Activ GP (Brasseler USA) consists of GP cones impregnated on the external surface with glass ionomer (see Fig. 7.14). Single cones are used with a glass ionomer sealer. Available in 0.04 and 0.06 taper cones, the sizes are laser-verified to help ensure a more precise fit. The single cone technique is designed to provide a bond between the dentinal canal wall and the master cone. A bacterial leakage study comparing Activ GP/glass ionomer sealer, Resilon/Epiphany, and GP/AH Plus demonstrated no statistically significant differences in leakage at 65 days.[95]

Custom cones

When the apical foramen is excessively large or the prepared RCS is large, a custom cone may need to be fabricated (Fig. 9.26). This permits the adaptation of the cone to the canal walls, reduces the potential for extrusion of the core material, and may improve the resultant seal.[26,180] The technique involves selection of a master cone and fitting that cone 2 to 4 mm short of the prepared length with frictional resistance. The cone is grasped with locking cotton pliers or a hemostat so that it can be placed into the RCS in the same spatial relationship each time. The tip of the GP cone is removed and the resultant new tip is softened in chloroform, eucalyptol, or halothane for 1 or 2 seconds, depending on the clinical requirements. Only the outer superficial portion of the cone is softened. The central core of the cone should remain semirigid. The cone is then placed back into the RCS to the working length. The process can be repeated until an adequate impression of the canal is obtained at the prepared length. A radiograph is exposed to verify proper fit and position. An alternative to solvents is softening with heat.[145]

F) Radiograph shows a tooth with a radiopaque crown, radiopaque upper canal and radiolucent lower canal.

A large RCS may necessitate the custom fabrication of a large master cone before canal adaptation. This may be accomplished by heating two, or more, large GP cones and rolling the mass between two glass slabs until an appropriate size is obtained (Fig. 9.27). A spatula may also be used to shape the cone.

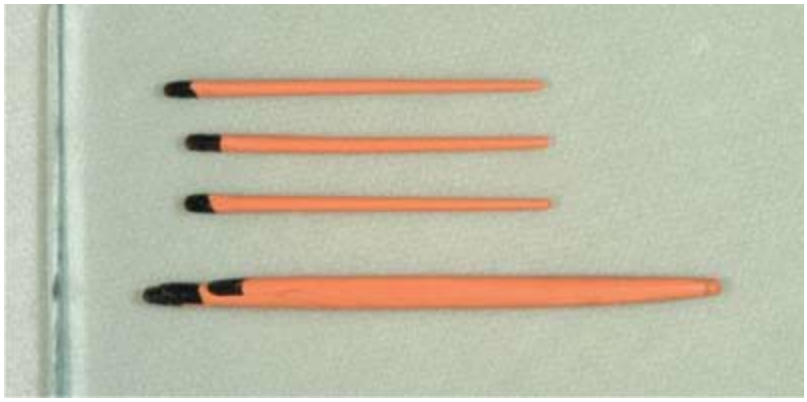

FIG. 9.27 For large RCS, several GP points can be heated and rolled together, using a spatula or two glass slabs.

A set of three smaller and one large gutta percha points.

Methods of obturation

To date, little evidence exists to support one method of obturation as being superior to another based on outcome assessment investigations.[14,195] The prospective Toronto studies have suggested that warm vertical compaction may be superior to lateral compaction.[73] However, definitive evidence is lacking.[218]

Lateral compaction

Lateral compaction is a common method for obturation (Figs. 9.28 and 9.29).[50] The technique can be used in most clinical situations and provides for predictable length control during compaction.[103] A disadvantage is that

Telegram: @dental_k

www.konkur.in

the technique may not fill canal irregularities[315] as well as warm vertical compaction or other thermoplastic techniques.[309] The procedure can be accomplished with any of the acceptable sealers.

After RCS preparation, a standard cone is selected that has a tip and taper consistent with the prepared canal diameter at the working length established by the master apical file. Standard cones generally have less taper when compared with nonstandard cones and will permit deeper spreader penetration, which will result in a better-quality resultant seal.[220] An alternative is to adapt an appropriately tapered nonstandard cone by cutting small increments from the tip. This “master cone” is measured and grasped with forceps so that the distance from the tip of the cone to the reference point on the forceps is equal to the prepared length. A reference point on the cone can be made by pinching the cone. The cone is placed into the RCS and, if an appropriate size is selected, there will be resistance to displacement or “tug back.” If the cone is loose, it can be adapted by removing small increments from the tip. If the master cone fails to go to the prepared length a smaller cone can be selected. Devices are available to cut cones accurately at a predetermined length (Tip Snip; SybronEndo). When the cone extends beyond the prepared length, a larger cone must be adapted or the existing cone shortened until there is resistance to displacement at the corrected working length.

The master cone placement is confirmed with a radiograph. The canal is irrigated and dried with paper points. Sealer is applied to the canal walls and a spreader is prefit so as to allow it to be inserted to within 1 to 2 mm of the working length. Appropriately sized accessory points are also selected to closely match the size of the spreader to be used. The correlation between spreader size and nonstandard cones is variable,[43,322]

Telegram: @dental_k

www.konkur.in

Finger spreaders may provide better tactile sensation and are less likely to induce fractures in the root when compared with the more traditional D-11T hand spreader.[164] In addition to the type of spreader, forces applied, and amount of dentin removed, spreader size may be a factor in root fracture, with large sizes inducing more stress.[225] Spreaders made from nickel titanium are available and provide increased flexibility,[30] reduced stress,[101] and deeper penetration when compared with stainless steel instruments.[258] The spreader should fit to within 1 to 2 mm of the prepared length, and, when introduced into the RCS with the master cone in place, it should be within 2 mm of the working length.[8] There appears to be a correlation between the establishment of a higher quality seal and the depth of spreader penetration.[8]

After the spreader has been placed to its maximum depth, it is removed by rotating it back-and-forth as it is withdrawn. An accessory cone is placed in the space vacated by the spreader. The process is repeated until the spreader no longer goes beyond the coronal one third of the canal. The excess GP is removed with heat and the coronal mass is compacted with an appropriate unheated plugger. Only light pressure is required during lateral compaction because the GP is not condensed, and because as little as 1.5 kg of pressure is capable of fracturing a root (Fig. 9.30). In addition to the force applied, investigators have noted that removal of excessive amounts of dentin during preparation is a significant factor in root fracture.[307]

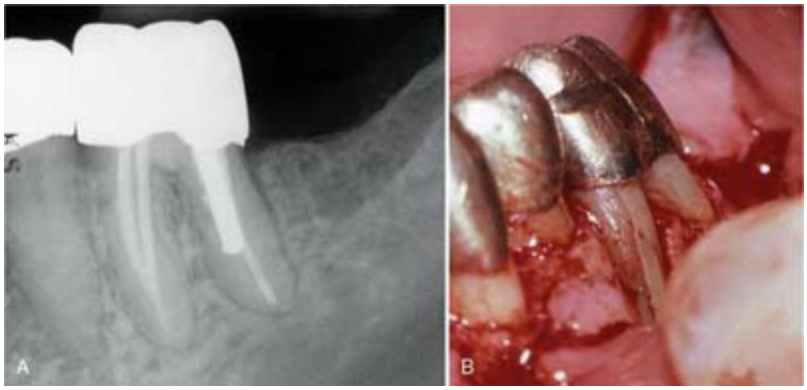

FIG. 9.30 Vertical root fractures can occur with excessive compaction forces. **A,** Follow-up radiograph of a mandibular left first molar. A deep isolated periodontal probing defect was associated with the buccal aspect of the mesiobuccal root. **B,** Flap reflection revealed a vertical root fracture.

www.konkur.in

A) Radiograph shows a tooth with radiopaque crown, radiolucent segmented left canal and radiopaque upper canal and radiolucent lower canal.

B) Close-up of lateral section of teeth covered with silver caps with exposed roots.

A disadvantage to lateral compaction is that the process does not produce a homogeneous mass. The accessory and master cones are laminated and remain separate. It is envisaged that the space between each of the cones is filled with sealer to aid in establishment of a water-tight seal

The excess GP in the chamber is then seared off and vertically compacted with a heated plugger at the orifice or approximately 1 mm below the orifice in posterior teeth. In anterior teeth, the desired level is the cementoenamel junction on the facial surface to avoid aesthetic issues if the dentin should become stained. An alternative to lateral compaction with finger spreaders is the use of ultrasonics and a clinical study reported a 93% success rate.[321]

Warm vertical compaction

Schilder introduced warm vertical compaction of GP as a method of obturating the radicular space in three dimensions.[256] Preparation requirements for the technique include preparing an RCS with a continuously tapering funnel and keeping the apical foramen as small as possible.

Various ISO standardized instruments are also available (Fig. 9.31).

The technique involves fitting a master cone 0.5 to 2 mm short of the prepared working length with resistance to displacement (Fig. 9.32). This ensures that the cone diameter is larger than the prepared canal at the terminus. Nonstandard cones that closely replicate the canal taper are best

Telegram: @dental_k

www.konkur.in

because they permit the development of hydraulic pressure during compaction. After the adaptation of the master cone, it is removed and sealer is applied to the cone and the walls of the prepared canal. The cone is placed in the canal and the coronal portion is removed with a heated instrument. A heated spreader or plugger is used to remove portions of the coronal GP in successive increments and soften the remaining material in the canal. The Touch 'n Heat (Kerr) (Fig. 9.33) and System B (Kerr Dental) (Fig. 9.34) are alternatives to applying heat with a flame-heated instrument because they permit improved temperature control. A plugger is inserted into the RCS and the GP is compacted, forcing the plasticized material apically. The process is repeated until the apical portion has been reached. The coronal RCS is back-filled using small preheated pieces of GP. The sectional method consists of placing 3 to 4 mm sections of GP approximating the size of the canal into the root, applying heat, and compacting the mass with a plugger.

One study measured temperature changes in an RCS with warm vertical

Telegram: @dental_k

www.konkur.in

compaction.[34] The maximal temperatures occurred coronally and decreased apically. The authors reported that the maximal temperature in the canal was 118°C 8 mm from the apex. At 0 to 2 mm from the apical terminus, the maximal temperature had decreased to 44°C. Another study compared root surface temperatures for warm vertical obturation using the System B heat source, the Touch 'n Heat device, and a flame-heated carrier in maxillary and mandibular incisors and premolars 2 mm below the cementoenamel junction. System B and the Touch 'n Heat produced a surface temperature rise that was less than 10°C for all maxillary incisors and premolar teeth. The Touch 'n Heat produced a greater than 10°C rise in mandibular incisors. The flame-heated carrier produced temperature changes greater than 10°C in all experimental teeth. Because the critical level of root surface heat required to produce irreversible bone damage is believed to be greater than 10°C, the findings suggest that warm vertical compaction with the System B should not damage supporting periodontal structures. However, caution should be exercised with the Touch 'n Heat and flame-heated carriers.[161] The flame-heated spreader has no heat controls and the Touch 'n Heat controls only send heat to the tip and receive no feedback from the tip based on clinical conditions. The System B has a built-in computer that allows it to receive feedback from the tip and adjust the tip temperature based on the clinical conditions, which allow the tip to remain at the dialed-in temperature.

The potential for vertical root fracture is also present with warm vertical compaction.[33] The forces developed appear to be equal to lateral compaction. Investigators compared warm vertical compaction and lateral compaction as a function of time. Results indicated that the forces developed with the two techniques were not significantly different. In a follow-up study, the mean value for wedging with warm vertical compaction was 0.65 ± 0.07 kg, whereas for lateral compaction it was 0.8 ± 0.1 kg.

Warm thermoplastic techniques have the advantage of producing movement of the plasticized GP within the obturated RCS, creating a more homogeneous mass of resultant GP and filling irregularities and accessory canals better than lateral compaction.[311] This was illustrated in a study that reported a correlation between the quality of adaptation and the depth of heat application and canal size. Heat application close to the apical extent of the preparation produced the best results, and adaptation was better in small RCS

Telegram: @dental_k

www.konkur.in

when compared with wider ones.[310] However, thermoplasticized techniques resulted in more extrusion of obturating materials.[154] There appeared to be no consistent differences between the techniques in sealing the RCS.[311] Warm vertical compaction also influenced setting time and flow of sealers.[228]

Advantages of warm vertical compaction include filling of canal irregularities and accessory canals. Disadvantages include a slight risk of vertical root fracture because of compaction forces, less length control than with lateral compaction, and the potential for overextension of obturation materials into the periradicular tissues. Warm vertical compaction is also difficult in more curved RCS where the rigid pluggers may be unable to penetrate to the necessary depth. Occasionally, the RCS have to be enlarged and tapered more to enable rigid carriers to penetrate within 4 to 5 mm of the working length. Additional removal of RCS dentin can weaken the root, making it more susceptible to root fracture.

Continuous wave compaction technique

A variation of warm vertical compaction is the continuous wave compaction technique.[45] The increasing use of nickel titanium rotary preparation techniques and the fabrication of greater taper standard cones have resulted in more clinicians using thermoplasticizing techniques. The manufacturing of GP cones to mimic the tapered preparation permits the application of greater hydraulic force during compaction when appropriately tapered pluggers are used. The continuous wave compaction technique employs the System B connected to 0.04, 0.06, 0.08, 0.10, or 0.12 tapered stainless steel dead-soft pluggers (see Fig. 9.34). The 0.06 tapered plugger also approximates the fine nonstandard GP cone, while the 0.08 plugger approximates the fine-medium cone, the 0.10 plugger the medium cone, and the 0.12 plugger the medium-large cone. Pluggers are consistent with the ProFile GT instruments (DENTSPLY Sirona), and Autofit GP cones (Kerr Endo) are also available. In summary, after selecting an appropriate master cone, a series of pluggers from large to small are prefitted to finally reach within 5 to 7 mm of the prepared length (Fig. 9.35).[45]

Telegram: @dental_k

www.konkur.in

FIG. 9.35 System B plugger fit.

Close-up of lateral section of cutaway tooth shows an open crown with a system B plugger tip in the lower left canal.

The continuous wave and warm backfill technique cause significantly higher temperatures than other obturation techniques by virtue of the technique.[80] This occurs because the plugger of the System B unit is inserted into the canal orifice and activated to remove excess coronal material, while the series of compaction and removal of GP takes place until the plugger is moved rapidly (1 to 2 seconds) to within 3 mm of the binding point (Fig. 9.36). The continuous wave technique was reported to have higher temperatures at 3 mm and 6 mm from the apex than the warm backfill technique.[80]

Telegram: @dental_k

www.konkur.in

FIG. 9.36 System B activation and compaction.

Close-up of lateral section of cutaway tooth shows an open crown with a compacted gutta percha segment in the lower canal and a plugger tip inserted in the left upper canal.

It should be noted that with the continuous wave technique, the tip of the heated plugger is placed only to within 5 to 7 mm from the tip of the GP. The apical portion of the GP remains essentially a single-cone technique as the heat transfer does not take place in the apical 2 to 5 mm of the GP.[109]

In ovoid canals, where the canal configuration may prevent the generation of hydraulic forces, an accessory cone can be placed alongside the master cone before compaction. With type II canals, the master cones are placed in both canals before compaction. A hand plugger is used to stabilize the cone in one canal while the other is being obturated.

Filling the space left by the plugger may be accomplished by a thermoplastic injection technique (Obtura II or Ultrafil 3D [Coltène/Whaledent], Calamus [DENTSPLY Sirona Dental Specialties], Elements free [Kerr Dental], or HotShot [Discus Dental, Culver City, CA]) (Fig. 9.37)[138] or by fitting an accessory cone into the space with sealer,

Thermoplastic injection techniques

Heating of GP outside the tooth and injecting the material into the canal is an additional variation of a thermoplastic technique (Fig. 9.38). The Obtura III (Fig. 9.39), Calamus (Fig. 9.40), Elements (Fig. 9.41), HotShot (Fig. 9.42), and Ultrafil 3D (Fig. 9.43) are available devices. The Obtura II system heats the GP to 160°C, whereas the Ultrafil 3D system employs a low-temperature GP that is heated to 90°C.

Close-up of ultrafil three-dimensional system shows a heating unit, a gun-shaped injection syringe and gutta percha cannula tubes.

Obtura III

The Obtura III system (Obtura Spartan, Earth City, MO, USA) consists of a handheld "gun" that contains a chamber surrounded by a heating element into which pellets of GP are loaded (see Fig. 9.40). Silver needles (varying gauges of 20, 23, and 25) deliver the thermoplasticized material into the RCS. The control unit allows the operator to adjust the temperature and thus the viscosity of the GP. At 6 mm from the apex, one study reported that the highest internal temperature with the Obtura system was 27°C.[283]

Telegram: @dental_k

www.konkur.in

Canal preparation is similar for other obturation techniques. The apical terminus should be as small as possible to prevent overextension of GP. The technique requires the use of sealer and, once the canal is dried, the canal walls are coated with sealer using the last file used to length or a paper point. GP is preheated in the gun and the needle is positioned in the RCS so that it reaches within 3 to 5 mm of the apical preparation. GP is then gradually, passively injected by squeezing the trigger of the "gun." The needle backs out of the canal as the apical portion is filled. Room-temperature prefittted pluggers, dipped in alcohol, are used to compact the GP. A segmental technique may also be used, in which 3- to 4-mm segments of GP are sequentially injected and compacted. In either case, compaction should continue until the GP cools and solidifies to compensate for the contraction of the GP that takes place on cooling.

The difficulties with this system include lack of length control. Both overextension and underextension are common results. To overcome this drawback, a hybrid technique may be used in which the clinician begins obturating the RCS by a lateral compaction technique. When the master cone and several accessory cones have been placed so that the mass is firmly lodged in the apical portion of the canal, a hot plugger is introduced, searing the points off approximately 4 to 5 mm from the apex. Light vertical compaction is applied to restore the integrity of the apical plug of GP. The remainder of the canal is then filled with thermoplasticized GP injected as previously described, and the risk of overextension of GP is reduced.

Investigators studied, at 3, 6, and 12 months posttreatment, the healing rate of 236 teeth obturated with the Obtura system. Results indicated that 96% of the cases healed with the highest healing rate being in teeth filled flush with the radiographic apex (97%) when compared to overextensions (93%) and filling short (93%).[228]

Ultrafil 3D

Ultrafil 3D (Coltène/Whaledent) is a thermoplastic GP injection technique involving GP cannulas, a heating unit, and an injection syringe (see Fig. 9.43). The system employs three types of GP cannulas. Regular Set is a low-viscosity material that requires 30 minutes to set. Firm Set is also a low-viscosity material but differs in that it sets in 4 minutes. The manufacturer

Telegram: @dental_k

www.konkur.in

recommends compaction after the initial set with both materials. Endoset has a higher viscosity and does not flow as well. It is recommended for techniques employing compaction and sets in 2 minutes. The heater is preset at 90°C and does not require adjustment.

Each cannula has a 22-gauge stainless steel needle that measures 21 mm in length. The needles can be precurved. Cannulas can be disinfected but are not designed for heat sterilization procedures. Heating time varies but, for a cold unit, it takes 10 to 15 minutes. In a warm heater the recommended time is 3 minutes. After removing the cannula from the heater, the needle should be placed on the hot part of the heater for several seconds. The GP remains able to flow for 45 to 60 seconds depending on the viscosity.

Calamus

The Calamus flow obturation delivery system (DENTSPLY Sirona) is a thermoplastic device equipped with a cartridge system with 20- and 23-gauge needles (see Fig. 9.40). The unit permits control of temperature and the flow rate. Pluggers are also available for use with the system. The 360-degree activation switch allows great tactile sensation during use.

Elements

The Elements obturation unit (Kerr Endodontics) consists of a System B heat source and plugger as well as a hand piece extruder for delivering thermoplastic GP or RealSeal from a disposable cartridge (see Fig. 9.42). The cartridges come with 20-, 23-, and 25-gauge needles for GP and 20- and 23-gauges for RealSeal.

HotShot

The HotShot delivery system (Discus Dental) is a cordless thermoplastic device that has a heating range from 150°C to 230°C (see Fig. 9.43). The unit is cordless and can be used with GP. Needles are available in 20, 23, and 25 gauges.

Carrier-based gutta-percha

Thermafil, profile GT obturators, GT series X obturators, and

Telegram: @dental_k

www.konkur.in

ProTaper universal obturators

Guttacore and Thermafil (DENTSPLY Sirona Dental Specialties) were introduced as GP obturation materials with a solid core (Fig. 9.44). Originally manufactured with a metal core and a coating of GP, the carrier was heated over an open flame. The technique was popular because the central core provided a rigid mechanism to facilitate the placement of the GP. Advantages included ease of placement and the pliable properties of the GP. Disadvantages were that the metallic core made placement of a post challenging and that retreatment procedures were difficult. Additionally, the GP was often stripped from the carrier, leaving the carrier as the obturating material in the apical area of the canal. Reports have stated that carrier-based systems resulted in minimal gaps and voids in the resulting obturation mass.[325] Other reports have stated that there were no differences in healing rates between carrier-based systems and lateral compaction of GP.[117]

FIG. 9.46 The Thermafil oven with carrier in place (DENTSPLY Tulsa Dental Specialties, Tulsa, OK).

A thermafill obturation oven with a central radiopaque plastic core with two obturations over the top for heating gutta percha.

As with all techniques, sealer is required. Grossman formulation sealers and resin sealers consistent with AH-26 and AH Plus are acceptable. However, Tubli-Seal and Wach's paste are not recommended.

The carrier is placed in the heating device. When the carrier is heated to the appropriate temperature, the clinician has approximately 10 seconds to retrieve it and insert it into the RCS (Fig. 9.47). This is accomplished without rotation or twisting. Evidence suggests that the insertion rate affects the obturation. The fill length and obturation of irregularities increase with increasing insertion rates, and a rapid insertion rate enhances obturation.[165]

www.konkur.in

FIG. 9.47 Thermafil carrier placed in a distal canal.

Close-up of lateral section of cutaway tooth shows an open crown with a gutta percha around a thermafill carrier inserted in the right canal.

Vertical compaction of the coronal GP can then be accomplished. When necessary, GP can be added, heat softened, and compacted. An advantage to this technique is the potential for movement of GP into the lateral and accessory canals (Fig. 9.48);[308] however, extrusion of material beyond the apical extent of the root anatomical apex is a disadvantage.[154,197]

Pro-Post drills (DENTSPLY Sirona) are recommended if post space is required for restoration of the tooth. The unique eccentric cutting tip keeps the instrument centered in the canal while friction softens and removes the GP and plastic carrier.

When retreatment is necessary, the plastic carrier has a groove along its length to provide a potential access point for placement of a file to remove the carrier. Chloroform and hand files can be used to remove the GP surrounding the carrier. Rotary #.04 and #.06 nickel titanium files may also be used to remove the obturation materials. Retreatment rotary nickel titanium files are available in three different sizes to facilitate removal of GP and the carrier.

The plastic carriers are composed of two nontoxic materials. Sizes #20 to

Telegram: @dental_k

www.konkur.in

#40 are manufactured from a liquid crystal plastic. Sizes #40 to #90 are composed of polysulfone polymer. Both have similar physical characteristics, with the polysulfone carriers being susceptible to dissolution in chloroform.

GuttaCore (DENTSPLY Sirona), the latest generation of core carriers, uses cross-linked GP as the carrier of the outer thermoplasticized GP. This supposedly makes retreatment simpler as the clinician can simply drill through the carrier to gain access into the canal space. A recent in vitro study comparing the time required to remove GuttaCore, Thermafil Plus, and thermoplasticized GP from moderately curved RCS with ProTaper retreatment files reported that GuttaCore was removed in significantly less time when compared with the other two techniques.[25] The survival and healing rates after NS RCT with carrier-based obturation technique seem to be comparable to those previously reported for other obturation techniques.[223]

SuccessFil

SuccessFil (Coltène/Whaledent) is a carrier-based system associated with Ultrafil 3D (Fig. 9.49); however, the GP used in this technique comes in a syringe. Titanium or radiopaque plastic carriers are inserted into the syringe to the measured length of the canal. The GP is expressed on the carrier with the amount and shape determined by the rate of withdrawal from the syringe. Sealer is lightly coated on the canal walls, and the carrier with GP is placed into the RCS to the prepared length. The GP can be compacted around the carrier with various pluggers depending on the canal morphology. This is followed by severing of the carrier slightly above the orifice with a bur.

www.konkur.in

FIG. 9.49 SuccessFil is an additional carrier system (Coltène/Whaledent, Cuyahoga Falls, OH).

Close-up shows a package of titanium cores and a syringe with a plastic barrel, plunger and a cap

Simplifill

Simplifill (Kerr Endo) is GP manufactured for use after canal preparation with LightSpeed instruments (Fig. 9.50). The carrier has an apical plug with 5 mm of GP. The technique involves fitting a carrier that is consistent with the master apical rotary file to within 1 to 3 mm of the prepared length (Fig. 9.51). The apical GP plug can be modified by clipping the end in 1 mm increments to obtain an appropriate fit if the plug is too small. Once the cone is fitted, it is withdrawn and sealer applied to the canal walls. AH Plus is recommended. The Simplifill carrier is slowly advanced to the prepared length. This may require firm pressure. With the plug at the corrected working length, the handle is quickly rotated a minimum of four complete terms in a counterclockwise direction to separate the shaft from the apical GP. The coronal space can then be filled with GP using lateral compaction or a warm thermoplastic technique. When using lateral compaction, it is recommended that the first cone be the same size as the Simplifill carrier. This sectional technique is efficient and leakage potential is similar to that of other common techniques.[247]

www.konkur.in

Close-up of lateral section of cutaway tooth shows an open crown with a gutta percha around a light speed file inserted in the right canal.

Thermomechanical compaction

McSpadden introduced the McSpadden Compactor, with flutes similar to a Hedström file, but in reverse. When activated in a slow-speed hand piece, the instrument would generate friction, soften the GP, and move it apically. Rotary compactors similar in design have been developed and advocated. To increase flexibility, the instrument is available in nickel titanium.

The technique requires fitting a GP master cone short of the prepared length and applying sealer. A compactor is selected on the basis of the size of the final RCS and inserted alongside the GP cone 3 to 4 mm from the prepared length. The hand piece is activated, and the friction of the rotating instrument heats the GP. The pliable mass is compacted apically and laterally as the device is withdrawn from the canal.

Advantages include simplicity of the armamentarium, the ability to fill canal irregularities,[251] and time. Disadvantages include possible extrusion of material, instrument fracture,[200] gouging canal walls, the inability to use the technique in curved canals, and possible excessive heat generation.[252] Microseal condensers (Kerr Dental) and the Gutta Condenser (DENTSPLY Sirona) are variations of this product.

Solvent techniques

GP can be plasticized with solvents, for example, chloroform, eucalyptol, or xylol. Disadvantages include shrinkage caused by evaporation of the solvent, voids, the inability to achieve predictable length control of the obturating material, and irritation of periradicular tissues. Obturation techniques using solvents have been abandoned and replaced with materials and methods that exhibit minimum shrinkage.

Pastes

Pastes fulfill some of the criteria outlined by Grossman[110] and can adapt to the complex internal canal anatomy. However, the flow characteristic can result in extrusion or incomplete obturation. The inability to control the

Telegram: @dental_k

www.konkur.in

material is a distinct disadvantage, and, when extrusion occurs, it is possible that it can be corrected only by surgical intervention. In addition, pastes are sometimes used as a substitute for complete C&S procedures, and the addition of paraformaldehyde results in severe toxicity.

Immediate obturation

Apical barriers may be necessary in cases with immature apical development, cases with external apical root resorption, and cases where instrumentation extends beyond the confines of the RCS. Dentin chips, $Ca(OH)_2$, demineralized dentin, lyophilized bone, tricalcium phosphate, hydroxyapatite, and collagen have been advocated for placement as a barrier in RCS exhibiting an open apex. The barriers are designed to permit obturation without extrusion of materials into the periradicular tissues but are often incomplete and do not seal the RCS.[242]

Dentin chips appear to confine materials to the RCS during instrumentation/obturation and may encourage development of a biologic seal.[242] A concern with this technique is contamination of the dentin with bacteria or other nonhost materials, because investigators found that infected dentin adversely affected healing.[208]

Calcium hydroxide has also been extensively used as a common apical barrier. $Ca(OH)_2$ has been shown to induce an apical barrier in apexification procedures. Calcifications similar to dentin plugs have been noted at the apical foramen.[208] Calcium hydroxide has the advantage of being free of bacterial contamination and may provide a better, although imperfect, apical seal.[303]

MTA (ProRoot MTA; DENTSPLY Sirona) has been successfully employed as an apical barrier material before obturation as an alternative to apexification, inducing cementum deposition and bone formation (Fig. 9.52).[264]

Telegram: @dental_k

www.konkur.in

FIG. 9.52 Mineral trioxide aggregate is available as ProRoot MTA. This material is advocated for use in apexification, repair of root perforations, repair of root resorption, root-end fillings, and pulp capping.

Close-up of mineral trioxide aggregate used for treating root canals in a sachet pack.

Source: (Courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, OK, USA. All rights owned by and used with permission from DENTSPLY International Inc.)

After C&S procedures, the RCS is dried and a small increment of MTA is placed to the radiographic apex and the location verified through a radiograph. If the material is overextended, it can be easily removed by irrigating with sterile saline. If it is short of the radiographic apex, it can be compacted with prefitted pluggers to move it to the radiographic apex. The material is compacted into the apical portion of the root to form a barrier. After the material sets, any thermoplasticized technique can be used to backfill with GP without concern of overextension (Fig. 9.53). Hand compaction of MTA is superior to direct placement of ultrasonic activation.[9] However, indirect ultrasonic placement of a 4 mm apical plug of MTA improved the seal.[317]

Telegram: @dental_k

www.konkur.in

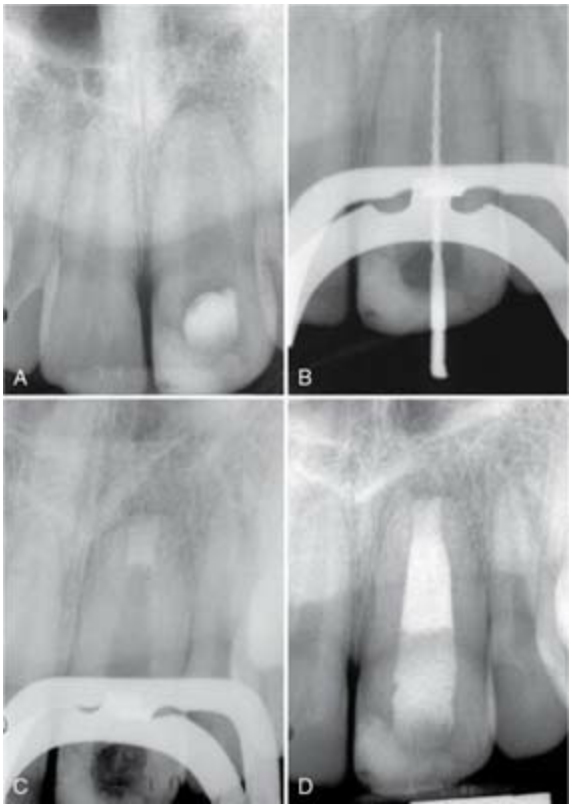

FIG. 9.53 Immediate obturation employs a barrier technique to prevent extrusion when the apex is open. This case involves a maxillary left central incisor with pulp necrosis caused by trauma. **A,** Pretreatment radiograph demonstrates a large canal with an open apex. **B,** Working length is established and the RCS is prepared. **C,** Mineral trioxide plug is placed. **D,** The canal is obturated with GP.

A) Radiograph shows a tooth with radiopaque square patch on the crown with radiolucent tooth surface.

B) Radiograph shows a tooth with a black square patch on the crown. A radiopaque outline of a working length file and clamp is visible.

C) Radiograph shows a tooth with a black patch on the crown. A radiopaque outline of mineral trioxide plug is visible.

D) Radiograph shows a tooth with a radiolucent crown, radiopaque neck and radiopaque canal.

MTA is biocompatible and capable of inducing hard tissue formation.

Clinical evidence supports the use of bioactive endodontic cements like MTA.[292] In a study comparing $Ca(OH)_2$ with MTA in 15 children, each having paired immature teeth with necrotic pulps, two teeth treated with

Telegram: @dental_k

www.konkur.in

$Ca(OH)_2$ exhibited pathosis on recall examination whereas all the teeth treated with MTA were clinically and radiographically successful.[87] A prospective clinical study found the success rate of MTA barriers and immediate obturation in 43 cases to be 81%.[269] In another study, 85% of 20 teeth with immature apical development were considered healed and 5% were considered healing after immediate barrier placement.[127] The time required for healing is comparable to traditional apexification with $Ca(OH)_2$, and treatment time is reduced.[226]

Another option for treating immature teeth with pulp necrosis involves regenerative endodontic techniques (see Chapter 12). Advantages include continued increasing thickness of the canal walls, continued apical root development, and apical closure.

Coronal orifice seal

No matter which technique is used to obturate the RCS, coronal microleakage can occur within a short time through seemingly well-obturated canals,[293] potentially causing infection of the periapical area. Early research efforts focused on the quality of the seal in the apical part of the RCS to prevent percolation of apical fluids. However, contemporary research efforts have identified the greater importance of maintaining a coronal seal to prevent bacterial leakage.[137] Cavit (Premier Dental Products, 3M ESPE) has traditionally been advocated as an acceptable material. One study demonstrated that the placement of 3.5 mm of Cavit or Super EBA cement (Bosworth, Skokie, IL, USA) decreased bacterial leakage by 85% and 65%, respectively, when compared with unsealed controls, which all leaked at 45 days.[224] Another method to slow leakage through the obturated RCS, should failure of the coronal restoration occur, is to cover the floor of the pulp chamber with a lining of bonded material after the removal of excess GP and sealer to the canal oriface.[162] Investigators found that this procedure resulted in none of the experimental RCS demonstrating bacterial leakage at 60 days.[60] A material with a different color than dentin may be used for identification in case subsequent placement of a post is desired.

Future technology and nanodiamond-embedded gutta-percha

Ongoing clinical trials are researching nanodiamond-embedded GP with some promising progress report and no adverse events.[159,160]

These studies might be the foundation for the continued clinical research of nanodiamond biomaterial and their application in endodontics.

10: Nonsurgical retreatment

Robert S. Roda, Bradley H. Gettleman, Scott C. Johnson

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Nonsurgical root canal therapy has become a routine procedure in modern dentistry. Recent technical and scientific advances in endodontics have resulted in the retention of millions of teeth that would otherwise be lost. Even as recent advances in surgical and prosthetic restorative care have made tooth replacement less onerous than in the past, it is universally accepted that a natural tooth with a good prognosis is a superior choice to loss and replacement.

Unfortunately, not all treatments result in optimum long-term healing. Given the large numbers of treatments performed, the very small rate of unsuccessful outcomes translates into relatively large numbers of patients requiring further treatment. Dental clinicians should be able to diagnose persistent or reintroduced endodontic disease and be aware of the options for treatment. If they wish to approach treating these teeth, they should have the appropriate armamentarium and be capable of performing these very specialized techniques at the highest level (Fig. 10.1). Also, clinicians must always have a scientifically sound, evidence-based rationale for every treatment decision that is made so that they may best serve the patients who entrust them with their care. The purpose of this chapter is to provide information to allow the reader to maximize the likelihood of success in the treatment of persistent endodontic disease.

Telegram: @dental_k

www.konkur.in

FIG. 10.1 Some of the armamentarium needed to perform retreatment at the highest level.

A set of medicinal kits, Gonon universal post extractor kit with an extracting plier, five trephines, five corresponding tubular taps, torque bar, tube spacers and rubber bumpers of varying diameters, Thomas screw post dental kit, IRS kit with core drills etcetera are kept on a blue platform.

Etiology of posttreatment disease

In the past, undesirable outcomes of endodontic therapy were described as failures. Clinicians quote failure rates based on published success/failure studies. Using the words “success” and “failure” may be a holdover from a time when clinicians felt they needed to congratulate themselves on their successes and blame themselves for the failures of their treatment endeavors. This thought process does not reflect reality and can be potentially destructive. There are many instances where treatments performed at the highest level of clinical competence result in an undesirable outcome, and there are other instances where a procedure is performed well below a scientifically acceptable standard and yet provides long-term success.[232] We must begin to dissect the science from emotion and ego, and this separation may start with nomenclature. Friedman states that “most patients can relate to the concept of disease-treatment-healing, whereas failure, apart from being a negative and relative term, does not imply the necessity to pursue

Telegram: @dental_k

www.konkur.in

treatment."[73] He has suggested using the term *posttreatment disease* to describe those cases that would previously have been referred to as treatment failures. This will be the term used in the remainder of this chapter to describe persistent or reintroduced endodontic disease.

