals of standardized root segments and incubated for 28 days at 37°C. The canals were flushed with standardized volumes of EDTA and saline using either positive pressure with a side-vented needle (PP) or positive pressure with ultrasonic activation of irrigants (PUI). There was no difference in labeled TAP removal among groups with only approximately 20% of the medicament being removed by the irrigation protocols (**A**). In contrast, >80% of $Ca(OH)_2$ was removed, with more efficient removal observed in canals irrigated with PUI (**B**). Data are presented as the mean percentage of total radiolabeled medicament removal ± standard error of the mean. $*P < .05$ tested by the Student *t* test ($n = 12$/group).

Fig. 12.12 Dentin conditioning for 7 days with medicaments used in REPs has a profound effect on SCAP survival. Standardized dentin disks were treated for 7 days with TAP or double antibiotic paste (DAP) (concentrations of 1000 mg/mL or 1 mg/mL), $Ca(OH)_2$ (Ultracal), or sterile saline (control).

Telegram: @dental_k

www.konkur.in

SCAP in a Matrigel scaffold (BD Biosciences; Bedford, MA) was seeded into the lumen of the disks after the medicaments were removed and cultured for 7 days. Cell viability (survival) was determined using a luminescent assay. SCAP culture on dentin treated with TAP or DAP at the concentration of 1000 mg/mL resulted in no viable cells. Conversely, dentin conditioning with TAP or DAP at the concentration of 1 mg/mL supported cell viability with no difference from untreated dentin disks (control). Greater survival and proliferation were detected in the group treated with $Ca(OH)_2$. Data are presented as mean ± standard deviation of relative luminescence units (n = 12/group). *P < .05; ***P < .001; n.s., no statistical difference as tested by 1-way analysis of variance.

Fig. 12.13 Revascularization case illustrating treatment delivered to a 9-year-old male patient with a diagnosis of pulpal necrosis secondary to trauma, with a class 3 fracture in tooth #8 and a class 2 fracture in tooth #9 (**A**). The patient reported moderate to severe pain in both teeth. The teeth were isolated, accessed, and irrigated with 5% sodium hypochlorite, followed by placement of a mixture of ciprofloxacin, metronidazole, and minocycline for 55 days. Upon recall, the teeth were isolated, and the triple antibiotic paste was removed by irrigation. Bleeding was established in tooth #9 but not in tooth #8, where CollaCote was placed prior to mineral trioxide aggregate (MTA). The root canal systems were sealed with white MTA and a composite restoration (**B**).

Fig. 12.14 Regenerative endodontic case illustrating treatment delivered to a 13-year-old female patient with a diagnosis of pulpal necrosis secondary to caries, with an unspecified prior history of trauma (**A**). The tooth was isolated, accessed, and irrigated with 5% sodium hypochlorite, followed by placement of a mixture of ciprofloxacin, metronidazole, and minocycline for 21 days. Upon recall, the tooth was isolated, and the triple antibiotic paste was removed by irrigation. Bleeding was established in both teeth, and the root canal system was sealed with white mineral trioxide aggregate and a composite restoration (**B**).

Fig. 12.15 Regenerative endodontic case illustrating treatment delivered to a 9-year-old male patient with a diagnosis of pulpal necrosis secondary to trauma and periradicular chronic apical abscess on tooth #9 seen on preoperative periapical radiograph (**A**) with sinus track tracing with a gutta-

Telegram: @dental_k

www.konkur.in

percha cone **(A1),** and with CBCT (**B**). The patient was asymptomatic and has draining facial sinus tract. The tooth was treated with a regenerative procedure using double antibiotic paste (DAP), a mixture of ciprofloxacin and metronidazole for 1 month. At the second appointment, the sinus tract had resolved. Then, the tooth was isolated, and the double antibiotic paste was removed by irrigation with 20 mL 17% EDTA. Intracanal bleeding was evoked from the apical tissues using a precurved #25 hand-file extending approximately 2 mm beyond the root apex. A Collaplug barrier was placed at the mid-root level, then covered with 3-mm white MTA. Fuji II LC glass ionomer was used as a coronal seal of the MTA. The access was then restored with a composite resin and polished (**C**). At the 1-year follow-up, the patient was asymptomatic, responsive to electrical pulp test (EPT), periodontal probings were no greater than 3 mm, and the tooth exhibited grade I mobility without coronal discoloration. Importantly there was appreciable root maturation in addition to resolution of apical radiolucency seen on CBCT (**D**) and periapical radiograph (**E**).

Fig. 12.16 Regenerative endodontic therapy case illustrating treatment delivered to a 9-year-old female patient with a diagnosis of previously initiated endodontic therapy (pulpectomy) due to pain from pulpal inflammation on #29. Bilateral examination revealed presence of a talon cusp (dens evaginatus) which may have been the etiology of pulpal inflammation on #29. Radiographic examination revealed large periapical radiolucency on a periapical radiograph (**A**) and cone-beam computed tomography (CBCT) (**B**). The tooth was treated with a regenerative procedure using double antibiotic paste as an intracanal medicament for 48 days. On the second visit, the tooth was isolated, and the double antibiotic paste removed by saline irrigation followed by a final rinse with 17% EDTA. The canal was dried and bleeding was evoked followed by placement of an internal matrix of Collaplug 3–4 mm below the CEJ. Mineral trioxide aggregate (MTA) was then placed over it and the tooth was restored with Fuji II LC and Build It. There was complete resolution of apical radiolucency on 1-month recall (**C**), appreciable root development at 5 months recall (**D**) and complete root maturation seen at 1-year recall on both periapical radiograph and CBCT (**E** and **F**, respectively). Greater root maturation is observed at 2.5 years recall periapical radiograph (**G**) and CBCT (**H** and **I**). In addition, the tooth responded to EPT on the 1- and 2.5-year recall visits.

Fig. 12.17 Retrospective analysis of the percentage of change in dentinal wall thickness from preoperative image to postoperative image, measured at the apical third of the root (position of apical third defined in the preoperative image) in 40 control patients and in 48 patients following a revascularization procedure. *, $P < .05$ for each $P < .05$; ***, $P < .001$ versus mineral trioxide aggregate (MTA) apexification control group and NSRCT control group. $P < .05$ versus NSRCT control group only. $P < .05$ versus calcium hydroxide ($Ca[OH]_2$) and formocresol groups. $P < .05$ versus NSRCT control group only.

Fig. 12.18 Retrospective analysis of the percentage of change in root length from preoperative image to postoperative image, measured from the cementoenamel junction (CEJ) to the root apex in 40 control patients and in 48 patients following a revascularization procedure. ***$P < .001$ versus mineral trioxide aggregate (MTA) apexification control group ($n = 20$) and NSRCT control group ($n = 20$). $P < .05$ versus MTA control group only. Median values for each group are depicted by horizontal line, and individual cases are indicated by the corresponding symbol.

Fig. 12.19 Example of a revascularization case. Treatment was delivered to a 12-year-old boy who suffered trauma on tooth#9 2 years prior to the appointment. First appointment: (**A**), Clinical examination revealed a pain upon percussion and palpation. A working length file was placed into the root canal system (**B**). The tooth was slowly irrigated with 20 mL of 1.5% sodium hypochlorite (NaOCl) followed by 20 mL of saline using a Max-I-Probe needle inserted to the apical third (**C**). The canals were dried and medicated with calcium hydroxide paste (Ultracal) (**D**). The patient returned asymptomatic 1 month later. The tooth was isolated, accessed, and the medicament removed by slow irrigation with 1.5% NaOCl followed by 17% EDTA. After the canal was adequately dried, intracanal bleeding was achieved by lacerating the apical tissues (**E**). Blood clotting was observed after approximately 10 minutes **(F).** CollaPlug was placed below the CEJ (**G**) to serve as a matrix to position the white mineral trioxide aggregate coronal to the blood clot (**H**). The tooth was then sealed with a layer of Fuji IX (**I**), etched and restored with a composite (**J**). A final radiograph was taken (**K**). The tooth responded to electrical pulp tested at the 1-year recall, and demonstrated apical closure and moderate dentinal wall thickening (**L**).

Fig. 12.20 Trilevel outcome assessment pyramid. Regenerative endodontic procedures must be assessed and evaluated in a systematic manner, acknowledging that there are different levels of possible outcomes that carry different meanings and value for patients, clinicians, and scientists. The patient-centered outcomes represent the base of this pyramid, symbolizing the fundamental importance of achieving healing, reestablishment of function, and patient satisfaction and overall well-being.

Fig. 12.21 Schematic illustrating the different possible outcomes in root development following regenerative endodontic procedures. Type I shows root development and narrowing of the apical foramen. Type II shows root development but failure of apex closure. Type III shows no root development but closure of the apical foramen. Type IV shows no developments and failure to apex closure.

mitochondria.

Fig. 13.22 Schematic drawing showing distribution of nerve fibers in the dentin-pulp border zone. **A,** Fibers running from the subodontoblastic plexus to the odontoblast layer. **B,** Fibers extending into the dentinal tubules in the predentin. **C,** Complex fibers that branch extensively in the predentin. **D,** Intratubular fibers extending into the dentin. *D,* Dentin; *Fb,* fibroblast; *OL,* odontoblast layer; *OP,* odontoblast process; *PD,* predentin.

Fig. 13.23 Schematic diagram of the pathway of transmission of nociceptive information from the orofacial region. The trigeminal pain system is a complex multilevel system that begins with the *detection* of tissue damaging stimuli in the periphery, the *processing* of that input at the level of the medullary spinal cord, and the final *perception* of what is felt as pain in the cerebral cortex. There is growing appreciation for the concept that once a noxious stimulus is detected in the periphery, there is the opportunity for a great deal of modification of the message prior to ultimate perception. *RF,* Reticular formation.

Fig. 13.24 Response of a single dog pulp nerve fiber to repeated hydrostatic pressure stimulation pulses. Lower solid wavy line of each recording indicates the stimulation pressure applied to the pulp. Upper line *(kPa)* is the femoral artery blood pressure curve recorded to indicate the relative changes in the pulse pressure and the heart cycle.

Fig. 13.25 The average number of impulses recorded from dentine after application of pressure stimuli to the dentine. More impulses are recorded after application of negative pressure (outward fluid flow) than after positive pressure (inward fluid flow).

www.konkur.in

odontoblasts (in this case on the left side of the crown). When reparative dentin *(rd)* forms, it alters conditions so that dentinal innervation is reduced. **B,** Shallow class I cavity preparation on the cervical root of a rat molar was made 4 days earlier. Primary odontoblast *(O)* layer survived, and many new CGRP-immunoreactive terminal branches spread beneath and into the injured pulp and dentin. Terminal arbor can be seen branching *(arrowhead)* from a larger axon and growing into the injury site. Scale bar: 0.1 mm.

Fig. 13.30 NGF-mRNA is upregulated in the mesial pulp horn 6 hours after cavity preparation.

Fig. 13.31 Plastic changes in the trigeminal system. After injury, trigeminal neurons upregulate production of autonomic neuropeptides like neuropeptide Y (NPY) (**A**) and growth-associated protein 43 (GAP 43) connected to neurite outgrowth and regeneration (**B**). **C,** Confocal image showing that NPY is upregulated in injured neurons expressing GAP 43. **D,** The interstitial cells of the trigeminal tract of medullary dorsal horn express c-*fos* during chronic tooth pulp inflammation in rat.

Fig. 13.32 Schematic diagram of the perception and modulation of orofacial pain. Activation of primary afferent fibers (in this example from an inflamed maxillary molar) leads to the entry of a nociceptive signal that is conveyed across a synapse in the subnucleus caudalis of the trigeminal spinal nucleus. The second-order neuron projects to the thalamus; the information is then relayed to the cortex. A great deal of processing of nociceptive input can occur at the level of the medullary dorsal horn (MDH). The *inset* depicts a typical wide dynamic range (WDR) projection neuron and its relationship with other components of the MDH. Primary afferent fibers release the excitatory amino acid, glutamate—which binds and activates either AMPA or NMDA receptors—and substance P—which activates NK-1 receptors on the WDR neuron or excitatory interneurons. Descending fibers from the locus coeruleus *(LC)* and nucleus raphe magnus *(NRM)* secrete serotonin *(5HT)* and norepinephrine *(NE)*, respectively, which inhibit transmission. Release of γ amino butyric acid *(GABA)*, the amino acid, glycine, and endogenous opioid peptides such as met-enkephalin *(M-ENK)* also inhibit transmission of nociceptive information. Projection neurons may have autocrine or paracrine effects by the synthesis and release of prostaglandins *(PGs)* and nitric oxide *(NO)* via the action of cyclooxygenase *(COX)* and nitric oxide synthase *(NOS)*, respectively. Glial cells can modulate nociceptive processing by the

fibers.

Fig. 13.54 High-power view of a pulp stone from Fig. 13.53, showing the relationship of mineralization fronts to collagen fibers.

Fig. 13.55 **A,** Calcific metamorphosis of pulp tissue after luxation of tooth as a result of trauma. Note presence of soft-tissue inclusion. **B,** High-power view showing cementoblasts *(arrows)* lining cementum *(C)*, which has been deposited on the dentin walls.

Fig. 13.56 Anatomical structures in the apical area. **A**, Cementum apposition during life will change the apical anatomical landmarks. Number *1* denotes the radiographic apex, *2* the apical foramen (major) and *3* the apical constriction (the minor apical foramen) representing the transition between the pulpal and periodontal tissues. The line that goes through *1* and *2* is often denoted the anatomical apex. **B**, Age-related sclerosis, making the dentinal tubules impermeable to bacteria, is a progressive event starting in the apical area *(white arrow)*.

Fig. 14.1 **A,** Whitlockite crystals occlude the dentinal tubules in sclerotic dentin. **B,** Dentinal sclerosis is radiographically apparent beneath a deep class II lesion.

Fig. 14.2 Reactionary dentinogenesis *(TD)*. Note the tubular morphology and the discontinuity of the tubules at the interface of secondary and reactionary dentin. Resident odontoblasts are still present.

Fig. 14.3 Tertiary dentin. The strong stimulus of the impinging infection is cytocidal for odontoblasts. The resultant dentin is irregular with soft-tissue inclusions. Intact secondary dentin is depicted by *arrow A*, and tertiary dentin is designated by *arrow B*.

Fig. 14.4 The early pulpal response to caries is represented by a focal accumulation of chronic inflammatory cells *(arrowheads)*. Note that peripheral to the inflammation the pulpal parenchyma is relatively unaffected.

Fig. 14.5 Odontoblasts exposed to lipopolysaccharide (LPS) in an in vitro culture model express IL-8 as evidenced by immunostaining with anti-IL-8 antibodies. **A,** Control cultures not exposed to LPS (negative control). **B,** Immunostaining for IL-8 in cultures exposed to LPS.

Fig. 14.6 Dental caries stimulates the accumulation of pulpal dendritic cells in and around the odontoblastic layer.

Fig. 14.7 Innate immunity in the odontoblast layer (ODL). Bacterial components from caries activate cytokine/chemokine release from

Telegram: @dental_k

www.konkur.in

odontoblasts, dendritic cells, and/or macrophages via Toll-like receptors *(TLRs)*. Proinflammatory cytokines released from these cells act as autocrine and paracrine signals to amplify cytokine responses including antimicrobial peptide, cytokine, and chemokine production. The release of chemokines creates a migration gradient for immune cells to ODL while antimicrobial peptides reduce bacterial load.

Fig. 14.8 A proliferative response to caries in a young tooth, typically referred to as proliferative pulpitis, hyperplastic pulpitis, or pulp polyp.

Fig. 14.9 Histological photomicrograph of a molar with carious pulp exposure. The exposure had been capped but had failed and the patient presented with symptoms. The photomicrograph shows an area of necrosis and extensive inflammation throughout the coronal pulp.

Fig. 14.10 Scanning electron microscope (SEM) image of an exposed dentin surface of a hypersensitive area. **A,** A large proportion of dentinal tubules *(arrows)* are seen to be open. **B,** SEM image of a fractured dentinal tubule of a hypersensitive area. The lumen of the dentinal tubule is partitioned by membranous structures *(arrow)*. **C,** SEM image of exposed dentin surface of a naturally desensitized area. The lumens of dentinal tubules *(arrows)* are mostly occluded, and the surface is extremely smooth. **D**, SEM image of a fractured dentinal tubule of a naturally-desensitized area. Rhombohedral platelike crystals of from 0.1 to 0.3 μm *(arrow)* are present.

Fig. 14.11 Smear layer treated with 30% dipotassium oxalate for 2 minutes plus 3% monopotassium and monohydrogen oxalate for 2 minutes. Dentin surface is completely covered with calcium oxalate crystals. (Original magnification ×1900.)

Fig. 14.12 Effects of infiltration anesthesia (i.e., 2% lidocaine with 1:100,000 epinephrine) on pulpal blood flow in the maxillary canine teeth of dogs. There is a drastic decrease in pulpal blood flow soon after the injection. *Arrow* indicates the time of injection. *Bars* depict standard deviation.

Fig. 14.13 Effects of ligamental injection (i.e., 2% lidocaine with 1:100,000 epinephrine) on pulpal blood flow in the mandibular canine and premolar teeth of dogs. Injection was given in the mesial and distal sulcus of premolar teeth. Injection caused total cessation of pulpal blood flow which lasted about 30 minutes in the premolar teeth. *Arrow* indicates time of injection.

Fig. 14.14 With adequate water and air spray coolant, the same cutting tools, and a comparable remaining dentin thickness, the intensity of the pulpal

Telegram: @dental_k

www.konkur.in

response with high-speed techniques (i.e., decreasing force) is considerably less traumatic than with lower speed techniques (i.e., increasing force).
Fig. 14.15 Without adequate water coolant, larger cutting tools (e.g., no. 37 diamond point), create typical burn lesions within the pulp when the remaining dentin thickness becomes less than 1.5 mm.
Fig. 14.16 Burn lesion with necrosis and expanding abscess formation in a 10-day specimen. Cavity preparation dry at 20,000 rpm, with remaining dentin thickness is 0.23 mm.
Fig. 14.17 Schematic of convergence of tubules toward the pulp. **A,** Periphery of the dentin. Most surface area is occupied by intertubular dentin (☆), with a few tubules surrounded by hypermineralized peritubular dentin (✪). **B,** Near the pulp, the increase in tubule diameter has occurred largely at the expense of the peritubular dentin. This substrate has high protein content. As the remaining dentin is made thinner (from A to B), the permeability of the dentin increases, because both diameter and density of dentinal tubules are increased.
Fig. 14.18 Effects of crown preparation in dogs, with and without water and air spray (at 350,000 rpm) on pulpal blood flow. Tooth preparation without water and air spray caused substantial decrease in pulpal blood flow, whereas that with water and air spray caused insignificant changes in the flow
Fig. 14.19 Transmission electron microscope (TEM) images of undemineralized specimens of resin-bonded caries-affected dentin. **A,** Stained TEM image of undemineralized specimens following the application of the self-etch ABF system to caries-affected dentin. The hybrid layer (*H,* between *arrows*) was about 3 μm thick, and the underlying un-demineralized dentin *U* was highly porous *(arrowhead)*. The dentinal tubule was covered with a smear plug *(SP)* and was partially obliterated with large caries crystals (pointer). *A,* Filled adhesive. **B,** Stained section of the total etch Single Bond adhesive bonded to caries-affected dentin. A hybrid layer *H* between 15 and 19 μm thick could be seen, with a partially demineralized zone *(open arrows)* above the undemineralized caries affected dentin *U. C*, Composite; *T*, dentinal tubule. **C,** Higher magnification of the basal part of the unusually thick hybrid layer *H* shown in *A*. Banded collagen fibrils *(open arrow)* were separated by unusually wide and porous interfibrillar spaces *(open arrowheads)*. A partially demineralized zone *(Pd)* was present along the demineralization front. This zone was not seen in phosphoric-acid-etched

Fig. 17.31 Forest plot showing pooled and individual study's probability of complete periapical healing following root canal retreatment.
Fig. 17.32 Forest plot showing pooled and individual study's odds ratio of periapical health for teeth with preoperative periapical radiolucency undergoing primary root canal treatment versus root canal retreatment (pooled OR = 1.5; 95% CI: 1.0, 2.1).
Fig. 17.33 Forest plot showing pooled and individual study's probability of complete periapical healing following apical surgery.
Fig. 18.1 Light microscopy images of a deciduous tooth showing both physiologic and pathologic (inflammatory) resorption. **A,** Tooth 7.5 in a 9-year-old boy. Extensive exposure of a mesial pulp horn occurred during caries excavation, and pulp capping was performed. The patient was brought to the dental office 4 months after the treatment because of severe spontaneous pain. The radiograph shows radiolucencies on both apices and interradicularly. The parents did not accept any treatment and requested extraction. **B,** Longitudinal section taken on a mesiodistal plane, passing approximately at the center of the mesial root. (Hematoxylin-eosin [H&E] stain; original magnification ×25.) **C,** Detail of the resorption area apically in **B** (original magnification ×100). **D,** Magnification of the area demarcated by the rectangle in **C.** Two odontoclasts are present in an area of dentin being

Telegram: @dental_k

www.konkur.in

resorbed, surrounded by fibroblasts and inflammatory cells (original magnification ×400). **E,** High-power view of the area indicated by the *arrow* in **C.** An odontoclast is in close contact with the dentin in a Howship lacuna. Its cytoplasm appears vacuolated and shows a more intense staining reaction than the cytoplasm of the adjacent cells (original magnification ×1000). **F,** High-power view of the upper odontoclast in **D.** The characteristic ruffled border can be distinguished (original magnification ×1000). **G,** Howship lacuna with an odontoclast in another area (original magnification ×400). **H–J,** Progressive magnification of the mesial root apex. The resorption process may be physiologic at this level (original magnification ×16, ×100, and ×400).

Fig. 18.2 External apical inflammatory resorption. **A,** Maxillary first molar in a 46-year-old female patient that was causing severe pain. The radiographs revealed material in the pulp chamber, a large distal caries, and apical radiolucencies. The tooth was extracted. **B,** Palatal root apex extracted with the pathologic tissue attached. Note the ingrowth of granulation tissue into the foramen and the massive resorption of the apical profile. Also note the resorption of lacunae on the left radicular profile. (H&E stain; original magnification ×25.) **C,** High magnification of the area of the external radicular profile indicated by the *arrow* in **B.** A resorption lacuna can be seen in the cementum. (H&E stain; original magnification ×400.) **D,** View from the center of the apical periodontitis lesion showing severe concentration of chronic inflammatory cells (mostly plasma cells) (original magnification ×400).

Fig. 18.3 External apical inflammatory resorption. **A,** Mandibular second premolar extracted with the periapical lesion attached. This section, which did not pass through the canal, shows extensive apical resorption. (H&E stain; original magnification ×25.) **B,** Section taken approximately 120 sections away encompasses the apical foramen. In addition to resorption, the opposite phenomenon can be observed; that is, a large calcification partly embedded in the right apical dentin wall (original magnification ×25).

Fig. 18.4 External apical inflammatory resorption. **A,** Mesial root of a mandibular first molar extracted with a periapical lesion attached. This section passes through the canal and the foramen. Extensive resorption of the foramen has occurred, and a calcification can be seen more coronally. Note that the tissue in the apical canal and in the resorptive defect appears

Telegram: @dental_k

www.konkur.in

structured and continuous with the apical periodontitis lesion. A thick biofilm can be discerned layering the root canal walls more coronally. (Taylor's modified Brown & Brenn stain; original magnification ×25.) **B,** Palatal root of a maxillary first molar extracted with the periapical lesion attached. A cyst cavity is present in the body of the lesion. Resorption of the foramen is present, and a portion of the right dentin wall has been replaced by bone *(arrowheads).* (H&E stain; original magnification ×25.)

Fig. 18.5 Apical resorption. **A,** 22-year-old male patient complained of pain on chewing. This was caused by a molar that had been treated endodontically 1 year earlier. A radiograph showed obturation material only at the root canal orifices and a periapical radiolucency on the mesial root. Endodontic retreatment was recommended, but the patient declined this treatment. **B,** The patient returned 3 years and 3 months later because of an abscess that was causing severe pain. A radiograph disclosed destructive mesial caries and large periapical radiolucencies on both roots, along with resorption of the whole apical third of the distal root.

Fig. 18.6 External cervical resorption with replacement. **A,** Asymptomatic mandibular third molar. ECR was diagnosed on a radiograph taken for neighboring teeth. The tooth was extracted. Overview of the tooth (H&E stain; original magnification ×2). **B,** High power view of the resorptive area occupied by granulation tissue indicated by the *arrow* in **A**. Severe concentration of acute and chronic inflammatory cells (original magnification ×400). **C,** Detail of the area demarcated by the *rectangle* in **A**. The large area of resorbed dentin has been partly repaired with bonelike tissue. Note the thin layer of dentin remaining. No inflammatory changes can be observed in the adjacent pulp (original magnification ×25). **D,** Detail from **C**. Normal appearance of dentin, predentin, and odontoblast layer. Absence of inflammation (original magnification ×50).

Fig. 18.7 NanoCT imaging of tooth 13 and 3D modeling using CTan, CTvol, and CTvox software, showing the thickness distribution of the pericanalar resorption resistant sheet (PRRS).

Fig. 18.8 **A,** Structure of pericanalar resorption resistant sheet *(PRRS)* and pulp tissue. PRRS is consisted of predentin, dentin and occasionally bonelike tissue. **B,** Calcification inside the pulp. Histologic staining was performed with a combination of Stevenel's blue and Von Gieson's picrofuchsin, visualizing mineralized tissue *(red)* and nonmineralized tissue *(blue-green)*.

Telegram: @dental_k

www.konkur.in

Fig. 18.9 External cervical resorption (ECR). **A,** A 55-year-old female patient presented with an asymptomatic "pink spot." She had no history of any predisposing factors. **B,** A periapical radiograph revealed radiolucent defects on the proximal aspects of the upper left central incisor; note the ragged borders. **C,** A reconstructed coronal cone beam computed tomography (CBCT) slice reveals the true extent of the ECR lesion. Note that the root canal wall appears to be intact. Inhibitory factors in the root canal wall/odontoblastic prevented the ECR lesion from penetrating the root canal. **D,** A 41-year-old male patient presented as a new patient. Routine radiographic examination revealed a poorly defined periapical radiolucency in the root of the upper right central incisor. The appearance is suggestive of ECR; the patient had orthodontic treatment in his early teens and remembered "knocking the tooth" at least twice when he was very young. Reconstructed sagittal **(E)** and coronal **(F)** CBCT slices revealed the true nature of the ECR lesion and showed that the lesion was not amenable to treatment. **G,** The treatment options were discussed with the patient, and it was decided to review the tooth periodically. The 4-year radiograph shows no change in size of this asymptomatic lesion.

Fig. 18.10 **A,** This patient's upper left central incisor had a pink spot and was cavitated. **B,** A radiograph revealed an unusual presentation of ECR; the lesion is circular and has well-defined margins. Note that the outline of the root canal is visible and intact through the radiolucent lesion. **C,** The tooth was unrestorable and was extracted; note the large amount of granulation tissue. **D,** Three-dimensional reconstruction of the extracted tooth from microtomography data revealed bonelike tissue below the overlying granulation tissue. Note the intact root canal wall *(red arrow)*. **E,** Coronal reconstruction from a microtomography scan reveals how the predentin *(red arrow)* prevented the ECR defect from invading the root canal. In addition, bonelike tissue can be seen *(yellow arrow)*. Posttreatment view **(F)** and radiograph **(G)** after replacement of the upper left central incisor with an implant-retained crown.

Fig. 18.11 External cervical resorption (ECR) with replacement. **A,** Radiograph of a maxillary central incisor of a 34-year-old female patient who recalled being struck in the face with a cricket ball when she was 11 years old. The dentist mistakenly diagnosed the resorptive defect as caries and attempted to manage it accordingly. The tooth was asymptomatic; however, a

Telegram: @dental_k

www.konkur.in

4-mm periodontal probing depth was identified on the palatal aspect of the tooth. A cone beam computed tomography (CBCT) scan confirmed an ECR defect. The tooth was deemed unrestorable and was extracted with the patient's consent. **B,** Palatal view of the tooth at the end of the demineralization process, while immersed in the clearing agent. The tooth was separated into four portions, which were embedded separately in paraffin blocks. **C,** CBCT axial section passing through the coronal third at the level of *line 1* in **B.** The corresponding histologic section shows that most of the dentin has been replaced by a bonelike tissue. The root canal is no longer present. (H&E stain; original magnification ×8.) **D,** CBCT axial section passing through the middle third at the level of *line 2* in **B.** The root canal can be appreciated at this level, although reduced in size, but it appears to be encircled by bonelike tissue (original magnification ×8). **E,** CBCT axial section taken from the apical third at the level of *line 3* in **B.** At this level, the canal is the same size of that of the contralateral tooth. The histologic section confirmed the absence of bonelike tissue (original magnification ×8). **F,** Detail from **C** showing the transition from dentin to bonelike tissue (original magnification ×100). **G,** Higher magnification of **F.** The metaplastic tissue does not show the lamellar structure typical of bone (original magnification ×400). **H,** Detail of the canal in **D.** The metaplastic bonelike tissue has concentrically replaced a consistent portion of dentin, leaving in place a reduced layer of the original dentin (original magnification ×25). **I,** High-power view confirms that the tissue surrounding the canal is dentin (original magnification ×400). *Considerations:* The resorption process, followed by replacement with a bonelike tissue, started in the cervical area and extended in an apical direction, tunneling dentin circumferentially up to the transition between the middle and apical thirds of the tooth.

Fig. 18.12 External cervical resorption with replacement. **A,** Mandibular first and second molars in a 27-year-old female patient. The patient had symptoms of irreversible pulpitis associated with the lower right second molar; the lower right first molar was asymptomatic. **B,** CBCT scan taken through the second molar at the level of the area indicated by the *arrow* in **A.** Note massive resorption involving the crown and root. **C,** Mesial portion of the crown of the second molar after clearing. **D,** Section taken on a buccolingual plane. Overview shows resorption and replacement on the lingual side, corresponding to the area indicated by the *arrow* in **C.** (H&E stain; original

Telegram: @dental_k

www.konkur.in

magnification ×6.) **E,** Detail of the area indicated by the *arrow* in **C.** Several areas of resorption, with replacement by metaplastic tissue, can be seen (original magnification ×100). **F,** Magnification of the area indicated by the right *lower arrow* in **E.** The metaplastic tissue closely resembles bone (original magnification ×400). **G,** High-power view of the area indicated by the right *upper arrow* in **E.** Note the lacuna in dentin occupied by a multinucleated clastic cell (original magnification ×1000). **H,** High-power view of the metaplastic bone tissue in the area indicated by the *arrow* in **F.** A bone trabecula is being resorbed by a typical osteoclast (original magnification ×1000). **I,** High-power view of the area indicated by the left *lower arrow* in **E.** A Howship lacuna with odontoclasts can be seen (original magnification ×1000). **J,** High-power view of the area indicated by the left *upper arrow* in **E.** Note the islands of bone tissue, with typical osteocytes, surrounded by dentin (original magnification ×1000). *Considerations:* In this case the metaplastic tissue was similar to normal lamellar bone. It is interesting that the bone tissue was undergoing remodeling, as evidenced by the presence of osteoclasts. Osteoclasts and odontoclasts can be observed in the same area and show morphologic similarity.

Fig. 18.13 Early internal root resorption. **A,** A 54-year-old male patient presented with a long story of pain on chewing and with cold stimuli. Recently the pain had become continuous and severe. The maxillary first molar, which had a mesial amalgam restoration, did not respond to sensitivity tests. A radiograph showed a periapical radiolucency on the palatal root. After removal of the restorative materials, a crack line involving the pulp chamber floor was diagnosed, and the tooth was extracted. **B,** Some pathologic tissue remained attached to the palatal root apex at extraction. A longitudinal section passing at the center of the canal demonstrated vital connective tissue in the apical third. (H&E stain; original magnification ×16.) **C,** Detail of the canal in **B.** Note the connective tissue with vessels and relatively few inflammatory cells, in addition to the resorption lacunae on the root canal walls (original magnification ×1000). **D,** High-power view of the area of the canal wall indicated by the upper *arrow* in **C.** Note the resorption lacuna with odontoclasts (original magnification ×1000). **E** and **F,** Progressive magnification of the area of the canal wall indicated by the lower *arrow* in **C.** Note the Howship lacuna housing clastic cells. Predentin is present in some areas of the wall, but it is absent in the areas with active

Telegram: @dental_k

www.konkur.in

resorption (original magnification ×400 and ×1000).

Fig. 18.14 **A** and **B,** Parallax views of the maxillary left lateral incisor showing internal root resorption with necrosis. A gutta-percha point has been used to track the sinus. The reconstructed sagittal **(C)** and axial **(D)** slices from a CBCT scan reveal that the lesion has resorbed the palatal aspect of the root *(arrows)* and has nearly perforated the root wall. **E,** The tooth has been obturated with gutta-percha using a thermoplasticized technique.

Fig. 18.15 Light microscopy images of a tooth with internal (root canal) replacement resorption. The tooth belonged to a 44-year-old male patient who was referred to the first author for management of a perforated root. The tooth was asymptomatic on examination, but there was a history of previous trauma. **A,** Radiograph of a maxillary central incisor with a radiolucent lesion in the middle third of the root canal. The radiolucent lesion appears to be mottled, which suggests internal root resorption with metaplasia. **B,** Clinical radiograph of the tooth after extraction, taken at a 90-degree angle, showing the continuity of the resorptive lesion with the canal space. **C,** Cross section taken approximately at the level of *line 1* in *B.* The low-magnification overview shows that the dentin around the root canal had been replaced by an ingrowth of bone tissue, and the root appears to have been perforated on the distopalatal aspect. (H&E stain; ×8.) **D,** Higher magnification of *C.* (H&E stain; ×16.) **E,** High magnification of the area demarcated by the rectangle in *D.* The intraradicular dentin has been resorbed. (H&E stain; ×100.) **F,** High-magnification view taken from the right part of *C,* showing that the resorbed dentin has been replaced by lamellar bone. Osteocytes are present in lacunae between the lamellae. A characteristic cross section of an osteon can be seen on the right *(open arrows),* with concentric lamellae surrounding a vascular structure. (H&E stain; ×100.) **G,** High-magnification view of the area indicated by the left open *arrow* in *E.* A multinucleated resorbing cell (odontoclast) can be seen in a dentinal lacuna, indicating active resorption of the dentinal wall. (H&E stain; ×1000.) **H,** High-magnification view of the bone surface indicated by the right *arrow* in *E.* The large cells are osteoblast-like cells. Once they produced mineralized tissue, they were embedded in the bone lacunae, assuming the characteristics of osteocytes. (H&E stain; ×1000.) **I,** Cross section taken approximately at the level of *line 2* in *B.* The root canal is still large at this level and is surrounded by a relatively thin layer of newly formed bone. (H&E stain; ×16.) **J,** Cross section taken

Telegram: @dental_k

www.konkur.in

approximately at the level of *line 3* in *B.* At this level the root canal appears consistently narrowed by a dense layer of newly formed bone. (H&E stain; ×16.)

Fig. 18.16 Light microscopy images of a variant of internal (root canal) replacement resorption with tunneling resorption. The lower right lateral incisor belonged to a 39-year-old former boxer who had suffered a jaw fracture in a boxing match in his early twenties and was placed in intermaxillary fixation. The patient developed symptoms 20 years later and complained of pain associated with his lower incisors. **A,** Radiograph of the mandibular right incisors. The lower right central incisor had asymptomatic apical periodontitis associated with a necrotic and infected pulp. The lower right lateral incisor showed a large area of internal root resorption. The tooth did not respond to sensitivity tests. **B,** Sagittal CBCT slice shows some calcified tissue in the resorptive defect. **C,** Cross section taken at the level of *line 1* in *A* and *B.* The overview shows that the canal was apparently empty at this level. (H&E stain; ×6.) **D,** High magnification of the area indicated by the *arrow* in *C.* Lamellar bone filling an area of previous resorption. Note the osteon structure *(arrow).* (H&E stain; ×100.) **E,** Cross section taken at the level of line 2 in *A* and *B.* Overview shows that the canal lumen was partly occupied by necrotic remnants, partly by bonelike tissue. (H&E stain; ×8.) **F,** High magnification of the lower part in *E.* (H&E stain; ×50.) **G,** Higher magnification of *F.* Bone trabeculae are surrounded by necrotic debris. (H&E stain; ×100.) **H,** Cross section taken from the same area as that in *E.* (Taylor's modified Brown & Brenn [TBB] stain; ×16.) **I,** High magnification of the area indicated by the *arrow* in *H.* A fragment of bonelike tissue can be seen surrounded by bacteria-colonized necrotic tissues. (TBB stain; ×100; inset ×1000.) **J,** Longitudinal section passing approximately through the center of the root apex. Dentin walls have been resorbed and replaced by a bonelike tissue. (H&E stain; ×16.).

Fig. 19.1 **A,** Patient complained of acute pain on biting at the upper left molar (tooth #15). **B,** Clinical thermal tests revealed pulpal necrosis and a preoperative radiograph taken (periapical lesions noted). **C,** The tooth was split in half.

Fig. 19.2 The American Association of Endodontists *(AAE)* Endodontic Case Difficulty Assessment Form and Guidelines, developed to assist the clinician in assessing the level of difficulty of a given endodontic case and to help

Fig. 19.9 Foreign object in tooth left open to drain. Patient used a sewing needle to clear out food particles that were blocking the canal and broke the needle in the tooth.

Fig. 19.10 **A,** Preoperative radiograph. **B,** Transillumination.

Fig. 19.11 **A,** Preoperative radiograph. **B,** Clinical view. **C,** Transillumination. **D,** Extracted tooth showing the extension of the stained longitudinal fracture.

Fig. 20.1 Femur shaft cross sections (**A**) untreated bone section; (**B**) saline-treated bone; (**C**) sodium hypochlorite (NaOCl)-treated bone section. Grossly, NaOCl caused significant changes in cancellous structure, leaving large structural craters of apparent demineralization.

Fig. 20.2 **A,** Clinical presentation 3 days following the extrusion of sodium hypochlorite (NaOCl) during treatment of the maxillary right canine. The patient had difficulty opening her right eye, and the swelling had extended to

Telegram: @dental_k

www.konkur.in

the submandibular/sublingual regions on the affected side; she also experienced limited mouth opening. There was altered sensation infraorbitally and in the region of the upper right lip, but no reported paresthesia of the alveolar or facial nerves. **B,** One-month postextrusion, the ecchymosis had resolved, with a return of sensation and full function. Therapy was completed without incident.

Fig. 20.3 **A,** Radiograph of the maxillary left lateral incisor (#10, #22) before post removal. Radicular root resection had been completed, and the canal space is empty. Prior to recementation, the canal was irrigated with 3% NaOCl, precipitating the extrusion event. **B,** Twenty-four hours postextrusion, there was altered sensation infraorbitally and from the upper left lip to the left lip corner. In addition, the buccal branch of the facial nerve was affected, as evidenced by a distinct loss of upper lip and cheek function (the corner of the mouth could not be pulled up by the mimic musculature). The mouth opening was limited to 20 mm (**C**), 3 years postincident. The weakness of the mimic musculature of the left face side is clearly visible. Attempts to laugh resulted in a hanging left lip corner secondary to the weakness of the motor innervation by the facial nerve. In the gray-marked area there is a permanent hypoesthesia.

Fig. 20.4 **A,** Radiograph of the mandibular left first molar with a long indistinct separated instrument obviously longer than 4.5 mm in the mesial root that is extruded beyond the radicular foramen. **B1,** Sagittal view of cone-beam computed tomography (CBCT) showing the radicular end of the separated instrument is extended into the IAN and it measures 14 mm on it. **B2,** Sagittal view of CBCT showing root perforation in the distal canal *(red arrow)*. **B3,** Axial view of CBCT showing the perforation in the distal canal *(red arrow)*. **B4,** Coronal view of CBCT showing the radicular end of the separated instrument is in the IAN. **C,** Separated instrument in the mesiobuccal canal upon removal of root filling materials *(red arrow)*. **D,** Radiograph showing removal of the root fillings in the mesiobuccal canal revealed the overall length of the separated instrument *(red arrow)*. **E,** Retrieved separated instruments measuring 14 mm on the ruler. **F,** Radiograph showing the completion of the separated instrument removal. **G,** Perforation site in the distal canal *(yellow arrow)*. **H,** Perforation repaired with mineral trioxide aggregate (MTA) *(yellow arrow)*. **I,** Postoperative radiograph showing root canal fillings in all the canals and perforation repair

Telegram: @dental_k

www.konkur.in

(yellow arrow). **J,** One-month postoperative radiograph revealing the periradicular lesions still present. **K,** Three-month postoperative radiograph showing periradicular healing.

Fig. 20.5 **A,** Separated file covered with debris. **B,** Mineral oil immediately permeated the spaces between the canal walls and the separated file revealing the surface of the file and broke through the entire file. **C,** Separated file covered with debris. **D,** Water did not permeate those spaces at all.

Fig. 20.6 **A**, Ninety-degree semicircular space created on the inner canal wall with the spoon tip on the microscopic view *(white arrow)*. **B**, A 150-degree semicircular space created on the inner canal wall with the straight tip, which is still not wide enough to make it "dance" because of the canal walls on both sides still holding the separated file *(white arrows)*. **C**, More than 180-degree semicircular space created on the inner canal wall with the straight tip, which results in loosening the separated file. **D**, Magnification of the spoon tip. **E**, Magnification of the Katana tip; a frontal view on the left (0.5 mm in width) and a side view on the right (0.1 mm in thickness). **F**, Magnification of the straight tip (0.1 mm in diameter).

Fig. 20.7 **A**, Thicker ultrasonic tip touches the top of the separated instrument before being placed into the space on the canal wall *(red arrow)*. **B**, Side view shows the thicker ultrasonic tip in relation to the separated instrument, which may result in pushing it into a radicular direction. **C**, Thinner ultrasonic tip can be placed into the space on the canal wall without touching the top of the separated instrument *(red arrow)*. **D**, Side view shows the thinner ultrasonic tip in relation to the separated instrument.

Fig. 20.8 **A,** Canal enlarged to the separated file with a large diameter rotary file. **B,** Space created on the inside curve with the spoon ultrasonic tip, followed by the straight tip. **C,** Space extended to about one third of the file length until the separated file dances. **D,** Ultrasonic activation from the outer curvature. **E,** Separated file redirected in a radicular direction by ultrasonic activation from the outer wall. **F,** Ultrasonic activation from the inner curvature. **G,** Separated file redirected in a coronal direction by ultrasonic activation from the inner wall. **H,** Ultrasonic tip placed on the separated file where there is no canal wall behind it, which may result in secondary fracture.

Fig. 20.9 The coronal one third of the file length is typically the part to be stuck in the canal walls, whereas the radicular portion of the file is typically

Telegram: @dental_k

www.konkur.in

not in contact with the canal walls. Stress is concentrated mostly on the coronal one third of the file length.

Fig. 20.10 **A,** Separated file may accidentally come out with ultrasonic activation during a preparation phase. **B,** EDTA solution is put into the canal to take advantage of cavitation and acoustic streaming effects for instrument retrieval. **C,** Ultrasonics must be activated within the space created. **D,** Separated file is removed from the canal with ultrasonics in the presence of EDTA solution or oil.

Fig. 20.11 **A**, Separated file in the canal with the space created on the inner wall *(right side)*. **B**, Separated file shifted to a different place in the space created *(red arrow)*. This movement shows the separated file is "dancing." **C**, Separated file in the canal with the space created on the inner wall *(right side)*. **D**, Separated file flexing to a different place *(red arrow)*. **E**. Separated file returning to the original place *(red arrow)*. This movement shows the separated file is "flexing."

Fig. 20.12 **A**, Nonvisible separated file around the second curve, beyond the first curve. **B**, Thin ultrasonic tip placed in the space on the inner canal wall of the second curve.

Fig. 20.13 **A**, Thin ultrasonic tip placed into the gap between the inner wall and the separated file and activated. **B,** Ninety-degree semicircular space created in this gap with ultrasonics. **C,** Ultrasonics activated directly on the separated file from this space. **D,** Canal walls contacting the separated file eliminated with ultrasonic oscillation transferred to the separated file from the vibrating ultrasonic tip. **D,** Separated file loosened and dislodged from the original position *(red arrow)*.

Fig. 20.14 **A,** Separated file beyond the severe curve in relation to the file placed in the mesiobuccal (MB) canal. **B,** Thin ultrasonic tip placed in the gap between the inner wall and the separated file. **C,** Separated file is not visible in the MB. **D,** Separated file coming out of the canal. **E,** Removal of the separated file confirmed on a radiograph. **F,** Retrieved separated file along with the original file

Fig. 20.15 **A**, Separated file loose beyond the radicular foramen. **B,** Ultrasonic irrigation such as ProUltra PiezoFlow using saline may help retrieve the separated file which is not engaged in the canal wall.

www.konkur.in

dissolving periapical lesion.

Fig. 20.29 Nonvisible ledge removal with ultrasonics. **A,** Ledge formed beyond the curve. Cone-beam computed tomography (CBCT) is taken to locate both the ledge and the original pathway. **B,** Canal coronal to the ledge is flared in an anticurvature direction with NiTi rotary files in brushing motions to possibly visualize the ledge and the original pathway. Original pathway to the canal terminus is explored with a #10 precurved K-file or the precurved TFRK-ME for a sticky feeling and then radiographs are taken with it inserted in the canal to see if it is in the original canal beyond the ledge. **C,** Straight ultrasonic tip is precurved the same way as the hand instrument used and placed into the original canal to eliminate/reduce the ledge and to open up the entrance to the original pathway. The red portion needs to be smoothed out to facilitate the insertion of the next larger file into the original pathway. **D,** Postoperative canal showing the ledge is significantly reduced.

Fig. 20.30 **A,** Preoperative radiograph of a maxillary right second molar showing periradicular lesions. Note the root filling in MB is overextended beyond the radicular foramen. **B,** A series of cone-beam computed tomography (CBCT) images in axial view from the apical third to the radicular foramen (**B1** to **B3**) reveals an oval MB canal turning round toward the radicular foramen and the original pathway *(red arrows)* curves in a distopalatal direction with the root filling turning away from the original canal (off-center). **C1** and **C2,** A pair of CBCT images in sagittal view clearly show both the overextended root filling (*red arrow* in **C1**) and the presence of the distally curved original canal (*red arrow* in **C2**). **D,** CBCT image in coronal view also shows a large lesion associated with the MB canal, with the root filling extruded beyond the radicular foramen (perforation). **E1 to E3,** A series of microscopic images shows the overextended root fillings being removed with the TFRK-GPR (**E1** and **E2**) and the original canal (**E3,** *red arrow*) was located in the MB canal and enlarged with ultrasonics. **F,** Original canal was negotiated and then the apical patency was established with a precurved micro-opener followed by a precurved ProTaper S1. **G,** Postoperative radiograph showing the completed root fillings including the original canal and the ledged canal with perforation *(red arrows)*. **H,** Three-month follow-up showing healing in progress. **I,** Six-month follow-up showing nice periapical healing. **J,** A series of 6-month postoperative CBCT images in axial view from the apical third to the

Telegram: @dental_k

www.konkur.in

radicular foramen (**J1** to **J3**) reveals root fillings in both the original canal and the ledged canal with nice periapical healing. **K,** A pair of 6-month postoperative CBCT images in sagittal view (**K1** and **K2**) shows nice periapical healing compared to the preoperative CBCT images. **L,** Six-month CBCT image in coronal view also shows nice periapical healing.

Fig. 20.31 **A,** Canal coronal to the ledge is enlarged with a #3 GG bur. **B,** Small straight rotary file (#10/.02 or #10/.04) rotating at 300 RPM or faster will not get into the original pathway. **C,** Small precurved rotary file rotating at 100 RPM or 150 RPM with 90-degree clockwise and 30-degree counterclockwise reciprocating motions will most likely get into the original pathway. **D,** Small precurved rotary file rotating at 300 RPM ended up going into the ledged canal *(red arrow)*. **E,** Small precurved rotary file rotating at 100 RPM was able to get into the original canal *(white arrow)*.

Fig. 20.32 **A,** Radiograph taken in 2010 for evaluation of the ledge *(red arrow)* in the mandibular left first premolar and the separated file *(white arrow)* in the mandibular left second premolar showing no radiographic periapical pathosis and both of the teeth were asymptomatic. **B,** Radiograph taken in 2019 for evaluation of those teeth showing the same without any sign of periapical pathosis *(red and white arrows)*.

Fig. 20.33 Maxillary sinus aspergillosis. **A,** Preoperative radiograph showing a lesion associated with the palatal root, from which the extrusion of the root filling materials occurred in the maxillary sinus. **B,** Cone-beam computed tomography (CBCT) image in sagittal view showing the relation between mucositis on the maxillary sinus floor and the gutta-percha filling materials. **C,** CBCT image in axial view showing the relation between mucositis on the mesial wall of the maxillary sinus and the extruded root filling materials. **D,** CBCT image in coronal view showing the relation between the palatal root and the extruded root filling materials. **E,** Postoperative radiograph of orthograde root canal retreatment on the maxillary left first molar showing the mesiobuccal, distobuccal, and palatal root canals were adequately filled without overextension of the filling materials. **F,** Aspergillus was found on the filling materials retrieved from the maxillary sinus.

Fig. 20.34 Root filling materials extruded beyond the radicular foramen. **A,** Preoperative radiograph showing overextension of the root filling material with a large lesion associated with the root. **B,** Root filling in the canal was mechanically removed, but the extruded portion of it remained in the

Telegram: @dental_k

www.konkur.in

periradicular tissues. **C,** Mineral trioxide aggregate (MTA) was filled in the canal with the extruded portion remaining in the lesion. **D,** Six-month postoperative radiograph showing the reduced size of the lesion, but the lesion surrounding the extruded portion stayed the same in size for the next 6 months, indicating infection of the extruded gutta-percha point. The extruded portion was surgically removed from the lesion at this point. **E,** Three-month follow-up radiograph after the surgery showing the resolving lesion. **F,** Twelve-month follow-up radiograph after the surgery showing a more periradicular healing. **G,** Gutta-percha point retrieved from the lesion.

Fig. 20.35 **A,** Preoperative radiograph showing a large periradicular lesion associated with the root of the mandibular left incisor. **B,** Interoperative radiograph showing the cast post and the root filling in the canal was mechanically removed. Calcium hydroxide was placed as an intracanal dressing on the first appointment. **C,** Postoperative radiograph on the second appointment showing the canal was obturated with mineral trioxide aggregate (MTA), which resulted in overextension of the material into the periradicular tissues. **D,** Six-month postoperative radiograph showing the significantly reduced size of the lesion. **E,** One-year postoperative radiograph showing a nice periradicular healing with hard tissues formed on the radicular end of the MTA filling, resulting in a longer root aside from a residual of the MTA root filling extruded into the periradicular tissues. **F,** Three-year postoperative radiograph showing the tooth has maintained healthy periradicular tissues with the extruded MTA filling reduced in size. **G,** Twelve-year postoperative radiograph showing the tooth has maintained healthy periradicular tissues with the extruded MTA filling completely dissolved in the bone. **H,** Sixteen-year postoperative radiograph showing the tooth has maintained healthy periradicular tissues with healthy lamina dura surrounding the root.

Fig. 20.36 **A,** Preoperative radiograph of the mandibular right first molar showing extruded root filling materials into periapical tissues *(red arrows)*. **B1** and **B2,** Cone-beam computed tomography (CBCT) images in axial view showing the perforation site from the mesiobuccal canal into the furcation *(red arrow)*. **C,** CBCT image in sagittal view showing extruded root fillings from the distal root *(red arrow)* and the perforation *(white arrow)*. **D1** and **D2,** CBCT images in coronal view showing the mesial root without extruded root fillings *(red arrow)* (**D1**) and the distal root with extruded root fillings *(red arrow)* (**D2**). **E,** Magnification of the MB canal with perforation *(red*

www.konkur.in

arrow). **F,** Interoperative radiograph showing removal of the intracanal root fillings. **G,** Magnification of the MB canal showing removal of the extruded root fillings from the perforation with an XP-Endo Shaper. **H,** Magnification of the distal canal showing removal of the extruded root fillings from the distal root end with an XP-Endo Shaper. **I,** Magnification of the root canals after the removal of extruded root fillings *(white arrows)*. **J,** Postoperative radiograph showing all the root canals including the perforation were successfully filled with mineral trioxide aggregate (MTA). **K,** Three-month postoperative radiograph showing reduced periapical lesions. **L,** Ten-month postoperative radiograph showing nice periapical healing. **M,** Ten-month postoperative CBCT image in sagittal view showing furcal healing. **N,** Ten-month postoperative CBCT image in sagittal view showing nice periapical healing around the perforation site *(white arrow)*. **O,** Ten-month postoperative CBCT image in coronal view showing nice periapical healing associated with the mesial root *(white arrow)*. **P,** Ten-month postoperative CBCT image in coronal view showing nice periapical healing associated with the distal root *(white arrow)*. **Q** and **R,** Ten-month postoperative CBCT image in axial view showing periapical healing associated with the perforation site *(white arrows)*.

Fig. 20.37 Diagrams showing removal of gutta-percha filling materials extruded beyond the radicular foramen. **A,** Solid gutta-percha filling extruded beyond the radicular foramen. **B,** Small space is created between the canal wall and the gutta-percha filling with a thin ultrasonic tip (such as TFRK-6/12 and TFRK-S ultrasonic tips). **C,** Gutta-percha removal hand instrument, such as the TFRK-GPR and the EGPR, is brought into the space with the tiny projection pressed against the gutta-percha filling to pull it out. **D,** Extruded gutta-percha root filling portion separated from the coronal portion within the canal. **E,** Chloroform or some other solvent is filled in the canal to agitate it beyond the widened radicular foramen with a gutta-percha removal hand instrument or expandable rotary files to dissolve the extruded portion. **F,** Gutta-percha filling material is diluted, dissolved with the hand instrument in push-and-pull motions, and is irrigated out with a minimally invasive irrigant such as saline. **G,** Extruded gutta-percha filling material can also be braided out with those expandable rotary files with caution not to break them or not to damage the inferior alveolar nerve if close to it.

Fig. 20.38 **A,** Panoramic radiograph demonstrating significant overfilling and

Telegram: @dental_k

www.konkur.in

extension in the radicular vacuoles and overlying the mandibular canal. **B,** A coronal CT section demonstrating that the extruded material is lateral and below the mandibular bundle *(arrows).* The patient's sensory complications were temporary.

Fig. 20.39 Cone-beam computed tomography (CBCT) image in coronal view showing that the mesiobuccal root apex of a maxillary second molar is in close proximity with the sinus floor.

Fig. 20.40 Cross section of mandible in the molar region showing the presence of bone vacuoles *(yellow arrows)*.

Fig. 20.41 Longitudinal mandible cross section in the molar region showing the spongy bone cover of the neurovascular bundle. Note the multiple fenestrations and honeycombed trabeculations.

Fig. 20.42 Overfill of the distal root under direct observation. Note the proximity of the extruded material to the artery and nerve bundle (pedicle).

Fig. 20.43 Full-thickness reflection of the flap in the region of the premolar root apices reveals the mental nerve exiting the foramen; note how the tissue "funnels" from the reflected flap to the foramen.

Fig. 20.44 Infiltration dentistry is dependent upon the site and procedure.

Fig. 20.45 **A,** Nerve injury proximal to endodontically treated tooth. Cause = endo. **B,** Inferior dental block nerve injury initially will cause neuropathy of the whole dermatome.

Fig. 20.46 **A,** Facial presentation after the rubber dam was removed. **B,** Close-up view reveals marked distention of the left suborbital region, with ptosis of the eye and loss of the nasolabial fold. There was marked crepitus upon palpation, but the patient was pain-free. **C,** She was placed on an antibiotic regime, as per the protocol, 2 days after the incident, the emphysema has resolved and the tissues are normal in color and texture.

Fig. 20.47 **A,** Preoperative radiograph tooth #10[158]; dystrophic calcification has obliterated the pulp chamber and the coronal half of the canal space. **B,** A #10 file inserted to estimated working length; the file is actually through a facial perforation of the root at the radicular extent of the ultrasonic excavation. Repeated drying of the canal space using an air syringe forced air through the perforation site and precipitated the emphysema seen in Fig. 20.26, *A* and *B*. **C,** The radicular perforation site was sealed with mineral trioxide aggregate (MTA) before the canal space was obturated. The tooth

Telegram: @dental_k

www.konkur.in

has remained asymptomatic since the incident.

Fig. 21.1 Dichlorodifluoromethane (−40°F [−40°C]) gas is sprayed on a cotton pellet and then placed on the incisal edge of the maxillary incisor.

Fig. 21.2 Laser Doppler machine.

Fig. 21.3 An occlusal film of a luxation injury of central incisors. Both were diagnosed to be laterally luxated with apical translocation. Note that the left central is completely obliterated and has a history of being luxated some years prior.

Fig. 21.4 **A,** Panoramic radiograph taken on a patient with past history of dentoalveolar trauma. Tooth #9 appeared to have arrested root development with a periapical radiolucency. **B,** Sagittal view of tooth #9 of same patient from CBCT imaging. This revealed that tooth #9 had arrested root development, a large periapical radiolucency, and extensive root resorption along the palatal surface that was *not* evident on the panoramic image. **C,** Periapical radiograph of tooth #9 with extensive complicated crown fracture. The clinical examination revealed the crown fracture extended subgingivally on the palatal aspect. **D,** Sagittal view of tooth #9 of same patient from CBCT imaging. This revealed that the apical extent of the fractured palatal portion extended just apical to the crest of bone. The correct diagnosis of this injury was complicated crown-root fracture. **E,** Periapical radiograph of teeth #8, #9 revealed crown fractures. **F,** Sagittal view of tooth #9 of same patient from CBCT imaging. This revealed that tooth #9 suffered a lateral luxation displacement injury with extensive concomitant alveolar fracture. The necessary treatment of repositioning and splinting was apparent. **G,** Periapical radiograph of tooth #9 following dentoalveolar trauma. Tooth #8 was avulsed and tooth #9 appeared to be severely intruded. **H,** Sagittal view of tooth #9 of same patient from CBCT imaging. This revealed the labial position of tooth #9. **I,** Periapical radiograph of tooth #8 revealed a lateral luxation injury. **J,** Sagittal view of tooth #8 from CBCT imaging. The extensive tooth displacement and concomitant alveolar are evident. **K,** Periapical radiograph of teeth #8 to #10, that had recently been splinted in an emergency room. This image revealed that these teeth were not properly repositioned before splinting, evidenced by the spaces along each root. **L,** Axial view of maxillary anterior region of same patient from CBCT imaging. This revealed that teeth #8 to #10 are labially displaced. **M,** Sagittal view of tooth #10 of same patient revealed how severe the displacement was.

Telegram: @dental_k

www.konkur.in

Following consent and local anesthesia, the splint was removed and teeth #8 to #10 were repositioned and resplinted.

Fig. 21.5 Patient sustained complicated crown fractures on the left lower incisors and later on the canine tooth. **A,** An emergency pulp capping; Band-Aid composite was placed on the teeth. Six days later the patient was referred to the clinic because of a poorly healed laceration on the lip. **B,** Radiograph of the lip revealed a portion of the lateral crown still in the lip. The patient was anesthetized and the crown removed. **C,** Healing was quick and uneventful.

Fig. 21.6 **A1,** A clinical photograph of a maxillary right central incisor that sustained a crown-root fracture. **A2,** A periapical radiograph that failed to show the extent of the crown-root fracture. **A3,** A CBCT image revealed the extent of the crown-root fracture. **B1,** A clinical photograph of a right maxillary central incisor that had sustained a crown fracture that was restored with composite resin by the referring dentist. **B2,** A periapical radiograph revealed a vertical fracture in the crown and the coronal third of the root. An area of bone loss just below the alveolar crest on the mesial aspect of the root suggested further injury. **B3,** A CBCT image revealed the further injury as a transverse root fracture.

Fig. 21.7 Complicated crown fracture involving enamel, dentin, and pulp.

Fig. 21.8 Histologic appearance of the pulp within 24 hours of a traumatic exposure. The pulp proliferated over the exposed dentinal tubules. There is approximately 1.5 mm of inflamed pulp below the surface of the fracture.

Fig. 21.9 Histologic appearance of the pulp days after a traumatic exposure. Superficial necrosis above a zone of inflamed pulp is seen.

Fig. 21.10 Pulp necrosis of 1.5 mm as a result of the high pH of calcium hydroxide.

Fig. 21.11 Hard-tissue barrier after calcium hydroxide partial pulpotomy. **A,** Histologic appearance of replacement odontoblasts and a hard-tissue barrier. **B,** Clinical appearance of the barrier on removal of the coronal restoration 3 months after placement of the calcium hydroxide. **C,** Radiographic appearance of the hard-tissue barrier *(arrow)*.

Fig. 21.12 Cvek partial pulpotomy. **A,** The fractured teeth are cleaned and disinfected; a rubber dam is placed. **B,** Cavities are prepared at high speed with a round diamond bur 1 to 2 mm into the pulpal tissue. **C,** Calcium hydroxide on a plugger **(D)** is placed on the soft tissue of the pulp. **E,** Care is

Fig. 21.26 **A,** The intact central incisor after extraction and formalin fixation. **B,** The histologic appearance of the extracted tooth sectioned in a mesiodistal sagittal plane showing the interposition of fibrous connective tissue *(FCT)* calcification of the root canals but evidence of residual pulp tissue *(P)* (H&E, original magnification ×4). **C,** View of the fracture site showing dentin resorption lines *(RL)* repaired with reparative hard tissue *(RHT)* and the interposed dense fibrous connective tissue *(DFCT)* (H&E, original magnification ×10). **D,** Higher-power view showing dense connective tissue, generally with a parallel orientation to the fractured dentin surfaces that show reparative hard tissue laid down on previously resorbed dentin. There is minimal vascularity, but some extravasated erythrocytes are evident (Van Gieson stain, original magnification ×20). **E,** Highlighted section from **(C)** using polarised light to demonstrate Sharpey fiber insertion into the reparative hard tissue *(arrows)* (original magnification ×40).

Fig. 21.27 **A,** Pulp canal calcification after a luxation injury. Radiographic appearance of a calcified maxillary lateral incisor; note that despite calcification, it has now become necrotic and infected, evident by the periapical lesion. **B,** The typical yellow appearance of the tooth caused by thickened dentin in the pulp chamber.

Fig. 21.28 Internal root resorption in the root fracture area; tooth was diagnosed with compound midroot fracture. **A,** Coronal portion was repositioned and then splinted to the lateral incisor with a composite splint. **B,** At 6-month recall, the pulp responded normally to cold, but an internal root-resorptive defect was noted on radiograph. No treatment was indicated, because the pulp did respond normally to vitality tests. **C,** At 42-month recall, the tooth was still asymptomatic, and the pulp still responded to vitality tests. The resorptive defect had healed, and signs of dystrophic calcifications were evident in the apical and coronal segments.

Fig. 21.29 Histologic section showing previous root resorptive defect healed with new cementum and periodontal ligament.

Fig. 21.30 Histologic appearance of replacement resorption. There is direct contact between bone and root structure. Resorptive defects are seen in the bone and root tissue, which is the normal physiologic process of bone turnover. The resorptive defects are filled by new bone and additional areas resorbed. In this way the entire root is replaced by bone at a rate dependent on the metabolic rate of the patient.

Fig. 22.9 **A** to **E,** Vertical root fractures observed with periapical radiograph, cone-beam computed tomography and clinically after extraction.
Fig. 22.10 Coronally located sinus tracts. **A,** A draining sinus tract at a coronal location originating from a buccal vertical root fracture (VRF) in the first left maxillary premolar. **B,** A draining sinus tract at the gingival margin of a right first mandibular molar with a buccal VRF in the mesial root.
Fig. 22.11 Radiographic examination of filled versus empty canals. **A,** The buccolingual projection of a filled root will fail to detect a vertical root fracture (VRF) at an early stage. **B,** The removal of the root filling and use of radiography at different mesiodistal angulations may reveal the VRF.
Fig. 22.12 Early versus late radiographic presentation of a vertical root fracture–associated bone defect. At an early stage, a bone defect *(red)* is not likely to be detected in a periapical radiograph, as the root will overlap with the defect **(A** and **B).** At later stages, when major damage has occurred to the cortical plate **(C),** the bone defect may be large enough to extend beyond the silhouette of the root **(C** and **D)** and appear as a radiolucent defect along the root **(E).**
Fig. 22.13 Radiographic presentations of longstanding vertical root fractures (VRFs). **A,** J-shaped "halo" associated with a VRF in a second right mandibular premolar. **B,** Extensive bone damage associated with a complete VRF in a second right maxillary premolar. **C,** Limited bone damage associated with a midroot VRF in a second left maxillary premolar. **D,** Bone damage associated with a VRF in the mesial root of a first left mandibular molar. All such presentations are typical of longstanding VRFs.
Fig. 22.14 Radiographs of longstanding vertical root fractures. No special diagnostic skills are needed to diagnose such cases.
Fig. 22.15 Vertical root fracture *(VRF)* pocket. **A,** Periodontal pockets *(left)* are wide coronally, whereas VRF pockets *(right)* are narrow and deep. **B,** Periodontal pockets *(left)* are loose and allow probing at various sites, whereas VRF pockets *(right)* are narrow and tight. If not checked carefully at every millimeter of the sulcus, an early VRF pocket can easily be missed. Note that periodontal pockets appear more commonly in the proximal sides of the root, whereas VRF pockets are more common on the buccal or lingual sides.
Fig. 22.16 Tight vertical root fracture (VRF) pockets. **A,** The distal root of a second right mandibular molar with a VRF. VRF pockets were found on both

Telegram: @dental_k

www.konkur.in

the lingual **(B)** and the buccal **(C)** sides. VRF pockets are tight, so inserting a probe into these pockets causes pressure blanching of the surrounding tissues.
Fig. 22.17 Rigid versus flexible probes. **A,** In a loose periodontal pocket, a rigid metal probe can easily reach the depth of the pocket. **B,** In a tight, early-stage vertical root fracture (VRF) pocket, a rigid probe may be of limited value, as the bulge of the crown often prevents the insertion of the probe into the tight, deep pocket. **C,** A flexible probe **(D)** is more likely to detect VRF pockets at an early stage.
Fig. 22.18 Radiography of an empty canal: a clinical case. The right maxillary lateral incisor underwent a root canal treatment a few years ago. The patient complained about occasional pain on the palatal side. The tooth was sensitive to percussion and palpation on the palatal side. Radiography revealed a periapical radiolucency **(A).** An isolated, deep, and narrow pocket was found on the palatal side of the root. Both the patient and the referring dentist were reluctant to extract the tooth, assuming that the pocket could potentially be a sinus tract, and decided on retreatment. A radiograph taken with a file during the process **(B)** could have missed essential information that was obscured by the file, which was an evident vertical root fracture **(C).**
Fig. 22.19 Diagonal radiographs for detection of vertical root fracture (VRF). **A,** Orthoradial radiograph: very limited bone loss is seen. **B,** A different horizontal angulation reveals a radiolucent lesion along the root. **C,** Schematic presentation. Although a radiograph in an orthoradial direction *(blue lines)* cannot pick up the radiolucency along the root, diagonal angulation *(black lines)* may do so, as in **B.**
Fig. 22.20 **A,** Periapical radiograph of maxillary left first molar. **B,** Cone beam computed tomography (CBCT) coronal view revealing bone loss between the buccal and palatal roots, suggestive of a vertical root fracture. **C,** CBCT axial view revealing bone loss between the buccal and palatal roots, suggestive of a vertical root fracture.

Oval anatomy combined with endodontic treatment has

Telegram: @dental_k

www.konkur.in

been associated with a higher incidence of vertical root fractures (VRFs). **C** and **D,** Concavities on the distal aspect of the mesial roots of mandibular molar may establish a "danger zone" in which excessive instrumentation, combined with straightening of the canal, may result in a thinner dentin wall that may allow strain concentration. **E** and **F,** Concavities in the palatal side of the buccal root of maxillary first premolar (**E**, sections; **F**, axial view from a CBCT). These depressions may also represent a potential danger zone. Neither the concavity in **C** and **D** nor the concavity in **E** and **F** would be evident in a planar periapical radiograph. It should be noted that CBCT scans should not be used for routine screening but should be limited to the indications delineated in the joint statement of the American Association of Endodontists (AAE) and the American Academy of Oral and Maxillofacial Radiology (AAOMR).[5,6] **G,** Histology of VRF. **H,** Radiograph revealing peri-radicular bone loss.

Fig. 22.23 Finite element analysis of the strain distribution in an oval root. Note the strain concentration on the inner side of the highest convexity of the remaining dentin wall. Red and orange represent areas of higher strains than blue areas.

Fig. 22.26 **A,** Periapical radiograph of mandibular right first molar revealing suspected periradicular bone loss. **B,** Cone-beam computed tomography (CBCT) sagittal view of same tooth revealing bone loss from crestal bone to apex. **C,** CBCT anatomic view revealing mesial osseous defect. **D,** CBCT axial view revealing buccal and lingual bone loss midroot.

Fig. 23.1 The negative impact of poor initial biomechanical status on restoration success. **A** and **B,** Preoperative radiographic views following the removal of the old metallic foundation. **C,** A new amalgam core, using post and self-anchorage into mesial root structure, was performed. **D,** Prosthetic restorations on working model. **E,** Full arch view after 3 years. **F,** The tooth is symptomatic due to furcation involvement and periapical lesion. **G,** This

Telegram: @dental_k

www.konkur.in

untreatable tooth was finally extracted and replaced by an implant. **H,** Eight-year postoperative radiograph showing a stable situation. Other teeth with less extensive biomechanical damage overcame functional stresses.

Fig. 23.2 Severe discoloration can significantly disturb aesthetics, even in the lateral area of the smile. When not treatable with bleaching agents or veneers, this condition might justify tooth preparation for a full crown.

Fig. 23.3 **A,** Stress distribution within a metallic post and core foundation and residual tooth structure, according to photoelastic studies. The post is cemented and usually penetrates the apical portion of the root. Functional stresses accumulate inside the foundation, slightly around the post and further inside the canal, around the apex of the post; there is less stress buildup in the cervical area compared to that with a fiber post (as shown in Fig. 23.3, *B*). This configuration more ideally protects the coronocervical structures, but when failing, it results in severe untreatable root fractures. **B,** Stress distribution within a fiber post/composite foundation and residual tooth structure, according to photoelastic and FEM studies. The post is bonded to the canal walls and penetrates the canal less apically. Functional stresses mainly accumulate around the post in the cervical area. This configuration protects the cervical area less efficiently but tends to prevent untreatable root fractures. The presence of a ferrule is mandatory.

Fig. 23.4 Failure of prosthetic foundations can have dramatic consequences on both overlying restorations and surrounding tissues. A better understanding of compositional and structural changes that affect tooth resistance to repeated functional forces is mandatory to improve treatment success in endodontically treated teeth.

Fig. 23.5 **A,** Current recommendations for the treatment of nonvital anterior teeth. *Normal function and anterior guidance; **moderate to severe parafunctions and abnormal occlusion/anterior guidance. **B,** Current recommendations for the treatment of nonvital posterior teeth. *Relatively flat anatomy and canine guidance, normal function; **group guidance, steep occlusal anatomy, parafunctions.

Fig. 23.6 Direct composite restorations on front teeth (following bleaching). Nonvital anterior tooth with sufficient amount of residual tissue and intact, healthy neighboring teeth, usually in rather young patients. **A,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha were removed from the cavity to expose a clean dentin substrate.

Telegram: @dental_k

www.konkur.in

Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. **B,** Bleaching procedures. Two sessions of internal bleaching were needed to adapt the color of both traumatized anterior teeth (tooth #11), using a mixture of 3% hydrogen peroxide and sodium perborate powder. Each bleaching session extended over a 10-day period. Between sessions and until the given delay to proceed with final restoration (1 to 2 weeks up to 6 to 8 weeks), access cavity is closed with either a temporary filling material or flowable resin composite. **C** and **D,** Restorative procedures. A layer of adhesive is applied over all cavity surfaces. An etch-and-rinse system is frequently preferred when the dentinal tissue is highly sclerotic or was contaminated (e.g., by eugenol). A hard cement such as glass ionomer (not a resin-modified glass ionomer because of water uptake and further expansion) was used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. Two or three layers are usually used to replace the missing tissue, preferably following the "natural layering concept," which aims to build up the restoration with two basic masses, namely dentin and enamel, with the help of a silicone index. **E** and **F,** Postoperative views. The two conservative restorations are shown after finishing and polishing, with the rubber dam still in place **(E)** and after several weeks **(F)**. Note that aesthetic integration cannot be evaluated before full rehydration has occurred (4 to 6 hours at least).

Fig. 23.7 Direct composite restoration on posterior tooth. Nonvital posterior tooth with sufficient amount of residual tissue and mostly intact, rather healthy, neighboring teeth. No significant discoloration of buccal tooth substrate and absence of severe parafunctions or group guidance or other unfavorable occluso-functional condition. **A,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for a later placement of a post. **B,** Adhesive procedure. An etch-and-rinse adhesive system was used here owing to the presence of sclerotic and contaminated dentin. **C** to **E,** Restoration base and layering technique. Resins

Telegram: @dental_k

www.konkur.in

or glass ionomer cements can be used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. A dentin composite mass is used to replace missing dentinal tissue, and enamel composite is used to build up proximal walls and the occlusal anatomy. **F,** The postoperative view demonstrates the advantage of this conservative approach in the context of teeth with appropriate biomechanical status.

Fig. 23.8 Veneer. Nonvital anterior tooth with sufficient amount of residual tissue and rather healthy neighboring teeth. Discoloration resisted bleaching or relapsed, despite several retreatments. Preferably thick biotype to limit the risk of gingival recession and loss of aesthetic integration. **A,** Closing the lingual cavity. A hard cement such as glass ionomer (not resin-modified glass ionomer because of water uptake and possible expansion) can be used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. **B,** Preparation. A sufficient amount of buccal tooth structure must be removed to allow for a good aesthetic result (preparation depth is dictated by the discoloration severity). Cervical margins closely follow gingival contours, preventing soft-tissue impingement, but they assume complete coverage of discolored tooth structure. **C** and **D,** Adhesive procedure. Hydrophobic bonding systems are preferred to wet-etched enamel when no dentin is exposed. An etch-and-rinse adhesive system is preferred when dentin is exposed (here, in the presence of significant areas of sclerotic dentin). Restoration. Ceramic is etched and silanated. Just before cementation, a last layer of bonding resin is applied but not light-cured until placement. **E,** Luting technique. A light-curing, highly filled, translucent and fluorescent restorative material is preferably used for cementation. This allows better control of restoration placement and minimal wear and fatigue of the cement layer. **F,** Postoperative view. The postoperative view demonstrates satisfactory aesthetics. This approach is sometimes suitable to meet a patient's high aesthetic demands.

www.konkur.in

Fig. 23.9 Onlay/overlay. Nonvital posterior tooth with sufficient amount of residual tissue to justify partial restoration. Preparation involves both proximal surfaces or only two surfaces, but in a less favorable occluso-functional environment (thin walls). No significant discoloration of visible buccal tooth substrate. Option is favorable for short clinical crowns. **A** and **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. Thin and weak occlusal walls are removed until reaching sufficient thickness for the restoration (1.5 to 2 mm in occlusal-free and occlusal areas, respectively). Adhesive procedure: an etch-and-rinse adhesive system is preferably used here owing to the presence of sclerotic and contaminated dentin (a self-etch adhesive system can also be used). A resin composite base is made with a restorative composite or preferably with flowable composite (for limited volume and thickness) to smooth internal angles, fill undercuts, and, when needed, relocate cervical margins occlusally. **C** and **D,** After impression and model fabrication, the restoration is generated in the laboratory to optimize restoration anatomy, function, and aesthetics. The restoration can be made of different tooth-colored materials: ceramics (fired, pressed, or CAD-CAM generated) or resin composite. This treatment option provides optimal tissue conservation, function, and aesthetics and is a good alternative to full crowns.

Fig. 23.10 Endocrown. Nonvital posterior tooth with reduced amount of residual cervical tissue but sufficient tissue to provide supragingival restoration margins and good stabilization within former pulpal chamber. No or limited discoloration in visible buccal tooth substrate. Favorable option for short clinical crowns. **A** and **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. Thin and weak walls are removed until reaching sufficient thickness (1.5 mm minimum); as much residual cervical structure as possible is then maintained to avoid restoration interference with periodontal tissues. **C,** Prosthetic restoration on working model. **D,** Restoration base. Adhesive procedures: An etch-and-rinse adhesive system is preferably used here owing to the presence of sclerotic and contaminated

Telegram: @dental_k

www.konkur.in

dentin (a self-etch adhesive system can also be used). Restoration base: A resin composite base is made with a restorative composite or preferably with flowable composite (for limited volume and thickness) to smooth internal angles, fill undercuts, and, when needed, relocate cervical margins occlusally. **E,** Impression and restoration fabrication. After impression and model fabrication, the restoration is generated in the laboratory to optimize restoration anatomy, function, and aesthetics. The restoration can be made of different tooth-colored materials: ceramics (fired, pressed, or CAD-CAM generated) or resin composite. **F,** Postoperative result. Despite their relatively rare application, endocrowns combine biomechanical advantages with facilitation of clinical procedures and minimal if any involvement of biologic width. It is an interesting alternative to full crowns.

Fig. 23.11 Amalgam core. Nonvital posterior teeth with reduced tooth structure and wall height. Amalgam core stability is granted by extension of the restoration into the coronal portion of the canal (curved roots) and post (only if straight root anatomy) and remaining pulpal chamber undercuts. Today, this option is considered obsolete or historical because of the intrinsic staining of amalgam, the nonadhesive technique, and the less-than-ideal biomechanical behavior of amalgam. **A** and **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Thin and weak walls are removed until reaching sufficient thickness (1.5 to 2 mm); existing retentions are used to stabilize the amalgam core, together with a post. The metal post (with passive and anatomic design, preferably made of titanium) extends into the root for about the same length as its coronal extension. **C** to **E,** Restoration fabrication. After placing a matrix or cupper ring to envelop the preparation, amalgam is compacted into the cavity, superior root canal portion, and around the post until the appropriate coronal volume is restored. Preparation of cores is made to manage optimal space for porcelain fused to metal (PFM) crowns. **F,** Posttreatment result. This treatment approach is feasible for teeth already restored with amalgam cores and when PFM restorations are mandated. Satisfactory aesthetics can be attained with intrasulcular restoration margins.

Fig. 23.12 Composite core (without post). Nonvital tooth with more than half the coronal structure left and sufficient wall thickness. Core stability is granted by adhesion, remaining pulpal chamber, and residual wall height. **A**

Telegram: @dental_k

www.konkur.in

and **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. The tooth is prepared to evaluate precisely the height and thickness of residual tooth structure. Half of the abutment height and more than 1.5 mm wall thickness must be present to restore the tooth without a post. If aforementioned conditions are met, a thin layer of hard cement (calcium hydroxide, zinc phosphate, or glass ionomer; not resin-modified glass ionomer) is applied at the entrance of the root canal to enable possible retreatment in the future. **C,** Adhesive procedures and core fabrication. All walls are covered with the adhesive system (etch-and-rinse or self-etch) before applying in layers a direct light-curing restorative composite or a self-curing material, in case of limited restoration volume. **D,** Postoperative view. The advantage of this approach is the ease of application and excellent aesthetics. It is considered a good restorative solution for highly aesthetic ceramic crowns placed on teeth with limited tissue loss and discoloration.
Fig. 23.13 Composite core with white post (resin-reinforced fiber or zirconia post). Nonvital tooth with less than half the coronal structure left or insufficient wall thickness. Core stability is improved through adhesion and a tooth-colored post (resin-reinforced fiber or ceramic posts). **A,** Preoperative view. **B** and **C,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. The tooth is prepared to evaluate precisely the height and thickness of residual tooth structure. If less than half of the abutment height or 1.5-mm wall thickness remain, the abutment requires a post to increase core retention and foundation stability. **D** and **E,** Post-and-core fabrication. Post placement: The post space is prepared with ad hoc instruments until reaching a length equivalent to core height or slightly less depending on remaining wall height. Increased length is not needed, because retention is predominantly achieved through adhesion. Any tooth-colored post can be used, but fiber posts are usually preferred to limit stress buildup into the root structure, even though they provide less rigidity to the foundation. Post cementation: A self-curing adhesive system is applied on all cavity walls and into post preparation before luting the post with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). Core fabrication: The remaining core volume is built up in layers, using a direct light-curing restorative composite or with a single

Telegram: @dental_k

www.konkur.in

increment of a self-curing material when only limited volume is to be completed. **F,** Postoperative view. The primary advantage of this approach is the excellent aesthetic outcome. It is considered a good restorative solution for highly aesthetic ceramic crowns placed on teeth with more tissue loss but moderate discoloration.

Fig. 23.14 Composite core with prefabricated metal post. Nonvital tooth with reduced coronal structure and ferrule effect or insufficient wall thickness. Core stability is improved through adhesion and a metal (opacified) post (titanium posts are usually preferred). **A,** Preoperative view. **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose the remaining tooth structure and a clean dentin substrate. The absence of coronal tissue and ferrule effect mandates the use of a more rigid post (ceramic posts are considered too rigid and contraindicated in this situation). **C** to **F,** Post and core fabrication. Post space preparation: The post space is prepared with ad hoc instruments until reaching a length equivalent to about core height. More length is not needed, because retention is predominantly achieved through adhesion. Post preparation: The metal post (titanium here) is sandblasted (silicoating can be used to increase adhesion; i.e., Rocatec or CoJet systems, 3M), followed by silane application. An opaque resin or flowable composite can be used to mask metal dark color and improve aesthetics. Post cementation: A self-curing adhesive system is applied on all cavity walls and into post preparation before luting the post with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). Core fabrication: The remaining core volume is built up in layers, using a direct light-curing restorative composite or a single increment of a self-curing material when only limited volume is to be completed.

Fig. 23.15 Nonvital teeth with limited coronal structure or numerous abutments. Indirect post and core fabrication helps to achieve proper parallelism and core anatomy. Core retention is assumed by a conventional or adhesive cement. Today, this solution is considered mostly for extended metal-ceramic restorations or sometimes for multiple full-ceramic restorations. **A,** Preoperative view. **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose the remaining tooth structure and a clean dentin substrate. Despite the indirect approach, all healthy coronal structures must

Telegram: @dental_k

www.konkur.in

be maintained to improve foundation stability. Access cavity and coronal walls are prepared with minimal convergence (6 to 10 degrees) to allow for easy insertion. **C** and **D,** Cast gold post and core fabrication and luting. Post space preparation: The post space is prepared with ad hoc instruments until reaching a length equivalent to about core height or more. More length is needed here, as retention cannot always be achieved through adhesion (endodontic retreatment or highly sclerotic contaminated dentin). Then a conventional glass ionomer or zinc phosphate cement is used. Post and core preparation: The gold post is sandblasted (or eventually sandblasted and coated if adhesive procedures are possible) using Rocatec or CoJet systems, 3M + silane. Post cementation: The post and core is luted with the aforementioned conventional cements or adhesive technique. Next, a self-curing adhesive system is applied on all cavity walls and into post preparation (before the insertion of the post and core) and covered with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). **E** and **F,** Restoration fabrication and placement. A second impression is needed for the final prosthetic work to optimize restoration precision and quality. Lab-made PFM or full ceramic crowns are made with optimal foundation design and alignment.

Fig. 24.1 Radiographs of carious molars in patients aged 12 to 38 years. **A,** Mandibular left first molar in a 23-year-old with minor symptoms. **B,** Asymptomatic maxillary right second molar in a 16-year-old. **C,** Asymptomatic maxillary left first molar in a 38-year-old. **D,** Deep caries in the mandibular right first molar of a 12-year-old. All patients were referred to the endodontist for root canal treatment based on radiographic appearance. They exhibited normal vitality with cold testing, and all were treated successfully with vital pulp therapy.

Fig. 24.2 A 15-year-old female patient presented with full orthodontic banding and deep cervical caries of the mandibular right first molar (tooth #30). The tooth was sensitive to cold and biting pressure. **A,** Periapical radiograph revealing large carious lesion and normal periapical structures. **B,** Clinical photograph showing advanced cervical caries extending below crestal gingiva. **C,** View of initial pulp exposure during caries excavation guided by caries detector dye. **D,** Photograph after complete caries removal, large pulp exposure and 6% sodium hypochlorite hemostasis. **E,** Clinical photograph after placement of thick white mineral trioxide aggregate aliquot

www.konkur.in

over entire pulp and surrounding dentin. **F,** Radiograph showing pulp capped molar with temporary restoration (Photocore). **G,** Four-year radiographic control showing recurrent caries and fractured distal marginal ridge tooth #30. **H,** Five-year radiographic review showing no detectable apical pathosis and recently cemented full coverage porcelain fused to metal crown. The molar was asymptomatic and responded normally to sensibility testing.
Fig. 24.3 A 24-year-old male patient presented with a deep distal carious lesion extending to the inner pulpal quarter in a maxillary right second premolar. The tooth was symptomatic but responded normally to sensibility testing. **A,** Magnified bitewing radiograph showing extension of advanced caries close to coronal pulp. **B,** Preoperative radiograph with period indentical device for precise comparison. **C,** Eighteen-month radiographic review after indirect pulp capping completed with calcium hydroxide. **D,** Five-year radiographic control. Pulp sensibility test response was positive with a well-defined lamina dura demonstrated on the periapical radiograph.
Fig. 24.4 An 7-year-old male patient referred after trauma displaying a horizontal coronal fracture of his maxillary right central incisor #8 with a pulp exposure covered with a glass ionomer cements by the general dentist and a retained deciduous left central incisor *(F)*. **A,** Clinical photograph showing horizontally fractured right maxillary incisor and retained deciduous left central incisor. **B,** Periapical radiograph reveals open apex #8 and unerupted maxillary left permanent incisor #9. In addition, a mesiodens is visible. **C,** Photograph after shallow Cvek coronal pulpotomy. **D,** View of access cavity after sodium hypochlorite hemostasis and placement of 3 to 4 mm Biodentine (Septodont, Saint-Maur-des-Fossés, France) plug. **E,** Radiograph after pulpotomy and temporary restoration placement. **F,** Clinical photograph 3 days after verified calcium silicate cements setting and reattachment of the fractured coronal segment after bonding. **G,** Radiograph of #8 with bonded crown segment reattachment showing immature open apex. **H,** Clinical photograph of full mouth banding after extraction of *(F)* and the mesiodens to permit normal eruption of tooth #9. **I,** Four-year clinical photograph with full orthodontic banding and complete eruption of #9 into the occlusal plane. Tooth #8 responded normally to cold sensibility testing at 1-, 2-, and 3-year recalls. **J.** Four-year periapical radiograph showing root-end closure of tooth #8 with normal periapical appearance. **K,** Five-year radiographic review of tooth #8 demonstrating complete radicular maturation.

Telegram: @dental_k

www.konkur.in

The incisor responded positive to cold testing. **L,** Clinical photograph at 5 years after finishing of a resin composite veneer created with a layering technique on tooth #8.

Fig. 24.5 A 10-year-old female was referred with a mandibular right first molar pulp exposure generated during caries excavation and temporized by the general dentist. **A,** Radiograph showing open apices with no evident apical pathosis. The tooth was diagnosed with reversible pulpitis. The patient received a new resin composite buildup to provide better isolation before a complete pulpotomy was performed. **B,** Clinical photograph of access opening through the buildup showing a sterile cotton pellet on the pulpal floor saturated with 5% sodium hypochlorite (NaOCl) for hemostasis. **C,** Photograph of radicular pulp in orifices after complete pulpotomy and 5% NaOCl hemostasis **D,** View through access opening after 5 mm thickness white mineral trioxide aggregate (MTA) (ProRoot MTA, Tulsa/Dentsply, Tulsa, OK) placement onto radicular pulp tissue and pulpal floor. **E,** Postoperative radiograph showing white MTA with wet cotton pellet and provisional restoration. One month later, MTA setting was verified and a permanent composite restoration provided. **F,** Radiographic review at 6 years shows apical maturation and thickening of the root walls. The patient remained asymptomatic and the tooth responded positively to electric pulp testing.

Fig. 24.6 Reparative bridge formation compared in dog pulps using mineral trioxide aggregate *(MTA)* and calcium hydroxide *(CH)*. **A,** Two-week pulp response to CH showing inflammatory cells *(IC)*. **B,** Tissue specimen showing lack of bridge formation and disorganized tissue proximal to CH. **C,** An 8-week specimen with partial reparative bridge *(RB)* formation subjacent to CH. **D,** Two-week pulpal response to MTA showing notable barrier formation and layer of organized odontoblast-like cells *(OLC)*. **E,** Pulp tissue section demonstrating complete calcific bridge formation proximal to MTA at 4 weeks. **F,** Sample section pulp capped with MTA at 8 weeks showing organized hard tissue formation with no inflammatory cell infiltrate.

Fig. 24.7 A 50-year-old male patient with deep recurrent caries associated with a mandibular right first molar (#30). The patient had no history of pain and responded normally to cold testing. **A,** Periapical radiograph showing distal caries in the mandibular right second premolar (#29) and large carious lesion below mesial aspect of composite restoration in the molar. Note

retained deciduous root tip mesial totooth #29 and normal periapical appearance of #30. **B,** Pulpal hemorrhaging evident after complete caries removal with hand excavators. **C** and **D,** Clinical photographs after bleeding was controlled using cotton pellets soaked in buffered 0.5% sodium hypochlorite (NaOCl). Note presence of reparative dentin protecting mesiolingual pulp horn *(red arrow)*. A 2 mm–thick layer of white mineral trioxide aggregate (Dentsply, Tulsa Dental, Tulsa, OK) placed directly over the exposure and surrounding dentin and covered with a thin wet cotton pellet. The tooth was provisionalized for 1 week and restored permanently with composite resin. **E,** One-year radiographic follow-up; tooth responded normally to cold sensibility testing. **F,** Control radiograph at 3 years. Patient was asymptomatic and exhibited normal pulp testing response.

Fig. 24.8 Symptomatic mandibular left first molar in a 32-year-old male patient with temporary restoration placed over deep caries on the distal aspect and referred for root canal treatment. Sensibility testing elicited a normal pulpal response. **A,** Periapical film showing deep caries extending towards the distal pulp horn. **B,** Radiograph of direct mineral trioxide aggregate (Dentsply, Tulsa Dental, Tulsa, OK) pulp capping after 5.25% sodium hypochlorite hemostasis and placement of a three-surface bonded composite restoration. **C,** Nine-year 6-month radiographic control. The tooth was positive to cold testing and without symptoms. Note presence of mesial carious lesion in the second molar.

Fig. 24.9 **A,** Periapical radiograph of deep caries in a partially symptomatic mandibular left first molar in a 29-year-old female patient. **B,** Direct pulp capping completed with white mineral trioxide aggregate (MTA); the final bonded restoration was placed during the second visit after MTA curing. **C,** Radiographic recall at 7 years. Tooth was asymptomatic with normal response to CO_2 ice. **D,** Thirteen-year 10-month recall radiograph showing normal periapical appearance. The molar responded positive to cold testing and demonstrated normal mobility and periodontal probings.

Fig. 24.10 **A,** Bitewing radiograph of quadrants 2 and 3 showing defective restoration in a mandibular left first molar (#19) of a 27-year-old female patient. **B,** Clinical photograph showing pulp exposure *(white arrow)* after cavity preparation and complete caries excavation. **C,** Pulp capping and restorative base completed under slight pressure using Biodentine

horizontal crown fracture of the maxillary left central incisor. **A.** Clinical photograph showing midcoronal horizontal fracture. The pulp was exposed and exhibited normal vitality. **B,** Photograph of access cavity after Cvek pulpotomy and placement of gray mineral trioxide aggregate (MTA) (ProRoot MTA, Tulsa/Dentsply, Tulsa, OK). **C,** Photograph of fractured incisal segment before bonding and reattachment. **D,** Six-month radiograph with bonded fractured segment showing initial reparative bridge formation with absence of apical pathosis. The incisor was asymptomatic and responded normally to cold sensibility testing. **E,** Clinical photograph of incisor at 6-month recall. **F,** Eight-year radiographic review. **G,** Eleven-year radiographic recall. Tooth was asymptomatic wth normal mobility, probings, and positive response to cold test.

Fig. 24.17 Pulpotomy procedures completed for two patients clinically diagnosed with irreversible pulpitis using calcium enriched mixture (CEM) cement (BioniqueDent, Tehran, Iran). **A,** Preoperative radiograph from 27-year-old male patient with deep caries associated with maxillary right quadrant. The first molar was symptomatic with calcified tissue evident in the pulp chamber. **B,** Radiograph after complete pulpotomy using CEM cement restored with bonded composite. **C,** Five-year radiographic recall. The tooth was asymptomatic, firm, with normal probings. **D,** Preoperative radiograph showing deep caries in the mandibular left first (#19) and second (#18) molars in a 41-year-old male patient. Both teeth demonstrated lingering pain to cold testing and tooth #18 was sensitive to percussion. **E,** Postoperative radiograph showing completed miniature pulpotomy #19 and partial pulpotomy #18 after sodium hypochlorite hemostasis and application of CEM cement. Both molars were restored with bonded composites. Tooth #18 demonstrated resolution of symptoms after 24 hours. **F,** Six-year radiographic recall, patient remained asymptomatic and both teeth registered a positive response to sensibility testing.

Fig. 24.18 A 51-year-old patient who presented with a deeply carious but asymptomatic maxillary right first molar. **A,** Preoperative radiograph reveals extensive mesial caries and an occlusal amalgam. **B,** Postoperative radiograph after 1.5 mm pulpal exposure, sodium hypochlorite hemostasis, mineral trioxide aggregate (ProRoot MTA, Tulsa/Dentsply, Tulsa, OK) direct pulp cap, wet cotton pellet placement, and Photocore provisionalization. **C,** Radiograph 1 week after pulp capping and placement of a permanent bonded

www.konkur.in

composite restoration. The patient was asymptomatic and showed a positive response to cold testing. **D,** Six-year radiographic recall; cold testing revealed normal vitality.

Fig. 24.19 Clinical examples of diseased pulp tissues after sodium hypochlorite hemostasis. **A,** Photograph of exposed pulp tissue of a mandibular right first molar in a 13-year-old patient. Note necrotic pulp tissue *(arrows)* that was subsequently removed with the remaining coronal pulp during a complete pulpotomy procedure. **B,** Clinical presentation of mandibular right molar in a 7-year-old patient after pulp exposure during caries excavation using a caries detector dye. Note the extruded seminecrotic, nonhemorrhagic tissue *(arrow)*. The tooth later underwent mineral trioxide aggregate partial pulpotomy and permanent restoration.

Fig. 24.20 Thirty-four-year-old female patient presented for root canal treatment with temporary restoration 1 week after caries excavation and pulp exposure of the maxillary right first molar (#3). The patient had mild discomfort and responded with a short lingering pain to cold testing. **A,** Periapical radiograph showing temporary restoration in tooth #3 with normal apical structures. **B,** Photograph of pulpal hemorrhage after temporary removal. **C,** Clinical photograph showing diminished bleeding after 5-minute exposure to 5.25% sodium hypochlorite. **D,** Photograph showing hemorrhage controlled in 10 minutes and 2 mm pulp exposure after continued caries excavation. The exposure and peripheral dentin received bulk OrthoMTA (BioMTA, Seoul, Korea) pulp capping and was covered with a thin wet cotton pellet and provisionalized with Photocore. The tooth was restored permanently with composite resin 1 week later. **E,** Two-year 6-month radiographic follow-up; tooth responded positive to sensibility testing. **F,** Control radiograph at 4 years. Patient exhibited normal pulp testing response and was asymptomatic with normal mobility and probings.

Fig. 24.21 An 8-year-old male presented following a traumatic injury to the maxillary left central incisor 2 months earlier. **A,** Periapical radiograph revealed an open apex with a developing radiolucency. The tooth was sensitive to palpation, percussion and negative to cold testing. The diagnosis was necrotic pulp and acute apical periodontitis. **B,** Clinical photograph after access cavity preparation, vital pulp tissue visible coronally. The diagnosis was changed to reversible pulpitis and a partial (Cvek) pulpotomy was performed. **C,** Photograph of white mineral trioxide aggregate (MTA)

Telegram: @dental_k

www.konkur.in

(ProRoot MTA, Tulsa/Dentsply, Tulsa, OK) applied over the pulp to a thickness of approximately 3 mm. **D,** Radiograph after MTA pulpotomy with provisional restoration. A definitive composite restoration was placed 1 week later. **E,** One-year radiographic recall showing advancing apical closure. **F,** Four-year clinical photograph reveals a slight grey discoloration from the MTA in the cervical area of the tooth. Parents declined option of internal bleaching. **G,** Radiographic review at 9 years reveals apical maturation and thickening of the root walls. The tooth responded positively to cold sensibility testing.

Fig. 24.22 **A,** Preoperative radiograph of a 7-year-old male patient exhibiting a dens evaginatus anatomical anomaly associated with the maxillary right lateral incisor. The parents had been advised to extract the tooth, which was symptomatic and nonresponsive to vitality tests. **B,** A periapical radiograph after cleaning the coronal portion of the canal and irrigation with 2.12% sodium hypochlorite. A coronal plug using ProRoot MTA (Tulsa/Dentsply, Tulsa, OK) was placed and sealed with a provisional restoration. **C,** Four-year radiographic review demonstrates complete root formation with maturation and apical root closure. The tooth was asymptomatic with normal mobility and probings.

Fig. 25.1 Endodontic and periodontal pathways. **A,** Endodontic lesions. The pathway of inflammation is through the apical foramen, furcation canals, and lateral accessory canals to the periodontium. This results in a primary endodontic lesion, sometimes progressing to secondary periodontal involvement. **B,** Periodontal lesions. This is the progression of periodontitis by way of the lateral canal and apex to induce a secondary endodontic lesion. **C,** True combined endodontic and periodontal lesion and concomitant endodontic and periodontal lesions.

Fig. 25.2 Primary endodontic lesion. Mandibular molar showing endodontic filling material extending into the furcation and along the lateral root surface because of inadequate canal preparation. Furcation could be probed.

Fig. 25.3 Primary endodontic lesion on mandibular first molar. **A,** Mandibular first molar with deep restoration and pulpal necrosis; apical radiolucency on mesial and distal roots with furcation radiolucency. **B,** Probing of 12 mm with periodontal probe. **C,** X-ray image of completed root canal treatment. **D**, Eight months after root canal treatment, there is evidence of osseous healing at both the apex and furcation area.

Telegram: @dental_k

www.konkur.in

Fig. 25.4 Primary endodontic lesion with secondary periodontal involvement. **A,** The mesial aspect of the mandibular second premolar had deep periodontal pocketing (a periodontal probe in place demonstrated 6 mm of probing depth), even after periodontal therapy. **B,** Pulp tests were performed on the premolar; the tooth was nonresponsive. After endodontic treatment, the periodontal pocket resolved (filling of a lateral accessory canal after obturation is demonstrated).

Fig. 25.5 Primary periodontal lesion. **A,** Mandibular cuspid exhibits extensive periodontal destruction; the tooth responded normally to pulp tests. **B,** Extracted tooth depicts extensive calculus accumulation and root concavity.

Fig. 25.6 True combined pulpal and periodontal lesions on the mandibular second premolar and first molar. Periodontal probing depths were to the apices in both teeth.

Fig. 25.7 Concomitant pulpal and periodontal lesion on the maxillary second premolar. An endodontic lesion was noted at the apex, with a noncommunicating periodontal pocket on the distal side.

Fig. 25.8 Vertical root fracture. **A,** A radiograph revealed a widened periodontal ligament with a J-shaped radiolucency around the apex. **B,** A periodontal probe indicated more than 12 mm of probing depth. **C,** Exploratory surgery confirmed a vertical root fracture.

Fig. 25.9 Cemental tear. **A,** Radiographs revealed an endodontically treated tooth with post, separated instrument, and apical osseous breakdown; the tooth was very tender to both percussion and palpation. **B,** An “eggshell” piece of cementum on the buccal surface of the root before root-end resection; the cementum was removed with curettage. **C,** Postoperative radiographs after root-end resection, root-end preparation, and root-end filling. **D,** Six-month follow-up radiographs demonstrate periapical healing; the tooth was asymptomatic.

Fig. 25.10 Palatogingival groove on a maxillary lateral incisor with a periodontal defect.

Fig. 25.11 Cervical enamel projection on a mandibular molar.

Fig. 25.12 Lateral periodontal cyst. **A,** Clinical photograph showing mild gingivitis around tooth #24; there is a 5-mm probing defect on the mesial aspect of tooth #24. **B,** A radiograph depicts the beginning lesion 2 years earlier. **C,** A radiograph shows the extent of the lesion at the time of referral

Telegram: @dental_k

www.konkur.in

to the periodontist. **D,** Initial flap reflection; the lesion is present interproximally between teeth #24 and #25. **E,** The lesion was enucleated and submitted for histologic evaluation; the diagnosis was a lateral periodontal cyst. **F,** Three-month posttreatment clinical photograph; tooth #24 was nonvital and symptomatic and was referred for root canal treatment. **G,** One-year posttreatment radiograph showing completed root canal treatment and osseous defect still present; continuous recall recommended. **H,** One-year posttreatment clinical photograph; probing depths were within normal limits; continuous recall was recommended.

Fig. 25.13 Root resection to correct endodontic and periodontal defect. **A,** Pretreatment radiograph depicts severe periodontal involvement on the mesial. Endodontic treatment was performed before surgical removal of the mesial root. **B,** Five-year follow-up shows the remaining tooth well maintained.

Fig. 25.14 Hemisection. **A,** Initial presentation of mandibular molars with severe attachment loss on the mesial aspect of tooth #31 and the distal aspect of tooth #30. **B,** Radiograph exhibiting interproximal periodontal defects. **C,** Occlusal view of hemisection after endodontic treatment. **D,** Suturing after removal of mesial half of tooth #31 and distal half of tooth #30. **E,** Eighteen-month follow-up with fixed restoration in place. **F,** Postoperative radiograph at 18 months showing normal bony and periodontal architecture.

Fig. 25.15 Periradicular endodontic surgery using the combination of bone replacement grafts and collagen guided tissue regeneration barrier membranes. **A,** A buccal flap was reflected (note extensive apical lesion). **B,** An osseous window was created with a bur. **C,** The defect was repaired with demineralized freeze-dried bone allograft and covered with a collagen membrane. **D,** Radiographs show condition before surgery, at the time of surgery, and at 6 months and 2 years after surgery. At 2 years, the radiograph reveals complete bone regeneration.

Fig. 25.16 Periodontal surgery using guided bone regeneration. **A,** A pretreatment radiograph demonstrates a significant osseous defect on the mesial aspect of tooth #14. **B,** Pretreatment clinical photograph of teeth #12 to #16. **C,** A full-thickness mucoperiosteal flap reflected with a periodontal probe 7 mm into osseous defect. **D,** Osseous defect filled with BioOss (cancellous bovine bone). Root canal treatment (RCT) was started for the patient before the surgical appointment; RCT was completed 6 weeks after

Art and science of diagnosis

Diagnosis is the art and science of detecting and distinguishing deviations from health and the cause and nature thereof.[6] The purpose of a diagnosis is to determine what problem the patient is having and why the patient is having that problem. Ultimately, this will directly relate to what treatment, if any, will be necessary. No appropriate treatment recommendation can be made until all of the *whys* are answered. Therefore, careful data gathering as well as a planned, methodical, and systematic approach to this investigatory process is crucial.

Gathering objective data and obtaining subjective findings are not enough to formulate an accurate clinical diagnosis. The data must be interpreted and processed to determine what information is significant, and what information might be questionable. The facts need to be collected with an active dialogue between the clinician and the patient, with the clinician asking the right questions and carefully interpreting the answers. In essence, the process of determining the existence of an oral pathosis is the culmination of the art and science of making an accurate diagnosis.

The process of making a diagnosis can be divided into five stages:

1. The patient tells the clinician the reasons for seeking advice.
2. The clinician questions the patient about the symptoms and history that led to the visit.
3. The clinician performs objective clinical tests.
4. The clinician correlates the objective findings with the subjective details and creates a tentative list of differential diagnoses.
5. The clinician formulates a definitive diagnosis.

This information is accumulated by means of an organized and systematic approach that requires considerable clinical judgment. The clinician must be able to approach the problem by crafting what questions to ask the patient and how to ask these pertinent questions. Careful listening is paramount to begin painting the picture that details the patient’s complaint. These subjective findings combined with the results of diagnostic tests provide the critical information needed to establish the diagnosis.

Neither the art nor the science is effective alone. Establishing a differential

Telegram: @dental_k

www.konkur.in

diagnosis in endodontics requires a unique blend of knowledge, skills, and the ability to interpret and interact with a patient in real time. Questioning, listening, testing, interpreting, and finally answering the ultimate question of *why* will lead to an accurate diagnosis and in turn result in a more successful treatment plan.

Chief complaint

On arrival for a dental consultation, the patient should complete a thorough registration that includes information pertaining to medical and dental history (Figs. 1.1 and 1.2). This should be signed and dated by the patient, as well as initialed by the clinician as verification that all of the submitted information has been reviewed (see Chapter 27 for more information).

Signed: Patient or Parent: blank space, Date blank space.

The reasons patients give for consulting with a clinician are often as important as the diagnostic tests performed. Their remarks serve as initial important clues that will help the clinician to formulate a correct diagnosis. Without these direct and unbiased comments, objective findings may lead to an incorrect diagnosis. The clinician may find a dental pathosis, but it may not contribute to the pathologic condition that mediates the patient's chief complaint. Investigating these complaints may indicate that the patient's concerns are related to a medical condition or to recent dental treatment.

Telegram: @dental_k

www.konkur.in

Certain patients may even receive initial emergency treatment for pulpal or periapical symptoms in a general hospital.[93] On occasion, the chief complaint is simply that another clinician correctly or incorrectly advised the patient that he or she had a dental problem, with the patient not necessarily having any symptoms or any objective pathosis. Therefore, the clinician must pay close attention to the actual expressed complaint, determine the chronology of events that led to this complaint, and question the patient about other pertinent issues, including medical and dental history. For future reference and in order to ascertain a correct diagnosis, the patient's chief complaint should be properly documented, using *the patient's own words.*

Medical history

The clinician is responsible for taking a proper medical history from every patient who presents for treatment. Numerous examples of medical history forms are available from a variety of sources, or clinicians may choose to customize their own forms. After the form is completed by the patient, or by the parent or guardian in the case of a minor, the clinician should review the responses with the patient, parent, or guardian, and then initial the medical history form to indicate that this review has been done. The patient "of record" should be questioned at each treatment visit to determine whether there have been any changes in the patient's medical history or medications. A more thorough and complete update of the patient's medical history should be taken if the patient has not been seen for over a year.[51,52]

Baseline blood pressure and pulse should be recorded for the patient at each treatment visit. Elevation in blood pressure or a rapid pulse rate may indicate an anxious patient who may require a stress reduction protocol, or it may indicate that the patient has hypertension or other cardiovascular health problems. Referral to a physician or medical facility may be indicated. It is imperative that vital signs be gathered at each treatment visit for any patient with a history of major medical problems. The temperature of patients presenting with subjective fever or any signs or symptoms of a dental infection should be taken.[57,80,105]

The clinician should evaluate a patient's response to the health questionnaire from two perspectives: (1) those medical conditions and current medications that will necessitate altering the manner in which dental care will

Telegram: @dental_k

www.konkur.in

be provided and (2) those medical conditions that may have oral manifestations or mimic dental pathosis.

Patients with serious medical conditions may require either a modification in the manner in which the dental care will be delivered or a modification in the dental treatment plan (Box 1.1). In addition, the clinician should be aware if the patient has any drug allergies or interactions, allergies to dental products, an artificial joint prosthesis, organ transplants, or is taking medications that may negatively interact with common local anesthetics, analgesics, sedatives, and antibiotics.[80] This may seem overwhelming, but it emphasizes the importance of obtaining a thorough and accurate medical history while considering the various medical conditions and dental treatment modifications that may be necessary before dental treatment is provided.

Box 1.1

Medical Conditions That Warrant Modification of Dental Care or Treatment

Cardiovascular: High- and moderate-risk categories of endocarditis, pathologic heart murmurs, hypertension, unstable angina pectoris, recent myocardial infarction, cardiac arrhythmias, poorly managed congestive heart failure.[57,80,105]

Pulmonary: Chronic obstructive pulmonary disease, asthma, tuberculosis.[80,129]

Gastrointestinal and renal: End-stage renal disease; hemodialysis; viral hepatitis (types B, C, D, and E); alcoholic liver disease; peptic ulcer disease; inflammatory bowel disease; pseudomembranous colitis.[25,34,48,80]

Hematologic: Sexually transmitted diseases, human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), diabetes mellitus, adrenal insufficiency, hyperthyroidism and hypothyroidism, pregnancy, bleeding disorders, cancer and leukemia, osteoarthritis and rheumatoid arthritis, systemic lupus erythematosus.[35,43,76,80,83,88,100,135]

Neurologic: Cerebrovascular accident, seizure disorders, anxiety, depression and bipolar disorders, presence or history of drug or alcohol abuse, Alzheimer disease, schizophrenia, eating disorders, neuralgias, multiple sclerosis, Parkinson disease.[36,44,80]

Telegram: @dental_k

www.konkur.in

Several medical conditions have oral manifestations, which must be carefully considered when attempting to arrive at an accurate dental diagnosis. Many of the oral soft-tissue changes that occur are more related to the medications used to treat the medical condition rather than to the condition itself. More common examples of medication side effects are stomatitis, xerostomia, petechiae, ecchymoses, lichenoid mucosal lesions, and bleeding of the oral soft tissues.[80]

When developing a dental diagnosis, a clinician must also be aware that some medical conditions can have clinical presentations that mimic oral pathologic lesions.[13,28,32,74,80,102,107,133] For example, tuberculosis involvement of the cervical and submandibular lymph nodes can lead to a misdiagnosis of lymph node enlargement secondary to an odontogenic infection. Lymphomas can involve these same lymph nodes.[80] Immunocompromised patients and patients with uncontrolled diabetes mellitus respond poorly to dental treatment and may exhibit recurring abscesses in the oral cavity that must be differentiated from abscesses of dental origin.[43,76,80,83] Patients with iron deficiency anemia, pernicious anemia, and leukemia frequently exhibit paresthesia of the oral soft tissues. This finding may complicate making a diagnosis when other dental pathosis is present in the same area of the oral cavity. Sickle cell anemia has the complicating factor of bone pain, which mimics odontogenic pain, and loss of trabecular bone pattern on radiographs, which can be confused with radiographic lesions of endodontic origin. Multiple myeloma can result in unexplained mobility of teeth. Radiation therapy to the head and neck region can result in increased sensitivity of the teeth and osteoradionecrosis.[80] Trigeminal neuralgia, referred pain from cardiac angina, and multiple sclerosis can also mimic dental pain (see also Chapter 4). Acute maxillary sinusitis is a common condition that may create diagnostic confusion because it may mimic tooth pain in the maxillary posterior quadrant. In this situation the teeth in the quadrant may be extremely sensitive to cold and percussion, thus mimicking the signs and symptoms of pulpitis. This is certainly not a complete list of all the medical entities that can mimic dental disease, but it should alert the clinician that a medical problem could confuse and complicate the diagnosis of dental pathosis; this issue is discussed in more detail in subsequent chapters.

Telegram: @dental_k

www.konkur.in

If, at the completion of a thorough dental examination, the subjective, objective, clinical testing, and radiographic findings do not result in a diagnosis with an obvious dental origin, then the clinician must consider that an existing medical problem could be the true source of the pathosis. In such instances, a consultation with the patient's physician is always appropriate.

Dental history

The chronology of events that lead up to the chief complaint is recorded as the *dental history*. This information will help guide the clinician as to which diagnostic tests are to be performed. The history should include any past and present symptoms, as well as any procedures or trauma that might have evoked the chief complaint. Proper documentation is imperative. It may be helpful to use a premade form to record the pertinent information obtained during the dental history interview and diagnostic examination. Often a SOAP format is used, with the history and findings documented under the categories of *S*ubjective, *O*bjective, *A*ppraisal, and *P*lan. There are also built-in features within some practice management software packages that allow digital entries into the patient's electronic file for the diagnostic workup (Figs. 1.3 and 1.4).

FIG. 1.3 When taking a dental history and *performing* a diagnostic examination, often a premade form can facilitate complete and accurate documentation.

A dental history form shows blank space for patient's last name and first name along with date and tooth. It is followed by chief complaint and history of present illness under the “S. (subjective)” heading. Thereafter, the different options for nature of pain are shown, followed by O. (Objective) heading that has extra oral and intraoral issues, which is further followed by radiographic findings. Next, two headings, A. (Assessment) and P. (Plan) are followed by different options.

Source: (Courtesy Dr. Ravi Koka, San Francisco, CA.)

Telegram: @dental_k

www.konkur.in

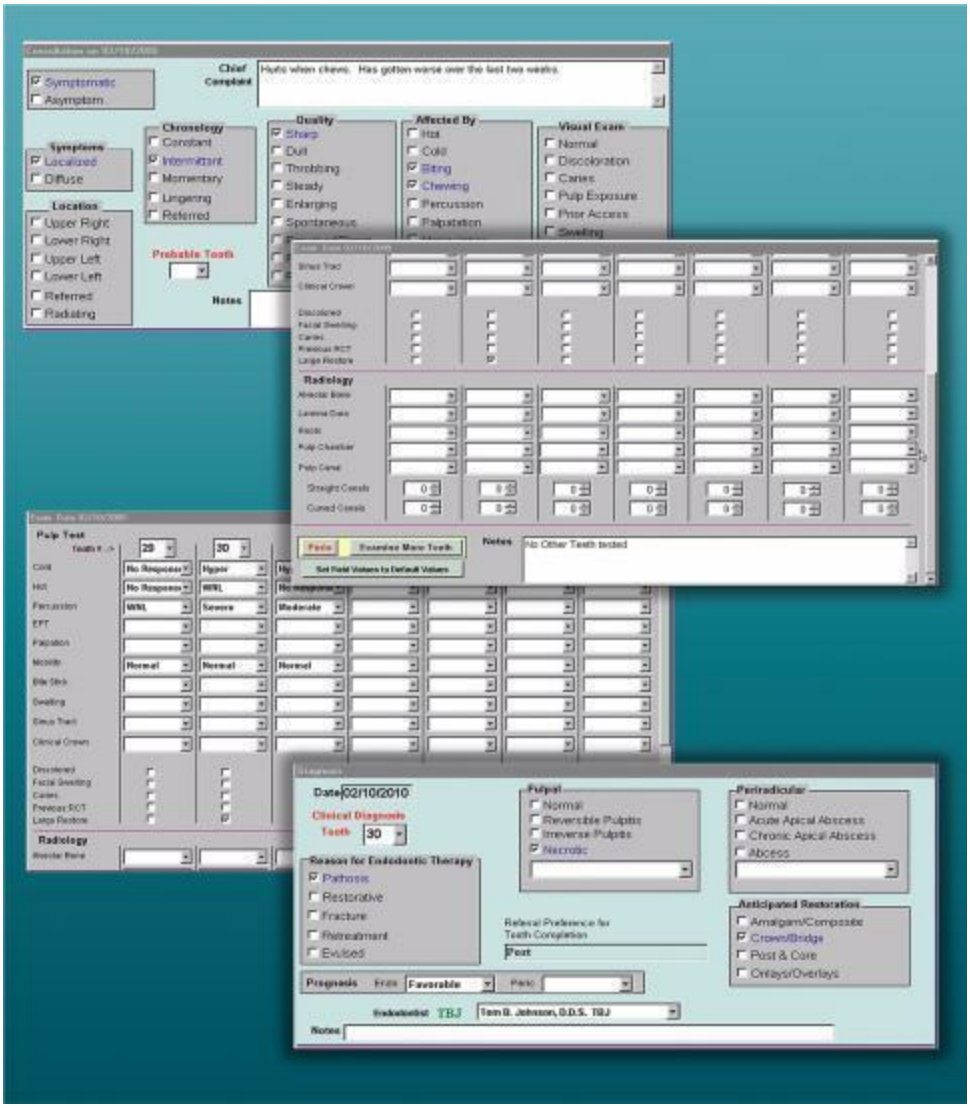

FIG. 1.4 Several practice management software packages have features for charting endodontic diagnoses using user-defined drop-down menus and areas for specific notations. Note that for legal purposes, it is desirable that all recorded documentation have the ability to be locked, or if any modifications are made after 24 hours, the transaction should be recorded with an automated time/date stamp. This is necessary so the data cannot be fraudulently manipulated.

Four panels are shown as follows:

1) Chief complaint is hurts when chews. Has gotten worse over the last two weeks. Tab on the upper left corner reads, symptomatic and asymptomatic. The headings are symptoms, location, chronology, quality, affected by, visual exam each with different options. Probable tooth is selected from dropdown option.

2) It has drop down lists for sinus test and clinical crown, followed by

Telegram: @dental_k

www.konkur.in

symptoms (discolored, facial swelling, caries, previous RCT, and large intestine each with blank check box) and radiology (alveolar bone, lamina dura, roots, pulp chamber, and pulp canal each with drop down options). It is further followed by options for straight canals and curved canals.

3)Different options (cold, hot, percussion, EPT, palpation, mobility, bite stick, swelling, sinus track, and clinical crown, each with drop down list) for pulp test are shown. It is further followed by options such as discolored, facial swelling, caries, previous RCT and large intestine, each with a blank check box. At the bottom, radiology has the option alveolar bone followed by drop down boxes.

4) It has date, followed by clinical diagnosis and tooth number with drop down list. The various options are given under the headings reason for endodontic therapy, pulpal, periradicular, anticipated restoration, and prognosis. At the bottom, note is followed by blank check box.

Source: (Courtesy PBS Endo, Cedar Park, TX.)

History of present dental problem

The dialogue between the patient and the clinician should encompass all of the details pertinent to the events that led to the chief complaint. The clinician should direct the conversation in a manner that produces a clear and concise narrative that chronologically depicts all of the necessary information about the patient's symptoms and the development of these symptoms. To help elucidate this information, the patient is first instructed to fill out a dental history form as part of the patient's office registration. This information will help the clinician decide which approach to use when asking the patient questions. The interview first determines *what is going on* in an effort to determine *why it is going on* for the purpose of eventually determining *what is necessary to resolve the chief complaint.*

Dental history interview

After starting the interview and determining the nature of the chief complaint, the clinician continues the conversation by documenting the sequence of events that initiated the request for an evaluation. The dental history is divided into five basic directions of questioning: localization, commencement, intensity, provocation or attenuation, and duration.

Localization. "Can you point to the offending tooth?" Often the patient can

Telegram: @dental_k

www.konkur.in

point to or tap the offending tooth. This is the most fortunate scenario for the clinician because it helps direct the interview toward the events that might have caused any particular pathosis in this tooth. In addition, localization allows subsequent diagnostic tests to focus more on this particular tooth. When the symptoms are not well localized, the diagnosis is a greater challenge.

Commencement. "When did the symptoms first occur?" A patient who is having symptoms often remembers when these symptoms started. Sometimes the patient will even remember the initiating event. It may have been spontaneous in nature; it may have begun after a dental visit for a restoration; trauma may be the etiology; biting on a hard object may have initially produced the symptoms; or the initiating event may have occurred concurrently with other symptoms (e.g., sinusitis, headache, chest pain). However, the clinician should resist the tendency to make a premature diagnosis based on these circumstances. The clinician should not simply assume "guilt by association" but instead should use this information to enhance the overall diagnostic process.

Intensity. "How intense is the pain?" It often helps to quantify how much pain the patient is actually having. The clinician might ask, "On a scale from 1 to 10, with 10 the most severe, how would you rate your symptoms?" Hypothetically, a patient could present with "an uncomfortable sensitivity to cold" or "an annoying pain when chewing" but might rate this "pain" only as a 2 or a 3. These symptoms certainly contrast with the type of symptoms that prevent a patient from sleeping at night. Often the intensity can be subjectively measured by what is necessary for the diminution of pain (e.g., acetaminophen versus a narcotic pain reliever). This intensity level may affect the decision to treat or not to treat with endodontic therapy. Pain is now considered a standard vital sign, and documenting pain intensity (scale of 0 to 10) provides a baseline for comparison after treatment.

Provocation or attenuation. "What produces or reduces the symptoms?" Mastication and locally applied temperature changes account for the majority of initiating factors that cause dental pain. The patient may relate that drinking something cold causes the pain or possibly that chewing or biting is the only stimulus that "makes it hurt." The patient might say that the pain is only reproduced on "release from biting." On occasion, a patient may present to the dental office with a cold drink in hand and state that the symptoms can

Telegram: @dental_k

www.konkur.in

only be *reduced* by bathing the tooth in cold water. Nonprescription pain relievers may relieve some symptoms, whereas narcotic medication may be required to reduce others. Note that patients who are using narcotic as well as non-narcotic (e.g., ibuprofen) analgesics may respond differently to questions and diagnostic tests, thereby altering the validity of diagnostic results. Thus, it is important to know what drugs patients have taken in the previous 4 to 6 hours. These provoking and relieving factors may help the clinician to determine which diagnostic tests should be performed to establish a more objective diagnosis.

Duration. "Do the symptoms subside shortly, or do they linger after they are provoked?" The difference between a cold sensitivity that subsides in a few seconds and one that subsides in minutes may determine whether a clinician repairs a defective restoration or provides endodontic treatment. The duration of symptoms after a stimulating event should be recorded to establish how long the patient felt the sensation in terms of seconds or minutes. Clinicians often first test control teeth (possibly including a contralateral "normal" tooth) to define a "normal" response for the patient; thus, "lingering" pain is apparent when comparing the duration between the control teeth and the suspected tooth.

With the dental history interview complete, the clinician has a better understanding of the patient's chief complaint and can concentrate on making an objective diagnostic evaluation, although the subjective (and artistic) phase of making a diagnosis is not yet complete and will continue after the more objective testing and scientific phase of the investigatory process.

Examination and testing

Extraoral examination

Basic diagnostic protocol suggests that a clinician observe patients as they enter the operatory. Signs of physical limitations may be present, as well as signs of facial asymmetry that result from facial swelling. Visual and palpation examinations of the face and neck are warranted to determine whether swelling is present. Many times a facial swelling can be determined only by palpation when a unilateral "lump or bump" is present. The presence of bilateral swellings may be a normal finding for any given patient;

Telegram: @dental_k

www.konkur.in

however, it may also be a sign of a systemic disease or the consequence of a developmental event. Palpation allows the clinician to determine whether the swelling is localized or diffuse, firm or fluctuant. These latter findings will play a significant role in determining the appropriate treatment.

Palpation of the cervical and submandibular lymph nodes is an integral part of the examination protocol. If the nodes are found to be firm and tender along with facial swelling and an elevated temperature, there is a high probability that an infection is present. The disease process has moved from a localized area immediately adjacent to the offending tooth to a more widespread systemic involvement.

Extraoral facial swelling of odontogenic origin typically is the result of endodontic etiology because diffuse facial swelling resulting from a periodontal abscess is rare. Swellings of nonodontogenic origin must always be considered in the differential diagnosis, especially if an obvious dental pathosis is not found.[77] This situation is discussed in subsequent chapters.

A subtle visual change such as loss of definition of the nasolabial fold on one side of the nose may be the earliest sign of a canine space infection (Fig. 1.5). Pulpal necrosis and periradicular disease associated with a maxillary canine should be suspected as the source of the problem. Extremely long maxillary central incisors also may be associated with a canine space infection, but most extraoral swellings associated with the maxillary centrals express themselves as a swelling of the upper lip and base of the nose.

FIG. 1.5 **A,** Canine space swelling of the left side of the face extending into and involving the left eye. **B,** Swelling of the upper lip and the loss

of definition of the nasolabial fold on the patient's left side, which indicates an early canine space infection.

A) Front view of patient's face shows inflammation on eye lid and under eye area.

B) Front view of patient's face shows bump on the right side of upper lip.

If the buccal space becomes involved, the swelling will be extraoral in the area of the posterior cheek (Fig. 1.6). These swellings are generally associated with infections originating from the buccal root apices of the maxillary premolar and molar teeth and the mandibular premolar (Fig. 1.7) and first molar teeth. The mandibular second and third molars also may be involved, but infections associated with these two teeth are just as likely to exit to the lingual where other spaces would be involved. For infections associated with these teeth, the root apices of the maxillary teeth must lie superior to the attachment of the buccinator muscle to the maxilla, and the apices of the mandibular teeth must be inferior to the buccinator muscle attachment to the mandible.[77]

Extraoral swelling associated with mandibular incisors will generally exhibit itself in the submental (Fig. 1.8) or submandibular space. Infections associated with any mandibular teeth, which exit the alveolar bone on the lingual and are inferior to the mylohyoid muscle attachment, will be noted as swelling in the submandibular space. Further discussions of fascial space infections may be found in Chapter 16.

Close-up view shows the lower face of a person with a large round bump near the root canal of incisors on the chin.

Sinus tracts of odontogenic origin may also open through the skin of the face (Figs. 1.9 and 1.10).[2,56,64] These openings in the skin will generally close once the offending tooth is treated and healing occurs. A scar is more likely to be visible on the skin surface in the area of the sinus tract stoma than on the oral mucosal tissues (see Fig. 1.10, *C* and *D*). Many patients with extraoral sinus tracts give a history of being treated by general physicians, dermatologists, oncologists, or plastic surgeons with systemic or topical antibiotics or surgical procedures in attempts to heal the extraoral stoma. In these particular cases, after multiple treatment failures, the patients may finally be referred to a dental clinician to determine whether there is a dental cause. Raising the awareness of physicians to such cases will aid in more accurate diagnosis and faster referral to the dentist or endodontist.

Intraoral examination

The intraoral examination may give the clinician insight as to which intraoral areas may need a more focused evaluation. Any abnormality should be

Telegram: @dental_k

www.konkur.in

carefully examined for either prevention or early treatment of associated pathosis.[4,30,75,113,110,126] Swelling, localized lymphadenopathy, or a sinus tract should provoke a more detailed assessment of related and proximal intraoral structures.

Soft-tissue examination

As with any dental examination, there should be a routine evaluation of the intraoral soft tissues. The gingiva and mucosa should be dried with either a low-pressure air syringe or a 2-by-2-inch gauze pad. By retracting the tongue and cheek, all of the soft tissue should be examined for abnormalities in color or texture. Any raised lesions or ulcerations should be documented and, when necessary, evaluated with a biopsy or referral.[82]

Intraoral swelling

Intraoral swellings should be visualized and palpated to determine whether they are diffuse or localized and whether they are firm or fluctuant. These swellings may be present in the attached gingiva, alveolar mucosa, mucobuccal fold, palate, or sublingual tissues. Other testing methods are required to determine whether the origin is endodontic, periodontic, or a combination of these two or whether it is of nonodontogenic origin.

Swelling in the anterior part of the palate (Fig. 1.11) is most frequently associated with an infection present at the apex of the maxillary lateral incisor or the palatal root of the maxillary first premolar. More than 50% of the maxillary lateral incisor root apices deviate in the distal or palatal directions. A swelling in the posterior palate (Fig. 1.12) is most likely associated with the palatal root of one of the maxillary molars.[77]

Telegram: @dental_k

www.konkur.in

Close-up view of upper teeth shows a sore tissue in the soft palate.

Intraoral swelling present in the mucobuccal fold (Fig. 1.13) can result from an infection associated with the apex of the root of any maxillary tooth that exits the alveolar bone on the facial aspect and is inferior to the muscle attachment present in that area of the maxilla (see also Chapter 15). The same is true with the mandibular teeth if the root apices are superior to the level of the muscle attachments and the infection exits the bone on the facial. Intraoral swelling can also occur in the sublingual space if the infection from the root apex spreads to the lingual and exits the alveolar bone superior to the attachment for the mylohyoid muscle. The tongue will be elevated and the swelling will be bilateral because the sublingual space is contiguous with no midline separation. If the infection exits the alveolar bone to the lingual with mandibular molars and is inferior to the attachment of the mylohyoid muscle, the swelling will be noted in the submandibular space. Severe infections involving the maxillary and mandibular molars can extend into the parapharyngeal space, resulting in intraoral swelling of the tonsillar and pharyngeal areas. This can be life threatening if the patient's airway becomes obstructed.[77,80]

Intraoral sinus tracts

On occasion, a chronic endodontic infection will drain through an intraoral communication to the gingival surface and is known as a *sinus tract.*[12] This pathway, which is sometimes lined with epithelium, extends directly from the source of the infection to a surface opening, or *stoma,* on the attached gingival surface. As previously described, it can also extend extraorally. The term *fistula* is often inappropriately used to describe this type of drainage. The fistula, by definition, is actually an abnormal communication pathway between two internal organs or from one epithelium-lined surface to another epithelium-lined surface.[6]

Histologic studies have found that most sinus tracts are not lined with epithelium throughout their entire length. One study found that only 1 out of the 10 sinus tracts examined were lined with epithelium, whereas the other 9 specimens were lined with granulation tissue.[55] Another study, with a larger sample size, found that two thirds of the specimens did not have epithelium extending beyond the level of the surface mucosa rete ridges.[12] The remaining specimens had some epithelium that extended from the oral mucosa surface to the periradicular lesion.[12] The presence or absence of an epithelial lining does not seem to prevent closure of the tract as long as the source of the problem is properly diagnosed and adequately treated and the endodontic lesion has healed. Failure of a sinus tract to heal after treatment will necessitate further diagnostic procedures to determine whether other sources of infection are present or whether a misdiagnosis occurred.

In general, a periapical infection that has an associated sinus tract is not painful, although often there is a history of varying magnitudes of discomfort before sinus tract development. Besides providing a conduit for the release of infectious exudate and the subsequent relief of pain, the sinus tract can also provide a useful aid in determining the source of a given infection. Sometimes objective evidence as to the origin of an odontogenic infection is lacking. The stoma of the sinus tract may be located directly adjacent to or at a distant site from the infection. Tracing the sinus tract will provide objectivity in diagnosing the location of the problematic tooth. To trace the

Telegram: @dental_k

www.konkur.in

sinus tract, a size #25 or #30 gutta-percha cone is threaded into the opening of the sinus tract. Although this may be slightly uncomfortable to the patient, the cone should be inserted until resistance is felt. After a periapical radiograph is exposed, the origin of the sinus tract is determined by following the path taken by the gutta-percha cone (Fig. 1.14). This will direct the clinician to the tooth involved and, more specifically, to the part of the root of the tooth that is the source of the pathosis. Once the causative factors related to the formation of the sinus tract are removed, the stoma and the sinus tract will close within several days.

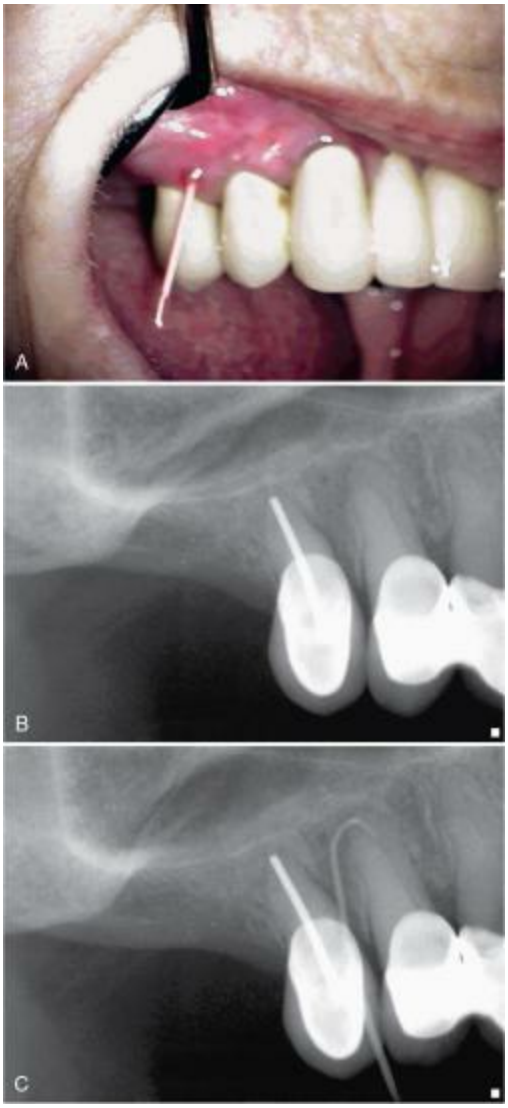

FIG. 1.14 **A,** To locate the source of an infection, the sinus tract can be traced by threading the stoma with a gutta-percha point. **B,**

Radiograph of the area shows an old root canal in a maxillary second premolar and a questionable radiolucent area associated with the first premolar, with no clear indication of the etiology of the sinus tract. **C,** After tracing the sinus tract, the gutta-percha is seen to be directed to the source of pathosis, the apex of the maxillary first premolar.

A) Close-up view shows a gutta-percha cone being inserted in the root canal above first premolar.

B) Radiograph shows two teeth where a thread is inserted through the first tooth. The first tooth is radiopaque while the second tooth is partially radiolucent.

C) Radiograph shows two teeth with a thread passing from them.

The stomata of intraoral sinus tracts may open in the alveolar mucosa, in the attached gingiva, or through the furcation or gingival crevice. They may exit through either the facial or the lingual tissues depending on the proximity of the root apices to the cortical bone. If the opening is in the gingival crevice, it is normally present as a narrow defect in one or two isolated areas along the root surface. When a narrow defect is present, the differential diagnosis must include the opening of a periradicular endodontic lesion, a vertical root fracture, or the presence of a developmental groove on the root surface. This type of sinus tract can be differentiated from a primary periodontal lesion because the latter generally presents as a pocket with a broad coronal opening and more generalized alveolar bone loss around the root. Other pulp testing methods may assist in verifying the source of infection.[111,112,121]

Palpation

In the course of the soft-tissue examination, the alveolar hard tissues should also be palpated. Emphasis should be placed on detecting any soft-tissue swelling or bony expansion, especially noting how it compares with and relates to the adjacent and contralateral tissues. In addition to objective findings, the clinician should question the patient about any areas that feel unusually sensitive during this palpation part of the examination.

A palpation test is performed by applying firm digital pressure to the mucosa covering the roots and apices. The index finger is used to press the mucosa against the underlying cortical bone. This will detect the presence of

Telegram: @dental_k

www.konkur.in

periradicular abnormalities or specific areas that produce painful response to digital pressure. A positive response to palpation may indicate an active periradicular inflammatory process. However, this test does not indicate whether the inflammatory process is of endodontic or periodontal origin.

Percussion

Referring back to the patient's chief complaint may indicate the importance of percussion testing for this particular case. If the patient is experiencing acute sensitivity or pain on mastication, this response can typically be duplicated by individually percussing the teeth, which often isolates the symptoms to a particular tooth. Pain to percussion does not indicate that the tooth is vital or nonvital but is rather an indication of inflammation in the periodontal ligament (i.e., symptomatic apical periodontitis). This inflammation may be secondary to physical trauma, occlusal prematurities, periodontal disease, or the extension of pulpal disease into the periodontal ligament space. The indication of where the pain originates is interpreted by the mesencephalic nucleus, receiving its information from proprioceptive nerve receptors. Although subject to debate, the general consensus is that there are relatively few proprioceptors in the dental pulp; however, they are prevalent in the periodontal ligament spaces.[24] This is why it may be difficult for the patient to discriminate the location of dental pain in the earlier stages of pathosis, when only the C fibers are stimulated. Once the disease state extends into the periodontal ligament space, the pain may become more localized for the patient; therefore, the affected tooth will be more identifiable with percussion and mastication testing.

Before percussing any teeth, the clinician should tell the patient what will transpire during this test. Because the presence of acute symptoms may create anxiety and possibly alter the patient's response, properly preparing the patient will lead to more accurate results. The contralateral tooth should first be tested as a control, as should several adjacent teeth that are certain to respond normally. The clinician should advise the patient that the sensation from this tooth is normal and ask to be advised of any tenderness or pain from subsequent teeth.

Percussion is performed by tapping on the incisal or occlusal surfaces of the teeth either with the finger or with a blunt instrument. The testing should

Telegram: @dental_k

www.konkur.in

initially be done gently, with light pressure being applied digitally with a gloved finger tapping. If the patient cannot detect significant difference between any of the teeth, the test should be repeated using the blunt end of an instrument, like the back end of a mirror handle (Fig. 1.15). The tooth crown is tapped vertically and horizontally. The tooth should first be percussed occlusally, and if the patient discerns no difference, the test should be repeated, percussing the buccal and lingual aspects of the teeth. For any heightened responses, the test should be repeated as necessary to determine that it is accurate and reproducible, and the information should be documented.

FIG. 1.15 Percussion testing of a tooth, using the back end of a mirror handle.

Close-up view shows a front tooth in the upper jaw being tapped with a mirror handle.

Although this test does not disclose the condition of the pulp, it indicates the presence of a periradicular inflammation. An abnormal positive response indicates inflammation of the periodontal ligament that may be of either pulpal or periodontal origin. The sensitivity of the proprioceptive fibers in an inflamed periodontal ligament will help identify the location of the pain. This test should be done gently, especially in highly sensitive teeth. It should be

Telegram: @dental_k

www.konkur.in

repeated several times and compared with control teeth.

Mobility

Like percussion testing, an increase in tooth mobility is not an indication of pulp vitality. It is merely an indication of a compromised periodontal attachment apparatus. This compromise could be the result of acute or chronic physical trauma, occlusal trauma, parafunctional habits, periodontal disease, root fractures, rapid orthodontic movement, or the extension of pulpal disease, specifically an infection, into the periodontal ligament space. Tooth mobility is directly proportional to the integrity of the attachment apparatus or to the extent of inflammation in the periodontal ligament. Often the mobility reverses to normal after the initiating factors are repaired or eliminated. Because determining mobility by simple finger pressure can be visually subjective, the back ends of two mirror handles should be used, one on the buccal aspect and one on the lingual aspect of the tooth (Fig. 1.16). Pressure is applied in a facial-lingual direction as well as in a vertical direction and the tooth mobility is scored (Box 1.2). Any mobility that exceeds +1 should be considered abnormal. However, the teeth should be evaluated on the basis of how mobile they are relative to the adjacent and contralateral teeth.

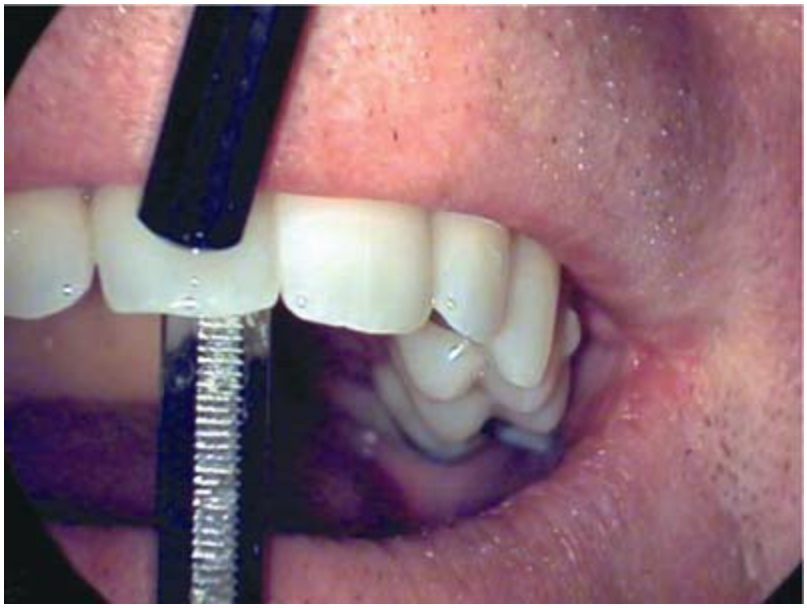

FIG. 1.16 Mobility testing of a tooth, using the back ends of two mirror

handles.

Close-up view shows one of the upper incisors being examined through two mirror handles present on either side of the tooth.

Box 1.2

Recording Tooth Mobility

+1 mobility: The first distinguishable sign of movement greater than normal
+2 mobility: Horizontal tooth movement no greater than 1 mm
+3 mobility: Horizontal tooth movement greater than 1 mm, with or without the visualization of rotation or vertical depressability

Periodontal examination

Periodontal probing is an important part of any intraoral diagnosis. The measurement of periodontal pocket depth is an indication of the depth of the gingival sulcus, which corresponds to the distance between the height of the free gingival margin and the height of the attachment apparatus below. Using a calibrated periodontal probe, the clinician should record the periodontal pocket depths on the mesial, middle, and distal aspects of both the buccal and lingual sides of the tooth, noting the depths in millimeters. The periodontal probe is "stepped" around the long axis of the tooth, progressing in 1-mm increments. Periodontal bone loss that is wide, as determined by a wide span of deep periodontal probing, is generally considered to be of periodontal origin and is typically more generalized in other areas of the mouth. However, isolated areas of vertical bone loss may be of an endodontic origin, specifically from a nonvital tooth whose infection has extended from the periapex to the gingival sulcus. Again, proper pulp testing is imperative, not just for the determination of a diagnosis but also for the development of an accurate prognosis assessment. For example, a periodontal pocket of endodontic origin may resolve after endodontic treatment, but if the tooth was originally vital with an associated deep periodontal pocket, endodontic treatment will not improve the periodontal condition. In addition, as discussed in Chapter 22, a vertical root fracture may often cause a localized

Telegram: @dental_k

www.konkur.in

narrow periodontal pocket that extends deep down the root surface. Characteristically, the adjacent periodontium is usually within normal limits.

Furcation bone loss can be secondary to periodontal or pulpal disease. The amount of furcation bone loss, as observed both clinically and radiographically, should be documented (Box 1.3). Results of pulp tests (described later) will aid in diagnosis.

Box 1.3

Recording Furcation Defects

Class I furcation defect: The furcation can be probed but not to a significant depth.
Class II furcation defect: The furcation can be entered into but cannot be probed completely through to the opposite side.
Class III furcation defect: The furcation can be probed completely through to the opposite side.

Pulp tests

Pulp test (pulp sensibility test) is a diagnostic procedure to determine pulp status. It can be performed with electrical, mechanical, or thermal stimuli, or by the assessment of the blood supply to the tooth.[6] It involves attempting to make a determination of the responsiveness of pulpal sensory neurons.[62,63] It aims to obtain a subjective response from the patient (i.e., to determine whether the pulpal nerves are functional), or the tests may involve a more objective approach using devices that detect the integrity of the pulpal vasculature. Unfortunately, the quantitative evaluation of the status of pulp tissue can only be determined histologically, as it has been shown that there is not necessarily a good correlation between the objective clinical signs and symptoms and the pulpal histology.[122,123]

Thermal

Various methods and materials have been used to test the pulp's response to thermal stimuli. The baseline or normal response to either cold or hot is a patient's report that a sensation is felt but disappears immediately upon

Telegram: @dental_k

www.konkur.in

removal of the thermal stimulus. Abnormal responses include a lack of response to the stimulus, a lingering or intensification of a painful sensation after the stimulus is removed, or an immediate, excruciatingly painful sensation as soon as the stimulus is placed on the tooth.

Cold testing is the primary pulp testing method used by many clinicians today. It is especially useful for patients presenting with porcelain jacket crowns or porcelain-fused-to-metal crowns where no natural tooth surface (or much metal) is accessible. If a clinician chooses to perform this test with sticks of ice, then the use of a rubber dam is recommended, because melting ice will run onto adjacent teeth and gingiva, yielding potentially false-positive responses.

Frozen carbon dioxide (CO_2), also known as *dry ice* or *carbon dioxide snow*, or *CO_2 stick*, has been found to be reliable in eliciting a positive response if vital pulp tissue is present in the tooth.[46,98,99] One study found that vital teeth would respond to both frozen CO_2 and skin refrigerant, with skin refrigerant producing a slightly quicker response.[66] Frozen carbon dioxide has also been found to be effective in evaluating the pulpal response in teeth with full coverage crowns for which other tests such as electric pulp testing is not possible.[11] For testing purposes, a solid stick of CO_2 is prepared by delivering CO_2 gas into a specially designed plastic cylinder (Fig. 1.17). The resulting CO_2 stick is applied to the facial surface of either the natural tooth structure or crown. Several teeth can be tested with a single CO_2 stick. The teeth should be isolated and the oral soft tissues should be protected with a 2-by-2-inch gauze or cotton roll so the frozen CO_2 will not come into contact with these structures. Because of the extremely cold temperature of the frozen CO_2 (−69°F to −119°F; −56°C to −98°C), burns of the soft tissues can occur. It has been demonstrated on extracted teeth that frozen CO_2 application has resulted in a significantly greater intrapulpal temperature decrease than either skin refrigerant or ice.[11] Also, it appears that the application of CO_2 to teeth does not result in any irreversible damage to the pulp tissues or cause any significant enamel crazing.[61,104]

www.konkur.in

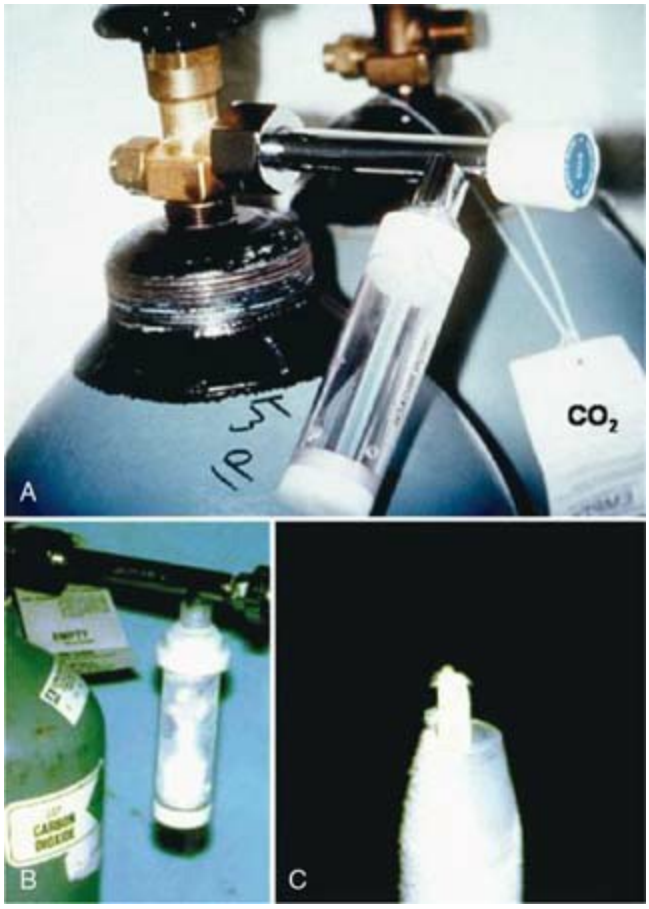

FIG. 1.17 **A,** Carbon dioxide tank with apparatus attached to form solid CO_2 stick/pencil. **B,** CO_2 gas being transformed into a solid stick/pencil. **C,** CO_2 stick/pencil extruded from end of a plastic carrier and ready for use.

Set of three photographs marked A through C depict transformation of carbon dioxide gas from a cylinder into a carbon dioxide stick or pencil.

The most popular method of performing cold testing is with a refrigerant spray. It is readily available, easy to use, and provides test results that are reproducible, reliable, and equivalent to that of frozen CO_2.[46,66,96,141] One of the current products contains 1,1,1,2-tetrafluoroethane, which has zero ozone depletion potential and is environmentally safe. It has a temperature of −26.2°C.[66] The spray is most effective for testing purposes when it is applied to the tooth on a large #2 cotton pellet (Fig. 1.18). In one study,[65] a significantly lower intrapulpal temperature was achieved when a #2 cotton pellet was dipped or sprayed with the refrigerant compared with the result when a small #4 cotton pellet or cotton applicator was used. The sprayed

Telegram: @dental_k

www.konkur.in

cotton pellet should be applied to the midfacial area of the tooth or crown. As with any other pulp testing method, adjacent or contralateral "normal" teeth should also be tested to establish a baseline response. It appears that frozen CO_2 and refrigerant spray are superior to other cold testing methods and equivalent or superior to the electric pulp tester for assessing pulp vitality.[11,46] However, one study found that periodontal attachment loss and gingival recession may influence the reported pain response with cold stimuli.[116]

FIG. 1.18 **A,** Refrigerant spray container. **B,** A large cotton pellet made of a cotton roll, or a ready-made size #2 (large) cotton pellet, can be used to apply the refrigerant spray to the tooth surface. The small #4 cotton pellet does not provide as much surface area as the #2 cotton pellet, and therefore should not be used to deliver the refrigerant to the tooth surface. **C,** A large cotton pellet sprayed with the refrigerant and ready to be applied to the tooth surface.