Approximately 22.3 million root canal procedures were performed in 2006[59] and, with success rates varying between 86% and 98%,[74,75] it has proven to be a very reliable treatment option. Conversely, the incidence of posttreatment disease, although small, translates into a very large number of cases where further treatment is needed. When faced with such a situation, the clinician must determine the etiology of the persistent pathosis and devise a rationale and strategy for treatment.

There are many causes for "failure" of initial endodontic therapy that have been described in the endodontic literature (Fig. 10.2). These include iatrogenic procedural errors such as poor access cavity design, untreated canals (both major and accessory),[298] canals that are poorly cleaned and obturated,[43,125] complications of instrumentation (ledges, perforations, or separated instruments),[259] and overextensions of root filling materials.[183] Coronal leakage[145,162,224,264,278] has also been blamed for posttreatment disease as has persistent intra- and extracanal infection[185,205,244,260] and radicular cysts.[181] These etiologies may be obvious at the time of diagnosing the diseased, root-filled tooth, or they may remain uncertain until the completion of successful therapy. Occasionally, the cause of posttreatment disease may take years to become discernable or may ultimately never be known. The most important causative factors for the clinician, however, are those related to treatment planning and determination of prognosis. In order to treatment plan effectively, the clinician may place the etiological factors into four groups (Fig. 10.3).[259]

1. Persistent or reintroduced intraradicular microorganisms
2. Extraradicular infection
3. Foreign body reaction
4. True cysts

1. *Persistent or reintroduced intraradicular microorganisms.* When the root canal space and dentinal tubules are contaminated with microorganisms or their by-products, and if these pathogens can contact the periradicular tissues, apical periodontitis ensues. As stated earlier, inadequate cleaning, shaping, obturation, and final restoration of an endodontically diseased tooth can lead to posttreatment disease. If initial endodontic therapy does not render the canal space free of bacteria, or if the obturation does not adequately entomb those that may remain, or if new microorganisms can reenter the cleaned and sealed canal space, then posttreatment disease can and

Telegram: @dental_k

www.konkur.in

usually does occur. In fact, it has been asserted that persistent or reintroduced microorganisms are the major cause of posttreatment disease.[182] Many iatrogenic treatment complications, such as creation of a ledge or separation of an instrument, result in persistence of bacteria in the canal system. It is not the complication itself, however that results in persistent disease; rather, it is the inability to remove or entomb the microorganisms present that creates the pathologic state. Although infected root canals of endodontically untreated teeth generally contain a polymicrobial, predominantly anaerobic flora,[258] cultures of infected, previously root-filled teeth produce very few or even one single species. The infecting flora are predominantly gram positive, not anaerobic, and a very commonly isolated species is *Enterococcus faecalis*,[80,206] which has been shown to be very resistant to canal disinfection regimens.[21,37] One recent study, however, hints at greater diversity in the microflora of infected, root filled teeth than had been detected before and may show a correlation between increasing diversity and specific clinical features.[219] Interestingly, if the previous root canal treatment is done so poorly that the canal space contains no obturating material in the apical half of the root canal space, its flora is more typical of the untreated necrotic infected pulp than that of classic "failed" root canal therapy.[259] Though posttreatment disease has been primarily blamed on bacteria in the root canal system, fungi, notably *Candida albicans*, are frequently found in persistent endodontic infections and may be responsible for the recalcitrant lesion.[242]

2. *Extraradicular infection.* Occasionally, bacterial cells can invade the periradicular tissues either by direct spread of infection from the root canal space, via contaminated periodontal pockets that communicate with the apical area,[240] extrusion of infected dentin chips,[112] or by contamination with overextended, infected endodontic instruments.[288] Usually, the host response will destroy these organisms, but some microorganisms are able to resist the immune defenses and persist in the periradicular tissues, sometimes by producing an extracellular matrix or protective plaque.[279] It has also been shown[185,244,260] that two species of microorganisms, *Actinomyces israelii* and *Propionibacterium propionicum*, can exist in the periapical tissues and may prevent healing after root canal therapy.

3. *Foreign body reaction.* Occasionally, persistent endodontic disease occurs in the absence of discernable microorganisms and has been attributed

Telegram: @dental_k

www.konkur.in

to the presence of foreign material in the periradicular area. Several materials have been associated with inflammatory responses including lentil beans[239] and cellulose fibers from paper points.[139] In the seemingly endless debate about which endodontic obturation technique is superior, there has been much discussion about the effect of overextended root canal filling materials upon apical healing. Outcomes assessments generally show that filling material extrusion (root filling flush to the radiographic apex or gross overextension) leads to a lower incidence of healing.[72,243] Many of these cases involved not only overextension but also inadequate canal preparation and compaction of the root filling whereby persistent bacteria remaining in the canal space could leak out. Gutta-percha and sealers are usually well tolerated by the apical tissues, and if the tissues have not been inoculated with microorganisms by vigorous overinstrumentation, then healing in the presence of overextended filling materials can still occur.[72,79,152]

4. *True cysts.* Cysts form in the periradicular tissues when retained embryonic epithelium begins to proliferate due to the presence of chronic inflammation. The epithelial cell rests of Malassez are the source of the epithelium, and cyst formation may be an attempt to help separate the inflammatory stimulus from the surrounding bone.[204] The incidence of periapical cysts has been reported to be 15% to 42% of all periapical lesions,[181,251] and determining whether periapical radiolucency is a cyst or the more common periapical granuloma cannot be done radiographically.[28] There are two types of periapical cysts: the periapical true cyst and the periapical pocket cyst. True cysts have a contained cavity or lumen within a continuous epithelial lining, whereas, with pocket cysts, the lumen is open to the root canal of the affected tooth. True cysts, due to their self-sustaining nature, probably do not heal following nonsurgical endodontic therapy[125,184] and usually require surgical enucleation (Fig. 10.4).

When a patient presents with posttreatment disease, clinical decision-making depends upon determining the cause of the persistent disease and then assessing how best to treat the pathologic condition. In the following section, the reader will be presented with a rationale and methods for

Telegram: @dental_k

www.konkur.in

performing endodontic diagnosis, which will allow for the greatest likelihood of a successful outcome.

Diagnosis of posttreatment disease

It has been stated that "there may be different ways of treating a disease, however there can be but one correct diagnosis."[11] The proper diagnosis is probably the most important portion of any endodontic procedure. This is not as bold of a statement as one may first suspect when consideration is given to what the patient may undergo if treatment is performed based on an incorrect diagnosis (Fig. 10.5). For the clinician to make a correct diagnosis, they must rule out nonodontogenic etiology, perform all of the appropriate tests, properly interpret the patient's responses to these tests, derive at a definitive diagnosis, and decide on treatment options. When performing a diagnosis in endodontic cases where there is no history of previous endodontic therapy, both a pulpal and periradicular diagnosis are necessary. In cases of persistent disease, the diagnosis may not be as straightforward as the clinician may be dealing with partially treated pulp canals and missed canals as well as many other types of problems associated with the previous treatment. These must be included in the diagnostic description for each case.

FIG. 10.5 This patient was misdiagnosed for years and underwent unnecessary endodontic therapy. The actual cause of the patient's complaint was nondental pain.

Radiograph of frontal upper and lower set of teeth. The crowns, root canals and root tips with tiny dots like attachments are radiopaque while the pulp of the teeth is radiolucent.

www.konkur.in

Endodontic diagnosis has been thoroughly discussed in an earlier chapter and the reader is referred there for further details on these procedures. The diagnostic method requires collecting subjective information, developing objective findings, and using these to arrive at a diagnosis and plan of treatment.

The subjective information is collected by questioning the patient and then actively listening to the responses. Of particular interest in cases of suspected posttreatment disease is whether the patient recalls the use of aseptic techniques during the previous endodontic therapy. If a rubber dam was not used, for example, and this can be confirmed with a call to the previous clinician, nonsurgical retreatment will almost certainly be necessary since the canals can be assumed to be contaminated regardless of how esthetically pleasing the previously filled case may appear on the radiograph. The diagnostician should be careful to avoid or to minimize communicating to the patient any negative feelings he or she has toward the previous treatment, however bad it may seem. This approach allows the patient to become more comfortable with the current clinician and the proposed corrective treatment. An irate patient is an irate patient, and negativity will color his or her emotional state, level of trust, and ability to accept current or future treatment plans. If the patient asks a direct question about the previous treatment, an honest answer is necessary, but avoid the temptation to imply superiority by disparaging the former clinician. To state the situation honestly and correctly without being inflammatory, use a sentence such as, “Well, it may be that your previous dentist (endodontist) had some difficulty with that tooth. Let’s see if we can figure out what could have been the problem.”

Following a thorough review of the patient’s health history, the next step is to gather all the objective information needed to obtain an accurate diagnosis. This information will include the clinical and radiographic examination. The clinical examination should include a visual extraoral and intraoral examination, and a thorough periodontal evaluation. Visual examination is greatly aided by magnification and illumination, which can allow the clinician to identify significant conditions invisible to the naked eye, such as very fine fractures on root surfaces (Fig. 10.6). Exposed dentin from recession and narrow probing defects may be the result of an endodontic infection draining through the sulcus; however, they are sometimes indicative

Telegram: @dental_k

www.konkur.in

of vertical root fracture.[46] The presence of occlusal wear facets indicates the presence of occlusal trauma that may complicate diagnosis and treatment outcome by predisposing the tooth to fracture,[101] and has been associated with posttreatment disease.[126]

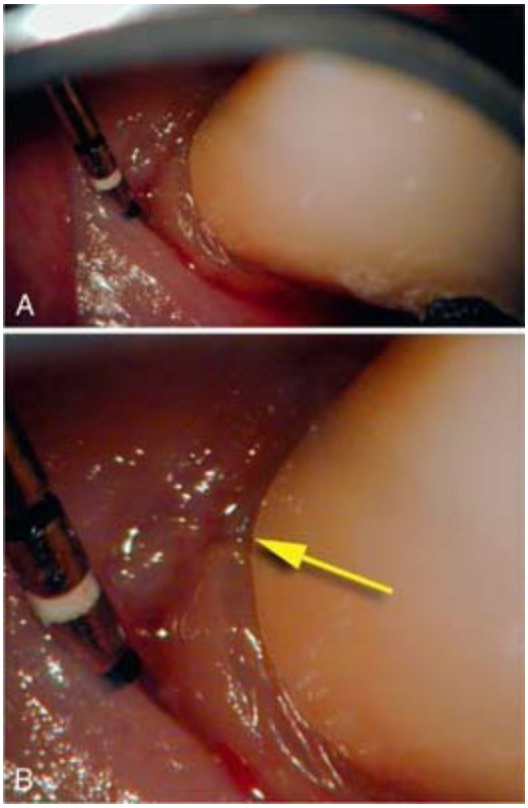

FIG. 10.6 **A,** Buccal aspect of a premolar with posttreatment disease. **B,** Higher magnification reveals a vertical fracture *(arrow)*.

A) Close-up view of a gum and a tooth with dark patches around it. Water is sprayed into the mouth using a water spray nozzle.

B) Close-up view of a gum shows an arrow pointing to a vertical line depicting fractured tooth on the root surface.

Radiographic assessment is obligatory. Even though radiographs may be a critical aid to the clinician, they should never be the sole support for a conclusive diagnosis. They are only one piece of the puzzle in determining endodontic etiology.[67] In cases with previous endodontic therapy, radiographs are very useful in the evaluation of caries, defective restorations, periodontal health, the quality of the obturation, existence of missed canals,

Telegram: @dental_k

www.konkur.in

impediments to instrumentation, periradicular pathosis, perforations, fractures,[267] resorption, and canal anatomy. Radiographs should be properly exposed and have a sharp, clear image. They should include the tooth and surrounding tissues, and multiple angulated images should be used to determine endodontic etiologies using the buccal object moves most rule (Fig. 10.7).[90] Bitewing radiographs are useful in determining periodontal bone height and to look for caries or fractures. All sinus tracts should be traced with a cone of gutta-percha followed by a radiograph to localize their origin.[124]

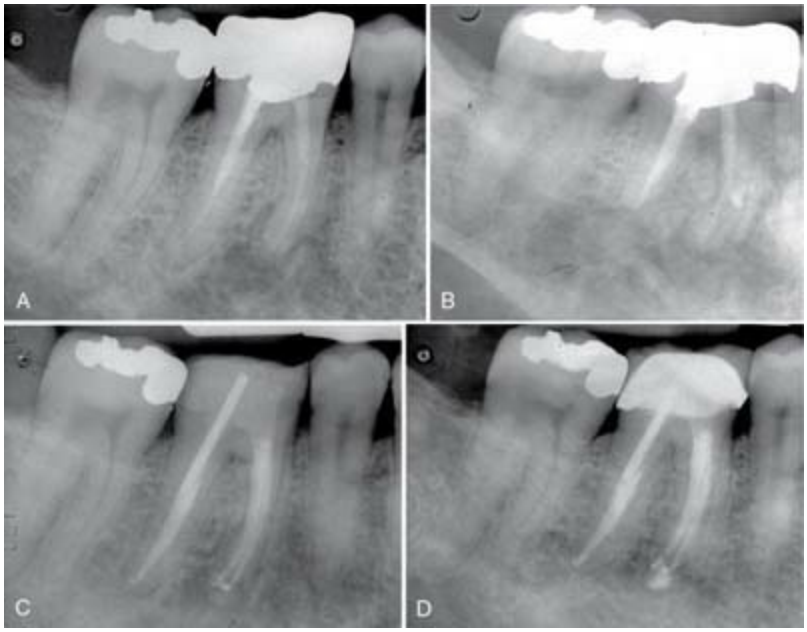

FIG. 10.7 **A,** Posttreatment disease. D) Radiograph of teeth shows radiopaque crown and root canal of the first molar and radiopaque white patch on a part of crown of second molar.

Recently, cone-beam computed tomography (CBCT) has been introduced into endodontics, and its usefulness in the management of endodontic retreatment is unquestioned.[209] It has provided a quantum leap in our ability to determine the causes of posttreatment apical periodontitis by giving the clinician, for the first time, the ability to easily, safely, and inexpensively visualize the tooth and surrounding structures in three dimensions. Several recent studies have shown that if clinicians are given all the collected diagnostic data (including periapical radiographs) for a patient, and they make a treatment plan, if they are then given a CBCT volume of the same patient, they change the treatment plan in up to 62% of the cases.[58,177,210] This indicates the unprecedented diagnostic power of CBCT technology. CBCT use in endodontics is discussed in detail in another chapter, but when faced with a tooth needing retreatment, it is especially helpful. The CBCT allows the clinician to determine the true size, extent, and position of periapical and resorptive lesions as well as giving added information about tooth fractures, missed canals, root canal anatomy, and the nature of the alveolar bone topography around teeth.[48] CBCT technology has greatly enhanced presurgical diagnosis and treatment planning, since the relationship of adjacent anatomical structures such as the maxillary sinus and inferior alveolar nerve to the root apices can be clearly visualized. This helps the clinician to decide on when to perform endodontic retreatment surgically or nonsurgically. CBCT is more accurate than periapical radiography in the diagnosis of apical periodontitis, and it can reveal the details of the lesions and adjacent structures thus providing enhanced clinical diagnosis and treatment planning.[48,150,197,198]

There are many manufacturers and brands of CBCT machines on the market today, but the most useful ones for endodontic retreatment are those that produce the clearest image with the highest resolution.[172] These would be the small field-of-view (FOV) machines that image a small volume and use the smallest picture element (voxel) dimensions available. Radiation exposure to the patient with these machines is in the range of 23 to 488 μSv[157] which is very small, but the ALARA (as low as reasonably

Telegram: @dental_k

www.konkur.in

achievable) principle applies and so its use in every diagnostic case is not encouraged. In a joint position statement in 2010, The American Association of Endodontists and the American Association of Oral and Maxillofacial Radiologists state that “CBCT should only be used when the question for which imaging is required cannot be answered adequately by lower dose conventional dental radiography or alternate imaging modalities.”[1] When managing posttreatment disease, however, almost every case will benefit from the use of three-dimensional (3D) imaging and this has been recommended in the 2016 update to the AAE/AAOMR guidelines.[2]

One major cause of posttreatment apical periodontitis is untreated canals, and the CBCT gives an unprecedented ability to discover those (Fig. 10.8). In a recent study, endodontist evaluators failed to identify at least one root canal system in approximately 4 of 10 teeth when using images obtained by conventional digital radiography compared to images from cone-beam computed tomography.[169] Another recent study showed that significantly more MB2 canals were located when a preoperative CBCT image was available.[257]

www.konkur.in

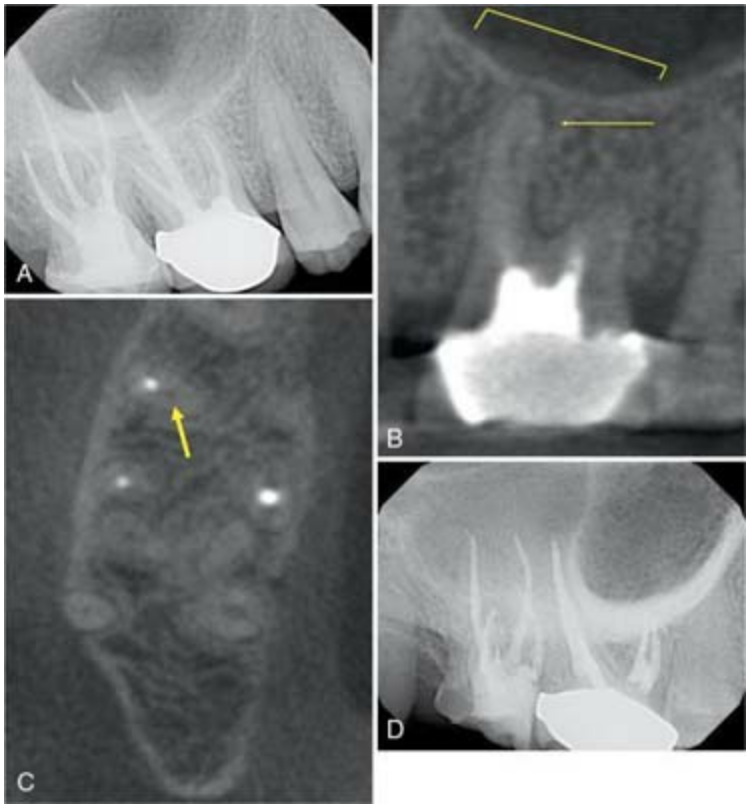

FIG. 10.8 **A,** Preoperative radiograph of symptomatic tooth #3. **B,** Sagittal slice of tooth #3 showing periodontal ligament thickening and associated sinus mucosal thickening. **C,** Axial slice showing untreated MB2 canal *(arrow)*. **D,** Treated case.

A) Radiograph shows circular dark patch at the root tips of first molar. The crown is radiopaque while the root tips are partially radiolucent.

B) Radiograph of the sagittal view of tooth shows black outlines formed around the gum and pulp of the tooth. The crown is radiolucent with a radiopaque neck.

C) Radiograph of horizontal section of canal shows three radiopaque dots where an arrow points to one of the dots.

D) Radiograph shows circular dark patch at the root tips of first molar. The crown and the root canal of the tooth are radiopaque.

Avoiding treatment that will lead to a predictable failure is beneficial for both the clinician and the patient. The ability to obtain 3D images of teeth will give the clinician help in avoiding these mishaps. The diagnosis of root fractures frequently frustrates the clinician, as a definitive diagnosis is often difficult and treating these teeth has a high likelihood of a poor outcome.

Telegram: @dental_k

www.konkur.in

While visualizing root fractures in teeth with root fillings is still not predictable using CBCT,[51,57,107,136,265] the patterns of bone loss indicative of root fracture can sometimes be seen[308] and this helps the clinician to infer their presence. The prognosis for the treatment of root resorption is directly related to the extent of the resorption, and this usually cannot be determined accurately using conventional radiography. Using small FOV CBCT, however, the extent of the lesions and the prognosis can be determined,[63] usually saving the patient from an exploratory procedure that may be doomed to fail (Fig. 10.9).

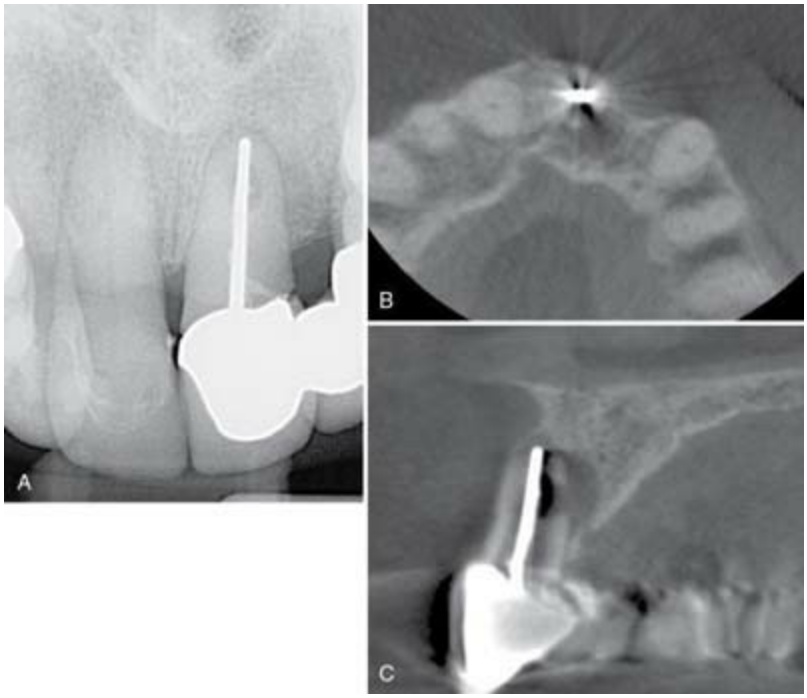

FIG. 10.9 **A,** Preoperative radiograph showing suspected small area of resorption associated with an endodontically treated tooth filled with a silver cone. **B,** Axial slice showing how beam hardening artifact from the metallic root filling obscures the image. **C,** Sagittal view showing very large palatally oriented external root resorption. The prognosis for retention of this tooth was poor and the patient elected to extract it.

C) Radiograph of sagittal view of set of teeth with radiopaque white outline of the silver cone. Part of the head of the silver cone is radiolucent.

Telegram: @dental_k

www.konkur.in

The use of CBCT for preoperative assessment also has allowed for the possibility of treating only those roots in a multirooted tooth that show disease.[192] This concept of selective root retreatment has been advocated to minimize needed retreatment procedures and limit therapy to only those roots that show evidence of disease. This method, it is argued, gives nonsurgical retreatment a more selective approach, much like apical surgery where only diseased roots are treated. More research would need to be done in this area to validate this interesting development.

Though most clinicians believe that CBCT is not necessary for every patient treated, there are many retreatment situations where the additional information gained (relative to conventional radiography) is extremely valuable. Specific protocols for use are being developed,[2] but they are continuously being updated, so the authors recommend that the clinician use available guidelines and their own best judgment when deciding when to use this new technology.

Comparative testing is the next procedure performed in order to collect objective information about the pulpal and periradicular status. Most useful are the periradicular tests that include percussion, bite, and palpation.[287] These will allow the diagnostician to begin developing a sense of the status of the periradicular tissues. These tests are of great importance anytime an endodontic diagnosis is needed. However, they are of even greater importance when evaluating teeth that have been previously treated with endodontic therapy due to the lack of significant and consistent evidence that can be gained from pulp vitality tests in these cases. If a tooth exhibits percussion tenderness, it may be due to persistent endodontic disease, but recent trauma or occlusal trauma may also cause this finding[101] as can periodontal disease.[287]

Pulp vitality tests are often of little value when examining teeth with previous endodontic therapy. However, if the patient’s chief complaint reveals the need for these tests, they must be performed. When there is vital tissue remaining in the canals of a previously root-filled tooth, either by way of a completely missed canal or from an improperly cleaned canal, patients may complain of sensitivity to heat or cold.[101] Pulp vitality tests should then be performed to assess the situation. They are also useful in testing adjacent

Telegram: @dental_k

www.konkur.in

and opposing nonendodontically treated teeth to rule out those as etiologies for poorly localized pain. Once the tissue is removed from the pulp chamber after root canal therapy, the results of these tests should almost always be negative, even with radicular pulp remaining. Thus a negative response with previously treated teeth is not necessarily conclusive; whereas a positive response usually means there is responsive pulp tissue remaining in the tooth.[101] Care is always warranted in interpreting pulp test results, however, since false positive and negative results may occur.[231] As with cold tests, the same limits apply to heat tests as far as the reasons for false results and accuracy relative to retreatment cases.

The remaining pulp vitality tests, electric pulp test, test cavity, and direct mechanical dentin stimulation, are of even lesser value than thermal testing when evaluating teeth that have already received endodontic therapy. These are usually precluded by the existing restoration or endodontic therapy.

When all diagnostic information is collected, a diagnosis must be developed. It is important to record the diagnosis in the patient's record so that anyone reading the record can discern the clinician's rationale for treatment. The pulpal diagnosis will usually be recorded as previous endodontic treatment, but the periradicular diagnosis will vary depending on the clinical picture presented. In the case of previous endodontic treatment, however, a brief note about the suspected etiology of the persistent disease is warranted.

Treatment planning

Once the diagnosis is complete, the cause of the persistent disease will usually become apparent. At this point in the clinical process, information must be given to the patient by the clinician as to what treatment options are available and the likely outcomes of each choice. The patient is then allowed to decide based upon his or her own perceptions of the options not by the clinician's opinion as to what is "best" for the patient. The reader is reminded, however, that if the cause of the posttreatment condition remains unknown despite thorough diagnostic workup, then any decision results in an empirical, "trial and error" type of treatment. This approach should be avoided if possible, and prior to definitive treatment, consultation with an

Telegram: @dental_k

www.konkur.in

endodontist or other colleague is in order. This consultation may be as simple as a brief conversation or even referral of the patient, but a second opinion is extremely useful in these situations. In most instances due to the interdisciplinary nature of modern dentistry, consultation with other clinicians who are treating the patient becomes a necessity to enhance the potential for successful treatment outcomes.

Occasionally, a patient will have persistent symptoms that mimic posttreatment disease, but these symptoms are the result of nonendodontic conditions such as occlusal trauma, concurrent periodontal disease, or nondental pain conditions. Appropriate diagnostic procedures should allow the clinician to sift through these options and treat accordingly.

The patient harboring true endodontic posttreatment disease has four basic options for treatment, which are as follows:

1. Do nothing
2. Extract the tooth
3. Nonsurgical retreatment
4. Surgical retreatment

The first option is to do nothing with the condition and allow it to take its course (Fig. 10.10). This approach is sometimes a useful, short-term option if the etiology of the condition remains unknown and the clinician feels that another diagnostic sampling would help with diagnosis. Even though most clinicians would find this approach to be a less-than-desirable long-term course of action, the decision belongs to the patient. The clinician is bound, however, to ensure that the patient has complete information about what will happen if nothing is done. The events in the progression of the disease and a reasonable timeline are necessary, and the conversation needs to be thoroughly documented in the patient record to avoid possible subsequent accusations of abandonment. The question of whether the clinician is required to follow up with the patient or dismiss the patient from the practice is one that each clinician must make based upon the clinician’s experience, judgment, and knowledge of the patient.

www.konkur.in

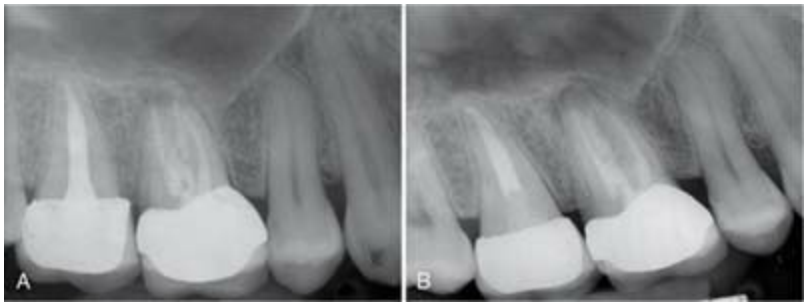

FIG. 10.10 **A,** Radiograph indicating presence of asymptomatic persistent apical periodontitis 7 years after initial treatment. The patient elected no treatment at that time. **B,** Six-year follow-up. Lesion has enlarged and the tooth has become symptomatic.

A) Radiograph of two teeth show a radiopaque crown and root canal and a radiopaque crown and radiolucent root canal.

B) Radiograph of two teeth show a black patch around the gum. The teeth in the right shows a radiopaque crown and radiolucent root canal and teeth in left shows radiopaque crown and radiolucent part of root canal.

Extraction of the tooth is usually considered a viable option. Recent advances in both prosthetic reconstruction techniques and in dental implantology have made extraction and replacement a more desirable option in certain cases where previously “heroic” (read: expensive with an unknown prognosis) methods were needed to “save” the tooth. This alternative, however, provides results that are inferior, more expensive, and much more time consuming than preserving the natural tooth. The average titanium root-form implant restoration can take up to 6 months to finish not counting preimplant site preparation, which can add months more. Despite published long-term success rates for dental implants,[5] postimplant disease does occur[5,95,96] (Fig. 10.11) and can leave the patient with very few options. The cost of implant treatment is high and may not be covered under dental benefit plans, so the net financial impact on the patient can be large. Implant esthetics can be inferior to that of natural teeth in the esthetic zone of the mouth, and there are patients that are just not candidates for implant procedures.[5] Fixed partial dentures are another replacement alternative with a very long history of successful use, but there are negative outcomes possible also. Most concerning to the endodontist is the likelihood that retainer fabrication procedures will result in endodontic disease of the abutment teeth[171] that may potentially occur at a rate of up to 10% (Fig. 10.12).[166,284]

Telegram: @dental_k

www.konkur.in

Removable partial dentures are a less desirable option for the patient because they are generally less comfortable, usually require a long period of patient adaptation, and frequently result in damage to adjacent oral tissues (tooth, gingiva, and mucosa) if not meticulously cleaned. Due to these factors, patient compliance with removable dentures is relatively low, and their use is declining. Occasionally, a patient will choose to have a tooth extracted and not pursue replacement. This decision is usually disastrous for the patient, but there are a few situations where this choice is a reasonable alternative. Diseased maxillary second molars with no opposing tooth, or with an opposing tooth in Class I or Class III occlusion that articulates with another tooth, may be extracted without concern for future inappropriate movement of the remaining teeth, which can be so occlusally and periodontally damaging. In most instances, however, removal of a tooth will result in the need for replacement, and unless the tooth is hopelessly nonrestorable, retaining the tooth with endodontic procedures is better for the patient.

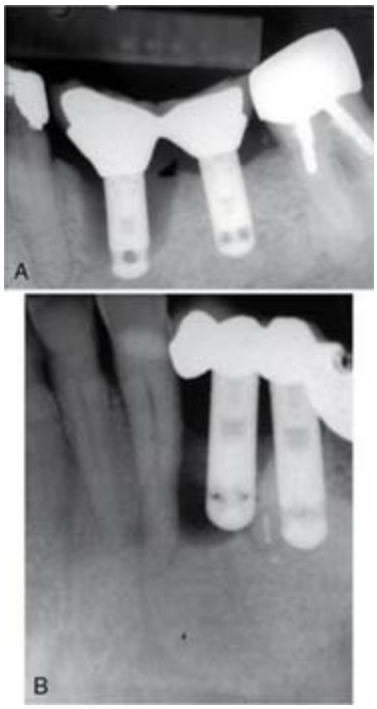

FIG. 10.11 **A,** Classic peri-implantitis. The implant needed removal. **B,** Another peri-implantitis. Note the endodontically treated root tip apical to the implant that may have contributed to the persistent disease. Perhaps apicoectomy should have been performed.

B) Radiograph of teeth shows black outline around the pulp of a tooth with a radiopaque white outline of two peri-implantitis.

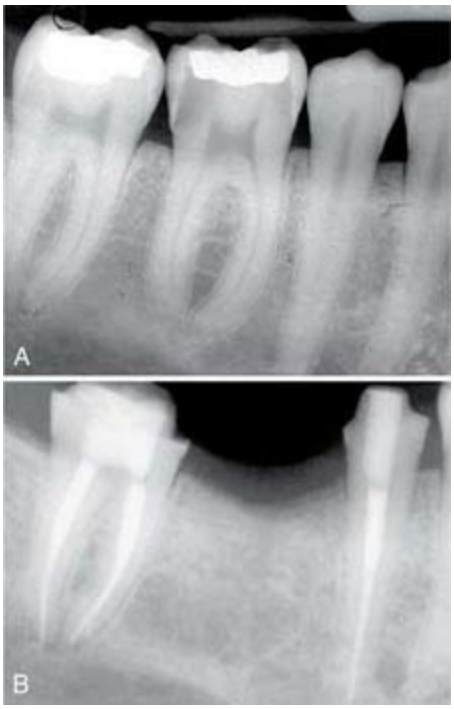

FIG. 10.12 **A,** Preoperative film showing deep caries approaching the pulp. The patient's holistic dentist advised extraction and replacement rather than endodontic therapy to retain the tooth. **B,** Fixed partial denture fabrication procedures resulted in irreversible pulpitis on both abutments requiring endodontic therapy.

A) Radiograph of teeth shows a white radiopaque patch in the crown of first molar and slightly larger radiopaque patch in the crown of second molar. Outlines of black are visible around the neck towards the root tips.

B) Radiograph shows gap between two teeth that show radiopaque crown and root canal.

Various situations may render a tooth nonrestorable (Fig. 10.13); however, the line of demarcation between restorable and nonrestorable is a movable one, depending on who is evaluating the tooth. There are several widely agreed upon situations that render a tooth nonrestorable. These include

Telegram: @dental_k

www.konkur.in

extensive caries or coronal fracture approaching or entering the furcation or the biologic width. This situation may render pre-prosthetic periodontal procedures ineffective (leaving a furcation involvement or poor crown to root ratio, for example) or worse, remove bone that would otherwise be useful for implant procedures. Terminal periodontal disease (extensive pocketing or mobility) or root fracture[45] generally results in loss of the tooth despite all efforts at treatment. If the patient has a life-threatening endodontic infection with extensive trismus, most oral surgeons are going to extract the tooth rather than allow less aggressive management. Some previously root-filled teeth may have endured procedural complications, such as a nonretrievable separated instrument or irreparable ledge formation. In combination with the proximity to vital anatomic structures, such as the inferior alveolar canal, endodontic retreatment, either surgical or nonsurgical, may not be feasible and extraction may be the only option. These situations are, fortunately, quite rare, and in most instances, teeth presenting with posttreatment disease can be retained with endodontic procedures.

FIG. 10.13 **A,** Deep caries approaching the furcation and the biologic width. Necessary crown-lengthening surgery would open the furcation to bacterial invasion and persistent periodontal disease. **B,** Distal root vertical fracture resulting in a split root. **C,** Severe caries and post perforation. Inadequate root structure remaining to restore. **D,** Multiple

Telegram: @dental_k

www.konkur.in

distal root perforations so weaken the root as to make it nonrestorable. Note: Cases *A, B,* and *D* could have resective endodontic surgery such as hemisection, but long-term prognosis is poorer than for extraction and replacement.[35,142]

A) Radiograph of first molar shows radiopaque crown with radiolucency near the neck and circular cavity in the left side of crown. Second molar shows radiopaque crown with radiolucency near the neck and black smudge on the left side of crown.

B) Radiograph of a molar shows white radiopaque patch in the crown and a radiolucent root canal split in two lateral halves.

C) Radiograph of teeth with a radiopaque white outline of the perforation tool.

D) Radiograph of teeth shows a radiopaque crown and root canals with left root canal visibly segmented into chunks.

Once the decision has been made to retain the tooth, there are several choices for treatment. These can be grouped together into either nonsurgical or surgical endodontic treatments. The surgical options can be further broken down into periradicular curettage, apical root resection (with or without root filling), root amputation or hemisection, and intentional replantation (extraction/replantation).[100,190] Occasionally, a situation arises that will require both nonsurgical and surgical types of treatment to effect healing. The American Association of Endodontists has published guidelines that may help the clinician with clinical decision-making.[9] However, the choice of which option to undertake will be determined by the clinician's experience, knowledge, patient considerations, and the preoperative diagnosis. If the etiology of the posttreatment disease can be made known, the choices become more obvious. In a previous section, four basic etiologies were presented. If the suspected etiology is in the first group, which is persistent or reintroduced microorganisms, then several choices are available. However, if the cause of the posttreatment disease is either persistent extraradicular infection, foreign body reaction, or the presence of a true cyst, then nonsurgical root canal therapy has little likelihood of allowing healing to occur, and surgical methods should be employed.[259] The problem for the clinician is that, in most instances, it cannot be determined which of these etiologies exist, and so the treatment becomes more empirical.