Telegram: @dental_k

www.konkur.in

To be most reliable, cold testing should be used in conjunction with an electric pulp tester (described later in this chapter) so that the results from one test will verify the findings of the other test. If a mature, nontraumatized tooth does not respond to both cold testing and electric pulp testing, then the pulp can be considered necrotic.[23,98,141] However, a multirooted tooth, with at least one root containing vital pulp tissue, may respond to a cold test and electric pulp test even if one or more of the roots contain necrotic pulp tissue.[98]

Another thermal testing method involves the use of heat. Heat testing is most useful when a patient's chief complaint is intense dental pain on contact with any hot liquid or food. When a patient is unable to identify which tooth is sensitive, a heat test is appropriate. Starting with the most posterior tooth in that area of the mouth, each tooth is individually isolated with a dental dam. An irrigating syringe is filled with a liquid (most commonly plain water) that has a temperature similar to that which would cause the painful sensation. The liquid is then expressed from the syringe onto the isolated tooth to determine whether the response is normal or abnormal. The clinician moves forward in the quadrant, isolating each individual tooth until the offending tooth is located. That tooth will exhibit an immediate, intense painful response to the heat. With heat testing, a delayed response may occur, so waiting 10 seconds between each heat test will allow sufficient time for the onset of symptoms. This method can also be used to apply cold water to the entire crown for cases in which cold is the precipitating stimulus.

Another method for heat testing is to apply heated gutta-percha or compound stick to the surface of the tooth. If this method is used, a light layer of lubricant should be placed onto the tooth surface before applying the heated material to prevent the hot gutta-percha or compound from adhering to the dry tooth surface. Heat can also be generated by the friction created when a dry rubber-polishing wheel is run at a high speed against the dry surface of a tooth. However, this latter method is not recommended. Another approach is the use of electronic heat-testing instruments.[20]

If the heat test confirms the results of other pulp testing procedures, emergency care can then be provided. Often a tooth that is sensitive to heat may also be responsible for some spontaneous pain. The patient may present with cold liquids in hand just to minimize the pain (Fig. 1.19). In such cases,

Telegram: @dental_k

www.konkur.in

the application of cold to a specific tooth may eliminate the pain and greatly assist in the diagnosis. Typically, a tooth that responds to heat and then is relieved by cold is found to be necrotic.

FIG. 1.19 Irreversible pulpitis associated with the mandibular right second molar. Patient has found that the only way to alleviate the pain is to place a jar filled with ice water against the right side of his face.

A patient places an ice jar at the right corner of lips.

Electric

Assessment of pulp neural responses *(sensibility)* can also be accomplished by electric pulp testing.[79] Electric pulp testers of different designs and manufacturers have been used for this purpose. Electric pulp testers should be an integral part of any dental practice. It should be noted that the sensibility of the pulp is determined by the intactness and health of the vascular supply, not by the status of the pulpal nerve fibers. Even though advances are being made with regard to determining the status of the pulp on the basis of the blood supply, this technology has not been perfected enough at this time to be

Telegram: @dental_k

www.konkur.in

used on a routine basis in a clinical setting.

The electric pulp tester has some limitations in providing predictable information about the status of the pulp. The response of the pulp to electric testing does not reflect the histologic health or disease status of the pulp.[122,123] A response by the pulp to the electric current only denotes that some viable nerve fibers are present in the pulp and are capable of responding. Numeric readings on the pulp tester have significance only if the number differs significantly from the readings obtained from a control tooth tested on the same patient with the electrode positioned at a similar area on both teeth. However, in most cases, the response is scored as either present or absent. Studies[122,123] have shown that electric pulp test results are most accurate when no response is obtained to any amount of electric current. This lack of response has been found most frequently when a necrotic pulp is present. In addition, false-positive and false-negative responses can occur (Box 1.4), and the clinician must take it into account when formulating the final diagnosis.

Box 1.4

Potential Common Interpretation Errors of Responses Obtained From Electric Pulp Testing

False-positive responses

- Partial pulp necrosis
- Patient's high anxiety
- Ineffective tooth isolation
- Contact with metal restorations

False-negative responses

- Calcific obliterations in the root canals
- Recently traumatized teeth
- Immature apex
- Drugs that increase patient's threshold for pain
- Poor contact of pulp tester to tooth

Telegram: @dental_k

www.konkur.in

The electric pulp tester will not work unless the probe can be placed in contact with or be bridged to the natural tooth structure.[95] With the advent of universal precautions for infection control, the use of rubber gloves prevents the clinician from completing the circuit.[7] Some pulp testers may require the patient to place a finger, or fingers, on the tester probe to complete the electric circuit; however, the use of lip clips is an alternative to having patients hold the tester. Proper use of the electric pulp tester requires the evaluated teeth to be carefully isolated and dried. A control tooth of similar tooth type and location in the arch should be tested first in order to establish a baseline response and to inform the patient as to what a "normal" sensation is. The suspected tooth should be tested at least twice to confirm the results. The tip of the testing probe that will be placed in contact with the tooth structure must be coated with a water- or petroleum-based medium.[86] The most commonly used medium is toothpaste. The coated probe tip is placed in the incisal third of the facial or buccal area of the tooth to be tested.[15] Once the probe is in contact with the tooth, the patient is asked to touch or grasp the tester probe, unless a lip clip is used (Fig. 1.20, *A*). This completes the circuit and initiates the delivery of an electric current to the tooth. The patient is instructed to remove his or her finger(s) from the probe when a "tingling" or "warming" sensation is felt in the tooth. The readings from the pulp tester are recorded (Fig. 1.20, *B*) and will be evaluated once all the appropriate teeth have been tested by the electric pulp tester and the other pulp testing methods.

Telegram: @dental_k

www.konkur.in

FIG. 1.20 **A,** Electric pulp tester with probe. The probe tip will be coated with a conducive medium, such as toothpaste, and placed in contact with the tooth surface. The patient will activate the unit by placing a finger on the metal shaft of the probe. **B,** View of the electric pulp tester control panel; the knob on the front right of the unit controls the rate at which the electric current is delivered to the tooth. The plastic panel on the left front displays the digital numerical reading obtained from the pulp test. The digital scale runs from 0 to 80.

Set of two photographs marked A and B depict components of an electric pulp tester with a probe.

Source: (Courtesy SybronEndo, Orange, CA.)

If a complete coverage crown or extensive restoration is present, a bridging technique can be attempted to deliver the electric current to any exposed natural tooth structure.[95] The tip of an endodontic explorer is coated with toothpaste or other appropriate medium and placed in contact with the natural tooth structure. The tip of the electric pulp tester probe is coated with a small amount of toothpaste and placed in contact with the side of the explorer. The

Telegram: @dental_k

www.konkur.in

patient completes the circuit and the testing proceeds as described previously. If no natural tooth structure is available, then an alternative pulp testing method, such as cold, should be used.

One study compared the ability of thermal and electric pulp testing methods to register the presence of vital pulp tissue.[99] The *sensibility*, which is the ability of a test to identify teeth that are diseased, was 0.83 for the cold test, 0.86 for heat test, and 0.72 for the electric test. This means the cold test correctly identified 83% of the teeth that had a necrotic pulp, whereas heat tests were correct 86% of the time and electric pulp tests were correct only 72% of the time. This same study evaluated the *specificity* of these three tests. Specificity relates to the ability of a test to identify teeth without disease. Ninety-three percent of teeth with healthy pulps were correctly identified by both the cold and electric pulp tests, whereas only 41% of the teeth with healthy pulps were identified correctly by the heat test. From the results of the testing, it was found that the cold test had an accuracy of 86%, the electric pulp test 81%, and the heat test 71%.

Some studies have indicated there might not be a significant difference between pulp testing results obtained by electric pulp tester and those obtained by the thermal methods.[46,98,99] However, cold tests have been shown to be more reliable than electric pulp tests in younger patients with less developed root apices.[5,42,98] This is the reason to verify the results obtained by one testing method and compare them with results obtained by other methods. Until such time that the testing methods used to assess the vascular supply of the pulp become less time consuming and technique sensitive, thermal and electric pulp testing will continue to be the primary methods for determining pulp sensibility.

Laser doppler flowmetry

Laser Doppler flowmetry (LDF) is a method used to assess blood flow in microvascular systems. Attempts are being made to adapt this technology to assess pulpal blood flow. A diode is used to project an infrared light beam through the crown and pulp chamber of a tooth. The infrared light beam is scattered as it passes through the pulp tissue. The Doppler principle states that the light beam's frequency will shift when hitting moving red blood cells but will remain unshifted as it passes through static tissue. The average

Telegram: @dental_k

www.konkur.in

Doppler frequency shift will measure the velocity at which the red blood cells are moving.[114]

Several studies[40,60,69,84,114,115,117] have found LDF to be an accurate, reliable, and reproducible method of assessing pulpal blood flow. One of the great advantages of pulp testing with devices such as the LDF is that the collected data are based on objective findings rather than subjective patient responses. As is discussed in Chapter 21, certain luxation injuries will cause inaccuracies in the results of electric and thermal pulp testing. LDF has been shown to be a great indicator for pulpal vitality in these cases.[130] However, this technology is not being used routinely in the dental practice.

Pulse oximetry

The pulse oximeter is another noninvasive device (Fig. 1.21). Widely used in medicine, it is designed to measure the oxygen concentration in the blood and the pulse rate. A pulse oximeter works by transmitting two wavelengths of light, red and infrared, through a translucent portion of a patient's body (e.g., a finger, earlobe, or tooth). Some of the light is absorbed as it passes through the tissue; the amount absorbed depends on the ratio of oxygenated to deoxygenated hemoglobin in the blood. On the opposite side of the targeted tissue, a sensor detects the absorbed light. On the basis of the difference between the light emitted and the light received, a microprocessor calculates the pulse rate and oxygen concentration in the blood.[118] The transmission of light to the sensor requires that there be no obstruction from restorations, which can sometimes limit the usefulness of pulse oximetry to test the status of the pulp tissue.

A digital pulse oximeter is shown. The plastic panel records pulse with a highest reading of 99 and lowest reading of 65 on the left.

Source: (Courtesy Nellcor Puritan Bennett, Boulder, CO; now part of Covidien.)

Custom-made sensors have been developed and were found to be more accurate than electric and thermal pulp tests.[31,54] This sensor has been especially useful in evaluating teeth that have been subjected to traumatic injuries, as such teeth tend to present, especially in the short term, with questionable neural response using conventional pulp testing methods.[8,31,53]

Studies regarding the ability of pulse oximetry to diagnose pulp health have drawn various conclusions. Several studies have found pulse oximetry to be a reliable method for assessing pulp health.[69,70,118,125,140] Others have stated that in its present form the pulse oximeter may not be predictable for such diagnoses.[140] Most of the problems appear to be related to the currently available technology. Some investigators have concluded that the devices used for pulp testing are too cumbersome and complicated to be used on a routine basis in a dental practice.[68,118,140]

Special tests

Bite test

Telegram: @dental_k

www.konkur.in

Bite tests and percussion tests are indicated when a patient presents with pain while biting. On occasion, the patient may not know which tooth is sensitive to biting pressure, and percussion and bite tests may help to localize the tooth involved. The tooth may be sensitive to biting when the pulpal pathosis has extended into the periodontal ligament space, creating a *symptomatic apical periodontitis,* or the sensitivity may be present secondary to a crack in the tooth. The clinician can often differentiate between periradicular periodontitis and a cracked tooth or fractured cusp. If periradicular periodontitis is present, the tooth will respond with pain to percussion and biting tests regardless of where the pressure is applied to the coronal part of the tooth. A cracked tooth or fractured cusp will typically elicit pain only when the bite or percussion test is applied in a certain direction to one cusp or section of the tooth.[22,108]

For the bite test to be meaningful, a device should be used that allows the clinician to apply pressure to individual cusps or areas of the tooth. A variety of devices have been used for bite tests, including cotton tip applicators, toothpicks, orangewood sticks, and rubber polishing wheels. There are several devices specifically designed to perform this test. The Tooth Slooth (Professional Results, Laguna Niguel, CA) (Fig. 1.22) and FracFinder (Hu-Friedy, Oakbrook, IL) are just two of the commercially available devices used for the bite test. As with all pulp tests, adjacent and contralateral teeth should be used as controls so that the patient is aware of the “normal” response to these tests. The small cupped-out area on these instruments is placed in contact with the cusp to be tested. The patient is then asked to apply biting pressure with the opposing teeth to the flat surface on the opposite side of the device. The biting pressure should be applied slowly until full closure is achieved. Firm pressure should be applied for a few seconds; the patient is then asked to release the pressure quickly. Each individual cusp on a tooth can be tested in a similar manner. The clinician should note whether the pain is elicited during the pressure phase or on quick release of the pressure. A common finding with a fractured cusp or cracked tooth is the frequent presence of pain upon release of biting pressure.

Telegram: @dental_k

www.konkur.in

FIG. 1.22 To determine which tooth, or tooth part, is sensitive to mastication, having the patient bite on a specially designed bite stick is often helpful.

Close-up view shows a plastic bite stick between patient's teeth.

Test cavity

The test cavity method for assessing pulpal response is not routinely used since, by definition, it is an invasive irreversible test. This method is used only when all other test methods are deemed impossible or the results of the other tests are inconclusive. An example of a situation in which this method can be used is when the tooth suspected of having pulpal disease has a full coverage crown. If no sound tooth structure is available to use a bridging technique with the electric pulp tester, and the cold test results are inconclusive, a small class I cavity preparation is made through the occlusal surface of the crown. This is accomplished with a high-speed #1 or #2 round bur with proper air and water coolant. The patient is not anesthetized while this procedure is performed, and the patient is asked to respond if any painful sensation is felt during the drilling procedure. If the patient feels pain once the bur contacts sound dentin, the procedure is terminated and the class I cavity preparation is restored. This sensation signifies only that there is some viable nerve tissue remaining in the pulp, not that the pulp is totally healthy. If the patient fails to feel any sensation when the bur reaches the dentin, this

Telegram: @dental_k

www.konkur.in

is a good indication that the pulp is necrotic and root canal therapy is indicated. The patient should be given a full explanation and reassurance of the procedure before the test cavity is attempted.

Staining and transillumination

To determine the presence of a crack in the surface of a tooth, the application of a stain to the area is often of great assistance. It may be necessary to remove the restoration in the tooth to better visualize a crack or fracture. Methylene blue dye, when painted on the tooth surface with a cotton tip applicator, will penetrate into cracked areas. The excess dye may be removed with a moist application of 70% isopropyl alcohol. The remaining dye will indicate the possible location of the crack.

Transillumination using a bright fiberoptic light probe to the surface of the tooth may be very helpful (Fig. 1.23). Directing a high-intensity light directly on the exterior surface of the tooth at the cementum-enamel junction (CEJ) may reveal the extent of the fracture. Teeth with fractures block transilluminated light. The part of the tooth that is proximal to the light source will absorb this light and glow, whereas the area beyond this fracture will not have light transmitted to it and will show dark by comparison.[101] Although the presence of a fracture may be evident using dyes and transillumination, the full extent of the fracture cannot always be determined by these tests alone.

Telegram: @dental_k

www.konkur.in

FIG. 1.23 Sometimes there is no clear indication of why a tooth is symptomatic. This radiograph shows a mandibular second molar with a moderately deep restoration **(A);** the pulp tests nonvital. Without any transillumination, a fracture cannot be detected **(B).** However, by placing a high-intensity light source on the tooth surface, a root fracture can be observed on the buccal surface **(C)** and the distal-lingual surface **(D).**

A) Radiograph shows a radiolucent region in and around the root of second molar.

B) Close-up view of tooth isolated by rubber dam clamp shows a filling in the cavity.

C) Close-up view shows the isolated tooth being examined under a light source.

D) Close-up view shows yellow and soft tissue of the fractured tooth. The enamel layer is peeled off at the edge.

Selective anesthesia

When symptoms are not localized or referred, the diagnosis may be challenging. Sometimes the patient may not even be able to specify whether the symptoms are emanating from the maxillary or mandibular arch. In these

Telegram: @dental_k

www.konkur.in

instances, when pulp testing is inconclusive, *selective anesthesia* may be helpful.

If the patient cannot determine which arch the pain is coming from, then the clinician should first selectively anesthetize the maxillary arch. This should be accomplished by using a periodontal ligament (intraligamentary) injection. The injection is administered to the most posterior tooth in the quadrant of the arch that may be suspected, starting from the distal sulcus. The anesthesia is subsequently administered in an anterior direction, one tooth at a time, until the pain is eliminated. If the pain is not eliminated after an appropriate period of time, then the clinician should similarly repeat this technique on the mandibular teeth below. It should be understood that periodontal ligament injections may anesthetize an adjacent tooth and thus are more useful for identifying the arch rather than the specific tooth.

Radiographic examination and interpretation

Intraoral radiographs

The radiographic interpretation of a potential endodontic pathosis is an integral part of endodontic diagnosis and prognosis assessment. Few diagnostic tests provide as much useful information as dental radiography. For this reason, the clinician is sometimes tempted to prematurely make a definitive diagnosis based solely on radiographic interpretation. However, the image should be used only as one sign, providing important clues in the diagnostic investigation. When not coupled with a proper history and clinical examination and testing, the radiograph alone can lead to a misinterpretation of normality and pathosis (Fig. 1.24). Because treatment planning will ultimately be based on the diagnosis, the potential for inappropriate treatment may frequently exist if the radiograph alone is used for making final diagnosis. The clinician should not subject the patient to unnecessary multiple radiation exposures; two pretreatment images from different angulations are often sufficient. However, under extenuating circumstances—especially when the diagnosis is difficult—additional exposures may be necessary to determine the presence of multiple roots, multiple canals, resorptive defects, caries, restoration defects, root fractures, and the extent of root maturation and apical development.

Telegram: @dental_k

www.konkur.in

FIG. 1.24 Radiograph showing what appears to be a mandibular lateral incisor associated with periapical lesion of a nonvital tooth. Although pulp necrosis can be suspected, the tooth tested vital. In this case, the appearance of apical bone loss is secondary to a cementoma.

Radiograph shows a dark and roughly triangular patch at the root canal of incisor, with blur image of two tooth to the left of patch.

The radiographic appearance of endodontic pathosis can sometimes be highly subjective. In a study by Goldman and colleagues, there was only 50% agreement among interpreters for the radiographic presence of pathosis.[49] When the cases were reevaluated several months later, the same evaluators agreed with their own original diagnosis less than 85% of the time.[50] This further emphasizes the necessity for additional objective diagnostic tests, as well as the importance of obtaining and comparing older radiographs of the same area of the patient.

For standard two-dimensional radiography, clinicians basically project x-radiation through an object and capture the image on a recording medium, either x-ray film or a digital sensor. Much like casting a shadow from a light source, the image appearance may vary greatly depending on how the radiographic source is directed. Thus, the three-dimensional interpretation of the resulting two-dimensional image requires not only knowledge of

Telegram: @dental_k

www.konkur.in

normality and pathosis but also advanced knowledge of how the radiograph was exposed. By virtue of "casting a shadow," the anatomic features that are closest to the film (or sensor) will move the least when there is a change in the horizontal or vertical angulation of the radiation source (Fig. 1.25). This may be helpful in determining the existence of additional roots, the location of pathosis, and the unmasking of anatomic structures. Changes in the horizontal or vertical angulation may help elucidate valuable anatomic and pathologic information; it also has the potential to hide important information. An incorrect vertical angulation may cause the buccal roots of a maxillary molar to be masked by the zygomatic arch. An incorrect horizontal angulation may cause roots to overlap with the roots of adjacent teeth, or it may incorrectly create the appearance of a one-rooted tooth, when two roots are actually present.

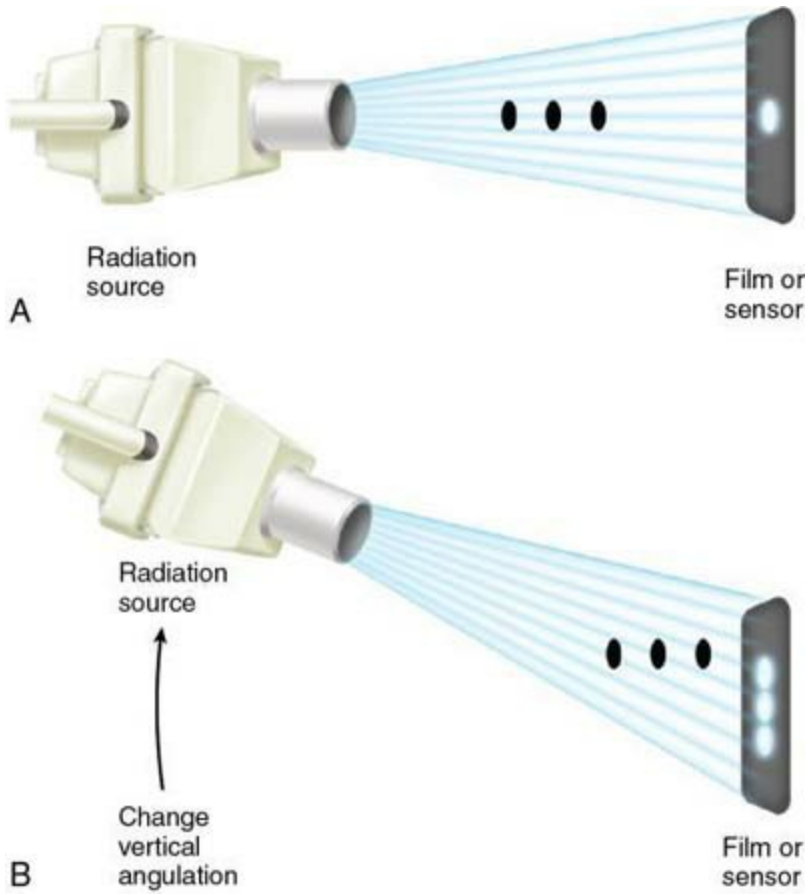

FIG. 1.25 Radiographic images are only two-dimensional, and often it is difficult to discriminate the relative location of overlapping objects. **A,** When the source of radiation is directly perpendicular to overlapping

Telegram: @dental_k

www.konkur.in

objects, the image is captured without much separation of the objects. However, when the radiation source is at an angle to offset the overlapping objects, the image is captured with the objects being viewed as separated. **B,** The object that is closest to the film (or sensor) will move the least, with the object closest to the radiation source appearing farthest away.

Set of two illustrations marked A and B depict ways that may lead to casting of shadow resulting in changes in inaccurate diagnosis.

In general, when endodontic pathosis appears radiographically, it appears as a radiolucency in the area of the periapex. The pathosis may present merely as a widening or break in the lamina dura—the most consistent radiographic finding when a tooth is nonvital[67]—or it may present as a radiolucent area at the apex of the root or in the alveolar bone adjacent to the exit of a lateral or furcation accessory canal. On occasion no radiographic change can be seen at all, even in the presence of a disease process in the alveolar bone. This is mainly due to the fact that the disease process did not reach the cortical plate of the bone.

Two-dimensional dental radiography has two basic shortcomings: the lack of early detection of pathosis in the cancellous bone, because of the density of the cortical plates, and the influence of the superimposition of anatomic structures. Variability in the radiographic expression of an osseous pathosis has much to do with the relative location of the root of the tooth and how it is oriented with respect to the cortical and cancellous bone. Radiographic changes from bone loss will not be detected if the loss is only in cancellous bone.[16] However, the radiographic evidence of pathosis will be observed once this bone loss extends to the junction of the cortical and cancellous bone. In addition, certain teeth are more prone to exhibit radiographic changes than others, depending on their anatomic location.[17] The radiographic appearance of endodontic pathosis is correlated with the relationship of the periapex of the tooth and its juxtaposition to the cortical-cancellous bone junction. The apices of most anterior and premolar teeth are located close to the cortical-cancellous bone junction. Therefore, periapical pathosis from these teeth is exhibited sooner on the radiograph. By comparison, the distal roots of mandibular first molars and both roots of mandibular second molars are generally positioned more centrally within the cancellous bone, as are maxillary molars, especially the palatal roots.

Telegram: @dental_k

www.konkur.in

Periapical lesions from these roots must expand more before they reach the cortical-cancellous bone junction and are recognized as radiographic pathosis. For these reasons, it is important not to exclude the possibility of pulpal pathosis in situations in which there are no radiographic changes.

Many factors can influence the quality of the radiographic interpretation, including the ability of the person exposing the radiograph, the quality of the radiographic film, the quality of the exposure source, the quality of the film processing, and the skill with which the film is viewed. Controlling all of these variables can be a difficult challenge but is paramount for obtaining an accurate radiographic interpretation.

Digital radiography

Digital radiography has been available since the late 1980s and has recently been refined and popularized with better hardware and a more user-friendly interface. It has the ability to capture, view, magnify, enhance, and store radiographic images in an easily reproducible format that does not degrade over time. Significant advantages of digital radiographs over conventional radiographs include lower radiation doses, instant viewing, convenient manipulation, efficient transmission of an image via the Internet, simple duplication, and easy archiving.

Digital radiography uses no x-ray film and requires no chemical processing. Instead, a *sensor* is used to capture the image created by the radiation source. This sensor is either directly or wirelessly attached to a local computer, which interprets this signal and, using specialized software, translates the signal into a two-dimensional digital image that can be displayed, enhanced, and analyzed. The image is stored in the patient's file, typically in a dedicated network server, and can be recalled as needed. Further information about digital radiography may be found in Chapter 2.

The viewing of a digital radiographic image on a high-resolution monitor allows for rapid and easy interpretation for both the clinician and the patient. The image appears almost instantly, with no potential for image distortion from improper chemical processing. The clinician can magnify different areas on the radiograph and then digitally enhance the image in order to better visualize certain anatomic structures; in some cases, the image can even be colorized, which is a useful tool for patient education (Fig. 1.26).

Telegram: @dental_k

www.konkur.in

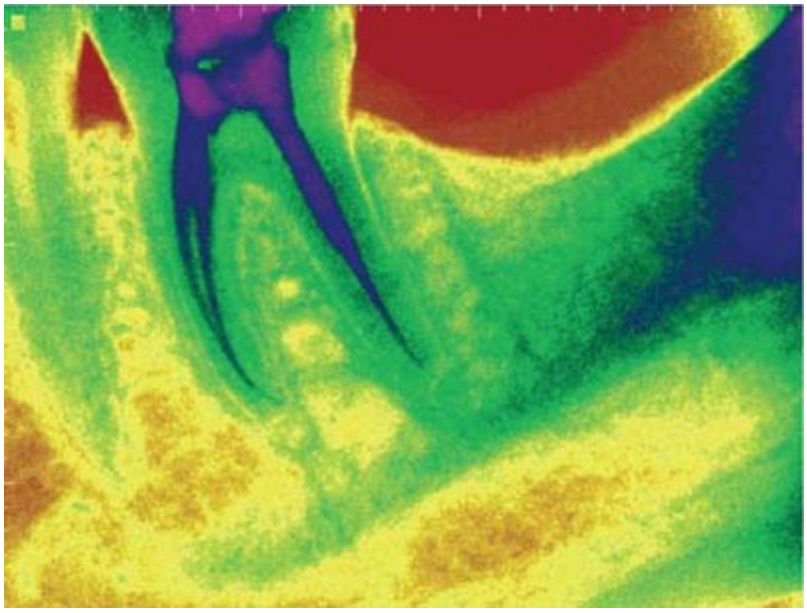

FIG. 1.26 Digital radiography has an advantage over conventional film in that the image can be enhanced and colorized—a useful tool for patient education.

Multi-colored radiograph shows blue colored thin-density tissue in the root and a little space between root and neck present on a greenish-yellow background.

In the past, x-ray film has had a slightly better resolution than most digital radiography images, at about 16 line pairs per millimeter (lp/mm).[87] However, current sensors offer resolutions beyond that of conventional film. Under the best of circumstances, the human eye can see only about 10 lp/mm, which is the lowest resolution for most dental digital radiography systems. Digital sensors are much more sensitive to radiation than conventional x-ray film and thus require 50% to 90% less radiation in order to acquire an image, an important feature for generating greater patient acceptance of dental radiographs.

The diagnostic quality of this technology has been shown to be comparable to conventional film-based radiography.[39,73,97] The interpretation of a digital radiograph can be subjective, similar to that of the conventional film.[134] Factors that appear to have the most impact on the interpretation of the image are the years of experience of the examiner and familiarity of the operator with the given digital system.[134]

Telegram: @dental_k

www.konkur.in

Cone-beam computerized tomography

Limitations in conventional two-dimensional radiography promulgated a need for three-dimensional imaging, known as *cone-beam computerized tomography* (CBCT) (also known as *cone-beam volumetric tomography* [CBVT]) or as *cone-beam volumetric imaging* [CBVI]. Although a form of this technology has existed since the early 1980s,[106] specific devices for dental use first appeared almost two decades later.[90] Most of these machines are similar to a dental panoramic radiographic device, whereby the patient stands or sits as a cone-shaped radiographic beam is directed to the target area with a reciprocating capturing sensor on the opposite side (Fig. 1.27). The resulting information is digitally reconstructed and interpreted to create an interface whereby the clinician can three-dimensionally interpret "slices" of the patient's tissues in a multitude of planes (Figs. 1.28 and 1.29).[37,33] The survey of the scans can be interpreted immediately after the scan. Various software applications have been used to enable the images to be sent to other clinicians. This is accomplished either in printed format or with portable and transferable software that can be used interactively by another clinician.

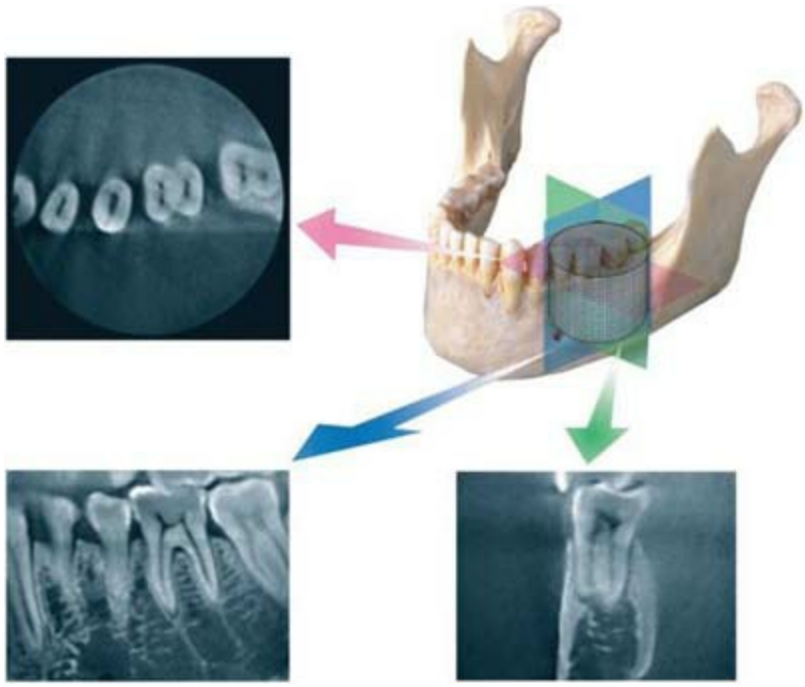

FIG. 1.29 Cone-beam volumetric tomography has the advantage of being able to detect pathosis in the bone or associated with the teeth without the obstruction of anatomic structures. The planes of vision may be axial, sagittal, or coronal.

Three insets marked from the lower jaw bone leads to radiographs as follows: 1) An occlusal view of premolar or canine with cavities inside. 2) Close-up view of teeth with radiolucent pulp and root canals. 3) A molar teeth with less-density tissue between crown and root.

Source: (Courtesy J. Morita USA, Irvine, CA.)

In general, many dental applications only require a limited field of vision, confining the study to the maxilla and mandible. However, many devices have the ability to provide a full field of vision for viewing more regional structures. Clinicians should thoroughly understand the ethical and medical-legal ramifications of doing scans with full fields of view. Incidental nondental findings have been seen from these scans, such as intracranial aneurysms, which, when undetected, could be life threatening.[91]

The radiation source of CBCT is different from that of conventional two-dimensional dental imaging in that the radiation beam created is conical in shape. Also, conventional digital dental radiography is captured and interpreted as *pixels*, a series of dots that collectively produces an image of the scanned structure. For CBCT, the image is instead captured as a series of

Telegram: @dental_k

www.konkur.in

three-dimensional pixels, known as *voxels.* Combining these voxels gives a three-dimensional image that can be "sliced" into various planes, allowing for specific evaluations without a necropsy (Fig. 1.30). One of the advantages of using a device that has a limited field of vision is that the voxel size can be less than half that of a device using a full field of vision, thereby increasing the resolution of the resulting image and providing for a more accurate interpretation of anatomic structures and pathologic conditions. The development of limited field of vision devices has also contributed to decreasing the radiation and cost of these machines, making them more practical for endodontic use.[41]

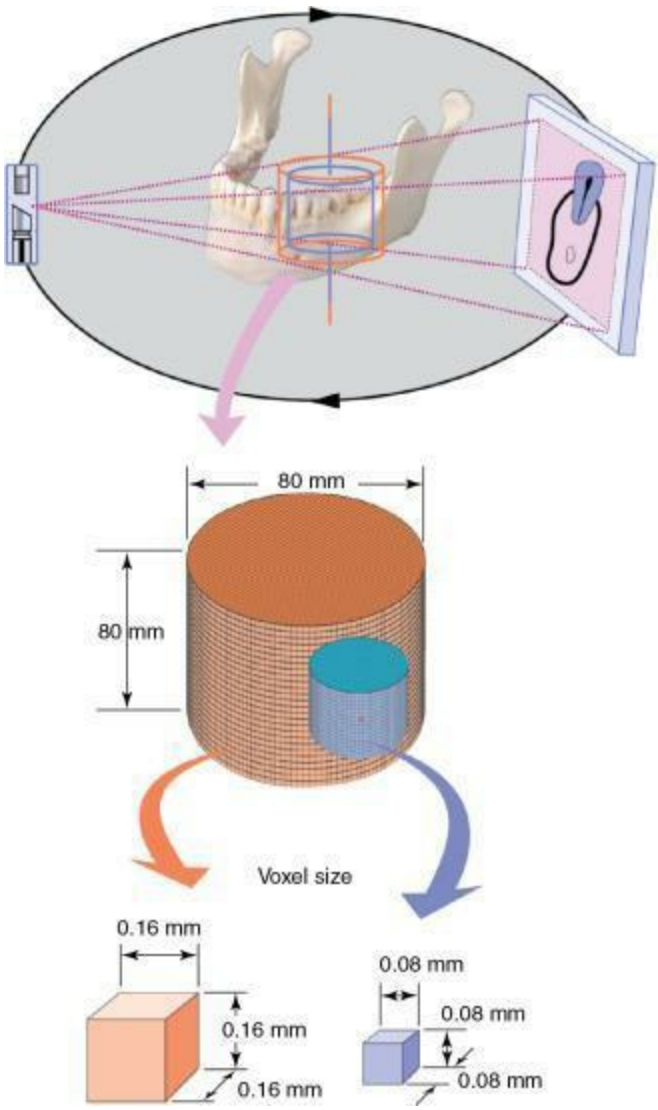

FIG. 1.30 The radiation source in cone-beam volumetric tomography

Telegram: @dental_k

www.konkur.in

is conical. The receiving sensor captures the image as “voxels,” or three-dimensional pixels of information, allowing digital interpretation.

Side view of lower jaw bone shows the analysis of mandible quadrant using CBCT. Cone shaped X-ray beams produce the image of tooth with its root canal on the left. An arrow from the lower jaw bone on the left leads to a large cylindrical structure with a smaller cylindrical structure inside indicating 3D voxel size. The height and breadth of the large cylindrical structure are each 80 millimeters. Two arrows from the 3D voxel size leads to a larger and smaller cuboid. The larger cuboid has dimensions of 0.16 times 0.16 times 0.16 millimeters. The smaller cuboid has dimensions of 0.8 times 0.8 times 0.8 millimeters.

Compared with two-dimensional radiographs, CBCT can clearly visualize the interior of the cancellous bone without the superimposition of the cortical bone. Studies show that CBCT is much more predictable and efficient in demonstrating anatomic landmarks, bone density, bone loss, periapical lesions, root fractures, root perforations, and root resorptions.[1,21,26,27,38,47,71,78,81,85,92,94,128,131,142]

The superimposition of anatomic structures can also mask the interpretation of alveolar defects. Specifically, the maxillary sinus, zygoma, incisive canal and foramen, nasal bone, orbit, mandibular oblique ridge, mental foramen, mandibular mentalis, sublingual salivary glands, tori, and the overlap of adjacent roots may either obscure bone loss or mimic bone loss, making an accurate interpretation of conventional radiography sometimes difficult or impossible. Several studies have demonstrated the advantages of CBCT in the differential diagnosis of such structures from pathologic conditions.[21,29,71,137]

CBCT should not be seen as a replacement for conventional dental radiography, but rather as a diagnostic adjunct. The advantage of conventional dental radiography is that it can visualize most of the structures in one image. CBCT can show great detail in many planes of vision but can also leave out important details if the “slice” is not in the area of existing pathosis (Fig. 1.31). There is a promising future for the use of CBCT for endodontic diagnosis and treatment. It has already proven invaluable in the detection of dental and nondental pathoses (Fig. 1.32). For a further review of CBCT and radiography, see Chapter 2.

Apical pathosis should be ruled out. **B,** Cone-beam volumetric tomography revealed salivary indentation of the mandible in the area apical and lingual to the mandibular second molar, consistent with a Stafne defect. **C,** Enlargement of coronal section in the area of the mandibular second molar and the Stafne defect located on the lingual aspect of the mandible.

Set of three radiographs marked A through C compares periapical radiograph with cone beam computed tomograph for mandibular second molar.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has also been suggested for dental

Telegram: @dental_k

www.konkur.in

diagnosis. It may offer simultaneous three-dimensional hard- and soft-tissue imaging of teeth without ionizing radiation.[58] The use of MRI in endodontics is still limited.

Cracks and fractures

The wide variety of types of cracks and fractures in teeth and their associated signs and symptoms often make their diagnosis difficult. The extensiveness of the crack or fracture line may directly alter the prognosis assessment for a given tooth and should be examined before treatment decision making. Certain types of cracks may be as innocent as a superficial enamel craze line, or they may be as prominent as a fractured cusp. The crack may progress into the root system to involve the pulp, or it may split the entire tooth into two separate segments. The crack may be oblique, extending cervically, such that once the coronal segment is removed the tooth may or may not be restorable. Any of these situations may present with mild, moderate, or severe symptoms or possibly no symptoms at all.

Crack types

There have been many suggestions in the literature of how to classify cracks in teeth. By defining the type of crack present, an assessment of the prognosis may be determined and treatment alternatives can be planned. Unfortunately, it is often extremely difficult to determine how extensive a crack is until the tooth is extracted.

Cracks in teeth can be divided into three basic categories:

- Craze lines
- Fractures (also referred to as *cracks*)
- Split tooth/roots

Craze lines are merely cracks in the enamel that do not extend into the dentin and either occur naturally or develop after trauma. They are more prevalent in adult teeth and usually occur more in the posterior teeth. If light is transilluminated through the crown of such a tooth, these craze lines may show up as fine lines in the enamel with light being able to transmit through them, indicating that the crack is only superficial. The use of optical

Telegram: @dental_k

www.konkur.in

coherence tomography (OCT) has also been suggested for the detection of enamel cracks.[59] Craze lines typically will not manifest with symptoms. No treatment is necessary for craze lines unless they create a cosmetic issue.

Fractures extend deeper into the dentin than superficial craze lines and primarily extend mesially to distally, involving the marginal ridges. Dyes and transillumination are helpful for visualizing potential root fractures.

Symptoms from a fractured tooth range from none to severe pain. A fracture in the tooth does not necessarily indicate that the tooth has split into two pieces; however, left alone or especially with provocations such as occlusal prematurities, the fracture may progress into a split root. A fractured tooth may be treated by a simple restoration, endodontics (nonsurgical or surgical), or even extraction, depending on the extent and orientation of the fracture, the degree of symptoms, and whether the symptoms can be eliminated. This makes the clinical management of fractured teeth difficult and sometimes unpredictable.

A definitive combination of factors, signs, and symptoms that, when collectively observed, allows the clinician to conclude the existence of a specific disease state is termed a *syndrome*. However, given the multitude of signs and symptoms that fractured roots can present with, it is often difficult to achieve an objective definitive diagnosis. For this reason, the terminology of *cracked tooth syndrome*[22,108] should be avoided.[6] The subjective and objective factors seen in cases of fractured teeth will generally be diverse; therefore, a tentative diagnosis of a fractured tooth will most likely be more of a prediction. Once this prediction is made, the patient must be properly informed as to any potential decrease in prognosis of the pending dental treatment. Because treatment options for repairing fractured teeth have only a limited degree of success, early detection and prevention, and proper informed consent, are crucial.[9,10,72,119,120,124,132]

Split tooth/roots occur when a fracture extends from one separating them into two segments. If the split is more oblique, it is possible that once the smaller separated segment is removed, the tooth might still be restorable—for example, a fractured cusp. However, if the split extends below the osseous level, the tooth may not be restorable and endodontic treatment may not result in a favorable prognosis.

Proper prognosis assessment is imperative before any dental treatment but

Telegram: @dental_k

www.konkur.in

is often difficult in cases of cracked teeth. Because of the questionable long-term success from treating cases of suspected or known fractures, the clinician should be cautious in making the decision to continue with treatment and should avoid endodontic treatment in cases of a definitive diagnosis of a split tooth or root.

Vertical root fractures

One of the more common reasons for recurrent endodontic pathosis is the *vertical root fracture*, a severe crack in the tooth that extends longitudinally down the long axis of the root (Figs. 1.33 and 1.34). Often it extends through the pulp and to the periodontium. It tends to be more centrally located within the tooth, as opposed to being more oblique, and typically traverses through the marginal ridges. These fractures may be present before endodontic treatment, secondary to endodontic treatment, or may develop after endodontic treatment has been completed. Because diagnosing these vertical root fractures may be difficult, they often go unrecognized. Therefore, diagnosing the existence and extent of a vertical root fracture is imperative before any restorative or endodontic treatment is done, as it can dramatically affect the overall success of treatment.

Telegram: @dental_k

www.konkur.in

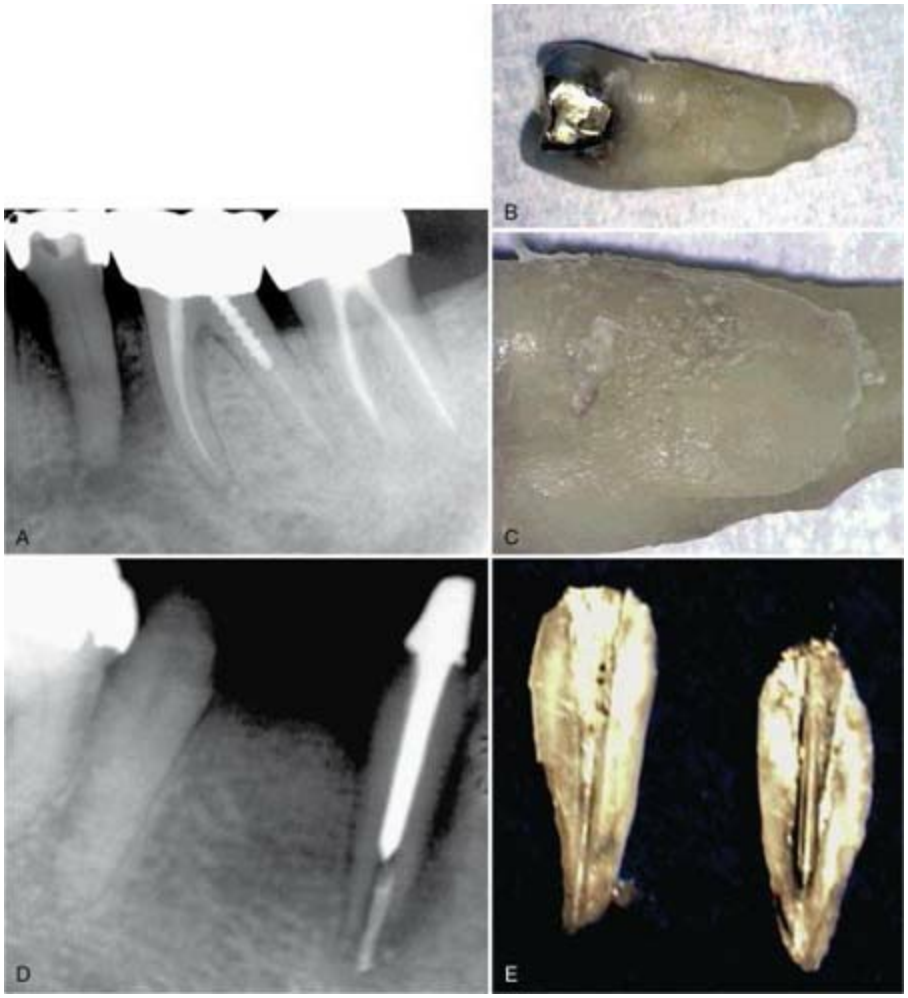

FIG. 1.33 Poorly fitting intracoronal restorations can place stresses within the tooth that can cause a vertical root fracture. **A,** This radiograph of a mandibular second premolar (with a gold inlay) reveals extensive periapical and periradicular bone loss, especially on the distal aspect. **B,** The tooth pulp tested nonvital, and there was an associated 12-mm-deep, narrow, isolated periodontal pocket on the buccal aspect of the tooth. After the tooth was extracted, the distal aspect was examined. **C,** On magnification (×16) the distal aspect of the root revealed an oblique vertical root fracture. Similarly, the placement of an ill-fitting post may exert intraradicular stresses on a root that can cause a fracture to occur vertically. **D,** This radiograph depicts a symmetrical space between the obturation and the canal wall, suggesting a vertical root fracture. **E,** After the tooth is extracted, the root fracture can be easily observed.

Set of five radiographs marked A through E depicts stress of poorly fitted intracoronal restorations resulting in a vertical root fracture.

Telegram: @dental_k

www.konkur.in

FIG. 1.34 Physical trauma from sports-related injuries or seizure-induced trauma, if directed accordingly, may cause a vertical root fracture in a tooth. This fracture occurred in a 7-year-old child secondary to trauma from a grand mal seizure.

Radiograph of two teeth shows teeth on the left having a slant line of fracture extended toward the apex.

A patient who consents to endodontic treatment must be informed if the tooth has a questionable prognosis. The clinician must be able to interpret the subjective and objective findings that suggest a vertical root fracture or split tooth, be able to make a prediction as to the eventual potential of healing, and convey this information to the patient. A more detailed discussion on vertical root fractures is described in Chapter 22.

Perforations

Root perforations are clinical complications that may lead to treatment failure. When root perforation occurs, communications between the root canal system and either periradicular tissues or the oral cavity may reduce the prognosis of treatment. Root perforations may result from extensive carious lesions, resorption, or operator error occurring during root canal instrumentation or post preparation.

Telegram: @dental_k

www.konkur.in

The treatment prognosis of root perforations depends on the size, location, time of diagnosis and treatment, degree of periodontal damage, as well as the sealing ability and biocompatibility of the repair material.[45] It has been recognized that treatment success depends mainly on immediate sealing of the perforation and appropriate infection control. Among the materials that are commonly used to seal root perforations are mineral trioxide aggregate (MTA), super ethoxybenzoic acid (EBA) cement, intermediate restorative material (IRM), glass ionomer cements, and composites. The topic of perforations is further discussed in Chapter 20.

Clinical classification of pulpal and periapical diseases

Many attempts have been made over the years to develop classifications of pulpal and periapical disease. However, studies have shown that making a correlation between clinical signs and symptoms and the histopathology of a given clinical condition is challenging.[122,123] Therefore *clinical* classifications have been developed in order to formulate treatment plan options. In the most general terms, the objective and subjective findings are used to classify the suspected pathosis, with the assigned designations merely representing the presence of healthy or diseased tissue.

The terminology and classifications that follow are based on those suggested by the American Association of Endodontists in 2016.[6]

Pulpal disease

Normal pulp

This is a clinical diagnostic category in which the pulp is symptom-free and normally responsive to pulp testing.[6] Teeth with normal pulp do not usually exhibit any spontaneous symptoms. The symptoms produced from pulp tests are mild, do not cause the patient distress, and result in a transient sensation that resolves in seconds. Radiographically, there may be varying degrees of pulpal calcification but no evidence of resorption, caries, or mechanical pulp exposure. No endodontic treatment is indicated for these teeth.

Telegram: @dental_k

www.konkur.in

Pulpitis

This is a clinical and histologic term denoting inflammation of the dental pulp, clinically described as reversible or irreversible and histologically described as acute, chronic, or hyperplastic.[6]

Reversible pulpitis

This is a clinical diagnosis based on subjective and objective findings indicating that the inflammation should resolve and the pulp return to normal.[6] When the pulp within the tooth is irritated so that the stimulation is uncomfortable to the patient but reverses quickly after irritation, it is classified as *reversible pulpitis*. Causative factors include caries, exposed dentin, recent dental treatment, and defective restorations. Conservative removal of the irritant will resolve the symptoms. Confusion can occur when there is exposed dentin, without evidence of pulp pathosis, which can sometimes respond with sharp, quickly reversible pain when subjected to thermal, evaporative, tactile, mechanical, osmotic, or chemical stimuli. This is known as *dentin* (or *dentinal*) *sensitivity* (or *hypersensitivity*). Exposed dentin in the cervical area of the tooth accounts for most of the cases diagnosed as dentin sensitivity.[103]

As described in Chapter 14, fluid movement within dentinal tubules can stimulate the odontoblasts and associated fast-conducting A-delta nerve fibers in the pulp, which in turn produce sharp, quickly reversible dental pain (Fig. 1.35). The more open these tubules are (e.g., from a newly exposed preparation, dentin decalcification, periodontal scaling, tooth-bleaching materials, or coronal tooth fractures), the more the tubule fluid will move and, subsequently, the more the tooth will display dentin sensitivity when stimulated. When making a diagnosis, it is important to discriminate this dentin sensitivity sensation from that of reversible pulpitis, which would be secondary to caries, trauma, or new or defective restorations. Detailed questioning about recent dental treatment and a thorough clinical and radiographic examination will help to separate dentin sensitivity from other pulpal pathosis, as the treatment modalities for each are completely different.[18]

Telegram: @dental_k

www.konkur.in

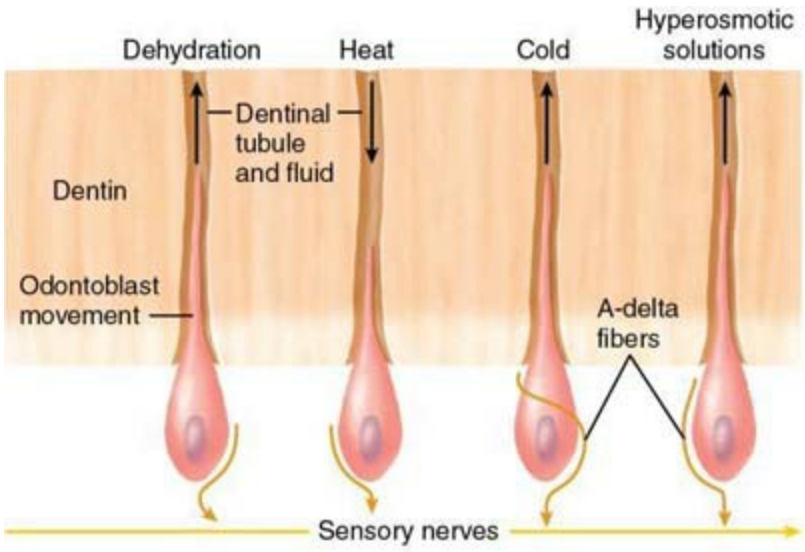

FIG. 1.35 Dentinal tubules are filled with fluid that, when stimulated, will cause sensation. Temperature changes, air, and osmotic changes can provoke the odontoblastic process to induce the stimulation of underlying A-delta fibers.

An illustration shows tooth stimulated by dehydration, heat, cold, and Hyper-osmotic solutions. Dehydration: An arrow, labeled dentinal tubule and fluid, points up toward the root and corresponding odontoblast movement leads to dental pain. Heat: Dentinal tubule and fluid go toward pulp at the bottom. In cold and hyper-osmotic solutions, dentinal tubule and fluid go up that stimulate A-delta fibers. A rightward arrow below all illustrations is labeled sensory nerves.

Irreversible pulpitis

As the disease state of the pulp progresses, the inflammatory condition of the pulp can change to *irreversible pulpitis.* At this stage, treatment to remove the diseased pulp will be necessary. This condition can be divided into the subcategories of *symptomatic* and *asymptomatic* irreversible pulpitis.

Symptomatic irreversible pulpitis.

This is a clinical diagnosis based on subjective and objective findings indicating that the vital inflamed pulp is incapable of healing.[6] Teeth that are classified as having *symptomatic irreversible pulpitis* exhibit intermittent or spontaneous pain. Rapid exposure to dramatic temperature changes (especially to cold stimuli) will elicit heightened and prolonged episodes of

Telegram: @dental_k

www.konkur.in

pain even after the thermal stimulus has been removed. The pain in these cases may be sharp or dull, localized, diffuse, or referred. Typically, there are minimal or no changes in the radiographic appearance of the periradicular bone. With advanced irreversible pulpitis, a thickening of the periodontal ligament may become apparent on the radiograph, and there may be some evidence of pulpal irritation by virtue of extensive pulp chamber or root canal space calcification. Deep restorations, caries, pulp exposure, or any other direct or indirect insult to the pulp, recently or historically, may be present. It may be seen radiographically or clinically or may be suggested from a complete dental history. Patients who present with symptomatic anterior teeth for which there are no obvious etiologic factors also should be questioned regarding past general anesthesia or endotracheal intubation procedures.[3,127,138] In addition, patients should be questioned about a history of orthodontic treatment. Typically, when symptomatic irreversible pulpitis remains untreated, the pulp will eventually become necrotic.[109,139]

Asymptomatic irreversible pulpitis.

This is a clinical diagnosis based on subjective and objective findings indicating that the vital inflamed pulp is incapable of healing.[6] However, the patient does not complain of any symptoms. On occasion, deep caries will not produce any symptoms, even though clinically or radiographically the caries may extend well into the pulp. Left untreated, the tooth may become symptomatic or the pulp will become necrotic. In cases of *asymptomatic irreversible pulpitis,* endodontic treatment should be performed as soon as possible so that symptomatic irreversible pulpitis or necrosis does not develop and cause the patient severe pain and distress.

Pulp necrosis

This is a clinical diagnostic category indicating death of the dental pulp. The pulp is usually nonresponsive to pulp testing.[6] When pulpal *necrosis* (or *nonvital pulp*) occurs, the pulpal blood supply is nonexistent and the pulpal nerves are nonfunctional. It is the only clinical classification that directly attempts to describe the histologic status of the pulp (or lack thereof). This condition is subsequent to symptomatic or asymptomatic irreversible pulpitis. After the pulp becomes completely necrotic, the tooth will typically become

Telegram: @dental_k

www.konkur.in

asymptomatic until such time when there is an extension of the disease process into the periradicular tissues. With pulp necrosis, the tooth will usually not respond to electric pulp tests or to cold stimulation. However, if heat is applied for an extended period of time, the tooth may respond to this stimulus. This response could possibly be related to remnants of fluid or gases in the pulp canal space expanding and extending into the periapical tissues.

Pulpal necrosis may be partial or complete and it may not involve all of the canals in a multirooted tooth. For this reason, the tooth may present with confusing symptoms. Pulp testing over one root may give no response, whereas over another root it may give a positive response. The tooth may also exhibit symptoms of symptomatic irreversible pulpitis. Pulp necrosis, in the absence of restorations, caries, or luxation injuries, is likely caused by a longitudinal fracture extending from the occlusal surface and into the pulp.[19]

After the pulp becomes necrotic, microbial growth can be sustained within the canal. When this infection (or its microbial byproducts) extends into the periodontal ligament space, the tooth may become symptomatic to percussion or exhibit spontaneous pain. Radiographic changes may occur, ranging from a thickening of the periodontal ligament space to the appearance of a periapical radiolucent lesion. The tooth may become hypersensitive to heat, even to the warmth of the oral cavity, and is often relieved by applications of cold. As previously discussed, this may be helpful in attempting to localize a necrotic tooth (i.e., by the application of cold one tooth at a time) when the pain is referred or not well localized.

Previously treated

This is a clinical diagnostic category indicating that the tooth has been endodontically treated and the canals are obturated with various filling materials other than intracanal medicaments.[6] In this situation, the tooth may or may not present with signs or symptoms but will require additional nonsurgical or surgical endodontic procedures to retain the tooth. In most such situations, there will no longer be any vital or necrotic pulp tissue present to respond to pulp testing procedures.

Previously initiated therapy

Telegram: @dental_k

www.konkur.in

This is a clinical diagnostic category indicating that the tooth has been previously treated by partial endodontic therapy (e.g., pulpotomy, pulpectomy).[6] In most instances, the partial endodontic therapy was performed as an emergency procedure for symptomatic or asymptomatic irreversible pulpitis cases. In other situations, these procedures may have been performed as part of vital pulp therapy procedures, traumatic tooth injuries, apexification, or apexogenesis therapy. At the time these cases present for root canal therapy it would not be possible to make an accurate pulpal diagnosis because all, or part, of the pulp tissue has already been removed.

Apical (periapical) disease

Normal apical tissues

This classification is the standard against which all of the other apical disease processes are compared. In this category the patient is asymptomatic and the tooth responds normally to percussion and palpation testing. The radiograph reveals an intact lamina dura and periodontal ligament space around all the root apices.

Periodontitis

This classification refers to an inflammation of the periodontium.[6] When located in the periapical tissues it is referred to as apical periodontitis. Apical periodontitis can be subclassified to symptomatic apical periodontitis and asymptomatic apical periodontitis.

Symptomatic apical periodontitis

This condition is defined as an inflammation, usually of the apical periodontium, producing clinical symptoms including a painful response to biting or percussion or palpation. It might or might not be associated with an apical radiolucent area.[6] This tooth may or may not respond to pulp sensibility tests, and the radiograph or image of the tooth will typically exhibit at least a widened periodontal ligament space and may or may not show an apical radiolucency associated with one or all of the roots.

Telegram: @dental_k

www.konkur.in

Asymptomatic apical periodontitis

This condition is defined as inflammation and destruction of apical periodontium that is of pulpal origin; it appears as an apical radiolucent area, and does not produce clinical symptoms.[6] This tooth does not usually respond to pulp sensibility tests, and the radiograph or image of the tooth will exhibit an apical radiolucency. The tooth is generally not sensitive to biting pressure but may "feel different" to the patient on percussion. Manifestation of persistent apical periodontitis may vary among patients.[89]

Acute apical abscess

This condition is defined as an inflammatory reaction to pulpal infection and necrosis characterized by *rapid onset*, spontaneous pain, tenderness of the tooth to pressure, pus formation, and swelling of associated tissues.[6] A tooth with an *acute apical abscess* will be acutely painful to biting pressure, percussion, and palpation. This tooth will not respond to any pulp sensibility tests and will exhibit varying degrees of mobility. The radiograph or image can exhibit anything from a widened periodontal ligament space to an apical radiolucency. Swelling will be present intraorally and the facial tissues adjacent to the tooth will almost always present with some degree of swelling. The patient will frequently be febrile, and the cervical and submandibular lymph nodes may exhibit tenderness to palpation.

Chronic apical abscess

This condition is defined as an inflammatory reaction to pulpal infection and necrosis characterized by *gradual onset*, little or no discomfort, and the intermittent discharge of pus through an associated sinus tract.[6] The sinus tract can appear intraorally or extraorally. In general, a tooth with a *chronic apical abscess* will not present with clinical symptoms. The tooth will not respond to pulp sensibility tests, and the radiograph or image will exhibit an apical radiolucency. Usually the tooth is not sensitive to biting pressure but can "feel different" to the patient on percussion. This entity is distinguished from asymptomatic apical periodontitis because it will exhibit intermittent drainage through an associated sinus tract.

Telegram: @dental_k

www.konkur.in

Referred pain

The perception of pain in one part of the body that is distant from the actual source of the pain is known as *referred pain*. Whereas pain of nonodontogenic origin can refer pain to the teeth, teeth may also refer pain to other teeth as well as to other anatomic areas of the head and neck. This may create a diagnostic challenge in that the patient may insist that the pain is from a certain tooth or even from an ear when, in fact, it is originating from a distant tooth with pulpal pathosis. Using electronic pulp testers, investigators found that patients could localize *which* tooth was being stimulated only 37.2% of the time and could narrow the location to three teeth only 79.5% of the time, illustrating that patients may have a difficult time discriminating the exact location of pulpal pain.[44]

Referred pain from a tooth is usually provoked by an intense stimulation of pulpal C fibers, the slow conducting nerves that, when stimulated, cause an intense, slow, dull pain. Anterior teeth seldom refer pain to other teeth or to opposite arches, whereas posterior teeth may refer pain to the opposite arch or to the periauricular area but seldom to the anterior teeth.[14] Mandibular posterior teeth tend to transmit referred pain to the periauricular area more often than maxillary posterior teeth. One study showed that when second molars were stimulated with an electric pulp tester, patients could discriminate accurately which arch the sensation was coming from only 85% of the time, compared with an accuracy level of 95% with first molars and 100% with anterior teeth.[136] The investigators also pointed out that when patients first feel the sensation of pain, they are more likely to accurately discriminate the origin of the pain. With higher levels of discomfort, patients have less ability to accurately determine the source of the pain. Therefore, in cases of diffuse or referred pain, the history of where the patient first felt the pain may be significant.

Because referred pain can complicate a dental diagnosis, the clinician must be sure to make an accurate diagnosis to protect the patient from unnecessary dental or medical treatment. After all the testing procedures are complete and if it is determined that the pain is not of odontogenic origin, then the patient should be referred to an orofacial pain clinic for further testing. For further information on pain of nonodontogenic origin, see Chapter 4.

Summary

Endodontics is a multifaceted specialty, with much emphasis on how cases are clinically treated. Clinicians have increased their ability to more accurately perform endodontic procedures by way of increased visualization using the operating microscope, precise apical foramen detection using electronic apex locators, enhanced imaging techniques using digital radiography, three-dimensional imaging, and more. Practices have incorporated more refined canal cleaning and shaping techniques by using ultrasonics and rotary-driven nickel titanium files facilitated with computer-assisted electronic handpieces. Many other advancements also have been introduced with the objective of achieving an optimal result during endodontic treatment. However, these advancements are useless if an incorrect diagnosis is made. Before the clinician ever considers performing any endodontic treatment, the following questions must be answered:

- Is the existing problem of dental origin?
- Are the pulpal tissues within the tooth pathologically involved?
- Why is the pulpal pathosis present?
- What is the prognosis?
- What is the appropriate form of treatment?

Testing, questioning, and reasoning are combined to achieve an accurate diagnosis and to ultimately form an appropriate treatment plan. The art and science of making this diagnosis are the first steps that must be taken before initiating any endodontic treatment.

2: Radiographic interpretation

Madhu K. Nair, Martin D. Levin, Umadevi P. Nair

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Radiographic interpretation

Interpretation of information captured by radiographic imaging modalities is central to the diagnostic process. It is very important to capture a diagnostically useful image using appropriate exposure parameters and view it with interactive manipulation of brightness and contrast or window/level (for cone-beam computed tomography [CBCT] studies) in an optimal environment to adequately evaluate anatomy and diagnose pathoses. Accurate interpretation of root and canal morphology, determination of

Telegram: @dental_k

www.konkur.in

radiographic canal length, diagnosis of radicular and periradicular disease (Fig. 2.1), and postsurgical and long-term evaluation of the outcome of endodontic treatment are some of the routine diagnostic imaging tasks in endodontics.[218] Systematic and methodical interpretation processes must be followed for all images. Recognition of anatomy, anatomic variants, and pathologic conditions or deviations from normal is important. Various imaging modalities exist in radiology. Some use ionizing radiation, whereas others use ultrasonic waves (ultrasonography [US]) or powerful external magnetic fields (magnetic resonance imaging [MRI]). Interventional and noninterventional imaging modalities are also available. Imaging modalities using ionizing radiation are most frequently used in endodontic diagnoses. The different image capture modalities include digital receptors using different technologies.

FIG. 2.1 **A,** A well-angulated periapical radiograph of the maxillary right first molar taken during a diagnostic appointment for endodontic evaluation of the maxillary right quadrant. At first glance, there is little radiographic evidence of significant or periradicular change. **B,** Contemporaneous CBCT image of same tooth gives an entirely different perspective; periapical changes are visible on all three roots in all three anatomic planes of section.

A) Radiograph shows right first molar with extremely radiopaque crown. Its adjacent tooth has wedge-shaped radiolucency.

B) Four panels show three radiographs depicting axial, coronal, and sagittal views of teeth, whereas the fourth panel shows a multitude of planes with X, Y, and Z planes. First radiograph: Teeth arranged horizontally with obscure view. Second radiograph: Three teeth with partially radiolucent region at the

Telegram: @dental_k

www.konkur.in

crown of right firsts molar. The tooth on the left shows fractured enamel, and there is significant space between adjacent teeth. Third radiograph: close-up view of tooth with inflammation at the root is shown.

Source: (*B* taken with J. Morita Veraviewepocs 3D [J. Morita, Osaka, Japan].)

Imaging modalities

Digital radiography using electronic sensors or photostimulable phosphor (PSP) plates is widely used in endodontics. Digital imaging modalities in endodontics use different image capture technologies, which include a charge-coupled device (CCD), a complementary metal oxide semiconductor (CMOS), or a PSP (also sometimes referred to as an indirect acquisition modality).

CCD-based solid-state sensors were used extensively in endodontics initially. However, the earlier generation sensors had a smaller active area and limited x-ray absorption and conversion efficiency, in addition to being bulky. Sensors use an array of radiation-sensitive elements that generate electric charges proportionate to the amount of incident radiation. To reduce the amount of radiation needed to capture an image, a light-sensitive array was developed that uses a scintillation layer laid on top of the CCD chip or added with a fiberoptic coupling. The generated charge is read out in a "bucket brigade" fashion and transferred to an analog-to-digital converter in the frame grabber assembly of the workstation. The digital information is processed, and an image is formed. CMOS-based sensors, on the other hand, have an active transistor at each element location. The area available for signal generation is relatively less, and there is a fixed pattern noise. These sensors are less expensive to manufacture and have been shown to be equally useful for specific diagnostic tasks.[114] Unlike the CCD, the CMOS chip requires very little electrical energy; therefore, no external power supply is needed to support USB utilization, and wireless applications are feasible. Wireless sensors are available (Fig. 2.2). However, radiofrequency interference may be a problem with these sensors. The current Wi-Fi sensor is less bulky and has a wire attached to it that enables transmission via 802.11 b/g standard. It uses a lithium-ion polymer battery that can last for approximately 100 exposures.

Telegram: @dental_k

www.konkur.in

FIG. 2.2 **A** and **B,** High-resolution complementary metal oxide semiconductor (CMOS) sensors are available from many manufacturers. Note that Figure In **B,** wireless CMOS sensors transmit images to the chairside workstation by 2.4 GHz radiofrequency.

A) Three digital dental sensors, named Schick 33, varying in size are placed on a white background.

B) Schick Wi-Fi wireless sensor on a white background.

Source: (Courtesy SIRONA DENTAL SYSTEMS, Long Island City, NY.)

Yet another type of sensor uses PSPs for image capture. PSP technology is also referred to as *computed radiography* (CR).[114,199] Unlike the CCD and CMOS sensors, PSP sensors are wireless. The phosphor is activated by a process called *doping*, which enables charges to be generated and stored when exposed to radiation. A latent image is stored in the sensor, and a PSP reader with a laser beam of specific wavelength is used to read out the image. Previously captured images can be erased by exposing the PSP sensor to white light. PSP plates can be damaged easily by scratching, but they are not as expensive as CCD or CMOS sensors. Incomplete erasure of the image can lead to ghost images when the plate is reused, and delayed processing can result in a decrease in image clarity.[6] PSP-based sensors are used in high-volume scenarios. Spatial resolution is lower with this type of sensor, but it has a wider dynamic range. These sensors can tolerate a wider range of exposures to produce a diagnostically useful image.

Radiation dose continues to be a concern with all imaging studies. The lowest possible dose must be delivered for each study. Most dental offices would not be in compliance with the latest recommendations of the National Council for Radiation Protection (NCRP) on reducing the radiation dose from

Telegram: @dental_k

www.konkur.in

intraoral radiographs (Box 2.1). Two terms have been specifically defined in the NCRP's report. The terms *shall* and *shall not* indicate that adherence to the recommendation would be in compliance with the standards of radiation safety. The terms *should* and *should not* indicate prudent practice and acknowledge that exceptions may be made in certain circumstances. In addition, the report establishes nine new recommendations for image processing of conventional film.

Box 2.1

Recommendations of the National Council on Radiation Protection

1. Dentists must examine their patients before ordering or prescribing x-ray images (this is not a new guideline).
2. The use of leaded aprons on patients shall not be required if all other recommendations in this report are rigorously followed (read full Report #145).
3. Thyroid shielding shall be used for children and should be provided for adults when it will not interfere with the examination (e.g., panoramic imaging).
4. Rectangular collimation of the beam, which has been recommended for years, shall be routinely used for periapical radiographs. Each dimension of the beam, measured in the plane of the image receptor, should not exceed the dimension of the image receptor by more than 2% of the source-to-image receptor distance. Similar collimation should be used, when feasible, for bitewing radiographs.
5. Image receptors of speeds slower than ANSI speed Group E films shall not be used for intraoral radiography. Faster receptors should be evaluated and adopted if found acceptable. For extraoral radiography, high-speed (400 or greater) rare earth screen-film systems or digital-imaging systems of equivalent or greater speed shall be used.
6. Dental radiographic films shall be developed according to the film manufacturer's instructions using the time-temperature method. In practical application, this means that sight development (reading wet x-ray films at the time of the procedure) shall not be used.

Telegram: @dental_k

www.konkur.in

7. Radiographic techniques for digital imaging shall be adjusted for the minimum patient dose required to produce a signal-to-noise ratio sufficient to provide image quality to meet the purpose of the examination.
8. Clinicians designing new offices or remodeling existing locations will need shield protection to be provided by a qualified expert.

Modified from the National Council on Radiation Protection and Measurements: Radiation protection in dentistry, Report #145, Bethesda, MD, 2003. Available at www.ncrppublications.org/Reports/145.

A strong argument can be made for clinicians to switch to a direct digital radiography (DDR) system to avoid all the drastic changes necessary to ensure compliance with the new recommendations. Even though restriction of an intraoral dental x-ray beam is mandated by federal law to a circle no greater than 7 cm, rectangular collimation has been proven to significantly reduce the radiation dose to the patient and is strongly recommended in the NCRP Report #145.

The American Dental Association (ADA) Council on Scientific Affairs has made the following statement:

> *Tissue area exposed to the primary x-ray beam should not exceed the minimum coverage consistent with meeting diagnostic requirements and clinical feasibility. For periapical (PA) and bitewing radiography, rectangular collimation should be used whenever possible because a round field beam used with a rectangular image receptor produces segments of the beam circle that are not used in receptor exposure, which causes unnecessary radiation exposure to the patient.*[4]

Image characteristics and processing

Spatial resolution achieved with current generation digital sensors is equally good or better than that of conventional intraoral radiographic film. Intraoral film has a resolution of 16-line pairs per millimeter (lp/mm) as measured

Telegram: @dental_k

www.konkur.in

using a resolution tool, and it increases to 20 to 24 lp/mm with magnification. *Spatial resolution* is defined as the ability to display two objects that are close to each other as two separate entities. *Contrast resolution* is defined as the ability to differentiate between areas on the image based on density. Most diagnostic tasks in endodontics require a high-contrast resolution.[142] However, image quality is not only a function of spatial resolution. The choice of appropriate exposure parameters, sensor properties, the image processing used, and viewing conditions and modalities directly affect diagnostic accuracy.

Postprocessing of images may be carried out to alter image characteristics. Radiographs need not be reexposed if image quality is not adequate. Diagnostic information can be teased out of the image if appropriate image processing is used. However, the original image must be acquired with optimal exposure parameters to accomplish meaningful image processing.[212] Suboptimally exposed images cannot be processed to yield diagnostic information, which may lead to a reduction in the diagnostic accuracy of the image. Image enhancement must be task specific. Signal-to-noise ratio (SNR) must be optimized to extract necessary information from the image. The bit-depth of images also has a direct relationship to image quality. It indicates the number of shades of gray that the sensor can capture for display. For example, an 8-bit image can depict 256 shades of gray. Most sensors are 12 or 14 bits in depth, capturing 4096 or 65,536 shades of gray, respectively. If the sensor captures several thousand shades of gray, the image can be manipulated through enhancement techniques to display those shades of gray that best depict the anatomy of interest. The human visual system is limited in the number of shades of gray that can be read at any point in time. Therefore, image enhancement is a must for all images, so as to delineate signals of interest through manipulation of the grayscale. Most endodontic tasks require a high contrast and thus a shorter grayscale.

Digital radiographs can be saved in different file formats. Several file formats are available: DICOM (*D*igital *I*maging and *C*ommunications in *M*edicine); tiff (*t*agged *i*mage *f*ile *f*ormat); jpeg (*j*oint *p*hotographic *e*xperts' *g*roup); gif (*g*raphics *i*nterchange *f*ormat); BMP (Windows' bitmap image file); PNG (*p*ortable *n*etwork *g*raphics); and so on. There also are several proprietary formats. "Lossy" and "lossless" compression schemes can be

Telegram: @dental_k

www.konkur.in

used for saving images, although lossless compression is preferred.[72]

Digital imaging and communications in medicine

DICOM is a set of international standards established in 1985 by the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA)[60,205] to address the issue of vendor-independent data formats and data transfers for digital medical images. The ADA has promoted the interoperability of dental images through the efforts of its Working Group 12.1.26. DICOM serves as a standard for the transferal of radiologic images and other medical information between computers, allowing digital communication between systems from various manufacturers and across different platforms (e.g., Apple iOS or Microsoft Windows).[60] The DICOM standard provides for several hundred attribute fields in the record header, which contains information about the image (e.g., pixel density, dimensions, and number of bits per pixel), in addition to relevant patient data and medical information. Although earlier versions did not specify the exact order and definition of the header fields, each vendor is required to publish a DICOM conformance statement, which gives the location of pertinent data. The big hurdle is to support medical and dental consultations between two or more locations with different imaging software.[60] With DICOM in place, dental clinicians can change vendors and maintain database interoperability. Most software vendors are striving to achieve full DICOM compliance, and some have achieved at least partial compliance. However, proprietary DICOM images are still produced in different systems, with the capability to export in universal DICOM format as needed. Diagnostic images are best saved as DICOM files to preserve image fidelity or as tiff files with no compression. Diagnosis suffers when images undergo lossy compression.[64,123,217]

Based on the DICOM model, the ADA Standards Committee on Dental Informatics has identified four basic goals for electronic standards in dentistry: (1) interoperability, (2) electronic health record design, (3) clinical workstation architecture, and (4) electronic dissemination of dental information.[10] The dental profession must continue to promote DICOM compatibility so that proprietary software and file types do not hinder communication and risk making data obsolete.

Diagnostic tasks in endodontics

It is important to analyze the type of sensor used, software, processing, video card and monitor, and viewing conditions to determine whether the sensor is good for a specific diagnostic task. Calibration improves diagnostic accuracy.[128] Likewise, the use of optimal processing parameters improves image quality to the extent of making a significant difference in the diagnostic outcome. For instance, density plot analysis was shown to help with endodontic file measurements.[172] The major advantage of direct digital radiography (CCD, CMOS) is that the dose is significantly less compared with that required for film. The use of DDR, therefore, is justified when its performance is comparable to that of film with no statistically significant differences.[120]

The three types of measurement generally available with digital imaging software are (1) linear measurement, the distance between two points in millimeters (Fig. 2.3); (2) angle measurement, the angle between two lines; and (3) area measurement, the area of the image or a segment of the image. Because magnification and distortion errors play a significant role in the accuracy of two-dimensional (2D) radiographic measurement, both film and digital systems are subject to parallax error. However, a study that compared endodontic file length images of human teeth taken with a custom jig suggested that “measurement error was significantly less for the digital images than the film-based images.”[63] This was true even though, as the authors pointed out, the measurement differences may not have been clinically significant. Sophisticated calibration algorithms are under development, and accurate measurement of parallel images should be more feasible in the future.[41]

Diagnosis and healing

Image enhancement of direct and indirect digital radiographs based on the diagnostic task at hand has been shown to increase diagnostic accuracy compared to film-based images, which cannot be enhanced.[6,226] Posttreatment endodontic evaluation of healing of apical radiolucent areas is a challenge. Early changes indicating healing and bone fill are difficult to detect on conventional or digital radiographs. However, bone fill can be detected using more sensitive techniques, such as digital subtraction radiography (DSR), in which two images, separated in time but acquired with the exact same projection geometry and technique factors, can be subtracted from one another to tease out subtle changes in the periodontium and surrounding bone. Subtraction techniques are difficult to carry out in routine clinical practice because they are technique sensitive and can yield incorrect information if not performed accurately. Several studies have shown the usefulness of subtraction radiography using digital sensors.[138,150,231]

Three-dimensional imaging

Computed tomography (CT) was introduced by Sir Godfrey Hounsfield in the 1970s. *Tomography* refers to "slice imaging," in which thin slices of the anatomy of interest are captured and synthesized manually or using an algorithm. CT makes use of automated reconstruction. Medical-grade CT used a translate-rotate image acquisition scheme as the technology developed, but the modality always resulted in higher radiation dose delivery because of redundancy of data capture, in addition to longer scan times with the potential for motion artifact. Multiple detectors and x-ray sources were used in later generations of CT units to reduce scanning times. The increased radiation dose, artifacts from metallic restorations, cost of scanning, long acquisition times, and lack of adequate dental-specific software have been drawbacks limiting the use of the technology in dentistry until recently. The advent of cone-beam volumetric computed tomography (CBVCT) introduced a faster, low-dose, low-cost, high-contrast imaging modality that could capture information in three dimensions using a limited field of view (FOV).

CBVCT, or cone beam CT (CBCT), is a relatively new diagnostic imaging modality that has been recently added to the endodontic imaging armamentarium. This modality uses a cone beam instead of a fan-shaped beam in multidetector computed tomography (MDCT), acquiring images of the entire volume as it rotates around the anatomy of interest. Compared with MDCT images, CBCT offers relatively high-resolution, isotropic images, allowing effective evaluation of root canal morphology and other subtle changes within the root canal system. Even though the resolution is not as high as that of conventional radiographs (18 microns), the availability of three-dimensional (3D) information, the relatively higher resolution, and a significantly lower dose compared to MDCT make CBCT the imaging modality of choice in challenging situations demanding localization and characterization of root canals.

The adoption of advanced imaging modalities such as CBCT for select diagnostic tasks is becoming popular with clinicians performing endodontic procedures. Two-dimensional grayscale images, whether conventional film-based or digital, cannot accurately depict the full 3D representation of the teeth and supporting structures. In fact, traditional images are poor representations of even the pulpal anatomy. They grossly underestimate canal

Telegram: @dental_k

www.konkur.in

structure and often cannot accurately visualize PA changes, especially where there is thick cortical bone, as in the presence of anatomic obstructions (Fig. 2.4, *A*). CBCT, however, allows the clinician to view the tooth and pulpal structures in thin slices in all three anatomic planes: axial, sagittal, and coronal. This capability alone allows visualization of PA pathoses and root morphology that was previously impossible to assess (see Fig. 2.4, *B* and *C*). Several tools available in CBCT, such as the ability to change the vertical or horizontal angulation of the image in real time, in addition to thin-slice, grayscale data of varying thicknesses, will never be available for conventional or even digital radiography. Furthermore, the use of CBCT data to view the region of interest in three anatomic planes of section at very low x-ray doses has never been as easy or accessible as it is today.

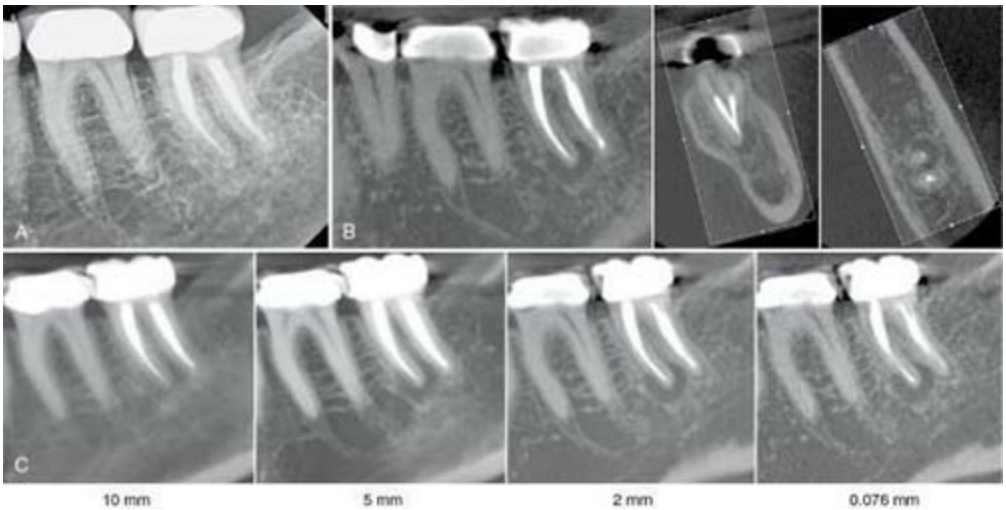

FIG. 2.4 This case demonstrates the difficulty in assessing lesions in the mandibular posterior region when there is a dense cortex. **A,** This well-angulated periapical radiograph shows a normal periapical region associated with the mandibular left second molar, for which the patient has presented for evaluation and possible retreatment. **B,** The CBCT corrected sagittal, coronal, and axial reconstructed multiplanar views, (*left to right,* sagittal, coronal, and axial views) show previous endodontic treatment, with a 6 mm diameter radiolucency with a well-defined, mildly corticated border, centered over a point on the buccal aspect of the root, 2 mm coronal to the apex; these are features consistent with an apical rarefying osteitis. **C,** The ray sum images of the sagittal view, where the image is "thinned" by decreasing the number of adjacent voxels using postprocessing software, simulates a curvilinear projection, showing diminishing superimposition (*left to right,* image layer of 10 mm, 5 mm, 2 mm, and 0.076 mm).

Microcomputed tomography (micro-CT) has also been evaluated in endodontic imaging.[103,169,170] Comparison of the effects of biomechanical preparation on the canal volume of reconstructed root canals in extracted teeth using micro-CT data was shown to assist with characterization of morphologic changes associated with these techniques.[170] Peters et al.[169] used micro-CT to evaluate the relative performance of nickel-titanium (Ni-Ti) instruments after the shaping of root canals of varying preoperative canal geometry. A study to examine the potential and accuracy of micro-CT for imaging of filled root canals showed it to be a highly accurate and nondestructive method for the evaluation of root canal fillings and its constituents. The qualitative and quantitative correlations between histologic and micro-CT examination of root canal fillings were high.[103] However, it is important to note that micro-CT remains a research tool and cannot be used for human imaging in vivo.

This chapter discusses the principles, applications, imaging attributes, image artifacts, and potential liability of adopting CBCT technology for endodontic procedures. Given this information, the student of endodontics will begin to realize the significant advantages, limitations, and diagnostic and treatment planning capabilities of this radiographic imaging modality.

Principles of cone beam computed tomography

Two important parameters of cone beam imaging are described in the following sections:

- Voxel size
- Field of view (FOV)

Voxels and voxel sizes

Telegram: @dental_k

www.konkur.in

Voxels are cuboidal elements that constitute a 3D volume, unlike pixels, which are 2D. Data are acquired and represented in three dimensions using voxels. Unlike with MDCT, typically used in medicine, cone beam units acquire x-ray information using low kV and low mA exposure parameters in a single pass from 180 to 360 degrees of rotation around the anatomy of interest. Medical scanners use higher voltages of 120 kV or more and a current of about 400 mA. Several units used in maxillofacial imaging use significantly lower exposure parameters (Figs. 2.5 to 2.7). The x-ray dose for all cone beam units is significantly lower than the dose received from a MDCT unit. Image attributes are also different in that volumes are reconstructed from isotropic voxels; that is, the images are constructed from volumetric detector elements that are cubical in nature and have the same dimensions of length, width, and depth. These voxel sizes can be as small as 0.076 to 0.6 mm.[139] By comparison, MDCT slice data are 0.5 mm to 1 cm thick. Fig. 2.8 illustrates the difference between a pixel and a voxel, the difference between an anisotropic pixel of MDCT and an isotropic pixel (voxel) of CBCT, and how the pixel data are acquired from both modalities.

The patient is positioned on a gantry in an MDCT unit, and images are acquired multiple slices at a time, which prolongs the acquisition time. The number of slices acquired is a direct function of the sensor array configuration. Spiral CT uses continuous translator motion of the gantry as images are acquired, thus shortening the acquisition time. This results in significantly higher absorbed x-ray doses for the patient. A typical CBCT examination would expose the patient to only about 20 to 500 μSv in a single study, whereas a typical medical examination of the head would approach 2100 μSv because the image data are gathered one section at a time. Therefore, soft-tissue imaging is better with MDCT because the signal intensity is higher. However, this is not a requirement for dental diagnostic tasks because hard tissue visualization is more important. Consequently, CBCT data have a much higher resolution than MDCT data for hard tissue visualization because of the smaller voxel sizes that medical-grade scanners are incapable of achieving at a significantly lower dose. Increased noise is observed as a result of volumetric acquisition, but the SNR is maintained at a desirable level that facilitates adequate diagnosis based on hard tissue signals.

Field of view

The FOV (Figs. 2.9 and 2.10) ranges from as small as a portion of a dental arch to an area as large as the entire head. The selection of the FOV depends on several factors. Among the most important are the following:

- Diagnostic task
- Type of patient
- Spatial resolution requirements

Telegram: @dental_k

www.konkur.in

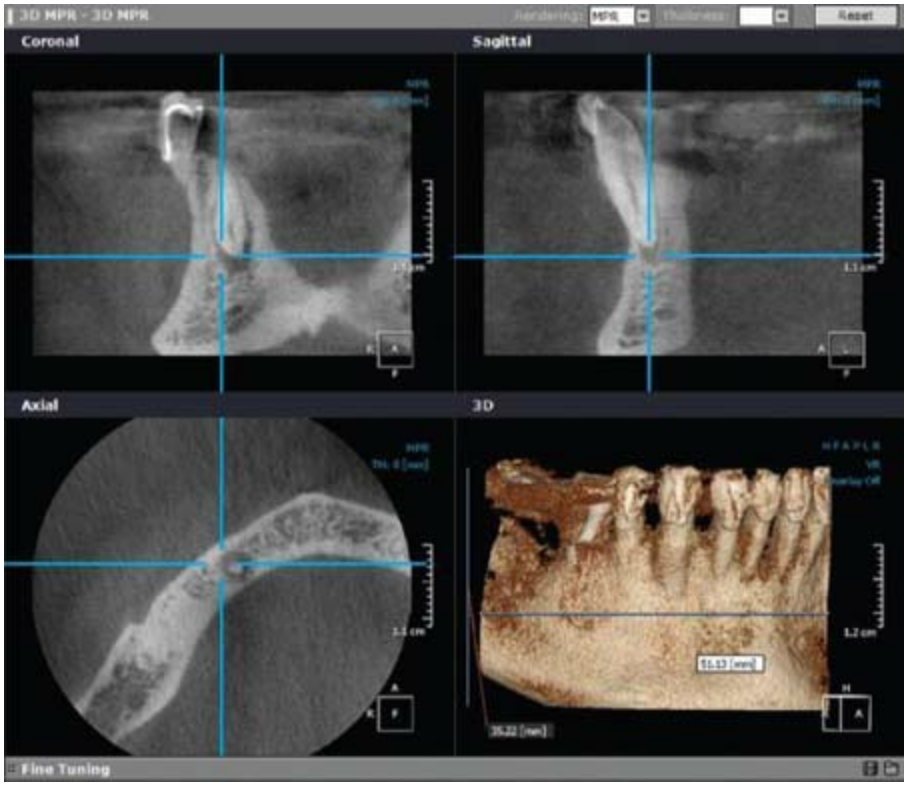

FIG. 2.9 Multiplanar and 3D color reconstructed views of the mandibular quadrant taken on a CBCT machine with a volume size of 37 × 50 mm.

Diagnostic task

The diagnostic task is the single most important determinant of the FOV in any imaging study. Based on the outcome of the clinical assessment, history, and evaluation of previous and other available imaging studies, a segment of the jaw or a larger area may need to be imaged using an appropriate FOV. If systemic conditions or generalized disorders are suspected, a larger FOV is sometimes required. For most endodontic purposes, a limited FOV can be used if no signs or symptoms of systemic conditions are reported or noted. Under no circumstances should a screening study be done using a large FOV in the absence of signs and symptoms justifying the procedure. Several multifunctional cone beam units are available that allow the clinician to acquire several image types. Image quality has a direct impact on the diagnostic outcome; therefore, the choice of a FOV should be made carefully.

Fig. 2.11 illustrates the advantages of using multiple image types for an endodontic case.

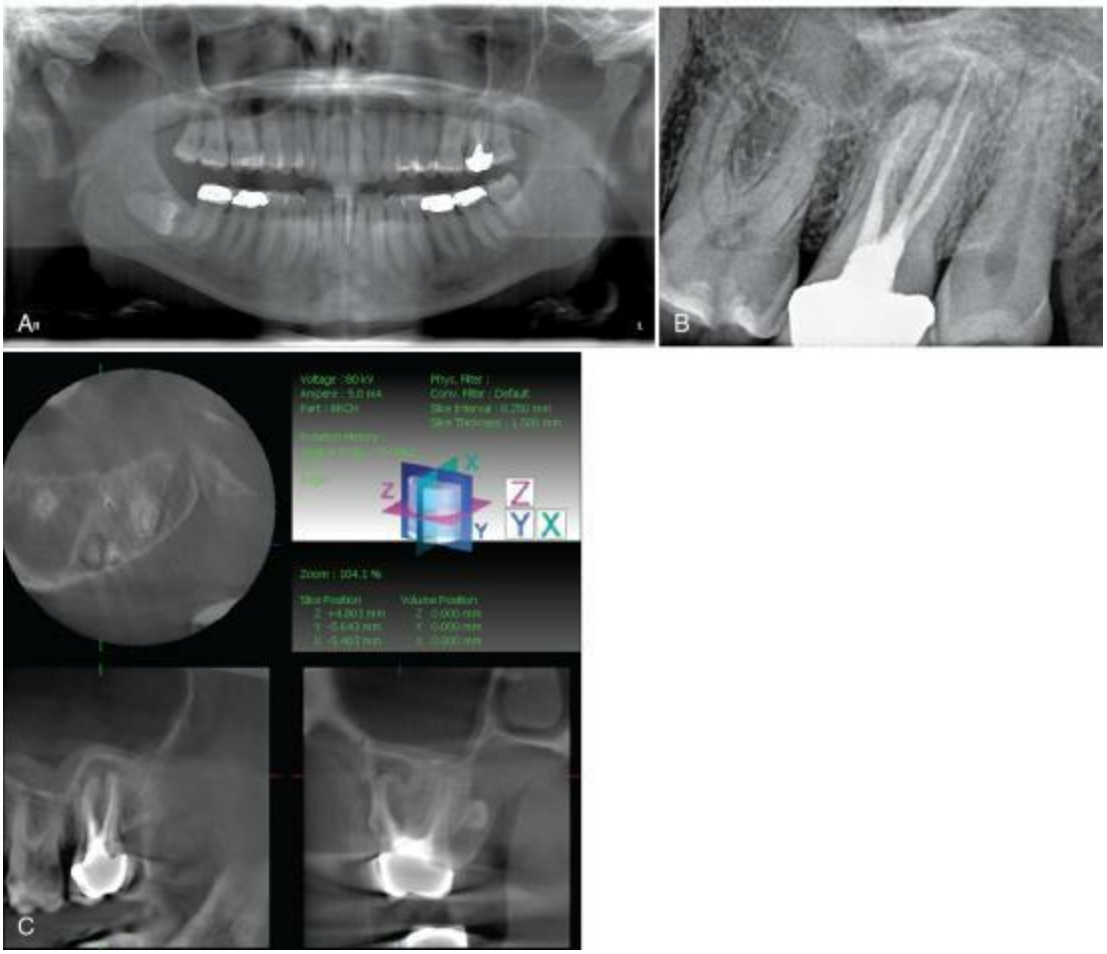

FIG. 2.11 **A,** Panoramic 2D image exposed with the JMorita Veraviewepocs 3D for evaluation of the mandibular left central incisor. Other radiographic findings also were revealed, including the horizontal bony impaction of the mandibular right third molar and a possible lesion of endodontic origin associated with the endodontically treated maxillary left second molar. Data available from the scan allowed a 3D reconstruction to be made for areas of concern. **B,** Periapical radiograph of the maxillary left second molar on the same patient revealed a periapical area of low attenuation in the region of the periapex of the mesiobuccal root. In this case, also, changes could be evaluated in greater detail with CBCT imaging. **C,** CBCT of the maxillary left second molar revealed detailed periapical and periradicular changes in all three orthogonal planes of the section, specifically illustrating the lesion of endodontic origin associated with the mesiobuccal root. Examination of the width of the mesiobuccal root in both the axial and coronal views (buccolingually) showed that the

Telegram: @dental_k

www.konkur.in

mesiobuccal root possibly had two canals and that only a single canal was treated during the initial endodontic therapy.

A) Radiograph shows front view of the open mouth. Crowns of some premolars and molars are extremely dense.

B) CBCT shows a central tooth with radiopaque crown and three root canals.

C) Four panels show three radiographs depicting axial, coronal, and sagittal views of teeth, whereas the fourth panel shows a multitude of planes with X, Y, and Z planes. The first radiograph less dense tissue around the right tooth. The second radiograph shows two teeth. One tooth on the right has two root canals. The central part of crown is less dense. The third radiograph shows close-up of tooth with two root canals.

Source: (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, GA].)

Additional benefits of CBCT imaging software include allowing the clinician to format the volume to generate an image that looks like a panoramic radiograph. Conventional panoramic machines, although not commonly used by endodontists, use the focal trough, or zone of sharpness, to position patients so as to minimize distortion along multiple axes. All inherent problems associated with panoramic imaging, including distortion, magnification, blurring, ghost shadows, and other artifacts, can be expected on the resulting image if patient positioning is not accurate. With CBCT, such artifacts are not generated, resulting in a distortion-free panoramic reconstruction (Fig. 2.12). However, it must be noted that CBCTs should not be generated in patients requiring a panoramic radiograph alone because of dose concerns.

Telegram: @dental_k

www.konkur.in

FIG. 2.12 **A,** This reconstructed panoramic image from CBCT data approximates the view one would see with a conventional panoramic radiograph. It is somewhat difficult to see the lesion on the maxillary left first molar. **B,** This thin-slice pseudopanoramic image (0.01 mm) shows the lesion without most of the anatomic superimposition. These slices of the maxillary left first molar show the lesion in sagittal **(C)** and coronal **(D)** views, confirming the features seen in the pseudopanoramic view.

A) Radiograph shows front view of teeth.

B) Front view of teeth with porous bone at the center and dark patches at the top.

C) Lateral view of the jaw shows a large dark cavity above the teeth and inflamed tissue around the lower teeth.

D) Panoramic view shows two teeth with large holes above them.

Newer hybrid units, such as the CS 9300 3D Extraoral Imaging System (Carestream Dental, Atlanta, GA), have a wide range of FOV choices for a variety of diagnostic tasks, in addition to a conventional panoramic imaging option (Fig. 2.13). The CS 9000 unit offers the lowest voxel size of 76 microns, whereas the CS 9300 can resolve down to 90 microns, with a range extending to 500 microns for larger FOV studies. Likewise, the Morita 3D Accuitomo 80 (J. Morita USA, Irvine, CA) generates isotropic voxels of 80

Telegram: @dental_k

www.konkur.in

microns. Although not necessary for use in every case, this technology, when appropriate, improves visualization and ultimately leads to better care in select situations. A record of exposure and doses must be maintained for each patient.

FIG. 2.13 CS 9300 3D Extra-Oral Imaging System.

A 3D dental scanner with multimodality imaging system has a platform installed to rest face on it while the patient stands.

Source: (Courtesy Carestream Dental LLC, Atlanta, GA.)

Type of patient

Patient size and thus the amount of regional anatomy captured in the study also help determine the FOV. The smallest possible FOV must be chosen for the task at hand. Just because a clinician owns a cone beam machine does *not* mean that every patient should be exposed to a cone beam study.[140] If previous studies are available, they need to be evaluated first in a recall patient. Use of imaging in children must be minimized. Cone beam units with smaller FOVs can somewhat limit the radiation dose to critical organs and tissues of the head and neck in these cases.

Telegram: @dental_k

www.konkur.in

Several CBCT units allow the use of a wheelchair to position special needs patients or a regular chair for patients to sit down during image acquisition. The potential to reduce motion artifacts may be an advantage (Figs. 2.14 and 2.15).

Spatial resolution requirements

All endodontic imaging procedures require high spatial resolution. Assessment of canal structure, canal length, and lesions of endodontic origin (LEOs)[189] showing apical change, in addition to an understanding of possible retreatment cases, are important tasks requiring minute detail. If CBCT is used, the data acquisition should be performed at the smallest voxel size: the smaller the voxel size, the higher the spatial resolution. Many of the larger stand-alone cone beam machines, such as the i-CAT (Imaging Sciences International, Irvine, CA), default to a 0.4 mm voxel size. This voxel size is inadequate for high spatial detail. However, these units often have a voxel size selection option that allows smaller voxel sizes to be used during the image acquisition. The absolute maximum voxel size for endodontic imaging should be 0.2 mm.[44] Units typically use voxel sizes of 0.075 to 0.16 mm for their native image capture (Fig. 2.16).

Imaging tasks improved or simplified by cone beam volumetric computed tomography

The Executive Opinion of the American Academy of Oral and Maxillofacial Radiology and, later, the position paper on the use of CBCT in endodontics jointly developed by the American Association of Endodontists (AAE) and the American Academy of Oral and Maxillofacial Radiology (AAOMR), list indications for potential use in selected cases, including evaluation of the anatomy and complex morphology, differential diagnosis of complex pathoses with certain qualifiers, intraoperative or postoperative assessment of endodontic treatment, dentoalveolar trauma, resorption, presurgical case planning, outcomes assessment, and dental implant case planning.[1] Use of CBCT must be determined on a case-by-case basis only. These indications do not in any way mandate the use of CBCT for every case that falls into one of the preceding categories. For endodontic treatment and assessments, there are at least five primary imaging tasks in which CBCT scans have a distinct advantage over traditional 2D radiographs. These tasks include the evaluation of the following factors:

1. Differential diagnosis

Telegram: @dental_k

www.konkur.in

    a. Lesions of endodontic origin
    b. Lesions of nonendodontic origin
2. Evaluation of anatomy and complex morphology
    a. Dental anomalies
    b. Root canal system morphology
3. Diagnosis of endodontic treatment failures
4. Intraoperative or postoperative assessment of endodontic treatment complications
    a. Vertical root fractures
    b. Overextended root canal obturation material
    c. Separated endodontic instruments
    d. Calcified canals
    e. Perforations
5. Presurgical treatment planning
6. Dentoalveolar trauma
7. Internal and external root resorption
8. Endodontic treatment outcomes assessment
9. Dental implant case planning
10. 3D guided endodontics

Differential diagnosis

Lesions of endodontic origin

Clinical endodontic diagnosis relies on subjective and objective information collected during patient examinations. Diagnosis of the pulpal status of the teeth can sometimes be challenging if adequate radiographic information is unavailable. It is fundamental to understand that LEOs arise secondary to pulpal breakdown products and form adjacent to canal portals of exit.[183,190] These radiolucent lesions, formed as a result of loss of bone mineralization, can and do form three dimensionally anywhere along the root surface anatomy.[184] A 30% to 40% mineral content loss is needed for these lesions to be visualized on conventional radiographs.[137] Furthermore, the thickness of the cortical plate covering the lesion may significantly affect the radiographic appearance of the lesion on a conventional image.[229] DSR has been observed to increase diagnostic capability with observers identifying incipient PA

Telegram: @dental_k

www.konkur.in

lesions in more than 70% of the cases.[137]

Before the advent of CBCT, clinicians were unable to routinely visualize the presence, specific location, and extensiveness of PA bone loss using conventional radiography.[127] This was especially true in areas with superimposition of anatomic structures. Visual obstruction from anatomic features, such as buccal bone and the malar process over the apices of maxillary roots, simply "disappears" when the examiner can scroll through the slices of the bone from facial to palatal in 0.1 mm sections while also changing axial orientations. CBCT showed significantly higher rates of detection of PA lesions in maxillary molars and premolars compared to PA radiography.[129] CBCT also showed a significantly higher diagnostic accuracy to detect apical periodontitis (AP) when compared to PA radiographs using human histopathology as the gold standard.[108]

In a comparative investigation of the use of CBCT and PA radiography in the evaluation of the periodontal ligament (PDL), Pope et al.[176] showed that necrotic teeth examined with CBCT had widened PDLs but 60% of vital teeth showed a PA widening of 0.5 mm or more. They called for further investigation to determine whether health and disease can be appropriately judged using CBCT in epidemiologic investigations. See Chapter 3 for more information.

Lesions of nonendodontic origin

Differential diagnosis of PA pathology is crucial to endodontic treatment planning. Substantial evidence in the literature points to a significant chance that lesions of the tooth-supporting structures are nonendodontic in origin, such as PA cemento-osseous dysplasia; central giant cell granulomas; lateral periodontal cyst, simple bone cysts; odontogenic cysts, tumors, or malignancies; and neuropathic pain (Figs. 2.17 and 2.18).[39,68,100,168,179,180]

Neuropathic orofacial pain or atypical odontalgia (AO), also known as *chronic continuous dentoalveolar pain* (CCDAP)[153] and *persistent dentoalveolar pain* (PDAP),[98] is related to a tooth, teeth, or pain at an extraction site where no clinical or radiographic pathosis is evident. Two systematic reviews of AO showed the incidence of persistent pain of more than 6 months' duration after nonsurgical and surgical endodontic treatment, excluding local inflammatory causes, was 3.4%.[151] The pathophysiology of this pain is uncertain, but it is hypothesized to involve deafferentation of peripheral sensory neurons in predisposed patients. The diagnosis of AO is challenging and depends on the patient history and clinical examination findings in addition to the absence of radiographic findings. In some cases, the symptoms from AP and AO are closely related. Pigg et al.[173] conducted a study of 20 patients with AO. All the patients had at least one tooth in the region of discomfort that had undergone invasive treatment; 21 of 30 teeth had undergone endodontic treatment. These researchers found that 60% had no PA lesions, and among those who did, CBCT showed 17% more PA lesions than conventional radiography. This study demonstrated that CBCT may be a useful supplement to 2D radiography (see Fig. 2.18).

FIG. 2.18 A 62-year-old female was referred for evaluation and possible treatment for persistent dentoalveolar pain (PDAP) in the maxillary left region. The patient could alleviate this condition by placing a moist cotton roll in the adjacent vestibule to prevent the buccal mucosa from contacting the alveolus supporting the maxillary teeth in this area. This condition began after a history of local

anesthetic administration, persisted for 1 year, and led to three successive new crowns and endodontic treatment on the “offending tooth,” in an effort to remedy the condition without improvement. The response to endodontic tests, TMJ, and myofascial evaluations were normal. Application of topical xylocaine resulted in cessation of pain for 15 minutes. **A,** A PA radiograph showed a root-treated, maxillary left first molar with no apparent radiographic lesion. **B,** A limited FOV CBCT of the maxillary left posterior was acquired. The corrected sagittal view showed an approximately 4 mm, well-defined, ovoid, mildly corticated area of low attenuation (radiolucent) centered over the apex of the mesiobuccal root and extending to the junction of the middle and apical third of the mesiobuccal root *(yellow arrow)*. There was mild mucositis *(green arrow)*. **C,** There was a previously untreated mesioaccessory canal *(yellow arrow)* and mild mucositis. A diagnosis of neuropathic pain and a chronic apical periodontitis was made. Daily application of topical ketamine, gabapentin, and clonidine was prescribed. Endodontic revision of the maxillary left first molar was performed 3 months after the patient was stabilized with the topical medications.

Set of three radiographs marked A through C depict results of evaluation of a 62-year-old female with a complaint of persistent dentoalveolar pain (PDAP) in the maxillary left region.

Source: (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D [Carestream Dental, LLC. Atlanta, GA].)

The 3D radiographic appearance of a PA lesion provides additional information about the lesion’s relationship to the tooth and other anatomic structures (e.g., the vascular bundle) and about the aggressiveness of the lesion. This information, along with pulp sensitivity testing, is useful for adequate treatment planning and management of these conditions (see also Chapter 3).

Evaluation of anatomy and complex morphology

The precise location and visualization of dental anomalies, root morphology, and canal anatomy are vastly improved with CBCT data. Root curvature, additional roots, and anomalies within the canals themselves (e.g., obstructions, narrowing, bifurcation) are made more apparent when all three anatomic planes of section are available for review, especially with the capability of narrowing the slice thickness to as little as 0.075 mm. Visual obstruction from anatomic features such as buccal bone and the malar process

Dental anomalies

The use of CBCT technology has been reported in the diagnosis and treatment planning of various dental anomalies (e.g., dens invaginatus) that often have complex morphologic presentations.[152] The prevalence of dens invaginatus was as high as 6.8% in the adolescent Swedish population studied.[21] The complex nature of the anomaly presents a diagnostic challenge when conventional radiographs are used.[160] In case reports in which CBCT was used for diagnosis and treatment planning, treatment options included conservative endodontic treatment of the invagination, surgical treatment of the PA pathology, and complete revascularization of the dens after removal of the invagination (Fig. 2.20).[144,222]

Root canal system morphology

As the adage goes, nature seldom makes a straight line and never makes two of the same. This statement is dramatically illustrated in the evaluation of root canal system morphology. With ever-present unusual and atypical root shapes and numbers, there is sometimes a need to look further than what a clinician can see or imagine with 2D radiography (Fig. 2.21). Variations in root canal morphology have been studied using various in vitro techniques.[70,174,220,221] The results of these studies point to the fact that there is significant variation in the root canal morphology among various ethnic population groups.[8,90,91,149,224] CBCT has been reported to be comparable to canal staining and clearing techniques for identification of the root canal morphology,[145] and CBCT studies report variation in the root canal morphology among various ethnic groups.[146,204,236,238] Accuracy of CBCT imaging for detection of second mesiobuccal canal in maxillary molars has been shown to be 96%, and the prevalence of midmesial canals in mandibular molars was found to be 16.4%.[203]

Telegram: @dental_k

www.konkur.in

FIG. 2.21 **A,** Mandibular left second molar referred for endodontic evaluation and possible treatment. This 2D radiograph reveals significant pulp stones and canal calcification developing not only in the coronal aspect of the root canal system, but also extending down the visible distal canal. The apical third of the canal system appears unusual and dilacerated. Cone-beam computed tomography (CBCT) would be beneficial in visualizing the root canal anatomy, to create the ideal endodontic access. **B,** Single slice of the CBCT image for the same tooth. Information about the direction of the root canal anatomy is provided in all three planes of the section: axial, coronal, and sagittal. Interestingly, the axial slice shows that the mesial lingual root actually traverses buccally as it approaches its terminal extent. This is valuable information for the clinician before the entire root canal system is cleaned and shaped; it may also establish a higher degree of treatment predictability.

Set of two 2D radiographs marked A and B depict endodontic evaluation and treatment of mandibular left second molar.

Diagnosis of endodontic treatment failures

The failure of previous endodontic therapy can be attributed to various factors, such as procedural errors, missed canals, or persistent PA pathosis. Knowledge of the cause of failure is pertinent to the treatment of these cases because it allows the cause to be adequately rectified. With the advent of CBCT, in select cases of retreatment in which the cause of failure is otherwise undetectable, adequate information may be collected to apply to the treatment plan. Use of CBCT in these situations will aid in treatment

Telegram: @dental_k

www.konkur.in

planning and improve outcomes (Fig. 2.22).[109] A study by Rodriguez et al. showed that the endodontic retreatment strategies were altered in 49.8% of cases after CBCT images were included for diagnosis by general dentists and endodontists.[181]

FIG. 2.22 This 38-year-old female patient presented for evaluation and treatment of a symptomatic mandibular right second molar, which had been endodontically treated more than 10 years previously. This tooth was sensitive to percussion and biting forces; periodontal findings were normal. Microscopic examination of the exposed dentin was negative for a vertical fracture. **A,** The PA radiograph showed the previous endodontic treatment; a post present in the distal canal; and an approximately 5 mm diameter, unilocular, well-defined area of uniform low density centered at the periapex of the distal root—features consistent with an apical periodontitis. Contemporaneous **(B)** CBCT sagittal and **(C)** axial reformations revealed a previously untreated distobuccal canal *(yellow arrow)*.

Three radiographs are marked A through C as follows:

A) Two teeth with radiopaque crown and two root canals. The tissue at the tip is less dense.

B) A dashed arrow pointing at a tooth depicting inflammation at the tip of root.

C) Axial view shows a dashed arrow pointing at the three round structures, each with a denser tiny dot at the center in the distobuccal canal.

Source: (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, GA].)

Use of CBCT in evaluation of previously endodontically treated teeth aids in visualizing missed canals, canal deviations, resorption, procedural errors

Telegram: @dental_k

www.konkur.in

such as perforation, and other pathology.

The technology is most useful in detecting uninstrumented and unfilled canals, extension of the root canal filling, and the presence and extent of periradicular bone loss. The incidence of missed canals in failed endodontic treatments were found to be 23.04% with the highest incidence in upper molars. These teeth had 4.38 more likelihood of having a PA lesion.[109] The sensitivity of CBCT and PA radiographs for diagnosing strip perforations in root-filled teeth has been shown to be low, although CBCT showed a significantly higher sensitivity when compared to PA radiographs.[194] Radiopaque filling materials in the root canals of endodontically treated teeth can produce streak artifacts, which can mimic fracture lines or perforations.[194,237] Use of lower exposure parameters and nonmetallic fiber posts can significantly reduce these artifacts, allowing for an improved diagnosis.[59]

Intraoperative or postoperative assessment of endodontic treatment complications

Vertical root fractures

Vertical root fractures (VRFs) that run along the long axis of a tooth are often difficult to diagnose clinically. The prevalence of VRF in endodontically treated teeth has been reported to range from 8.8% to 13.4%.[77,207,233] These fractures typically run in the buccolingual direction and are confined to the roots, making it difficult to visualize the fracture. Visualizing the fracture on a conventional radiograph is possible when the x-ray beam is parallel to the plane of the fracture.[182] Challenges in diagnosis with regard to the extent and exact location of the fracture often lead to unwarranted extraction of teeth. Since the introduction of CBCT to dentistry, various reports of the application of the technology to detect vertical root fractures have been published. The reported sensitivity for detection of VRFs has ranged from 18.8% to 100%[136]; by comparison, conventional radiographs have a reported sensitivity of approximately 37% (Fig. 2.23).[62,95] CBCT has been used to visualize VRFs in controlled clinical studies in which clinical diagnosis was difficult.[62] VRFs were successfully detected at a spatial resolution ranging

Telegram: @dental_k

www.konkur.in

from 76 to 140 microns. However, only a limited number of units provide such high resolution. A comparison of various CBCT units for the detection of VRFs demonstrated that the units with flat panel detectors (FPDs) were superior to the image intensifier tube (IIT)/CCD–based detectors; the smaller FOV and the ability to view axial slices also improved detection of VRFs.[96] Continued improvement of sensor technology, including the use of FPDs, has resulted in enhanced resolution. Voxel dimensions are smaller in these units. Detection of vertical root fractures with thickness ranging from 0.2 to 0.4 mm was found to be more accurate with CBCT than with digital radiography.[155,161] The presence of root canal filling in the teeth lowers the specificity of CBCT in detecting vertical root fractures[95,96,111]; this has been attributed to the radiopaque material causing streak artifacts that mimic fracture lines.[237]

FIG. 2.23 Root fracture in an endodontically obturated maxillary right central incisor. **A,** Axial view with artifacts from a highly attenuating (opaque) obturant. **B,** View without artifacts from obturant. **C,** Oblique parasagittal view. **D,** Paracoronal view.

Four radiographs are marked A through D as follows:

A) Panoramic view of upper jaw shows a tooth with artifacts that appears hazy.

B) Upper jaw shows tooth at the center with fractured root.

C) Tooth shows the diagonal fracture in-between root.

D) Two teeth are shown. One tooth on the left has radiopaque tissue in root, whereas the tooth on the right has radiolucent tissue.

Source: (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, GA].)

Zhang et al. reported a low sensitivity of 33.3% for detection of subtle vertical root fractures in a clinical study. However, the study showed the presence of vertical bone loss in a high number of the cases.[235] Bone loss pattern around teeth with vertical root fractures viewed on CBCT images may assist clinicians in diagnosis of VRF.[211]

Overextended root canal obturation material

CBCT scans provide the opportunity to map endodontic treatment complications through the examination of 3D representations of the teeth and supporting structures in different planes. Few high-level studies related to the effects of endodontic treatment complications have been published in the endodontic literature.[206] However, it is generally recognized that the overfilling of the root canal, causing damage to vital structures such as the inferior alveolar neurovascular (IAN) bundle (Fig. 2.24) or the maxillary sinus, can cause significant morbidity.[34,35,76,80]

Telegram: @dental_k

www.konkur.in

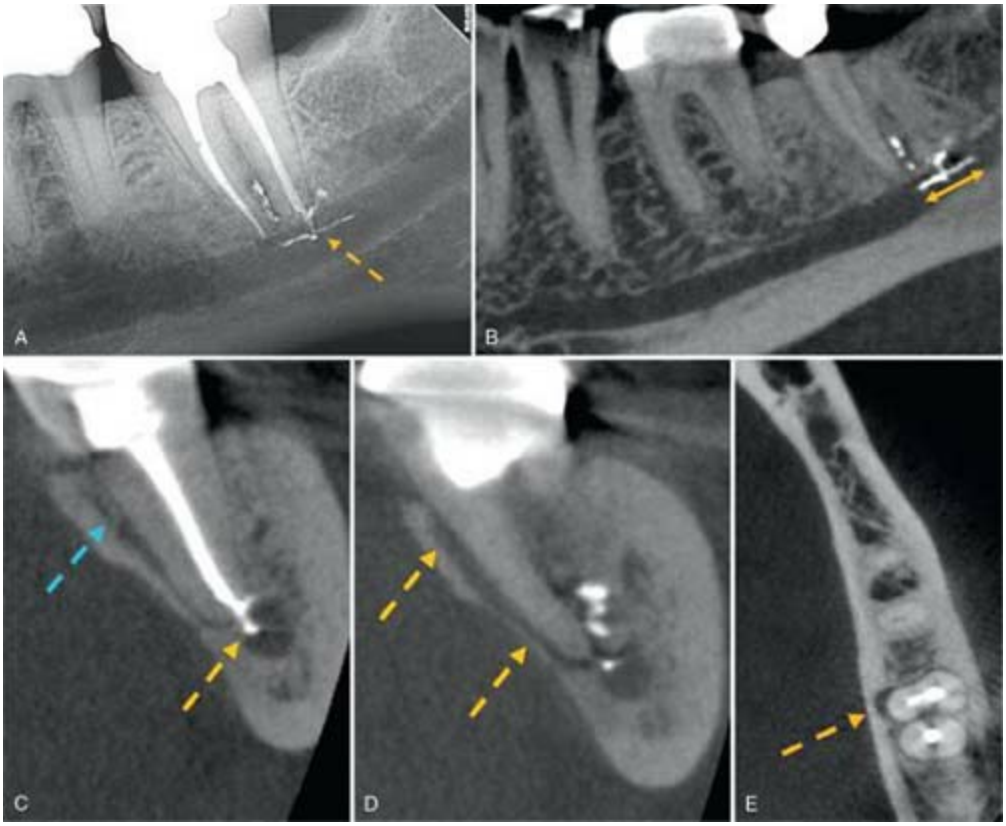

FIG. 2.24 This 64-year-old male patient presented with sensitivity when biting on the mandibular left second molar. The history included endodontic revision more than 6 months earlier and subsequent transient paresthesia and dysesthesia along the distribution of the inferior alveolar nerve, which persisted for 1 week after the retreatment. Epicritic and protopathic sensibility was normal. The results of periodontal probing, staining and microscopic examination of the exposed root surface at the sulcus were normal. **A,** Initial PA radiograph showed the approximate location of excess radiopaque material, a feature consistent with extruded root canal sealer *(yellow arrow)*. **B,** Contemporaneous CBCT corrected sagittal reformation shows approximate length of extruded material, measuring 3.4 mm *(yellow arrow)*. **C and D,** Corrected cross-sectional reformation shows the foreign material interior to the inferior alveolar canal *(yellow arrow)*, an area of low attenuation extending from the apex superiorly to an area near the alveolar crest *(blue arrow)*, and erosion of the lingual endosseous surface. **E,** The same feature was shown in the corrected axial view *(yellow arrow)*, bisected by a dark line extending from the obturant to the surface of the root—features suggestive of a vertical fracture. Examination of the extracted tooth revealed a vertical fracture at the lingual aspect of the distal root.

Five radiographs marked A through E depict results of periodontal probing to treat sensitivity in mandibular left second molar.

Endodontic therapy undertaken in close proximity to the IAN bundle should receive special attention because direct trauma, mechanical compression, chemical neurotoxicity, and an increase in temperature greater than 10°C may cause irreversible damage.[65,85,88,214] Scolozzi et al. reported that sensory disturbances can include pain, anesthesia, paresthesia, hypoesthesia, and dysesthesia.[191] The IAN bundle is located in the cribriform bone-lined mandibular canal and courses obliquely through the ramus of the mandible and horizontally through the mandible body to the mental foramen and the incisive foramen.[11] There are many anatomic variations of the IAN bundle, including the anterior loop and bifid mandibular canals.[45] Kovisto et al.[116] used CBCT measurements from 139 patients to show that the apices of the mandibular second molar were closest to the IAN bundle. In females, the mesial root of the second molar was closer than in males, and the distances in all roots measured increased with the age of the patient. There was a high correlation between the measurements from left to right side in the same patient, and an average distance of 1.51 to 3.43 mm in adults.[116] Procedures involving the mandibular second molar were most likely to cause nerve damage.[126] Further research is required to clarify the risks and benefits of CBCT when endodontic treatment is contemplated on teeth with a proximal relationship between the IAN and root apices. Porgrel treated 61 patients with involvement of the IAN bundle after root canal therapy during a 7-year period. Eight patients were asymptomatic; 42 patients were seen for mild symptoms or were examined more than 3 months postoperatively, with only 10% experiencing improvement. Five patients underwent surgical treatment before 48 hours elapsed and recovered completely. Six patients underwent surgery between 10 days and 3 months, with four experiencing partial recovery; the remaining two had no improvement.[175]

New imaging technologies, such as high-resolution magnetic resonance imaging (MRI-HR) and magnetic resonance neurography (MRN), promise to improve isolation of the IAN from the neighboring artery and vein contained within the inferior alveolar bony canal. MRN studies have documented the ability to demonstrate nerve continuity and localize extraneural nerve

Telegram: @dental_k

www.konkur.in

compression before surgical nerve exploration. Postoperative PA radiographs should be exposed on the day of endodontic treatment completion or a suspected iatrogenic event, and any suspected compromise of the IAN bundle or other vital structures should be evaluated immediately. In all cases in which trauma to the IAN bundle is suspected from PA or panoramic radiography or by the report of symptoms consistent with nerve injury, exposure of a CBCT image volume should be considered. It is generally accepted that immediate surgical debridement should be attempted to maximize recovery.[65,177] With the introduction of MRI algorithms for dental diagnostic purposes, it is expected that this imaging modality will be increasingly used in diagnostic and treatment planning. MRI has the capability to demonstrate vascularity to the tooth of interest, in addition to the presence of inflammatory exudates in the apical regions, without exposing the patient to ionizing radiation. Receiver coils are being developed to enhance the image quality of maxillofacial and dental magnetic resonance studies.

The accidental introduction of root canal instruments, irrigating solutions, obturation material, and root tips into the maxillary sinus has been reported. Serious consequences associated with the intrusion of foreign bodies into the maxillary sinus include pain, paresthesia, and aspergillosis, a rare but well-documented complication of endodontic treatment.[24] Guivarc'h et al. reported that the overextension of heavy metal–containing root canal sealers, such as zinc oxide eugenol cement, may promote fungal infection in immunocompromised patients, leading to bone destruction and damage to adjacent structures. This case report described the use of CT to assess the patient before surgery and at 6 months.[89] The use of CBCT as an aid in the localization and retrieval of an extreme overextension of thermoplasticized injectable gutta-percha into the sinus and contiguous soft tissues has been described by Brooks and Kleinman.[37]

Separated endodontic instruments

Instrument fracture can occur at any stage of endodontic treatment, and in any canal location. The incidence of this complication, reported in clinical studies on a per canal or per tooth basis, ranges from 0.39% to 5.0%.[56,157] Molars are predominantly affected by instrument fracture, with the highest

Telegram: @dental_k

www.konkur.in

incidence found in the apical third of mandibular molars.[7,52,123,147]

A systematic review and meta-analysis showed that when endodontic treatment was performed at a high technical standard, instrument fracture did not significantly reduce the prognosis. More specifically, when no initial radiographic PA lesion was present, 92.4% of cases remained healthy; when a PA lesion was present initially, 80.7% of PA lesions showed radiographic healing. However, the presence or absence of periradicular lesions on preoperative and postoperative examinations was based on planar radiographic assessments, which calls these findings into question.[156] Other studies showed that the chances of endodontic failure increased if the canal system could not be thoroughly disinfected, if a periradicular periodontitis was present, or if technical standards were compromised.[51,110,198,200] Use of CBCT to triangulate the retained instrument and assess the canal shape, especially in cases in which the operating microscope does not allow direct visualization, can be helpful in formulating a removal strategy. If the fractured instrument is lodged in the lingual aspect of a ribbon-shaped canal, for example, an instrument may be inserted toward the buccal to bypass and remove the imbedded instrument without forcing the fragment further apically. Without the use of CBCT, intracanal instruments can be reliably removed or bypassed in 85.3% of cases if straight-line access is possible; however, reliable removal or bypass is possible in only 47.7% of cases if the instrument is not visible (Fig. 2.25).[147] When a separated instrument is lodged in the apical third of a root canal, the chances of retrieval are the lowest, but the apical terminus may be adequately sealed by treatment of an anastomosing canal, if present.[79] The possibility of instrument removal based on CBCT triangulation has not been published to date.

Telegram: @dental_k

www.konkur.in

FIG. 2.25 Unexpected torsional and flexural failure of endodontic instruments can occur during instrumentation. **A,** PA radiograph shows a separated file *(yellow arrow)* located at the midroot of the mandibular left lateral incisor in a patient referred for revision treatment. **B,** To aid development of a retreatment strategy, CBCT was used to localize the instrument *(yellow arrow)* in the lingual canal, with identification of the buccal canal *(green arrow)* to facilitate bypassing the instrument and **(C),** subsequent removal. **D,** Obturation was completed without complication.

Four radiographs are marked A through D as follows:

A) Incisor shows a vertical fracture in the root.

B) Axial view shows fracture in the lingual canal of tooth.

C) Incisor shows wedge-shaped radiolucency in the root.

D) Incisor shows wedge-shaped radiopaque region in the root.

Calcified canals

Telegram: @dental_k

www.konkur.in

According to the Pew Research Center, 10,000 US individuals will reach the age of 65 every day until 2030, and the nation's 65-year-old and over cohort will grow to 81 million in 2050, up from 37 million in 2005.[171] This aging population will present increasing challenges for dental clinicians because calcification of the root canal system increases as part of the natural aging process,[86] possibly leading to more untreated canals that may serve as a niche for microorganisms.[28,104] Pulp chambers in the crown of the tooth decrease in size, forming more rapidly on the roof and floor of posterior teeth.[219] Typically, root canals calcify at the coronal aspect first, with decreasing calcification as the canal travels apically. Magnification and illumination are essential tools for the identification and treatment of calcified canals, but CBCT can assist in the perioperative treatment of such conditions.[23] Preoperative assessment of calcified teeth using CBCT can suggest the best tactic for locating calcified canals in the chamber floor and roots using software-based measurement tools. The insertion of radiopaque markers, such as instruments or obturation material, can facilitate reliable canal localization using available multiplanar reformations. The increased sensitivity and specificity provided by CBCT can also assist in the determination of the PA status of calcified root canals that may not require measures that can lead to procedural errors, such as off-course access, instrument fracture, or root perforation.[118] The difficulty in locating calcified canals can be further compounded by morphologic anomalies associated with gender and ethnic origin.[192] CBCT can be an important adjunct to magnification and illumination in these cases.

Perforations

A *perforation* is defined as a "mechanical or pathologic communication between the root canal system and external tooth surface"[9]; it is usually associated with an iatrogenic event, accounting for about 10% of all nonhealed cases.[102] Root perforations can be caused by a post preparation, the search for a calcified canal, a strip perforation, or an attempt to retrieve a fractured instrument. They are often difficult to localize with conventional imaging because no information about the buccolingual dimension can be obtained.[232] Shemesh et al.[194] compared the sensitivity and specificity of

Telegram: @dental_k

www.konkur.in

CBCT scans with two-angulation PA imaging using phosphor plates to assess the likelihood of detecting root or strip perforations after root canal treatment with laterally compacted gutta-percha and sealer. They found that the two methods showed similar specificity, but the CBCT image volumes showed higher sensitivity. Single-angulated PA radiographs showed 40% of the perforations, and two-angled PAs showed 63%, suggesting that if PA radiographs alone are used, two-angled images were superior. There was no significant difference in the detection of root perforations between PA and CBCT radiography. The researchers noted that the results may have been affected by the small size of the perforations and that the method of obturation did not favor extravasation of obturation material.[194] CBCT images suffer from beam hardening artifact resulting from root canal obturation and restorative materials (e.g., gutta-percha, posts, and perforation repair materials), which creates challenges to the interpretation of root integrity. An approach advocated by Bueno et al.[40] suggested that a map-reading strategy of viewing sequential axial slices reduces the beam hardening effect. Improved CBCT software algorithms are expected to reduce artifact formation in the future.

Presurgical treatment planning

Surgical endodontic treatment is often performed in cases of endodontic nonhealing when nonsurgical retreatment is not possible. In the past, conventional and digital 2D PA radiographs were the only means of assessing the apical region. Unfortunately, the information available from these images may not adequately prepare the clinician to treat the pathosis surgically. For example, the clinician may be unable to observe whether the lesion has perforated the buccal or palatal cortical plates, as in the example that follows, or even observe which root or roots are involved. Presurgical confusion is resolved with cone beam imaging. Multiplanar views allow the clinician to see the defect and suspected causes from the axial, sagittal, and coronal aspects; 3D grayscale or color imaging helps the clinician visualize the entire defect before the incision is made. This is an immense improvement over conventional imaging and helps with better assessment of the prognosis prior to the surgical treatment (Fig. 2.26).

Five radiographs, F through I, show labels as follows:

F) Superior genial canal, inferior genial canal.

G) Axial view of mandible.

H) Panoramic reformation.

I) Crestal bone loss, mandibular tori, extraction defect.

J) Extraction defect, fracture.

Six radiographs, K through P, show labels as follows:

K) Nasal fossa, nasal septum, hard palate, lingual cortical plate, buccal cortical plate, maxillary sinus with mucositis or fluid.

L) Maxillary sinus with mucositis, oro-antral communication, extraction defect.

M) Lateral wall of nasal fossa, nasal fossa, maxillary sinus with mucositis, deviation of nasal septum, nasal septum.

N) Nasal fossa, anterior nasal spine, hard palate.

O) Incisive canal, buccal cortex, lingual cortex.

P) Nasal septum, incisive canal, inferior nasal conch, maxillary sinus, mucositis, hard palate.

Seven radiographs, Q through W, show labels as follows:

Q) Incisive canal, nasal fossa, hard palate, opening of incisive canal.

R) Maxillary sinus, nasal fossa, maxillary sinus, nasal septum, widened apical periodontal ligament spaces.

S) Nasal fossa, anterior nasal spine, palate with torus.

T) Inferior nasal conch, nasal septum, mucositis, right maxillary sinus, palatal torus, healing oro-antral communication.

U) Nasal fossa, nasal septum, radicular fracture following trauma, cervical abfraction, voids.

V) Nasal fossa, buccal cortical plate, dentinoenamel junction, orthodontic hardware, palatal cortex, crestal bone loss.

W) Lingual cortex, focal osteoporotic bone marrow defect, mental foramen, buccal cortex.

The relationship of the teeth and the associated pathology to important anatomic landmarks must be taken into consideration in the treatment planning for endodontic surgical procedures. These anatomic landmarks include, but are not limited to, the maxillary sinus, the mandibular canal, the mental foramen, the incisive canal, and the buccal and lingual/palatine cortical plate. The close proximity of the maxillary posterior teeth to the sinus has been linked to maxillary sinusitis of odontogenic origin; changes in the maxillary sinus have ranged from thickening of the Schneiderian membrane to actual accumulation of fluid in the sinuses.[130,131,134] The relationship of the roots of the posterior teeth to the sinus during presurgical treatment planning and the changes within the sinus can be best appreciated with the use of CBCT images.[32,131,193]

The relationship of the roots of the mandibular posterior teeth and associated PA pathoses to the mandibular canal, the presence of an anterior loop, and the distance of the mandibular canal from the buccal and lingual cortical plates are pertinent pieces of information when surgical procedures in mandibular posterior teeth are planned.[31] The 3D nature of this relationship can be best assessed using CBCT.[113] A potential difference in the location of the mandibular canal with respect to age and gender has been reported.[116,197]

The determination of the thickness of the buccal cortical plates and anatomy of the root apex prior to endodontic surgical procedures enables the clinician to preplan the osteotomy and the root end resection. The thickest buccal cortical plate was determined to be in the second molar area as per a recent study.[234]

Dentoalveolar trauma

Dental trauma is common during the lifespan, with prevalence in the primary dentition of approximately 30% and in the permanent dentition of approximately 20%.[12] Systematic epidemiologic data at a large medical center suggest a prevalence of 48.2% for dental injuries in all facial trauma, resulting in injuries to the dentition in 57.8% of household and play accidents, 50.1% of sports accidents, 38.6% of work-related accidents, 35.8%

Telegram: @dental_k

www.konkur.in

of acts of violence, and 34.2% of traffic accidents, with 31% unspecified.[78] The prevalence of traumatic dental injuries varies according to the population studied, but these injuries occur most commonly in children 7 to 10 years of age (also see Chapter 21).[18] Dental traumatic injuries affect one fourth of all schoolchildren, with most injuries occurring before the age of 19.[81] Maxillary central incisors sustain approximately 80% of all dental traumatic injuries, followed by maxillary lateral incisors and mandibular incisors.[16] The most common type of traumatic dental injuries in the primary dentition are luxation injuries, whereas crown fractures are the predominant dental injury to the permanent dentition.[117] Determination of the extent of injury to the dentinopulpal complex requires a methodical approach that evaluates the teeth, periodontium, and associated structures (Fig. 2.27) and may result in significant long-term complications.[55]

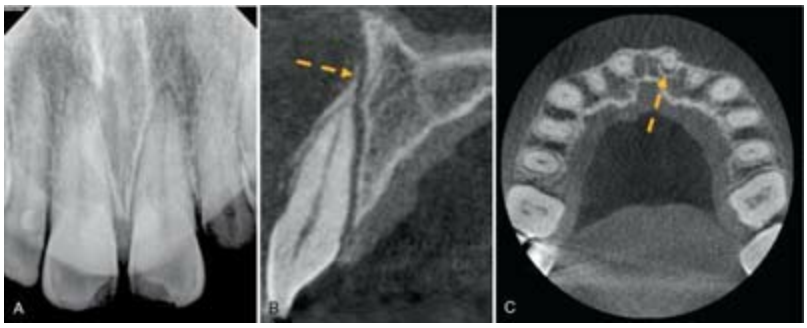

FIG. 2.27 After a traumatic injury to the maxillary right and left central incisors, crown fractures were noted. The PA radiograph showed an extrusive luxation injury in the maxillary left central incisor **(A).** The alveolar fracture (**B,** *yellow arrow*) and true extent of the displacement (**C,** *yellow arrow*) became evident with CBCT.

Three radiographs are marked A through C as follows:

A) Two teeth show part of the crown being broken.

B) Sagittal view of the fractured tooth shows less-density tissue around the periphery of root followed by porous tissue.

C) Panoramic view of teeth shows the fractured tooth at the center.

Trauma to the orofacial complex can result in the following injuries to the permanent dentition, based on the International Association of Dental Traumatology (IADT) guidelines: (1) infraction; (2) enamel fracture; (3) enamel-dentin fracture; (4) enamel-dentin-pulp fracture; (5) crown-root fracture without pulp exposure, (6) crown-root fracture with pulp exposure; (7) root fracture; (8) alveolar fracture; (9) concussion; (10) subluxation; (11) extrusive luxation; (12) lateral luxation; (13) intrusive luxation; and (14) avulsion.[13,58] (These guidelines can be reviewed at www.dentaltraumaguide.org.) The IADT guidelines for assessment of permanent teeth at initial visit recommend exposing several projections and angulations, with additional radiographs indicated when foreign objects become embedded in soft tissue. However, the recommendations suggest that CBCT may be beneficial when used to assess patients after dental traumatic injuries, especially in cases of lateral luxation, root fracture, complications, and monitor healing. The heterogeneity of dental traumatic injuries and difficulty in assessing affected teeth using intraoral radiography, especially when in the plane of PA radiographs, is evident from the guideline recommendations.[58]

Intra-alveolar root fractures generally affect the permanent dentition of males and are relatively uncommon, accounting for 0.5% to 7% of dental impact injuries.[19,54,84,154] Root-fractured teeth present diagnostic challenges, and the limitations of planar radiography have been well documented in the dental literature.[50,58,115,159] A systematic retrospective study showed that maxillary central (68%) and lateral (27%) incisors were primarily affected, with only limited occurrence in mandibular incisors (5%). This retrospective study concluded that CBCT allowed for improved treatment planning and showed the true nature of the injury compared with PA imaging alone.[228] At least seven systematic laboratory studies and one systematic in vivo animal study reported significantly improved accuracy for the detection of root fractures when CBCT was compared with PA radiography.[95,96,101,135,155,225] In a systematic clinical study, Bornstein et al.[33] examined 38 patients with 44 permanent teeth that sustained intra-alveolar fractures. In the study sample reported, 68.2% of teeth had oblique fractures that extended to the cervical third of the root, contradicting the findings of previous studies conducted with PA imaging alone. CBCT imaging offered improved visualization of the

Telegram: @dental_k

www.konkur.in

location and angulation of root fractures compared to PA and occlusal intraoral radiographs.[33]

Injuries that include fractures and comminution injures to the supporting structures or are difficult to visualize with intraoral imaging because of compression of overlying tissues, may be evident on CBCT scans. Several of these studies suggest that lower resolution scans using voxel sizes in excess of 0.3 mm may not improve radiographic assessments.[96,225] A study by Wang et al.[223] showed that the sensitivity and specificity of PA radiography for root fractures were 26.3% and 100%, respectively; the findings for CBCT were 89.5% and 97.5%, respectively. CBCT images of root-filled teeth with fractures showed lower sensitivity and unchanged specificity, whereas 2D images showed the same sensitivity and specificity.[223] CBCT allows for the management of traumatic injuries in which a root fracture or alveolar fracture is suspected by providing undistorted multiplanar views of the dentition and supporting bone without the superimposition of anatomic structures.[47,127,187] CBCT image volumes provide superior sensitivity in detecting intra-alveolar root fractures compared with multiple PA radiographs; this allows for the detection of dental and alveolar displacements, including damage to other perioral structures, such as the maxillary sinus and nasal floor.[105] The presence of root canal fillings and posts affected the specificity of the findings as a result of artifact generation.[96,135] Outcome measurements of a region of interest can be compared over time with greater geometric accuracy using CBCT.[94]

Injury to the soft tissues, such as the lips, cheek and tongue, by embedded debris and tooth fragments, usually require additional radiographic images when relying on intraoral radiography. CBCT scans will aid in wound management by locating the precise size and shape of the foreign body, possibly reducing the scope of surgical interventions.[195]

The healing of root fractures is influenced by many factors, most prominently the stage of root development, with immature roots showing better healing than mature roots.[73] Other factors that influence healing are the extent of dislocation and repositioning, the type of splinting, the use of antibiotics, and the location of the fracture on the root. The long-term survival of teeth with intra-alveolar root fractures was evaluated in a systematic review by Andreasen et al.[17] This study showed that the type of

Telegram: @dental_k

www.konkur.in

healing (e.g., hard tissue fusion, PDL interposition with and without bone) and the location of the fracture on the root had the most influence on tooth loss. Yearly clinical and intraoral radiographic follow-up examinations are recommended by the IADT for some injuries for up to 5 years posttrauma.[58] Further evidence-based comparisons of outcomes for traumatic dental injuries after treatment interventions were addressed by the IADT with the development of a Core Outcome Set for children and adults.

Limited FOV CBCT should be considered when placement of individual PA radiographs will adversely affect patient management or result in retakes; PA radiographs will produce a higher radiation dose for assessment of the region of interest[105]; intra-alveolar fracture of the root or supporting structures is suspected and sufficient information cannot be obtained with conventional radiography; or foreign bodies are present in the lip, cheek, or tongue.[164] The decision to use CBCT imaging for assessment of traumatic injuries should be based on the diagnostic yield expected and in accordance with the "as low as reasonably achievable" (ALARA) principle. CBCT scan volumes that use the most appropriate detector size and shape, beam projection geometry, and beam collimation should be selected to produce high-resolution images and reduce x-radiation exposure whenever possible.[188] In all cases, it should be recognized that children and young adults are more susceptible to the effects of radiation than adults, and CBCT studies should answer specific clinical questions that cannot be answered by lower dose PA and panoramic imaging techniques.[97] In compliance with the Image Gently Alliance recommendations for pediatric imaging, always select x-rays when essential for diagnosis and treatment; use the fastest image receptor available, use CBCT only when necessary, collimate beam to area of interest, always use thyroid shield, and reduce exposure time and technique factors, such as mA.[227] New technologies that allow for comparison of matched CBCT images in a serial fashion at a reduced dose have been tested. This technology promises a dose reduction of 10 to 40 times by using the initial scan as prior knowledge and adaptive prior image constrained compressed sensing (APICCS) algorithms to greatly reduce the number of projections and x-ray tube current levels required (Fig. 2.28).

Internal and external root resorption

As described in Chapter 18, root resorption results in the loss of dentin, cementum, or bone by the action of clastic cells.[22] In the primary dentition, root resorption is caused by normal physiologic processes, except when resorption is premature; in the permanent dentition, root resorption is caused by inflammatory processes.[46,66,165] Root resorption can be classified according to location as either internal, appearing on the wall of the root canal, and external, affecting the outer surface of the root. Both internal and external root resorption have subtypes that show specific radiographic characteristics.[208]

The successful management of root resorption in the adult dentition depends on clinical and radiographic examination leading to early detection and accurate diagnosis.[166] Unfortunately, teeth affected by root resorption have a poor prognosis if the causative lesion is not treated.[163]

2D radiographic projections suffer from inherent limitations that mask lesions: superimposition of 3D structures,[27] geometric distortion,[215] and

Telegram: @dental_k

www.konkur.in

misrepresentation.[127] Although parallax intraoral imaging techniques can be helpful in localizing root resorption[15] by observing lesion shift on changing angulation, only CBCT assessments can provide the true size and position of all resorptive defects in the region of interest.[46,163] Intraoral radiography is not reliable when lesions are small or located on the labial or lingual/palatal surfaces.[15] In ex vivo studies, CBCT showed improved accuracy in the detection of simulated internal and external resorptive lesions of all sizes.[107] Intraoral imaging produced false-negative results in 51.9% of cases studied and false-positive results in 15.3%.[143]

The use of CBCT in the evaluation of root resorption eliminates superimposition and compression of 3D features, is accurate in all multiplanar views, and can reliably represent the anatomy of three-dimensional structures. Patel et al.[163] compared the sensitivity and specificity of PA imaging with CBCT scans using the receiver operating characteristic (ROC) analysis, a standard measure of diagnostic performance. PA imaging showed satisfactory accuracy (Az 0.78), whereas CBCT showed perfect results (Az 1.00).[163]

Internal root resorption (IRR) is usually idiopathic and can be subdivided into either internal inflammatory or internal replacement resorption. IRR is a relatively rare occurrence that is usually detected on routine diagnostic radiographs.[122,162] It is characterized by internal structural changes in the tooth that can appear in any location and can exhibit varied features, such as smooth or irregular borders and radiodensity of uniform or mixed attenuation.[99] IRR is usually asymptomatic, associated with pulpal necrosis coronal to the resorptive lesion and vital or partially vital pulps where active.[163] When viewed with intraoral radiographs, IRR can easily be confused with external cervical resorption (ECR) owing to the similarity of the two lesions.[92] Parallax intraoral radiographs may aid identification because the lesion will maintain its position relative to the root canal. However, assessment may be affected by radiographic superimposition and by teeth with complex anatomy. CBCT is helpful for diagnosing the location and exact size of IRR. In a study by Estrela et al.,[66] 48 PA radiographs and CBCT scans were exposed on 40 individuals.[66] IRR was detected in 68.8% of PA radiographs, whereas CBCT scans showed 100% of the lesions.

Telegram: @dental_k

www.konkur.in

Conventional radiographs were able to detect only lesions between 1 and 4 mm in 52.1% of the images, whereas CBCT was able to show 95.8% of the lesions. This finding agreed with other studies that demonstrated the value of tomographic analysis.[46,125] In a study by Kim et al.,[112] the extent and location of the IRR was accurately reproduced with the fabrication of a rapid prototyping tooth model. Although relatively few systematic studies on artificially induced IRR have been reported because of the difficulty in creating such defects, Kamburoglu and Kursun[106] concluded that high-resolution CBCT imaging performed better than low-resolution CBCT imaging in detecting simulated small internal resorptive lesions.

External root resorption (ERR) can be divided into four subtypes: external surface resorption, external inflammatory resorption, external replacement resorption, and external cervical resorption (ECR). ERR may progress rapidly, and early treatment is recommended.[61]

The recommended timing of radiographic examinations using CBCT has not been established with a strong evidence grade. Many ERR cases involve young patients in whom the radiation dose is a critical factor and multiple scans would be difficult to justify. To minimize radiation dose to children the following guidelines have been suggested: Select radiographs based on a patient's individual needs, not as a routine; use the fastest image receptor possible; collimate the x-ray beam to expose only the area of interest; use thyroid collars; reduce the exposure as appropriate for the size of the child; use only when necessary, never as a screening tool.[227]

External surface resorption depends on the nature of the stimulus and can vary from small, concave lesions to extensive destruction of the root.[14] Commonly caused by orthodontic treatment, proximity to other teeth, or cysts and tumors, radiographic imaging with CBCT allows for accurate multiplanar mapping of the lesion. These excavations normally show small irregularities on the root surface with intact PDL and lamina dura. The appearance of the ERR may help indicate the nature of the lesion, where benign lesions tend to displace teeth and where more aggressive lesions, such as malignant tumors, tend to cause extensive root resorption, showing either blunting of the root apex or spiked/knife-edge destruction (Fig. 2.29).[165]

www.konkur.in

FIG. 2.29 **A,** External cervical resorption was evaluated in this patient after PA radiographic image, and **(B)** visual examination showed pathognomonic signs of this lesion *(yellow arrow)*. A CBCT image was exposed to determine the true extent of resorption and restorability. **C,** The lesion showed a perforative defect at the CEJ on the facial *(yellow arrow)* and **(D)** palatal aspects *(yellow arrow)*. **D,** The presence of an intact layer of mineralized dentin, the "pericanalar resorption-resistant sheet" *(blue arrow)*, is a hallmark of this condition.

Set of four radiographs are marked A through D as follows:

A) Radiograph shows dark patch at the root of tooth on the right and radiolucent roots on the left.

B) Close-up view shows receding gum line below tooth.

C) Tooth shows fracture at one side of the tooth on the left between crown and root.

D) Tooth shows less-density pulp along with a fracture on the right.

Source: (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, GA].)

External inflammatory resorption resulting from pulpal necrosis or traumatic injuries is radiographically characterized by concave and occasionally patchy excavations of low density that affect the root surface

Telegram: @dental_k

www.konkur.in

and the supporting bone. Lesion borders are irregular, show loss of lamina dura, and are often associated with the apical region due to the proximity of the apical terminus.

External replacement resorption is caused by damage to the periodontium, which may result from dental trauma or orthodontic treatment.[74] The teeth are immobile, have a distinctive tone on percussion, and show disappearance of the normal periodontal membrane—features consistent with a direct union with alveolar bone.

External cervical resorption is a result of damage to the cementum layer of the root by clastic activity. Further destruction of cementum and then dentin[93] is dependent on stimulating factors that include microorganisms from the periodontium.[82] ECR is a complex and aggressive process and usually begins at the cervical region and may result in a pink discoloration of the overlying enamel. Patients affected by ECR are usually asymptomatic because the pericanal resorption-resistant/retarding sheet protects the pulp until the later stages.[209] Orthodontic treatment, trauma, parafunctional habits, and malocclusion account for most of these lesions, with a combination of factors resulting in increased occurance.[167] Intraoral radiography shows significant variability, with areas of low density affecting the dentin extending coronally and/or apically with sometimes greater destruction distant from the origin on the buccal or lingual/palatal aspect of the root, confounding 2D radiographic assessment. The radiographic appearance of these lesions is often mixed owing to the level of fibro-osseous and granulomatous tissue present. External cervical resorption is located on the external surface of the root, showing an intact root canal wall that can be traced through the lesion, whereas IRR is continuous with the canal wall.

External cervical resorption is always associated with bony resorption, making comparability of laboratory studies problematic because the lesions lack the changes in the periodontal membrane and associated bony changes that would improve visualization. The early stages of ERR are difficult to view with conventional radiography, and lesions less than 0.6 mm in diameter and 0.3 mm in depth could not be detected. Medium-sized lesions were visible in 6 of 13 cases, with improved visualization for proximal lesions without regard to the root third being examined.[15] Patel et al. showed that the accuracy of parallax and single parallel PA radiographs were similar,

Telegram: @dental_k

www.konkur.in

and that more teeth were considered unrestorable when assessed with CBCT (78.7%) than with PA imaging (49.3%).[158] This study further highlights the benefits of using CBCT to assess ECR.[158] Vaz de Souza et al. showed that CBCT was significantly better than PA radiography at diagnosing ECR according to the Heithersay classification.[216]

ERR is difficult to detect if the lesion is confined to the buccal, palatal, or lingual surfaces of the root.[30,83] Liedke et al.[125] conducted systematic diagnostic performance tests and showed similar sensitivity and specificity among the different voxel sizes studied (0.4, 0.3, and 0.2 mm); however, the likelihood ratio showed better probability of correct identification of ERR with either 0.3 or 0.2 mm scans. These researchers suggested the use of a 0.3 mm voxel size protocol rather than a 0.2 mm one, to reduce scanning time and the resulting dose.[125] Although voxel size is an important consideration, the SNR of different detectors, the radiation dose, viewing conditions, and the processing algorithms also affect detection probability.

Even though many in vitro studies have been performed on the ability of CBCT to detect root resorption, additional evaluations that use in vivo methodology will add to the cumulative knowledge.

Endodontic treatment outcomes assessment

The reduction of inflammation and healing through regeneration or repair are the ideal outcomes for endodontic treatment.[148] However, endodontic treatment outcome predictors using PA radiographs and CBCT imaging have been shown to vary and are influenced by factors such as patient inclusion and exclusion criteria.[124] Historically, PA radiographs and physical examinations were used to determine the success of endodontic treatment, and the absence of posttreatment periradicular radiolucencies and symptoms was considered by many to be the criterion for success. However, these planar imaging-based studies have resulted in an overestimation of successful outcomes, compared to CBCT assessments,[230] because AP confined within the cancellous bone or lesions covered by a thick cortex may be undetectable with conventional radiographic assessments.[26] Additional discrepancies between PA radiography and CBCT have resulted from geometric distortion, limiting comparisons of temporal evaluations, even with careful attention to

Telegram: @dental_k

www.konkur.in

paralleling technique factors.[133]

A clinical study comparing the sensitivity, specificity, predictive values, and accuracy of PA and panoramic radiography and CBCT imaging in 888 consecutive patients showed that the prevalence of AP in root-treated teeth was 17.6%, 35.3%, and 63.3%, respectively. Conventional radiography showed increased accuracy when the larger lesions were assessed.[67]

Using histologic examination as the gold standard, a systematic review and meta-analysis of the literature by Dutra et al.[121] compared different radiographic modalities in the binary assessment of AP versus no lesion in humans—a very important measure in outcome studies. Significantly, only nine studies were ultimately selected for qualitative synthesis and only six for meta-analysis. All included studies were limited by using only artificially induced apical lesions, possible bias, variation in bone lesion sizes, poor or no inter-and intraobserver agreement, and except for one study, did not evaluate the maxilla, where more tissue compression occurred. This study showed the accuracy values of 0.72 for digital PA radiographs, 0.73 for film-based PA radiographs, and 0.96 for CBCT.[121]

Outcome predictors identified with PA radiographs and CBCT scans may be different depending on the research performed. Liang et al.[124] retrospectively evaluated 115 endodontically treated teeth with vital pulps 2 years after treatment. The authors noted that the recall rate of 36% was comparable to that in other studies, but the result may have been affected because patients with symptomatic or already extracted teeth may not have responded. This lost-to-follow-up cohort significantly reduced the level of evidence.[75] PA radiography identified PA lesions in only 12.6% of teeth compared to CBCT images, which identified 25.9% of teeth with PA lesions. In multivariate logistic regression analysis, the extent of root fillings and density were outcome predictors when using PA imaging, whereas density of root fillings and quality of the coronal restoration were outcome predictors when using CBCT scans.

The predictive value and diagnostic accuracy of radiologic assessments are critical to the practice of dentistry, and the diagnostic value of radiographs depends on the radiograph's ability to show the histology of AP. De Paula-Silva et al.[53] evaluated the periapex of 83 root-treated and untreated dogs' teeth using PA radiography, CBCT scans, and histopathologic analysis. PA

Telegram: @dental_k

www.konkur.in

radiography detected AP in 71% of roots; CBCT scans detected AP in 84%; and histologic analysis detected AP in 93%. These findings, corroborated by other studies,[38,87,178] emphasized the low negative predictive value (NPV) of PA radiography at 0.25, showing that when the PA tissues had a normal appearance, 75% actually had AP. CBCT scans resulted in an NPV almost two times higher than that for PA radiography; however, CBCT scans were not able to detect some AP that was confined to the apical foramen or had little volumetric bone loss. The positive predictive value was the same for PA radiography and CBCT scans compared with histologic examination, but true positive and true negative diagnosis of AP using CBCT scans occurred in 92% of cases.

Continuing development of sophisticated postprocessing software now allows for modeling of AP and anatomic structures in 3D. Using either manual or semiautomatic segmentation, the resulting virtual models allow for alignment and analysis of temporal changes, with some limitations. Bony changes can be depicted in quantitative and qualitative datasets, showing bone density changes such as repair or osteolysis. One of these programs, ITK-SNAP, an open-source software originally developed for MRI assessments, allows for construction of virtual 3D models from DICOM datasets, showing volumetric measurements in voxels and cubic millimeters. Additional tools allow for calculation of the mean intensity of the PA rarifying lesion(s) of interest. The resulting scan data can then be exported in STerioLithography format (STL) and shown in 3DMeshMetric software (Figs. 2.30 and 2.31).

Risks and benefits for patients who are medically complex and subject to possible increased morbidity from AP, such as patients with an altered immune system (i.e., chemotherapy or anti-HIV protocols or prosthetic joints and/or infective endocarditis), should be considered in the decision about whether to expose a CBCT scan. The American Academy of Periodontology has published a position paper stating that periodontal disease may contribute to adverse systemic health conditions.[186] The scientific basis for the relationship of AP and adverse systemic health conditions has not been established[43]; however, new associations between AP and systemic health should be predicated on research that uses CBCT in the detection of endodontic disease.[49]

The determination of successful outcomes is nuanced and complex. New AAE-sponsored initiatives to study outcomes is underway and will ultimately result in an agreed standardized set of criteria, called a “core outcomes set,” facilitating data synthesis and possibly resulting in more transparent and complete reporting.

Dental implant case planning

Successful endosseous implant site assessment requires the development of a prosthetically driven approach,[2] with special emphasis on the evaluation of bone volume, the osseous topography, and the location of anatomic structures in relation to the positioning of the implant. The AAOMR has published advisory recommendations suggesting all radiographic studies should

Telegram: @dental_k

www.konkur.in

interface with the dental and medical histories, clinical examinations, and treatment planning. Panoramic radiography, which may be supplemented by PA radiography, should be used for initial imaging assessments. Cross-sectional imaging, including CBCT, should not be used as an initial imaging examination. The AAOMR affirms the need for cross-sectional imaging in the preoperative diagnostic phase, recommending CBCT because it provides the highest diagnostic yield at an acceptable radiation dose risk. CBCT should be used at the smallest FOV necessary, with optimized technique factors, to minimize radiation dose in accordance with the ALARA principle.[213]

CBCT allows for precise planning and delivery of implants that can reproduce the anatomy with submillimetric accuracy, leading to improved outcomes.[201] The use of CBCT to assess linear measurements, proximity to vital anatomic structures, mapping of the alveolar ridge topography, and fabrication of surgical guides is supported by the dental literature. The use of CBCT to gauge bone density, provide intraoperative surgical navigation, and assess implant integration is generally considered an area that requires further research.[25]

Virtual implant planning using CBCT data allows clinicians to visualize the result before the commencement of treatment, facilitating the virtual investigation of multiple treatment scenarios until the best plan is attained. The evaluation of bone dimensions, bone quality, the long axis of the alveolar bone, internal anatomy, and jaw boundaries; the detection of pathologic features; and the transfer of radiographic information are the main imaging goals. Use of static, CT-generated guide stents and dynamic navigation systems provide improved accuracy when compared with freehand methods.[29]

Pathoses of the jaws, such as retained root tips, inflammatory lesions, cysts, and tumors, in addition to extraoral structures, such as the sinuses and temporomandibular joints (TMJs), must also be assessed.[97] CBCT imaging should be considered to evaluate implant sites in the region of teeth with a high likelihood of periradicular pathosis.[239]

3D-guided endodontics

3D-guided surgical and nonsurgical endodontic treatment is an emerging

Telegram: @dental_k

www.konkur.in

application using guides manufactured with the aid of CBCT images and intraoral scanning of the area of interest. Although studies with high level of evidence is lacking in this area, several in vitro studies and case reports have been published.[5,48,118,132]

The technology is currently being utilized in endodontic treatment of teeth with calcified canals and teeth that have anatomical variations of the root canal system. A template is created by superimposition of CBCT images on intraoral scanned images with sleeves placed in the images for creating a 3D printed guide with a directed sleeve. Most often implant treatment planning software is used for the creation of the guide (Fig. 2.32).[48,118,132] Recent study evaluating access on calcified teeth showed a higher detection of canal (91.7% vs. 41.7%) using guided approach. There was significantly lower amount of tooth substance loss using the guided access (49.9 mm vs. 9.8 mm).[48]

Endodontic microsurgery aims to create conservative osteotomy utilizing magnification and microsurgical instruments. Various studies have shown improved prognosis with the microsurgical procedures when compared to traditional endodontic surgery.[210] Surgical treatment planning with CBCT images have aided clinicians in identifying anatomical structures in the surgical area and increasing precision of the procedure.[119] Surgical endodontics with 3D-guided templates has further helped in making microsurgical procedures more precise.[3,5,71] A recent study comparing "freehand" CBCT-aided surgery to surgery using template guides showed a deviation of 1.743 mm when using guides from the target location identified on preoperative CBCT. Freehand surgery showed a deviation of 2.638 mm.[3] Use of prefabricated grids placed while acquiring CBCT images were used as guides for creating osteotomy during endodontic surgery in a recent study. Deviation from the target point was significantly lower when compared to nonguided drilling (Fig. 2.33).[71]

Image perception and viewing environment

Medical image perception is an important area of knowledge, and ongoing research relies on an understanding of perceptual issues, such as psychological factors, dwell time, visual search physiology, search tactics, appreciation for the reading environment, and fatigue factors, to increase search satisfaction. Understanding these issues may improve the ability to interpret and report on dental radiographic findings.[185]

The increasing use of digital radiography in the dental environment has led to a sea change in workflow and the necessity for new ways to view and document radiographic images. Simple to accomplish, but important to improve, are the viewing conditions for softcopy interpretation, including moderately reduced ambient lighting, ranging from 25 to 40 lux.[36]

The future of cone-beam computed tomography

The first decade of the 21st century saw the development of a wide range of

Telegram: @dental_k

www.konkur.in

CBCT applications, especially in dentistry. Lower radiation dose, higher spatial resolution, smaller FOV, and relatively lower cost may contribute to CBCT becoming the standard of care in 3D dentomaxillofacial imaging in selected cases. CBCT systems are increasingly being used in medical applications, such as operating rooms, emergency departments, intensive care units, and private otolaryngology offices. Operating room–based C-arm systems have been in use for a number of years, with applications in interventional angiography, cancer surgery, vascular surgery, orthopedic surgery, neurosurgery, and radiotherapy.[69] Applications in otolaryngology and mammography are common, and imaging of extremities in weight-bearing scenarios is under development. Many of these applications rely on systems that use task-specific protocols that benefit from CBCT's 2D FPDs, which allow for a single rotation of the source to generate a study of the region of interest, as opposed to complex MDCTs that use redundant imaging via multiple slice acquisitions to generate a 3D volume.[196]

The introduction of new, high-performance, flat-panel detectors and software algorithms centering on improving the noise-power spectrum and noise-equivalent quanta will continue to increase the utility of CBCT systems in the future. Areas of research include (1) image perception and image quality assessment, to better understand how physicians and dentists analyze radiographic images and thereby improve diagnostic decision making[202]; (2) iterative reconstruction that uses sophisticated algorithms to reduce artifacts; (3) known-component reconstructions that use a model-based 3D image reconstruction and iterative software to reduce image artifacts in the presence of metallic devices such as screws and implants; (4) image registration to align tissues for image-guided surgery and outcomes assessment;[141] (5) image-guided procedures that provide instantaneous surgical navigation; (6) segmentation to allow discrimination between normal and diseased tissues and permit volumetric measurements (see Figs. 2.30 and 2.31); and (7) use of metallic artifact reduction algorithms that help partly remove distracting signals and artifacts from a CBCT study. Note, however, that there is potential for loss of diagnostic information as well, especially in situations where high spatial resolution is required, such as detection of vertical root fractures in roots with posts.

Telegram: @dental_k

www.konkur.in

Magnetic resonance imaging

MRI has been explored as a potentially useful imaging modality in dentistry, and in particular endodontics. Advantages include nonexposure to ionizing radiation; capability to acquire images in any desired plane without having to reformat data; capability to image edema, effusion, and inflammation in the adjacent bone; spread of infection; better soft-tissue delineation; and assessment of root structure and variations in canal morphology and/or number. Disadvantages include high cost of a scanner, longer acquisition times, interpretation challenges due to differences in appearance of hard and soft tissue as compared to CBCT or conventional radiographs, potential for motion artifacts, limited resolution, lack of easy access, choice of appropriate protocol based on scanner parameters, and generation of artifacts unlike those seen on x-ray–based images. All of these challenges need to be addressed in order for the imaging modality to be widely accepted and used in endodontics. Various pulse sequences have been developed for optimizing image quality for endodontic diagnostic purposes, but a magnetic field strength that is sufficiently high to improve resolution and further fine-tuning of task-specific regional receiver coils are required.[20,57]

Conclusions

Digital radiography has several advantages and has become an indispensable diagnostic tool for many dentists in daily practice. Once the digital image appears on the monitor, the dental x-ray software allows image enhancement, which should be used with caution and be based on the diagnostic task. Inappropriate use of enhancement has been shown to adversely affect diagnosis.[142] If digital radiographs are exported using various software packages created for graphic design and image manipulation, digital information can be altered, added, or removed. The DICOM standard has been accepted as the universal standard for image transmission and archiving, so that each image can be transmitted and stored without the use of proprietary software that would seriously limit its distribution. DICOM ensures that all images are readable in any viewing software without loss of fidelity or diagnostic information. Image enhancement features of digital radiography allow mishandling of images, leading to potential abuse.

Telegram: @dental_k

www.konkur.in

Published studies illustrate the potential for fraudulent use of digital radiography.[42]

There is a dearth of studies related to the diagnostic performance of the different sensor types currently available on the market. Slight to moderate differences in spatial resolution capabilities exist. With rapid advancement in sensor technology and frequent software upgrades, selection of one system over another for a specific diagnostic task may appear challenging. A review of the most commonly used solid-state sensors notes that most systems perform comparably with intraoral film and also allow for postprocessing of images, which is not possible with film-based images. Other factors that assume significance in this context are the availability of technical and customer support, frequency of both hardware and software upgrades, dimensions of the sensor and its active area, number of sensors needed in a practice (and thus cost issues), the detector quantum efficiency (DQE), and conformance to the DICOM standard for seamless integration with other systems. CCD/CMOS sensors appear to offer the best contrast and spatial resolution, in addition to facilitating instantaneous image capture, and therefore are recommended for endodontic applications. Careful and appropriate image processing further helps tease out the signal of interest. In an enterprise-wide setting or in larger private practices that have multiple specialty areas, PSP-based sensors may be more cost effective for large volume imaging (e.g., full mouth series of radiographs). However, at least one or two CCD/CMOS-based systems should be available for faster image acquisition, such as for endodontic purposes and intraoperative procedures.

It is recommended that the literature be constantly reviewed for updates on digital radiography and advanced imaging modalities for specific endodontic applications because hardware and software upgrades continue to make rapid progress. Previous studies have shown that most digital images performed comparably to conventional intraoral film for a variety of diagnostic tasks. Most of these studies were done with earlier generation sensors. The advances in sensor technology have resulted in greatly enhanced image quality, and this trend is expected to continue. Also of interest in the future will be the use of task-based, appropriate image processing parameters that result in a reduced radiation dose and significant enhancement of the diagnostic information. Automation of this process will result in faster and

Telegram: @dental_k

www.konkur.in

more consistent image processing based on the diagnostic task. Such procedures are routinely carried out in medical radiology.

Three-dimensional imaging will continue to be used extensively as sensor characteristics improve and more user-friendly software is introduced. As bit-depth and spatial resolution of images increase, CBCT will continue to be explored for more applications in endodontics. Image interpretation also is important. Occult pathology and incidental findings in adjacent regions can be easily missed or go unrecognized by those who have not received specific training in the interpretation of regional anatomy. Image processing can greatly alter signal characteristics, thus rendering the task fairly challenging. Besides, if other pathoses are discovered, additional imaging may be necessary, including MRI, nuclear medicine studies, or even MDCT, for the evaluation of soft tissues, with and without the use of contrast.

The advent of 3D imaging has provided the endodontist with tools that were not available until now, facilitating interactive image manipulation and enhancement and thus significantly increasing the amount of information that can be gleaned from a volume. Lack of distortion, magnification, artifacts associated with conventional radiography, and the relative low radiation dose compared to medical-grade CT will result in more clinicians adopting such technology to enable accurate diagnoses and treatment planning, in addition to long-term follow-up and the evaluation of healing. Judicious use of CBCT and all other imaging modalities using ionizing radiation is advocated. The AAE/AAOMR position paper provides recommendations for the use of CBCT in endodontics[1] and is presented at the end of this chapter.

When the clinician works with different vendor products, it is important to have a quality assurance program in place. This is not being done currently. Additionally, accreditation of stand-alone imaging laboratories is now a requirement for reimbursement of medical and dental diagnostic procedures from government agencies and some major third-party insurance providers. Several states are considering enforcing this requirement to prevent abuse of CBCT.

Likewise, definitive referral criteria are lacking. Indications, contraindications, and choice of alternate imaging modalities need to be considered before CBCT is used. There is a learning curve to this technology, and appropriate positioning, choice of exposure parameters (and thus the

Telegram: @dental_k

www.konkur.in

effective dose), reconstruction schemes, choice of postprocessing algorithms based on diagnostic task, voxel sizes, and cost must be considered. The literature contains few studies to help us formulate definitive guidelines for the use of CBCT in dentistry.

It is equally important to record the doses associated with each study. Accreditation criteria have been developed by the Intersocietal Accreditation Commission for CT in dentistry that are useful for ensuring the safe use of these units. The lowest possible dose must be imparted to the patient as part of a radiologic examination to minimize stochastic effects that have no known threshold for expression. No dose can be considered a “safe dose.” The benefits of any radiographic study must outweigh the risks. All studies must be interpreted fully because signals from adjacent areas may appear in the volume of interest, including small FOV studies. Retakes can be avoided by adhering to protocol selection based on the task at hand. The ALARA principle must be followed, regardless of the dose values reported by the vendor, to optimize the dose for the specific examination. Use of thyroid collars and lead aprons is recommended in the NCRP guidelines, as long as they do not interfere with image acquisition.

Joint position statement of the American Association of endodontists and the American Academy of Oral and Maxillofacial Radiology on the use of cone beam computed tomography in endodontics: 2015/2016 update

This statement was prepared by the Special Committee to Revise the Joint AAE/AAOMR Position Statement on Use of CBCT in Endodontics and approved by the AAE Board of Directors and AAOMR Executive Council in 2016.

Introduction

This updated joint position statement of the American Association of Endodontists (AAE) and the American Academy of Oral and Maxillofacial Radiology (AAOMR) is intended to provide scientifically based guidance to clinicians regarding the use of cone-beam computed tomography (CBCT) in endodontic treatment and reflects new developments since the 2010 statement.[1] The guidance in this statement is not intended to substitute for a clinician's independent judgment in light of the conditions and needs of a specific patient.

Endodontic disease adversely affects quality of life and can produce significant morbidity in afflicted patients. Radiography is essential for the successful diagnosis of odontogenic and nonodontogenic pathoses, treatment of the root canal systems of a compromised tooth, biomechanical instrumentation, evaluation of final canal obturation, and assessment of

Telegram: @dental_k

www.konkur.in

healing.

Until recently, radiographic assessments in endodontic treatment were limited to intraoral and panoramic radiography. These radiographic technologies provide two-dimensional representations of three-dimensional anatomic structures. If any element of the geometric configuration is compromised, the image may demonstrate errors.[2] In more complex cases, radiographic projections with different beam angulations can allow parallax localization. However, complex anatomy and surrounding structures can render interpretation of planar images difficult.

The advent of CBCT has made it possible to visualize the dentition, the maxillofacial skeleton, and the relationship of anatomic structures in three dimensions.[3] CBCT, as with any technology, has known limitations, including a possible higher radiation dose to the patient. Other limitations include the potential for artifact generation, high levels of scatter and noise, and variations in dose distribution within a volume of interest.[4]

CBCT should be used only when the patient's history and a clinical examination demonstrate that the benefits to the patient outweigh the potential risks. CBCT should not be used routinely for endodontic diagnosis nor for screening purposes in the absence of clinical signs and symptoms. Clinicians should use CBCT only when the need for imaging cannot be met by lower dose two-dimensional (2D) radiography.

Volume size(s)/field of view

There are numerous CBCT equipment manufacturers, and several models are available. In general, CBCT is categorized into large, medium, and limited-volume units based on the size of their "field of view" (FOV). The size of the FOV describes the scan volume of CBCT machines. That volume determines the extent of anatomy included. It is dependent on the detector size and shape, beam projection geometry, and the ability to collimate the beam. To the extent practical, FOV should only slightly exceed the dimensions of the anatomy of interest.

Generally, the smaller the FOV, the lower the dose associated with the study. Beam collimation limits the radiation exposure to the region of interest and helps ensure that an optimal FOV can be selected based on disease

Telegram: @dental_k

www.konkur.in

presentation. Smaller scan volumes generally produce higher resolution images. Because endodontics relies on detecting small alterations such as disruptions in the periodontal ligament space, optimal resolution should be sought.[5]

The principal limitations of large FOV CBCT imaging are the size of the field irradiated and the reduced resolution compared to intraoral radiographs and limited volume CBCT units with inherent small voxel sizes.[4] The smaller the voxel size, the higher is the spatial resolution. Moreover, the overall scatter generated is reduced due to the limited size of the FOV. Optimization of the exposure protocols keeps doses to a minimum without compromising image quality. If a low-dose protocol can be used for a diagnostic task that requires lower resolution, it should be employed, so long as strong indications to the contrary are absent.

In endodontics, the area of interest is limited and determined prior to imaging. For most endodontic applications, limited FOV CBCT is preferred to medium or large FOV CBCT because there is less radiation dose to the patient, higher spatial resolution, and shorter volumes to be interpreted.

Dose considerations

Selection of the most appropriate imaging protocol for the diagnostic task must be consistent with the “as low as reasonably achievable” (ALARA) principles that every effort should be made to reduce the effective radiation dose to the patient “as low as reasonably achievable.” Because radiation dose for a CBCT study is higher than that for an intraoral radiograph, clinicians must consider overall radiation dose over time. For example, will acquiring a CBCT study now eliminate the need for additional imaging procedures in the future? It is recommended to use the smallest possible FOV, the smallest voxel size, the lowest mA setting (depending on the patient’s size), and the shortest exposure time in conjunction with a pulsed exposure-mode of acquisition.

If extension of pathoses beyond the area surrounding the tooth apices or a multifocal lesion with possible systemic etiology is suspected, and/or a nonendodontic cause for devitalization of the tooth is established clinically, appropriate larger field of view protocols may be employed on a case-by-case

Telegram: @dental_k

www.konkur.in

basis.

There is a special concern with overexposure of children (up to and including 18-year-olds) to radiation, especially with the increased use of computed tomography scans in medicine. The AAE and the AAOMR support the Image Gently Campaign led by the Alliance for Radiation Safety in Pediatric Imaging. The goal of the campaign is "to change practice; to raise awareness of the opportunities to lower radiation dose in the imaging of children." Information on use of CT is available at http://www.imagegently.org/Procedures/ComputedTomography.aspx.

Interpretation

If a clinician has a question regarding image interpretation, it should be referred to an oral and maxillofacial radiologist.[6]

Recommendations

The following recommendations are for limited FOV CBCT scans.

Diagnosis

Endodontic diagnosis is dependent upon thorough evaluation of the patient's chief complaint, history, and clinical and radiographic examination. Preoperative radiographs are an essential part of the diagnostic phase of endodontic therapy. Accurate diagnostic imaging supports the clinical diagnosis.

Recommendation 1: Intraoral radiographs should be considered the imaging modality of choice in the evaluation of the endodontic patient.

Recommendation 2: Limited FOV CBCT should be considered the imaging modality of choice for diagnosis in patients who present with contradictory or nonspecific clinical signs and symptoms associated with untreated or previously endodontically treated teeth.

Rationale

- In some cases, the clinical and planar radiographic examinations are inconclusive. Inability to confidently determine the etiology of

Telegram: @dental_k

www.konkur.in

endodontic pathosis may be attributed to limitations in both clinical vitality testing and intraoral radiographs to detect odontogenic pathoses. CBCT imaging has the ability to detect periapical pathosis before it is apparent on 2D radiographs.[7]

- Preoperative factors such as the presence and true size of a periapical lesion play an important role in endodontic treatment outcome. Success, when measured by radiographic criteria, is higher when teeth are endodontically treated before radiographic signs of periapical disease are detected.[8]
- Previous findings have been validated in clinical studies in which primary endodontic disease detected with intraoral radiographs and CBCT was 20% and 48%, respectively. Several clinical studies had similar findings, although with slightly different percentages.[9,10] Ex vivo experiments in which simulated periapical lesions were created yielded similar results.[11,12] Results of in vivo animal studies, using histologic assessments as the gold standard, also showed similar results as those observed in human clinical and ex vivo studies.[13]
- Persistent intraoral pain following root canal therapy often presents a diagnostic challenge. An example is persistent dentoalveolar pain also known as atypical odontalgia.[14] The diagnostic yield of conventional intraoral radiographs and CBCT scans was evaluated in the differentiation between patients presenting with suspected atypical odontalgia versus symptomatic apical periodontitis, without radiographic evidence of periapical bone destruction.[15] CBCT imaging detected 17% more teeth with periapical bone loss than conventional radiography.

Initial treatment

Preoperative

Recommendation 3: Limited FOV CBCT should be considered the imaging modality of choice for the initial treatment of teeth with the potential for extra canals and suspected complex morphology, such as mandibular anterior teeth, and maxillary and mandibular premolars and molars, and dental anomalies.

Telegram: @dental_k

www.konkur.in

Intraoperative

Recommendation 4: If a preoperative CBCT has not been taken, limited FOV CBCT should be considered as the imaging modality of choice for intra-appointment identification and localization of calcified canals.

Postoperative

Recommendation 5: Intraoral radiographs should be considered the imaging modality of choice for immediate postoperative imaging.

Rationale

- Anatomical variations exist among different types of teeth. The success of nonsurgical root canal therapy depends on the identification of canals, the cleaning, shaping and obturation of root canal systems as well as the quality of the final restoration.
- 2D imaging does not consistently reveal the actual number of roots and canals. In studies, data acquired by CBCT showed a very strong correlation between sectioning and histologic examination.[16,17]
- In a 2013 study, CBCT showed higher mean values of specificity and sensitivity when compared to intraoral radiographic assessments in the detection of the MB2 canal.[18]

Nonsurgical retreatment

Recommendation 6: Limited FOV CBCT should be considered the imaging modality of choice if clinical examination and 2D intraoral radiography are inconclusive in the detection of vertical root fracture (VRF).

Rationale

- In nonsurgical retreatment, the presence of a vertical root fracture significantly decreases prognosis. In the majority of cases, the indication of a vertical root fracture is more often due to the specific pattern of bone loss and periodontal ligament space enlargement than to direct visualization of the fracture. CBCT may be

Telegram: @dental_k

www.konkur.in

recommended for the diagnosis of vertical root fracture in unrestored teeth when clinical signs and symptoms exist.

- Higher sensitivity and specificity were observed in a clinical study where the definitive diagnosis of vertical root fracture was confirmed at the time of surgery to validate CBCT findings, with sensitivity being 88% and specificity 75%.[19] Several case series studies have concluded that CBCT is a useful tool for the diagnosis of vertical root fractures. In vivo and laboratory studies evaluating CBCT in the detection of vertical root fractures agreed that the sensitivity, specificity, and accuracy of CBCT were generally higher and reproducible.[20,21] The detection of fractures was significantly higher for all CBCT systems when compared to intraoral radiographs. However, these results should be interpreted with caution because detection of vertical root fracture is dependent on the size of the fracture, presence of artifacts caused by obturation materials and posts, and the spatial resolution of the CBCT.

Recommendation 7: Limited FOV CBCT should be the imaging modality of choice when evaluating the nonhealing of previous endodontic treatment to help determine the need for further treatment, such as nonsurgical, surgical or extraction.

Recommendation 8: Limited FOV CBCT should be the imaging modality of choice for nonsurgical re-treatment to assess endodontic treatment complications, such as overextended root canal obturation material, separated endodontic instruments, and localization of perforations.

Rationale

- It is important to evaluate the factors that impact the outcome of root canal treatment. The outcome predictors identified with periapical radiographs and CBCT were evaluated by Liang et al.[22] The results showed that periapical radiographs detected periapical lesions in 18 roots (12%) as compared to 37 on CBCT scans (25%); 80% of apparently short root fillings based on intraoral radiographs images appeared flush on CBCT. Treatment outcome, length and density of

Telegram: @dental_k

www.konkur.in

root fillings, and outcome predictors determined by CBCT showed different values when compared with intraoral radiographs.

- Accurate treatment planning is an essential part of endodontic retreatment. Incorrect, delayed, or inadequate endodontic diagnosis and treatment planning places the patient at risk and may result in unnecessary treatment. Treatment planning decisions using CBCT versus intraoral radiographs were compared to the gold standard diagnosis.[23] An accurate diagnosis was reached in 36% to 40% of the cases with intraoral radiographs compared to 76% to 83% with CBCT. A high level of misdiagnosis was noted in invasive cervical resorption and vertical root fracture. In this study, the examiners altered their treatment plan after reviewing the CBCT in 56% to 62.2% of the cases, thus indicating the significant influence of CBCT.

Surgical retreatment

Recommendation 9: Limited FOV CBCT should be considered as the imaging modality of choice for presurgical treatment planning to localize root apex/apices and to evaluate the proximity to adjacent anatomical structures.

Rationale

The use of CBCT has been recommended for treatment planning of endodontic surgery.[24,25] CBCT visualization of the true extent of periapical lesions and their proximity to important vital structures and anatomical landmarks is superior to that of periapical radiographs.

Special conditions

a. Implant placement

Recommendation 10: Limited FOV CBCT should be considered as the imaging modality of choice for surgical placement of implants.[26]

b. Traumatic injuries

Recommendation 11: Limited FOV CBCT should be considered the

Telegram: @dental_k

www.konkur.in

imaging modality of choice for diagnosis and management of limited dento-alveolar trauma, root fractures, luxation, and /or displacement of teeth and localized alveolar fractures, in the absence of other maxillofacial or soft-tissue injury that may require other advanced imaging modalities.[27]

c. Resorptive defects

Recommendation 12: Limited FOV CBCT is the imaging modality of choice in the localization and differentiation of external and internal resorptive defects and the determination of appropriate treatment and prognosis.[28,29]

Outcome assessment

Recommendation 13: In the absence of clinical signs or symptoms, intraoral radiographs should be considered the imaging modality of choice for the evaluation of healing following nonsurgical and surgical endodontic treatment.

Recommendation 14: In the absence of signs and symptoms, if limited FOV CBCT was the imaging modality of choice at the time of evaluation and treatment, it may be the modality of choice for follow-up evaluation. In the presence of signs and symptoms, refer to Recommendation #7.

Rationale

- Use of limited FOV CBCT for evaluation of healing following nonsurgical and surgical treatment must be considered on a case-by-case basis, with due consideration given the risks and benefits of exposing the patient to ionizing radiation, the patient's history, clinical findings, mode of endodontic intervention, preexisting radiographic appearance, temporal changes, and any other systemic or extraneous factors that could confound the healing process.
- Accurate diagnosis of complete and uneventful healing as determined radiographically, with unequivocal clinical correlation supporting the radiographic diagnosis, is challenging.[30–33] The healing process is dependent on various factors, both extraneous and

Telegram: @dental_k

www.konkur.in

host related. In the future, once the parameters associated with healing are fully confirmed by evidence-based studies, the use of limited FOV CBCT for outcome assessment can be better interpreted.

3: Lesions that mimic endodontic pathosis

David J. Landwehr

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Importance of differential diagnosis

It has long been recognized that periapical cysts and granulomas make up the majority of radiographic lesions in the tooth-bearing regions of the jaws.[17,28,137,243] Many of these radiolucencies are asymptomatic and discovered on routine radiographs. For clinicians, it is easy to assume that any periapical radiolucency associated with pain is of pulpal or inflammatory origin, especially if the tooth has a significant restorative history. However, numerous disease entities of variable clinical significance can be identified in the periradicular regions, and differentiating the typical endodontic presentation from that of a potentially more life-threatening or insidious etiology is of critical importance to ensure ideal management and outcome (Fig. 3.1).[139,141,187,216,235]

FIG. 3.1 A well-defined radiolucency near the apex of the maxillary first premolar and canine. Although the premolar did not respond to pulp testing, the location of the lesion and clinical presentation were suspicious and a biopsy revealed an odontogenic keratocyst.

Radiograph shows radiolucency between canine and first premolar. Crown of the first premolar is less dense toward the edge and is fused to adjacent canine.

Limits of pulp testing

The use of pulp testing in conjunction with medical history, dental history, clinical examination and radiographic findings is considered the standard routine to differentiate pulpal pathology from that of a noninflammatory or nondental etiology.[73] In spite of this, pulp testing has significant limitations as historical studies suggest there is not a correlation between the histologic status of the pulp and a patient's clinical signs and symptoms.[228,229] However, a more recent investigation reported a correlation between the histologic and clinical diagnosis of irreversible pulpitis in 84.4% of cases and agreement was even higher for normal pulps and reversible pulpitis.[209] It is

Telegram: @dental_k

www.konkur.in

not uncommon to encounter patients with extensive caries throughout the dentition, suggesting significant pulpal inflammation, but no history of pain (Fig. 3.2).

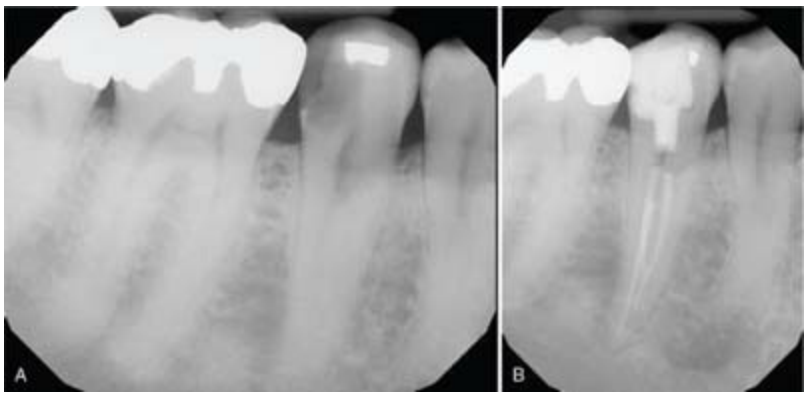

FIG. 3.2 **A,** Deep caries in the mandibular second premolar, but the patient was asymptomatic with no history of pain. **B,** Tooth #29 responded normally to both cold and electric pulp testing, but nonsurgical root canal treatment was completed for restorative reasons.

A) Radiograph of lower jaw shows a small radiopaque rectangular patch with a large radiolucent blotch in the second premolar toward the molar tooth.

B) Radiograph shows second premolar with two filled root canals and a large radiopaque region in the crown.

The accuracy of diagnostic testing is further complicated by a lack of proprioceptive fibers in the dental pulp, which results in the patient's inability to localize the source of pain.[167,228] Thermal and electric pulp testing are actually a measure of the pulp's ability to sense a stimulus rather than a representation of overall health, and these measurements are susceptible to both false-positive and false-negative responses.[5,98,118,119,168,197,264] Given the diagnostic limitations of pulp testing, many clinicians place an undue amount of importance on radiographic findings.

Limits of radiology

According to a 2012 systematic review of cross-sectional studies evaluating the periapical status of over 300,000 teeth, 5% of all teeth had periapical

Telegram: @dental_k

www.konkur.in

radiolucencies.[188] The prevalence of periapical radiolucencies in the population illustrates the critical importance of being able to formulate an accurate differential diagnosis of these radiographic abnormalities. Historically, radiographs could not demonstrate periapical lesions located in cancellous bone until mineral loss resulted in a lesion of 1 to 7 mm.[18,20] This suggests the prevalence of periapical inflammatory disease is even higher because all teeth with inflamed or necrotic pulps will not result in a periapical radiolucency. Different anatomical locations within the oral cavity have variable likelihoods for identification of a radiolucent lesion based on the thickness of the cortical plate and volume of bone.[19] Additionally, the actual size of a radiolucent defect is larger clinically than can be appreciated with 2D radiographic imaging.[230] In less common clinical situations, the periodontal ligament (PDL) space can be widened or displaced prior to pulp necrosis due to the cytokine cascade from an inflamed pulp.[2,270] Because of the technical limits of traditional imaging, a 2D radiograph should not be considered a panacea in the diagnostic process.

The interpretation of 2D films and digital radiographs is subjective due to significant intraobserver and interobserver variability.[32,95,248] Three-dimensional cone-beam computed tomography (CBCT) technology is a more accurate way of identifying periapical inflammatory disease,[10,57,75,150,193,259] but the interpretation of 3D images is also subjective and based on the experience of the clinician and quality of the images.[16,190,202,254] Moreover, clinicians must be able to identify all of the incidental findings that may be discovered with these larger data sets.[67,185,210] The American Association of Endodontists and the American Academy of Oral and Maxillofacial Radiology published a Joint Position Statement in 2015 providing 14 scientifically based guidelines for the use of CBCT in endodontic treatment. This position paper and other reports recommended the judgment of the treating clinician should determine the need for a CBCT and suggested that patient history and clinical examination should demonstrate that the benefits of the scan outweigh the potential risks.[1,151] “CBCT should not be used routinely for endodontic diagnosis or for screening purposes in the absence of clinical signs and symptoms. Clinicians should use CBCT only when the need for imaging cannot be met by lower dose two-dimensional radiography.”[1] Furthermore, when indications arise for the use of CBCT a

Telegram: @dental_k

www.konkur.in

limited field of view is recommended to minimize the amount of radiation and maximize the image resolution. A CBCT can serve as a valuable tool to differentiate subtle radiographic changes and facilitate the development of a more comprehensive differential diagnosis compared to conventional radiography (Fig. 3.3).[57,192]

FIG. 3.3 A limited field CBCT is a useful adjunct when the findings on a periapical image are not conclusive. **A,** A subtle radiolucent area is present at the mesial root apex of the mandibular first molar. **B,** Sagittal, **(C)** axial and **(D)** coronal CBCT images reveal a more prominent loss of density at this root apex.

A) CBCT image shows radiopaque crown and comparatively less opaque two root canals in mandibular first molar.

B) Sagittal view shows first molar with radiolucent crown. One root canal is radiolucent, whereas other root canal is radiopaque.

C) Axial view shows teeth arranged diagonally. Two teeth have tiny dense dots at the center.

D) Coronal view shows radiolucent root canals and crown. Some of the regions at the neck region and edges appear radiopaque.

Differential diagnosis of periapical pathosis

In many cases, the radiographic findings associated with noninflammatory pathologies can very closely mimic the presentation of the more common periapical cyst or periapical granuloma, and there is no way to definitively determine the clinical importance of a lesion based on radiographic features alone.[17,137,139,141,235,243] However, accurate interpretation of the bone abnormalities in conjunction with a thorough review of the medical history, dental history, pulp testing, and clinical examination can yield a differential diagnosis that could result in earlier treatment and potentially a better prognosis. Given the limitations of both pulp testing and radiographic interpretation, the diagnosis of periapical inflammatory disease is associated with a variable level of uncertainty. As a result, using a repeatable method when evaluating radiographic abnormalities can aid the clinician in developing a comprehensive differential diagnosis.

Multilocular radiolucencies

Periapical cysts and periapical granulomas have a wide spectrum of radiographic presentations with some causing extensive bone destruction and others resulting in minimal radiographic abnormalities (Fig. 3.4). Irrespective of size, the presentation of periapical inflammatory disease should be radiographically unilocular and confirmed with a lack of responsiveness to pulp testing. If a multilocular radiolucency is identified on a periapical image, then a panoramic radiograph or CBCT is recommended to confirm the multilocular growth pattern and extent of the lesion. The differential diagnosis of multilocular radiolucencies is extensive, but the most common are odontogenic keratocyst (OKC), ameloblastoma, and central giant cell lesion (CGCL) (Box 3.1).

Telegram: @dental_k

www.konkur.in

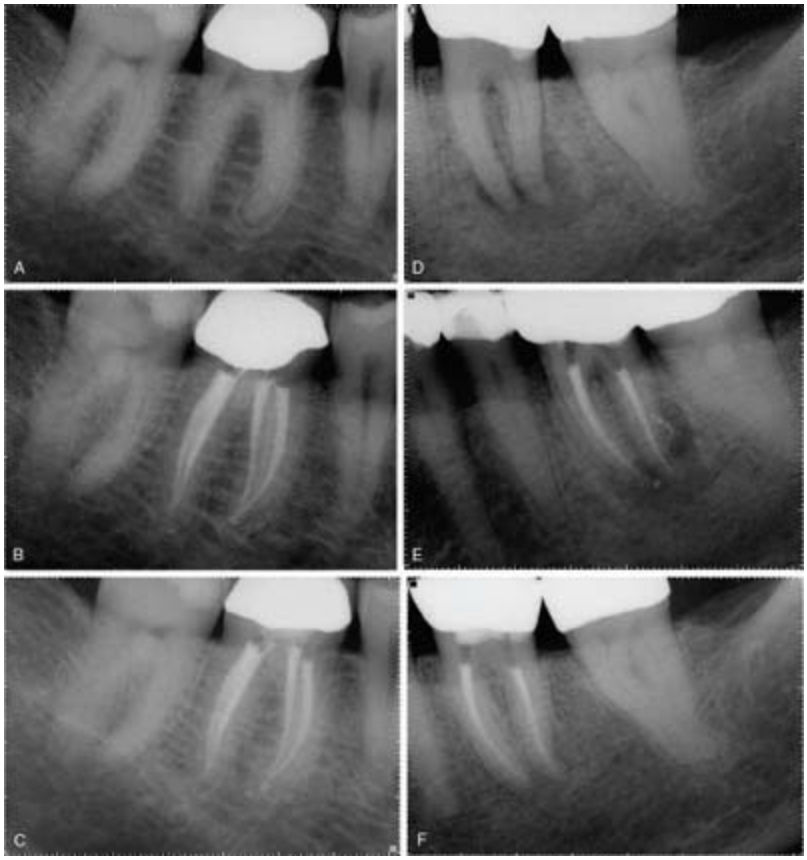

FIG. 3.4 Periapical inflammatory disease presents with a wide spectrum of radiographic changes. **A,** Preoperative periapical image of a mandibular first molar with a necrotic pulp and asymptomatic apical periodontitis. There is a widened PDL space and subtle radiolucency at the mesial root apex. **B,** Nonsurgical root canal treatment was completed. **C,** Evidence of bone healing at 6-month recall. **D,** Preoperative periapical image of a mandibular first molar with a necrotic pulp and asymptomatic apical periodontitis. This lesion is considerably larger than in image **A** and involves the mesial and distal root apices with coronal extension along the distal aspect. **E,** Nonsurgical root canal treatment was completed and a lateral canal is present in the apical half of the root. **F,** Evidence of bone healing at 6-month recall.

A) Radiograph shows central tooth with radiopaque crown and root with medium density. The apex of one of the root canals shows a radiolucent space close to adjacent lamina dura.

B) Radiograph shows central tooth with filled root canals. The tissue between the bifurcated region appears less dense. Beside this, the neck region at the one edge is radiolucent.

C) Radiograph is same as that of B, except that the tissue at the central of bifurcated region and neck is dense.

Odontogenic keratocyst

The OKC is a developmental cyst that accounts for 3% to 11% of all odontogenic cysts.[42] In 2005, the World Health Organization reclassified the OKC as a neoplasm with the designation keratocystic odontogenic tumor because of molecular genetic changes found in other neoplasms, but in 2017 the name was changed back to the original OKC.[69,238] As a result, both names will appear in the literature and it is important to distinguish OKCs from lesions of inflammatory origin due to substantial growth potential and recurrence risk.

The OKC can be identified at any age, but most are discovered as a solitary lesion between the ages of 10 and 40.[42] If multiple OKCs are present or a single OKC is diagnosed before the age of 10, nevoid basal cell carcinoma

Telegram: @dental_k

www.konkur.in

syndrome would be suspected.[81] Histologically, the basal layer of the cyst lining has palisaded cuboidal cells, often with hyperchromatic nuclei, and the surface of the cyst exhibits parakeratin production. The OKC has a thin, noninflamed, stratified squamous epithelial cyst lining consisting of six to eight layers of cells that is easily dislodged from the underlying connective tissue during surgical treatment increasing the likelihood for recurrence. The growth pattern also influences the reported recurrence rates because a multilocular presentation is more difficult to completely remove with curettage.[121] Most reports indicate a recurrence rate of approximately 30%.[23,49] However, the rate of recurrence is variable, depending on the study protocol, and recurrence can occur more than 5 years after the original surgical intervention, suggesting long-term follow-up is mandatory.[23,81]

Radiographic features.

The OKC presents as a well-defined radiolucency and can be found at any location in either jaw (Fig. 3.5).[6,91,216] They can occur in the periapical region, but there is an uneven distribution of OKCs throughout the maxilla and mandible with the highest incidence in the posterior body and ramus of the mandible (Fig. 3.6).[182,250] When an OKC is associated with an impacted tooth (25% to 40% of cases), it should not be confused with a lesion of endodontic origin due to its location surrounding the crown. This presentation would be indistinguishable from that of a dentigerous cyst (Fig. 3.7). Smaller OKCs are most often asymptomatic and commonly present as a unilocular radiolucency while larger OKCs tend to have the classic multilocular appearance.[250] Larger OKCs may present with pain and swelling, but many are asymptomatic with no evidence of bone expansion.

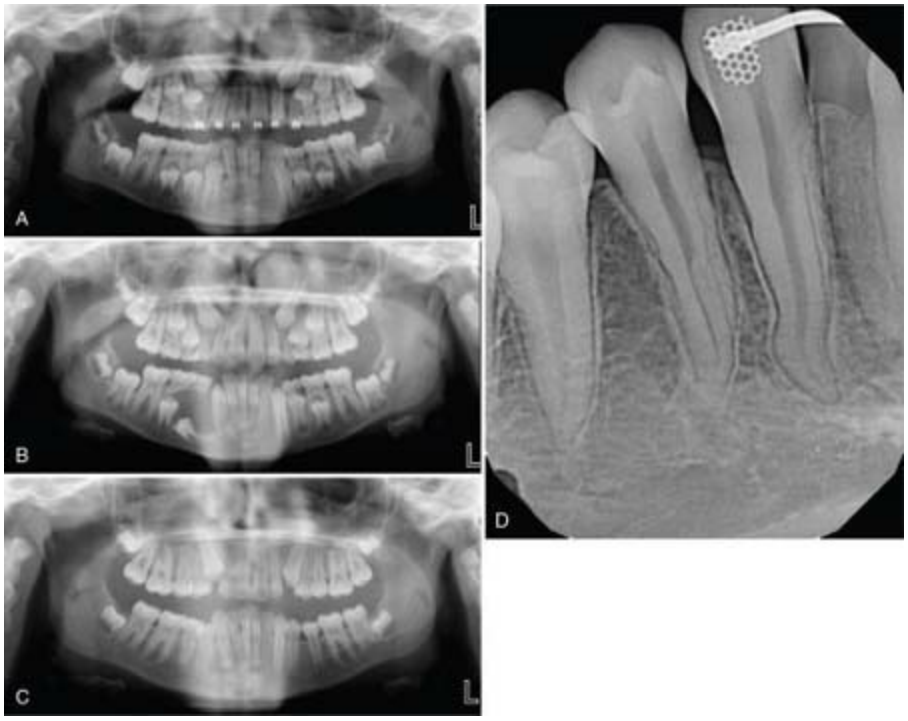

FIG. 3.7 **A,** A panoramic radiograph of a 10-year-old female with a mixed dentition. **B,** Serial panoramic images were obtained for orthodontic reasons and a well-defined expansile lesion developed in the mandibular right premolar region over 9 months. This type of radiolucency should not be confused with an inflammatory etiology due to its location around the crown of an unerupted tooth. This odontogenic keratocyst was treated by unroofing the cyst without removal of the entire lesion. **C,** Panoramic image with no evidence of recurrence at 2 years. **D,** Periapical image with no evidence of recurrence at 6 years.

A) Radiograph shows open mouth with irregular arrangement of teeth. Some teeth arrange at the root apex of the other teeth except the central part.

B) Radiograph is similar to A radiograph, except that there a hollow cavity is created adjacent to the center.

C) Radiograph shows open mouth with almost regular arrangement of teeth. The teeth at the center in the mandible appear slightly clustered.

D) Radiograph shows four teeth with a rectangular framework and a white strip on the third tooth. Part of the crown of fourth tooth is broken at one side.

Ameloblastoma

Ameloblastoma is the most common odontogenic tumor. It presents over a

Telegram: @dental_k

www.konkur.in

wide age range with an equal frequency after the age of 20, but it is uncommon before 20 years of age and rare before the age of 10.[122] These benign tumors are slow growing but can become large and disfiguring if left untreated. There are six histologic subtypes, but these differences have no impact on the treatment options or recurrence rate.[31] Ameloblastomas will often infiltrate normal bone resulting in extension beyond radiographic margins and higher recurrence rates. A more aggressive surgical resection with a larger margin will result in a lower recurrence rate, but this may not be possible due to the size of the tumor or its location near important anatomical structures. Marginal resection is the most common treatment, but recurrence rates of 15% have prompted some surgeons to recommend a 1 to 2 cm resection margin due to the infiltrative growth pattern. However, when the tumor presents near vital structures, a resection may not be possible and the resulting curettage is associated with a recurrence rate that ranges from 50% to 90%.[94] As the molecular pathways involved in the pathogenesis of ameloblastoma are better understood, it may be possible to block these mechanisms with targeted chemotherapeutics, preventing the need for surgery.[109,219] As with OKCs, recurrence can occur many years following the initial surgical intervention and long-term follow-up is mandatory.

Radiographic features.

Ameloblastoma can occur at any location in the maxilla or mandible, but 66% are found in the mandibular posterior region and only 15% present in the maxilla.[179] Smaller lesions are often asymptomatic and may present as a unilocular radiolucency found on routine radiographic examination. A small, unilocular ameloblastoma in the periapical region may be indistinguishable from a periapical cyst or granuloma.[77,97] Larger ameloblastomas often result in a painless swelling, and expansion of the cortical plate may help differentiate an ameloblastoma from both inflammatory lesions and OKCs (Fig. 3.8). As with OKCs, many ameloblastomas are associated with an impacted tooth and should not be confused with a lesion of endodontic origin. Ameloblastomas may cause resorption of adjacent teeth, and irregular scalloping of the margin is highly suggestive of the diagnosis.[48] However, when an ameloblastoma presents as a typical nonexpansile multilocular radiolucency, it cannot be distinguished from any other lesion with this

Central giant cell lesion

Long recognized by the term *central giant cell granuloma*, the most recent World Health Organization classification now designates this entity as CGCL.[69] Like OKCs and ameloblastomas, the CGCL will often present as a multilocular radiolucency. It has an unknown etiology that may be a reactive process, but a benign neoplastic origin has not been ruled out. The diagnosis of CGCL is made over a wide age range, with the majority discovered before the age of 30.[172,265] Most case series report a female predilection, and 70% of CGCLs are located in the mandible with a tendency to cross the midline (Fig. 3.9).[143] Histologically, the CGCL is identical to the brown tumor of hyperparathyroidism, and the distinguishing microscopic feature is the presence of multinucleated giant cells. The number and size of the giant cells vary considerably throughout the lesion, and there is controversy about the prognostic significance of this finding, with some studies suggesting a more aggressive behavior.[143,265] Curettage is the most common treatment for CGCL, but a more extensive surgery may be needed for aggressive or recurrent lesions. Alternative treatments for CGCL include, but are not limited to, intra-lesional corticosteroids, bisphosphonates, and imatinib.[54] The overall recurrence rate for CGCL is variable, with most studies reporting a rate near 20%.[53]

Telegram: @dental_k

www.konkur.in

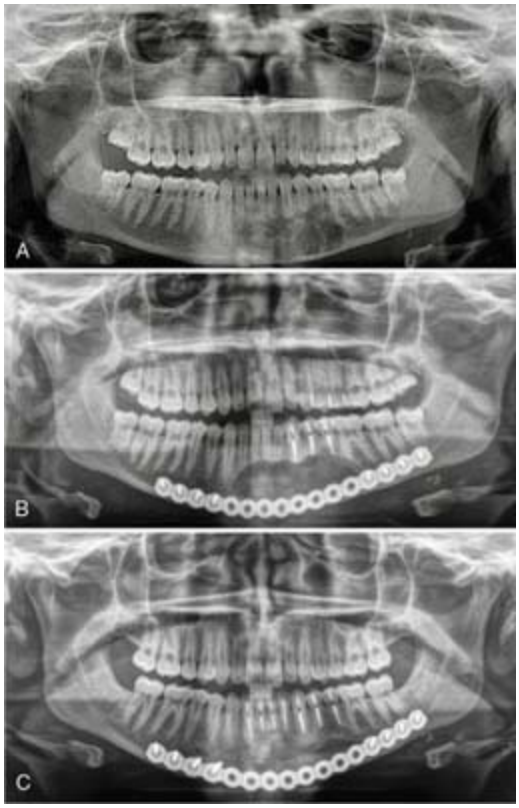

FIG. 3.9 **A,** Central giant cell lesion extending from left mandibular premolar region across the midline in a 17-year-old female. This radiolucency cannot be differentiated from other multilocular lesions without a biopsy (see Box 3.1). **B,** The left mandibular premolars and canine had nonsurgical endodontic treatment prior to removal of the central giant cell lesion and the mandibular incisors had nonsurgical endodontic treatment after removal of the lesion, when it was determined intraoperatively the blood supply to these teeth had been compromised. **C,** Eighteen-month recall with evidence of increased bone density, but incomplete healing.

A) Radiograph shows panoramic view of teeth with sore tissues below the root of teeth near the center.

B) Radiograph shows large bulge below the teeth extending from incisors to premolars. Below the bulge, there is a white chain made of circular rings extending from the third molar to first molar on the other side.

C) Radiograph shows a slightly dense tissue in place of the bulge with the same chain extending from the third molar to second molar on the other side.

Radiographic features.

The characteristic presentation of CGCLs can be subdivided into two

Telegram: @dental_k

www.konkur.in

categories.[44] Nonaggressive CGCLs tend to be asymptomatic and are often discovered on routine radiographs or due to a subtle expansion. These lesions are smaller and grow more slowly than the aggressive subtype. Additionally, nonaggressive CGCLs should not cause perforation of the cortical plate or resorption of roots. Aggressive CGCLs are more likely to exhibit pain and rapid growth.[53] Aggressive CGCLs may result in perforation of the cortical plate, resorption of roots, paresthesia, and extension into soft tissues following perforation. These lesions are usually larger at the time of diagnosis and exhibit a higher recurrence rate.

Most commonly, a CGCL will have a well-defined but noncorticated border. The size can vary from several millimeters to more than 10 cm. As a result, the amount of expansion and thinning of the cortical plate will be highly unpredictable as will the number and size of the loculations (Fig. 3.10). When a smaller lesion is discovered in the periapical region, it can look identical to a periapical cyst or periapical granuloma and larger CGCLs may resemble both OKC and ameloblastoma.[51,226]

CT scan shows an arc-shaped lower jaw at the top of a large irregular structure. The arc shows multiple vesicles with thin tissue.

Radiopacities in the periapical region

Although a multilocular radiolucency is consistent with a noninflammatory etiology, any of the multilocular radiolucencies can also present as a unilocular lesion in its earlier stages prior to reaching full growth potential. As a result, other radiographic features need to be considered when forming a differential diagnosis. Endodontic lesions of inflammatory origin most often present as radiolucent lesions with no indication of radiopacity.[21] As a result, if any evidence of radiopacity is identified, suspicion of a noninflammatory etiology should be elevated, especially if a limited restorative history is present or pulp testing is inconclusive. Exceptions to this rule would include condensing osteitis and maxillary sinusitis of endodontic origin (MSEO).

Condensing osteitis

Condensing osteitis is an area of bone sclerosis in the periapical region that results from an inflammatory stimulus secondary to chronic pulpal inflammation or necrosis. It is most commonly diagnosed in children and young adults, but it can occur in older individuals. Compact bone replaces the fatty marrow, and there are variable levels of fibrosis consistent with an osteoblastic response to a low-grade stimulus.[99] Treatment is focused on the removal of the inflammatory stimulus, and Eliasson et al. reported 85% of these lesions resolve to some extent following root canal treatment or extraction of the compromised tooth.[68] This study is limited by a small sample size, and it is should be noted that regression of the dense bone did not correlate with the quality of the root canal fillings.

Radiographic features.

The true incidence of condensing osteitis in the population is unknown, as there is a small amount of literature on the condition, and historically it has likely been confused with idiopathic osteosclerosis due to similar radiographic appearances and clinical presentation. Condensing osteitis most commonly presents in the premolar and molar regions of the mandible.[76] The

Telegram: @dental_k

www.konkur.in

involved tooth exhibits a widened PDL space and is associated with a localized radiodense zone apical to a carious or heavily restored tooth (Fig. 3.11). The sclerotic bone is asymptomatic, but the involved tooth may be painful due to pulpal inflammation or necrosis.

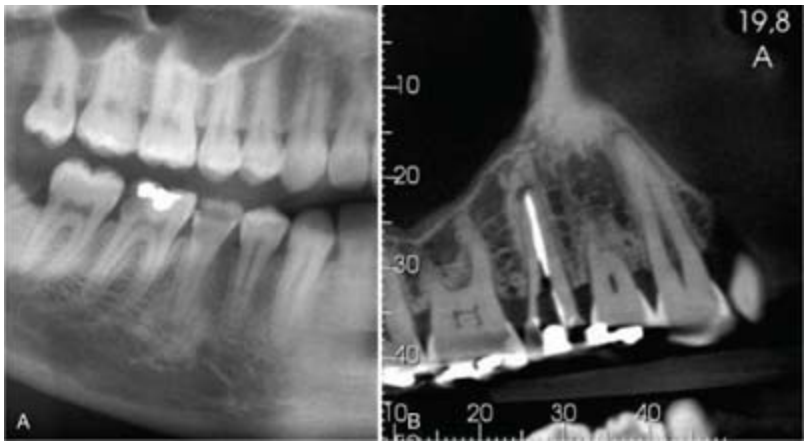

FIG. 3.11 **A,** Cropped panoramic image of condensing osteitis exhibiting a widened PDL space with a radiodense rim at the apex of a carious tooth #29. **B,** Sagittal CBCT image of maxillary premolar with previous endodontic treatment. A homogeneous high-density lesion is present with circumferential loss of density at the root apex suggesting an inflammatory etiology.

Set of two radiographs marked A and B depict

Maxillary sinusitis of endodontic origin

MSEO is an inflammatory disease of microbial origin caused by a necrotic pulp or a root canal–treated tooth with posttreatment disease and may account for 10% of sinusitis cases.[169] The teeth most closely associated with the maxillary sinus include the second molar, first molar, and second premolar. Eberhardt et al. reported that the distance from the MB root of maxillary second molars to the sinus floor is less than 1 mm, while Tian et al. measured similar distances between root ends and the sinus floor but also found that this difference increases with age.[65,249] More than 40% of maxillary molars have a root that protrudes into the sinus.[125] Because of the close anatomical proximity of some root ends to the maxillary sinus and the thin plate of bone

Telegram: @dental_k

www.konkur.in

separating the roots from the sinus lining, an endodontic infection can cause bone destruction leading to a communication through the floor of the sinus. This communication can result in the accumulation of inflammatory mediators elevating the sinus lining or triggering an osteoblastic reaction. Other potential bacterial pathways as an etiology for sinusitis include periodontal disease, root fractures, extractions, and the placement of dental implants.

The sinus component is often asymptomatic and, although the pulpally involved tooth may be painful, the typical symptoms of an endodontic infection may not be obvious. Because MSEO results from a necrotic pulp or a tooth with posttreatment disease, there will be no thermal sensitivity. Swelling and percussion symptoms are less common due to the release of pressure into the sinus. Headache, facial pain, unilateral nasal obstruction, postnasal drip, and nasal discharge are clues to the presence of MSEO, especially when these symptoms are concurrent with a bacterial etiology of endodontic origin.[268,269]

In spite of a reported prevalence ranging from 1.5% to 14%, MSEO often goes undiagnosed, and the literature suggests dental infections contribute to a large percentage of maxillary sinusitis cases.[33,160,179,191] If MSEO is not diagnosed, patients may be erroneously prescribed multiple rounds of antibiotics or undergo unnecessary sinus surgeries due to chronic sinus infections. Treatment involves the elimination of the bacterial etiology with root canal treatment, endodontic surgery, or extraction.[183] Any attempt to directly treat the sinus with a surgical approach will be ineffective, as the source of the infection will not be directly addressed. Likewise, systemic antibiotic therapy may reduce symptoms temporarily, but will not result in a long-term cure.

Radiographic features.

MSEO is often difficult to identify with conventional imaging due to the superimposition of root ends, sinus, cortical plates, and the zygoma (Fig. 3.12). As a result, a high percentage of MSEO cases are missed with routine periapical radiographs.[184,246] A panoramic radiograph may exhibit a sessile, slightly radiopaque dome-shaped elevation. Limited field CBCT will detect a greater percentage of cases of MSEO than other imaging modalities, and two

Telegram: @dental_k

www.konkur.in

distinct patterns can be identified.[160]

FIG. 3.12 **A,** Periapical image of #14 demonstrating cervical resorption and superimposition of the maxillary sinus over the palatal root apex. There is no way to determine the presence of inflammatory changes in the sinus based on this image. **B,** Sagittal CBCT image obtained because of resorption in first molar. Teeth in the field of view were asymptomatic and responded normally to pulp testing. There is no indication of mucosal thickening in the sinus. **C,** Periapical image of necrotic #3 with well-defined radiolucencies at the apices. **D,** Sagittal CBCT image confirms areas of low density at the root apices and reveals resorption of the maxillary sinus floor with localized mucosal thickening. **E,** Coronal CBCT image illustrates collateral edema into the sinus with a perforation of the sinus floor near the palatal root apex.

Telegram: @dental_k

www.konkur.in

Set of five radiographs marked A through E depict evaluation and results of superimposition of the maxillary sinus over the palatal root apex.

Periapical osteoperiostitis.

The inflammatory process from an odontogenic infection can expand the sinus periosteum and displace it superiorly into the sinus. Periapical osteoperiostitis is the osteoblastic reaction that results in new bone formation under the periosteum as it is elevated vertically, resulting in a dome-shaped radiopacity on the sinus floor.[246]

Periapical mucositis.

Periapical mucositis occurs when odontogenic infections displace the sinus lining without the reactive osteoblastic changes. This will also present as a dome-shaped lesion radiographically, but because the mucosal thickening and tissue edema is limited to the soft tissues, periapical mucositis is more difficult to identify than periapical osteoperiostitis (Fig. 3.13). This type of radiographic change has also been termed *antral pseudocyst*.[90]

Telegram: @dental_k

www.konkur.in

FIG. 3.13 **A,** Periapical image of #2. This tooth is nonresponsive to thermal testing and painful to percussion. Radiographically there is a slightly increased density in the maxillary sinus near the palatal root apex, but superimposition of normal anatomical structures limits the diagnostic accuracy of the image. **B,** Sagittal CBCT image reveals a homogeneous dome-shaped elevation into the maxillary sinus.

Set of two radiographs marked A and B depict antral pseudocyst.

Osteomyelitis with proliferative periostitis

Proliferative periostitis is a reactive bone formation in response to the presence of inflammation similar to periapical osteoperiostitis that occurs with MSEO. However, the reactive bone is deposited in parallel rows expanding the surface of the involved jaw, usually in a child or adolescent.[179] It is thought that subperiosteal spread of an inflammatory process elevates the periosteum, stimulating new bone formation.[266] Dental caries with a secondary odontogenic infection is the most common cause. Like condensing osteitis, most cases arise in the premolar and molar area of the mandible, but unlike condensing osteitis, there is obvious expansion, most often of the

Telegram: @dental_k

www.konkur.in

lower border of the mandible and buccal cortical plates.[128] Removal of the inflammatory stimulus via appropriate endodontic treatment or extraction should result in bone healing over a 6 to 12 month time frame, but biopsy should be considered if bone expansion is present and/or a dental source of infection cannot be identified with clinical examination and pulp testing.

Radiographic features.

Because of superimposition of the lesion over normal bone, proliferative periostitis may be difficult or impossible to visualize with conventional intra-oral radiography (Fig. 3.14). A CBCT or an occlusal radiograph will demonstrate a variable number of layers of reactive bone.[252,274] The boney sheets are typically parallel to each other and the cortical plate. Numerous small radiolucent areas may be identified within the body of the lesion.[66]

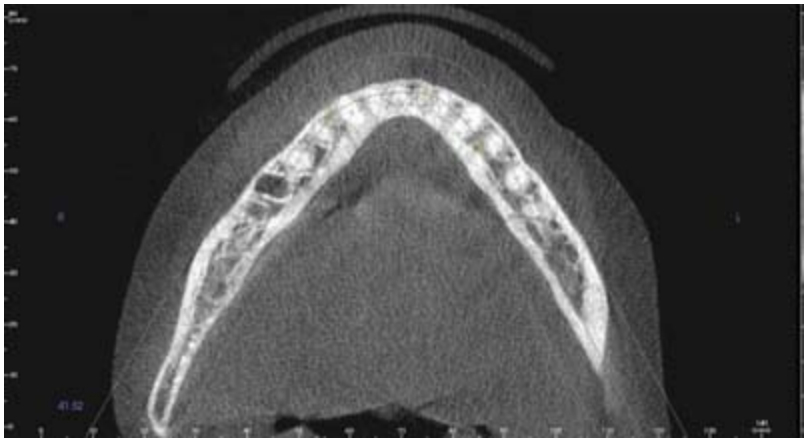

FIG. 3.14 Axial CBCT image of mandibular arch demonstrates irregular medullary bone destruction and cortical defects from tooth #25 to tooth #31. There is new bone formation along the inferior facial cortex consistent with osteomyelitis and proliferative periostitis.

CBCT images shows teeth forming an inverted U-shape. A radiolucent cavity in place of the tooth is shown toward the center with a cloudy tissue on one side. The left side of the radiograph shows extremely thin tissue.

Source: (Courtesy Dr. Laurence Gaalaas.)

Although a radiopacity may be the result of an osteoblastic reaction to an inflammatory stimulus, if pulp testing and clinical history do not indicate an endodontic etiology, other disease entities should be considered in the

Telegram: @dental_k

www.konkur.in

differential diagnosis. These radiopacities may occur for idiopathic reasons, be developmental in nature, be the result of an underlying bone disorder, or represent variations of normal.

Idiopathic osteosclerosis

Idiopathic osteosclerosis is typically an incidental radiographic finding characterized by an increased bone density of unknown etiology. The prevalence is estimated to be approximately 5%, but due to inconsistent nomenclature in the literature and the similarity in clinical presentation to condensing osteitis, the true prevalence is unknown.[93,129,198] Idiopathic osteosclerosis is most commonly found in adolescents and may remain unchanged or continue to enlarge slightly until normal growth and development is complete.[198] At that point, the majority of lesions will remain unchanged, but a small number may resolve.[104] The diagnosis of idiopathic osteosclerosis is based on clinical presentation of the lesion, pulp testing of teeth in the area, and restorative history. If any of the clinical findings are suspicious, a biopsy could be done, but typically the diagnosis can be made based on the clinical characteristics and no treatment is indicated.

Radiographic features.

Idiopathic osteosclerosis is identified as an asymptomatic, well-defined, nonexpansile radiopacity (Fig. 3.15). The size of the lesion varies from a few millimeters up to 2 cm, and the outline is often irregular. Like condensing osteitis, it is most commonly located in the first molar region, and there is an overwhelming predilection for the mandible.[198,272] It typically presents as a solitary lesion of uniform radiodensity, but multiple radiopacities have been reported in the same patient.[272] Idiopathic osteosclerosis usually occurs near a root apex and root resorption is possible, but uncommon.

Odontoma

Odontomas are common developmental abnormalities and should not be considered neoplasms. They are composed of tissues found in normal teeth, including enamel, dentin, and variable amounts of pulp and cementum.

Telegram: @dental_k

www.konkur.in

Compound odontomas are made up of multiple structures that resemble teeth and are most often located in the anterior maxilla, while complex odontomas are composed of an unorganized aggregate of enamel and dentin and are most often diagnosed in the molar regions.[37] However, both types will occasionally be found in any maxillary or mandibular site and in the periapical areas.[200] If the diagnosis can't be made based on radiographic findings, surgical removal has an excellent prognosis.

Radiographic features.

Most odontomas are diagnosed before the age of 20 as asymptomatic findings on routine radiographs.[245] Often they are identified when a normal tooth fails to erupt. They are usually smaller than a tooth, but larger odontomas of greater than several centimeters have been reported.[245] Compound odontomas resemble teeth radiographically and are surrounded by a radiolucent border (Fig. 3.16). Complex odontomas have the same radiodensity as teeth and are also associated with a radiolucent border but lack the shape of normal teeth (Fig. 3.17). An early odontoma could resemble a periapical radiolucency if it appears near a root apex prior to calcification.

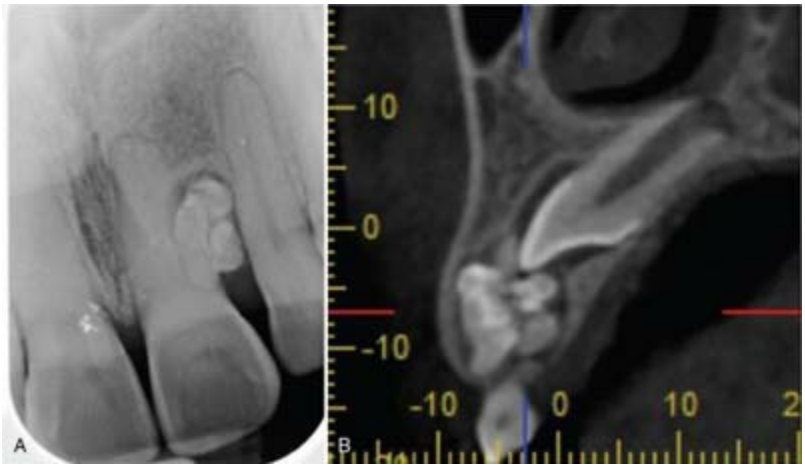

FIG. 3.16 **A,** Periapical image of a compound odontoma in a 35-year-old female. Multiple radiopacities resembling teeth are located interproximal to the maxillary central and lateral incisors. **B**, CBCT image demonstrating multiple high-density toothlike structures in association with a corticated low-density zone resembling dental follicle.

Paget disease of bone

Paget disease is a common metabolic bone disorder characterized by a highly variable and mixed radiographic presentation due to the abnormal and haphazard deposition and resorption of bone. A defect in osteoclasts, and to some degree osteoblasts, results in thickened, enlarged, and weakened bones.[224] It is rare before the age of 40 and tends to affect older white adults with a prevalence that is geographically variable.[179] The highest incidence is found in people of British ancestry, and the prevalence in the United States is estimated to be 1% to 2%.[179] Paget disease has an unknown etiology, and both genetic and environmental factors may be involved. A family history has been reported in as high as 40% of cases, and the decline in overall

Telegram: @dental_k

www.konkur.in

prevalence over the last 25 years suggests a possible link to a paramyxovirus.[46]

Paget disease is often asymptomatic at the time of diagnosis, but bone pain is not uncommon.[154] Test results indicate an elevated level of serum alkaline phosphatase with normal blood calcium and phosphorus levels. However, alkaline phosphatase is not always abnormal in patients with limited disease. Asymptomatic patients with limited involvement require no treatment and bisphosphonates are used for symptomatic patients to reduce bone turnover and decrease pain. Paget disease tends to be a chronic and slowly progressive disease, but malignant transformation to osteosarcoma is possible.[41]

Radiographic features.

Paget disease typically arises from several bones at the same time. The pelvis, femur, lumbar vertebrae, tibia, and skull are commonly involved.[205,224] The jaws are involved in less than 20% of cases and the maxilla is twice as likely to be affected compared to the mandible. Maxillary involvement is characterized by an enlargement of the midface, and symptoms may include a deviated septum, nasal obstruction, and sinus obliteration. Additionally, enlarged alveolar ridges resulting in space between teeth can occur in either jaw.

Early in the disease process there is decreased radiodensity with a coarse trabecular pattern (Fig. 3.18). During this early resorptive stage, the lesions are very vascular resulting in significant bleeding during oral surgical procedures. Following the resorptive changes, patchy areas of confluent bone sclerosis become more prominent.[39] These sclerotic areas have classically been described as having a “cotton wool” radiographic appearance and may exhibit poor wound healing and an increased risk of osteomyelitis following surgery.[22] Teeth in affected areas may develop hypercementosis with radiographic features similar to cemento-osseous dysplasia.

Exostoses and tori

An exostosis is a boney outgrowth from the cortical plate. There is a high degree of uncertainty in the literature about the cause and prevalence of exostoses, and they should be considered variations of normal anatomy that have a multifactorial etiology.[86,108,171,189] An exostosis is a relatively common finding on routine clinical examination, but there is minimal literature on the topic and the prevalence within the population is unknown. The most common exostoses are the torus mandibularis and torus palatinus.[179] Exostoses are usually asymptomatic unless trauma results in localized inflammation or ulceration. Treatment is usually unnecessary with the classic clinical presentation. Removal of sizable exostoses may be needed for normal function or for prosthetic reasons.

Radiographic features.

In some cases, the bone density will be high enough that an exostosis will be seen as a radiopacity on dental radiographs. It is rare to see a palatal torus on dental radiographs, but it is not uncommon to visualize a mandibular torus

Telegram: @dental_k

www.konkur.in

superimposed on the roots (Fig. 3.19).

FIG. 3.19 **A,** A radiodense ridge superimposed over the coronal portion of the roots extending from the implant in the #19 position to the mesial of tooth #30. This represents a prominent lingual exostosis and should not impact endodontic diagnosis but could interfere with visualization of the canals radiographically. This panoramic image also demonstrates well-defined uniform radiopacities inferior to tooth #21 and tooth #27 consistent with idiopathic osteosclerosis. **B,** Axial CBCT image of a maxillary torus characterized by a well-defined high-density area in the midline.

A) Panoramic radiograph shows a radiopaque tooth on the left. The space between upper and lower rows of teeth has fibrous tissues at the center. Crown and root canals of one tooth are radiopaque on the right in the lower jaw. The upper jaw shows tooth with radiopaque crown.

B) Radiograph of maxillary arch shows two fused tooth-like structures at the center below the teeth.

Multifocal presentations

Although it is not common to have asymptomatic radiolucencies resulting from simultaneous pulpal necrosis in multiple teeth, it can’t be ruled out on radiographic examination alone. Pulp testing and dental history are important if multiple necrotic pulps are suspected (Fig. 3.20), but a multifocal presentation also raises concerns about a nonbacterial etiology.

Telegram: @dental_k

www.konkur.in

FIG. 3.20 **A,** Multiple periapical radiolucencies suggest the possibility of a noninflammatory etiology. However, teeth #12 and #13 did not respond to cold testing and both teeth were tender to percussion and palpation. The diagnosis for tooth #12 and tooth #13 was pulpal necrosis and symptomatic apical periodontitis. Nonsurgical root canal treatment was completed in both teeth. **B,** A 6-month recall demonstrated bone healing at the root ends of both teeth.

A) Radiograph shows large dark blotch next to roots of teeth. Two teeth on the right have radiolucency at the root tip.

B) Radiograph shows two teeth on the right with filled root canals.

Periapical cemento-osseous dysplasia

Periapical cemento-osseous dysplasia (PCOD) is the most common multifocal radiolucency to mimic lesions of endodontic origin and has been known by a variety of terms in the literature including, but not limited to, periapical cemental dysplasia, cementoma, and periradicular fibrous dysplasia.[178,227] Like the other fibro-osseous lesions (Box 3.2), PCOD is characterized by the replacement of bone with fibrous and mineralized tissue. PCOD occurs in the anterior mandible and has a predilection for black

Telegram: @dental_k

www.konkur.in

females.[8,179] The diagnosis is most often made between 30 and 50 years of age and it is uncommon prior to the age of 20. The teeth in the area are usually asymptomatic, and the diagnosis is most often made from routine radiographs.[227] The teeth are often unrestored and should respond normally to pulp testing. Treatment is not necessary unless the area is symptomatic.[159] If there is uncertainty about the diagnosis, a biopsy can be obtained, but this comes with an increased risk for infection, bone necrosis, or a disruption in the pulpal blood supply.[15]

Box 3.2

Fibro-Osseous Lesions

Periapical cemento-osseous dysplasia
Fibrous dysplasia
Focal cemento-osseous dysplasia
Florid cemento-osseous dysplasia
Ossifying fibroma

Radiographic features.

The radiographic presentation of PCOD is dynamic, variable, and changes as the patient ages.[130,218] Early lesions are mostly radiolucent and will have a strong resemblance to the osteolytic changes that result from pulpal necrosis (Fig. 3.21). As a result, misdiagnosis of PCOD will commonly result in unnecessary root canal treatment. As the lesions change with time, they will take on a mixed radiolucent radiopaque appearance radiographically, and late stage PCOD is characterized by well-circumscribed radiopacities with a well-defined radiolucent border (Fig. 3.22). A multifocal presentation is most common, but solitary lesions that are indistinguishable from periapical cysts or periapical granulomas have been reported.[179] The PDL space is usually unaltered, and even late stage lesions will rarely exceed 1.0 cm.

Telegram: @dental_k

www.konkur.in

FIG. 3.21 Multiple well-defined radiolucencies in the anterior mandible. The patient reported no history of trauma and was asymptomatic. These teeth had no significant dental history and responded to both cold and electric pulp testing. Based on this clinical presentation, a diagnosis of periapical cemento-osseous dysplasia was made and no treatment was indicated.

Radiograph shows radiolucent root canals in teeth. Beside this, root tips show a dark patch.

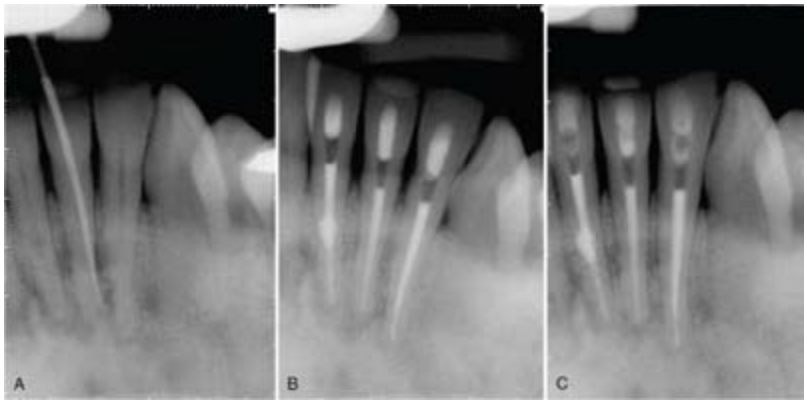

FIG. 3.22 **A,** A 55-year-old female presented with pain, a sinus tract facial to #24, and a history of biopsy in the area several years prior. Teeth #23, #24, and #25 did not respond to cold or electric pulp testing. Radiographically the mixed radiolucent and radiopaque lesions were

Telegram: @dental_k

www.konkur.in

consistent with periapical cemento-osseous dysplasia, but the sinus tract and pulp testing indicated pulpal necrosis in teeth #23, #24, and #25. Pulpal necrosis was likely due to a disruption of the pulpal blood supply at the time of the biopsy. **B,** Nonsurgical root canal treatment was completed and there was no indication of vital pulp tissue in the canals. The previous biopsy report was obtained prior to root canal treatment, and the diagnosis of periapical cemento-osseous dysplasia was confirmed. **C,** At the 6-month recall the sinus tract had healed and the patient was asymptomatic. Because the radiographic lesions were not the result of a bacterial etiology, there was no expectation to see a significant change in the bone at the 6-month recall.

A) Radiograph shows two teeth with radiolucent root canals. Tooth at the center of both teeth undergoes root canal treatment.

B) Radiograph shows three teeth with filled root canals. At the neck region, root canals are radiolucent. The tooth on the right shows a circular mass globule at the center of root canal.

C) Radiograph similar as that of B, except that there are oval radiolucent patches below crown in the first and third teeth.

Florid cemento-osseous dysplasia

Florid cemento-osseous dysplasia (FCOD) most commonly exhibits bilateral, multifocal involvement of the mandible, and all four quadrants can be affected. However, there is no abnormality in blood chemistry.[27,56,233] The lesions can occur in the anterior mandible, but unlike PCOD, the lesions are not limited to the anterior region. Similar to PCOD, there is a predilection for black females, but patients tend to be older at the time of initial diagnosis.[12,56] FCOD can be asymptomatic and discovered on routine radiographs, but pain and exposed bone are also possible.[56,158,222] Because the bone lesions possess a diminished vasculature compared to normal bone, these areas are susceptible to osteomyelitis and the formation of boney sequestra. Tooth extraction and root canal treatment have been reported to initiate secondary infection and symptoms in FCOD.[221] Generally, no treatment is indicated in the asymptomatic patient and the diagnosis can be made based on radiographic findings, clinical examination, and pulp testing.[55] If secondary infection occurs with symptoms, treatment options include antibiotics and surgery.

Telegram: @dental_k

www.konkur.in

Radiographic features.

FCOD exhibits a similar radiographic maturation to that of PCOD. Early lesions are radiolucent and, as they evolve, a mixed radiolucent and radiopaque presentation is common (Fig. 3.23). As patients age, FCOD lesions become more uniformly radiopaque with a thin radiolucent border. These lesions may be well defined, but they are often ill defined, blending with the normal bone.[56,233] An axial computed tomography (CT) will show high-density masses surrounded by a low-density layer with possible cortical expansion but no perforation of the cortical plate.[12,27] Unlike PCOD, FCOD can fuse with the root apex and blend with the normal bone.[12] A single periapical radiograph may suggest the diagnosis, but a panoramic image would be needed to demonstrate the multiquadrant involvement characteristic of the process.

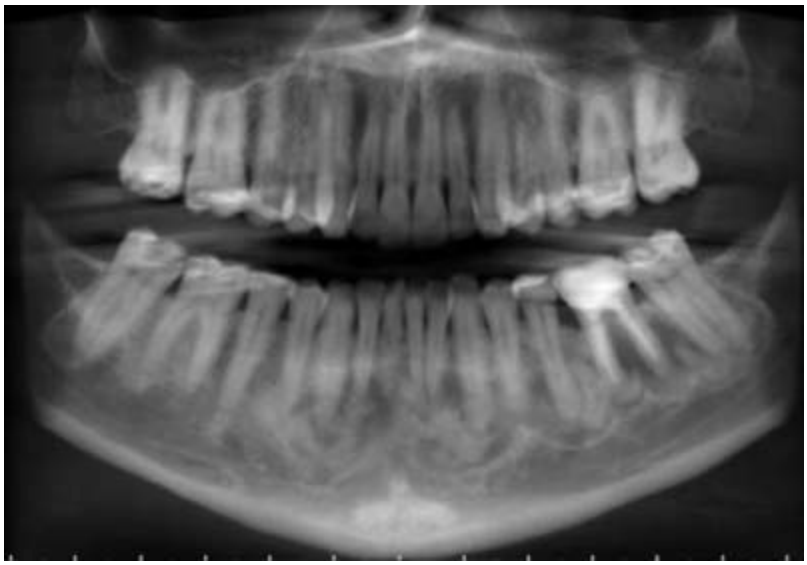

FIG. 3.23 Florid cemento-osseous dysplasia. A mixed radiolucent and radiopaque presentation with multiquadrant involvement. These teeth should respond normally to pulp testing unless there is a history of previous endodontic treatment. If a radiolucent area is present near the root apex of a previous root canal, it may be impossible to determine if the bone loss is due to a bacterial etiology or a manifestation of florid cemento-osseous dysplasia.

Radiograph shows mixture of radiolucent and radiopaque tissues in the jaw bone next to teeth.

Hyperparathyroidism

Parathyroid hormone (PTH) is normally produced due to decreased levels of serum calcium. Primary hyperparathyroidism results from an uncontrolled overproduction of PTH and is most often due to a parathyroid adenoma. Primary hyperparathyroidism is usually asymptomatic and can be found with routine testing. These patients have an elevated risk for kidney stones due to elevated levels of serum calcium. Additionally, there is an increased likelihood for the development of duodenal ulcers. Primary hyperparathyroidism is treated by the surgical removal of the parathyroid adenoma or hyperplastic tissue responsible for the excess PTH production.[179,201]

Secondary hyperparathyroidism develops due to chronic overproduction of PTH in the presence of low serum calcium resulting from chronic renal disease. A dietary and pharmacological approach is initially utilized to treat secondary hyperparathyroidism. If this is not successful, the parathyroid glands can be removed or a renal transplant may restore normal vitamin D metabolism.[47]

Radiographic features.

Hyperparathyroidism is characterized by a generalized loss of lamina dura around roots of teeth. Alterations in the trabecular pattern of bone resulting in a “ground glass” appearance tends to be more striking in patients with secondary hyperparathyroidism, and this may be associated with significant bone enlargement clinically.[206] Secondary hyperparathyroidism has also been associated with pain and increased cortical bone density.[3] Additionally, lytic lesions resembling periapical inflammatory disease can occur (Fig. 3.24).[120,155]

Source: (Courtesy Dr. Marcel Noujeim.)

The brown tumor of hyperparathyroidism may develop with long-standing disease, especially in female patients with primary hyperparathyroidism.[3] It presents as a well-defined unilocular or multilocular radiolucency. These lesions can be single or multiple and may be located in the mandible, clavicles, ribs, and pelvis.[179,201] A single, well-defined, unilocular brown tumor of hyperparathyroidism on a periapical radiograph would be indistinguishable from a periapical cyst or a periapical granuloma.

Langerhans cell histiocytosis

Langerhans cell histiocytosis (LCH) has historically been known by several designations (histiocytosis X, eosinophilic granuloma), and there is controversy about its status as a reactive process or a true neoplasm because LCH also contains a diverse inflammatory infiltrate of eosinophils, lymphocytes, and plasma cells. Additionally, LCH is characterized by a wide spectrum of clinical presentations not typical of a neoplastic process, ranging from single organ involvement that may not require treatment to disseminated and life-threatening systemic disease. However, genetic studies have shown a mutation in an oncogene associated with abnormal cell proliferation in more than 50% of LCH cases, suggesting a true neoplasm.[14]

Telegram: @dental_k

www.konkur.in

Langerhans cells normally act as antigen presenting cells to T lymphocytes and are located in skin and mucosa. Historically, LCH was thought to arise from these cells due to the presence of Birbeck granules using electron microscopy and immunoreactivity to specific cell surface markers. More recent research has shown that Birbeck granules are not exclusive to Langerhans cells. Currently, there is debate regarding the actual cell of origin that results in LCH with some suggesting that immature myeloid dendritic cells of bone marrow origin are the causative cells.[7,25] Because of its diverse presentation, standardized treatment protocols are limited and ultimately treatment and prognosis are determined by the location and extent of the disease.

Radiographic features.

Patients present over a wide age range, but the majority are diagnosed before the age of 15.[179] LCH typically presents as single or multiple punched out radiolucencies with well-defined borders, but an ill-defined margin is also possible.[50,112] A solitary well-defined lesion on a periapical radiograph may be indistinguishable from a periapical cyst or periapical granuloma, but the LCH lesion may be more destructive.[196] LCH can have a widespread distribution and affect any bone, but jaw involvement is more common than soft-tissue involvement in the maxillofacial region, and the mandible is affected three times more than the maxilla.[112,179] LCH can result in the loss of alveolar bone and the loosening of teeth, resembling severe periodontal disease (Fig. 3.25).

Ill-defined pathologies

At first glance, the peripheral demarcation of a radiolucency may not seem important because periapical cysts and periapical granulomas are the most common ill-defined and well-defined radiolucencies. The differential diagnoses for ill-defined radiolucencies is more ominous and as a result, if pulp testing is not confirmed by the clinical findings at the time of root canal treatment, further investigation and referral would be indicated (Box 3.3). For example, a necrotic pulp would be expected in a tooth with a significant

Telegram: @dental_k

www.konkur.in

caries history that is nonresponsive to pulp testing and painful to percussion. However, if vital pulp is identified and the patient's symptoms do not resolve following root canal treatment, a biopsy would be recommended if the radiolucent area is ill defined and there is evidence of root resorption, tooth mobility, bone expansion, or perforation of the cortical plates.

Osteomyelitis

Osteomyelitis is an uncommon acute or chronic inflammatory process that spreads through the bone away from the initiating site of infection. In acute cases, symptoms usually present within 2 weeks of the infection while it may take more than 6 weeks to develop symptoms with chronic osteomyelitis. Most commonly, a polymicrobial bacterial infection composed of organisms indigenous to the oral cavity serves as the precipitating factor leading to inflammatory bone destruction and the formation of bone sequestra, which are fragments of necrotic bone that are displaced from the viable bone.[140,242] Less commonly, a fungal or mycobacterial infection initiates the osteomyelitis. Predisposing factors include chronic systemic diseases, an immunocompromised state, or any condition that impacts the vascularity of bone. The incidence of chronic osteomyelitis may be increasing due to an increased prevalence of diabetes and peripheral vascular disease in the aging population as well as the increased use of fixation devices in orthopedic surgery.[106] The mandible is more commonly involved due to its more limited vascular supply. Osteomyelitis can occur at any age, and there is a strong

Telegram: @dental_k

www.konkur.in

male predilection.[140]

Acute osteomyelitis.

Acute osteomyelitis is characterized by the spreading of infection and inflammation through the bone. Patients typically have the signs and symptoms of acute infection, including fever, lymphadenopathy, tenderness to palpation, and elevated white blood cell counts.[242] Paresthesia of the lower lip is possible due to nerve compression, and the extent of swelling is dependent on how the infection spreads.[140] Treatment consists of surgical intervention to remove the source of infection, promote drainage, and remove any infected or necrotic bone. Antibiotics and multiple surgeries may be needed to resolve the infection in some cases, and the emergence of antibiotic-resistant bacteria has served to complicate treatment in an increasing number of cases.[64]

Radiograph changes associated with acute osteomyelitis can be subtle as the infection spreads through the medullary spaces.[124] Periapical images may reveal an ill-defined radiolucency with widened PDL spaces and the loss of lamina dura. As expected, a CBCT will often show the spread of the infection more clearly than conventional dental imaging and, although not practical in the dental setting, magnetic resonance imaging (MRI) can demonstrate edema and inflammatory changes in the marrow spaces characteristic of acute osteomyelitis.[11,13,124] If the infection spreads under the periosteum, there can be an osteoblastic reaction leading to new bone formation with radiopacity or an ill-defined lesion of mixed radiodensity.[105,242]

Chronic osteomyelitis.

Chronic osteomyelitis is the result of an unresolved acute infection causing the inflammatory response to form a layer of granulation tissue around the bacteria. The granulation tissue forms a space that is difficult to access with antibiotics and also serves as a reservoir for bacteria. As seen in acute osteomyelitis, pain is a common presenting symptom.[242] However, swelling and drainage are more likely to be present with chronic osteomyelitis. In advanced cases, tooth mobility and significant bone loss are possible prior to pathologic fracture. Management of chronic osteomyelitis is more difficult due to the pockets of dead bone and infection that are isolated behind the

Telegram: @dental_k

www.konkur.in

granulation tissue wall.[132] Surgery to remove all infected and necrotic bone is mandatory, and jaw resection may be necessary in some cases. Systemic or intravenous (IV) antibiotics are used in conjunction with surgery. Hyperbaric oxygen has been used in extreme cases, but this is typically not needed if all infected bone has been removed.

The radiographic presentation of chronic osteomyelitis is variable, depending on the duration and extent of the infection and the differing amounts of bone destruction.[273] Chronic osteomyelitis is often characterized by an irregular, ragged, and ill-defined radiolucency. The radiolucent area may contain sequestra and zones of increased density resulting in a mixed radiolucent and radiopaque appearance (Fig. 3.26).[273] Large areas of bone necrosis are possible if blood supply is compromised, and the destructive "moth eaten" nature of some lesions suggests the potential for a malignant neoplasm (Fig. 3.27).[105,116]

FIG. 3.26 **A,** 50-year-old male with a complaint of increasing pain and swelling from the maxillary left canine region over the last year. Examination revealed a palatal swelling and radiographically there was an ill-defined radiolucent lesion near teeth #11 and #12. **B,** A periapical image with a mixed radiolucent and radiopaque lesion is present, but the margins are more well-defined than on the panoramic image. A biopsy was done to rule out a salivary gland neoplasm due to the palatal swelling and destructive nature of the radiolucency. The biopsy revealed both acute and chronic inflammation with sequestrum formation and bacterial colonies consistent with a diagnosis of osteomyelitis.

FIG. 3.27 **A,** Nonsurgical root canal treatment completed in tooth #30 due to pulpal necrosis. **B,** A 1-year recall due to increasing pain in the area. Radiographs revealed an ill-defined radiolucency associated with teeth #28, #29, and #30. These teeth exhibited abnormal mobility and there was significant soft-tissue inflammation, gingival bleeding, and exposed bone. The destructive nature of the bone loss and clinical presentation suggested malignancy, but a biopsy revealed sheets of chronic inflammatory cells and necrotic bone consistent with osteomyelitis. **C,** A panoramic image reveals complete osseous healing at 4-year recall.

A) Radiograph shows molar with radiopaque crown and filled root canals.

B) Radiograph shows three teeth. First tooth has radiopaque edges at the top. Second tooth has radiopaque crown and filled root canals. Some part of the crown is radiopaque in third tooth and its root canal is radiolucent. All three teeth are poorly fitted.

C) Panoramic radiograph shows properly fitted teeth. Most of the teeth are missing in lower right quadrant.

Medication-related osteonecrosis of the jaw

Telegram: @dental_k

www.konkur.in

Bisphosphonate osteonecrosis of the jaw was first reported when an association was identified between the use of intravenous bisphosphonates and an increased frequency of jaw necrosis.[162,213] However, since these initial reports, other drug classes have been implicated and the name was changed to reflect this in 2014.[214] New medications are frequently being added to the list of causative agents (Table 3.1), and osteonecrosis has been reported in other osseous sites including the small bones of the inner ear and femoral head.[92,166,211]

Table 3.1

Other Medications Implicated in Pathogenesis of Medication-Related Osteonecrosis of the Jaw

Generic Name	Trade Name
Imatinib	Gleevec
Regorafenib	Stirvarga
Axitinib	Inlyta
Pazopanib	Votrient
Cabozantanib	Cometriq
Dasatinib	Sprycel
Methotrexate	Otrexup, Trexall
Corticosteroids	
Adalimumab	Humira
Infliximab	Remicade
Rituximab	Rituxan
Romosozumab	Evenity
Aflibercept	Zaltrap
Everolimus	Afinitor
Temsirolimus	Torisel
Sirolimus	Rapamune
Radium 223	Xofigo
Raloxifene	Evista

According to the American Association of Oral and Maxillofacial Surgeons position statement,[214] patients may be considered to have medication-related osteonecrosis of the jaw (MRONJ) if all of the following

Telegram: @dental_k

www.konkur.in

characteristics are present:

1. Current or previous treatment with antiresorptive or antiangiogenic agents
2. Exposed bone or bone that can be probed through an intraoral or extraoral fistula in the maxillofacial region that has persisted for more than 8 weeks
3. No history of radiation therapy to the jaws or obvious metastatic disease to the jaws

Antiresorptive medications.

The exact mechanisms leading to MRONJ are unknown and the pathogenesis is likely multifactorial. Osteoclasts are involved in normal bone healing by signaling osteoblasts and influencing angiogenesis. As a result, any medication that impacts osteoclast number or function may influence bone resorption, new bone formation, and the local vasculature. Most cases arise following dentoalveolar surgery, suggesting an inflammatory or infectious etiology could be a contributor to the initiation of MRONJ.[260,271] Periodontal disease and periapical inflammation from a necrotic dental pulp are recognized risk factors for MRONJ, but the risk of developing osteonecrosis in patients exposed to antiresorptive medications following root canal treatment is unknown.[80,214,260,271] Other risk factors for the development of MRONJ include IV bisphosphonate use in cancer patients, corticosteroids, chemotherapy, diabetes, alcohol consumption, poor oral hygiene, and bisphosphonate use for more than 3 years. Smoking and advanced age may increase risk, but the current literature is not definitive.[145,261] In spite of these recognized risk factors, there is no way to reliably predict the development of MRONJ in any individual patient. The use of serum C-telopeptide cross-link of type 1 collagen (sCTX) has been advocated as a biomarker of bone metabolism and a predictor for the development of MRONJ.[163] However, several variables impact sCTX levels, and a systematic review concluded that current evidence does not support the use of sCTX levels as a predictor for the development of MRONJ.[70]

Bisphosphonates suppress osteoclast activity by increasing apoptosis. These medications have an extremely long half-life and exert an effect for

Telegram: @dental_k

www.konkur.in

many years or decades.[110] MRONJ risk is much higher for cancer patients taking IV doses of bisphosphonates compared to either IV or oral doses for the treatment of osteoporosis. However, the true incidence of MRONJ is not known, and patients with a history of antiresorptive treatment should be made aware of the risks and benefits prior to any treatment linked to the development of jaw necrosis.[9]

Denosumab (Prolia, Xgeva) is a human monoclonal antibody that confers an antiresorptive effect by preventing the development and maturation of osteoclasts. This medication is used both for the treatment of osteoporosis and skeletal-related events due to malignancy. Osteoclasts are derived from the monocyte/macrophage lineage and have a short lifespan of approximately 2 weeks. As a result, osteoclasts need to be continually replenished to keep cell counts constant. Blocking the maturation of these rapidly differentiating cells has a swift and significant impact on the number of functional osteoclasts. Unlike bisphosphonates, denosumab is not deposited in bone and the half-life is less than 1 month, resulting in complete clearance of the drug within 4 to 5 months. In spite of these differences, the risk for the development of MRONJ is very similar for cancer patients taking either denosumab or an IV bisphosphonate.[84,111,241]

Antiangiogenesis medications.

Osteoclasts govern the local vasculature during normal bone healing, and the administration of antiresorptive medications may influence the development of MRONJ by exerting an indirect effect on osteoclast-mediated angiogenesis. However, in some cancer patients, a more direct and profound impact on angiogenesis is desired in an attempt to prevent neovascularization in the tumor or metastatic spread. Sunitinib (Sutent) and sorafenib (Nexavar) are multiple tyrosine kinase inhibitors that block vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF), resulting in decreased angiogenesis, tumor growth, and cancer progression. Bevacizumab (Avastin) is a monoclonal antibody that also targets and inhibits VEGF to limit tumor growth and metastasis. Unlike other initiators of MRONJ, in which the pathogenesis is likely multifactorial, the role of antiangiogenic drugs in the development of osteonecrosis is more intuitive. VEGF and PDGF are involved in normal bone remodeling and wound repair, and the

Telegram: @dental_k

www.konkur.in

inhibition of their activity leads to a disruption of the normal blood supply, especially in patients undergoing cancer chemotherapy with a compromised immune or healing state. There are multiple case reports linking antiangiogenesis medications to the development of MRONJ.[74,85,115,136,180]

The estimated risk of MRONJ in cancer patients receiving IV bisphosphonates is reported to be 1%, and as stated previously, this is comparable to cancer patients exposed to the RANK-L inhibitor denosumab. The risk for patients receiving VEGF inhibitors is much lower and is estimated to be 0.2% with bevacizumab.[214] However, patients that are treated with combined antiresorptive and antiangiogenic therapies are reported to develop MRONJ at a significantly higher rate, demonstrating the importance of a thorough medical history that includes both current and past medications.[26,43,100]

Treatment options for MRONJ are limited, therefore prevention is key and all patients should have a complete dental screening prior to initiating antiresorptive or antiangiogenesis treatment. For patients undergoing cancer treatment, oral surgery procedures should be completed while allowing several weeks for healing prior to starting medications with the potential to initiate MRONJ. If a cancer patient has already been exposed to antiresorptive or antiangiogenesis medications, it is best to minimize trauma to the bone, and root canal treatment would be preferred over extraction.[110] If oral surgery is necessary in these patients, the use of a drug holiday has been suggested, but there is little evidence in the literature to support this concept.

Radiographic findings.

Most areas involved with MRONJ are painful due to the presence of necrotic and exposed bone, but this is not universal. The mandible is affected more commonly than the maxilla and both jaws can be involved simultaneously.[217] Panoramic radiographs may show increased radiodensity of the crestal bone in both jaws, and CBCT is better able to demonstrate the sclerotic changes and cortical irregularities commonly associated with MRONJ.[102,256] Prior to necrosis, there is increased radiopacity due to the lack of bone resorption. After the osteonecrosis has been initiated, there will most likely be an irregular, “moth eaten”, and ill-defined radiolucent area with or without sequestra.[256] This radiographic appearance can be very similar to that of

Telegram: @dental_k

www.konkur.in

chronic osteomyelitis (Fig. 3.28). Depending on the location and extent of the necrosis, the radiographic appearance could also resemble periodontal disease or mimic a lesion of endodontic origin. Additionally, with a "moth-eaten" and destructive radiographic presentation, malignancy needs to be ruled out.[89]

FIG. 3.28 Medication-related osteonecrosis of the jaw. A cropped panoramic radiograph shows a sclerotic rim of bone over the mesial buccal root of tooth #3 and the root apex of tooth #4. There is a well-defined radiolucent area over the midroot of tooth #4 suggesting localized periodontal disease. Purulent discharge and exposed bone were present from teeth #2 to #5.

Panoramic radiograph shows slightly tilted teeth with inverted U-shaped radiopaque region and porous tissue on either side below the teeth. Few teeth show radiolucent root tips.

Non-Hodgkin lymphoma

Malignant lymphomas are a heterogeneous group of diseases characterized by a proliferation of lymphoid cells and their precursors. Lymphomas can be divided into two categories: Hodgkin and non-Hodgkin. Hodgkin lymphomas are far less frequent than non-Hodgkin lymphomas and rarely involve extranodal sites. Oral involvement of Hodgkin lymphomas is exceedingly rare and would not mimic lesions of endodontic origin.[267]

Non-Hodgkin lymphomas represent a group of malignancies that most often arise in the lymph nodes and grow as a solid mass, but 40% can arise in

Telegram: @dental_k

www.konkur.in

an extranodal site outside the lymphoid system.[72,186] In the maxillofacial region, non-Hodgkin lymphomas can result from the spread of disease into the area or they can arise de novo in soft tissue or bone.[186] These lymphomas can originate from either B lymphocytes or T lymphocytes. The incidence is increasing and approximately 70,000 cases are diagnosed each year in the United States with B lymphocytes being the most common cell of origin.[72,134] Patients with immunologic abnormalities have an increased risk for the development of non-Hodgkin lymphoma, and several different viruses have been implicated in the pathogenesis.[157,165]

Non-Hodgkin lymphomas are diagnosed over a wide age range and are more common in adults, but younger individuals can also be affected.[134] The early stage of the disease is characterized by a nontender, slow growing mass that is most likely associated with a group of lymph nodes. This emphasizes the importance of a complete and thorough examination of the maxillofacial region prior to any dental treatment. With time, the number of lesions increases and there may be growth outside of the lymph nodes into surrounding tissues.

Chemotherapy directed against the cell of origin is a common treatment strategy and the prognosis is influenced by the extent of the disease at the time of diagnosis.[165] High-grade lymphomas are treated with chemotherapy and radiation if localized, but radiation will not be used if the disease has spread. The treatment for low-grade lymphomas in older individuals is more debatable. Many of these patients may have no treatment initially, as these lymphomas tend to recur following treatment, and survival of 8 to 10 years without treatment is not unexpected. However, 40% of low-grade non-Hodgkin lymphomas transform to high-grade disease requiring aggressive treatment, and the overall cure rate is low.[179]

Radiographic features.

The radiographic and clinical presentation is variable, depending on the aggressiveness of the tumor at the time of diagnosis. Dull, vague pain that mimics a toothache is present in some cases, while others may have significant pain, swelling, or paresthesia. The maxilla is more commonly involved, but mandibular involvement should not be considered rare.[134] Early lesions may be radiographically subtle and difficult to identify with

Telegram: @dental_k

www.konkur.in

panoramic imaging.[117] These lesions can resemble a periapical cyst or periapical granuloma and may demonstrate a loss of lamina dura and widening of the PDL space (Fig. 3.29).[61,82,131,138,170,194,236,220] CT and MRI will more clearly reveal bone marrow involvement, often with less cortical destruction than would be expected given the aggressive nature of the neoplastic process. These findings are not specific for non-Hodgkin lymphoma, and other inflammatory and neoplastic diseases need to be considered in the differential diagnosis.[117,164] As the disease progresses, an ill-defined and destructive radiolucency more consistent with a malignant process is likely to emerge. If the lymphoma remains undiagnosed, it will continue to expand and ultimately perforate the cortical plate.

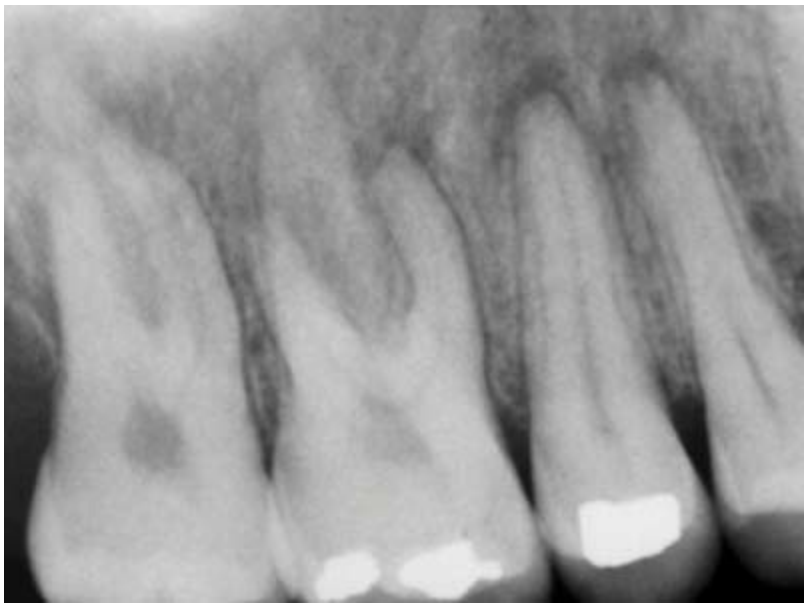

FIG. 3.29 A 29-year-old female with a history of numbness and swelling. These teeth responded normally to pulp testing, but there was a firm and tender buccal swelling from tooth #2 to #6. A diffuse radiolucency was present in the area of the buccal swelling with well-defined radiolucencies at the root apices. Teeth #3 and #4 had limited restorative histories and #2 and #5 were unrestored. Given this clinical presentation a noninflammatory etiology was suspected and biopsy revealed a lymphoma.

Radiograph shows four teeth. The first tooth has radiolucency in the pulp. The second tooth has radiopaque patches at the crown and thin tissue at the root apex. The third tooth has a rectangular radiopaque region at the crown with radiolucency at the root tips of both third and fourth teeth.

Metastatic disease

Metastatic deposits of a primary carcinoma can spread via the bloodstream into the jaws, but this is a rare occurrence.[133] Bones that are more commonly involved include the vertebrae, ribs, pelvis, and skull. Although any malignancy has the potential for metastasis, the most common carcinomas to spread to bone are breast, lung, thyroid, kidney, and prostate. Metastatic disease can be asymptomatic or produce pain, swelling, mobility, and paresthesia. The pain level and presentation can mimic pulpal origin.[63,114] In some cases, metastatic disease can precede the diagnosis of the primary tumor, requiring an extensive workup to determine the location of the primary malignancy.[63,113]

Metastatic disease is more likely to occur in older individuals, corresponding to the increased incidence of primary malignancies in adults. However, metastatic disease has been reported over a wide age range. By definition, a metastatic deposit means an advanced stage of disease progression, and treatment is usually palliative. Bisphosphonates have been used to reduce pain levels and limit the risks of a pathologic fracture, but the overall survival rates are poor.

Radiographic features.

Radiographically, metastatic deposits present most commonly as ill-defined radiolucencies in the mandibular molar region that can be destructive leading to pathologic fracture (Fig. 3.30).[63,207] However, metastatic disease can be very subtle in presentation with only a slight widening of the PDL space or, in some instances, the bone may be radiographically normal.[179] It is possible for breast and prostate metastasis to stimulate an osteoblastic reaction locally, resulting in a radiopaque appearance.[96] Depending on location and growth pattern, metastatic deposits can mimic periodontal disease or an endodontic infection radiographically.[59,87,135,225,255]

Multiple myeloma

Multiple myeloma is an uncommon malignancy of plasma cells that commonly presents with simultaneous involvement in many bones. Multiple myeloma makes up only 1% of all malignancies but is the second most common hematologic malignancy, trailing only lymphoma in incidence.[204] The diagnosis is made using electrophoresis of serum and concentrated urine to demonstrate the presence of M-protein, which is the overproduction of one abnormal immunoglobulin by the malignant plasma cells.[29,203,240]

Multiple myeloma has a mean age at diagnosis of 66 to 70 years and is rarely diagnosed before the age of 40. Most reports suggest there is a slight

Telegram: @dental_k

www.konkur.in

male predilection, but the incidence for blacks is two times greater than for those of European ancestry.[147] Bone pain is the most common symptom, and this may be associated with fatigue if there is underlying anemia.[71,83] Fever and infection can be present due to neutropenia. A nodular tongue is found in nearly 15% of patients because of amyloid deposition from the abnormal aggregation of M-protein. Additionally, the excessive circulating light chain component of the M-protein can lead to renal failure resulting in proteinuria.[29]

Several chemotherapy regimens have been used historically, but autologous stem cell transplantation has become the first-line treatment for patients deemed healthy enough to tolerate the procedure.[29,204] Radiation for isolated bone lesions is considered palliative, and bisphosphonates are utilized to reduce the likelihood for fracture and pain.[29] Newer chemotherapeutic regimens have resulted in better survival rates, but multiple myeloma is difficult to cure, and treatment often seeks to control disease and prolong survival. Thalidomide, lenalidomide, and bortezomib used in combination with dexamethasone has resulted in improved survival.[144] The prognosis is less favorable for older patients with disseminated disease, and the overall 5-year survival approximates 50% in most reports with a median survival of 6 to 7 years.[204] Medical consultation with the patient's oncologist would be recommended prior to any dental care.[240]

Radiographic features.

Radiographically, there are typically multiple radiolucent areas, some with well-defined, punched-out borders and others that present with more irregular and diffuse margins (Fig. 3.31).[71,149] The presence of multiple lesions suggests a noninflammatory etiology, but a solitary lesion on a single periapical radiograph could mimic a periapical cyst or periapical granuloma. As a result, a panoramic radiograph is recommended if multiple myeloma is suspected.[30] Root resorption is not common but has been reported.[257]

Well-defined unilocular periapical radiolucencies

As stated previously, a unilocular, well-defined apical radiolucency most likely represents a periapical cyst or periapical granuloma if the dental history and clinical testing are consistent with an inflammatory etiology. However, many pathologies, with a wide range of clinical significance, can exhibit the identical radiographic presentation as periapical cysts and periapical granulomas, and the dental literature is replete with case reports of noninflammatory pathologies misdiagnosed as periapical inflammatory disease. The astute clinician needs to consider all possibilities when forming a differential diagnosis.[235]

Periapical cysts and periapical granulomas

Pulp necrosis occurs due to the presence of bacteria within the root canal system.[123] Periapical granulomas represent an accumulation of inflamed granulation tissue as a result of a necrotic pulp. Bacteria and byproducts of bacterial metabolism trigger an immune response, most often at the root apex, but this reaction can occur anywhere along the root surface if the pulp space communicates with the PDL via accessory anatomy or a fracture. The affected tooth should be nonresponsive to pulp testing, unless partial necrosis of a multirooted tooth results in variable levels of responsiveness and a more difficult diagnosis.

The exact mechanism of cyst formation is unknown and numerous theories have been proposed.[175,247,251,253] If epithelium near the root apex of a necrotic tooth is stimulated by an inflammatory response, a periapical cyst can result.[152] There is likely a combination of interactions between the resident tissues in the area, including epithelium, bone, extracellular matrix, and the inflammatory cascade.[24] As with periapical granulomas, the affected tooth does not respond to pulp testing and the diagnosis can be more confusing if partial necrosis is present in a multirooted tooth.

Historically, lesions that were larger than 1.5 cm and well demarcated were considered cysts, and it was thought surgery or extraction would be necessary for complete healing.[88,176] However, this concept has evolved and it is generally accepted that there is no way to differentiate periapical cysts from periapical granulomas using conventional imaging (Fig. 3.32), irrespective of the size or cortication of the radiolucency.[38,208] The ability to differentiate

Telegram: @dental_k

www.konkur.in

periapical cysts and periapical granulomas utilizing CBCT has also been the focus of numerous studies with inconsistent findings. Guo and colleagues suggested that CBCT is moderately accurate at differentiating periapical cysts from granulomas, while Simon et al. reported CBCT is an accurate differentiator, but found agreement between the pathologist and radiologist in only 76% of cases.[101,232] Other studies concluded that biopsy remains the gold standard to differentiate periapical cysts from periapical granulomas (Fig. 3.33).[35,212]

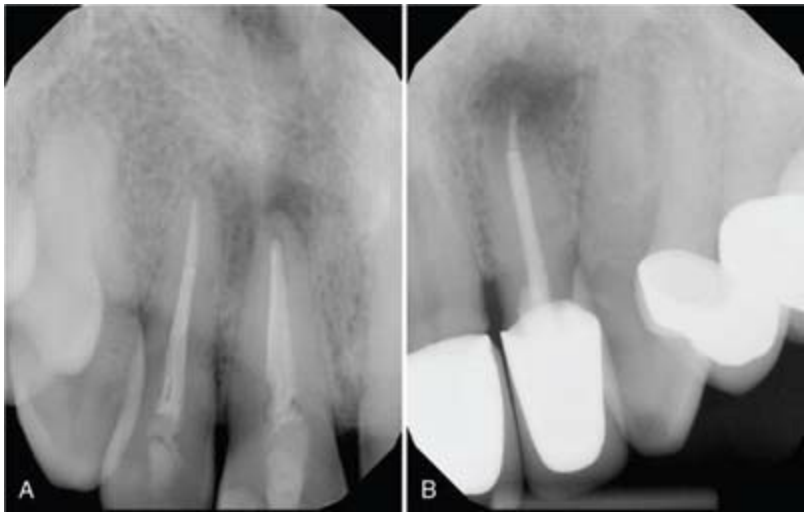

FIG. 3.32 **A,** Well-defined radiolucency at the root apex of tooth #8. The previous root canal filling is short of the apex and exhibits numerous voids. A tissue sample obtained during apical surgery revealed a periapical granuloma. **B,** Well-defined radiolucency at the root apex of tooth #10. Apical surgery was completed, and the biopsy confirmed a periapical cyst. There is no way to differentiate periapical cysts from periapical granulomas using conventional imaging.

A) Radiograph shows left tooth with filled root canal and thin tissue at the root apex.

www.konkur.in

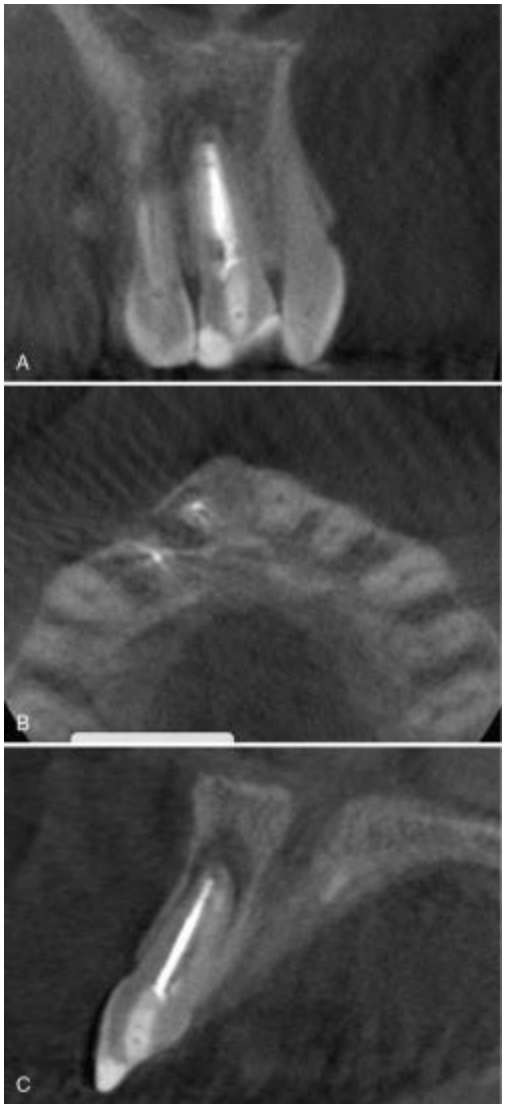

FIG. 3.33 CBCT images of the periapical granuloma from Fig. 3.32, *A*. It is not possible to differentiate periapical cysts from periapical granulomas using CBCT, and biopsy remains the best method to definitively make this distinction. **A,** Sagittal CBCT image of periapical granuloma. **B,** Axial CBCT image of periapical granuloma. **C,** Coronal CBCT image of periapical granuloma.

Three CBCT images, A through C, show sagittal, axial, and coronal sections of poorly anchored tooth due to lesions at the root tip in the periapical region.

Multislice-CT has been reported to have a high degree of accuracy distinguishing periapical cysts from periapical granulomas, but this technology requires significantly more radiation exposure and the quality of the image is not as accurate as CBCT.[45,258] Both ultrasound and MRI may be able to differentiate periapical cysts from periapical granulomas, but clinical

Telegram: @dental_k

www.konkur.in

usage has been limited and these devices are not readily available in the typical dental setting. However, early reports are encouraging and more research is needed to support the use of these technologies.[4,60,153,161]

Because there is no way of knowing whether a radiolucency represents a periapical cyst or a periapical granuloma with imaging alone, it is impossible to know the true incidence of these inflammatory lesions and to subsequently determine if there is a difference in their healing potential following endodontic treatment. Apical surgery or extraction is needed to confirm the diagnosis, and this may lead to a sampling bias of cases that have not healed following routine endodontic treatment. Additionally, in spite of histopathology being considered the gold standard at differentiating periapical cysts from periapical granulomas, this is not without controversy. Some pathologists will make the diagnosis of periapical cyst if an epithelial lining is seen in a histologic section in association with granulation tissue, while other pathologists require visualization of the cyst lining on a basement membrane and an intact luminal surface.

During apical surgery, tissue is curetted from the apex and the sample is typically not removed in a single piece. This may result in a breakdown of the cyst lumen and a decreased likelihood for the diagnosis of a cyst. Moreover, for larger lesions, the entire tissue sample may not be evaluated histologically and slides of representative samples will be viewed by the pathologist. This increases the potential to overlook a small cyst contained in the unviewed tissue. Studies that have utilized intact resected specimens and serial sections to evaluate the entire lesion have reported a lower incidence of cysts compared to many other historical studies.[173,231]

The reported incidence of periapical cysts and periapical granulomas is highly variable in the literature, ranging from 6% to 55%.[17,146,156,174,237] True cysts are completely lined by epithelium and lack any communication with the root canal space. As a result, the healing potential for true cysts may be limited following conventional root canal treatment. In contrast, pocket cysts are in direct contact with the root canal system and may have a greater likelihood for healing following endodontic treatment.[173,231]

Treatment of periapical cysts and periapical granulomas is identical. Both require identification of the offending tooth, allowing removal of the inflammatory stimulus with root canal treatment or extraction. Treatment

Telegram: @dental_k

www.konkur.in

choices will depend on the patient's treatment plan, periodontal status, restorability of the tooth, and patient desires. The diagnosis of periapical inflammatory disease becomes more complicated if the radiolucency is associated with a previously root canal–treated tooth because pulp testing is no longer relevant.

Radiographic features.

Periapical granulomas and periapical cysts present with variable levels of discomfort, from mild awareness to debilitating pain, and the symptoms often correspond to the pain levels identified with percussion and palpation during clinical examination. Many periapical granulomas and periapical cysts are asymptomatic and are discovered on routine radiographs.

In the earliest stages of infection, neutrophils predominate and there can be very little or no bone involvement, consistent with acute dental pain, but no evidence of abnormality on radiographic evaluation. As the inflammatory cascade persists, there is the potential for more bone destruction and a radiolucent area can develop, ranging from a subtle widening of the PDL space to extensive bone loss of more than several centimeters (Fig. 3.34). The radiolucent area can exhibit a well-defined and corticated margin or the inflammatory process can stay within the medullary spaces and lack definition radiographically (Fig. 3.35). Root resorption is not uncommon and the outline and definition of the radiolucency can be altered depending on the angle used to obtain a two-dimensional periapical radiograph. As a result, it is often necessary to obtain multiple radiographs to identify a subtle periapical lesion, but this may not improve diagnostic accuracy in all cases.[36] A CBCT may be a better alternative if there is doubt about the presence of periapical pathology.[142]

There is a loss of trabeculation at the apex blending into normal bone resulting in an ill-defined radiolucency. **B,** Well-defined periapical granuloma at the root apex of tooth #27 was confirmed with a biopsy when bone loss and symptoms persisted following nonsurgical root canal treatment. Size and radiographic definition of periapical cysts and periapical granulomas are highly variable.

A) Radiograph shows radiopaque crown and broken root canal with a cystic lesion (low-density tissue) at the root apex.

B) Radiograph shows 27th tooth with radiolucent root canal and a square-shaped patch at the root apex.

Lateral radicular cyst

The bacterial etiology of a lateral radicular cyst is identical to that of a periapical cyst or periapical granuloma; the only difference is in the location affected. As a result, pulp testing is critical to determine the causative tooth because several other pathologies can look radiographically identical in this area. Endodontic treatment or extraction is indicated depending on the patient's treatment plan, periodontal status, restorability of the tooth, and patient preference.

Radiographic features.

Lateral radicular cysts are most commonly well-defined radiolucencies, and some may have a corticated border (Fig. 3.36). However, these lesions will exhibit the same growth patterns as periapical cysts and periapical

Telegram: @dental_k

www.konkur.in

granulomas resulting in an ill-defined radiolucency when the inflammatory cascade is confined to the medullary spaces. A CBCT will better demonstrate the radiographic changes when the lesion is small or lacks definition. The differential diagnosis for radiolucencies in the lateral location includes, but is not limited to, the following: OKC, ameloblastoma, and lateral periodontal cyst (LPC).

FIG. 3.36 Lateral radicular cyst. **A,** Preoperative image with gutta-percha tracing a draining sinus tract. Patient has a history of biopsy in the area that was diagnosed as a dentigerous cyst. Tooth #20 responds to both cold and electric pulp testing. Options included root canal treatment, extraction, or a second biopsy. The sinus tract suggests a necrotic pulp and the potential for a false-negative pulp test. Also, the diagnosis of dentigerous cyst is not accurate because the tooth has erupted. Nonsurgical root canal treatment was completed. **B,** Several lateral canals can be seen opposite the radiolucent areas and

Telegram: @dental_k

the sinus tract resolved within 1 week. **C,** Healing of bone is evident at 18-month recall.

A) Radiograph shows extremely less-density tissue at gum line between teeth. A wedge-shaped structure lies next to the 20th tooth.

B) Radiograph shows 20th tooth with filled root canal and radiolucent region in-between. The gum line on one side of the tooth appears dense.

C) Radiograph shows 20th tooth with filled root canal and normal tissue with small dark patch at one side of the tooth.

Lateral periodontal cyst

The LPC is an uncommon developmental cyst of odontogenic origin thought to arise from rests of dental lamina. Although the LPC is developmental and occurs over a wide age range, diagnosis is uncommon before 30 years of age. The mandibular canine and premolar areas are the predominant sites of involvement, but reports indicate that it can occur in either arch.[40,79,234] LPCs are often discovered as an asymptomatic finding on routine radiographs, but expansion, tenderness to palpation, and pain are possible. Most present as a single lesion, but LPCs can have a multifocal presentation, and a multicystic variant known as a botryoid LPC has also been described.[127,263] Surgical removal is the treatment of choice and recurrence is not likely. However, due to the multicystic nature of the botryoid subtype, a higher recurrence rate is possible.[103,199]

Radiographic features.

Radiographically, the LPC is characterized by a unilocular, well-defined, oval-shaped radiolucency that is indistinguishable from lateral radicular cysts in many cases (Fig. 3.37). However, the adjacent teeth should respond to pulp testing, unless there is pulpal pathology for unrelated restorative reasons. This radiographic presentation is also very similar to early unilocular OKCs or ameloblastoma (Fig. 3.38). Because they are slow growing, most are less than 1 cm at the time of diagnosis. Less commonly, an LPC can be located near a root apex, suggesting a lesion of endodontic origin.[181] The botryoid subtype can present as a multilocular radiolucency, but it is most often unilocular in spite of its multicystic growth pattern.

Focal cemento-osseous dysplasia

Focal cemento-osseous dysplasia is another fibro-osseous lesion characterized by replacement of bone with fibrous and mineralized tissue. As the name implies, focal cemento-osseous dysplasia involves a single site, unlike PCOD, which is more commonly multifocal. Although the exact etiology is unknown, the proximity to root ends and a cementum-like component suggest the cells of origin reside in the PDL.[244] As with PCOD, the majority of cases affect females and are diagnosed after 30 years of age.[130,244] Although there is a predilection for the black population, it is not as strong as is seen with PCOD. The diagnosis could be based on radiographic findings and pulp testing, but other pathologies, with more significant growth potentials, can resemble FCOD, necessitating a biopsy for definitive diagnosis. After the diagnosis has been established, routine follow-up of the affected bone is indicated.

Radiographic features.

Focal cemento-osseous dysplasia usually involves the posterior mandible, is commonly asymptomatic, and is discovered on routine radiographic examination.[159,244] Most lesions are smaller than 1.5 cm and exhibit a variable and mixed radiolucent radiopaque appearance, but some may be completely radiolucent (Fig. 3.39). There is usually a well-defined border, but not always. They tend to occur near root ends and will mimic periapical inflammatory disease if no radiopacity is present within the lesion.[62]

Nasopalatine duct cyst

Nasopalatine duct cysts, also referred to as incisive canal cysts, are the most common nonodontogenic cyst in the jaws with a prevalence of approximately 1%.[177,179] They are likely developmental but are most often diagnosed after the age of 30, suggesting a possible traumatic or bacterial etiology. The diagnosis is typically based on radiographic findings, and nasopalatine duct cysts have an excellent prognosis following surgical removal.

Radiographic features.

Nasopalatine duct cysts can occur at any age, but they are more likely found in adults and are rare before 10 years of age.[107,223] Swelling, drainage, and pain are the most common symptoms associated with these cysts. Many are asymptomatic and discovered on routine radiographs. They present as a well-

Telegram: @dental_k

www.konkur.in

defined, round or heart-shaped radiolucency in the maxillary midline or just lateral to the midline (Fig. 3.40). Most are between 1 cm and 2 cm, but they will uncommonly exceed 5 cm and exhibit a more destructive nature.[195,215] Due to superimposition over the root ends of central incisors, pulp testing and clinical correlation are necessary to avoid mistaking nasopalatine duct cysts for lesions of pulpal origin.[78]

FIG. 3.40 **A,** Periapical image with a well-defined unilocular radiolucency at the root apex of tooth #8. Asymptomatic and no history of trauma. Tooth #8 responded to both cold and electric pulp testing. A biopsy revealed a nasopalatine duct cyst. **B,** The more classic presentation of nasopalatine duct cyst with a rounded radiolucency in the midline.

A) Radiograph shows the central tooth that has a radiolucent circular patch with a vertical radiopaque line inside in the crown. Radiolucent tissue extends from the gum line toward the root apex.

B) Radiograph shows dark patch of abscess between teeth near the root tips.

Source: (Courtesy A, Dr. Christel Haberland; B, Dr. Martin Rogers.)

Stafne defect

Stafne defects are asymptomatic radiolucencies most commonly located near the angle of the mandible, but a less common anterior position has been reported.[34,52,126,239] The exact etiology is unknown and it is often considered

Telegram: @dental_k

www.konkur.in

to be developmental in nature. However, the radiolucent area is usually not diagnosed until middle age, leading some investigators to postulate pressure resorption as the cause. There is a strong male predilection and due to the classic radiographic presentation, the diagnosis of posterior defects is typically made based on radiographic findings alone. No treatment is indicated unless there is uncertainty about the diagnosis, and biopsy most often yields normal salivary gland tissue.

Radiographic features.

Because Stafne defects are asymptomatic they are most often discovered as an incidental finding on panoramic radiographs.[148] They present as radiolucencies on the lingual side of the mandible inferior to the mandibular canal with a well-defined and corticated border (Fig. 3.41).[262] Although the size is variable, most Stafne defects are between 1 cm and 2 cm and, in some instances, the radiolucent area will approximate the root ends of the mandibular teeth, suggesting a periapical cyst or periapical granuloma (Fig. 3.42). Anterior Stafne defects associated with the sublingual gland are less common. Superimposition over anterior root ends and the atypical position suggest periapical inflammatory disease or any other unilocular well-defined radiolucency. In these cases, it is important to correlate clinical and restorative histories with the radiographic findings to ensure appropriate treatment.[58] Additionally, both the axial and coronal planes of a CBCT will demonstrate the lingual concavity and lack of involvement at the root ends.

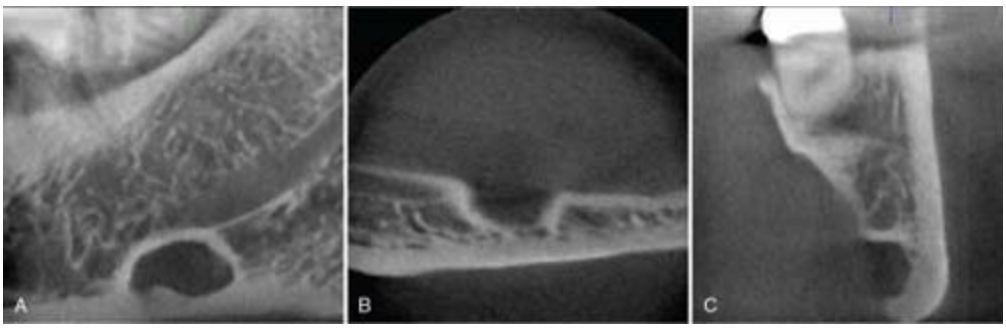

FIG. 3.41 Stafne defect. **A,** Sagittal CBCT image showing a well-defined loss of density inferior to the mandibular canal. **B,** Axial CBCT image demonstrating a lingual concavity. **C,** Coronal CBCT image also exhibiting a lingual concavity inferior to the mandibular canal with no involvement of the root ends.

A) CBCT image shows a bone cavity in the lower jaw. Surrounding tissue appears fibrous.

B) CBCT image shows top view of teeth with U-shaped cavity at the upper side.

C) CBCT image shows the cavity at the lower end of the jaw.

Source: (Courtesy Dr. Bruno Azevedo.)

FIG. 3.42 Anterior Stafne defect. **A,** Periapical image exhibiting a well-defined radiolucency near, but not at, the root apex of tooth #23. The lack of restorative history and location of the lesion suggest a noninflammatory etiology and these teeth respond to pulp testing. **B,** Reformatted panoramic image showing a loss of density near the apex of tooth #23. **C,** Coronal CBCT images reveal a concavity in the lingual cortex of bone with no involvement of the root ends.

A) Radiograph shows a dark globular patch near the root tip of tooth. All teeth have radiolucent root canals.

B) Radiograph shows lower jaw with the dark patch almost near the center.

C) A series of two radiographs shows hollow cavities in the lingual cortex of 23rd tooth.

Summary

For practitioners, it is important to remember that the great majority of radiographic abnormalities encountered on a daily basis will be due to a bacterial etiology as the result of a necrotic pulp. However, it is imperative that clinicians also understand that developmental, metabolic, and neoplastic etiologies can very closely resemble an inflammatory cause.

A multilocular radiolucency should not be the result of a necrotic pulp, and further diagnostic workup is indicated when this type of change is identified. Most radiographic lesions of inflammatory origin are going to be radiolucent, and the presence of calcification suggests a higher likelihood for a nonpulpal etiology. Furthermore, a multifocal presentation should arouse suspicion about noninflammatory etiologies, especially if the dental history and pulp testing are not consistent with pulp necrosis in multiple teeth. Periapical inflammatory disease can be well defined and corticated radiographically or the lesion can have ill-defined margins when the radiographic change is confined to the medullary spaces. However, rapid cortical expansion or perforation of the cortical plate, extensive tooth mobility, irregular root resorption, and a “moth eaten” appearance suggest a more ominous differential diagnosis.

This chapter categorized lesions based on the most typical radiographic presentations encountered in clinical practice, but many of these pathologies defy classification into a single category and may exhibit a wide variety of radiographic appearances. This review also focused on the most common noninflammatory lesions that present in the periradicular regions, but it is in no way a comprehensive account of all potential pathologies affecting the region.

Radiographs are one piece of the diagnostic puzzle, and accurate interpretation of radiographic findings in conjunction with a thorough review of the medical history, dental history, pulp testing, and clinical examination will yield a differential diagnosis when a nonbacterial etiology is suspected. It is not necessary, nor is it possible, to make a definitive diagnosis of many radiographic abnormalities based exclusively on imaging. However, making the determination that a radiographic lesion is not pulpal in origin should be possible in most cases and further evaluation, in conjunction with referral to the appropriate medical or dental provider, can result in a timely and accurate

diagnosis, significantly influencing disease progression and prognosis for many patients.

4: Diagnosis of the nonodontogenic toothache

Alan S. Law, Donald R. Nixdorf, Donna Mattscheck

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

> *An unthinking dentist is a bad dentist. Perfect technique misapplied is at least as unconscionable as sloppy work.*
>
> **Marjorie Jeffcoat**

A nonodontogenic toothache is, of course, an oxymoron. How can one have a toothache that is not odontogenic in etiology? The answer lies in the differentiation of people's perceptions of where they sense their pain, termed the *site of the pain*, from the location of a pathophysiologic process giving rise to the pain that may or may not be in the same region, termed the *source of the pain.* This concept of the attribution of pain to an anatomic region that is different from the location of the etiologic process is generically known as the *referred pain phenomenon* and can occur in multiple areas of the body. Thus, a nonodontogenic toothache has a source of pain that is not the tooth the patient has indicated, clearly demonstrating the diagnostic challenge (Fig. 4.1).

Pain is common. It causes human suffering and has significant socioeconomic effects. Pain is a motivator that provokes individuals to seek care. But protracted chronic pain debilitates and can significantly impair the quality and productivity of a person's life. One survey revealed that 66% of respondents reported experiencing pain or discomfort over a 6-month period. Significantly, 40% of respondents reported that this pain affected them to a "high degree."[19] A study published in 2003 estimated the lost productive work time attributed to common pain conditions among active workers to cost $61.2 billion per year.[127] One investigator reported that over a 6-month period, 22% of Americans experienced at least one of five types of facial pain. Of these pains, the most common type (12.2%) was toothache.[81]

Although toothache is the most common pain entity occurring in the facial region,[81] many other types of pain can occur in the same general area. A primary responsibility of a dental practitioner is to diagnose pathologic entities associated with the oral cavity and masticatory apparatus. Many of these pathologic entities have pain as a primary component of their presentation. Because dental practitioners are sought out daily for the alleviation of odontogenic pain, it is imperative for them to have a basic

Telegram: @dental_k

www.konkur.in

working knowledge of other types of facial pain in order to make an accurate diagnosis and properly select care for patients. It is paramount to realize that not all pain entities presenting as toothache are of odontogenic origin. The presenting toothache may be a heterotopic symptom of another disorder. A heterotopic symptom is perceived to originate from a site that is different from the tissue that is actually the source of the pain. This is in contrast to primary pain, in which the perceived site of pain is the actual tissue from which the pain originates. Before discussing pain entities that mimic toothache, it is helpful to understand the neurobiologic mechanisms of orofacial pain.

Review of neuroanatomy

Somatic structures

To understand the pathways by which orofacial pain occurs, one must first gain a basic understanding of the structures involved in its transmission to higher brain centers. Structures of the orofacial region can be divided into two broad categories: somatic and neural structures. Somatic structures are those that make up the different nonneural tissues and organs. The somatic structures can be further anatomically divided into superficial and deep structures. Superficial structures include the skin, mucosa, and gingiva; pain that arises from these superficial structures is usually well localized (e.g., a sharp explorer penetrating the gingiva results in well-localized pain). Deep structures include musculoskeletal and visceral tissues. Pains from these deep structures are typically poorly localized and diffuse in nature.

Neural structures

Neural structures involved in the perception of pain include the afferent (toward the brain) and efferent (away from the brain) regulation of somatic structures. Nerve impulses are transmitted from orofacial structures to the brain via the peripheral nervous system, whereas modulation and interpretation of these impulses into what we feel as pain occurs in the central nervous system. Pain can arise solely from either central or peripheral nervous tissue but heterotopic pain, which is often involved with

Telegram: @dental_k

www.konkur.in

nonodontogenic toothache, likely requires central modulation to occur.

Peripheral nervous system

Pain arises as a result of tissue damage, or the potential for tissue damage, and is transmitted via terminal nerve fibers known as primary afferent nerve fibers. Two major classes of nociceptive (or pain-sensing) primary afferent nerve fibers can detect potentially damaging noxious stimuli: the A-delta and C fibers. Both fiber types have a wide distribution throughout the skin, oral mucosa, and tooth pulp. In addition, separate classes of nerve fibers exist that are involved in detecting nonnoxious stimuli such as vibration and in proprioception. These fibers can be found in the periodontal ligament (PDL), skin, and oral mucosa and include the A-beta fibers.

Primary afferent neurons.

Primarily the trigeminal, or fifth cranial, nerve detects and encodes noxious stimuli for the orofacial region. The majority of cell bodies of the trigeminal sensory fibers are in the trigeminal ganglion located on the floor of the middle cranial fossa. The peripheral axons of the trigeminal ganglion run in three divisions—the ophthalmic (V1), maxillary (V2), and mandibular (V3)—which innervate most of the oral mucosa, the temporomandibular joint (TMJ), the anterior two thirds of the tongue, the dura of the anterior and middle cranial fossae, the tooth pulp, the gingiva, and the periodontal membrane.

In the peripheral nervous system, these neurons or nerves are referred to as primary afferent (i.e., sensory) fibers. The primary afferent fibers can broadly be divided into A-beta fibers, which transmit light touch or proprioceptive information, and A-delta and C fibers, which encode pain. The tooth is densely innervated by afferent nerve fibers, which are believed to transmit pain mainly in response to thermal, mechanical, or chemical stimuli. The majority of dental nerves are C fibers that innervate the central pulp, most of which terminate beneath the odontoblasts.[23]

A-beta fibers.

The rapidly conducting myelinated neurons that respond to light touch are called A-beta fibers. Under normal conditions, activation of the A-beta fibers

Telegram: @dental_k

www.konkur.in

by high-intensity stimulation results in low-frequency output in the central nervous system. Activation of A-beta fibers is normally interpreted as nonpainful mechanical stimulation[133] or, under certain conditions, can be perceived as a “prepain” sensation.[23] A-beta fibers also have been shown to undergo phenotypic changes that allow them to encode painful stimuli under certain inflammatory conditions.[98]

A-delta fibers.

The A-delta fibers are lightly myelinated, have a faster conduction velocity than C fibers, and are believed to transmit a sharp or pricking sensation. A-delta fibers respond primarily to noxious mechanical stimuli rather than to chemical or thermal stimuli. Other A-delta fibers may be polymodal (responding to mechanical, chemical, and thermal stimuli)[13] or respond only to cold/mechanical[78] or hot/mechanical noxious stimuli.[39]

In the tooth pulp, A-delta fibers traverse the odontoblastic layer and terminate in the dentinal tubules.[25] Because of their location and their sensitivity to mechanical stimulation, A-delta fibers are believed to respond to stimuli that result in movement of fluid within the dentinal tubules (e.g., osmotic, mechanical probing, or thermal stimuli applied to the external surface of the tooth).[18] Consistent with the hypothesized mechanism of dentinal pain is the fact that the stimuli that cause dentinal fluid movement result in a sharp pain associated with A-delta fiber activation.[95] When intense noxious stimuli activate the A-delta fibers, the input to the central nervous system consists of high-frequency action potentials.

C fibers.

The C fibers are unmyelinated, have slower conduction velocity, and are associated with a dull, aching, or burning sensation. Most C fibers are polymodal, responding to mechanical, thermal, and chemical stimuli. Because of the difference in conduction velocities, A-delta fibers are believed to transmit early, shooting pain, whereas C fibers would transmit late, dull pain. Noxious stimuli that exceed the receptor threshold of these nociceptive primary afferent terminals result in action potentials that travel centrally, signaling tissue damage. In the pulp tissue, the more centrally located C fibers respond to thermal, mechanical, and chemical stimuli and are believed

Telegram: @dental_k

www.konkur.in

to be sensitized by inflammation.[39] All visceral structures are innervated primarily by afferent fibers conducting nociceptive information such as that carried by A-delta and C fibers.

Central nervous system

The primary afferent fibers are responsible for the transduction and transmission of sensory information to higher brain centers, and they do so by synapsing on neurons located within the trigeminal nucleus, which spans the midbrain and cervical spinal cord. This point marks the beginning of the central nervous system and is the point at which processing of pain information begins (Fig. 4.2).

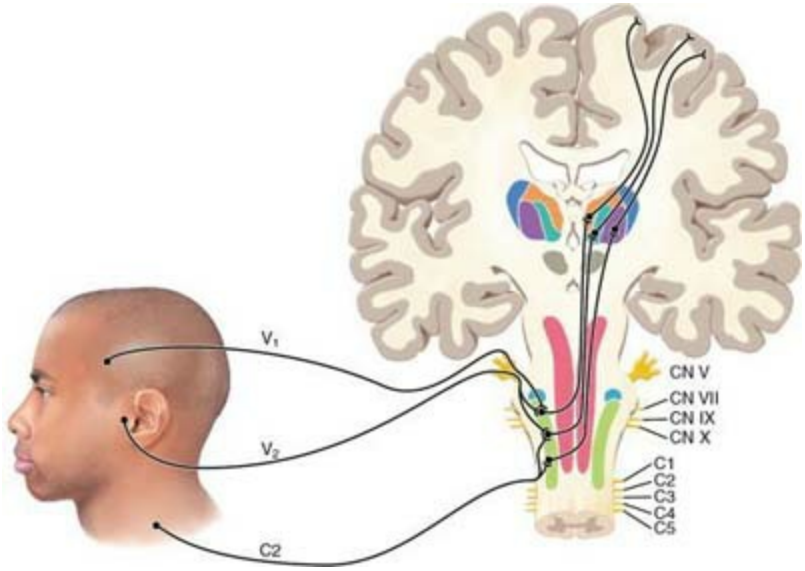

FIG. 4.2 A graphic depiction of the trigeminal nerve entering the brainstem. The primary afferent neuron synapses with a second-order neuron in the trigeminal nucleus. The second-order neuron carries pain information to the thalamus, from which it is sent to the cerebral cortex for interpretation.

A tree-like structure, the trigeminal nerve, on the right shows labels as follows: CN V, CN VII, CN IX, CN X, C1, C2, C3, C4, and C5. To the left, side view of human face is shown. V1, V2, and C2 from the trigeminal nerve lead to regions near the forehead, tragus of ear, and neck at the center, respectively.

Source: (Redrawn from Okeson JP: *Bell's orofacial pains*, ed 5, Chicago, 1995, Quintessence Publishing.)

Telegram: @dental_k

www.konkur.in

Just as there are different types of sensory neurons in the periphery, in the trigeminal nucleus, there are also different types of neurons that receive nociceptive input from the periphery. The ascending neurons located in the trigeminal nucleus are known collectively as *second-order* or *projection neurons* and can be subdivided into three distinct groups of neurons based on the type of information they receive: (1) low-threshold mechanoreceptors, (2) nociceptive-specific, and (3) wide dynamic range neurons.

The primary central site of termination for nociceptive fibers is the subnucleus caudalis, located in the most caudal region of the trigeminal nucleus,[39,57,144] which anatomically and functionally resembles the dorsal horn of the spinal cord and has been referred to as the medullary dorsal horn.[57] Four major components of nociceptive processing are located in the dorsal horn of the subnucleus caudalis: central terminals of afferents, local circuit neurons (interneurons), projection neurons, and descending neurons.[71] Within the subnucleus caudalis, the A-delta and C fibers terminate primarily in the outer laminae (I and IIa) and lamina V. Local circuit neurons are composed of islet cells (which are thought to be inhibitory) and stalked cells (which are believed to be excitatory).[38] Combined, the local circuit neurons may modulate nociceptive transmission from the primary afferents to the projection neurons.

The fourth component of the dorsal horn are the terminal endings of descending neurons. The descending neurons originate in the nucleus raphe magnus (NRM), the medullary reticular nuclei, and the locus ceruleus (LC). Descending brainstem neurons release serotonin (from the NRM) or norepinephrine (from the LC), which may inhibit the activity of projection neurons directly or by activating local opioid interneurons. These neurons are responsible for the endogenous abatement of pain; blockade of their activity increases pain transmission and reduces pain thresholds.

Second-order neurons.

Projection neurons have axons that cross to the contralateral medulla to ascend in the trigeminothalamic tract and project to the ventral posterior medial and intralaminar nuclei of the thalamus, where additional neurons project to the cortex. Projection neurons involved in the transmission of painful stimuli can be divided into two classes: wide dynamic range and

Telegram: @dental_k

www.konkur.in

nociceptive-specific neurons. Wide dynamic range neurons receive input from mechanoreceptors, thermoreceptors, and nociceptors, whereas nociceptive-specific neurons are excited solely by nociceptors. These two types of projection neurons may be responsible for signaling the severity and location of pain, respectively.[79]

Multiple primary afferent neurons may synapse on a single projection (i.e., convergence). This occurs to a much greater degree in deep tissues as opposed to cutaneous tissues. Primary afferent fibers of nontrigeminal origin, such as those derived from vagus, glossopharyngeal, facial, and cervical spinal ganglia have been shown to converge and synapse onto trigeminal projection neurons located as far caudal as spinal level C4.[74] This phenomenon of convergence may result in the clinical finding of pain that radiates beyond an area of tissue injury. Convergence may also explain why pain appears to be associated with a site other than the injured area. Interestingly, when projection neurons receive input from superficial and deep structures, the more superficial inputs usually predominate.[121] Thus, pain originating from deep structures would typically be referred to superficial areas (e.g., pain originating from the jaw muscles would typically be referred to the face rather than deeper structures).

Autonomic nervous system

The stellate ganglia supply the entire sympathetic innervation of the orofacial region, which is located bilaterally at the level of the seventh cervical vertebra. Under normal conditions, sympathetic stimulation has no influence on sensory function. However, afferent sympathetic fibers in an area of trauma may become involved in the response to pain and may also play a role in chronic pain states. Specifically, C fibers in the area of partial nerve injury may become responsive to sympathetic nerve stimulation. The modulation of nociception by the sympathetic nervous system has been shown such that release of pain neurotransmitters may be altered in the presence of sympathetic agonists and by blockade of the sympathetic nervous system, using antagonists.[70] Whether the effects of sympathetic nerve fibers on pain transmission are direct (via homeostatic regulation) or indirect remains unclear. The parasympathetic division of the autonomic nervous system has not been shown to be involved in the development or modulation of pain.

Review of neurophysiology

Peripheral sensitization

After tissue insult there is an inflammatory reaction that often produces pain. The severity of pain that follows is related to several aspects of the injury, such as the type, extent, and location; the innervation of the tissue; and the phase of the inflammation. In the nociceptive system, tissue injury can manifest itself as increased responsiveness or reduced thresholds to a noxious stimulus, referred to as hyperalgesia. Hyperalgesia can be partially accounted for by sensitization of nociceptors (primary hyperalgesia) and by central nervous system mechanisms (secondary hyperalgesia).

In the absence of tissue damage, activation of C or A-delta fibers produces a transient pain. This pain is believed to serve as a physiologic warning. When there is tissue injury, afferent fibers may be activated by lower intensity stimuli than usual, and the quality of pain may be more persistent and intense. This phenomenon is due, in part, to the sensitization of nociceptors, including an increase in spontaneous activity.

At the site of tissue injury, there are a number of inflammatory mediators that can directly or indirectly sensitize primary afferent nociceptors (see Chapter 13 for more details). These inflammatory mediators may be released from the local tissue cells, circulating and resident immune cells, vasculature and endothelial smooth muscle cells, and peripheral nervous system cells.

Central sensitization

After peripheral tissue injury there is an afferent barrage from C fibers resulting from peripheral tissue inflammation, decreased afferent thresholds, and spontaneous firing of afferent fibers. When a second-order neuron receives a prolonged barrage of nociceptive input, the second-order neuron may also become sensitized. This results in a phenomenon referred to as central sensitization.[17] The result of central sensitization is enhanced processing (i.e., amplification) of neural impulses that are being transmitted to higher brain centers. Two effects of central sensitization are secondary hyperalgesia and referred pain.