The choice of nonsurgical retreatment versus apical surgery becomes the

Telegram: @dental_k

www.konkur.in

focus of the decision in most instances. Outcomes assessment studies provide some help in making this decision. This thought process has recently undergone significant change, however, due to more recent outcome studies. Past literature reported on outcomes related to older methods of performing periradicular surgery. They reported healing rates of nonsurgical retreatment that range between 74% and 98%,[75] but with older methods of apical surgery alone, only 59% heal completely.[72] When these methods of apical surgery were preceded by orthograde retreatment, however, the incidence of complete healing rose to 80%.[72] Therefore, in general, nonsurgical retreatment was the preferred choice, since it seemed to provide the most benefit with the lowest risk. It had the greatest likelihood of eliminating the most common cause of posttreatment disease, which is intraradicular infection. Nonsurgical retreatment is usually less invasive than surgery and has a less traumatic postoperative course. There is less likelihood of incurring damage to adjacent vital structures such as nerves, adjacent teeth, and sinus cavities. However, nonsurgical retreatment may be more costly than surgical treatment, especially if large restorations must be sacrificed during disassembly procedures prior to the retreatment. In addition, the amount of time needed for retreatment is usually longer than surgical intervention. There are times when the clinician may not be able to achieve the complete elimination of microorganisms from the canal space, and complete obturation may not be possible. Apical surgery was considered a potentially less successful option and was therefore chosen when nonsurgical retreatment was not possible or when the risk-to-benefit ratio of nonsurgical retreatment was outweighed by that of surgery.[73,159] Recently, several meta-analyses of longer-term surgical outcomes of newer microsurgical techniques have shown greatly improved rates of healing compared to older methods.[133,236,249,281] These studies indicated that endodontic microsurgery had success rates between 89% and 94%, much higher than the traditional surgical techniques that the previous treatment planning thought process depended on. This shift in the decision paradigm has now moved endodontic surgery to the forefront, and the decision of when to do surgery versus nonsurgical retreatment has become more well defined. Apical surgery is no longer the second choice in how to manage posttreatment disease, and this has caused greatly renewed interest among clinicians in acquiring the armamentarium, skills, and experience to

Telegram: @dental_k

www.konkur.in

perform surgery at a higher level.

There are many other factors to consider when deciding whether to retreat surgically or nonsurgically. The patient must be fully aware of the proposed treatment and the alternatives, and he or she must be motivated to follow through with all treatment including the final restoration. For nonsurgical management, the patient must have adequate time to undergo the required procedures. If not, then apical surgery alone may be indicated. The clinician must be armed with the best equipment and knowledge available, and critical self-evaluation should allow the experienced clinician to know what is and is not treatable. The tooth must be restorable and retreatable. Attempting nonsurgical retreatment on teeth where there is little likelihood of improving the previous treatment provides little benefit to the patient. Thus in disease situations where there is an apparently adequate root filling and no evidence of coronal leakage, surgery may be indicated.[203] If the previous treatment falls below any acceptable standard and there is no evidence of apical periodontitis, then there is no indication for any treatment unless a new coronal restoration is planned. In that case, conservative retreatment is indicated and the reported success rates are very high.[72,75] If there has been a previous procedural complication, such as a ledge that cannot be bypassed or a separated instrument that cannot be removed, then surgery may become a better option. Most times, however, it is still prudent to attempt the retreatment since ledges or separated instruments that appear impenetrable on diagnostic films can frequently be bypassed. Even if they cannot, nonsurgical retreatment can enhance the success of subsequent apical surgery as noted earlier. The clinician must be careful not to worsen the situation by overly vigorous attempts to treat the previous complication since root perforation, worsening of a ledge, or another separated instrument may be the result. Previous failed apical surgery should be retreated nonsurgically and then followed up since many surgical failures are due to poorly cleaned and filled canal systems (Fig. 10.14).[214] In many instances, performing the surgery a second time can be avoided altogether. If there is evidence of root fracture (narrow-based probing defect) and/or a J-shaped radiolucency encompassing the root apex and progressing in a coronal direction (Fig. 10.15),[266] then nonsurgical retreatment would be unlikely to improve that situation. Apical exploratory surgery may be necessary that could result in root resection or

Telegram: @dental_k

www.konkur.in

even extraction of the tooth.

Each case should be approached as a unique set of considerations that need to be reviewed and interpreted prior to selecting a treatment method. Once the selected option is undertaken, however, the prudent clinician is always

Telegram: @dental_k

www.konkur.in

watchful, since additional pieces of information can be discovered during treatment that may modify previous decisions.

Nonsurgical endodontic retreatment

The primary difference between nonsurgical management of primary endodontic disease and posttreatment disease is the need to regain access to the apical area of the root canal space in the previously treated tooth. After that, all the principles of endodontic therapy apply to the completion of the retreatment case. Coronal access needs to be completed, all previous root filling materials need to be removed, canal obstructions must be managed, and impediments to achieving full working length must be overcome. Only then can cleaning and shaping procedures be instituted that will allow for effective obturation and case completion. The remainder of this chapter will be devoted to these topics in the order that they generally present themselves to the clinician treating the previously root-filled tooth.

Coronal access cavity preparation

Retreatment access has been called coronal disassembly[214,215] because of the frequent need to take apart or remove the previous coronal and radicular restoration. Following initial endodontic therapy, most teeth require and receive a full coverage restoration, and many times that restoration is supported by a post and core. Coronal-radicular access for retreatment is much more complicated in these cases when compared to endodontically treated teeth that have been minimally restored. The goal of the access preparation is to establish straight-line access to the root canal system while conserving as much tooth structure as possible. The ideal access preparation allows for instruments to enter the canals without being deflected by the access cavity walls. This is reasonably easy to achieve when the tooth is completely intact, and a pulp chamber is present since surface and internal anatomic landmarks can guide the search for the canals. Unfortunately, when endodontic retreatment is necessary, the tooth structure has almost always been altered and is commonly quite misrepresentative of the original anatomy of the tooth.

When presented with a tooth in need of retreatment that has a full coverage

Telegram: @dental_k

www.konkur.in

restoration, the decision for the clinician becomes whether to attempt to preserve the restoration or to plan its replacement. This decision is made simpler if there is a defect or caries associated with the restoration or if the treatment plan calls for a new crown. The old one is simply removed and replaced later in the treatment sequence (Fig. 10.16). When the crown is considered to be satisfactory, the decision becomes more complex. If the restoration is maintained, the cost for replacement can be avoided, isolation is easier, the occlusion is preserved, and the esthetics will be minimally changed. Even if the crown requires replacement, the clinician may elect to retain it during the endodontic retreatment to allow for better isolation with the rubber dam. Unfortunately, retreatment may be more difficult with the crown in place as this could lead to an increased chance for an iatrogenic mishap due to restricted visibility. In addition, removal of canal obstructions, such as posts, will be more difficult, and there is an increased chance the clinician may miss something important such as hidden recurrent caries, a fracture, or an additional canal. To preserve the restoration, two approaches can be taken: access through the crown or crown removal and replacement when retreatment is completed. The simplest choice is to prepare an access cavity through the existing crown, although there is a significant risk of damaging the restoration resulting in the need to replace it.[179] This risk must be communicated to the patient prior to instituting therapy. If the clinician decides to access through the existing restoration, there are several choices of access burs to use, depending on what material the preparation will be cut through. If the access will be primarily cut through metal (amalgam alloy or cast metal) or composite resin, carbide fissure burs such as the #1556 are usually chosen. With many restorations, it is advisable to consider using a combination of burs to achieve access. For example, when a porcelain fused to metal (PFM) crown is encountered, a round diamond is used to cut through the porcelain layer. Once the metal substructure is encountered, an end-cutting bur, such as the Transmetal bur (Dentsply Maillefer, York, PA) or the Great White bur (SS White, Staten Island, NY), can be used to cut through to and remove the core material efficiently. An important consideration for the clinician is the potential for porcelain fracture, which may occur during the preparation or possibly at a later date after completion of the treatment. This damage is especially common with porcelain jacket crowns. Restorations

Telegram: @dental_k

www.konkur.in

fabricated completely of porcelain are becoming more and more popular, thus creating added concern due to the increased likelihood of crack formation during access. Porcelain is a glass, and drilling through this material will create many micro-fractures, which in turn may weaken the structure of the restoration, making it more prone to future failure.[105] Copious coolant water spray and the use of diamond burs are recommended during access through porcelain to minimize occurrence of this event.[263] In a novel approach, Sabourin et al.[216] recently showed that, compared to the use of drills, air abrasion produced almost no defects in the porcelain structure of all ceramic crowns when used for endodontic access. It was, however, significantly more time consuming to access through the crown this way. Crowns made of zirconia are also becoming more popular due to their greater strength and acceptable esthetics. This material is very hard and resistant to cutting. Conventional diamond burs may not be able to cut this material well, and when attempting to do so, the production of small flashes of light, or sparks, may be seen at the interface of the spinning diamond and the zirconia. This is sometimes how it is discovered that it is indeed zirconia being cut, since many times these crowns resemble porcelain jacket crowns. Some types of tooth-colored crowns have a zirconia substructure that is overlaid with a ceramic veneer. In preparing the access, the external ceramic layer is easily cut, but upon reaching the zirconia substructure, progress slows, and light flashes can again be detected. In such cases, the veneered ceramic layer may have a higher incidence of fracture damage compared to a monolithic zirconia crown.[98] Newer diamond burs designed to cut through zirconia are available, which are much more efficient at removing the material and they do not produce the aforementioned light flashes. Copious irrigation should be used to minimize heat generation while accessing through zirconia crowns.[167]

www.konkur.in

FIG. 10.16 **A,** Limited visibility and access with crown present. **B,** Enhanced visibility and access with crown off. Note: isolation achieved by using a Silker-Glickman clamp and sealing putty.

A) Close-up view of a molar with open crown exposing the decayed dentin.

B) Close-up view of a molar with three small ruptures in the crown exposing the decayed dentin.

If the decision is made to remove the crown for reuse, the visibility is increased, allowing for much easier removal of canal obstructions and a decrease in the potential for operator error; however, rubber dam clamp placement and tooth isolation may become a bigger problem. Also, despite all the varying techniques and armamentaria available for the removal of an existing restoration, the procedure remains unpredictable and many times can also result in damage to the restoration or the inability to remove it at all.

The clinician must decide how to remove the crown. If the crown is of no value, even as a temporary, then the clinician can take the easiest road and simply cut it off. However, if the crown is to be preserved, then a more conservative approach must be used. Two considerations, which may influence the decision about removal of a crown or bridge, are what material the restoration is made of and what is it cemented with. Conservative removal efforts are difficult with traditional, all-metal restorations cemented with nonbonded cements. This situation is even more of a concern lately due to the increasing popularity of tooth-colored restorations, mainly different types of porcelain, PFM, and zirconia restorations, which are being bonded to the tooth. These restorations are less likely to withstand the stresses of removal than those comprised completely of metal, and restorations that are bonded are much more difficult to remove due to the adhesive strengths of bonding agents. Each new generation of bonding agent is stronger than the previous,

Telegram: @dental_k

www.konkur.in

making removal increasingly more difficult as cosmetic dentistry advances.

There have been many devices developed specifically for the conservative removal of crowns. Some of the more commonly used devices are forceps, which have been designed specifically for crown removal such as the K.Y. Pliers (GC America, Alsip, IL) (Fig. 10.17), which uses small replaceable rubber tips and emery powder to enable a firm grasp of the crown without damaging it. Other instruments of this type include the Wynman Crown Gripper (Miltex, York, PA), the Trial Crown Remover (Hu-Friedy, Chicago, IL), and the Trident Crown Placer/Remover (CK Dental, Orange, CA). Unfortunately, a crown that has been cemented with long-term cement or has been bonded to the tooth will usually not be removed with one of these instruments. There are also forceps designed specifically to engage the margins of the crown while using an adjacent tooth as a fulcrum. Squeezing the handles together will cause the crown to be elevated off the tooth. The Roydent Bridge Remover (Roydent, Rochester Hills, MI) works in this fashion and can be effective in crown removal, but care must be taken to avoid damage to fine, fragile margins, especially on porcelain crowns. Another type of instrument can be engaged under the margin, and a subsequent impact delivered at this site will dislodge the restoration. The Easy Pneumatic Crown and Bridge Remover (Dent Corp, White Plains, NY) and the Coronaflex (KaVo, Lake Zurich, IL) create this impact from compressed air; whereas, the Morrell Remover (Henry Schein, Port Washington, NY) applies the force manually using a sliding weighted handle. The ATD Automatic Crown & Bridge Remover (J. Morita, Irvine, CA) uses vibrations to break the crown to preparation bond, and the Crown-A-Matic (Peerless International, South Easton, MA) delivers a shock impulse to loosen the crown. As mentioned before, crown margin damage may result as can inadvertent extraction of the tooth if the periodontium is compromised (see Fig. 10.17, *E*).[207] A different approach to conservative crown removal involves drilling a small hole through the crown in order to allow a device to thread a screw through the hole. This approach creates a lifting force that separates the crown and the tooth. The instruments that work in this manner are the Metalift (Classic Practice Resources, Baton Rouge, LA), the Kline Crown Remover (Brassler, Savannah, GA), and the Higa Bridge Remover (Higa Manufacturing, West Vancouver, BC, Canada). While very effective

Telegram: @dental_k

www.konkur.in

on metal crowns, these instruments may cause damage to porcelain occlusal surfaces on PFM restorations, and their use in both anterior teeth and in all-porcelain restorations is generally precluded.

Endodontic therapy was performed in hand and the tooth was replanted; a procedure known as unintentional replantation. **F,** Kline Crown Remover (Brasseler, Savannah, GA).

Set of five images shows tools for non surgical endodontic retreatment.

Another interesting technique designed to remove a crown without causing damage is performed using the Richwil Crown & Bridge Remover (Almore, Portland, OR). This material is a water-soluble resin, which is softened using warm water (Fig. 10.18). The small block of material is placed on the crown to be removed, and the patient bites into this material until the resin cools and hardens, at which point the patient opens his or her mouth, generating enough force to pull the crown off. Care must be taken by the clinician to avoid using this technique when the opposing tooth is extensively restored, since the opposing restoration may inadvertently be removed during the procedure.

Telegram: @dental_k

www.konkur.in

None of these techniques works in every case, and they may produce damage to the restoration being removed or possibly others. These are, however, methods that are available and may work while permitting reuse of the restoration.

Post removal

Once the access is prepared, it is very common to encounter a post because posts are frequently used in the restoration of endodontically treated teeth. There are many different types of posts the clinician may encounter during retreatment (Fig. 10.19). These can be classified into two categories:

Telegram: @dental_k

www.konkur.in

prefabricated posts and custom cast posts. Historically, cast posts were more commonly used than prefabricated posts; however, over the past three decades, cast posts have become much less popular.[229] The main reason for this decrease is the convenience of placing the prefabricated post immediately after post preparation as opposed to waiting for a laboratory to fabricate the casting. There is also less likelihood of the interappointment contamination that frequently occurs with temporary post/core/crowns that are needed for cast/custom post and core fabrication. Prefabricated posts come in a variety of shapes, designs, and materials. The shapes can be subclassified into two groups: parallel sided or tapered. The design of posts also can be subclassified into active (threaded), passive, vented, fluted, and acid etched groups. There are also many materials that have been used to fabricate posts, such as stainless steel, gold, titanium, ceramic, zirconia, and fiber-reinforced composite posts. Cast posts, which are fabricated in a laboratory, will always be made up of precious or nonprecious metal alloys. These posts will also come in a variety of shapes and configurations since they are custom manufactured for each root in which they are placed. Most of these will have some degree of taper, and many will be cast in one piece with the core included.

Source: (Courtesy Dentsply Endodontics.)

In addition to the shape, design, and material of posts, there are two more very important factors that will have some influence on the clinician's ability to remove them. These factors are the adhesive material used to cement the post and the location in the arch of the tooth that requires post removal.

The same concerns regarding cements that were discussed in the section on crown removal apply to post removal. The main consideration is whether the post was cemented with traditional cement or bonded with a composite resin and dentin-bonding agent. Several post systems on the market today, such as the ProPost (Dentsply, York, PA), use acid-etched metal posts that are bonded into the canal with cements, such as Panavia (Kuraray America, New York, NY) or C&B Metabond (Parkell, Farmingdale, NY). Removal of these posts is extremely difficult and occasionally impossible, regardless of which technique is used.[94] A recent study[83] has shown that heat generation with ultrasonic vibration may help to decrease the retention of resin-cemented posts, but concern for heat-generated periodontal ligament damage may

Telegram: @dental_k

www.konkur.in

preclude this technique.[229]

Regarding location, the more posterior in the arch, the more difficult the post is to remove. This predicament is a result of accessibility. The more accessible the tooth is, the easier the post is to remove, since the clinician will have more techniques and instruments available to use.[3] Also, the more anterior the tooth is, the less the opposing occlusion will interfere with post removal.

Post removal techniques

After initial access and the post to be removed has been located, the clinician is faced with the decision of how to remove it. There have been many techniques developed for the sole purpose of post removal. Regardless of which technique is chosen, there is one simple yet extremely important rule to follow: it is not only what is removed, but what is left behind that is important. This rule applies to the removal of all intracanal obstructions. The reason for this rule is to make sure that the remaining tooth, after removal of the obstruction, can be restored predictably with a good long-term prognosis. For example, there is little use in successfully removing a post and leaving behind a root that is eggshell thin and prone to fracture (Fig. 10.20).

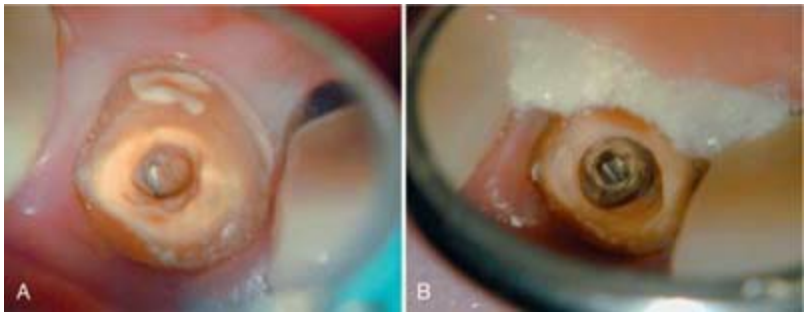

FIG. 10.20 **A,** Broken post (incisal view before excavation). **B,** Root has been so thinned and weakened by excavation procedures that restorability is questionable.

A) Close-up of the superior view of a molar with a broken and thinned post.

B) Close-up of the superior view of a thin rooted molar exposing the post.

The first step in post removal is to expose it properly by removal of all adjacent restorative materials. With preformed posts, the bulk of the core

Telegram: @dental_k

www.konkur.in

material around the post and within the chamber can be removed with a high-speed handpiece using cylindrical or tapered carbide or diamond burs. When most of the restorative material is removed, a less aggressive instrument, such as a tapered bur in a slow-speed handpiece or a tapered, mid-sized ultrasonic tip, should be used to remove the last of the embedding core material. This process is greatly facilitated by use of magnification and illumination. Once there is minimal restorative material remaining, a smaller-sized ultrasonic instrument should be used to minimize the risk of removing unnecessary tooth structure or thinning of the post. The more post that is left, the more options for removal, and the more tooth structure that is left, the more options for restoration. At this point, a high-speed bur is too risky to use. When the core is cast in one piece with the post, a high-speed instrument can perform this process to generate a shape that can facilitate removal.

Once the post is well isolated and freed from all restorative materials, the clinician can begin the retrieval process. There are many instruments and kits on the market that can be used to remove posts; however, prior to using one, the retention of the post should be reduced. The clinician can usually continue to use the same medium-sized ultrasonic tip which helped get to this point. Using this instrument at the interface between the post and the tooth (the cement line) and constantly moving it around the circumference of the post will disrupt the cement structure along the post/canal wall interface and decrease post retention facilitating removal[24,36,132]; although the effects of ultrasonic vibration may be minimal in reducing retention of well-fitted, long, large diameter titanium posts.[25] Titanium has a lower modulus of elasticity than stainless steel, so it may dampen the ultrasonic vibrations, which may decrease the effectiveness of the ultrasonic; however, a recent study[109] failed to duplicate this effect. Nonetheless, care should be taken not to push the ultrasonic tip against the post with too much force as this will dampen the ultrasonic wave and reduce the effectiveness of this technique. Taking away a small amount of the dentin around the coronal aspect of the post is not critical at this time as this will aid in the reduction of post retention without unduly weakening the root. If the root is thin, however, and the amount of space between the cement line and the root surface is restricted, the size of the tip that can be used may be limited. Unfortunately, the smaller tips are not only less effective for post removal they are also more prone to breakage. At this

Telegram: @dental_k

www.konkur.in

point, the ultrasonic handpiece should be used with copious air-water spray as a coolant. Due to the heat that can be generated from this procedure, the tip should be removed from the access every 10 to 15 seconds to allow the use of an air/water syringe to clean not only the area of debris but also to reduce the temperature produced that could potentially cause damage to the periradicular tissues.[229,307] If a rubber dam is in place, the area around the post may be flooded with a solvent, such as chloroform, prior to activating the ultrasonic instrument as this will help dissolve the cement around the post. Using a solvent in conjunction with removal of cemented obstructions may prove beneficial, since the ultrasonic energy produced will set up shock waves in the solvent and make it penetrate deeper into the canal space exerting a faster solvent action on the cement.[88]

Using an ultrasonic instrument in this fashion is not simply helpful in reducing post retention; this may also prove to be all that is needed to remove the post. Many times, after judicious use of the ultrasonic instrument, the post will loosen and spin out of the preparation completing post removal (Fig. 10.21). In addition, if post removal cannot be accomplished in this manner, the resulting post exposure will be very beneficial in contributing to the predictable use of other techniques as many of the instruments to be discussed involve using a trephine bur to shape the coronal end of the post. Ultrasonic exposure will facilitate this process. Another instrument to consider for exposing and loosening a post is the Roto-Pro bur (Ellman International, Hewlett, NY) (Fig. 10.22). There are three shapes available, all of which are six-sided, noncutting tapered burs that are used in a high-speed handpiece around the circumference of the post. The vibrations created when the noncutting flutes contact the post decrease the retention of the post, facilitating its removal.

If retention reduction does not remove the post, some form of vice is needed to pull the post from its preparation. Many post removal kits are available on the market today with varying degrees of effectiveness. One such device is the Gonon Post Removing System (Thomas Departement Dentaire, FFDM-Pneumat, Bourge, France) that is a very effective instrument for removing parallel or tapered, nonactive preformed posts.[160,218] This kit utilizes a hollow trephine bur that is aligned with the long axis of the post and

Telegram: @dental_k

www.konkur.in

placed over its newly exposed end. The trephine then cuts in an apical direction shaving off the post's outer layer not only to remove tooth structure adjacent to the post but also to reduce the circumference of the post to a specific size and shape. This procedure is necessary to allow a specific, matched-size extraction mandrel to create or tap a thread onto the exposed milled portion of the post. Once the extraction mandrel with its associated washer/bumpers (Fig. 10.23) is attached to the post, the extraction forceps or vice is applied to the tooth and post. Turning the screw on the handle of the vice applies a coronal force in a similar fashion as a corkscrew removes a cork from a bottle of wine. This method is effective because all the force is applied to the bond between the tooth and the post ideally in the long axis of the root. The main problem with this technique is the size of the vice that can make access in the molar region and between crowded lower incisors difficult. Also, if the extraction force applied is not directed in the long axis of the root, root fracture may occur.[41]

H) Close-up of the exposed post being screw-turned by a vice.

G) Close-up of the removed post in the extraction device.

The Thomas Screw Post Removal Kit (Thomas Departement Dentaire, FFDM-Pneumat, Bourge, France) (Fig. 10.24) is an instrument designed specifically for the removal of active or screw posts. The trephine burs are identical to those used with the Gonon Post Removal System; although the extraction mandrels are threaded in the opposite direction. The mandrels are reverse threaded to enable them to tap onto the screw post in a counterclockwise direction so that continued torquing force while creating the thread will unscrew the post.

post. **B,** Head of post being contoured to a roughly cylindrical shape. **C** and **D,** Thomas Post Removal Kit. **E,** Domer bur creating a shape that the trephine bur can engage. **F,** Trephine bur milling the post. **G,** Application of counterclockwise rotational force using the wrench. **H,** Post removed.

A) Close-up of an open mouth exposing the upper jaw with a broken screw post.

B) Close-up of an open mouth held by a gloved thumb shaping the post by a dental contouring tool.

C) Close-up of the Thomas screw post dental kit trephines and corresponding tubular taps.

D) Close-up of the components of Thomas screw post dental kit.

E) Close-up of an open mouth held by gloved thumbs shaping the post by a domer bur.

F) Close-up of an open mouth held by gloved thumbs milled by a trephine bur.

G) Close-up of the exposed post being screw-turned by a wrench.

H) Close-up of the removed post in the wrench.

The Ruddle Post Removal System (Kerr Corporation, Orange, CA)[214] (Fig. 10.25) and the Universal Post Remover (Thomas Departement Dentaire, FFDM-Pneumat, Bourge, France) were designed to combine the properties of both the Gonon and Thomas Kits. Both of these very similar kits are not only useful in the removal of parallel or tapered passive types of posts but also in removing screw posts. They can even be adapted to remove large separated instruments in the coronal straight portion of a large canal. These kits also use a trephine bur to machine the post to a specific size that will dictate which mandrel to use. These mandrels tap in the counterclockwise direction so that the same taps can be used for both passive and active posts. Once the mandrel is tapped onto the post, the extraction jaws, or vice, is applied and activated enabling removal of passive posts, or the tap is continuously rotated counterclockwise to unthread screw-type posts.

B) Close-up of the components of Ruddle screw post dental kit; an extracting plier, transmetal bur, five trephines, five corresponding tubular taps, torque bar, tube spacers and rubber bumpers of varying diameters.

C) Close-up of a Thomas screw post extracting plier, two trephine burs and a tubular tap.

D) Radiograph of a molar shows a radiopaque root canals with left root canal showing a lateral segment and right root canal shows radiopaque outline of a post inserted into it.

Another device that works in a similar fashion as the Gonon and the Ruddle Post Removal System is the JS Post Extractor (Roydent Dental Products). The biggest advantage of this kit is the size, as this is the smallest of the kits that work using a pulling action, which may help with cases where access is difficult. However, this kit does have one disadvantage; it does not have as large of a variety of trephine burs and extraction mandrels as some of the others. Therefore the size of the post may be a limiting factor.

Another post removal device is the Post Puller also known as the Eggler

Telegram: @dental_k

www.konkur.in

Post Remover (Automaton-Vertriebs-Gesellschaft, Germany) (Fig. 10.26).[255] This device works in a similar manner as some of the others; however, there are no trephine burs or extraction mandrels. The design of this instrument enables it to be used more efficiently with the crown removed. In addition, the design also allows this instrument to be used for cases in which the post and core are cast as one unit. This device consists of two sets of jaws that work independently of one another. With this device, both the post and the tooth are reduced to allow attachment of the post puller. Since there are no trephine burs, this reduction is done with a high-speed handpiece and bur. Next, the first set of jaws are attached to the post while the second set of jaws push away from the tooth in line with the long axis of the tooth removing the post from the canal.[255] Care must be taken to align the pulling forces of this instrument with the long axis of the root to prevent fracture,[41] and also, this technique is not recommended for the removal of screw posts. In a survey of the Australian and New Zealand Academy of Endodontists, this was the most commonly used technique for post removal.[40] However, in a survey of the American Association of Endodontists, this was one of the least used techniques.[256] Clearly, techniques that are common in one country are not always that common in another.

The recent increased popularity of cosmetic dentistry has created an impetus towards the use of tooth-colored posts that are fabricated from ceramic, zirconia, or various types of fiber-reinforced composite. Unfortunately, as with all posts, cosmetic posts also will need to be removed periodically. Neither the use of the Gonon Kit nor ultrasonic instruments

Telegram: @dental_k

www.konkur.in

allows for removal of cosmetic posts while the use of a high-speed bur to channel down through the post may result in a high rate of root perforation.[200,229] It is important for the clinician who is removing cosmetic or tooth-colored material or posts from the canal, to stain the coronal area of the post with a dye such as methylene blue (Fig. 10.27). By doing this, a determination can be made as to the nature of the substance to be removed and this then allows the clinician to remove as little remaining tooth structure as possible. The dye may penetrate the composite or a fiber post but more likely, it will simply outline them and the canal walls so that under the high magnification of the microscope, only the restorative material, cement, or post is removed conserving precious tooth structure. This contrasts with the task of removing a metal post where oftentimes more dentin removal is required.

FIG. 10.27 Methylene blue dye applied to cosmetic materials in the canal orifice. The dye may outline or penetrate the materials/fiber posts but will allow more conservative removal of the obstruction preserving dentin. If no dye penetration occurs at all, the post may be made of ceramic or zirconia requiring a different removal strategy. **A,** Composite outlined. **B,** Composite penetrated. **C,** Fiber post outlined. **D,** Fiber post penetrated.

Set of four images shows a horizontal section of tooth colored cosmetic material with a circular rupture in the center held in a clamp displaying an outline or penetration of methylene blue dye.

The use of the Largo Bur (Dentsply, York, PA)[85] and the Peeso drill[200] to remove these posts has been advocated and most of the post manufacturers' have removal burs in their kit.[53] These manufacturers removal kits have been

Telegram: @dental_k

www.konkur.in

shown to be more efficient at removing their own fiber posts than the use of diamond burrs and ultrasonics.[153] In addition, a new bur, the GyroTip (MTI Precision Products, Lakewood, NJ), has been designed for the specific purpose of removing fiber-reinforced composite posts (Fig. 10.28). These drills consist of a heat-generating tip designed to soften the matrix that binds the fibers within the fiber-reinforced post. The fibers within the post are parallel, which assists the axial travel of the drill through the center of the post. The fluted zone of the drill allows the fibers to be safely removed, creating access to the root canal filling. Above the fluted zone, a layer of plasma-bonded silica carbide reduces the heat generation that would otherwise occur if a smooth carbide surface were rotating in contact with enamel and/or dentin. This abrasive zone also provides for a straight-line access preparation and facilitates the placement of a new post. Ceramic and zirconia posts are usually impossible to retrieve. They are more fragile than metal posts, and though ceramic posts may be removed by grinding them away with a bur (a procedure with a high risk of root perforation), zirconia has a hardness approaching that of diamond and cannot be removed by this method.[229]

J) Radiograph of a tooth shows a radiopaque crown with two radiolucent root canals. Radiopaque outline of a post is visible in right root canal.

Regardless of the post type or retrieval method used, once the post has been removed, the final step in exposing the underlying root filling material is to ensure that none of the post cement remains in the apical extent of the post space. This step can be easily accomplished by visualizing the cement using magnification and illumination and then using a straight ultrasonic tip to expose the underlying canal filling.

Potential complications of post removal

As with many dental procedures, post removal has risks. These risks include fracture of the tooth,[38] leaving the tooth nonrestorable due to excessive dentin removal, root perforation, post breakage, and inability to remove the post.[256] An additional concern is ultrasonically generated heat damage to the periodontium.[229]

Even though there may still be some who feel that posts strengthen teeth, it is widely accepted that they do not.[229] Actually, it has been shown that post preparation alone weakens teeth.[280] Therefore it seems obvious that any additional work which may require removal of further tooth structure will further weaken the tooth, increasing the likelihood of fracture. An in vitro study showed that cracks can form in radicular dentin during post removal using both the Gonon Kit and using ultrasonics, but there was no significant

Telegram: @dental_k

www.konkur.in

difference between these two groups and teeth with posts that were not removed.[8] The authors speculated that the potential for vertical root fracture might be increased; however, the clinical significance of this remains unknown. A more recent study, however, concluded that the incidence of root fracture during post removal was extremely low and that with good case selection, post removal is, in fact, a very predictable procedure.[3] If, however, post removal would also leave the remaining tooth structure in a state that may not be predictably restored with a good prognosis and if this situation can be predicted ahead of time, then surgery may be the preferred treatment option.

Perforation is an additional possible complication that can happen during post removal, especially if the post is removed by simply attempting to drill it out with high-speed burs.[200] If perforation occurs, the clinician should repair it immediately as the prognosis will worsen as the time between perforation and repair lengthens.[29,234] Once a perforation occurs, the clinician must reconsider the prognosis and determine whether the tooth should be salvaged. Terminating the procedure and pursuing a different treatment option could be considered at this point. Extraction and replacement with an implant and/or a fixed prosthesis was a treatment option prior to initiating the retreatment, and some may consider this treatment the best option once a perforation has occurred. However, with the recent development of mineral trioxide aggregate (Pro-Root MTA, Dentsply, York, PA) and other bioceramics, perforations can be repaired with a favorable prognosis.[208] The techniques and materials for perforation repair will be discussed in detail in a later section of this chapter.

Another complication is separation of the post, causing removal of the coronal segment while leaving a small portion of the post with even less accessibility. This separation will decrease the likelihood of removal and occurs more frequently when attempting to retrieve titanium posts.[229]

The use of ultrasonic energy for prolonged periods of time can generate excessive amounts of heat. The heat generated can cause damage to the surrounding periodontium.[88,229] This damage may be as serious as both tooth and permanent bone loss (Fig. 10.29). For this reason, stopping periodically to cool off the area with a water spray is necessary. This will be discussed in detail in a later section.

If the clinician is unable to remove the post, then he or she will be faced with a decision of what to do. This decision is based on whether the post is being removed for restorative purposes or due to the persistence of disease. If the reason is for restorative purposes and the clinician can adequately restore the tooth with the existing post or post segment, then he or she should do so. If the tooth cannot be properly restored without removal of the post and placement of a new post, then extraction and replacement with an implant and/or fixed prosthesis will be needed. If the reason for post removal is due to

Telegram: @dental_k

www.konkur.in

the persistence of disease, the tooth should be treated surgically and restored as well as possible.

Regaining access to the apical area

Once the coronal-radicular access is made and all posts and obstructing restorations have been removed, then the clinician must regain access to the apical area by removing the previous root-filling materials (Fig. 10.30). This part of nonsurgical retreatment is complicated by the large variety of types of root fillings used. Today, most root fillings are performed using gutta-percha in various forms; however, many other materials have been and are still being used. Silver points were very popular until the 1970s and various types of pastes are, unfortunately, still in use. The authors have seen cases of definitive root filling with phenol-soaked paper points and sometimes no root filling at all. New materials, such as various bioceramic materials and sealers, are coming on the market all the time. Though all root-filling materials have their advocates and their critics, the only certainty is that all will have some incidence of persistent disease and may need retreatment.

FIG. 10.30 Accumulation of materials removed from retreated teeth in a 3-month period.

During the diagnostic phase, it is very important to ascertain the nature of

Telegram: @dental_k

www.konkur.in

the root filling to minimize surprises when attempting retreatment. Sometimes this is readily apparent, but, in other instances, this determination may require contacting the previous clinician to discover what type of root filling was used. Occasionally, this information cannot be determined until canal entry, so extreme caution should be used when performing access so as not to possibly remove parts of the root filling that may be useful in its removal, such as the core material in solid core obturators.

Gutta-percha removal

One of the great advantages of using gutta-percha for root filling is its relative ease of removal. When the canal contains gutta-percha and sealer or a chloropercha filling, it is relatively easy to remove this material using a combination of heat, solvents, and mechanical instrumentation.[78,214] It should be noted, however, that there is no technique, instrument, or solvent that can, by itself, remove all of the previous root filling materials from a canal space.[212] Clinicians must use multiple techniques tailored to the individual tooth and patient being treated to achieve maximal root filling removal. Upon access, it is usually relatively easy to find the treated canal orifices with the visible pink gutta-percha material inside. Initial probing with an endodontic explorer into the material can help rule out the possibility that there is a solid core carrier. If there is a plastic carrier, then heat should not be used to remove the coronal gutta-percha (more on this later). If there is no carrier, heat is applied using an endodontic heat carrier that has been heated to a cherry red glow in a torch. Unfortunately, the carrier begins to cool upon removal from the flame, and so endodontists are now using a heat source, such as the Touch ‘n Heat (Sybron Endodontics, Orange, CA) (Fig. 10.31, *A*), to provide constant, consistent heat application to soften the gutta-percha in the coronal portion of the canal.[156] Care must be exercised, however, not to overheat the root, which can cause damage to the periodontal ligament.[146,221,222] Thus, the heat should be applied in a short burst to allow the instrument to penetrate the gutta-percha mass, followed by cooling, which will cause the material to adhere to the heat carrier facilitating its removal (see Fig. 10.31, *B*). After removing as much gutta-percha as possible with the heated instrument, then remove any remaining coronal material with small Gates-Glidden drills, taking care not to overenlarge the cervical portion of the

Telegram: @dental_k

www.konkur.in

canal. However, since the previously treated tooth may have had an underprepared cervical third of the canals, these drills can also be used to flare the coronal aspect in an anticurvature direction to facilitate enhanced straight line access to the apical one third of the canal and to create a reservoir for potential solvent use.[165] Again, probe the canal, this time using a #10 or #15 K-file. It is sometimes possible to remove or bypass the existing cones of gutta-percha if the canal has been poorly obturated, thus eliminating the need for solvents.[254] If that is not possible, then a gutta-percha solvent must be used to remove the remaining material in the apical portion of the canal.