Secondary hyperalgesia is an increased response to painful stimulation at

Telegram: @dental_k

www.konkur.in

the site of pain resulting from central nervous system changes. This is in contrast to primary hyperalgesia, which is a lowered pain threshold resulting from sensitization of peripheral neurons. Secondary hyperalgesia might be felt in superficial (e.g., gingiva or skin) or deep structures (e.g., muscles or teeth).

Terminology

In general, as research progresses and uncovers new ways for us to look at pain, the terminology changes. This can introduce some confusion, especially when older terms are used. Therefore, it may be helpful to present contemporary definitions of some of the basic terms and review some of the previously mentioned terms (Box 4.1).

Box 4.1

Types of Pain

Pain

An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.[86]

Nociceptive pain

Pain arising from activation of nociceptors.[86]

Neuropathic pain

Pain arising as a direct consequence of a lesion or disease affecting the somatosensory system.[86,135]

Peripheral sensitization

Increased responsiveness and reduced thresholds of nociceptors to stimulation of their receptive fields.[86]

Central sensitization

Increased responsiveness of nociceptive neurons in the central nervous system to their normal or subthreshold afferent input.[86]

Heterotopic pain

Telegram: @dental_k

www.konkur.in

Any pain that is felt in an area other than its true source is heterotopic pain. There are three types of heterotopic pain: referred, central, and projected.[105,106] Referred pain is felt in an area innervated by a nerve different from the one that mediates the primary pain. Referred pain cannot be provoked by stimulation of the area where the pain is felt; rather, it is brought on by manipulation of the primary source of pain (Fig. 4.3). In addition, referred pain cannot be arrested unless the primary source of pain is anesthetized. The referral of pain tends to occur in a laminated fashion (Fig. 4.4). This is because peripheral nociceptors enter the spinal trigeminal tract in a laminated fashion. As a result, there are general referral patterns in the face. In addition, the referral of pain is usually in a cephalad or upward direction. This is evidenced clinically in that pain from mandibular molars typically is referred to maxillary molars, as opposed to premolars or incisors.

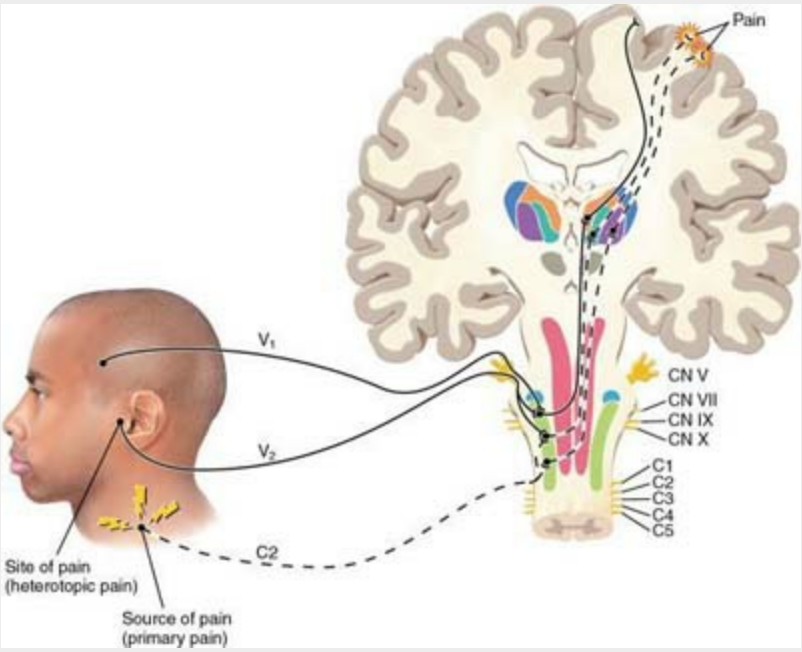

FIG. 4.3 Illustration of pain that is referred from an area innervated by one nerve *(C2)* to an area innervated by a different nerve *(V2)*. Note that this phenomenon occurs secondary to the convergence of different neurons onto the same second-order neuron in the trigeminal nucleus. The sensory cortex perceives two locations of pain. One area is the trapezius region that represents the source of pain. The second area of perceived pain is felt in the temporomandibular joint area, which is only a site of pain, not a source of pain. This pain is heterotopic (referred).

A tree-like structure, the trigeminal nerve, on the right shows labels as

Clinical entities that can present as toothache

Sources of odontogenic toothache

Telegram: @dental_k

www.konkur.in

Before considering heterotopic pains that may present as toothache, it is important to fully understand odontogenic pain as a primary source for toothache. Only two structures serve as sources for primary odontogenic pain: the pulp–dentin complex and the periradicular tissues. The innervation of the pulp is similar to that of other deep visceral tissues; thus, in various states of pathosis, it will have pain characteristics similar to deep visceral tissues. The primary nociceptors of the pulp that respond to inflammation are the slow-conducting, high-threshold C fibers. Because their threshold is high and they rarely terminate in dentinal tubules, C fibers do not respond to normal or nonpathologic dentinal stimulation. C fibers typically conduct pain that is associated with tissue damage. In addition, C fibers respond in a threshold manner that can be termed "all or nothing." For example, a slightly cold stimulus that is below the C fiber threshold will fail to produce any sensation. Only when a stimulus is intense enough to reach the threshold will the C fiber fire, resulting in the sensation of pain.

Pulpal pain is mediated by C fibers and is dull, aching, or throbbing in nature. This is in contrast to the quick, short, sharp sensation produced by A-delta fibers that mediate dentinal pain. Therefore, when pulp testing, it is meaningful to note not only whether the patient perceived the stimulus but also the nature of the stimulus perceived. A simple notation would be to use an "s" (short) to indicate a response more typical of an A-delta fiber (dentinal pain) or a "p" (prolonged) to indicate the response was more indicative of a C fiber response (pulpal pain).

Tissue inflammation can result in sensitization of nerve fibers. When peripheral nociceptors (e.g., pulpal C fibers) are sensitized, the threshold of firing in response to a given stimulus (e.g., temperature and pressure) is lowered. In states of sensitization these nociceptors can be provoked with a less intense stimulus. The threshold for excitation is still "all or nothing" but the required level of stimulation has decreased. These fibers can become so sensitized that they may fire at as low a temperature threshold as body temperature,[95] normally not sufficient to stimulate a C fiber. In fact, they can become so sensitized that they will fire in response to the normal pulse pressure of cardiac contraction, eliciting a complaint of "I can feel my heartbeat in my tooth" or "my tooth is throbbing." Sensitized C fibers can even fire without provocation, resulting in spontaneous pain.

Telegram: @dental_k

www.konkur.in

Similar to deep visceral tissues, the pulpal nociceptors demonstrate a high degree of convergence in the central nervous system. In a study of cat brain, 74% of the neurons tested in the subnucleus caudalis showed convergence from multiple tooth pulps.[22] In addition, the dental pulp has little to no proprioceptive neurons. The high degree of convergence from pulp tissue and the lack of proprioceptive information provided are the key factors in why purely pulpal pain can be so difficult for patients to localize. In addition to reducing localization of pain, convergence increases the referral of pain to tissues not actually affected by the inflammation. The fact that neurons from the pulps of mandibular teeth converge with those of maxillary teeth can result in pain from a mandibular pulpitis being referred to the maxillary arch. Because the patient may poorly localize pulpal pain, it is important for the clinician to localize the source of the pain. This is often accomplished through the use of tests that are employed in an attempt either to reproduce the eliciting stimulus of a patient's pain or to eliminate the pain. For example, pulpal pain should be aggravated with hot or cold stimulation and should be eliminated or significantly reduced with local anesthetic.

Unlike pulpal pain, pain of periradicular origin is easier to localize. Mechanoreceptors are numerous in the PDL and are most densely concentrated in the apical one third.[87] Once inflammation from pulpal disease extends into the PDL, patients are able to locate the source of the pain much more readily. As a musculoskeletal structure, the PDL responds to noxious stimulation in a graded fashion—that is, the degree of discomfort a patient feels in relation to periradicular pain depends on the degree of peripheral sensitization and the amount of provocation to this structure. A sensitized PDL will be uncomfortable to a patient if percussed lightly but more uncomfortable if percussed heavily. This is known as a graded response. It is, therefore, appropriate to record periradicular testing such as percussion and palpation in terms of degrees of tenderness (versus "all or nothing"). As with pulpal pain, pain of periradicular origin should also have an identifiable etiology. Periradicular pain tends to be dull, aching, or throbbing and should resolve completely with local anesthesia. If pain of suspected periradicular origin is nonresponsive to local anesthetic, it is a strong indication that the pain may be nonodontogenic in origin.

The tooth is unique in the human body in that it has a visceral-like

Telegram: @dental_k

www.konkur.in

component, the pulp, and a musculoskeletal component, the PDL. Therefore, odontogenic pain can have a wide variety of presentations. Tooth pain can be diffuse or well localized, mild or intense, or spontaneous or provoked with various stimuli applied at various intensities. The quality can vary between sharp and dull and aching or throbbing. This potential for extreme variability makes it possible for toothaches to mimic or be mimicked by many other types of pain that occur in the head and neck. In addition, because both the pulp tissue and PDL can be categorized as deep somatic tissue, continued nociceptive input from odontogenic pain has a great propensity to produce central excitatory effects such as secondary hyperalgesia, referred pain, secondary co-contraction of muscles, myofascial trigger points, and autonomic changes. These effects add to the complexity of diagnosing odontogenic pain and differentiating tooth pain from other sources in the region.

Sources of nonodontogenic toothache

This chapter provides information that will help the dental clinician to identify toothaches with a nonodontogenic etiology. The clinician must have a thorough knowledge of all possible causes of orofacial pain, which includes both odontogenic and nonodontogenic conditions. This knowledge prevents misdiagnosis and allows for proper treatment selection and referral if necessary. For information about treatment of these disorders, other references should be used.

Consensus on the exact taxonomy with diagnostic criteria and their interrelationships among various orofacial pain disorders has not been established. Various health care professions involved in the diagnosis and treatment of such pains have used different terms in the literature. This, of course, can and has led to confusion, especially within what we refer to as neuropathic pain. The terms used in the literature are diverse, and they overlap in meaning to an unknown degree; for example, *phantom tooth pain* and *atypical odontalgia* are used interchangeably. At other times, the literature uses the same terms to describe seemingly different disorders; for example, trigeminal neuralgia has the connotation of an idiopathic pain disorder characterized either as intense, intermittent lightning bolt–type pain within one or more distributions of the trigeminal nerve, or as continuous

Telegram: @dental_k

www.konkur.in

pain that is often mild to moderate in intensity that arises in association with injury to a specific branch of the trigeminal nerve. Efforts have resulted in a working diagnostic framework for neuropathic pains.[135] Our classification scheme uses this framework to enhance the clarity of communication and follows the American Academy of Orofacial Pain's guidelines for assessment, diagnosis, and management for orofacial pain,[30] even though the application of these criteria to pains that present in the orofacial region is known to be associated with misclassification.[35]

Overall, one can classify the nonodontogenic reasons for toothache into five broad groups of pain disorders:

1. Musculoskeletal and other nonprogressive pains arising from somatic structures
2. Neurovascular pain, otherwise known as headache disorders
3. Neuropathic pains
4. Pain associated with a pathologic process
5. Pain of purely psychologic origin, otherwise known as psychogenic toothache

Musculoskeletal and somatic pain

Myofascial pain.

Although any deep somatic tissue type in the head and neck has the propensity to induce central excitatory effects and therefore cause referral of pains to teeth, pains of muscular origin appear to be the most common.[46] Myofascial pain (MFP) emanates from small foci of hyperexcitable muscle tissue. Clinically these areas feel like taut bands or knots and are termed *trigger points.*[134] Typically the pain is described as a diffuse, constant, dull, aching sensation; this may lead the clinician to a misdiagnosis of pulpal pain. Another potentially misleading characteristic of masticatory muscle pain is that patients may report pain when chewing. This feature is similar to pain that is periradicular, not pulpal, in origin. On further investigation, it should become clear that the pain is triggered by contraction of masticatory muscles rather than loading of PDLs. Palpation of the muscles of mastication should reproduce the pain, whereas percussion of the teeth should not. The intensity

Telegram: @dental_k

www.konkur.in

of the pain will increase and can be perceived in a distant site. MFP that is perceived to emanate from a tooth is a referred type of heterotopic pain—that is, the pain is felt in an area other than the nerve branch that innervates the trigger point. Typically muscles that refer pain to teeth are the masseter, temporalis, and lateral pterygoid; muscles of the neck and nonmuscular deep structures of the face can also be a source for this type of pain.[134,142]

Although the definitive pathogenesis of MFP is unknown, authors have theorized that muscles may become disturbed through injury or sustained contraction such as clenching.[45,105] Clinically, this muscular contraction might occur as a parafunctional habit or as a protective response by localized muscle to an ongoing deep noxious input such as dental pain. Considering this theory and what is witnessed clinically, trigger points appear to be induced or aggravated by toothache. It also appears that trigger points can persist after the toothache has been resolved. This can be confusing for the clinician and frustrating for the patient. It is important to realize the relationship of these two entities. MFP can mimic toothache, and toothaches may induce the development of MFP.

Toothaches of myofascial origin may arise with or without evidence of pulpal or periapical pathosis. Definitive diagnosis is based on lack of symptoms after pulp testing and percussion or palpation sensitivity, or failure to resolve symptoms with local anesthetic blockade. In contrast, jaw function and palpation of the masticatory muscle(s) elicit toothaches of myofascial origin. Typically, local anesthetic infiltration into the trigger point(s) will resolve symptoms.

Common therapeutic modalities used to treat MFP include deep massage, relaxation techniques, “spray and stretch,” muscle relaxants, and trigger point injections. Deep massage and relaxation techniques have the advantage of being noninvasive and easily administered. Spray and stretch involves an application of a vapor coolant spray to the skin overlying the trigger point, followed by a gentle stretching of the muscle. Trigger point injections are used for both the diagnosis and treatment of MFP. Specifically, if the pain complaint is diminished on injection of the trigger point(s), then the source of the pain has been confirmed. The therapeutic efficacy of a trigger point injection varies. Some patients might experience lasting relief with one injection or several, whereas others may not. See the Additional Tests section

Telegram: @dental_k

www.konkur.in

for further information about trigger point injections.

Pain of sinus or nasal mucosal origin.

Sinus/nasal mucosal pain is another source of pain that can mimic toothache.[1,2,28,138] Sinus pain can exhibit symptoms of fullness or pressure below the eyes but is generally not particularly painful unless the nasal mucosa is also affected.[37] Pain from the nasal mucosa tends to be dull and aching and can also have a burning quality typical of visceral mucosal pain. In general, these pains are of viral, bacterial, or allergic etiology. Other symptoms consistent with these types of disease (e.g., congestion or nasal drainage) should be noted in the patient history.

Typical of deep visceral-like tissues, sinus/nasal mucosal pain can induce central excitatory effects such as secondary hyperalgesia, referral of pain, and autonomic changes. It is this tendency that gives sinus/nasal pain the ability to masquerade as toothache.[129a] Secondary hyperalgesia, seen clinically as a concentric spread of pain beyond the area of tissue injury, results in tenderness of the mucosa in the area of the maxillary sinuses as well as tenderness to percussion of several maxillary teeth. Teeth tender to percussion and palpation suggest periradicular inflammation. Autonomic sequelae might present as edema or erythema in the area, which could suggest a dental abscess. However, when an etiology for pulpal and therefore periradicular pathosis is absent, sinus/nasal mucosal disease should be suspected. The three cardinal symptoms of acute rhinosinusitis are (1) purulent nasal discharge, (2) nasal obstruction, and (3) facial pain-pressure-fullness.[118] Other symptoms of sinus disease include sensitivity to palpation of structures overlying sinuses (i.e., paranasal tenderness) and a throbbing or increased pain sensation when the head is placed lower than the heart. Dental local anesthetic blockade will not abate sinus/nasal mucosal pain, although topical nasal anesthetic will.

Patients with suspected sinus/nasal mucosal disease should be referred to an otolaryngologist for further diagnosis and treatment. Physical examination as well as adjunctive tests may be necessary for a definitive diagnosis. Tests may include nasal cytologic and ultrasound studies and the use of nasal endoscopes, in addition to imaging tests such as radiology and computed tomographic imaging.[36,125] Treatment of sinus/nasal mucosal pain is

Telegram: @dental_k

www.konkur.in

dependent on the etiology (e.g., bacterial, viral, allergic, or obstructive).

Salivary gland pain.

Pain referred from one or more of the salivary glands may be perceived as tooth pain; the authors have not encountered this response in clinical practice, but it has been reported to present as a nonodontogenic toothache.[80,115] Because the primary somatosensory innervation of the major salivary glands comes from the mandibular branch, it is conceivable that such a presentation will occur most often in mandibular teeth.

Neurovascular pain

Neurovascular pains, otherwise and interchangeably referred to as headache disorders, have qualities similar to pulpal pain. These types of pain can be intense, often pulsatile, and are known to occur only in the head. The International Headache Society (Oxford, UK) has developed a classification system that is widely accepted even though validation studies of these criteria have yet to be published. The interested reader should consult the classification system for more details on this topic.[56] Primary neurovascular pain disorders are thought to be a referred pain phenomenon, meaning that intracranial branches of the trigeminal nerve become sensitized via incompletely understood mechanisms and the associated pain and symptoms are perceived in the somatic structures of the head. Most commonly people report pain presenting in the forehead, back of the head, and temples but also in the sinuses, jaws, and teeth.

The current understanding of the pathophysiology of headaches implies that dental disease and treatments are not likely to be a cause of a person developing a headache disorder, but rather, because the same neuroanatomic circuitry is involved, these aspects of dentistry can be thought of as an inciting event, similar to the analogy that exercise producing increased demands on the cardiovascular system can be an inciting event for an acute myocardial infarction. For this reason, dental clinicians should be aware of the diagnostic status of their patients, because patients with headache disorders are likely to experience more peritreatment pain complications that are related to the innate hyperexcitability of the trigeminal nervous system in these people.

Telegram: @dental_k

www.konkur.in

Of most interest to the dental clinician are the primary headache disorders, which make up the bulk of the headache disorders that occur within the population and have been reported to present as nonodontogenic toothache. To simplify thinking, these primary headache disorders can be grouped into three major subdivisions: (1) migraine, (2) tension-type headache, and (3) cluster headache and other trigeminal autonomic cephalalgias (TACs).

Migraine is a common headache experienced by about 18% of females and 6% of males.[82,128] It is associated with significant amounts of disability, which is the motivating factor that brings the patient to seek care and the reason why this type of headache is the one most often seen in medical clinics.[131] Migraine has been reported to present as toothache[4,26,34,52,96,103] and is likely the most common neurovascular disorder to do so. In addition, people with migraine headaches are thought of as having increased regional pain sensitivity that has diagnostic and treatment implications for the clinician.[102]

Migraine headaches typically last between 4 and 72 hours. They tend to be unilateral in presentation and pulsatile in quality, with a moderate to severe intensity to the pain. Patients may also experience nausea or vomiting, as well as photophobia or phonophobia, which are different from toothache. The headache is usually aggravated with routine physical activity, such as walking up stairs. Caffeine/ergotamine compounds have been used widely in the past as abortive agents for migraine headaches, but in contemporary times they have been replaced with triptans, such as sumatriptan and rizatriptan.[93] Of note, migraine headaches may partially or fully abate with the use of nonsteroidal anti-inflammatory medications in a similar fashion as toothaches.

Tension-type headache is the most frequent headache disorder experienced, with a wide range of reported prevalence (41% to 96%).[117,123] The concept of tension-type headache pain presenting as toothache has not been reported in the literature to our knowledge, likely because the construct of what a tension-type headache is has not been clearly defined. Some research supports the notion that a tension-type headache has a significant musculoskeletal component to the pain,[129] whereas other research suggests otherwise. Tension-type headaches are likely a heterogeneous group of similarly presenting head pains that have overlapping pathophysiologic

Telegram: @dental_k

www.konkur.in

mechanisms, which has led some researchers to consider aspects of tension-type headache to be the same as musculoskeletal orofacial pain, otherwise known as temporomandibular disorders (TMDs).[55] This has further been supported by data from a TMD validation study to derive criteria for such headaches that are of TMD origin.[6,122]

Cluster headaches and other TACs are rare neurovascular disorders that are strictly unilateral pains defined by the concurrent presentation of at least one ipsilateral autonomic symptom—such as nasal congestion, rhinorrhea, lacrimation, eyelid edema, periorbital swelling, facial erythema, ptosis, or miosis—that occurs with the pain. The major distinguishing features between these headache disorders are the duration and frequency of the pain episodes, as well as the gender most often afflicted. Cluster headache is the most common of the group, occurring in men three to four times more often than in women, with pain episodes lasting between 15 minutes and 2 hours that occur at a frequency of eight episodes per day to one every other day. These headaches come in clusters, with active periods of 2 weeks to 3 months,[56] thus the name. Elimination of pain after 10 minutes with inhalation of 100% oxygen is diagnostic for cluster headache,[49] whereas sublingual ergotamine and sumatriptan are also effective acute treatments for cluster headache.[42] Paroxysmal hemicrania, which has a 3:1 female predilection, presents with characteristics similar to those of cluster headache but with a frequency of more than five per day and a duration lasting 2 to 30 minutes.[56] This headache disorder has a 100% response to indomethacin but is refractory to other treatments,[65] thus underscoring the need for obtaining an accurate diagnosis from an experienced clinician.

From a nonodontogenic perspective, cluster headache[4,14,21,51] and almost all the other TACs have been reported in the literature to present as nonodontogenic toothache.[4,11,12,31,74a,92,110,120] The concurrent autonomic features, such as discoloration or swelling in the anterior maxilla, might compound the diagnostic problem by suggesting tooth abscess. It is important to note that neurovascular headaches tend to be episodic with complete remission between episodes, whereas toothache pain usually has at least some background pain that stays between any exacerbations. Provocation of the tooth should not result in a clear increase in pain but cause a slight alteration because this tissue has become hypersensitized. Local anesthetic is

Telegram: @dental_k

www.konkur.in

unpredictable in these cases and can mislead the clinician. Management by the typical clinician is to determine that the pain is not of odontogenic origin and then to refer the patient to an appropriate care provider. Other neurovascular disorders not classified as primary headaches have been reported to present as nonodontogenic toothache, such as cough headache.[91] One would not expect a dental clinician who does not have a specific focus on orofacial pain to arrive at such a specific diagnosis but rather to be aware of and sensitive to the fact that more obscure headache disorders exist and should be considered in the differential diagnosis of a nonodontogenic toothache that is not easily classified.

Neuropathic pain

All previously described pain entities can be classified as somatic pain. That is, they are a result of noxious stimulation of somatic structures. These impulses are transmitted by normal neural structures, and their clinical characteristics are related to stimulation of normal neural structures. Neuropathic pain actually arises from abnormalities in the neural structures themselves, specifically the somatosensory system. The clinical examination generally reveals no somatic tissue damage, and the response to stimulation of the tissue is disproportionate to the stimulus. For this reason, neuropathic pains can be misdiagnosed as psychogenic pain simply because a local cause cannot be readily identified. There are many ways to categorize neuropathic pain in the orofacial region. For the purposes of this chapter and ease of discussion, neuropathic pain is divided into four subcategories: neuralgia, neuroma, neuritis, and neuropathy. It should be acknowledged that these subcategories are arbitrary and are not mutually exclusive.

Neuralgia.

As alluded to previously, not all uses of the term *neuralgia* refer to what is often thought of as the classic trigeminal neuralgia or tic douloureux. Sometimes the term *neuralgia* is used to describe pain felt along a specific peripheral nerve distribution, such as with postherpetic neuralgia and occipital neuralgia, as opposed to a focus of pain disorders that have similar characteristics and are thought to have common underlying pathophysiologic mechanisms. When used in the generic sense to describe pains that present

Telegram: @dental_k

www.konkur.in

intraorally, the term can lead to a great deal of confusion.

Although deviations are not uncommon, trigeminal neuralgia is characteristically an intense, sharp shooting pain that is most often unilateral. Ipsilateral to the perceived location of the symptoms is an area that, on stimulation such as light touch, elicits sharp shooting pain. The area that elicits the pain is referred to as a trigger zone, and it can be in the distribution of the resultant pain or in a different distribution—but is always ipsilateral. Although most patients present with a characteristic trigger zone, not all patients will present with this finding. An important characteristic of trigger zones is that the response to the stimulus is not proportional to the intensity of the stimulus—that is, slight pressure on a trigger zone results in severe pain. In addition, once triggered, pain typically subsides within a few minutes until triggered again. This is in contrast to odontogenic pain, which may come and go but does not do so in such a predictable and repeatable manner. Finally, the trigger for odontogenic pain is an area that has no sensory abnormalities (e.g., dysesthesia or paresthesia).

Trigger zones for trigeminal neuralgia tend to be related to areas of dense somatosensory innervation, such as the lips and teeth. For this reason, triggers that elicit this type of pain may include chewing and may lead both the patient and clinician to think of a diagnosis of odontogenic pain. In addition, because the trigger involves peripheral input, anesthetizing the trigger zone may diminish symptoms. This can be very misleading to the clinician if the assumption is that local anesthetic blocks only odontogenic pain.

Because symptoms can be quite severe, patients may consent to or even insist on treatment even though the clinical findings do not definitively support an odontogenic etiology. The possibly misleading symptoms, along with the willingness of the patient to consent to what may seem to be desperate measures, emphasize the importance of a thorough history and clinical evaluation. The absence of a dental etiology for the symptoms (e.g., large restorations, dental trauma, or recent dental treatment) in the presence of the characteristic sharp shooting pain should alert the clinician to consider trigeminal neuralgia in the differential diagnosis. In general, these individuals should be referred to a neurologist or orofacial pain/oral medicine clinician for a complete diagnostic workup and treatment, because case series have

Telegram: @dental_k

www.konkur.in

suggested 15% to 30% of patients have secondary reasons for their pain,[58,143] such as brain tumors and multiple sclerosis.

Trigeminal neuralgia typically presents in individuals older than 50 years of age. The etiology is thought to be irritation/compression of the root of the trigeminal nerve, prior to the Gasserian ganglion, possibly as a result of carotid artery pressure. Individuals with multiple sclerosis develop trigeminal neuralgia more frequently than the general population. For this reason, a person younger than 40 years of age who develops trigeminal neuralgia should also be screened for multiple sclerosis[147] or other intracranial pathosis.[58]

The two general treatment options for trigeminal neuralgia are pharmacologic and surgical procedures. Because of the possible complications associated with surgery, this form of treatment is usually considered only after attempting pharmacologic therapies. Several medications, including carbamazepine, baclofen, gabapentin, and more recently pregabalin and oxcarbazepine, have been used to treat trigeminal neuralgia. Drugs aimed at relieving nociception, such as nonsteroidal anti-inflammatory agents, have no significant benefit in these patients, nor do opioid-based analgesics. Clinical trials support carbamazepine as a first-line drug for treating trigeminal neuralgia.[8] In patients who experience pain relief from carbamazepine, the effect is usually rapid; most will report a decrease in severity of symptoms within the first couple of days.

What is thought to be a variation of trigeminal neuralgia, and may also mimic toothache, is pretrigeminal neuralgia. Pretrigeminal neuralgia, as the name suggests, has been described as symptoms that are different from those of classic trigeminal neuralgia but that respond to pharmacotherapy like classic trigeminal neuralgia and, over time (usually weeks to 3 years), take on the classic characteristics of trigeminal neuralgia. The definitive features include the presence of a dull aching or burning pain that is less paroxysmal in nature but still triggered by a light touch within the orofacial region, with variable periods of remission.[48] The subsequent onset of true neuralgic pain may be sudden or may appear several years later,[105] which emphasizes the need for long-term follow-up of these patients to obtain an accurate final diagnosis.

Telegram: @dental_k

www.konkur.in

Neuroma.

The term *neuroma* has been around for many years and is often overused in an attempt to describe other types of neuropathic pain. A traumatic neuroma, also known as an amputation neuroma, is a proliferative mass of disorganized neural tissue at the site of a traumatically or surgically transected nerve. A part of the diagnosis, therefore, is confirmation of a significant event that would account for the damage to the nerve. Symptoms will not develop until the neural tissue on the proximal stump has had time to proliferate, typically about 10 days after the event. Tapping over the area of a neuroma elicits volleys of sharp electrical pain (i.e., Tinel sign) similar to trigeminal neuralgia. In contrast to trigeminal neuralgia, there should be a zone of anesthesia peripheral to the area of the neuroma[111] that can be identified by checking for loss of pinprick sensibility, such as with the use of an explorer.

Treatment of a neuroma involves pharmacologic management, often via local measures, and may involve surgical coaptation of the nerve with prognosis being variable and dependent on adequate distal nerve tissue and the time interval between injury and reconstruction.[148] Therefore, early recognition and referral are of key importance to prevent significant distal nerve degeneration.[76] Although neuromas most commonly develop in the area of the mental foramen, lower lip, and tongue, there is some evidence that they can also form in extraction sites and after pulpal extirpation. Neuromas were found to form in extraction sites between 4 and 6 months after removal of the tooth in an experimental animal model.[69] Although not all neuromas that form are painful, this could be a potential explanation for ongoing pain in extraction sites after healing has appeared to occur.[111] It is interesting to ponder the possibility of neuroma formation in deafferentation injuries such as pulpectomy and the implications this might have on continued PDL sensitivity after adequate root canal treatment. For treatment of neuromas that are not amenable to surgical correction, see the Neuropathy section of this chapter.

Neuritis.

Neuritis is a condition caused by inflammation of a nerve or nerves secondary to injury or infection of viral or bacterial etiology. In general, pain from a virally induced neuritis, such as recurrent herpes simplex or herpes

Telegram: @dental_k

www.konkur.in

zoster, is associated with skin or mucosal lesions (Fig. 4.5). This presentation does not result in much of a diagnostic challenge, but pain can precede the vesicular outbreak by many days or even weeks.[47] Because neuritic disorders are caused by reactivation of a virus that has been dormant in the trigeminal ganglion, they are considered projected pain with distribution within the dermatomes innervated by the affected peripheral nerves. The nerves affected by the virus may solely supply deeper tissues and therefore may not produce any cutaneous lesions. In the absence of skin or mucosal lesions, a viral neuritis can be difficult to diagnose[47,60,67] and should be considered in the differential diagnosis of a patient with a history of primary herpes zoster infection. Bacterial infection of the sinuses or dental abscess can also cause neural inflammation that may result in pain. This pain occurs simultaneously with pain of the infected tissues and usually dissipates once the etiology is addressed. In susceptible individuals, virally or bacterially induced neuritis may produce a postinfection neuropathy of the infected nerve. The pain is fairly constant and can be dull, aching, and burning. Also, the pain may be accompanied by allodynia, a painful response to normally nonnoxious stimulation such as light brushing of the skin. Oral acyclovir has become the most common treatment for acute herpetic outbreaks and has been shown to be efficacious in decreasing the duration and severity of pain after herpes zoster infection. Efficacy is based only on administration in the prevesicular, not the vesicular, stage. The addition of prednisolone to acyclovir produces only slight benefits over acyclovir alone. Neither acyclovir alone nor its combination with prednisolone appears to reduce the frequency of postherpetic neuralgia.[140]

www.konkur.in

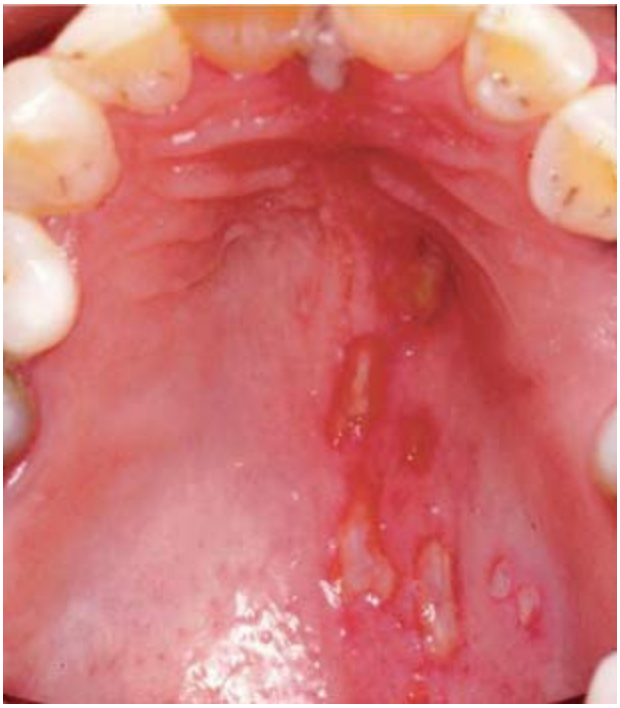

FIG. 4.5 Herpes zoster involving the maxillary division of the left trigeminal nerve of the palate of a 45-year-old male. He complained of a deep, diffuse dull ache of his maxillary left quadrant for 1 week before this vesicular outbreak.

Close-up view of upper teeth shows several mucosal lesions on the palate next to the teeth. The inner side of teeth have yellow stains.

Localized traumatic injury can also induce neuritis. This injury can be chemical, thermal, or mechanical in nature. A classic endodontic example of a chemical injury to a nerve is the overextension of a highly neurotoxic paraformaldehyde-containing paste (e.g., Sargenti paste) onto the inferior alveolar nerve canal. Chemical trauma can be due to certain toxic components of the endodontic filling materials (such as eugenol), irrigating solutions (such as sodium hypochlorite), or intracanal medicaments (such as formocresol) (Fig. 4.6).[94] Mechanical compression, in addition to thermal trauma, may be a factor when thermoplasticized material is overextended, using an injectable[50] or carrier-based technique. Mechanical nerve trauma is more commonly associated with oral surgical procedures, such as orthognathic surgery, and third molar extraction.

Telegram: @dental_k

www.konkur.in

FIG. 4.6 Extrusion of the filling material from the distal canal of tooth #30 of a 36-year-old female. Her complaint was of extreme pain after completion of the root canal treatment followed by sharp, burning continuous pain that could be made worse by a light touch of the tooth.

Radiograph on the left shows a single tooth with filled root canal that is broken near the tip. The root is anchored in porous tissue. Enamel of the tooth is radiopaque. Radiograph on the right shows six teeth. The central tooth in the lower jaw has filled root canals. One of the root canals is comparatively long. Roots of all teeth are surrounded by porous tissue and well-defined radiolucency.

Neuritic complications have also been documented after mandibular implant surgery at a rate of 5% to 15%, with permanent neuropathies, which are discussed later, resulting in approximately 8% of these cases.[66] It is unfortunate that traumatic neuritis is often misdiagnosed as a posttreatment chronic infection and that the area is reentered and debrided. Additional surgical insult further traumatizes the nerve, prolonging the already present nociceptive barrage, which puts the patient at an increased risk of developing central hyperalgesia. Undiagnosed and mistreated cases of acute neuritis not only lead to unnecessary dental procedures but may also aggravate the neuritis and, therefore, the neuritic pain has a greater chance of becoming chronic, something that is often referred to as neuropathic pain.

Neuritic pain typically is a persistent, nonpulsatile burning often associated with sensory aberrations such as paresthesia, dysesthesia, or anesthesia. The pain can vary in intensity, but when stimulated, the pain provoked is

Telegram: @dental_k

www.konkur.in

disproportionate to the stimulus.

Treatment of acute neuritis is based on its etiology. In instances of chemical trauma (e.g., Sargenti paste) where an obvious irritant is present, surgical debridement of the nerve to remove any substance that can continue to irritate the nerve is an important aspect of treatment. With neuritis secondary to mechanical compression (e.g., implant placement) of a nerve, nerve decompression by removal of the implant fixture is indicated. Such localized, acute, traumatically induced neuritis is inflammatory in nature and, therefore, can also benefit from supportive pharmacotherapies such as steroids. For management of neuritis that is not responsive to the previously cited treatments, medications used to treat neuropathic pain may be used (see Neuropathy). For neuritis occurring secondary to an infection, such as one of odontogenic or viral etiology, treatment is directed at eliminating the offending pathogen and minimizing injury to the afferent nerves.

Neuropathy.

In this chapter we use the word *neuropathy* as the preferred term for localized, sustained nonepisodic pain secondary to an injury or change in a neural structure. Historically, other terms have been used including *atypical facial pain.* This term suggests pain that is felt in a branch of the trigeminal nerve and that does not fit any other pain category. Pain of an unknown source that is perceived in a tooth may be labeled *atypical odontalgia.* Pain that persists after the tooth has been extracted is referred to as *phantom tooth pain.* The major limitation in the use of all these terms is that they merely suggest an area where a pain of unknown etiology exists and completely lack any information regarding the pathophysiology. Although each of these terms has been extensively described in the literature,[88,89] probably none actually represents one discrete condition but rather a collection of various conditions. Based on these thoughts, a consensus process resulted in proposing new terminology, *persistent dentoalveolar pain disorder (PDAP)*, and diagnostic criteria (Fig. 4.7).[99]

Telegram: @dental_k

www.konkur.in

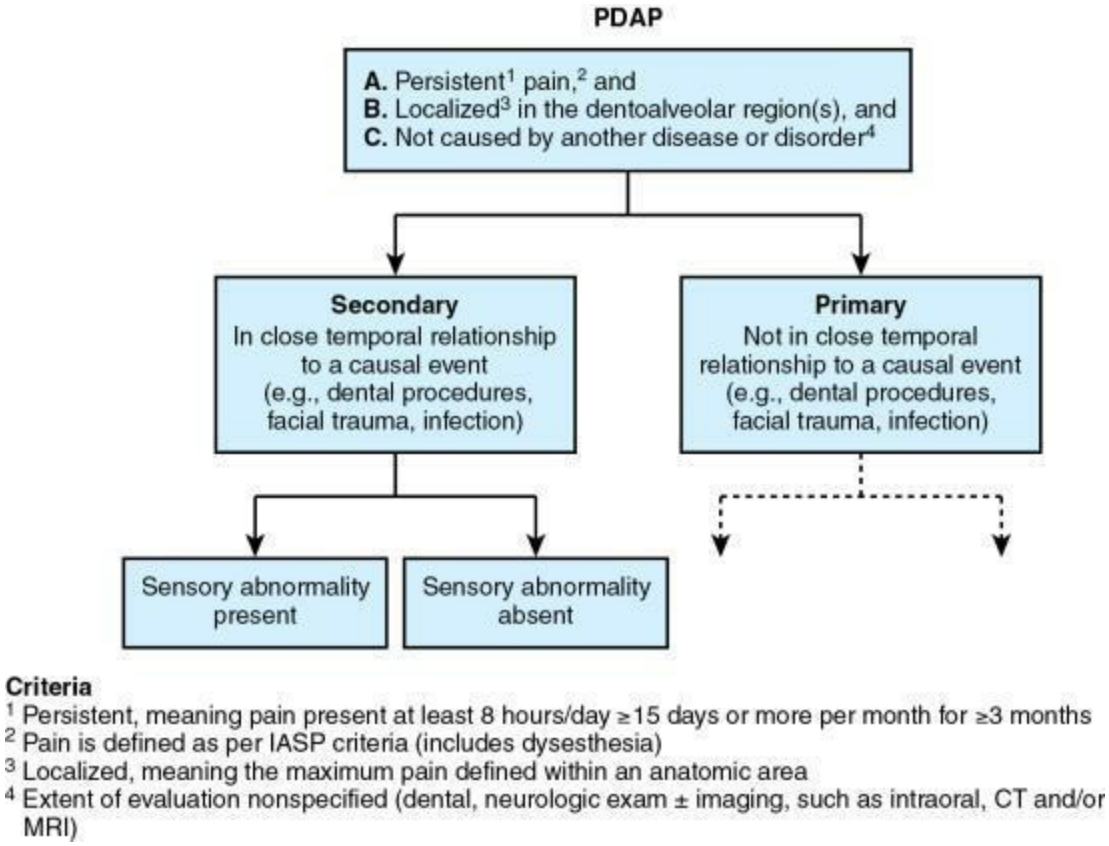

FIG. 4.7 Diagnostic criteria for persistent dentoalveolar pain disorder *(PDAP)*. *CT,* Computed tomography; *IASP,* International Association for the Study of Pain; *MRI,* magnetic resonance imaging.

Flow chart shows criteria for PDAP. A. Persistent (1) pain, (2) and; B. Localized (3) in the dentoalveolar region(s), and; C. Not caused by another disease or disorder (4). It leads to two text boxes, one is titled secondary and the other is titled primary. Text below secondary reads, In close temporal relationship to a causal event (e.g., dental procedures, facial trauma, infection). Text below primary reads, Not in close temporal relationship to a causal event (e.g., dental procedures, facial trauma, infection). The first text box titled secondary further leads to two boxes, each reads, sensory abnormality present.

Four criteria's are as follows:

1. Persistent, meaning pain present at least 8 hours/day greater than or equal to 15 days or more per month for greater than or equal to 3 months.

2. Pain is defined as per IASP criteria (includes dysesthesia).

3. Localized, meaning the maximum pain defined within an anatomic area.

4. Extent of evaluation non-specified (dental, neurologic exam ± imaging, such as intraoral, CT and/or MRI).

Telegram: @dental_k

www.konkur.in

Once a nerve has been sensitized via injury or disease it may remain so and present as a peripherally sensitized nerve. This peripheral sensitization and the ongoing pain (nociceptive barrage) that accompanies it can induce changes in the central nervous system. *Peripheral* sensitization and *central* sensitization can potentially impact the clinical presentation of a neuropathy. A typical clinical course of someone with an undiagnosed neuropathy might consist of treatment for a toothache. When the pain does not resolve with nonsurgical root canal treatment, it might then be followed by apical surgery and then perhaps an extraction. The extraction site might then be explored and debrided in a misguided attempt to remove any potential source of the patient's ongoing pain. After each treatment, there tends to be a reduction of the pain for a short time and then a return to its original, or even increased, level of pain intensity. It is likely that this is a result of a new neural injury consisting of reorganization and resprouting that increases the inhibition of nerve firing for a time. Surgical approaches to neuropathies are not effective because they do not desensitize the nerve. On the contrary, surgical intervention may aggravate the situation by inflicting an additional neural injury in the periphery and contributing to the already present nociceptive input. This intervention therefore puts the patient at increased risk of developing persistent pain, which is supported by a couple of long-term observational studies[3,113] and further supported by the observation that patients with pain following root canal therapy did not uniformly experience elimination of this pain with apicoectomy surgery.[108]

A diagnosis of neuropathy is based primarily on history and examination with the use of selected diagnostic tests to rule out other potential etiologies. The history should reveal some inflammation-inducing event (see the earlier sections Neuritis and Neuroma), although the nature of the initial insult is not always identified, as seemingly spontaneous development of such pains has been reported.[99] Typically, the examination is grossly unremarkable with no evidence of local tissue damage, leaving the clinician to rely mainly on the patient's report of symptoms. Although quality of pain is no longer thought to be capable of distinguishing neuropathic pains from others, patients repeatedly reported several features that may be key for identification purposes (Box 4.2).[40] Regarding examination features, the area where the pain is perceived may be hyperalgesic or allodynic—that is, noxious

Telegram: @dental_k

www.konkur.in

stimulation to the area will be perceived as more painful or nonnoxious stimulation will now be perceived as painful. This phenomenon is documented by reports where standardized applications of stimuli to the affected tissue are performed and demonstrate exaggerated responses.[85,90,146] Besides gain in sensory function, loss of function has also been observed,[85] which is more in line with a general definition for neuropathic pain.[135] Furthermore, maintenance of pain following local anesthesia to the affected region[83] and a lack of pain reduction with fentanyl and ketamine[7] all suggest the role of a central pain-related mechanism.

Box 4.2

Recurrent Patient-Reported Themes Regarding Their Persistent Dentoalveolar Pain Disorder

- Difficult for patients to respond to history taking because their words do not adequately describe what they feel; therefore, time may be needed to obtain the necessary information
- Well localized to a region within the dentoalveolar structures
- Pain is perceived to be deep in the tissues, rather than on the surface
- Continuous pain, one that never stops and seems to always be there
- Pain has the sensation of feeling pressure with a dull ache quality
- Complex and confounding descriptors, such as itching, tingling, or pricking, are sometimes present

Research related to the diagnostic imaging of cases that may be PDAP suggests two roles: first, to identify pathosis contributing to the pain presentation and, second, as a means of obtaining a positive finding for this enigmatic chronic pain disorder. As for the first role, diagnostic imaging is recommended to assess for odontogenic-related pathosis and other regionally presenting disease, as most pain in the dentoalveolar region is tooth related. For patients suspected of having PDAP, the diagnostic yield of cone-beam computed tomography (CT) was reported to be superior to periapical radiograph, but the findings were of questionable significance.[112] For patients without local pathosis and PDAP, magnetic resonance imaging (MRI) of the

Telegram: @dental_k

www.konkur.in

brain revealed several cases of intracranial findings thought to be related to the pain presentation (e.g., cysts, tumors, infarcts).[104] This is consistent with the clinical experience of one of the authors, which has led to brain imaging being routine prior to a diagnosis of PDAP being rendered. As for the second role of diagnostic imaging, conventional dental radiographic techniques have consistently been found to be unable to identify patients with PDAP, thus prompting pilot investigation into other imaging techniques. Results suggest high levels of sensitivity and specificity can be reached using thermography[64] revealing a "cold" image profile.[63] On the contrary, results suggest that a technetium-99 bone scan had low sensitivity and specificity for detecting dentoalveolar regions with chronic pain,[32] and MRI techniques do not seem to have been studied.

Neuropathic disorders have a predilection for women but can affect both genders. These patients are usually older than 30 years of age and may have a history of migraine.[126] In the orofacial region, neuropathies are most commonly seen in the maxillary premolar area and molar region.[61,108]

Neuropathies can be classified on the basis of their clinical presentation and response to therapies. *Peripheral neuropathy* may develop after sensitization of a peripheral nerve and presents clinically as described previously. Diagnosis of peripheral neuropathy is based on its favorable response to peripheral neural blockade. Treatment is directed at decreasing the sensitization of peripheral nerves and reducing ectopic neuronal firing. Topical as well as systemic medications can be used to treat cutaneous peripheral neuropathies. Topical medications include topical anesthetics, capsaicin-containing compounds, and anticonvulsants, as well as nonsteroidal antiinflammatory drugs (NSAIDs), sympathomimetic agents, and *N*-methyl-d-aspartate (NMDA) receptor-blocking agents[109] with encouraging results.[72]

The clinical presentation of a *central neuropathy* is similar to that of a peripheral neuropathy. After sensitization of peripheral nerves and the accompanying nociceptive barrage, the pain is nonremitting and lacks evidence of tissue insult. Unlike its peripheral counterpart, allodynia and secondary hyperalgesia are clearly present—that is, the area of pain is significantly larger than the initial site of injury. The most telling sign that a neuropathy has taken on a more central component is that local anesthetics are no longer effective. Therefore, the treatment must be directed toward the

Telegram: @dental_k

www.konkur.in

central processing of pain. This is done with medications such as NMDA receptor agonists (ketamine), gabapentin, tricyclic antidepressants, and opioids. The prognosis for a central neuropathy is not as good as for a peripheral neuropathy, as central neuropathic pain tends to become more refractory with time. Treatment is often based on the management of pain, rather than its cure, and sometimes is best performed in a multidisciplinary chronic pain clinic facility.

The last variation of neuropathic pain is sympathetically enhanced or maintained pain. In cases of sympathetically maintained pain (SMP), peripheral nerve fibers upregulate the expression of adrenergic receptors, making them responsive and sensitive to sympathetic input. SMP may also have a central component, whereby the constant sympathetic drive alters neuronal excitability. Neuronal injury may induce sprouting of sympathetic axons into the trigeminal spinal nucleus because basket-like formations of sympathetic fibers have been reported around the cell bodies of sensory neurons in the dorsal root ganglia.[141] Increases in sympathetic drive, such as with stress and fever, may aggravate SMP. Diagnosis of SMP is based on blocking sympathetic outflow to the affected region via sympathetic nerve blocks. In the orofacial region this would require a stellate ganglion block. The block is considered diagnostic for SMP if it effectively decreases the patient's pain. Multiple blocks can also be used as a form of therapy. Other therapies include drugs that target peripheral α_2-adrenoceptors (agonists) or α_1-adrenoceptors (antagonists), such as guanethidine, phentolamine, and clonidine. SMP presenting in the orofacial region is extremely rare and therefore makes clinicians prone to deriving a falsely positive diagnosis of this condition.[54,101] Furthermore, researchers have failed to produce SMP-type pain in animals,[10] something that is presumed to be due to the fact that the efferent nerve fibers in the head and neck region run with the blood vessels as opposed to the afferent nerves, as they do elsewhere in the human body. For these reasons, the likelihood of this type of pain presenting as "toothache" is extremely low and thus does not require much discussion here.

Toothache referred from a distant organic source

A variety of pathologies that seem to be unrelated have been reported to present as nonodontogenic toothache.[107,115] The only common link that can

Telegram: @dental_k

www.konkur.in

be identified is that branches of cranial nerves innervate the involved tissues and hence the trigeminal nucleus processes nociceptive input. Therefore, conceivably, any somatic structure with cranial nerve innervation has the potential to cause pain that the patient perceives as a toothache. For this reason, once dentoalveolar etiologies for such pain have been ruled out, all possible sources of nonodontogenic pain, including distant pathology, should be considered in the differential diagnosis. Several of these types of organic pathologies that have been reported to present as toothache are described in the following sections.

Cardiac and thoracic structures.

Cardiac pain has been cited as the cause of nonodontogenic toothache in a number of case reports.[9,41,62,77,97,136] Classically, cardiac pain presents as a crushing substernal pain that most commonly radiates to the left arm, shoulder, neck, and face. Although not as common, anginal pain may present solely as dental pain, generally felt in the lower left jaw.[16] Similar to pain of pulpal origin, cardiac pain can be spontaneous and diffuse, with a cyclic pattern that fluctuates in intensity from mild to severe. The pain can also be intermittent and the patient may be completely asymptomatic at times. The quality of cardiac pain when referred to the mandible is chiefly aching and sometimes pulsatile. Cardiac pain may be spontaneous or increased with physical exertion, emotional upset, or even the ingestion of food.[9] Cardiac pain cannot be aggravated by local provocation of teeth. Anesthetizing the lower jaw or providing dental treatment will not reduce the pain. It can be decreased with rest or a dose of sublingual nitroglycerin. Diagnosis of cardiac pain, along with immediate referral, is mandatory to avoid impending myocardial infarction.

Besides pain of cardiac origin, other chest structures have been reported to produce nonodontogenic toothache pain. Various cancerous lesions of the lungs have been described to present a mandibular pain, with the pain being both ipsilateral and contralateral to the side where the tumor is present.[24,59] Furthermore, diaphragmatic pain is mediated via the phrenic nerve and may present as nonodontogenic tooth pain.[15]

Intracranial structures.

Telegram: @dental_k

www.konkur.in

Space-occupying lesions within and around the brain are known to impinge on structures innervated with somatosensory fibers, such as the dural and perivascular tissues, causing pain. These pains are highly variable, with a common complaint being headache or head pain. Just as intracranially derived pain may be referred to the face and jaws in neurovascular disorders, it may also present as a toothache.[137] To outline the vast differences in clinical features of such pain, intracranial lesions have also been reported to cause trigeminal neuralgic pain in response to treatment of what was first thought to be toothache.[29] This extreme variability has been observed by one of the authors, which leads to the recommendation that if local etiologic factors are not readily identified in a patient with toothache symptoms, magnetic resonance brain imaging should be considered.

Throat and neck structures.

Nonodontogenic toothache has been reported to arise from various structures of the neck, but these reports are sparse, and hence, it is not possible to draw conclusions regarding how patients with these pain-provoking disorders may present. Squamous cell carcinoma of the lateral pharyngeal surface presenting as ipsilateral mandibular molar pain has been observed by one of the authors. This finding is consistent with previous reports of nonodontogenic pain being associated with smooth muscle tumors of a similar location.[139] Vascular structures of the neck have also been implicated in the production of toothache symptoms, with a report of a patient initially presenting for dental care when pain was from the result of a life-threatening carotid artery dissection.[119]

Craniofacial structures.

Clinically, pain from other craniofacial structures has been observed as being the most common reason for organic pathologies presenting as nonodontogenic toothache, likely because these structures are innervated by branches of the trigeminal nerve. Tumors in the maxillary sinus[27,43,145] and jaw,[132] as well as metastatic disease, particularly within the mandible,[33,53,114,124] have been reported. The clinical presentation of symptoms is highly variable, but a common feature is sensory loss along the distribution of the nerve, the result of pain arising from nerve impingement.

Telegram: @dental_k

www.konkur.in

This underscores the need for regional imaging techniques, such as pantomography or CT (as opposed to just periapical radiographs). This is especially true in patients who have a history of cancer. One must also not forget that nerve impingement anywhere along the distribution of the trigeminal nerve, even within the cranial vault itself,[20] can elicit nonodontogenic tooth pain.

Vascular structures within the craniofacial region have also been reported to present as nonodontogenic toothache, with arteritis being the pain-provoking pathology.[68,73] These pains have been described as a continuous dull pain that can sometimes be made worse with jaw function. The stereotypical presentation includes a history of eyesight changes, such as blurred vision, and the examination feature of pulseless, indurated temporal arteries that are painful to palpation. A laboratory finding of an elevated erythrocyte sedimentation rate (ESR) is suggestive of the disorder, and diagnosis is confirmed by temporal artery biopsy. Treatment includes administration of corticosteroids; therefore, because permanent blindness is a possible sequela if cranial arteries are left unmanaged, immediate referral to the appropriate medical colleague is indicated.

Psychogenic toothache

A group of mental disorders known as somatoform disorders, which is when a patient has somatic complaints yet lacks a physical cause, is the only type of psychological disorder that has the potential of presenting as tooth pain. Patients with somatoform disorders are not fabricating the suffering or consciously seeking benefit with their toothache complaint; rather it is a reflection of their distorted perception and presentation based on their psychological disorder. There are four specific diagnoses worth covering within this group, to provide a basis of the different presentations, and they are[111a]:

1. A conversion disorder, which is when a neurological symptom that is inconsistent with a neurologic disease but is nevertheless genuine and distressing yet attributable to a psychological trigger, such as in an instance when a child witnesses the tragic deaths of both parents and becomes mute.[5] It is possible a conversion disorder could manifest as

Telegram: @dental_k

www.konkur.in

a psychogenic toothache, but to our knowledge it has not been reported in the literature and has not be observed in our clinical practices. Rather, when the psychologic disorder manifests as pain, the complaint tends to be more regional in nature and not as specific as toothache.

2. A somatization disorder, and its variants, present with unexplained physical symptoms beginning at a young age of an adult (i.e., <30 years old), persisting for years in duration, and multiple complaints of gastrointestinal, pain, neurological, and sexual symptoms.[111a] Somatization disorder is up to 10 times more common in females, much more common related individuals, but no definitive cause has been identified. There is usually a pattern of high levels of health care utilization, with such individuals being very familiar in chronic pain clinics because of the persistence of a pain complaint being part of the presenting symptomology. While somatization disorder is usually only discussed in general as it may present a tooth-related complaint and the frequency of such presentations is unknown, it is well known to present with TMDs, and screening for somatoform symptoms is included in the Diagnostic Criteria for TMD.[90,110,126]
3. Hypochondriasis is a misinterpretation of a physical symptom and fixation on the fear of it being a life-threating condition, presenting in equal proportions in men and women.[111a] Therefore, strictly speaking, a hypochondriacal patient would present with odontogenic tooth pain that is real, so it would not be a nonodontogenic reason for toothache, and the psychological disorder would manifest as exaggerated fear in relationship to the meaning this pain has to the patient.
4. Body dysmorphic disorder is a debilitating preoccupation with a physical defect, real or imagined[111a]. Sensory perceptions are not part of this disorder's presentation, but related complaints such as an "uneven bite" is what has been reported in the literature in relation to this disorder.[81]

It is important to make a distinction between somatoform disorders and factitious pain or malingering behavior.[5] In factitious pain there are physical

Telegram: @dental_k

www.konkur.in

or psychological symptoms that are produced by the individual and are under voluntary control. Malingering is similar to factitious pain with the added characteristic that the symptoms are presented for obvious and recognizable benefit.[54] This category poses a significant diagnostic challenge because evidence of local tissue damage typical of heterotopic pain entities previously discussed in this chapter is lacking. It is important to emphasize that psychogenic pain is rare. When arriving at this diagnosis it is critical that all other potential diagnoses have been ruled out.

The diagnosis of psychogenic toothache is one of exclusion and is based on the clinician's awareness of other heterotopic pain characteristics and behavior. Of particular note are centrally emanating pains, cardiac pain, neurovascular pain, and neuropathic pain. Adding to the diagnostic difficulty is that comorbid psychologic disorders are commonly present with chronic intraoral pain disorders, including those erroneously presenting as toothache.[84,130] This has led to the current thinking that psychologic disorders (i.e., depression, anxiety, somatization) may not be related to the initiation or perpetuation of chronic pain disorders but rather are a consequence of living with chronic pain.

Psychogenic pain is known to be precipitated by severe psychologic stress. These pains present a general departure from the characteristics of any other pain condition—that is, they may not fit normal anatomic distributions or physiologically plausible patterns. The pain may be felt in multiple teeth and may jump around from one tooth to another. The intensity of pain reported tends to be more severe than is reflected by the patient's level of concern about the condition. Patients' responses to therapy are variable and include a lack of response or an unusual or unexpected response. Early identification of psychogenic pain and referral to a psychologist or psychiatrist is necessary to avoid irreversible and unnecessary dental treatment.

Frequency of nonodontogenic toothache

The prevalence of nonodontogenic toothache in the population is unknown, as is the prevalence of such a presentation for dental care. Specific to endodontics, pain is thought to be present in 5.3% of patients 6 or more months following treatment[100] with about half of those individuals being estimated to have nonodontogenic etiologies accounting for their complaint

Telegram: @dental_k

www.konkur.in

of that pain by literature review.[100] Clinical evaluation of patients that received root canal treatment 3 to 5 years prior revealed 5% experiencing persistent pain and about two thirds of those patients having nonodontogenic pain.[141a] A questionnaire-based assessment of root canal–treated patients 6 months following care found 10% reporting persistent pain, and a clinical evaluation of a subset of these patients revealed about half having nonodontogenic pain.[102a] The most common diagnosis of nonodontogenic pain in this small number of patients, comprising about three fourths of the cases, was MFP referring pain from muscles of mastication, with the remaining one fourth being neuropathic pain.[102a] These diagnoses and distribution of patients with nonodontogenic pain is similar to what was reported as being referred for evaluation by endodontists.[82a]

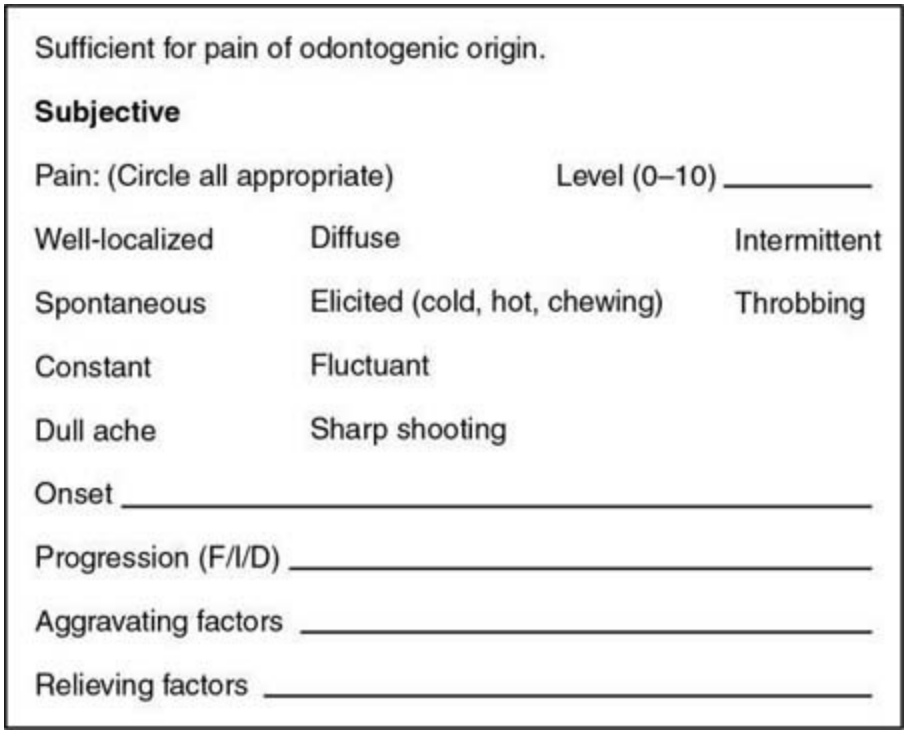
Taking a patient's history

Pain diagnosis is largely based on the patient's subjective history; however, patients rarely give all pertinent diagnostic information about their pain of their own accord. Often it is necessary to carefully extract the details of the patient's pain complaint through systematic and thorough questioning. This is known as "taking a history," and it involves both careful listening and astute questioning. Fig. 4.8 is an example of a basic diagnostic workup for odontogenic pain. It can be easily used to obtain histories of typical odontogenic pain by circling all descriptors that apply and then filling in the remaining blanks. As the details of a patient's pain complaint are gathered, the clinician should be mentally progressing through an algorithm of possible diagnoses, as each detail should lend itself to one type of pain over another. After completing a thorough and accurate history of the complaint(s) (Fig. 4.9), often the diagnosis has already been narrowed down to one particular pain entity. This is particularly true with odontogenic pain. The only question that will remain is "which tooth is it?" It is critical to keep in mind that whereas patients will provide information about the perceived site of pain, it is the clinician's examination that will reveal the true source of their pain. With more complicated pain complaints, the clinician may have a list of possible diagnoses. This is known as a differential diagnosis. This differential will guide the examination and testing in an effort to confirm one diagnosis

Telegram: @dental_k

www.konkur.in

while ruling out all others. If after completing the subjective examination all items on the differential are outside the clinician's scope of practice, then the clinician should continue the examination until he or she has a firm idea of the possible diagnosis so that a proper referral can be made. In addition, it is paramount that all odontogenic sources have been ruled out and that this information is communicated to the health care provider to whom the patient is referred. If no differential can be formulated after the history has been taken, then the history should be redirected to the patient to confirm that the information is complete and accurate. If the patient is unable to provide sufficient information regarding the pain complaint, then it may be helpful to have the patient keep a pain history, detailing the aspects of the pain on a daily basis. Of utmost importance is to avoid treatment when the diagnosis is uncertain. Diagnostic therapy (i.e., "let's do a root canal treatment and see if it helps") may result in costly treatment that does not improve the patient's condition and could be a factor in aggravating and perpetuating a patient's pain. Treatment should always specifically address a diagnosis.



Sufficient for pain of odontogenic origin.

Subjective

Pain: (Circle all appropriate) Level (0–10) _____

Template to evaluate pain history is as follows:

Chief complaint: Prioritize complaints, specify location, and VAS 0–10. Initial

Telegram: @dental_k

www.konkur.in

onset: When did you first notice this? Progression: Frequency, intensity, duration. Previous similar complaints: Have you ever had this type of pain before? Characterize complaint: Daily, not daily, constant, fluctuant, intermittent, duration, temporal pattern, quality. Aggravating factors: What makes this pain worse? Be specific! Alleviating factors: What makes this pain better? How much better? Associated factors: Swelling, discoloration, numbness. Relationship to other complaints: Would your jaw hurt if your tooth didn't hurt? Prior consults/treatment: Who? When? What was the diagnosis? What was done? How did it affect the pain? Blank spaces are given for filling information.

A complete medical history along with current medications and drug allergies should always be ascertained. It is also important to make note of demographic information, as patients of certain genders and ages are more at risk for some disorders compared with others.

Recording a patient's *chief complaint* in the patient's own words is a medical legal necessity but falls short of constituting a thorough pain history. A complete history begins with a patient's general pain complaint—for example, "My tooth hurts." Patients may have more than one pain complaint—for example, "My tooth hurts and it is starting to make my jaw hurt." All pain complaints should be noted and investigated separately. Understanding the specific components of the complaints makes it possible to discern the relationship between them—that is, either the complaints are wholly separate and two types of pathosis are present, or one source of pain is merely creating a heterotopic pain that is wholly secondary to the first.

Begin with determining the *location* at which the patient perceives the pain. Aspects of the location involve localization and migration. Pain should be definable as either well localized or diffuse and either superficial or deep. Easily localized superficial pain tends to be cutaneous or neurogenic. Musculoskeletal pain is felt deeply and is more localizable once it is provoked. Deep, diffuse pain is suggestive of deep somatic pain, be it visceral or musculoskeletal. Both tissue types are involved in a high degree of nociceptor convergence in the trigeminal nucleus and, therefore, much more likely to be involved in creating heterotopic pain. Typical referral patterns of deep somatic pain tend to follow peripheral dermatomes that reflect the laminations in the trigeminal nucleus. Referred pain also tends to occur in a cephalad direction. Therefore, referred pain from a deep somatic tissue such as tooth pulp, cardiac tissue, or skeletal muscle will respect this pattern. Pain

Telegram: @dental_k

www.konkur.in

that spreads distally along a nerve branch is much more indicative of a projected type of heterotopic pain. Projected pains imply a neurogenic source and possibly one that is secondary to impingement from intracranial pathosis. Recall that superficial sources of pain are not likely to be involved in referral, so if a patient is indicating that the pain is superficial and spreading, this is highly suggestive of a neurogenic rather than a cutaneous source.

Assessment of the *intensity* of pain is easily accomplished using a verbal analog scale (VAS). This question is best phrased, “On a scale of one to ten, zero being no pain and ten being the worst pain you can imagine, how bad is your pain?” Not only can intensity provide insight about pain type; it can also help guide posttreatment pain management as well as provide a baseline for response to therapies.

Identifying the *onset* of pain may provide information regarding etiology. Question if the onset followed a particular event such as a dental appointment or a traumatic injury. Beware of these relationships, as they can be misleading. Having a temporal correlation does not necessarily ensure a cause-and-effect relationship. The onset of pain may be either gradual or sudden. Severe pain of sudden onset can signal a more serious problem. Pain that has been present over a protracted period of time, particularly if the pain has been unchanging, is highly suggestive of a nonodontogenic pain source.

Other *temporal* aspects of pain include frequency and duration. The clinician should ask the patient, “How often does the pain occur and how long does it last?” These temporal aspects may establish patterns that point more clearly to one condition over another.

Progression of the patient’s pain over time should be noted. Whether pain is better, worse, or unchanging since its onset should be broken down into three factors: frequency, intensity, and duration. Static pain that does not change over time is typically not odontogenic in origin.

The *quality* of pain—that is, “what it feels like”—is a critical aspect of a pain history. Knowledge of pain characteristics as they relate to tissue types is essential. Pain quality can be difficult for patients to describe, and it is often necessary to provide them with a list of descriptors from which to choose. In instances of odontogenic pain, the list is fairly short. The deep visceral and musculoskeletal components of a tooth limit true odontogenic pain to having qualities that are dull, aching, or throbbing. If there is an aspect of sharpness to the pain, it is helpful to understand whether the

Telegram: @dental_k

www.konkur.in

sharpness is stabbing in nature, which would indicate A-delta fiber–mediated dentinal pain, or whether it is electrical in nature, which would indicate neuralgia. Common examples of pain descriptors and their respective pain types are listed in Table 4.1.

Table 4.1

Examples of Pain Descriptors

Origin	Quality of Pain
Muscular	Dull, aching
Neurogenic	Shocking, burning
Vascular	Throbbing, pulsatile

Factors that precipitate or aggravate the patient's pain complaint are of key importance in diagnosis. Not only do aggravating factors suggest the tissue types that may be involved, but they also aid in directing the objective tests. When gathering information, it is important to be specific. If a patient reports pain while eating, keep in mind that many structures are stimulated during mastication, such as muscles, TMJs, mucosa, PDLs, and, potentially, pulps. Be specific as to the aggravating factor. The lack of any aggravating factors indicates that the pain is not of odontogenic origin.

Alleviating factors can provide insight as to the nature of the pain. If a medication relieves the pain, it is critical to know the specific medication, its dosage, and the degree to which the pain was attenuated. It is equally important to know what has no effect on the intensity of the pain. For example, if a pain of midlevel intensity is completely unresponsive to anti-inflammatory drugs, then it is probably not inflammatory in origin.

Associated factors such as swelling, discoloration, and numbness must be ascertained, as well as their correlation with symptoms. Swelling of acute onset suggests an infection, and its concurrent pain would be of inflammatory origin. Swelling that comes and goes with the intensity of pain suggests an autonomic component. The same can be said for discoloration, such as redness. Numbness or any other type of sensory aberrations should be recorded. If the altered sensation is a major component of the pain complaint, then it should be investigated separately and its relationship to the pain

Telegram: @dental_k

www.konkur.in

determined. Pains that occur with sensory aberrations tend to have a strong neurogenic component.

If the patient complains of more than one pain, an effort should be made during the subjective history to determine the *relationship of the complaints*. One pain might serve as an aggravating factor to the other. There may be a correlation as to the onset, intensity, or progression of the complaints. Also, keep in mind that patients may actually have more than one type of pathosis occurring concurrently and there may be no relationship whatsoever. Ask whether there have been any *previous similar complaints* and, if so, what happened. Recurrence of similar pains might reveal a pattern that lends itself to a particular pain diagnosis.

It is critical to gain knowledge of any prior consultations that have occurred. Details regarding the type of clinician, actual workup performed, and diagnosis rendered will help to narrow down a differential. Any treatment that was performed should be ascertained along with its effect on the chief complaint.

Patient examination

As stated previously, the purpose of the history is to gather information about a patient's pain complaint in order to formulate a list of possible diagnoses based on specific pain characteristics. Poor or improper symptom analysis will lead to a false differential, and any testing will therefore have limited meaning. Performing a general examination, including an extraoral, intraoral, and hard- and soft-tissue assessment, is requisite to confirm the health of various structures and to identify possible pain-producing etiologies. When a patient presents with a toothache, the pain is usually of odontogenic origin. Diagnostic procedures are often limited to confirming a suspect tooth rather than identifying a nonodontogenic source of pain. Standard pulpal and periradicular tests serve to aid in both ruling in odontogenic pain and therefore ruling out nonodontogenic pain as a diagnosis. Remember that the site of pain is determined by patient history, but the true source of the pain should be revealed with testing. If the chief complaint cannot be reproduced with standard tests, then additional tests may be necessary to narrow down a differential diagnosis. For details on general examinations and standard tests, please refer to Chapter 1.

Telegram: @dental_k

www.konkur.in

Additional tests

Further tests should be chosen with forethought in an effort to develop a workable differential that can guide the clinician toward a meaningful consultation or an appropriate referral for the patient. These tests may consist of palpation or provocation of various structures, sensory testing, or diagnostic blocks. The application of these tests is not covered in detail in this chapter. For more information about the application and interpretation of these tests, please consult other sources.

Palpation and percussion are common tests to differentiate odontogenic pain from pain of sinus origin. Palpation of the sinuses consists of firm pressure placed over the involved sinus (usually maxillary). In addition, pain of sinus origin may be provoked with a lowering of the patient's head.

If pain of muscular origin is suspected, then an attempt to reproduce this pain can be done by palpation of the muscles of mastication or provocation via functional manipulation. The temporalis, deep and superficial masseter, medial pterygoid, and digastric muscles should be palpated in an effort to discover tenderness or trigger points that reproduce the pain complaint. The medial pterygoid is only partially accessible to palpation and may need to be functionally tested by stretching the muscle (opening wide) or contracting the muscle (biting firmly). The lateral pterygoid may be difficult if not impossible to palpate intraorally and therefore is more appropriately assessed by functional manipulation. Pain emanating from this muscle may be increased by protruding the jaw against resistance. Exacerbating the chief complaint by muscular function provides a strong indication of a myofascial source of pain.

Because of the complexity of innervation and the occurrence of heterotopic pain in the orofacial region, it may be difficult to definitively determine the origin of pain by testing alone. It cannot be stressed enough that primary pain should not only be provoked by local manipulation but also be relieved by anesthetic blocking. In diagnostic anesthesia the relief of pain has a typical onset and duration, depending on the particular anesthetic used. In addition, the pain should be completely diminished or else suspicion of a central component or a coexisting disorder should arise. The use of diagnostic anesthesia may be necessary and useful in augmenting the diagnostic workup (Fig. 4.10). Topical anesthetic can be helpful in the investigation of

Telegram: @dental_k

www.konkur.in

cutaneous pain and peripheral neuropathies. Anesthetic injection, including peripheral nerve blocks, can be used to determine whether the etiology of the pathosis is peripheral to the area of the block. Pain that persists after the onset of usual signs of anesthesia suggests a central component. The patient's history and general examination are of key importance in differentiating between the pain of a central neuropathy and the central pain emanating from an intracranial mass.

www.konkur.in

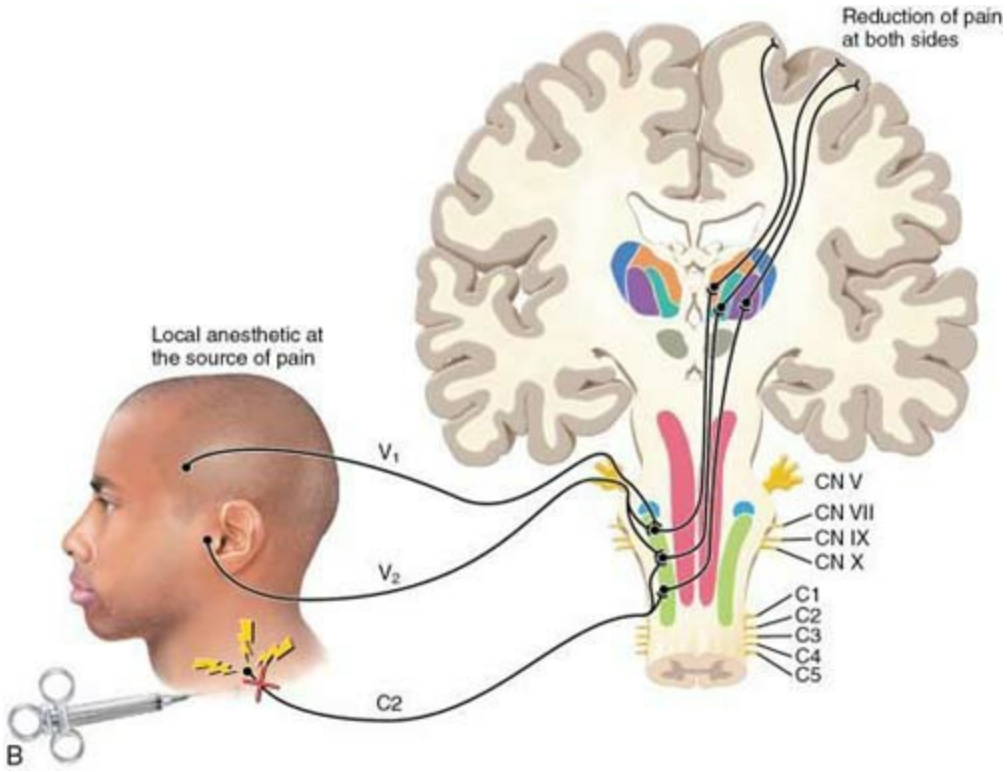

FIG. 4.10 **A**, Local anesthetic at the site of pain fails to reduce the pain. **B**, Local anesthetic at the source of pain reduces the pain at the source as well as at the site.

A) A tree-like structure, the trigeminal nerve, on the right shows labels as follows: CN V, CN VII, CN IX, CN X, C1, C2, C3, C4, and C5. To the left, side view of human face is shown. V1, V2, and C2 from the trigeminal nerve lead to regions near the forehead, tragus of ear, and neck at the center. Source of pain (primary pain) is marked in the neck. Local anesthetic at the site of pain is injected near the ear that doesn't cause any change in pain.

B) Local anesthetic at the source of pain is injected, which results in reduction of pain at both sides.

Source: (Redrawn from Okeson JP: *Bell's orofacial pains*, ed 5, Chicago, 1995, Quintessence Publishing.)

Pain that is primarily muscular, as suggested by trigger points discovered on examination, can be further investigated by local anesthetic injection into the trigger point. Trigger point injections are typically performed with either a 27- or a 25-gauge needle and a minimally myotoxic anesthetic such as 2% lidocaine or 3% mepivacaine without a vasoconstrictor. Myofascial trigger point injections may temporarily relieve pain at the trigger point as well as at the site of referral.

Telegram: @dental_k

www.konkur.in

Sympathetic efferent activity can play a role in the enhancement or maintenance of chronic pain. In the head and neck, sympathetic activity flows through the stellate ganglion located bilaterally near the first rib. When there is suspicion of a sympathetic component to a patient's pain, a stellate ganglion block can be used to provide diagnostic insight. A trained anesthesiologist usually performs this procedure. An effective block delivered to the stellate ganglion will interrupt sympathetic outflow to the ipsilateral side of the face, resulting in a partial Horner syndrome. This is evidenced by flushing, congestion, lacrimation, miosis of the pupil, ptosis, and anhidrosis.[75] A sympathetic blockade that diminishes or eliminates a pain state may guide future treatment such as repeated blocks or systemic treatment with sympathetically active drugs (e.g., clonidine and prazosin).[116]

Neurologic conditions, both peripheral and central, can present as pain in the orofacial region. A role of the clinician is to help rule out gross neurologic conditions secondary to intracranial pathosis. Systemic complaints such as nausea, dizziness, or changes in one of the special senses should raise suspicion of intracranial pathosis. A neurologic screening examination, including a gross sensory and motor evaluation of cranial nerves II through XII, should be performed. For details on cranial nerve examination, please refer to other sources.[44] Investigation of sharp/dull differentiation as well as light touch discrimination between the different branches of the trigeminal nerve can provide insight as to the location and etiology of the pathosis.

Case studies

Case 1

A 56-year-old male presents with a chief complaint of "This tooth still hurts and it's getting worse. It even hurts when I smile." He has a history of angina secondary to a 70% occlusion of his right coronary artery. He also reports a history of hypercholesterolemia. He has no history of myocardial infarction and denies any other significant medical history. The patient is taking lovastatin (Mevacor, 400 mg/day), nifedipine (Procardia, 60 mg once per day), and atenolol (50 mg once per day). He has no known drug allergy.

The patient was referred by a periodontist for evaluation of continued pain associated with tooth #3. He had been receiving periodontal maintenance

Telegram: @dental_k

www.konkur.in

therapy for generalized moderate adult periodontitis for more than 5 years. He had root canal treatment and a mesial buccal root amputation of tooth #3 as treatment for a localized area of advanced periodontitis 6 months ago.

Subjective history.

After careful questioning, it becomes apparent that the patient is experiencing pain of two different qualities: an intermittent ache associated with tooth #3 and an intermittent sharp shooting pain also associated with tooth #3. The intermittent dull ache was of gradual onset 9 months ago. This pain was unaffected by the nonsurgical root canal treatment and root amputation. This pain has increased in frequency, intensity, and duration over the past 3 months. There is no temporal component. The dull ache is aggravated by biting and by the occurrence of the sharp shooting pain. The sharp shooting pain had a sudden onset 6 months ago. It has also increased in frequency, intensity, and duration without a temporal component. It can occur spontaneously or when the patient is “smiling big.” The patient reports that the sharp shooting pain can also be aggravated by pressing lightly on his face in the area overlying #3, but not by pressing intraorally on #3.

Examination.

The coronal portion of the amputated mesiobuccal root had been restored with IRM (Intermediate Restorative Material; DENTSPLY Caulk, Milford, DE). No cracks, fractures, sinus tracts, or swelling is detected. There are generalized probing depths of 4 mm throughout the upper right sextant. Tooth #3 has an 8-mm-broad probing defect mesially with bleeding on probing. For the results of clinical testing, see Table 4.2.

Table 4.2

*Endo Ice (Coltène/Whaledent, Cuyahoga Falls, OH) is used to detect pulp vitality.

†*s*, Pain of short duration.

A periapical radiograph (Fig. 4.11) shows evidence of prior nonsurgical root canal treatment and mesiobuccal root amputation of tooth #3. Mild to moderate horizontal bone loss is evident in the quadrant. No radiographic evidence of caries or apical radiolucencies is noted.

FIG. 4.11 Periapical radiograph showing prior nonsurgical root canal treatment and mesiobuccal root amputation of tooth #3.

Radiograph shows four teeth. Crowns of two teeth have a large diffused radiopaque patch. Root canal of one of the two teeth is filled with a significant radiolucency near it. The gum line shows low-density tissue in-between two teeth.

Additional tests.

In the absence of a clear etiology, a more extensive extraoral examination is performed. Cranial nerves II through XII are intact. The sharp shooting pain is predictably produced with light brushing of the skin over the area of tooth #3. This examination increases the patient's subjective complaint of a dull ache associated with tooth #3. With the likelihood of two possible sources of pain existing, a diagnostic anesthetic block of tooth #3 is performed: buccal infiltration of tooth #3 with 27 mg of 3% mepivacaine without epinephrine. After 3 minutes the patient no longer reports a dull ache at tooth #3 and he is

Telegram: @dental_k

www.konkur.in

nontender to percussion. His sharp shooting pain can still be initiated with light brushing of the skin over the area of tooth #3 and continues to cause a dull ache in the area of tooth #3. Diagnoses of trigeminal neuralgia and advanced localized adult periodontitis of tooth #3 are made. The patient is referred to a neurologist for evaluation and treatment. The diagnosis of trigeminal neuralgia is confirmed and he is placed on carbamazepine at 100 mg/day.

Case 2

A 28-year-old male presents with a chief complaint of “My teeth on the right side hurt.” His medical history is not significant. He denies any systemic disease and has no known drug allergies. He is currently taking 600 mg of ibuprofen as needed for pain. He is taking no other medications. The patient was referred by his general clinician for evaluation of pain associated with his teeth on the right side.

Subjective history.

After careful questioning, it is determined that the patient is experiencing pain of two different types. The most distressing pain to the patient is a diffuse, right-sided, constant low-grade dull ache (3/10 on a VAS). The onset was gradual, beginning 2 years ago. The pain has recently increased in intensity and duration. This pain is aggravated by opening wide and increases in intensity after the occurrence of a sharp pain that is induced by biting down. There is no notable temporal component, and the patient has made no attempts to obtund the pain.

His other pain type had a sudden onset approximately 4 months ago. This pain is localized to the area of the right first molars. It is an intermittent sharp shooting pain (8/10 on VAS) that occurs when biting.

Examination.

Tooth #3 has an occlusal amalgam with cracks evident on the mesial marginal ridge and the buccal groove. Tooth #30 has an occlusal amalgam, and cracks are noted on the mesial and distal marginal ridges of the tooth. There are no swellings or sinus tracts and no probing greater than 4 mm on the right side. A periapical radiograph demonstrates no evidence of caries or

Telegram: @dental_k

www.konkur.in

apical radiolucencies. The patient's sharp pain is reproduced with a bite test applied to the mesial lingual cusp of tooth #30. After the bite test, the patient reports that his dull ache has intensified. For the results of clinical testing, see Table 4.3. Thirty seconds after pulp testing has been completed, the patient again reports that his dull ache has intensified.

Table 4.3

Case 2: Clinical Results of Testing

	TOOTH					
Test	**#2**	**#3**	**#4**	**#31**	**#30**	**#29**
Endo Ice	+ (s)	+ (s)	+ (s)	+ (s)	+ (s)	+ (s)
Percussion	–	–	–	–	–	–
Palpation	–	–	–	–	–	–

Additional tests.

In consideration of an uncertain diagnosis, a more extensive examination is performed. Palpation and provocation tests of the muscles of mastication reveal a trigger point in the patient's right deep masseter. Palpation of this trigger point immediately intensifies his "toothache." A trigger point injection of 3% mepivacaine without epinephrine is done in an effort to clarify a diagnosis. After a trigger point injection, all tests are repeated. Palpation of the trigger point no longer produces pain. The bite test and cold test still produce a short sharp pain but are no longer followed by a dull ache.

Diagnoses of reversible pulpitis secondary to a cracked tooth #31 and MFP of the right masseter are made. The patient is given home care instructions for treatment of his MFP, and he is referred to his general clinician for cuspal coverage of both teeth #3 and #30.

Summary

As clinicians who are frequently called on to diagnose and treat complaints of orofacial pain, it is important to have a thorough knowledge of the odontogenic and nonodontogenic causes. The basis for this knowledge begins

Telegram: @dental_k

www.konkur.in

with an understanding of the anatomy and physiology of the pain system, and how alterations in this system can result in pain that is poorly localized and therefore misdiagnosed. A realization that pain does not always originate in the structures in which they are felt, along with an understanding of the neurobiologic basis of heterotopic pain, is necessary to ensure accurate diagnosis of orofacial pain.

There are several indicators that a toothache may be nonodontogenic in origin. Red flags for nonodontogenic pain include toothaches that have no apparent etiology for pulpal or periradicular pathosis; pain that is spontaneous, poorly localized, or migratory; and pain that is constant and nonvariable. In addition, pain that is described as burning, pricking, or "shock-like" is less likely to be pulpal or periradicular in origin.

A thorough pain history and an examination of dental and nondental structures are essential to differentiate between odontogenic and nonodontogenic sources of pain. Examples of key components of the pain history and examination are included in this chapter for reference. In addition, the chapter has focused on the more common nonodontogenic sources of orofacial pain. As stated previously, the role of the dental clinician is to diagnose and treat disorders of the oral cavity and masticatory structures. In the event that a nondental pathosis is suspected, a differential diagnosis of probable disorders is essential as part of a referral to a more appropriate health care provider. In addition, an understanding of any potential role or interaction of dental structures in the patient's pain complaint should be communicated as part of the referral.

5: Case assessment and treatment planning

Paul A. Rosenberg, Matthew Malek

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

The process of case selection and treatment planning begins after a clinician has diagnosed an endodontic problem. The clinician must determine whether the patient's oral health needs are best met by providing endodontic treatment and maintaining the tooth or by advising extraction. The use of cone beam computed technology (CBCT), rotary instruments, ultrasonics, and microscopy, as well as new materials, has made it possible to retain teeth that previously would have been extracted. In addition, even teeth that have failed initial endodontic treatment can often be successfully retreated using nonsurgical or surgical procedures.

Increased knowledge of factors involved in intraoperative and postoperative pain have led to new pain preventive strategies. For example, recognition of the importance of anxiety control, premedication with a nonsteroidal antiinflammatory drug (NSAID) or acetaminophen, profound local anesthesia, and appropriate occlusal adjustment enables clinicians to complete endodontic procedures without intraoperative or posttreatment pain.

The scope of endodontics has changed; the clinician now has more viable options than ever before. In recent years, there is increasing evidence to support the implementation of regenerative procedures for some immature teeth, vital pulp therapy, and replantation of teeth with failed non-surgical or surgical endodontic procedures. Treatment planning must now include those options as well as nonsurgical or surgical endodontics.

Questions concerning tooth retention and possible referral can only be answered after a complete patient evaluation. The evaluation must include assessment of medical, psychosocial, and dental factors as well as

Telegram: @dental_k

www.konkur.in

consideration of the relative complexity of the endodontic procedure. Although most medical conditions do not contraindicate endodontic treatment, some can influence the course of treatment and require specific modifications. Comprehensive texts are available that review the subject of dental care for the medically compromised patient.[15,51,118] The American Academy of Oral Medicine (Edmonds, WA) has an excellent website (www.aaom.com) that can be used to elicit information about medically compromised patients.

The American Dental Society of Anesthesiology (ADSA) has produced a valuable source of information, “Ten Minutes Saves a Life” application, which is available for most common smartphone platforms. Its goal is to optimize patient safety and outcomes during in-office medical emergencies (see https://www.adsa-arf.org/tenminutes).

Perhaps the most important advice for a clinician who plans to treat a medically compromised patient is to be prepared to communicate with the patient’s physician. The proposed treatment can be reviewed, and medical recommendations should be documented. Fig. 5.1 depicts a sample medical consultation letter that can be modified as necessary.

Michael White, MD
1 Walker Street
Brown City, OK

Dear Dr. White,

Your patient, Ms. Mary Smith, presented for consultation on August 10, 2009, concerning tooth #19. The tooth is asymptomatic at this time, but a small (4 mm x 3 mm), well-circumscribed periradicular radiolucency associated with the palatal root was noted on radiographic examination. The tooth was tested for vitality using thermal and electrical modalities and found to be nonvital, indicating an odontogenic cause for the lesion. The tooth will require endodontic treatment in order to be maintained. The prognosis for nonsurgical endodontic treatment in this case is good. I anticipate that her dental medication plan would include lidocaine with epinephrine for anesthesia and ibuprofen for postoperative pain control.

In a review of the patient's medical history she noted that she is being treated for a malignancy of the thyroid gland and is undergoing radiation therapy. She was unable to provide more specific informatior about her treatment.

I would appreciate information regarding her ability to undergo endodontic treatment at this time. Please call me if there is further information that you would require concerning the dental treatment to be provided. Thank you.

Yours truly,

Peter Jones, DDS

The American Society of Anesthesiologists (ASA; Park Ridge, IL) Physical Status Classification system is commonly used to express medical risk (Box 5.1). The ASA classification system remains the most widely used assessment method for preanesthetic patients, despite some inherent limitations to its use as a peritreatment risk predictor. This classification system is a generally accepted useful guide for pretreatment assessment of relative risk but does not advise appropriate treatment modifications. The clinician should go beyond the classification system and gather more information from the patient and physician, including the patient's compliance with suggested medication, frequency of physician visits, and most recent visit.

Box 5.1

American Society of Anesthesiologists Physical Status Classification System

ASA I: A normal healthy patient healthy, non-smoking, no or minimal alcohol use.

ASA II: A patient with mild systemic disease, mild diseases only without substantive functional limitations. Examples include (but not limited to): current smoker, social alcohol drinker, pregnancy, obesity (30 < BMI < 40), well-controlled DM/HTN, mild lung disease.

ASA III: A patient with severe systemic disease, substantive functional limitations; one or more moderate to severe diseases. Examples include (but not limited to): poorly controlled DM or HTN, COPD, morbid obesity (BMI ≥40), etc.

ASA IV: A patient with severe systemic disease that is a constant threat to life. Examples include (but not limited to): recent (<3 months) MI, CVA, TIA, or CAD/stents, etc.

Telegram: @dental_k

www.konkur.in

ASA V: A moribund patient who is not expected to survive without the operation.
ASA VI: A declared brain-dead patient whose organs are being removed for donor purposes.

ASA, American Society of Anesthesiologists; *BMI*, body mass index; *CAD*, coronary artery disease; *COPD*, chronic obstructive pulmonary disease; *CVA*, cerebrovascular accident; *DM*, diabetes mellitus; *HTN*, hypertension; *MI*, myocardial infarction; *TIA*, transient ischemic attack.
Excerpted from ASA Physical Status Classification System 2019 of the American Society of Anesthesiologists. A copy of the full text can be obtained from ASA, 1061 American Lane, Schaumburg, IL, 60173-4973 or online at www.asahq.org.

Typical questions include the following: *Do you take medication as prescribed by your physician?* Or, *when was the last time you were examined by your physician?* Other systems have been proposed that would better reflect the increasing number of medically complex patients treated by clinicians as Americans live longer.[35] Regardless of the classification system used, these generalized guidelines need to be individualized for the patient under care.

An alternative means of considering risk assessment is to review the following issues:

- History of allergies
- History of drug interactions, adverse effects
- Presence of prosthetic valves, joints, stents, pacemakers, and so on
- Antibiotics required (prophylactic or therapeutic)
- Hemostasis (normal expected, modification to treatment)
- Patient position in chair
- Infiltration or block anesthesia with or without vasoconstrictor
- Significant equipment concerns (radiographs, ultrasonics, electrosurgery)
- Emergencies (potential for occurrence, preparedness)
- Anxiety (past experiences and management strategy)

Telegram: @dental_k

www.konkur.in

A review of these areas provides the clinician with essential background data before initiating treatment.

Common medical findings that may influence endodontic treatment planning

Cardiovascular disease

Patients with some forms of cardiovascular disease are vulnerable to physical or emotional stress that may be encountered during dental treatment, including endodontics. Patients may be confused or not understand the specifics of their particular cardiovascular problem.

In those situations, consultation with the patient's physician is mandatory before initiation of endodontic treatment. "For patients with symptoms of unstable angina or those who have had an MI (myocardial infarction) within the past 30 days (major risk category), elective treatment should be postponed."[51] However, one study found "no significant increase in the risk of experiencing a second vascular event after dental visits, including those that involved invasive procedures, in periods up to 180 days after a first recorded ischemic stroke, transient ischemic attack (TIA) or acute MI."[101]

The use of vasoconstrictors in local anesthetics poses potential problems for patients with ischemic heart disease. In these patients, local anesthetics without vasoconstrictors may be used as needed. If a vasoconstrictor is necessary, patients with intermediate clinical risk factors (i.e., a past history of MI without ischemic symptoms) and those taking nonselective beta-blockers can safely be given up to 0.036 mg epinephrine (two cartridges containing 1:100,000 epinephrine) at a single appointment. For patients at higher risk (i.e., those who have had an MI within the past 7 to 30 days and unstable angina), the use of vasoconstrictors should be discussed with the physician.[51]

Vasoconstrictors may interact with some antihypertensive medications and should be used only after consultation with the at-risk patient's physician. Local anesthetic agents with minimal or no vasoconstrictors are usually adequate for nonsurgical endodontic procedures (see also Chapter 6 on pain control).[51] A systematic review of the cardiovascular effects of epinephrine

Telegram: @dental_k

www.konkur.in

concluded that the increased risk for adverse events among uncontrolled hypertensive patients was low, and the reported adverse events associated with epinephrine use in local anesthetics was minimal.[6] Another review highlighted the advantages of including a vasoconstrictor in the local anesthesia and stated that "pain control was significantly impaired in those patients receiving the local anesthetic without the vasoconstrictor as compared to those patients receiving the local anesthetic with vasoconstrictor."[14]

Some heart conditions make a patient more susceptible to an infection of the heart valves, induced by a bacteremia. That infection, called *infective* or *bacterial endocarditis,* is potentially fatal. In 2008, the American College of Cardiology and American Heart Association (AHA) Task Force on Practice Guidelines published an update on their previous guidelines, which focused on infectious endocarditis. This guideline stated that prophylaxis against infective endocarditis is reasonable for the following patients at highest risk for adverse outcomes from infective endocarditis who undergo dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa: patients with prosthetic cardiac valves or prosthetic material used for cardiac valve repair, patients with previous infective endocarditis, and patients with select congenital heart diseases.[73]

The specific recommendations are summarized in an American Association of Endodontists (AAE) (Chicago, IL) reference guide found online at https://www.aae.org/specialty/wp-content/uploads/sites/2/2017/06/aae_antibiotic-prophylaxis-2017update.pdf. Because the AHA periodically revises its recommended antibiotic prophylactic regimen for dental procedures, it is essential that the clinician stay current concerning this important issue.

There is a low compliance rate among at-risk patients regarding their use of the suggested antibiotic coverage before dental procedures. Therefore, the clinician must question patients concerning their compliance with the prescribed prophylactic antibiotic coverage before endodontic therapy. If a patient has not taken the antibiotic as recommended, it may be administered up to 2 hours after the procedure.[51]

Patients with artificial heart valves are considered susceptible to bacterial

Telegram: @dental_k

www.konkur.in

endocarditis. Consulting the patient's physician in such cases regarding antibiotic premedication is essential. Some physicians elect to administer parenteral antibiotics in addition to or in place of the oral regimen.

A dentist may be the first to detect elevated blood pressure if he or she routinely evaluates blood pressure before treatment. Furthermore, patients receiving treatment for hypertension may not be controlled adequately because of poor compliance or inappropriate drug therapy. Abnormal blood pressure readings may be the basis for physician referral.

There is a widespread belief among dentists and physicians that oral anticoagulation therapy with drugs such as warfarin (Coumadin, Bristol-Myers Squibb, New York, NY, USA) must be discontinued before dental treatment to prevent serious hemorrhagic complications, especially during and after surgical procedures. Aspirin is a drug commonly used as an anticoagulant on a daily basis without the supervision of a physician. However, clinical studies do not support the routine withdrawal of anticoagulant therapy before dental treatment for patients who are taking such medications.[12,41,51]

When patients report they are receiving an anticoagulant medication, they can benefit from the clinician using the following guidelines:

- Identify the reason why the patient is receiving anticoagulant therapy.
- Know the drug classification, mechanism of action, and its half-life. For instance, 1 to 2 hours for standard heparin, 2 to 4 hours for heparin with low-molecular-weight preparations, and 4 to 5 days for warfarin.[51]
- Assess the potential risk versus benefit of altering the drug regimen.
- Know the laboratory tests used to assess anticoagulation levels. For example, the international normalized ratio (INR) value should be 3.5 or less for patients who are taking warfarin to safely undergo dental or surgical endodontic procedures. However, newer-generation direct thrombin inhibitors, such as dabigatran (Pradaxa) (Pradaxa Boehringer Ingelheim Pharmaceuticals, Ingelheim, Germany), do not require INR monitoring.[51]
- Be familiar with methods used to obtain hemostasis both

Telegram: @dental_k

www.konkur.in

intraoperatively and postoperatively.
- Be familiar with the potential complications associated with prolonged or uncontrolled bleeding.
- Consult the patient's physician to discuss the proposed dental treatment and to determine the need to alter the anticoagulant regimen.

Diabetes

The Centers for Disease Control and Prevention (CDC, Atlanta, GA) in 2017 reported that an estimated 30.3 million people of all ages, or 9.4% of the US population, had diabetes in 2016. (See National Diabetes Statistics Report available at https://www.cdc.gov/diabetes/pdfs/data/statistics/national-diabetes-statistics-report.pdf.) Diabetes was the seventh leading cause of death in the United States in 2016 (heart disease being the first).[119]

Diabetes mellitus appears to have multiple causes and several mechanisms of pathophysiology.[51] It can be thought of as a combination of diseases that share the key clinical feature of glucose intolerance. Patients with diabetes, even those who are well controlled, require special consideration during endodontic treatment. The patient with well-controlled diabetes who is free of serious complications such as renal disease, hypertension, or coronary atherosclerotic disease is a candidate for endodontic treatment. However, special considerations exist in the presence of acute infections. The non–insulin-controlled patient may require insulin, or the insulin dose of some insulin-dependent patients may have to be increased.[83] When surgery is required, consultation with the patient's physician is advisable in order to consider adjustment of the patient's insulin dosage, antibiotic prophylaxis, and dietary needs during the posttreatment period.

The clinician should ask patients with diabetes, who self-monitor their glucose levels, to bring a glucometer to each visit. If pretreatment glucose levels are below normal fasting range (80 to 120 mg/dL), it may be appropriate to take in a carbohydrate source.[5] A source of glucose (e.g., glucose tablets, orange juice, or soda) should be available if signs of insulin shock (hypoglycemic reaction caused by over-control of glucose levels) occur.[51] Signs and symptoms of hypoglycemia include confusion, tremors, agitation, diaphoresis, and tachycardia.[5] The clinician can avoid a

Telegram: @dental_k

www.konkur.in

hypoglycemic emergency by taking a complete, accurate history of the time and amount of the patient's insulin and meals. When questions arise concerning the appropriate course to follow, the patient's physician should be contacted or treatment deferred.

Appointments should be scheduled with consideration given to the patient's normal meal and insulin schedule.[83] Usually, a patient with diabetes who is well managed medically and is under good glycemic control without serious complications such as renal disease, hypertension, or coronary atherosclerotic heart disease can receive any indicated dental treatment.[60] However, patients with diabetes who have serious medical complications may need a modified dental treatment plan. For instance, although prophylactic antibiotics are generally not required, it "may be prescribed for a patient with brittle (very difficult to control) diabetes, for whom an invasive procedure is planned but whose oral health is poor and the fasting plasma glucose exceeds 200 mg/dL."[51] Local anesthesia would not be an issue in the presence of well-controlled diabetes, "but for patients with concurrent hypertension or history of recent myocardial infarction, or with a cardiac arrhythmia, the dose of epinephrine should be limited to no more than two cartridges containing 1:100,000 epinephrine."[51]

There is some evidence in support of a relationship between glycemic control and periapical inflammation in diabetic patients.[8] A literature review of human studies also indicated a positive association between diabetes and larger number of periapical lesions.[16] One study determined that although apical periodontitis may be significantly more prevalent in untreated teeth in patients with type 2 diabetes, the disease does not seem to influence the response to root canal treatment.[55] However, other studies suggest that diabetes is associated with a decrease in the success of endodontic treatment in cases with pretreatment periradicular lesions.[30,105] In a prospective study on the impact of systemic diseases on the risk of tooth extraction, it has been also shown that an increased risk of tooth extraction after nonsurgical root canal treatment was significantly associated with diabetes mellitus, hypertension, and coronary heart disease.[113] The nature of such an association has not been fully explained, and may not be a causal relationship.

It is suggested that clinicians discuss the possible negative effect of

Telegram: @dental_k

www.konkur.in

diabetes on the outcome of endodontic treatment with appropriate patients. Patients with diabetes and other systemic diseases may be best served by referral to an endodontist for treatment planning.

Pregnancy

Although pregnancy is not a contraindication to endodontics, it may require modification of treatment planning. Protection of the fetus is a primary concern when administration of ionizing radiation or drugs is considered. The most important of safety devices associated with dental radiography is the protective lead apron with thyroid collar. Also important are the use of high-speed film, digital imaging, filtration, and collimation.[93] The American College of Obstetricians and Gynecologists' "Committee Opinion" published in 2013 and reaffirmed in 2017 recommends that clinicians reassure patients that "prevention, diagnosis, and treatment of oral conditions, including dental x-rays (with shielding of the abdomen and thyroid) and local anesthesia (lidocaine with or without epinephrine), are safe during pregnancy" (this document can be accessed at: https://www.acog.org/-/media/project/acog/acogorg/clinical/files/committee-opinion/articles/2013/08/oral-health-care-during-pregnancy-and-through-the-lifespan.pdf). The US Food and Drug Administration also states that "the risk of not having a needed x-ray could be much greater than the risk from the radiation" (refer to https://www.fda.gov/Radiation-Emitting Products/RadiationEmittingProductsandProcedures/MedicalImaging/MedicalX Rays/ucm142632.htm).

Over the last three decades, the use of prescription medication in the first trimester has increased by over 60%, and use of four or more medications more than tripled. By the year 2008, approximately 50% of women reported taking at least 1 medication during pregnancy.[61] These data suggest the increasing need for both the patient and the clinician to be informed about the indications, contraindications, and safety of consuming drugs during pregnancy. Box 5.2 presents commonly used dental drugs usually compatible with both pregnancy and breast-feeding. It should be noted that most clinicians are used to the old five-alphabet pregnancy categorization of the drugs (A, B, C, D, and X). In 2014, the US Food and Drug Administration changed its Pregnancy and Lactation Labeling. The new labels include "a

Telegram: @dental_k

www.konkur.in

summary of the risks of using the drug during pregnancy and lactation, a discussion of the data supporting that summary, and relevant information to help health care providers make prescription decisions and counsel women about the use of drugs during pregnancy and lactation" (see https://www.fda.gov/media/100406/download).

Box 5.2

Partial List of Drugs Usually Compatible With Both Pregnancy and Breast-Feeding

- Local anesthetics including lidocaine, etidocaine, and prilocaine
- Many antibiotics including penicillins, clindamycin, and azithromycin
- Acetaminophen
- Acyclovir
- Prednisone
- Antifungals including fluconazole and nystatin

One of the areas of concern in treating pregnant patients is to select the safest type of analgesics.

The analgesic of choice during pregnancy had been acetaminophen.[82] However, a link between acetaminophen and childhood asthma has been suggested. Research has found that "the use of acetaminophen in middle to late but not early pregnancy may be related to respiratory symptoms in the first year of life."[78] This finding, although not completely validated, and questioned due to possible confounding factors,[4] should be discussed with pregnant patients when an analgesic is being considered. In a 2016 advisory, the National Health Service of Great Britain advised pregnant patients not to take ibuprofen from the 30th week of pregnancy onwards. They stated that at that stage of pregnancy there is an association with increased risks of complications including heart problems. They went on to advise that before 30 weeks of pregnancy, patients should avoid taking ibuprofen, as it may lead to increased risks of complications including miscarriage (see https://www.nhs.uk/common-health-questions/pregnancy/can-i-take-ibuprofen-when-i-am-pregnant/). Aspirin and NSAIDs also convey risks for

Telegram: @dental_k

www.konkur.in

constriction of the ductus arteriosus, as well as for postpartum hemorrhage and delayed labor.[82] In a recent large epidemiology study done on 29,078 case and 10,962 control mothers from 1997 to 2011, the authors found that "compared to periconceptional use of acetaminophen, selected birth defects occurred more frequently among infants of women using NSAIDs and/or opioids." However, the authors were not able to definitely determine whether these risks were related to the drugs or to indications for treatment.[37] Due to ongoing research in this area, the clinician is strongly advised to routinely review current information concerning the use of medications before prescribing them for pregnant patients. Other than the CDC, one of the resources for both the clinician and the patient is the following website, a service of the nonprofit Organization of Teratology Information Specialists (OTIS), which is an excellent resource for evidence-based information on the safety of medications and other exposures during pregnancy and while breast-feeding: https://mothertobaby.org.

Based on US Food and Drug Administration pregnancy risk factor definitions,[35] local anesthetics administered with epinephrine generally are considered safe for use during pregnancy. Lidocaine is one of the safest local anesthetics, therefore delaying dental care during pregnancy is not advisable; however, the dose and type of the local anesthetic must be carefully determined for women who have contracted medical conditions that can induce serious pregnancy-related complications.[43] Few anxiolytics are considered safe to use during pregnancy. However, a single, short-term exposure to nitrous oxide–oxygen (N_2O-O_2) for less than 35 minutes is not thought to be associated with any human fetal anomalies, including low birth weight.[51] If a need exists for antibiotic therapy, penicillins, cephalosporins, and macrolides are considered first-line agents.

A major concern is that a drug may cross the placenta and be toxic or teratogenic to the fetus. In addition, any drug that is a respiratory depressant can cause maternal hypoxia, resulting in fetal hypoxia, injury, or death. Ideally, no drug should be administered during pregnancy, especially during the first trimester. If a specific situation makes adherence to this rule difficult, then the clinician should review the appropriate current literature and discuss the case with the physician and patient.[13,58,74]

Further considerations exist during the postpartum period if the mother

Telegram: @dental_k

www.konkur.in

breast-feeds her infant. A clinician should consult the responsible physician before using any medications for the nursing mother. Alternative considerations include using minimal dosages of drugs, having the mother bank her milk before treatment, having her feed the child before treatment, or suggesting the use of a formula for the infant until the drug regimen is completed. Limited data are available on drug dosages and the effects on breast milk.[51]

In terms of treatment planning, elective dental care is best avoided during the first trimester because of the potential vulnerability of the fetus. The second trimester is the safest period in which to provide routine dental care. Complex surgical procedures are best postponed until after delivery.

Malignancy

Some malignancies may metastasize to the jaws and mimic endodontic pathosis, whereas others can be primary lesions (Fig. 5.2). The most common malignancies metastasize to the jaws are breast, lung, thyroid, and prostate.[56] A panoramic radiograph and a cone-beam computed tomographic image are useful in providing an overall view of all dental structures. When a clinician begins an endodontic procedure on a tooth with a well-defined apical radiolucency, it might be assumed to result from a nonvital pulp. However, pulp sensibility testing is essential to confirm a lack of pulp vitality. A vital response in such cases indicates a nonodontogenic lesion.

Telegram: @dental_k

www.konkur.in

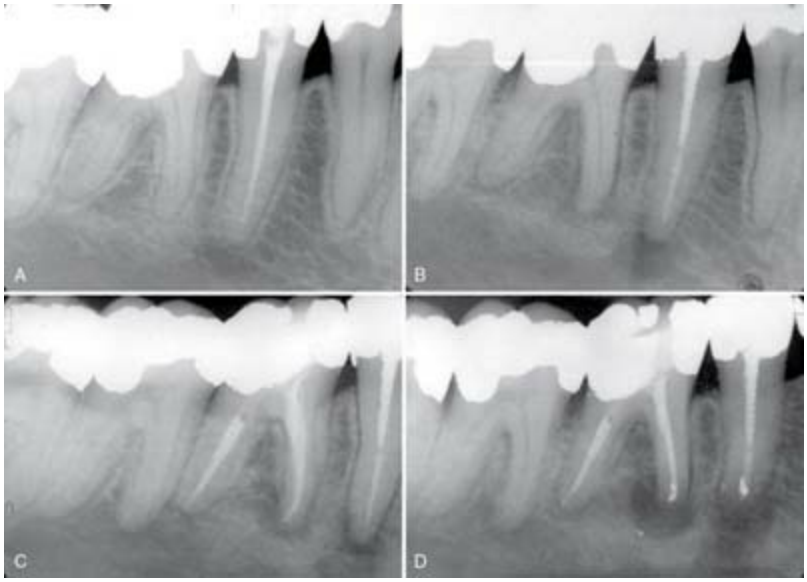

FIG. 5.2 **A,** Periapical view of tooth #29 after endodontic treatment by a general dental clinician. The diagnosis was irreversible pulpitis. **B,** Patient was referred to an endodontist 4 months later to evaluate radiolucencies of teeth #29 and #30. Symptoms indicated irreversible pulpitis of tooth #30, with concurrent lower right lip and chin paresthesia. Past medical history revealed breast cancer in remission. **C,** Nonsurgical endodontics was performed on tooth #30. Immediate referral was made to an oncologist/oral surgeon for biopsy to rule out nonodontogenic origin of symptoms. **D,** Surgical posttreatment radiograph of teeth #29 and #30. The biopsy report confirmed metastatic breast cancer.

A) Radiograph shows low-density tissue between teeth. 29th tooth has filled root canal with a porous tissue next to the root tip.

B) Radiograph shows a cleavage at the mid-way of root canal in 29th tooth. The region near root tip shows a dark circular patch.

C) Radiograph shows molar tooth with filled root canals. Root is surrounded by trabecular tissues.

D) Radiograph shows a well-defined circular patch at root apex of the molar.

Source: (Courtesy Dr. R. Sadowsky, Dr. L. Adamo, and Dr. J. Burkes.)

Careful examination of pretreatment radiographs from different angulations is important because lesions of endodontic origin would not be shifted away from the radiographic apex in the various images. Alternative methods, such as CBCT, may provide important diagnostic information (see

Telegram: @dental_k

www.konkur.in

Chapter 2 on radiographic interpretation).

A definitive diagnosis of periradicular lesions can be made only after biopsy. When a discrepancy exists between the initial diagnosis and clinical findings, consultation with an endodontist is advisable.

Patients undergoing chemotherapy or radiation to the head and neck may have impaired healing responses.[51] Treatment should be initiated only after the patient's physician has been consulted. A dialogue among the dentist, physician, and patient is required prior to determining whether a tooth or teeth should be extracted or endodontically treated prior to radiation.

The effect of the external beam of radiation therapy on normal bone is to decrease the number of osteocytes, osteoblasts, and endothelial cells, thus decreasing blood flow. Pulps may become necrotic from this impaired condition.[51] Toxic reactions during and after radiation and chemotherapy are directly proportional to the amount of radiation or dosage of cytotoxic drug to which the tissues are exposed. Delayed toxicities can occur several months to years after radiation therapy.

Oral infections and any potential problems should be addressed before initiating radiation. It is advised that symptomatic nonvital teeth be endodontically treated at least 1 week before initiating radiation or chemotherapy, whereas treatment of asymptomatic nonvital teeth may be delayed.[51] The outcome of endodontic treatment should be evaluated within the framework of the toxic results of radiation and drug therapy. The white blood cell (WBC) count and platelet status of a patient undergoing chemotherapy should also be reviewed before endodontic treatment. In general, routine dental procedures can be performed if the granulocyte count is greater than 2000/mm^3 and the platelet count is greater than 50,000/mm^3. If urgent care is needed and the platelet count is below 50,000/mm^3, consultation with the patient's physician is required.[51]

Medication-related osteonecrosis of the jaws

Bisphosphonates offer great benefits to patients at risk of bone metastases and in the prevention and treatment of osteoporosis, although this and other drugs (e.g., denosumab) are associated with a rare occurrence of osteonecrosis.[90]

To distinguish medication-related osteonecrosis of the jaws (MRONJ)

Telegram: @dental_k

www.konkur.in

from other delayed healing conditions, the following working definition of MRONJ has been adopted by the American Association of Oral and Maxillofacial Surgeons (AAOMS): Patients may be considered to have MRONJ if all of the following three characteristics are present[90]:

1. Current or previous treatment with an antiresorptive drug such as a bisphosphonate or an antiangiogenic drug such as sunitinib (Sutent) (Pfizer, New York, NY, USA), sorafenib (Nexavar) (Bayer, Leverkusen, Germany), or sirolimus (Rapamune) (Pfizer, New York, NY, USA).
2. Exposed, necrotic bone, or bone that can be probed through an intraoral or extraoral fistula in the maxillofacial region that has persisted for more than 8 weeks.
3. No history of radiation therapy to the jaws.

A patient's risk of developing osteonecrosis of the jaw while receiving oral bisphosphonates appears to be low, but there are factors known to increase the risk for MRONJ (Box 5.3). According to aforementioned position statements of the AAOMS, such risks include a history of taking intravenous (IV) bisphosphonates, as opposed to intraoral (IO), taking bisphosphonates for treatment of cancer (high risk), corticosteroid therapy, history of tobacco use, duration of bisphosphonate therapy (>2 to 3 years), a history of an oral operative procedure (i.e., dentoalveolar surgery and extraction), anatomical factors (mandible higher risk than maxilla), concomitant oral diseases (i.e., periodontal disease or periapical pathology), gender (female), age, and genetic predispositions.

Box 5.3

Risk Factors for Development of Bisphosphonate-Associated Osteonecrosis

- History of taking bisphosphonates for more than 2–3 years, especially with intravenous therapy
- History of cancer, osteoporosis, or Paget disease
- History of traumatic dental procedure

Telegram: @dental_k

www.konkur.in

- Patient more than 65 years of age
- History of periodontitis
- History of chronic corticosteroid use
- History of smoking
- History of diabetes

Treatment outcomes of MRONJ are unpredictable, and prevention strategies are extremely important. Management of high-risk patients might include nonsurgical endodontic treatment of teeth that otherwise would be extracted. The combination of orthodontic extrusion and bloodless extraction —exfoliation of the extruded roots after their movement—has also been suggested with the aim of minimizing trauma and enhancing the health of the surrounding tissues in patients at risk of developing MRONJ or when a patient refuses to undergo conventional tooth extraction.[102]

For patients at higher risk of MRONJ, surgical procedures such as extractions, endodontic surgery, or placement of dental implants should be avoided. (See https://www.aaoms.org/docs/govt_affairs/advocacy_white_papers/mronj_posi Sound oral hygiene and regular dental care may be the best approach to lowering the risk of MRONJ. Patients taking bisphosphonates and undergoing endodontic therapy should sign an informed consent form, inclusive of the risks, benefits, and alternative treatment plans. The following recommendations have been suggested to reduce the risk of MRONJ associated with endodontic treatment[62]:

- Apply a 1-minute mouth rinse with chlorhexidine prior to the start of the treatment with the aim of lowering the bacterial load of the oral cavity.
- Avoid the use of anesthetic agents with vasoconstrictors in order to prevent impairment of tissue vascularization.
- Work under aseptic conditions, including removing of all caries and placement of rubber dam prior to intracanal procedures.
- Avoid damage to the gingival tissues during the placement of rubber dam.
- Avoid maintaining patency of the apical foramen to prevent

Telegram: @dental_k

www.konkur.in

bacteremia.

- Use techniques that reduce the risk of overfilling and overextension.

Aggressive use of systemic antibiotics is indicated in the presence of an infection in a patient taking bisphosphonates.[51] Discontinuing bisphosphonate therapy may not eliminate any risk of developing MRONJ.[54,57,59] Some clinicians have proposed use of the CTX (C-terminal telopeptide of type I collagen α_1 chain) test (Quest Diagnostics, Madison, NJ) for assessing the risk of developing bone osteonecrosis (BON). For patients who have developed MRONJ, close coordination with an oral maxillofacial surgeon or oncologist is highly recommended.

The AAE updated guideline published on 2018 titled: Endodontic Implications of MRONJ, states: “absent data, the committee considers the risk for ONJ after dental implant placement and endodontic or periodontic procedures that require exposure and manipulation of the bone as comparable to the risk associated with tooth extraction.” (See https://www.aae.org/specialty/wp-content/uploads/sites/2/2018/07/AAE_MedRelated_ONJ.pdf.) An astute awareness of the potential risk of MRONJ in patients receiving bisphosphonate therapy is critical. Increased attentiveness to the prevention, recognition, and management of MRONJ will allow the clinician to make the best treatment decisions. Our knowledge of MRONJ is developing rapidly, and it is essential that the clinician monitor the literature for changes in treatment protocols.[54,57,59]

Human immunodeficiency virus and acquired immunodeficiency syndrome

From 1987 through 1994, human immunodeficiency virus (HIV) disease mortality increased and reached a plateau in 1995. Subsequently, the mortality rate for this disease decreased an average of 33% per year from 1995 through 1998, and 6.2% per year from 1999 through 2016.[119] This dramatic improvement seems to be due to the use of a combination of highly active antiretroviral therapy (HAART) and improved preventive strategies.[51]

It is important, when treating patients with acquired immunodeficiency syndrome (AIDS), that the clinician understand the patient’s level of

Telegram: @dental_k

www.konkur.in

immunosuppression, drug therapies, and the potential for opportunistic infections. Although the effect of HIV infection on long-term prognosis of endodontic therapy is unknown, it has been demonstrated that clinicians may not have to alter their short-term expectations for periapical healing in patients infected with HIV.[80] The clinical team must also minimize the possibility of transmission of HIV from an infected patient, and this is accomplished by adherence to universal precautions. (See Universal Precautions for Prevention of Transmission of HIV and Other Bloodborne Infections, available at https://www.cdc.gov/niosh/topics/bbp/universal.html.)

Although saliva is not the main route for transmission of HIV, the virus has been found in saliva and its transmission through saliva has been reported.[32] Infected blood can transmit HIV, and during some procedures it may become mixed with saliva. Latex gloves and eye protection are essential for the clinician and staff. HIV can be transmitted by needlestick or via an instrument wound, but the frequency of such transmission is low, especially with small-gauge needles. Nevertheless, "Patients at high risk for AIDS and those in whom AIDS or HIV has been diagnosed should be treated in a manner identical to that for any other patient—that is, with standard precautions."[51]

A vital aspect of treatment planning for the patient with HIV/AIDS is to determine the current $CD4^+$ lymphocyte count and level of immunosuppression. In general, patients having a $CD4^+$ cell count exceeding 350 cells/mm^3 may receive all indicated dental treatments. Patients with a $CD4^+$ cell count of less than 200 cells/mm^3 or severe neutropenia (neutrophil count lower than 500/μL) will have increased susceptibility to opportunistic infections and may be effectively medicated with prophylactic drugs. WBC and differential counts, as well as a platelet count, should be ordered before any surgical procedure is undertaken. Patients with severe thrombocytopenia may require special measures (platelet replacement) before surgical procedures. Care in prescribing medications must also be exercised with any medications after which the patient may experience adverse drug effects, including allergic reactions, toxic drug reactions, hepatotoxicity, immunosuppression, anemia, serious drug interactions, and other potential problems. The practitioner should also be aware of oral manifestations of the disease as far as it concerns diagnosis and treatment planning. For instance,

Telegram: @dental_k

www.konkur.in

candidiasis of the oral mucosa, Kaposi sarcoma, hairy leukoplakia of the lateral borders of the tongue, herpes simplex virus (HSV), herpes zoster, recurrent aphthous ulcerations, linear gingival erythema, necrotizing ulcerative periodontitis, necrotizing stomatitis, oral warts, facial palsy, trigeminal neuropathy, salivary gland enlargement, xerostomia, and melanotic pigmentation are all reported to be associated with HIV infection. It is essential that consultation with the patient's physician occurs before performing surgical procedures or initiating complex treatment plans.[51,94]

Prosthetic implants

Patients with prosthetic implants are frequently treated in dental practices. The question concerning the need for antibiotic prophylaxis to prevent infection of the prosthesis has been debated for many years. A brief review of the subject should of interest to clinicians.

A statement was issued jointly in 2003 by the American Dental Association (ADA; Chicago, IL) and the American Academy of Orthopaedic Surgeons (AAOS; Rosemont, IL) in an attempt to clarify the issue.[30] The statement concluded that scientific evidence does not support the need for antibiotic prophylaxis for dental procedures to prevent prosthetic joint infections. It should be noted that although endodontics has been shown to be a possible cause of bacteremia,[21,42] the risk is minimal in comparison with extractions, periodontal surgery, scaling, and prophylaxis.[75] Nevertheless, there had been numerous conflicting opinions about the need to premedicate such patients that were raised over the next 15 years after the publication of the original statement in 2003, such as the 2009 statement of the AAOS entitled Antibiotic Prophylaxis for Bacteremia in Patients with Joint Replacements, which recommended that clinicians consider antibiotic prophylaxis for all total joint replacement patients prior to any invasive procedure that may cause bacteremia. (See American Academy of Orthopaedic Surgeons: AAOS releases new statement on antibiotics after arthroplasty, www.aaos.org/news/aaosnow/may09/cover2.asp.) In 2012, an evidenced-based guideline was published that included recommendations of the AAOS-ADA clinical practice guideline for Prevention of Orthopaedic Implant Infection in Patients Undergoing Dental Procedures. This guideline stated that there is limited evidence for discontinuing the practice of routinely

Telegram: @dental_k

www.konkur.in

prescribing prophylactic antibiotics for patients with hip and knee prosthetic joint implants undergoing dental procedures. (See American Academy of Orthopaedic Surgeons: Prevention of orthopaedic implant infection in patients undergoing dental procedures, available at www.aaos.org/research/guidelines/PUDP/PUDP_guideline.pdf.) In 2015, the *Journal of the American Dental Association* published an article based on the review of prior research stating that "for patients with prosthetic joint implants, prophylactic antibiotics are not recommended prior to dental procedures to prevent prosthetic joint infection. The practitioner and patient should consider possible clinical circumstances that may suggest the presence of a significant medical risk in providing dental care without antibiotic prophylaxis, as well as the known risks of frequent or widespread antibiotic use."[103] The 2017 update of the AAE's Antibiotic Prophylaxis Reference Guide also reflect this position. (See https://www.aae.org/specialty/wp-content/uploads/sites/2/2017/06/aae_antibiotic-prophylaxis-2017update.pdf.)

Consultation with the patient's physician on a case-by-case basis is advisable to assess the need for prophylaxis.

Behavioral and psychiatric disorders

Stress reduction is an important factor in the treatment of patients with behavioral and psychiatric disorders. Sensitivity to the patient's needs must be part of the dental team's approach. Significant drug interactions and side effects are associated with tricyclic antidepressants, monoamine oxidase inhibitors, and antianxiety medications.[51] Consultation with physicians in such cases is essential before using sedatives, hypnotics, antihistamines, or opioids.

Psychosocial evaluation

The initial visit, during which medical and dental histories are collected, provides an opportunity to consider the patient's psychosocial status and how they value their oral health. Although some patients may want to maintain a tooth with a questionable prognosis, others may lack the ability to comprehend the potential risks and benefits. It would be a mistake to lead patients beyond what they can understand and appreciate. Furthermore, patients should not be allowed to dictate a treatment plan that has a poor

Telegram: @dental_k

www.konkur.in

prognosis.

The clinician should also assess the patient's level of anxiety as an important part of preparation for the procedure to follow. It is reasonable to assume that most patients are anxious to some degree, especially when they are about to undergo endodontic treatment. A conversation describing the procedure and what the patient can expect is an important part of an anxiety-reduction protocol.

A study evaluated the most common pathways of fear and anxiety in patients who previously had root canal treatment or were planning to have that procedure. Cognitive conditioning and parental pathways seemed to be the primary cause ($P < .05$) of fear and anxiety with root canal treatment. Females were significantly more likely to be influenced by indirect conditioned experiences such as informative, parental, verbal threat, and vicarious pathways. It was concluded that the origin of patients' fears requires more attention to the importance of treating endodontic-related fear and anxiety. More knowledge about these factors would enable dentists to better manage patients in a multicultural society.[17] More information will be provided in the Anxiety segment of this chapter.

Development of the endodontic treatment plan

The long-term strategic value of a tooth should be considered before presenting an endodontic treatment plan. For example, a restorative plan could be endangered by including a tooth with a questionable endodontic prognosis. Currently, endodontic treatment options exist that were not previously supported by significant levels of evidence. The options include vital pulp therapy, regenerative procedures, and intentional replantation. Although some decisions may be straightforward, considering alternative treatment options can be challenging, as the clinician weighs multiple factors that will play a role in determining the ultimate success or failure of the case. For example, if initial endodontic nonsurgical or surgical procedure has failed, the most common alternative has been an implant or a fixed or removable prosthesis. However, there is increasing evidence that intentional replantation is a cost-effective procedure that may be accomplished, in select cases, with a good prognosis. It is important to note that even if replantation fails, a dental implant remains as an additional option.

Telegram: @dental_k

www.konkur.in

Referral of the patient to a specialist should be considered when the complexity of a procedure is beyond the ability of a clinician. The complexity can be due to restorative factors, unusual anatomy, and calcification of the chamber and/or the canal. Other factors that affect endodontic prognosis include periodontal, restorative, and the patient's systemic health.

Endodontic prognosis

Prognostic studies have identified a number of preoperative factors affecting the outcome of primary endodontic treatment. In a systematic review, it was determined that the absence of periapical radiolucency improves the outcome of root canal treatment significantly. The same study also showed that tooth vitality does not have an impact on the endodontic prognosis, as long as the periapex is healthy.[72] Studies have shown that the size of the radiolucency may also affect the outcome of endodontic treatment.[72,87] It was found that the existence of sinus tract, narrow but deep periodontal probing depth, pain, and discharging sinus have a significant effect on the outcome of nonsurgical root canal treatment.[69] Preoperative pain is not only one of the most important predictors of postoperative pain,[66] it also has an impact on tooth survival after endodontic treatment.[68]

These findings suggest that all preexisting signs and symptoms that may affect the prognosis of treatment, along with the prognostic factors associated with other disciplines—which will be discussed in the next segment—should be taken into consideration when developing a treatment plan. It is of utmost importance that the prognosis and risks and benefits of the treatment be relayed to the patient before the initiation of the treatment as well.

There is a general belief that the prognoses for retreatment cases are poorer than for primary treatment, but this is not universally supported. In a systematic review it was suggested that the outcomes of retreatment cases should be similar to treatment cases as long as access to the apical infection can be reestablished.[67] However, there is some evidence indicating that the incidence of postoperative pain and flare-up is higher in retreatment cases in comparison to treatments.[36] The presence of preoperative periapical lesion, apical extent of root filling, and quality of coronal restoration has been proved to significantly affect the outcome of retreatment cases.[67]

Telegram: @dental_k

www.konkur.in

Retreatment cases offer a particular set of challenges to the clinician (Figs. 5.3 and 5.4), and this topic is covered extensively in Chapter 10. Important questions to be considered before retreatment include the following:

- Why did the treatment fail?
- Can the point of bacterial entry to the canal space be identified?
- Are prior radiographs available for review?
- Is there an obvious endodontic procedural problem that can be corrected?
- Is the canal system readily accessible for reentry?
- There are additional factors (i.e., a significant periodontal defect or being under immunotherapy) that may have contributed to the failure.
- Is the tooth critical to the treatment plan? (Keeping in mind that including a tooth with a questionable endodontic or periodontal prognosis may endanger an entire prosthesis.)
- Does the patient understand the prognosis for the tooth and want to attempt retreatment? This question and its answer should be documented in the patient's record. The dentist could enter in the patient's record the following statement: "All reasonable options including extraction were presented to the patient and advantages and disadvantages of each were explained."

radiographic diagnosis by sensibility testing. Tooth #7 was vital, and tooth #8 was successfully retreated after removal of the post.

Radiograph on the left shows 7th tooth with radiolucent root canal with a small radiopaque patch in the pulp. 8th tooth radiopaque root canal and crown without enamel. The region near seventh tooth is extremely radiolucent extending from gum line to the root apex.

Radiograph on the right shows eighth tooth with radiopaque crown and root canal with radiolucent enamel. The tissue near seventh tooth has high-density.

Source: (Courtesy Dr. Leon Schertzer.)

A retreatment plan should be developed after the clinician has determined the cause of failure and weighed other factors that may affect the prognosis (e.g., root fracture, defective restoration) (Figs. 5.5 to 5.8). Retreatment cases may require surgical endodontics in combination with nonsurgical retreatment. Referral to a specialist is often helpful when planning treatment for complex cases. If retreatment (with or without surgery) of a tooth with a new restoration is being considered, it should be weighed against the possibility of intentional replantation or an implant. Many variables must be considered before a reasonable conclusion can be reached.

FIG. 5.5 Many years after endodontic treatment of tooth #19, the patient returned with a chief complaint of pain and an inability to chew

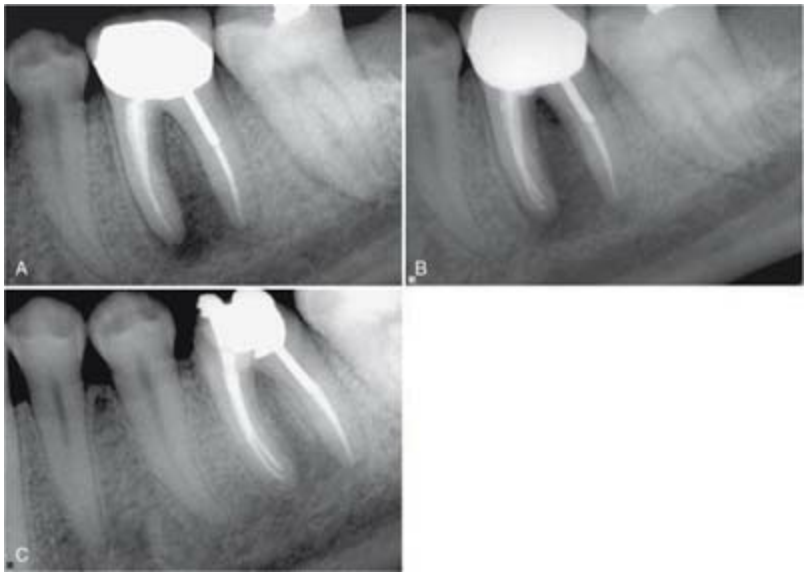

FIG. 5.8 Despite several exacerbations during endodontic retreatment, this case responded rapidly after the completion of therapy. Radiographic evaluation indicates a good periapical response after only 4 months. **A,** Radiograph taken 2 years after initial root canal therapy. **B,** Retreatment of the mesial root. **C,** Radiograph taken 4 months following retreatment.

A) Radiograph shows tooth at the center with radiopaque crown and root canals. The tissue is less dense at the center of root and root tips.

B) Radiograph shows porous tissue in the bifurcated root of tooth.

C) Radiograph shows slightly dense tissue at the center of root and root tips.

Single-visit versus multiple-visit treatment

Treatment planning includes considering a multiple or single visit approach. The number of roots, canal anatomy, time available, and the clinician's skills are among the factors to be considered. Severity of the patient's pretreatment symptoms is another important consideration. For example, a patient in severe pain, with or without swelling, is not a prime candidate for single visit endodontics. The initial goal for the patient in severe pain should be directed at alleviating pain, with filling of the canal deferred until the symptoms have been brought under control. The clinician's judgment of what the patient can comfortably tolerate (regarding duration of the visit) is made on a case-by-case basis. The second visit allows the clinician to determine the effect of the initial treatment and then complete instrumentation and filling if the tooth is

Telegram: @dental_k

www.konkur.in

no longer symptomatic.

Numerous studies have compared single and multiple visit cases and reached different conclusions about the outcomes of each approach. For example, some studies have reported less posttreatment pain in single-visit cases,[52,84,104] whereas a systematic review found that the incidence of postobturation discomfort was similar in the single- and multiple-visit approaches.[29] In another systematic review, it was concluded that there was a lack of compelling evidence, indicating a significantly different prevalence of posttreatment pain/flare-up with either single- or multiple-visit root canal treatment.[92] Differences in research methodology explain the conflict in these findings.

Regarding the healing rate of single- and multiple-visit cases, systematic reviews have found that there is no detectable difference in the effectiveness of root canal treatment in terms of radiologic success between single and multiple visits,[29] even in cases of infected teeth.[104]

Teeth with nonvital pulps and apical periodontitis pose a microbiologic problem. It is important to avoid pushing bacterial debris into the periapical tissues. Agreement is lacking concerning the appropriateness of single-visit endodontics for treating these patients. Some have postulated that the intervisit use of an antimicrobial dressing is essential to thoroughly disinfect the root canal system.[99,100,110] In contrast, other researchers have found no statistically significant difference in success when using the single-visit or multiple-visit approach to the nonvital tooth with apical periodontitis.[29,63,77,79,87,91,116]

Differences in research findings concerning single or multiple visits might be due to variations in research methodology, including sample size, duration of follow-up, and treatment methods.

It is possible that total elimination of bacteria may not be absolutely necessary for healing. Perhaps maximal reduction of bacteria, effective root canal filling, and a timely satisfactory coronal restoration can result in a high level of clinical success. However, regardless of the number of appointments, effective bacteriologic disinfection of the root canal system is critical.

Treatment planning for an endodontic case should be based on biologic considerations. Patients who present with acute symptoms present a different set of biologic and clinical issues than those with an asymptomatic tooth.

Telegram: @dental_k

www.konkur.in

Swelling associated with an abscess, cellulitis, or presence of a stoma represent signs of pathologic processes. The biologic significance of these conditions should be considered before determining specific goals for each visit.

Developing goals for each visit helps to organize the treatment. For example, an asymptomatic anatomically uncomplicated anterior, premolar, or molar tooth may be a candidate for a single-visit plan, depending on the skills of the practitioner. However, as the complexity of the case increases and/or symptoms become more severe, a multi-visit approach becomes more appropriate.

These recommendations have a biologic basis. Biologically, it is not reasonable to partially instrument root canal systems, thereby leaving residual inflamed pulpal remnants or necrotic debris in the canal, because such remnants may cause pain and be susceptible to infection. The clinician would be well advised to begin canal instrumentation only if time permits the extirpation of all pulp tissue and complete debridement of the root canal system.

In most cases, the clinical procedures required to complete endodontic treatment can be accomplished in a single visit. However, that does not mean it is the wiser course of treatment. What can be done and what should be done represent two very different approaches to endodontic treatment. The patient's systemic health, level of anxiety, and symptoms, as well as the complexity of the root canal system, and clinician's experience are all factors that must be considered.

A study concerning the outcome of initial endodontic treatment noted the complexity of treating apical periodontitis.[87] The author commented that treatment of this disease cannot be improved merely by changing treatment techniques. Because apical periodontitis results from interactions between microorganisms, their environment, and the host immune system, only the use of effective modifiers of any of these three factors might significantly improve the outcome of treatment.

Surgical endodontics

Surgical evaluation is particularly valuable in the diagnosis of lesions that may be nonodontogenic. Biopsy is the definitive means of diagnosing

Telegram: @dental_k

www.konkur.in

osseous pathosis, which may mimic a lesion of endodontic origin. When retreatment is being considered, the clinician must determine whether nonsurgical, surgical, or combined treatment is appropriate. This decision is influenced by the presence of complex restorations, posts, and the radiographic assessment of prior endodontic therapy.

Endodontic surgery is most often performed in an attempt to improve the apical seal and correct failure of nonsurgical therapy. Bacteria are the essential cause of failure. It is important that the clinician determine the bacterial path of ingress. For example, a deficient restoration or recurrent decay will result in microleakage into the root canal space. Unless that issue is addressed, the outcome of apical surgery may not be predictable (Fig. 5.9).

FIG. 5.9 Four years after endodontic therapy, the patient complained of pain and swelling associated with tooth #6. The initial impression was that apical surgery was indicated. However, further radiographs revealed the true cause of the endodontic failure. The initial endodontic access through the crown or caries damaged the coronal seal and recurrent decay followed.

Set of three radiographs are marked left to right as follows:

Radiograph shows 6th tooth with radiopaque crown and receding gum line. The tissue on one side of tooth is porous.

Second radiograph shows filled root canal of 6th root with slightly dense tissue near the gum line and less-dense tissue at the root tip. Third radiograph shows well-defined radiolucency in the neck region.

When a deficient restoration is identified, it must be replaced to prevent continued bacterial penetration. Endodontic surgery (see Chapter 11) may

Telegram: @dental_k

www.konkur.in

also be performed as a primary procedure when there are complications such as calcific metamorphosis. In those cases, by using surgery as primary therapy, an apical seal can be established while preserving the crown of the tooth. The treatment plan for these cases is determined after reviewing multiple radiographs and considering the possibility of completing nonsurgical therapy without destroying an otherwise functional crown or natural tooth. Endodontic surgery without prior nonsurgical therapy should be considered a treatment of last resort and only when nonsurgical treatment is not possible.

Reviewing the best available evidence for alternative treatments is an important aspect of treatment planning for a tooth with failed endodontics. Evidence concerning the healing potential after endodontic surgery is an important consideration in the management of posttreatment disease.[86] Numerous studies have examined the outcome of apical surgery and the results vary considerably.[111,114,121] This variability may reflect actual outcome differences or reflect variations in case selection techniques, recall periods, and methodology.

A prospective study indicated that there is an increased odds ratio for disease persistence for teeth with larger pretreatment lesions and pretreatment root canal filling of adequate length.[114] Another study found that patients presenting with pain at the initial examination before surgery had a significantly lower rate of healing at the 1-year follow-up compared with patients who did not have pain at the initial examination.[111]

It should also be noted that the periodontal condition of the tooth, including the interproximal bone levels and the amount of marginal bone loss, has been shown to significantly affect the long-term prognosis of periapical surgery.[112,115] Moreover, it has been shown that isolated endodontic lesions have much higher success rates at the 1- to 5-year follow-up (95.2%) in comparison with endodontic-periodontal combined lesions (77.5%).[46]

Dramatic changes in surgical technique and materials have occurred. The advent of microscopy, endoscopy, and ultrasonics, as well as improved retrograde filling materials, represents important modifications of surgical technique. An outcome study comparing traditional root-end surgery (TRS) and endodontic microsurgery (EMS) found that the probability of success for

Telegram: @dental_k

www.konkur.in

EMS was 1.58 times greater than the probability of success for TRS.[97] Another study comparing the EMS techniques with and without the use of higher magnification found that the difference of probability of success between the groups was statistically significant for molars, but no significant difference was found for the premolar or anterior teeth.[96] CBCT has proved to be of value in some surgical cases, producing three-dimensional images of a tooth, pathosis, and adjacent anatomic structures. It is beneficial for localizing the mandibular canal,[48] mental foramen, maxillary sinus, and nasal cavity.[18]

Intentional replantation

Intentional replantation is a procedure that has long been thought of as a measure of last resort and rarely considered during treatment planning. Its increasing popularity may be based on evidence indicating that its success rate, when specific guidelines are followed, may approach that of other endodontic procedures and dental implants. When compared to dental implants, the procedure offers a more cost-effective and timely means of maintaining a tooth that would otherwise be lost. In terms of patient-centered outcomes, replantation should be considered prior to extraction of previously endodontically treated teeth. While non-surgical or surgical endodontic treatment remains the preferred treatment for most patients, evidence is building supporting the concept that replantation of a tooth is a valuable option for some patients. It should be noted that in those cases, where replantation is not successful, a dental implant remains an option.

In 2017, a systematic review compared the survival of teeth intentionally replanted, using a modern technique and cost effectiveness, compared with single-tooth implants. Six studies met the inclusion criteria. Meta-analysis resulted in a survival rate of 89.1%. Compared with a single- tooth implant, intentional replantation was more cost-effective, even when custom post/core and crown were also needed. The authors concluded that based on the meta-analysis, there was a high survival rate for intentional replantation. Although the survival rate for implants was higher, intentional implantation is a more cost-effective treatment modality. The authors concluded that, “When nonsurgical and surgical retreatments of a tooth are not feasible or have a poor prognosis, intentional replantation with a modern technique is a reliable

Telegram: @dental_k

www.konkur.in

and cost-effective method of treating teeth. The option of intentional replantation should be discussed with patients as an alternative to extraction and implant placement."[53] (For further information please visit Chapter 11.)

Regenerative endodontics

Regenerative endodontics is a developing area in the treatment of immature teeth with infected root canals that has been described as a "paradigm shift"[22] in the management of these teeth and may result in continued root maturation and apical closure. Traditional approaches using calcium hydroxide for apexification and apical barrier techniques using mineral trioxide aggregate (MTA) have been used in the treatment of immature teeth with pulp necrosis. When using that technique, there is usually no further root development. The roots remain thin and fragile with a high risk of fracture and tooth loss.[81] It has been suggested that regenerative endodontic procedures (REPs) that utilize endogenous stem cells that are introduced in the canal by lacerating the periapical tissues to fill the canal with blood should be used for the treatment of immature teeth with pulp necrosis. Regenerative endodontics has been defined as "biologically based procedures designed to replace damaged structures, including dentin and root structures, as well as cells of the pulp-dentin complex."[22] The AAE recently updated the developed clinical considerations for regenerative procedures; this can be found on the AAE website (https://www.aae.org/specialty/wp-content/uploads/sites/2/2018/06/ConsiderationsForRegEndo_AsOfApril2018.
Most studies that have compared REPs with the traditional approaches of calcium hydroxide apexification and MTA apical barrier techniques have shown comparable outcomes.[3,44] However, a study that compared traditional and regenerative treatment protocols showed revascularization was associated with significantly greater increases in root length and thickness compared with calcium hydroxide apexification and MTA barrier placement as well as higher overall survival rates.[40]

There are several factors that must be taken into consideration when planning REP treatment for a tooth, such as: (a) remaining tooth structure, (b) tooth location, (c) level of tooth maturity, (d) number of visits, and (e) patient's compliance.

It must be noted that although REP is becoming more common, the

Telegram: @dental_k

www.konkur.in

traditional apexification techniques still have their own place in the treatment planning process for a premature tooth. For instance, the amount of remaining crown structure is one of the factors to be considered. Placing a post after a REP is usually difficult; therefore, if the tooth has lost most of its crown structure and may need a post in the future, other treatment modalities such as traditional $Ca(OH)_2$ or MTA plug apexification should be considered. Another factor to consider in the treatment planning stage is the location of the tooth. New materials are being introduced on a frequent basis, and each one may or may not be a suitable choice for all teeth. It is of utmost importance for the clinician to refer to the highest level of scientific evidence in treatment planning such cases. For example, MTA is the most common material used in REP; however, one of the common complications with MTA is tooth discoloration, which is a serious esthetic concern with anterior teeth. In these teeth, other materials, such as Biodentine, may be favored.[7] With regards to apical maturity, REP is mostly considered for immature teeth, since this area is rapidly developing, it is important for the clinician to have a broad knowledge on the protocols and biomaterials.

Tooth maturity is another factor to consider. Although it has been suggested that less mature teeth are more suitable for regenerative endodontics,[47] there have been reports of using REP in treating teeth with necrotic pulps and apical periodontitis.[106] Therefore, it is of utmost importance that the clinician discuss all treatment options prior to suggesting the definitive treatment.

The number of visits and patient's compliance are other critical elements in treatment planning for premature teeth. According to the AAE clinical protocol (mentioned earlier), RET usually requires two treatment and few follow-up visits; however, $Ca(OH)_2$ calcification requires multiple observation visits prior to definitive treatment session. It is important to discuss the number of sessions and their frequency with the patient or the parent/guardian in terms of patient's availability and compliance. Patients with fewer complaints may be more suitable for less technique-sensitive treatments or ones with fewer required number of sessions. (For more information refer to Chapter 12.)

www.konkur.in

Interdisciplinary treatment planning

Periodontal considerations

Complex cases may require a multidimensional approach. For example, extensive periodontal lesions may complicate the prognosis of endodontic treatment. A periodontist and an endodontist might be able to add their insights to the prognosis of treatment and avoid future problems.

A 4-year retrospective study found that attachment loss and periodontal status affected endodontic prognosis of endodontically treated molars.[95] It is crucial that the dental practitioner be aware of the periodontal factors that may influence the prognosis of endodontic treatment, such as root perforations, bone loss, and clinical attachment loss.

When establishing the prognosis of a tooth with an endodontic/periodontal lesion, there are essential factors to be considered. Determination of pulp vitality and the extent of the periodontal defect are central to establishing the prognosis and developing a treatment plan for a tooth with an endodontic/periodontal lesion (see also Chapter 25).

In primary endodontic disease, the pulp is nonvital, whereas in primary periodontal disease, the pulp retains vitality. True combined endodontic-periodontal disease occurs less frequently. The combined lesion is found when the endodontic disease process advances coronally and joins with a periodontal pocket progressing apically. There is significant attachment loss with this type of lesion, and the prognosis is questionable.[85] The radiographic appearance of combined endodontic-periodontal lesions may be similar to that of a vertically fractured tooth. Therapy for true combined lesions requires both endodontic and periodontal therapy. Sequencing of treatment is based on addressing the initial chief complaint.

The prognosis and treatment of each type of endodontic-periodontal disease vary. Primary endodontic disease should be treated solely by endodontic therapy, and the prognosis is usually good (Figs. 5.10 and 5.11). Primary periodontal disease should be treated only by periodontal therapy, and the prognosis varies depending on the severity of the disease and patient's response to treatment.[85]

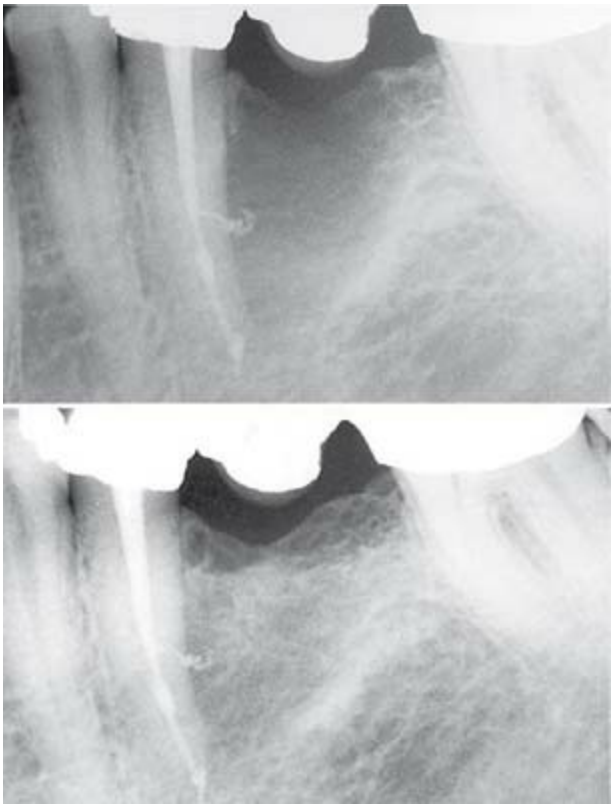

FIG. 5.11 A large, bony defect associated with tooth #20 healed after endodontic therapy. The tooth was nonvital, and no significant periodontal probing depth indicated pulpal disease.

Radiograph on the top shows well-defined radiolucency with receding gum line adjacent to tooth. Radiograph at the bottom shows dense tissue in place of the radiolucency.

Pathogenesis of the lesion can be better understood after sensibility testing, periodontal probing, radiographic assessment, and evaluation of dental history. When extensive prostheses are planned, the potential risk of including a tooth with a questionable prognosis must be considered. It is not prudent to incorporate a chronic problem into a new complex prosthesis (Fig. 5.12).

Telegram: @dental_k

www.konkur.in

FIG. 5.12 Tooth #30 has a poor prognosis. Periodontal probing reached the apex of the distal root. Extraction is indicated and should be done as soon as possible to prevent further damage to the mesial bone associated with tooth #31. Implant site preservation is another consideration in treatment planning for this case.

Radiograph shows the central tooth with radiopaque crown and a perforated dark patch along the one side of root.