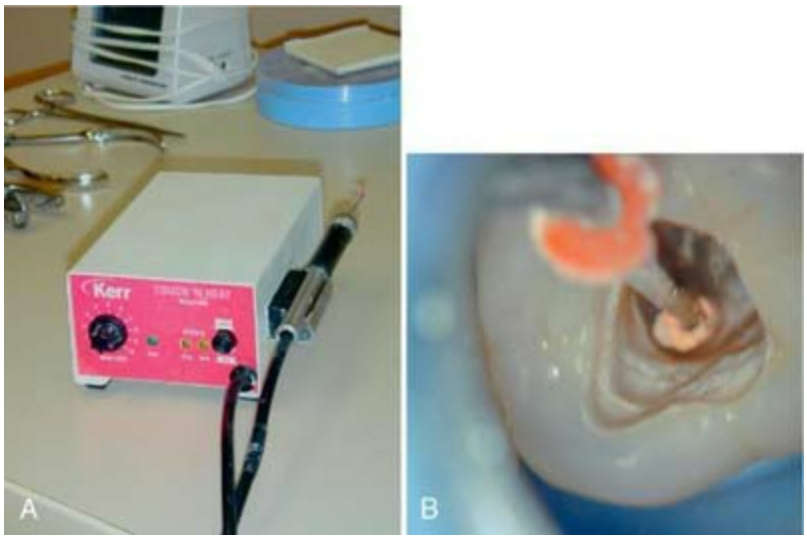

FIG. 10.31 **A,** Touch 'n Heat instrument. **B,** Gutta-percha adhering to the Touch 'n Heat tip as it cools.

A) Close-up of touch and heat device with a connected heat carrier pen with tip.

Several solvents have been recommended to dissolve and remove gutta-percha for retreatment (Fig. 10.32) including chloroform,[170] methylchloroform,[290] eucalyptol,[306] halothane,[118,141] rectified turpentine,[134] and xylene.[104] All the solvents have some level of toxicity,[19,44] so their use should be avoided if possible; however, a solvent is usually needed to remove

Telegram: @dental_k

www.konkur.in

well condensed gutta-percha. The most popular solvent is chloroform since it dissolves the gutta-percha rapidly and has a long history of clinical use. In 1976, the US Food and Drug Administration banned the use of chloroform in drugs and cosmetics due to a report of suspected carcinogenicity.[282] There was no associated ban on its use in dentistry[170]; however, the report did result in the search for alternatives some of which are listed earlier. When used carefully, chloroform is regarded as a safe and effective endodontic solvent.[44,170] All of the others generally have been reported to be less effective or have some other drawback that limits their use. Xylene and eucalyptol dissolve gutta-percha slowly and only approach the effectiveness of chloroform when heated.[301] Rectified turpentine has a higher level of toxicity than chloroform[19] and produces a very pungent odor in the operatory. Halothane has been shown to be as effective a solvent as chloroform in several studies,[118,141] but a more recent study indicated that the time for removal of the root filling was longer than using chloroform.[294] The increased cost and volatility of halothane and the potential for idiosyncratic hepatic necrosis make it less desirable to use as a gutta-percha solvent.[44] While methylchloroform is less toxic than chloroform, it is also less effective as a solvent for gutta-percha.[290] Both halothane and chloroform have been shown to affect the chemical composition of dentin[60,135] and may affect bonding strengths of adhesive cements to the altered dentin.[61,272] The clinical significance of these effects remains unknown, however. The evidence for the carcinogenicity of chloroform in humans is suspect,[170] but with careful use, its toxicity may be eliminated as a risk factor to both the patient[44] and the personnel in the operatory.[7] As such, its continued use as a gutta-percha solvent is recommended.

Telegram: @dental_k

www.konkur.in

FIG. 10.32 **A,** Chloroform. **B,** Eucalyptol. **C,** Halothane. **D,** Rectified Turpentine. **E,** Xylenes.

Five sets of images, A to E show the solvents used to dissolve and remove gutta percha filling.

Using an irrigating syringe, the selected solvent is introduced into the coronal portions of the canals, which will then act as a reservoir for the solvent. Then, small hand files (sizes #15 and #20) are used to penetrate the remaining root filling and increase the surface area of the gutta-percha to enhance its dissolution. This procedure can be facilitated by using precurved, rigid files such as the C+ File (Maillefer, Baillagues, Switzerland) (Fig. 10.33), which can penetrate the gutta-percha mass more efficiently than the more flexible types of K-files. The C+ file is a stainless steel, end-cutting hand file that is twisted from a square blank. The secret to its stiffness is that the taper varies along the shaft giving it the rigidity and strength to cut through well-condensed gutta-percha efficiently. The gutta-percha must be removed carefully, however, to avoid overextending the resultant mixture of gutta-percha and solvent beyond the confines of the canal to minimize the risk of severe postoperative pain.[156] Unfortunately, electronic apex locators, which in nonretreatment situations are very accurate,[137] seem to misread the working length frequently when gutta-percha is initially being removed. This clinical observation may be due to the file being covered with chloropercha that may affect its conductivity. It has been shown that apex locators may be

Telegram: @dental_k

www.konkur.in

less accurate in retreatment situations[289]; however, in this study, the error was that readings indicated a working length that was too short. In a more recent study, an apex locator built into a rotary handpiece indicated working lengths that were too long in simulated retreatment situations.[283] Another recent study indicated that overestimation of length can occur in retreatment situations and could lead to overinstrumentation and overextension of root filling materials during retreatment.[164] It is recommended that a radiograph be made to gain a preliminary measurement when the estimated length is approached in order to avoid overextending root filling materials into the periodontium. Alternatively, recent studies have shown that CBCT imaging can be used to measure estimated working length more accurately than periapical radiographs.[304] If a CBCT was made for preoperative analysis of the tooth to be retreated, which is within the AAE/AAOMR guidelines, then the volume can also be used to estimate the preoperative working length.[151] Well into the retreatment, after the root fillings have been thoroughly removed, the apex locator will regain its accuracy if a clean file is used. Once the working length is reached, progressively larger diameter hand files are rotated in a passive, nonbinding clockwise reaming fashion to remove the bulk of the remaining gutta-percha until the files come out of the canal clean (i.e., with no pink material on them). Frequent replenishment of the solvent should be used, and when the last loose-fitting instrument is removed clean, the canal is flooded with the solvent, which then acts as an irrigant. The solvent is then removed with paper points. The wicking action of the absorbent points[214] will remove much of the remaining film of gutta-percha and sealer that remains adhering to the canal walls and in the irregularities of the canal system.[296] Cleanliness of canals after gutta-percha removal is not improved by using a microscope[16]; however, using kinked small files, the clinician should probe the canal wall looking for irregularities that may harbor the last remnants of gutta-percha. These irregularities can usually be felt rather than seen and should be cleaned using this method.[156]

Telegram: @dental_k

www.konkur.in

FIG. 10.33 C+ files. These rigid instruments remove gutta-percha more efficiently than more flexible types of K-files.

A pack of six stiff and strong C plus files.

It should be noted that there exists a glass ionomer-based endodontic sealer (Ketac-Endo, ESPE, Seefeld, Germany) that is used in conjunction with gutta-percha.[202] This sealer is virtually insoluble in both chloroform and halothane,[292] and must be retreated by removing the gutta-percha and then by using ultrasonics to debride the canal walls. Canal cleanliness can approach that of other gutta-percha retreatment cases, but it is difficult and time consuming to achieve this result.[76,176] Recently, bioceramic sealers such as EndoSequence BC Sealer (Brasseler, Savannah, GA) have been introduced. These materials become hard when set and are also resistant to dissolution and removal from the canal system.[54]

Overextended gutta-percha removal can be attempted by inserting a new Hedstrom file into the extruded apical fragment of root filling using a gentle clockwise rotation to a depth of 0.5 to 1.0 mm beyond the apical constriction. The file is then slowly and firmly withdrawn with no rotation, removing the

Telegram: @dental_k

www.konkur.in

overextended material (Fig. 10.34).[173] This technique works frequently, but care must be taken not to force the instrument or else further extrusion of the gutta-percha or separation of the file may result. The overextended apical fragment should not be softened with solvent as this application can decrease the likelihood of the Hedstrom file getting a solid purchase hindering retrieval.[254]

Using rotary systems to remove gutta-percha in the canals has been advocated due to enhanced efficiency and effectiveness in removing gutta-percha from treated root canals.[214] This has generally been borne out in the

Telegram: @dental_k

www.konkur.in

literature. There are several types of mechanical rotary systems available for gutta-percha removal, including rotary file systems such as the ProFile (Dentsply, York, PA) (Fig. 10.35); a mechanical push-pull, quarter-turn file system, the Canal Finder (Endo Technique Co., Tustin, CA); and dedicated gutta-percha removal instruments, such as the GPX (Brasseler, Savannah, GA), the ProTaper Universal retreatment files (Dentsply, York, PA) (Fig. 10.36), and the Mtwo R (Sweden and Martina, Padua, Italy). These engine-driven instruments mechanically chop up the gutta-percha and sealer while thermoplasticizing the root filling mass via frictional heat to aid in removal. A recent survey of Australian dentists showed that 54% of the respondents who perform endodontic retreatment used rotary instrumentation to remove gutta-percha either always (15%) or sometimes (39%) with an increased likelihood of rotary gutta-percha removal if the clinician had more experience with the use of these instruments.[195] In vitro studies have generally shown these systems to be efficient in that they generally need less time to remove the bulk of the gutta-percha filling material than hand removal,[17,68,87,116,117,217,271] although in two studies, they were slower to remove the root filling than hand filing.[20,121] Assessments of canal cleanliness and extruded apical debris generally indicated that there were no overall differences between hand and mechanical gutta-percha removal.[20,68,116,117,122,187,217,246,271,310] In one study using Quantec SC instruments (Tycom, Irvine, CA), however, it was found that hand files with solvent cleaned canals more effectively.[27] This finding has been repeated recently using the ProTaper retreatment files,[103] but in another study in the same journal issue, ProTaper retreatment files were found to leave canals cleaner than hand files.[87] Clearly, this is an area where further research is warranted. It is recommended that after rotary gutta-percha removal, subsequent hand instrumentation is needed to remove the residual obturating materials completely from the canal. In several studies of mechanical gutta-percha removal, fracture of the mechanical instruments or the tooth root occurred.[17,27,32,117,121,271] However, this result was reported to occur less frequently when the instrument rotary speed was increased from 350 to 1500 rpm[32] and one study showed no separation or other canal defects when using dedicated retreatment files, the ProTaper Universal and Mtwo R instruments.[248] The dedicated retreatment files have end cutting tips to

Telegram: @dental_k

www.konkur.in

enhance penetration and removal of the root filling mass thus increasing their efficiency (see Fig. 10.36, *B*).[268] This, in combination with flute design and techniques advocated, may be the reason for the potential reduced risk of separation. In a more recent retrospective study, it was found that the incidence of instrument separation was significantly greater during retreatment than in de novo endodontic therapy.[6] While the mechanical gutta-percha removal systems may provide an enhanced efficiency, the increased risk of instrument separation, further complicating retreatment, may outweigh this benefit. Dedicated retreatment files may reduce this risk.

C) Micrograph shows a textured and spiral tip of nickel titanium rotatory file.

Engine-driven instruments can also help with the removal of residual root filling materials after the bulk of the gutta-percha has been removed. A new instrument, the Self-Adjusting File (SAF) (ReDent, Ra'anana, Israel), has been recommended for removal of the root-filling residue that remains after root-filling removal. When the Self-Adjusting Files were used after rotary retreatment files, reduction of canal residues were 66%, 68%, and 81% in the coronal, apical, and middle thirds of the canal, respectively, when compared to using ProTaper Universal retreatment files alone.[4] Another study compared the use of ProTaper Retreatment files followed by F1 and F2 ProTaper instruments to the use of a #25.06 Profile followed by the Self-

Adjusting File, for their effectiveness in removing gutta-percha-based root fillings.[247] With the use of high-resolution micro-CT and an arbitrarily selected threshold of less than 0.5% residue remaining as effectively cleaned, the ProTaper group had no cases meet this threshold while 57% of the cases in the ProFile/SAF group met the threshold. Unfortunately, in both of the previously mentioned studies, none of the retreatment methods rendered all of the treated canals completely free of all root-filling residue. The SAF file is considered a canal conforming file, and there have been new additions to this group recently, such as the TruShape file (Dentsply, York, PA) and the XP File system (Brasseler, Savannah, GA). These more recent conforming files have multiple curvatures along the length of the cutting segment of a single instrument core in order to increase the amount of contact between the instrument and the walls of pulp canals with irregular contours (such as oval-shaped canals) (Fig. 10.37). Studies to date show that these instruments can reduce the amount of remaining root filling materials after endodontic retreatment to a larger extent than traditional cylindrical core tapered engine-driven files, but they still do not render the canals completely free of all residual filling materials.[15,191]

E) Close-up of a tight spirally textured shaper with removed gutta percha on the tip surface.

Use of the Nd:YAG laser to remove gutta-percha from root-filled teeth has been investigated in vitro.[285] The time taken to remove the gutta-percha was within the range of other studies of mechanical gutta-percha removal, and the addition of solvents did not improve the performance of the laser. As in most other studies, gutta-percha, in varying amounts, was left in the canals after laser removal. Root surface temperatures did increase, however, and without further investigation proving safety and efficacy, laser gutta-percha removal cannot be recommended at this time.

Resilon (Resilon Research, LLC) (Fig. 10.38) is a thermoplastic polyester polymer that was bonded into the canal space using an unfilled resin bonding system (Epiphany, Pentron Clinical Technologies, Wallingford, CT). It was also marketed as RealSeal (Sybron Endodontics, Orange County, CA). It was advocated as a root canal obturating material to replace traditional gutta-percha and sealer due to its apparent, enhanced sealing ability[238] and potential to strengthen root resistance to fracture as a result of internal bonding.[270] Resin-bonded obturation systems have been advocated in the past[149]; however, the inability to retreat canals filled with this obturating material has prevented its widespread use. The Resilon polymer itself is reported by the manufacturer to be soluble in chloroform and may be removed by heat application, a behavior that is like gutta-percha. Recent studies have shown that the polycaprolactone polymer of the Resilon is

Telegram: @dental_k

www.konkur.in

removed easily and leaves canal walls cleaner than removal of gutta-percha and AH+ sealer,[50,52,65,227] although this finding has been disputed. Hassanloo et al. found that there was less residue on the walls when removing gutta-percha/AH+ if the materials were allowed to set for a longer period.[108] This finding has been corroborated[227,269] and indicates that there may be a temporal effect, which introduces a methodological bias in these studies. There may also be a problem with removal of the unfilled Epiphany resin sealer, especially since the sealer tags have been shown to penetrate deep into dentinal tubules[238] and presumably also into anatomic ramifications of the canal that need cleaning during retreatment. After the Resilon core has been removed using heat and chloroform, the authors would recommend the use of a resin solvent such as Endosolv-R (Septodont, Paris, FR) (Fig. 10.39) to attempt elimination of the unfilled resin sealer prior to instrumentation.

Unfortunately, recent studies have shown that the Resilon material is not stable and breaks down within the tooth over time, presumably due to enzymatic degradation.[111] The authors have retreated cases obturated with Resilon and have found discolored, soft, easily removed breakdown materials in the canal. While this may make retreatment easier, it also appears to negatively affect the long-term success of teeth obturated with this material and it was withdrawn from the market in 2014.[18] Nevertheless, clinicians should be aware of it since, like any other obturation technique, there will be a need to retreat these cases occasionally.

Managing solid core obturators

Solid core canal obturation systems, such as Thermafil, Dens-Fil, and the GT Obturator (Dentsply Endodontics, Tulsa, OK), have become very popular since their introduction several years ago. After cleaning and shaping procedures are completed, the clinician, using this technique, heats a solid core obturator (alpha-phase gutta-percha surrounding a core that is attached to a handle) in an oven and places the carrier in the canal. The solid core carries the gutta-percha down in the canal and condenses it while the material is cooling. This system provides a rapid and simple technique for warm gutta-

Telegram: @dental_k

www.konkur.in

percha endodontic obturation; however, as with any obturating material, retreatment will be necessary occasionally.

Retreatment of solid core materials is considered to be more complex and difficult than is the case with removal of gutta-percha alone due to the presence of the solid carrier within the mass of gutta-percha. The nature of the carrier will determine the method used and complexity of the retrieval. There are three types of carriers found in these systems: metal (stainless steel or titanium), plastic, and modified gutta-percha. The plastic carriers are smooth sided, as are some brands of metal carriers; however, most metal carriers are fluted and resemble endodontic hand files with a layer of gutta-percha on the outside. The fluted metal carriers present an exceptional challenge to the retreating clinician since many times they are improperly inserted and either wedged or screwed into the canal to make up for inadequate canal shaping or the lack of skilled use of the size verifying techniques available. This makes them especially difficult to remove. Once the carrier has been placed, it is cut off in the pulp chamber using a bur and the tooth is restored. The level at which the metal carrier is severed is important in its retrieval. If it is cut down to the level of the canal orifice, retrieval is difficult,[156] so the prudent clinician plans for retrievability by severing the handle from the carrier, leaving 2 to 3 mm of carrier exposed in the access above the pulp chamber floor to allow easier removal if retreatment is ever needed. Unfortunately, this is not always the case. Some clinicians place a nick in the mid-canal level of the carrier to allow the clinician to rotate the carrier handle and sever the obturator deep in the canal. This technique is used to allow creation of a post space; however, the rotational force used to create the “twist off” apical plug can engage the flutes of a metal carrier, increasing the complexity of removal if retreatment is needed.[309]

It is advantageous to determine prior to initiating treatment if there is a solid core obturation in the root-filled tooth. The preoperative radiograph may show this, since the stainless steel carriers will exhibit a fluting effect on the radiograph (Fig. 10.40); however, the titanium carriers rarely are distinguishable from gutta-percha, and the plastic ones never are. Unfortunately, in most instances, the clinician finds that they are dealing with a carrier-based obturator after initial access to the pulp chamber. This is why,

Telegram: @dental_k

www.konkur.in

as was stated in an earlier section, careful access and probing of the root filling material is necessary when entering a canal. If there is a carrier, it will be detected as either a metallic structure embedded in the gutta-percha mass or a black or gray spot indicating a plastic or modified gutta percha carrier. Occasionally, the carrier may be found embedded in the coronal core material and so careful excavation with small burs and straight, tapered ultrasonic tips may be necessary to preserve the carrier intact to help with removal.[156]

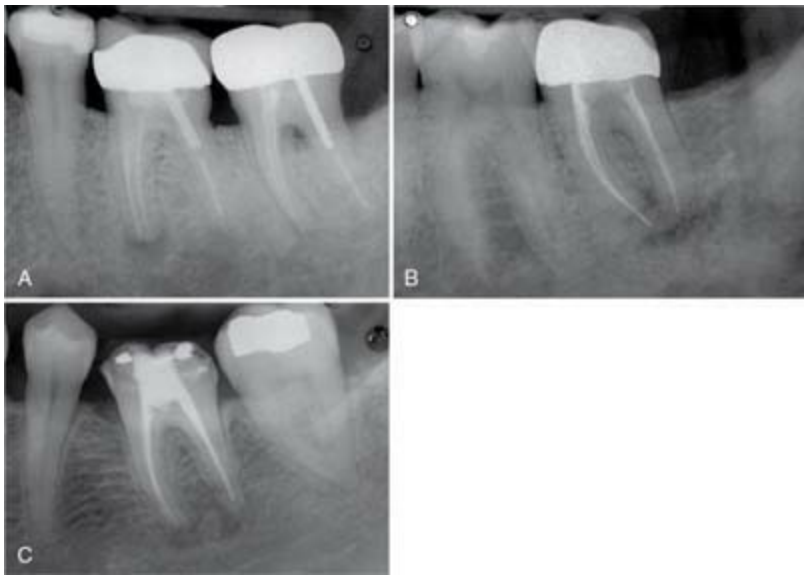

FIG. 10.40 Comparison of radiographic appearances of three different obturating materials. **A,** Gutta-percha. **B,** Stainless steel Thermafil carrier (note subtle fluting effect in the fill). **C,** Plastic Thermafil carrier.

Removal of a metal carrier is accomplished with initial use of heat application to the carrier that can soften the gutta-percha surrounding it, facilitating its removal with Peet silver point forceps (Silvermans, New York, NY) or modified Steiglitz forceps (Union Broach, York, PA) (Fig.

Telegram: @dental_k

www.konkur.in

10.41).[156,214,293,295] Often, there is not enough of the carrier remaining in the access to grasp with forceps, and so removal will require solvent application and removal of the surrounding coronal gutta-percha using small hand instruments, usually followed by ultrasonic excavation around the carrier and removing it like a separated instrument[156,214] (Fig. 10.42) as described in a later section of this chapter. Care should be exercised to avoid excessive heat generation during this procedure. This is also the case if the metal carrier has been sectioned for post space preparation. The metal carrier has been shown to be much more difficult to remove than plastic ones,[71,309] frequently resulting in nonretrieval. Fortunately, their use in endodontic therapy has been declining.

Removal of plastic carriers is similar to removal of gutta-percha root fillings, except that, generally, heat should be avoided to minimize the likelihood of damaging the carrier.[156] The older Thermafil plastic carriers were made of two different materials depending on their size. In the smaller sizes (up to size #40) the material used was Vectra, which is insoluble in available solvents; whereas the larger sizes used polysulfone, which is soluble in chloroform.[196] Solvents, on the other hand, seem not to affect the newer GT plastic carriers, so their use can be recommended (Fig. 10.43).[26] The access is flooded with a solvent, such as chloroform, and the gutta-percha surrounding the carrier is removed with hand files in a larger to smaller sequence (e.g., #25, #20, #15), with each file progressively penetrating deeper around the carrier. The solvent should be replenished frequently, and when a #08 file can penetrate to the apical extent of the carrier and there is little remaining gutta-percha, a larger Hedstrom file is inserted into the canal alongside the plastic carrier and gently turned clockwise to engage the flutes. When the file is withdrawn, it invariably brings the carrier with it, and the rest of the gutta-percha and sealer removal proceeds as described earlier. Care must be taken to avoid overstressing the Hedstrom file. It should not be “screwed” into the canal or separation of the file or the carrier may result.[26] Occasionally, grasping pliers will be needed to remove the carrier if it is accessible[123,214] after the gutta-percha has been removed. Another potential problem with retrieval is present if the carrier has been overextended beyond the apical foramen during the previous root canal treatment. This overextension may make it prone to separation and unable to be retrieved, potentially resulting in the need for apical surgery.[120]

Recently, a technique for plastic carrier removal has been described using a System B HeatSource (Sybron Endodontics, Orange, CA) to soften the gutta-percha surrounding the carrier without melting the carrier itself.[299] The temperature is set at 225°C, and the heat plugger is placed buccal and lingual to the carrier after which #50-55 Flex-R hand files are placed around the carrier and braided to engage the carrier and remove it. This technique has been shown to require significantly less time to remove the carrier compared to using solvent[299]; however, concerns regarding heat generation in the periradicular tissues have been raised[154] with the authors concluding that caution should be exercised when using this technique. When other techniques have been unsuccessful and the plastic carrier has been sectioned apical to the orifice resulting in limited access, the clinician may attempt to retrieve the carrier by placing a heated System B tip directly into it. As apical pressure is maintained, the heat is turned off. This allows the plastic carrier to adhere to the tip while cooling and may result in its removal upon withdrawal of the heat tip (Fig. 10.44).

Telegram: @dental_k

www.konkur.in

FIG. 10.44 Plastic Thermafil carrier adhering to a System B heat plugger.

A heat plugger with a conical tip and a right angled body is kept on a platform.

Rotary instruments have been advocated for use in removal of plastic carriers and gutta-percha, and a recent study showed that removal of plastic carriers was successful in all but one of the teeth obturated with them.[17] Unfortunately, root fracture occurred in the lone specimen that did not have a successful retrieval, and two instances of rotary instrument fracture also occurred in the study. As with gutta-percha removal, the clinician must carefully weigh the risks of rotary carrier removal against the perceived benefits.[213]

Modified gutta-percha is also being used as a core material for solid core obturation. This obturation system is called GuttaCore (Tulsa Dental Products, Tulsa, OK) and, at first glance, it appears very similar to plastic carrier-based systems. With GuttaCore, however, the carrier is fabricated from cross-linked gutta-percha rather than plastic. The cross-linking connects the polymer chains, which changes the material and gives the carrier different properties than the plastic carriers. The gutta-percha surrounding the carrier is alpha-phase gutta-percha, which is identical to that which encompasses the plastic carrier-based systems.

To understand how to effectively remove this type of filling material, one must understand how it is used. Obturation with GuttaCore is performed in a similar manner as obturation with Plastic Thermafil. The obturator is heated in a proprietary oven and then gently placed into the canal. While it is flexible, the modified gutta-percha carrier is much more brittle than the plastic carrier, and too much insertion force will cause the shank to collapse and the handle can break off prior to full insertion. Thus it is very difficult to

Telegram: @dental_k

www.konkur.in

wedge these obturators into underprepared canals and usually, in that instance, a short fill will result. This forces the operator to either accept a short fill or, ideally to enlarge the canal preparation prior to inserting the obturator, but in either case, retrieval of the root filling during retreatment is made easier by not having the carrier wedged into the canal.

While performing initial obturation, when it is time to section the carrier, the clinician will experience another difference from plastic carriers. While the use of a heat generating Prepi bur (Tulsa Dental Products, Tulsa, OK) or a System B Heat Source (Sybron Dental Specialties, Orange, CA) have proven to produce predictably reliable results in terms of sectioning plastic carriers at the desired level, heat has virtually no effect on the GuttaCore carrier and the authors found using heat to section the carrier to be unsuccessful. The modified gutta-percha core will not melt even when probed with a Touch ‘n Heat (Sybron Dental Specialties) tip at full power.

Because of the brittleness of the modified gutta-percha carrier, GuttaCore will separate by simply bending the carrier away from the access cavity wall. The material has very little ability to resist even the smallest of lateral forces without separation and so simply pushing down laterally on the carrier handle will separate the carrier handle from the canal fill. This has implications for retreatment since this separation method will generally result in the carrier being separated at or near the canal orifice level leaving little or nothing to grasp with forceps when attempting removal of the carrier.

Removal of the GuttaCore obturators is directly affected by the properties of the modified gutta-percha carrier, and so it is somewhat different from the approach taken to remove plastic carriers. Because of this, it is imperative that the clinician who has discovered a solid core, nonmetallic obturator while disassembling a tooth for nonsurgical retreatment can discern what type of core they are trying to remove. There are two ways to do this. First, the color of the modified gutta-percha carrier is pink or gray while the color of the plastic carriers is black (Fig. 10.45). Second, because the GuttaCore carrier is heat resistant, the clinician can lightly touch the coronal extent of the unknown carrier to see if it melts (plastic carrier) or if it does not (modified gutta-percha carrier). Once the nature of the carrier is determined, then the clinician can proceed with removal. If it is plastic, then the methods of removal described previously can be used, but if it is a GuttaCore carrier, then a different approach will be needed.

Telegram: @dental_k

www.konkur.in

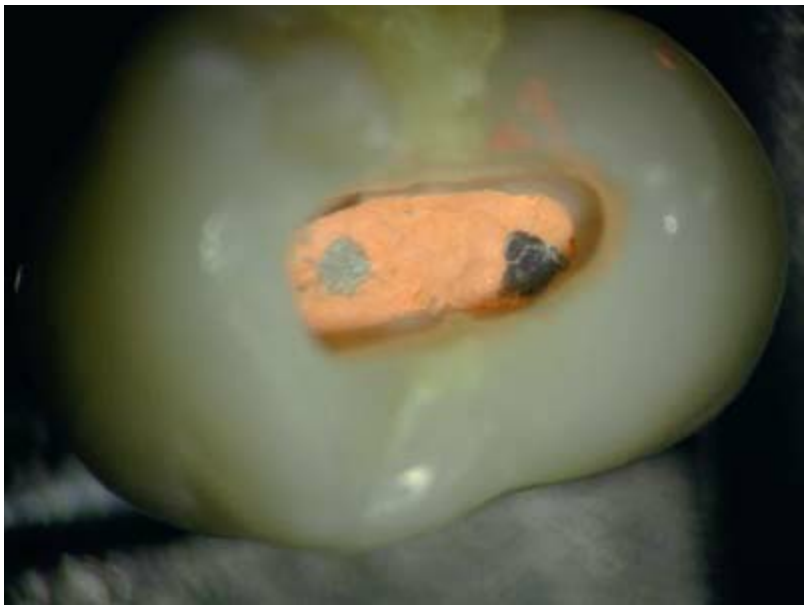

FIG. 10.45 Two different solid core carriers in an endodontic access preparation upon initial exposure. GuttaCore is on the left and a plastic carrier Thermafil Plus is on the right. Note the lighter grey color of the new modified gutta-percha core compared to the plastic carrier.

Close-up view of a molar with open crown shows residual gutta percha exposing a white dot depicting guta core in the left and a black dot depicting plastic carrier in the right.

The use of heat and solvents, which are two of the most common methods for endodontic retreatment, have no effect on the GuttaCore carrier. To date, the authors are unaware of any known solvents or chairside heat sources that can soften the cross-linked gutta-percha carrier. Also, the use of hemostats or other grasping pliers have shown inconsistent results. When straight-line access can be achieved and a few millimeters of the carrier is able to be grasped removal may be accomplished; however, due to the brittleness of the GuttaCore carrier many times it will end up separating at the apical extent of the grasping forceps. In spite of those concerns, the authors have found that Guttacore can be removed quite easily with predictable results using a variety of hand, rotary, and retreatment instruments. One study found that when using ProTaper retreatment files, GuttaCore was more efficiently removed from moderately curved canals than either thermoplasticized gutta percha or plastic carrier obturation.[22]

Telegram: @dental_k

www.konkur.in

The authors of this chapter have investigated various methods of removal of GuttaCore and confirmed the previous observation from the literature. The modified gutta-percha carrier is usually easily chopped up and removed by rotary ProTaper and reciprocal WaveOne (Tulsa Dental Products, Tulsa, OK) instruments and any remaining fragment of the carrier in the apical extent of the canal can be removed or penetrated using hand instruments. A problem arises, however, if the modified gutta-percha carrier has been overextended beyond the apical foramen. The authors' experience shows that upon removal of the segment of the carrier within the canal, the overextended tip of the carrier will separate, remaining in the periapical tissues. This potentially contaminated foreign material becomes difficult and many times impossible to remove. If this occurs, and post-retreatment apical periodontitis persists or recurs after initial resolution, then apical surgery or extraction will be necessary.

Another approach is to treat the carrier like some hard paste fills which the clinician is unable to find a solvent for. Using this approach, the clinician will find that using ultrasonic instruments in a similar fashion as they are used to remove pastes to be very helpful. Once a proper access preparation has been created, GuttaCore can be safely and easily removed with the use of ultrasonic instruments in the straight coronal portion of the canal. Upon reaching the canal curvature, the authors recommend using hand files or rotary files with safe noncutting tips in order to avoid perforation or excessive thinning of canal walls.

Once the carrier has been removed, the remaining gutta-percha and sealer must be removed from the canal, and like removal of root-filling materials described previously, there is no technique that completely removes all materials from the canal system. Canal cleaning may be even more difficult when removing carrier-based obturations since the more highly processed gutta-percha used with these carriers may be more difficult to remove than other forms of the material. Wilcox and Juhlin described a sticky film of gutta-percha and sealer adhering to the canal walls upon removal of metal carrier obturators and found more of it than if the canals had been obturated with lateral condensation.[295] Their findings have not been corroborated, however, and other studies have shown no difference in residual debris remaining after carrier-based removal.[71,123,309] It is important to remove as

Telegram: @dental_k

www.konkur.in

much of the residual gutta-percha and sealer from the pulpal anatomic spaces as possible, so flooding the canal with solvent and “wicking” it out with paper points is also recommended for carrier-based retreatment.[214]

Paste retreatment

Various pastes have been used as root canal obturating materials, especially outside of North America. Because of the wide variety of paste compounds used in endodontics, it is impossible to categorize them all. The individual clinician who is using it formulates most pastes, so the ultimate composition of a paste found in a tooth with persistent disease is generally indiscernible. Many of the pastes used, such as N2 or RC2B, contain formaldehyde and heavy metal oxides and so are toxic and potentially present a danger to the patient’s health, both local and systemic if overextended beyond the confines of the root canal system.[30,194] None has the potential to seal the canal effectively,[102] and many render a tooth impossible to retreat,[228] so their use is strongly discouraged. On radiographic examination, they can usually be discerned due to their lack of radiopacity, the presence of voids, and they usually show evidence of inadequate canal shaping and poor length control (Fig. 10.46). When a paste fill is suspected or found in a tooth, a telephone call to the previous treating dentist should be made, if possible, to find out the exact formulation of the paste, since this information may help in its removal.

Note the material extending out through a sinus tract.

A) Radiograph shows a molar with radiopaque root canals and radiolucent pulp. Two irregular L-shaped white patches of paste filling below the canals are visible.

B) Radiograph shows a tooth with radiopaque root canal and radiolucent pulp. An irregular projection of white patch of paste filling below the canal is visible.

C) Radiograph shows a tooth with parts of radiopaque radiolucent canal extending into a white smudge across the tooth surface.

D) Close-up an open mouth held with gloved thumbs shows an illuminated dot over the upper gum. An exposed central left incisor is stained and a material tract extends across the frontal teeth.