Restorative and prosthodontic considerations

A satisfactory restoration may be jeopardized by a number of factors. Subosseous root caries (perhaps requiring crown lengthening), poor crown-to-root ratio, and extensive periodontal defects or misalignment of teeth may have serious effects on the final restoration. These problems must be recognized before endodontic treatment is initiated. For complex cases, a restorative treatment plan should be in place before initiating endodontic treatment (see Chapter 23). Some teeth may be endodontically treatable but nonrestorable, or they may represent a potential restorative complication because of a large prosthesis. Reduced coronal tooth structure under a full-coverage restoration makes endodontic access more difficult because of reduced visibility and lack of radiographic information about the anatomy of the chamber. It is not unusual for restorations to be compromised during endodontic access (see Fig. 5.12). Whenever possible, restorations should be

Telegram: @dental_k

www.konkur.in

removed before endodontic treatment.

Full coverage restorations are usually suggested after endodontic treatment. In a systematic review on tooth survival following nonsurgical root canal treatment, four factors were found to be of significance in tooth survival[70]:

- A crown restoration after root canal treatment.
- Tooth having both mesial and distal proximal contacts.
- Tooth not functioning as an abutment for removable or fixed prosthesis.
- Tooth type or specifically nonmolar teeth.

Another systematic review found that the odds for healing of apical periodontitis increase with both adequate root canal treatment and adequate restorative treatment. However, poorer clinical outcomes may be expected with adequate root filling/inadequate coronal restoration and inadequate root filling/adequate coronal restoration, with no significant difference in the odds of healing between these two combinations.[34] These findings suggest that the quality of the coronal restoration is as important as the quality of the root canal treatment. Therefore, to increase the success of the treatment, it is strongly suggested that the clinician discuss the restorative plan of the tooth with both the patient and—if it is a referred patient—with the referring dentists before initiation of treatment.

Endodontic therapy or dental implant

The successful evolution of dental implants as a predictable replacement for missing teeth has had a positive impact on patient care. A clinician now has an additional possibility to consider when developing a treatment plan for a patient with a missing tooth or teeth. More challenging is the decision concerning whether or not to provide endodontic therapy for a tooth with a questionable prognosis or extract and use a single-tooth implant as a replacement or attempt replantation. Numerous studies have evaluated both the nonsurgical endodontic therapy[20,71,72,88,89,107] and endosseous dental implants.[1,19,38]

It is not possible to compare outcome studies because of variations in

Telegram: @dental_k

www.konkur.in

research methodologies, follow-up periods, and criteria associated with determining success or failure. A review of outcome studies points to the need for randomized controlled trials with standardized or similar methodologies that could provide a higher level of evidence to use in answering important clinical prognostic questions.

A synthesis of available evidence indicates that both primary root canal treatment and single-tooth implants are highly predictable procedures when treatment is appropriately planned and implemented. A study assessed clinical and radiographic success of initial endodontic therapy of 510 teeth over a 4- to 6-year period. It was found that 86% of teeth healed and 95% remained asymptomatic and functional.[20] Another study considered the outcomes of endodontic treatment on 1,462,936 teeth. More than 97% of teeth were retained after 8 years.[88] In a similar study, it was found that overall, 89% of the 4744 teeth were retained in the oral cavity 5 years after the endodontic retreatment.[89] A study concerning the outcome of endodontic therapy on 1312 patients in general practice with a mean follow-up time of 3.9 years found a combined failure rate of 19.1%, concluding that "failure rates for endodontic therapy are higher than previously reported in general practices, according to results of studies based on dental insurance claims data."[9]

The ADA's Council on Scientific Affairs has reported high survival rates for endosseous implants. An evaluation of 10 studies with more than 1400 implants demonstrated survival rates ranging from 94.4% to 99% with a mean survival rate of 96.7%.[1] In a recent systematic review, the authors claimed that with the mean range of 13.4 years follow-up, the survival rate of dental implants were 94.6% and the success rate for half of the cases, which used the same criterion with a mean period of follow-up of 15.7 years, was 89.7%, but a statistical analysis was not performed due to heterogenicity.[108] With such relatively high survival rates reported for endodontics and single-tooth implants, a clinician must consider a multiplicity of factors within the context of the best available evidence.

In a retrospective cross-sectional comparison of initial nonsurgical endodontic treatment and single-tooth implants, it was suggested that restored endodontically treated teeth and single-tooth implant restorations have similar survival rates, although the implant group showed a longer average and

Telegram: @dental_k

www.konkur.in

median time to obtain function and a higher incidence of posttreatment complications requiring subsequent treatment intervention.[24] Aside from success, the clinician must also consider the success rate of dental implants, which is usually significantly lower than success rates. The term "success" usually involves more complex parameters and criteria and is associated with the health and quality of the implants.[108] Any treatment intervention due to postoperative complications will affect the success of the implant without directly affecting its survival. In a study on long-term survival and success of dental implants, the authors found that "The cumulative complication rate after an observation period of 10 to 16 years was 48.03%, which meant that substantial amounts of chair time were necessary following implant placement."[98] In a recent study of patients who have received both nonsurgical root canal treatment and single-tooth implants, it was concluded that "the number of adjunct and additional treatments, the number of appointments, the elapsed time before the final restoration, the number of prescribed medications, and the cost of the treatment were significantly higher for single tooth implants in comparison with non-surgical root canal treatment."[109]

A review summarized the best available evidence concerning factors influencing treatment planning involving preservation of a tooth with endodontic therapy or replacement by a single-tooth implant. Factors considered included prosthetic restorability of the natural tooth, quality of bone, aesthetic concerns, cost-to-benefit ratio, systemic factors, potential for adverse effects, and patient preferences.[38] The authors concluded that "endodontic treatment of teeth represents a feasible, practical and economical way to preserve function in a vast array of cases and that dental implants serve as a good alternative in selected indications in which prognosis is poor."[38]

Aside from treatment outcome, number of sessions, duration of the treatment, and additional adjunct treatments, there are other factors involved in any treatment that the practitioner has to consider when making a treatment planning decision. In a study evaluating the quality of life of endodontically treated versus implant treated patients, the results showed a high rate of satisfaction with both treatment modalities.[31] One study found that when compared to endodontic molar retreatment and fixed partial dentures,

Telegram: @dental_k

www.konkur.in

implant-supported restoration, despite its high survival rate, has been shown to be the least cost-effective treatment option.[48] Another study found that "endodontically treated natural teeth may provide more effective occlusal contact during masticatory function compared with implant-supported restorations, leading to more efficient mastication."[117]

Another important factor is the patient's health status. Implants require a surgical procedure that may not be possible due to the patient's medical status. One area of concern is diabetes mellitus. However, it has been shown that dental implant osseointegration can be accomplished in these subjects, as long as they have good glycemic control.[39]

It seems clear that patients are best served by retaining their natural dentition as long as the prognosis for long-term retention is positive. It is not reasonable to extract a tooth if endodontics with a good prognosis can be completed. It is also not reasonable for a patient to invest in root canal therapy, a post, and a crown if the prognosis is highly questionable and an implant with a good prognosis can be placed. An important advantage of providing endodontic therapy is to allow rapid return of the patient's compromised dentition to full function and aesthetics. This rapid return is in marked contrast to the use of provisional restorations associated with dental implants while waiting for osseous integration. The challenge is to weigh all pretreatment variables and reach a reasonable conclusion concerning the prognosis for tooth retention or implant placement.

Interestingly, some endodontic advanced education programs are now including implant training in their curricula. This training will enable the endodontist to provide more value to the patient and referring the dental clinician as treatment plans are determined. Such dually trained endodontists will be well positioned to provide endodontic therapy or place an implant as best serves the patient.

Finally, the AAE Position Statement on Implants referring to the Ethics of Clinical Practice states: "Inappropriate treatment, such as: performing endodontic therapy on nonrestorable or periodontally hopeless teeth; or placing single-tooth implants when the natural tooth could predictably be retained, would also be considered unethical. Failure to adhere to these principles not only violates the trust placed in the dental profession, but leaves the dentist vulnerable to litigation" (see

Telegram: @dental_k

www.konkur.in

https://www.aae.org/specialty/wp-content/uploads/sites/2/2017/06/implantsstatement.pdf).

Other factors that may influence endodontic case selection

A variety of factors may complicate proposed endodontic therapy. Calcifications, dilacerations, or resorptive defects may compromise endodontic treatment of a tooth with potentially strategic value (Fig. 5.13).

FIG. 5.13 Resorptive defects can be successfully treated. Early intervention, before there is perforation of the root, increases the chance of success.

Radiograph on the left shows three teeth where the central tooth has radiolucency at the center of root with a porous tissue at the root apex. Radiograph on the right shows radiopaque root canal of the central tooth with slightly dense tissue at the root apex.

Source: (Courtesy Dr. Leon Schertzer.)

Diagnosis and treatment of resorptive defects may be challenging at times. Distinguishing external resorption from internal resorption is usually possible with routine radiographs using different angles; but in order to detect the

Telegram: @dental_k

www.konkur.in

exact location and extension of certain types of resorption, especially external cervical resorption (ECR), the use of the CBCT is paramount for treatment planning purposes.[28,76] Resorptive lesions are usually asymptomatic, and therefore, are often found accidentally when reviewing radiographs. As a result, in many cases, when the lesion is visible on a radiograph, a large portion of the tooth is already affected, making the treatment extremely difficult, if not impossible. In addition, when one tooth in a patient is affected, it is possible that other teeth may also be affected in the same dentition,[33] making the use of CBCT more justified in these cases (Fig. 5.14). Treatment of these lesions usually includes a combination of nonsurgical and surgical endodontic techniques (such as osteotomy and root repair, with or without intentional replantation) (for more information see Chapter 18).

www.konkur.in

D) Close-up view shows central tooth with oval-shaped light patch and a lesion below the root.

E) Close-up view shows tooth with filling at the root.

F) Radiograph shows tooth with filled root canal and filled dental tissue.

The inability to isolate a tooth is also a problem and may result in bacterial contamination of the root canal system. Extra roots and canals pose a particular anatomic challenge that radiographs do not always reveal (Fig. 5.15). A bitewing radiograph is useful in providing an accurate image of the pulp chambers of posterior teeth.

FIG. 5.15 The presence of curved roots and multiple canals is a complicating factor.

Radiograph on the top shows tooth with radiolucency in the dentine below radiopaque enamel and in-between bifurcated root. Radiograph at the bottom shows the same tooth with filled root canals with minor radiolucency at the

Telegram: @dental_k

www.konkur.in

The clinician should recognize these potential problems and be able to manage and factor them into the decision concerning the tooth's prognosis, including the possibility that the patient should be referred to a specialist.

As mentioned, CBCT is a tool that when used judicially can be helpful in identifying roots that are not visible with conventional radiography. For more information on clinical applications of CBCT, refer to the 2015/2016 AAE and American Academy of Oral and Maxillofacial Radiology (AAOMR) Joint Position Statement (available at https://www.aae.org/specialty/wp-content/uploads/sites/2/2017/06/conebeamstatement.pdf). The statement provides 11 specific recommendations and supporting evidence for when CBCT should be considered, and emphasizes that CBCT should not be routinely used for endodontic diagnosis or screening in the absence of clinical symptoms. Consistent with the principles of ALARA—keeping patient radiation doses "As Low as Reasonably Achievable"—the statement notes that the patient's history and clinical examination must justify the use of CBCT. (Refer to https://f3f142zs0k2w1kg84k5p9i1o-wpengine.netdna-ssl.com/specialty/wp-content/uploads/sites/2/2017/06/conebeamstatement.pdf.)

The revised position statement concludes with the following advisory: "CBCT is an emerging technology that is revolutionizing the approach to endodontic care of dental patients. The guidance in this statement is not intended to substitute for a clinician's independent judgment in patient care. The use of limited field of view (FOV) CBCT should be considered on a case-by-case basis, with due consideration given to the risks and benefits of exposing the patient to ionizing radiation, the patient's history, clinical findings and pre- existing radiographs so that superior treatment can be provided to the general public in need of endodontic care."

Another consideration is the stage of maturity of the tooth. Primary and immature permanent teeth may have a pulpal pathosis caused by caries or trauma; preserving these young teeth is essential. Premature loss of an anterior tooth can lead to malocclusion, predispose the patient to tongue habits, impair aesthetics, and damage the patient's self-esteem. (See Chapter 21 on dental traumatic injuries.)

Some clinicians use a simple formula for determining which endodontic

Telegram: @dental_k

www.konkur.in

cases they treat and which they refer to a specialist. The number of roots may be the determining factor in a decision concerning referral, or the key factor may be the chronic or acute status of the case. Others consider the complexity of the ultimate prosthesis as a factor in considering an endodontic referral. The most important variables in determining whether to refer a patient to a specialist are the skills of the clinician and the complexity of the case. The AAE developed guidelines for assessing endodontic case difficulty (available at https://www.aae.org/specialty/wp-content/uploads/sites/2/2017/10/2006casedifficultyassessmentformb_edited20 The AAE Endodontic Case Difficulty Assessment Form enables a clinician to assign a level of difficulty to a particular case. The form describes cases with minimal, moderate, and high degrees of difficulty. This form lists criteria that can be used to identify cases that should be referred to a specialist. The use of surgical operating microscopes, endoscopes, and ultrasonics enables the specialist to predictably treat teeth that would not previously have been treatable.

Anxiety

Anxiety presents a problem at many levels of dental care. Avoidance of dental treatment due to anxiety appears to be associated with significant deterioration of oral and dental health.[120] Even at the diagnostic stage, severe anxiety may confuse the process.[25] Several studies support the hypothesis that pain or fear of pain is a primary source of anxiety as well as an obstacle to seeking dental care.[50,120] Also, highly anxious patients appear to be more sensitive to pain.[26,49] High levels of anxiety have been found to negatively affect clinical procedures including local anesthesia.[64] In 2009, Binkley tested the hypothesis that having natural red hair color, which is caused by variants of the melanocortin-1 receptor *(MC1R)* gene, could predict a patient's experiencing dental care–related anxiety and dental care avoidance.[10] She found that participants with *MC1R* gene variants reported significantly more dental care–related anxiety and fear of dental pain than did participants with no *MC1R* gene variants. A more recent study confirmed the relationship between the red hair phenotype and anxiety. However, this study found no association between the red hair phenotype and the success of local anesthesia.[23]

Telegram: @dental_k

www.konkur.in

It has been demonstrated that dental anxiety and expectation of pain had a profound effect on a patient's ability to understand information provided.[27] A person's cognitive ability to process information is significantly affected by stress.[27] A study found that 40% of patients who had minor oral surgery did not remember receiving both written and verbal instructions, contributing to 67% noncompliance with antibiotic prescriptions.[11] Patients' anxiety can compromise their understanding of complex treatment plans. Decisions made by a patient concerning options involving tooth retention or loss may be markedly affected by anxiety. In the field of medicine, there strong evidence to show that behavioral intervention for the highly anxious patient before treatment decreases anxiety before and after surgery, reduces posttreatment pain, and accelerates recovery.[45]

Unfortunately, the impact that a high level of anxiety can have on patient's cognition, local anesthesia, and intraoperative and postoperative experiences is not always recognized. A landmark medical study found that pretreatment discussion of surgical treatments and associated discomfort reduced by 50% the need for posttreatment morphine and reduced the time to discharge.[24] Existing research has focused primarily on the effect of pretreatment information on reducing anxiety and stress during surgery.[27]

Calm setting, reassurance by the clinician and explanation of the treatment plan, as well as a discussion about pain prevention strategies are all important steps even before treatment starts.[65] A written description as well as a verbal description of the proposed treatment are helpful. It may also be of value to have a family member or friend accompany the patient for a discussion of the treatment plan.

Scheduling considerations

If a vital case is to be treated by a multivisit approach, it is suggested that the clinician allow 5 to 7 days between canal instrumentation and obturation to allow periradicular tissues to recover. When a vital case is to be treated in a single visit, adequate time must be scheduled so that the clinician can comfortably complete the procedure. Because profound inferior alveolar nerve block anesthesia may require approximately 15 to 20 minutes, it is wise to include that time when scheduling a patient's appointment (see also Chapter 6 on pain control and local anesthesia).

Telegram: @dental_k

www.konkur.in

Appointments to fill nonvital cases should be scheduled approximately 1 week after instrumentation to maximize the antimicrobial effect of the intracanal dressing when calcium hydroxide is used.[2,99,100] Acute (pain or swelling) nonvital cases should be seen every 24 to 48 hours to monitor the patient's progress and bring the acute symptoms under control. Further cleaning and shaping are important components of the treatment as the clinician seeks to eliminate persistent microbes in the canal system. Long delays between visits contribute to the development of resistant microbial strains and should be avoided.

Local anesthesia

Effective local anesthesia is the foundation of pain control in dentistry and especially endodontics. Regardless of the clinician's skills, both treatment and patient management are difficult or impossible to deliver without effective pain control. This chapter reviews the pharmacology of local anesthetics and the relative advantages and limitations of various anesthetics and routes of administration. Other chapters in this book provide complementary information on the use of local anesthetics in diagnosis (see Chapter 1) and the treatment of emergency patients (see Chapter 19). The authors assume that the reader is familiar with various anesthetic injection techniques; several excellent texts are available for review regarding this topic.[165,213,277]

Mechanisms of action for anesthetics

Most dental pharmacology courses teach that local anesthetics block sodium channels by partitioning into two types: the uncharged basic form of the molecule (RN), which crosses cell membranes, and the charged acid form of the molecule (RNH^+), which binds to the inner pore of the sodium channel. As a first approximation, this model is reasonably accurate. However, molecular research has demonstrated the existence of at least nine subtypes of voltage-gated sodium channels (VGSCs) that differ in their expression pattern, biophysical properties, and roles in mediating peripheral pain (Table 6.1). These channels have a clear clinical relevance.[30,146,198] Indeed, several groups of patients have been described with genetic mutations to a VGSC, with significant reported effects on pain sensitivity.

Table 6.1

Voltage-Gated Sodium Channels and Pain

Telegram: @dental_k

www.konkur.in

Channel Subtype	Tissue Expression	Tetrodotoxin Sensitive	Peripheral Role in Pain
Na_v 1.1	Central nervous system (CNS), sensory neurons	Yes	?
Na_v 1.2	CNS	Yes	No
Na_v 1.3	CNS	Yes	No
Na_v 1.4	Muscle	Yes	No
Na_v 1.5	Heart	Somewhat	No
Na_v 1.6	CNS, sensory neurons	Yes	?
Na_v 1.7	CNS, sensory neurons	Yes	?
Na_v 1.8	Sensory neurons	No	Yes
Na_v 1.9	Sensory neurons	No	Yes

The broad class of VGSCs can be divided into channels that are blocked by a toxin (tetrodotoxin [TTX]) and those that are resistant to the toxin (TTX-R). Most TTX-R channels are found primarily on nociceptors (e.g., Na_v 1.8 and Na_v 1.9).[349] These channels also are relatively resistant to local anesthetics and are sensitized by prostaglandins (PGs).[127] As explained later in this chapter, the presence of TTX-R sodium channels may explain why local anesthetics are less effective when they are administered to patients with odontalgia. Many of the adverse effects of local anesthetics are attributed to their ability to block other VGSCs expressed in the central nervous system (CNS) or heart (see Table 6.1).

VGSCs consist of an alpha and a beta subunit. The alpha subunit serves as a voltage sensor, leading to channel activation and sodium ion passage when the channel detects an electrical field. The biologic basis for an electric pulp tester (EPT), therefore, is the generation of a small electrical field across the dental pulp that can activate VGSCs.[146] Interestingly, sensitization of TTX-R channels by PGs lowers the activation threshold and increases the number of sodium ions that flow through the channel.[129] Put another way, an inflammation-induced elevation in PG levels sensitizes TTX-R channels, leading to greater activation with weaker stimuli. This may explain the increased responsiveness to electrical pulp testing seen in patients with irreversible pulpitis.

Local anesthetics have other mechanisms that may contribute to their pharmacology for treating odontogenic pain. For example, local anesthetics modulate certain G protein–coupled receptors (GPCRs). The GPCRs are a major class of cell membrane receptors, and many classes of dental drugs

Telegram: @dental_k

www.konkur.in

(e.g., opioids, catecholamines) and endogenous mediators produce their effects by activating specific GPCRs and their related second messenger pathways. Studies suggest that local anesthetics inhibit the G-alpha-q (Gaq) class of GPCRs, which includes receptors activated by inflammatory mediators such as bradykinin.[157] A local anesthetic may therefore block the actions of a major hyperalgesic agent.

Other studies have indicated that local anesthetics potentiate the actions of the G-alpha-i (Gai) class of GPCRs.[22] This could have a major effect in potentiating the actions of vasoconstrictors, including the newly recognized analgesic role that vasoconstrictors play in inhibiting pulpal nociceptors.[33,145] Prolonged alteration of GPCR function might explain why analgesia obtained with long-acting local anesthetics persists well beyond the period of anesthesia.[72,91,237] More research is needed on this exciting aspect of local anesthetic pharmacology.

Clinically available local anesthetics

The most common forms of injectable local anesthetics are in the amide class. In 2003, the American Dental Association specified a uniform color code for dental cartridges to prevent confusion among brands (Table 6.2). Local anesthetics can be divided roughly into three types: short duration (30 minutes of pulpal anesthesia), intermediate duration (60 minutes of pulpal anesthesia), and long duration (over 90 minutes of pulpal anesthesia). However, clinical anesthesia does not always follow these guidelines, as it depends on whether the local anesthetic is used as a block or for infiltration. For example, bupivacaine is classified as a long-acting agent; when it is used in an inferior alveolar nerve (IAN) block, this is true.[98] However, when it is used for infiltration for anterior teeth, it has a shorter duration of anesthetic action than 2% lidocaine with 1:100,000 epinephrine[74,134] (this is discussed in more detail later in this chapter).

Table 6.2

Local Anesthetics Available in the United States*

Anesthetic	Vasoconstrictor	Dental Cartridge Color Codes†	Maximum Allowable Dose	Typical Maximum Dose
2% Lidocaine	1:100,000 epinephrine	Red	13	8
2% Lidocaine	1:50,000 epinephrine	Green	13	8
2% Lidocaine	Plain (no vasoconstrictor)	Light blue	8	8
2% Mepivacaine	1:20,000 levonordefrin	Brown	11	8
3% Mepivacaine	Plain (no vasoconstrictor)	Tan	7	5½
4% Prilocaine	1:200,000 epinephrine	Yellow	5½	5½
4% Prilocaine	Plain (no vasoconstrictor)	Black	5½	5½
0.5% Bupivacaine	1:200,00 epinephrine	Blue	10	10
4% Articaine	1:100,000 epinephrine	Gold	7	7
4% Articaine	1:200,000 epinephrine	Silver	7	7

*This table provides the maximum dosage in two formats. The maximum allowable dose is generally approached only with complex oral and maxillofacial surgical procedures. The typical maximum dose is the usual outer envelope of drug dosage for most endodontic, surgical, and restorative dental procedures. Both columns show the number of cartridges that would be required for an adult weighing 67.5 kg (150 pounds).

†Uniform dental cartridge color codes were mandated by the American Dental Association in June 2003.

Selection of a local anesthetic: Possible adverse effects and medical history

Possible adverse effects

Possible adverse reactions to local anesthetics can be divided into six major categories: cardiovascular reactions, systemic effects, methemoglobinemia, peripheral nerve paresthesia, allergic reactions to the anesthetic and/or latex, and reactions to anesthetics containing a sulfite antioxidant. These reactions range from fairly common (e.g., tachycardia after intraosseous [IO] injection of 2% lidocaine with 1:100,000 epinephrine) to extremely rare (e.g., allergic reactions to lidocaine).

Cardiovascular reactions

Although classic research studies have reported that large dosages or intravenous injections of local anesthetics were required to produce cardiovascular effects,[163,336] it now is well recognized that even comparatively small amounts of epinephrine can induce measurable

Telegram: @dental_k

www.konkur.in

tachycardia after nerve block or IO injection.[99,129,282] Several authors have reported increases in heart rate with infiltration injections and nerve blocks using 2% lidocaine with 1:100,000 epinephrine[2,149,195,298,335]; others have reported that no significant changes in heart rate occurred or that the changes were clinically insignificant.[228,330,338] When specific information was given on dosing and heart rate increases, several studies found mean heart rate increases.[2,149,194,335] Two studies found increases on average of about 4 beats/min with approximately 20 µg of epinephrine[149,194]; three studies recorded increases of 10 to 15 beats/min with 45 to 80 µg of epinephrine[2,194,298]; and one study found increases of approximately 21 beats/min using 144 µg.[335] Increasing the amount of epinephrine in an infiltration or block injection, therefore, increases the likelihood of an elevated heart rate.

Tachycardia after injection is primarily a pharmacologic effect. The cardiovascular effects are the result of alpha-adrenoceptor stimulation by systemic distribution of the vasoconstrictor throughout the vascular compartment. The patient may also report heart palpitations associated with anxiety or fear and may experience transient tachycardia and changes in blood pressure. Large doses or inadvertent intravenous injection may lead to lidocaine toxicity and CNS depression.[100,244] To reduce this risk, the clinician should always aspirate before making the injection, inject slowly, and use dosages within accepted guidelines. The maximal dosages for local anesthetics are listed in Table 6.2.

Systemic effects

Acute toxicity from an overdose of a local anesthetic is often the result of inadvertent intravenous administration or of a cumulative large dose (e.g., repeated injections). As shown in Table 6.1, VGSCs are found in the CNS and the myocardium, the two major sites of anesthetic-induced toxicity. Although systemic effects from a local anesthetic are rare, they can include an initial excitatory phase (e.g., muscle twitching, tremors, grand mal convulsions) and a subsequent depressive phase (e.g., sedation, hypotension, and respiratory arrest).[78,100] It should be noted that symptomatic management (possibly including cardiopulmonary resuscitation [CPR], airway support, and supplemental oxygen) is the primary response to this adverse

Telegram: @dental_k

www.konkur.in

event.[191,193] An acute hypotensive crisis with respiratory failure has also been interpreted as the result of hypersensitivity to local anesthetics[55]; these patients should be evaluated with allergy testing. To reduce the risk of systemic effects from anesthetics, the clinician must always aspirate before giving the injection and must use dosages within accepted guidelines (see Table 6.2). Finder and Moore[100] proposed a "rule of 25" as a simple means of remembering maximal local anesthetic dosages: with currently formulated local anesthetic cartridges, it is generally safe to use one cartridge of local anesthetic for every 25 pounds of patient weight (e.g., six cartridges for a patient weighing 150 pounds [67.5 kg]).

Methemoglobinemia

The metabolism of certain local anesthetics (e.g., prilocaine, benzocaine, articaine, and to a lesser extent lidocaine) can produce a metabolite that causes methemoglobinemia; this effect often occurs several hours after injection of the local anesthetic.[214,354] Typical signs and symptoms include cyanosis, dyspnea, emesis, and headache. In a study on benzocaine-induced methemoglobinemia, 67% of reported adverse effects with benzocaine were associated with methemoglobinemia; of these events, 93% occurred with spray formulations and only one case involved the gel formulation.[239] To reduce the risk of methemoglobinemia, clinicians should take care to refrain from giving excessive dosages of local anesthetics.

Peripheral nerve paresthesia

Postinjection paresthesia is a rare adverse effect of local anesthetics.[136,214,365] The incidence of paresthesia (which involved the lip and/or tongue) associated with articaine and prilocaine was higher than that found with either lidocaine or mepivacaine.[114,121,136] Another study evaluated patients referred with a diagnosis of damage to the inferior alveolar and/or lingual nerve that could only have resulted from an IAN block; it was found that 35% were caused by lidocaine and 30% by articaine.[272] The conclusion was that there was not a disproportionate involvement from articaine, although this interpretation does not account for large differences in clinical use of the two solutions. This same author published a paper on IAN block involvement with the following proportions: 25% lidocaine, 33% articaine, and 34%

Telegram: @dental_k

www.konkur.in

prilocaine.[271] Another investigative group also noted more occurrences of paresthesia with articaine and prilocaine.[269] Paresthesia can be caused by any anesthetic agent. Since paresthesia is noted in the literature to be higher with articaine and because articaine does not have higher pulpal anesthetic success rates when given as an IAN block, articaine use may be best reserved for infiltrations. With any alteration in nerve sensation, documentation of the area of altered sensation (patient reported and clinically tested), the type of altered sensation (e.g., anesthesia, paresthesia, dysesthesia), and regular follow-up are important.[371]

Allergic reactions

The amide local anesthetics appear to have little immunogenicity and therefore have an extremely low rate of true allergic reactions,[20,244,303,292] but case reports of hypersensitivity reactions after the administration of local anesthetics have been published.[32,55,141,240,303,310,318] Referral for allergy testing (with dental anesthetic cartridges) or deep sedation may be indicated in patients with true allergic reactions (anaphylaxis, etc.).[303]

Local anesthetic formulations that contain vasoconstrictors also contain a sulfite to prevent oxidation of the agent. The reaction to sulfites in dental anesthetics may be different from the reaction caused by foods.[318] This reaction is unlikely to occur, but the use of local anesthetics without vasoconstrictors is a possible alternative in patients with severe sulfite allergies.

Effects of systemic diseases or conditions on local anesthetics

It has been stated that vasoconstrictors should be avoided in patients with high blood pressure (higher than 180 mm Hg systolic or 120 mm Hg diastolic), cardiac dysrhythmias, unstable angina, less than 6 months since myocardial infarction or cerebrovascular accident, or severe cardiovascular disease.[213] However, these conditions are contraindications to *routine* dental treatment.

Local anesthetics may interact with a patient's medications, so a thorough review of the medical history is an absolute requirement. Potential drug-drug

Telegram: @dental_k

www.konkur.in

interactions occur primarily with the vasoconstrictors in local anesthetic formulations (Table 6.3). Judicious use of local anesthetic solutions without vasoconstrictors (e.g., 3% mepivacaine) is a reasonable alternative for those adult patients.

Table 6.3

Possible Drug Interactions With Vasoconstrictors

Drugs	Possible Adverse Effects	Recommendations
TRICYCLIC ANTIDEPRESSANTS		
Amitriptyline, doxepin	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
NONSELECTIVE BETA BLOCKERS		
Nadolol, propranolol	Hypertension, bradycardia	Reduce or eliminate vasoconstrictors
RECREATIONAL DRUGS		
Cocaine	Hypertension, myocardial infarction, dysrhythmias	Instruct patient to abstain from drug use for 48 h before procedure; do not use vasoconstrictors
COMT INHIBITORS		
Entacapone, tolcapone	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
ANTIADRENERGIC DRUGS		
Guanadrel, guanethidine	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
NONSELECTIVE ALPHA-ADRENERGIC BLOCKERS		
Chlorpromazine, clozapine, haloperidol	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
DIGITALIS		
Digoxin	Dysrhythmias (especially with large dosage of vasoconstrictor)	Reduce or eliminate vasoconstrictor
HORMONE		
Levothyroxine	Dysrhythmias (especially with large dosage of vasoconstrictor)	*Euthyroid:* No precaution *Hyperthyroid:* Reduce or eliminate vasoconstrictors
MONOAMINE OXIDASE INHIBITORS		
Furazolidone, linezolid, selegiline, tranylcypromine	No interaction	None

COMT, Catecholamine *O*-methyl transferase.

Many of the commonly available local anesthetics are safe for use in pregnant or lactating women.[137] The US Food and Drug Administration (FDA) has classified lidocaine and prilocaine as category B and mepivacaine, bupivacaine, and articaine as category C. The point in pregnancy (trimester)

Telegram: @dental_k

www.konkur.in

and emergent need for care need to be considered. The most important aspect of care with pregnant patients is to eliminate the source of pain by performing the indicated endodontic treatment.[137]

Clinical factors

Traditional methods of confirming anesthesia usually involve questioning the patient, probing the soft tissue, and/or starting treatment and waiting for the patient's reaction. These approaches may not be effective for determining pulpal anesthesia.[53,154,225,340]

Anesthesia in asymptomatic vital teeth can be measured more objectively by applying a cold refrigerant (Fig. 6.1) or by using an EPT, as described in Chapter 1 (Fig. 6.2). Application of cold or the EPT can be used to test the tooth under treatment for pulpal anesthesia before a clinical procedure is started.[49,88,170,198,210]

Source: (Courtesy SybronEndo, Corporation Orange, CA.)

In symptomatic vital teeth (after administration of a local anesthetic), testing with a cold refrigerant or an EPT can also be used to evaluate pulpal anesthesia before starting a treatment.[62,88,253,357] If there is a positive response to testing, supplemental anesthesia will be necessary. However, in these particular patients, a negative response does not guarantee pulpal anesthesia,[92,259,349] and supplemental anesthesia may still be necessary. If the pulp chamber contains necrotic tissue and the canals have vital tissue, no objective test can predict the level of pulpal anesthesia.

Why patients in pain have difficulty with anesthesia is a complicated

Telegram: @dental_k

www.konkur.in

question. If there was an easy answer, we would have an easy way to provide predictable profound anesthesia for every patient every time. Theories related to pH, hyperalgesia, altered resting potentials and lowered excitability thresholds, increased sodium channel expression, TTX-R (resistant) sodium channels, and lowered pain thresholds have been suggested as potentially compromising the efficacy of local anesthetics.[146,44,343,230,293,320,347,349] This is different from the central core theory, which has been offered as an explanation for failure with the IAN block in asymptomatic vital teeth.[77,325] This theory relates to the inner portion of the nerve bundle supplying the anterior teeth and the outer portion of the nerve bundle supplying the posterior teeth (Fig. 6.3), explaining part of the higher failure rates in anterior teeth.

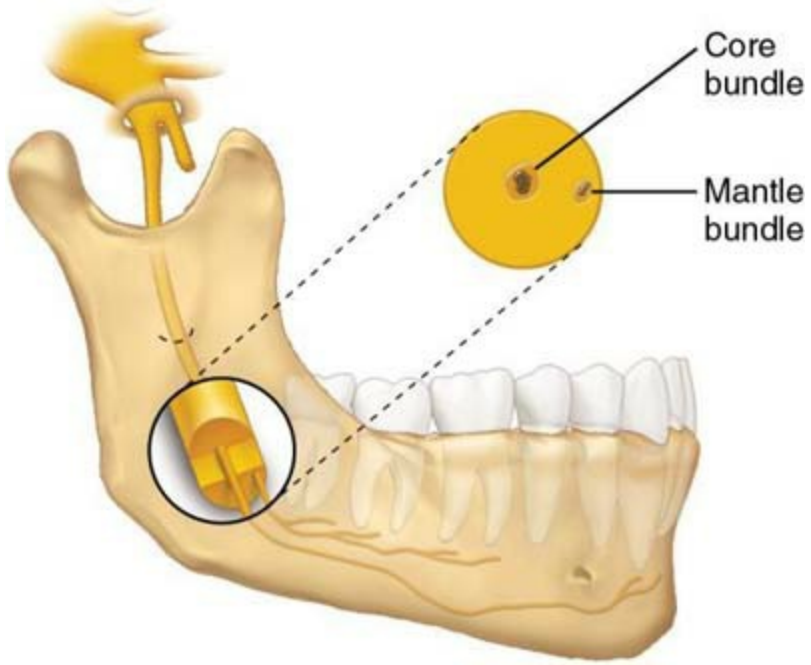

FIG. 6.3 The central core theory. The axons in the mantle bundle supply the molar teeth, and those in the core bundle supply the anterior teeth. The extraneural local anesthetic solution diffuses from the mantle to the core.

Part of mandible at the left end is enlarged that shows a core bundle inside a circle with a circular structure marked mantle bundle near the periphery.

Inferior alveolar nerve block

2% lidocaine and 1:100,000 epinephrine

Because failure occurs most often with the IAN block,[180] factors that modify mandibular anesthesia must be carefully reviewed. The technique for administering an IAN block can be reviewed in available textbooks.[165,213] The following discussion reviews the expected outcomes after administration of a conventional IAN block to asymptomatic patients using 1.8 mL of 2% lidocaine with 1:100,000 epinephrine (Xylocaine, Lignospan, Octocaine). Although anesthesia requirements vary among dental procedures, the following discussion concentrates on *pulpal* anesthesia in asymptomatic patients.

Anesthetic success, duration, and difficulty

Anesthetic success for nerve blocks has been defined in the majority of studies as the percentage of subjects who achieve two consecutive nonresponsive readings on electrical pulp testing within 15 minutes and continuously sustain this lack of responsiveness for 60 minutes. The clinical condition would be pulpal anesthesia within 15 minutes that lasts for 1 hour. Using this criterion, the percentage of cases in which anesthesia was obtained after IAN block injections ranged from 10% (central incisor) to 65% (second molar).[53,140,154,225,252,277,340] In all of these studies, patients reported profound lip numbness, meaning that these are not “missed” blocks. Profound lip numbness *does not* predict pulpal anesthesia. However, lack of soft-tissue anesthesia is a useful indicator that the block injection was not administered accurately for that patient. This will occur approximately 4% to 6% of the time in asymptomatic patients.[106] The authors also found that administration of a two-cartridge volume was significantly better for avoiding a missed block than a one-cartridge volume in asymptomatic subjects. It is important to note, however, that a two-cartridge volume does not provide a higher success rate for pulpal anesthesia.[106,341,366] Once pulpal anesthesia does occur, it usually persists for approximately 2½ hours.[98] Fig. 6.4 depicts the time course for complete pulpal anesthesia for an asymptomatic first

Telegram: @dental_k

www.konkur.in

molar, as defined by the percentage of patients who did not respond to a stimulus (EPT) across time for 60 minutes. Most patients achieved pulpal anesthesia within 15 minutes and had a duration of anesthesia of at least 1 hour, but the success rate was not 100%.

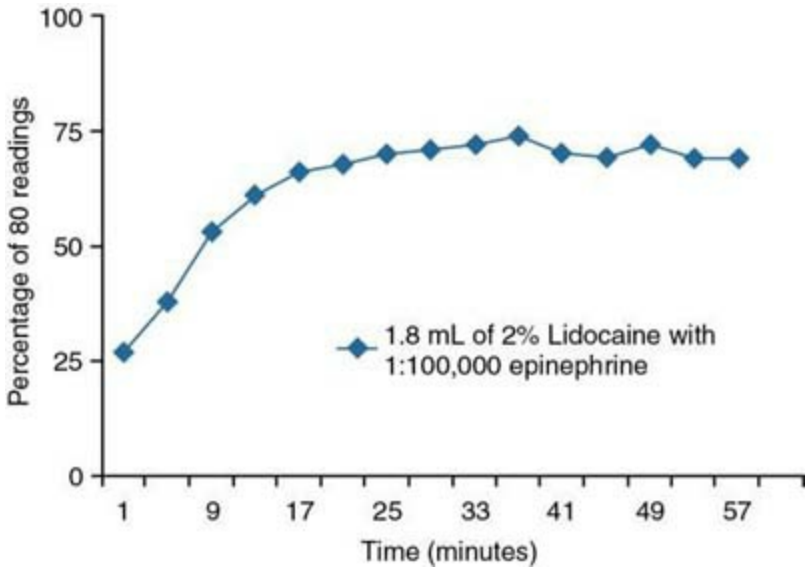

FIG. 6.4 Incidence of first mandibular molar anesthesia as determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes.

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100 in increments of 25. The horizontal axis ranges from 1 to 57. The data points for 1.8 milliliters of 2 percent Lidocaine with 1 to100,000 epinephrine are represented by diamond shapes. A line connects the data points. The line originates from the point 25 on the vertical axis, rises, and reaches at (70, 17), from where the line remains constant, starts fluctuating after (33, 74), and terminates on the extreme right below the point 75. All data are approximate.

Anesthetic failure can be defined as the percentage of subjects who never achieved two consecutive nonresponsive EPT readings at any time during a 60-minute period. Using this criterion, anesthetic failure rates range from 17% (second molar) to 58% (central incisor).[53,98,140,154,225,252,277,309,340,341]

Another presentation of mandibular anesthesia is noncontinuous anesthesia, which may be related to the action of the anesthetic solution on the nerve membrane (blocking and unblocking the sodium channels). This occurs in about 12% to 20% of patients.[53,135,140,154,225,252,277,340]

Telegram: @dental_k

www.konkur.in

After a conventional IAN block injection, the onset of pulpal anesthesia occurs within 10 to 15 minutes in most cases (see Fig. 6.4).[53,98,140,154,225,252,277,309,340,341] Slow onset of anesthesia can occur in a percentage of subjects who are nonresponsive to the EPT after 15 minutes. In mandibular teeth, slow onset occurs in 12% to 20% of patients.

Alternative anesthetic solutions for the inferior alveolar nerve block

Solutions without epinephrine

Plain solutions (mepivacaine, prilocaine) have been found to obtain pulpal anesthesia for an IAN block at rates similar to those for lidocaine with 1:100,000 epinephrine.[62] These findings support the selection of 3% mepivacaine as a local anesthetic when medical conditions or drug therapies suggest caution in the administration of solutions containing epinephrine; however, the duration of pulpal anesthesia is reduced to approximately 50 minutes.[225]

Articaine with 1:100,000 or 1:200,000 epinephrine

Articaine is classified as an amide. It has a thiophene ring (instead of a benzene ring like the other amide local anesthetics) and an extra ester linkage, which results in hydrolysis of articaine by plasma esterases.[219] Lidocaine and articaine have the same maximal dose of 500 mg for adult patients (recommended dose, 6.6 to 7 mg/kg), but the maximum number of cartridges is different because of the differences in drug concentration (see Table 6.2).[213]

Many clinical trials and some meta-analyses have failed to demonstrate any statistical superiority of articaine over lidocaine for IAN blocks in both symptomatic and asymptomatic patients.[17,35,57,197,273,311,319,332]

Long-acting anesthetics

Clinical trials with bupivacaine (Marcaine) have been conducted in patients undergoing oral surgery,[76,292] endodontic treatment,[91,98,237,262,299], and

Telegram: @dental_k

www.konkur.in

periodontic treatment.[71,207] Bupivacaine was found to have a slower onset of pulpal anesthesia than lidocaine for IAN blocks.[98] Generally, bupivacaine provides prolonged analgesia and is indicated when postoperative pain is anticipated, but not all patients want lip numbness for an extended period.[292] Patients should be questioned about their preference. Although bupivacaine has a somewhat slower onset than lidocaine, its duration of pulpal anesthesia in the mandible is almost twice as long (4 hours) (Fig. 6.5).[98]

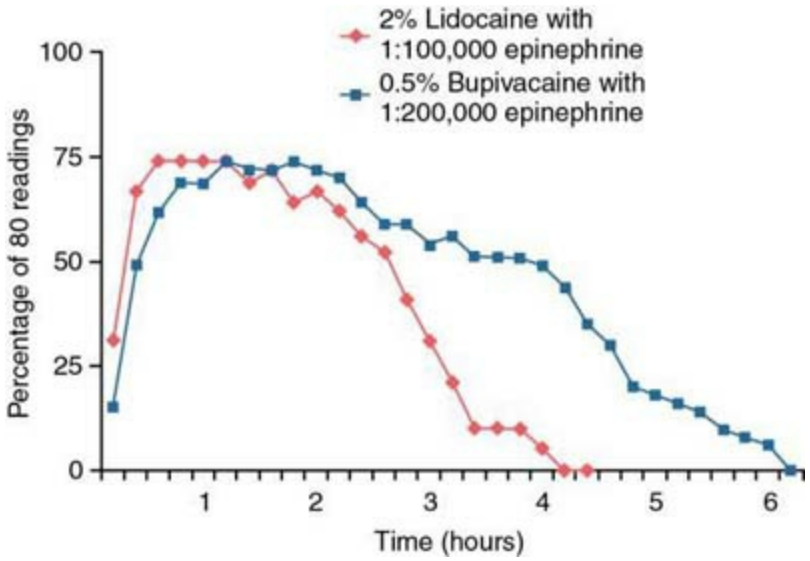

FIG. 6.5 Incidence of first mandibular molar anesthesia: comparison of 0.5% bupivacaine with 1:200,000 epinephrine to 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 6 hours. The bupivacaine solution showed a longer duration of anesthesia than the lidocaine solution.

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 0 to 6. The data points for 2 percent Lidocaine with 1 to 100,000 epinephrine and 0.5 percent Bupivacaine with 1:200,000 epinephrine are represented by diamond and square shapes, respectively. Two lines are fitted to both diamond and square data points. The line for 0.5 percent Bupivacaine originates from (0, 18), reaches at a height (1.2, 75), fluctuates while slopes downward, and terminates at (6, 0). The line for 2 percent Lidocaine originates from (0, 28), reaches at a height (0.5, 75), intersects the line of 0.5 percent Bupivacaine, fluctuates while slopes down, and terminates at (4.3, 0). All data are approximate.

Ropivacaine (Naropin), a relatively new long-acting local anesthetic, is a

Telegram: @dental_k

www.konkur.in

structural homolog of bupivacaine.[187] It is currently unavailable in dental cartridge form. A number of studies have shown that ropivacaine has a lower potential for toxic CNS and cardiovascular effects than bupivacaine but produces equivalent pharmacologic effects.[187] Ropivacaine and levobupivacaine are being developed as potentially new local anesthetics based on their stereochemistry. Both are S-isomers and are thought to cause less toxicity than the racemic mixture of bupivacaine currently marketed.[312] A medical clinical trial has indicated that levobupivacaine showed significantly better postoperative pain control at 4 and 24 hours after infiltration injection than ropivacaine.[259,215]

Liposomal bupivacaine (Exparel, Pacira Pharmaceuticals, San Diego, CA) has been approved for infiltration use by the FDA. The formulation is a preservative-free aqueous suspension of multivesicular liposomes (DepoFoam) containing bupivacaine at a concentration of 13.3 mg/mL (expressed as anhydrous bupivacaine hydrochloride [HCl] equivalent).[258,275] A small amount (3%) is free bupivacaine, which provides immediate numbness, whereas the remaining drug is released from the liposomes over time.[275] The FDA has *not* approved Exparel for nerve blocks. In clinical endodontic studies, Exparel did not significantly reduce symptomatic irreversible pulpitis pain or pain medication usage as compared with bupivacaine in untreated cases.[41] In another endodontic clinical trial using symptomatic patients diagnosed with pulpal necrosis who were experiencing moderate to severe preoperative pain and receiving endodontic treatment, a 4.0-mL infiltration of liposomal bupivacaine did not result in a statistically significant decrease in posttreatment pain compared with an infiltration of 4.0 mL of 0.5% bupivacaine with 1:200,000 epinephrine.[126]

Buffered lidocaine

Buffering lidocaine using sodium bicarbonate raises the pH of the anesthetic solution. In the medical literature, there is evidence that the use of buffered lidocaine results in less pain during the injection.[48,139] In the dental literature, some studies[11,12,34,177,296] found that buffered lidocaine produced less pain on injection and a faster onset of anesthesia. However, other dental studies[274,351,296,155] did not find less pain on injection or a faster onset with

Telegram: @dental_k

www.konkur.in

buffered lidocaine for IAN block. In symptomatic patients with a diagnosis of pulpal necrosis and associated acute swelling, no significant decrease in pain of infiltrations or significant decrease in the pain of an incision-and-drainage procedure was found when the buffered anesthetic formulation was used.[30,148]

Diphenhydramine as a local anesthetic agent

Diphenhydramine (Benadryl) has been advocated for patients who are allergic to local anesthetics. Multiple studies have found lower effectiveness as well as more pain and adverse effects with injection of this drug.[355,59] Diphenhydramine should not be used as an alternative to local anesthetics.

Alternative injection sites

Gow-gates and vazirani-akinosi techniques

Some clinicians have reported that the Gow-Gates technique[132] has a higher success rate than the conventional IAN block injection,[211,213] but controlled experimental studies have failed to show superiority of the Gow-Gates technique.[8,128,233,329,297] Studies have found no superiority of Gow-Gates for pulpal anesthesia in cases of symptomatic irreversible pulpitis.[4,306,60] A recent study indicated that a combination of Gow-Gates and IAN block injection was significantly superior to the Gow-Gates or IAN blocks alone.[297] The Vazirani-Akinosi technique[9,146,213] also has not been found to be superior to the standard inferior alveolar injection.[146,219,314,329,369] The Vazirani-Akinosi technique is indicated for cases involving a limited mandibular opening to assist with further opening. After using the Vazirani-Akinosi technique, conventional IAN blocks should be given to ensure pulpal anesthesia.

Articaine infiltrations

Articaine is significantly better than lidocaine for buccal infiltration of the mandibular first molar.[69,171,173,285] However, articaine alone does not predictably provide pulpal anesthesia of the mandibular first molar. There is

Telegram: @dental_k

www.konkur.in

no difference between 4% articaine with 1:100,000 and 1:200,000 epinephrine for buccal infiltration for pulpal anesthesia.[223]

In anterior teeth, buccal and lingual infiltrations of articaine provide initial pulpal anesthesia, but the anesthesia declines over 60 minutes.[161,256]

Volume and concentration

Increasing the volume of 2% lidocaine with epinephrine to 3.6 mL (two cartridges) does not increase the incidence of pulpal anesthesia with the IAN block (Fig. 6.6).[105,252,366] Also, no advantage has been seen in using a higher concentration (1:50,000 versus 1:100,000) of epinephrine.[73,341]

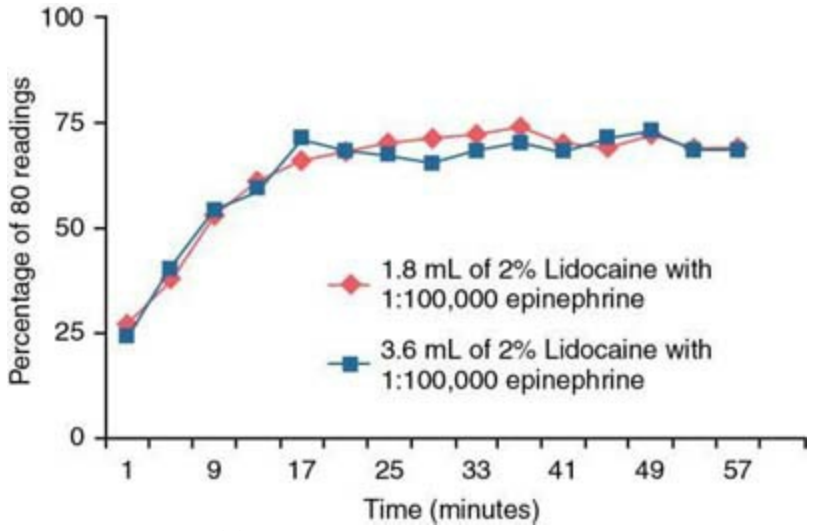

FIG. 6.6 Incidence of first mandibular molar anesthesia: comparison of 1.8 and 3.6 mL of 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. No significant difference between the two volumes was noted.

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 1 (near the origin) to 57. The data points for 1.8 milliliters of 2 percent Lidocaine with 1 to100,000 epinephrine and 3.6 milliliters of 2 percent Lidocaine with 1 to100,000 epinephrine are represented by diamond and square shapes, respectively. Two lines are fitted to both diamond and square data points. The line for 1.8 milliliters of 2 percent Lidocaine originates from (1, 25), increases in a concave down manner, fluctuates, and terminates at (57, 65). The line for 3.6 milliliters of 2 percent Lidocaine originates from (0, 26), merges with the

Telegram: @dental_k

www.konkur.in

first line, reaches at a height (17, 73), fluctuates while crossing the first line, and terminates at (57, 65). All data are approximate.

Factors in failure of the inferior alveolar nerve block

Many theories abound to explain the failure to achieve pulpal anesthesia with an IAN block; these include accessory and cross innervation, injection accuracy, needle beveling, and needle deflection. The mylohyoid nerve is the accessory nerve most often cited as a cause of failure of mandibular anesthesia.[111,366] A controlled clinical trial compared the IAN block alone with a combination of the IAN block and a mylohyoid nerve block using a peripheral nerve stimulator (Fig. 6.7); it was found that the mylohyoid injection did not significantly enhance pulpal anesthesia of the IAN block (Fig. 6.8).[58] Experimentally, cross innervation has been implicated in the failure of anterior pulpal anesthesia. Although this does occur in incisors,[289,368] it plays a very small role in the failure of an IAN block. It has also been theorized that an inaccurate injection contributes to inadequate mandibular anesthesia, but a number of studies have determined that the use of ultrasound, a peripheral nerve stimulator, or radiographs to guide needle placement for IAN blocks did not result in more successful pulpal anesthesia.[26,116,140,309] Needle deflection has also been proposed as a cause of failure with the IAN block.[64,75,156] Several in vitro studies have shown that beveled needles tend to deflect toward the nonbeveled side (i.e., away from the bevel).[10,64,75,156,168,286] In one clinical investigation, however, no significant difference in anesthetic success was seen when the needle bevel was oriented away from the mandibular ramus (so that the needle would deflect toward the mandibular foramen [90% success]) compared with the needle bevel oriented toward the mandibular ramus (92% success).[324]

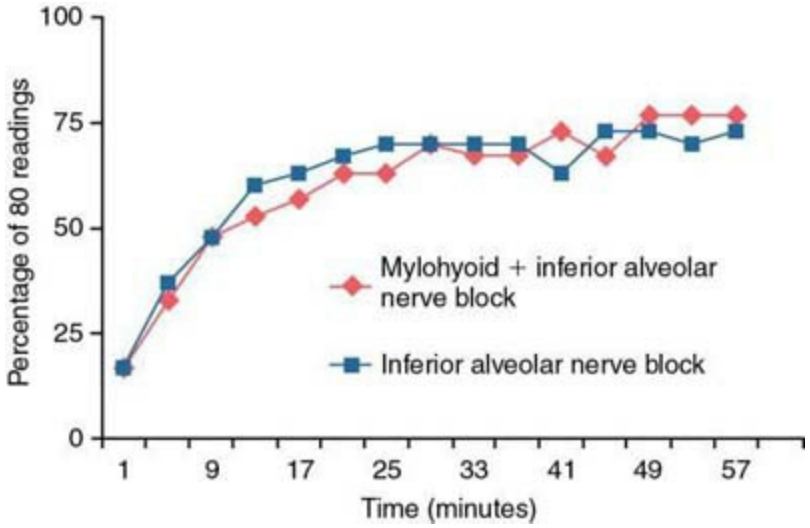

FIG. 6.8 Incidence of first mandibular molar anesthesia: comparison of the combination mylohyoid infiltration plus the inferior alveolar nerve block to the inferior alveolar nerve block alone. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. No significant difference between the two techniques was noted.

Telegram: @dental_k

www.konkur.in

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 1 (near the origin) to 57. The data points for mylohyoid plus inferior alveolar nerve block and inferior alveolar nerve block are represented by diamond and square shapes, respectively. Two lines connect the data points. The first line of mylohyoid plus inferior alveolar nerve block originates from (1, 18), rises up, fluctuates, and terminates at (57, 75). The second line of inferior alveolar nerve block originates from the same point as that of the first line, crosses the first line, increases in a concave down manner, remains constant, again crosses the first line, and terminates just below the first line. All data are approximate.

Speed of injection and success

A slow IAN block is more successful than a fast injection,[172] but not for patients diagnosed with irreversible pulpitis.[6]

Supplemental anesthesia for vital pulps in the mandible

Indications

A supplemental injection is used if the standard injection is not effective. It is useful to repeat an initial injection only if the patient is not exhibiting the classic signs of soft-tissue anesthesia, such as profound lip numbness. Generally, if the classic signs are present, reinjection is not very effective.[175] For example, after the IAN block, the patient develops lip, chin, and tongue numbness and quadrant “deadness” of the teeth. A useful procedure, as previously described, is to pulp test the tooth with a cold refrigerant or an EPT before the cavity preparation is begun.[49,88] If the patient feels pain to cold, a supplemental injection is indicated.

Supplemental injections include the infiltration injection, the IO injection, the intraligament (IL) injection (formerly called the periodontal ligament [PDL] injection), the intraseptal (IS) injection, and the intrapulpal (IP) injection.

Infiltrations

Telegram: @dental_k

www.konkur.in

Supplemental mandibular buccal, lingual, or buccal plus lingual infiltrations of articaine

Although the infiltration of articaine is effective in restorative dentistry as a supplemental technique (after the IAN block),[138] its use in endodontically involved teeth does not result in predictable pulpal anesthesia.[104,221,257,304,310] A buccal infiltration of lidocaine is also not effective for profound, predictable pulpal anesthesia. An important clinical finding is that an articaine infiltration of the first molar, premolars, and anterior teeth after an IAN block should provide pulpal anesthesia for approximately 1 hour.[138,174,256]

Buccal infiltration alone and buccal plus lingual infiltrations alone (or after an IAN block) do not result in complete pulpal anesthesia.[3,4,7,87,95,273,305] Therefore IO and IL injections are the preferred techniques for supplemental anesthesia, and the IP injection is indicated when the other injections are not successful.

Intraosseous anesthesia

The IO injection is a supplemental technique that has been shown to be effective by substantial research and clinical use. It is particularly useful in conjunction with an IAN block when it is likely that supplemental anesthesia will be necessary (e.g., in mandibular second molar teeth).[90,118,135] The IO injection allows placement of a local anesthetic directly into the cancellous bone adjacent to the tooth. When a primary IO injection was compared with an infiltration injection, the IO technique showed a quicker onset and a shorter duration of anesthesia (Fig. 6.9).[254]

Telegram: @dental_k

www.konkur.in

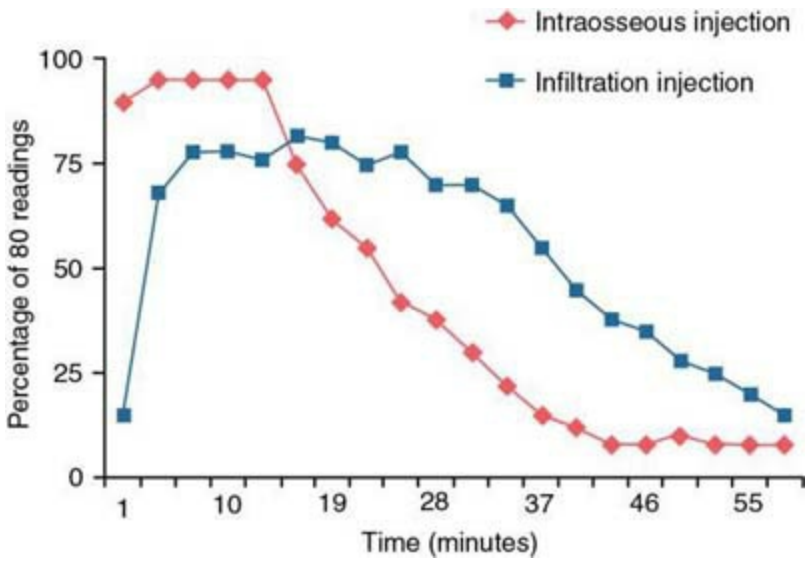

FIG. 6.9 Incidence of anesthesia for intraosseous and infiltration injections. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The intraosseous injection showed a quicker onset and a shorter duration of anesthesia.

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 1 (near the origin) to 55. The data points for intraosseous injection and infiltration injection are represented by diamond and square blocks, respectively. Two lines connect the data points. The first line for intraosseous injection originates from (1, 93), stays constant until (13, 94), slops down in a concave up decreasing manner, and terminates at (57, 10). The second line for infiltration injection originates from (1, 18), reaches at a height (9, 76), intersects the first line (17, 76), fluctuates while slopes down, and terminates at (57, 17). All data are approximate.

The Stabident IO system (Fairfax Dental Inc., Miami, FL) utilizes a slow-speed, handpiece-driven perforator and a solid 27-gauge beveled wire that drills a small hole through the cortical plate (Fig. 6.10). The anesthetic solution is delivered into cancellous bone through a 27-gauge ultrashort needle placed into the perforation made by the perforator (Fig. 6.11).

Telegram: @dental_k

www.konkur.in

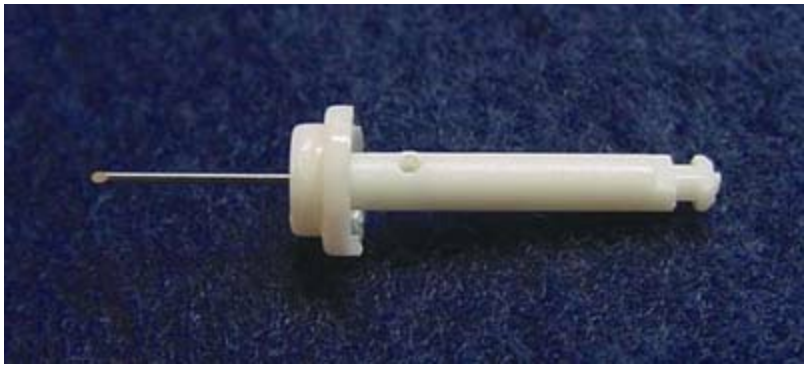

FIG. 6.10 The Stabident perforator, a solid 27-gauge wire with a beveled end that is placed in a slow-speed handpiece.

Stabident shows a plastic handle with a large needle at the center.

FIG. 6.11 The anesthetic solution is delivered to the cancellous bone through a needle placed into the hole made by the perforator.

Close-up view of open mouth shows an injection being inserted near the gum line in-between teeth in the lower right quadrant. The tooth adjacent to injection site has a cavity.

The X-Tip IO anesthetic delivery system (Dentsply International, York, PA) consists of an X-tip that separates into two parts, the drill and the guide sleeve (Fig. 6.12). The drill, a special hollow needle, leads the guide sleeve through the cortical plate; it is then separated from the guide sleeve and

Telegram: @dental_k

www.konkur.in

withdrawn. The remaining guide sleeve is sized to receive a 27-gauge needle for deposition of the anesthetic solution (Fig. 6.13). The guide sleeve is removed after the IO injection is complete.

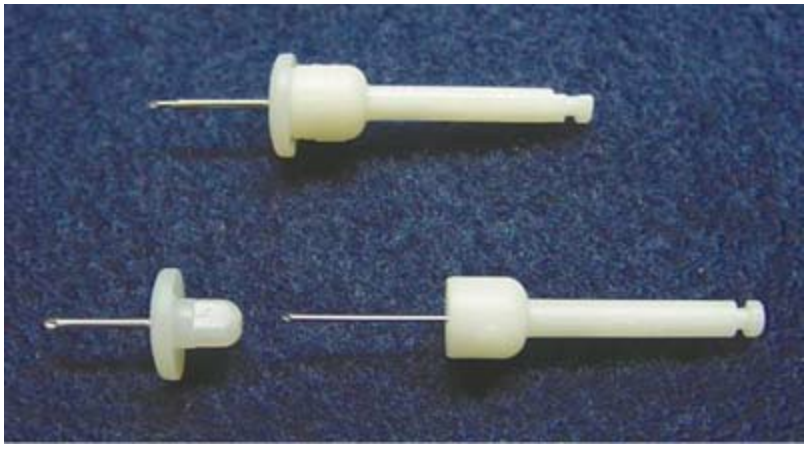

FIG. 6.12 The X-Tip anesthetic delivery system consists of an X-Tip *(top)* that separates into two parts: the drill (a special hollow needle) and the guide sleeve component *(bottom).*

Three X-tips are shown. Two X-tips have Y-shaped handle and a needle. One X-tip shows U-shaped handle with a flat bottom at the base and a needle at the center.

www.konkur.in

sleeve.

Close-up view shows an X-tip being inserted below the gum line in the lower right quadrant.

Another technique available is the TuttleNumbNow (TNN) system. It consists of a Septodont Evolution needle (needle with a secondary scalpel bevel) (Fig. 6.14) and a TNN needle guide that allows the needle to be safely bent by 90 degrees (Fig. 6.15). Instead of a motor-driven perforator, the needle is rotated back and forth 180 degrees as pressure is applied by hand via the anesthetic syringe. The beveled needle is claimed to perforate the cortical bone and allows for delivery of anesthetic into the cancellous bone. It is important to note that this is a system that is intended to deliver anesthetic intraosseously without a separate perforator.

The techniques for IO injection of anesthetic using the Stabident, X-Tip, or TNN system can be reviewed in the systems' instruction manuals or in published papers or books.[61,119,280–282]

Success and duration

Supplemental IO injections of lidocaine and mepivacaine with vasoconstrictors allow quick onset and increase the success of the IAN block for approximately 60 minutes (Fig. 6.16).[90,135] The addition of a supplemental IO injection reduced the incidence of slow onset of pulpal anesthesia to zero compared with the IAN block alone (18% incidence).[90] Using 3% mepivacaine plain results in pulpal anesthesia for approximately 30 minutes (Fig. 6.17).[118] Repeating the IO injection—using 1.4 mL of 2% lidocaine with 1:100,000 epinephrine 30 minutes after the initial IO injection—provides an additional 15 to 20 minutes of pulpal anesthesia, similar to the

Telegram: @dental_k

www.konkur.in

duration of the initial IO injection.[167]

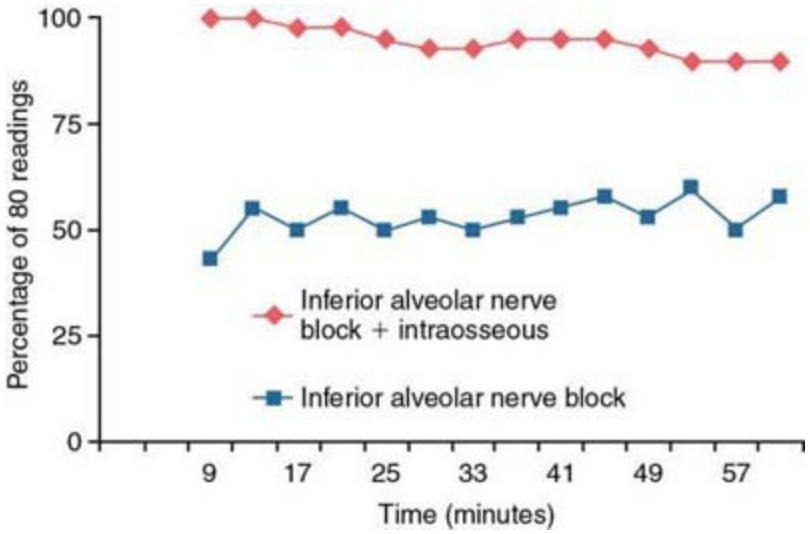

FIG. 6.16 Incidence of first mandibular molar anesthesia: comparison of the combination intraosseous injection of 2% lidocaine with 1:100,000 epinephrine plus the inferior alveolar nerve block to the inferior alveolar nerve block alone. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The combination technique was significantly better at all postinjection times.

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 9 (slightly away from the origin) to 57. The data points for inferior alveolar nerve block plus intraosseous and inferior alveolar nerve block are represented by diamond and square blocks, respectively. Two lines connect the data points. The first line of inferior alveolar nerve block plus intraosseous originates from (9, 100), fluctuates slightly, and terminates at (59, 98). The second line of inferior alveolar nerve block originates from (9, 43), rises up to (13, 52), fluctuates, and terminates at (59, 52). All data are approximate.

www.konkur.in

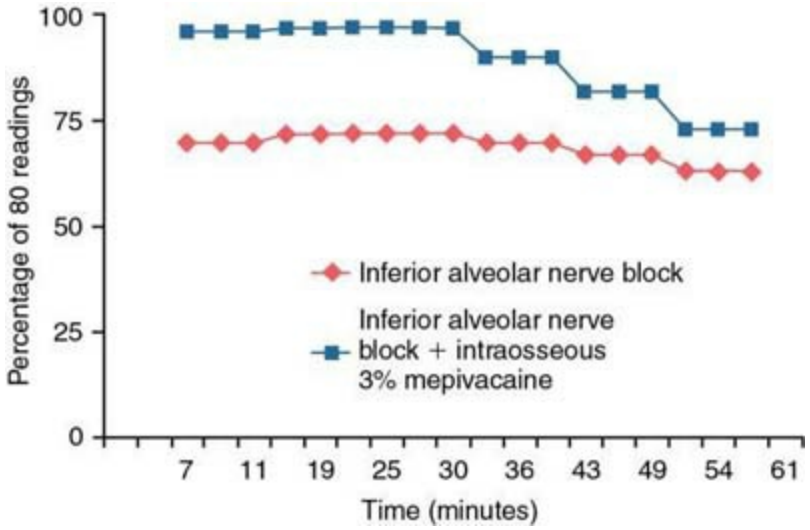

FIG. 6.17 Incidence of first mandibular molar anesthesia: comparison of the combination intraosseous injection with 3% mepivacaine plus the inferior alveolar nerve block to the inferior alveolar nerve block alone. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The combination technique proved to be significantly better for approximately 30 minutes.

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 7 (slightly away from the origin) to 61. The data points for inferior alveolar nerve block and inferior alveolar nerve block plus intraosseous 3 percent mepivacaineare represented by diamond and square blocks, respectively. Two lines connect the data points. The first line of inferior alveolar nerve block originates from (7, 98), moves constantly upto (32, 98), slopes down, forms ladder-like steps, and finally terminates at (57, 75). The second line of inferior alveolar nerve block plus intraosseous originates from (7, 72), fluctuates a little bit, and finally terminates at (57, 70). All data are approximate.

Long-acting anesthetics do not show an extended duration of anesthesia when injected by the IO route.[159,322] Bupivacaine has cardiotoxic effects[18] and for IO anesthesia offers no advantage, clinically, to 2% lidocaine with epinephrine in terms of efficacy, duration, and heart rate effects. Therefore bupivacaine should not be used for IO anesthesia.

Articaine use in the IO injection has also been found not to provide superior results compared with lidocaine.[27]

Success in symptomatic irreversible pulpitis

High success rates (around 90%) have been reported when the IO injection

Telegram: @dental_k

www.konkur.in

was used as a supplemental injection with irreversible pulpitis.[27,221,250,253,257] Three percent mepivacaine has an 80% success rate, which increases to 98% with a second IO injection of 3% mepivacaine.[349]

An initial supplemental IO injection of 0.45 to 0.9 mL of 2% lidocaine with 1:100,000 epinephrine was successful in 79% of posterior mandibular teeth.[260] A second IO injection of the remaining cartridge increased the success rate to 91%. Therefore, initially giving a quarter to a half cartridge of 2% lidocaine with 1:100,000 epinephrine was less successful than initially giving a full cartridge.

Although some authors[264,278] have suggested an IO injection alone successfully anesthetizes patients presenting with irreversible pulpitis, it is very doubtful that this would be successful.[27,96,221,250,253,257]

Complications/contraindications.

During an IO injection, if the anesthetic solution flows out of the perforation site (backflow), anesthesia will not occur.[120] Reperforation or use of another perforation site is a practical way to gain access to the cancellous bone in such cases. In fewer than 10% of cases, constricted cancellous spaces may limit the distribution of the anesthetic solution around the apices of the teeth.[61,90,120,135,250,253,279–282,322] In such cases, failure may result even if the anesthetic solution is delivered intraosseously. Reports have shown that approximately 1% of Stabident cases had the metal perforator separate from the plastic shank of the Stabident system during use.[61,90,120,250,280–282] The metal perforator can be easily removed with a hemostat but may require a small gingival flap to access the separated component. Separation usually occurs during a difficult perforation (e.g., dense cortical bone) and may be caused by the wire being heated excessively due to friction, thus causing the plastic hub to melt. No perforator breakage (metal perforator breaking into parts) has been reported in numerous published clinical studies.[61,90,120,250,280–282] However, excessive torqueing of the perforator laterally by an inexperienced operator may result in breakage. When the IO injection is used as a primary injection, pain is experienced about 25% of the time.[61,119,280–282] When the IO injection is used as a supplemental injection, fewer patients experience pain.[90,119,135,280,322] With the Stabident system, fewer than 5% of patients develop swelling or exudate at the site of bone

Telegram: @dental_k

www.konkur.in

perforation.[61,135,280–282] The X-Tip system may show a higher incidence of postoperative swelling.[119] With both systems, the swelling and/or exudate may persist for several weeks after the injection, but should resolve with time.[63,119,135,280–282] Slow healing of perforation sites may be the result of overheating of the bone caused by pressure during perforation.

With both the Stabident and X-Tip systems, approximately 4% to 15% of patients may report that the tooth "feels high" during chewing.[63,119,135,280–282] This sensation is probably due to an increased awareness to pressure due to soreness in the treated area caused by damage from perforation or inflammation of the bone. The incidence of this effect is lower for the IO injection than that reported for the IL injection (36% to 49%).[72,300] When IO injections are given with the Stabident system, either as a primary or a supplemental technique, most patients report no or only mild pain; approximately 2% to 15% report moderate pain.[63,135,280–282] Less postoperative discomfort is reported for the Stabident IO injection than for IL injection.[300]

One study found that significantly more men experienced postoperative pain with the X-Tip system than with the Stabident system.[119] The authors interpreted these results as being due to the denser, more mineralized bone in the posterior mandible in men and to the fact that the diameter of the X-Tip perforating system is larger than that of the Stabident perforator, meaning the X-Tip system generates more frictional heat during perforation. No clinical research has been published about the TNN system.

Systemic effects

A transient increase in heart rate has been reported in 46% to 93% of cases involving Stabident and X-Tip IO injection of solutions containing epinephrine or levonordefrin.[61,90,120,135,250,253,280–282,322] Four clinical trials using techniques such as objective electrocardiographic recordings and pulse oximetry have shown that subjects experienced a transient tachycardia (mean increase of 12 to 32 beats/min) after Stabident IO injection of 1.8 mL of 2% lidocaine with 1:100,000 epinephrine, 1.8 mL of 2% mepivacaine with 1:20,000 levonordefrin, or 1.8 mL of 1.5% etidocaine with 1:200,000 epinephrine.[50,135,283,322] Another clinical trial reported transient tachycardia after IO injection, but not with infiltration injection, of 1.8 mL of 2%

Telegram: @dental_k

www.konkur.in

lidocaine with 1:100,000 epinephrine in the maxillary anterior region.[358] All of these studies showed that the heart rate returned to original baseline readings within 4 minutes in most patients. Therefore IO injection of anesthetic solutions containing vasoconstrictors with either the Stabident or X-Tip system results in a transient tachycardia. No research has been conducted with the TNN system, although similar results would be expected. However, no significant changes in diastolic, systolic, or mean arterial blood pressure has been reported with the IO injection of 2% lidocaine with 1:100,000 epinephrine.[50,283]

Although the patient is likely to notice the transient tachycardia that occurs after Stabident or X-Tip IO injection of 2% lidocaine with 1:100,000 epinephrine, it is generally not clinically significant in healthy patients.[283] The clinical significance, cardiovascular effects, and contraindications to the use of vasoconstrictors in IO injections have been reviewed.[283]

No significant tachycardia occurs when 3% mepivacaine is used for IO anesthesia.[118,283] Clinicians should keep in mind that this anesthetic is an alternative for IO injection in patients whose medical condition or drug therapy suggests caution in the use of solutions containing epinephrine or levonordefrin.[118,283]

Plasma levels of lidocaine after intraosseous injection.

Some authors have warned that administration of a large volume of local anesthetic via an IO injection could lead to overdose reactions.[160] One experimental study using volunteers found that injection of 1.8 mL of 2% lidocaine with 1:100,000 epinephrine produced venous plasma levels of lidocaine that were the same for maxillary anterior IO and infiltration injections (Fig. 6.18).[358] Although systemic concentrations of vasoconstrictors have a short-lived effect on the heart rate, the plasma concentration of lidocaine delivered with IO injection is similar to that delivered via infiltration, so the IO technique should not be considered an intravascular injection with regard to lidocaine. Therefore the precautions for the maximum amount of lidocaine for an infiltration injection would seem to apply to an IO injection.

Telegram: @dental_k

www.konkur.in

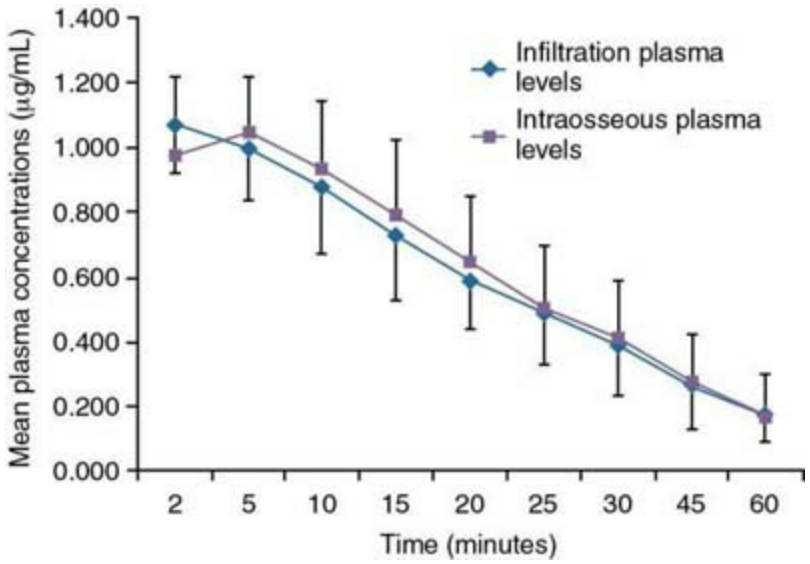

FIG. 6.18 Mean plasma concentrations of lidocaine for the intraosseous and infiltration injection techniques. No statistical differences were seen between the two techniques at any time period.

Graph shows mean plasma concentrations in micro grams per milliliters against time in minutes. The vertical axis ranges from 0.0 0 0 to 1.4 0 0. The horizontal axis ranges from 2 (slightly away from the origin) to 60. The data points for infiltration plasma levels and intraosseous plasma levels are represented by diamond and square blocks, respectively. Two lines connect the data points. The first line of infiltration plasma levels originates from (2, 1.0 4 0), slopes down, and terminates at (60, 0.1 6 0). The second line of intraosseous plasma levels originates from (2, 0.9 8 0), intersects the first line at (4, 1.0 0 0), moves further, slopes down, and again merged with the first line. The second line ends with the first line at the same point. All data are approximate.

Intraligament anesthesia

The IL injection is another technique that is used if a conventional injection is unsuccessful.[317,344] The technique for the IL injection of anesthesia is reviewed in a number of published papers and textbooks.

Success, onset, and duration

For use as a primary injection, IL injections have a reported success rate of about 75% in mandibular posterior teeth, with a duration of pulpal anesthesia of 10 to 15 minutes.[300,352] Success rates are low in anterior teeth.[224,300,352]

For use as a supplemental injection (e.g., when standard techniques have

Telegram: @dental_k

www.konkur.in

failed to provide adequate anesthesia), good success rates are achieved, but the duration of pulpal anesthesia is approximately only 23 minutes.[54]

The onset of anesthesia is immediate with an IL injection,[72,324,300,317,344,352] which means that no waiting period is required for the anesthesia to take effect. If anesthesia is still not adequate, reinjection may be necessary.

Success in symptomatic irreversible pulpitis

The overall success of supplemental IL injections in achieving pulpal anesthesia for endodontic procedures has been reported to be 50% to 96%.[63,212,317,344] If a first IL injection fails, reinjection results in a success rate of 92%.[344] Similar results have been reported by other investigators.[317] IL injection is not successful in mandibular anterior teeth.[226,352] In addition, supplemental IL injections are not as successful as supplemental IO injections.[175,370]

Mechanism of action

An IL injection forces anesthetic solutions through the cribriform plate into the cancellous bone around the tooth.[88,113,276,316,346] The primary route of anesthetic is *not* via the PDL, and unlike the IP injection,[329,339] the mechanism of action is not a pressure anesthesia.[92,234] The IL injection should be considered an IO injection.

Back pressure and amount of solution delivered

Studies have shown that the most important factor for anesthetic success with an IL injection is delivery of anesthetic under *strong back pressure*.[316,344] Pressure is necessary to force the solution into the marrow spaces. Usually about 0.2 mL of solution is deposited with each injection and the use of traditional or pressure syringes. However, the exact amount of anesthetic delivered is not always known because some of the anesthetic solution may escape from the injection site.

Anesthetic solutions

A vasoconstrictor significantly increases the efficacy of an IL

Telegram: @dental_k

www.konkur.in

injection.[133,179,190,226,300] Anesthetic solutions with reduced vasoconstrictor concentrations are not very effective with the IL technique.[133,169,179] Articaine is equivalent to lidocaine.[5,25]

Injection discomfort.

When the IL injection is used as a primary injection, needle insertion and injection have the potential to be painful about one third of the time.[234,300,352] The IL injection may be quite painful in maxillary anterior teeth[352] and should not be used in these teeth; infiltration is preferred. The potential for pain with the IL technique is greatly reduced when the injection is used as a supplemental injection after an IAN block.[54]

Selective anesthesia.

Although some authors have reported that the IL injection can be used to differentially diagnose pulpally involved teeth,[209] clinical studies have shown that adjacent teeth can also become anesthetized with the IL injection.[234,300,352] Therefore the IL injection should *not* be used for differential diagnosis.

Postoperative discomfort

When the IL injection is used as a primary technique, postoperative pain occurs in one third to three quarters of patients, with a duration of 14 hours to 3 days.[72,234,300,317,344,352] The discomfort is related to damage from needle insertion rather than to the pressure of depositing the solution.[72] About one fourth of patients report that their tooth feels “high” in occlusion.[300,352]

Systemic effects

When a high-pressure syringe was used in dogs, IL injection of solutions containing epinephrine caused cardiovascular responses similar to those seen with intravenous injections.[315] Clinical studies using a high-pressure syringe in human beings found that IL injections of such solutions did not significantly change the heart rate, rhythm, or amplitude or the blood pressure.[46,247] These studies support the conclusion that IL injections do not cause significant changes in heart rate in human beings.

Telegram: @dental_k

www.konkur.in

Other factors

Different needle gauges (25, 27, or 30) are equally effective.[344] Special pressure syringes have been marketed but have not been proven more effective than a standard syringe.[300,344,352]

Safety of the periodontium and pulp

Clinical and animal studies have demonstrated the safety of the IL injection technique.[36,112,113,117,208,234,266,300,344,352] Minor transient damage occurs only at the site of needle penetration, but the tissue subsequently undergoes repair. In rare cases, periodontal abscesses and deep pocket formation have occurred after IL injections.[50,352] A small clinical risk of periodontal abscess formation and bone loss exists with this technique, and although these effects are rare, the clinician should be aware of them. Localized areas of root resorption after IL injections have also been reported.[265,284]

IL injections have been shown to be safe in cases of mild to moderate gingival inflammation or incipient periodontitis.[70]

Studies have shown that IL injections have no permanent impact on the pulp.[205,234,267,284,300,352] However, IL injection of a solution containing epinephrine does produce a rapid and prolonged decrease in blood flow to the pulp tissue.[190] Some have suggested that using the IL injection technique during restorative procedures could result in an accumulation of inflammatory mediators in the pulp that could not be effectively removed because of the decreased blood flow.[190] This hypothesis was directly tested, and the IL injection of an anesthetic solution containing a vasoconstrictor in conjunction with a deep cavity preparation did *not* produce a more severe pulpal reaction than in controls (cavity preparation only).[270] It was reported that the depth of the cavity preparation was the biggest factor dictating pulpal responses. IL injections are therefore unlikely to cause pulpal necrosis.

Intraseptal injection

IS injections are somewhat similar to IL injections in that anesthetic is deposited directly into the interdental septum and the anesthetic gains access to the cancellous bone surrounding the tooth. The injection technique involves placing the needle in the center of the papillary triangle at a 45-

Telegram: @dental_k

www.konkur.in

degree angle and advancing the needle until it contacts the bony crest.[295,359] The needle may then be pressed into the IS bone and anesthetic delivered with the same back pressure as achieved during an IL injection.

Clinical research has shown the anesthetic success to range from 35% to 90% as a primary injection when used for extractions, restorations, or anesthetic evaluations.[28,31,38] For patients diagnosed with symptomatic irreversible pulpitis, Webster and coworkers[348] reported that the success of the IS injection as a supplement to the IAN block was only 29%.

Intrapulpal injection

In about 5% to 10% of mandibular posterior teeth with irreversible pulpitis, supplemental IO or IL injections, even when repeated, do not produce profound pulpal anesthesia and pain is experienced by the patient when the pulp is entered. This is an indication for the IP injection.

The major drawback of the IP injection technique is that the needle and injection are made directly into vital and very responsive pulp tissue; this injection is quite often moderately to severely painful.[253] The endodontic literature offers more efficacious methods of supplemental pulpal anesthesia; therefore the IP injection should be given only after all other supplemental anesthetic techniques have failed. Another disadvantage of the technique is the duration of pulpal anesthesia (15 to 20 minutes). The pulpal tissue must be removed quickly and completely to prevent a recurrence of pain during instrumentation. Also, in order to give the IP injection, the pulp must be exposed to allow direct injection. Anesthetic problems frequently occur before exposure while the clinician is still working in dentin; thus patients may experience pain immediately prior to exposure of the pulp.[221,250,251,253,263,279,310]

The advantage of the IP injection is that it produces profound anesthesia if it is given under back pressure.[29,339] The onset of anesthesia is immediate, and no special syringes or needles are required. The methods for this technique can be found in many endodontic textbooks. As mentioned previously, strong back pressure is the major factor in achieving successful IP anesthesia.[29,339] Simply depositing the anesthetic solution into the chamber will be insufficient because the anesthetic solution will not diffuse throughout the pulp tissue.

Telegram: @dental_k

www.konkur.in

Maxillary anesthesia

Descriptions of conventional techniques for maxillary anesthesia are available for review in numerous articles and textbooks.[165,213] The most commonly used injection for anesthetizing maxillary teeth is infiltration with a cartridge of 2% lidocaine with 1:100,000 epinephrine. Infiltration results in a fairly high incidence of successful pulpal anesthesia (around 87% to 92%).[40,94,134,178,202,220,231,254,261,277,302] However, some patients may not be anesthetized because of individual variations in response to the drug administered, operator differences, and variations of anatomy and tooth position. Pulpal anesthesia usually occurs within 3 to 5 minutes.[40,94,134,178,202,220,231,254,261,277,302] The duration of pulpal anesthesia is a problem with maxillary infiltrations.[40,94,134,178,202,220,236,254,261,277,302] Pulpal anesthesia of the anterior teeth declines after about 30 minutes, with most losing anesthesia by 60 minutes.[40,94,134,178,202,220,236,254,261,277,302] In premolars and first molars, pulpal anesthesia is good until about 40 to 45 minutes and then it starts to decline.[40,94,134,178,202,220,236,254,261,277,302] Additional local anesthetic should be administered depending on the duration of the procedure and the tooth group affected.

Alternative anesthetic solutions for maxillary infiltrations

Plain solutions: 3% mepivacaine (carbocaine, polocaine, scandonest) and 4% prilocaine (citanest plain)

Anesthesia duration is shorter with these solutions.[178,220] Therefore these are best used for procedures of short duration (10 to 15 minutes) (Fig. 6.19). They are generally not as safe as anesthetic solutions with vasoconstrictors, especially if *large* volumes are administered. They are rapidly absorbed systemically, thus resulting in excessive plasma concentrations and possible toxic reactions.[213]

Telegram: @dental_k

www.konkur.in

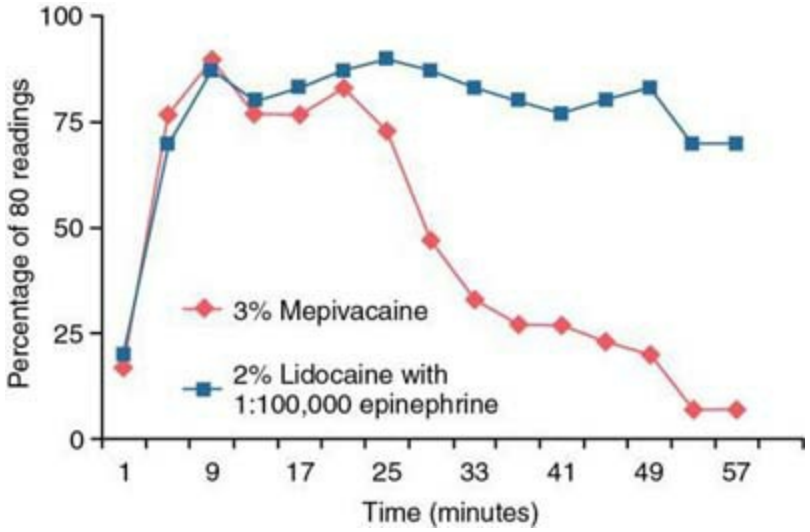

FIG. 6.19 Incidence of first maxillary molar anesthesia: comparison of 3% mepivacaine to 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The 3% mepivacaine showed a shorter duration of anesthesia than the lidocaine solution.

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 1 (near the origin) to 57. The data points for 3 percent Mepivacaine and 2 percent Lidocaine with 1 to 100,000 epinephrine are represented by diamond and square shapes, respectively. Two lines connect the data points. The first line representing 3 percent Mepivacaine originates from (1, 20), moves up, and reaches at a height (9, 90), slopes down, fluctuates, and terminates at (57, 8). The second line representing 2 percent Lidocaine with epinephrine originates just above the first line, merges with the first line, reaches a height at (9, 90), fluctuates horizontally, and terminates at (57, 75). All data are approximate.

4% prilocaine with 1:200,000 epinephrine (citanest forte), 2% mepivacaine with 1:20,000 levonordefrin (carbocaine with neo-cobefrin), and 4% articaine with 1:100,000 epinephrine (septocaine, articadent, zorcaine)

These formulations are similar to 2% lidocaine with 1:100,000 epinephrine.[94,178,202]

0.5% bupivacaine with epinephrine (marcaine)

Success rates with bupivacaine range from 80% to 95% in the maxillary

Telegram: @dental_k

www.konkur.in

lateral incisor compared with 50% in the maxillary second premolars.[73,134,187,328] Although bupivacaine can provide long-term anesthesia with the IAN block, it *does not* provide prolonged pulpal anesthesia with maxillary infiltration injection.[74,134,187]

Extending the duration of pulpal anesthesia for maxillary teeth

A two-cartridge volume of 2% lidocaine with epinephrine extends the duration of pulpal anesthesia, but not for 60 minutes.[231] Adding another cartridge of 2% lidocaine with epinephrine at 30 minutes in anterior teeth and 45 minutes in posterior teeth significantly improves the duration of pulpal anesthesia and may be the best way to extend the duration of pulpal anesthesia (Fig. 6.20).[302]

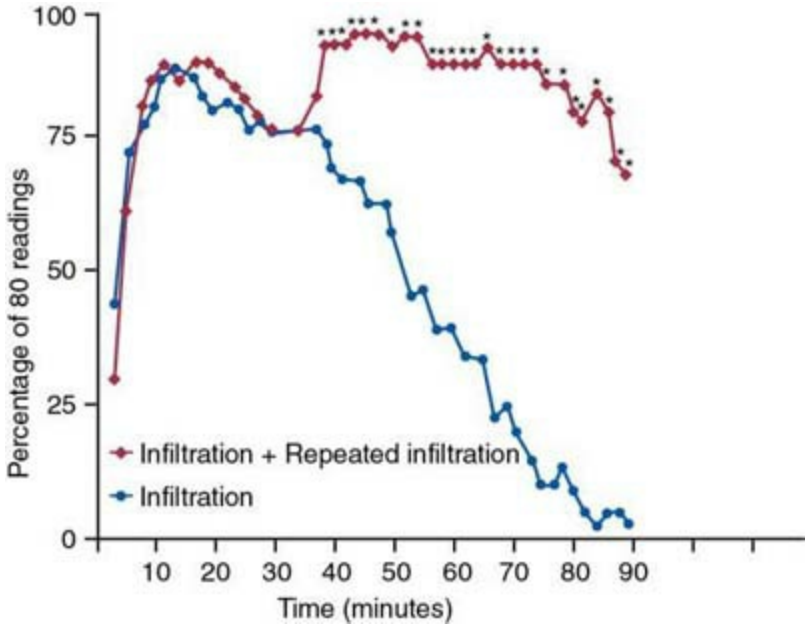

FIG. 6.20 Incidence of maxillary lateral incisor pulpal anesthesia using an initial infiltration and a repeated infiltration 30 minutes later (both infiltrations used 1.8 mL of 2% lidocaine with 1:100,000 epinephrine). Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings). The repeated infiltration injection significantly prolonged the duration of pulpal anesthesia.

Telegram: @dental_k

www.konkur.in

Graph shows percentage of 80 readings against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 10 (away from the origin) to 90. The data points for infiltration plus repeated infiltration and infiltration are represented by diamond and square shapes, respectively. Two lines connect the data points. The first line representing infiltration plus repeated infiltration originates from (3, 29), reaches a height at (10, 88), forms a U-shape, fluctuates, and terminates at (90, 70). The data points are marked with asterisks from (40, 92) to (90, 70). The second line representing infiltration originates from (2, 45), reaches a height at (11, 88), fluctuates while slopes down, and terminates at (90, 2). All data are approximate.

Alternative maxillary injection techniques

For routine restorative and endodontic procedures, posterior superior alveolar (PSA),[209,268] anterior middle superior alveolar (AMSA),[107,108,110,127,203,251] palatal-anterior superior alveolar (P-ASA),[44,109,110,248] infraorbital,[24,176] and second division nerve blocks[39,101] are not advocated. Infiltrations of the area are preferred for pulpal anesthesia.

Kovanaze is an intranasal 3% tetracaine plus 0.05% oxymetazoline formulation designed to provide anesthesia of the maxillary anterior and premolar teeth. Kovanaze is a needle-free anesthetic delivered as an intranasal atomized plume of solution. It was developed as an alternative to needle delivery systems because of the anxiety, fear, and needle sticks associated with traditional systems. Kovanaze has already been studied for its cardiovascular and pharmacokinetic effects[56,152,124] and in restorative procedures in maxillary anterior and posterior teeth.[56,153,152] Studies evaluating pulpal anesthesia are likely to follow to determine its future use in endodontics.

Management of anesthesia in endodontic cases

The management of anesthesia in endodontic cases generally includes use of the solutions, injection types, and supplemental anesthesia modalities mentioned throughout this chapter. Anesthesia types and indications will differ depending on pulpal diagnosis. For a thorough review of each clinical

Telegram: @dental_k

www.konkur.in

scenario with clinical flowcharts, the reader is directed to more in-depth texts on this topic.[277]

Summary and future directions for effective anesthesia

The emergence of evidence-based dentistry has rapidly drawn interest across all fields of dentistry. Fortunately, the large number of high-quality randomized controlled studies in anesthesia and analgesia provide a wealth of information supporting evidence-based recommendations. The practitioner must focus on high-quality research when clinical decisions are being made.

The prudent practitioner knows that there is no “magic bullet” in pain control. Rather, the clinician must be knowledgeable about the advantages and disadvantages of several anesthetic-vasoconstrictor combinations and the various routes of injection. Clearly, judicious selection of local anesthetics, delivered through multiple sites of injection, is likely to provide predictable anesthesia with minimal exposure to side effects.

Analgesics and therapeutic recommendations

Nonnarcotic analgesics

Management of endodontic pain is multifactorial and directed at reducing the peripheral and central components of hyperalgesia and allodynia through combined endodontic procedures and pharmacotherapy. A major class of drugs for managing endodontic pain comprises the nonnarcotic analgesics, which include both nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen. NSAIDs have been shown to be very effective in managing pain of inflammatory origin and, by virtue of their binding to plasma proteins, actually exhibit increased delivery to inflamed tissue via the extravasation of plasma proteins.[33,82,147] Although these drugs classically are thought to produce analgesia through peripheral mechanisms, the CNS is believed to be an additional site of action.[216,326] NSAIDs inhibit the synthesis of PGs by blocking the enzyme cyclooxygenase (COX), which has two known isoforms, COX-1 and COX-2. Some researchers have proposed that a splice variant of COX-1 (i.e., COX-3) is expressed predominantly in the CNS and is the major site of action of acetaminophen.[52,192,255,301] However, recent studies[151] indicate that the antipyretic and analgesic effects of acetaminophen do not involve inhibition of COX-3; they are more likely exerted through effects of an active metabolite on CNS cannabinoid receptors,[14] and this metabolite appears to act by blocking a calcium channel ($Ca_V3.2$).[188]

Numerous NSAIDs are available for the management of pain and inflammation (Table 6.4). Ibuprofen is generally considered the prototype of contemporary NSAIDs and has a well-documented efficacy and safety profile.[80] New formulations of ibuprofen include ibuprofen sodium dihydrate, which is an effective analgesic and has a faster onset of action than ibuprofen acid. Other NSAIDs may offer certain advantages over ibuprofen.[327] For example, etodolac (i.e., Lodine) causes less gastrointestinal (GI) irritation,[16] and ketoprofen (i.e., Orudis) has been shown in some studies to be somewhat

Telegram: @dental_k

www.konkur.in

more analgesic than ibuprofen.[67] An intranasal formulation of ketorolac tromethamine (Sprix, Regency Therapeutics, Shirley, NY) is now available and provides significant pain relief within 30 minutes of administration in patients with endodontic pain.[337] Recent studies suggest that in addition to inhibiting COX, ketorolac and diclofenac inhibit peripheral *N*-methyl-d-aspartate (NMDA) receptors, which may contribute to their analgesic effects.[47,85] The advantages of NSAIDs include their well-established analgesic efficacy for inflammatory pain. Many of the NSAIDs listed in Table 6.4 have been shown to be more effective than traditional acetaminophen and opioid combinations such as acetaminophen with codeine.[66,80,334]

Table 6.4

Summary of Selected Nonnarcotic Analgesics

Analgesic	Trade Name	Dose Range (mg)	Daily Dose (mg)
Acetaminophen	Tylenol and others	325–650	4000
Aspirin	Many	325–1000	4000
Diclofenac potassium	Cataflam	50–100	150–200
Diflunisal	Dolobid	250–1000	1500
Etodolac	Lodine	200–400	1200
Fenoprofen	Nalfon	200	1200
Flurbiprofen	Ansaid	50–100	200–300
Ibuprofen acid	Motrin et al.	200–800	2400 (Rx)
Ibuprofen sodium dihydrate	Fast-acting Advil	256–512	1536
Ketoprofen	Orudis	25–75	300 (Rx)
Ketorolac*	Toradol	30–60 (oral)	60
	Sprix	31.5	126 mg
Naproxen	Naprosyn	250–500	1500
Naproxen Na	Anaprox and others	220–550	1650 (Rx)

*A new package insert for ketorolac tablets includes the instructions that the drug should be used only as a transition from injectable ketorolac and for no longer than 5 days. The package insert for intranasal ketorolac states that for patients 65 years of age or older, renally impaired patients, and patients weighing less than 50 kg, the dose should be limited to 15.75 mg and the maximum daily dose should be limited to 63 mg.

Note: Cyclooxygenase-2 (COX-2) inhibitors are not included (see text). Rx, Prescription strength

Modified from Cooper SA: Treating acute dental pain, *Postgrad Dent* 2:7, 1995.

A 2002 paper represents the first systematic review comparing all endodontic pain studies evaluating oral NSAIDs.[158] The authors concluded that NSAIDs combined with other drugs (e.g., flurbiprofen with tramadol[86]) or pretreatment and posttreatment application of NSAIDs provides effective pain control. Table 6.5 lists the results of a large ongoing systematic review of the relative efficacy of analgesics in inflammatory pain conditions. Importantly, the data are generated based on postoperative patients having moderate to severe pain, and the number needed to treat (NNT) is based on the relative superiority of the analgesic over placebo for producing a 50% relief in pain. These data, therefore, constitute important, clinically relevant information for clinicians who want to compare the relative efficacy of posttreatment analgesics. Of course other issues, such as the potential adverse effects of drugs and the patient's medical history, must be considered when a treatment plan for postendodontic pain is developed.

*Analgesics are listed in descending order from most to least effective based on the NNT. The NNT reflects the superiority of an analgesic over a placebo treatment; therefore an analgesic with a lower NNT has greater efficacy than an analgesic with a higher NNT. The NNT is calculated for the proportion of patients with at least 50% pain relief over 4 to 6 hours compared with placebo in randomized, double-blind, single-dose studies in patients with moderate to severe pain. The 95% confidence interval contains the upper and lower estimates of the NNT with a 95% chance of accuracy.

†Drugs were given orally except where noted.

IM, Intramuscular; *IR*, immediate release; *NA*, not applicable

Modified from http://www.bandolier.org.uk/booth/painpag/Acutrev/Analgesics/lftab.html.

The introduction of selective inhibitors of COX-2 offered the potential for both analgesic and anti-inflammatory benefits and reduced GI irritation.[81,189]

Telegram: @dental_k

www.konkur.in

However, most selective COX-2 inhibitors have been withdrawn from the market due to prothrombic adverse effects, and the only coxib still available, celecoxib, has not received FDA approval for the treatment of acute inflammatory pain. Concern has been raised that the COX-2 inhibitors may also cause at least some GI irritation in patients with preexisting GI disease.[342]

Another major concern centers on the recognized prothrombic adverse effects of the COX-2 inhibitors. Two meta-analyses have examined the cardiovascular (CV) safety of traditional NSAIDs and COX-2 inhibitors. Kearney et al.[182] conducted a meta-analysis of 138 randomized trials, and McGettigan and Henry[224] conducted a meta-analysis of 23 controlled observational studies.[182,224] Kearney et al.[182] estimated a relative risk for CV events associated with COX-2 to be 1.42 (95% CI, 1.64 to 2.91). Naproxen was found to have no significant adverse effects on the CV system in either meta-analysis. Diclofenac (Voltaren) is a relatively COX-2–selective drug and seems to have a degree of COX-2 selectivity similar to that of celecoxib. Diclofenac was associated with increased CV events. In the randomized trial analysis, there was an increase in CV risk with high-dose ibuprofen. Based on the available data, the FDA has requested that manufacturers of all prescription products containing nonselective NSAIDs revise their product labeling to include (1) a boxed warning regarding the potential serious adverse CV events and the serious, potentially life-threatening GI adverse events associated with the use of this class of drugs; (2) a contraindication to use in patients who have recently undergone coronary artery bypass surgery; and (3) a medication guide for patients regarding the potential for CV and GI adverse events associated with the use of this class of drugs. The available data do not suggest an increased risk of serious CV events for the short-term, low-dose use of NSAIDs available over the counter, but the FDA has requested changes to the label to better inform consumers about the safe use of these products. Given this situation and reasonable alternative NSAIDs, we recommend against the use of COX-2 inhibitors for the treatment of patients with routine endodontic pain.

Limitations and drug interactions

Clinicians should educate themselves not only on the efficacy of the

Telegram: @dental_k

www.konkur.in

nonnarcotic analgesics but also on their limitations and interactions with other drugs.[45] For example, NSAIDs exhibit an analgesic ceiling that limits the maximal level of analgesia; they also induce side effects, including those affecting the GI system (3% to 11% incidence) and the CNS (1% to 9% incidence of dizziness and headache). NSAIDs are contraindicated in patients with ulcers and aspirin hypersensitivity.[199,357] They are also associated with severe GI complications, and the risk of adverse effects increases with an increasing lifetime-accumulated dose of these drugs and the concurrent intake of aspirin, steroids, or coumadin.[15,83,199,357] A strategy for avoiding GI bleeding associated with NSAIDs is to use a proton pump inhibitor (PPI). A combination of a PPI (esomeprazole magnesium) with naproxen (Vimovo, Patheon/Astrozenica, Wilmington, DE) is now available. Although this is a cost-effective approach, it does not protect the lower GI tract.[321] Another approach is to use a histamine receptor H_2 antagonist in combination with an NSAID. The combination of famotidine (an H_2-receptor antagonist) and ibuprofen (Duexis, Horizon Pharma, Northbrook, IL) was recently approved by the FDA. Also, as mentioned earlier, there is an increased CV risk with some NSAIDs, including ibuprofen.

The NSAIDs have been reported to interact with a number of other drugs (Table 6.6). Acetaminophen and opioid combination drugs are alternatives for patients unable to take NSAIDs.[65] Further information is available on the pharmacology and adverse effects of this important class of drugs.[45,63,83,115,364] Other resources are also available for the evaluation of drug interactions, including internet drug search engines such as *rxlist.com*, *Epocrates.com*, and *Endodontics.UTHSCSA.edu*.

Table 6.6

Summary of Selected Drug Interactions With Nonsteroidal Anti-inflammatory Drugs

Drug	Possible Effect
Angiotensin-converting enzyme (ACE) inhibitors	Reduced antihypertensive effectiveness of captopril (and especially indomethacin)
Anticoagulants	Increase in prothrombin time or bleeding with

Telegram: @dental_k

www.konkur.in

	anticoagulants (e.g., coumarins)
Beta blockers	Reduced antihypertensive effects (e.g., propranolol, atenolol, pindolol)
Cyclosporine	Increased risk of nephrotoxicity
Digoxin	Increase in serum digoxin levels (especially ibuprofen, indomethacin)
Dipyridamole	Increased water retention (especially indomethacin)
Hydantoins	Increased serum levels of phenytoin
Lithium	Increased serum levels of lithium
Loop diuretics	Reduced effectiveness of loop diuretics (e.g., furosemide, bumetanide)
Methotrexate	Increased risk of toxicity (e.g., stomatitis, bone marrow suppression)
Penicillamine	Increased bioavailability (especially indomethacin)
Sympathomimetics	Increased blood pressure (especially indomethacin with phenylpropanolamine)
Thiazide diuretics	Reduced antihypertensive effectiveness

Data from Facts and Comparisons: *Drug facts and comparisons*, ed 54, St Louis, 2000, Facts and Comparisons; Gage T, Pickett F: *Mosby's dental drug reference*, ed 5, St Louis, 2000, Mosby; and Wynn R, Meiller T, Crossley H: *Drug information handbook for dentistry*, Hudson, OH, 2000, Lexi-Comp.

Acetaminophen

Acetaminophen (*N*-acetyl *p*-aminophenol) is one of the most commonly used analgesic and antipyretic drugs. Acetaminophen alone is not comparable with ibuprofen in relieving moderate to severe pain; however, a combination of ibuprofen and acetaminophen provides greater pain relief than either drug alone, as evidenced by large systematic reviews.[238] In a randomized double-blind placebo-controlled study, patients who had undergone pulpectomy were administered a single dose of either a combination of acetaminophen (1000 mg) and ibuprofen (600 mg) or ibuprofen (600 mg) alone. The combination of the two analgesics provided greater pain relief in the immediate postoperative period (8 hours) than ibuprofen (600 mg) alone.[230]

Acetaminophen is one of the most common drugs found in combination products for the relief of pain and symptoms of cold or flu. It is considered safe when taken at normal doses; in higher doses, however, acetaminophen causes liver toxicity and is associated with nearly half of the cases of acute

Telegram: @dental_k

www.konkur.in

liver failure in the United States.[201] Most acetaminophen is conjugated in the liver to form inactive metabolites. A small portion is metabolized by the cytochrome P450 system to form *N*-acetyl-*p*-benzoquinone imine (NAPQI), which is very toxic but is generally detoxified by glutathione and converted into nontoxic compounds. Large doses of acetaminophen saturate the main route of metabolism, causing more acetaminophen to be converted to NAPQI. Liver injury occurs once glutathione becomes depleted and NAPQI is allowed to accumulate. To minimize this risk, it has been recommended that healthy adults not take more than 3 g (3000 mg) of acetaminophen in a 24-hour period (*www.tylenolprofessional.com/extra-strength-tylenol-dosage-faq.html*). The FDA requires a boxed warning to be added to the label of all oral prescription drug products that contain acetaminophen. (A boxed warning, the strongest warning that the FDA requires, indicates that the drug carries a significant risk of serious adverse effects.)

Opioid analgesics

Opioids are potent analgesics and are often used in dentistry in combination with acetaminophen, aspirin, or ibuprofen. Most clinically available opioids activate mu opioid receptors at several important sites in the brain and on afferent neurons. Studies indicate that they activate peripheral opioid receptors in dental pulp and that IL injection of morphine significantly reduces pain in endodontic patients and in other inflammatory pain states.[84,97,143] Gender-dependent differences appear to exist in response to at least the kappa opioid agonists.[122] In a randomized controlled clinical trial, women taking a combination of pentazocine and naloxone had significantly less postoperative endodontic pain than men taking the same medications.[294]

Although opioids are effective as analgesics for moderate to severe pain, it is important to remember that they have no anti-inflammatory effects and as such will have no effect on the inflamed periapical tissues. The current opioid epidemic in the United States highlights the risks associated with even a single prescription of opioids—that is, opioid diversion, their misuse, and the development of opioid use disorders. Adverse effects associated with these drugs include nausea, emesis, dizziness, drowsiness, and the potential for respiratory depression and constipation. Because the dosage is limited by side

Telegram: @dental_k

www.konkur.in

effects, these medications are almost always used in combination drugs to manage dental pain. A combination formulation is preferred because it permits a lower dose of the opioid, thereby reducing side effects (Table 6.7).

Table 6.7

Selected Opioid Combination Analgesic Drugs

Formulation	Trade Name*	Possible Rx
APAP 300 mg and codeine 30 mg	Tylenol with codeine no. 3	2 tabs q4h
APAP 500 mg and hydrocodone 5 mg	Vicodin, Lortab 5/500	1–2 tabs q6h
APAP 325 mg and oxycodone 5 mg	Percocet	1 tab q6h
APAP 500 mg and oxycodone 5 mg	Tylox	1 tab q6h
ASA 325 mg and codeine 30 mg	Empirin with codeine no. 3	2 tabs q4h
ASA 325 mg and oxycodone 5 mg	Percodan	1 tab q6h

*Several generics are available for most formulations.

APAP, Acetaminophen; *ASA*, acetylsalicylic acid (aspirin); *Rx*, prescription.

Codeine is often considered the prototype opioid for orally available combination drugs. Most studies have found that the 60-mg dose of codeine (the amount in two tablets of Tylenol with codeine no. 3) produces significantly more analgesia than placebo, although it often produces less analgesia than either aspirin 650 mg or acetaminophen 600 mg.[65,66] In general, patients taking only 30 mg of codeine report about as much analgesia as those taking a placebo.[22,334] Table 6.8 provides comparable doses of other opioids equivalent to 60 mg of codeine.

Table 6.8

Corticosteroids

Posttreatment pain or a flare-up after endodontic treatment can be attributed to inflammation, infection, or both in the periradicular tissues. Establishing patency and subsequently debriding and shaping the root canal system may irritate the periradicular tissues and inadvertently introduce bacteria, bacterial products, necrotic pulp tissue, or caustic irrigating solution through apical foramina.

In response to this irritation, inflammatory mediators (e.g., PGs, leukotrienes, bradykinin, platelet-activating factor, substance P) are released into the tissues surrounding the apical area of the tooth. As a result, pain fibers are directly stimulated or sensitized, and an increase in vascular dilation and permeability results in edema and increased interstitial tissue pressure.

Glucocorticosteroids are known to reduce the acute inflammatory response by suppressing vasodilation, the migration of polymorphonuclear (PMN) leukocytes, and phagocytosis and by inhibiting the formation of arachidonic acid from neutrophil and macrophage cell membrane phospholipids, thus blocking the COX and lipoxygenase pathways and respective synthesis of PGs and leukotrienes. It is not surprising that a number of investigations have evaluated the efficacy of corticosteroids (administered via either intracanal or systemic routes) in the prevention or control of postoperative endodontic pain or flare-ups.[217]

Intracanal administration

Several studies have evaluated the intracanal administration of steroids.[51,243,333] A large-scale clinical trial of 223 patients reported significantly less posttreatment pain in patients after intracanal administration of Ledermix (triamcinolone acetonide and demeclocycline HCl) compared with either calcium hydroxide or no intracanal dressing.[93] Intracanal steroids appear to have significant effects for reducing postoperative pain.[287]

Systemic administration

Some studies have evaluated the systemic route of administration of corticosteroids on posttreatment pain or flare-ups.[181,204,218]

In a double-blind placebo-controlled study, patients with irreversible pulpitis were given 4 mg of dexamethasone or placebo by means of a supraperiosteal injection at the apex of the treated tooth after pulpectomy.[229] This is an injection technique that most clinicians would be familiar with (as opposed to intramuscular injection). Posttreatment pain was significantly reduced in the steroid group during the first 24 hours. There was no difference at 48 hours.

Yet another study evaluated the effect of IO injection of methylprednisolone or placebo in patients with irreversible pulpitis. Highly significant pain reduction in the steroid group was maintained for 7 days after a single injection.[123]

Animal studies have histologically evaluated the anti-inflammatory effects of corticosteroids on inflamed periradicular tissues. In one study, after an acute inflammatory reaction was induced in the molar teeth of rats by overextending endodontic instruments, sterile saline or dexamethasone was infiltrated supraperiosteally into the buccal vestibule adjacent to the treated teeth. Dexamethasone significantly reduced the number of neutrophils present and thus had an anti-inflammatory effect on the periradicular tissues of the treated teeth.[246]

Other studies of systemic administration have evaluated the effect of oral administration of corticosteroids on the incidence and severity of posttreatment endodontic pain. In a double-blind controlled clinical trial, 50 patients randomly received either 0.75 mg of dexamethasone or a placebo tablet orally after initial endodontic treatment.[196] Oral dexamethasone significantly reduced posttreatment pain after 8 and 24 hours compared with

Telegram: @dental_k

www.konkur.in

placebo. A follow-up study evaluated the effect a larger oral dose of dexamethasone (i.e., 12 mg given every 4 hours) on the severity of posttreatment endodontic pain.[125] Results showed that dexamethasone was effective in reducing posttreatment endodontic pain up to 8 hours after the treatment was completed; no effect on the severity of pain was seen at 24 and 48 hours after treatment. In a double-blind study comparing etodolac and dexamethasone, the perioperative administration of oral dexamethasone was similar to that of etodolac in reducing pain after endodontic surgery. In a randomized clinical trial,[206] 40 patients received a single dose of prednisolone (30 mg) or placebo 30 minutes before initiation of endodontic treatment. Prednisolone significantly reduced posttreatment pain at 6, 12, and 24 hours compared to placebo.[164]

Collectively, these studies on systemic steroid administration indicate that corticosteroids reduce the severity of posttreatment endodontic pain compared with placebo treatment. However, given the relative safety/efficacy relationship between steroids and NSAIDs, most investigators choose an NSAID as the drug of first choice for postoperative pain control.

Of note is an interesting study reporting that 17.7% of patients on steroid therapy developed dentin hypersensitivity–like pain.[308] A positive correlation was noted between the steroid dose and pain scores. Discontinuation of the steroids resolved the pain in all the study subjects.

Antibiotics

Because bacteria are involved in endodontic cases with apical periodontitis, the incidence of a posttreatment infection or flare-up is a concern to clinicians providing endodontic treatment. Prescribing an antibiotic to prevent such an occurrence might make sense, but the use of antibiotics is controversial for several reasons.[102] First, the overprescribing of antibiotics, especially when these drugs are not indicated, has led to increased bacterial resistance and patient sensitization. Second, antibiotics have been mistakenly prescribed for patients with severe pain who have a vital tooth (i.e., when bacteria are unlikely to be a causative factor in periradicular pain).[367] Third, even when bacteria are likely to be present, data from controlled clinical trials provide little or no support for the hypothesis that antibiotics reduce pain.[183]

Telegram: @dental_k

www.konkur.in

A series of clinical studies evaluated the efficacy of prophylactically administered systemic antibiotics for preventing posttreatment endodontic flare-ups. Working on the premise that the incidence of infectious flare-ups after endodontic treatment is 15%, Morse et al.[242] randomly prescribed a prophylactic dose of either penicillin or erythromycin to patients after endodontic treatment of teeth with a diagnosis of necrotic pulp and chronic periradicular periodontitis (no placebo was used). The results showed that the overall incidence of flare-ups was 2.2%, with no difference between penicillin and erythromycin. Similar results were obtained in a study in which dental students (instead of private practitioners) provided the endodontic treatment.[1] Outcomes found a 2.6% incidence of flare-ups, with no statistically significant differences between penicillin and erythromycin. However, neither the original nor the follow-up study was a randomized placebo-controlled clinical trial. This observation appears to be highly significant for clinical recommendations because in general, randomized controlled studies fail to detect any analgesic benefit from antibiotics, whereas open-label or historical control studies often report profound effects.[102]

To determine whether the timing of administration of an antibiotic altered the occurrence of flare-ups and pain unassociated with flare-ups, researchers analyzed components of two separate prospective studies of patients undergoing endodontic treatment for teeth with necrotic pulps and chronic periradicular periodontitis. In the first study, prophylactic penicillin was provided; in the second study, patients were instructed to take penicillin (or erythromycin if they were allergic to penicillin) at the first sign of swelling.[241,242] The authors concluded that prophylactic administration of antibiotics is preferable to having the patient take antibiotics at the first sign of an infection.

In a multicenter two-part clinical study, 588 consecutive patients received one of nine medications or placebos and were monitored for 72 hours after treatment.[331] The results showed that ibuprofen, ketoprofen, erythromycin, penicillin, and penicillin plus methylprednisolone significantly reduced the severity of pain within the first 48 hours after treatment. The second part of the study then evaluated the incidence of posttreatment pain after obturation of the same teeth in the first phase of the study.[331] Although only 411 of the

Telegram: @dental_k

www.konkur.in

original 588 patients participated in this phase, they were randomly given the same medications or placebo after completion of the obturation appointment. The incidence of posttreatment pain was lower after obturation (5.83%) than after cleaning and shaping (21.76%) of the root canal system, and no significant difference was found in the effectiveness of the various medications and placebo in controlling posttreatment pain after obturation.

Walton and Chiappinelli[345] were concerned that previous studies were uncontrolled, retrospective, or carried out on different patient groups at different times and with different treatment modalities. They conducted a randomized prospective double-blind clinical trial to test the hypothesis that an antibiotic (e.g., penicillin) can prevent a posttreatment endodontic flare-up.[345] Eighty patients with teeth that had necrotic pulp and chronic periradicular periodontitis were randomly divided into three groups. In the first two groups, either penicillin or a placebo was administered 1 hour before and 6 hours after the individual appointments on a double-blind basis. Upon completion of the individual appointments—which included debridement, shaping, and possibly obturation of the root canal system—the patients completed questionnaires at 4, 8, 12, 24, and 48 hours. No significant difference was found among the three groups in the incidence of flare-ups, pain, or swelling. The authors concluded that the use of prophylactic penicillin offers no benefit for postoperative pain or flare-up, and prophylactic administration of penicillin should not be used routinely in patients undergoing endodontic treatment of necrotic teeth and chronic periradicular periodontitis.

In another randomized prospective placebo-controlled clinical study, a group of investigators examined whether supplemental penicillin reduced symptoms or shortened the course of recovery of emergency patients diagnosed with necrotic pulp and acute apical abscess.[103] Patients were randomly given penicillin, a placebo, or no medication. Using a visual analog scale, the subjects then evaluated their postoperative pain and swelling for up to 72 hours. No significant difference was found among the three groups. Recovery occurred as a result of endodontic treatment alone.

It is well recognized that antibiotics may be indicated for the management of infections of endodontic origin. However, a review of the available literature indicates that prophylactic use is contraindicated in

Telegram: @dental_k

www.konkur.in

immunocompetent patients with no systemic signs of infection and with swelling localized to the vestibule. Controlled clinical studies indicate that antibiotics offer little or no benefit for pain reduction under these circumstances, but they may be indicated for immunocompromised patients and for patients with systemic signs and symptoms of an infection or an infection that has spread into the fascial spaces of the head and neck.

Pain management strategies

When pain in an individual patient is being managed, the skilled clinician must customize the treatment plan, balancing the general principles of endodontics, mechanisms of hyperalgesia, and pain management strategies with the particular factors of the individual patient (e.g., medical history, concurrent medications).[147,184,185,291,313]

Effective management of endodontic pain starts with the "three Ds": *diagnosis*, *definitive* dental treatment, and *drugs* (Box 6.1). Comprehensive reviews on *diagnosis* and *definitive* dental treatment (e.g., incision and drainage, pulpectomy) are provided elsewhere in this text. As described earlier in this chapter, the management of endodontic pain should focus on the removal of peripheral mechanisms of hyperalgesia and allodynia (see Box 6.1). This generally requires treatment that removes and reduces causative factors (e.g., bacterial and immunologic factors). For example, both pulpotomy and pulpectomy have been associated with substantial reduction in patient reports of pain compared to pretreatment pain levels.[86,150,222,263] However, pharmacotherapy is often required to reduce continued nociceptor input (e.g., NSAIDs, local anesthetics) and suppress central hyperalgesia (e.g., NSAIDs, opioids).

Box 6.1

Considerations for Effective "Three D" Pain Control

1. Diagnosis
2. Definitive dental treatment
3. Drugs

Telegram: @dental_k

www.konkur.in

- Pretreatment with nonsteroidal anti-inflammatory drugs or acetaminophen when appropriate.
- Use of long-acting local anesthetics when indicated.
- Use of a flexible prescription plan.
- Prescription “by the clock” rather than as needed.

Pretreatment

Treatment with an NSAID before a procedure has been shown to have a significant benefit in many studies[80,162] but not all.[245] The rationale for pretreatment is to block the development of hyperalgesia by reducing the input from peripheral nociceptors. For patients who cannot take NSAIDs, pretreatment with acetaminophen has also been shown to reduce postoperative pain.[236] Patients can be pretreated 30 minutes before the procedure with either an NSAID (e.g., ibuprofen 400 mg or flurbiprofen 100 mg) or acetaminophen 1000 mg.[86,162,236]

Long-acting local anesthetics

A second pharmacologic approach for pain management is the use of long-acting local anesthetics, such as bupivacaine and ropivacaine. Clinical trials indicate that long-acting local anesthetics not only provide anesthesia during the procedure but also significantly delay the onset of posttreatment pain compared with local anesthetics that contain lidocaine.[80,130,131,166] Administration of long-acting local anesthetics by block injection has been shown to reduce posttreatment pain for 2 to 7 days after the oral procedure[130,131,166] because an afferent barrage of nociceptors can induce central hyperalgesia.[360–362] The analgesic benefit of long-acting local anesthetics is more prominent with block injections than infiltration injections, but the clinician should also be aware of adverse effects attributed to these agents.[18,235]

Flexible plan

A third pharmacologic approach is the use of a flexible plan for prescribing analgesics (Fig. 6.21).[13,66,142,144,147,184,186,334] A flexible prescription plan serves to minimize both postoperative pain and side effects. Given these

Telegram: @dental_k

www.konkur.in

goals, the clinician's strategy is twofold: (1) to achieve a maximally effective dose of the nonnarcotic analgesic (either an NSAID or acetaminophen for patients who cannot take NSAIDs) and (2) in the rare cases in which the patient still has moderate to severe pain, to consider adding drugs that increase the NSAID's analgesia. Because of its predictive value, the presence of preoperative pain or mechanical allodynia may be an indicator that such NSAID combinations should be considered.

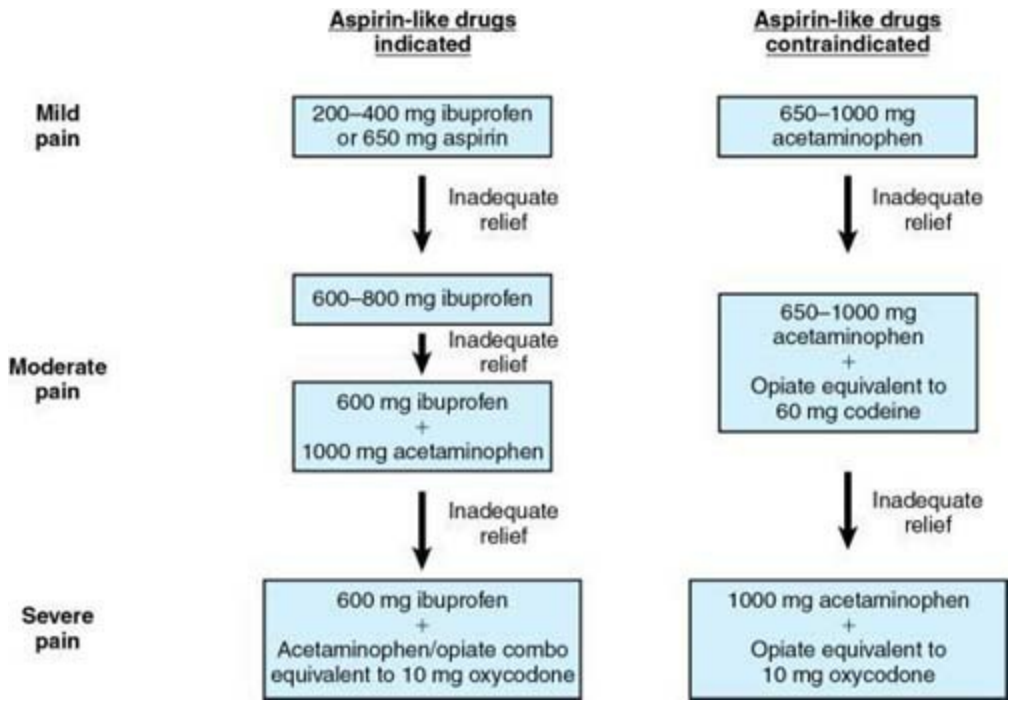

FIG. 6.21 A flexible analgesic strategy.

Schematic of analgesic strategy is as follows: Aspirin-like drugs indicated: mild pain: 200–400 mg ibuprofen or 650 mg aspirin leads to inadequate relief, 600–800 mg ibuprofen again leads to inadequate relief. Moderate pain: 600 mg ibuprofen plus 1000 mg acetaminophen leads to inadequate relief. Severe pain: 600 mg ibuprofen plus Acetaminophen/opiate combo equivalent to 10 mg oxycodone.

Aspirin-like drugs contraindicated: Mild pain: 650–1000 mg 650–1000 mg acetaminophen leads to inadequate relief. Moderate pain: 650 to 1000 mg acetaminophen plus Opiate equivalent to 60 mg codeine. Severe pain: 1000 mg acetaminophen plus opiate equivalent to 10 mg oxycodone.

Most studies report that combining an NSAID with acetaminophen 1000

Telegram: @dental_k

www.konkur.in

mg alone (i.e., no opioid) produces nearly twice the analgesic response as just the NSAID.[37,68,230,350] Administration of ibuprofen 600 mg with acetaminophen 1000 mg produced significant relief of posttreatment endodontic pain compared with ibuprofen alone or placebo (Fig. 6.22). However, in a recent study, the analgesic effect of a combination of ibuprofen 600 mg with acetaminophen 1000 mg did not differ from that of acetaminophen alone.[350] Studies have also shown that concurrent administration of an NSAID and an acetaminophen-opioid combination drug provided significantly greater analgesia than an NSAID alone.[37,323] The concurrent administration of acetaminophen and NSAID appears to be well tolerated, with no detectable increase in side effects or alterations in pharmacokinetics.[37,200,323,363]

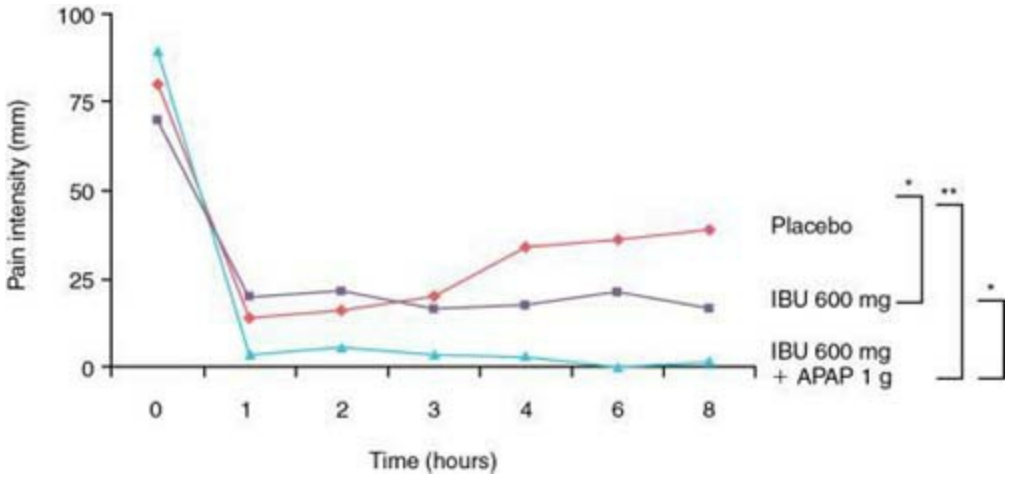

FIG. 6.22 Comparison of ibuprofen *(IBU)* 600 mg plus acetaminophen *(APAP)* 1000 mg with IBU alone or to placebo treatment in postendodontic pain patients.

Graph shows pain intensity (VAS) against time in minutes. The vertical axis ranges from 0 to 100. The horizontal axis ranges from 0 (away from the origin) to 8. The data points for placebo, IBU 600 mg, IBU 600 mg plus APAP 1 g are represented by diamond, square, and triangular blocks, respectively. Three lines connect the data points. The first line representing placebo originates from (0, 80), slopes down, and reaches at (1, 15). The line further moves up, reaches (4, 30), and terminates at (8, 31). The second line of IBU 600 mg originates from (0, 73), intersects the first line at (0. 8, 44), slopes down, fluctuates horizontally, and terminates at (8, 22). The third line of IBU 600 mg plus APAP 1 g originates from (0.3, 88), intersects the first two lines, reaches (1, 2), and terminates at (8, 1). All data are approximate.

Source: (From Menhinick KA, Gutmann JL, Regan JD, et al: The efficacy of pain control following nonsurgical root canal treatment using ibuprofen or a combination of ibuprofen and acetaminophen in a randomized, double-blind, placebo-controlled study, *Int Endod J* 37:531, 2004.)

In rare cases of severe pain, an NSAID may need to be administered with an opioid. Two general methods are used to combine NSAIDs and opioids to achieve the analgesic benefits of both. The first involves an alternating regimen of an NSAID followed by an acetaminophen-opioid combination.[13,66] Aspirin and opioid combinations are not used in this alternating schedule because of the potential for NSAID/aspirin interactions. The second method involves administration of a single drug consisting of an NSAID-opioid combination. For example, postoperative pain studies have shown that the combination of 200 mg of ibuprofen and 7.5 mg of hydrocodone (Vicoprofen) was about 80% more effective for analgesia than the ibuprofen alone, with about the same incidence of side effects.[353] Other opioids can be added to an NSAID for increased analgesia. A study on posttreatment endodontic pain demonstrated short-term benefits of the combination of flurbiprofen and tramadol.[86] Other NSAID and opioid combinations have also been evaluated.[83] However, the results of clinical trials on the use of NSAIDs alone and NSAIDs combined with acetaminophen (see Fig. 6.22) suggest that opioid combinations may be required only rarely.

Not all patients require concurrent use of NSAIDs with acetaminophen-opioid combinations or combinations of an NSAID and opioid. The basic premise of a flexible prescription plan is that the analgesic prescribed is matched to the patient's need. The major advantage of a flexible plan is that the clinician is prepared for those rare cases when additional pharmacotherapy is indicated to increase the efficacy of pain control. As mentioned, preoperative hyperalgesia may be an indicator for more comprehensive pharmacotherapy. When the clinician is considering the combination of various analgesics, she or he must make sure to use dosing regimens that do not exceed any of the drugs' maximal daily dosage.

Future directions

Telegram: @dental_k

www.konkur.in

COX-inhibiting nitric oxide (NO) donators (CINODs), a new class of NSAIDs, have a NO-donating moiety. These drugs, also known as NO-NSAIDs, were developed with the idea that the released NO would lead to improved vascular tone and mucosal blood flow, thus attenuating the adverse effects of NSAIDs on GI mucosa and blood pressure. Although none of the CINODS have yet been approved by the FDA, they may be available in the near future.

Current use of analgesics has been driven by clinical trials to arrive at doses that obtain the desired level of pain relief with acceptable side-effect profiles. After administration, drugs are absorbed and distributed to their site of action, where they interact with functional targets. They then undergo metabolism and eventual excretion. All of the steps along the way are influenced by a variety of environmental and genetic factors. The ability to predict how a patient's genome may affect the efficacy of a given analgesic drug is being discovered in the field of pain pharmacogenomics (for a review, see Rollason et al.[288]).

One example relevant to pain control in dentistry is the variable efficacy of codeine in a specific population. Many analgesic drugs are metabolized by the cytochrome P450 (CYP) family of hepatic enzymes, and the genes that encode for their biosynthesis have been identified. Codeine is a prodrug that is demethylated to produce morphine, which is responsible for its analgesic action. This demethylation is catalyzed by the enzyme cytochrome P402D6. It has been estimated that 6% to 7% of the Caucasian population has a nonfunctional CYP2D6 mutant allele, making them poor metabolizers of codeine to morphine.[79] These patients may be aware from past experience that codeine is ineffective in their systems and may request a different (usually more potent) form of narcotic. The clinician may suspect drug-seeking behavior when in fact there is a biochemical reason for such a request. Given the current state of clinical DNA analysis, it is not incomprehensible to envision a time when rapid (chairside) genomic evaluation will lead to specific recommendations for analgesic prescriptions.

Summary

The information and recommendations provided in this chapter were selected

Telegram: @dental_k

www.konkur.in

to aid the clinician in the management of acute endodontic pain. Clinical judgment must also take into account other sources of information—the patient history, concurrent medications, the nature of the pain, and the overall treatment plan—when the best means of alleviating patient pain are being determined. An effective approach to managing endodontic pain demands integration of the general principles of pain mechanisms and management with thorough, individualized clinical assessment.

*Any discussion of local anesthesia over the last 40 years would inevitably lead to conversations surrounding the work of Dr. Al Reader. Although this chapter no longer bears his name, it is based on his tireless efforts, astute research mind, and never-ending quest to provide positive patient experiences in dentistry through clinical research. The authors would like to thank Dr. Reader for all of his contributions to local anesthesia and for being the guiding force that has inspired countless others to continue in the search for better local anesthesia and pain control.

7: Tooth morphology and pulpal access cavities

James L. Gutmann, Bing Fan

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Telegram: @dental_k

www.konkur.in

The dental pulp presents with a variety of configurations and shapes throughout the dentition. Knowledge of the complexity of the root canal system is essential to understand the principles and problems encountered in access preparation from a traditional and contemporary standpoint. This chapter describes and illustrates current perspectives on tooth morphology and explains the techniques necessary to achieve direct access to the root canal system.

Initial anatomical evaluation of the pulpal anatomy is achieved with careful evaluation of two or more periapical radiographs, exposed at different horizontal angulations of the x-ray cone, and is essential, along with cone-beam computed tomography (CBCT) scans in some clinical situations (see Chapter 2). The detailed reading and interpreting of each radiograph before

Telegram: @dental_k

www.konkur.in

and during root canal procedures is necessary because many teeth present with unusual canal morphology. Unfortunately, the interpretation of traditional radiographs may not always result in the correct morphologic assessment, particularly when only a buccolingual view is taken. Furthermore, the recent development of microcomputed tomography (μCT) scanning of teeth has greatly increased clinical assessment of these complexities and three-dimensional (3D) relationships found in root canal systems. Therefore the use of a vast array of tools, such as magnification and illumination, is essential. This approach is particularly helpful in posterior teeth, where a vast array of anatomical complexities can be observed (Fig. 7.1).

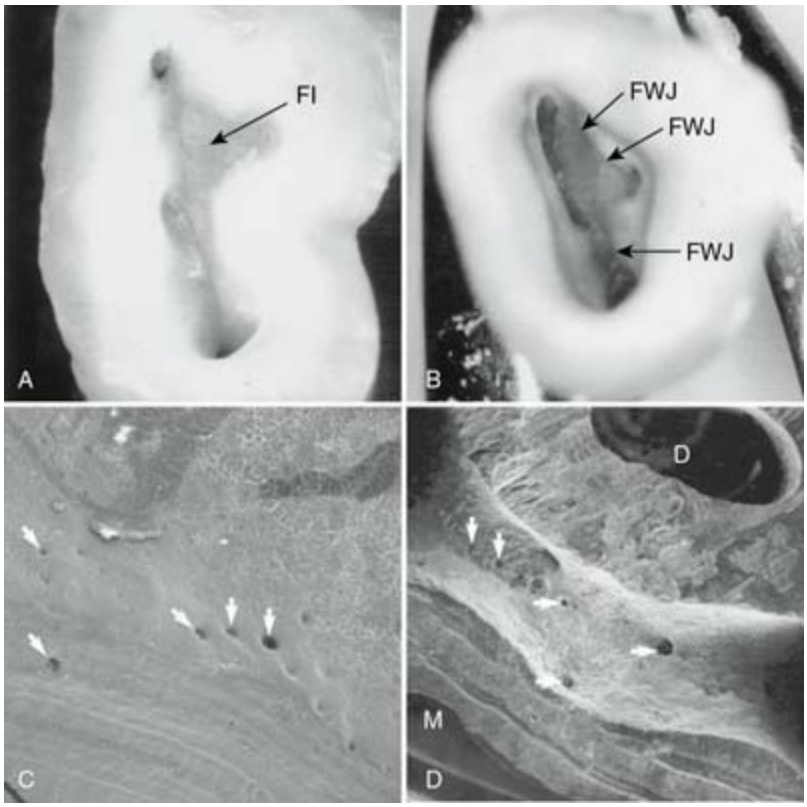

FIG. 7.1 **A,** The color of the pulp chamber floor *(FI)* is always darker than the walls. The orifices are usually located at the junction of the walls and the floor *(FWJ)*. **B,** The same is true for the maxillary first premolar. **C,** Electron photomicrograph of the pulp chamber floor of a mandibular first molar (×20). **D,** Electron photomicrograph of the furcation surface of a mandibular first molar (×30). *D,* Distal canal; *M,* mesial canals; *arrows*, accessory foramina. 2004.)

A) Cut specimen of a tooth shows dark chamber, marked FI.

B) Cut specimen of the first premolar shows the junction between light periphery tissues and a dark chamber inside, marked FWJ.

C) Electron photomicrograph of first molar shows holes in the pulp.

D) Electron photomicrograph of first molar shows well-defined dark patches in mesial and distal canals. The central diagonal strip has perforated tissue with holes.

The use of the dental operating microscope (DOM) that provides superior magnification, increased lighting, and enhanced visibility is recommended to determine the location of root canal orifices in the properly prepared coronal access (Fig. 7.2),[92,105] and has been shown to be superior to the use of the naked eye and magnifying loupes for this assessment.[11,96] As with all advances in technology, however, there are varying points of concurrence and disagreement. For example, one group of investigators determined that dental loupes and the DOM were equally effective for locating mesiopalatal canals in maxillary molars,[13] whereas other studies determined that the DOM did not significantly enhance the ability to locate canals.[34]

FIG. 7.2 The dental operating microscope (DOM) has vastly improved locating the position of the coronal canal anatomy.

www.konkur.in

A dentist with illuminated probe in gloved hands examines the teeth of a patient under DOM, with an assistant standing opposite to him.

Components of the pulp cavity

The pulp cavity (Fig. 7.3) is divided into two main portions: the pulp chamber, located in (or extending to just below) the anatomic crown of the tooth, and the root canal (or canals), found in the anatomic root. Other notable features are the pulp horns; accessory, lateral, and furcation canals; canal orifices; isthmus; fins; apical deltas; and apical foramina. The outline of the pulp cavity generally corresponds to the external contour of the tooth. However, factors such as physiologic aging, pathosis, trauma, and occlusion all can modify its dimensions through the production of dentin or reparative (irregular secondary, irritational, and tertiary) dentin (Fig. 7.4).[100]

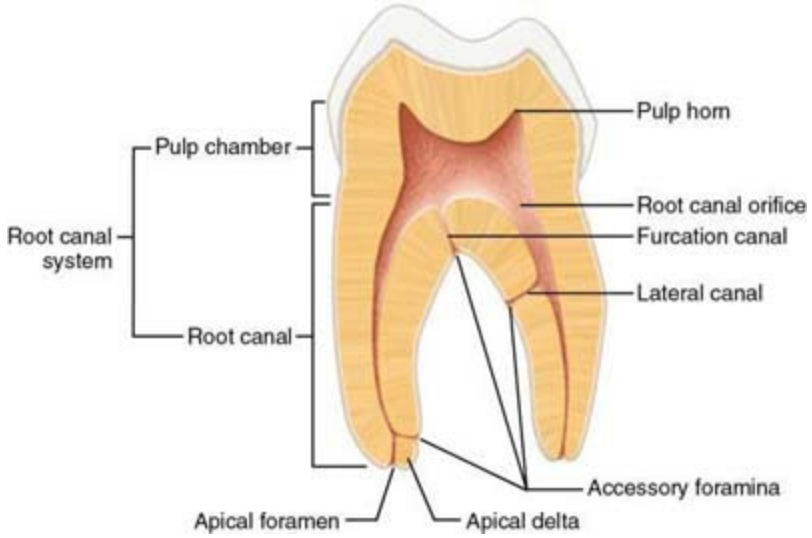

FIG. 7.3 Major anatomic components of the pulp cavity.

Cross-section diagram of a tooth shows labels for pulp horn, root canal orifice, furcation canal, lateral canal, accessory foramina, apical delta, apical foramen, Root canal system: pulp chamber and root canal.

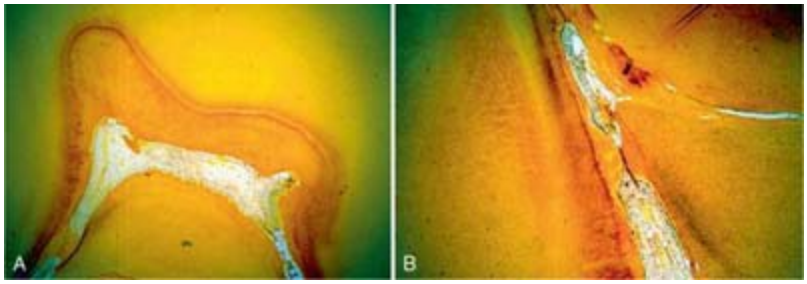

FIG. 7.4 **A,** Formation of reparative dentin and reduction of the pulp chamber space. **B,** Calcific narrowing and closing of a root canal as it leaves the pulp chamber.

A) Tooth shows a heart shaped crown with pulp below.

B) Tooth shows wedge shaped root canal closed at the center.

Source: (From Gutmann JL, Lovdahl PE: *Problem solving in endodontics*, ed 5, St. Louis, 2011, Elsevier.)

In single-rooted teeth, pulp chamber extends to the most apical portion of the cervical margin of the crown; in double/multirooted teeth, it extends to the floor of chamber located in the coronal third of the root.[2] The pulp horns are important because the pulp in them is often exposed by caries, trauma, or mechanical invasion, which usually necessitates vital pulp or root canal procedures. Also, the pulp horns undergo rapid mineralization, along with reduction of the size and shape of the pulp chamber because of the formation of reparative/irritational dentin over time.

The root canal begins as a funnel-shaped canal orifice, generally at or just apical to the cervical line, and ends at the apical foramen (AF), which opens onto the root surface at or within 3 mm of the center of the root apex.[14,35,36,87,113,115] Nearly all root canals are curved, particularly in a faciolingual direction, thereby posing problems during enlargement and shaping procedures because they are not evident on a standard two-dimensional (2D) radiograph. In most cases, the number of root canals corresponds to the number of roots; however, an oval root may have more than one canal.

Accessory canals are minute canals that extend in a horizontal, vertical, or lateral direction from the pulp space to the periodontium. In 74% of cases they are found in the apical third of the root, in 11% in the middle third, and in 15% in the cervical third.[113] The diameter, length, shape, and undulation

Telegram: @dental_k

www.konkur.in

may vary among accessory canals.[122] Apical deltas are multiple accessory canals that branch out from the main canal at or near the root apex (Figs. 7.5 and 7.6) (see Videos 7.1 and 7.2 online at the Expert Consult site). Accessory canals contain connective tissue and vessels but may not supply the pulp with sufficient circulation to form a collateral source of blood flow. They are formed by the entrapment of periodontal vessels in Hertwig's epithelial root sheath during mineralization.[24] They may play a significant role in the communication of disease processes, serving as avenues for the passage of irritants, primarily from the pulp to the periodontium, although communication of inflammatory processes may occur from either tissue.

FIG. 7.5 **A,** μCT reconstruction image of a maxillary molar showing the location of accessory canal. **B,** Morphological variations of accessory canal.

A) Maxillary molar shows the additional branched canal extending along one root canal.

B) Six types of canals are shown as follows: Wedge-shaped with the tapering end and a secondary branch near the center.

• Two pulp horns with a secondary branch near the tip.

• Triangular shape with secondary branches forming a loop near the tip.

• Curved tip with two secondary branches below the center.

Telegram: @dental_k

www.konkur.in

• Two pulp horns with multiple branches on the left.

• Fused branches with hollow chambers.

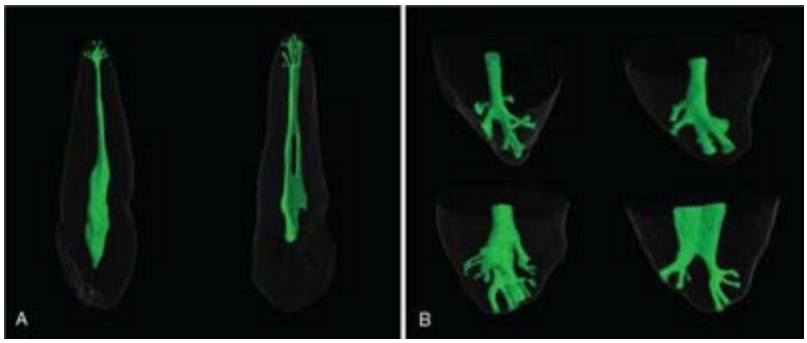

FIG. 7.6 **A,** Apical delta in maxillary canine and maxillary second premolar. **B,** Morphological variations of apical delta.

A) First tooth shows multiple branches at the root tip. Second tooth shows an oval chamber in the canal that extends from the neck.

B) Structure on top-left shows conical end with multiple branches. Structure on top-right shows a slightly diverted funnel shaped root apex with dense multiple branches. Structure on bottom-left shows a U-shaped root apex with dense fused multiple branches. Structure on bottom-right shows a U-shaped root apex that has a bifurcated canal with multiple branches.

Accessory canals that are present in the bifurcation or trifurcation of multirooted teeth are referred to as *furcation canals* (or *chamber canals*) (Fig. 7.7).[37,113,114] These channels form as a result of the entrapment of periodontal vessels during the fusion of the diaphragm, which becomes the pulp chamber floor.[24] In mandibular molars, these canals occur in three distinct patterns (Fig. 7.8) (see Expert Consult site—Tables 7.1 and 7.2). Pulpal inflammation can communicate to the periodontium via these canals and result in furcation lesions in the absence of demonstrable periodontal disease (Fig. 7.9). Likewise, the long-term presence of periodontal furcation lesions may influence the viability of the coronal or radicular pulp tissue when these aberrant channels are present.[39]

Telegram: @dental_k

www.konkur.in

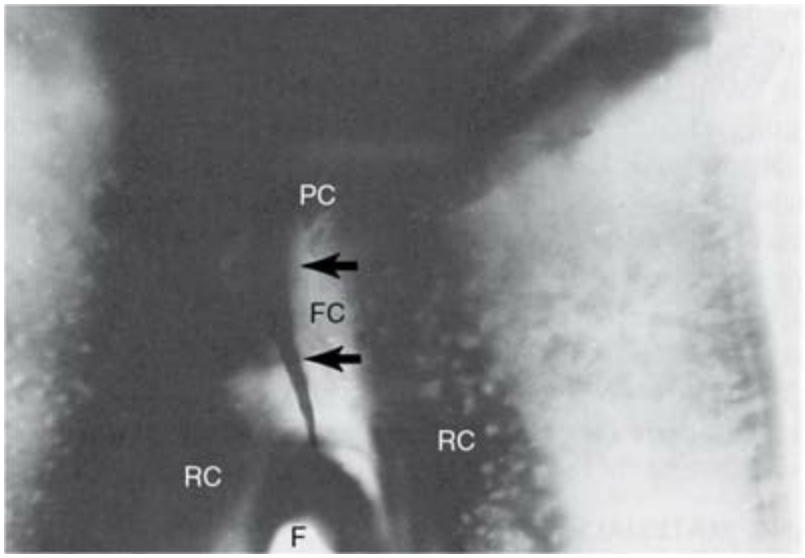

FIG. 7.7 Mandibular first molar showing a furcation canal *(FC, arrows)*. *F,* Furcation; *PC,* pulp chamber floor; *RC,* root canal.

Radiograph of first molar shows dark regions at the center, marked PC, and either sides of bifurcated root, marked RC. The light region along and in-between the root canals are marked FC and C, respectively.