For purposes of retreatment, paste fills can be categorized as soft or hard, and all should be considered potentially toxic. Great care should be exercised when removing the paste to avoid overextension, potentially severe

Telegram: @dental_k

www.konkur.in

postoperative pain,[97] and possible paresthesia/dysesthesia from the paste's potential neurotoxicity.[33,235] Soft pastes are generally easy to remove using crown-down instrumentation with copious sodium hypochlorite irrigation to minimize extrusion.[156] Greater difficulty arises when the paste is set hard.[228] Since the nature of the paste remains unknown, removing it becomes an empirical process. Following access preparation and coronal orifice exposure, the paste is probed with an endodontic explorer and files. If hard and impenetrable, then the coronal paste can be removed with burs[78] or a straight, tapered ultrasonic tip in the easily accessible straight portions of the canal using magnification and illumination.[214] Once the canal curvature is reached, further use of this method will result in damage to the canal walls and possible perforation. Precurved, small hand files are inserted to probe the apical area. Many times, the density of the paste filling material decreases in the apical extent of the fill so that penetration to the apex may be possible.[214] If not, a solvent must be used to attempt to soften the remaining paste. The choice of solvent is usually made by trial and error starting with chloroform. If that does not soften the material in a reasonable amount of time and does not allow penetration with small files, then the chloroform is wicked out of the canal and another solvent is chosen. There are two frequently used solvents for paste fills: Endosolv-E and Endosolv-R (Septodont, Paris, FR) (see Fig. 10.39). The Endosolv-E is selected if the paste contains zinc oxide and eugenol, and the Endosolv-R is chosen for resin-based pastes. The obvious problem is that the nature of the paste is usually unknown at the time of removal, so contacting the previous clinician, if possible, can help with this choice. Otherwise, the choice is just a guess. The chosen solvent should be placed in the access, and attempts should be made to penetrate the paste with hand or ultrasonic files; however, care must be taken to avoid creating a ledge or other defect in the canal that may preclude successful retreatment. The progress is frequently slow,[81] and the clinician may elect to leave some solvent in the canals between appointments to soften the paste.[214] Care should be taken in the choice of temporary restoration since the solvent left in the canal may also soften the temporary, potentially leading to breakdown of the interappointment seal.[175]

Ultrasonically activated files have been advocated for use in penetrating hard-set pastes in the curved apical segments of canals (Fig. 10.47).[130,140]

Telegram: @dental_k

www.konkur.in

The ultrasonic energy breaks up the paste, and the irrigation floats the fragments in a coronal direction until the apical terminus is reached.[78] This technique is reported to be very time consuming, and care must be exercised to avoid instrument separation, perforations, or alteration of canal morphology. On occasion, despite all best efforts, the paste cannot be removed from the tooth, so apical surgery or extraction should be considered in these cases.[97]

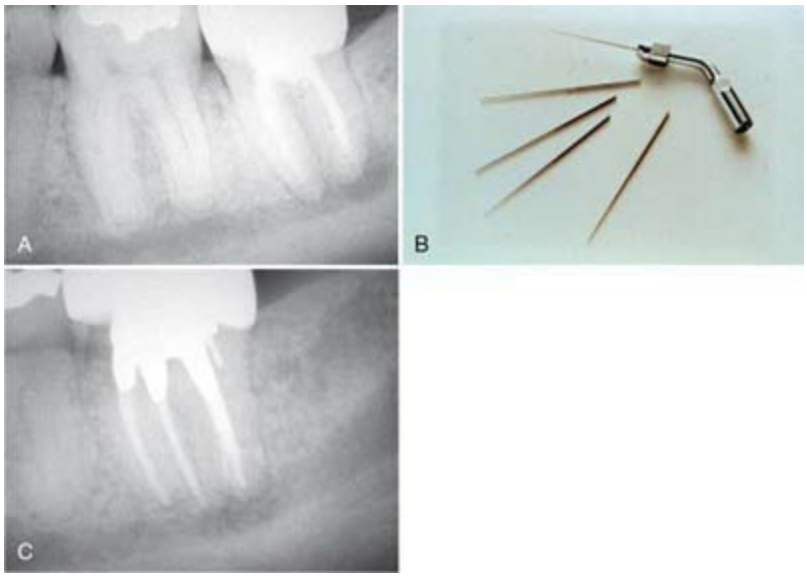

FIG. 10.47 **A,** Preoperative radiograph of a hard paste root filling exhibiting a short fill, inadequate seal, and periapical radiolucency. Note the proximity of the inferior alveolar canal. **B,** Ultrasonic files like this were used to break up the hard paste in the apical third of the canal allowing removal. **C,** Seventeen-month postoperative follow-up. Biocalex 6.9 (currently known as Endocal 10) (Fig. 10.48) is a hard setting calcium oxide paste that has been popular in Europe for over 30 years, but is

Telegram: @dental_k

www.konkur.in

now being used in North America since its recent FDA approval.[93] The paste seems to seal well, but there is an unacceptably high incidence of root fracture due to the large amount of expansion on setting.[93] Retreatment will be complicated by the hard setting nature of this material; however, since it is a calcium oxide paste, EDTA may soften it, facilitating its removal. Since the EDTA also softens dentin, care must be taken not to gouge or ledge the canal walls during retreatment, and root fractures must be suspected as a potential complicating factor in the outcome.

Silver point removal

Historically, the use of silver points for endodontic therapy has been extremely popular and quite successful because of their ease of handling and placement, ductility, radiopacity, and that silver appears to have some antibacterial activity.[230] However, over the past few decades, the usage of silver points has dramatically diminished, so presently they are considered a deviation from the standard of care.[307] The main reason for this change is because they corrode over time (Fig. 10.49), and the apical seal may be lost.[31] Also, silver points do not produce an acceptable 3D seal of the canal system; rather, they simply produce a plug in the apical constriction while not sealing the accessory canals that are frequently present (Fig. 10.50).[158,226] The corrosion of silver points occurs when they come in contact with tissue fluids and certain chemicals used in endodontics, including sodium hypochlorite and some sealers.[99] This corrosion produces chemicals such as silver sulfide, silver sulfate, silver carbonate, and silver amine hydrate,[233] which have been shown to be cytotoxic in tissue culture.[230] Corrosion occurs mainly at the apical and coronal portions of the points indicating that leakage is responsible.[233] Gutta-percha root-filling techniques do not suffer from these disadvantages and have replaced the use of silver points in endodontics. Due to this decrease in usage over the past quarter of a century, the quantity of cases the clinician will come across that will require silver point removal has also decreased. Nevertheless, there are still occasions when their removal will be necessary.

Many of the same techniques described for removing separated instruments in the following section apply to the removal of silver points. Silver points have a minimal taper and are smoothed-sided and corrosion may loosen the cone within the preparation. Therefore the clinician should encounter a much easier time removing them than would be the case with separated instruments, which may be mechanically engaged into canals. Silver point canal preparation techniques produced a milled, round preparation in the apical 2 to 3 mm of the canal and, coronal to that, the clinician will frequently find space between the round silver point and the flared canal walls that can usually be negotiated with hand files facilitating point removal.[214]

The first step in the removal of silver points is to establish proper access. Frequently, the coronal portion of the cone is embedded in the core material. This material must be carefully removed with burs and ultrasonics, taking care not to remove any of the silver point within the access cavity preparation. The more of the silver point the clinician has to work with, the more predictable will be its removal. Once proper access is established, the clinician should flood the access preparation with a solvent, such as chloroform, in order to soften or dissolve the cement, enabling easier

Telegram: @dental_k

www.konkur.in

removal. An endodontic explorer or small file may be used to carry the solvent down along the silver point to dissolve as much of the cement as possible. The chamber can be rinsed and dried, and this step may be repeated since fresh solvent enhances the efficiency of cement removal. At this point, the easiest technique, which is also very predictable, is to grasp the exposed end of the silver point with a Stieglitz pliers (Henry Schein, Port Washington, NY) (see Fig. 10.41) or other appropriate forceps, and gently pull it out of the access cavity preparation. If too much extraction force is needed, however, the point may separate so slow force application is advised. The clinician will need a variety of sizes and angles of forceps available to deal with the variety of cases that will need to be treated. Occasionally, the forceps may not get a good purchase on the silver cone and will slip off. In these instances, gripping the cone with the forceps and then gripping the forceps in a hemostat or needle driver to increase the squeezing force of the forceps will allow removal of the cone (Fig. 10.51).[156] If the silver point is held tight by the frictional fit in the preparation, indirect ultrasonics may be employed to loosen it. The silver point is retained in a pair of forceps and ultrasonic energy is applied to the forceps, not the point (Fig. 10.52). This transmits energy down the cone and may loosen it.

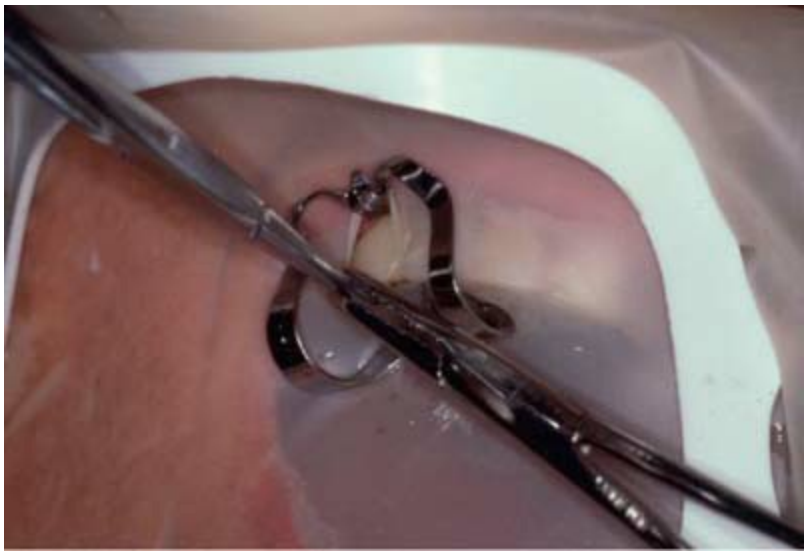

FIG. 10.51 Removal of a highly retentive silver point using a needle driver to squeeze the tips of the Steiglitz forceps. This applies increased gripping force to aid in removal.

Close-up of an open mouth covered by rubber dam and a clamp exposing the incisor shows removal of silver point by needle device and forceps.

If the silver point cannot be dislodged by the forgoing techniques, the clinician should consider using Hedstrom files to remove the silver point. The Hedstrom file technique requires at least some coronal length of canal space around the silver point to be negotiated first.[155] The sealer is dissolved as previously mentioned, and then files are negotiated as far apically as possibly in two to three areas around the silver point. If only one space can be negotiated, this technique may still be effective. The spaces surrounding the silver point are carefully instrumented to size 15, and then small Hedstrom files are gently screwed in as far as possible apically. They should not be screwed in too tightly to prevent breakage. The flute design of Hedstrom file allows for much better engagement into the silver point compared to other file designs. The files are then twisted together and pulled out through the access (Fig. 10.53). If the first attempt fails, this technique may be repeated, possibly using larger Hedstrom files. If this technique does not completely

Telegram: @dental_k

www.konkur.in

remove the silver point from the canal, it may still be dislodged to the point where it can be grasped by forceps and removed.

C) Close-up of an open mouth covered by rubber dam and a clamp shows a removed silver point using a set of files. A dental water spray is visible on the mouth surface.

If the clinician needs to expose more of the silver point to enable removal, the use of trephine burs and microtubes or ultrasonics may be necessary.[78] Trephine burs are used in the same manner as described for separated instrument removal; however, the clinician must be more careful when using ultrasonic instruments for the retrieval of silver points. When using ultrasonics for post removal, or separated instrument removal, the tip of the ultrasonic instrument can be placed at the interface between the obstruction and the canal wall. While applying the ultrasonic energy directly to a post or file may prove beneficial in vibrating them loose, silver points are much softer, and if ultrasonic instruments are applied directly to them, the portion

Telegram: @dental_k

www.konkur.in

in contact may be shredded, leaving a smaller segment to work with because elemental silver rapidly erodes during mechanical manipulation.[214] The ultrasonic instrument is used on tooth structure circumferentially around the silver point. This is a very delicate process requiring a microscope or other powerful source of magnification. The energy supplied by the careful use of the ultrasonic instrument can safely expose silver points as well as break up the cement around them.

In many cases, a silver point may have been sectioned deep in the canal to allow post space preparation. In these cases, where the most coronal portion of the silver point is well below the orifice, the use of Gates-Glidden burs to obtain straight-line access to the most coronal extent of the point may be necessary. The burs should be used in a brush-like manner, cutting on the outstroke while applying gentle pressure in an anticurvature direction to decrease the risk of root perforation. Following this, techniques that involve the use of an end-cutting trephine bur to remove tooth structure around the point and then use of an extraction device to remove it may be employed (Fig. 10.54). There are many kits that use these principals with slight variations from one another, including the Masserann Kit (Medidenta International, Woodside, NY) and the Extractor System (Roydent, Troy, MI) (Fig. 10.55). Additional techniques that are effective for removing silver points include the S.I.R. (Separated Instrument Retrieval) System (Vista Dental Products, Racine, WI), the use of a dental injection needle with a 0.14 mm wire, the use of stainless-steel tubing with a Hedstrom file,[214] and the Instrument Removal System (San Diego Swiss, San Diego, CA).

These kits are not only effective in the removal of silver points but also in the removal of separated instruments, and because of this common approach to removing both during endodontic retreatment, these techniques will be discussed in detail in the following section on separated instrument removal.

After the silver point is removed, it is very important that subsequent instrumentation procedures be performed in a crown-down manner to minimize extrusion of the silver corrosion products into the periradicular tissues to decrease the occurrence of painful acute flare-ups. This goal is complicated by the fact that ledges are frequently encountered at the level of the apical extent of the silver point due to the type of milled preparation that was frequently used in this technique. Managing ledges will be discussed in a following section of this chapter.

Occasionally, the apical portion of a silver point will separate upon the removal attempt. If it cannot be bypassed or removed, then the case should be completed and followed carefully (Fig. 10.56). Apical surgery or extraction could be necessary in the future (Fig. 10.57).

Removal of separated instruments

Causes of instrument separation

Occasionally during nonsurgical root canal therapy, an instrument will separate in a canal system, blocking access to the apical canal terminus. This instrument is usually some type of file or reamer but can include Gates-Glidden or Peeso Drills, lentulo spiral paste fillers, thermo-mechanical gutta-percha compactors, or the tips of hand instruments, such as explorers or gutta-percha spreaders. During retreatment, it may be obvious after completing the diagnostic phase that there is a separated instrument in the canal system or it may only become apparent after removal of the root filling

Telegram: @dental_k

www.konkur.in

materials (Fig. 10.58). It is therefore useful to expose a check radiograph after removal of the root filling to see if there is any metallic obstruction in the canal. Regardless of which type of instruments the clinician uses, whether stainless steel or nickel-titanium, and how they are used, by hand or engine driven, the potential for separation exists. The incidence of hand instrument separation has been reported to be 0.25%[127] and for rotary instruments, it ranges from 1.68% to 2.4%.[127,300]

www.konkur.in

The most common causes for file separation are improper use, limitations in physical properties, inadequate access, root canal anatomy, and possibly manufacturing defects.

A very common cause for instrument separation is improper use. Included in this are overuse or not discarding an instrument and replacing it with a new one when needed. The following is a list of guidelines for when to discard and replace instruments.[89]

> "1. Flaws, such as shiny areas or unwinding, are detected on the flutes.
> 2. Excessive use has caused instrument bending or crimping (common with smaller-sized instruments). A major concern with nickel-titanium instruments is that they tend to fracture without warning; as a result, constant monitoring of usage is critical.
> 3. Excessive bending or precurving has been necessary.
> 4. Accidental bending occurs during file usage.
> 5. The file kinks instead of curving.
> 6. Corrosion is noted on the instrument.
> 7. Compacting instruments have defective tips or have been excessively heated."[89]

Another type of improper use is to apply too much apical pressure during instrumentation,[277] especially when using engine-driven nickel-titanium files. This pressure can lead to deflection of the instrument within the canal system or increased frictional binding against the canal walls that can overstress the metal, resulting in separation. Regardless of which type of files the clinician uses, they should never use them in a dry canal, as attempting to instrument a dry canal will cause excessive frictional stresses on an instrument.[277] Continual lubrication of the canal with either irrigating solutions or lubricants is required[89] as this will reduce the frictional resistance as well as increase the efficiency of the instrument. All files have flutes that have the ability to build up with dentin shavings, which will decrease the efficiency of the instrument leading to greater frictional forces and ultimately separation. Therefore files should be periodically removed and cleaned during the instrumentation process.

Telegram: @dental_k

www.konkur.in

Inadequate access cavity preparations can lead to many problems, one of which is excessive or unnecessary force applied to the instrument if it is not allowed to enter the canal freely without interference from the access cavity walls. If the file is in contact with the access cavity wall during instrumentation, the chance for separation is greatly increased. Inadequately enlarged access preparations also increase the number and severity of curvatures that the file must negotiate. This underprepared access can lead to the creation of an iatrogenic S curve that can overstress the instrument. This situation is especially hazardous when using rotary instrumentation since traversing an S curve greatly stresses the rotating file, leading to separation (Fig. 10.59).

FIG. 10.59 Complicated canal anatomy can increase stress on rotary instruments leading to separation such as in this S-Shaped canal.

Radiograph of first molar shows a radiopaque crown and radiolucent neck and canals. Second molar shows radiolucent outlines of two rotatory tools.

Anatomy, such as abrupt curvatures or anatomic ledges, increases the likelihood of instrument fracture. When the file's progress is hindered, it is quite natural to try to force it further. This approach will rarely result in the file advancing along the naturally occurring path and indeed may result in file separation, perforation, or ledge creation.

Telegram: @dental_k

www.konkur.in

Some clinicians would like to blame instrument separation on manufacturing defects; however, this has never been shown to be of clinical relevance and is quite rare.[277]

The best treatment for the separated instrument is prevention. If proper techniques for cleaning and shaping of the root canal system are followed, file separation should be an infrequent occurrence. Nevertheless, an occasional event may take place. When instrument separation occurs, a radiograph should be taken immediately.[277] This radiograph will not only confirm the separation, it will also give the clinician information that may aid in removal, such as location, size of the file segment, root canal anatomy, and, ultimately, the possibility of removal. The patient should be advised of the accident as well as its effect on the prognosis.[47] In addition, when a file separates, as with other procedural accidents, detailed documentation is necessary for medical-legal considerations,[277] and the remaining segment of the file should not be discarded but rather placed in a coin envelope and kept in the patient record.[47,307]

Prognosis

A separated instrument does not necessarily mean surgery or loss of the tooth. Actually, the prognosis may not be reduced at all depending on what stage of instrumentation the separation occurs, the preoperative status of the pulp and periradicular tissues, and whether or not the file can be removed or bypassed.[252] The presence of a separated instrument in the canal in itself does not predispose the case to posttreatment disease. Rather, it is the presence of any necrotic, infected pulp tissue that remains in the apical canal space that determines the prognosis. The outcome is better if the canal was instrumented to the later stages of preparation when the separation occurs.[277] If the preoperative pulp was vital and noninfected (e.g., irreversible pulpitis), and there was no apical periodontitis, the presence of the separated instrument should not affect the prognosis.[49] If the file can be removed without excessive over enlargement of the canal[82] or causing an additional iatrogenic mishap, such as a perforation, the prognosis will not be affected. Bypassing the instrument and incorporating it into the obturation should also have no effect on the prognosis. However, if the instrument cannot be removed or bypassed in a tooth with a necrotic, infected pulp and apical periodontitis, the

Telegram: @dental_k

www.konkur.in

prognosis will be uncertain. These cases should be followed closely and, if symptoms persist, apical surgery or extraction should be considered.[277,303]

The potential to remove a separated instrument depends on many factors that should be considered during the diagnostic workup. The location of the separated instrument is of critical importance. If the separated instrument extends into the straight, coronal portion of the canal, retrieval is likely. If, however, the instrument has separated deep in the canal and the entire broken segment is apical to the canal curvature, then orthograde removal will not be possible and attempts to do so could lead to a much higher rate of iatrogenic complication.[237,250] If there is persistent disease and the file cannot be bypassed safely, either apical surgery or extraction will be necessary. Because of the need to enlarge the coronal radicular access, root curvatures, external root concavities, and root thickness all will be important factors to consider when deciding which treatment option will provide the best chance of long-term success. Teeth with thin roots and deep external root concavities have a greater likelihood of being perforated during the coronal radicular access, so surgery should be considered as an alternative to orthograde instrument retrieval. The type of material the separated instrument is made of will affect the chances of removal. Nickel-titanium files tend to shatter when ultrasonic energy is applied to them, hindering removal, whereas stainless steel instruments are more robust and more easily removed with ultrasonics.[214]

Removal techniques

Many different instruments and techniques will be discussed in this section, all of which are important to include in the armamentarium for separated instrument removal. None, however, is more important than the operating microscope (Fig. 10.60). This instrument will not only increase visibility using magnification and light, but it will also increase the efficiency and safety of almost all the techniques to be discussed. The use of a headlamp and magnifying loupes will help with the removal of many canal impediments. However, the use of the operating microscope has caused a quantum leap in visualization due to the enhanced lighting and magnification that it offers,[138] and many of the techniques to be described should not even be attempted without the use of this valuable tool.[262]

Telegram: @dental_k

www.konkur.in

FIG. 10.60 The surgical operating microscope is not only invaluable in helping to remove separated instruments; it is in fact a necessary tool for these procedures.

A surgical operating microscope shows the supporting structure, body of the microscope and the light source.

Once the patient has been advised of the treatment options and the decision has been made to attempt removal, the clinician's first choice in treatment will be based on the location of the instrument. If the file is clinically visible in the coronal access and can be grasped with an instrument, such as a hemostat or Stieglitz Pliers (Sullivan-Schein, Port Washington, NY) (see Fig. 10.41), then these should be used to obtain a firm hold of the file and extract it out through the access cavity preparation. Many different sizes and angles of forceps are available, and almost all are necessary in order to have the ability to remove obstructions from the many different angles and levels of accessibility presented to the clinician. These will work well if the object is loose fitting within the canal and if the clinician has good access. However, establishing a firm purchase can sometimes be difficult without removing excessive tooth structure. Once a purchase onto the file has been achieved, it is best to pull it from the canal with a slight counterclockwise action. This action will unscrew the flutes that are engaged in the dentin as the file is being removed. This is the easiest technique for removal of a separated file; however, unfortunately, many files separate at a point where these forceps cannot be used.

Frequently, a file will separate at a point deeper in the canal where

Telegram: @dental_k

www.konkur.in

visibility is difficult. In order to remove separated root canal instruments predictably, the clinician must create straight-line coronal radicular access. Either removing the crown or creating a large access cavity preparation establishes adequate coronal access to allow the use of the appropriate instruments. Straight-line radicular access can be created with the use of modified Gates-Glidden drills. These drills may be ground down or sectioned with a bur at their maximum cross-sectional diameter. This process will create a circumferential staging platform to facilitate ultrasonic use (Fig. 10.61).[214] A recent study showed that use of a similarly modified Lightspeed nickel-titanium rotary instruments (Lightspeed Technology, Inc., San Antonio, TX) created a staging platform that was more centered in curved canals than the Gates-Glidden drills.[128]

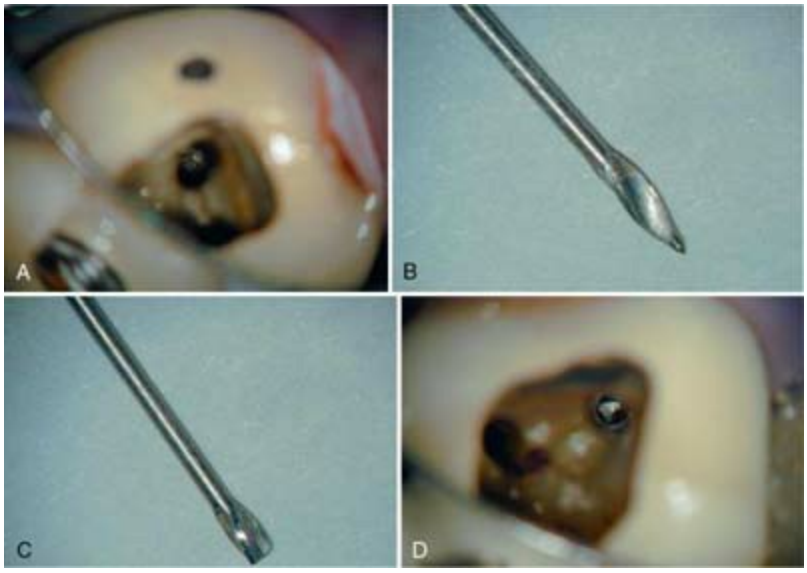

FIG. 10.61 **A,** Separated instrument in the mesiobuccal canal of a molar. **B,** Unmodified Gates-Glidden drill. **C,** Modified instrument. D) Close-up blur view of separated instrument and molar with open crown shows dentin exposing black dots inside the cavity.

Ultrasonic instruments have been shown to be very effective for the removal of canal obstructions.[42,180,214] The ultrasonic tip is placed on the staging platform between the exposed end of the file and the canal wall and is vibrated around the obstruction in a counterclockwise direction that applies an unscrewing force to the file as it is being vibrated. This technique will help with removing instruments that have a clockwise cutting action. If the file had a counterclockwise cutting action (such as the hand GT files), then a clockwise rotation will be needed. The energy applied will aid in loosening the file, and occasionally the file will appear to jump out of the canal. It is prudent to cover the orifices of the adjacent open canals with cotton or paper points to prevent the removed file fragment from falling into them, causing further case complications (Fig. 10.62, *A*).[214] There are many different sizes and angles of ultrasonic tips available for this purpose but, in general, the deeper in the canal the obstruction is, the longer and thinner an ultrasonic tip must be. It should be remembered that long, thin tips must be used on very low power settings to prevent tip breakage (see Fig. 10.62, *B*). Occasionally, if the separated instrument can be bypassed, the use of ultrasonic files can loosen it. Care must be taken, however, to avoid ultrasonic file separation or root perforation.[115] As mentioned previously, nickel-titanium instruments often break up into fragments when subject to the energy supplied by an ultrasonic instrument (Fig. 10.63). The clinician may be tempted to use this information to their advantage by applying the tip of the ultrasonic directly onto nickel-titanium files. Occasionally, this method may work; however, the chance of pushing the separated file further into the canal or beyond the apical foramen may increase the risk of this technique.

If the direct application of ultrasonic energy does not loosen the separated

Telegram: @dental_k

www.konkur.in

instrument sufficiently to remove it, the fragment must be grabbed and retrieved. This is accomplished with a variety of techniques, most using some variant of a microtube. The staging platform is further reduced by ultrasonics until enough of the separated instrument is exposed to retrieve (about 2 to 3 mm).[214] This reduction must be done carefully to avoid root perforation. One relatively simple microtube technique is to use a short piece of stainless-steel tubing that is pushed over the exposed end of the object. A small Hedstrom file is then pushed between the tube and the end of the object using a clockwise turning motion that produces a good mechanical lock between the separated instrument, the tube, and the Hedstrom file. The three connected objects can then be removed by pulling them in a coronal direction (Fig. 10.64).[261]

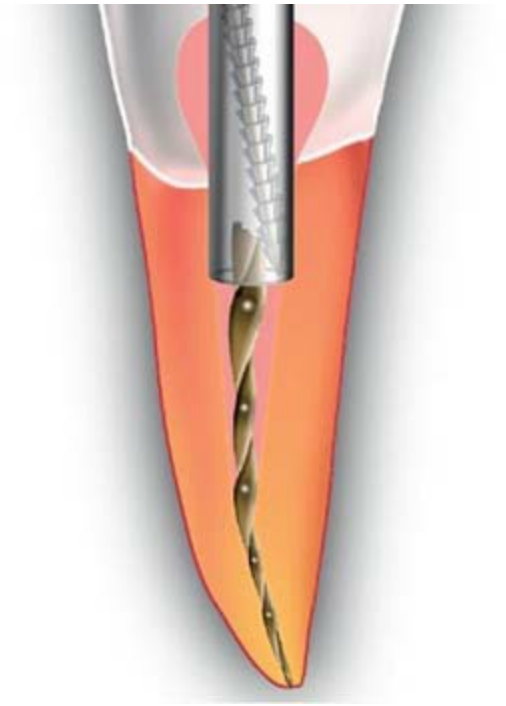

FIG. 10.64 Tube and Hedstrom file removal technique. The tube is slipped over the obstruction and a Hedstrom file is gently screwed into the space between the tube and the obstruction. Pulling the tube and Hedstrom file together can withdraw the obstruction.

A diagram of tooth with crown and root canal shows a tube with a spirally textured hedstrom file. File extracts the spirally textured pointed obstruction vertically upwards.

Telegram: @dental_k

www.konkur.in

Source: (Courtesy Dentsply Endodontics.)

Another technique is to use a 25-gauge dental injection needle along with a 0.14 mm diameter steel ligature wire. The needle is cut to remove the beveled end as well as the opposite end so it no longer extends beyond the hub. Both ends of the wire are then passed through the needle from the injection end until they slide out of the hub end creating a wire loop that extends from the injection end of the needle. Once the loop has passed around the object to be retrieved, a small hemostat is used to pull the wire loop up and tighten it around the obstruction and then the complete assembly is withdrawn from the canal.[211] Occasionally, a larger diameter tube and thinner 0.11 mm ligature wire will facilitate assembly of this extractor (Fig. 10.65).

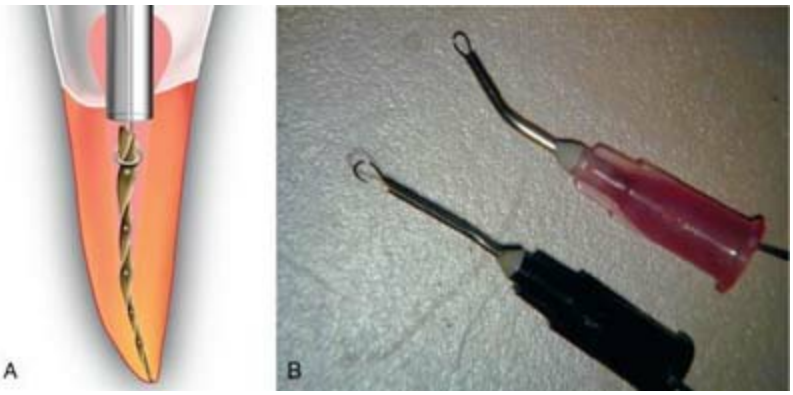

FIG. 10.65 **A,** Diagram illustrating the wire loop and tube method of obstruction removal. The wire loop is carefully placed around the obstruction, tightened, and then removed. **B,** Larger diameter tubes and smaller diameter 0.11 mm ligature wire enhances the efficiency of this technique.

Another effective technique, especially in cases where access or obtaining an adequate purchase on the file is difficult, is to use an end-cutting trephine bur to remove tooth structure around the file and then use an extraction

Telegram: @dental_k

www.konkur.in

device to remove it. There are many kits that use these principals with slight variations from one another, including the Meisinger Trephine Burs, the Masserann Kit (Medidenta International, Inc., Woodside, NY), and the Extractor System (Roydent Dental Products, Troy, MI) (see Fig. 10.55).

Tube and glue techniques use a cyanoacrylate adhesive, which bonds a hollow tube to the exposed end of the file for removal. This technique requires the use of hollow trephine burs followed by tube extractors with the adhesive inside the tip. The most important factor in using this technique is the snugness of fit between the extractor tube and the obstruction. It has been shown that, even with only 1 mm of overlap between the extractor tube and the obstruction, if there is a snug fit, the bond created with the cyanoacrylate may be strong enough to remove many obstructions. However, the recommended amount of overlap between the tube and the obstruction is 2 mm. The time needed for the adhesive to set to ensure adequate bond strength for removal is 5 minutes for a snug fit and 10 minutes for a loose fit.[86,253] One disadvantage of this technique is that the trephine burs may be much larger than the coronal end of the instrument to be removed, so the use of the smallest trephine burs that can expose the coronal end of the separated instrument is suggested. Smaller trephine burs correspond better with smaller extraction tubes and remove less dentin that can decrease the likelihood of weakening the root leading to fracture.[70] Another disadvantage is that the burs cut very aggressively when new but dull rather quickly. When new, this aggressive cutting may lead to perforation or even separation of the obstruction. Therefore great care is needed when using this technique (Fig. 10.66). Once the separated instrument has been removed, the extraction tubes may be reused, either by using acetone to remove the embedded instrument from the extractor tube or by simply cutting the extraction tube with a bur beyond the extent that the separated instrument has penetrated.

D) Close-up of a spirally textured file extracted by a tube in size 35.

E) Radiograph of tooth shows a radiopaque neck and canal. A radiopaque outline of dam clamp is visible.

The Masserann technique has also been recommended for the removal of separated instruments.[168] This technique is similar to the Endo Extractor in that it uses trephine burs and a specific extraction device. This kit comes with

Telegram: @dental_k

www.konkur.in

a very convenient gauge that aids in predicting the size of the bur and the extractor to be used, and it contains many different sizes of trephine burs. In addition, the trephine burs with this kit cut in a counterclockwise direction that provides an unscrewing force on separated files. The extraction mandrels have an internal stylus that wedges the file against the internal wall of the mandrel allowing the obstruction to be removed. While effective, this technique may require removal of an excessive amount of radicular dentin[78] leading to root weakening and the risk of perforation[305]; therefore this instrument must be used with caution.

The Extractor System from Roydent comes with only one bur and three extraction devices. The bur is very conservative and removes a minimal amount of tooth structure, enabling access to the obstruction. The extractor tubes are also quite small and, therefore, will only work for the removal of small obstructions. The extractor surrounds the obstruction with six prongs that can be tightened onto the object, enabling removal. This works in the same way a drill chuck tightens onto a drill bit (Fig. 10.67). The disadvantages of this kit are the lack of variety of instruments, the possibility of separating the obstruction with the bur, and the potential problem of breakage of the prongs in the extractor if they are submitted to bending rather than applying strict tensile force during removal.

FIG. 10.67 Close-up view of the Roydent Extractor tip. The tip is placed over the separated instrument and tightened to grasp the obstruction.

A Roydent extractor tip with a cylindrical body and a small screw wedge at the end, kept on a platform.

Another device designed specifically for the purpose of separated file removal is the Instrument Removal System (San Diego Swiss, San Diego, CA) (see Fig. 10.55, *E*). This kit consists of two different sizes of extraction devices that are tubes with a 45-degree bevel on the end and a side cutout window. Each tube has a corresponding internal stylus or screw wedge. Prior to usage of this instrument, 2 to 3 mm of the obstruction are exposed by troughing around it with an ultrasonic instrument. Once the file is exposed, the appropriate size microtube is selected and slid into place over the obstruction. Once in place, the screw wedge is turned counterclockwise to engage and displace the head of the obstruction through the side window. The assembly is then removed.[214] This instrument is very useful in the straight portion of the canal, but it is difficult to force large diameter separated files through the cutout window, hampering their removal (Fig. 10.68).

D) Radiograph of tooth shows a radiopaque crown and upper canal and radiolucent lower canal with a dot like attachment.

The S.I.R. (Separated Instrument Retrieval) System (Vista Dental Products) (see Fig. 10.55, *D*) is another microtube method of separated instrument retrieval. It utilizes extractor tubes bonded onto an obstruction, enabling removal. Once the obstruction is exposed using ultrasonics or the trephine burs from one of the other kits described, the bendable dead-soft tubes are bonded onto it. Once the adhesive is set, the obstruction is removed through the access cavity preparation. Included in this kit are the necessary bonding agent, a bottle of accelerator, five different sizes of tubes, assorted

Telegram: @dental_k

www.konkur.in

fulcrum props, and a hemostat. The accelerator causes the bonding agent to set almost instantaneously. The ability to bend these tubes allows for access in most areas of the mouth. A hemostat allows the clinician to establish a firm purchase onto the tube, creating the ability to lever the bonded obstruction out of the canal. A vinyl, autoclavable instrument prop provides protection for the next most anterior tooth, which is to be used as a fulcrum; however, if the clinician has access to grasp the extractor with the fingers to remove the extractor/obstruction unit, the hemostat may not be necessary.

There is now a commercially available kit containing multiple instruments that allow the clinician to use most of the aforementioned techniques. It is the Terauchi File Retrieval Kit (Dental Engineering Laboratories, Santa Barbara, CA) (Fig. 10.69). This kit contains modified Gates Glidden burs to prepare a staging platform, specialized ultrasonic tips for use deep in the canal space, and a tube and loop instrument to grasp the coronal extant of the separated instrument when it has been exposed. The kit is very effective for removing separated instruments and also contains a barbed tip gutta-percha removal instrument that efficiently removes fragments of gutta-percha that adhere to canal walls in the coronal portion of the canal.

A Terauchi file retrieval kit. The components include modified Gates Glidden burs, ultrasonic tips, a tube and barbed tip instrument for gutta percha removal.

Another interesting recent development is the use of the GentleWave (Sonendo, Inc., Laguna Hills, CA) canal irrigation system to remove separated instruments. This device creates multisonic energy in the canal system while dispensing irrigation solutions and has been advocated for canal cleaning and disinfection. The powerful vortices produced in the solutions within the canal system can dislodge and remove separated instruments (Fig. 10.70).[297] Until more science is developed regarding this particular use for this very interesting technology, including possible complications and parameters for implementation, caution should be exercised in attempting to remove separated instruments by this method.

Heat generation during retreatment procedures

There are many procedures in endodontic therapy that can generate heat, but perhaps the area with the greatest risk of heat-related tissue damage occurs during nonsurgical retreatment. Use of heat to soften canal filling materials to aid in their removal[146,154] and use of ultrasonics to dislodge posts[220] and separated instruments[106,161] can potentially generate enough heat to raise the temperature of the external root surface by 10°C or more. Temperature elevations of the periodontal ligament in excess of 10°C can cause damage to the attachment apparatus.[13,62,222,223]

The greatest danger of heat-related damage occurs with the use of ultrasonic energy to dislodge foreign objects in the canal space in order to gain access to the apical portion. As has been described earlier, this has recently become an extremely important and useful part of the clinician's armamentarium due to the ability of ultrasonic energy application to conserve tooth structure while removing the obstruction. These instruments have allowed clinicians to perform predictable retreatment when surgery would have been previously indicated. As with most instruments used in dentistry, however, these devices must be used with caution as in vitro research and clinical case reports imply that they have the potential to damage the tooth attachment apparatus due to the heat generated during usage.[34,88,229] One in vitro study has showed that ultrasonic vibration for post removal without coolant can cause root surface temperature increases approaching 10°C in as little as 15 seconds.[55] Thermal damage to the periradicular tissues may be so serious as to result in both tooth loss and permanent bone loss (see Fig. 10.29). This is not to say that ultrasound energy should be avoided for the removal of canal obstructions since it is many times the only way to reach the apical area of the canal.

The factors that may contribute to a heat-induced injury are the length of the post, post diameter, post material, and type of luting cement. Studies need to be done in order to establish heat reduction protocols based on these variables. Some have proposed that the dentin thickness between the outer surface of the post and the root surface may affect root surface temperature rise[91,92] and one study showed this.[220] However, a more recent study has shown that the dentin thickness is statistically insignificant as a factor in root surface temperature rise.[114] One possible mitigating factor would be the

Telegram: @dental_k

www.konkur.in

effect of the periradicular blood supply, which could act as a heat sink dissipating the generated thermal energy and thus helping to prevent injury. This may be why the effect of seemingly similar conditions of ultrasonic application can have such differing results on different patients. Clearly, more in vivo research is needed in this area.

It has become accepted that the heat-induced damage to periradicular tissues during the usage of ultrasound energy for post removal is time dependent.[34,119] Recent studies have advised cooling of the ultrasonic tips can greatly reduce heat buildup[34,119] despite reducing the efficiency of debonding resin bonded posts.[55,83] The amount of time the clinician can use these instruments safely is very difficult to determine as specific protocols that are evidence based using in vivo research have yet to be established. Therefore, the authors feel any specific recommendations regarding rest intervals between usage of ultrasound energy, ways of monitoring heat buildup, or duration of consistent activation cannot be made based on the available research at the time of publication. However, the authors do feel strongly with regards to several recommendations for the use of ultrasound energy during the removal of canal obstructions, and they are as follows:

- Use ultrasonic tips with water ports whenever possible.
- If your ultrasound device does not have tips with water ports, have your assistant use a continuous coolant air/water spray during usage.[64]
- Take frequent breaks in order to let the tooth cool down.
- Avoid using the ultrasound on the high-power setting.[64]

Prudent of clinicians must take extreme care when applying ultrasound energy to a canal obstruction as it has been shown that even with the use of water coolant, root surfaces can increase in temperature rapidly.[55,220] Thus until evidence-based heat reduction protocols are developed, caution when using instruments that can generate heat in the periodontal ligament is required.

Management of canal impediments

Following removal of all root-filling materials, further progress to the apical

Telegram: @dental_k

www.konkur.in

constriction may be prevented by the presence of a block or a ledge in the apical portion of the canal. Most of these impediments are iatrogenic mishaps resulting from vigorous instrumentation short of the appropriate working length and failure to confirm apical patency regularly during instrumentation. A blocked canal contains residual pulp tissue (sometimes necrotic, often fibrosed or calcified) and packed dentinal “mud” in the apical several millimeters of the canal system.[214] This debris is frequently infected resulting in persistent disease and must be removed if possible. A ledge is the result of placing non-precurved, end-cutting instruments into curved canals and filing with too much apical pressure.[89,129] It is a type of canal transportation that results in a canal irregularity on the outside of the canal curvature that is difficult or impossible to bypass. The canal space apical to the ledge is not thoroughly cleaned and sealed, so ledges frequently result in posttreatment disease. The best treatment for blocked and ledged canals, as with all iatrogenic problems, is prevention. If the clinician is careful and attentive during the instrumentation process, the chance for an impediment to develop is minimized. When the clinician becomes careless or hurried, problems occur. The strategies for the prevention of blocks and ledges are found in another chapter of this text.

During the treatment-planning phase, blocks and ledges may be detectible on radiographs as a root filling short of the ideal working length, and the patient should be warned that they might prove impenetrable and require future apical surgery or extraction.[77] This should not deter the clinician from choosing nonsurgical retreatment, however. In a recent study, 74% of teeth showing short root fillings were successfully negotiated to adequate length with the authors stating that presence of a short fill should not be considered a technical contraindication to retreatment.[66] The clinical encounter usually occurs after removal of the previous root-filling material when apical advancement of small files is impeded. At this point, the clinician may be unaware of which type of impediment exists, but a common approach to management is helpful in the early stages of the process. The coronal portion of the canal should be enlarged to enhance tactile sensation and remove cervical and middle third obstructions in the canal space. The canal should be flooded with irrigant, and instrumentation to the level of the impediment should be accomplished using non-end cutting rotary files, such as the

Telegram: @dental_k

www.konkur.in

Lightspeed (Lightspeed Endodontics, San Antonio, TX), the Profile or GT instruments (Dentsply, York, PA), or the K-3 instrument (Sybron Endodontics, Orange, CA), in a crown-down manner. This procedure will enlarge and flare the canal space coronal to the impediment while minimizing the likelihood of worsening any ledge present.

At this point, the impediment should be gently probed with a precurved #8 or #10 file to determine if there are any "sticky" spots that could be the entrance to a blocked canal. A directional rubber stop should be used so that the clinician knows in which direction the tip of the instrument is pointing, which helps in visualizing the 3D layout of the canal system. Frequently, evacuating the irrigant and using a lubricant, such as RC Prep (Premier, Plymouth Meeting, PA) or Pro-Lube (Dentsply, York, PA), will enhance the ability to place the small file into the apical canal segment. If repeated, gentle apical pressure or "pecking" of the hand file against the blockage results in some resistance when withdrawing the instrument on the outstroke ("stickiness"), then the clinician should continue to peck at the "sticky" spot until further apical advancement is accomplished.[214] This is frequently a slow and tedious process. The endeavor can be made more efficient by using precurved stiff files such as the C+ file (Maillefer, Baillagues, Switzerland), but there is a risk of deviating from the original canal path, creating a ledge and, ultimately, a false canal leading to zip perforation.[89] It is prudent to make a working radiograph when some apical progress has been made to confirm the placement of the instrument into the suspected apical extent of the canal. The clinician should resist the urge to rotate the file excessively. If the tip of a small instrument is tightly bound in the blocked segment of the canal and the tip has been worked by pecking, it is prone to fracture in the apical area, further complicating the case.[214] The separated file tip is frequently irretrievable and surgery or extraction may be the result. Dropping down to the next smaller size file and using a very gentle reciprocal rotational motion ("twiddling") will aid in advancement through the blocked canal. Frequently, as apical progress is being made, the clinician will be using an electronic apex locator to gauge the proximity of the apical constriction. Unfortunately, the apex locator is sometimes not able to give an accurate reading in a blocked canal, and because of the continued "sticky" feel that occurs even as the instrument bypasses the foramen and penetrates apical

Telegram: @dental_k

www.konkur.in

tissues, an overextension may result. In order to prevent this complication with its attendant risk of a painful postoperative flare-up, when the estimated working length is reached, a working length radiograph is necessary.[165] Once apical working length is achieved, apical patency should be confirmed, and gentle, short amplitude 1 to 2 mm push-pull strokes should be made until the file can pass freely to the apical constriction (Fig. 10.71).

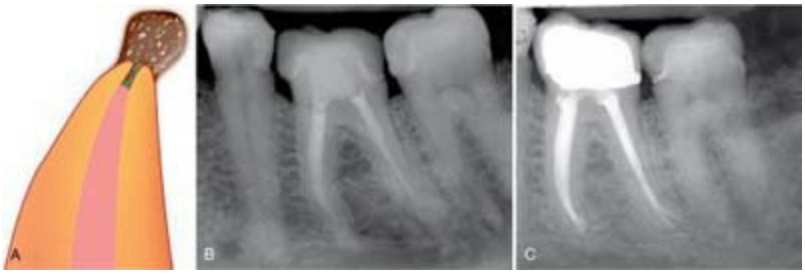

FIG. 10.71 **A,** Diagrammatic representation of a canal block. Fibrotic and/or calcified pulp and debris that is potentially infected remains in the apical segment of the canal when the canal is instrumented short of the apical constriction. **B,** Preoperative radiograph showing obturation short of ideal length. The patient was symptomatic and the canals were blocked. **C,** Three months posttreatment. Treatment took a total of 3.5 hours over three appointments due to the time-consuming nature of bypassing blocked canals.

If, after a reasonable amount of time, no sticky spot can be found, the clinician must consider the possible presence of a ledge despite possibly not detecting it on the preoperative radiograph. The main problem with ledges is that instruments will invariably find their way to the ledge while finding the original canal is many times impossible. They feel like a hard brick wall, short of length when encountered, and care must be used to prevent worsening the ledge by indiscriminately burrowing into it.[286] In order to

Telegram: @dental_k

www.konkur.in

manage a ledge, the tip of a small #08 or #10 file has a small bend placed in it 1 to 2 mm from the end,[129,277] so the tip of the file forms an approximately 45 degree angle with the shaft of the instrument. The directional stop is oriented to the bend, and the file is carefully negotiated to the level of the ledge. Since ledges form mainly on the outside of curvatures, the directional stop (and thus the bent tip of the file) is turned in the direction of the suspected apical curvature away from the ledge (Fig. 10.72). The file tip is slowly scraped along the internal wall of the canal curve slightly coronal to the level of the ledge[277] looking for another sticky spot. This spot will be the entrance to the apical canal segment and gentle reciprocal rotation will usually allow the file to be negotiated to the canal terminus. Confirm with a radiograph. Once the ledge has been bypassed, short amplitude push-pull and rotational forces keeping the file tip apical to the ledge will be needed to clean and enlarge the apical canal space. When the file can be easily negotiated around the ledge, anti-curvature filing will enable the clinician to blend the ledge into the canal preparation (Fig. 10.73). Many times this cannot be completely accomplished,[286] but as long as the apical segment can be cleaned and obturated, the prognosis should not be adversely affected.

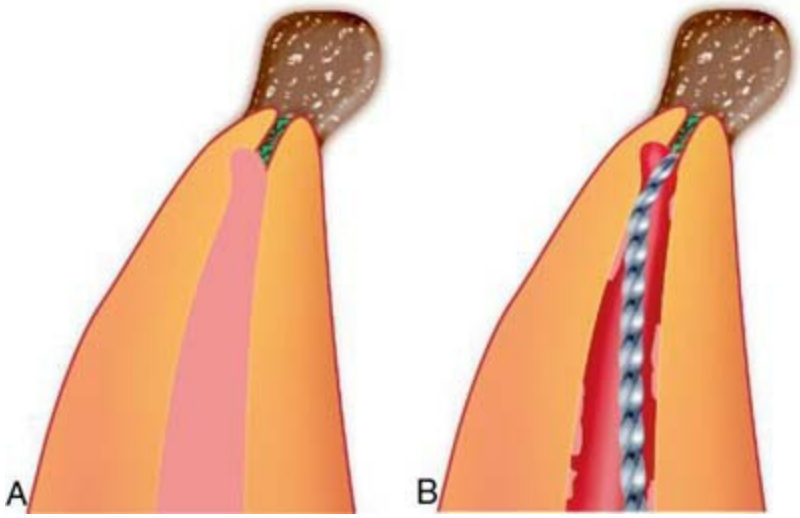

FIG. 10.72 **A,** Diagrammatic representation of a ledged canal. Potentially infected debris remaining in the apical segment can result in posttreatment disease. **B,** Attempting to bypass the ledge with a small file having a 45-degree bend in the tip. Telegram: @dental_k

www.konkur.in

The use of Greater Taper (GT) NiTi hand files (Dentsply Tulsa Dental) for the blending of ledges has been advocated.[214] The advantage these instruments have is that they are non-end cutting, and their rate of taper is two to six times that of conventional 0.02 tapered files, so they can do the work of multiple 0.02 tapered hand files. Once the ledge has been bypassed and the canal can be negotiated with a conventional size #15 or #20 K-file, a GT hand file is selected. The K-file creates a pilot hole so that the tip of the GT file can passively follow this glide path beyond the ledge. The GT file must have a tip diameter of 0.2 mm (#20) and a taper that will vary depending on the requirements of the preparation. The largest taper that will enter the apical segment is used; however, these instruments must be precurved, which presents a challenge since they are made from nickel-titanium alloy. In order to precurve this superelastic shape memory alloy, a file-bending tool, such as the Endo Bender Pliers (Kerr Corporation, Orange, CA), is needed. The pliers grasp the tip of the instrument, and the file is over curved between 180 and 270 degrees to plastically deform the alloy. At this time, the appropriate tapered GT file is then carried into the canal, and the rubber stop is oriented so that the instruments precurved, working end can bypass and move apical to the ledge. The GT file is then worked to length, and the ledge is either reduced or eliminated (Fig. 10.74).

If the canal blockage or ledge cannot be negotiated, then the canal space coronal to the impediment should be cleaned, shaped, obturated, and coronally sealed. The patient must be informed of this complication, the guarded prognosis, and the need for regular reevaluation (Fig. 10.75). If symptoms of posttreatment disease arise subsequently, apical surgery or extraction will be needed.[214,277]

Finishing the retreatment

After regaining the apical extent of the canal system, routine endodontic procedures are instituted to complete the retreatment. Any missed canals must be found using magnification, microexcavation techniques, and most importantly, the knowledge of canal anatomy that is discussed in another

Telegram: @dental_k

www.konkur.in

section of this text (Fig. 10.76). One cannot find a canal unless one suspects that it is there. Cleaning and shaping procedures must focus on a crown-down approach to minimize extrusion of irritants into the periradicular tissues, and also must emphasize enlargement of the apical portion of the preparation to ensure complete removal of apical debris. These aims are best accomplished using technique hybridization during instrumentation, keeping the goals of the retreatment procedure in mind. These matters are covered in detail in another chapter of this text. Canal disinfection procedures are, however, paramount after the completion of cleaning and shaping. Since the primary cause of posttreatment disease is usually microbial[73,182] and these microbes (i.e., *Enterococcus faecalis*) are frequently resistant to traditional canal disinfection regimes,[21] every effort must be made to eliminate these organisms from the canal system. This effort is complicated by the fact that no instrumentation regime can predictably remove the entire previous root filling from the canal space after retreatment.[16] This leaves areas where microbes can reside underneath fragments of root filling materials and remain protected from standard antimicrobial canal irrigants such as sodium hypochlorite. Whether the canal space can be adequately disinfected when completing treatment in one visit or whether an interappointment medicament such as calcium hydroxide is needed is still a matter of debate, and the reader is directed to the appropriate chapter of this text for details of the problem. It is important to keep in mind, however, that teeth that require retreatment also require the highest level of disinfection possible to ensure the most favorable outcome.

Repair of perforations

Occasionally, posttreatment endodontic disease will be the result of root perforation.[125] Root perforations are created pathologically by resorption and

Telegram: @dental_k

www.konkur.in

caries, and iatrogenically during root canal therapy (zip, strip, and furcation perforations) or its aftermath (e.g., post preparation perforation) (Fig. 10.77).[208] When they are present, perforations may usually be found during the diagnostic phase as areas where the root filling materials or possibly restorative materials such as posts are found to radiographically leave the confines of the presumed canal space and approach or cross the radiographic interface between the dentin and the periodontal ligament. Angled radiographs are of paramount importance in determining whether a perforation exists and locating which surface or surfaces of the root have been perforated. This information is necessary when deciding upon treatment options. The use of CBCT to evaluate potential perforations may also be useful, but if the canal space has already been obturated, the presence of beam hardening and other artifacts created by the radiopaque material in close proximity to the perforation site may limit the usefulness of this 3D imaging technology. Frequently, cervical and occasionally mid-root perforations are associated with epithelial downgrowth and subsequent periodontal defects, so thorough periodontal assessment is required (Fig. 10.78).[163,234] If there were no evidence of posttreatment disease associated with the defect or tooth, then no treatment would be indicated. If, however, there is evidence of periradicular periodontitis, repair may be instituted in one of two ways, either nonsurgically by approaching the defect internally through the tooth or surgically by using an external approach through the periradicular tissues.[208] In general, if all other factors are considered equal, internal nonsurgical perforation repair will be the preferred method since it is usually less invasive, produces less destruction of periradicular tissues via the surgical access wound needed, and isolation from microbes and disinfection is usually enhanced. If, however, the defect is readily accessible surgically, and disassembly of the existing restorations would impose an unacceptably high cost and long treatment time to the patient, surgical repair should be selected. If a longstanding defect has a periodontal lesion that has formed around it, surgery perhaps with guided tissue regeneration will usually be needed.[14] However, in most of these cases, nonsurgical retreatment and internal perforation repair prior to surgery will be beneficial to the treatment outcome. A multidisciplinary approach will be required, usually in consultation with the restorative dentist, a periodontist, and perhaps an

FIG. 10.78 **A,** Mesially angulated preoperative radiograph showing a palatally oriented post perforation in an upper incisor. **B,** An 8 mm narrow-based probing defect on the mesiopalatal corner of the tooth. **C,** Following coronal disassembly, the true canal can be seen lying in a facial direction relative to the palatal post preparation. **D,** The perforation was repaired with an external matrix of Colla-Cote and MTA. Subsequently, in conjunction with a periodontist, periodontal flap surgery was used to remove periodontal disease etiology from the long-standing pocket, and guided tissue regeneration procedures were instituted. **E,** Three-year reevaluation. The tooth is asymptomatic and mesiopalatal probing depth is 4 mm.

A) Radiograph of tooth shows a radiopaque crown with a black spot on the crown and radiolucent canal. An outline of a radiopaque spiral textured post is visible.

B) Close-up view of the posterior lower jaw shows a cracked tooth examined by a periodontal probe.

C) Close-up of the horizontal section of a molar held in a dam clamp shows an open crown with black spots visible in the cavity.

D) Radiograph of tooth shows a radiolucent crown and canal. An outline of the radiopaque rod-like dressing material is visible.

E) Radiograph of tooth shows a radiopaque crown and radiolucent canal. An outline of the radiopaque rod-like dressing material is visible.

Factors that affect the prognosis of perforation repair include location of perforation, time delay before perforation repair, ability to seal the defect, and previous contamination with microorganisms.[143,234,241] Generally, the more

Telegram: @dental_k

www.konkur.in

apical the perforation site, the more favorable the prognosis; however, the converse is true for the repair procedure itself. The difficulty of the repair will be determined by the level at which the perforation occurred. If the defect is in the furcal floor of a multirooted tooth, or in the coronal one third of a straight canal (access perforation), it is considered to be easily accessible. If it is in the middle third of the canal (strip or post perforations) difficulty increases, and in the apical third of the canal (instrumentation errors) predictable repair is most challenging and, frequently, apical surgery will be needed.

Immediate repair is better than delayed repair, since delay can cause breakdown of the periodontium, resulting in endoperio lesions that are difficult to manage,[131,240] and elimination of microbial contamination of the defect and sealing it properly is critical to success. Many materials have been advocated for the repair of perforations in the past; however, none provided predictable healing after treatment. Commonly used materials include amalgam, Super EBA cement (Bosworth, Skokie, IL), various bonded composite materials, and more recently, bioceramic materials such as mineral trioxide aggregate (Pro-Root MTA, Dentsply, York, PA and MTA Angelus, Londrina, PR, Brazil),[214] Biodentine (Septodont, Saint Maur des Fosses, France), and EndoSequence Root Repair Material (Brasseler USA, Savannah, GA) (Fig. 10.79).

Telegram: @dental_k

www.konkur.in

FIG. 10.79 Bioceramics are the materials of choice for perforation repair. **A,** ProRoot MTA (Dentsply Endodontics) is a medical grade of Portland cement that has had the arsenic removed so that it can be used in the human body. **B,** Brasseler Endosequence Root Repair Material (Brasseler USA). This material has better handling characteristics than MTA and minimizes discoloration of the tooth. **C**, Biodentine (Septodont) is another bioceramic that minimizes tooth discoloration.

Set of three images show the materials used for the repair of dental perforations. These are labeled from A through C.

When mineral trioxide aggregate was introduced for perforation repair, the choice of which repair material to use became more clear.[163,208] MTA has many advantages over previous restoratives when being used for perforation repair. The material seals well,[186,302] even when the cavity preparation is contaminated with blood.[273] It is very biocompatible,[193,201,274,276] rarely

Telegram: @dental_k

www.konkur.in

eliciting any response from the periradicular tissues, and a cementum-like material has been consistently shown to grow directly on the material after placement.[113,201] MTA has also been shown to have a high degree of clinically favorable long-term outcomes when used as a perforation repair material.[163,208] The main disadvantage of MTA is the long time required for setting[275] that makes this material inappropriate for transgingival defects such as those associated with cervical resorption. If the material is in contact with oral fluids, it will wash out of the defect prior to setting so a more rapid setting resin-ionomer such as Geristore (Den-Mat, Santa Maria, CA) is recommended for lesions that cross the gingival margin (Fig. 10.80).[23,56,225] MTA is available in the original gray formulation and an off-white option. Their sealing ability seems comparable,[69] but questions remain as to whether white MTA exhibits the same biocompatibility[199] and will have the same long-term success as the older variety. Also, both types of MTA cause significant tooth discoloration. This is an effect that is seen in all the bioceramics, but it is much less pronounced in the newer ones like Biodentine and EndoSequence Root Repair Material.[178]

FIG. 10.80 Geristore Kit. This and other resin-ionomers have been advocated for cervical perforation repair due to good biocompatibility and the shorter more controlled setting times that make them useful for transgingival root fillings.

Telegram: @dental_k

www.konkur.in

A display of Geristore kit shows components including syringes, auto-mix dispensing tips, intra-oral tips, light cure test rings and instructions.

If the perforation is to be repaired nonsurgically through the tooth, coronal-radicular access to the defect is prepared as stated previously (Fig. 10.81). First, the root canals are located and preliminarily instrumented to create enough coronal shape to allow them to be protected from blockage by the repair material. The defect is cleaned and sometimes enlarged with the use of ultrasonics or appropriate rotary drills, such as the Gates-Glidden, to remove any potentially contaminated dentin surrounding the perforation. Use of a disinfectant irrigating solution such as sodium hypochlorite should be considered if the perforation is not so large as to allow the irrigant to significantly damage the periradicular tissues. If the perforation is large, then sterile saline should be used as an irrigant and disinfection of the margins of the defect is performed using mechanical dentin removal. Arens and Torabinejad[12] have advocated the use of copious flushing of the defect with 2.5% hypochlorite, but in light of the potential severe complications of hypochlorite overextension through a perforation,[84] extreme care should be used. After the defect has been cleaned, vigorous bleeding may result. Hemostasis should be undertaken using collagen (Colla-Cote, Integra Life Sciences, Plainsboro, NJ) (see Fig. 10.8, *B*), calcium sulfate (Capset, Lifecore Biomedical, Chaska, MN), or calcium hydroxide[214]; however, astringents such as ferric sulfate should be avoided, since the coagulum they leave behind may promote bacterial growth and compromise the seal of the repair.[148]

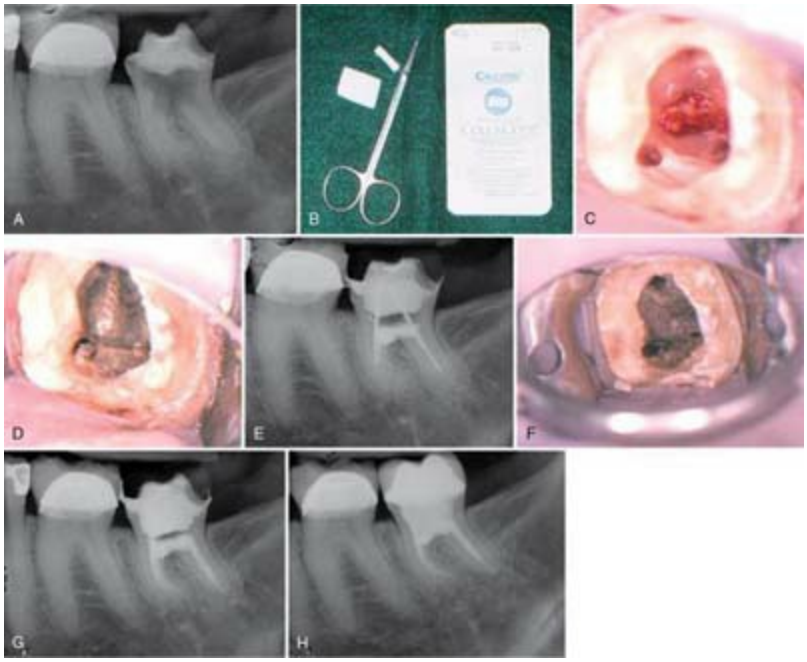

FIG. 10.81 **A,** Large furcal perforation created during an attempt at endodontic access. **B,** Colla-Cote (Integra Life Sciences, Plainsboro, NJ) to be used as an external matrix material to recreate the external root contour. **C,** Canals have been found, preliminarily instrumented, and the external matrix has been placed. **D,** Canals are protected from being blocked using large endodontic files cut off above the orifice. MTA has been placed into the defect. **E,** Radiograph showing the initial repair with MTA recreating the vault of the furcation. **F,** On the second appointment, the blocking files are removed with difficulty since the MTA has flowed into the flutes and set. At this time, endodontic therapy is completed as normal. **G,** Postobturation radiograph. Note the radiolucency in the furcal vault, which represents the Colla-Cote external matrix material. **H,** Nineteen-month reevaluation. The patient is asymptomatic and there is evidence of healing in the furcal vault area.

A) Radiograph of tooth shows a radiopaque uneven crown with a black patch around the neck and radiolucent pulp.

B) An image of a colla-cote with a pair of scissors on the left.

C) Close-up of the horizontal section of a molar shows an open crown exposing red cavity with holes around.

D) Close-up of the horizontal section of a molar shows an open crown exposing a textured cavity with an intensified hole.

E) Radiograph of tooth shows a radiopaque crown and radiolucent pulp. An 'A' shaped radiopaque outline of root repair material is visible.

F) Close-up of the horizontal section of a molar held in a dam clamp shows an

Telegram: @dental_k

www.konkur.in

open crown exposing a dark and textured cavity with intensified holes.

G) Radiograph of tooth shows a radiopaque crown, radiopaque segmented neck filled with root repair material and radiopaque canals.

H) Radiograph of tooth shows a radiopaque crown and radiolucent, radiopaque neck filled with root repair material and radiopaque canals.

When the bleeding has been controlled, some easily removable material should be placed over the entrances to the deeper portion of the canals to prevent the repair material from blocking reaccess to the apical terminus. The canals may be protected with cotton, gutta-percha cones, paper points, or shredded collagen. The use of severed files is not recommended, because removal of the files after placement of the repair material is very difficult since the material tends to lock into the instrument's flutes (see Fig. 10.81, *F*). After protecting the canals, the perforation site is inspected to determine if an external matrix is needed to ensure a proper contour of the restoration.[147] If the surrounding bone is closely adapted to the defect margins, minimal to no matrix material will be necessary; however, if the perforation is associated with a large osseous defect, this must be filled with an external matrix to minimize overcontouring of the repair restoration. The matrix material should be a biocompatible, usually absorbable material such as collagen, freeze-dried demineralized bone allograft (FDDB), hydroxylapatite, Gelfoam, or calcium sulfate.[208,214] Care must be exercised so that the external matrix material is not condensed so forcefully that it damages adjacent vital structures, such as the mental nerve or the floor of the sinus.

Following the preparation of the defect, the repair material is placed. It may be carried in a small syringe or amalgam carrier, and it is condensed with pluggers or microspatulas. In the case of MTA in an accessible defect, the butt end of paper points make an excellent condenser since they can wick some of the water out of the material giving it a firmer consistency, aiding condensation. Upon reentry, the material should be set hard and well retained in the perforation site (see Fig. 10.81, *F*).[245] If there is an overextension of the material beyond the normal external root contour, it seems not to affect the prognosis of the repair.[12,208] While the other bioceramics like Biodentine and EndoSequence Root Repair Material handle more easily than MTA and also set well in both moist and dry environments, the set materials are not as

Telegram: @dental_k

www.konkur.in

hard as set MTA.[39]

If the perforation is deeper in the canal, the objectives and principles or repair as just outlined all apply, except that access to the defect is more complicated (Fig. 10.82). Protecting the canal from blockage is somewhat more difficult and placement of the repair material requires the enhanced vision that is provided by the surgical operating microscope. Ideally, the canal should be fully shaped prior to the repair attempt,[214] and a canal patency protector should be placed apical to the defect. In some of these instances, protecting the canal can be accomplished by using a severed file, notwithstanding the previous warning, since not only can it protect the canal from blockage, but it can also be used as an indirect carrier for transmitting ultrasonic energy to the MTA, causing it to "slump" into the defect when direct condensation is impossible. The file is placed into the canal to a level well below the defect, and the MTA is carried to place. Once condensation has been performed as well as possible, the coronal extent of the file is touched with an ultrasonic tip to vibrate the MTA into the defect. After this is accomplished, the file must be vigorously instrumented in a short 1 to 2 mm amplitude push-pull motion to free it from the placed MTA so that it can be easily removed after the material is set (Fig. 10.83).[214] There is some evidence that ultrasonic placement of MTA may enhance the seal against bacteria in an apexification model,[144] although other researchers have not agreed with this conclusion, and found poorer canal wall adaptation when filling the apical extent of canals using ultrasonic condensation compared with hand filling.[10] Further study of ultrasonic MTA placement is warranted, but clinical observation suggests that this method has merit.

FIG. 10.83 **A,** This patient was in extreme pain following initial endodontic instrumentation by her dentist. Mid-root level perforation found on access. **B,** The original canal was found and protected with an endodontic file. MTA was vibrated using ultrasonic energy applied to the file and it flowed into the defect. Then the file is moved in a push-pull manner to dislodge it from the MTA prior to closure. Note that the defect was intentionally enlarged to allow for more predictable application of the MTA. **C,** On the second appointment, the file is withdrawn easily since it was detached from the MTA repair material. Now the endodontic therapy is concluded as normal. The patient has been asymptomatic since the end of the first appointment. **D,** Twenty-seven–month follow-up showing complete healing.

A) Radiograph of tooth shows a radiopaque crown with radiopaque thread-like structures in the canals.

B) Radiograph of tooth shows a radiopaque crown with outline of the root repair material in the upper left canal.

C) Radiograph of tooth shows a radiopaque crown with a radiopaque stain in the upper left canal.

D) Radiograph of tooth shows a radiopaque crown with radiopaque curved canals.

If the perforation is in the apical portion of the canal, it is usually due to a procedural accident during instrumentation of a curved canal and is invariably accompanied by a block or ledge. This type of perforation is the most difficult to repair, since repair not only involves cleaning and sealing the defect, but also finding, cleaning, and filling the apical canal segment. All

Telegram: @dental_k

www.konkur.in

the aforementioned techniques for managing blocks and ledges are required to find and clean the apical canal segment. When this has been accomplished, the decision is made as to whether the canal should be filled with a bioceramic or with gutta-percha and sealer. The bioceramic is undoubtedly more effective in sealing the canal (especially if it cannot be dried) and is much more biocompatible but carrying it predictably to the apical extent of a curved canal is problematic. If a holding file is placed in the apical canal segment to anticipate eventual gutta-percha placement after the bioceramic repair material is set, then the presence of the file precludes consistent extension of the bioceramic into the apical end of the defect. If a holding file is not placed, the bioceramic can be placed into the prepared apical segment, which may not be completely three-dimensionally obturated. Generally, whichever choice is made, the outcome will be unpredictable, and so the patient must be advised that regular reevaluation is necessary and apical surgery or extraction may ultimately be needed.

Prognosis of retreatment

When the proper diagnosis has been made, and all the technical aspects of retreatment are carefully performed, orthograde retreatment can be highly successful (Fig. 10.84). The prognosis depends to a large extent on whether apical periodontitis exists prior to retreatment.[188,189] In a systematic review of outcomes studies,[75] Friedman and Mor report that in the absence of prior apical periodontitis, the incidence of healed cases after both initial treatment and orthograde retreatment ranges from 92% to 98% up to 10 years after treatment. When prior apical periodontitis is present, the incidence of healing drops to 74% to 86%, regardless of whether initial treatment or orthograde retreatment was performed. The authors state that this “similar potential to heal after initial treatment and orthograde retreatment challenges the historic perception of the latter having a poorer prognosis than the former.”[75]

Unfortunately, these numbers mean that the desired outcome will not occur in potentially one-quarter of retreatment cases. Many techniques and devices for endodontic retreatment have been mentioned here to aid the clinician. However, none of this will guarantee success. Even when strict endodontic principles and fundamentals are followed, the result may be persistent posttreatment disease. When healing does not occur, the clinician is faced with the decision of what to do next. The choice is between four treatment options: observation, endodontic surgery, extraction-replantation, or extraction.

Many times, a tooth that has persistent apical periodontitis may remain in asymptomatic function for an extended period of time, a state that has been referred to as functional retention of the tooth.[75] If the patient's goal of treatment is not necessarily complete healing of the tooth, but simply to retain it in function and without pain, then regular evaluation by the clinician is warranted. If signs and symptoms of worsening infection such as progressive enlargement of a periapical radiolucency, pain, periodontal pocket formation, or sinus tract eruption occur, then further treatment may be needed. However, many teeth classified early on as uncertain healing may indeed be retained for many years.[174]

Endodontic surgery (Fig. 10.85) is a very predictable procedure[75,100,236] that can be performed on most teeth; however, there are some anatomical and medical concerns regarding treatment planning for this procedure that are covered in detail in another chapter. Extraction-replantation (Fig. 10.86), also referred to as intentional replantation,[190] is another treatment option. This involves extraction of the tooth and performing the apicoectomy and root-end filling while the tooth is out of the patient's mouth, followed by replantation and splinting if indicated. This procedure is also discussed in detail in another chapter. Extraction and replacement should be the treatment of last resort, to be selected only when the tooth has been shown to be nonrepairable. If the decision is made to extract the tooth, usually replacement will be necessary to prevent shifting of the dentition with its attendant problems. Replacement can be with an implant, a fixed partial-denture, or a removable partial-denture.

www.konkur.in

Conclusion

Posttreatment endodontic disease does not preclude saving the involved tooth. In fact, most of these teeth can be returned to health and long-term function by current retreatment procedures. In most instances, the retreatment option provides the greatest advantage to the patient since there is no replacement that functions as well as a natural tooth, and it can significantly improve a patient's quality of life and chewing ability over time.[110] Armed with the information in the preceding section, appropriate armamentaria, and the desire to do what is best for the patient, the clinician will provide the foundation for long-term restorative success.

www.konkur.in

Although nonsurgical endodontic treatment is a highly predictable option in most cases, surgery may be indicated for teeth with persistent periradicular pathoses that have not responded to nonsurgical approaches. Surgical root canal therapy, including root-end resection, has been practiced since at least the mid-1800s.[211] In 1906, Schamberg[473] described using radiographs to assist diagnosis and the use of surgical burs to perform a rapid osteotomy and root-end "ablation."

Perhaps the single most important development in dental practice in the

Telegram: @dental_k

www.konkur.in

early 20th century was the introduction of safe, effective local anesthesia, which allowed for more meticulous and comfortable surgical treatment. Formal recognition of endodontics as a specialty in 1963 ushered in a new era of basic and clinical research focused on the prevention and treatment of pulpal and periradicular pathosis.

Since the 1990s, periradicular surgery has continued to evolve into a precise, biologically based adjunct to nonsurgical root canal therapy. The parallel development of new instruments and materials, along with a better understanding of the biology of wound healing, has made surgical treatment a viable alternative to extraction and tooth replacement, rather than a treatment of last resort.

Periradicular surgery, when indicated, should be considered an extension of nonsurgical treatment, because the underlying etiology of the disease process and the objectives of treatment are the same: prevention or elimination of apical periodontitis. Surgical root canal treatment should not be considered as somehow separate from nonsurgical treatment, although the instruments and techniques are obviously quite different. Surgical treatment accounts for about 3% to 10% of the typical endodontic specialty practice.[1,75,374] A web-based survey found that 91% of active endodontists perform some type of root-end surgery, and almost all are using a dental operating microscope and ultrasonics.[115] Endodontists perform almost 78% of surgical root canal treatments; general dentists and other specialists perform 15.5% and 6.6%, respectively.[242] Although appropriately trained general dentists and other dental specialists may perform periradicular surgery, individuals with advanced training in endodontics have developed most of the current periradicular surgery techniques and science presented in this chapter. We believe that endodontists must continue to include periradicular surgery as a routine part of clinical endodontic practice and not abrogate this treatment option to others, who may not possess the same background, skills, or values.[343,424,439] When patient preferences and quality of life measures are considered, patients can be expected to place high value on endodontic treatment and the retention of a natural tooth.[153,180]

Indications for periradicular surgery

Telegram: @dental_k

www.konkur.in

Etiology of persistent periradicular disease

The first and arguably most important step in treatment decision making is attempting to determine the cause of persistent periradicular disease. Treatment then is directed at eliminating the etiology, which most often is the presence of bacteria and other microbial irritants in the root canal space.[492] Nonsurgical retreatment, when possible, is often the first choice for attempting to correct obvious deficiencies in the previous treatment.[564] However, microorganisms can survive even in apparently well-treated teeth in dentinal tubules, canal irregularities, deltas, and isthmus areas.[275,307,568] If residual microorganisms remain completely entombed in the root canal system, periradicular healing should occur. Sealing off all potential routes of microbial escape from the root canal system is the goal of both nonsurgical and surgical treatment. When microorganisms of sufficient pathogenicity and number gain access to the periradicular tissues, pathosis develops.