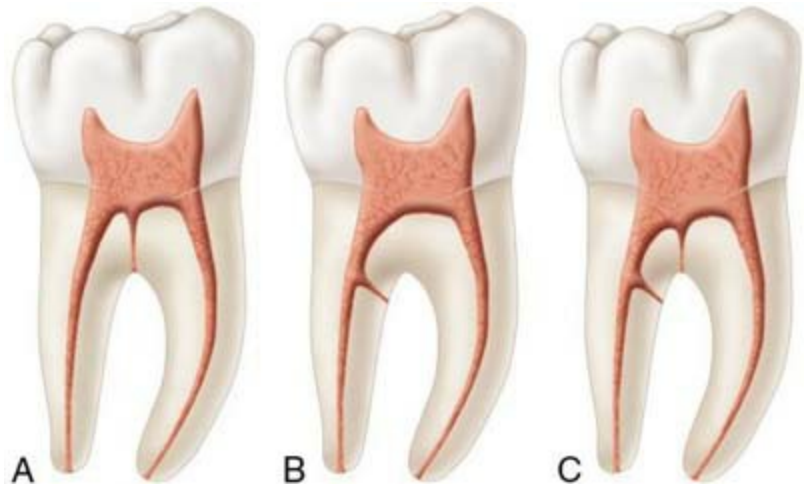

FIG. 7.8 Accessory canals occur in three distinct patterns in the mandibular first molars. **A,** In 13% a single furcation canal extends from the pulp chamber to the intraradicular region. **B,** In 23% a lateral canal extends from the coronal third of a major root canal to the furcation region (80% extend from the distal root canal). **C,** About 10% have both lateral and furcation canals.

Three models, marked A through C, show the anatomy of a double-rooted tooth with different pattern of accessory canals.

Telegram: @dental_k

www.konkur.in

FIG. 7.9 **A,** Furcation lesion. **B,** Healing occurred after treatment.

A) Radiograph shows first molar with radiopaque crown and radiolucent root canals with thin porous tissue inside.

B) Radiograph shows filled root canals of the first molar.

Root canal anatomy

The significance of canal anatomy has been underscored by studies that demonstrated that the natural variations in canal geometry had a greater effect on the changes that occurred during enlargement and shaping than did the instrumentation techniques used to achieve these objectives.[84–86] Most recently, Versiani and co-investigators have detailed the complete pulpal anatomy of the permanent dentition. In doing so they have both verified the findings of the last 125 years and have prepared the formative knowledge base for future studies.[110]

Multiple anatomic variations present in teeth are seen in Fig. 7.10. The only tooth that showed all eight possible configurations is the maxillary second premolar (see Expert Consult site—Tables 7.3 and 7.4).

Telegram: @dental_k

www.konkur.in

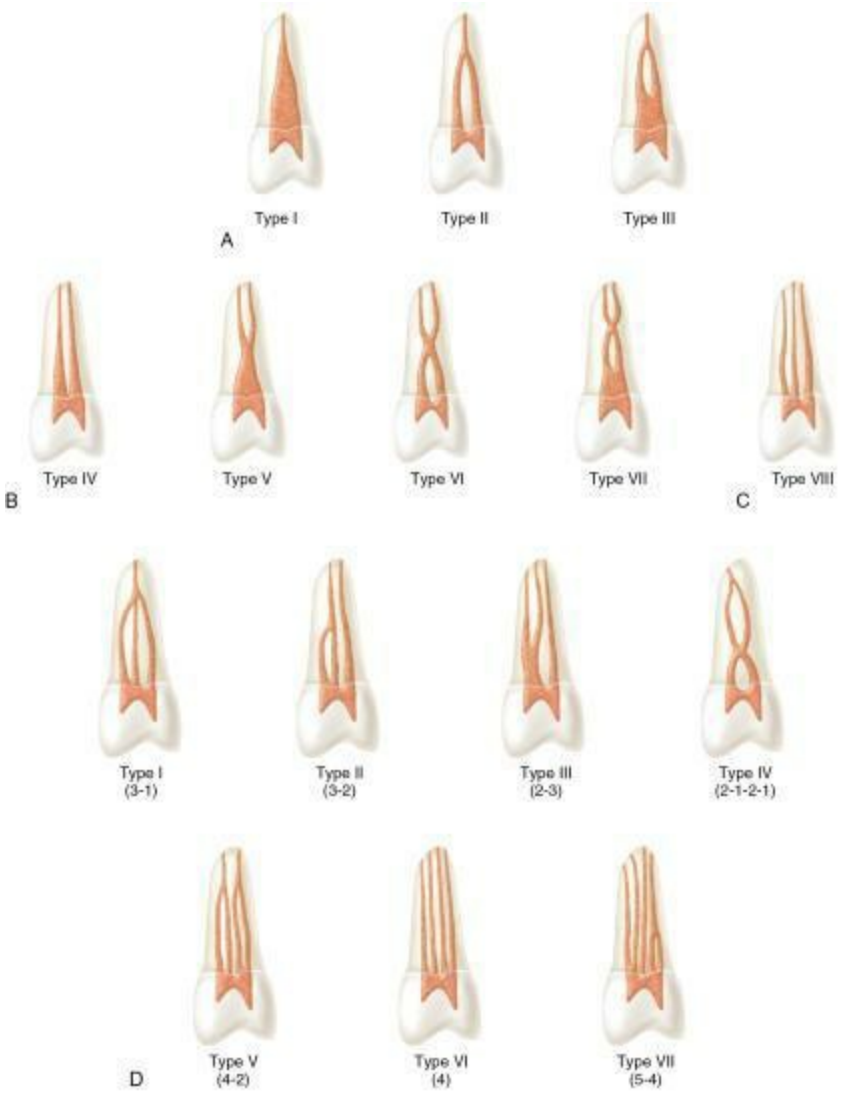

FIG. 7.10 Diagrammatic representation of canal configurations. **A,** One canal at apex based on the work of Vertucci. **B,** Two canals at apex based on the work of Vertucci. **C,** Three canals at apex based on the work of Vertucci. **D,** Supplemental canal configurations based on the work of Gulabivala and colleagues on a Burmese population.

A) Three teeth, type 1 to 3 show a large canal extending from pulp chamber to apex with two pulp horns, a large oval chamber in the single canal, and a small oval chamber near the root apex in the canal, respectively.

B) Two teeth, type 4 and type 5, show a bifurcated canal extending from the pulp chamber and the canal branched into two near the root apex, respectively.

C) Three teeth, type 6 to 8, show a large oval chamber with a bifurcation near the root apex, a small oval chamber with bifurcation toward the root apex, and trifurcation beginning from just below the pulp horns, respectively.

Telegram: @dental_k

www.konkur.in

D) Eight teeth, type 1 to 8, show bilocular canal (3-1), two root canals with an additional branch forming a loop (3-2), bifurcated canal with an additional branch at the center (2-3), two-chambered canal forming numeral 8 (2-1-2-1), canal forming two branches each with a hollow chamber (4-2), canal with four branches (4), and canal with multiple branches (5-4), respectively.

Source: (From Vertucci FJ, Seelig A, Gillis R: Root canal morphology of the human maxillary second premolar, *Oral Surg Oral Med Oral Pathol* 38:456–464, 1974.)

Similar observations have been described in large population studies with the exceptions that one canal was found in 23% of maxillary laterals, 55% of mesiobuccal roots of maxillary second molars, and 30% of distal roots of mandibular second molars.[17,119] Differences in these studies may be due to variations in the ethnic and racial populations studied. A well-recognized ethnic variant is the higher incidence of single-rooted and C-shaped mandibular second molars in Native American and Asians populations (Figs. 7.11 and 7.12),[26,27,64,65,118] which may also be seen in mandibular premolars and some maxillary molars. Recently, three classification system have been proposed, including (1) root and canal anomalies, (2) root and root canal configurations, and (3) accessory canal morphology that provides more detailed information on the morphological features of teeth and root canals essential for diagnosis and treatment, as well as training and research.[1–3]

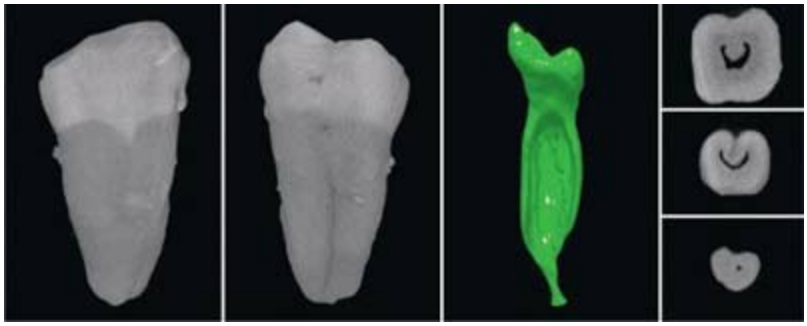

FIG. 7.11 Common variant of a C-shaped canal anatomy found in Native Americans and Asian populations.

Three models of molar are accompanied by their cross-sectional views. First molar shows a roughly U-shaped canal with two prolongations at the base. Second molar shows continuous C-shaped canal. Third molar shows a small hole at the center.

Telegram: @dental_k

www.konkur.in

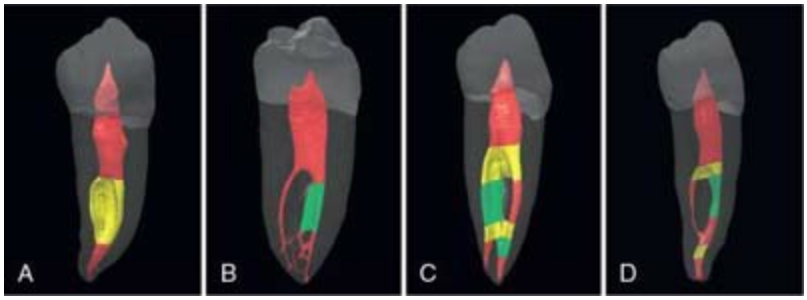

FIG. 7.12 μCT scans of mandibular premolars reflect a wide variation in canal morphology, moving from coronal to apical sections. The red color indicates a non–C-shaped canal space; green indicates a semilunar canal shape; and yellow indicates a continuous C-shaped configuration.

A) Tooth shows the canal with red color at the top, followed by yellow, and red at the base.

B) Tooth shows the canal with multiple branches toward the root apex. The canal has red region, followed by green, and again red.

C) Tooth shows the canal with an oval chamber and red region at the top, followed by yellow, green (left side)-red (right side), yellow, and red (left side)-and green followed by red (right side).

D) Tooth shows a large hollow chamber with a red region at the top, followed by yellow, red (left side)-green (right side), red, yellow, and red.

Clinical determination of the root canal configuration

Coronal considerations

Examination of the pulp chamber floor may reveal clues to the location of orifices and to the type of canal system present. If only one canal is present, it usually is located in the center of the access preparation. If only one orifice is found and it is not in the center of the root, another orifice probably exists on the opposite side (Fig. 7.13). The relationship of the two orifices to each other is also significant (Fig. 7.14). The closer they are, the greater the chance the two canals join at some point in the body of the root. As the distance between orifices in a root increases, the greater is the chance the canals will remain separate. The more separation between orifices, the less the degree of canal curvature.[19]

Telegram: @dental_k

www.konkur.in

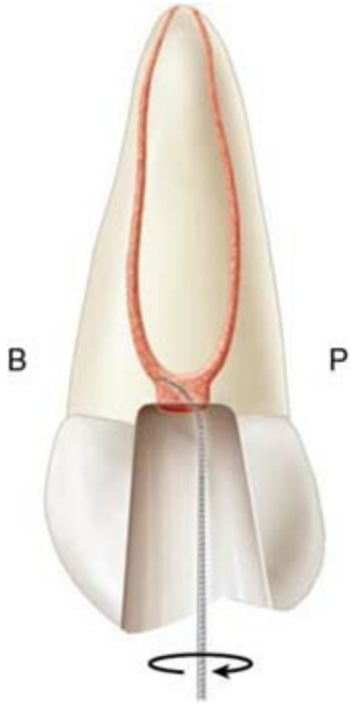

FIG. 7.13 An oval orifice must be explored with apically curved small instruments. When trying to locate the buccal canal, the clinician should place the file tip in the orifice with the tip curved to the buccal side. To explore for the palatal canal, a curved file tip is placed toward the palate. *B,* Buccal; *P,* palatal.

Tooth structure with two canals show an inverted U-shape chamber in the crown area and an instrument being inserted in the pulp. Buccal and palatal regions are marked on the left and right of the tooth, respectively.

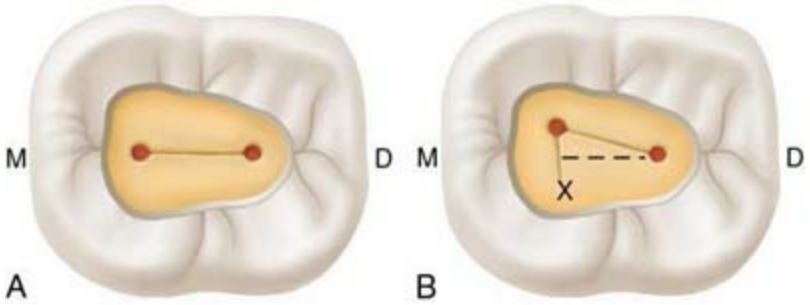

FIG. 7.14 **A,** In a mandibular second molar with two canals, both orifices are in the mesiodistal midline. **B,** If two orifices are not directly in the mesiodistal midline, a search should be made for another canal on the opposite side in the area of "X." *D,* Distal; *M,* mesial.

A) Model of molar shows two holes aligned horizontally in the pulp. The tooth

Telegram: @dental_k

www.konkur.in

is marked M on the left and D on the right.

B) Molar shows two holes aligned diagonally in the pulp. A vertical line from the first hole is labeled X. The tooth is marked M on the left and D on the right.

The direction a file takes when introduced into an orifice is also important. If the first file inserted into the distal canal of a mandibular molar points either in a buccal or lingual direction, a second canal is often present. If two canals are present, they will be smaller than a single canal. (See μCTs and cross sections of all tooth groups later in this chapter. In addition, rotational videos of these groups can be found online as Videos 7.3–7.19 at the Expert Consult site.)

Midroot considerations

As the canal leaves the coronal portion of the root and blends into the midroot portion, many changes can occur, including fins, webs, culs-de-sac, and isthmuses (also called *anastomoses*). These structures are narrow, ribbon-shaped communications between two root canals that contain pulp tissue, or they may midroot portion of the canal. Isthmuses are found in 15% of anterior teeth; in maxillary premolar teeth, they are found in 16% at the 1-mm level from the apex and in 52% at the 6-mm level, which puts them primarily in the middle third of the canal (Fig. 7.15). The prevalence of an isthmus increases in the mesiobuccal root of the maxillary first molar, from 30% to 50% near the junction of middle and apical thirds of the root. Eighty percent of the mesial roots of mandibular first molars have these communications at the apical to middle third junction, with the distal root display more in the apical third.

Telegram: @dental_k

www.konkur.in

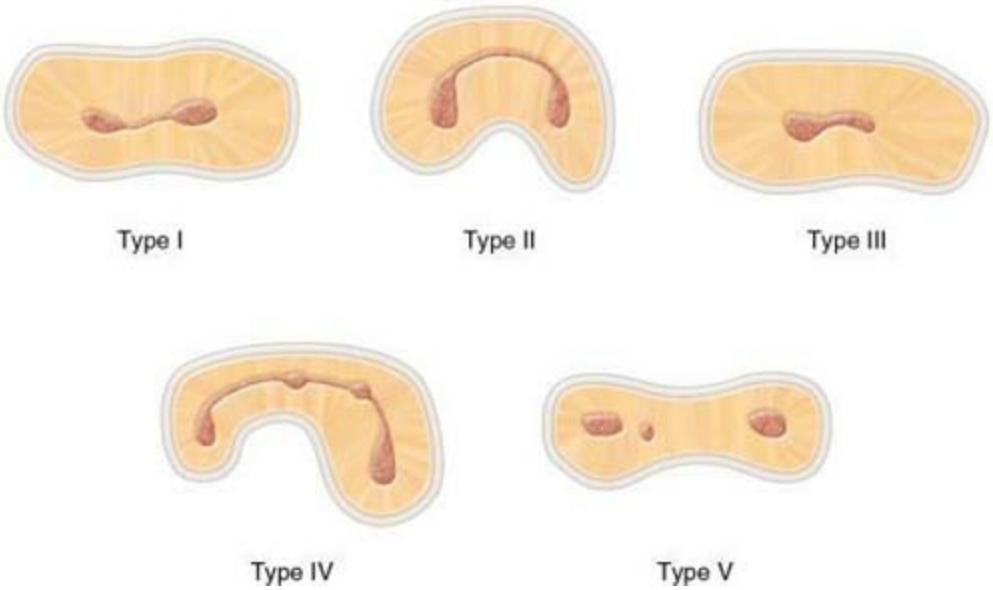

FIG. 7.15 Schematic representation of isthmus classifications described by Kim and colleagues. Type I is an incomplete isthmus; it is a faint communication between two canals. Type II is characterized by two canals with a definite connection between them (complete isthmus). Type III is a very short, complete isthmus between two canals. Type IV is a complete or incomplete isthmus between three or more canals. Type V is marked by two or three canal openings without visible connections.

Five structures, marked type 1 to 5, show a horizontal connection between two canals, inverted U-shape connection between two canals, a larger canal connected closely to a smaller canal, four connected canals, and a rectangular canal with a tiny lobe and roughly oval canal, respectively.

Source: (From Kim S, Pecora G, Rubinstein R, Dorscher-Kim J: *Color atlas of microsurgery in endodontics*, Philadelphia, 2001, Saunders.)

Another change that often occurs in the midroot portion is the splitting of a single canal into two or more canals, along with a wide variation in canal morphology. Likewise, canals often join in this area, starting coronally as two separate canals (see Fig. 7.12).

Whenever a root contains two canals that join to form one, the lingual/palatal canal generally is the one with direct access to the apex. When one canal separates into two, the division is buccal and palatal/lingual, and the lingual canal generally splits from the main canal at a sharp angle, sometimes nearly a right angle (Fig. 7.16). Although the splitting of one canal into two presents challenges, of greater concern is the very small canal that

Telegram: @dental_k

www.konkur.in

may split off, at times at almost a 90 degree angle, and cannot be located tactilely or even under magnification with the DOM. Although these canals may join the main canal at some point apically, some of them exit separately. This is not uncommon in mandibular first premolars.

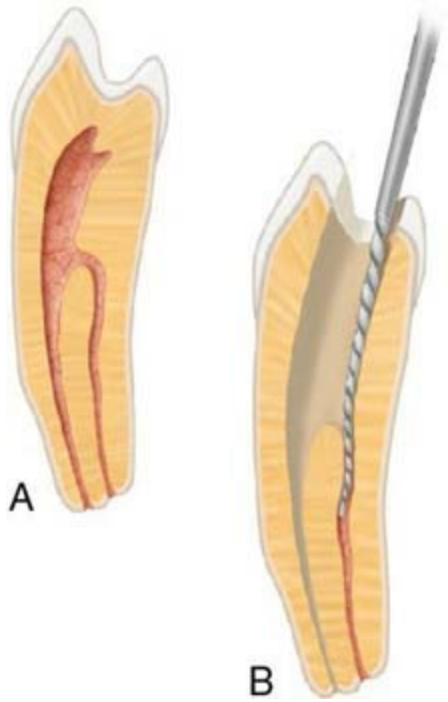

FIG. 7.16 **A,** Mesial view of a mandibular premolar with a type V canal configuration. The lingual canal separates from the main canal at nearly a right angle. **B,** This anatomy requires widening of access in a lingual direction to achieve straight-line access to the lingual canal. This should be done with a DOM.

A) Tooth shows a canal extending from pulp chamber to root apex with an additional branch.

B) Tooth shows an instrument being inserted into the additional root canal.

Apical considerations

The classic concept of apical root anatomy is based on three anatomic and histologic landmarks in the apical region of a root: the apical constriction (AC), the cementodentinal junction (CDJ), and the AF. Kuttler's description of the anatomy of the root apex has the root canal tapering from the canal orifice to the AC, which generally is 0.5 to 1.5 mm coronal to the AF (Fig.

Telegram: @dental_k

www.konkur.in

7.17).[51] The AC generally is considered the part of the root canal with the smallest diameter; it also is the reference point clinicians most often use as the apical termination for enlarging, shaping, cleaning, disinfecting, and filling. Violation of this area with instruments or filling materials is not recommended for long-term, successful outcomes.[38]

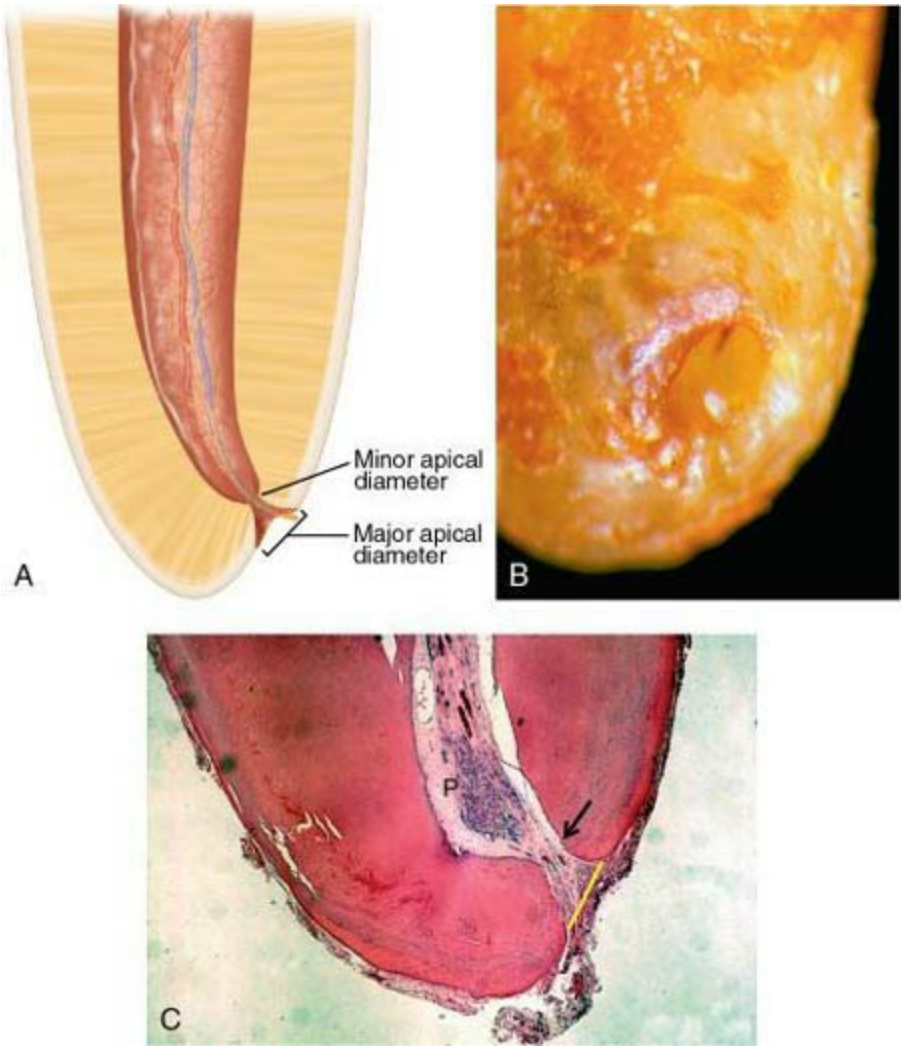

FIG. 7.17 **A**, Morphology of the root apex. From its orifice the canal tapers to the apical constriction, or minor apical diameter, which generally is considered the narrowest part of the canal. From this point the canal widens as it exits the root at the apical foramen, or major apical diameter. The space between the minor and major apical diameters is funnel shaped. **B,** Clinical view of major apical foramen. **C,** Histologic view of the apical constriction *(arrow)* and apical foramen *(yellow line)*. *P,* Pulp. A) Root of tooth shows two labels at the apex as follows: Minor apical diameter and major apical diameter.

B) Tip of the tooth root shows a large well-defined oval opening.

C) Histological view shows the shrinkage of canal slightly below the root tip.

The CDJ is the point in the canal where cementum meets dentin; it is also the point where pulp tissue ends and periodontal tissues begin (Fig. 7.18). The location of the CDJ in the root canal varies considerably. It generally is not in the same area as the AC, and estimates place it approximately 1 mm from the AF.[93,101]

FIG. 7.18 Root apex following root canal filling *(RCF)* short of the actual root length. Histologic evidence shows that hard tissue *(black arrows)* has formed from the cells of the periodontal ligament *(PDL)* adjacent to the root filling material. Cementum formation on the internal aspect of the apical foramen is indicated by the yellow arrows. These findings accentuate the variable nature of the apical tissues.

Stained micrograph shows filled root canal of tooth, marked RDF, surrounded by a dark black boundary and two holes at the base. This is followed by slightly dense tissue, marked PDL, with an oval patch.

Source: (From Gutmann JL, Lovdahl PE: *Problem solving in*

www.konkur.in

endodontics, ed 5, St. Louis, 2011, Elsevier.)

The AF is the "circumference or rounded edge, like a funnel or crater that differentiates the termination of the cemental canal from the exterior surface of the root."[51] The AF does not normally exit at the anatomic apex, but rather is offset 0.5 to 3 mm. This variation is more marked in older teeth through cementum apposition. Studies have shown that the AF coincides with the apical root vertex in 17% to 46% of cases.[14,35,36,87,113,115]

The location and diameter of the CDJ differ from those of the AF in maxillary anterior teeth.[88] Extension of cementum from the AF into the root canal differs considerably, even when opposite canal walls are compared (see Figs. 7.17 and 7.18). Cementum reaches the same level on all canal walls in only 5% of cases. The greatest extension generally occurs on the concave side of the canal curvature. This variability confirms that the CDJ and the AC generally are not in the same area and that the CDJ should be considered just a variable junction at which two histologic tissues meet in the root canal (see Fig. 7.18).

Scanning electron microscopy has been used to determine the number and size of main apical foramina, their distance from the anatomic apex, and the size of accessory foramina. The morphology of the apical third of the root reflects multiple anatomic variations, including numerous accessory canals; areas of resorption and repaired resorption; attached, embedded, and free pulp stones; varying amounts of reparative dentin; and varying root canal diameters (see Tables 7.5–7.7 in the Expert Consult site).[71,72] Primary dentinal tubules are found less often than in the coronal dentin and are more or less irregular in direction and density, or even absent. This variable nature of the apical structure and significant absence of dentinal tubules may lead to reduced chances of bacterial invasion into the dentinal walls; however, it also presents challenges for all root canal procedures, from cleaning and disinfection to obturation.

Clinically, considerable controversy exists over the exact termination point for root canal procedures in the apical third of the root; clinical determination of apical canal morphology is difficult at best.[39,98] Detailed perspectives, both historical and contemporary, can be found in the literature.[38] Some authors recommend that root canal procedures terminate at or within 3 mm of

Telegram: @dental_k

www.konkur.in

the radiographic apex, depending on the pulpal diagnosis. For vital cases, clinical and biologic evidence indicates that a favorable point at which to terminate therapy is 2 to 3 mm short of the radiographic apex.[46,99] This leaves an apical pulp stump, which prevents extrusion of irritating filling materials into the periradicular tissues in vital cases. However, what is not commonly recognized among clinicians is that this so-called pulp stump is actually not pulp tissue, but rather periodontal tissue that can ensure apical healing with cementum over the root end (see Fig. 7.18). Studies have shown that a better success rate is achieved when the procedure ends at or within 2 mm of the radiographic apex.[45,46,99] When short of the 2-mm point or extended past the radiographic apex, the success rate declined by 20%. For revision of procedural failures, apical procedures should extend to or preferably 1 to 2 mm short of the radiographic apex to prevent overextension of instruments and filling materials into the periradicular tissues.

Many investigators who have evaluated apical and periradicular tissues after root canal procedures concluded that the most favorable prognosis was obtained when procedures were terminated at the AC, and the worst prognosis was produced by treatment that extended beyond the AC.[54–57,90] Some studies support the termination of all procedures at or beyond the radiographic apex, thereby filling all apical ramifications and lateral canals.[95] This dictate is empirically based, and CBCT evaluation of procedures previously thought to be successful has allowed identification of more posttreatment disease.[18,83]

Objectives and guidelines for traditional access cavity preparation

Objectives

Access to the complex root canal system is the first important phase of any nonsurgical root canal procedure.[39,109] The objectives of access cavity preparation are to (1) remove all caries when present, (2) conserve sound tooth structure, (3) unroof the pulp chamber completely, (4) remove all coronal pulp tissue (vital or necrotic), (5) locate all root canal orifices, and (6) achieve straight- or direct-line access to the AF or to the initial curvature of

Telegram: @dental_k

www.konkur.in

the canal.

A properly prepared access cavity creates a smooth, straight-line path to the canal system and ultimately to the apex or position of the first curvature (Fig. 7.19, *A*). Straight-line access provides the best chance of débridement of the entire canal space; it reduces the risk of instrument breakage[73]; and it results in straight entry into the canal orifice, with the line angles forming a funnel that drops smoothly into the canal (or canals). Projection of the canal center line to the occlusal surface of the tooth indicates the location of the line angles (see Fig. 7.19, *B*).

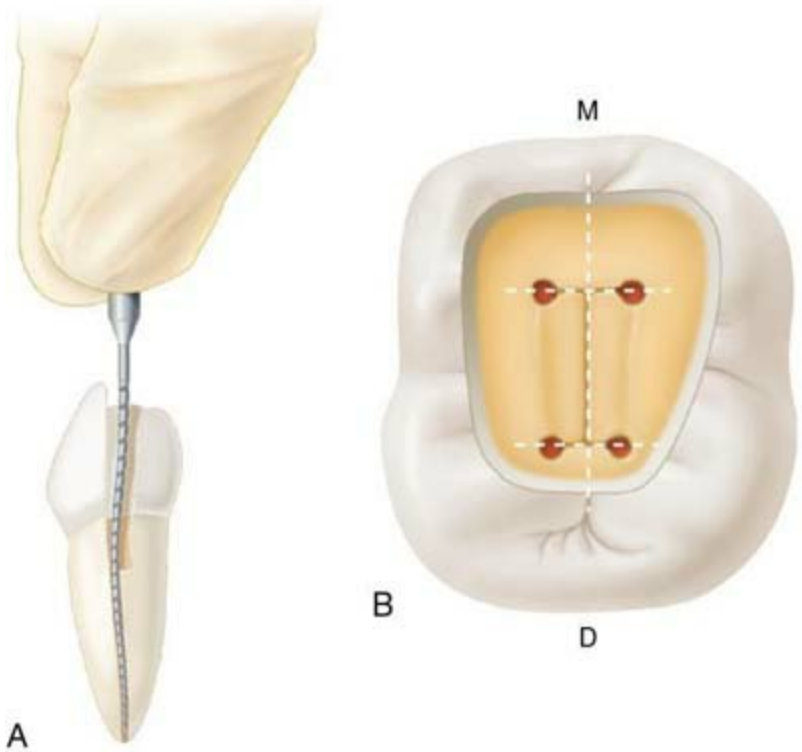

FIG. 7.19 **A,** Straight-line access to a canal. The instrument should not be deflected until it reaches the initial canal curvature. In some cases coronal tooth structure must be sacrificed to obtain direct access to the pulp chamber. **B,** Diagrammatic representation of centrality and concentricity of symmetry and location of canal orifices. *D,* Distal; *M,* mesial.

www.konkur.in

Key steps to consider in traditional access preparation

Evaluation of the cementoenamel junction and occlusal tooth anatomy

Traditionally, some access cavities have been prepared in relation to the occlusal or lingual anatomy. However, complete reliance on the anatomy is dangerous because this morphology can change as the crown is destroyed by caries and reconstructed with various restorative materials. Likewise, the root may not be perpendicular to the occlusal surface of the tooth; thus, complete dependence on the occlusal or lingual anatomy may explain the occurrence of some procedural errors, such as coronal perforations along the cervical line or into the furcation. Krasner and Rankow found that the cementoenamel junction (CEJ) was the most important anatomic landmark for determining the location of pulp chambers and root canal orifices. Their study demonstrated the existence of a specific and consistent anatomy of the pulp chamber floor.[49]

Preparation of the access cavity through the lingual and occlusal surfaces

Access cavities on anterior teeth usually are prepared through the lingual tooth surface, and those on posterior teeth are prepared through the occlusal surface. These approaches are the best for achieving straight-line access while reducing esthetic and restorative concerns. Some authors have recommended that the traditional anterior access for mandibular incisors be moved from the lingual surface to the incisal surface in selected cases[69]; this may allow for better access to the lingual canal and improve canal débridement (Fig. 7.20). In teeth that are lingually inclined or rotated, this is often the preferred choice for access and is performed before the dental dam is placed, or careful alignment of the root is determined before a bur is used.[39]

Telegram: @dental_k

www.konkur.in

FIG. 7.20 An incisal access cavity on mandibular anterior teeth may allow for improved straight-line access and canal débridement.

Tooth shows a wedge-shape opening extending from the crown to root apex.

Removal of all defective restorations and caries before entry into the pulp chamber

Removal of all defective restorations and caries before entering the root canal system is essential for many reasons.[39] Hidden caries or fractures are often identified, and the ability to determine the restorability of the tooth is enhanced (Fig. 7.21). In this respect, it is not uncommon, before entering the pulp chamber, to stop with the access opening preparation in favor of a crown lengthening procedure or adding a bonded buildup.[39]

Preparation of access cavity walls that do not restrict straight- or direct-line passage of instruments to the apical foramen or initial canal curvature

Sufficient tooth structure must be removed to allow instruments to be placed easily into each canal orifice without interference from canal walls, particularly when a canal curves severely or leaves the chamber floor at an obtuse angle. Hence, access design depends not only on the orifice location, but also on the position and curvature of the entire canal.[106]

Objectives and guidelines for minimally invasive access cavity preparation

The objectives are to preserve as much tooth structure as possible, while managing to locate, debride, enlarge, shape, and obturate the root canal(s). Much has been written and some studies have been done to verify this approach to access preparation; however, definitive, evidence-based outcomes have yet to be seen within this empirically based approach. Access

Telegram: @dental_k

www.konkur.in

openings must be crafted to preserve sound tooth structure and prevent tooth fracture (referred to as the guided endodontic technique,[33,58] or microguided technique,[23] contracted cavities,[6,66,74,97] truss access openings,[8] and orifice-directed dentin conservation access[77]). The prevention of gouging, cervically, laterally or into the floor of the pulp chamber is especially important (Figs. 7.22 and 7.23). However, access that is too restricted may or may not greatly impact the remaining and important root canal procedures (Fig. 7.24).[50,77,94] While judicious orifice location and careful canal penetration are essential, efforts should be made to minimize the excess removal of cervical tooth structure.[20–22,47,97] The literature indicates that loss of tooth structure in certain teeth may weaken the tooth cervically,[124] making them susceptible to fracture,[5,41,57,60,61] although this concept has been challenged.[91,97]

Mechanical phases of access cavity preparation

Magnification and illumination

For some clinicians, the access cavity is best prepared with the use of magnification and an appropriate light source.[15] In lieu of a DOM, surgical loupes with an auxiliary light source are highly recommended.

Burs

Numerous burs have been developed exclusively for access cavity preparation (Fig. 7.25). Most clinicians have their own set of preferred access burs. A significant trend in restorative dentistry is the increased use of zirconia-based crowns and onlays. Zirconia has different mechanical and thermal characteristics than metal. Carbide burs do not efficiently or safely cut zirconia. Zirconia is a brittle material and when cut can develop cracks that propagate through the framework and lead to eventual failure of the

Telegram: @dental_k

www.konkur.in

crown or onlay. Diamond bur manufacturers are aware of these issues, and they are currently introducing medium- and fine-grit diamond burs that efficiently cut zirconia (Komet USA, Savannah, GA; Prima Dental Gloucester, England; SS White). These diamond burs should be used with copious sprayed water to minimize heat buildup in the zirconia crowns during access preparations.[39]

FIG. 7.25 Access burs. **A,** #2, #4, and #6 round carbide burs. **B,** Safety-tip tapered diamond bur *(left)*; safety-tip tapered carbide bur *(right)*. **C,** Transmetal bur. **D,** Round-end cutting tapered diamond bur. **E,** #57 fissure carbide bur. **F,** #2 and #4 round diamond burs. **G,** Mueller bur *(left)*; LN bur or Extendo Bur *(right)*.

Seven images, marked A through G, show different dental tools used during surgeries.

Many teeth requiring access cavity preparations have metal restorations that must be penetrated. These restorations may be amalgams, all-metal cast restorations, or metal copings of porcelain fused to metal crowns. A transmetal bur (Dentsply Sirona, Ballaigues, Switzerland) is excellent for cutting through metal because of its exceptional cutting efficiency.

Telegram: @dental_k

www.konkur.in

Endodontic explorer and spoon

The DG-16 endodontic explorer is used to identify canal orifices and to determine canal angulation. An alternative, the JW-17 endodontic explorer (CK Dental Industries, Orange, CA) serves the same purpose, but its thinner, stiffer tip can be useful for identifying the possible location of a calcified canal. A sharp endodontic spoon, which comes in different sizes can be used to remove coronal pulp and carious dentin.

Ultrasonic unit and tips

Ultrasonic units and tips specifically designed for activities during access opening preparation are extremely valuable. Ultrasonic tips from various manufacturers can be used to trough and deepen developmental grooves, remove tissue, and explore for canals. These systems provide outstanding visibility compared with traditional handpiece heads, which typically obstruct vision.

Access cavity preparations

Anterior teeth

The following discussion outlines the steps for maxillary and mandibular anterior teeth. Tooth-specific access concerns are illustrated and discussed in the section Morphology of and Access Cavity Preparations for Individual Teeth, later in the chapter.

External outline form

For an intact tooth, cutting commences at the center of the lingual or palatal surface of the anatomic crown. An outline form is developed that is similar in geometry to an ideal access shape for the particular anterior tooth. The bur is directed perpendicular to the lingual surface as the external outline opening is created.

Penetration of the pulp chamber roof (Fig. 7.26)

Experienced clinicians usually penetrate the pulp chamber roof using a high-speed handpiece; however, less experienced clinicians may find the increased

Telegram: @dental_k

www.konkur.in

tactile sensation of a slow-speed handpiece a safer option. Continuing with the same round or tapered fissure bur, the angle of the bur is rotated from perpendicular to the lingual/palatal surface to parallel to the long axis of the root (see Fig. 7.26, *C* and *D*). Penetration into the tooth continues along the root's long axis until the roof of the pulp chamber is penetrated; frequently, a drop into the chamber effect is felt when this occurs. Measuring the distance from the incisal edge to the roof of the pulp chamber on a dimensionally accurate pretreatment radiograph may serve as guide in limiting penetration and possibly preventing a perforation. If the drop-in effect is not felt at this depth, a DG-16 explorer can be used to probe the depth of the access. Often a small opening into the chamber is present, or the dentin is very thin and the explorer penetrates into the chamber. The depth and angle of penetration should be assessed for any deviation away from the long axis of the root in both the mesiodistal and buccolingual dimensions, and the penetration angle should be realigned if necessary. Angled radiographs can be used to assess progress at any time if any confusion or doubt exists.

FIG. 7.26 **A,** In anterior teeth, the starting location for the access cavity is the center of the anatomic crown on the lingual surface *(X).* **B,** Preliminary outline form for anterior teeth. The shape should mimic the expected final outline form, and the size should be half to three fourths

Telegram: @dental_k

www.konkur.in

the size of the final outline form. **C,** The angle of penetration for the preliminary outline form is perpendicular to the lingual surface. **D,** The angle of penetration for initial entry into the pulp chamber is nearly parallel to the long axis of the root. **E,** Completion of removal of the pulp chamber roof; a round carbide bur is used to engage the pulp horn, cutting on a lingual withdrawal stroke.

A) Crown and neck region of the front tooth are shown with a label X at the center of crown.

B) Front tooth shows a triangular cavity at the center.

C) Round carbide bur is placed at 90 degrees to the center of crown.

D) Round carbide bur is placed straight and touches the center of crown.

E) Round carbide bur is penetrated into the canal from crown.

Removal of the chamber roof

Once the pulp chamber has been penetrated, the remaining roof is removed by catching the end of a round bur under the lip of the dentin roof and cutting on the bur's withdrawal stroke (see Fig. 7.26, *E*). Working in this manner enables the internal pulp anatomy to dictate the external outline form of the access opening. Copious irrigation with sodium hypochlorite helps control any hemorrhage present. Subsequently, the chamber roof, including the pulp horns, is removed and all internal walls are flared to the lingual surface of the tooth and complete roof removal is confirmed with an explorer.

Removal of the lingual shoulder and coronal flaring of the orifice

Once the orifice or orifices have been identified and confirmed, the lingual shoulder or ledge is removed. This is a shelf of dentin that extends from the cingulum to a point approximately 2 mm apical to the orifice (Fig. 7.27). Its removal improves straight-line access and allows for more intimate contact of files with the canal's walls for effective shaping and cleaning. Furthermore, its removal from mandibular anterior teeth may often expose an extra orifice and canal.

Telegram: @dental_k

www.konkur.in

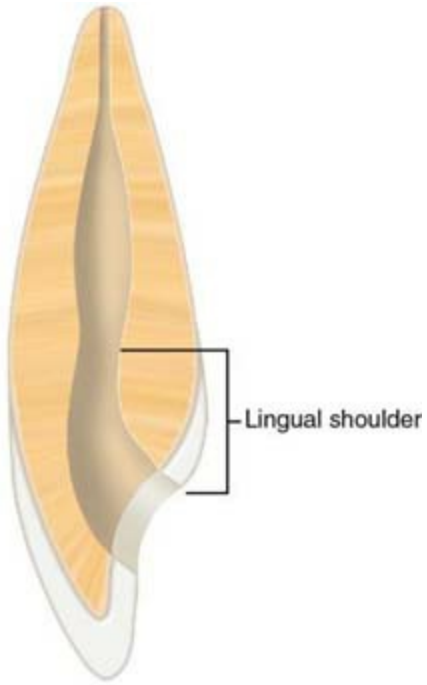

FIG. 7.27 Lingual shoulder of the anterior tooth, extending from the cingulum to 2 mm apical to the orifice.

Front tooth shows an opened canal with a lower right region, marked lingual shoulder.

The contemporary approach to flaring the orifice involves the use of rotary nickel-titanium (NiTi) orifice openers that allow rapid, safe removal of the lingual ledge, following the manufacturer's directions for use (DFUs). Some clinicians prefer the use of Gates-Glidden burs. These openers allow refinement of the orifice shape or help to enhance straight-line access to the canal with minimal removal of dentin when used properly. The bur should be placed so as to avoid putting a bevel on the incisal edge of the access preparation (Fig. 7.28). When Gates-Glidden burs are used, the largest that can be placed passively 2 mm apical to the orifice is used first with gentle pressure. During this process, the orifice is often concomitantly flared so that it is contiguous with all walls of the access preparation. If this is not achieved, use of the orifice openers is recommended.

Telegram: @dental_k

www.konkur.in

FIG. 7.28 Placing an incisal bevel on the lingual surface of a maxillary anterior tooth can lead to fracture of the permanent restoration during occlusal function.

Front tooth shows an opened canal with a slanted edge in the enamel, marked incisal bevel.

Straight-line access determination

Straight-line access to the canal orifice is the ideal goal. Preferably, a small intracanal file should reach the AF or the first point of canal curvature with no deflections. If the lingual shoulder has been removed and a file still binds on the incisal edge, the access cavity should be further extended incisally, until the file is not deflected (Fig. 7.29). The final position of the incisal wall of the access cavity is determined by two factors: (1) complete removal of the pulp horns and (2) straight-line access. However, the concept of straight-line access may not be totally feasible when using minimally invasive access preparations.

Telegram: @dental_k

www.konkur.in

FIG. 7.29 **A,** The lingual ledge of dentin remains, deflecting the file toward the labial wall. As a result, portions of the lingual canal wall will not be shaped and cleaned. **B,** Removal of the lingual ledge results in straight-line access.

A) Tooth shows the slightly curved shape of instrument inside the canal.

B) Tooth shows instrument without any bend inside the canal.

Refinement and smoothing of restorative margins

The final step in the preparation of an access cavity is to refine and smooth the cavosurface margins. Rough or irregular margins can contribute to coronal leakage through a permanent or temporary restoration.

Individual anterior teeth

See the figures in the section Morphology of and Access Cavity Preparations for Individual Teeth, later in this chapter.

Posterior teeth

Preparing access cavities on posterior teeth is similar to the process for anterior teeth, but significant differences warrant a separate discussion.[39]

Telegram: @dental_k

www.konkur.in

Posterior teeth requiring root canal procedures typically have been heavily restored, which may make the process more challenging, or the carious process was extensive, which may make the process much easier.

External outline form

Removal of caries and existing restorations from a posterior tooth often results in the development of an acceptable access outline form, with pulp chamber positioned in the center of the tooth at the level of the CEJ. Therefore, in maxillary premolars, the point of entry that determines the external outline form is on the central groove between the cusp tips (Fig. 7.30). Crowns of mandibular premolars are tilted lingually relative to their roots (Fig. 7.31); therefore, the starting location must be adjusted to compensate for this tilt (Fig. 7.32). In mandibular first premolars, the starting location is halfway up the lingual incline of the buccal cusp on a line connecting the cusp tips. Mandibular second premolars require less of an adjustment because they have less lingual inclination. The starting location for this tooth is one third the way up the lingual incline of the buccal cusp on a line connecting the buccal cusp tip and the lingual groove between the lingual cusps.

C) Tooth shows labels for B cusp tip, DL cusp tip in the lower left, and ML cusp tip in the lower right side. An X mark is located at the center.

D) Structure of tooth shows an arrow pointing just below the pulp horns.

To determine the starting location for molar access cavity preparations, the mesial-distal and apical-coronal boundary limitations for this outline must be determined (Fig. 7.33). Evaluation of bite-wing radiographs is an accurate method of assessing the extensions of the pulp chamber (Fig. 7.34). The mesial boundary for both the maxillary and mandibular molars is a line connecting the mesial cusp tips. Pulp chambers are rarely found mesial to this

Telegram: @dental_k

www.konkur.in

imaginary line. A good initial distal boundary for maxillary molars is the oblique ridge. For mandibular molars, the initial distal boundary is a line connecting the buccal and lingual grooves. For molars, the correct starting location is on the central groove halfway between the mesial and distal boundaries.

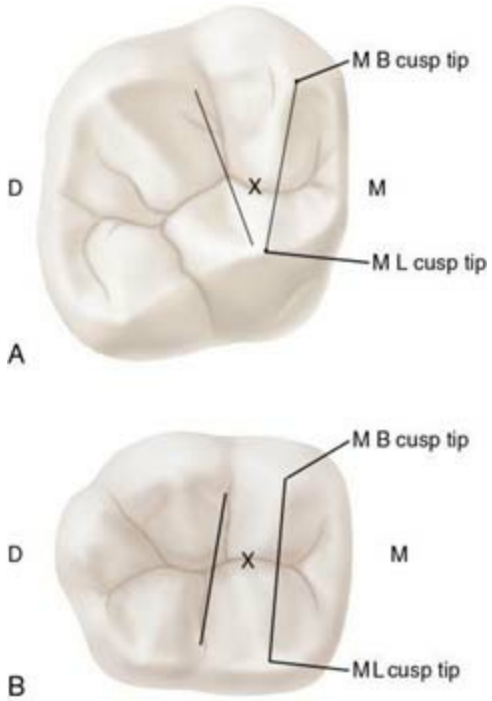

FIG. 7.33 **A,** Mesial and distal boundary of a maxillary molar with the access starting location *(X)*. **B,** Mesial and distal boundary of a mandibular molar showing the access starting location *(X)*. *D,* Distal; *M,* mesial; *MB,* mesiobuccal; *ML,* mesiolingual.

A) Radiograph shows upper right quadrant with radiolucent patches on the teeth and porous tissue in the root of central molar.

B) Radiograph shows some teeth with radiolucent pulp chambers and some with radiolucent root canals.

Penetration through the enamel into the dentin (approximately 1 mm) is achieved with a #2 or #4 round bur for premolars and a #4 or #6 round bur for molars. A tapered fissure bur may be used instead of round burs. The bur is directed perpendicular to the occlusal table, and an initial outline shape is created at about half to three fourths its projected final size. The premolar shape is oval and widest in the buccolingual dimension. The molar shape is also oval initially; it is widest in a buccolingual dimension for maxillary molars and in a mesiodistal direction for mandibular molars. The final outline shape for molars is approximately triangular (for three canals) or rhomboid (for four canals), even when a minimal access approach is used; however, the canal orifices dictate the position of the corners of these geometric shapes. Therefore, until the orifices have been located, the initial outline form should be left as roughly oval.

Telegram: @dental_k

www.konkur.in

Penetration of the pulp chamber roof

As with anterior teeth, penetration through the chamber roof is limited to the distance measured on a pretreatment radiograph. If the drop-in effect is not felt at this depth, a careful evaluation of the angle of penetration is necessary before going deeper into the chamber. In multirooted posterior teeth, lateral and furcation perforations may occur rapidly without attention to 3D detail during this penetration. Aggressive probing with a DG-16 explorer at any time during the penetration is encouraged. Once the pulp chamber has been penetrated, the remaining roof is removed by catching the end of a round bur under the lip of the dentin roof and cutting with the burs on a withdrawal stroke.

Identification of all canal orifices

The canal orifices play an important role in determining the final extensions of the external access outline form. Ideally, the orifices are located at the corners of the final preparation to facilitate all of the root canal procedures (Fig. 7.35).

FIG. 7.35 An endodontic explorer is used to search for canal orifices.

Telegram: @dental_k

www.konkur.in

Tooth shows four holes in the center. An endodontic explorer is passing from one of the holes on the left.

Removal of the cervical dentin bulges and orifice and coronal flaring

Internal impediments to an ideal access opening are the cervical dentin ledges or bulges and the natural coronal canal constriction in posterior teeth.[39] The cervical bulges are shelves of dentin that frequently overhang orifices in posterior teeth, restricting access into root canals and accentuating existing canal curvatures (Fig. 7.36).[60]

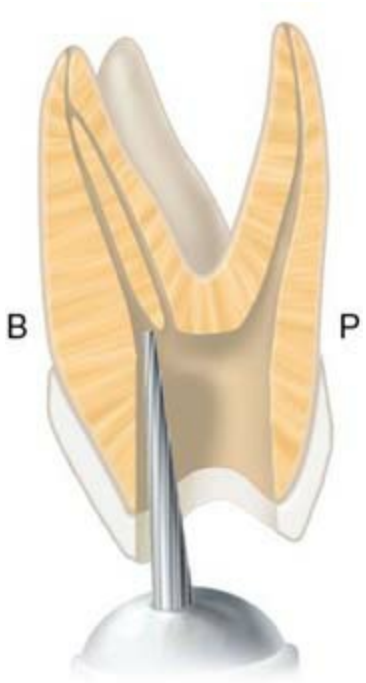

FIG. 7.36 Safety-tip carbide bur is used to shape the axial wall in one plane from the orifice to the cavosurface margin. *B,* Buccal; *P,* palatal.

Tooth shows carbide bur placed straight inside the canal toward buccal region.

Straight-line access determination

Straight-line access is paramount to successful shaping, especially given the complexity of the root canal systems in posterior teeth. However, this has not

Telegram: @dental_k

www.konkur.in

been verified when using a minimal access cavity. Files must have unimpeded access to the AF or the first point of canal curvature to perform properly.

Visual inspection of the pulp chamber floor

Floor and walls must be inspected, using appropriate magnification and illumination, to ensure that all canal orifices are visible and no roof overhangs are present (Fig. 7.37).

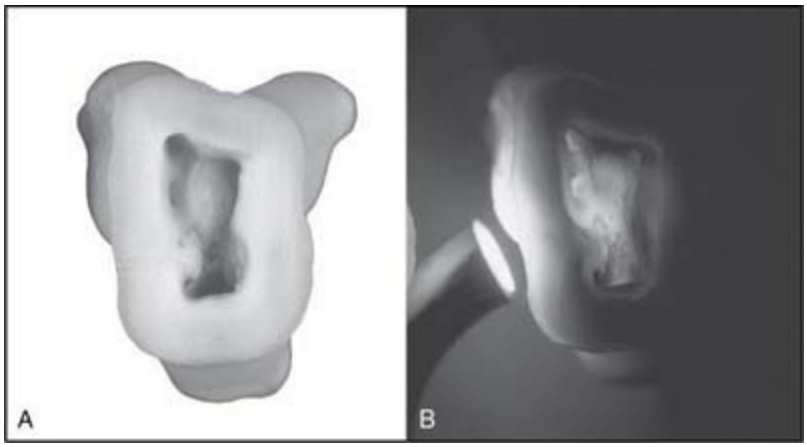

FIG. 7.37 A fiberoptic light can be applied to the cervical aspect of the crown to help obtain maximal visibility with magnification. Transillumination often reveals landmarks otherwise invisible to the unaided eye.

A) Cut specimen of tooth shows a dark chamber with orifices at the center.

B) The same specimen is observed under light that shows calcified pulp chamber with dense protuberances and dark tissues near the periphery in the center.

Challenging access preparations

Telegram: @dental_k

www.konkur.in

Access in teeth with presumed calcified canals

Chambers and roots that demonstrate the potential for significant calcifications may present problems with locating, penetrating, and negotiating the pulpal spaces.[39] The use of magnification and transillumination, as well as careful examination of color changes and pulp chamber shapes, assists in locating the canals (Fig. 7.38). However, the search for the root canal orifices should be made only after the pulp chamber has been completely prepared and its floor has been cleaned and dried (95% denatured ethanol may be useful for drying the floor and enhancing visibility). A fiberoptic light directed from the external through the CEJ can reveal subtle landmarks and color changes that may not otherwise be visible. The chamber floor is darker in color than its walls, and developmental grooves connecting orifices are lighter in color than the chamber floor. Awareness of these color differences when searching for small orifices is essential, especially when searching for those that are located at the angles formed by the floor and walls and at the end points of developmental grooves. Additional methods to help locate calcified root canals include staining the pulp chamber floor with 1% methylene blue dye, performing the sodium hypochlorite “champagne bubble” test (Fig. 7.39), and searching for canal bleeding points. These approaches are enhanced when the area is viewed through magnification, which would be essential with a minimal access cavity.

FIG. 7.38 Mandibular molar with what appears to be almost complete calcification of the pulp chamber and root canals. However, pathosis is present, which indicates the presence of bacteria and some necrotic tissue in the apical portion of the roots.

Radiograph shows two molars with radiopaque patches on the enamel. The root apices show porous tissue.

Telegram: @dental_k

www.konkur.in

FIG. 7.39 Allowing sodium hypochlorite (NaOCl) to remain in the pulp chamber may help locate a calcified root canal orifice. Tiny bubbles may appear in the solution, indicating the position of the orifice. This is best observed through magnification.

Two-rooted tooth shows sodium hypochlorite crystals in the pulp chamber below a U-shaped chamber.

Uncovering canals that contain calcified material is a challenge. When the canal is located, a small K-file (#6, #8, or #10 or, preferably, a C or C+ file [Dentsply Sirona—Ballaigues, Switzerland]) coated with a chelating agent should be introduced into the canal to determine patency. These instruments provide added stiffness to the shaft for better penetration. The file should not be removed until some canal enlargement has occurred. The file should be used in short up-and-down movements and in a selective circumferential filing motion, with most of the lateral pressure directed away from the furcation. This enlarges the coronal aspect of the canal safely and moves it laterally, to avoid thinning of the dentin wall adjacent to the furcation. It also creates a path of insertion for larger files and for coronal access burs. Figs. 7.40–7.45 illustrate several methods that can be used to locate calcified spaces. Furthermore, a guided access technique is advocated to perform the coronal entry into teeth with partially or completely calcified pulp chambers and/or obstructed root canals.[59]

Telegram: @dental_k

www.konkur.in

FIG. 7.44 At the first indication of a canal space, the smallest instrument (i.e., a #.06 or #.08 C or C+ file or micro openers) should be introduced into the canal. Gentle passive movement, both apical and rotational, often produces some penetration. A slight pull, signaling resistance, usually is an indication that the canal has been located. This should be confirmed by radiographs.

Tooth shows green patches at the root tips and a small K-file entering the root canal on the right.

Telegram: @dental_k

www.konkur.in

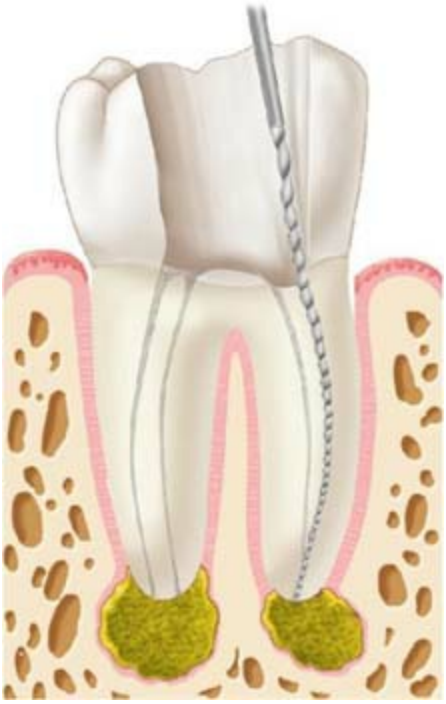

FIG. 7.45 A small K-file negotiates the canal to its terminus. An apex locator or radiograph is used to confirm the file's position.

Tooth shows green patches at the root tips and a small K-file curved slightly while passing from the root canal on the left.

Crowded or rotated teeth

Traditional or minimal access preparations may not be possible in patients with crowded or rotated teeth. The decision about an alternative approach must be based on straight-line access principles and conservation of tooth structure.[58] In certain circumstances, a buccal or incisal access preparation may be indicated, or developing the standard shape based on the degree of rotation (Fig. 7.46).[39]

Telegram: @dental_k

www.konkur.in

FIG. 7.46 **A,** Access cavity on crowded mandibular anterior teeth. The access preparation is cut through the buccal surface on the canine. The lateral incisor has also been accessed through the buccal surface; root canal procedures were performed, and the access cavity was permanently restored with composite. **B,** Obturation.

A) Close-up view shows a hollow chamber in the front tooth. The adjacent tooth is hold by a steel pear-shaped instrument.

B) Radiograph shows filled pulp chamber and root canals.

Other problems can occur when tooth angulations are not considered during access development, such as:

- Mistaken identification of an already located canal, resulting in a search in the wrong direction for additional canals. Whenever a difficult canal is located, a file should be placed in the canal and an angled radiograph taken.
- Failure to locate a canal or extra canals.
- Excessive gouging of coronal or radicular tooth structure.
- Instrument separation during attempts to locate an orifice.
- Failure to débride all pulp tissue from the chamber.

Morphology of and access cavity preparations for individual teeth

The anatomy shown in the following figures was obtained from human teeth through the use of recently developed 3D imaging techniques. The teeth were scanned in a high-resolution, microcomputer-assisted tomographic scanner. The data were then manipulated with proprietary computer programs to produce the 3D reconstructions and visualization. The following individuals

www.konkur.in

and sources are recognized to have contributed greatly to this endeavor.

Maxillary central incisor

The root canal system outline of the maxillary central incisor reflects the external surface outline (Fig. 7.47) (see Table 7.8 online at the Expert Consult site). The μCT scans of this tooth are seen in Fig. 7.48. (See Video 7.3 online at the Expert Consult site for rotational views of these teeth.) The external access outline form for the maxillary central incisor is a rounded triangle with its base toward the incisal aspect (Fig. 7.49).

FIG. 7.47 Maxillary central incisor. Average time of eruption—7 to 8 years; average age of calcification—10 years; average length—22.5 mm. Root curvature (most common to least common): straight, labial, distal.

First model shows wedge-shaped root canal with tapering root tip. Second model shows an oval outline with broader base in the crown. Third model shows roughly rectangular structure with a depression at the center. Fourth model shows two lines extending from pulp to edge of crown.

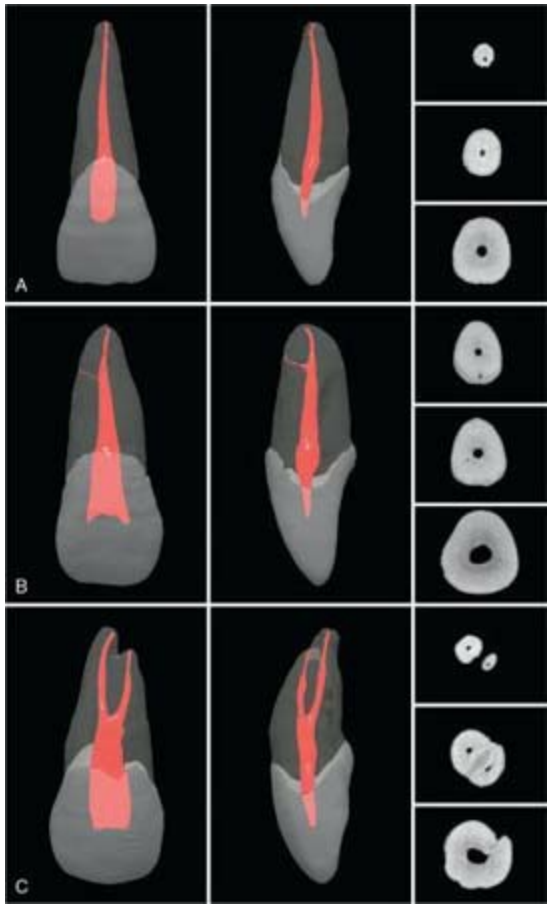

FIG. 7.48 µCT scans of maxillary central incisors. **A,** Common anatomic presentation. **B,** Central incisor with a lateral canal, which is common. **C,** Rare multiple-canal variation. All teeth are shown from both a buccal (vestibular) and a proximal perspective, along with the cross-sectional anatomy at the coronal, middle, and apical levels. (See Video 7.3 online at the Expert Consult site for rotational views of these teeth.)

A) First µ CT scan shows triangular crown with a wedge-shaped root canal extending from pulp chamber to apex. Second µ CT scan shows U-shaped edge at the lower part of crown with a thin convex root canal. Their coronal, middle, and apical views show a small hole near the edge, slightly large hole at the center, and a large hole surrounded by dark patch at the center, respectively.

B) First µ CT scan shows oval-shaped crown with two pulp horns above the pulp chamber and a very thin vertical line extending near the root apex. Second µ CT scan shows U-shaped edge at the lower part of crown with a curved thin branch near the root apex. Their coronal, middle, and apical views show oval shape with a small hole at the center and another very small hole near the base, slightly large hole at the center, and very large circular hole surrounded by dark patch at the center, respectively.

Telegram: @dental_k

www.konkur.in

C) First μ CT scan shows a wide square canal branched into two. Second μ CT scan shows thin canal branched into two. Their coronal, middle, and apical views show two circular structures each with a tiny hole inside, two holes in the tooth, and a circular hole in the tooth, respectively.

A) A triangular tooth with a small hollow chamber inside.

B) A large triangular tooth with a large hollow chamber inside.

Maxillary lateral incisor

The pulp chamber outline of the maxillary lateral incisor is similar to that of the maxillary central incisor; however, it is smaller, and two or no pulp horns may be present (Fig. 7.50) (see Table 7.9 online at the Expert Consult site). The μCT scans of this tooth are shown in Fig. 7.51. (See Video 7.4 online at the Expert Consult site for rotational views of these teeth.)

Maxillary canine

The root canal system of the maxillary canine is similar in many ways to that of the maxillary incisors (Fig. 7.52). A major difference is that it is wider labiolingually than mesiodistally. Another difference is that it has no pulp horns. Usually one root canal is present, although two canals have been reported (see Table 7.10 online at the Expert Consult site). The μCT scans for the maxillary canine can be seen in Fig. 7.53. (See Video 7.5 online at the Expert Consult site for rotational views of these teeth.)

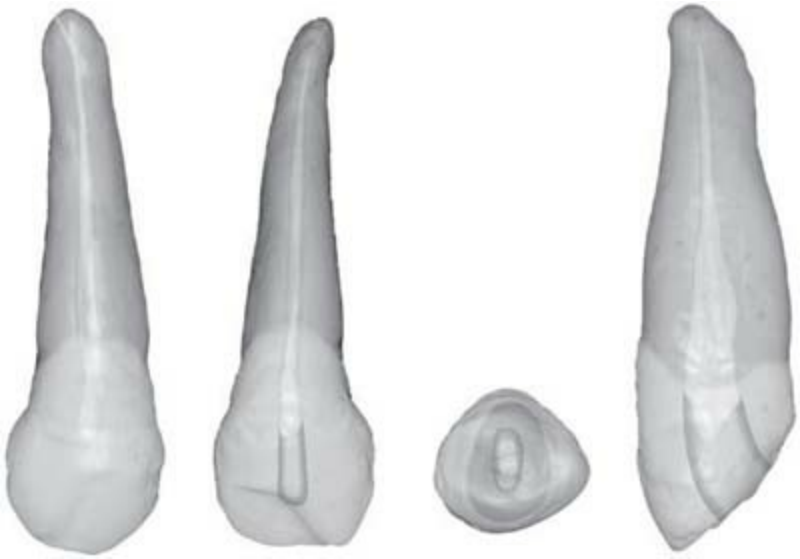

FIG. 7.52 Maxillary canine. Average time of eruption—10 to 12 years; average age of calcification—13 to 15 years; average length—26.5 mm. Root curvature (most common to least common): distal, straight, labial.

The normal external morphology of maxillary canine is followed by second model that has a U-shaped lucency in the crown, which is again followed by third model depicting the occlusal view of tooth and fourth model depicting two lucent canals in the crown.

www.konkur.in

Maxillary first premolar

Most maxillary first premolars have two root canals, regardless of the number of roots (Fig. 7.54). Ethnicity plays a factor in that Asian people have a higher incidence of one canal than do other ethnic groups.[62,81] A furcation groove or developmental depression on the palatal aspect of the buccal root is another anatomic feature. Its prevalence has been reported as 62% to 100%.[42,53,108] At the deepest part of the invagination, the average dentin thickness was found to be 0.81 mm. The pulp chamber of the maxillary first premolar is considerably wider buccolingually than mesiodistally. In the buccolingual dimension, the chamber outline shows a buccal and a palatal pulp horn. The buccal pulp horn usually is larger. The maxillary first premolar may have one, two, or three roots and canals; it most often has two (see Table 7.11 online at the Expert Consult site). The μCT scans for the maxillary first premolar can be seen in Fig. 7.55. (See Video 7.6 available online at the Expert Consult site for rotational views of these teeth.)

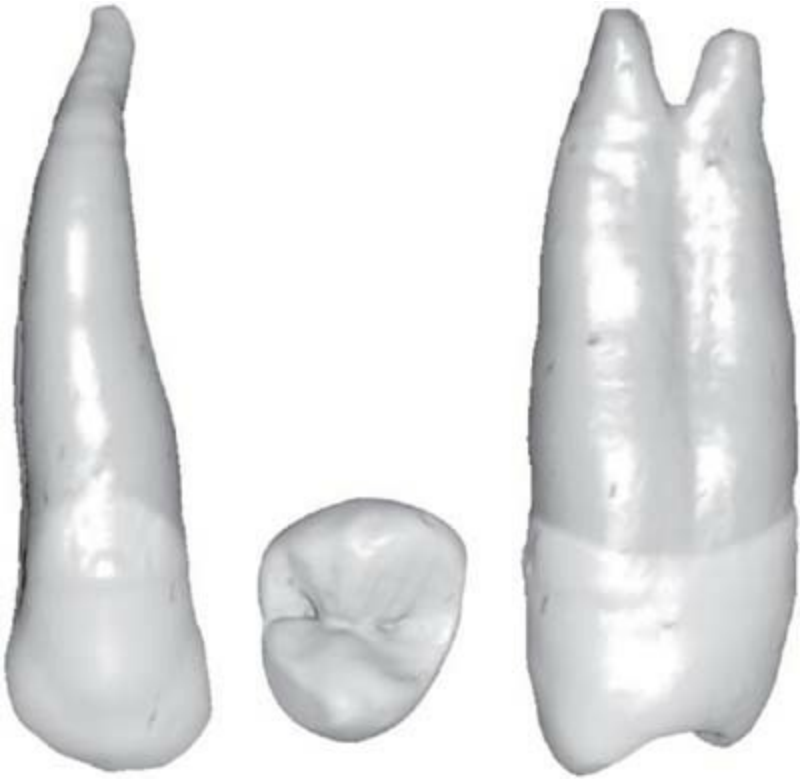

FIG. 7.54 Maxillary first premolar. Development and anatomic data:

respectively.

B) Two μ CT scans of premolar show wedge-shaped root canal and a root canal with two pulp horns, respectively. Three different views of tooth on the right show the coronal section with a smaller hole, middle section with a medium oval hole, and apical section with large hole.

C) Two μ CT scans show a trifurcated root canal near the root apex and bifurcated root canal with a V-shaped space in-between. Three different cross-sectional views of tooth on the right show three rings, fused rings, and a hollow chamber, respectively.

Maxillary second premolar

The root canal system of the maxillary second premolar is wider buccolingually than mesiodistally (Fig. 7.56). This tooth may have one, two, or three roots and canals (see Table 7.12 online at the Expert Consult site). Two or three canals can occur in a single root.[32] The scans for the maxillary second premolar can be seen in Fig. 7.57. (See Video 7.7 online at the Expert Consult site for rotational views of these teeth.)

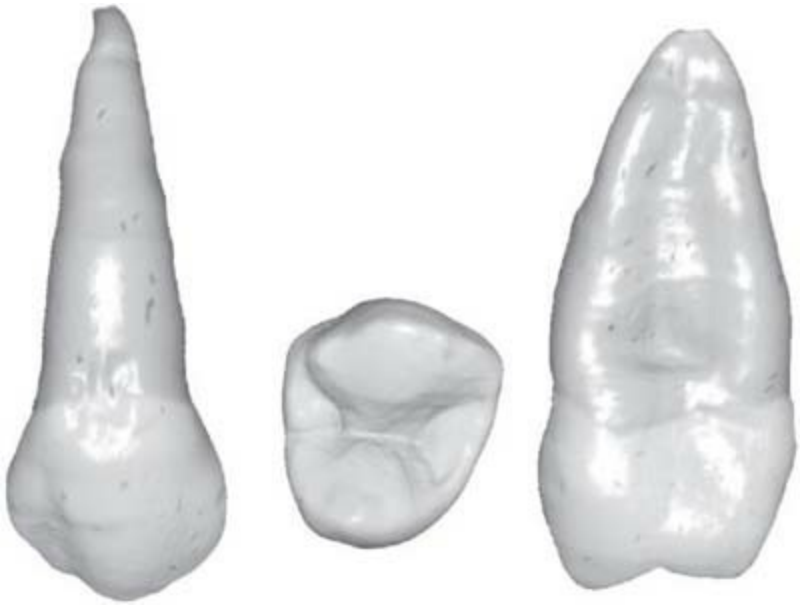

FIG. 7.56 Maxillary second premolar. Average time of eruption—10 to 12 years; average age of calcification—12 to 14 years; average length—21.5 mm. Root curvature (most common to least common): distal, bayonet, buccal, straight.

www.konkur.in

C) Two μ CT scans of tooth show root canal with three branches and two root canals with a V-shaped cavity in-between. Coronal and middle section show three small holes and large holes, respectively. Apical view shows an oval-shaped hole.

Maxillary first molar

The maxillary first molar is the largest tooth in volume and one of the most complex in root and canal anatomy (Fig. 7.58).[25] The pulp chamber is widest in the buccolingual dimension, and four pulp horns are present (mesiobuccal, mesiopalatal, distobuccal, and distopalatal). The pulp chamber's cervical outline form has a rhomboid shape, sometimes with rounded corners. The mesiobuccal angle is an acute angle; the distobuccal angle is an obtuse angle; and the palatal angles are basically right angles. The palatal canal orifice is centered palatally; the distobuccal orifice is near the obtuse angle of the pulp chamber floor; and the main mesiobuccal canal orifice is buccal and mesial to the distobuccal orifice and is positioned within the acute angle of the pulp chamber. When there is only one canal in mesiobuccal root, the orifice can be round, oval, or flat. (See Video 7.8 online at the Expert Consult site for rotational views of these teeth.) The mesiopalatal canal orifice (also referred to as the *MB-2*) is located palatal and mesial to the mesiobuccal orifice. It can be located close to or far away from mesiobuccal orifice. (See Video 7.8 online at the Expert Consult site for rotational views of these teeth.) A line drawn to connect the three main canal orifices—the mesiobuccal orifice, distobuccal orifice, and palatal orifice—forms a triangle, known as the *molar triangle* (see Tables 7.13–7.15 online at the Expert Consult site). The palatal root often curves buccally at the apical one third, which may not be obvious on a standard periapical radiograph. The μCT scans for the maxillary first molar can be seen in Fig. 7.59. (See Video 7.9 online at the Expert Consult site for rotational views of these teeth.)

show a circular structure with one hole and U-shaped structure with three holes inside. Apical section shows a rectangular structure with holes inside.

Maxillary second molar

Coronally, the maxillary second molar may closely resemble the maxillary first molar (Fig. 7.60). The root and canal anatomy are similar to those of the first molar, although there are differences. The distinguishing morphologic feature of the maxillary second molar is that its three roots are generally grouped closer together and are sometimes fused (see Tables 7.16–7.18 online at the Expert Consult site). The μCT scans for the maxillary second molar can be seen in Fig. 7.61. (See Video 7.10 online at the Expert Consult site for rotational views of these teeth.)

FIG. 7.60 Maxillary second molar. Average time of eruption—11 to 13 years; average age of calcification—14 to 16 years; average length—20 mm. Root curvature (most common to least common): mesiobuccal root—distal, straight; distobuccal root—straight, mesial, distal; palatal root—straight, buccal.

C) Two μ CT scans show tooth on left with trifurcated roots and tooth on right with U-shaped canal with an additional branch extending below the pulp. The right side shows their coronal, medial, and apical views.

D) Two μ CT scans show tooth on left with four root canals diverting toward the right and tooth on right with four root canals diverting toward the left, respectively. In the right tooth, two root canals are fused. The right side shows their coronal, medial, and apical views.

Maxillary third molar

Loss of the maxillary first and second molars is often the reason the third molar must be considered a strategic abutment (Fig. 7.62). However, sometimes a third molar is intentionally transplanted to a vacated first molar position; the same being true for mandibular third molars.[48] The radicular anatomy of the third molar is completely unpredictable, and it may be advisable to explore the root canal morphology to evaluate the likelihood and degree of success. This tooth can have one to four roots and one to six canals, and C-shaped canals also can occur. The third molar usually has three roots and three root canals (see Table 7.19 online at the Expert Consult site). The tooth may be tipped significantly to the distal, the buccal, or both, which creates an even greater access problem than with the second molar. The μCT scans for the maxillary molar can be seen in Fig. 7.63. (See Video 7.11 online at the Expert Consult site for rotational views of these teeth.)

whereas middle and apical view show a heart-shaped and large oval hole, respectively.

B) Two μ CT scans show single-rooted tooth with an accessory branch and one-rooted tooth with pulp horns at the lower part of crown. Coronal section shows two rings. Middle section and apical section show two fused rings and a rectangular structure with a large vertical hole inside, respectively.

C) Two μ CT scans show three interconnected root canals and two root canals extending from the lower part of crown, respectively. Coronal, middle, and apical section show two rings, three-fused rings, and a large hole at the center of structure, respectively.

D) Two μ CT scans show three-rooted tooth with addition branches on the left and three-rooted tooth with an additional brand on the right, respectively. Coronal, middle, and apical section show two rings, two rings with an 8-shape structure, and three fused rings, respectively.

Mandibular central and lateral incisors

The root canal systems and access cavities for the two mandibular incisors are so similar they are discussed together (Fig. 7.64). As with the maxillary incisors, a lingual shoulder must be eliminated to allow direct-line access. The shoulder conceals the orifice to a second canal that, if present, is found immediately beneath it. Most mandibular incisors have a single root with what radiographically appears to be a long, narrow canal. However, it is a broad canal labiolingually. Often a dentinal bridge is present in the pulp chamber that divides the root into two canals. The two canals usually join and exit through a single AF, but they may persist as two separate canals (Figs. 7.65 and 7.66). Occasionally, one canal branches into two canals, which subsequently rejoin into a single canal before reaching the apex (see Table 7.20 online at the Expert Consult site). (See Videos 7.12 and 7.13 online at the Expert Consult site for rotational views of these teeth.)

Mandibular canine

The root canal system of the mandibular canine is very similar to that of the maxillary canine, except that the dimensions are smaller, the root and root canal outlines are narrower in the mesiodistal dimension, and the mandibular canine occasionally has two roots and two root canals located labially and lingually (Fig. 7.67) (see Table 7.21 online at the Expert Consult site). The root canal of the mandibular cuspid is narrow mesiodistally but usually very broad buccolingually, and the access cavity for the mandibular canine is oval or slot-shaped.[112] The μCT scans of the mandibular canine can be seen in Fig. 7.68. (See Video 7.14 online at the Expert Consult site for rotational views of these teeth.)

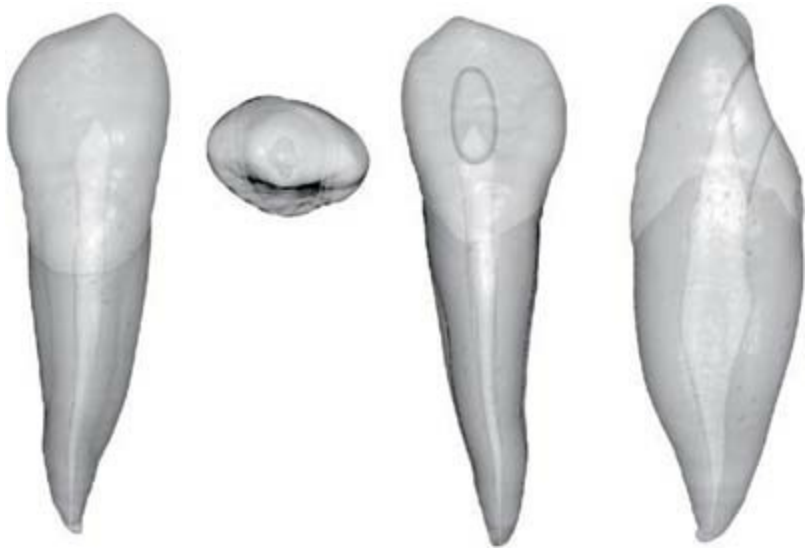

FIG. 7.67 Mandibular canine. Average time of eruption—9 to 10 years; average age of calcification—13 years; average length—25.6 mm. Root curvature (most common to least common): straight, distal, labial.

First model shows posterior side of incisor with filled root canal. Second model shows small mushroom-shaped structure of tooth. Third model shows tooth with an oval mark at the center. Fourth model shows curved root canal.

Mandibular first premolar

As a group, the mandibular premolars present significant anatomic challenges because of the extreme variations in their root canal morphology (Fig. 7.69).[63,82,121] The root canal system of the mandibular first premolar is wider buccolingually than mesiodistally.[123] Two pulp horns are present: a large, pointed buccal horn and a small, rounded lingual horn. At the cervical line, the root and canal are oval; this shape tends to become round as the canal approaches the middle of the root. If two canals are present, they tend to be round from the pulp chamber to their foramen. Direct access to the buccal canal is usually possible, whereas the lingual canal may be quite difficult to find. To address this situation, the lingual wall of the access cavity may have to be extended farther lingually; this makes the lingual canal easier to locate. The mandibular first premolar sometimes may have three roots and three canals (see Table 7.22 online at the Expert Consult site). Multiple studies have reported C-shaped canal anatomy in this tooth.[10,29,31,68,80] The μCT scans for the mandibular first premolar can be seen in Fig. 7.70. (See Video 7.15 online at the Expert Consult site for rotational views of these teeth.)

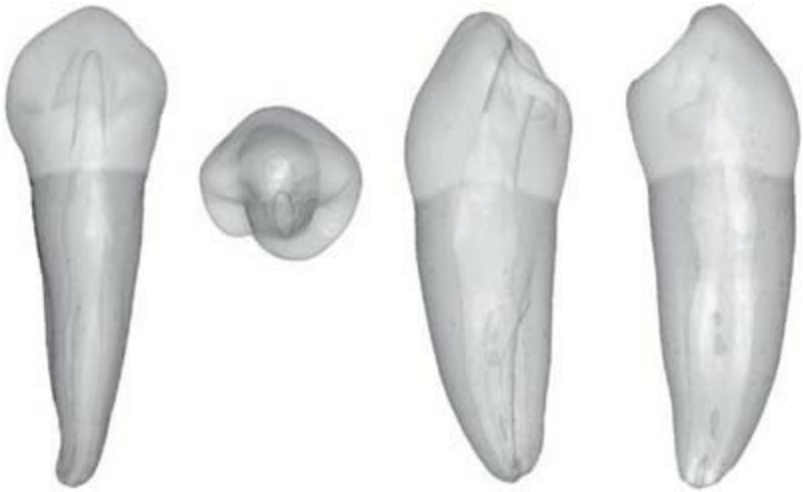

FIG. 7.69 Mandibular first premolar. Average time of eruption—10 to 12 years; average age of calcification—12 to 13 years; average length—21.6 mm. Root curvature (most common to least common): straight, distal, buccal.

First model shows single-rooted tooth with filled root canal extending from the enamel to root apex. Second model shows occlusal view of tooth with a groove inside. Third model shows diverted root canal. Fourth model shows

C) Two μ CT scans show an irregular root canal with multiple branches and two-rooted tooth with multiple branches at the apex, respectively. Three structures on the right shows an oval aperture, two holes, a C-shape with a knob at one end and a hole at the center, respectively.

Mandibular second premolar

The mandibular second premolar is similar to the first premolar, with the following differences: The lingual pulp horn usually is larger, the root and root canal are more often oval than round, the pulp chamber is wider buccolingually, and the separation of the pulp chamber and root canal is normally distinguishable compared with the more regular taper in the first premolar (Fig. 7.71). The canal morphology of the mandibular second premolar is similar to that of the first premolar with its many variations: two, three, and four canals and a lingually tipped crown. Fortunately, these variations are found less often in the second premolar (see Table 7.23 online at the Expert Consult site). The μCT scans for the mandibular second premolar can be seen in Fig. 7.72. (See Video 7.16 online at the Expert Consult site for rotational views of these teeth.)

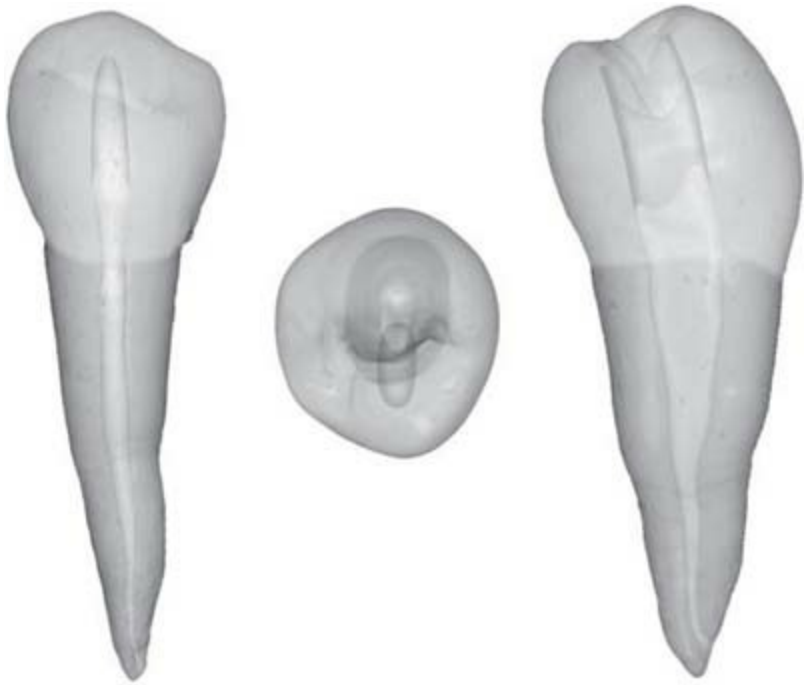

FIG. 7.71 Mandibular second premolar. Average time of eruption—11

B) Two μ CT scans show root canal with multiple branches near the root tip and interconnected branches of the root tip, respectively. The right side shows an oval structure with a hole, two-U shaped structures each with three holes. The second U-shaped structure is smaller.

C) Two μ CT scans show a root canal with two branches and two-rooted tooth. The right side shows oval structure with a vertical aperture inside, two structures each with two holes. The last structure is smallest.

Mandibular first molar

The mandibular first molar seems to be the tooth that most often requires an endodontic procedure (vital pulp capping, pulpotomy, root canal therapy); therefore, its morphology has received a great deal of attention (Fig. 7.73).[125] The occlusal appearance reflects a Y5 groove and cuspal pattern and the tooth usually has two roots, but occasionally it has three, with two or three canals in the mesial root and one, two, or three canals in the distal root (see Tables 7.24 and 7.25 online at the Expert Consult site). The μCT scans of the mandibular first molar can be seen in Fig. 7.74. (See Video 7.17 online at the Expert Consult site for rotational views of these teeth.)

FIG. 7.73 Mandibular first molar. Average time of eruption—6 years; average age of calcification—9 to 10 years; average length—21 mm. Root curvature (most common to least common): mesial root—distal, straight; distal root—straight, distal.

Four model of mandibular first molar show curved roots, occlusal view, U-shaped root, and root canal extending from the neck region to apex, respectively.

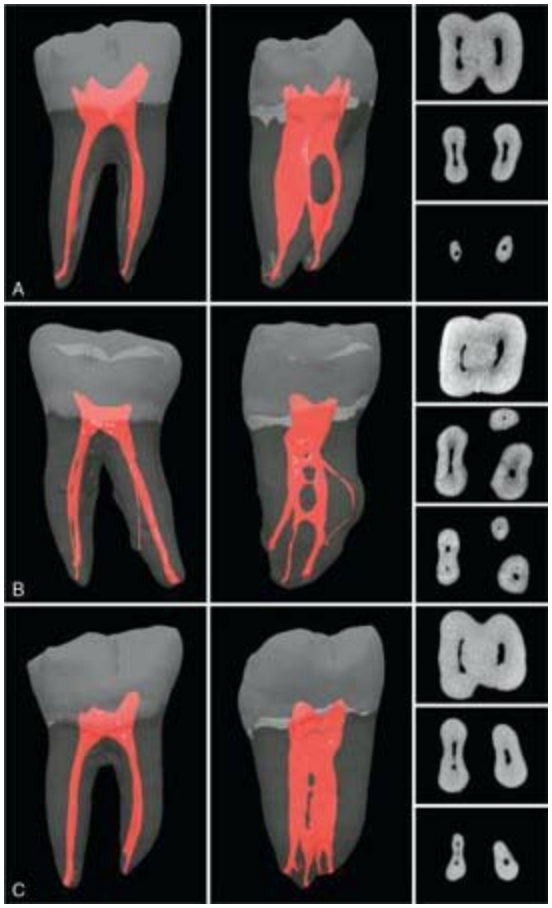

FIG. 7.74 µCT scans of mandibular first molars. **A,** Common anatomic presentation. **B,** First molar with three main canals and a deviant fourth canal/fourth root. **C,** First molar with wide connections or anastomoses between the mesial canals, demonstrating multiple canal exits. All teeth are shown from both a buccal (vestibular) and a proximal perspective, along with the cross-sectional anatomy at the coronal, middle, and apical levels. (See Video 7.17 online at the Expert Consult site for rotational views of these teeth.)

A) Two µ CT scans show two root canals with three pulp horns of tooth and two-rooted tooth with an oval aperture, respectively. The right side shows a two-chambered structure, second structure with two large vertical apertures and third structure with small holes, respectively.

B) Two µ CT scans show two-rooted tooth with secondary branches, and one-rooted tooth with secondary branches and chambers. The right side shows a bilocular chamber, two sets of three structures each with one or two holes.

C) Two µ CT scans show two-rooted canal and multiple branches grouped together, respectively. The right side shows a bilocular chamber, two sets of

Telegram: @dental_k

www.konkur.in

two structures each with one hole. The sizes of holes differ from one another in each section.

The canals in the mesial root are the mesiobuccal and mesiolingual canals. A middle mesial canal (MMC) sometimes is present in the developmental groove between the other mesial canals,[4,12,76,79,104,107,111] but it may only represent a wide anastomosis between the two mesial canals (Fig. 7.75), or in some cases it may actually be a separate canal from orifice to apex.[89] Troughing into the groove between the mesiobuccal and mesiolingual orifices may be indicated to identify this canal,[9,43,44] if present, or it may just result in blind search within the anastomosis with the risk of a perforation or root weakening due to the commonly found external invagination found both mesially and distally. The presence of two separate distal roots is rare, but this does occur. The mesial canal orifices are usually well separated in the main pulp chamber and connected by a developmental groove.[19]

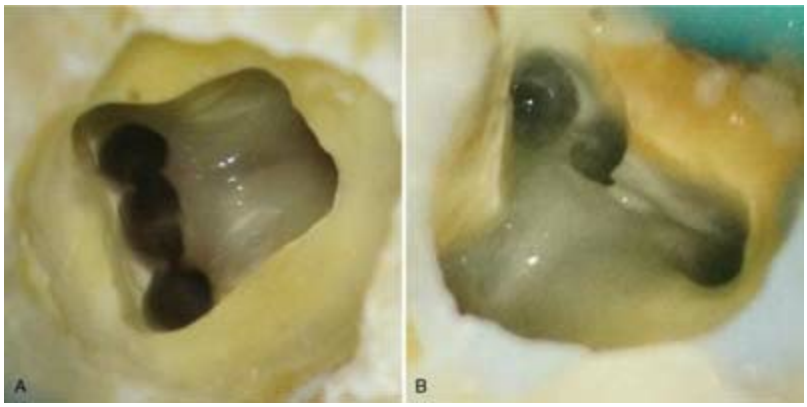

FIG. 7.75 **A,** A photograph (×8) of a mandibular molar showing fins between MB and ML canals**. B,** A photograph (×8) of a mandibular molar showing three mesial canals. *MB,* Mesiobuccal; *ML,* mesiolingual.

Telegram: @dental_k

www.konkur.in

When only one distal canal is present, the orifice is oval buccolingually and the opening generally is located distal to the buccal groove. This orifice usually can be explored from the mesial with either a DG-16 explorer or a small K-file. If the file tip takes a sharp turn in a distobuccal or distolingual direction, the clinician should search for yet another orifice.

Multiple accessory foramina may be located in the furcation of the mandibular molars.[37] These foramina are usually impossible to clean and shape directly, and therefore, extensive irrigation protocols should be applied.

The traditional access cavity for the mandibular first molar typically is trapezoid or rhomboid, regardless of the number of canals present.[120] When four or more canals are present, the corners of the trapezoid or rhombus should correspond to the positions of the main orifices. A variation in root morphology is the presence of an extra distolingual root.[103] The radix entomolaris (RE) is a supernumerary root located distolingually in mandibular molars (Fig. 7.76),[7,16] whereas the radix paramolaris (RP) is an extra root located mesiobuccally.[102]

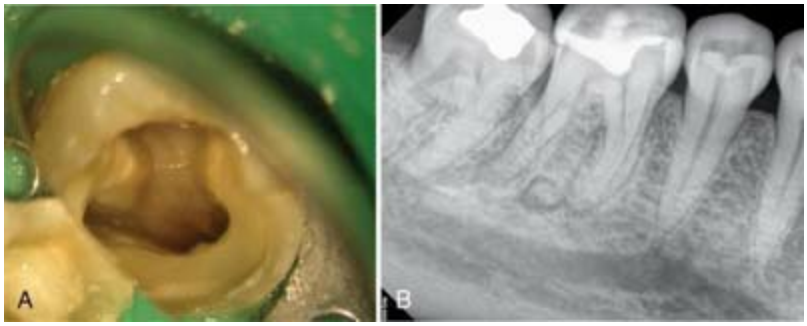

FIG. 7.76 **A,** Radix entomolaris. Notice lingual position of its orifice in relation to the two canals in the distal root. **B,** Radiograph with obvious radix entomolaris on mandibular first molar that curves to the buccal. Mandibular second molar

The mandibular second molar is somewhat smaller coronally than the first molar and tends to be more symmetric (Fig. 7.77). This tooth is identified by the proximity of its roots and its +4 occlusal groove and cuspal pattern. The two roots often sweep distally in a gradual curve, with the apices close together. In some teeth only one root is present. This tooth may have one, two, three, or four root canals (see Table 7.26 online at the Expert Consult site). The μCT scans for the mandibular second molar can be seen in Fig. 7.78. (See Video 7.18 online at the Expert Consult site for rotational views of these teeth.) The access cavity for a two-canal second molar is rectangular, wide mesiodistally and narrow buccolingually. The access cavity for a single-canal mandibular second molar is oval and is lined up in the center of the occlusal surface.

FIG. 7.77 Mandibular second molar. Average time of eruption—11 to 13 years; average age of calcification—14 to 15 years; average length —19.8 mm. Root curvature (most common to least common): mesial root—distal, straight; distal root—straight, distal, mesial, buccal; single root—straight, distal, bayonet, lingual.

Four models of mandibular second molar show two-rooted tooth, occlusal view, interconnected root canals forming a chamber, and curved root canals, respectively.

(See Video 7.18 online at the Expert Consult site for rotational views of these teeth.)

A) µ CT scan shows two root canals in the tooth, which are fused in the second scan. The right side shows a dumb-bell shaped structure with two holes, followed by similar structures with smaller holes.

B) Two µ CT scans show two root canals with an addition branch forming a chamber with the right canal and interconnected root canals with a hollow chamber, respectively. The right side shows a circular structure fused to a vertical structure each with a hole inside, followed by two sets of separated structures, one with a large hole and the other with small holes.

C) Two µ CT scans show two root canals with additional root branches and interconnected root canals, respectively. The right side shows a circular structure with three holes, followed by two sets of two irregular structures each with two holes inside. The second set has smaller holes.

Mandibular third molar

The mandibular third molar is anatomically unpredictable and must be

Telegram: @dental_k

www.konkur.in

evaluated on the basis of its root formation (Fig. 7.79).[52] More often than not it has an occlusal pattern similar to the first molar only much smaller in overall size. Fused short, severely curved, or malformed roots often support well-formed crowns. This tooth may have one to four roots and one to six canals (see Table 7.27 online at the Expert Consult site). The μCT scans for the mandibular third molar can be seen in Fig. 7.80. (See Video 7.19 online at the Expert Consult site for rotational views of these teeth.)

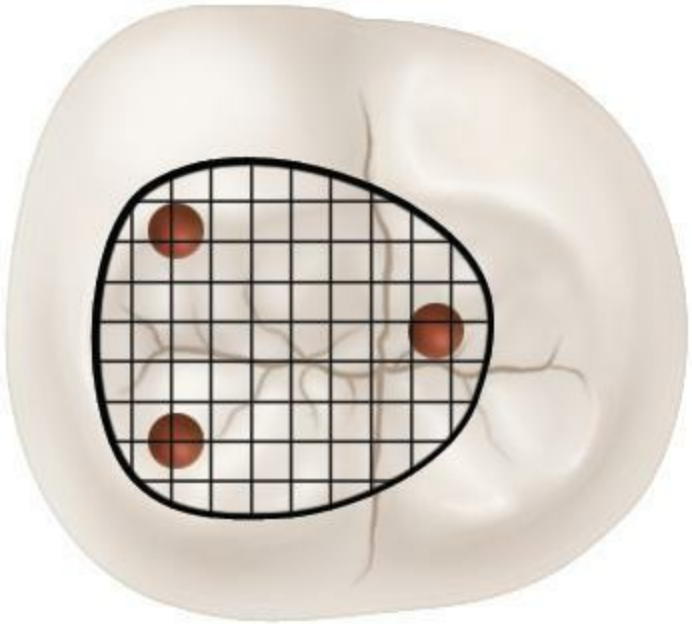

FIG. 7.79 Mandibular third molar. Average time of eruption—17 to 21 years; average age of calcification—18 to 25 years; average length—18.5 mm.

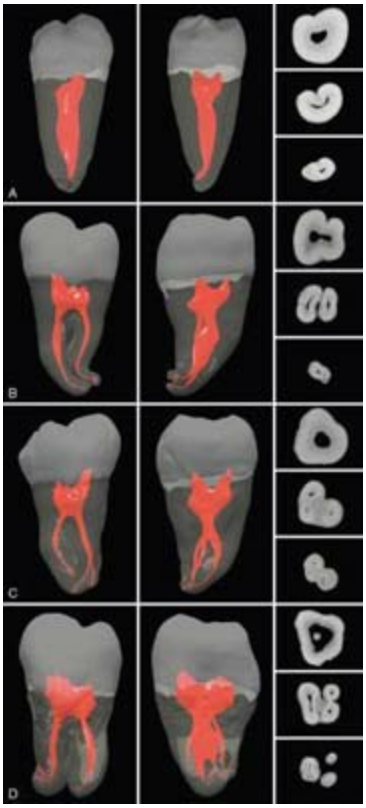

FIG. 7.80 µCT scans of mandibular third molars represent multiple variations for this tooth. **A**, Single C-shaped type canal. **B,** Complex anatomy with significant canal curvatures apically. **C,** Three canals that curve in multiple directions. **D,** Flattened, ribbon-shaped canals with significant apical curvatures. All teeth are shown from both a buccal (vestibular) and a proximal perspective, along with the cross-sectional anatomy at the coronal, middle, and apical levels. (See Video 7.19 online at the Expert Consult site for rotational views of these teeth.)

A) Two µ CT scans show root canal extending from the lower part of crown. The root is diverted in the second scan. The right side shows heart-shaped structure with a hole at the center, a C-shaped aperture in the next structure, and a small hole in the ovoid structure.

B) Two µ CT scans show root canals below the crown. The first scan shows curved root canals at the apex. The second scan shows a diverted fused root canals. The right side shows three structures with a horizontal aperture, two vertical apertures, and a small hole, respectively.

C) Two µ CT scans show two root canals with an additional branch near the apex of one root and curved multiple branches near the apex. The right side shows a structure with a deep hole at the center and two structures with three small holes. The third structure has small holes.

D) Two µ CT scans show two-rooted tooth and one-rooted tooth each with multiple branches. The right side shows a structure with a triangular cavity,

Telegram: @dental_k

www.konkur.in

two sets of three-fused structures each with a hole. The third structure has small holes.

C-shaped canals can also occur (Fig. 7.81).[40] Many of these teeth can be successfully root treated, regardless of anatomic irregularities; however, the long-term prognosis is determined by the root surface volume in contact with bone. The clinician must weigh the benefit of treatment against the prognosis.

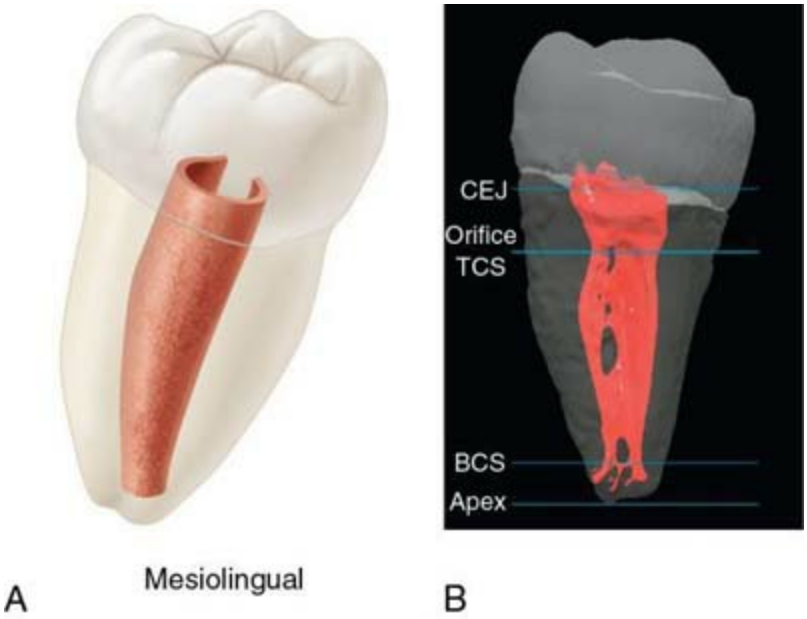

FIG. 7.81 **A,** Diagram of a C-shaped canal anatomy: one continuous canal from pulp chamber floor to apex. **B,** One large canal moving from the top of the C-shaped canal *(TCS)* to the apical-most or bottom of C-shaped canal *(BCS)*, encompassing most of the canal space. *CEJ,* Cementoenamel junction.

A) Mesiolingual view of tooth with a single root canal.

B) μ CT scan of tooth with labels as follows: CE, Orifice TCS, BCS, and Apex.

Teeth with C-shaped root canal systems

The main cause for C-shaped roots and canals is the failure of Hertwig's epithelial root sheath to fuse on either the buccal or lingual root surface (Fig. 7.82).[40] (See Videos 7.20, *A* and *B* online at the Expert Consult site for

Telegram: @dental_k

www.konkur.in

rotational views of these teeth.) The C-shaped canal system can assume many variations in its morphology (Fig. 7.83). Further cross section of types I, II, and III are seen in Fig. 7.83. The original classification[67] has been modified and has produced a more detailed description of C-shaped root and canal morphology. The C-shaped canal configuration can vary along the root depth so that the appearance of the orifices may not be good predictors of the actual canal anatomy.[26,28,70,117,126]

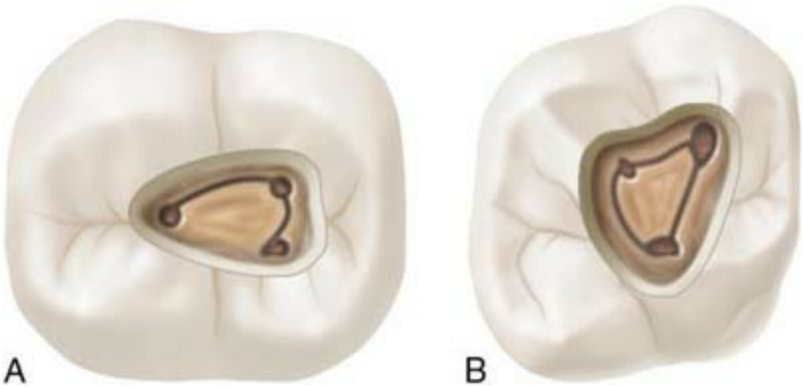

FIG. 7.82 C-shaped canal anatomy. **A,** Mandibular second molar. **B,** Maxillary first molar.

Source: (From Min Y, Fan B, Cheung G, et al: C-shaped canal system in mandibular second molars. III. The morphology of the pulp chamber floor, *J Endod* 32: 1155–1159, 2006.)

Most C-shaped canals occur in the mandibular second molar (Fig. 7.84),[117] but they also have been reported in the mandibular first molar,[118] the maxillary first and second molars, and the mandibular first premolar.[26,27,29,30,75,78,116,121,123,125,126]

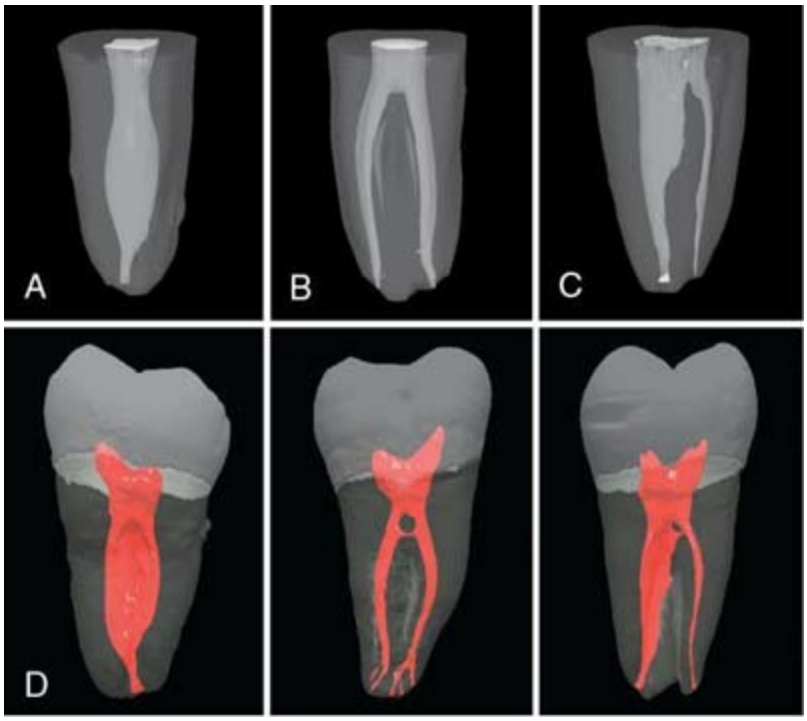

FIG. 7.84 Three-dimensional classification of C-shaped canal configuration. **A,** Merging type. **B,** Symmetrical type. **C,** Asymmetrical type. **D,** Additional C-shaped canal variations.

Telegram: @dental_k

www.konkur.in

Source: (From Gao Y, Fan B, Cheung G, et al: C-shaped canal system in mandibular second molars. IV. Morphological analysis and transverse measurement, *J Endod* 32:1062–1065, 2006.)

The access cavity for teeth with a C-shaped root canal system varies considerably and depends on the pulp morphology of the specific tooth. Teeth with C-shaped anatomy pose a considerable technical challenge; therefore, use of the DOM during all treatment phases is recommended.[15]

All tables in this section that provide literature documentation for the studies on root canal anatomy are available online at the Expert Consult site and can be accessed accordingly.

The 3D reconstructed images in this chapter were obtained from the tooth and canal morphology database at the School of Stomatology, Wuhan University, China. The database was established by Dr. Bing Fan's group and supported by the National Natural Science Foundation of China (grant no. 30572042, 30872881, 81070821) and the Key Technologies R&D Programme of Hubei Province of China (grant no. 2007AA302B06). The microcomputed tomography machine used for scanning was the μCT-50, Scanco Medical, Bassersdorf, Switzerland. The multiple software used for 3D reconstruction included 3D-Doctor (Able Software Corp., Lexington, MA) and VGStudio MAX (Volume Graphics GmbH, Heidelberg, Germany).

Access cavity illustrations: Designed and formatted by Dr. Richard Burns, San Mateo, CA; and Dr. Eric Herbranson, San Leandro, CA.

8: Cleaning and shaping of the root canal system

Ove A. Peters, Christine I. Peters, Bettina Basrani

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Telegram: @dental_k

www.konkur.in

Introduction

Clinical endodontics encompasses a number of treatments that share the common goal of preventing and treating microbial contamination of pulps and root canal systems. Treatment of traumatic dental injuries and vital pulp treatment are fundamentally different from pulpectomies and root canal instrumentation of teeth with infected pulps (see Chapter 1 for more details).

Telegram: @dental_k

www.konkur.in

Endodontic therapy is directed toward one specific set of aims: to cure or prevent periradicular periodontitis.[309,459] The ultimate goal is to aid in the long-term retention in patients' natural teeth in function and esthetics.

To date, available pertinent clinical trials[89,317,326,341] and in vitro studies suggest that certain practices in canal preparation and disinfection are more appropriate than others. This chapter provides a summary of this information.

Orthograde root canal treatment is a predictable and usually highly successful procedure, both in relatively straightforward (Fig. 8.1) and more complex cases (Fig. 8.2). In recent studies and reviews, favorable outcome rates of up to 95% were reported for the treatment of teeth diagnosed with irreversible pulpitis;[37,93,139] favorable outcome rates of up to 85% were reported for teeth with infected, necrotic pulps.[92,140,301,326,358]

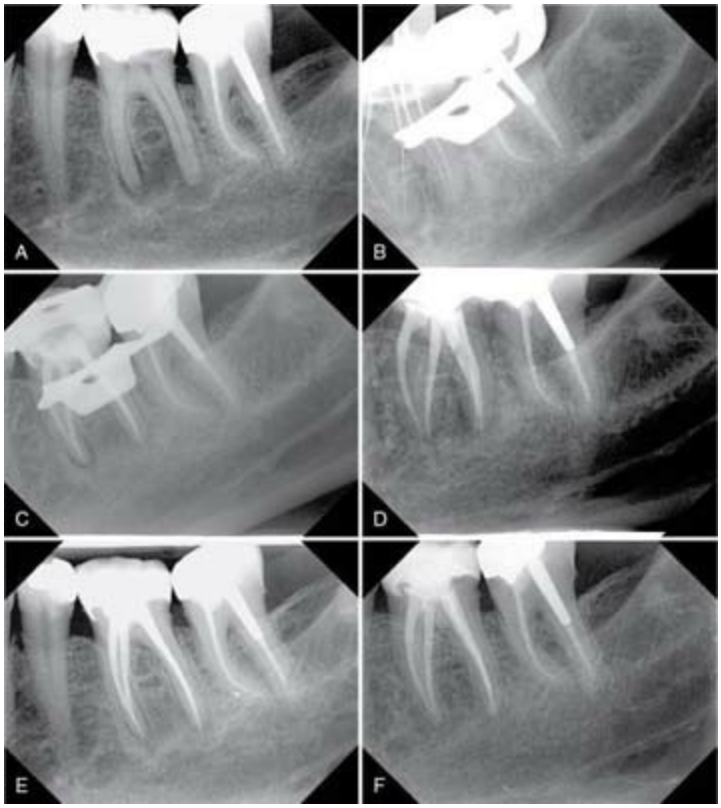

FIG. 8.1 Effect of routine root canal treatment of a mandibular molar. **A,** Pretreatment radiograph of tooth #19 shows radiolucent lesions adjacent to both mesial and distal root apices. **B,** Working length radiograph shows two separate root canals in the mesial root and two merging canals in the distal root. **C,** Posttreatment radiograph after shaping of root canal systems with nickel-titanium rotary files and

D) Radiograph of tooth shows a radiolucent crown with radiopaque neck and canals.

E) Radiograph of tooth shows a radiolucent crown with radiopaque neck and canals.

Source: (Courtesy Dr. H. Walsch.)

The ultimate cause of pulpal pathosis are microorganisms that can breach dental hard-tissue barriers through several avenues—the most common being dental caries (Fig. 8.3). Shaping and cleaning procedures (Box 8.1) as part of root canal treatment are directed against microbial challenges to the root canal system. However, proper disinfection per se does not guarantee long-term retention of root canal–treated teeth; there is good evidence that this outcome is closely related to placement of an adequate coronal restoration.[20,300,352,369] Moreover, the impact of preservation of radicular structural strength on tooth longevity has been emphasized.[154]

FIG. 8.3 Root canal therapy as part of a comprehensive treatment plan. The patient, who was recovering from intravenous drug addiction, requested restorative dental treatment. Because of extensive decay, several teeth had to be extracted, and nine teeth were treated endodontically. Root canal treatment was aided by nickel-titanium rotary instruments, and obturation was done with lateral compaction of

Telegram: @dental_k

www.konkur.in

gutta-percha and AH26 as the sealer. Microsurgical retrograde therapy was performed on tooth #8, and the distobuccal root of #14 had to be resected. Metal-free adhesively luted restorations were placed, and missing mandibular teeth were replaced by implants. **A,** Pretreatment intraoral status, showing oral neglect. **B,** Posttreatment intraoral status at 4-year follow-up, showing fully functional, metal-free, tooth-colored reconstructions. **C,** Panoramic radiograph at 4-year recall shows sound periradicular tissues in relation to endodontically treated teeth.

A) Close-up of frontal upper and lower jaw exposes extensively decayed central and lateral incisors.

B) Close-up of frontal upper and lower jaw exposes central, lateral incisors, canines and molars.

C) Radiograph of frontal upper and lower jaw shows radiopaque lower molars with extended radiopaque spirally textured posts for root treatment visible in the periradicular tissues.

Box 8.1

Basic Objectives in Cleaning and Shaping

The primary objectives in cleaning and shaping the root canal system are to:

- Remove infected soft and hard tissue
- Give disinfecting irrigants access to the apical canal space
- Create space for the delivery of medicaments and subsequent obturation
- Retain the integrity of radicular structures

Principles of cleaning and shaping

Endodontists agree that a major biologic aim of root canal therapy is to address apical periodontitis by disinfection and subsequent sealing of root canal systems. However, considerable disagreement exists over how this goal should be achieved. Although the terms “cleaning and shaping” are commonly used to describe root canal treatment procedures, reversing the order to “shaping and cleaning” may more correctly reflect the fact that enlarged canals direct and facilitate the cleaning action of irrigants.

Telegram: @dental_k

www.konkur.in

Microorganisms in the pulp cavity and coronal root canal may be readily killed by irrigants early in a procedure, but bacteria and their toxins in less accessible canal areas can survive and elicit or maintain apical periodontitis. In current everyday practice, these persisting bacteria can be targeted only after root canal preparation.

Mechanical objective

An ideal mechanical objective of root canal instrumentation is complete and centered incorporation of the original canals into the prepared shape, meaning that all root canal surfaces are mechanically prepared (*green areas* in Fig. 8.4, *A* and *B*); however, this goal is unlikely to be met with current techniques.[312,340]

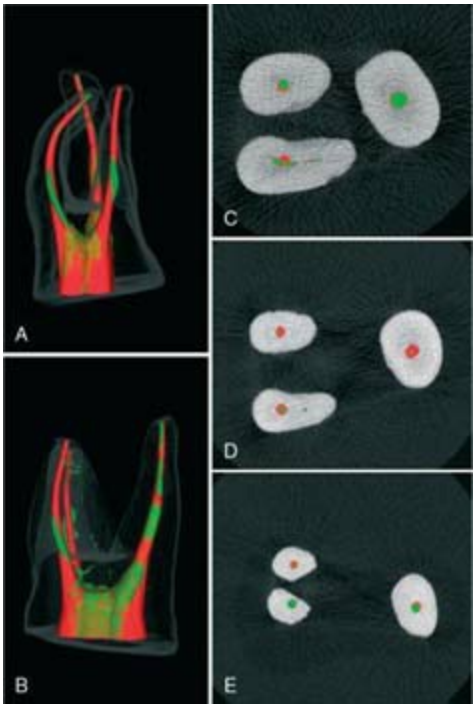

FIG. 8.4 Example of a desired shape, with the original root canal fully incorporated into the prepared outline. **A–B,** Micro–computed tomography reconstructions in clinical and mesiodistal views of a maxillary molar prepared with a NiTi rotary system. The *green area* indicates the pretreatment shape, and the *red area* indicates the posttreatment shape. Areas of *mixed red and green* indicate no change (i.e., no removal of radicular dentin). **C–E**, Cross sections of the coronal, middle, and apical thirds; the pretreatment cross sections *(green)* are encircled by the posttreatment outlines *(red)* in most areas.

Telegram: @dental_k

www.konkur.in

A) Scan shows a red tooth neck, root canals with green pigments towards the left and central canal. Green vertical curve is visible over the left and right canal and on the outlines of central canal.

B) Scan shows a red tooth neck, root canals with green pigments towards the right and central canal. Green vertical curves are visible over the left and right canal and around central canal.

C) Cross-section of coronal canal shows scattered red dots in the center and a streak of green over it; Cross-section of middle canal shows green dot in the center and an outline of red; and Cross-section of apical canal shows a green dot in the center and an outline of red on one side.

D) Cross-section of coronal canal shows a red dot in the center and green dot inside it with a green dot on the side; Cross-section of middle canal shows red dot in the center and green dot inside it; and Cross-section of apical canal shows red dot in the center and green dot inside it.

E) Cross-section of coronal canal shows a green dot with an outline of red on one side; Cross-section of middle canal shows green dot in the center with an outline of red on one side; and Cross-section of apical canal shows red dot in the center and green dot inside it.

Source: (***A–B***, From Hübscher W, Barbakow F, Peters OA: Root-canal preparation with FlexMaster: canal shapes analysed by micro-computed tomography, *Int Endod J* 36:740–747, 2003.)

Preparation errors such as deviations, zipping, and perforations should be absent. Although these negative effects of canal shaping and other procedural mishaps (see later) may not directly affect the probability of a favorable outcome,[254] they leave parts of the root canal system inaccessible for disinfection and are undesirable for that reason alone.

Another important mechanical objective is to retain as much cervical and radicular dentin as possible so as not to weaken the root structure, thereby preventing root fractures. Before root canal shaping, dentin wall thickness dimensions of 1 mm and below have been demonstrated in anatomical studies.[113] Straightening of canal paths can lead to precarious thinning of curved root walls (Fig. 8.5). Although no definitive minimal radicular wall thickness has been established, 0.3 mm is considered critical by some authors.[252] To avoid overpreparation and outright perforations, adequate access cavity preparation and optimal enlargement of the coronal third of the root canal has to be ascertained (see upcoming discussion).

Telegram: @dental_k

www.konkur.in

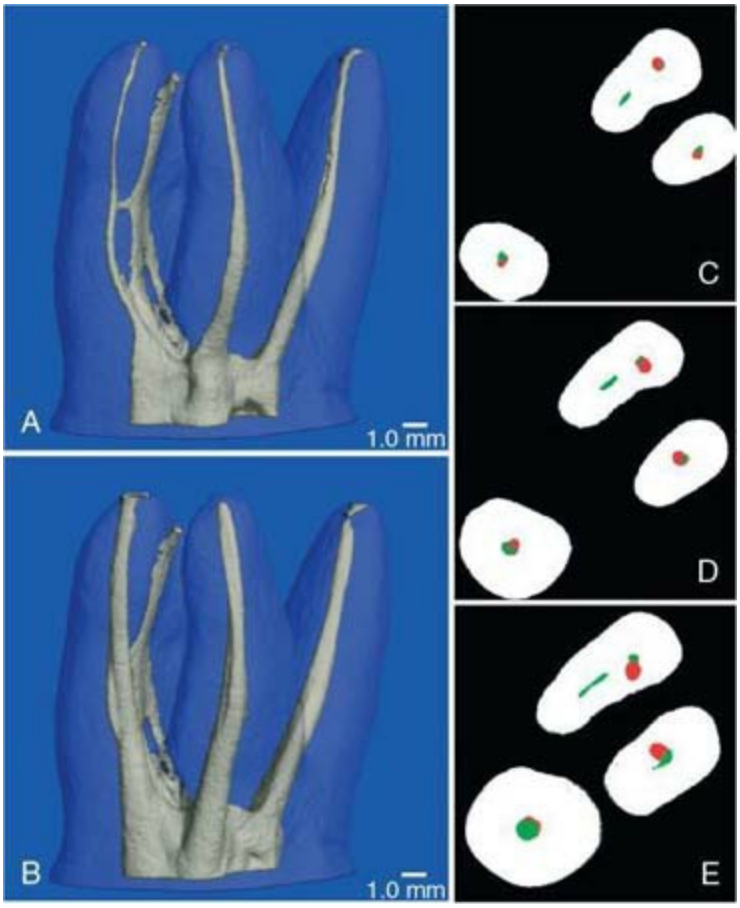

FIG. 8.5 Example of excessive thinning of dental structure during root canal treatment. **A–B**, Micro–computed tomography reconstructions show pretreatment and posttreatment root canal geometry of a maxillary molar. **C–E**, Cross sections of the coronal, middle, and apical thirds with pretreatment canal cross sections. Note the transportation and thinning, in particular, in the main mesiobuccal canal.

A) Scan of a maxillary molar shows a laterally split canal.

B) Scan of a maxillary molar shows partially filled and reconstructed split canal.

C) Cross-section of coronal canal shows red dot in the center with a green dot in it with a green streak on the side; Cross-section of middle canal shows overlapping green and red dots in the center; and Cross-section of apical canal shows a red dot in the center and an outline of green on one side.

D) Cross-section of coronal canal shows red dot in the center with an outline of green on one side and a green streak on the side; cross-section of middle canal shows overlapping green and red dots in the center; and cross-section of apical canal shows a red dot in the center and green dot in it.

E) Cross-section of coronal canal shows red and green dot in the center with a

Telegram: @dental_k

www.konkur.in

green streak on the side; Cross-section of middle canal shows green dot in the center with an outline of red on one side; and Cross-section of apical canal shows overlapping red and green dots in the center.

Biologic objective

Schilder suggested that canals should be prepared to a uniform and continuous taper;[386] however, this guideline was aimed at facilitating obturation rather than targeting antimicrobial efficacy. For optimal disinfection, preparation shape and antimicrobial efficacy are intimately related through efficient removal of infected pulp and dentin (Fig. 8.6) and creation of space for delivery of irrigants.

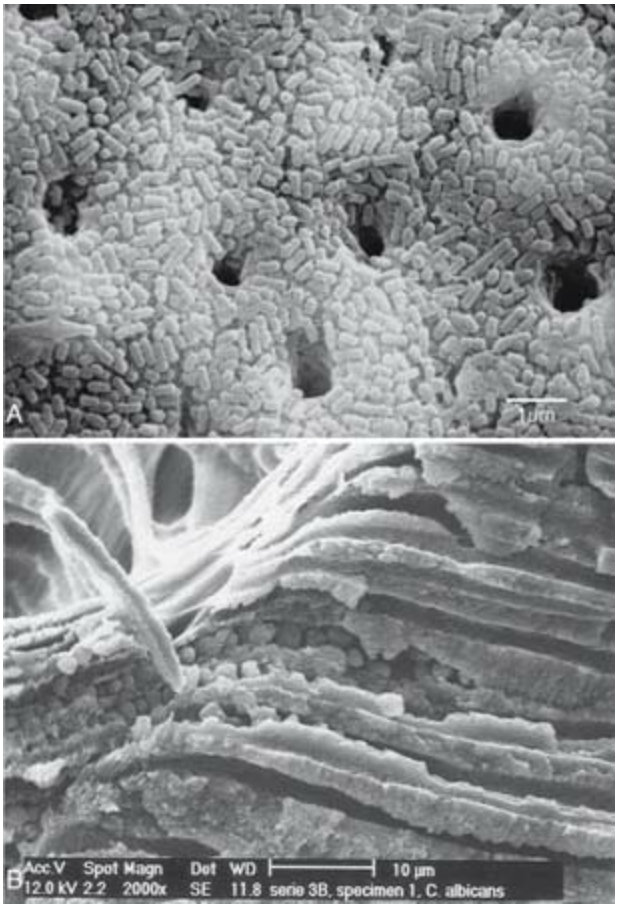

FIG. 8.6 Presence of microorganisms inside the main root canal and dentinal tubules. **A,** Scanning electron micrograph of a root canal surface shows a confluent layer of rod-shaped microbes (×3000). **B,** Scanning electron micrograph of a fractured root with a thick smear

Traditionally, fluids have been dispensed passively into root canals by syringe and needle (Fig. 8.7). When delivered with passive needle irrigation, solutions have been shown to progress only about 1 mm farther than the tip of the needle.[169,350,370] Enlarged apical canals and finer more flexible needles allow increasingly deeper needle placement, and this improves débridement and disinfection of canals.[14,464] Irrigation methods and solution are discussed in detail elsewhere in this chapter.

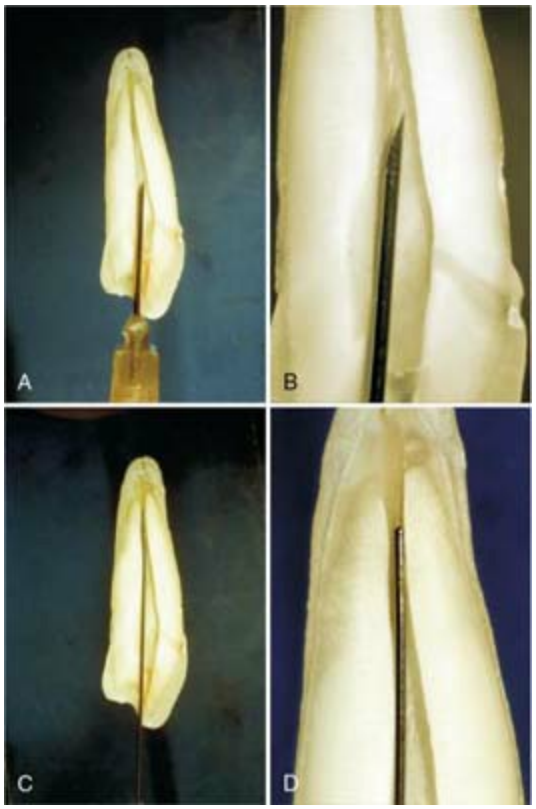

FIG. 8.7 Irrigation needles inserted into prepared root canals. **A–B**, A 27-gauge needle barely reaches the middle third. **C–D**, A 30-gauge,

side-venting needle reaches the apical third in adequately enlarged canals.

Close-up of a tooth with an exposed root canal shows an irrigation needle inserted into it as labeled from A through D.

Technical objective

While a continuous taper that encompasses the original shape and curvature of a given root canal is an accepted goal, final apical preparation size remains a much-disputed entity in root canal therapy, as does final taper of the preparation.[43] Arguments were made for better disinfection with larger sizes (i.e., #50 or greater)[79,363] in combination with smaller tapers of.02 to.05. Others found no difference whether the selected final size was small or large.[95,500]

Clinical issues

A wide spectrum of possible strategies exists for attaining the goal of removing the canal contents and eliminating infection. Lussi and colleagues[264] introduced an approach to removing canal contents and accomplishing disinfection that did not involve the use of a file: the so-called non-instrumentation technique. This system consisted of a pump, a hose, and a special valve that was cemented into the access cavity (Fig. 8.8, *A*) to provide oscillation of irrigation solutions (1% to 3% sodium hypochlorite) at a reduced pressure. Although in vitro data[263] suggested that canals could be cleaned and filled using this noninvasive system (see Fig. 8.8, *B* and *C*), clinical results were not as convincing (see Fig. 8.8, *D*).[25] Recently, a strategically similar technique was introduced, the GentleWave (Sonendo, Orange, CA, USA) unit, described in detail later.

At the opposite end of the spectrum of débridement strategies is to remove all intraradicular infection through extraction of the tooth in question. Almost invariably, periradicular lesions heal after extraction of the involved tooth.

Clinical endodontic therapy takes place somewhere along this spectrum of treatment strategies. This is reflected in some of the controversies that surround the cleaning and shaping process. Once the decision has been made to initiate endodontic treatment, a clinician must integrate their knowledge of dental anatomy, immunology, and bioengineering science with clinical information.

Endodontic therapy has been compared with a chain of events, wherein the chain is only as strong as each individual link. For the purpose of this chapter, shaping and cleaning of the root canal system is considered a decisive link, because shaping determines the efficacy of subsequent procedures. It includes mechanical débridement, the creation of space for the delivery of medicaments, and optimized canal geometries for adequate obturation.[326] These tasks are attempted within a complex anatomic framework, as recognized in the early 20th century by Walter Hess (Fig. 8.9; see also Chapter 7 for a complete description of root canal anatomy).[196]

A clinician must choose appropriate strategies, instruments, and devices to overcome challenges and accomplish precise preparation in shape, length, and width. This allows endodontic therapy to address various forms of the disease processes described previously (Fig. 8.10). Recall radiographs taken at appropriate intervals predictably demonstrate longevity and favorable outcomes (see Figs. 8.1, 8.2, and 8.11) if a systematic approach to root canal shaping is adhered to (see Box 8.1).

Endodontic files traditionally have been manufactured according to empiric designs, and most instruments still are conceived based on individual clinicians' philosophies rather than developed through an evidence-based approach. Similar to the development of composite resins in restorative dentistry, the development of new files is a fast and market-driven process. With new instruments becoming available, the clinician may find it difficult to pick the file and technique most suitable for an individual case. Clinicians must always bear in mind that all file systems have specific benefits and weaknesses. Ultimately, clinical experience, handling properties, usage safety, and case outcomes, rather than marketing or the inventor's name, should drive decisions toward a particular design. The following section describes typical instruments used in root canal shaping.

Endodontic instruments

General characteristics

Design elements

Root canal preparation instruments such as K-files and nickel-titanium rotary instruments follow certain design principles that relate to drills and reamers used for work in wood and metal, respectively, while other instruments such as broaches and Hedström files do not find a direct technological correlate. Design elements such as the tip, flutes, and cross sections are considered relevant for files and reamers used in rotary motion. These pertinent aspects are briefly described later; for a more detailed review, the reader is referred to the literature.[162,365,371,423]

Tip design.

In root canal preparation, an instrument tip has two main functions: to guide

Telegram: @dental_k

www.konkur.in

the file through the canal and to aid the file in penetrating deeper into the canal. A clinician unfamiliar with the tip design, in particular of a rotary instrument, may do either of the following: (i) transport the canal (if the tip is capable of enlarging the canal and is used too long in one position in a curved canal) or (ii) encounter excessive torsion and break the file (if a noncutting tip is forced into a canal with a smaller diameter than the tip).

The angle and radius of its leading edge and the proximity of the flute to its actual tip end determine the cutting ability of a file tip. Cutting ability and file rigidity determine the propensity to transport the canal. The clinician must keep in mind that as long as a flexible file with a noncutting tip is engaged, 360-degree canal transportation is unlikely to occur.[360]

Studies have indeed shown that tip design affects file control, efficiency, and outcome in the shaping of root canal systems.[283,284] The tip of the original K-file resembled a pyramid; instrument tips have been described as *cutting*, *noncutting*, and *partially cutting*, although no clear distinction exists among the three types (Fig. 8.12).

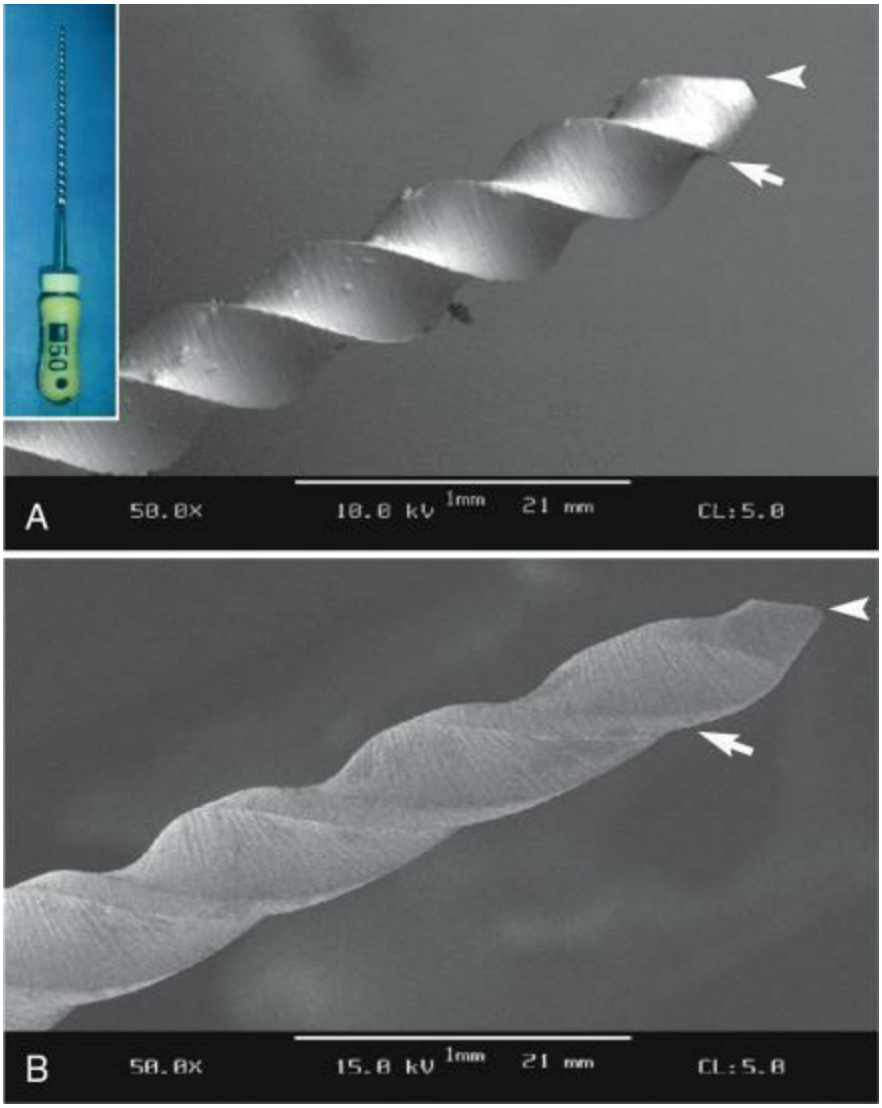

FIG. 8.12 Comparison of the flute geometry and tip configuration of a hand file *(insert)* and a NiTi rotary instrument. **A,** K-file with sharp cutting edges *(arrow)* and Batt tip *(arrowhead).* **B,** GT rotary file with rounded, noncutting tip *(arrowhead),* smooth transition, and guiding radial lands *(arrow).*

A) Close-up of a rotatory hand file shows arrows pointing to the conical flat tip and the sharply textured spiral surface.

B) Close-up of a rotatory hand file shows arrows pointing to the conical curved tip and the flatly textured spiral surface.

Noncutting tips, also called *Batt tips*, are created by grinding and smoothing the apical end of the instrument (see Fig. 8.12, *A*). A tip modification was introduced with the Flex-R file, which was manufactured

Telegram: @dental_k

www.konkur.in

fully by grinding so that the transitional angles between the tip and the instrument's working parts blend smoothly.[361] Similar techniques are required to manufacture NiTi K-files.[449]

For NiTi rotary files, typically rounded noncutting tips are used (see Fig. 8.12, *B*), which are effective in preventing preparation errors that were found with earlier so-called safe cutting tips.[210] One exception to this rule are rotaries specifically designed as retreatment instruments; cutting tips in that case facilitate removal of the existing root canal filling material and are sufficiently safe.

Longitudinal and cross-sectional design.

The *flute* of the file is the groove in the working surface used to collect soft tissue and dentin chips from the wall of the canal. The effectiveness of a flute depends on its depth, width, configuration, and surface finish. The surface with the greatest diameter that follows the groove (where the flute and land intersect) as it rotates forms the *leading (cutting) edge* or the *blade* of the file. The cutting edge creates and deflects dentin chips along the wall of the canal and severs or snags soft tissue. Its effectiveness depends on its angle of incidence and sharpness.

Some instruments have a feature between trailing and cutting edge that forms a larger contact area with the radicular wall; this surface is called a radial *land* (Fig. 8.13). This design is believed to reduce the tendency of the file to thread into the canal. It also supports the cutting edge and limits the depth of cut; its position relative to the opposing cutting edge and its width determine its effectiveness. On the other hand, landed files are typically less cutting efficient compared with triangular cross sections.[335]

www.konkur.in

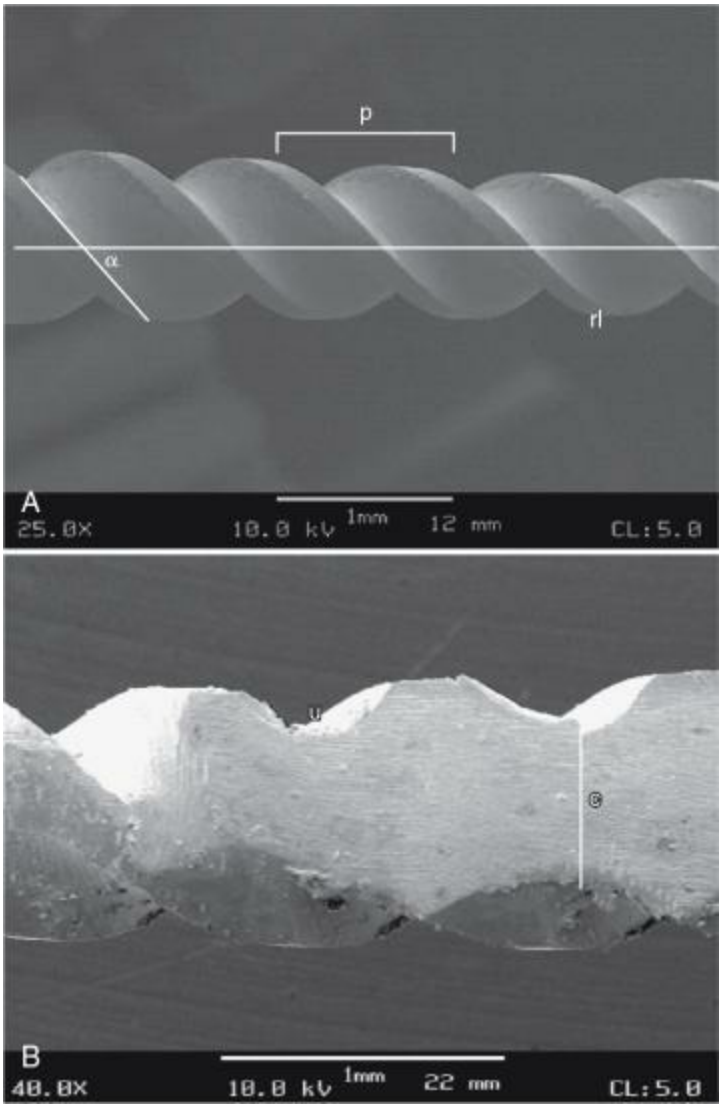

FIG. 8.13 Design characteristics of nickel-titanium rotary instruments. **A,** Lateral view showing the details of the helical angle, pitch *(p),* and the presence of guiding areas, or radial lands *(rl)* (scanning electron micrograph, ×25). **B,** Ground-working part of the instrument in **A,** showing U-shaped excavations and the dimension of the instrument core *(c).*

Set of two images show close-up of spirally textured geometry of nickel-titanium rotary file as labeled through A to B.

To reduce frictional resistance, some of the surface area of the land that rotates against the canal wall may be reduced to form the *relief.* The angle the cutting edge forms with the long axis of the file is called the *helical angle* (see Fig. 8.13).

If a file is sectioned perpendicular to its long axis, the *rake angle* is the

Telegram: @dental_k

www.konkur.in

angle formed by the leading edge and the radius of the file through the point of contact with the radicular wall. The rake angle may be *positive* or *cutting* (Fig. 8.14, *A*). If the angle formed by the leading edge and the surface to be cut is 90 degrees, the rake angle is said to be *neutral*. It may also be *negative* or *scraping* (see Fig. 8.14, *C*). The *cutting angle* is considered a better indication of a file's cutting ability and is determined by measuring the angle formed by the leading edge of the file and a tangent to the radicular wall in the point of contact. The clearance angle corresponds to the cutting angle at the trailing edge of the file and, in case of reciprocating action, becomes the cutting angle. The sum of cutting angle and rake angle is 90 degrees.

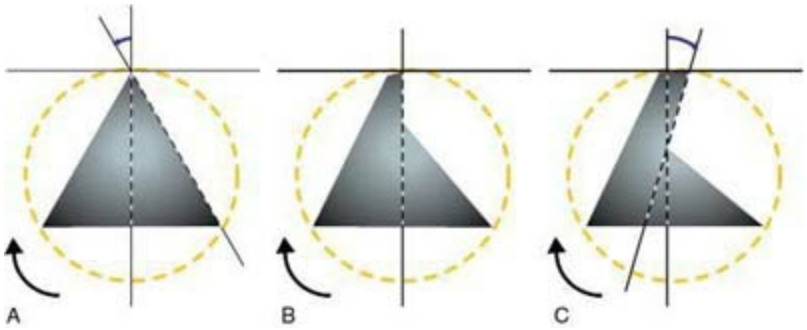

FIG. 8.14 The cutting angle of an endodontic file can be negative (**A**), neutral (**B**), or positive (**C**).

A) Diagram shows two halves of a triangle segmented vertically with a lined circle enclosing it. Right side of the triangle creates an anti-clockwise torque.

B) Diagram shows two halves of a triangle segmented vertically with a lined circle enclosing it. The right half of the triangle is smaller than the left half (which has slightly flat top).

C) Diagram shows two halves of a triangle segmented vertically with a lined circle enclosing it. The right half of the triangle is smaller than the left triangle which extends to the right half creating a clockwise torque.

The *pitch* of the file is the distance between a point on the leading edge and the corresponding point on the adjacent leading edge (the distance from one "spiral twist" to the next; see Fig. 8.13). The smaller the pitch or the shorter the distance between corresponding points, the more spirals the file has and the greater the helix angle. While K-files have a constant pitch typically in the range of 1 mm, many NiTi rotaries have a variable pitch—one that

Telegram: @dental_k

www.konkur.in

changes along the working surface. When variable pitch is used, for example to modify the helical angle, usually tighter spirals are located close to the tip of the file and more space between the flutes is located toward the coronal part of the file. A longitudinal section through an instrument reveals the *core* (see Fig. 8.13). The outer diameter of a tapered instrument increases from the file tip toward the handle. Depending on core dimensions, flutes may become proportionately deeper, resulting in a *core taper* that may be different from the *external taper*.

Cutting angles, helix angles, and external and core tapers may vary along the working surface of the file, and the ratios of these quantities can vary among instruments of the same series.

Taper.

The *taper* usually is expressed as the amount that the file diameter increases each millimeter along its working surface from the tip toward the file handle. For example, a size #25 file with a.02 taper would have a 0.27 mm diameter 1 mm from the tip, a 0.29 mm diameter 2 mm from the tip, a 0.31 mm diameter 3 mm from the tip, and so forth. Instruments can have constant or variable taper. Current instrument developments include variations in helical angle, pitch, and taper along the cutting portion, which along with variations in alloy and rotational speed (rpm) all affect cutting behavior.[335] The ability to determine cross-sectional diameter at a given point on a file can help the clinician determine the file size in the point of curvature and the relative stress being placed on the instrument. Instruments with greater tapers are designed so that the tip of the instrument functions as a guide, and the middle and coronal part of the instrument's working part is the one engaging the canals walls.

International Standards Organization norms

Standardized specifications have been established to improve endodontic instrument quality.[212] For example, the International Standards Organization (ISO) has worked with the Fédération Dentaire Internationale (FDI) and other stakeholders to define specifications. These standards are designated with an ISO number. The American Dental Association (ADA) also has been involved in this effort, as has the American National Standards Institute

Telegram: @dental_k

www.konkur.in

(ANSI); these standards are designated with an ANSI number. However, new instrument designs have resulted in a need for reconsideration of the standards.

Two ISO standards pertain to endodontic instruments: ISO No. 3630-1 deals with K-type files (as does ANSI No. 28), Hedström files (ANSI No. 58), and barbed broaches and rasps (ANSI No. 63). ISO No. 3630-3 deals with condensers, pluggers, and spreaders (ANSI No. 71); however, the term *ISO-normed instruments* is often synonymous for K-files (Fig. 8.15).

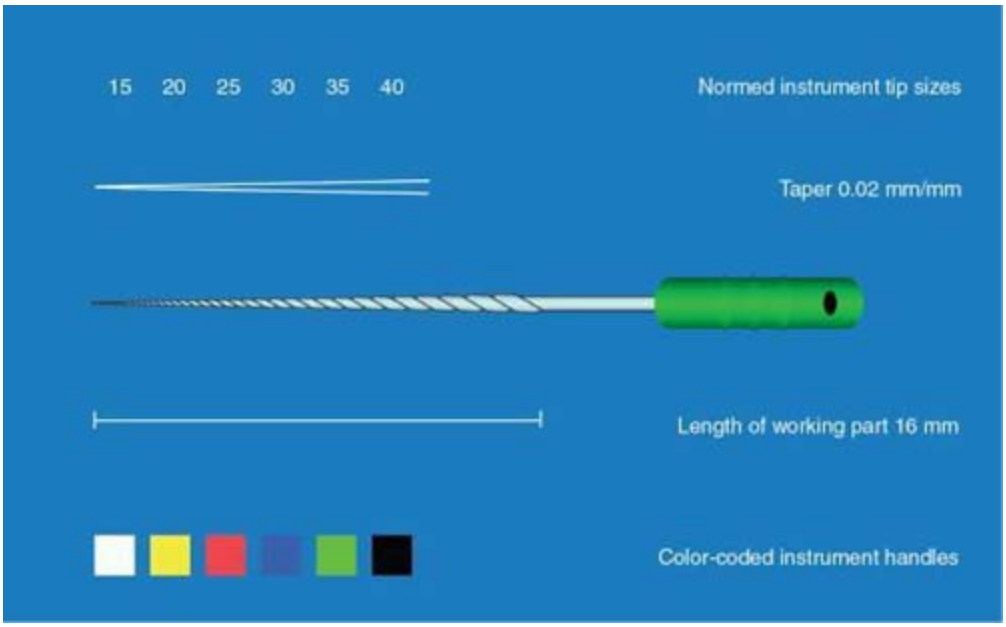

FIG. 8.15 Schematic drawing of an ISO-normed hand instrument size #35. Instrument tip sizing, taper, and handle colors are regulated by the ISO/ANSI/ADA norm.

Diagram of a hand file shows a spirally textured surface and tip with a green handle. The hand file come in sizes 15, 20, 25, 30, 35 and 40 with work length of 16 millimeters and color codes of white, yellow, red, purple, green and black.

One important feature of ISO-normed hand instruments is a defined increase in tip diameter of 0.05 or 0.1 mm, depending on the instrument size (Fig. 8.16). ISO-normed K- and Hedström files (Fig. 8.17) are available in different lengths (21, 25, and 31 mm), but all have a 16-mm-long section of cutting flutes (see Figs. 8.12 and 8.15). The cross-sectional diameter at the

Telegram: @dental_k

www.konkur.in

first rake angle of any file is labeled D_0. The point 1 mm coronal to D_0 is D_1, the point 2 mm coronal to D_0 is D_2, and so on up to D_{16}. The D_{16} point is the largest diameter of an ISO-normed instrument. Each file derives its numeric name from the diameter at D_0 and is assigned a specific color code (see Fig. 8.15). Another aspect of ISO files is the standard taper of 0.32 mm over 16 mm of cutting blades, or 0.02 mm increase in diameter per millimeter of flute length (.02 taper).

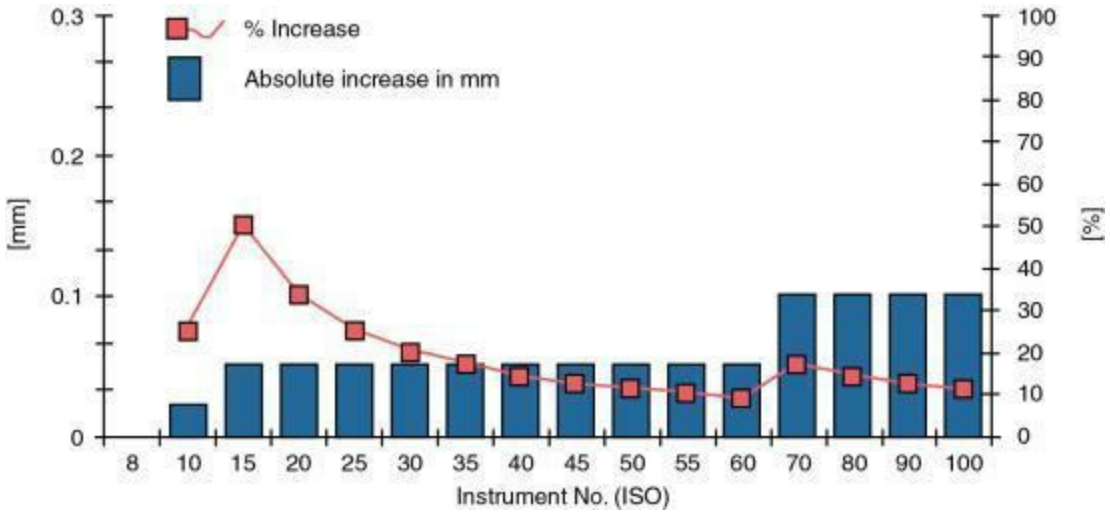

FIG. 8.16 Increase in tip diameter in absolute figures and in relation to the smaller file size. Note the particularly large increase from size #10 to size #15.

Plot shows instrument numbers versus with absolute increase in tip diameters (in millimeters) and increase (in percentage). The horizontal axis shows instrument numbers ranging from 0 to 100. The left vertical axis shows diameters (in millimeters) ranging from 0 to 0.3 in increments of 0.1. The right vertical axis shows percentage ranging from 0 to 100 in increments of 10.

The data for absolute increase depicted as bars is as follows:

10: 7, 15 to 60: 18; and 70 to 100: 34.

The data for percentage increase is as follows:

10: 0.066, 15: 0.135, 20: 0.1, 25: 0.066, 30: 0.65; decreasing to 0.33 at 60, which increases to 0.05 at 70 decreasing to terminate at 0.04 at 100.

Source: (***A–B***, Courtesy Dentsply Maillefer, Ballaigues, Switzerland.)

The ISO-normed design is a simplification that has specific disadvantages, and it may explain the clinical observation that enlarging a root canal from size #10 to #15 is more difficult than the step from size #55 to #60. The introduction of K-type files with tip sizes between the ISO-stipulated diameters seemed to solve the problem. However, the use of such file is not universally recommended, perhaps because the approved machining tolerance of 0.02 mm could negate any intended advantages. Moreover, although 0.02 mm tolerance is stipulated by the ISO norm, most manufacturers do not adhere to it.[223,389,437,511] Another suggested modification relates to tips with a constant 29% of diameter increments.