Enterococcus faecalis is commonly isolated from failing root canal–treated teeth and is known to be especially difficult to eliminate with standard instrumentation and irrigation techniques.[510] Unlike primary endodontic infections, which predominantly are associated with mixed anaerobic microbiota, it has been commonly accepted that treatment failures are more frequently associated with one or two microorganisms.[492] However, research using more sophisticated techniques (16S ribosomal RNA gene clone library analysis) has determined that multiple, previously uncultivated phylotypes can be identified in the majority of teeth with persistent apical periodontitis.[464] Fungi and viruses have also emerged as potential causes of root canal failure and may play either a primary or secondary role in persistent periradicular pathosis.[369,399,462,575]

Established extraradicular colonies of microorganisms also may be a reason for failure of some teeth to respond to nonsurgical treatment. When microorganisms are able to arrange in an extraradicular biofilm, they may be particularly resistant to elimination by host defense mechanisms and antimicrobial agents.[490] Persistent extraradicular root surface colonization cannot be diagnosed by noninvasive methods but may be suspected in well-treated cases that are refractory to nonsurgical treatment.[166,218,465,495,511] Although the presence of extraradicular microbial colonies has been

Telegram: @dental_k

www.konkur.in

somewhat controversial, studies using DNA-DNA hybridization techniques have confirmed the persistence of microorganisms in the periradicular tissues of some root canal–treated teeth.[187,509]

Overextended filling materials may contribute to treatment failure, presumably as a result of a chronic inflammatory response.[369] Although this is possible and even likely with certain toxic materials (e.g., pastes containing formaldehyde),[376] the role of relatively inert materials such as gutta-percha and set sealer is less clear, and these materials probably become a significant contributing factor only if microorganisms are present. If the root apex is close to the buccal cortical plate, apical fenestration may occur, leading to persistent symptoms, especially tenderness to palpation over the root apex.[72] Some have suggested that overextension of filling materials may contribute to endodontic failure because certain dental materials may induce periodontal ligament (PDL) cell apoptosis.[467] This specific interaction between filling materials and periradicular tissues is not fully understood and deserves further research. The poorer prognosis often reported with overextended root canal fillings also may be related simply to lack of an adequate apical seal and subsequent egress of microorganisms from the root canal space. Regardless, minor overextension of filling material is rarely a sole indication for surgery except when symptoms or periradicular pathosis develops. Significant overextension of filling material, especially when important anatomic areas and possibly toxic materials are involved, is an indication for referral to an endodontist or oral surgeon for evaluation and, possibly, treatment.

The presence of periradicular cholesterol crystals may interfere with healing after nonsurgical root canal treatment.[365] Although relatively uncommon, true periradicular cysts (completely enclosed, epithelium-lined cavities) may not be expected to resolve after nonsurgical treatment.[364] As with other extraradicular causes of failure, surgery is indicated, because definitive diagnosis and treatment require an excisional biopsy and removal of the periradicular tissue.

Vertical root fractures are a significant cause of failure and may be difficult to diagnose in the early stages.[90] Exploratory surgery often is required to confirm a root fracture. Cone-beam computed tomography (CBCT) is a promising tool for noninvasive diagnosis of root fractures[155,165] and is

Telegram: @dental_k

www.konkur.in

discussed in greater detail later in this chapter and in Chapter 2. Although several promising approaches to the management of vertical root fractures have been proposed,[226,268,506] the prognosis generally is believed to be poor. Extraction is usually the treatment of choice, especially if appropriate tooth replacement options are available. Root amputation or hemisection may be considered in a multirooted tooth if the remaining tooth structure is uninvolved and sufficient periodontal support is present.

The relationship between systemic disease and periradicular healing is not completely understood. The possible influence of certain systemic medications on wound healing is discussed later in the chapter. Compromised host healing capacity may be a contributing factor in delayed healing and failure of some root canal–treated teeth. For example, complete healing after nonsurgical root canal treatment is less likely in diabetic patients with preoperative periradicular pathosis.[78,175] Patients undergoing immunosuppressive therapy may be at greater risk for delayed healing, treatment failure, or acute exacerbation of a subclinical infection, although two studies involving subgroups of immunocompromised patients (bone marrow transplant and acquired immunodeficiency syndrome [AIDS]) did not find these patients to be at higher risk for complications related to endodontic treatment.[197,406]

Rationale for surgical treatment

Although nonsurgical retreatment generally is believed to be the preferred first approach in the management of persistent apical periodontitis,[77,492,510,564] periradicular surgery is indicated when nonsurgical retreatment is impractical or unlikely to improve on the previous result. In particular, a surgical approach may be the first choice for managing teeth with long posts or irretrievable separated instruments, non-negotiable ledges and canal blockages or transportation, hard cement filling materials, failure of previous nonsurgical retreatment, and suspected vertical root fracture, or when a biopsy is indicated (Figs. 11.1–11.4). Even when surgical treatment is the likely definitive approach, nonsurgical therapy before the procedure may be recommended to help reduce the number of microorganisms in the root canal system and ensure a more favorable long-term prognosis.[230] On the other hand, surgery may be the first choice even if a tooth can be treated

Telegram: @dental_k

www.konkur.in

nonsurgically if the risks and costs of retreatment are considered excessive. For example, disassembling a recently restored bridge abutment tooth to allow endodontic retreatment may be technically possible but not economically feasible. One study found that endodontic microsurgery may be the most cost-effective option for management of persistent periapical disease, compared to nonsurgical retreatment, extraction and placement of a fixed partial denture, and extraction and placement of a single tooth implant.[284] Case-specific variables and clinical judgment are key elements in the decision-making process, as current evidence supports the contention that the prognosis for surgical treatment is approximately the same as that for nonsurgical retreatment.[127,128,135,293,468,577]

FIG. 11.1 Previously treated maxillary lateral incisor with persistent periradicular disease. Nonsurgical retreatment is possible but would involve disassembly of an otherwise adequate coronal restoration. Periradicular surgery is a reasonable option.

Radiograph shows four teeth with first and third shows radiopaque dentin. A gray patch is present at the root of maxillary lateral incisor.

www.konkur.in

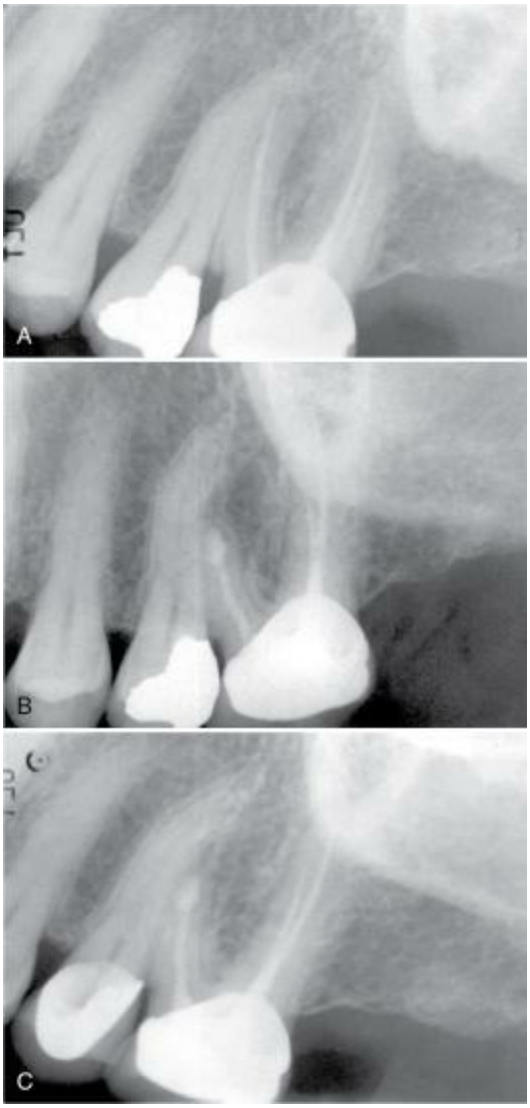

FIG. 11.2 **A,** Previously treated maxillary first molar with persistent periradicular disease and obvious transportation of the main mesiobuccal (MB-1) canal. Nonsurgical retreatment is unlikely to correct this iatrogenic condition, and surgery is the preferred choice. **B,** Immediate postsurgery radiograph. The root-end preparation and fill was extended from the MB-1 canal in a palatal direction to include the isthmus area and the second (MB-2) canal. **C,** One-year follow-up examination: the tooth is asymptomatic, and periradicular healing is apparent radiographically. Although surgery was the first-choice treatment in this case and the outcome was favorable, a good argument could be made for nonsurgical retreatment before surgery to ensure disinfection of the canal and to attempt to locate a MB-2 canal.

Set of three radiographs depict pre-treatment and post-treatment changes observed in the maxillary first molar. The radiograph shows healing of tooth on the left post-treatment depicted as radiopaque crown.

Clinical decision making

Clinical decision making is a process that combines the best available evidence, clinical judgment, and patient preferences. Treatment choices are always made under conditions of at least some uncertainty. Surgical root canal treatment rarely is the only possible choice. Clinicians and patients must weigh the relative benefits, risks, and costs of two or more acceptable alternatives. Patients and clinicians can be expected to hold different attitudes about the value of potential treatment outcomes.[269] In a prognosis study of single-tooth dental implants, Gibbard and Zarb[193] reported that factors considered significant by health care professionals may not be important to patients. Even among groups of dentists and dental specialists, the threshold for treatment varies widely and treatment recommendations may depend more on personal values and experience than objective analysis of treatment costs, prognosis, risks, and alternatives.[56,343,439]

Telegram: @dental_k

www.konkur.in

Shared decision making, in which the patient and clinician consider outcome probabilities and patient preferences and agree on the appropriate treatment, is preferable to a clinician-directed treatment decision.[46,179] Such a two-way exchange allows the clinician to provide the best available current evidence and case-specific clinical judgment while encouraging a decision that considers the patient's personal values and preferences. This decision-making model has been shown to increase patient knowledge about and satisfaction with the treatment choice.[262,386,387] In general, most patients prefer to be actively involved in the decision-making process but want to leave the specifics of the treatment to the clinician.[179] That is, the risks, benefits, and costs of treatment alternatives are important to patients, but the details of the procedure usually are not. Shared decision making is particularly relevant in light of the current trend in some areas to recommend implants as an alternative to root canal treatment.

Comparative probabilities for a successful outcome after surgical root canal treatment, nonsurgical retreatment, or extraction and replacement with a fixed prosthesis or implant are difficult to project. Many treatment variables are complex and not easily quantified, such as the affected location in the mouth, bone quality, practitioner's skill, possible influence of systemic disease on healing, periodontal support, bulk of the remaining tooth structure and resistance to fracture, quality of the coronal restoration, patient susceptibility to recurrent caries, materials used, and other factors. In addition, the definition of success varies considerably and is inconsistent from study to study.

Boioli and colleagues[66] performed a meta-analysis of implant studies and reported a 93% survival rate at 5 years. The 5- to 10-year success rate for implant retention routinely is reported to be 90% to 97%, depending on the location in the mouth and other variables.[302,309] Surgical root canal treatment was previously reported to have a lower success rate than implant placement.[230,546] However, most of these older studies would be considered weak by today's evidence-based standards and, more important, do not reflect the use of many of the newer surgical materials and techniques. With careful case selection, surgical skill, and the use of materials and techniques described later in this chapter, many studies have demonstrated success rates over 90% for surgical root canal treatment.[326,448,500,501,546,609] von Arx

Telegram: @dental_k

www.konkur.in

reported that the 5-year success for teeth receiving endodontic microsurgery was 8% less than observed at 1 year.[566] A similar study found an 85% success rate after 10 years.[500] A systematic review and meta-analysis comparing traditional root-end surgery to modern endodontic microsurgery (ultrasonic root-end preparation; root-end filling with intermediate restorative material [Denstply/Sirona, York, PA], Super EBA [ethoxybenzoic acid; Keystone Industries, Gibbstown, NJ], or mineral trioxide aggregate [MTA]; and high power [>×10] magnification and illumination) found that the outcome for endodontic microsurgery using current materials and techniques was 94%, compared to 59% success with traditional root-end surgery.[483]

In broad terms and under ideal conditions, the prognoses for nonsurgical retreatment, surgical treatment, and implant placement should be roughly equal. The choice of treatment should be based on the best available evidence, case-specific clinical judgment, and the patient's preferences. As a stronger evidence base continues to develop, we predict that algorithms encompassing multiple patient and treatment variables will be devised to assist clinical decision making.

General biologic principles of wound healing

Wound healing varies from region to region in the body and depends on several factors, including the type of tissue, the type of wound, and the type of healing. In periradicular surgery, the tissues include free and attached gingiva, the alveolar mucosa, periosteum, bone, the PDL, and cementum. The wound may be intentional surgical trauma, which includes incision, blunt dissection, and excision (surgical), or pathologic or traumatic wounds. Healing occurs by primary or secondary intention.[212]

An incisional blunt dissectional wound, for example, can be considered to heal typically by primary intention, whereas a dissectional wound involving the resected root surface and osseous crypt heals by secondary intention. An important concept of the wound healing process in general is the difference between regeneration and repair. The goal of all surgical procedures should be *regeneration*, which returns the tissues to their normal microarchitecture and function, rather than *repair*, a healing outcome in which tissues do not return to normal architecture and function. Repair typically results in the

Telegram: @dental_k

www.konkur.in

formation of scar tissue.

The wounding process varies, depending on the types of tissue and injury. However, all wounds progress through three broad, overlapping phases in the process of healing; these are the inflammatory phase, the proliferative phase, and the maturation phase.[240,570] Although these phases can be identified in healing tissue, none of them has a clear beginning or end. Furthermore, in a wound such as an endodontic surgical site, which involves more than one tissue type, these phases progress at different rates in each type of tissue.

Soft-tissue wound healing

Inflammatory phase

Broadly speaking, the inflammatory phase of healing is similar for all tissues.[543] This phase can be broken down further into clot formation, early inflammation, and late inflammation.

Clot formation

Clot formation begins with three events: (1) blood vessel contraction is initiated by platelet degranulation of serotonin, which acts on the endothelial cell and increases the permeability of the vessel, allowing a protein-rich exudate to enter the wound site; (2) a plug composed of platelets forms, primarily through intravascular platelet aggregation; and (3) both the extrinsic and intrinsic clotting mechanisms are activated. Several other events occur simultaneously, including activation of the kinin, complement, and fibrinolytic systems and the generation of plasmin.[34,247,521] These events stabilize hemostasis, begin the production of a number of mitogens and chemoattractants, and initiate the process of wound decontamination. The result is a coagulum consisting of widely spaced, haphazardly arranged fibrin strands with serum exudate, erythrocytes, tissue debris, and inflammatory cells. Compression of the surgical flap with sterile iced gauze immediately after surgery is designed to minimize the thickness of the fibrin clot and thereby accelerate optimal wound healing.

Early inflammation: Polymorphonuclear neutrophil organization

Telegram: @dental_k

www.konkur.in

As a result of production of chemoattractants by the various components of the clot, polymorphonuclear neutrophils (PMNs) begin to enter the wound site within 6 hours of clot stabilization. The number of PMNs increases steadily, peaking at about 24 to 48 hours after the injury. Three key steps mark PMN migration into the wound site: (1) *pavementing*, in which the red blood cells undertake intravascular agglutination, allowing the PMNs to adhere to the endothelial cells; (2) *emigration*, in which the PMNs actively pass through the vascular wall; and (3) *migration*, in which the PMNs use ameboid motion, under the influence of the various chemotactic mediators, to move into the injured tissues.[212]

The principal role of the PMNs is wound decontamination by means of phagocytosis of bacteria. The high number of PMNs in the wound site is relatively short lived; the number drops rapidly after the third day.

Late inflammation: Macrophage organization

About the time the PMN population is declining (48 to 96 hours after injury), macrophages begin to enter the wound site. They reach a peak concentration by approximately the third or fourth day. These cells, which are derived from circulating monocytes, leave the bloodstream under the influence of the chemoattractants in the wound site. The monocytes subsequently evolve into macrophages. Macrophages have a much longer life span than PMNs; they remain in the wound until healing is complete. Similar to PMNs, macrophages play a major role in wound decontamination through phagocytosis and digestion of microorganisms and tissue debris.

Macrophages are considerably more bioactive than PMNs and can secrete a vast array of cytokines. A key action of many of these bioactive substances is initiation of the proliferative phase of wound healing, which is accomplished by prompting the formation of granulation tissue. Two other major functions of macrophages are ingestion and processing of antigens for presentation to T lymphocytes, which enter the wound after the macrophages. Unlike PMNs, macrophages play an essential role in the regulation of wound healing.[109,224] A reduction in the number of macrophages in the wound site delays healing, because the wound does not progress to the next phase. For example, the age-related reduction in healing potential appears to be partly the result of loss of estrogen regulation of macrophages in healing tissues.[33]

Telegram: @dental_k

www.konkur.in

Proliferative phase

The proliferative phase is characterized by the formation of granulation tissue in the wound. Two key cell types, fibroblasts and endothelial cells, have a primary role in the formation of granulation tissue. Granulation tissue is a fragile structure composed of an extracellular matrix of fibrin, fibronectin, glycosaminoglycans, proliferating endothelial cells, new capillaries, and fibroblasts mixed with inflammatory macrophages and lymphocytes. Epithelial cells also are active during this phase of soft-tissue healing and are responsible for initial wound closure. Guided tissue regeneration (GTR) procedures are based on control of the epithelial cell growth rate during this phase.

Fibroblasts: Fibroplasia

Undifferentiated mesenchymal stem cells in the perivascular tissue and fibroblasts in the adjacent connective tissue migrate into the wound site on the third day after injury and achieve their peak numbers by approximately the seventh day. This action is stimulated by a combination of cytokines (e.g., fibroblast growth factor [FGF], insulin-like growth factor-1 [IGF-1], and 2-15 platelet-derived growth factor [PDGF]), which are produced initially by platelets and subsequently by macrophages and lymphocytes. As the number of macrophages declines and the fibroblast population increases, the tissue in the wound transforms from a *granulomatous* tissue to a *granulation* tissue.

Fibroblasts are the crucial reconstructive cell in the progression of wound healing because they produce most of the structural proteins forming the extracellular matrix (e.g., collagen). Collagen is first detected in the wound about the third day after injury. The fibroblasts produce type III collagen initially and then, as the wound matures, type I collagen. As this network of collagen fibers is laid down, endothelial and smooth muscle cells begin to migrate into the wound. Subsequently, as wound healing progresses, the collagen fibers become organized by cross-linking. Regularly aligned bundles of collagen begin to orient so as to resist stress in the healing wound.[108,286,413,516]

A focused type of fibroblast, known as a *myofibroblast*, plays a significant role in wound contraction, particularly in incisional-type wounds.[316,524] Myofibroblasts align themselves parallel with the wound surface and then

Telegram: @dental_k

www.konkur.in

contract, drawing the wound edges together. These cells are eliminated by apoptosis after wound closure.[137,138]

Endothelial cells: Angiogenesis

Capillary buds originate from the vessels at the periphery of the wound and extend into the wound proper. This occurs concurrently with fibroblast proliferation and can begin as early as 48 to 72 hours after injury. Without angiogenesis, the wound would not have the blood supply needed for further active healing. The capillary sprouts eventually join to form a network of capillary loops *(capillary plexuses)* throughout the wound.

In addition to a low oxygen concentration in the wound proper,[198,289] several factors have been identified as potent stimulators of angiogenesis, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), acidic FGF (aFGF), transforming growth factor–alpha (TGF-alpha) and transforming growth factor–beta (TGF-beta), epidermal growth factor (EGF), interleukin-1 (IL-1), and tumor necrosis factor–alpha (TNF-alpha),[145] as well as lactic acid.[248,258,503] All of these have been shown to stimulate new vessel development.

Epithelium

The first step in epithelial healing is the formation of an epithelial seal on the surface of the fibrin clot. This process begins at the edge of the wound, where the basal and suprabasal prickle cells rapidly undergo mitosis. The cells then migrate across the fibrin clot at a remarkable rate (0.5 to 1 mm/day). This monolayer of epithelial cells continues to migrate by contact guidance along the fibrin scaffold of the clot below. Migration stops as a result of contact inhibition of the epithelial cells from the opposing wound edge. Once the epithelium from both sides of the wound is in contact, an epithelial seal is achieved. In wounds healing by primary intention, formation of an epithelial seal typically takes 21 to 28 hours after reapproximation of the wound margins.[222]

Maturation phase

Under ideal conditions, maturation of the wound begins 5 to 7 days after injury. A reduction in fibroblasts, vascular channels, and extracellular fluids

Telegram: @dental_k

www.konkur.in

marks the transition to this phase of healing. During the early stages of wound maturation, the wound matrix is chiefly composed of fibronectin and hyaluronic acid. As the tensile strength of the wound increases, significant upregulation of collagen fibrogenesis occurs. Collagen remodeling ensues, with the formation of larger collagen bundles and alteration of intermolecular cross-linking. The result is a conversion of granulation tissue to fibrous connective tissue and a decreased parallelism of collagen to the plane of the wound. Aggregated collagen fibril bundles increase the tensile strength of the wound. As healing progresses in the wound, the collagen gradually reorganizes; this requires degradation and reaggregation of the collagen. The degradation of collagen is controlled by a variety of collagenase enzymes. Remodeling results in a gradual reduction in the cellularity and vascularity of the reparative tissue; the degree to which this occurs determines the extent of scar tissue formation. Active remodeling of scar tissue can continue very slowly for life.[138,247]

Maturation of the epithelial layer quickly follows formation of the epithelial seal. The monolayer of cells forming the epithelial seal differentiates and undergoes mitosis and maturation to form a definitive layer of stratified squamous epithelium. In this way an epithelial barrier is formed that protects the underlying wound from further invasion by oral microbes. The epithelial barrier typically forms by 36 to 42 hours after suturing of the wound and is characterized by a significant increase in wound strength.[222]

Hard-tissue healing: Excisional dentoalveolar wound

The inflammatory and proliferative phases of healing for hard tissue are similar to those for soft tissue. A clot forms in the bony crypt, and an inflammatory process ensues that involves PMNs initially and macrophages subsequently. This is followed by the formation of granulation tissue with an angiogenic component. However, the maturation phase of hard-tissue healing differs markedly from that for soft tissues, primarily because of the tissues involved: cortical bone, cancellous bone, alveolar bone proper, endosteum, PDL, cementum, dentin, and inner mucoperiosteal tissue.

Telegram: @dental_k

www.konkur.in

Osteoblasts: Osteogenesis

The healing of an excisional osseous wound that is approximately 1 cm in diameter is similar to that of a fractured long bone. It progresses from hematoma to inflammation, eradication of nonvital debris, proliferation of granulation tissue, callus formation, conversion of woven bone to lamellar bone, and, finally, remodeling of the united bone ends. The coagulum that initially forms delays healing and must be removed to allow wound healing to progress.

A major difference between soft- and hard-tissue wound healing is found in the role of the osteoclast. Functionally, osteoclasts act as organizational units to debride necrotic bone from the wound margin, much as macrophages remove tissue debris from the clot. Granulation tissue begins to proliferate from the severed PDL by 2 to 4 days after root-end resection.[223] This tissue rapidly encapsulates the root end. Simultaneously, endosteal proliferation into the coagulum occurs from the deep surface of the bony wound edge. The coagulum in the bony crypt is quickly converted into a mass of granulation tissue. In addition to those already discussed, several cell types migrate into the coagulum, including osteoprogenitor cells, preosteoblasts, and osteoblasts. These cells begin the formation of woven bone within the mass of granulation tissue. New bone formation is apparent about 6 days after surgery.[223]

Bone formation can be categorized into two types, each having several phases. The phases differ, depending on which type of formation is involved. One type of bone formation is a matrix vesicle–based process, and the other type is based on osteoid secretion. In both processes, osteoblasts produce the bone matrix. They secrete a collagen-rich ground substance that is essential for mineralization. Osteoblasts also cause calcium and phosphorus to precipitate from the blood.

In the formation of woven bone, which occurs by the matrix vesicle–based process, osteoblasts produce matrix vesicles through exocytosis (the release of substances contained in a vesicle within a cell by a process in which the membrane surrounding the vesicle unites with the membrane forming the outer wall of the cell) of their plasma membranes. As hydroxyapatite crystals accrue in the vesicles, they become enlarged and eventually rupture. This process begins with the deposition and growth of hydroxyapatite crystals in

Telegram: @dental_k

www.konkur.in

the pore regions. The crystals then amalgamate to form structures known as *spherulites.* Union of the separate spherulites results in mineralization.

The formation of lamellar bone does not require the production of matrix vesicles; rather, it proceeds by the osteoblast secretion process. Osteoblasts secrete an organic matrix composed of longitudinally arranged collagen matrix fibrils (mainly type I collagen). Mineralization occurs by mineral deposition directly along the collagen fibrils.[239,240] This stage has been associated with a rise in pH, most likely because of the enzyme alkaline phosphatase, which is secreted by osteoblasts and other cells and plays an important role in mineralization. The exact role of alkaline phosphatase during mineralization is unclear. The balance of evidence favors a positive catalytic role.[19,20] Some hypothesize[71,70,552,553] that alkaline phosphatase promotes mineralization through a combination of mechanisms involving various cells, extracellular matrix proteins, and elements. The interaction of alkaline phosphatase and phosphoproteins in both bone and dentin appears to be especially critical to the mineralization process.[71,72,557,558]

Inhibitor molecules, such as pyrophosphate and acidic noncollagenous bone proteins, regulate mineralization. Several growth factors also have been identified as key components in the production of osseous tissue. These include TGF-beta, bone morphogenic protein (BMP), PDGF, FGF, and IGF.[97,191,476,513] One clinical study demonstrated that the addition of autologous platelet concentrate to the surgical site decreased postsurgical pain and may accelerate the healing process.[134]

Three to 4 weeks after surgery, an excisional osseous wound is filled from 75% to 80% with trabeculae surrounded by intensely active osteoid and osteoblastic cells. A reforming periosteum can be seen on the outer surface of the wound; it is highly cellular and has more fibrous connective tissue oriented parallel to the plane of the former cortical plate. At 8 weeks after surgery, the trabeculae are larger and denser and the osteoblasts are less active; these cells occupy about 80% of the original wound. Also, fewer osteoid cells are associated with the maturing trabeculae. The overlying periosteum has reformed and is in contact with the newly developed bone. The osseous defect typically is filled with bone tissue by 16 weeks after surgery. However, the cortical plate has not yet totally reformed. Maturation and remodeling of the osseous tissue continues for several more months.[223]

Telegram: @dental_k

www.konkur.in

Local healing is also influenced systemically by the endocrine system and its three general categories of hormones: polypeptide regulators (parathyroid hormone, calcitonin, insulin, and growth hormone), steroid hormones (vitamin D_3, glucocorticoids, and the sex hormones), and thyroid hormones.[219]

Cementoblasts: Cementogenesis

During regeneration of the periradicular tissues, cementum forms over the surface of surgically resected root ends.[114] The exact spatial and temporal sequences of events leading to this formation of new cementum remains undefined; however, cementogenesis is important, because cementum is relatively resistant to resorption (osteoclasts have little affinity for attaching to cementum).

Cementogenesis begins 10 to 12 days after root-end resection. Cementoblasts develop at the root periphery and proceed centrally toward the root canal.[24] Considerable evidence indicates that the cells that regulate cementogenesis are derived from ectomesenchymal cells in the tooth germ proper rather than from bone or other surrounding tissues. The migration and attachment of precementoblasts to the root surface dentin is monitored by mediators from within the dentin itself.[140,210] Cementum covers the resected root end in approximately 28 days. Newly formed PDL fibers show a functional realignment that involves reorientation of fibers perpendicular to the plane of the resected root end, extending from the newly formed cementum to the woven bone trabeculae. This occurs about 8 weeks after surgery.[212,319,320]

Systemic medications and wound healing

Bisphosphonates

Bisphosphonates are commonly used for the treatment of osteopenia, osteoporosis, Paget disease of bone, multiple myeloma, and metastatic bone, breast, and prostate cancer. The potential association between bisphosphonate use and osteonecrosis of the jaw was first reported in 2003.[332,351] The current preferred term for this condition is antiresorptive agent-induced osteonecrosis

Telegram: @dental_k

www.konkur.in

of the jaw (ARONJ)[229] or medication-related osteonecrosis of the jaw (MRONJ). The change in terminology reflects the finding that, in addition to bisphosphonates, other antiresorptive agents can increase the risk for osteonecrosis of the jaw (e.g., denosumab). ARONJ can occur spontaneously but is more commonly associated with dental procedures that involve bone trauma. Patient variables that increase the risk for ARONJ include age (over 65 years old), chronic use of corticosteroids, use of bisphosphonates for more than 2 years, smoking, diabetes, and obesity.[278,334,340,583] It is important to note that the risk for ARONJ with commonly prescribed oral bisphosphonates appears to be very low, whereas the overall benefits of this drug class for reducing morbidity and mortality related to hip, vertebral, and other bone fractures are significant.[229] The estimated incidence for ARONJ in patients taking oral bisphosphonates ranges from zero to 1 in 2260 cases, although dental extractions may quadruple the risk of developing ARONJ.[7,340] A reasonable upper estimate of the risk of developing ARONJ in a patient who does not have cancer is about 0.1%.[229] One clinical study reported a much higher 4% risk for developing ARONJ in patients taking a specific oral bisphosphonate (alendronate sodium),[479] although this was a retrospective study using an electronic patient record at a dental school and may not have adequately controlled for other relevant variables. The majority of ARONJ cases have been reported in patients taking intravenous (IV) bisphosphonates (e.g., zoledronic acid and pamidronate). According to one report, approximately 20% of patients taking IV bisphosphonates may develop ARONJ.[7,340] A systematic review found that there was a strong association between cancer and risk of ARONJ, with the prevalence ranging from 0.7% to 13.3%.[352] Interestingly, this same review found that the higher-quality studies reported the highest prevalence of ARONJ in cancer patients.

Conservative and timely management of apical periodontitis is essential to reduce the risk of ARONJ in patients taking bisphosphonates. Because periapical pathosis may exacerbate or increase the risk for ARONJ, the “no treatment” option is not a viable choice. The potential risk for ARONJ should be thoroughly discussed with all patients that are taking bisphosphonates, as well as treatment options. Nonsurgical retreatment should usually be considered the first choice, especially for patients with a history of IV bisphosphonate use or other risk factors. Even so, surgical treatment may be

Telegram: @dental_k

www.konkur.in

indicated to manage chronic or acute apical periodontitis. When the only viable treatment options for the management of persistent periradicular inflammation are surgical root canal therapy or extraction, the question of which option is more or less likely to lead to ARONJ in at-risk patients remains unanswered. In general, the procedure that could most predictably eliminate the periradicular inflammation with the least amount of surgical trauma would be preferred. Conservative surgical technique, primary tissue closure, and use of chlorhexidine mouth rinses preoperatively and during the healing stage are recommended.[229] There is some limited evidence to support the use of prophylactic antibiotics and chlorhexidine mouth rinse to decrease the risk of ARONJ for patients undergoing surgical dental treatment.[229] Because bisphosphonates have a substantial half-life when incorporated into bone, discontinuation of bisphosphonates prior to dental treatment is unlikely to provide any measurable benefit and may place the patient at greater risk for complications that the drug is intended to prevent.

The possibility of predicting which patients may be at greater risk for ARONJ based on serum levels of C-terminal cross-linking telopeptide of type I collagen (cross-linking telopeptide [CTX]) has been suggested based on clinical observations.[333] This observation may provide a useful clue for future risk assessment but requires additional refinement and validation prior to widespread acceptance. In fact, one study found that although serum CTX levels were lower in patients taking bisphosphonates (as expected), there was no association between lower CTX levels and increased risk of ARONJ.[208] This same study found that patients taking a once-a-year dose of 5 mg zoledronic acid were at no greater risk for ARONJ than a control group (1 case in 5903 patients). Once ARONJ develops, treatment options are limited. A possible treatment strategy proposed in a series of case reports is the use of teriparatide, an anabolic drug that stimulates osteoblast formation and is used for the management of osteoporosis.[505]

Glucocorticoids

Glucocorticoid therapy has been shown to induce rapid bone loss within the first 3 months of treatment. Even inhaled steroids have been implicated as a cause of bone loss. Bone formation is inhibited partly through a decrease in osteoblast life span and function, a reduction in the mineral apposition rate,

Telegram: @dental_k

www.konkur.in

and a prolonged mineralization lag time. Biochemical markers of bone formation (i.e., osteocalcin and bone-specific alkaline phosphatase) are suppressed. In addition to this primary suppressive effect, glucocorticoids cause accelerated bone resorption. The number and activity of osteoclasts increase during early glucocorticoid exposure. With continued use of glucocorticoids, the rapid rate of osteoclast-mediated bone resorption slows, but suppression of bone formation continues as the overriding skeletal activity.[272] Bone loss is therefore progressive because bone resorption chronically exceeds bone formation.

The adverse effects of glucocorticoids on bone are mediated by sex steroid deficiency and expression of locally produced growth factors and related proteins, such as reduced production of IGF-1 and alterations in IGF-binding proteins in osteoblasts. The direct effect on calcium metabolism through alteration of vitamin D metabolism leads to a state of secondary hyperparathyroidism.[447,581,582]

Nonsteroidal antiinflammatory drugs

Bone homeostasis is regulated by many factors, including prostaglandins (PGs).[267] PGs are important to both normal and pathologic bone turnover. PGs modulate osteoblast proliferation and differentiated functions.[426,427] The levels of prostaglandin E (PGE) and prostaglandin F (PGF) are elevated in the early phase of fracture healing, and administration of PGE_2 has increased the rate of osseous repair in several animal studies.[272] Nonsteroidal antiinflammatory drug (NSAID) inhibition of the enzyme cyclooxygenase (COX), which is involved in the synthesis of PGs, is the same mechanism by which NSAIDs control pain. By inhibiting the COX enzymes and the subsequent production of PGs, NSAIDs accomplish the desired antiinflammatory effects—but also prevent the increased production of PGs required for bone healing. In vitro studies using animal models have shown that NSAIDs inhibit osteoblast proliferation and stimulate protein synthesis.[235] These drugs also have been shown to delay fracture healing and to affect bone formation adversely in animals and humans.[15,192] In one study, the use of NSAIDs reduced the amount of bony ingrowth into an orthopedic implant.[220]

Telegram: @dental_k

www.konkur.in

In other studies, NSAIDs reduced bone resorption associated with experimentally induced periapical lesions,[18,390] and systemic NSAIDs may play a positive role in maintaining bone height around endosseous titanium dental implants.[257] Additional research is needed to clarify the specific influence of NSAIDs on healing after periradicular surgery.

Cyclooxygenase-2 inhibitors

Although both COX-1 and COX-2 have been identified in osteoblasts, the different roles of the two COXs in bone formation remain unclear. A study using COX-1 and COX-2 knockout mice compared the roles of the two enzymes in fracture healing. COX-2 was shown to have an essential role in both endochondral and intramembranous bone formation during wound healing. COX-2 knockout mice showed a persistent delay in cartilage tissue ossification. No difference in fracture healing was observed between the COX-1 knockout mice and the wild-type control used in this study.[603] Additional studies have shown a persistent delay in healing with COX-2 NSAIDs[202,203]; however, this difference in effect was not apparent clinically in a study examining the healing of spinal fusion wounds.[182]

Preoperative evaluation of medically complex patients

The preoperative assessment must take into account both the type of procedure planned and the type of patient (i.e., physical health and psychological status). Healthy patients clearly can be expected to tolerate surgical procedures better than medically complex patients. Clinicians should anticipate and prepare for the inevitability of treating more medically complex patients as the population ages. It is beyond the scope of this brief section to cover all possible medical considerations; rather, the most common issues that may require modification of an endodontic surgical treatment plan are presented. Relatively few absolute contraindications to periradicular surgery exist for patients well enough to seek care in an ambulatory dental office. Nonetheless, if any question arises about a patient's ability to tolerate a surgical procedure, medical consultation is advised. A thorough medical history and assessment of vital signs are required parts of the presurgical

Telegram: @dental_k

www.konkur.in

evaluation.