Further changes to the numbering system for files with different sizes have been implemented by several manufacturers. One system has introduced

Telegram: @dental_k

www.konkur.in

“half” sizes in the range of #15 through #60, resulting in instruments in sizes #15, #17.5, #20, #22.5, and so on.

Alloys

There are currently two principally different types of alloys used for endodontic instruments: stainless steel and nickel-titanium. Most manually operated endodontic instruments are fabricated from stainless steel and have considerable resistance to fracture. A clinician who is careful in applying force and adheres to a strict program of discarding instruments after use should have few instrument fractures. Stainless steel files are comparably inexpensive so that adequate cleaning and sterilization for reuse of files in sizes up to #60 may not be cost effective. Indeed, files in the range up to #60 have been considered disposable instruments.[429]

Several burs and instruments designed for slow-speed handpiece operation such as Gates Glidden drills, Peeso burs, and pilot drills for intraradicular posts are also manufactured from stainless steel. Instruments designed for rotary root canal instrumentation, however, are typically made of nickel-titanium.[393] This alloy offers unique properties, specifically flexibility, and corrosion resistance.

Physical and chemical properties of steel and nickel titanium alloys.

Basic engineering terms relate to metals and their behavior when used to manufacture endodontic instruments. Stress-strain diagrams describe the response of metal wires under loading depending on their crystal configuration (Fig. 8.18).

Telegram: @dental_k

www.konkur.in

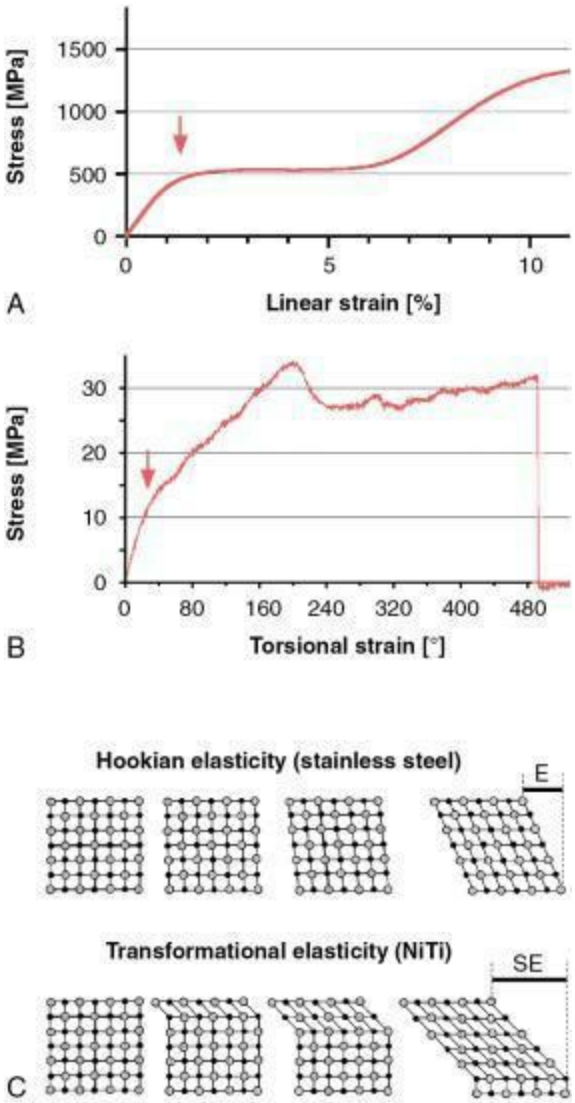

FIG. 8.18 Stress-strain behavior of nickel-titanium alloy. **A,** Schematic diagram of linear extension of a NiTi wire. **B,** Torque to failure test of a size #60,.04 taper ProFile NiTi instrument. Note the biphasic deformation, indicated by arrows in **A–B. C,** Comparison of stainless steel and nickel-titanium crystal lattices under load. Hookian elasticity accounts for the elastic behavior *(E)* of steel, whereas transformation from martensite to austenite and back occurs during the pseudoelastic *(PE)* behavior of NiTi alloy.

Source: (***C***, Modified from Thompson SA: An overview of nickel-titanium alloys used in dentistry, *Int Endod J* 33:297–310, 2000.)

During the development of the equiatomic *nitinol* (this acronym is derived from **ni**ckel-**ti**tanium investigated at the **N**aval **O**rdinance **L**aboratory) alloy (55% [by weight] nickel and 45% [by weight] titanium), several effects were noted that relate to its specific crystal arrangement with two stable main phases, *austenite* and *martensite* (Fig. 8.19): a shape memory effect as temperature- and strain-dependent pseudoelasticity, all attributable to specific thermodynamic properties of the new alloy.[69,119,310,331,449]

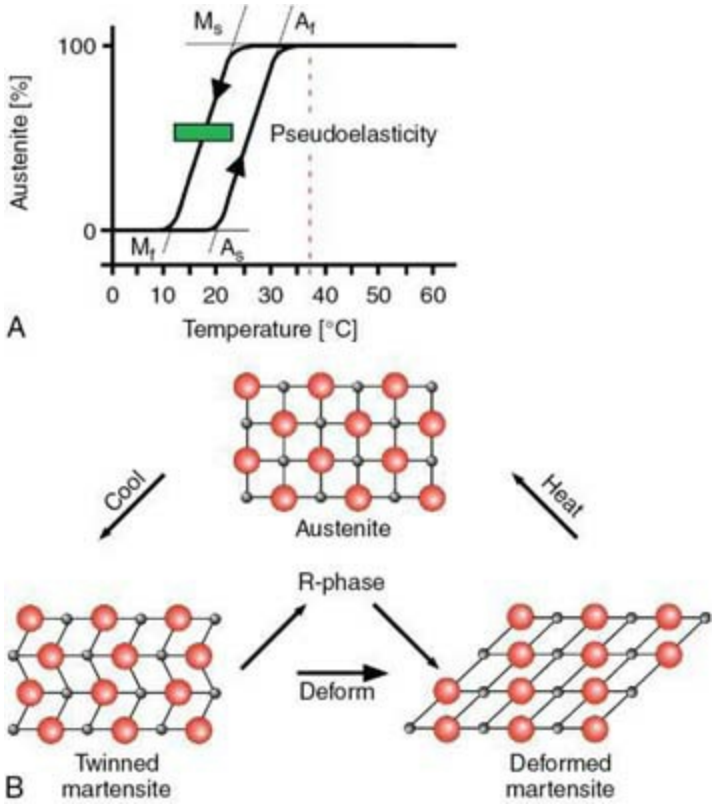

FIG. 8.19 Pseudoelastic behavior of nickel titanium is based on the two main crystal configurations, martensite and austenite, which depend on temperature (**A**) and applied strain (**B**). Formation of the respective configuration initiates at the start temperatures, M_s and A_s.

Telegram: @dental_k

www.konkur.in

A) Plot shows temperature (in Celsius) versus austenite (in percents). The horizontal axis ranges from 0 to 60 in increments of 10. The vertical axis ranges from 0 to 100. A curve M sub 1 increases from (0,0) to (65, 100) with a green box at (15, 50). A curve A sub S increases from (0,0) to (65, 100). An vertical pseudoelasticity line increases from (36.5, 0) to (36.5, 100).

B) Twinned martensite with zigzag lattice deforms through R-phase into deformed martensite with rhomboidal lattice. Deformed martensite is heated to form austenite with square lattice which cools backs to twinned martensite.

Walia and others[474] thought that the pseudoelastic properties of 55-nitinol might prove advantageous in endodontics and initially tested hand instruments. They found that size #15 NiTi instruments were two to three times more flexible than stainless steel instruments; moreover, the instruments showed superior resistance to angular deflection.[474]

Furthermore, hardly any plastic deformation of cutting flutes was recorded when an instrument was bent up to 90 degrees, and forces required to bend endodontic files to 45 degrees were reduced by 50% with nickel titanium, also known as NiTi.[393,474] Serene and others[393] speculated that heat, probably during sterilization cycles, could even restore the molecular structure of used NiTi files, resulting in an increased resistance to fracture. Such a behavior is claimed to occur for current martensitic instruments.[332]

These unusual properties are the result of a molecular crystalline phase transformation in specific crystal structures of the austenitic and martensitic phases of the alloy.[449] External stresses transform the austenitic crystalline form of NiTi into a martensitic crystalline structure that can accommodate greater stress without increasing the strain. As a result, a NiTi file has transformational elasticity, also known as *pseudoelasticity*, or the ability to return to its original shape after being deformed (see Fig. 8.19, *B*). This property dictates that typical NiTi instruments are manufactured by milling rather than twisting. Twisting incorporates plastic deformation and is used, for example, to produce stainless steel K-files. Another recently introduced manufacturing technique is electric discharge machining, which apparently does not introduce defects.[344]

Similar to the application of deforming forces, temperature changes also result in phase transformation (see Fig. 8.19, *A*) from austenite to martensite and vice versa.[190,282] Moreover, thermal heat applied either during the

Telegram: @dental_k

www.konkur.in

production of the raw wire or after manufacturing of the file can be used to modify its properties, most importantly, its flexibility.[172,399] For austenitic endodontic instruments a recoverable elastic response of up to 7% is expected (Fig. 8.20). However, more martensitic instruments will have less of an elastic range and are more likely to plastically deform during use.[332,399]

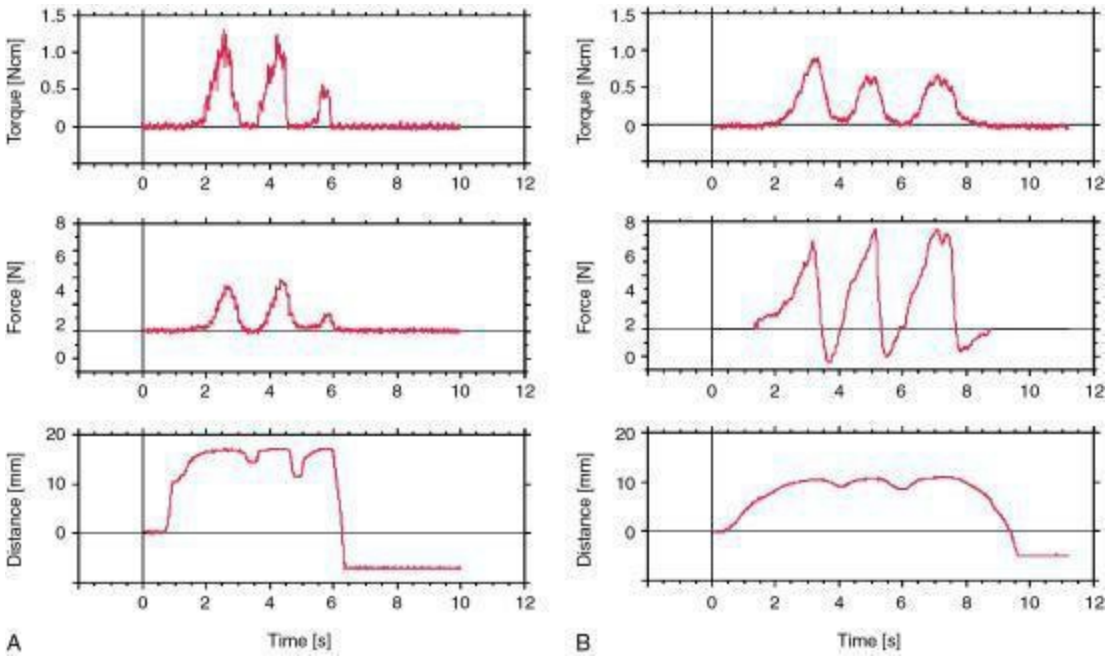

FIG. 8.20 Physical factors (torque, axial force, and insertion depth) that affect root canal instrumentation documented with a torque-testing platform. **A,** ProFile size #45,.04 taper used in a mildly curved canal of a single-rooted tooth, step-back after apical preparation to size #40. **B,** FlexMaster size #35,.06 taper used in a curved distobuccal canal of a maxillary first molar, crown-down during the initial phase of canal preparation.

E) Line graph of force (in Newtons) against time (in seconds) shows a curve with zigzag crests and troughs. The curve begins at (1.5, 2) and ends at (8.9, 2).

C) Line graph of distance (in millimeters) against time (in seconds) shows a U-shaped curve with internal crests and troughs. The curve begins at (0, 0) and ends at (11.8, negative 5).

NiTi instruments may have imperfections such as milling marks, metal flash, or rollover.[474] Some researchers have speculated that fractures in NiTi instruments originate at such surface imperfections.[13]

Surface irregularities may provide reservoirs of corrosive substances—most notably sodium hypochlorite (NaOCl). Chloride corrosion may lead to micropitting[372] and possibly subsequent fracture in NiTi instruments.[184] Immersion in various disinfecting solutions for extended periods (e.g., overnight soaking) produced corrosion of NiTi instruments and subsequent decreased torsional resistance.[304,424] For ProTaper,[46] RaCe, and ProFile[339] instruments, also 2-hour immersion damaged the integrity of the alloy.

In the majority of studies sterilization procedures did not appear to negatively impact torsional strength[199,407] or fatigue resistance[71,198] of most NiTi instruments: austenitic[470] and martensitic[81] alloy behaved grossly similarly in this aspect. Some NiTi instruments are available in presterilized form, which eliminates the need to process and sterilize before use and provides a simpler workflow overall. There is an ongoing discussion over the impact of other aspects of clinical usage on the mechanical properties of NiTi rotaries. Most likely, clinical usage leads to some changes in the alloy, potentially through work hardening,[12,224]

Another strategy to improve file characteristics is electropolishing. Surface coatings and ion implantation have been tried. Electropolishing is a process that removes surface irregularities such as flash and bur marks. It is believed to improve material properties, specifically fatigue and corrosion resistance; however, the evidence for both these claims is contradictory. One study[19] found an extension of fatigue life for electropolished instruments, while others found no improvement of fatigue resistance of electropolished

Telegram: @dental_k

www.konkur.in

instruments.[70,195] Boessler et al.[54] suggested a change in cutting behavior with an increase of torsional load after electropolishing.

Perhaps more relevant than surface treatment are modifications of the base alloy that significantly alter material properties within the atomic ratio.[323] The first commercialized alloy to exploit this was M-Wire (SportsWire, Langley, OK, USA), which was shown to have higher fatigue resistance with similar torsional strength.[220]

More recently, most instrument are manufactured from drawn standard NiTi wires, which are then worked by micro milling and finally submitted to specific annealing and cooling steps.[331,399] Instruments manufactured with this workflow tend to be relatively more martensitic at room and possible at body temperature during root canal treatment, as defined by their M_s temperature (see Fig. 8.19, A). Typically, such heat-treated alloys are more flexible[447] and present higher fatigue resistance.[332] Examples are the so-called gold and blue alloys types (Dentsply Sirona, York, PA, USA) or so-called controlled memory alloy used in Hyflex instruments (Coltene Endo, Cuyahoga Falls, OH, USA).

Manually operated instruments

Endodontic trays contain many items familiar from general dentistry, but certain hand instruments are designed specifically for endodontic procedures. This includes instruments employed for procedures inside the pulp space—for example, hand- and engine-driven instruments for root canal preparation and energized instruments for root canal shaping. Special instruments and devices for root canal obturation are selected for filling prepared canal spaces.

K-type instruments

Manually operated instruments are generically called *files.* Defined by function, files are instruments that enlarge canals with apico-coronal insertion and withdrawal motions.

Files were first mass produced by the Kerr Manufacturing Co. of Romulus, Michigan, in the early 1900s—hence the name K-type file (or K-file). K-files and K-reamers were manufactured by the same process (i.e., by twisting square or triangular metal blanks along their long axis; see Fig. 8.17, *A*).

Telegram: @dental_k

www.konkur.in

Three or four equilateral, flat surfaces were ground at increasing depths on the sides of a piece of wire, producing a tapered pyramidal shape. The wire then was stabilized on one end, and the distal end was rotated to form the spiral instrument. The number of sides and the number of spirals determine whether the instrument is best suited for filing or reaming. In general, a three-sided configuration with fewer spirals (e.g., 16 per 16 mm working portion) is used for reaming (i.e., cutting and enlarging canals with rotational motions). A file has more flutes per length unit (e.g., 20) than a reamer, whereas a three-sided shape is generally more flexible than a four-sided one.[381]

K-type instruments are useful for penetrating and enlarging root canals. In general, a reaming motion (i.e., constant file rotation) causes less transportation than a filing motion (translational or "in-and-out" motion).[153] *Transportation* in root canal preparation may be defined in general as the movement away from the initial canal axis and is described in more detail later in this chapter.

Stainless steel K-files may be precurved by overbending; this procedure subjects the file to substantial strain and should therefore be done carefully. Permanent deformation occurs when the flutes become wound more tightly or opened more widely (Fig. 8.21). When such deformation occurs, an instrument should no longer be used; file fracture is likely to occur during clockwise motion after plastic deformation.[395]

Telegram: @dental_k

www.konkur.in

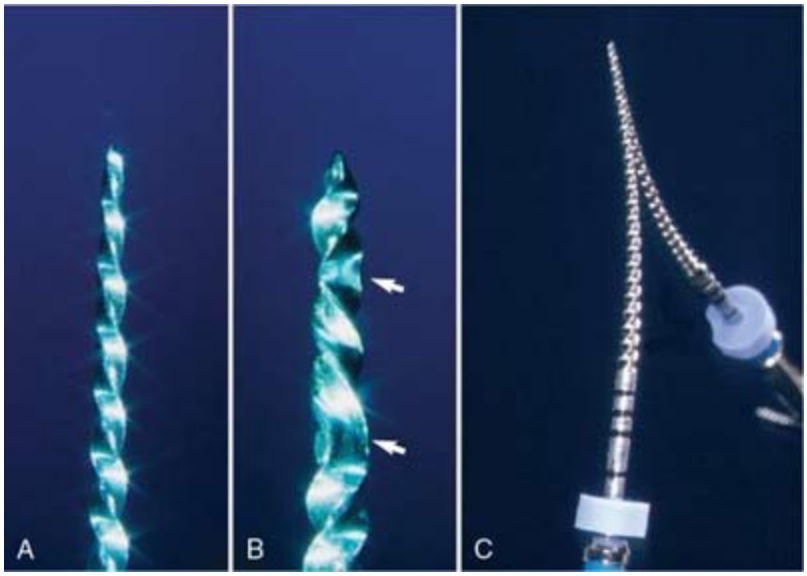

FIG. 8.21 Deformation of endodontic instruments manufactured from nickel-titanium alloy. **A** and **B,** Intact and plastically deformed ProFile instruments (*arrow* indicates areas of permanent deformation). **C,** ProFile instrument placed on a mirror to illustrate elastic behavior.

A) Close-up of a nickel titanium file shows a tight spirally textured sharp body with a sharp tip.

B) Close-up of a deformed nickel titanium file with arrows pointing to the large and small curvature of the spiral scales after deformation.

C) Close-up of a spirally textured instrument shows a mirror on one end and a hook on the other end.

Interestingly, although the force required for failure is the same in both directions of rotation,[244] failure occurs in the counterclockwise direction at half the number of rotations required for failure in the clockwise direction. Therefore K-type instruments should be operated more carefully when pressure is applied in a counterclockwise direction.

Cross-sectional analysis of a K-file reveals why this design allows careful application of clockwise and counterclockwise rotational and translational working strokes: The cross section is symmetrical with negative rake angles, allowing dentin to be adequately cut in both clockwise and counterclockwise direction.

H-type instruments

H-type instruments, also known as Hedström files (see Fig. 8.17, *B*), are

Telegram: @dental_k

www.konkur.in

milled from round, stainless steel blanks. These files are very efficient for translational strokes[381] because of a positive rake angle and a blade with a cutting rather than a scraping angle. Rotational working movements are discouraged because of the possibility of fracture. Hedström files up to size #25 can be efficiently used to relocate canal orifices and, with adequate filing strokes, to remove overhangs. Similarly, wide oval canals can be instrumented with Hedström files, as well as with rotary instruments. On the other hand, overzealous filing can lead to considerable thinning of the radicular wall and strip perforations (Fig. 8.22).

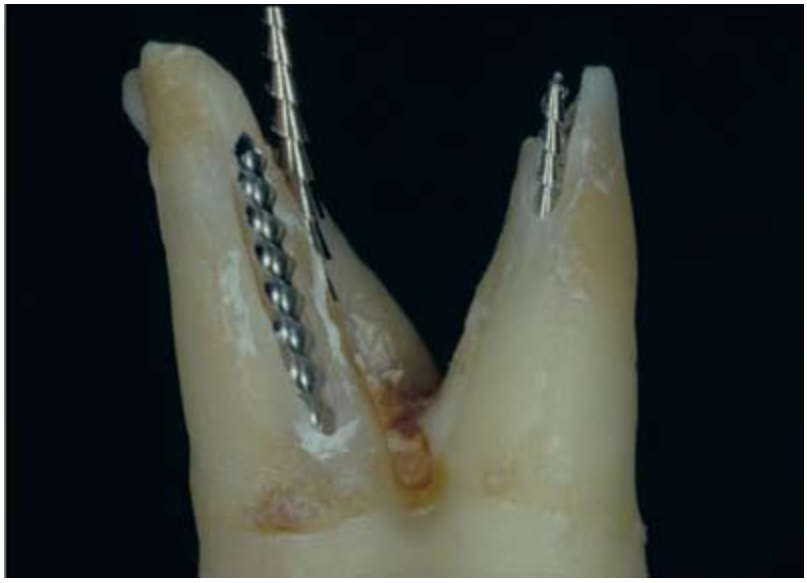

FIG. 8.22 Result of an overenthusiastic attempt at root canal treatment of a maxillary second molar with large stainless steel files. Multiple strip perforations occurred, so consequently the tooth had to be extracted.

Close-up of a maxillary second molar with roots exposing spirally and conically textured stainless steel files.

Precurving Hedström files results in points of greater stress concentration than in K-type instruments. Such prestressed areas may lead to the propagation of cracks and ultimately fatigue failure.[182] Note that clinically, fatigue fractures may occur without visible signs of deformation.

Hedström files are produced by grinding a single continuous flute into a tapered blank. Computer-assisted machining technology has allowed the development of H-type instruments with very complex forms. Because an H-

Telegram: @dental_k

www.konkur.in

file generally has sharper edges than a K-file, it has a tendency to thread into the canal during rotation, particularly if the instrument's blades are nearly parallel. Awareness of threading-in forces is important to avoid instrument failure, also with NiTi rotary instruments.

Effectiveness and wear of instruments.

The ability of an endodontic hand instrument to cut and machine dentin is essential; however, no standard exists for either the cutting or machining effectiveness of endodontic files, nor have clear requirements been established for resistance to wear. In any study of the effectiveness of an instrument, two factors must be investigated: (1) effectiveness in cutting or breaking loose dentin and (2) effectiveness in machining dentin.

Attempts have been made to evaluate the effectiveness of an instrument when used with a linear movement,[383] and these studies showed that instruments might differ significantly, not only when comparing brands and types but also within one brand and type. For K-files, effectiveness varies 2 to 12 times between files of the same brand. This variation for Hedström files is greater, ranging from 2.5 to more than 50 times.[436]

During canal preparation, a file's rake edge shaves off dentin that accumulates in the grooves between the rake edges. The deeper and larger this space, the longer the stroke can be before the instrument is riding on its own debris, making it ineffective. These design variations and the rake angle of the edges determine the effectiveness of a Hedström file. Of the hybrid files, the K-Flex (Kavo Kerr Endo, Orange, CA, USA) file has properties similar to those of K-files. The Flex-R file (Integra Miltex, Plainsboro, NJ, USA), which is a ground instrument with a triangular cross section similar to a K-file, more closely resembles a Hedström file in its variations in cutting behavior. It also is more effective at substrate removal than the K-files but cannot measure up to the H-files' ability to machine radicular dentin.[436]

Barbed broaches

Barbed broaches (Fig. 8.23) are produced in a variety of sizes and color codes. They are manufactured by cutting sharp, coronally angulated barbs into metal wire blanks. Broaches are intended to remove vital pulp from root canals, and in cases of mild inflammation and a large canal space, they work

Telegram: @dental_k

www.konkur.in

well for severing pulp at the constriction level in toto. The use of broaches has declined since the advent of NiTi rotary instruments, but broaching occasionally may be useful for expediting emergency procedures (see Chapter 19) and removing materials (e.g., cotton pellets or absorbent points) from root canals.

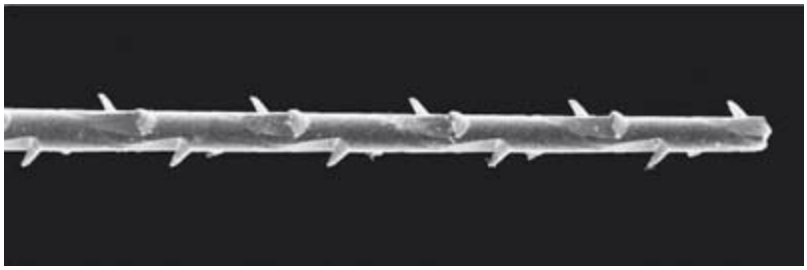

FIG. 8.23 Scanning electron micrograph of a barbed broach.

Close-up of a barbed broach shows a tapered round shaft with lifted up portions of metal shaft.

Low-speed engine-driven instruments

Burs

Specialized burs are available for endodontic access cavities. These burs are used in both high-speed and slow-speed handpieces and are manufactured from stainless steel. (Access cavity preparation and used materials are described in detail in Chapter 7.)

Gates-Glidden drills

Gates-Glidden (GG) drills (Fig. 8.24) have been used for almost 150 years without noteworthy design changes. GG drills are typically used to enlarge coronal canal areas.[107] When misused, GG drills can dramatically reduce radicular wall thickness.[155,213]

B) Micrograph of gates-glidden bur shows an axially twisted top with a conical tip.

Source: (***A***, From Johnson WT: *Color atlas of endodontics*, St Louis, 2002, Saunders.)

GG instruments are available in six sizes and various lengths, by several manufacturers. Each instrument has a long, thin shaft with parallel walls and a short, oval cutting head with safety tips (see Fig. 8.24, *B*); these drills with tip diameters of 0.5 to 1.1 mm are produced in stainless steel and NiTi varieties. Because of their design and physical properties,[62] GG drills are side-cutting instruments; they can be used to cut dentin as they are withdrawn from the canal (i.e., on the outstroke) and should be used only in the straight portions of a canal.[456]

Two procedural sequences have been proposed: With the step-down technique, the clinician starts with a large drill and progresses to smaller ones; conversely, with the step-back technique, the clinician starts with a small drill and progresses to larger ones. Either technique efficiently opens root canal orifices and works best when canals exit the access cavity without severe angulations.

When used adequately, GG instruments are inexpensive, safe, and clinically beneficial tools. However, high speeds excessive pressure, an incorrect angle of insertion, and the use of GG instruments to aggressively drill into canals have resulted in mishaps such as strip perforation.

Telegram: @dental_k

www.konkur.in

Peeso reamers and similar drills

Peeso reamers and other drills are occasionally used in root canal preparation for coronal flaring or during postpreparation. At this point, these drills are manufactured mainly from stainless steel and commonly by milling blanks. Peeso drills are available with cutting and noncutting tips but should be used with caution to avoid excessive preparation and thinning of radicular dentin walls.[8] Materials and clinical procedures for post space generation are described in Chapter 23.

Engine-driven instruments for canal preparation

Instrument types

Engine-driven instruments for root canal preparation made of stainless steel have been in use for more than half a century—the first decades mainly in handpieces that permitted reciprocation (alternating clockwise-counterclockwise motion). The major two problems with this type of instrument were canal transportation and file fracture. This changed with the advent of NiTi rotaries in the early 1990s; the much more flexible alloy allowed continuous rotation and reduced both canal preparation errors and instrument fracture compared with earlier engine-driven techniques.

Currently more than 100 types of rotary instrument systems are marketed, and more continue to be developed.[148] The instruments vary greatly in terms of design, alloy used, and recommended cutting movement (Table 8.1). Various built-in features may help prevent procedural errors, increase efficiency, and improve the quality of canal shaping. For example, a longer pilot tip may guide the instrument and help to stay centered in the canal long axis.

Another direction of instrument development is the prevention of instrument fractures (Fig. 8.25). There are several ways to modify an instrument to make it less likely to fracture—for example, increasing the core diameter will increase torsional resistance. Another approach is to use a

Telegram: @dental_k

www.konkur.in

torque-limiting motor (see later). Alternatively, a zero taper or nearly parallel and fluted working portion of the file may be provided for curved canals so that the apical portion of the canal can be enlarged without undue file stress and compression of debris. Changing continuous rotation to reciprocation motion when applied to NiTi rotary instruments has been successful in preventing threading-in and instrument fractures in general. Another direction of instrument development is to improve shaping as it relates to circumferential root canal wall contact, also described as conforming shaping. One example for this strategy is a file manufactured from an expandable and flexible hollow NiTi tube, the so-called Self-adjusting File (SAF; ReDent-Nova, Raanana, Israel) (Fig. 8.26).

More recently, a substantial S-shape was imposed onto a flexible NiTi rotary. This strategy provides an adaptable, larger envelope of motion while maintaining a limited maximum flute diameter (TRUShape, Dentsply Sirona; XP Shaper, Brasseler, Savannah, GA, USA). Marketed files vary greatly in terms of their specific design characteristics, such as tip sizing, taper, cross section, helix angle, and pitch (see Fig. 8.13). Some of the early systems have been removed from the market or relegated to minor roles.

Most instruments described in the following section are manufactured by multiaxial grinding or micromilling processes, although some are produced by laser etching and yet others by plastic deformation under specific heating and cooling processes or electric discharge machining.

Many variables and physical properties influence the clinical performance of NiTi rotaries.[239,329,393,449] Clinical practice has generated much of what is known about NiTi instruments, including reasons for instrument fracture and the application of specific instrument sequences; NiTi rotary instruments have substantially reduced the incidence of relevant canal shaping errors.[89]

Table 8.1 and the following sections describe the instrument groups most widely used for root canal preparation at this point in time. Typical clinical strategies apply to all NiTi rotary instruments, regardless of the specific design or brand. However, three design groups will be analyzed separately next: group I, instruments designed for passive preparation; group II, rotary instruments designed for active cutting; and group III, unique designs that do not fit in either group I and II.

Group I: Passive preparation; presence of radial lands.

The first commercially successful rotary instruments were ProFile (Dentsply Sirona), Lightspeed (marketed in its current form by Kavo Kerr, Orange, CA, USA), and GT rotaries (Dentsply Sirona), and have in common a cross section with so-called radial lands (Fig. 8.27, red arrow). These are created by three round excavations, also known as the U-shape. The design of the instrument tip and also the lateral file surface (radial land) guide the file as it

Telegram: @dental_k

www.konkur.in

progresses apically. This makes rotaries listed in group I fairly safe regarding preparation errors. On the other hand, it results in a reaming action rather than cutting of dentin, and this makes them less efficient. Moreover, the smear layer produced with radial-landed rotaries is different in consistency and amount compared with the debris and smear created by cutting files.[318]

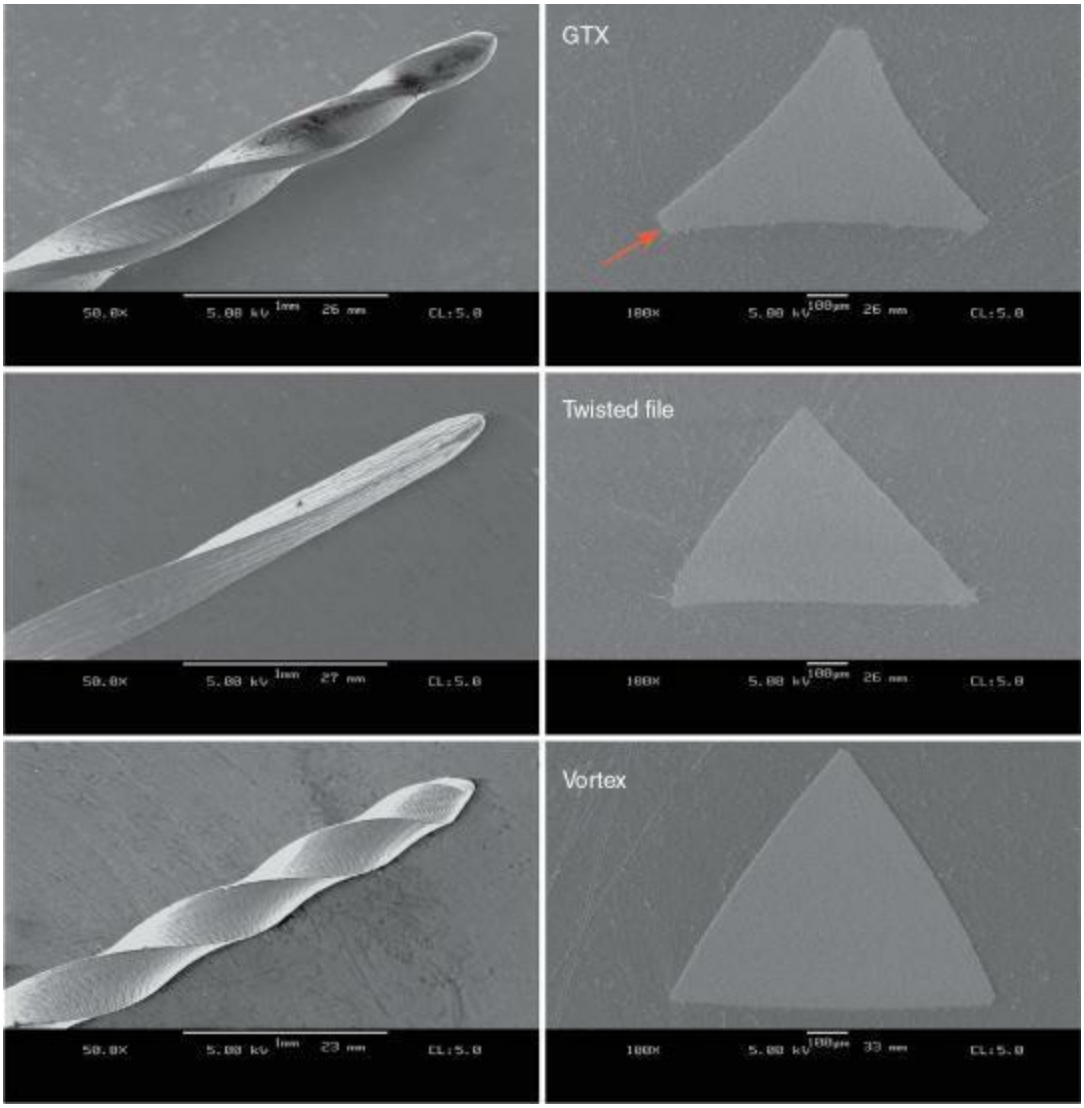

FIG. 8.27 Scanning electron micrographs (SEM) of current nickel-titanium rotary instruments, seen laterally (*left panel*, ×50) and in cross sections (*right panel*, ×100). Note the radial landed cross section of the *GTX* instrument (*red arrow*).

corner.

B) Micrograph of a nickel titanium instrument shows axially textured surface body with a sharp conical tip. Cross-section of twisted file shows a triangular shape with straight sides and two sharp and one irregular corner.

C) Micrograph of a nickel titanium instrument shows sharp textured tight spiral surface body with a conical tip. Cross-section of vortex shows a triangular shape with outward sides and partially sharp corners.

LightSpeed.

The LightSpeed file, developed by Drs. Steve Senia and William Wildey in the early 1990s and later known as *LS1*, was introduced as an instrument with a thin, noncutting shaft and short anterior cutting head. The same design principles apply to the subsequently marketed LSX instrument (Kavo Kerr) that is manufactured not by milling but by a stamping process. A full set consists of 25 LightSpeed LS1 instruments in sizes #20 to #100, including half sizes (e.g., 22.5, 27.5); LSX does not have half sizes, and a set includes sizes #20 to #80.

ProFile.

The ProFile system (Dentsply Sirona) was introduced by Dr. Ben Johnson in 1994. ProFile instruments have increased tapers compared with conventional hand instruments. The tips of the original ProFile Series 29 rotary instruments had a constant proportion of diameter increments (29%). Later, a ProFile series with ISO-sized tips (Dentsply Maillefer, Ballaigues, Switzerland) was developed and marketed in Europe.

Cross sections of a ProFile instrument show a U-shape design with radial lands (Fig. 8.28) and a parallel central core. Lateral views show a 20-degree helix angle, a constant pitch, and bullet-shaped noncutting tips (see Fig. 8.12). Together with a slightly negative rake angle, this configuration facilitates a reaming action on dentin rather than cutting. ProFile instruments shaped canals without major preparation errors in a number of in vitro investigations.[66,67,451,452]

GT and GTX files.

The Greater Taper, or GT file, was introduced by Dr. Steve Buchanan in 1994. This instrument incorporates a radial landed cross-sectional design and was marketed as ProFile GT (Dentsply Sirona). The instruments were available in four tapers (.06,.08,.10, and.12), and the maximum diameter of the working part was 1 mm. The design limited the maximum shank diameter and decreased the length of the cutting flutes with increasing taper. The instruments had a variable pitch and a growing number of flutes in progression to the tip; the apical instrument diameter was 0.2 mm.

K3.

In a sequence of design developments by their inventor, Dr. McSpadden, the Quantec 2000 files were followed by the Quantec SC, the Quantec LX, and the current K3 system (all by Kavo Kerr Endo). K3, similar to ProFile instruments, includes instruments with.02,.04, and.06 tapers. The most obvious difference between the Quantec and K3 models is the K3's unique cross-sectional design: a slightly positive rake angle for greater cutting efficiency, wide radial lands, and a peripheral blade relief for reduced friction. Unlike the Quantec, a two-flute file, the K3 features a third radial land to help prevent threading-in. K3 features a round safety tip, but the file is about 4 mm shorter than other files (although it has the same length of cutting flutes) because of the so-called Axxess handle. The instruments are coded by ring color and number.

In the lateral aspect, the K3 has a variable pitch and variable core diameter, which provide apical strength. Manufacturing this intricate design can result in some metal flash.

Summary.

Radial landed rotary instruments are considered very safe, even when accidentally taken beyond the confines of the root canal. Fracture resistance

Telegram: @dental_k

www.konkur.in

to torsional loading and cyclic varies depending on specific instrument design. The limited cutting efficacy of these files was perceived as a downside and is a reason that the market share has diminished.[50] However, their track record in clinic and research continue to support the use of rotaries listed in group I.

Group II: Active cutting; triangular cross section.

Rotary instruments in group II all have a more active cutting flute design in common and have the largest market share. Radial lands are absent (see Fig. 8.13), and this fact results in a higher cutting efficacy. This translates to a higher potential for preparation errors, in particular when the instrument is taken through the apical foramen, thus eliminating the guide derived from the noncutting tip.

ProTaper Universal, Gold.

The ProTaper system originally comprised six instruments: three shaping files and three finishing files. This set is now complemented by two larger finishing files and a separate set of three retreatment rotaries. ProTaper instruments were designed by Drs. Cliff Ruddle, John West, and Pierre Machtou. In cross sections, ProTaper shows a convex triangle with sharp cutting edges and no radial lands. The cross section of finishing files F3, F4, and F5 is slightly relieved for increased flexibility. The three shaping files have tapers that increase coronally, and the reverse pattern is seen in the five finishing files.

Shaping files Nos. 1 and 2 have tip diameters of 0.185 mm and 0.2 mm, respectively, 14-mm-long cutting blades, and partially active tips. The finishing files (F1 to F5) have tip diameters of 0.2, 0.25, 0.3, 0.4, and 0.5 mm, respectively, between D_0 and D_3, and the apical tapers are.07,.08,.09,.05, and.04, respectively. The finishing files have rounded noncutting tips.

Two aspects of handling have been emphasized for ProTaper. The first is the preparation of a glide path, either manually[321] or with special rotary instruments.[47] An enlargement to a size approaching the subsequent rotaries' tips, at least larger than the file's core diameter, prevents breakage and allows assessment of the canal size.[321] This means that a glide path should

Telegram: @dental_k

www.konkur.in

correspond to a size #15 or 20. Glide path preparation is currently recommended for most NiTi instruments.

The second specific recommendation for ProTaper use is the use of a more laterally directed “brushing” working stroke. Such a stroke allows the clinician to coronally direct larger files away from danger zones and counteract any “threading-in” effect.[53] Brushing strokes should be applied judiciously and away from the furcation in molars to avoid thinning of radicular structure.

In a study using plastic blocks, ProTaper created acceptable shapes more quickly than GT rotary, ProFile, and Quantec instruments[502] but also created somewhat more aberrations. A study using micro-CT showed that the original ProTaper file created consistent shapes in constricted canals, without obvious preparation errors, although wide canals may be insufficiently prepared with this system.[338]

A newer version, called ProTaper Next, was introduced in 2013. Current research suggests that mechanical properties of these instruments, manufactured from M-Wire, are better than ProTaper Universal.[23,121,322]

HERO 642, HERO Shaper.

Several systems in group II (see Table 8.1) were designed with positive rake angles, which provide greater cutting efficiency. HERO instruments (MicroMega, Besançon, France) are an example, the original version was known as *HERO 642* (the name *HERO* is an acronym for *h*igh *e*lasticity in *ro*tation); the name has now changed to HERO Shaper, with few apparent differences in the instrument design.

Cross sections of HERO instruments show geometries similar to those of an H-file without radial lands. Tapers of.02,.04, and.06 are available in sizes ranging from #20 to #45. The instruments are relatively flexible but maintain an even distribution of force into the cutting areas.[460,461] HERO instruments have a progressive flute pitch and a noncutting passive tip, similar to other NiTi rotary systems. The instruments are coded by handle color.

RaCe, BioRaCe, BT RaCe.

The RaCe file has been manufactured since 1999 by FKG and was later distributed in the United States by Brasseler. The name, which stands for

Telegram: @dental_k

www.konkur.in

r*eamer with* a*lternating cutting* e*dges*, describes just one design feature of this instrument. Light microscopic imaging shows flutes and reverse flutes alternating with straight areas; this design is aimed at reducing the tendency of files to thread into a root canal. Cross sections are triangular or square for.02 instruments with size #15 and #20 tips. The lengths of cutting parts vary from 9 to 16 mm.

The surface quality of RaCe instruments has been modified by electropolishing, and the two largest files (size #35,.08 taper and size #40,.10 taper) are also available in stainless steel. The tips are round and noncutting, and the instrument handles are color-coded and marked by milled rings. RaCe instruments have been marketed in various packages to address small and large canals; recently they are sold as BioRaCe, purportedly to allow larger preparation sizes, with an emphasis on the use of.02 tapered instruments. A new variant, BT RaCe was recently introduced and incorporates different tip designs, as well as different sequences.

Few results of in vitro experiments comparing RaCe to other contemporary rotary systems are available;[384,385] canals in plastic blocks and in extracted teeth were prepared by the RaCe system with less transportation than with ProTaper files.[384] In another study, ProTaper and RaCe performed similarly when canals were prepared to an apical size #30.[313] As with any rotary system, this file may be included in a hybrid hand-rotary technique. BioRace instruments prepared S-shaped canals in plastic blocks (to size #40) similarly to ProTaper and MTwo but were superior when combined with S-Apex.[56]

EndoSequence.

The EndoSequence rotary instrument is produced by FKG in Switzerland and marketed in the United States by Brasseler. This instrument adheres to the conventional length of the cutting flutes, 16 mm, and to larger tapers,.04 and.06, to be used in a crown-down approach. The overall design, including the available tapers and cross sections, is thus similar to many other files; however, the manufacturer claims that a unique longitudinal design called *alternating wall contact points* (ACP) reduces torque requirements and keeps the file centered in the canal. It also has varying comparatively small helical angles. Another feature of the Sequence design is an electrochemical treatment after manufacturing, similar to that of RaCe files, resulting in a

Telegram: @dental_k

www.konkur.in

smooth, polished surface. This is believed to promote better fatigue resistance; hence a rotational speed of 600 rpm is recommended for EndoSequence.[231] Most in vitro results, however, suggest that EndoSequence is not superior to other files in cyclic fatigue resistance.[195,243,353]

Twisted file.

In 2008, SybronEndo, now Kavo Kerr Endo, presented the first fluted NiTi file manufactured by plastic deformation, a process similar to the twisting process that is used to produce stainless steel K-files: the Twisted File (TF). According to the manufacturer, a thermal process allows twisting during a phase transformation into the so-called R-phase of nickel-titanium. The instrument is currently available with size tip from 25 to 50 and in tapers from.04 to.12.

The unique production process is believed to result in superior physical properties; indeed, early studies suggested significantly better fatigue resistance when size #25.06 taper TFs were compared with K3 instruments of the same size GTX instrument.[144] Moreover, as determined by bending tests according to the ISO norm for hand instruments, 3630-1, TFs size #25.06 taper were more flexible than ProFiles of the same size.[143] Others found similar levels for fatigue resistance for TF and Profile of similar size.[243] A more recent development for TF is the use of an electric motor that allows different file movement, both continuous rotation and reciprocation, depending on the clinical situation (TF Adaptive, Kavo Kerr).

Profile Vortex.

Profile Vortex instruments are manufactured from NiTi. Two versions are on the market—one made from M-Wire and another from so-called blue wire (Vortex Blue, which showed greater resistance to cyclic fatigue and increased torque resistance) and have varying helical angles to counteract the tendency of nonlanded files to thread into the root canal. Vortex instruments are recommended to be used at 500 rpm; higher rotational speed results in less torque generated.[35] Canal preparation with ProFile Vortex in vitro was similar to other rotary instruments.[75,493] Vortex instruments are available in sizes 15 to 50 and in.04 and.06 tapers.

Telegram: @dental_k

www.konkur.in

MTwo.

This instrument entered the European market in 2004. It possesses a two-fluted S-shaped cross section. The original strategy allowed for three distinct shaping approaches after the use of a basic sequence with tip sizes from #10 to #25, and tapers ranging from.04 to.06. Subsequent enlargement was meant to either create apical sizes up to #40.04, alternatively to #25.07 or to larger apical sizes with so-called apical files. MTwo is a well-researched and cutting-efficient instrument; clinically it is an example for the so-called single length technique. Canal shapes with MTwo were similar to other contemporary root canal instruments, either in rotation or reciprocation.[72]

Edge files.

A selection of instruments in designs that are similar to other designs, made primarily from heat-treated NiTi alloys, are available from Edge Endo (Albuquerque, NM, USA). There is comparatively limited research available for the individual files but extended fatigue life has been reported for them, at least at room temperature.[22]

Summary.

The market share for rotary files without radial lands continues to expand because of perceived higher efficacy. The overall incidence of clinically relevant preparation errors (see later for details) appears to be low, in spite of more aggressive cutting by files without radial lands. Instrument fractures remain a concern as does the tendency of continuously rotating instruments to thread or pull into the canal, specifically as working length (WL) is approached.

Group III, atypical instruments

WaveOne, Reciproc, Gold, Blue.

A way to mitigate problems with continuous rotation (e.g., taper lock, fatigue fracture, threading-in) is to replace continuous rotation by reciprocation action. A case report[496] described this approach using ProTaper instruments. Based on experiments evaluating the maximal rotational angle before plastic deformation for the selected instrument, a forward angle of 144 degrees,

Telegram: @dental_k

www.konkur.in

followed by a reverse rotation of 72 degrees, was recommended.[496]

Subsequently, two instruments specifically designed for reciprocation were brought to the market (WaveOne, Dentsply Sirona) and Reciproc (VDW, Munich, Germany, currently not available in the United States). WaveOne instruments are available in three tip sizes, #21, #25, and #40, with tapers of.06 and.08, respectively. Corresponding sizes for Reciproc are tips of #25, #40, and #50, with tapers of.08,.06, and.05, respectively. Both instruments feature variable tapers that are largest toward the tips. The main WaveOne cross section is triangular, similar to ProTaper, while Reciproc is a two-fluted file with a design similar to MTwo (VDW).

Special motors are used for both systems to provide reciprocation action with alternating counterclockwise and clockwise rotations of about 150 to 170 and 30 to 50 degrees, respectively.[134]

Both files are machined with left-leaning flutes, and therefore the cutting direction for both is clockwise. One problem that may occur with this design is the transportation of dentin debris into the apical area, rather than moving debris coronally. There is mixed evidence for this phenomenon[73,110] in vitro. Clinically, frequent careful cleaning of the cutting blades with a moist gauze is recommended.

Shaping ability of these systems seems, according to current in vitro data, similar to established systems with continuous rotation.[72,278,469]

Self-adjusting File.

The SAF (ReDent-Nova) represented a completely different approach, both in file design and mode of operation.[280] It is a cylindrical, hollow design with a thin-walled NiTi lattice displaying a lightly abrasive surface (see Fig. 8.26). An initial glide path to a #20 K-file allows insertion of the SAF file. The file is operated with a handpiece that generates in-and-out movements (4000 per minute) and 0.4 mm amplitudes.

In vitro data for this system suggest that indeed more wall contact is made compared with rotary files,[336] resulting in better débridement and superior antimicrobial efficacy.[415] Shaping quality is also on par with rotary instruments.[336]

TRUShape.

Telegram: @dental_k

www.konkur.in

Two strategies have recently emerged in file design, which are both present in the TRUShape (Dentsply Sirona) instrument: so-called conforming shaping and a limited maximum flute diameter. The strong S-shaped longitudinal design allows TRUShape to expand and contract during rotation, similar to what had been described for the SAF, in an attempt to increase wall contact. TRUShape is marketed in sizes #20, #25, #30, and #40, all with a maximum fluted diameter of 0.8 mm, thus limiting coronal dentin removal. Used in continuous rotation at 300 rpm, TRUShape has been shown to create adequate shapes in vitro during initial canal preparation in molars[328] and premolars.[216] Specifically in root canal retreatment, the ability of TRUShape files to create more canal wall contact has attracted attention.

Further design developments led to the TruNatomy system (Dentsply Sirona), which includes a dedicated Orifice Modifier, Glide Path file, and three shaping instruments, as well as a special irrigation needle and conforming gutta percha. TruNatomy is operated at 500 rpm and 1.5 Ncm and with gentle stroking motion.

XP-Shaper, XP-Finisher.

A similar design is incorporated in the XP instruments. Both have strong curves in the longitudinal aspect and a small taper, so that the maximum fluted diameter is limited. The files are made of a NiTi solution that changes its conformation in the transition from room to body temperature, which in turn leads to some stiffening and specific preparation outcomes. The finisher is thought of as an irrigation enhancement device and is run at about 800 rpm. Initial reports suggest that using the XP-Shaper resulted in acceptable canal preparation[28] and that the use of the finisher had débridement potential that is similar or better than with other shaping and cleaning strategies.[122]

Sonic and ultrasonic shaping instruments.

An alternative way of instrumenting root canals was introduced when clinicians became able to activate files by electromagnetic ultrasonic energy. Piezoelectric ultrasonic units are also available for this purpose (Fig. 8.29). These units activate an oscillating sinusoidal wave in the file with a frequency of about 30 kHz.

Telegram: @dental_k

www.konkur.in

FIG. 8.29 Example of an ultrasonic unit (Neutron P5 piezoelectric).

A Neutron P5 piezoelectric ultrasonic device consisting of a control unit, a slim hand piece comprising of ceramic transducer and a tip or a file.

Source: (Courtesy Satelec, Merignac Cedex, France.)

Two types of units, ultrasonic and sonic, are marketed. Ultrasonic devices, which operate at 25 to 30 kHz, include the magnetostrictive Cavi-Endo (Dentsply Caulk, Milford, DE, USA), the piezoelectric ENAC (Osada, Tokyo), the EMS Piezon Master 400 (Electro Medical Systems, Vallée de Joux, Switzerland), and the P5 Neutron (Satelec, Merignac Cedex, France).

Sonic devices, which operate at 2 to 3 kHz, include the Sonic AirMM 1500 (Micro Mega, Prodonta, Geneva, Switzerland), the Megasonic 1400 (Megasonic Corp, House Springs, MO, USA), and the Endostar (Syntex Dental Products, Valley Forge, PA, USA).

The piezoelectric transducer transfers more energy to the file than does the magnetostrictive system, making it more cutting efficient. The file in an ultrasonic device vibrates in a sinus wavelike fashion. A standing wave has areas with maximal displacement (i.e., antinodes) and areas with no displacement (i.e., nodes). The tip of the instrument exhibits an antinode. If powered too high, especially with no contact with the canal wall, the instrument may break because of the intense vibration. Therefore, files must be used only for a short time, must remain passive within the canal, and the

Telegram: @dental_k

www.konkur.in

power must be controlled carefully. The frequency of breakage in files used for longer than 10 minutes may be as high as 10%, and the breakage normally occurs at the nodes of vibrations.[9] Ultrasonic devices have been linked to a higher incidence of preparation errors and to reduced radicular wall thickness.[260,277,512]

Summary.

An abundance of NiTi systems is currently on the market, Table 8.1 lists these instruments systematically and illustrates some of the most relevant properties. Most systems included in Table 8.1 have files with tapers greater than the.02 stipulated by the ISO norm, while some have variable tapers and yet others have canal-conforming shapes and limited maximum flute diameters. Differences exist in tip designs, cross sections, and manufacturing processes. In vitro tests continue to identify the effect of specific designs on shaping capabilities and fracture resistance. An attractive goal is the instrumentation of more canal surface, in an effort to make biofilm more susceptible to subsequent chemical disinfection. At the same time, instrumentation paradigms that conserve more dentin appear desirable to promote long-term function.[154] Meaningful differences in clinical outcomes in regard to various specific design variations have yet to be ascertained.

Motors

Motors for rotary instruments have become more sophisticated since the simple electric motors of the first generation in the early 1990s (Fig. 8.30, *A*). Electric motors with gear reduction are most suitable for rotary NiTi systems, because they ensure a constant rpm level and constant torque. They can also be programmed to provide alternative rotation patterns—for example, reciprocation with freely selectable angles of rotation.[134] Electric motors often have presets for rpm and torque and are capable of delivering torques much higher than those required to break tips. Some authors believe that torque-controlled motors (see Fig. 8.30, *B–D*) increase operational safety.[142] Others have suggested that such motors may mainly benefit inexperienced clinicians.[499] These motors probably do not reduce the risk of fracture caused by cyclic fatigue, and even if the torque is below the fracture load at D_3, a fracture at a smaller diameter (D_2) is still possible.

www.konkur.in

FIG. 8.30 Examples of motors used with rotary nickel-titanium endodontic instruments. **A,** First-generation motor without torque control. **B,** Fully electronically controlled second-generation motor with sensitive torque limiter. **C,** Frequently used simple torque-controlled motor. **D,** Newer-generation motor with built-in apex locator and torque control.

Set of four images shows types of motors with hand-held dental drills labeled as A through D.

To complicate matters further, a differential exists between torque at failure at D_3 and the working torque needed to operate an instrument effectively (Fig. 8.31 and Box 8.2).[52,329,376] In many cases, the working torque is greater than the torque required to fracture the instrument's tip.

Box 8.2

Instrument Breakage With Torsional Load (MacSpadden Factor)

For rotary instrument tips, susceptibility to breakage is governed by the quotient of torque needed to fracture divided by working torque. Simply put, the larger the value, the safer the file.

This differential between working torque and tip fracture load is especially large with files with a taper equal to or greater than.06; therefore, these files are rather ineffective in most torque-controlled motors. Some contemporary motors offer microprocessor-controlled features, for example, information about the specific instrument being used, such as the presets and the usage history, as well additional connectivity for example to an apex locator.

Some motors have built-in apex locators (see Fig. 8.30, *D*). This type of motor may be programmed to stop a rotary instrument when WL is reached or go into reverse gear. Similar changes in movement can occur in an adaptive fashion, depending on the torsional load that the instrument experiences in the root canal. The TF Adaptive motor (Kerr Endo) is an example for this technology that appeared only recently.

Some of the factors besides the motor itself that may influence the incidence of fracture in engine-driven NiTi rotary instruments are lubrication, specific instrument motion, and speed of rotation. It cannot be overemphasized that NiTi rotary instruments should only be used in canals that have been flooded with irrigants. Although lubricants such as RC-Prep (Premier, Norristown, PA) and Glyde (Dentsply Maillefer) have been recommended in the past, their benefit appears to be restricted to plastic blocks,[18] and could not be demonstrated when rotary instruments engage dentin surfaces. To the contrary, experimental data suggests that the use of gel-type lubricants fails to reduce torque values during simulated canal preparation.[55,330] Finally, because of chemical interactions between NaOCl and ethylenediamine tetra-acetic acid (EDTA),[164] alternating irrigants and using lubricants that contain EDTA may even be counterproductive. Details

Telegram: @dental_k

www.konkur.in

regarding irrigation solution interactions are described later in this chapter.

For instrument motion, some manufacturers recommend a pecking, up-and-down motion. This not only prevents threading in of the file; it is also believed to distribute stresses away from the instrument's point of maximum flexure where fatigue failure would likely occur.[250,348] However, such in-and-out movements did not significantly enhance the lifespan of ProFile size.04 or GT rotary instruments rotated around a 5-mm radius cylinder with a 90-degree curve.[329,333] Furthermore, large variations were noted in the lengths of the fractured segments.[203,462] This suggests that ductile fractures may originate at points of surface imperfections. Files made of more martensitic alloy tend to work better with longer sweeping or brushing strokes. The notion of "brushing" is not directly related to a paintbrush motion, since this would predispose a file to bending and subsequent fatigue.[346] Rather it should be considered as stroking against the wall away from the danger zone—the inner curvature of a curved root. Specifically, highly martensitic files may benefit from a low-impact gentle brushing with low torque setting.

Rotational speed may influence instrument deformation and fracture. Some studies indicated that ProFile instruments with ISO-norm tip diameters failed more often at higher rotational speed,[117] whereas other studies did not find speed to be a factor.[222] For Vortex, 300 rpm and 400 rpm appeared to reduce the generated torque and force; this higher rpm preset did not result in an increase of instrument fractures in vitro.[35] As mentioned before, there is a trend to using higher rotational speeds and comparatively low torques—for example, for XP-Shaper and BioRace (Brasseler) and for TruNatomy (Dentsply Sirona) instruments.[28]

Clinicians must fully understand the factors that control the forces exerted on continuously rotating NiTi instruments (Box 8.3). To minimize fractures and prevent taper lock, motor-driven rotary instruments should not be forced in an apical direction. Similarly, acute apical curves limit the use of instruments with higher tapers because of the risk of cyclic fatigue. The incidence of instrument fracture can be reduced to an absolute minimum if clinicians use data from well-designed torque and stress studies. Adequate procedural strategies, such as an adequate glide path, a detailed knowledge of anatomic structures, with avoidance of extreme canal configurations, and

Telegram: @dental_k

www.konkur.in

specific instrumentation sequences may also improve shaping results.

Box 8.3

Factors Governing the Potential for Nickel-Titanium Rotary Instrument Fractures

- Clinician's handling (most important)
- Combination of torsional load, bending, and axial fatigue
- Root canal anatomy
- Manufacturing process and quality

Certain procedures have evolved for removing fractured instruments from root canals (see Fig. 8.25); these are discussed in detail elsewhere in this book (see Chapter 19). Most of those methods require the use of additional equipment, such as a dental operating microscope and ultrasonic units. However, the best way to deal with instrument fracture is prevention. An understanding of the anatomy of the root canal system, together with a clear plan for selecting, sequencing, and using shaping instruments, can certainly help prevent procedural mishaps.

Steps of cleaning and shaping

Access—principles

Access cavity preparation is essential for root canal treatment and is described in detail elsewhere in this book (see Chapter 7). However, it should be emphasized at this point that mishaps during access (e.g., perforation) significantly affect the long-term outcome of a root canal–treated tooth. Overenlargement or gouging during access significantly reduces structural strength[354] and may lead to root fracture and nonrestorable conditions.

Rationally, the use of a cylindrical diamond bur, followed by a tapered fluted bur with noncutting tip and perhaps a small round bur is recommended (Fig. 8.32). A recent experiment suggested that more conservative access cavities, in particular in premolars, may increase fracture resistance and permit similar shaping outcomes.[238] The use of ultrasonically powered tips

Telegram: @dental_k

www.konkur.in

under magnification is aimed at achieving ideal access cavities (Fig. 8.33), including discovery and perhaps relocation of the canal orifices.

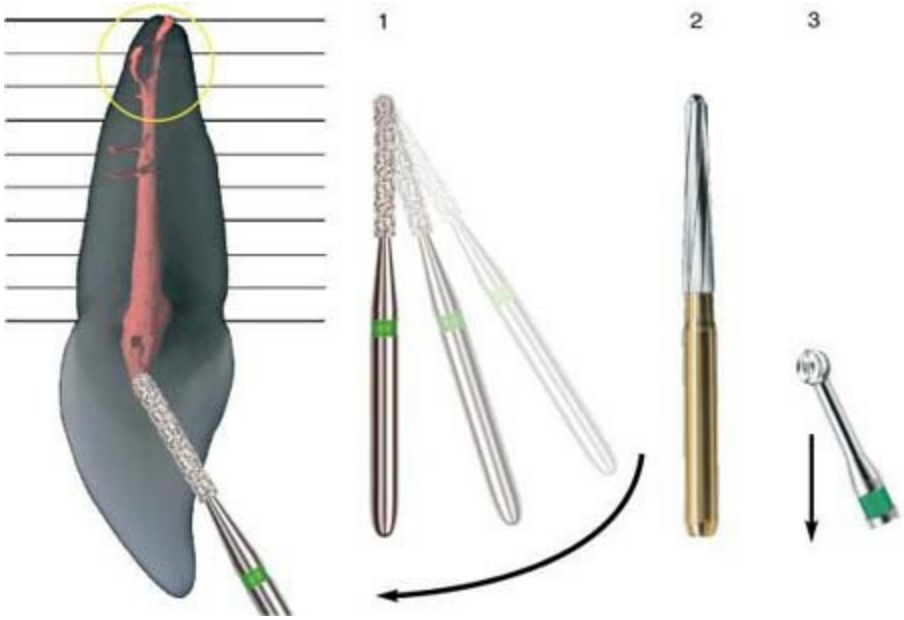

FIG. 8.32 Sequence of instruments used for optimal preparation of an access cavity (e.g., in an incisor). A parallel-sided diamond or steel bur is used to remove overlying enamel in a 90-degree angle toward the enamel surface *(1).* The bur is then tilted vertically to allow straight-line access to the root canal *(arrow).* A bur with a noncutting tip (e.g., Endo-Z bur or ball-tipped diamond bur) is then used to refine access *(2).* Overhangs or pulp horns filled with soft tissue are finally cleared with a round bur used in a brushing or pulling motion *(3).*

Set of four images show the steps of accessing a cavity in the root of a canal as numbered from 1 to 4.

seen through an operating microscope (×20). **A,** Modification with an ultrasonically activated tip (**B**).

A) Close-up of a molar shows an open crown exposing a golden filled vertical cavity.

B) Close-up of a molar shows an open crown exposing a vertical cavity with a circumference of hard filling around the crown.

Coronal modification

The extension of an access cavity into the coronal-most portion of the root canal has been called “coronal flaring” but may be more appropriately described as orifice modification. If a canal is constricted, mineralized, or difficult to access, directed enlargement of the coronal portion prior to any deep entry into the root canal is beneficial. This canal modification should be preceded by a scouting step, in which a small (e.g., size #10) K-file is passively placed several millimeters into the root canal. Tools for preflaring include Gates-Gliddens and dedicated NiTi instruments (Fig. 8.34). Specific orifice shaping rotaries have been developed that are used as a single instrument, rather than in a sequence.

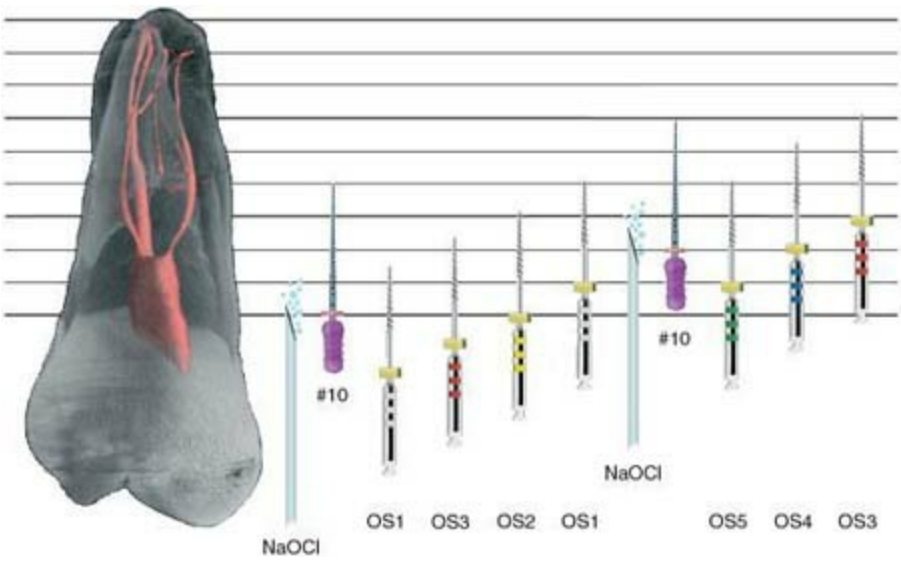

FIG. 8.34 Diagram of coronal enlargement in a more complicated maxillary posterior tooth. This maxillary molar presents several difficulties, including a narrow mesiobuccal canal that exits the pulp cavity at an angle. A possible approach in a case involving difficult

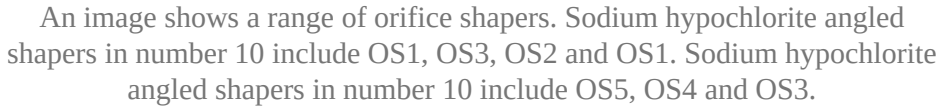
Telegram: @dental_k

www.konkur.in

entry into the root canal system is to use a small orifice shaper *(OS1)* after ensuring a coronal glide path with a K-file. Use of a sequence of orifice shapers *(OS3 to OS1)* then allows penetration into the middle third of the root canal. Wider canals can accept a second sequence of orifice shapers. Copious irrigation and securing a glide path with a size #10 K-file are prerequisites for use of NiTi rotary instruments.



An image shows a range of orifice shapers. Sodium hypochlorite angled shapers in number 10 include OS1, OS3, OS2 and OS1. Sodium hypochlorite angled shapers in number 10 include OS5, OS4 and OS3.

The use of laterally cutting NiTi rotaries allows clinicians to modify the root canal orifice to form a receptacle for subsequent instrumentation. This is related to removal of coronal mineralization and to relocation of the canal pathway by removal of restrictive dentin. For example, a second mesiobuccal canal of a maxillary molar typically exits the pulp chamber toward the mesial under a dentin shelf and then curves towards the distal. It is this curve in a small canal that often leads to formation of a ledge, which in turn prevents shaping to length.

Preenlargement of the coronal portion of a root canal allows files unimpeded access to the apical one third and gives the clinician better tactile control in directing small, adequately precurved negotiating files (Fig. 8.35).

Telegram: @dental_k

www.konkur.in

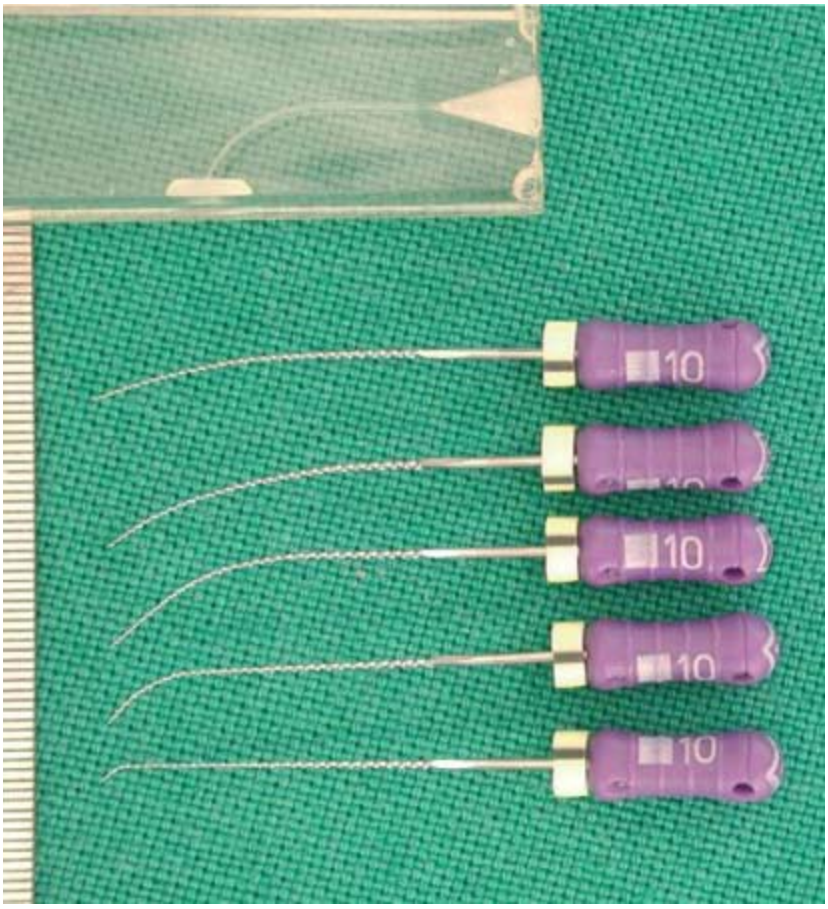


FIG. 8.35 Various precurved, stainless steel hand files for path finding and gauging. Compare the curves in the instruments to the ones in a plastic training block (gradation of ruler is 0.5 mm).

An image of five spirally textured hand files in size ten.

One of the purported benefits of orifice modification is early access of disinfecting irrigation solutions and prevention of pushing contaminated coronal debris apically. This has not been confirmed in experiments. On the other hand, a documented benefit of coronal flaring is mitigation of WL changes during canal preparation.[435]

Comparatively little is known about the efficacy of individual flaring instruments. A recent study compared the cutting efficacy of radial-landed and triangular cross sections.[292] The latter were shown to be more cutting efficient compared with radial-landed design; somewhat surprisingly, flexible martensitic alloy was cutting more rapidly compared with conventional NiTi alloys.

Telegram: @dental_k

www.konkur.in

Patency and glide path preparation

A *patency file* is a small K-file (usually a size #10 or #15) that is passively extended just through the apical foramen. Demonstration of apical patency has been suggested as a procedural for most rotary techniques. It is believed to remove accumulated debris, to help maintain WL, and thereby to translate into greater clinical success.[301] One concern with the patency file was that instead of having a cleaning effect, the file would drive contaminated debris through the foramen. However, an in vitro study suggested that the risk of inoculation was minimal when canals were filled with NaOCl.[214] Maintaining patency throughout an endodontic procedure does not lead to an increase in posttreatment symptoms.[21] Only initial clinical evidence exists either favoring the use of a patency file; however, experience suggests that this technique involves relatively little risk and provides some benefit as long as small files are used carefully.

The file that has reached the apical foramen has already formed a so-called glide path. This term has been used in endodontics for more than a decade[337] and relates to securing an open pathway to the canal terminus that subsequent engine-driven instruments can follow. The presence of a glide path is essential for the predictable use of rotary instruments since it minimizes the so-called screw-in or threading-in effect[173] and risk of torsional failure. It has been considered that taper lock may occur if the canal cross section is smaller than the tip of the instrument;[337] in that regard, a glide path reduces the contact area between subsequent shaping instruments and the canal wall, consequently the torsional loads induced by shaping rotary instruments are lower.[52]

It is advocated to explore and shape a root canal at least to a #15 size instrument before the use of a rotary NiTi instrument to full WL[442] to create a glide path for the safe advancement of the rotary shaping instrument tip.[321] The presence of an appropriate glide path is indicated by the fact that a straight size #15 K-file can passively and smoothly travel to WL with long in-and-out movements.

Classically, a glide path was created and secured with K-file sizes #10 and #15 used in watch-winding or balanced-force motion. However, recently NiTi rotary instruments with small tip diameter have been designed

Telegram: @dental_k

www.konkur.in

specifically to simplify the process after a size #10 K-file has reached WL.

Various small engine-driven instruments were introduced that are aimed at simplifying the glide path process—for example, Pathfiles (Dentsply Sirona),[47] Scout RaCe (FKG),[298] and G-file (MicroMega).[101] Copious irrigation and frequent recapitulations with a smaller file to WL may be required, and in some instances of highly mineralized canals, clinicians must devise strategies using small crown-down and/or step-back sequences.

The creation of a rotary glide path has demonstrated better preservation of the canal anatomy with fewer shaping aberrations[11,47] and has shown a less incidence of postoperative pain.[320] However, some studies have also reported acceptable performance of manual instruments for glide path preparation.[101,303]

Working length determination

Devices

Radiographs, tactile sensation, the presence of moisture on paper points, and knowledge of root morphology have been used to determine the length of root canal systems. Following earlier experiments by Custer,[99] subsequently Sunada[439] developed the first commercialized electronic apex locator, suggesting that the apical foramen could be localized using a direct electric current. Currently the electronic apex locator is considered an accurate tool for determining WL.[135] One study reported that the use of electronic apex locators in a dental student clinic resulted in a higher quality of obturation length control and an overall reduction in the number of radiographs taken.[135] However, these devices must not be considered flawless, because several variables are known to affect their accuracy. For example, immature roots can present problems.[208] Once roots mature (i.e., form a narrow apical foramen) and instruments are able to contact the canal walls, an electronic apex locator's accuracy greatly improves. Some investigators have found no statistical difference between roots with vital and necrotic tissue.[157,275] Because apical root resorption is prevalent in necrotic cases with long-standing apical lesions,[473] it may be concluded that apical resorption does not have a significant effect on the accuracy of electronic apex locators.

Telegram: @dental_k

www.konkur.in

Recently some clinicians have advocated the use of the electronically determined WL in lieu of WL estimations using the placement of a file in the canal and a radiograph. However, combined use of both radiographic and electronic techniques has been shown to result in greater accuracy.[120] Furthermore, radiographs may add essential anatomic information that could be missed if electronic apex locators are used exclusively.

The first two generations of electronic apex locators were sensitive to the contents of the canal and irrigants used during treatment. The development of an algorithm called the *ratio measurement method* distinguished the third generation of apex locators.[230] To arrive at this method, the impedance of the canal was measured with two current sources of different frequencies, and a quotient was determined using the electrical potentials proportional to each impedance.[230] This study found that electrolytes did not have a significant effect on the accuracy of the unit. Some third-generation apex locators are the Endex Plus, or Apit (Osada, Los Angeles, CA, USA); the Root ZX (J. Morita, Kyoto, Japan);[135,242] and the Neosono Ultima EZ (Satelec, Mount Laurel, NJ, USA). The Endex Plus device uses 1 and 5 kHz and provides apex location based on subtraction. The Root ZX emits currents at frequencies of 8 and 0.4 kHz and provides apex location based on the resulting quotient. In addition to latest model apex locators, manufacturers have developed smaller models (Fig. 8.36, *B*).

Apex locators are generally safe to use; however, manufacturers' instructions state that they should not be used on patients with pacemakers without consulting the patient's cardiologist. However, when connected directly to cardiac pacemakers in vitro, electronic apex locators did not interfere with the function of the pacemaker[145] and did not interfere with the functioning of any of the cardiac devices tested in a clinical study under ECG monitoring.[487]

Strategies

Anatomic studies and clinical experience suggest that typically teeth are 19 to 25 mm long. Most clinical crowns are approximately 10 mm long, and most roots range from 9 to 15 mm in length. Roots, therefore, can be divided into thirds that are 3 to 5 mm long. An important issue in root canal treatment is the apical endpoint of the prepared shape in relation to the apical anatomy. Traditional treatment has held that canal preparation and subsequent obturation should terminate at the *apical constriction*, the narrowest diameter of the canal (Fig. 8.37). This point is believed to coincide with the cementodentinal junction (CDJ; see Chapter 9) and is based on histologic sections and ground specimens. However, the position and anatomy of the CDJ varies considerably from tooth to tooth, from root to root, and from wall to wall in each canal. Moreover, the CDJ cannot be located precisely on radiographs. For this reason, some have advocated terminating the preparation in necrotic cases at 0.5 to 1 mm short of the radiographic apex and 1 to 2 mm short[187,357,492] in cases involving irreversible pulpitis. Although there is no definitive validation for this strategy at present,[379] well-controlled follow-up studies seem to support it.[297,419]

L) Cross-section of canal shows three larger black dots lying side by side to each other resulting in a rupture in the canal.

Working to shorter lengths may lead to the accumulation and retention of debris, which in turn may result in apical blockage (Fig. 8.38). If the path to the apex is blocked, working to short lengths may contribute to procedural errors such as apical perforations and fractured instruments. Such obstacles (which consist of collagen fibers, dentin mud, and most importantly, residual microbes) in apical canal areas are a major cause of persistent or recurrent apical periodontitis,[178,296,409] or posttreatment disease (also see Chapters 15 and 16).[138,490]

FIG. 8.38 Presence of dentin dust as a possible source of microbial irritation. Tooth #18 underwent root canal therapy. The clinician noted an apical blockage but was unable to bypass it. Unfortunately, intense

Telegram: @dental_k

www.konkur.in

pain persisted and at the patient's request, the tooth was extracted a week later. **A,** Mesial root of tooth #18; mesial dentin has been removed. **B,** Magnified view (×125) of rectangle in **A** shows an apical block (gradation of ruler is 0.5 mm).

A) Close-up of a cutaway tooth shows a canal with an inset marked on the root showing removed dentin dust.

B) Micrograph of an extracted tooth shows a blocked root canal with dentin dust.

Using an electronic apex locator has helped clinicians identify the position of apical foramina more accurately and allow safe canal shaping as close as 0.5 mm to the canal terminus.

Canal enlargement/preparation

Rationale

Like the position of the apical constriction, apical diameters are difficult to ascertain clinically.[240] Some clinicians have recommended gauging canal diameters by passing a series of fine files apically until one fits snugly. However, such an approach is likely to result in underestimation of the diameter.[486] This is a crucial point because the initial canal size is a major determinant for the desired final apical diameter, with the second relevant dimension being the size that allows deep irrigation needle penetration.

An ongoing debate exists between those who prefer smaller apical preparations combined with tapered shapes and those who favor larger apical preparations for better removal of infected dentin and to allow irrigation fluids access to the apical areas (Table 8.2). Both sides stress the importance of maintaining the original path of the canal during preparation; otherwise, bacteria in the apical one third of the root canal may not be reached by sufficient amounts of an antimicrobial agent.[289] Investigators demonstrated a higher percentage of bacterial elimination in single-root canal systems in situ by using a combination of significant enlargement of the apical third and NaOCl irrigation.[79] However, preparation errors (e.g., zips, canal transportation) may occur in such larger preparations specifically in curved canals, both with stainless steel and NiTi instruments (Fig. 8.39).

Table 8.2

Characteristics of Wide and Narrow Apical Preparations

Root Canal Preparation	Benefits	Drawbacks
Narrow apical size	Minimal risk of canal transportation and extrusion of irrigants or filling material	Little removal of infected dentin Questionable rinsing effect

Telegram: @dental_k

www.konkur.in

	Can be combined with tapered preparation to counteract some drawbacks Less compaction of hard tissue debris in canal spaces	in apical areas during irrigation Possibly compromised disinfection during interappointment medication Not ideal for lateral compaction
Wide apical size	Removal of infected dentin Access of irrigants and medications to apical third of root canal	Risk of preparation errors and extrusion of irrigants and filling material Not ideal for thermoplastic obturation

Thorough disinfection of the apical part of a root canal is essential, because this area is most likely to harbor residual intraradicular bacteria.[297] Wider apical preparations remove potentially infected dentin, allowing the delivering needle and subsequently antimicrobial irrigants to penetrate the root canal more deeply.[91,130]

A study investigating rotary NiTi files of three tapers (.06,.08, and.10) with file tips in sizes #20, #30, and #40 showed that size #20 instruments left significantly more debris in the apical third compared with size #40 instruments.[464] On the other hand, a study in which half the samples were prepared to a size #25 file and the other half to a size #40 file found no statistically significant difference in bacterial growth after instrumentation, with no growth observed after 1 week of treatment with a $Ca(OH)_2$ dressing.[500] Step-down sequences with additional apical enlargement to ISO size #35 and a serial step-back technique with no apical enlargement were compared, using NaOCl and EDTA as irrigants. Here, no significant difference was detected in colony-forming units with or without apical enlargement.[95] These researchers concluded that dentin removal in the apical third might be unnecessary if a suitable coronal taper is achieved.

Despite the disagreement over the appropriate width of a preparation (see Table 8.2), these studies suggest that root canal preparations should be confined to the canal space, should be sufficiently wide, and should incorporate the original root canal cross sections (see Fig. 8.4).

Traditional cleaning and shaping strategies (e.g., the step-back technique)

Telegram: @dental_k

www.konkur.in

focused immediate preparation of the apical third of the root canal system, followed by various flaring techniques to facilitate obturation.[161,380,453] In an attempt to reach the canal terminus, the clinician first selected a small file, placed an appropriate curve on the instrument, and then tried to work the file to full length. If the terminus could not be reached, the file was removed and, after irrigation, either the same file or a smaller one was inserted. However, not infrequently, full length was not obtained, either because of blockage or because of coronal binding.

Coronal binding is caused by overhangs at the orifice level and when the canal is less tapered than an instrument, making it bind coronally. Moreover, a straight root often contains a curved canal, such as buccal and lingual curvatures that cannot be seen on radiographs.[98,343] In addition, passing a precurved negotiating file through a coronally tight canal will straighten the instrument.[425]

Various instrumentation sequences have been developed for hand and rotary instruments; these are discussed later in this chapter. However, the shape of the access cavity is the prerequisite that must be optimized before any canal preparation can take place (see Chapter 7).

Basic cleaning and shaping strategies for root canal preparation can be categorized as crown-down, step-back, apical widening, and hybrid techniques. In a crown-down approach, the clinician passively inserts a large instrument into the canal up to a depth that allows easy progress. The next smaller instrument is then used to progress deeper into the canal; the third instrument follows deeper again, and this process continues until the terminus is reached. Both hand and rotary instruments may be used in a crown-down manner. However, instrument sets with various tip diameters and tapers allow the use of either decreasing tapers or decreasing diameters for apical progress. Debate continues as to which of those strategies is superior for avoiding taper lock; currently no compelling evidence favors either of them.

In the step-back approach, WLs decrease in a stepwise manner with increasing instrument size. This prevents less flexible instruments from creating ledges in apical curves while producing a taper for ease of obturation.

As discussed previously, the aim of apical widening is to fully prepare apical canal areas for optimal irrigation efficacy and overall antimicrobial

Telegram: @dental_k

www.konkur.in

activity. Recently, apical enlargement has been broken down into three phases: pre-enlargement, apical enlargement, and apical finishing.[476]

Many rotary techniques require a crown-down approach to minimize torsional loads[52] and reduce the risk of instrument fracture. Used sequentially, the crown-down technique can help enlarge canals further. All basic techniques described so far may be combined into a hybrid technique to eliminate or reduce the shortcomings of individual instruments.

Provided adequate tools are used and the access cavity design is appropriate, excessive thinning of radicular structures can be avoided (see Fig. 8.5). Vertical root fractures and perforations are possible outcomes of excessive removal of radicular dentin in zones that have been termed "danger zones."[7] Overenthusiastic filing, for example, may lead to more procedural errors (see Figs. 8.22 and 8.39). On the other hand, ideal preparation forms without any preparation errors and with circular incorporation of the original canal cross sections may be achieved with suitable techniques (see Fig. 8.4).

Techniques

Standardized technique.

The standardized technique adopts the same WL definition for all instruments introduced into a root canal. It therefore relies on the inherent shape of the instruments to impart the final shape to the canal. Negotiation of fine canals is initiated with lubricated fine files in a so-called watch-winding movement. These files are advanced to WL and worked either in the same hand movement or with "quarter-turn-and-pull" until a next larger instrument may be used. Conceptually, the final shape should be predicted by the last instrument used. A single matching gutta-percha point may then be used for root canal filling. In reality, this concept is often violated: curved canals shaped with the standardized technique will be wider than the last used instrument,[16] exacerbated by the pulling portion of the hand movement. Moreover, adequate compaction of gutta-percha in such small a taper (~.02) is difficult or impossible (see Chapter 9).[15]

Step-back technique.

Realizing the importance of a shape larger than that produced with the

Telegram: @dental_k

www.konkur.in

standardized approach, Weine et al.[483] suggested the step-back technique, incorporating a stepwise reduction of the WL for larger files, typically in 1 mm or 0.5 mm steps, resulting in flared shapes with.05 and.10 taper, respectively. Incrementally reducing the WL when using larger and stiffer instruments also reduced the incidence of preparation errors, in particular in curved canals. This concept appeared to be clinically very effective.[293]

Although the step-back technique was primarily designed to avoid preparation errors in curved canals, it applies to the preparation of apparently[98,382] straight canals as well. Several modifications of the step-back technique have been described over the years, to explore and provide some enlargement prior to reaching the WL.

Step-down technique.

Other clinicians[156] described a different approach. They advocated shaping the coronal aspect of a root canal first before apical instrumentation commenced. This technique is intended to minimize or eliminate the amount of necrotic debris that could be extruded through the apical foramen during instrumentation;[129] moreover, by first flaring the coronal two thirds of the canal, apical instruments are unimpeded through most of their length. This in turn may facilitate greater control and less chance of zipping near the apical constriction.[246]

Crown-down technique.

Multiple modifications of the original step-down technique have been introduced, including the description of the crown-down technique.[133,274,378] The more typical step-down technique includes the use of a stainless steel K-file exploring the apical constriction and establishing WL. In contrast, a crown-down technique relies more on coronal flaring and then determination of the WL later in the procedure.

To ensure penetration during step-down, one may have to enlarge the coronal third of the canal with progressively smaller GG drills or with other rotary instruments. Irrigation should follow the use of each instrument and recapitulation after every other instrument. To properly enlarge the apical third and to round out ovoid shape and lateral canal orifices, a reverse order of instruments may be used starting with a size #20 (for example) and

Telegram: @dental_k

www.konkur.in

enlarging this region to a size #40 or #50 (for example). The tapered shape can be improved by stepping back up the canal with larger instruments, bearing in mind all the time the importance of irrigation and recapitulation.

The more typical crown-down, or double-flare technique,[133] consisted of an exploratory action with a small file—a crown-down portion with K-files of descending sizes and an apical enlargement to size #40 or similar. The original technique included stepping back in 1-mm increments with ascending file sizes and frequent recapitulations with a small K-file and copious irrigation. It is further emphasized that significant wall contact should be avoided in the crown-down phase to reduce hydrostatic pressure and the possibility of blockage. Several studies[377,378] demonstrated more centered preparations in teeth with curved root canals shaped with a modified double-flare technique and Flex-R files compared with shapes prepared with K-files and step-back technique. A double-flare technique was also suggested for ProFile rotary instruments.[387]

Balanced force technique.

Regarding hand movements, a general agreement exists that the so-called balanced force technique creates the least canal aberrations with K-files. This technique has been described as a series of rotational movements for Flex-R files,[362] but it can also be used for K-files and other hand instruments such as GT hand files. Many different explanations have been offered for the obvious and undisputed efficacy of the balanced force approach,[84,241,382] but general agreement exists that it provides excellent canal-centering ability, superior to other techniques with hand instruments.[29,65]

The balanced force technique involves three principle steps.[362] The first step (after passive insertion of an instrument into the canal) is a clockwise rotation of about 90 degrees to engage dentin (Fig. 8.40). In the second step, the instrument is held in the canal with adequate axial force and rotated counterclockwise to break loose the engaged dentin chips from the canal wall; this produces a characteristic clicking sound. Classically, in the third step, the file is removed with a clockwise rotation to be cleaned; however, because files used with the balanced force technique are not precurved, every linear outward stroke essentially is a filing stroke and may lead to some straightening of the canal path. Therefore, in many cases, the clinician may

Telegram: @dental_k

www.konkur.in

advance farther apically rather than withdrawing the file, depending on the grade of difficulty.

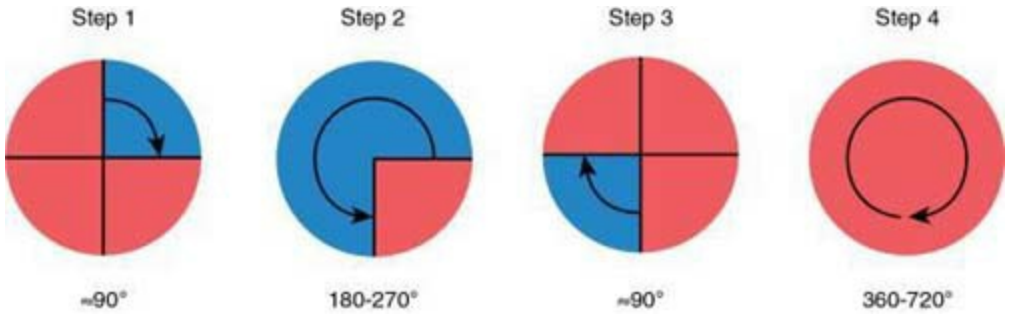

FIG. 8.40 Diagram of handle movements during balanced force hand preparation. STEP 1: After pressureless insertion of a Flex-R or NiTiFlex K-file, the instrument is rotated clockwise 90 degrees, using only light apical pressure. STEP 2: The instrument is rotated counterclockwise 180 to 270 degrees; sufficient apical pressure is used to keep the file at the same insertion depth during this step. Dentin shavings are removed with a characteristic clicking sound. STEP 3: This step is similar to step 1 and advances the instrument more apically. STEP 4: After two or three cycles, the file is loaded with dentin shavings and is removed from the canal with a prolonged clockwise rotation.

D) Diagram of a red circle shows a clockwise arrow at 360 to 720 degrees.

Rotary instrumentation.

NiTi rotary instruments are invaluable devices in the preparation of root canals, although hand instruments may be able to enlarge some canals just as efficiently when used in appropriate sequences. After orifice modification, the access cavity and canals are flooded with irrigant, and a small file is advanced into the canal. Application of a lubricant when using hand instruments can help prevent apical blockage at this early stage. Once the WL

Telegram: @dental_k

www.konkur.in

has been established (aided by an electronic apex locator and radiographically verified), apical preparation begins to facilitate a glide path for subsequent rotary instrumentation (Fig. 8.41; also see earlier discussion).

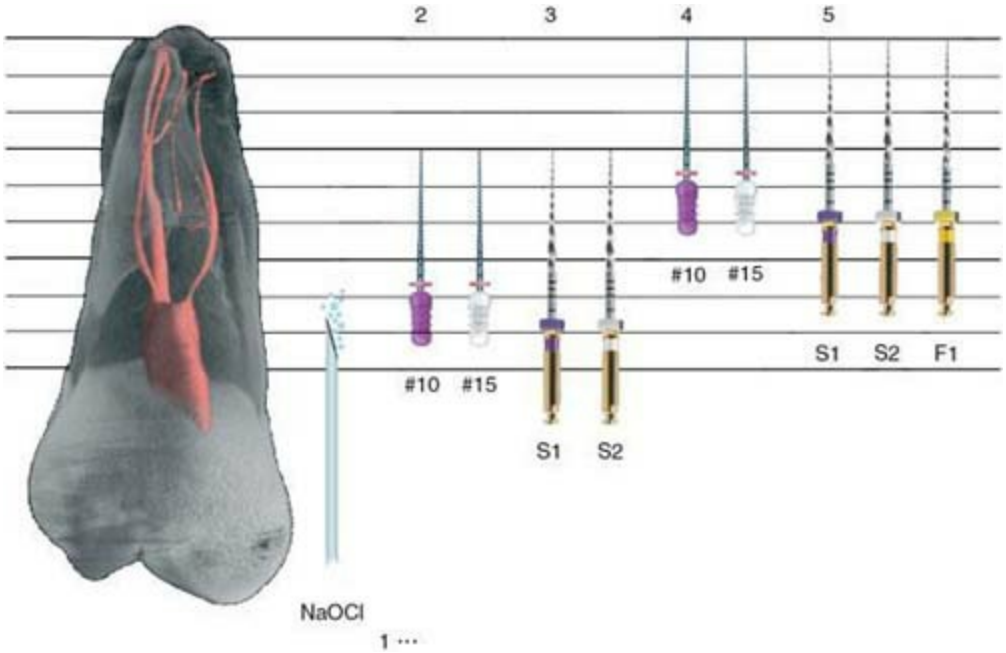

FIG. 8.41 Instrumentation of root canals with the single length technique, in this example using the ProTaper instruments. After irrigation and scouting (*1* and *2*), the coronal thirds are enlarged with shaping files *S1* and *S2*. Hand files then are used to determine the WL and to secure a glide path. Apical preparation is completed with S1 and S2. Finishing files are used to the desired apical width.

A cutaway diagram of coronal enlargement in a maxillary posterior tooth with a narrow canal that exits the pulp cavity at an angle. Specific nickel titanium (NiTi) instrumentation techniques

Crown-down.

This was the dominant approach for many years and is still being used, for example for ProFile and other instruments with standard.04 and.06 tapers. It must be noted that the manufacturers' instructions for these systems vary somewhat, and the instructions for GT rotary, RaCe, and the TF vary even more. Clinicians should always consult the manufacturers' instructions for details on working with any endodontic instrument.

Coronal preenlargement is suggested, the WL then is determined as described previously, and an open glide path is secured with K-files up to size #15 or #20, depending on the canal anatomy. If canal size permits, canal

Telegram: @dental_k

www.konkur.in

preparation begins with.06 taper instruments in descending tip diameters.[52] In more difficult small canals,.06 tapers are followed by.04-tapered instruments, also with descending tip diameters. Apical preparation is performed either with multiple shaping waves, as suggested for GT rotary files,[68] or in a step-back manner.[386] Recapitulation with a small hand file is recommended throughout the preparation.

Single length.

The approach for ProTaper and ProTaper Next instruments differs from that for earlier NiTi rotary files in that no traditional crown-down procedure is performed (see Fig. 8.44, later).

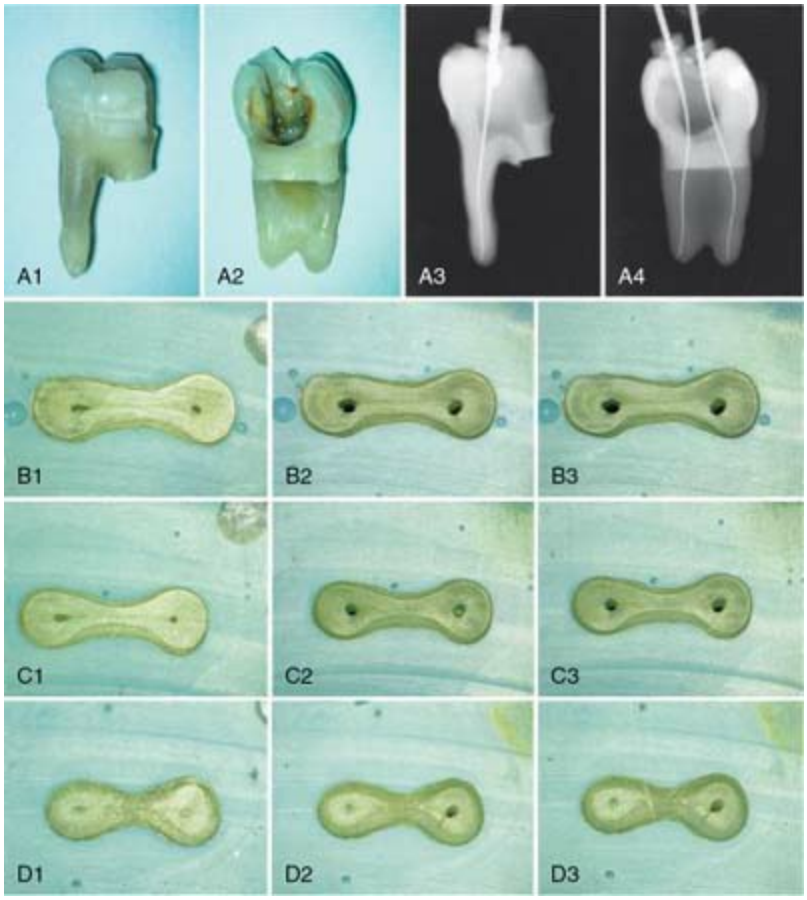

FIG. 8.44 Effect of a hybrid technique on root canal anatomy studied in a Bramante model. **A1–A4,** Both mesial canals of an extracted mandibular molar have been instrumented. First, size #10 and #15 hand files are passively inserted into the coronal two thirds of a root canal as pathfinding files, which confirm the presence of a smooth, reproducible glide path. This step is essential for ProTaper shaping

Telegram: @dental_k

www.konkur.in

instruments, because they are mostly side-cutting and have fine, rather fragile tips.

Shaping files S1 and S2 are then passively inserted into the scouted canal spaces, which have been filled with irrigant (preferably NaOCl). If necessary, the SX file can be used at this stage to relocate orifices or remove obstructing dentin. After each shaping file is used, the canals are reirrigated, and a size #10 file is used to recapitulate to break up debris and move it into solution. This process is repeated until the depth of the pathfinding #10 or #15 file is reached.

After irrigation, the apical third is fully negotiated and enlarged to at least a size #15 K-file, and WL is confirmed (see Fig. 8.44). Depending on the canal anatomy, the rest of the apical preparation can be done with engine-driven ProTaper shaping and finishing hand files. As an alternative, handles may be placed on these instruments' shanks, so that they can be used for a manual balanced force technique.

ProTapers S1 and S2 are then carried to full WL, still in a floating, brushing motion. WL should be confirmed after irrigation and recapitulation with a K-file, aided by an electronic apex locator and/or radiographs. Because of the progressive taper and more actively cutting flutes in the ProTaper design, interferences in the middle and coronal thirds are removed at this stage.

The preparation is finished with one or more of the ProTaper finishing files, used in a nonbrushing manner; because of their decreasing taper, these files will reach the WL passively. Recapitulation and irrigation conclude the procedures (see Fig. 8.41). Many other contemporary engine-driven techniques use the single-length concept—for example, WaveOne Gold, TRUShape, and XP-Shaper. However, the emphasis on Orifice Modification prior to deep instrument penetration allows these techniques to retain many of the benefits of the classic crown-down techniques, such as less change of WL during the procedure, deep and early access of irrigants, and less stress on fragile files.[327]

Hybrid techniques.

For many years, established clinical practice has suggested combining various NiTi preparation systems[79,476] to address certain shortcomings of

Telegram: @dental_k

www.konkur.in

most current instruments (Box 8.4). Although many combinations are possible, the most popular and useful ones involve coronal preenlargement followed by various apical preparation sequences. However, clinicians must keep in mind that anatomic variations in each canal must be addressed individually with specific instrument sequences. Most important, oval canals extend deep into the apical area,[442,482,491] and apical foramina may in fact be oval in most cases.[64] Naturally, a rotating file can produce a round canal at best (Fig. 8.43); therefore a strategy must be devised for adequately shaping oval canals without overly weakening radicular structure (compare Figs. 8.4 and 8.5).

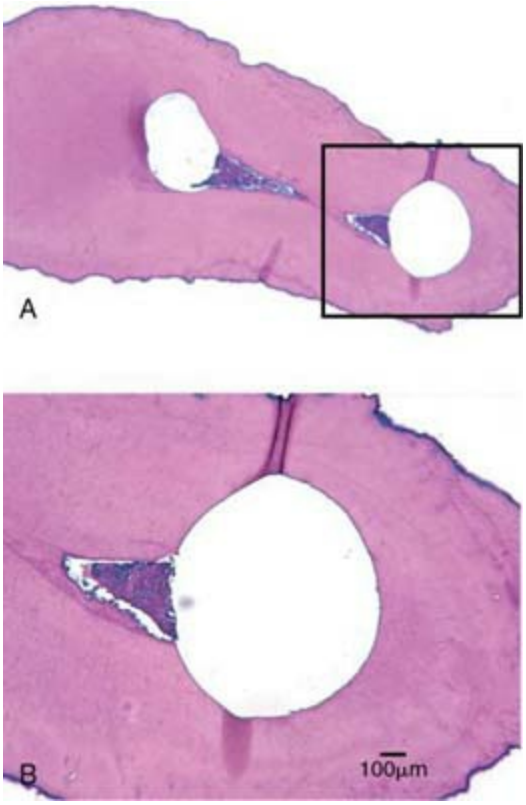

FIG. 8.43 Remaining potentially infected tissue in fins and isthmus configuration after preparation with rotary instruments. **A,** Cross section through a mesial root of a mandibular molar, middle to coronal third of the root. Box 8.4

Benefits of Using a Combination of Instruments for Endodontic Therapy

- Instruments can be used in a manner that promotes their individual strengths and avoids their weaknesses (most important).
- Hand instruments secure a patent glide path.
- Tapered rotary instruments efficiently enlarge coronal canal areas.
- Less tapered instruments allow additional apical enlargement.

Histologic slides (see Fig. 8.43) and microcomputed tomography reconstructions show critical areas that were not mechanically prepared despite the use of various individual rotary techniques. The aim of hybridizing NiTi rotary techniques, therefore, is to increase apical size using a fast and safe clinical procedure (Fig. 8.44).

The principle involves the use of a variety of instruments: for example, K-files for establishing patency, ProTaper instruments for body shaping and apical preenlargement, NiTi K-files or LightSpeed instruments for apical widening, and various instruments for final smoothing.[476]

Final apical enlargement

Conceptually, file sizes during canal preparation were termed “initial apical file,” “master apical file,” and “final file,” or IAF, MAF, and FF, respectively. The first file to bind, the IAF, is supposed to give clinicians a guide in determining the final size of their canal preparation. On the other hand, many current instrumentation techniques have, due to their design, predefined final sizes—for example, WaveOne Gold shaping aims at final sizes #25.07, #35.06, and #45.05 taper.

Telegram: @dental_k

www.konkur.in

Whichever apical size was conceptually aimed for, after achieving a tapered canal form, the apical size at that point should be verified by apical gauging. K-files or K-FlexOFiles of the same size are often recommended for this step. During gauging, files should be gently moved to WL and the binding point should be noted. Presence of an apical narrowing means that WL is reached without any shaping effort, with a size-corresponding K-file. However, the next larger K-file size will stay back by a small distance. Finally, maintenance of patency should be verified. If apical gauging stops short of WL, which suggests that a canal is undershaped, additional enlargement should be accomplished with any technique appropriate to the specific anatomy of the root canal. This often necessitates a hybrid technique.

Disinfection of the root canal system

Irrigation is defined as "to wash out a body cavity or wound with water or a medicated fluid" and aspiration as "the process of removing fluids or gases from the body with a suction device." Disinfectant, meanwhile, is defined as "an agent that destroys or inhibits the activity of microorganisms that cause disease."[1]

The objectives of irrigation in endodontics are mechanical, chemical, and biological. The mechanical and chemical objectives are as follows: (i) Flush out debris, (ii) lubricate the canal, (iii) dissolve organic and inorganic tissue, (iv) prevent the formation of a smear layer during instrumentation or dissolve it once it has formed, and (v) detach and disrupt biofilms.[38] Mechanical effectiveness will depend upon the ability of irrigation to generate optimum streaming forces within the entire root canal system, interact with the canal walls, and reach areas that cannot be prepared by mechanical instruments, including fins, isthmuses, and even lateral canals.[479] Chemical effectiveness depends upon the concentration of the antimicrobial irrigant, the area of contact, and the duration of interaction between irrigant and infected material.[58] Final efficiency of endodontic disinfection depends upon its chemical and mechanical effectiveness.[170]

The biological function of irrigants is related to their antimicrobial effects and their capacity to effectively eradicate or maximally reduce intracanal bacteria.

Telegram: @dental_k

www.konkur.in

In principle, irrigants should (i) have high efficacy against anaerobic and facultative microorganisms in their planktonic or biofilm states, (ii) inactivate endotoxin, (iii) be nontoxic when they come in contact with vital tissues, and not cause an anaphylactic reaction.[38]

Hydrodynamics of irrigation

Irrigation dynamics refers to how irrigants flow, penetrate, and readily exchange within the root canal walls as well as the forces produced by them. A better understanding of the fluid dynamics of different modes of irrigation contributes to achieving predictable disinfection of the root canal system. Hence, in endodontic disinfection, the process of delivery is as essential as the antibacterial characteristics of the irrigants.[58]

The effectiveness of root canal irrigation in terms of debris removal and eradication of bacteria depends on several factors that can be controlled by the operator: penetration depth of the needle, diameter of the root canal, inner and outer diameter of the needle, irrigation pressure, viscosity of the irrigant, velocity of the irrigant at the needle tip, and type and orientation of the needle bevel (Fig. 8.45).

Telegram: @dental_k

www.konkur.in

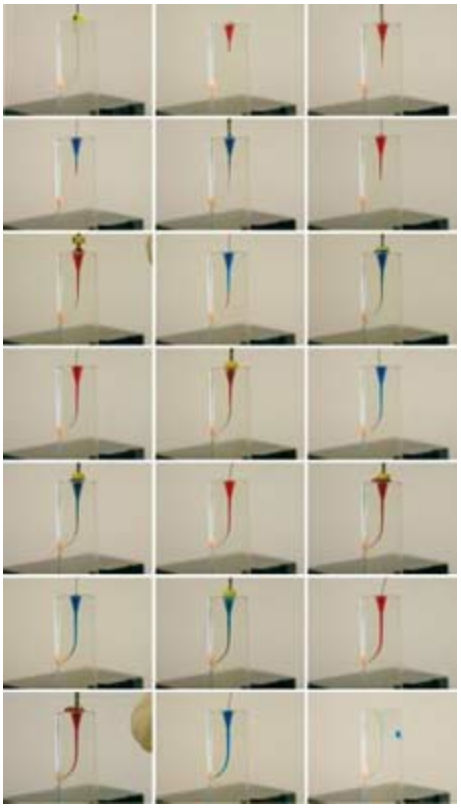

FIG. 8.45 Irrigation and movement of irrigants depends on canal shape. Sequential enlargement of a canal in clear plastic block was performed with a sequence of ProFile instruments in accordance with the manufacturer's recommendations. Alternating irrigation with blue and red fluid was done after each preparation step. Note the apical presence of irrigant after sufficient shape has been provided. Note the distribution of fluid immediately after irrigation with a 30-gauge needle.

A panel of twenty one glass samples with root shaped hollows depicts root shapes and sizes using different colored fluid fillings.

The size and length of the irrigation needle—to root canal dimensions—are of utmost importance for the effectiveness of irrigation. Apical root canal diameter and taper have an impact on needle penetration depth (see earlier in this chapter for details regarding apical preparation size; see Fig. 8.7 and Table 8.2).

The external needle diameter is of relevance for the depth of introduction into the root canal (Fig. 8.46) and rigidity of the needle body, an essential consideration for irrigation of curved canals. Common 27 gauge injection needles have an external diameter of 0.42 mm, but smaller stainless steel irrigation tips with external diameters of 0.32 mm (30 gauge) and even 31

Telegram: @dental_k

www.konkur.in

gauge or 0.26 mm (Navitip, Ultradent, South Jordan, UT, USA) are available. The Stropko Flexi-Tip (30 gauge) needle is fabricated from nickel-titanium to improve penetration into curved root canals. More recently, a flexible plastic irrigation tip was introduced (TruNatomy, Dentsply Sirona).

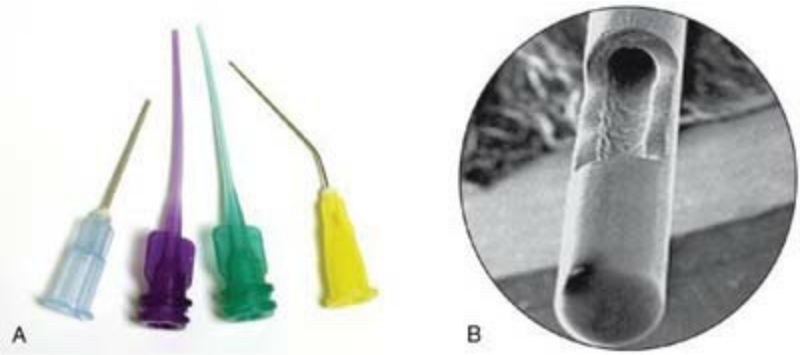

FIG. 8.46 **A,** Various types of needles for root canal irrigation. Shown are examples with open end and closed end, side vented. These are manufactured from plastic and stainless steel. **B,** SEM image of 30 gauge safety needle.

Apical pressure is the force applied perpendicular to the apical wall surface. Internal syringe diameter determines the pressure necessary for moving the syringe plunger. Speed of the plunger determines the velocity with which the irrigant is extruded. Fine needles require more pressure onto the plunger and extrude the irrigant with higher velocity than large needle sizes, which extrude significantly greater amounts of irrigants but for safety reasons cannot be introduced as deeply.

To improve the safety of irrigation and prevent extrusion of the irrigant through the apical foramen, some needle types release the solution via lateral openings and have a closed, safe-ended tip. The orientation of the bevel is crucial to produce a turbulence effect on the dentinal wall of the canal. Wall shear stress has a direct impact on the quality and efficacy of root canal wall

Telegram: @dental_k

www.konkur.in

débridement[61] and is one of the most critical fluid mechanics parameters. Side-vented and double side-vented needles led to maximum shear stress concentrated on the wall facing the outlet (the proximal outlet for the double side-vented needle).[60]

Flow is defined as the quantity of material passing a given area in a unit time period. The flow depends on many factors. Some of them are pressure: Pressure difference is needed to make flow happen. Flow occurs from higher pressure to lower pressure and the greater the difference, the greater the flow. Flow also changes with the diameter of tube or needle: the larger the needle, the more flow. Finally, the longer the length of the needle, the less the flow. In endodontics, anatomical constrains of the root canal make irrigation flow a challenge.

Irrigants

An optimal irrigant would have all of the characteristics considered beneficial in endodontics but none of the negative or harmful properties. Presently, no solution can be regarded as optimal. However, the combined use of selected irrigation products dramatically contributes to the successful treatment outcomes (Boxes 8.5 and 8.6).

Box 8.5

Benefits of Using Irrigants in Root Canal Treatment

- Removal of particulate debris and wetting of the canal walls
- Destruction of microorganisms
- Dissolution of organic debris
- Opening of dentinal tubules by removal of the smear layer
- Disinfection and cleaning of areas inaccessible to endodontic instruments

Box 8.6

Properties of an Ideal Irrigant for Root Canal Treatment

Telegram: @dental_k

www.konkur.in

An ideal irrigant should:

- Be an effective germicide and fungicide.
- Be nonirritating to the periapical tissues.
- Remain stable in solution.
- Have a prolonged antimicrobial effect.
- Be active in the presence of blood, serum, and protein derivates of tissue.
- Have low surface tension.
- Not interfere with repair of periapical tissues.
- Not stain tooth structure.
- Be capable of inactivation in a culture medium.
- Not induce a cell-mediated immune response.
- Be able to completely remove the smear layer, and be able to disinfect the underlying dentin and its tubules.
- Be nonantigenic, nontoxic, and noncarcinogenic to tissue cells surrounding the tooth.
- Have no adverse effects on the physical properties of exposed dentin.
- Have no adverse effects on the sealing ability of filling materials.
- Be convenient in its application.
- Be relatively inexpensive.

Sodium hypochlorite

NaOCl is the most commonly used irrigating solution[285] because of its antibacterial capacity and the ability to dissolve necrotic tissue, vital pulp tissue, and organic components of dentin and biofilms in a fast manner.[392]

NaOCl solution is frequently used as a disinfectant or a bleaching agent. It is the irrigant of choice in endodontics, owing to its efficacy against pathogenic organisms and pulp digestion, and satisfies most of the preferred characteristics stated earlier.[285]

History.

Hypochlorite was first produced in 1789 in France. Hypochlorite solution

Telegram: @dental_k

www.konkur.in

was used as a hospital antiseptic that was subsequently sold under the trade names “Eusol” and “Dakin’s solution.” NaOCl as a buffered 0.5% solution was recommended for the irrigation of wounds during World War I by Dakin.[103] In 1919 Coolidge[97] introduced NaOCl to endodontics as an intracanal irrigation solution.[504]

Mode of action.

When sodium hypochlorite contacts tissue proteins, nitrogen, formaldehyde, and acetaldehyde are formed. Peptide links are fragmented, and proteins disintegrate, permitting hydrogen in the amino groups (-NH-) to be replaced by chlorine (-NCl-) forming chloramines. This plays a vital role in the antimicrobial effectiveness. Necrotic tissue and pus are dissolved, and the antimicrobial agent reaches and cleans the infected areas.

Estrela[125] reported in 2002 that sodium hypochlorite exhibits a dynamic balance (Fig. 8.47):

1. Saponification reaction: Sodium hypochlorite acts as an organic and fat solvent that degrades fatty acids and transforms them into fatty acid salts (soap) and glycerol (alcohol), reducing the surface tension of the remaining solution.
2. Neutralization reaction: Sodium hypochlorite neutralizes amino acids by forming water and salt. With the exit of hydroxyl ions, the pH is reduced.
3. Hypochlorous acid formation: When chlorine dissolves in water, and it is in contact with organic matter, it forms hypochlorous acid. Hypochlorous acid is a weak acid with the chemical formula HClO that acts as an oxidizer. Hypochlorous acid ($HOCl^-$) and hypochlorite ions (OCl^-) lead to amino acid degradation and hydrolysis.
4. Solvent action: Sodium hypochlorite also acts as a solvent, releasing chlorine that combines with protein amino groups (NH) to form chloramines (chloramination reaction). Chloramines impede cell metabolism; chlorine is a strong oxidant and inhibits essential bacterial enzymes by irreversible oxidation of SH groups (sulphydryl group).[143]

Telegram: @dental_k

www.konkur.in

5. High pH: Sodium hypochlorite is a strong base (pH >11). The antimicrobial effectiveness of sodium hypochlorite, based on its high pH (hydroxyl ions action), is similar to the mechanism of action of calcium hydroxide. The high pH interferes in cytoplasmic membrane integrity due to irreversible enzymatic inhibition, biosynthetic alterations in cellular metabolism, and phospholipid degradation observed in lipidic peroxidation.[125]

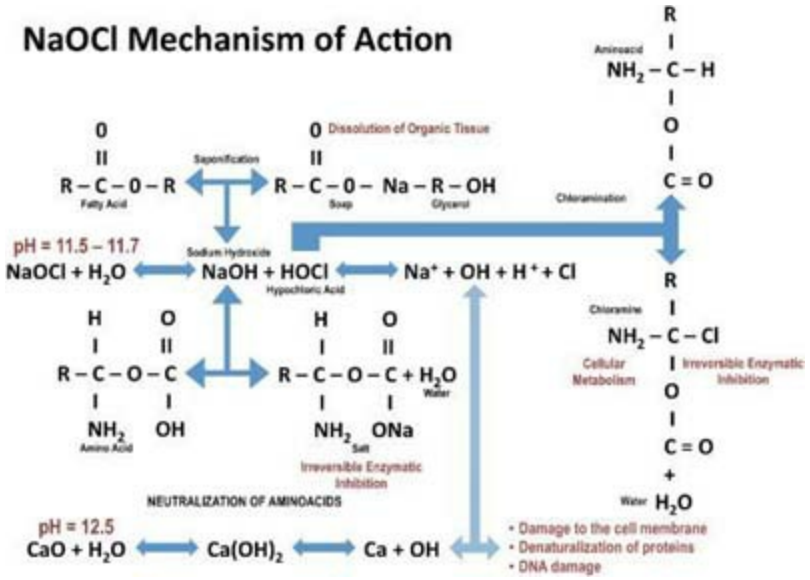

FIG. 8.47 Schematic diagram of the mechanism of action of NaOCl with the main interactions and properties highlighted. This diagram shows the chemical reaction of NaOCl when in contact with organic matter. The solution produces glycerol and soap (saponification reaction) and acts as a fat solvent degrading fatty acids. Moreover, hypochlorous acid is formed with a reduction of the pH and formation of chloramines (chloramination reaction). Damage to the cell membrane, denaturalization of proteins, and DNA damage may be observed.

The reaction are shown as follows:

Fatty acid on saponification leads to dissolution of organic tissue resulting in formation of soap and glycerol.

Sodium hypochlorite plus water (pH = 11.5 minus 11.7 gives sodium hydroxide and hypochloric acid which further give sodium plus hydroxide plus hydrogen plus chlorine.

Amino acid plus sodium hydroxide gives salt in an irreversible enzymatic inhibition reaction.

Telegram: @dental_k

www.konkur.in

Hypochloric acid, chloramine (cellular metabolism) and water on chlorination gives amino acid in an irreversible enzymatic inhibition.

Neutralization of amino acids: Calcium oxide plus water (pH = 12.5) yields calcium hydroxide which further gives calcium and hydroxide resulting in damage to the cell membrane, denaturalization of proteins and D N A damage.

Allergic reactions to sodium hypochlorite.

Although few reports have been published[127,180] on allergic reactions to NaOCl, real allergies to NaOCl are unlikely to occur, since both Na and Cl are essential elements in the physiology of the human body. It must be remembered that the hypochlorous acid (the active component of the sodium hypochlorite) is a chemical substance that is elaborated by neutrophils in the process of phagocytosis; it may create local tissue damage when it is produced in excess (liquefaction necrosis: purulent exudate) but does not cause allergic responses. Nevertheless, hypersensitivity and contact dermatitis may occur in rare situations. A recent case report[355] describes a severe chemical burn in an endodontist's eye caused by accidental contact with 3.5% NaOCl used as an irrigant during the root canal.

When hypersensitivity to NaOCl is suspected or confirmed, chlorhexidine (CHX) should not be used either because of its chlorine content. Individuals who genetically have more possibilities than the average population to generate allergies to multiple elements (allergies to food or latex) a skin test for both NaOCl and CHX may be indicated. The use of an alternative irrigant with high antimicrobial efficacy, such as iodine potassium iodide (IKI), should be considered, assuming there is no known allergy to that irrigant. Solutions such as alcohol or tap water are less effective against microorganisms and do not dissolve vital or necrotic tissue; however, $Ca(OH)_2$ could be used as a temporary medicament because it dissolves both vital and necrotic tissue.[17,188]

Temperature.

Increasing the temperature of low-concentration NaOCl solutions improves their immediate tissue-dissolution capacity (Fig. 8.48).[504] Furthermore,

Telegram: @dental_k

www.konkur.in

heated hypochlorite solutions remove organic debris from dentin shavings more efficiently. Bactericidal rates for NaOCl solutions, the capacity of human pulp dissolution, and increased efficacy were detailed in several studies.[418] There are various devices to preheat NaOCl syringes (Fig. 8.49); however, it was demonstrated that as soon as the irrigant touches the root canal system, the temperature reaches the body temperature.[508] Therefore, in situ heating of NaOCl is recommended by some authors. This can be done by activating ultrasonic or sonic tips to the NaOCl inside the root canal for a couple of minutes (see irrigation timings later). Macedo et al.[265] state that the efficacy of NaOCl on dentin is improved by refreshment, ultrasonic activation, and exposure time. In that investigation, a 10°C temperature rise during ultrasonic activation was insufficient to increase the reaction rate. However, there are no clinical studies available at this point to support the use of heated NaOCl.[38,94]

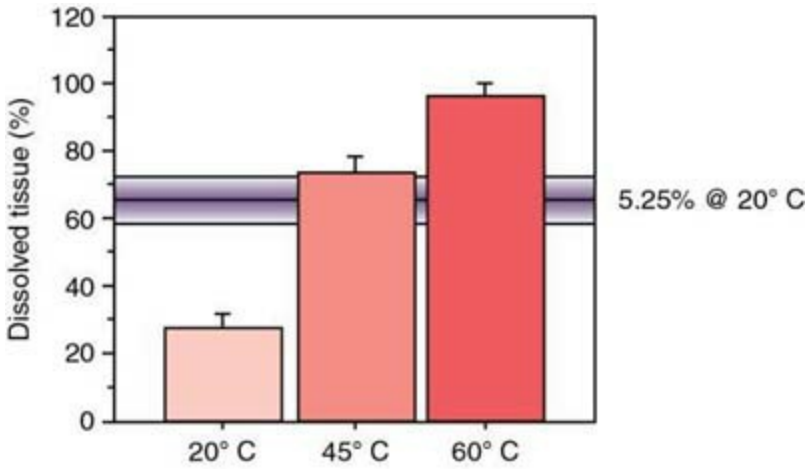

FIG. 8.48 Effect of heating on the ability of 0.5% sodium hypochlorite (NaOCl) to dissolve pulp tissue: NaOCl heated to 113°F (45°C) dissolved pulp tissue as well as the positive control (5.25% NaOCl) did. When the NaOCl was heated to 140°F (60°C), almost complete dissolution of tissue resulted.

Plot shows three bars representing degrees in Celsius versus dissolved tissue (in percentage) and increase (in percentage). The horizontal axis has three bars for 20 degree Celsius, 45 degree Celsius and 60 degree Celsius. The vertical ranges from 0 to 120 in increments of 20. The data is as follows:

Concentration.

NaOCl is used in concentrations between 0.5% and 6% for root canal irrigation. Controversy exists over recommended concentrations of sodium hypochlorite during root canal treatment. Several studies have tried to evaluate the influence of different concentrations of NaOCl on various aspects of the treatment such as antimicrobial efficacy, tissue dissolution,

Telegram: @dental_k

www.konkur.in

penetration into dentin, capacity to remove the smear layer, decalcification of dentin, microhardness, viability of stem cells in the apical region, viscosity, amount of debris extrusion, tooth surface strain, and postoperative pain. The results of these studies have been conflicting in nature. Some in vitro studies have shown that NaOCl in higher concentrations is more effective against *Enterococcus faecalis* and *Candida albicans*.[159,349,478] In contrast, clinical studies have indicated both low and high concentrations to be equally effective in reducing bacteria from the root canal system.[77,100] NaOCl in higher concentrations has a better tissue-dissolving ability.[186] However, in lower concentrations when used in high volumes, it can be equally effective.[290,413] Higher concentrations of NaOCl are more toxic than lower concentrations[430]; however, perhaps due to the anatomy of the root canal system, higher concentrations have successfully been used during root canal treatment, with a low incidence of problems. Higher concentrations cause more cytotoxicity, erosion of dentin, collagen degradation, decalcification, dentin deproteination, and tooth surface strain while reducing microhardness, elastic modulus, and flexural strength of dentin.[468] In the root canal environment, using higher NaOCl concentrations does not necessarily change outcomes, because a high volume of irrigation and frequent exchanges can compensate for the effects of the concentration.[149]

Time.

Retention time and the volume of irrigation are essential factors influencing the antibacterial activity of NaOCl.[149] There is conflicting evidence regarding the time course of the antibacterial effect of NaOCl.[38,176] In some articles hypochlorite kills the target microorganism in seconds, even at low concentrations, while other reports have published considerably longer times for the killing of the same species.[160] Such differences are likely a result of several factors such as irrigant concentration and presence of organic matter (inflammatory exudates, hard and soft tissue remnants and microbial biomass).

Several studies showed[174,291] that the presence of dentin caused marked delays in the killing of *E. faecalis* by 1% NaOCl. Many of the earlier studies were performed in the presence of an unknown amount of organic matter. When such confounding factors are eliminated, it has been shown that NaOCl

Telegram: @dental_k

www.konkur.in

kills the target microorganisms rapidly, even at low concentrations of less than 0.1%.[176,471] However, in vivo, the presence of organic matter consumes NaOCl and weakens its effect. Therefore continuous replenishing of irrigation solution and allowing sufficient contact time are important factors for the effectiveness of NaOCl.[176]

The chlorine ion, which is responsible for the dissolving and antibacterial capacity of NaOCl, is unstable and consumed rapidly (probably within the first 2 minutes) during the first phase of tissue dissolution,[290] which provides another reason for continuous replenishment. This should especially be considered because rotary root canal preparation techniques have expedited the shaping process. The optimal time that a hypochlorite irrigant at a given concentration needs to remain in the canal system is an issue yet to be resolved.[504] Hypochlorite should be used throughout the instrumentation, and for 1 to 2 minutes after completing the instrumentation.[177]

Toxicity.

If NaOCl is used without caution, it is very toxic and destructive to intraoral soft tissues, the periradicular vasculature, and cancellous bone where it can elicit severe inflammatory responses and degradation of organic components. Because of its high pH and strong oxidizing capacity, complete lysis of erythrocytes can occur at low concentration.

Even though the incident of NaOCl accident is reported as low, the actual frequency of such accidents is unknown, as many of them may not be reported, while minor extrusion incidents might even remain undetected due to the absence of severe symptoms.

A survey conducted on 314 diplomates of the American Board of Endodontics indicated that only 132 members reported experiencing a NaOCl accident.[228] Significantly more women experienced sodium hypochlorite accidents compared with men. More maxillary teeth than mandibular teeth and more posterior than anterior teeth were involved. A diagnosis of pulp necrosis with radiographic findings of periradicular radiolucency was positively associated with such accidents. Most respondents reported that patient signs and symptoms entirely resolved within a month. The occurrence of an accident, by itself, did not adversely affect the endodontic prognosis of the involved tooth. Anatomic variations may contribute significantly to the

Telegram: @dental_k

www.konkur.in

occurrence of a sodium hypochlorite accident.[228]

It is essential to recognize the symptoms and act accordingly. Accidental extrusion of NaOCl into the tissue results in severe pain, edema of neighboring soft tissues, possible extension of edema over injured half side of face/upper lip, profuse bleeding from root canal, profuse interstitial bleeding with hemorrhage of skin and mucosa (ecchymosis), chlorine taste, and irritation of throat after injection into maxillary sinus; secondary infection or even reversible anesthesia or paresthesia is possible.

NaOCl is cytotoxic and a potent dissolver of organic matter. This is the reason why edema may be perceived as a protective tissue response when a hyperosmotic and cytotoxic liquid is extruded into the vicinity of periradicular tissues. The ecchymosis involves the dissolution of blood vessel walls and hemorrhage around the subcutaneous soft tissues. Also, it is a potent oxidant, and the mechanism of injury from undiluted NaOCl is primarily oxidation of proteins. Depending on the concentration employed for root canal irrigation, NaOCl may also be very hypertonic (2800 mOsm/kg for 3% to 6% solutions) concerning tissue fluids; this partially accounts for the rapid appearance of edema during a NaOCl accident.[510]

If NaOCl is inadvertently extruded through the apex, accidents may occur (Fig. 8.50, *A–C*). For the management of these lesions, it is recommended to inform the patient and to control pain with local anesthesia and analgesics and close follow-up in the hours and days after the accident. To gain rapid pain relief, anesthetic infiltration had been attempted. However, if swelling is present, infiltration anesthesia is contraindicated to avoid spreading of any existing infection; a nerve block should be used instead.[167] Very little information was provided regarding the use of vasoconstrictors and the location of the injection attempted for pain relief. Theoretically, vasoconstrictors might limit the diffusion of NaOCl, but this would likely increase the risk of promoting tissue necrosis, especially with highly concentrated solutions promoting local ischemia.[167]

A) Close-up of an open mouth with a gauge exposes a lesion over lateral set of teeth.

B) Close-up of an open mouth shows a lesion over lateral set of teeth. The lesion exposes underlying teeth anatomy.

Some reports used saline to dilute the NaOCl or even CHX, but the latest should be avoided to prevent the formation of the precipitate (see later).

In general, postextrusion management is ambulatory using only oral medications. However, it was reported that about one third of patients (18/52) were hospitalized for monitoring and intravenous administration of drugs.[227] The application of extraoral cold compresses for reduction of swelling is also useful. After 1 day, warm compresses and frequent warm mouth rinses for stimulation of local systemic circulation should be used. Patients should be recalled daily to monitor recovery. The use of antibiotics is not obligatory and recommended only in cases of high risk or evidence of secondary infection. The administration of antihistamine is also not obligatory, and the use of corticosteroids is controversial. Further endodontic therapy with sterile saline or CHX as root canal irrigants and referral to hospital in case of worsening symptoms were suggested.[227]

Permanent sequelae could be divided into nerve lesions and scar tissues. Neurologic examination of the trigeminal and facial nerves should systematically be performed once anesthesia has dissipated. Tooth loss has not been reported as a direct result of NaOCl extrusion, but it may be involved. The latter is a real trauma for the patient, and it can lead to subsequent refusal to achieve endodontic treatment.[167]

Chlorhexidine

History.

CHX was developed in the United Kingdom and first marketed as an antiseptic cream.[131] It has been used for general disinfection purposes and the treatment of skin, eye, and throat infections in both humans and animals.[131,257] It has been used as an irrigant and medicament in endodontics for more than a decade.[266,286,315]

Molecular structure.

The CHX molecule is a strong base with a pH between 5.5 and 7 that belongs to the polybisguanide group; it consists of two symmetric four-chlorophenyl rings and two bisguanide groups connected by a central hexamethylene chain. CHX digluconate salt is easily soluble in water and very stable (Fig. 8.51).[165]

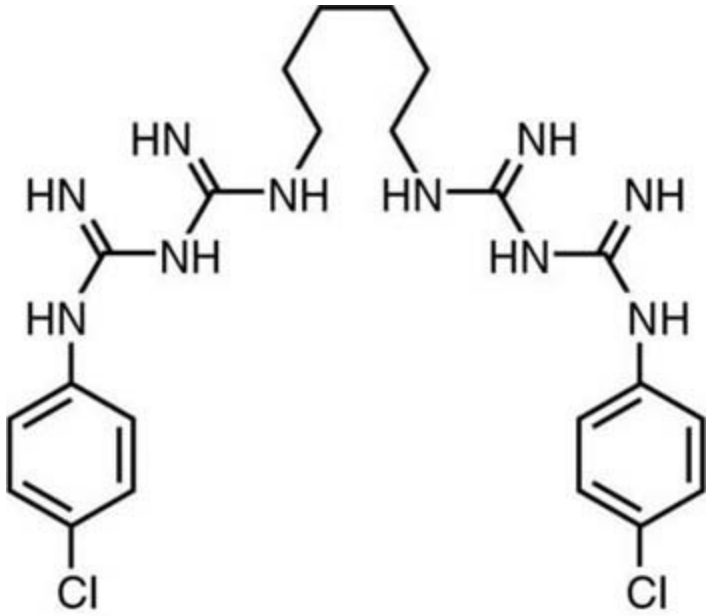

FIG. 8.51 Schematic drawing of the chlorhexidine molecule.

Molecular structure of chlorhexidine is shown.

Mode of action.

CHX, because of its cationic charges, is capable of electrostatically binding

Telegram: @dental_k

www.konkur.in

to the negatively charged surfaces of bacteria,[105] damaging the outer layers of the cell wall and rendering it permeable.[204] CHX is a wide-spectrum antimicrobial agent, active against gram-positive, gram-negative bacteria and yeasts.[115]

Depending on its concentration, CHX can have both bacteriostatic and bactericidal effects. At high concentrations, CHX acts as a detergent, and exerts its bactericidal effect by damaging the cell membrane and causes precipitation of the cytoplasm. At low concentrations, CHX is bacteriostatic, causing low molecular-weight substances (i.e., potassium and phosphorous) to leak out without the cell being permanently damaged.[39]

Substantivity.

Unlike NaOCl, CHX is capable of remaining in the dentin because of the cationic nature of its molecule. Its adsorption to dental hard tissues with gradual and prolonged release at therapeutic levels is usually called the residual effect or substantivity. This effect depends on the concentration of CHX and the contact time with the dentin; moreover, it has been detected in root canal dentin up to 120 days.[427] Komorowski et al.[233] showed that 5-minute application of CHX did not induce substantivity on dentin. Thus a short time inside the root canal can interfere with the adsorption of CHX on dentin.

At low concentrations of 0.005% to 0.01%, only a constant monolayer of CHX is adsorbed on the tooth surface, but at higher concentrations (0.02%) a multilayer of CHX is formed on the surface, providing a reservoir of CHX that can rapidly release the excess into the environment as the concentration of CHX in the surrounding environment decreases.[123] Time and concentration of CHX can influence the antibacterial substantivity, and the conclusions are inconsistent. Some studies demonstrated that 4% CHX has greater antibacterial substantivity than 0.2% after 5 minutes application.[286] Other studies stated that CHX should be left for more than 1 hour in the canal to be adsorbed by the dentin.[1] Komorowski et al.[233] suggested that a 5-minute application of CHX did not induce substantivity, so dentin should be treated with CHX for 7 days. However, when Paquette and Malkhassian[316] in their in vivo study medicated the canals with either liquid or gel forms of CHX for 1 week, neither of them could achieve complete disinfection.

Telegram: @dental_k

www.konkur.in

Therefore, residual antimicrobial efficacy of CHX in vivo remains to be demonstrated.

Cytotoxicity.

In the medical field, CHX is typically used at concentrations between 0.12% and 2.0%. According to Löe,[257] at these concentrations CHX has a low level of tissue toxicity, both locally and systemically. In another report, when 2% CHX was used as a subgingival irrigant, no apparent toxicity was noted on gingival tissues.[258,426] Moreover, CHX rinses have been reported to promote the healing of periodontal wounds.[24] Based on these reports, Jeansonne et al.[215] assumed that the periapical tissues would be as tolerant of CHX as gingival tissues. In two studies when CHX and NaOCl were injected into subcutaneous tissues of guinea pigs and rats, an inflammatory reaction developed; however, the toxic reaction from CHX was less than that of NaOCl.[306] Furthermore, when CHX was applied as a rinse in the extraction sites of third molars on the day of surgery and several days after, it was reported to reduce the incidence of alveolar osteitis.[80] Few reports of allergic and anaphylactic reactions to CHX exist in the literature.[146,305]

Conversely, some studies have reported unfavorable effects of CHX on tissues. Hidalgo and Dominguez[197] demonstrated that CHX is cytotoxic to some lines of cultured human skin fibroblasts. Recently the behavior of osteoblastic human alveolar bone cells in the presence of CHX and povidone-iodine (PI) has been investigated. It has been reported that CHX has a higher cytotoxicity profile than povidone iodine.[78] Faria et al.[132] also demonstrated that CHX injected in the hind paw of mice could induce severe toxic reactions. They reported that CHX induced apoptosis at lower concentrations and necrosis at higher concentrations when added to cultured L929 fibroblast cells.

A byproduct of combining CHX with NaOCl is the formation of toxic products such as parachloroaniline (PCA) that may harm tissues.[42] The toxicity level of CHX on periapical tissues when applied in the root canals, especially with other irrigants, merits further investigation.

Chlorhexidine as an endodontic irrigant.

CHX has been extensively studied as an endodontic irrigant and intracanal

Telegram: @dental_k

www.konkur.in

medication, both in vivo[33,255,268,316,494] and in vitro.[40,41,215,233,248,412,443,472] The antibacterial efficacy of CHX as an irrigant is concentration dependent. It has been demonstrated that 2% CHX has better antibacterial efficacy than 0.12% CHX in vitro.[41] When compared with the effectiveness of NaOCl, controversial results can be found. NaOCl has an obvious advantage over CHX with the dissolution capacity of organic matter that CHX lacks; therefore, even though in vitro studies suggest some advantages with the use of CHX, as soon as organic and dental tissue is added, NaOCl is clearly preferable.

When studied in vivo, investigators[359] reported that 2.5% NaOCl was significantly more effective than 0.2% CHX when the infected root canals were irrigated for 30 minutes with either of the solutions. In a controlled and randomized clinical trial, the efficacy of 2% CHX liquid was tested against saline using culture technique. Their results showed better disinfection of the root canals using CHX compared with saline as a final rinse.[503]

In a recent study, the antibacterial efficacy of 2% CHX gel was tested against 2.5% NaOCl in teeth with apical periodontitis, with the bacterial load assessed using real-time quantitative polymerase chain reaction (RTQ-PCR) and colony forming units (CFU). The bacterial reduction in the NaOCl group was significantly higher than the CHX group when measured by RTQ-PCR. Based on culture technique, bacterial growth was detected in 50% of the CHX-group cases compared with 25% in the NaOCl group.[472] On the other hand, another study based on this culture technique revealed no significant difference between the antibacterial efficacy of 2.5% NaOCl and 0.12% CHX liquid when used as irrigants during the treatment of infected canals.[414]

In a systematic review, Ng and colleagues[301] demonstrated that abstaining from using 2% CHX as an adjunct irrigant to NaOCl was associated with superior periapical healing. In summary, CHX lacks a tissue-dissolving property; therefore, NaOCl is still considered the primary irrigating solution in endodontics.

Interaction between CHX, NaOCL, and EDTA.

NaOCl and CHX when in contact, produce a change of color and a precipitate (Fig. 8.52). The reaction is dependent on the concentration of NaOCl. The higher the concentration of NaOCl, the larger the precipitate is if

Telegram: @dental_k

www.konkur.in

2% CHX is used.[42] Furthermore, concerns have been raised that the color change may have some clinical relevance because of staining, and the resulting precipitate might interfere with the seal of the root obturation. Basrani et al.[42] evaluated the chemical nature of this precipitate and reported the formation of 4-chloroaniline (PCA). Furthermore, a recent study[232] using a specific mass spectrometry analysis (TOFSIMS), demonstrated the penetration of PCA inside dentinal tubules. PCA is toxic in humans with short-term exposure, resulting in cyanosis, which is a manifestation of methemoglobin formation. The combination of NaOCl and CHX causes color changes and formation of a possibly toxic insoluble precipitate that may interfere with the seal of the root obturation. Alternatively, the canal can be dried using paper points before the final CHX rinse.[504]

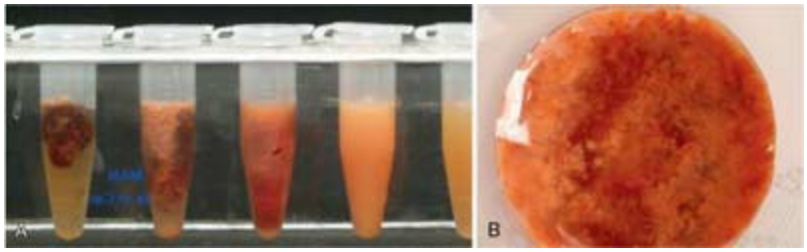

FIG. 8.52 Red precipitate forming after contact between NaOCl and chlorhexidine. **A,** When 2% chlorhexidine (CHX) is mixed with different concentration of NaOCl, a change of color and precipitate occurs. The higher the concentration of NaOCl, the larger is the precipitate formation. **B,** Detail of the interaction between 2% CHX and 5% NaOCl.

A) Five test-tubes with liquids show first test-tube with unmixed red precipitate at the top and yellow at lower, second test-tube with partially mixed red precipitate at the top and yellow at lower, third test-tube with almost mixed red and yellow precipitates, fourth test-tube with reddish yellow mixture and fifth test-tube with almost yellow mixture.

B) Close-up of an laterally filled test-tube with reddish yellow pigmented liquid.

The combination of CHX and EDTA produces a white precipitate, so a group of investigators[351] did a study to determine whether the precipitate involves the chemical degradation of CHX. The precipitate was produced and re-dissolved in a known amount of dilute trifluoroacetic acid. Based on the results, CHX was found to form a salt with EDTA rather than undergoing a

Telegram: @dental_k

www.konkur.in

chemical reaction.

Allergic reactions to chlorhexidine.

Allergic responses to CHX are rare and there are no reports of reactions following root canal irrigation with CHX.[209] The sensitization rate has been reported in several studies to be approximately 2%.[236] However, some allergic reactions such as anaphylaxis, contact dermatitis, and urticaria have been reported following direct contact to mucosal tissue or open wounds.[342,391,472] Patients with history of atypical reaction to any irrigant should undergo a basic immunologic evaluation before CHX or NaOCl are used. If any of these tests is positive, alternative substance should be use.[104]

Decalcifying agents.

Debris is defined as dentin chips or residual vital or necrotic pulp tissue attached to the root canal wall. Smear layer was defined by the American Association of Endodontists in 2003 as a surface film of debris retained on dentin or other surfaces after instrumentation with either rotary instruments or endodontic files; it consists of dentin particles, remnants of the vital or necrotic pulp tissue, bacterial components, and retained irrigants. While it has been viewed as an impediment to irrigant penetration into dentinal tubules (Fig. 8.53), there is still a controversy about the influence of smear layer on the outcome of endodontic treatment. Some researchers emphasize the importance of removing the smear layer to allow irrigants, medications, and sealers to penetrate dentinal tubules and improve disinfection. On the other hand, other researchers focused on keeping the smear layer as protection for bacterial invasion, apical and coronal microleakage, bacterial penetration of the tubules, and the adaptation of root canal materials. The majority of the conclusions on the smear layer are based on in vitro studies. A recent clinical study by Ng et al.[301] found that the use of EDTA significantly increased the odds of success of retreatment.

hole with an outline of blue on greenish white surface.

Middle one-third: 17 percent EDTA: A horizontal section of middle one third shows a hole with rings of blue, green and white colors with outlines of green and blue.

Apical one-third: Water: A horizontal section of apical one third shows a hole with an outline of blue on greenish white surface.

Apical one-third: 17 percent EDTA: A horizontal section of apical one third shows a hole with sectorial outlines of green and white and outlines of white, blue and green.

Ethylenediaminetetraacetic acid

Ethylenediaminetetraacetic acid, widely abbreviated as EDTA, is a polycarboxylic amino acid, and a colorless, water-soluble solid EDTA is often suggested as an irrigation solution because it can chelate and remove the mineralized portion of the smear layer (Fig. 8.54). It is a polyaminocarboxylic acid with the formula $[CH_2N(CH_2CO_2H)_2]_2$. Its prominence as a chelating agent arises from its ability to sequester di- and tricationic metal ions such as Ca^{2+} and Fe^{3+}. After being bound by EDTA, metal ions remain in solution but exhibit diminished reactivity.[433]

A) Micrograph of middle third with densely granuled smear layer.

B) Micrograph of apical third with granuled smear layer and large irregular debris on the surface.

History.

The compound was first described in 1935 by Ferdinand Munz, who prepared it from ethylenediamine and chloroacetic acid. Chelating agents were introduced into endodontics as an aid for the preparation of narrow and calcified root canals in 1957 by Nygaard-Østby.[206] Today, EDTA is mainly synthesized from ethylenediamine (1,2-diaminoethane), formaldehyde (methanal), and sodium cyanide.[206]

Mode of action.

On direct exposure for an extended time, EDTA extracts bacterial surface

Telegram: @dental_k

www.konkur.in

proteins by combining with metal ions from the cell envelope, which can eventually lead to bacterial death.[206] Chelators such as EDTA form a stable complex with calcium. When all available ions have been bound, equilibrium is formed and no further dissolution takes place; therefore, EDTA is self-limiting.[206]

Applications in endodontics.

EDTA alone usually cannot remove the smear layer effectively; a proteolytic component, such as NaOCl, must be added to remove the organic components of the smear layer.[158] For root canal preparation, EDTA has limited value alone as an irrigation fluid.[158] EDTA is generally used in a concentration of 17% and can remove the smear layers when in direct contact with the root canal wall for less than 1 minute. Even though EDTA has self-limited action, if it is left in the canal for longer or NaOCl is used after EDTA, erosion of dentin has been demonstrated (Fig. 8.55).

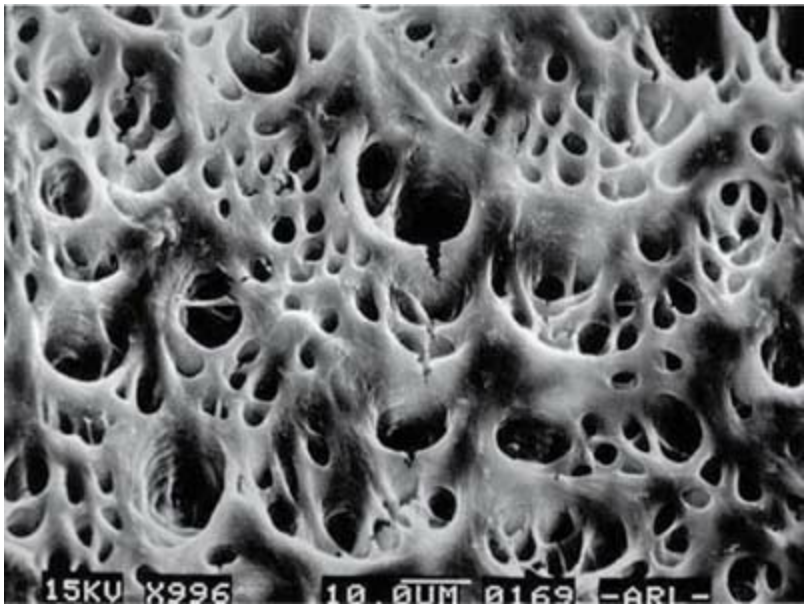

FIG. 8.55 Scanning electron microscope (SEM) image of root canal dentin exposed to 2 minutes of EDTA.

Micrograph of dentin shows thin walls with porous surface.

Although citric acid appears to be slightly more potent at similar concentration than EDTA, both agents show high efficiency in removing the

Telegram: @dental_k

www.konkur.in

smear layer. In addition to their cleaning ability, chelators may detach biofilms adhering to root canal walls.[168] This may explain why an EDTA irrigant proved to be highly superior to saline in reducing intracanal microbiota, even though its antiseptic capacity is relatively limited.[168] Antiseptics such as quaternary ammonium compounds (EDTAC) or tetracycline antibiotics (MTAD; see irrigants combination later) have been added to EDTA and citric acid irrigants, respectively, to increase their antimicrobial capacity. The clinical value of this, however, is questionable. EDTAC shows similar smear-removing efficacy as EDTA, but it is more caustic.

The effect of chelators in negotiating narrow, tortuous, calcified canals to establish patency depends on both canal width and the amount of active substance available since the demineralization process continues until all chelators have formed complexes with calcium.[206,506] Therefore, studies should be read with caution because one study showed demineralization up to a depth of 50 μm into dentin,[210] but other reports demonstrated significant erosion after irrigation with EDTA.[44]

A comparison of bacterial growth inhibition showed that the antibacterial effects of EDTA were stronger than citric acid and 0.5% NaOCl but weaker than 2.5% NaOCl and 0.2% CHX.[410] EDTA had a significantly better antimicrobial effect than saline solution. It exerts its strongest effect when used synergistically with NaOCl, although no disinfecting effect on colonized dentin could be demonstrated.[192]

Interaction of EDTA and NaOCL.

Investigators[164] studied the interactions of EDTA with NaOCl. They concluded that EDTA retained its calcium-complex ability when mixed with NaOCl, but EDTA caused NaOCl to lose its tissue-dissolving capacity, with virtually no free chlorine detected in the combinations. Clinically, this suggests that EDTA and NaOCl should be used separately. In an alternating irrigating regimen, copious amounts of NaOCl should be administered to wash out remnants of the EDTA. In modern endodontics, EDTA is used once the cleaning and shaping are completed for around 1 minute. It can be activated with ultrasonic activation for better penetration in dentinal tubules. It should be taken into consideration that raising the temperature of EDTA is

Telegram: @dental_k

www.konkur.in

not desirable, as chelators have a temperature range that they work their best. When EDTA is heated from 20 to 90 degrees, the calcium binding capacity decreases.[505]

HBPT and other phosphate bases tensides

HEBP (1-hydroxyethylidene-1, 1-bisphosphonate; also called etidronic acid) is a weak chelator.[504] It is a potential alternative to EDTA because it has no short-term reactivity with NaOCl. It can be used in combination with NaOCl without affecting its proteolytic or antimicrobial properties.[504] It is nontoxic[26,111] and it is used in medicine to treat bone diseases.[314]

Combination irrigants.

Irrigants with low surface tension are assumed to penetrate better in dentinal tubules and anatomic irregularities. Detergents (e.g., Tween 80) are added to irrigants to lower their surface tension. However, Boutsioukis and Kishen[58] did not find support for this rationale, perhaps because the effect of surface tension is important only at the interface between two immiscible fluids (e.g., between irrigant and an air bubble, but not between irrigant and dentinal fluid). Recent studies have also confirmed that surfactants do not enhance the ability of NaOCl to dissolve pulp tissue[221] or the efficacy of common chelators to remove calcium or smear layer.[58,111,506]

BioPure MTAD and Tetraclean.

Two other irrigants, based on a mixture of antibiotics, citric acid, and a detergent, are commercially available. They are capable of removing both the smear layer and organic tissue from the infected the root canal system.[454] MTAD (Fig. 8.56), introduced by Torabinejad and Johnson[455] at Loma Linda University in 2003, is an aqueous solution of 3% doxycycline, a broad-spectrum antibiotic; 4.25% citric acid, a demineralizing agent; and 0.5% polysorbate 80 detergent (Tween 80).[455] It is mixed from a liquid and powder before use. MTAD has been recommended in clinical practice as a final rinse after completion of conventional chemomechanical preparation.[44]

Source: (Courtesy Dentsply Tulsa Dental Specialties, Tulsa, OK, USA.)

Tetraclean (Ogna Laboratori Farmaceutici, Muggio, Italy) is a combination product similar to MTAD. The two irrigants differ in the concentration of antibiotics (doxycycline 150 mg/5 mL for MTAD and 50 mg/5 mL for Tetraclean) and the kind of detergent (Tween 80 for MTAD, polypropylene glycol for Tetraclean).

Telegram: @dental_k

www.konkur.in

Mode of action.

All of the tetracyclines are derivatives of the four-ringed nucleus that differ structurally regarding the chemical groups at 2, 5, 6, 7 positions. These derivatives exhibit different characteristics, such as absorption, protein binding, metabolism, excretion, and degree of activity against the susceptible organism.[191] Tetracyclines inhibit protein synthesis by reversibly binding to the 30S subunit of bacterial ribosome in susceptible bacteria. It is effective against *Aggregatibacter actinomycetemcomitans* (A.a), *Porphyromonas gingivalis*, and *Prevotella intermedia* and affects both gram-positive and gram-negative bacteria, with a more pronounced gram-negative effect. Tetracycline is a bacteriostatic antibiotic, but in high concentrations tetracycline may also be bactericidal. Doxycycline, citric acid, and Tween 80 together may have a synergistic effect on the disruption of the bacterial cell wall and the cytoplasmic membrane.

Smear layer removal.

In two studies, the efficacy of MTAD or EDTA in the removal of the smear layer was confirmed, but no significant difference between these two solutions was reported.[444,445]

Antibacterial efficacy.

Earlier independent in vitro research on MTAD showed its antimicrobial efficacy over conventional irrigants.[106,235] Torabinejad et al.[455] found that MTAD was effective in killing *E. faecalis* up to a 200× dilution. Shabahang and Torabinejad[396] showed that the combination of 1.3% NaOCl as a root canal irrigant and MTAD as a final rinse was significantly more effective against *E. faecalis* than the other regimens.[397] A study using extracted human teeth contaminated with saliva showed that MTAD was more effective than 5.25% NaOCl in disinfection of the teeth. In contrast to the previously mentioned studies, later research suggested less than the optimal antimicrobial activity of MTAD.[152,219,225] Krause et al.,[235] using bovine tooth sections, showed that 5.25% NaOCl was more effective than MTAD in disinfection of dentin discs inoculated with *E. faecalis*.[396,411]

Telegram: @dental_k

www.konkur.in

Clinical trials.

Malkhassian et al.[267] in a controlled clinical trial of 30 patients reported that the final rinse with MTAD did not reduce the bacterial counts in infected canals beyond levels achieved by chemomechanical preparation using NaOCl alone.

Protocol for use.

MTAD was developed as a final rinse to disinfect the root canal system and remove the smear layer. The effectiveness of MTAD to altogether remove the smear layer is enhanced when a low concentration of NaOCl (1.3%) is used as an intracanal irrigant before placing 1 mL of MTAD in a canal for 5 minutes and rinsing it with an additional 4 mL of MTAD as the final rinse.[396]

Combinations of irrigants

QMiX was introduced in 2011 as a combination product introduced for root canal irrigation (Fig. 8.57). It is recommended to be used at the end of instrumentation, after NaOCl irrigation. According to the patent,[175] QMix contains a CHX-analog, Triclosan (N-cetyl-N,N, N-trimethylammonium bromide), and EDTA as a decalcifying agent; it is intended as an antimicrobial irrigant as well as the removal of canal wall smear layers and debris.

FIG. 8.57 QMiX 2in1. Combination of CXH, EDTA, and detergent. QMix irrigating solution is a single solution used as a final rinse after bleach for one-step smear layer removal and disinfection

Telegram: @dental_k

www.konkur.in

Source: (Courtesy Dentsply Tulsa Dental Specialties, Tulsa, OK, USA).

Protocol.

QMiX is suggested as a final rinse. If sodium hypochlorite was used throughout the cleaning and shaping, saline could rinse out NaOCl remnants to prevent the formation of any precipitate.

Smear layer removal.

Stojic et al.[438] investigated the effectiveness of smear layer removal by QMiX using scanning electron microscopy. QMiX removed smear layer equally well as EDTA. Dai et al.[102] examined the ability of two pH versions of QMiX on the removal of canal wall smear layers and debris using an open canal design. Within the limitations of an open canal design, the two experimental QMiX versions are as useful as 17% EDTA in removing canal wall smear layers after the use of 5.25% NaOCl as the initial rinse.

Antibacterial efficacy and effect on biofilms.

Stojic et al.[438] also assessed the in vitro efficacy of QMiX against *E. faecalis* and mixed plaque bacteria, both in the planktonic phase and biofilms. QMiX and 1% NaOCl killed all planktonic *E. faecalis* and plaque bacteria in 5 seconds. QMiX and 2% NaOCl killed up to 12 times more biofilm bacteria than 1% NaOCl ($P < .01$) or 2% CHX ($P < .05$; $P < .001$). Wang et al.[480] compared the antibacterial effects of different disinfecting solutions on young and old *E. faecalis* biofilms in dentin canals using a novel dentin infection model and confocal laser scanning microscopy. Six percent NaOCl and QMiX were the most effective disinfecting solutions against the young biofilm, whereas, against the 3-week-old biofilm, 6% NaOCl was the most effective, followed by QMiX. Both were more effective than 2% NaOCl and 2% CHX. Morgental et al.[291] showed that QMiX was less effective than 6% NaOCl and similar to 1% NaOCl in bactericidal action. According to their in vitro study, it appears that the presence of dentin slurry has the potential to

Telegram: @dental_k

www.konkur.in

inhibit most current antimicrobials in the root canals system.

Moreover, Ordinola et al.[307] found that several endodontic irrigants containing antimicrobial compounds such as chlorhexidine (QMiX), cetrimide, maleic acid, iodine compounds, or antibiotics (MTAD) lacked an effective antibiofilm activity when the dentin was infected intraorally. The irrigant solutions 4% peracetic acid and 2.5% to 5.25% sodium hypochlorite decreased the number of live bacteria significantly in biofilms, providing also cleaner dentin surfaces ($P < .05$). They concluded that several chelating agents containing antimicrobials could not remove nor kill significantly biofilms developed on intraorally infected dentin, except for sodium hypochlorite and 4% peracetic acid. Dissolution ability is mandatory for an appropriate eradication of biofilms attached to dentin.

Clinical trials.

The efficacy and biocompatibility of QMiX were as yet only demonstrated via nonclinical in vitro and ex vivo studies. Further clinical research from independent investigators is needed to corroborate the findings.

Iodine potassium iodide.

IKI is a root canal disinfectant that is used in concentrations ranging from 2% to 5%. IKI kills a broad spectrum of microorganisms found in root canals but shows relatively low toxicity in experiments using tissue cultures.[430] Iodine acts as an oxidizing agent by reacting with free sulfhydryl groups of bacterial enzymes, cleaving disulphide bonds. *E. faecalis* often is associated with therapy-resistant periapical infections (see Chapter 16), and combinations of IKI and CHX may be able to kill $Ca(OH)_2$-resistant bacteria more efficiently. One study[416] evaluated the antibacterial activity of a combination of $Ca(OH)_2$ with IKI or CHX in infected bovine dentin blocks. Although $Ca(OH)_2$ alone was unable to destroy *E. faecalis* inside dentinal tubules, $Ca(OH)_2$ mixed with either IKI or CHX effectively disinfected dentin. Others[31] demonstrated that IKI was able to eliminate *E. faecalis* from bovine root dentin when used with 15-minute contact time. A distinct disadvantage of iodine is a possible allergic reaction in some patients. Although iodine is not generally considered an allergen, some patients are hypersensitive to this compound

Telegram: @dental_k

www.konkur.in

and may be considered to have an iodine “allergy.”

Intracanal medication

Intracanal medication is used when treatment cannot be completed in one appointment (see Chapters 5 and 15). The surviving intracanal bacteria after cleaning and shaping may increase between appointments.[76,477] The main objectives for the intracanal medication are restrict bacterial regrowth, supply continued disinfection, and create a physical barrier.

Calcium hydroxide

Calcium hydroxide is the most popular intracanal medication use. It was introduced by Hermann[194] in 1920. Although its use was well documented for its time, evidence of its efficacy in clinical endodontics is controversial. A series of articles[76,77] promoted the antibacterial efficacy of $Ca(OH)_2$ in human root canals. Subsequent studies substantiated these reports,[308,420] and the routine use of $Ca(OH)_2$ as an interappointment intracanal medicament became widespread.[373]

However, newer clinical studies and systematic reviews failed to show a clear benefit of $Ca(OH)_2$ to further eliminate bacteria from the root canal.[325,373] $Ca(OH)_2$ mostly is used as a slurry of $Ca(OH)_2$ in a water base; at body temperature, less than 0.2% of the $Ca(OH)_2$ is dissolved into Ca++ and OH ions. Because $Ca(OH)_2$ needs water to dissolve, water should be used as the vehicle for the $Ca(OH)_2$ paste. In contact with air, $Ca(OH)_2$ forms calcium carbonate ($CaCO_3$). However, this is a lengthy process and of little clinical significance. $Ca(OH)_2$ paste, with a significant amount of calcium carbonate, feels granular because the carbonate has a very low solubility.[367,420]

$Ca(OH)_2$ is a slow-acting antiseptic; direct-contact experiments in vitro show that a 24-hour contact period is required for complete killing of enterococci.[367,420] Another study of 42 patients found that NaOCl canal irrigation reduced the bacteria level by only 61.9%, but use of $Ca(OH)_2$ in the canals for 1 week resulted in a 92.5% reduction.[403] These researchers

Telegram: @dental_k

www.konkur.in

concluded that $Ca(OH)_2$ should be used in infected cases to more predictably obtain débridement and decontamination.

In addition to killing bacteria, $Ca(OH)_2$ has the useful ability to hydrolyze the lipid moiety of bacterial lipopolysaccharides (LPS), thereby inactivating the biologic activity of the lipopolysaccharide and reducing its effect.[368] This is a desirable effect because dead cell wall material remains after the bacteria have been killed and can continue to stimulate inflammatory responses in the periradicular tissue.

The main characteristics of $Ca(OH)_2$ include limited solubility, high pH, broad-spectrum antimicrobial agent, and antimicrobial action sustained for long periods.

Other uses of $Ca(OH)_2$.

Long-term calcium hydroxide treatment can be used to induce apexification of the immature tooth with pulpal necrosis before placing an obturation material such as gutta-percha in the root canal system.[137] Also, in cases where revascularization/guided pulpal repair is desired, $Ca(OH)_2$ may be used instead of antibiotic pastes (for more details, see later and Chapter 12).

Clinical protocol.

Calcium hydroxide should be in contact with the tissue to act. $Ca(OH)_2$ powder may be mixed with sterile water or saline and placed into the canal using a lentulo paste filler.[324] Alternatively, the mix may be applied from sterile, single-dose packages (e.g., Calasept [J.S. Dental, Ridgefield, CT, USA]; Calcijet [Centrix, Shelton, CT, USA]; and DT Temporary Dressing [Global Dental Products, North Bellmore, NY, USA]; Fig. 8.58). The mixture should be thick to carry as many $Ca(OH)_2$ particles as possible; however, it should not be overdried to retain enough moisture and to promote continued dissociation with a resulting high pH. For maximum effectiveness, the root canal should be filled homogeneously to the WL with a slurry, and a radiograph should be taken to confirm this.

Source: (*A,* Courtesy Dr. S. Friedman. *B,* Courtesy Centrix, Shelton, CT, USA.)

Accidents with $Ca(OH)_2$ placement have been reported and the dentist should be aware of them, and because it is a strong base that may cause irreversible injury to vital tissue that comes into contact with this substance, specifically nerve damage may occur. Therefore, care must be taken not to extrude $Ca(OH)_2$ through the apex, as this carries the risk of reaching the maxillary sinus or the mandibular canal. Calcium hydroxide can also cause blindness when it comes into contact with the eye. Clinicians should take adequate precautions to prevent this serious complication.[256]

Limitations of calcium hydroxide.

There are some concerns regarding the use of $Ca(OH)_2$. The handling and proper placement of $Ca(OH)_2$ present a challenge to the average clinician.[417] Moreover, the removal of $Ca(OH)_2$ is frequently incomplete, resulting in a residue covering 20% to 45% of the canal wall surfaces, even after copious irrigation with saline, NaOCl, or EDTA.[242] Residual $Ca(OH)_2$ can shorten the setting time of zinc oxide eugenol–based endodontic sealers.[271] Notably, it may interfere with the seal of the root filling and compromise the quality of

Telegram: @dental_k

www.konkur.in

treatment. An additional concern is that $Ca(OH)_2$ is not effective against several endodontic pathogens, including *E. faecalis* and *C. albicans*.[478] In fact, in vitro studies have shown that dentin can inactivate the antibacterial activity of $Ca(OH)_2$,[174,347] and one clinical study[325] demonstrated that the number of bacteria-positive canals increased after $Ca(OH)_2$ medication. Other studies have further indicated that $Ca(OH)_2$ could not predictably eliminate bacteria or that cultures changed from negative to positive after $Ca(OH)_2$ placement.[325,477]

When different studies report inconsistent results, a systematic review and meta-analysis technique can clarify conflicting research data and the current state of knowledge regarding specific issues. Therefore, based on the current best available evidence, $Ca(OH)_2$ has limited effectiveness in eliminating bacteria from human root canals when assessed by culture techniques. The quest for better antibacterial protocols and sampling techniques must continue to ensure that bacteria can be reliably eradicated before obturation.

Chlorhexidine

In vitro, CHX used as intracanal medicament has at least as good or even better antimicrobial efficacy than $Ca(OH)_2$.[411] Notably, 2% CHX was very effective in eliminating a biofilm of *E. faecalis*.[253] In vivo, it inhibits experimentally induced inflammatory external root resorption when applied for 4 weeks.[255] In infected root canals, it reduces bacteria as effectively as $Ca(OH)_2$ when applied for 1 week.[33] Unlike $Ca(OH)_2$, CHX has a substantive antimicrobial activity that, if imparted onto the root dentin, has the potential to prevent bacterial colonization of root canal walls for prolonged periods.[215,233] This effect depends on the concentration of CHX, but not on its mode of application, which may be as a liquid, gel, or controlled-release device.[40]

CHX as intracanal medication has been the focus of many in vitro[36,114,233,247,411] and in vivo studies.[33,255,268,316,509] The results of in vitro experiments were mostly in favor of CHX regardless of its mode of application. In vivo, variable results were reported; one of the reasons for this is that researchers[174] developed an experimental model using dentin powder

Telegram: @dental_k

www.konkur.in

particles to investigate the possible inactivation of some antibacterial medicaments when they come in contact with dentin. They showed that dentin powder had inhibitory effects on all medicaments tested. The effect was dependent on the concentration of the medicament and the duration of contact. The effect of $Ca(OH)_2$ was abolished by the presence of dentin powder. The effect of 0.05% CHX and 1% NaOCl was reduced but not eliminated by the presence of dentin.

In vitro and animal studies suggest that CHX has the potential to replace $Ca(OH)_2$ as an intracanal medicament, but the listed limitations of the in vitro experiments make the conclusions obtained challenging to extrapolate to actual clinical situations. In vivo, human studies are therefore required to test the efficacy of CHX as an intracanal medication.

Compared with the number of in vitro studies, very few clinical studies have been conducted to assess the effectiveness of CHX as an intracanal medication. An in vivo investigation[33] assessed the antibacterial efficacy of three different intracanal medications: camphorated paramonochlorophenol, $Ca(OH)_2$, and 0.12% CHX liquid by applying them for 1 week in single-rooted teeth of patients. Using a culture method, it was reported that the proportions of positive cultures were not significantly different among the tested medications, but they were slightly lower in teeth medicated with CHX (0.12%) liquid than those medicated with camphorated paramonochlorophenol or $Ca(OH)_2$.[33]

Another in vivo study evaluated the antibacterial effectiveness of 2% CHX liquid as an intracanal medication in teeth with apical periodontitis.[316] The results showed a moderate increase in bacterial counts during a medication period of 7 to 14 days that was similar to outcomes seen and reported for $Ca(OH)_2$ by Peters et al.[325] It was speculated that the CHX liquid may have partially escaped from the apical foramen and that the higher-viscosity gel form might have been better suited as an intracanal medication.[316]

However, a different study[268] demonstrated that intracanal medication with $Ca(OH)_2$, 2% CHX gel, or a mixture of $Ca(OH)_2$/CHX applied for 7 days did not reduce the bacterial concentration beyond what was achieved after chemomechanical preparation using 1% NaOCl. The results were not significantly different among the medication groups. Similar results were

Telegram: @dental_k

www.konkur.in

found by other investigators,[267] when after a randomized controlled trial of 30 patients, they concluded that a final rinse with MTAD (a *m*ixture of *t*etracycline, *a*cid, and *d*etergent) and intracanal application of 2% CHX gel did not reduce bacterial counts beyond levels achieved by chemomechanical preparation using NaOCl.

Chlorhexidine mixed with calcium hydroxide.

During the last few years, researchers have studied the combination of $Ca(OH)_2$ and CHX, with the concept that their antimicrobial properties interact in a synergistic fashion that enhances their efficacy. The high pH of $Ca(OH)_2$ was unaffected when combined with CHX.[42] However, the results have not been conclusive. Some in vitro studies had reported an improved antibacterial action when both agents were combined,[41,128,504] while other studies reported contradictory results.[181]

Recent animal studies have evaluated the tissue reactions to the mix of $Ca(OH)_2$/CHX, showing that the combination exerts excellent antimicrobial properties[421] and improves healing of the periapical tissues. In vivo studies have shown that the mix is at least as good as both agents applied separately in necrotic teeth with apical periodontitis,[268] as well as in previously treated cases with persistent apical periodontitis. A more recent study utilizing a CHX-based protocol of 0.12% CHX as an irrigant followed by a 7-day intracanal medication of $Ca(OH)_2$/0.12% CHX has shown promising results. The authors concluded that chemomechanical canal shaping using 0.12% CHX solution as an irrigant significantly reduced the number of intracanal bacteria, but it failed to render the canals bacteria free. Further intracanal medication with a $Ca(OH)_2$/CHX paste significantly improved the results by reducing the number of bacteria.[408] Therefore, it seems that the usefulness of mixing $Ca(OH)_2$ with CHX remains controversial.

Phenolic preparations

Phenol (C_6H_5OH) and phenolic preparation used to be very commonly used intracanal medicament in endodontics. It was thought that because of their volatile properties, it could penetrate dentinal tubules and anatomical irregularities. However, it was later demonstrated that these compounds have

Telegram: @dental_k

www.konkur.in

a short life and their volatility can diffuse through the temporary fillings and also through the periapical tissue causing toxicity. Despite the severe toxicity of phenolic preparations, derivatives of phenol, such as paramonochlorophenol (C_6H_4OHCl), thymol ($C_6H_3OHCH_3C_3H_7$), and cresol ($C_6H_4OHCH_3$), remain available. Currently, $Ca(OH)_2$ or no medication is preferred.[147] Phenol is a nonspecific protoplasm poison that has an optimal antibacterial effect at 1% to 2%. Many dental preparations use much too high a concentration of phenol (e.g., in the range of 30%).[147] At such a concentration, the antimicrobial effect in vivo is lower than optimal and of short duration.[279] Derivatives of phenol are stronger antiseptics and more toxic than phenol. Phenolic compounds are available as camphorated solutions.[430] Camphoration results in a less toxic phenolic compound because it slows the release of toxins to the surrounding tissues. Studies in vitro have shown that phenol and phenol derivatives are highly toxic to mammalian cells, and their antimicrobial effectiveness does not sufficiently balance their toxicity.[430] Phenols are ineffective antiseptics under clinical conditions.[76]

Formaldehyde

Formaldehyde, used as formocresol, is highly toxic, mutagenic, and carcinogenic; however, historically it has been used extensively in endodontic therapy.[249] These formulations are still being recommended in pediatric dentistry when treating deciduous teeth. The formaldehyde component of formocresol may vary substantially between 19% and 37%. Tricresol formalin, another formaldehyde preparation, contains 10% tricresol and 90% formaldehyde.[249] All of these preparations have formaldehyde content well above the 10% generally used for fixation of pathologic specimens. Formaldehyde is volatile and releases antimicrobial vapors when applied to a cotton pellet for pulp chamber disinfection. All formaldehyde preparations are potent toxins with antimicrobial effectiveness much lower than their toxicity.[431,432] There is no clinical reason to use formocresol as an antimicrobial agent for endodontic treatment, based on what is known at this time. The alternatives are better antiseptics with significantly lower toxicity.[431,432]

Halogens

Telegram: @dental_k

www.konkur.in

Chlorinated solutions have been used for many years to irrigate root canals. They are also used as intracanal dressings in the form of chloramine-T, an N-chloro-tosylamide sodium salt. Iodine, in the form of IKI, is a very effective antiseptic solution with low tissue toxicity. IKI is an effective disinfectant for infected dentin and can kill bacteria in infected dentin in 5 minutes in vitro.[367] IKI releases vapors with a durable antimicrobial effect. The solution can be prepared by mixing 2 g of iodine in 4 g of potassium iodide; this mixture then is dissolved in 94 mL of distilled water. Tincture of iodine (5%) has proved to be one of the few reliable agents for disinfection of rubber dam and tooth surfaces during the preparation of an aseptic endodontic work-field.[288]

Steroids

Steroids have been used locally, within the root canal system to reduce pain and inflammation. Ledermix (Lederle Pharmaceuticals, Wolfratshausen, Germany) is a commercially available product that was developed about 1960 by Prof. André Schroeder.[390] The active ingredients are the potent anti-inflammatory corticoid triamcinolone acetonide in combination with the broad-spectrum antibiotic demeclocycline. It is an intracanal medicament paste popularly used in some countries. Ledermix paste has been advocated as an initial dressing, mainly if the patient presents with endodontic symptoms.[390] Ledermix paste contains triamcinolone acetonide as an anti-inflammatory agent, at a concentration of 1%.[229] The clinical effect is a rapid relief of pain associated with acute inflammatory conditions of the pulp and periodontium.

Ledermix paste is a nonsetting, water-soluble paste material for use as root canal medicament or as a direct or indirect pulp-capping agent. The mechanisms of action of this substance are based on inhibition of the ribosomal protein synthesis in the bacteria. The release and dentin diffusion characteristics of triamcinolone from Ledermix paste, when used as a root canal medicament, have been investigated under different conditions.[5,6] Collectively, these studies show that triamcinolone is released from Ledermix paste in the root canal and can reach the systemic circulation via diffusion through dentinal tubules, lateral canals, and the apical foramen. Also, because of its root resorption inhibition property, it was tested for replanted teeth in

Telegram: @dental_k

www.konkur.in

dogs. The results showed that the groups treated with Ledermix, triamcinolone, and demeclocycline had significantly more favorable healing and more remaining root structure than the group filled with gutta-percha and sealer (positive control).[85] The use of the steroid triamcinolone in combination with a zinc oxide eugenol paste has recently been popularized with the introduction of Odontopaste (Australian Dental Manufacturing, Brisbane, Australia); however, data regarding the clinical efficacy of this product are limited.

Triple-antibiotic paste

Antibiotic combinations have been studied over the past few years as a regimen during regenerative endodontic strategies. The literature is inconsistent on the effectiveness of double and triple antibiotic pastes (DAP and TAP), respectively, against mono- and multispecies biofilms. The triple-antibiotic regimen, composed of metronidazole, ciprofloxacin, and minocycline, was first tested[374] for its effectiveness against *Escherichia coli*–infected dentin in vitro. The same research group also tested its bactericidal efficacy against microbes from carious dentin and infected pulp. They found that the mixture of antibiotics is sufficiently potent to eradicate the bacteria.[448] The clinical effectiveness of the triple-antibiotic paste in the disinfection of immature teeth with apical periodontitis has been reported.[488] One potential concern of using an intracanal antibiotic paste is that it may cause bacterial resistance. In addition, intracanal use of minocycline can cause tooth discoloration, creating potential cosmetic complications. For this reason, a dual paste (metronidazole, ciprofloxacin) and, alternatively, abandonment of this protocol in favor of $Ca(OH)_2$ have been considered.[245] Another reason for such a change could be the reported high toxicity to stem cells of paste prepared from antibiotic powder,[364] and possible allergic reactions in patients, remain important concerns with this category of medicaments. With the current available evidence, it remains unclear if intracanal medicaments are effective against multispecies biofilms.[299]

Lubricants

In root canal treatment, lubricants are mostly used to emulsify and keep in suspension debris produced by mechanical instrumentation. Although

Telegram: @dental_k

www.konkur.in

irrigation solutions serve as lubricants for hand instrumentation, particular gel-type substances are also marketed. Two of these are wax-based RC-Prep, which contains EDTA and urea peroxide, and glycol-based Glyde. Another purported function of lubricants is to facilitate the mechanical action of endodontic hand or rotary files. A study evaluating the effects of lubrication on cutting efficiency found that tap water and 2.5% NaOCl solutions increased cutting efficiency compared with dry conditions.[501] The authors of this study cited the ability of an irrigant to remove debris as the factor for the increased efficiency. Similarly, a reduction of torque scores was found when canals in normed dentin disks were prepared with ProFile and ProTaper instruments under irrigation, but the use of a gel-type lubricant did not, resulting in similar torques as in dry, nonlubricated canals.[55,330]

In summary, irrigation is an essential step in root canal treatment to ensure disinfection. NaOCl is the irrigant of choice because of its tissue-dissolving and disinfecting properties. EDTA or other chelators should be used at the end of a procedure to remove the smear layer, followed by a final flush with NaOCl for 1 minute for maximum cleaning efficiency and to minimize dentin erosion. This strategy also minimizes the inactivation of NaOCl by chemical interactions.

Disinfection devices and techniques

Syringe delivery

Application of an irrigant into a canal using a syringe and needle allows exact placement, replenishing of existing fluid, rinsing out of larger debris particles, as well as allowing direct contact to microorganisms in areas close to the needle tip. In passive syringe irrigation, the actual exchange of irrigant is restricted to 1 to 1.5 mm apical to the needle tip, with fluid dynamics taking place near the needle outlet.[59,504] Volume and speed of fluid flow are proportional to the cleansing efficiency inside a root canal.[59] Therefore, both the diameter and position of the needle outlet determine successful chemomechanical débridement; placement close to WL is required to guarantee fluid exchange at the apical portion of the canal, but close control of insertion depth is required to avoid extrusion.[59,201] Therefore, the choice of an appropriate irrigating needle is important. Although larger-gauge needles

Telegram: @dental_k

www.konkur.in

allow a quicker and larger amount of fluid exchange, the wider diameter does not allow cleaning of the apical and narrower areas of the root canal system (see the discussion of irrigation dynamics earlier in this chapter; see also Fig. 8.7). Excess pressure or binding of needles into canals during irrigation with no possibility of backflow of the irrigant should be avoided under all circumstances[205] to prevent extrusion into periapical spaces. In immature teeth with wide, apical foramina or when the apical constriction no longer exists, special care must be taken to prevent irrigation extrusion and potential accidents.[100]

There are different sizes and types of irrigation needles. The size of the irrigation needle[91] should be chosen depending on the canal size and taper.[79,281] Most root canals that have not been instrumented are too narrow to be reached effectively by disinfectants, even when appropriate irrigation needles are used (see Figs. 8.7 and 8.45). Therefore, effective cleaning of the root canal must include intermittent agitation of the canal content with a small endodontic instrument[276,466] to prevent debris from accumulating in general (see Fig. 8.43) and specifically at the apical portion of the root canal.

Preparation size[281] and to some extent taper[95] determine how closely a needle can be placed to the final apical millimeters of a root canal. Open-ended needles are recommended over the end open needles to prevent extrusion of the irrigant. Some needles and suction tips may be attached to the air/water syringe to increase both the speed of irrigant flow and the volume of irrigant. Examples include the Stropko Irrigator (Vista Dental Products), an adapter that connects to the air/water syringe and accepts standard Luer-lock needle tips for irrigant removal and application as well as air-drying.

Manually activated irrigation

Liquid placed inside the root canal more effectively reaches crevices and mechanically untouched areas if it is agitated inside the root canal. Corono-apical movements of the irrigation needle,[205] stirring movements with small endodontic instruments,[276,467] and manual push-pull movements using a fitted master gutta-percha cone have been recommended.[202]

Other than conventional irrigation, additional techniques for endodontic disinfection have been proposed and tested, including laser systems and

Telegram: @dental_k

www.konkur.in

gaseous ozone. Specific devices for endodontic irrigation and/or disinfection have been introduced, among which are the EndoActivator System (Dentsply Sirona), passive ultrasonic irrigation (PUI), the EndoVac (Discus, Culver City, CA, USA), the Safety-Irrigator (Vista Dental Products, Racine, WI, USA), the Self-adjusting File (see earlier), photoactivation disinfection, ozone generators, and others. These devices use pressure, vacuum, oscillation, and a combination of suction.

Sonically activated irrigation

The EndoActivator System uses safe, noncutting polymer tips in an easy-to-use subsonic handpiece to quickly and vigorously agitate irrigant solutions during endodontic therapy (Fig. 8.59).

FIG. 8.59 The EndoActivator, a sonic frequency system.

Close-up of endoactivator handpiece with an activator tip fixed in the front with three microholes.

Source: (Courtesy Dentsply Tulsa Dental Specialties, Tulsa, OK, USA.)

In a study,[116] the safety of various intracanal irrigation systems was analyzed by measuring the apical extrusion of irrigant. The authors concluded that EndoActivator had a minimal statistically insignificant amount of irrigant extruded out of the apex in comparison with manual, ultrasonic, and Rinsendo (Dürr Dental, Bietigheim-Bissingen, Germany) groups.[116]

When cleanliness of the root canal walls was analyzed,[366] investigators suggested that both passive sonic or ultrasonic irrigation rendered root canals significantly cleaner than manual preparation in comparison with manual syringe irrigation.[74,465] When comparing sonic with ultrasonic irrigation, the results can be controversial. The majority of the studies favors ultrasonic irrigation.[217,366] The difference lies in the oscillating movements: sonic

Telegram: @dental_k

www.konkur.in

devices range between 1500 and 6000 Hz, and ultrasonic equipment requires vibrations greater than 20,000 Hz.[217,262] If the sonic device is left in the canal for extended periods, cleaning is improved. Sonic or ultrasonic irrigation may be carried out with activated smooth wires or plastic inserts, endodontic instruments, or activated irrigation needles. Examples include EndoSonor (Dentsply Maillefer) and EndoSoft ESI (EMS, Nyon, Switzerland) inserts, IrriSafe (Satelec, Acteon, Merignac, France), the EndoActivator System, and the Vibringe sonic syringe (Cavex, Haarlem, Netherlands). Inadvertent cavitation of root canal walls has not been observed with sonic activation of instruments.[276]

Ultrasonic-assisted irrigation

Ultrasonic devices were first introduced in endodontics by Richman.[356] The files are driven to oscillate at ultrasonic frequencies of 25 to 30 kHz to mechanically prepare the root canal walls.[475] Recently, it has been shown that ultrasonically driven files are useful to activate the irrigation liquids inside the root canal system by inducing acoustic streaming and cavitation.

Two types of ultrasonic irrigation have been described in the literature[10,485]: one in which irrigation is combined with simultaneous ultrasonic instrumentation (UI) and another without simultaneous instrumentation, called *passive ultrasonic instrumentation* (PUI). During UI, the file is intentionally brought into contact with the root canal wall. However, because of the complex canal anatomy, UI never contacts the entire walls, and it may result in the uncontrolled cutting of the root canal walls without effective disinfection.[10] In a study by Macedo[265] instrument oscillation frequency, ultrasonic power, and file taper determined occurrence and extent of cavitation. Some degree of cavitation occurred between the file and canal surface and reached lateral canals and isthmuses.

PUI was first described by Weller et al.[485] The term “passive” is related to the noncutting action of the ultrasonically activated file.[10] PUI relies on the transmission of acoustic energy from an oscillating file or smooth wire to an irrigant in the root canal.

PUI should be introduced in the canal once the root canal system has a final apical size and taper. A fresh solution of irrigant should be introduced, and a small file or smooth wire (e.g., size #15) is ultrasonically activated.

Telegram: @dental_k

www.konkur.in

Since the root canal has already been shaped, the file or wire can move more freely,[467] and the irrigant can penetrate the apical part of the root canal system,[237] with the cleaning effect being more significant.[261] Using this noncutting approach, the potential to create aberrant shapes within the root canal is reduced to a minimum. A file larger than a #15 or #20 requires a wide root canal to reduce oscillation dampening by wall contact.

Ultrasonic activation of the irrigant seems to improve débridement of the root canal system in vitro; the results in vivo present some controversy. Therefore objective guidelines regarding their risks and benefits have not been ascertained.[251] Ultrasonic activation of the irrigant can be intermittent or continue. The ProUltra PiezoFlow (Dentsply Sirona) has been introduced to irrigate and activate the liquids at the same time. The device consists mainly of an ultrasonically energized needle connected to a reservoir of sodium hypochlorite (NaOCl). This continuous ultrasonic irrigation (CUI) system allows simultaneous continuous irrigant delivery and ultrasonic activation; unlike PUI, it does not require the intermittent replenishment of irrigant between ultrasonic file activations. Research shows better elimination of debris and better penetration of irrigant into dentinal tubules.[82,218]

Negative apical pressure irrigation

Another approach to afford better access to irrigation solution to the apical portion of the canal is the so-called negative-pressure irrigation (Fig. 8.60). Here, irrigant is delivered into the access chamber, and a very fine needle connected to the dental unit's suction device is placed into the root canal. Excess irrigant from the access cavity is then transported apically and ultimately removed via suction. First, a macrocannula, equivalent to an ISO size #55,.02 taper instrument, removes coronal debris. Subsequently, a microcannula, equivalent to a size #32,.02 taper, removes particles lodged close to WL. Such a system is commercially available (EndoVac, Discus Dental) and may prove a valuable adjunct in canal disinfection.[302] One of the main characteristics of the system is safety. Several studies demonstrated that EndoVac use is unlikely to extrude irrigation solution through the apex. On the other hand, because the irrigation is deposited in the coronal area, the irrigant flow in the apical last millimeters of the canal is very passive, and some concerns were expressed that flow is laminar and passive in the apical

Telegram: @dental_k

www.konkur.in

region. In a recent study, the apical negative pressure mode of irrigation generated the lowest wall shear stress.[86]

Another device that makes use of pressure-suction technology is the RinsEndo system (Dürr Dental, Bietigheim-Bissingen, Germany). It aspirates the delivered rinsing solution into an irrigation needle that is placed close to WL and at the same time activates the needle with oscillations of 1.6 Hz amplitude.[63]

Telegram: @dental_k

www.konkur.in

Safety-Irrigator

The Safety-Irrigator (Vista Dental Products) is an irrigation/evacuation system that apically delivers the irrigant under positive pressure through a thin needle containing a lateral opening and evacuates the solution through a large needle at the root canal orifice (Fig. 8.61). The Safety-Irrigator features a large coronal evacuation tube, enabling the user to irrigate and evacuate simultaneously safely. It fits any standard Luer-lock syringe. Designed to limit the risk of NaOCl accidents, this "negative-pressure" irrigation device comes fully assembled and fitted with side-vented irrigating needle for added safety. This system was tested in vitro to evaluate the removal of dentin debris from artificially made grooves in standardized root canals and showed that there was no significant difference between the manual dynamic activation (MDA) with a nontapered gutta-percha cone, the Safety Irrigator, and the apical negative pressure irrigation. These techniques produced better cleaning efficacy than syringe irrigation (P <.005) but significantly worse than MDA with a tapered cone (P <.05). CUI was significantly better than all the other techniques tested in this study (P <.001).[218]

GentleWave system

The GentleWave (GW) system (Sonendo Inc, Laguna Hills, CA) was introduced in the United States in 2016. The device is composed of a console,

Telegram: @dental_k

www.konkur.in

a so-called procedure instrument, which is a single-use tip attached to a handpiece (for either molars or anterior and premolar treatment), and a central unit that contains three individual irrigation solution containers, one waste canister, a degassing system, and a pressure generator (Fig. 8.62). The system delivers an energized flow of irrigation solutions from the central unit to the procedural instrument. According to the manufacturer, the fluid stream entering the tooth creates a shear force, which in turn causes hydrodynamic cavitation. The implosion of micro-bubbles then creates an acoustic field of broadband frequencies, which travels through the fluid into the root canal system. The programmed irrigation regimen begins with 3% NaOCl followed by 8% EDTA, with a rinse of distilled water in between and at completion. The fluid within the root canal space is continuously collected and removed from the chamber through a five-point vented suction system built in the sealing lid of the procedural instrument.[179] A sealed environment is needed between the tooth and the GW Procedure Instrument to allow for constant refreshing of degassed procedure fluids and simultaneous evacuation of debris. The system operates within an air-free, sealed root canal system, filled only with procedure fluid and appears to induce a vertical flow within the root canal system with a slight negative pressure at the apices, which reduces the potential for extrusion. The system applies advanced fluid dynamics, acoustics, and tissue dissolution chemistry to remove tissue and debris from the entire root canal system simultaneously.[179]

Telegram: @dental_k

www.konkur.in

FIG. 8.62 The GentleWave system (Sonendo, Irvine, CA, USA). The system uses multisonic energy to develop a broad section of waves within the irrigation solution to clean inside the roots canal system. It has two main components: a hand piece and a console (shown in figure).

Close-up of a safety irrigator shows a console and a handpiece connected to it.

The studies investigating cleaning and disinfection of the root canal system concluded that GW irrigation results in a faster dissolution rate than other systems[179] and that can clean canals efficiently with minimal instrumentation and can reduce residual debris[287] and promote better penetration into dentinal tubules compared with needle irrigation.[83]

The latter study,[83] using MicroCT, further concluded that GW irrigation was effective in the removal of accumulated dentin from the isthmus of mesial roots in mandibular molars. GentleWave irrigation was superior to needle irrigation but statistically similar to continuous ultrasonically powered irrigation (CI), with debris reductions for canals and isthmuses, respectively, of 96.4% and 97.9% for GW and 91.2% and 93.5% for CI.

As of the writing of this chapter, only three in vivo studies are published,

Telegram: @dental_k

www.konkur.in

all by the same group. The first two reports[405,406] evaluated the 6- and 12-month healing outcome after endodontic treatment using GW. The cumulative success was 97% at 12 months, with 92% and 5% of the necrotic pulp cases classified as healed and healing, respectively. However, in these studies, only 23% of the total sample had preoperative signs of asymptomatic apical periodontitis, which is a well-established outcome predictor.

The subsequent report[404] addressed this concern by assessing the 12-month healing outcome in teeth with a score greater than 3 in the periapical index (PAI). A reduction in PAI scores occurred in 98% of the teeth that received treatment with GW, with 82% and 16% of the teeth classified as healed and healing, respectively. However, despite initial encouraging data, more independent studies on GW are essential to fully describe the clinical applicability of this technique.

Laser-activated irrigation

Lasers are widely used in dentistry and include a diode, Nd:YAG, erbium and CO_2, which produces radiation in both the near and far infrared electromagnet spectrum.[166] Laser devices have been proposed to improve the efficacy of irrigants.[166] Lasers have been studied for their ability to clean and effectively disinfect root canals. The Er:YAG laser wavelength (2940 nm) has the highest absorption in water and high affinity to hydroxyapatite, which makes it suitable for use in root canal treatment.[96]

Laser energy may be used to activate irrigant solutions in different ways, for example at a molecular level, as in photo-activated disinfection (PAD) or at a bulk flow level as in laser-activated irrigation (LAI). Several studies in vivo and ex vivo indicated that laser activated irrigation is promising in removing smear layer[150] and dentin debris[108] in less time than PUI. The mechanism of action[51] is based on the generation of a secondary cavitation effect with expansion and the successive implosion of fluids.[51]

These results are in agreement with data related to a new erbium laser technique that used photon-induced photoacoustic streaming (PIPS) of irrigants. In that technique, the laser tip is placed into the coronal access opening of the pulp chamber only and is kept stationary without advancing into the orifice of the canal.[118] The use of a tapered and stripped tip with specific minimally ablative laser settings is required: low energy (20 mJ),

Telegram: @dental_k

www.konkur.in

pulse repetition rate (15 Hz), and short pulse duration (50 μs). The difference in laser penetration and bacterial killing is attributed to the difference in the degree of absorption of different wavelengths of light within the dentin. Bergmans et al.[45] concluded in their in vivo study that the Nd:YAG laser irradiation is not an alternative, but a possible supplement to existing protocols for canal disinfection as the properties of laser light may allow a bactericidal effect beyond 1 mm of dentin. Endodontic pathogens that grow as biofilms, however, are challenging to eradicate even upon direct laser exposure.[58]

Photoactivated disinfection

Photodynamic therapy (PDT) or light-activated therapy (LAT) may have endodontic applications because of its antimicrobial effectiveness.[185] In principle, antimicrobial photodynamic therapy (APDT) is a two-step procedure that involves the introduction of a photosensitizer (step 1: photosensitization of the infected tissue) followed by light illumination (step 2: irradiation of the photosensitized tissue) of the sensitized tissue, which would generate a toxic photochemistry on the target cell, leading to cell lysis. Each of these elements used independently will not have any action, but together they have a synergism effect of producing antibacterial action. Indeed, in vitro experiments showed promising results as an adjunct disinfected device. Shrestha and Kishen[400] concluded that the tissue inhibitors existing within the root canal affected the antibacterial activity of PDT at varying degrees and further research is required to enhance their antimicrobial efficacy in an endodontic environment. Photosensitizers combined with nanoparticles such as Rose Bengal may have a promising antibacterial efficacy.[401]

Antibacterial nanoparticles

The concept of nanotechnology was first discussed in 1959 by Richard Feynman; the topic has recently been reviewed by Shrestha and Kishen.[402] Nanotechnology is the science conducted at the nanoscale, using particles about 1 to 100 nm, and it can be used in chemistry, biology, physics, materials science, and engineering. The particles can be classified depending on their shape as atom clusters, grains, fibers, films, nanoholes, and

Telegram: @dental_k

www.konkur.in

composites from these combinations. Nanomaterial properties vary majorly from other materials due to the increase in surface area per unit mass.

In dentistry, nanotechnology is currently investigated in the following fields: local nanoanaesthesia, hypersensitivity cure, tooth repositioning, nanorobotic dentifrice, dental durability, cosmetics, nanodiagnostics, and gene therapy.[49] More specifically, the research on nanomaterials is focusing on nanocomposites, nanosolution, nanoadhesives, and impression materials.

Nanoparticles in endodontics are being developed for their efficient disinfection of root canals, due to the broad-spectrum antibacterial activity. The nanoparticles evaluated in endodontics include Chitosan (CS-np), zinc oxide (ZnO-np), and silver (Ag-np) nanoparticles.[273]

CS-np have been widely studied and appear to be effective against monospecies *(E. faecalis)* and multispecies biofilms, even in the presence of tissue inhibitors, and it has been attributed to their ability to disrupt the cell wall.[402] Silver nanoparticles are also being evaluated for use as root canal disinfecting agents. In gel and liquid form, such nanoparticles have been shown to be able to kill and disrupt *E. faecalis* biofilm.

Biactive glass (SiO_2-Na_2O-CaO-P_2O_5) is another revolutionary introduction in the field of nanotechnology, and it has been suggested for root canal disinfection. The antimicrobial effect of bioactive glass is due to its ability to maintain an alkaline environment over a period of time.[273] When used in root canals, bioactive glass was found to kill bacteria, but the mechanism of action was not pH related and dentin did not seem to alter its effect.[507]

It is recently being researched for its use for endodontic regeneration in which diseased or necrotic pulp tissues are removed and replaced with healthy pulp tissues to revitalize teeth. It was reported the first use of nanostructured and functionalized multilayered films was as a new active biomaterial for endodontic regeneration.

HealOzone.

Ozone, in the gaseous or aqueous phase, is a powerful and reliable antimicrobial agent against bacteria, fungi, protozoa, and viruses. The mechanism of action is based on the destruction of cell walls and cytoplasmic membranes of bacteria and fungi by the oxidant potential of the ozone.

Telegram: @dental_k

www.konkur.in

During this process, ozone attacks glycoproteins, glycolipids, and other amino acids and inhibits the enzymatic control system of the cell with an increase of the membrane permeability leading to immediate functional cessation. The ozone molecules then readily enter the cell and effectively kills microorganisms.[272]

It is applied to oral tissues in the following forms: ozonated water, ozonated olive oil, and oxygen/ozone gas. In vitro studies showed promising results on their antibacterial effect, clinical results demonstrated the opposite.[126,193,294,295] Ozone gas is currently used clinically for endodontic treatment; however, the results from in vivo studies are inconclusive.[193,294,295] This inconsistency is attributed to the lack of information about the maximum duration of application and concentration that should be used.[27,226] The hazards of ozone, when used in endodontics, have not been investigated. Care should be taken concerning the patient's and the dentist's exposure to the gas.

Water preparations.

Super-oxidized water,[171] also called electrochemically activated water[270,422] or potential oxidative water,[189,394] is effectively saline that has been electrolyzed to form superoxidized water, hypochlorous acid, and free chlorine radicals. It is commercially available as Sterilox (Sterilox Technologies, Radnor, PA, USA). This solution is nontoxic to biologic tissues, yet able to kill microorganisms. The solution is generated by electrolyzing saline solution—a process no different from that used in the commercial production of NaOCl.[136] The difference, however, is that the solution accumulating at the anode is harvested as the anolyte and at the cathode as the catholyte. These solutions display properties that are dependent upon the strength of the first saline solution, the applied potential difference, and the rate of generation. The technology that allows harvesting of the respective solutions resides in the design of the anode and the cathode and originates either in Russia (electrochemically activated water) or Japan (potential oxidative water).[269] Although the solutions bear different names, the principles in the manufacturing process appear to be similar.

The use of superoxidized water is sparsely described in the endodontic literature but shows early promise. The solutions from both technologies have

Telegram: @dental_k

www.konkur.in

been tested for their ability to débride root canals,[189] remove the smear layer,[394,422] and kill bacteria[200] and bacterial spores.[259] Results are generally favorable, while also showing biocompatibility with vital systems.[211]

Anolyte and catholyte solutions generated from one such technology (Radical Waters Halfway Johannesburg, South Africa) have shown promise as antibacterial agents against laboratory-grown, single-species biofilm models.[151] Such solutions have been recommended as suitable for removing biofilms in dental unit water lines[269] and have even been marketed for this purpose. Cautious clinicians may prefer to wait for more studies to demonstrate safety and efficacy under normal clinical setting conditions before adopting newer, less tested irrigating solutions.

Criteria to evaluate cleaning and shaping[4]

Well-shaped canals

The main aims of canal shaping are to directly remove tissues and microbial irritants and to provide sufficient geometric space for subsequent obturation (see Table 8.2). In order to achieve these goals, the prepared canal should include the original canal (see *red areas* in Fig. 8.4); there should be an apical narrowing and the canal should be tapered. These concepts have been popularized by Schilder[386] and are still maintained today.[3,124]

Therefore, a well-shaped canal is defined more specifically by the absence of procedural errors (see later) and the achievement of disinfection; more recently, another element was added to this equation—the retention of as much tooth structure as feasible.[154]

The fact that a canal is adequately shaped can often be determined by a clinician from radiographs and clinical experience—for example, when fitting a cone. At this time, the feel would be of tug-back, a slight resistance to pull; a radiograph should demonstrate a symmetrical canal shape lateral of the cone, the presence of an intact apical narrowing, and no thinned out radicular wall sections.

Using magnification, clinicians should inspect the canal orifice and the coronal third of each shaped canal for clean canal walls.[319] Immediately after irrigation with sodium hypochlorite, an absence of visible turbidity and

Telegram: @dental_k

www.konkur.in

effervescence should be noted. If present, these phenomena along with visible deposits on the canal walls are indicative of organic matter still in suspension or adherent to the radicular walls.

Signs of mishaps

Instrument fracture

Most reports suggest that manual endodontic file fracture or rotary instrument fracture occur at a rate of approximately 1% to 6% and 0.4% to 5%, respectively.[434,463] Such fractures are untoward events and perceived as such by clinicians.[50] Evidently retained instrument fragments limit access of disinfecting irrigants to the root canal system, possibly impeding sufficient elimination of microorganisms.[178] However, the current clinical evidence does not suggest that the presence of a retained instrument must result in a significant higher rate of failing root canal treatments when done by specialists.[434]

In general, instruments used in rotary motion break in two distinct modes —torsional and flexural.[329,375,462] Torsional fracture occurs when an instrument tip is locked in a canal while the shank continues to rotate, thereby exerting enough torque to fracture the tip. This also may occur when instrument rotation is sufficiently slowed in relation to the cross-sectional diameter. In contrast, flexural fracture occurs when the cyclic loading leads to metal fatigue. This problem precludes the manufacture of continuously rotating stainless steel endodontic instruments, because steel develops fatal fatigue after only a few cycles.[393] NiTi instruments can withstand several hundred flexural cycles before they fracture,[250,348,462] but they still can fracture in the endodontic setting after a low (i.e., below 10,000) number of cycles.[87]

Repeated loading and cyclic fatigue tests for endodontic instruments are not described in pertinent norms. Initially, rotary instruments such as GG burs and Peeso reamers were tested with a superimposed bending deflection.[62] In another study, stainless steel and NiTi hand files were rotated to failure in steel tubes with an acute 90-degree bend and an unspecified radius.[393] Under these conditions, size #40 stainless steel instruments fractured after fewer than 20 rotations, whereas various NiTi files of the same

Telegram: @dental_k

www.konkur.in

size withstood up to 450 rotations.

Cyclic fatigue was also evaluated for ProFile.06 taper instruments using a similar device.[498] The number of rotations to failure for unused control instruments ranged from 1260 (size #15 files) to 900 (size #40 files). These scores did not change when the instruments were tested under simulated clinical conditions such as repeated sterilization and contact with 2.5% NaOCl. Subsequently, control instruments were compared with a group of instruments used in the clinical setting in five molar cases;[497] again, no significant differences were found in resistance to cyclic fatigue.

One study[183] used a different testing method involving tempered metal cylinders with radii of 5 and 10 mm that produced a 90-degree curve. They reported fatigue fractures for size #15,.04 taper ProFile instruments after about 2800 cycles with the 10 mm cylinders. In size #40,.04 taper ProFile instruments, fractures occurred after about 500 cycles with the 5-mm cylinders. In comparison, size #15,.06 taper ProFile instruments also failed after about 2800 revolutions with the 10-mm cylinders, but failure occurred in size #40,.06 taper ProFile specimens after only 223 cycles with the 5-mm cylinders.

Rotary NiTi instruments with larger tapers and sizes consistently fractured after fewer rotations,[345] and although the radius of the curves was halved, fatigue-life was reduced by 400%. Another investigation[183] reported similar results for selected HERO instruments, and their findings were confirmed by other tests on GT rotary instruments. Size #20,.06 taper GT files failed after 530 rotations in a 90-degree curve with a 5-mm radius; size #20,.12 taper GT files failed after 56 rotations under the same conditions.[334]

Reuse of rotary instruments depends on safety, specifically on assessment of fatigue and also the potential to properly clean NiTi surfaces.[34,304,311,398,424,428,458] Specific instruments perform differently in this regard, since fatigue depends more on the amount of metal in cross section at the point of stress concentration[163,457] than on the specifics of instrument design.[88]

On the other hand, manufacturers constantly claim that their instrument has been equipped with design elements that render it more fatigue resistant. For example, LightSpeed LSX is manufactured without a milling process. However, no data have been published regarding its fatigue resistance. GTX

Telegram: @dental_k

www.konkur.in

is manufactured from a novel NiTi alloy, M-Wire, to increase its fatigue resistance.[220] However, investigators[234] could not confirm these findings. Similarly, another study[243] did not find the TF, which is not milled and hence believed to be fatigue resistant,[143] to perform better than conventionally manufactured ProFile rotaries. Another feature, electropolishing (as discussed earlier), does not appear to confer a significantly increased fatigue resistance to EndoSequence[243,353] and RaCe.[457,458,495] One possible reason for these variable outcomes are the different testing environments used in vitro[90]; clinically, even greater variability is to be expected.

Recently, cyclic fatigue tests are sometimes conducted under more directly clinically applicable conditions, such as varying ambient temperature or introducing dynamic movement. For example, while the latest martensitic alloys we showed to have significantly increased fatigue resistance at room temperature, this benefit was greatly reduced at body temperature.[22,109]

Attempts have been made to use tests according to norms and specifications described for stainless steel hand instruments such as K-files and Hedström files,[2] since no comparable norms exist for instruments used in continuous rotary motion. Consequently, a number of models have been devised to assess specific properties of NiTi rotary instruments, including torque at failure, resistance against cyclic fatigue, and others (Fig. 8.63). These systems may simultaneously assess torque at failure, working torque axial force, and cyclic fatigue.

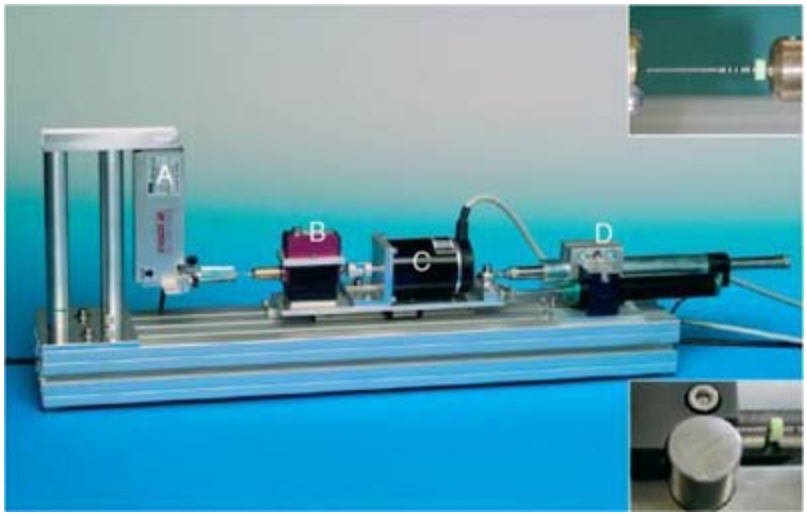

FIG. 8.63 Testing platform for analysis of various factors during

Telegram: @dental_k

www.konkur.in

simulated canal preparation with rotary endodontic instruments. Labeled components are a force transducer *(A)*, a torque sensor *(B)*, a direct-drive motor *(C)*, and an automated feed device *(D)*. For specific tests, a cyclic fatigue phantom or a brass mount compliant with ISO No. 3630-1 *(inserts)* may be attached.

Four different nickel titanium rotary instruments kept on a platform are labeled from A through D (left to right).

According to the norms mentioned previously, torque at failure is recorded with the apical 3 mm of the instrument firmly held in the testing device while the instrument's handle is rotated. A wide variety of rotary NiTi endodontic instruments have been tested in this way. For example, ProFile NiTi rotary files in ISO sizes #25, #30, and #35 (.04 taper) fractured at 0.78, 1.06, and 1.47 Ncm, respectively.[441]

When analyzing clinical factors involved in instrument fracture, one must consider both torsional load and cyclic fatigue.[375] However, these are not separate entities, especially in curved canals.[57] Working an instrument with high torque may lower resistance to cyclic fatigue.[141] Conversely, cyclic prestressing has been shown to reduce the torsional resistance of ProTaper finishing files,[462] as well as K3[30] and MTwo.[345] Also, cyclic fatigue occurs not only in the lateral aspect when an instrument rotates in a curved canal but also axially when an instrument is bound and released by canal irregularities.[48]

The torque generated during canal preparation depends on a variety of factors, and an important one is the contact area.[52] The size of the surface area contacted by an endodontic instrument is influenced by the instrumentation sequence or by the use of instruments with different tapers.[388] A crown-down approach is recommended to reduce torsional loads (and thus the risk of fracture) by preventing a large portion of the tapered rotating instrument from engaging root dentin (known as *taper lock*).[52,499]

The clinician can further modify torque by varying axial pressure, because these two factors are related (see Fig. 8.20).[388] In fact, a fairly light touch is recommended for all current NiTi instruments to avoid forcing the instrument into taper lock. The same effect might occur in certain anatomic situations, such as when canals merge, dilacerate, and divide.

The torsional behavior of NiTi rotary endodontic instruments cannot be

Telegram: @dental_k

www.konkur.in

described properly without advanced measurement systems and a new set of norms. However, the clinician must be able to interpret correctly the stress-strain curves for all rotary NiTi instruments used in the clinical setting to be able to choose an appropriate working torque and axial force.

Therefore a careful evaluation should be performed before the attempt is made to remove any retained fragment (see Fig. 8.25). In fact, Ward and others[481] suggest any attempt of fragment removal only when the fragment is located coronal of a significant root canal curve and thus visible with the aid of magnification.

There are sophisticated means and strategies to remove retained fragments, which are described in detail in Chapter 20 of this book.

Of note, assessment of physical parameters governing rotary root canal preparation was considered crucial because NiTi rotary in vitro had increased risk of fracture compared with K-files. Some clinicians also describe instrument fracture as a main issue for concern.[50]

In a study using plastic blocks, as many as 52 ProFile Series 29 instruments became permanently deformed.[450] Three fractures were reported in a subsequent study on ISO-norm ProFile size.04 instruments, and three other instruments were distorted.[66] An even higher fracture incidence was shown in a study on rotary instruments used in plastic blocks in a specially designed testing machine.[446] These findings were supported by two studies, in which high fracture incidences were reported for LightSpeed and Quantec rotary instruments used in a clinical setting.[32,375]

On the other hand, as stated earlier, a retrospective clinical study suggests similar outcomes with and without retained instrument fragments[434]; moreover, others' experience suggests that the number of rotary instrument fractures is lower than previously estimated.[112,489] Removal of such fragments is possible in many situations, but there is also the potential for further damage (e.g., perforation) rather than successful removal.[440,489] Consequently, a benefit-versus-risk analysis should be carried out prior to attempts to remove NiTi instrument fragments, addressing the reasons and the clinical consequences of instrument fracture.

Canal transportation

Perhaps the most frequent adverse outcomes during canal shaping are

Telegram: @dental_k

www.konkur.in

aberrations from the original canal path. Much has been written on the appearance of such aberrations using labels such as zip and elbow formation, ledging, perforation, stripping, and others.[484]

Canal transportation is at the root of all these clinical problems and may be defined as "the removal of canal wall structure on the outside curve in the apical half of the canal due to the tendency of files to restore themselves to their original linear shape during canal preparation."[3]

As files tend to straighten in the canal, this typically occurs toward the inner (or convex) radicular wall at midroot as well as to the outer curvature apically. Such a shift of the canal axis during shaping results in excessive loss of dentin and may ultimately result in strip perforation, while apical transportation may lead to zipping or overt apical perforation (see Fig. 8.39).

Conceptually, any canal preparation will shift the canal axis, which is often determined as the center of gravity in cross sections. It has been held that a transportation of about 100 to 150 μm may be clinically acceptable.[207,326]

If canal transportation has led to ledge formation, subsequent instruments will bypass the area of the ledge only when adequately precurved. In case of rotary instrumentation, hand-operated instruments of comparable size are then recommended (Fig. 8.64).

A) Close-up of five ProTaper instruments with spirally textured bodies and pointed tips.

B) Close-up of four GT hand instruments with different depths of spirally textured surface.

Perforation

As indicated, perforation may be the ultimate result of canal transportation when it occurs within the root canal system. Other perforations are those in the access cavity; a discussion of access cavity preparation may be found in Chapter 7. Obviously, preparing mineralized canals requires advanced operator skills and is facilitated by magnification (Fig. 8.65).

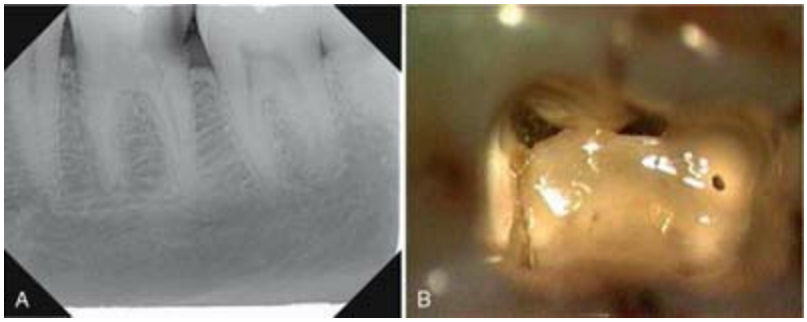

FIG. 8.65 Evidence of coronal hard-tissue deposition. **A,** Periapical radiograph of tooth #19 shows evidence of reduced coronal and radicular pulp space. **B,** Intraoral photograph, taken through an operating microscope (×25), of access cavity of the tooth shown in **A**; note the calcific metamorphosis.

A) Radiograph of a tooth shows radiopaque crown, neck and lower canals with black upper canals.

B) Close-up of an open crown exposes two black cavities in the dentin in presence of light.

Three types of perforations can be defined—strip perforations that occur toward the furcation in multirooted teeth (also known as “danger zones”[7]), perforations associated with canal curvatures, and perforations though the apical foramen.

Blockage

A canal may become impassable during the process of cleaning and shaping due to two distinct, but often connected, occurrences. A ledge is a dentinal shelf that is created by shaping instruments that straighten and dig into the convex side of the canal wall. In less severe cases, ledges can be corrected and smoothed out with precurved instruments. This condition may lead to false paths and impede optimal obturation, when WL cannot be reached with master cones.

A blockage refers mainly to a root canal area that is filled with densely compacted debris or collagenous pulp remnants (see Fig. 8.38). It may also be caused by other obstacles such as fractured files or remnants of a preexisting coronal or radicular filling materials. Clinically the presence of ledge or block is signaled by the inability for a straight flexible instrument to penetrate deeper into the root canal; however, this needs to be differentiated from a small or mineralized canal, which causes longer portions of the

Telegram: @dental_k

www.konkur.in

instrument's cutting flutes to bind.

Obviously, such a blockage prevents the apical canal portion from being disinfected. For details of strategies to deal with ledge and blockage, refer to Chapter 10.

Another reason for a perceived blockage may be a very abrupt canal curvature.

Sample protocol for contemporary cleaning and shaping procedures

- Using well-angulated preoperative radiographs, analyze case difficulty using well-established parameters.
- Place rubber dam and estimate WL.
- Prepare a conservative access cavity sufficient enough to reveal all root canal orifices.
- Scout canals with a #10 K-file in the presence of a lubricant.
- If the selected series of rotary instruments advances easily to the estimated WL, confirm patency and determine WL using an electronic apex locator.
- If the instruments meet resistance and the file does not progress gently to WL, use a dedicated NiTi instrument. It is prudent to modify the orifice to create a coronal receptacle for the subsequent rotaries. Negotiate, confirm patency, and determine WL.
- Create a reproducible glide path to WL with appropriate instruments.
- Irrigate with sodium hypochlorite throughout the shaping procedure.
- Advance the selected series of rotary instruments (based on canal anatomy) passively in the presence of sodium hypochlorite to shape the middle third. When shaping canals that have a larger buccal-lingual dimension, consider shaping as two canals.
- Clean cutting flutes routinely upon removal and remove debris with an alcohol-moistened gauze. If the selected rotary does not progress easily, remove irrigate, recapitulate with a #10 K-file, and choose a different, often smaller, instrument.
- Use copious irrigation, reverify canal patency and working length

Telegram: @dental_k

www.konkur.in

throughout and upon completion of shaping. Gauge the size of the foramen with an appropriate hand file.

- Protocol for irrigation:
  - Irrigate using copious amounts of sodium hypochlorite.
  - Activate the irrigant.
  - Select irrigation solution for smear layer management.
  - Perform final irrigation.
- Dry the canal thoroughly and obdurate with a technique that promotes a three-dimensional fill.
- Restore the endodontically treated tooth in a timely manner.

Summary

Cleaning and shaping are important, interdependent steps in root canal treatment. Cleaning, as demonstrated by an intracanal surface free of smear layer, can be done only after root canals have been sufficiently enlarged to accommodate adequate irrigation needles. Canal preparation is optimized when mechanical aims are fulfilled and enlargement is acceptable; such aims include avoiding both significant preparation errors and weakening of the radicular structure, which can result in fractures.

Taken together and performed to a high standard, the procedures described in this chapter lay the foundation for biologic success in both straightforward (Fig. 8.66) and more complicated (Fig. 8.67) clinical cases. Recall radiographs confirm favorable outcomes or biologic success (i.e., prevention or healing of periradicular periodontitis) over the years. Similarly, adherence to the principles discussed leads to predictable outcomes for root canal treatments.

www.konkur.in

Importance of effectively sealing the root canal system

The authors of a meta-analysis of factors influencing the efficacy of nonsurgical root canal treatment (NS RCT) reported that the following four factors influenced success: the absence of a periapical lesion (PL), root canal obturations containing no radiographic voids, obturation to within 2.0 mm of the radiographic apex, and an adequate coronal restoration.[196] On the basis of the current best available evidence, both the quality of the endodontic treatment and the coronal restoration are significant in any healing outcome.[104]

In a recent controlled animal study, evidence suggests that cleaning and shaping (C&S) of the radicular space is more important than the method of obturation.[240] PLs were created by removing the pulp and leaving the teeth open to the oral cavity. In the control group, the canals were cleaned and shaped before obturation with gutta-percha (GP) and a resin-based sealer. The teeth of the experimental group were cleaned and shaped as in the control group but left unobturated. At 190 days, the animals were killed and histological evaluations were performed. There was no difference in the healing between the instrumented and obturated teeth and the instrumented and unobturated teeth.

To date, there is no effective method for determining whether C&S procedures have been effective.[10,11] There is some evidence that the criteria of clean dentinal filings and/or enlargement beyond the first file to bind at the working length have proven to result in a healing outcome.[244] Although the length of preparation has been emphasized, the irregular canal diameter may be a more significant factor in healing or nonhealing outcomes.[133] Evidence indicates root canal systems (RCS) are often underprepared in the apical one third of the RCS.[56] Historically, culturing has been employed and obturation delayed until a “negative” culture was obtained. In contemporary endodontic treatment, culturing has been abandoned during routine care.[250] When dealing with vital pulp tissue, preventing bacterial contamination is a primary concern. In RCS with a necrotic pulp, the organisms involved in the disease

Telegram: @dental_k

www.konkur.in

process are primarily facultative or obligate anaerobes that may not grow in culture. Molecular microbiologic techniques (polymerase chain reaction) have demonstrated that a variety of organisms are present that do not grow in culture.[13,237,273] The role these organisms play in the disease process is not well understood.[189] The reader is referred to Chapters 15 and 16 for a fuller discussion.

The process of C&S determines both the degree of disinfection and the ability to obturate the radicular space. Obturation is therefore a reflection of the C&S and is evaluated on the basis of length, taper, density, level of GP obturation, and the coronal seal, that is, an adequate provisional or definitive restoration (Fig. 9.1). It is not possible to assess the quality of the seal established during obturation with a radiograph, and it is important to recognize that no material or technique prevents leakage.[4,58,81,139,182,209,210] Indeed, obtaining an impervious seal may not be feasible because of the porous tubular structure of dentin[4] and canal irregularities.

FIG. 9.1 Examples of inadequate obturation. **A,** Maxillary right canine with adequate length but lacking density and no coronal seal. Central

incisor is filled to adequate length, but obturation exhibits voids. **B,** Maxillary central incisors. Maxillary right central incisor exhibits a lack of density and taper. Maxillary left central incisor has voids and unfilled canal space. **C,** Mandibular left first molar with adequate obturation; provisional restoration shows poor adaptation on the distal because of the failure to remove caries.

A) Radiograph of a tooth shows a missing part of crown, radiopaque neck and canals.

B) Radiograph of teeth shows two radiopaque crowns with radiolucent canals.

C) Radiograph of a tooth shows a radiolucent neck and radiopaque canals.

The primary etiology of pulpal and periradicular pathosis is, as discussed in Chapter 16, microbiological.[141,181,186,239] Pulpal remnants, necrotic tissues, bacteria, and bacterial by-products remaining in the inaccessible areas of a C&S RCS can initiate and/or perpetuate a PL because the host defense mechanisms are unable to remove them. Studies indicate that an RCS cannot be completely cleaned and disinfected.[10,11,122] Obturation of the radicular space is necessary to minimize coronal leakage from the oral environment. Obturation reduces coronal leakage and bacterial contamination, seals the apex from the periapical tissue fluids, and entombs the remaining irritants in the canal.

Coronal leakage has been proposed to contribute to treatment failure based on in vitro leakage studies.[293,294] The clinical implication is that retreatment has to be performed in those teeth that are not restored definitively 3 months after NS RCT. The clinical significance of this issue has been challenged.[232,233] A recent systematic review and meta-analysis of the results derived from nine similar studies indicate that poor-quality NS RCT and poor-quality coronal restorations have similar odds in adversely affecting the healing of apical periodontitis.[104] Based on the best available current evidence, the odds for healing apical periodontitis increase with both adequate NS RCT and an adequate restorative treatment.[104] It must be emphasized that these two factors were examined in isolation in those studies. These postoperative prognostic factors, along with other preoperative and intraoperative prognostic factors, have been reported to contribute significantly to periapical healing in primary and secondary NS RCT.[194] Nevertheless, maintaining an effective coronal seal through optimal

Telegram: @dental_k

www.konkur.in

obturation of the instrumented RCS and placing an appropriate restoration, as discussed in Chapter 23, should be considered essential components of a positive healing outcome for NS RCT.[124,132]

Clinicians are concerned with whether it is more appropriate to place a definitive restorative material instead of a temporary material to prevent leakage.[169,295] This is a controversial issue, as previous studies failed to provide definitive evidence to demonstrate that the presence of a definitive restoration will contribute to a long-term healing outcome for NS RCT when those RCS are optimally obturated.[62,243] These results have been supported by a more recent prospective clinical study that examined the factors affecting the outcomes of NS RCT.[194] In this study, the authors reported that the type of coronal restoration had no significant influence on periapical healing as long as those restorations were of good quality. Paradoxically, the same group of authors reported in a separate study that cast restorations, when compared with temporary restorations, significantly improved the survival of teeth that had undergone primary or secondary NS RCT.[194] This may be due to protection of remaining, weakened tooth structure by full-coverage cast restorations that enabled those teeth to function longer. Regarding the necessity for retreatment of root-filled teeth without definitive restorations, there is no clear evidence to justify that retreatment has to be performed in teeth in which a temporary restoration had been inserted for more than 3 months solely because of the suspicion of microleakage.[5,144] One may consider replacing the temporary restoration with a definitive coronal restoration immediately and to observe the tooth for at least 3 months before placing a full-coverage restoration.[144]

Three-dimensional obturation of the RCS is essential to a long-term healing outcome. The RCS should be sealed apically, coronally, and laterally. Various methods have been advocated for obturation. Unfortunately, all materials and techniques result in some degree of leakage.[314] Although a poorly obturated RCS and leakage are correlated, there are no standardized techniques to evaluate and measure microleakage.[134] Also, radiographic evaluation of obturation does not correlate well with leakage.[119] An adequate two-dimensional radiographic appearance of the obturation may not correlate with an adequate seal (Fig. 9.2).[119] Variation in radiographic interpretation by the clinician, the overlying osseous structures, and the lack of uniformity in

Telegram: @dental_k

www.konkur.in

the obturation materials are significant variables.[83,84,146,290]

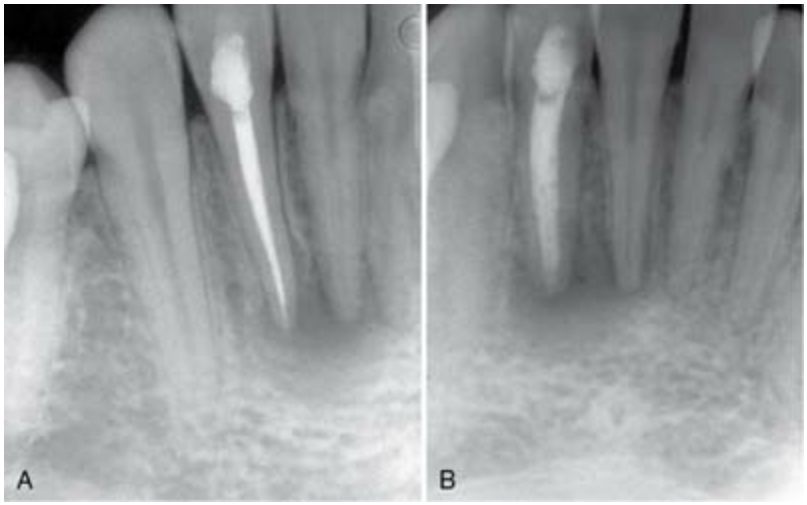

FIG. 9.2 **A,** Posttreatment radiograph of a mandibular left lateral incisor with ostensibly adequate obturation. **B,** Angled view reveals voids.

A) Radiograph of a tooth shows a radiopaque crown, radiopaque neck and canals.

B) Radiograph of a tooth shows a radiopaque crown, radiolucent neck and radiopaque canals.

The diagnostic outcome of NS RCT is based on clinical and radiographic findings. In a series of prospective studies, the Toronto group evaluated the success and failure of NS RCT at 4 to 6 years after completion of treatment. For primary NS RCT,[72,93,97,177] teeth with preexisting apical periodontitis were found to have a lower healing rate (82%) compared with teeth without a periapical radiolucency (93%). Better outcomes were associated with teeth without a periapical radiolucency, with single roots, and without midtreatment complications, such as a root perforation. Teeth were treated by using a flared preparation and vertical compaction of warm GP or step-back preparation and lateral compaction of GP. Differences were noted with the adequacy of the obturation and the treatment technique. Adequate length had a higher healing rate (87%) when compared with inadequate length (77%). The flared preparation and vertical compaction had a higher success rate (90%) when compared with a step-back preparation and lateral compaction

Telegram: @dental_k

www.konkur.in

(80%). For retreatment NS RCT,[73,92] teeth with preexisting apical periodontitis were also found to have a lower healing rate (80%) compared with teeth without a periapical radiolucency (93%). Better outcomes were achieved in teeth with an inadequate previous obturation, without perforation and a radiolucency. Similar results were reported in a more recent prospective clinical study that examined the effects of primary or secondary NS RCT on periapical healing.[194] The percentage of roots with complete periapical healing after primary (83%) or retreatment (80%) NS RCT was similar. Absence of preoperative apical periodontitis was identified as one of the prognostic factors affecting primary or secondary NS RCT. In the presence of apical periodontitis, treatment prognosis was significantly improved by the presence of a smaller PL. These studies agree with earlier work[275,282] indicating preexisting apical pathosis as a major factor reducing a favorable prognosis and highlighted obturation technique as a factor influencing healing or nonhealing outcomes.

Although periapical radiographs have been used to examine the healing of posttreatment apical periodontitis since 1922,[195] their suitability for evaluating the outcomes of NS RCT has recently been challenged, in that previously reported outcomes based on this assessment modality may have overestimated the healing rates of apical periodontitis.[12,313] With the advent of cone-beam computed tomography (CBCT), a better diagnosis of PL within the cancellous bone can be made. This is because CBCT creates reconstructed images from slices of data in any plane and location of the volume of interest, thus eliminating the lack of three-dimensional assessment and anatomical noise, which hampers the accuracy of periapical radiography. This results in a higher signal-to-noise ratio and image contrast, and improves the detection of periapical radiolucencies.[217,253] Although intraoral radiographs are the imaging modality of choice, when two-dimensional intraoral radiography is inconclusive, the use of CBCT imaging was reported to have twice the odds of detecting periapical pathosis than traditional periapical radiography.[12] Though different expectations in endodontic outcomes provide insight into the definition of the success of these procedures, it remains questionable whether this gain of additional information with CBCT in endodontic outcomes would lead to a better healing outcome in endodontic treatment. The results of these studies

Telegram: @dental_k

www.konkur.in

emphasized that developing good technical skills for obturating an RCS should not be underscored and that suitable canal obturation methods should be developed to achieve more compacted, void-free filling materials and at the correct length.

Historical perspectives

Over the past 70 to 80 years, the dental community has seen attempts to improve the nature of root canal obturation with cements/sealers and with variations in the delivery of GP to the prepared RCS. During this era, the impetus for these developments was based heavily on the continued belief in the concept of focal infection, elective localization, the hollow-tube theory, and the concept that the primary cause for failure of NS RCT was the apical percolation of fluids, and microorganisms into a poorly obturated RCS.[81] Despite endeavors reporting an adequate RCS obturation radiographically, a "perfect" seal is not achievable, as most current materials have no antimicrobial activity and do not seal the RCS.[47] From this chronological perspective of technical and scientific thought, this chapter clarifies and codifies contemporary concepts in the obturation of the C&S RCS.

Timing of obturation

Factors influencing the appropriate time to obturate an RCS include the patient's signs and symptoms, status of the pulp and periradicular tissues, the degree of difficulty, and patient management.

Vital pulp tissue

At present, the consensus is that one-step treatment procedures are acceptable when the patient exhibits a completely or partially vital pulp.[175] Removal of the normal or inflamed pulp tissue and performance of the procedure under aseptic conditions should result in a healing outcome because of the relative absence of bacterial contamination. Obturation at the initial visit also precludes contamination as a result of coronal leakage during the period between patient visits.

Elective NS RCT for restorative reasons can be completed in one visit

Telegram: @dental_k

www.konkur.in

provided the pulp is vital, to some degree, and time permits. Obturation of RCS in patients whose condition is urgent depends on the pretreatment diagnosis. When pain occurs as the result of irreversible pulpitis, obturation can occur at the initial visit because removal of the vital pulp tissue will generally resolve the patient's pain.

Necrotic pulp tissue

Patients who present with pulp necrosis, with or without asymptomatic periradicular pathosis, for example, asymptomatic apical periodontitis, chronic apical abscess, or condensing osteitis, may be treated in one visit based on the best available information. When patients present with acute symptoms caused by pulp necrosis and acute periradicular abscess, obturation is generally delayed until the patient is asymptomatic. However, more than 30 years ago, investigators demonstrated that cases with soft-tissue swelling could be completed in one visit with appropriate endodontic treatment, incision for drainage, and a regimen of antibiotics.[277] Management of these patients, however, may be more difficult should problems persist or become worse after the completion of treatment.

During the 1970s, there was concern about the timing of obturation. Performing endodontic treatment in one visit was controversial. Conventional wisdom suggested that patients would have a higher incidence of posttreatment pain. However, clinical studies[185,213,298] and systematic reviews[175] indicated that there was no significant difference in the healing rates of apical periodontitis between single-visit and multiple-visit NS RCT. Patients experienced less frequency of short-term postobturation pain after single-visit than those receiving multiple-visit NS RCT.[281]

With the introduction of the concept of biofilms, other investigators examined the intracanal microbial status of 16 mesial roots of human mandibular first molars with primary apical periodontitis immediately after one-visit NS RCT.[190] In that study, the instrumented RCS were irrigated with 5.25% NaOCl and 17% ethylenediaminetetraacetic acid (EDTA), and obturated with GP and zinc oxide eugenol sealer. The apical portion of the root of each tooth was surgically removed and prepared for correlative light and transmission electron microscopy examination. Fourteen of the 16 root-treated teeth revealed residual intracanal infection after instrumentation,

Telegram: @dental_k

www.konkur.in

antimicrobial irrigation, and obturation. The microbes existed mostly as biofilms in inaccessible recesses of instrumented main canals, the intercanal isthmus, and accessory/lateral canals.

In a histobacteriological study, the in vivo microbiological status of the mesial roots of mandibular molars with primary apical periodontitis were examined after single-visit or two-visit NS RCT.[298] Those roots were instrumented and irrigated with 5% NaOCl, 17% EDTA, and 2% chlorhexidine. In the single-visit group, the RCS were immediately obturated, while in the two-visit group, calcium hydroxide ($Ca[OH]_2$) dressing was placed in the RCS for 1 week prior to obturation. In the single-visit group, no RCS, out of the six RCS examined, was completely free of bacteria. Residual biofilms were identified in the main RCS, isthmus, apical ramifications, and dentinal tubules. In the two-visit group, two out of seven roots were rendered bacteria-free. Residual biofilms were found predominantly in the isthmus and ramifications, intermixed with necrotic tissues and debris. Taken together, these studies illustrate that microbes are extremely difficult to eliminate within the complex RCS and continued endeavors have been made to improve microbiological status. Current evidence points out that the use of 5% NaOCl and 17% EDTA is efficacious in reducing microbes.[194] When one appointment is not achievable, the use of $Ca(OH)_2$ has been advocated as it remains the best medicament available to reduce residual microbial flora.[157] Calcium hydroxide has been advocated as an antimicrobial and temporary dressing in necrotic cases that cannot be treated in one visit[274] because investigators noted that bacteria in instrumented, unfilled RCS can multiply and reach their pretreatment numbers in 2 to 4 days.[48] Nevertheless, the ability of $Ca(OH)_2$ to completely eradicate microbial species from the RCS has recently been questioned. In vitro studies demonstrated that the antibacterial activity of $Ca(OH)_2$ can be inactivated by dentin.[116] Other clinical studies reported that the number of bacterial positive RCS did not decrease after the use of $Ca(OH)_2$ as an interappointment dressing.[222] A systematic review and meta-analysis of eight clinical studies concluded that $Ca(OH)_2$ is useful but have limited effectiveness in completely eliminating bacteria from human RCS when evaluated by culture techniques.[249] Although $Ca(OH)_2$ has a wide range of antimicrobial activity against common

Telegram: @dental_k

www.konkur.in

endodontic pathogens and is an effective antiendotoxin agent, it is less effective against *Enterococcus faecalis* and *Candida albicans*.[91,184] Alternative interappointment dressings such as the use of chlorhexidine gel, $Ca(OH)_2$ in chlorhexidine gel, or triple antibiotic paste (metronidazole, minocycline, and ciprofloxacin) has been proposed, with dichotomous results.[15,75,203,272,302] Although there are clinical trials to support the use of $Ca(OH)_2$ or alternative interappointment dressings, they do not reduce microbes beyond levels already achieved by canal preparation with NaOCl.[172,176,271] It is fair to say that interappointment antimicrobial dressings are fairly well accepted by clinicians in cases that cannot be treated in a single visit.

In general, obturation can be performed after C&S procedures when the RCS can be dried and the patient is not experiencing significant pain and or swelling. An exception is the presence or persistence of exudation from the canal. Obturation of an RCS that cannot be dried is contraindicated. Procedural concerns also dictate the time of obturation. Difficult cases may require more time for preparation and can be managed more uneventfully in multiple appointments. Patients may require multiple short appointments because of medical conditions, their psychological state of mind, and/or fatigue.

Length of obturation

One of the controversies in endodontics that remains unresolved is the apical limit of NS RCT and obturation.[194,231,255] Early studies identified the dentinocemental junction as the apical limit for obturation.[153] However, this histologic landmark cannot be determined clinically and it has been found to be irregular within the canal. For example, the dentinocemental junction may be several millimeters higher on the mesial canal wall when compared with the distal wall. Additionally, the dentinocemental junction does not coincide with the narrowest portion of the canal or apical constriction. The reader is referred to Chapter 7 for more information about this anatomy.

Traditionally, the apical point of termination has been approximately 1 mm from the radiographic apices as determined by radiographs. Kuttler[153] noted that the apical anatomy consists of the major diameter of the foramen and the

Telegram: @dental_k

www.konkur.in

minor diameter of the constriction (Fig. 9.3), with the apical constriction identified as the narrowest portion of the canal. The average distance from the foramen to the constriction was found to be 0.5 mm, with the foramen varying in distance from the apex up to 2.5 mm. Kuttler also noted that the foramen-to-constriction distance increases with age because of cementum deposition. Supporting this finding, other investigators reported that the location of the foramen was not at the apex. Deviations occurred in 92% of the roots and averaged 0.6 mm.[46] Another study noted the average apex-to-constriction distance was 0.9 mm and that 95% of the constrictions were between 0.5 and 1 mm in diameter.[85] This study also noted that the classic apical anatomy described by Kuttler was present in only 46% of teeth. Other variations identified were a tapering constriction, the multiconstriction, and the parallel constriction. Other investigators examined 230 roots of permanent teeth stereomicroscopically and with radiographs.[31] Results of this study indicated a deviation of the foramen from the apex in 76% of the roots with microscopy and 57% with radiography. The mean distance was 1 mm.

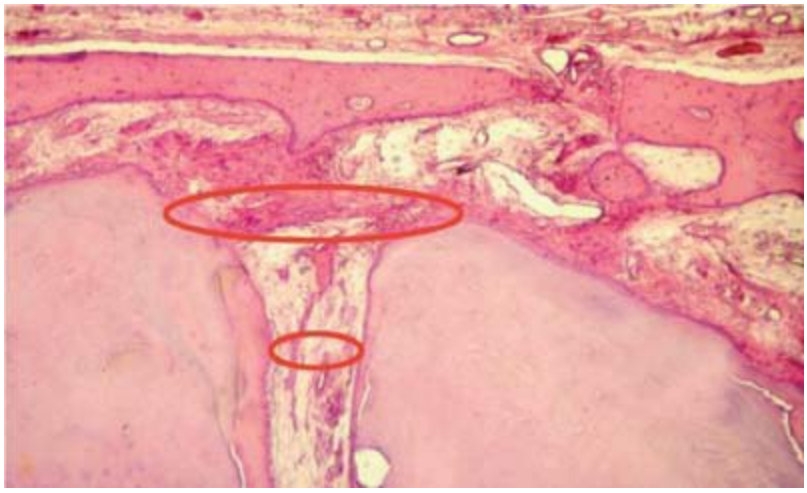

FIG. 9.3 Histologic section of a root apex, demonstrating anatomy of the classic foramen and constriction.

Micrograph of the upper part of root tip shows a hollow bony foramen and narrow constriction in the lower root both encircled in red ellipsoid.

The authors of a scanning electron microscopic study reported that no foramina coincided with the longitudinal axis of the root with the distance

Telegram: @dental_k

www.konkur.in

ranging from 0.2 to 3.8 mm (Fig. 9.4).[114] Another group of authors, using CBCT, reported that the most frequent position of the apical foramen was central but it varied.[90] Root resorption is an additional factor in length determination. Resorption is more common with pulp necrosis and apical bone resorption and this can result in loss of the constriction (Fig. 9.5).[94,173] On the basis of these findings, it appears that an RCS obturated to the radiographic apex reflect an overextension of the obturating material. If overextension occurs that cannot be retrieved, and there appears to be resultant nerve damage, the practitioner is obligated to refer the patient to a qualified practitioner skilled in cases of this type.[105]

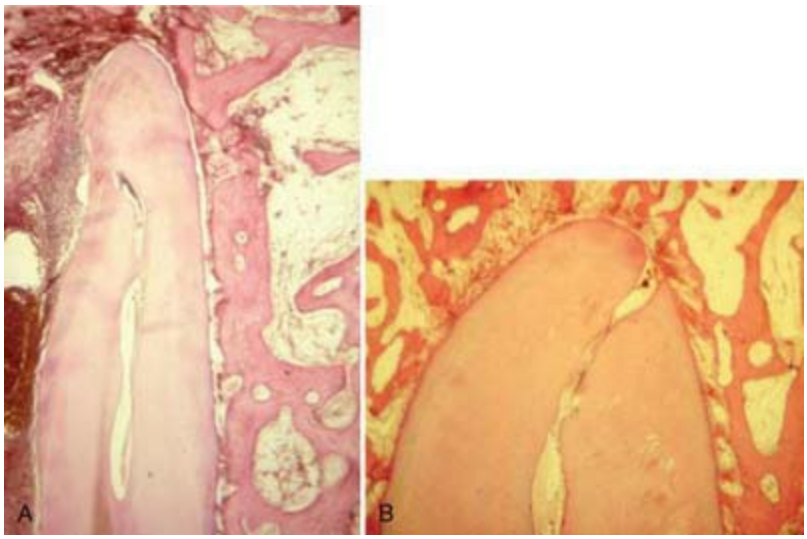

FIG. 9.4 Histologic sections demonstrating the foramen exiting short of the root apex.

FIG. 9.5 Scanning electron microscopy of a tooth exhibiting a necrotic pulp and apical pathosis and resorption.

Micrograph of a tooth shows a textured surface with two large hollow canals.

In a study by the Toronto group on the prognosis of retreatment identified perforation,[73] pretreatment periradicular disease and adequate length of the root canal filling were identified as factors significantly influencing healing or nonhealing outcomes. The authors speculated that canals obturated more than 2 mm short of the radiographic apex harbored necrotic tissue, bacteria, and irritants that, when retreated, could be cleaned and sealed. The success rate for negotiating the apical unfilled canal was 74%.

Controversy also exists regarding the role that accessory canals play in healing and nonhealing outcomes (Fig. 9.6). A scanning electron microscopy (SEM) study of the apical anatomy of each tooth group except third molars noted no pattern for foraminal openings.[113] The number of accessory canals ranged from 1 to 16. Although lateral canals can be associated with pathosis, one study that examined root-treated teeth from human cadavers reported no relationship between unfilled lateral canals and periradicular pathosis.[21] Accessory/lateral canals are often obturated by chance and only serendipitously identified on a posttreatment radiograph (Fig. 9.7).

Telegram: @dental_k

www.konkur.in

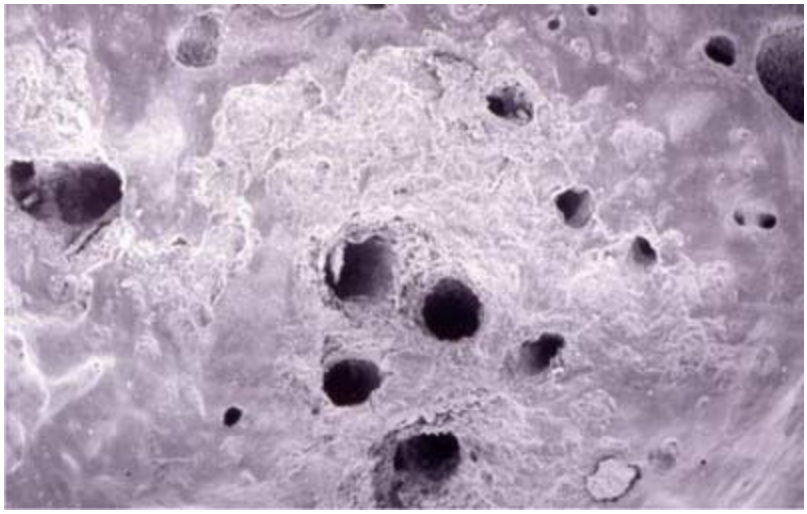

FIG. 9.6 Scanning electron microscopy of the apex of an extracted tooth that was removed because of pulp necrosis. Note the multiple accessory foramina and resorption.

Micrograph of a tooth shows an extremely textured surface with many holes of different sizes.

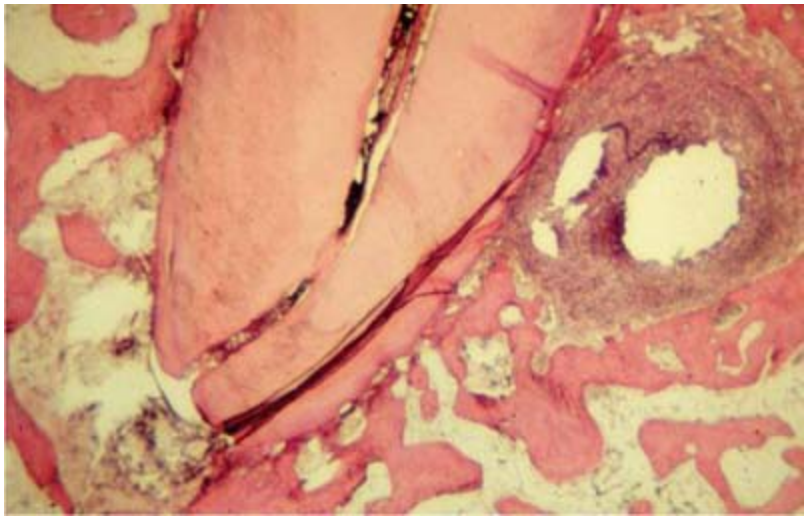

FIG. 9.7 Histologic section of a mesial root of a mandibular molar with a lateral canal present and associated lesion. Will the lesion resolve after the removal of the main canal contents, or will the lesion persist because of necrotic pulpal remnants in the lateral canal? The question remains unanswered.

Micrograph of a tooth with gingival surface shows a canal exiting through the root tip. A yellow patch with an outline of red is visible near the tooth.

Telegram: @dental_k

www.konkur.in

A subsequent histobacteriological study also found no evidence to support the concept that lateral canals must be obturated to achieve a healing long-term treatment outcome (Fig. 9.8).[236] In cases with vital pulps, forcing obturation materials into lateral canals resulted in unnecessary damage to the periradicular tissues with consequential inflammation. In cases with necrotic, infected pulps in which lateral canals appeared radiographically obturated, they were actually not sealed or disinfected. Moreover, the remaining tissue in the ramification was inflamed and enmeshed with obturation materials. This, however, does not mean that lateral canals should not be optimally debrided and disinfected by contemporary irrigant delivery and agitation techniques to reduce microbes and/or biofilms that reside within those spaces prior to obturation of the RCS with obturation materials and sealers.

FIG. 9.8 Posttreatment radiograph of a mandibular right first molar with a lateral canal associated with the distal root.

Radiograph of a tooth shows a radiopaque crown, neck, left canal and laterally segmented right canal.

The importance of length control in obturation relates to possible overextension of root filling materials. In a quantitative systematic review of the literature,[255] the authors critically analyzed 12 outcome studies that fulfilled the following criteria: (i) a minimum follow-up period of 2 years; (ii) data available on termination of obturation/instrumentation; (iii) adequate

Telegram: @dental_k

www.konkur.in

definition of treatment failure; (iv) data available on healing/nonhealing outcomes of NS RCT in relation to the obturation/instrumentation length; and (v) presence or absence of a periapical radiolucency. The 12 studies were classified into three categories based on the obturation length from the radiographic apex: (A) 0 to 1 mm; (B) >1 mm but <3 mm; and (C) obturated past the radiographic apex, including sealer. From the 12 studies, only 4 studies that included data that could be placed into the three length categories were further subjected to meta-analysis. Results of the meta-analysis indicated that the healing rate in group A (obturated 0 to 1 mm from apex) was marginally better than group C (obturated past apex) by 29%. Although group A demonstrated better healing than group B (obturated >1 mm short), the difference was not statistically significant. The authors concluded that a higher healing rate was achieved when treatment involved obturation short of the apex.

The aforementioned results derived from the sophisticated meta-analysis of multiple publications highlighted the data presented in the classic work performed by Sjögren and coworkers on healing of root-treated teeth with necrotic pulps and PL 8 to 10 years after treatment.[275] When those teeth were obturated within 2 mm of the apex, 94% revealed normal periapical conditions with the use of periapical radiography at the follow-up examination. Conversely, roots with overextended root fillings and those with obturations more than 2 mm short of the apex demonstrated significantly lower healing rates of 76% and 68%, respectively.

Similar results were also reported in a prospective clinical study on the healing[194] and survival[194] of teeth that had undergone primary or secondary NS RCT for 2 to 4 years. Absence of root-filling overextension was found to be a highly significant postoperative prognostic factor affecting the healing of both primary and secondary NS RCT.[194] With respect to tooth survival, overextension of GP obturations did not have any effect on tooth survival within the first 22 months but significantly increased the risk of tooth loss beyond 22 months.[194] This prognostic factor was common to both primary and secondary NS RCT. The authors attributed the delayed effect of overextension of GP obturations on tooth survival to the possibility of subcritical cracks created by excessive forces during compaction of GP, which eventually propagated during function and ultimately resulted in

Telegram: @dental_k

www.konkur.in

catastrophic failure.

On the basis of biologic and clinical principles, the conclusions derived from studies performed for more than two decades apart are all agreeable in that instrumentation and obturation should not extend beyond the apical foramen.[191] This was also demonstrated in a histological study that evaluated 41 human root-filled teeth from 36 patients.[234] In six cases exhibiting overextensions, histologic examination revealed severe inflammation.

Whereas the guideline of 1 mm from the radiographic apex remains rational when using radiographs, the point of apical termination of the preparation and obturation remains empirical. The use of an apex locator in conjunction with radiographs and sound clinical judgment makes this decision more logical. The need to compact the GP and sealer against the apical dentin matrix is necessary to prevent overextension of obturation materials into the periapical tissues. Deciding where the apical constriction of the RCS lies is based on the clinician's basic knowledge of apical anatomy, tactile sensation, radiographic interpretation, apex locators, apical bleeding, and, if not anesthetized, the patient's response.

Preparation for obturation

During the C&S process, organic pulpal materials and inorganic dentinal debris accumulate on the canal wall, producing an amorphous irregular smear layer (Fig. 9.9).[170,178,215] As shown in one of these studies, the smear layer is superficial, with a thickness of 1 to 5 μm.[178] This superficial debris can be packed into the dentinal tubules to various distances.[3]

Telegram: @dental_k

www.konkur.in

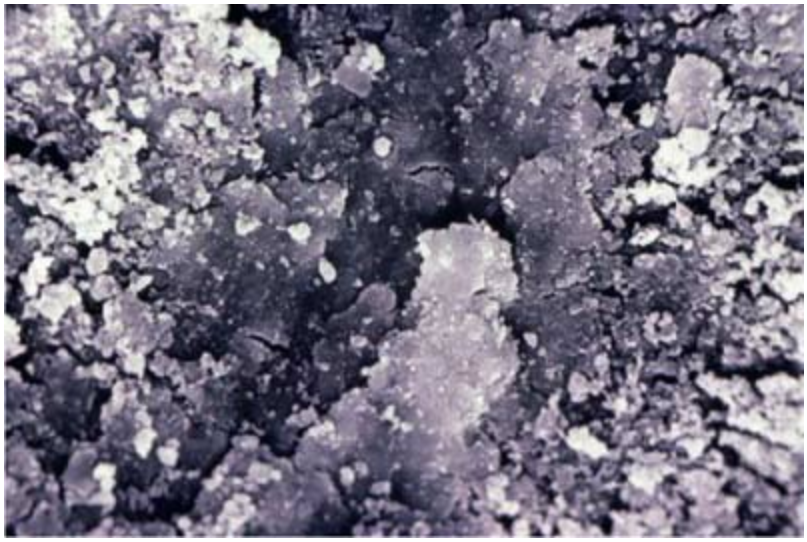

FIG. 9.9 Scanning electron microscopy of a prepared canal wall. The tubules are covered with a smear layer of organic and inorganic material.

Micrograph of a canal wall shows a granuled layer of smear over the wall surface.

In cases of pulpal necrosis, this layer may also be contaminated with bacteria and their by-products. For example, one study reported that bacteria can extend 10 to 150 μm into the dentinal tubules of necrotic teeth.[261] Another study noted that capillary action and fluid dynamics play a role in packing debris into the tubules.[5] Another investigation noted a mean penetration of 479 μm after a 28-day incubation period.[219]

The smear layer is not a complete barrier to bacteria but may act as a physical barrier, decreasing bacterial penetration into tubules. This was illustrated by a study reporting that removal of the smear layer permitted colonization of the dentinal tubules at a significantly higher rate when compared with leaving the smear layer in place.[82]

The smear layer may also interfere with adhesion and penetration of sealers into dentinal tubules.[305] Evidence indicates that sealer penetration into dentinal tubules does not occur when the smear layer is present.[99,211] For example, one study reported that removal of the smear layer permitted Roth 811 (Roth International, Ltd., Chicago, IL, USA), Calciobiotic root canal sealer (CRCS; Coltène/Whaledent, Cuyahoga Falls, OH, USA), and Sealapex (SybronEndo, Orange, CA, USA) to penetrate to between 35 and 80 μm,

Telegram: @dental_k

www.konkur.in

whereas the presence of the smear layer obstructed tubular penetration of all sealers.[297] Other studies reported that smear layer removal increased bond strength and reduced microleakage in teeth obturated with AH-26 (DENTSPLY Maillefer, Ballaigues, Switzerland).[86,100] Another investigation reported that a combination of smear layer removal, AH-26 as the sealer, and vertical compaction of GP had a cumulative effect in reducing leakage.[289]

There does not appear to be a consensus on removing the smear layer before obturation and the advantages/disadvantages of smear layer removal remains inconclusive.[59,262,265] However, growing evidence supports removal of the smear layer before obturation.[131,194,265] The organic debris present in the smear layer might constitute a substrate for bacterial growth.[215] It has been suggested that the smear layer prohibits sealer contact with the canal wall and permits leakage.[27] Bacterial penetration in the presence of a smear layer in RCS obturated with thermoplasticized GP and sealer has been shown to be significantly higher than with smear layer removal before obturation.[215] An additional consideration is the presence of viable bacteria that remain in the dentinal tubules and use the smear layer for sustained growth and activity.[39] Removal of the smear layer introduces the possibility of reinfecting the dentinal tubules if leakage occurs.[262] However, one study demonstrated that bacteria present before obturation are not viable after obturation.[77]

The smear layer may also interfere with the action of irrigants used as disinfectants.[204] When the smear layer is not removed, the dentinal tubules provide a long-term sanctuary for previously entrapped microorganisms to participate in reinfections. Additionally, the smear layer may slowly disintegrate and dissolve around leaking obturation materials or it may be removed by bacterial by-products such as acids and enzymes.[262]

The smear layer may interfere with the adhesion and penetration of root canal sealers. It also may prevent GP penetration during thermoplastic obturation techniques.[115] Significant tubular penetrations of GP and sealers have been reported with thermoplasticized obturations[115] and with dentin-bonded composite resins.[162] Removal of the smear layer also enhances the adhesion of sealers to dentin and tubular penetration.[162,201,262,304] Root canal filling materials adapt better to the canal walls after smear layer

Telegram: @dental_k

www.konkur.in

removal.[79,201,304,305]

An additional method for removing the smear layer involves sonic and ultrasonic instruments. In early studies of ultrasonic instrumentation, investigators noted the technique was effective in removing the smear layer.[69] Another investigator also demonstrated smear layer removal with ultrasonication and NaOCl.[53] One study compared the cleaning efficacy of short-term sonic and ultrasonic passive irrigation with 5.25% NaOCl after hand instrumentation in the apical 3 to 6 mm of maxillary molar root canals.[241] Passive sonic or ultrasonic irrigation for 30 seconds resulted in significantly cleaner canals than hand filing alone, and ultrasonic irrigation produced significantly cleaner canals than irrigation. However, other studies found ultrasonication and NaOCl to be ineffective in removing the smear layer.[23,300] In a more recent study, a group of investigators reported that the use of the Vibringe, EndoActivator, or needle irrigation did not significantly improve sealer penetration when compared with conventional irrigation.[36]

After the completion of C&S procedures, removal of the smear layer is generally accomplished by irrigating the canal with 17% disodium EDTA and 5.25% NaOCl (Fig. 9.10).[24] Chelators remove the inorganic components leaving the organic tissue elements intact. Sodium hypochlorite is necessary for removal of the remaining organic components. Citric acid has also been shown to be an effective method for removing the smear layer,[22,125] as has doxycycline[20] and tetracycline.[121]

Telegram: @dental_k

www.konkur.in

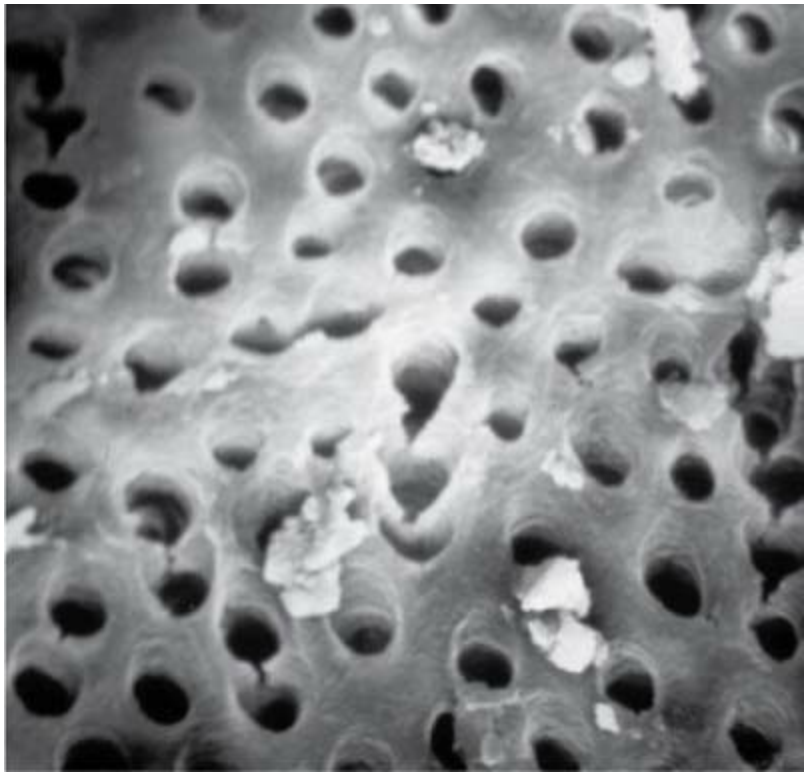

FIG. 9.10 Scanning electron microscopy of the canal wall after removal of the smear layer with 17% EDTA and 5.25% sodium hypochlorite.

Micrograph of a canal wall shows a porous surface with chunks of white fragments scattered over the surface and inside the pores.

Chelating agents were introduced to endodontic treatment by Nygaard-Østby in 1957 for treatment of calcified narrow RCS.[199] EDTA is the chelating solution customarily used in endodontic treatment. It is available in both liquid and viscous forms with common concentrations between 15% and 17%,[131] and its effectiveness is related to time, pH, and concentration.[199] Demineralization results in increased dentin permeability[112] because of the removal of the smear layer and plugs and enlargement of the tubules. It appears that the tubular enlargement is due to selective removal of the peritubular dentin.[129] The action of chelators and acids appears to be more effective in the coronal and middle thirds of the root and is reduced apically.[131,167] This reduced activity may reflect canal size.[210] This is a clinical concern because of the more irregular structure of dentin in the apical third. Another investigation demonstrated marked variations in the apical

Telegram: @dental_k

www.konkur.in

portion of the root,[183] including accessory RCS, areas of resorption and repaired resorptions, pulp stones, irregular or absent primary tubules, irregular secondary dentin, and cementum-like tissue lining the apical root canal wall. The variable structure of the apical region of human teeth presents challenges to the use of endodontic obturation techniques requiring adhesives, because this may influence the dentin bonding ability in the apical region.[183]

Although EDTA is mildly cytotoxic,[299] the irrigant appears to be biocompatible when used clinically;[199] however, irreversible decalcification of periapical bone and neuroimmunological disturbances have been noted.[259] EDTA decreases the microhardness of dentin.[67] Extrusion of both NaOCl and EDTA in clinical treatment should be avoided.[120,216,286]

The recommended time for removal of the smear layer is 1 to 5 minutes.[51,131,254] The small particles of the smear layer are primarily inorganic with a high surface-to-mass ratio that facilitates removal by acids and chelators. Investigators have found that a 1-minute exposure to 10 mL of EDTA was adequate to remove the smear layer and that a 10-minute exposure caused excessive removal of both peritubular and intratubular dentin.[51]

The use of EDTA in combination with NaOCl is recommended[24,316] and may enhance the cleaning[167] and antimicrobial effects of these solutions when compared with using them alone.[49] Although the use of EDTA alone does not cause erosion of the canal wall dentin, it should be noted the adjunctive use of NaOCl with EDTA may result in erosion of the intraradicular dentin depending on the timing and the concentrations of irrigants employed.[171,227,319]

New smear layer–removing irrigants are commercially available that combine calcium chelation of the inorganic component of the smear layer with antimicrobial activities. Examples of these irrigants include QMix 2in1 Irrigating Solution (DENSPLY Tulsa Dental Specialties).[16,70]

The ideal root canal obturation materials

Various endodontic materials have been advocated for obturation of the RCS.

Telegram: @dental_k

www.konkur.in

Most techniques employ a core material and sealer. Regardless of the core material, a sealer is essential to every technique and helps achieve a fluid-tight seal.

The American Association of Endodontists' *Guide to Clinical Endodontics* outlines contemporary endodontic treatment.[2] NS RCT of permanent teeth "involves the use of biologically acceptable chemical and mechanical treatment of the RCS to promote healing and repair of the periradicular tissues." The process is accomplished under aseptic conditions with rubber dam isolation. Regarding obturation, the guide states, "Root canal sealers are used in conjunction with a biologically acceptable semi-solid or solid obturating material to establish an adequate seal of the RCS." In this area, the guidelines indicate, "Paraformaldehyde-containing paste or obturating materials have been shown to be unsafe. Root canal obturation with paraformaldehyde-containing materials is below the standard of care for endodontic treatment" (Fig. 9.11). Chapter 27 gives further information about this issue.

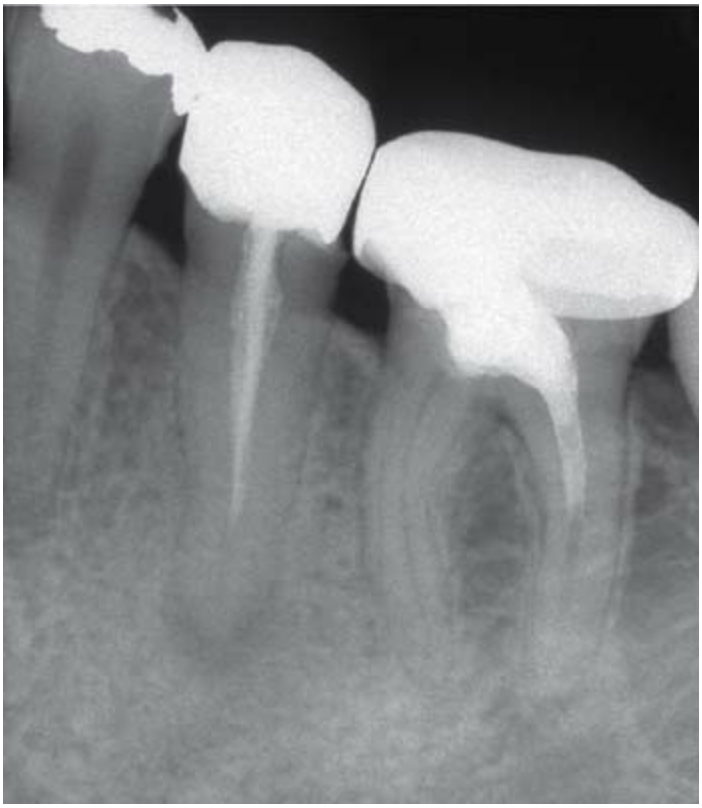

FIG. 9.11 A periapical radiograph of a mandibular left second premolar

Telegram: @dental_k

www.konkur.in

and first molar, demonstrating Sargenti paste NS RCT. In addition to the toxic material, the technique often accompanies inadequate C&S procedures.

Radiograph of a tooth shows a radiopaque crown, with dark neck and canals. An outline of canal filling paste is visible.

Assessment of nonsurgical treatment is based primarily on the posttreatment radiographic examination. The radiographic criteria for evaluating obturation include the following categories: length, taper, density, GP and sealer removal to the facial cementoenamel junction in anterior teeth and to the canal orifice in posterior teeth, and an adequate provisional or definitive restoration (Fig. 9.12).

FIG. 9.12 **A,** Posttreatment radiograph of a maxillary right first molar demonstrating adequate length, density, and taper. **B,** Posttreatment radiograph of a mandibular right first molar with an adequate obturation.

A) Radiograph of a tooth shows a radiopaque part of the crown, with radiolucent neck and canals.

Telegram: @dental_k

www.konkur.in

B) Radiograph of a tooth shows a radiopaque crown, with dark neck and radiopaque canals.

Quality assurance is accomplished through a careful evaluation of treatment procedures. Only by this approach can deficiencies be identified and corrected. Although the anatomy and morphology of RCS vary tremendously, the obturated RCS should reflect the original shape of the RCS. Procedural errors in preparation, such as loss of length control, ledging, apical transportation, apical perforation, stripping perforation, and separated instruments, may not be correctable. Errors in obturation, such as length, voids, inadequate removal of prior obturation materials, and temporization, may be correctable.

Radiographic interpretation may vary among clinicians because of differences in radiopacity in root canal sealer/cements, constituents in specific brands of GP, interpretation of voids in vivo versus in vitro,[318] the overlying bony anatomy, radiographic angulation, and the limited two-dimensional view of the obturated RCS.

An often overlooked aspect in the assessment of RCS obturation is the density of the apical portion of the obturation. The apical third of the RCS may be filled with a sea of root canal cement and a single master cone or poorly compacted mass of previously softened GP. Radiographically, the apical third of the canal appears less radiodense. An ill-defined outline to the canal wall is evident, along with obvious gaps or voids in the filling material or its adaptation to the confines of the RCS. Because of the use of highly radiopaque root canal sealers/cements, the apical portion may be filled only with sealer giving the clinician the false impression of a dense, three-dimensional obturation with GP.

Root canal sealers vary in radiopacity.[230,285] Some contain silver particles or significant amounts of barium sulfate to enhance their radiopacity. Although these components may enhance the visualization of anatomic structures such as lateral canals, it is important to realize they do not increase the sealing ability of the sealer and the quality of the obturation. They may also give the impression that an RCS is well obturated when voids are masked by the density of the sealer. It is erroneous to claim that obturations with highly radiopaque sealers are better than those made with less radiopaque materials. This type of comparison and claim to superiority are

Telegram: @dental_k

www.konkur.in

both unfounded and unwarranted. The radiographic appearance or aesthetic appearance of the obturated canal system should be secondary to meticulous C&S. Although assessment of the RCS obturation is based on radiographic findings, root canal sealers do not have to be highly radiopaque to be effective.

Types of sealers

Root canal sealers are necessary to seal the space between the dentinal wall and the obturating core interface. Sealers also fill voids and irregularities in the RCS, lateral and accessory canals, and spaces between GP points used in lateral compaction. Sealers also serve as lubricants during the obturation process. Grossman outlined the properties of an ideal sealer (Box 9.1).[110] Presently, no sealer satisfies all the criteria.

Box 9.1

Properties of an Ideal Sealer

- Exhibits tackiness when mixed to provide good adhesion between it and the canal wall when set
- Establishes a hermetic seal
- Radiopaque, so that it can be seen on a radiograph
- Very fine powder, so that it can mix easily with liquid
- No shrinkage on setting
- No staining of tooth structure
- Bacteriostatic, or at least does not encourage bacterial growth
- Exhibits a slow set
- Insoluble in tissue fluids
- Tissue tolerant; that is, nonirritating to periradicular tissue
- Soluble in a common solvent if it is necessary to remove the root canal filling

Sealers should be biocompatible and well tolerated by the periradicular

Telegram: @dental_k

www.konkur.in

tissues.[140] All sealers exhibit toxicity when freshly mixed; however, their toxicity is greatly reduced on setting.[142,155] Sealers are resorbable when exposed to tissues and tissue fluids, but not all extruded sealers are predictably removed from the periradicular tissues.[17,235] Tissue healing and repair generally appear unaffected by most sealers, provided there are no adverse breakdown products of the sealer over time.[35,40-42,44] Breakdown products from sealers may have an adverse effect on the proliferative capability of periradicular cell populations, specifically in the presence of the apical lesion.[235] As a result, sealers should not be placed routinely in the periradicular tissues as part of an obturation technique.

The most popular sealers are zinc oxide–eugenol formulations, $Ca(OH)_2$ sealers, glass ionomer sealers, resin-based epoxy resin or methacrylate resin sealers, and the recently introduced calcium silicate–based sealers. Despite claims by the manufacturers on the advantages of each class, there is no evidence-based data, based on randomized clinical trials, demonstrating the superiority of one sealer over another. Regardless of the sealer selected, all exhibit toxicity until they have set. For this reason, extrusion of sealers into the periradicular tissues should be avoided (Fig. 9.13).[246]

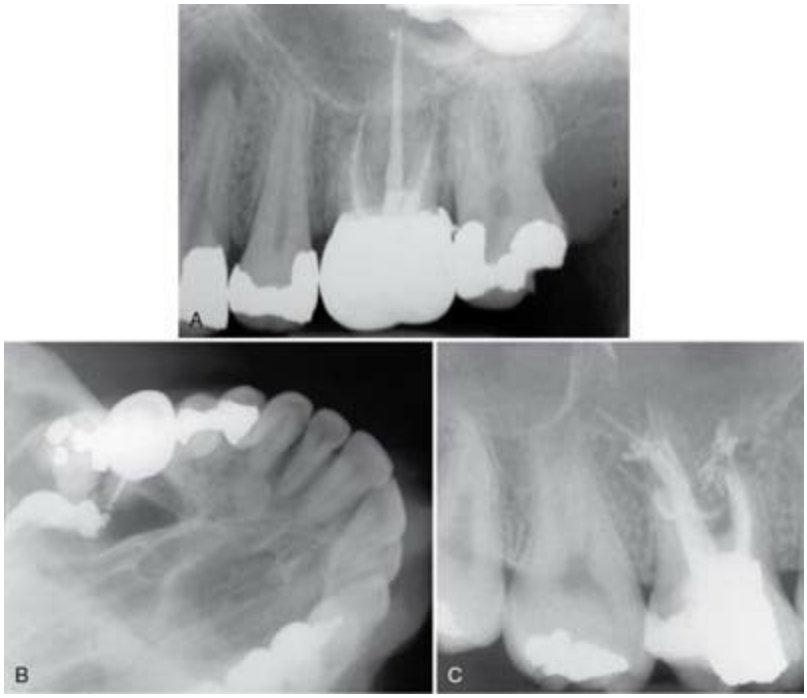

FIG. 9.13 **A,** Extrusion of sealer evident on the posttreatment

B) Radiograph of set of teeth shows a tooth with radiopaque crown. A radiopaque outline of the sealer is visible.

C) Radiograph of a tooth shows a radiopaque crown and irregular canals. A radiopaque outline due to the extrusion of the sealer is visible.

Zinc oxide and eugenol

Zinc oxide–eugenol sealers have a history of successful use over an extended period of time. Zinc oxide–eugenol sealers will resorb if extruded into the periradicular tissues.[17] They exhibit a slow setting time,[7] shrinkage on setting,[143] solubility,[221] and they can stain tooth structure.[151] An advantage to this sealer group is antimicrobial activity.[6,19,123]

Marketed as Pulp Canal Sealer (Kerr Endo) and Pulp Canal Sealer EWT (extended working time), this sealer is popular with clinicians using thermoplastic techniques.

Grossman modified the formulation and introduced a nonstaining formula in 1958 but it has been discontinued (Table 9.1),[111] but Pulp Canal Sealer EWT (>6 hours on the mixing pad) and EWT (Kerr) have a similar formulation. Tubli-Seal (Kerr) is a catalyst/base zinc oxide–eugenol sealer that is convenient to mix but has a faster setting time when compared with the liquid/powder sealers. Tubli-Seal EWT provides an extended working time.

Barium sulfate	15 parts
Sodium borate, anhydrous	1 part

Although zinc oxide–eugenol sealers possess marked cytotoxic and tissue-irrigating potencies in ex vivo cell culture studies,[142] their clinical usefulness has been well demonstrated in retrospective and prospective human clinical studies.[66,291] This discrepancy between the results of in vitro and in vivo cytotoxicity testing may be explained by the fact that most cell culture systems are represented by only one cell type, that is, no cell-cell interactions, which is often monoclonal in origin. Another important issue to consider is the fact that culture conditions are not homeostatic and there is no elimination of toxic substances as there would be in vivo. By contrast, the human body possesses a lymphatic system and periapical defenses such as polymorphonuclear leukocytes, plasma cells, and macrophages to help eliminate toxic substances.[55] These mechanisms do not exist in a culture plate and must be taken into account for interpretations of the results of cell culture-based cytotoxicity studies reported in the endodontic literature.

Calcium hydroxide sealers

Calcium hydroxide sealers were developed for therapeutic activity. It was thought that these sealers would exhibit antimicrobial activity and have osteogenic–cementogenic potential. Unfortunately, these actions have not been demonstrated.[78,184] Solubility is required for release of $Ca(OH)_2$ and sustained activity. This is inconsistent with the purpose of a sealer. CRCS is a zinc oxide–eugenol sealer with $Ca(OH)_2$ as one ingredient. Sealapex (SybronEndo) is a catalyst/base system. The base contains zinc oxide, $Ca(OH)_2$, butyl benzene, sulfonamide, and zinc stearate. The catalyst contains barium sulfate and titanium dioxide as radiopacifiers in addition to resin, isobutyl salicylate, and aerosol R972. Apexit and Apexit Plus (Ivoclar Vivadent, Schaan, Liechtenstein) consist of an activator (disalicylate, bismuth hydroxide/bismuth carbonate, and fillers) and a base [$Ca(OH)_2$, hydrated colophonium (i.e., pine resin) and fillers].

Although an osteogenic response has been observed with $Ca(OH)_2$-based root canal sealers,[128,276,284] the ability of these sealers to sustain a high pH

Telegram: @dental_k

www.konkur.in

over time and produce an alkaline pH at the root surface has been questioned.[89]

Better biocompatibility and osteogenic potential have been reported by $Ca(OH)_2$-producing tricalcium silicate-based root canal sealers than those with conventional $Ca(OH)_2$ sealers (Sealapex).[61]

Noneugenol sealers

Developed from a periodontal dressing, Nogenol (GC America, Alsip, IL) is a root canal sealer without the irritating effects of eugenol. The base contains zinc oxide, barium sulfate, and bismuth oxychloride.

Glass ionomer sealers

Glass ionomers have been advocated for use in obturation because of their dentin-bonding properties. Ketac-Endo (3M ESPE, Minneapolis, MN, USA) enables adhesion between the material and the canal walls.[98] It has been reported to have compatible outcomes compared with previous studies.[98] However, it is difficult to properly treat the dentinal walls in the apical and middle thirds with conditioning agents to receive the glass ionomer sealer. A disadvantage of glass ionomers is that they are more difficult to remove if retreatment is required.[187] This sealer has minimal antimicrobial activity.[63]

Activ GP (Brasseler USA) consists of a glass ionomer–impregnated GP cone with a glass ionomer external coating and a glass ionomer sealer (Fig. 9.14). Available in 0.04 and 0.06 tapered cones, the sizes are laser verified to ensure a more precise fit. This single cone technique is designed to provide a bond between the dentinal canal wall and the master GP cone that would be impregnated with glass ionomer filler particles resulting in an alleged monoblock.[95]

Close-up of two Activ gutta percha system shows two bottles in a liquid and powder combination with a set of gutta percha points coated with glass ionomer.

Resin sealers

Resin sealers have a long history of use, provide adhesion, and do not contain eugenol. There are two major categories: epoxy resin and methacrylate resin.

Epoxy resin sealers

AH-26 (DENTSPLY DeTrey, Konstanz, Germany) is a slow-setting epoxy resin that was found to release formaldehyde when setting.[149,278] AH Plus (DENTSPLY DeTrey) is a modified formulation of AH-26 in which formaldehyde is not released (Fig. 9.15).[163] The sealing abilities of AH-26 and AH Plus appear comparable. AH Plus is an epoxy resin-amine based system that comes in two tubes. The epoxide paste tube contains a diepoxide (bisphenol A diglycidyl ether) and fillers as the major ingredients, while the amine paste tube contains a primary monoamine, a secondary diamine, a disecondary diamine, silicone oil, and fillers as the major ingredients. It

Telegram: @dental_k

exhibits a working time of approximately 4 hours.

FIG. 9.15 AH Plus sealer is a resin formulation.

Close-up of two AH plus sealer tubes used for sealing root canals.

Methacrylate resin sealers

Four generations of methacrylate resin-based root canal sealers have been marketed for commercial use.[147,212] The first generation of hydrophilic methacrylate resin-based material (Hydron; Hydron Technologies, Inc., Pompano Beach, FL, USA) was designed for en masse obturations and appeared in the mid-1970s when scientific foundations behind dentin bonding were in their infancy stage of development. The major component of Hydron was poly [2-hydroxyethyl methacrylate] (poly [HEMA]), which was injected into an RCS and polymerized in situ within the RCS without the adjunctive use of a core obturation material. Hydron became obsolete in the 1980s as subsequent clinical outcomes were unacceptable.[156]

Following the marketing of self-priming, self-etching, and self-adhesive resin cement technologies in restorative dentistry, functionally analogous, low viscosity methacrylate resin-based root canal sealers have since been available for use in endodontics. This type of bondable root canal sealers has

Telegram: @dental_k

www.konkur.in

been aggressively promoted with the highly desirable property of creating monoblocks within the RCS space.[288] The term *monoblock* refers to the idealized scenario in which the canal space becomes perfectly filled with a gap-free, solid mass that consists of different materials and interfaces, with the purported advantages of simultaneously improving the seal and fracture resistance of an obturated RCS.

The second generation of bondable sealer is nonetching and hydrophilic in nature and does not require the adjunctive use of a dentin adhesive. It is designed to flow into accessory canals and dentinal tubules to facilitate resin tag formation for retention and seal after smear layer removal with NaOCl and EDTA. EndoREZ (Ultradent Products Inc., South Jordan, UT, USA) is a dual-cured radiopaque hydrophilic methacrylate sealer that contains nonacidic diurethane dimethacrylate. The addition of triethyleneglycol dimethacrylate to the sealer composition renders it hydrophilic, so that it may be used in the wet environment of the RCS and be very effective in penetrating dentinal tubules and forming long resin tags.[29,287] The sealer was found to seal best when applied to slightly moist intraradicular dentin.[324] EndoREZ is recommended for use with either a conventional GP cone or specific EndoREZ points that are resin-coated GP. A retrospective clinical and radiographic study evaluating the 10-year treatment outcome of one-visit NS RCT using GP and the EndoREZ sealer reported accumulative probability of success of 92.1% after 10 years.[323] The authors concluded that EndoREZ may be recommended as an alternative to other commonly used root canal sealers. Unfortunately, no additional root canal sealer was used in that study for comparison.

New generations of self-etching (third generation) and self-adhesive (fourth generation) resin cements have been introduced to restorative dentists to simplify bonding procedures. They became commercially available shortly after the introduction of those resin cement systems. The third-generation self-etching sealers contain a self-etching primer and a dual-cured resin composite root canal sealer. The use of self-etching primers reintroduced the concept of incorporating smear layers created by hand/rotary instruments along the sealer-dentin interface. An acidic primer is applied to the dentin surface that penetrates through the smear layer and demineralizes the superficial dentin. The acidic primer is air-dried to remove the volatile carrier

Telegram: @dental_k

www.konkur.in

and then a dual-cured moderately filled flowable resin composite sealer is applied and polymerized. Provided that these materials are sufficiently aggressive to etch through thick smear layers, the technique sensitivity of bonding to RCS may be reduced when smear layers are inadvertently retained in the apical third of instrumented canal walls.

Third-generation methacrylate resin-based sealers that incorporate the use of self-etching primers became popularized following the introduction of Resilon (Resilon Research LLC, Madison, CT, USA), a dimethacrylate-containing polycaprolactone-based thermoplastic root filling material.[266] Resilon has been removed from the market and is no longer available.

The fourth-generation methacrylate resin-based sealers (e.g., MetaSEAL, Parkell Inc., RealSeal SE, SybronEndo) is functionally analogous to a similar class of recently introduced self-adhesive resin luting cements in that they have further eliminated the separate etching/bonding step.[229] Acidic resin monomers that are originally present in dentin adhesive primers are now incorporated into the resin-based sealer/cement to render them self-adhesive to dentin substrates. The combination of an etchant, a primer, and a sealer into an all-in-one self-etching, self-adhesive sealer is advantageous in that it reduces the application time as well as errors that may occur during each bonding step. MetaSEAL is the first commercially available fourth-generation self-adhesive dual-curable sealer.[158] The sealer purportedly bonds to thermoplastic root-filling materials as well as radicular dentin via the creation of hybrid layers in both substrates. MetaSEAL is also marketed as Hybrid Bond SEAL (Sun Medical Co. Ltd., Shiga, Japan) and had been reported to produce equivalent or slightly inferior sealing properties as conventional nonbonding epoxy resin-based sealers.[28,202]

Silicone sealers

RoekoSeal (Coltène/Whaledent AG, Altstätten, Switzerland) is a polydimethylsiloxane that has been reported to expand slightly on setting.[205]

GuttaFlow and GuttaFlow2 (Coltène/Whaledent) are cold flowable matrices that are triturated. They consist of GP in a particulate form less than 30 μm added to RoekoSeal (Fig. 9.16). The material is provided in capsules for trituration. The technique involves injection of the material into the RCS, followed by placement of a single master cone. The material provides a

Telegram: @dental_k

www.konkur.in

working time of 15 minutes and it cures in 25 to 30 minutes. Evidence suggests that the material fills canal irregularities with consistency[320] and is biocompatible,[65,174] but the setting time is inconsistent and may be delayed by final irrigation with sodium hypochlorite.[37]

FIG. 9.16 GuttaFlow trituration capsule and injection syringe (Coltène/Whaledent, Cuyahoga Falls, OH).

Close-up of the gutta flow trituration system shows a cylindrical capsule with a cap and a gun-shaped injection syringe with a metallic barrel and V-shaped trigger point.

GuttaFlow bioseal, the most recent introduction to this family of silicone sealers, incorporates bioactive ingredients such as calcium and silicate into the original formulation, which is claimed by the manufacturer to stimulate tissue healing and regeneration.[52] A recent study reported that GuttaFlow bioseal promotes spontaneous differentiation of human periodontal ligament stem cells into cementoblast-like cells in the absence of adjunctive growth factors.[238] If these results can be validated in in vitro experiments, GuttaFlow bioseal should have the potential to promote the regeneration of the cementum in teeth with apical periodontitis or chronic abscess.

Tri/dicalcium silicate sealers

Root canal sealers based on tricalcium silicates and dicalcium silicates are the

Telegram: @dental_k

www.konkur.in

latest group of bioactive root canal sealers introduced for obturation of an RCS.[135] These sealers are an outgrowth of the popularity of mineral trioxide aggregate (MTA) materials, which are based on tricalcium silicate and dicalcium silicate, a water-setting hydraulic powder used for various surgical and vital pulp therapy treatments.[18,214,292] This type of root canal sealer is attractive because of the bioactivity that has been reported for MTA-type materials,[198] which are also known for being hydrophilic.[54]

MTA is a hydraulically active powder that contains primarily tricalcium silicate, dicalcium silicate, and a radiopaque powder, often bismuth oxide. Because of staining of crown dentin by the bismuth oxide component, which may be rendered brown in the presence of NaOCl, gray in the presence of chlorhexidine, or even black in the presence of glutaraldehyde, the radiopacifier has now been replaced with other materials such as zirconia dioxide or tantalum oxide in some commercial formulations. The radiopaque agent, bismuth oxide, zirconia, or tantalum oxide, is important, without which MTA would not be distinguishable on a radiograph. Minor phases of tricalcium aluminate and calcium sulfate are often present. Some MTA-type products contain calcium carbonate, or tetracalcium aluminoferrite. The term MTA is used here to denote all the tri- and dicalcium silicate products.

Tri/dicalcium silicate cements/sealers are set by reaction with water and form a highly alkaline (pH ; 12) mixture consisting of a rigid matrix of calcium silicate hydrates and $Ca(OH)_2$.[68,71] These hydrates form on the surface of the original calcium silicate particles, and hydration gradually penetrates inward. When a tricalcium silicate cement sets, the dimensional change is less than 0.1% expansion, which helps with creating a barrier, which is especially important for its use during endodontic treatment. Setting time for tricalcium silicate cements is lengthy, about 165 minutes for the initial set and less than 6 hours for the final set, which has been a major drawback for using them in some indications, but not for its use as a sealer. During the early stage of development, the inconsistency of MTA products with water has rendered it not suitable for use as a sealer. Additionally, the coarseness of the first MTA products, intended for surgical uses, made them unsuitable for use as a sealer, as their film thickness was too high (>50 μm).

To date, many tri/dicalcium silicate-based sealers have been available commercially (Figs. 9.17–9.19).[135,166,179,267,296,301]

Product	Manufacturer	System	Composition	Radiopacifier
NeoMTA Plus	Nu Smile, Houston, TX, USA	Powder/water-based gel	Tri/dicalcium silicate	Ta_2O_5
NeoSealer		Organic liquid paste in Syringe	Tri/dicalcium silicate	Ta_2O_5
BioRoot RCS	Septodont, Saint-Maur-des- Fossés, France	Powder/water-based liquid	Tri/dicalcium silicate	ZrO_2
iRoot, EndoSequence BC, Edge Endo, TotalFill BC sealer	Innovative BioCeramix Inc.; Brasseler USA	Organic liquid paste in syringe	Tri/dicalcium silicate	ZrO_2, Ta_2O_5
Endo CPM sealer	EGEO SRL Buenos Aires, Argentina	Powder/liquid	Tri/dicalcium silicate	Bi_2O_3, $BaSO_4$
MTA Fillapex	Ângelus Indústria de Produtos Odontlógicos Ltda	Dual paste	Disalicylate resins	Bi_2O_3
Bio-C		Organic liquid paste in syringe	Tri/dicalcium silicate	ZrO_2
Seal Plus BC	MK Life, Porto Alegre, RS, Brazil	Organic liquid paste in syringe	Tri/dicalcium silicate	ZrO_2

iRoot SP (EndoSequence BC Sealer), TotalFill Sealer, and Bio-C Sealer are premixed sealers. MTA Fillapex and Seal Plus BC are available as two paste syringes that are combined in a mixing tip. BioRoot RCS, Endo CPM Sealer, and MTA Plus sealers are powder/gel systems that the user can mix to the consistency desired. The available materials' manufacturers descriptions are vague. For example, MTA Fillapex has "natural or diluent resins," with "filler and thickening agents." However, what is believed to be in common is that tricalcium silicate powder is a component of all these sealers.

The MTA Fillapex and iRoot SP sealers have nonaqueous vehicles in which the powders are dispersed. For the tricalcium silicate particles to contribute to sealing, they must become hydrated in the tooth by exchange of the nonaqueous vehicle for water in the RCS. EndoCPM Sealer and MTA Plus sealer rely on mixing with water-based gels just before use without a nonaqueous resin. The proportions of the tricalcium silicate powders are not known in any of these materials but are most likely to be highest in MTA Plus because no inert liquid vehicle is included. The inert vehicle is the liquid medium in the pastes of MTA Fillapex and iRoot SP that does not react with the powder. The bioactivity of MTA-type materials has made the use of tricalcium silicate powders in sealers of interest. The possibility of overextension past the apex with a bioactive material leads to the supposition that healing in the periapical area would occur more readily with a tricalcium

Telegram: @dental_k

www.konkur.in

silicate product. However, two of the sealers have the tricalcium silicate powders dispersed in a nonreactive organic medium, which may detract from the potential benefit of the bioactive powder. To date, no peer-reviewed papers have been published to establish the benefits of tricalcium silicate powders in sealers in human clinical studies. All studies and reports were based on in vitro testing and in vivo animal models. Calcium carbonate is added to Endo CPM Sealer to reduce the pH from 12.5 to 10.0 after setting. By doing so, the manufacturer claimed that surface necrosis in contact with the material is reduced, thereby optimizing the conditions for the enzymatic action of alkaline phosphatase.[107]

The physical properties of some of these sealers have been published. Table 9.3 contains values that are known for comparison to the ISO 6876/ADA 57 methods and requirements and the AH Plus sealer. The flow, film thicknesses, solubility, dimensional stability, and radiopacity of the new sealers meet the ISO 6876 requirements. The flow of these sealers varies, but so do the values for AH Plus. The dimensional stability is excellent. The solubility of the sealers is higher than AH Plus, which may be attributed to the formation of partially soluble $Ca(OH)_2$ within the set tricalcium silicate. The radiopacities are less than AH Plus, which is known for its radiopacity.

§Antimicrobial effect against the Enterococcus faecalis.

MTA, Mineral trioxide aggregate; *NR*, no requirement.

The working and setting times of the iRoot SP and MTA Plus materials are longer than the MTA Fillapex sealer. iRoot SP has the longest setting time and requires diffusion of water from the dentinal tubules into the sealer to set.[188] In a test where water was added to the EndoSequence BC sealer (iRoot SP), the setting time was reduced to about 150 hours but the hardness was significantly diminished.[168] The EndoSequence BC sealer has been tested for strengthening teeth when used with glass ionomer-coated cones and has been found to be stronger in vitro.[102]

Biocompatibility tests have been performed with some of these sealers. EndoSequence BC sealer was more cytotoxic than AH Plus root canal sealer. The time to become non-cytotoxic as judged from mitochondrial enzymatic activity using succinic dehydrogenase was 5 weeks for EndoSequence BC sealer and 3 weeks for AH Plus sealer.[168] Another study reported that, after setting, the cytotoxicity of MTA Fillapex decreased and the sealer presented suitable bioactivity to stimulate hydroxyapatite nucleation.[61,245] A calcium silicate-based sealer possesses a higher modulus of elasticity than AH Plus sealer, unmodified and modified GP cones, and provided better adhesion and sealer penetration at the apical area.[206] A recent systematic review evaluated the biocompatibility of different bioceramic materials in both human and animal mesenchymal cells and reported that all tricalcium silicate materials have similar biological properties to those of MTA, including low cytotoxicity, promotion of cell adhesion and proliferation, and reduced inflammatory cytokines, cells, and mediations.[76] Thus, given the similarity, the choice of bioceramic material should be a professional's decision.

To date, no peer-reviewed papers have been published to establish the benefits of tricalcium silicate powders in sealers in human clinical studies. All studies and reports were based on in vitro testing and in vivo animal models. Despite the lack of well-designed long-term clinical trials, the premixed calcium silicate-based sealers show good physicochemical and biological properties in vitro, with results similar or better than conventional

root canal sealer sealers, as observed in in vitro and in vivo animal studies.[268]

A concern associated with the use of tri/dicalcium silicate sealers is the potential difficulty in retreating a hard material.[126,150] It has to be remembered though that, similar to the recommendations for other root canal sealers, a tri/dicalcium sealer is supposed to be employed as a thin film instead of being used en bloc, for both single cone and lateral compaction techniques. For retreatment of root canals that had been filled with GP and tri/dicalcium silicate sealers, removal of the sealer remnants and the regaining of apical patency were no worse than with epoxy or resin-based sealers.[57,192]

Medicated sealers

Sealers containing paraformaldehyde are strongly contraindicated in endodontic treatment (Fig. 9.20). Although the lead and mercury components may have been removed from these zinc oxide–eugenol formulations over time, the severely toxic paraformaldehyde content has remained a constant. These sealers are not approved by the U.S. Food and Drug Administration[1] and are unacceptable under any circumstances in clinical treatment because of the severe and permanent toxic effects on periradicular tissues.[263] A paste containing 6.5% paraformaldehyde as well as lead and mercury was advocated for use by Sargenti[248] and originally marketed as N-2. Lead has been reported in distant organ systems when N2 is placed within the radicular space.[207] In another study the investigators reported the same results regarding systemic distribution of the paraformaldehyde component of N2.[32] Removal of the heavy metals resulted in a new formulation: RC2B. Other paraformaldehyde sealers include Endomethasone, SPAD, and Reibler's paste. The toxic in vivo effects of these materials on the pulp and periapical tissues have been demonstrated over time.[64,193]

www.konkur.in

osteomyelitis and paresthesia,[88] where irreversible neurotoxicity has manifested as dysesthesia as a result of paraformaldehyde being forced through the apical foramen into the periapical tissues.[148] The reader is referred to Chapter 27 for further discussion about this harmful material and technique.

Sealer placement

Various methods of sealer placement have been advocated, including a master cone, lentulo spiral, a file and/or reamer, and ultrasonics. Investigators compared sealer placement using a file rotated counterclockwise, the lentulo spiral (Fig. 9.21), an ultrasonic file, and coating the master GP cone.[306] Placement did not differ with the various techniques. However, the investigators noted the most variation in sealer coating was in the apical area.[306] Another study compared sealer placement with a K-type file, the lentulo spiral, and using the master cone in curved canals. Results demonstrated no significant differences in the techniques after obturation. No technique covered more than 62.5% of the RCS.[118] Other investigators reported that ultrasonics produced the best sealer distribution when used circumferentially.[3,279] In the past, it has been presumed that instrumented RCS need to be thoroughly dried prior to obturation with root filling materials and sealers. Indeed, there were leakage studies reporting that a better apical seal might be achieved by drying the canals with 95% ethanol prior to obturation.[280] A recent study reported that, for some sealers (iRoot SP, AH Plus, Epiphany, and MTA Fillapex), better adhesion to the dentinal walls might be achieved by leaving the canals slightly moist. This can be accomplished by drying the RCS with low vacuum via a Luer adapter for 5 seconds followed by insertion of a paper point for 1 second.[188] Similar results were also reported with the use of the EndoREZ sealer.[324] This, however, does not mean that a RCS should remain totally flooded with water prior to obturation because such a level of residual moisture would adversely affect the adhesive of those root canal sealers to intraradicular dentin.[188]

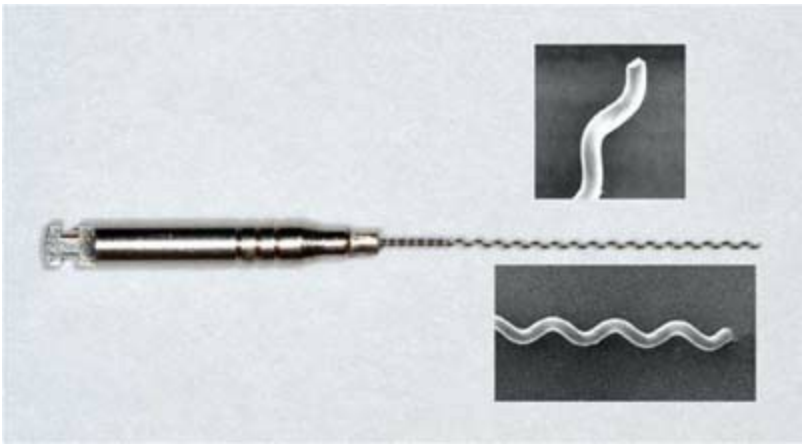

FIG. 9.21 Lentulo spiral used for sealer placement during obturation.

Close-up shows a lentulo spiral instrument with a metallic handle, a spiral body and an almost flat tip.

The method of obturation does not seem to affect the sealer distribution on the canal wall in the apical portion of the canal. However, lateral compaction results in better distribution in the midcoronal areas when compared with warm vertical compaction.[312] Another well-controlled study reported that none of five evaluated obturation techniques resulted in uniform sealer distribution along the entire length of the core obturation material.[130] Evidence indicates that the method of obturation affects the sealer penetration into tubules. This was exemplified by a study reporting that thermoplastic techniques produced deeper sealer penetration into tubules.[74] Removal of the smear layer enhances sealer penetration into the dentinal tubules.[152]

Core materials

Although a variety of core materials have been used in conjunction with a sealer/cement, the most common method of obturation involves GP as a core material. Regardless of the obturating technique, emphasis should be placed on the process of C&S the RCS. The materials and techniques described do not routinely create an impervious seal of the RCS. All materials leak to some extent.[4] The choice of the obturation technique(s) depends on the unique circumstances with which each case presents.

The properties of an ideal obturation material have been outlined by Grossman (Box 9.2).[110] Historically, a variety of materials have been

Telegram: @dental_k

www.konkur.in

employed to obturate the RCS. Solids, semisolid materials, and pastes have been employed. A common solid material used in the past was the silver cone.

Box 9.2

Properties of an Ideal Obturation Material

- Easily manipulated and provides ample working time
- Dimensionally stable with no shrinkage once inserted
- Seals the canal laterally and apically, conforming to its complex internal anatomy
- Nonirritating to the periapical tissues
- Impervious to moisture and nonporous
- Unaffected by tissue fluids—no corrosion or oxidization
- Inhibits bacterial growth
- Radiopaque and easily discernible on radiographs
- Does not discolor tooth structure
- Sterile
- Easily removed from the canal if necessary

Silver cones

Jasper introduced cones made of silver, which he claimed produced the same success rate as GP and were easier to use.[136] The rigidity provided by the silver cones made them easier to place and permitted more predictable length control; however, their inability to fill the irregularly shaped RCS permitted leakage (Fig. 9.22). Silver cones were believed to possess an oligodynamic property which, if true, would have resulted in the destruction of microbes within the RCS. Unfortunately, it was not true. Moreover, when silver points contact tissue fluids or saliva, they corrode.[38] The corrosion of such products has been found to be cytotoxic and produces pathosis or impedes periapical healing.[260]

FIG. 9.22 Silver cones have been advocated for ease of placement and length control. **A,** Radiograph of a maxillary right central incisor obturated with a silver cone. **B,** Tissue discoloration indicating corrosion and leakage. **C,** Lingual view indicates coronal leakage. **D,** Corroded silver cone removed from the tooth. **E,** Posttreatment radiograph of the tooth.

A) Radiograph shows a tooth with two radiolucent patches on the crown. A radiopaque patch is visible on the central crown with a radiopaque canal. A radiopaque outline of the silver cone is visible.

B) Close-up of a frontal set of central incisors shows a black patch under labial frenulum.

C) Close-up of a posterior set of central incisors shows a part of the silver cone exposed from a thinned right incisor.

D) Close-up of a removed cylindrical cone with silver ends and black center.

E) Radiograph shows a tooth with segmented radiopaque crown, radiolucent neck and radiopaque canal.

With the introduction of rigid silver cones, it became possible to easily place them to length. This resulted in clinicians often failing to properly clean

Telegram: @dental_k

www.konkur.in

and shape RCS before obturation. Treatment failures were the result of leakage and failure to remove the irritants from the RCS. The use of silver cones today is considered to be below the standard of care in contemporary endodontic practice. For further information about this material and technique, the reader is referred to Chapter 27.

Gutta-percha

GP is the most popular core material used for obturation. Major advantages of GP are its plasticity, ease of manipulation, minimal toxicity, radiopacity, and ease of removal with heat or solvents. Disadvantages include its lack of adhesion to dentin and, when heated, shrinkage upon cooling. GP is the *trans*-isomer of polyisoprene, natural rubber, and exists in two crystalline forms, α and β.[108] In the unheated β phase, the material is a solid mass that is compactable. When heated, the material changes to the α phase and becomes pliable and tacky and can be made to flow when pressure is applied. A disadvantage to the α phase is that the material shrinks on setting.[257]

GP cones consist of approximately 20% GP, 65% zinc oxide, 10% radiopacifiers, and 5% plasticizers.[96] Attempts have been made to make GP more antimicrobial, but the clinical effectiveness of adding these materials has not been demonstrated. Moreover, to exert an antimicrobial pharmacological effect, the active ingredient must leach out of the GP, which could have a detrimental effect on long-term sealability.

Unlike rubber, room temperature GP cannot be compacted or made to flow. Compaction results in transmission of forces to the material and the canal wall equally and may result in root fracture. GP can be made to flow if it is modified by either heat or solvents such as chloroform. This permits adaptation to the irregularities of the canal walls.

The α form of GP melts when heated above 65°C. When cooled extremely slowly, the α form will recrystallize. Routine cooling results in the recrystallization of the β form. Although the mechanical properties for the two forms are the same, when α-phase GP is heated and cooled, it undergoes less shrinkage, making it more dimensionally stable for thermoplasticized techniques. The use of α-phase GP for obturation has increased as thermoplastic techniques have become more common.

GP cones are available in standardized and nonstandardized sizes.

Telegram: @dental_k

www.konkur.in

Standardized sizes conform to requirements contained in specification published by the International Organization of Standardization (ISO) or ADA American National Standards Institute (ADA ANSI). The nonstandard nomenclature refers to the dimensions of the tip and body (Fig. 9.23). A fine-medium cone has a fine tip with a medium body. Standardized cones are designed to match the taper of stainless steel and nickel titanium instruments (Figs. 9.24 and 9.25). A size 40, 0.04 cone has a tip of 0.4 mm and a taper of 0.04 mm per millimeter. Unfortunately, ISO and ADA ANSI standards allow tolerances and, coupled with less-than-completely accurate manufacturing processes, the actual cone size varies as does the tip and taper of the master apical file.[106]