The American Society of Anesthesiologists (ASA) has developed a widely used system for establishing surgical risk. Patients categorized as ASA 1 are healthy and usually require no modification of the surgical treatment plan. Patients classified as ASA 4 or ASA 5 are not treated in a dental office; these individuals have significant medical problems that take priority over dental considerations. Patients considered ASA 2 or ASA 3 are commonly seen on an outpatient basis and may require medical consultation and modification of the surgical treatment plan. Patients in the ASA 2 and ASA 3 categories have mild to moderate systemic disease and often are undergoing treatment with one or more prescription medications. The ASA classification system should only be used as a general guide because, when used alone, the ASA system is not a reliable predictor of operative risk.[201] In addition, even experienced anesthesiologists exhibit differences of opinion when using the ASA system to classify patients.[227,395] The patient's psychological status and anticipated procedural stress should be considered in addition to the ASA classification of physical health. A stress reduction protocol may be helpful for patients who report moderate dental anxiety with concurrent mild to moderate systemic disease.

Surgical procedures typically require a larger amount of local anesthetic with a vasoconstrictor than a nonsurgical root canal treatment. An essential part of the presurgical evaluation is an assessment of the patient's cardiovascular status and tolerance for local anesthetics that contain epinephrine. In particular, patients with advanced cardiovascular disease, geriatric patients, and patients taking certain medications may have a reduced tolerance for local anesthetics containing a vasoconstrictor. Treatment-induced stress associated with surgical procedures can cause a significant increase in heart rate and systolic blood pressure when compared to nonsurgical root canal therapy.[189] The use of local anesthetics with vasoconstrictors was addressed in the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).[231] An updated version of this report (JNC 8) was issued in 2013. In patients with cardiovascular disease, 0.036 to 0.054 mg of epinephrine (approximately two to three cartridges of local anesthetic with 1:100,000 epinephrine) should be safe for most patients except those with

Telegram: @dental_k

www.konkur.in

severe cardiovascular disease or other specific risk factors.[38,231,594] Local anesthetics with vasoconstrictors should be avoided or used with extreme caution in patients with the following cardiovascular conditions: severe or poorly controlled hypertension, arrhythmias that are refractory to treatment, myocardial infarction within the past month, stroke within the past 6 months, coronary artery bypass graft within the past 3 months, and uncontrolled congestive heart failure.[311] Patients unable to tolerate vasoconstrictors may not be good candidates for periradicular surgery, because a local anesthetic with a vasoconstrictor is essential for obtaining adequate hemostasis and visibility during this type of procedure. Surgery can be performed using only local anesthetics without vasoconstrictors, but this is not recommended.

The potential for multiple drug interactions is increasing because of the aging population and the introduction of many new drugs. Many elderly patients have diminished liver and kidney function and therefore cannot metabolize and excrete drugs as efficiently as younger, healthy patients. The potential for drug interactions and decreased metabolism and excretion of drugs should be considered, even for commonly used agents such as local anesthetics and analgesics.

A transient bacteremia is a virtual certainty with periradicular surgery; therefore patients at high risk for bacterial endocarditis should receive appropriate antibiotic prophylaxis as recommended by the American Heart Association. New guidelines for prevention of infective endocarditis were published in 2007 and represent a significant change from previous American Heart Association guidelines.[588] For example, antibiotic prophylaxis is no longer recommended for patients with a history of mitral valve prolapse (with or without regurgitation), rheumatic heart disease, bicuspid valve disease, aortic stenosis, and certain congenital heart conditions. Antibiotic prophylaxis is now only recommended for patients with valvular disease associated with the highest risk of adverse outcomes from infective endocarditis. For patients in the highest risk category, antibiotic prophylaxis is recommended for dental procedures that involve manipulation of gingival tissues or the periapical region of teeth or perforation of the oral mucosa. For all other patients with valvular disease, the risks associated with routine antibiotic prophylaxis are greater than the potential benefits.[588] Although these guidelines represent the best available current evidence, practitioners

Telegram: @dental_k

www.konkur.in

should be aware that a recent study from England found a significant increase in cases of infective endocarditis after widespread adoption of the new guidelines in 2008. However, the authors point out that their data do not establish a causal relationship and recommend adherence to the current guidelines at this time.[130a]

New clinical practice guidelines for the management of patients with prosthetic joints were co-developed by the American Association of Orthopaedic Surgeons and the American Dental Association in December 2012.[578] The working group conducted a systematic review and presented three recommendations. Recommendation 1 states that "the practitioner might consider discontinuing the practice of routinely prescribing prophylactic antibiotics for patients with hip and knee prosthetic joint implants undergoing dental procedures." The level of evidence to support this recommendation was classified as "limited," but that was the highest level of evidence assigned to any of the three recommendations. Two case-control studies provide evidence for this recommendation.[51,498] In recommendation 2, the group was unable to recommend for or against the use of topical antimicrobial agents (grade of recommendation = inconclusive). Recommendation 3 was a consensus recommendation to support the maintenance of appropriate oral hygiene (grade of recommendation = consensus). A recent American Dental Association Council on Scientific Affairs report added further clarification by concluding that: "In general, for patients with prosthetic joint implants, prophylactic antibiotics are not recommended prior to dental procedures to prevent prosthetic joint infection.[499a]

Management of patients undergoing anticoagulant therapy depends on the type of anticoagulant, the reason for anticoagulant therapy, and the type of oral surgery planned. Warfarin (Coumadin), a commonly prescribed anticoagulant used to treat or prevent thromboembolisms, blocks the formation of prothrombin and other clotting factors. The international normalized ratio (INR) value is the accepted standard for measuring prothrombin time (PT). The desired therapeutic range for the INR usually is 2 to 3.5, depending on the underlying medical indication for anticoagulant therapy. Limited oral surgery procedures, such as simple forceps extraction of one to three teeth, may be performed safely on patients with INR values

Telegram: @dental_k

www.konkur.in

within the normal therapeutic range.[8,89,255,478] Periradicular surgery, however, may present a greater challenge for hemostasis, even for patients well maintained within the therapeutic range. The clear field visibility normally required for proper surgical management of the root end may not be possible in patients undergoing anticoagulant therapy. The patient's physician must be consulted for assistance in developing an appropriate treatment plan. Some patients may be able to tolerate discontinuation of warfarin therapy 2 days before a planned surgical procedure, which allows the INR to drift downward. In a prospective cohort study, Russo and colleagues[461] reported that suspension of warfarin 2 days before a surgical procedure resulted in no bleeding problems and no thromboembolic events. They found that the average time spent at an INR below 2 (critical value) was 28 hours and that 90% of the patients returned to the desired therapeutic INR value within 7 days. However, this strategy may place certain patients at greater risk for a thromboembolic event; therefore discontinuation of anticoagulant therapy would not be recommended.

In general, patients undergoing anticoagulant therapy should present minimal risk for significant bleeding during or after oral surgery, and local measures to control bleeding should be adequate.[88,569] In a review prepared for the American Dental Association Council on Scientific Affairs and Division of Science, Jeske and Suchko[260] recommended against routine discontinuation of anticoagulant therapy before dental procedures, including surgical procedures. Regardless of the management approach selected, consultation with the patient's physician and an INR test on the day of surgery are strongly recommended. A retrospective study of an urban dental school population found that INR values for 43% of patients taking warfarin were not within the recommended therapeutic range.[266] To underscore the challenge of maintaining anticoagulation levels within an appropriate therapeutic range, warfarin has been implicated in more emergency hospital admissions than any other medication.[83]

Hospitalization and conversion to heparin therapy may be considered in special cases, but the patient, physician, and surgeon must carefully weigh the potential risks against the expected outcome and benefits. A new category of heparin anticoagulant, low-molecular-weight heparins (LMWHs), allows patient self-administration and may be an alternative for patients who need to

Telegram: @dental_k

www.konkur.in

maintain a high level of anticoagulation but want to reduce the cost and time required for traditional heparin conversion therapy.

Novel oral anticoagulant drugs (NOACs) have recently emerged as an alternative to warfarin for most indications (e.g., previous stroke, atrial fibrillation, and deep vein thrombosis) *except* for mechanical heart valves. Examples include: apixaban (Eliquis), dabigratran (Pradaxa), edoxaban (Lixiana), and rivaroxaban (Xarelto). NOACs have fewer interactions with foods and other drugs, and there is no need for routine blood work monitoring. However, although NOACs are known to prolong PT by inhibiting factor X to Xa conversion, there is currently no reliable test to accurately measure level of anticoagulation. Medical consultation may be indicated to help evaluate the relative benefits and risks of discontinuing NOAC drugs for 1 or 2 days prior to endodontic surgery.

Low-dose aspirin therapy is known to increase bleeding time by irreversibly inhibiting platelet aggregation. A common practice has been to advise patients to discontinue aspirin therapy for 7 to 10 days before oral surgery.[28] At low-dose therapeutic levels (<100 mg/day), aspirin may increase bleeding time and complicate surgical procedures. However, Ardekian and colleagues[28] concluded that low-dose aspirin therapy should *not* be discontinued before surgical procedures and that bleeding could be controlled by local measures. Higher-dose therapy may create a greater risk of bleeding during or after surgery.

Although a patient undergoing aspirin therapy may not be at high risk for significant bleeding during or after surgery, a concern in periradicular surgery is the visibility problems created by oozing blood. The clinician should consult the patient's physician about the medical reason for aspirin therapy and should weigh the risks and benefits of discontinuing aspirin before the proposed surgery. It should be possible to perform periradicular surgery without discontinuing aspirin therapy if necessary, but visibility during the procedure may be compromised, which may adversely affect the prognosis.

Herbs, dietary supplements, and vitamins can contribute to bleeding problems during surgery, and patients often fail to report use of these substances in the preoperative evaluation.[385] In a survey of surgical patients, approximately one third reported using a nonprescription medication that might inhibit coagulation or interact with anesthetics.[384] In particular, ginkgo

Telegram: @dental_k

www.konkur.in

biloba, ginger, garlic, ginseng, feverfew, and vitamin E inhibit platelet aggregation and can increase the risk of bleeding.[96] Ingredients in over-the-counter (OTC) weight loss products can potentiate the effect of epinephrine and increase cardiac stress, although the most obvious example of this phenomenon, ephedra, has been removed from the US market by a Food and Drug Administration (FDA) order.

Patients with inherited or acquired bleeding disorders are also at risk for excessive bleeding during and after periradicular surgery. Impaired liver function associated with past or current alcohol or drug abuse may also predispose a patient to excessive bleeding during surgery. A thorough medical history and patient interview should help identify these patients and, in consultation with the patient's physician, allow for any necessary treatment modifications.

Many other medical conditions, such as recent myocardial infarction, stroke, cardiac arrhythmias, diabetes, radiation therapy for head and neck cancer, immunocompromising conditions, seizure disorders, adrenal suppression, liver or kidney disease, and pregnancy may require modification of the treatment plan. However, these conditions usually present more general problems that are not unique to a surgical procedure. The value of a thorough medical history and patient interview cannot be overemphasized.

Anatomic considerations

Evaluating the access to the surgical site is one of the most important steps in case selection for periradicular surgery. Anatomic studies can provide some guidance, but individual variation is great, and there is no substitute for a complete clinical examination. A small oral opening, active facial muscles, shallow vestibule, and thick buccal alveolar bone all can significantly increase the difficulty of the procedure, even in cases that appear straightforward on radiographic examination.

Posterior mandible

The primary anatomic structure of concern for periradicular surgery in the posterior mandible is the neurovascular bundle that courses through the mandibular canal and exits through the mental foramen. The relationship

Telegram: @dental_k

www.konkur.in

among the mandibular canal, the mental foramen, and the root apices of mandibular teeth has been well studied; however, anthropometric averages have limited value in the treatment of individual patients. An understanding of the typical anatomic relationships is important, but even more important is an evaluation of the individual patient to develop a case-specific risk assessment.

The depth of the vestibular fornix generally is a good predictor of the possible difficulty involved in obtaining surgical access to the mandibular posterior teeth.[305] A shallow vestibule usually portends thicker alveolar bone and more difficult access to the root end.

The mental foramen, another key anatomic structure, is usually located between and apical to the mandibular first and second premolars[118,356]; however, this varies considerably, and the practitioner must examine each patient carefully to determine its location (Figs. 11.5 and 11.6). Vertical location of the mental foramen may vary even more than horizontal location. Moiseiwitsch[356] found that the average location was 16 mm inferior to the cementoenamel junction (CEJ) of the second premolar, although the range was 8 to 21 mm, which would place approximately 20% of the foramina at or coronal to the root apex. Fortunately, the mental foramen usually is easily visualized with standard periapical and panoramic radiographs. A vertically positioned periapical radiograph often may be more useful than a horizontally positioned one, especially in individuals with longer roots. Also, the mental foramen can usually be palpated.

Telegram: @dental_k

www.konkur.in

foramen *(white arrow),* which was not visible on a standard periapical radiograph.

Radiograph of lateral view of jaw shows a white arrow pointing at a dark spot present in the mandibular region.

When a vertical releasing incision is indicated, it typically is made at the mesial line angle of the mandibular canine. This location is always mesial to the mental foramen, because the foramen is located in the area ranging from the apex of the mandibular first premolar to slightly distal to the second premolar. The nerve bundle exits from the foramen in a distal direction. An alternative technique for gaining access to mandibular posterior teeth involves a distal releasing incision between the mandibular first and second molars.[355] This approach may be especially useful for access to the mandibular second premolar and first molar. Care must be taken to avoid the facial artery as it crosses the level of the inferior vestibular fornix near the mandibular first molar. Inadvertent contact with the facial artery is unlikely if the incision is not extended beyond the depth of the vestibule.

Regardless of the approach selected, it is obviously important to avoid making an incision in the immediate vicinity of the mental foramen. The mental nerve is encased in a relatively tough sheath, and permanent damage can be avoided if careful blunt dissection is used in the area. A misguided vertical releasing incision, however, may sever the nerve, causing permanent injury. Trauma to the nerve from blunt dissection in this area or from pressure from a misplaced retractor may cause temporary paresthesia but is much less likely to do permanent injury. (Documentation and management of nerve injuries are discussed later in the chapter.)

The borders of the mandibular canal often are more difficult to visualize with conventional radiographic techniques. A parallel periapical radiograph, either horizontally or vertically positioned, usually can provide a reasonably accurate image of the relationship between the superior border of the mandibular canal and the root apices. However, the mandibular canal sometimes cannot be readily visualized. Such cases should be approached with extreme caution, because an increased risk of paresthesia secondary to nerve injury may be an unacceptable risk for many patients. CBCT imaging can be very useful for identifying the location of the mandibular canal and determining its relationship to the root apices (see Chapter 2).[68,285,556]

Telegram: @dental_k

www.konkur.in

In the buccolingual dimension, the mandibular canal commonly follows a curving pathway from the buccal half of the mandible near the distal root of the second molar to the lingual half of the mandible near the first molar, then curving back to the buccal near the second premolar as it exits the mental foramen.[136] The average vertical distance from the superior border of the mandibular canal to the distal root apex of the mandibular second molar is approximately 3.5 mm; this increases gradually to approximately 6.2 mm for the mesial root of the mandibular first molar and to 4.7 mm for the second premolar.[136,312] This relationship typically provides a greater margin of safety for surgery on the mandibular first molar compared with the second premolar and especially the second molar. Surgery on the mandibular second molar may be further complicated by relatively thick overlying buccal bone, lingual inclination of the roots, and a more buccal location of the mandibular canal. This is not to say that periradicular surgery should not be performed on mandibular second molars; rather, it points out that the relative risks and benefits must be carefully considered. Often the most prudent choice for a mandibular second molar is an intentional replantation procedure or extraction and placement of an implant.

Posterior maxilla

The primary anatomic structure of concern in the posterior maxilla is the maxillary sinus. CBCT allows for a more precise preoperative three-dimensional evaluation of the relationship between the roots of maxillary posterior teeth and the sinus.[69,79] Perforation of the sinus during surgery is fairly common, with a reported incidence of about 10% to 50% of cases.[157,177,456] Even without periradicular pathosis, the distance between the root apices of the maxillary posterior teeth and the maxillary sinus sometimes is less than 1 mm.[225] An inflammatory periradicular lesion often increases the likelihood of sinus exposure during surgery. Fortunately, perforation of the maxillary sinus rarely results in long-term postoperative problems.[225] In a report of 146 cases of sinus exposure during periradicular surgery, Watzek and colleagues[579] found no difference in healing compared with similar surgical procedures without sinus exposure. The sinus membrane usually regenerates, and a thin layer of new bone often forms over the root end, although osseous regeneration is less predictable.[50,157,579] The general rule of

Telegram: @dental_k

www.konkur.in

placing a vertical releasing incision at least one tooth mesial and distal to the surgical site is especially important when sinus perforation is possible, because the exposure site should be completely covered with the mucoperiosteal flap to provide primary closure.

If the maxillary sinus is entered during surgery, special care must be taken to prevent infected root fragments and debris from entering the sinus. The most commonly used root resection technique involves grinding the root apex with a high-speed drill for approximately 3 mm in an apical to coronal direction; therefore an opening could allow infected debris into the sinus. A sinus opening can be temporarily occluded with a material such as Telfa gauze, although the gauze should be secured so as to prevent inadvertent displacement into the sinus. A suture can be placed through the packing material to prevent displacement and aid retrieval. Jerome and Hill[259] suggested securing the apical root segment by drilling a small hole in the root tip and threading a piece of suture material through the hole. The root is then resected at the appropriate level, and the root-end fragment is removed in one piece. If a root fragment or other foreign object is displaced into the sinus, it should be removed. An orascope or endoscope may be useful for visualizing the foreign object, but referral for evaluation and surgical removal may be indicated if the fragment cannot be located and removed.

The palatal roots of maxillary molars present a special challenge for surgical access. Palatal roots may be reached from either a buccal (transantral) or palatal approach. Wallace[572] described a transantral approach in which a buccal flap is reflected, the buccal roots are resected, the osteotomy access into the sinus is enlarged to approximately 1 by 1.5 cm, and the palatal root tip is resected, ultrasonically prepared, and filled. The sinus may be packed with moist gauze to catch debris, and it should be irrigated with sterile saline upon completion of the surgery. In some cases, careful reflection and retraction of the sinus membrane may be possible, allowing access to the palatal root end without direct invasion of the sinus.[16] Many who have tried this approach find it more challenging than it might initially seem. The enhanced illumination and magnification provided by a dental operating microscope, endoscope, or orascope are essential aids in this type of surgery.[40]

A palatal approach to the palatal root of maxillary molars may seem more

Telegram: @dental_k

www.konkur.in

direct than a transantral approach, but it can present certain difficulties. Visibility in the surgical field is reduced and manipulation of instruments is more difficult than with most routine buccal approaches. Patients with a deep, vertical palatal vault are better candidates for this approach than individuals with a wide, shallow palate. A sinus tract or a large lesion on the palatal root may allow easier access and better visualization of the palatal root because only limited bone removal would be required. The position of the anterior palatine artery must be carefully considered when the incision is made and the flap reflected. This artery emerges from the greater palatine foramen distal to the maxillary second molar at the junction of the vertical section of the alveolar process and the flat portion of the palate and continues anteriorly (Fig. 11.7). A vertical releasing incision can be placed between the maxillary first premolar and canine, where the artery is relatively narrow and branches off into smaller arteries. If needed, a short distal vertical releasing incision may be made distal to the second molar, but it should not approach the junction of the alveolar process and roof of the palate. If the anterior palatine artery is severed, local clamping and pressure may not stop the hemorrhage, and ligation of the external carotid artery may be necessary. Because of the palatal vault's concave shape, repositioning the flap may be challenging. An acrylic surgical stent may be fabricated before surgery to assist repositioning of the flap and to help prevent pooling of blood under the flap.

foramen *(arrows)*. The approximate location of the anterior palatine artery is marked in *red*.

Close-view of palatal view shows red arc marked in between depicting anterior palatine artery, with two opposite arrows pointing at two holes at the bottom of arc representing greater palatine foramen.

Anterior maxilla and mandible

Periradicular surgery on anterior teeth generally involves fewer anatomic hazards and potential complications than in posterior teeth. Nonetheless, access to the root apex in some patients may be unexpectedly difficult because of long roots, a shallow vestibule, or lingual inclination of the roots. As shown in Fig. 11.5, the root apices of maxillary central and lateral incisors can be quite close to the floor of the nose and the bony anterior nasal spine. Fig. 11.8 demonstrates isolation and protection of the nasopalatine neurovascular bundle during maxillary anterior surgery. The average maxillary canine is about 26 mm long and usually presents no difficulty for surgical access; however, the combination of a shallow vestibule and a longer than average root length could complicate access to the root apex area. In such cases, the creation of an osteotomy apical to the root end may be impossible. An alternative approach for long-rooted teeth and root tips in the vicinity of critical anatomic structures is to enter the bone and resect the root at a level approximately 3 mm coronal to the apex. After the root tip is removed, the area apical to the root can be inspected and curetted as needed.

Source: (Courtesy Dr. Tim Rogers.)

Periradicular surgery on mandibular incisors often is more challenging than expected. The combination of lingual root inclination, a shallow vestibule, and a prominent mental protuberance all can increase the degree of difficulty, as can proximity to adjacent roots and the need for perpendicular root-end resection and preparation to include a possible missed lingual canal.

Cone-beam computed tomography

Radiographic examination is an essential component in all aspects of endodontic treatment from diagnosis and treatment planning to assessing outcome (see also Chapter 2). Information gained from conventional films and digital periapical radiographs is limited by the fact that the three-dimensional anatomy of the area is compressed into a two-dimensional image. As a result of superimposition, periapical radiographs reveal limited aspects of the three-dimensional anatomy. In addition, there may also be geometric distortion of the anatomic structures imaged. These problems may be overcome using small volume CBCT imaging techniques, which can produce three-dimensional images of individual teeth and the surrounding tissues. CBCT may be particularly useful in diagnosis and treatment planning for periradicular surgery (Fig. 11.9).[112,163,249,318] The term *cone-beam computed tomography* is often used interchangeably with *cone-beam volumetric tomography* (CBVT).

CBCT confirmed root fracture and the treatment plan was changed to extraction with possible bone graft and guided tissue regeneration for ridge augmentation prior to implant placement. **B,** Axial CBCT view demonstrating extent of lesion. **C,** Coronal CBCT view demonstrating root fracture *(red arrow)* and perforation of buccal cortical plate in area of root fracture but intact bone in the cervical area.

Set of three radiographs depict fracture in the root of a tooth obtained using different techniques.

Differences between computed tomography and cone-beam computed tomography imaging

The benefits of three-dimensional medical computed tomography (CT) imaging are already well established in certain dental specialties. Current CT scanners have a linear array of multiple detectors, allowing multiple slices to be taken simultaneously, resulting in faster scan times and often less radiation exposure to the patient.[507] The slices of data are then “stacked” and can be reformatted to obtain three-dimensional images. The high-radiation dose, cost, availability, poor resolution, and difficulty in interpretation have resulted in limited use of CT imaging in endodontics. These issues may be addressed by cone-beam innovations in CBCT technology.

Telegram: @dental_k

www.konkur.in

In 2000, the FDA approved the first CBCT unit for dental use in the United States. Cone-beam technology uses a cone-shaped beam of radiation to acquire a volume in a single 360-degree rotation, similar to panoramic radiography. The volume of acquired images by a CBCT is composed of voxels. Essentially, a voxel is a 3D pixel. Because the data are captured in a volume as opposed to slices, all the voxels are isotropic, which enables objects within the volume to be accurately measured in different directions. Unlike the CBCT voxel, a medical CT voxel is not a perfect cube, and measurements made in multiple planes are not accurate. In addition to increased accuracy and higher resolution, CBCT offers significant scan-time reduction, radiation dose reduction, and reduced cost for the patient.[472,595,606] CBCT systems can be classified into two categories: limited (dental or regional) CBCT or full (ortho or facial) CBCT. The field of view (FOV) of limited CBCT ranges in diameter from 40 to 100 mm, whereas the FOV of full CBCT ranges from 100 to 200 mm.[112] Another difference between the limited CBCT and full CBCT is that a voxel is generally smaller for the limited version (0.1 to 0.2 mm vs. 0.3 to 0.4 mm). Thus limited CBCT systems offer higher resolution and are better suited for endodontic applications. Limited volume CBCT scanners capture small volumes of data that can include just two or three individual teeth. The most important and clinically useful feature of CBCT technology is the highly sophisticated software that allows the huge volume of data collected to be reconstructed. Tomographic slices, as thin as one voxel, may be displayed in a number of ways. One option, for example, is for the images to be displayed in the three orthogonal planes—axial, sagittal and coronal—simultaneously. The axial and proximal (sagittal in the anterior, coronal in the posterior) views are of particular value because they are generally not seen with conventional periapical radiography. The ability to reduce or eliminate superimposition of the surrounding structures makes CBCT superior to conventional periapical radiography.[314]

Scan times are typically 10 to 40 seconds, although the actual exposure time is significantly less (2 to 5 seconds) as scans involve a number (up to 360) of separate, small, individual exposures rather than one continuous exposure. With medical CT scanners, the scanning and exposure times for the skull can be significantly longer. Most CBCT scanners are much smaller than

Telegram: @dental_k

www.konkur.in

medical CT scanners, taking up about the same space as a dental panoramic machine. They are also significantly less expensive than medical CT scanners. With the help of viewer software, the clinician is able to scroll through the entire volume and simultaneously view axial, coronal, and sagittal 2D sections that range from 0.125 to 2 mm thick. Comparing the radiation dose of different CBCT scanners with medical CT scanners may be confusing because different units of radiation dose are often used. There are three basic measurement units in radiation dosimetry: the radiation absorbed dose (D), the equivalent dose (H), and the effective dose (E). The *radiation absorbed dose* is defined as the measure of the amount of energy absorbed from the radiation beam per unit mass of tissue and is measured in joules per kilogram. The *equivalent dose* is defined as a measure that indicates the radiobiologic effectiveness of different types of radiation and thus provides a common unit. The *effective dose* is calculated by multiplying the equivalent dose by different tissue weighting factors, which converts all doses to an equivalent whole-body dose and allows doses from different investigations of different parts of the body to be compared. The unit remains as the Sievert (Sv) and can be used to estimate the damage from radiation to an exposed population. The reported effective doses from CBCT scanners vary, but it can be almost as low as those from panoramic dental x-ray units and can be considerably less than that from medical CT scanners.[398] The higher effective doses from particular models of CBCT scanners is in part due to the larger size of the FOV used as well as the type of image receptor employed. The small volume scanners capture information from a small region of the jaw, approximately the same area as a periapical radiograph. The effective dose has been reported to be in the same range as two to three standard periapical radiograph exposures, whereas the effective dose for a full mouth series of periapical radiographs has been reported to be similar to the effective dose of a large volume CBCT scan.[124,194] If multiple teeth in different quadrants require endodontic evaluation or treatment, a large volume CBCT scan with a large FOV may be more appropriate. If endodontic information is required from multiple teeth in one jaw, a large volume CBCT scan with the FOV only limited to the jaw of interest could be the investigation of choice. This has the advantage of reducing the effective dosage from the full large volume CBCT scan by up to 65%.[321]

Potential applications of cone-beam computed tomography in the management of endodontic posttreatment disease

Clinical radiographic examinations are usually limited to two-dimensional views captured using radiographic film or digital sensors. Crucial information related to the true three-dimensional anatomy of teeth and adjacent structures is obscured. Even with paralleling techniques, distortion and superimposition of dental structures in periapical views is unavoidable. A major reported advantage of CBCT is the accuracy of measurements in all dimensions.[331] The ability to view thin sagittal, coronal, and axial slices effectively eliminates the problem of superimposition of anatomic structures. For example, roots of maxillary posterior teeth and surrounding tissues can be viewed without superimposition of the zygomatic buttress, alveolar bone, maxillary sinus, and other roots (Fig. 11.10). CBCT enables clinicians to detect changes in apical bone density at an earlier stage when compared to conventional periapical radiographs and therefore has the potential to detect previously undiagnosed periradicular pathoses.[163,314,371] CBCT may also prove to be a useful tool for noninvasive differentiation of periapical cysts and granulomas,[489] a previously unattainable goal using conventional radiographic imaging.

www.konkur.in

surgery). **E,** Clinical image after surgical access removal of granulation tissue, and root-end resection (note sinus perforation [*arrow*]). **F,** Placement of bone graft and Capset. **G,** Immediate postoperative radiograph. **H,** Two-year follow-up radiograph demonstrating good healing.

Set of eight figures marked A through H depicts evaluation films and results of surgical treatment of periapical defect associated with tooth number 4 to 6.

Three-dimensional imaging allows for clear identification of the anatomic relationship of the root apices to important neighboring anatomic structures such as the mandibular canal, mental foramen, and maxillary sinus (Fig. 11.11). Velvart and colleagues reported that the relationship of the inferior alveolar canal to the root apices could be determined in every case when utilizing medical CT, but in less than 40% of cases when using conventional radiography.[556] It is likely that similar results could be achieved with CBCT using considerably less radiation. Rigolone and coworkers concluded that CBCT may play an important role in periapical microsurgery of palatal roots of maxillary first molars.[442] The distance between the cortical plate and the palatal root apex could be measured using CBCT and the presence of the maxillary sinus between the roots could be assessed. Additional information such as the thickness of the cortical plate, cancellous bone pattern, fenestrations, and inclination of the roots can be obtained prior to surgical entry.[371] Root morphology (shape, size, curvature, and number of canals) can be visualized in three dimensions. Unidentified (and untreated) canals in root-filled teeth can be routinely visualized in axial slices. CBCT has been used to determine the location and extent of invasive external root resorptive defects.[398]

Telegram: @dental_k

www.konkur.in

FIG. 11.11 **A,** Periapical radiograph demonstrating persistent periradicular pathosis following nonsurgical retreatment of tooth #19. The extension of the lesion in the vicinity of the mandibular canal and possible involvement of tooth #20 was uncertain based on interpretation of periapical and panoramic radiographs. Tooth #20 responded WNL to pulp vitality test. **B,** Coronal CBCT demonstrates that the periradicular lesion does not extend apical or lingual to the mandibular canal. **C,** Axial CBCT view demonstrating perforation of the buccal cortical plate and extension into, but not through, the furcation of #19 and presence of intact bone around #20.

Set of three radiographs marked A through C conducted to rule out extension of lesion from tooth 19 in the vicinity of mandibular canal to the adjacent tooth.

One of the most useful potential applications of CBCT may be the assessment of endodontic treatment outcomes, both nonsurgical and surgical. When compared to two-dimensional film and digital images, CBCT is dimensionally precise and can detect smaller changes in bone density.[331]

It is worth remembering that CBCT still uses ionizing radiation and is not without risk. It is essential that patient exposure is kept as low as reasonably practical and that justifiable selection criteria for CBCT use are developed. CBCT may be indicated when it is determined that the additional information obtained is likely to result in a more accurate diagnosis and enhanced patient safety.

Patient preparation for surgery

Informed-consent issues specific to surgery

The general principles of informed consent discussed in Chapter 27 form the basis for informed consent for periradicular surgery. The patient must be thoroughly advised of the benefits, risks, and other treatment options and must be given an opportunity to ask questions. The main consent issues specific to surgical procedures are closely related to the anatomic considerations discussed in the previous section. That is, major neurovascular bundles may be traumatized, and a sinus exposure may occur. Paresthesia after mandibular posterior surgery is uncommon but should be discussed with the patient because this potential complication is a risk that some patients may be unwilling to assume. Postoperative swelling, bruising, bleeding, and infections are possible complications that typically are self-limiting or readily manageable. Although the incidence of serious complications related to surgical procedures is very low, patients should be advised of any risks unique to their situation. Prompt attention to any surgical complications and thorough follow-up are essential from a medical-legal standpoint.

Premedication: Nonsteroidal antiinflammatory drugs, antibiotics, chlorhexidine, and conscious sedation

Administration of an NSAID, either before or up to 30 minutes after surgery, enhances postoperative analgesia.[494] NSAIDs generally have proved more effective in the management of postoperative oral surgery pain than placebo or acetaminophen and codeine combinations.[9,41,143] The combination of preoperative administration of an NSAID and use of a long-acting local anesthetic may be particularly helpful for reducing postoperative pain.[144] Many types of NSAIDs are available, but ibuprofen remains the usual standard for comparison. Ibuprofen (400 mg) provides analgesia approximately equal to that obtained with morphine (10 mg) and significantly greater than that from codeine (60 mg), tramadol (100 mg), or acetaminophen (1000 mg).[346] The analgesic effectiveness of ibuprofen tends to level off at about the 400-mg level *(ceiling effect)*, although a slight increase in analgesic potential may be expected in doses up to 800 mg.

Telegram: @dental_k

www.konkur.in

The value of antibiotic prophylaxis before or after oral surgery is controversial, and the current best available evidence does not support the routine use of prophylactic antibiotics for periradicular surgery.[11] For most patients, the risks of indiscriminate antibiotic therapy are believed to be greater than the potential benefits.[526] The incidence of infection after oral surgery in healthy patients is very low. Peterson reported that only 1% of patients developed infections after third molar extractions.[355] A systematic review of the use of antibiotics to prevent complications after placement of dental implants found that evidence was lacking either to recommend or discourage the use of antibiotics for this purpose.[162] However, the use of prophylactic antibiotics for more invasive procedures, such as orthognathic surgery, has significantly reduced the risk of postoperative infection and complications.[146] Although routine use of prophylactic antibiotics for periradicular surgery is not currently recommended, clinical judgment is important in determining exceptions to the general rule. For example, immunocompromised patients may be good candidates for prophylactic antibiotic coverage. Certain categories of medically complex patients also may benefit from antibiotic coverage. Diabetic patients have shown impaired healing capacity after nonsurgical root canal treatment,[78,175] and a like pattern of delayed or impaired healing may emerge in studies of surgical outcomes. The global problems associated with overprescription of antibiotics are significant and should prompt due caution in the decision on whether to use these drugs prophylactically.

Chlorhexidine gluconate (0.12%) often is recommended as a mouth rinse to reduce the number of surface microorganisms in the surgical field, and its use may be continued during the postoperative healing stage.[7,281,545] Although no solid evidence supports this practice in periradicular surgery, the use of chlorhexidine follows from the general surgical principle of surface disinfection before incision and opening into a body cavity. In addition, chlorhexidine has proved to be a safe, effective adjunct in the treatment of periodontitis, and short-term use (i.e., several days) poses little or no risk. Chlorhexidine may be useful for reducing the risk of postoperative infection after oral surgery,[67,598] although the evidence in this area is conflicting. Postoperative use of chlorhexidine mouth rinse can reduce bacterial growth on sutures and wound margins,[389] but it may interfere with fibroblast

Telegram: @dental_k

www.konkur.in

reattachment to the root surface.[14] A useful empirical regimen is to have the patient rinse for 30 seconds twice a day beginning 1 or 2 days before surgery and continuing until the sutures are removed.

Conscious sedation, either by an orally administered sedative or by nitrous oxide/oxygen inhalation analgesia, may be useful for patients who are anxious about the surgical procedure or dental treatment in general. Benzodiazepines with a short half-life are particularly useful because they generally have a wide margin of safety, good absorption after oral administration, and limited residual sedative effects. When these drugs are used in sedative-hypnotic doses, the blood pressure, pulse, and respiration must be monitored, and states differ in their requirement for additional training or certification of staff members who do this monitoring. With oral conscious sedation, pulse oximetry should be used to monitor the pulse and blood oxygen saturation during the surgery.[84] As with all orally administered drugs, the dosage cannot be closely titrated; therefore the effect of the agent varies somewhat. A typical protocol is a single dose at bedtime the evening before the procedure and a second dose 1 hour before the start of surgery. The patient should not drive to or from the office and should have a responsible adult for assistance as needed. In appropriate doses, benzodiazepines and similar drugs may allow for a more relaxed patient and thus a less stressful surgical experience for both patient and surgeon.

Instruments and operatory setup

The development of microsurgical techniques and new materials has changed the typical surgical instrument tray dramatically. Instruments have been designed to take full advantage of the increased visibility obtained with dental operating microscopes, endoscopes, and orascopes. Better visualization of the surgical site would have limited value without microsurgical instruments, such as ultrasonic tips for root-end preparation and micromirrors for inspecting the root end. Fig. 11.12 shows a typical basic surgery tray arrangement. This setup is not a definitive guide to surgical armamentarium but rather an adequate, efficient starting point for most periradicular surgical procedures. Although the number of instruments can easily be doubled or even tripled, the ease of locating a specific instrument is

Telegram: @dental_k

www.konkur.in

inversely proportional to the number of instruments on a tray. Specialized instruments can be kept readily available in separate sterilized bags or trays and opened as needed. A skilled surgeon can use a wide variety of instruments (Figs. 11.12–11.24) to achieve excellent results.

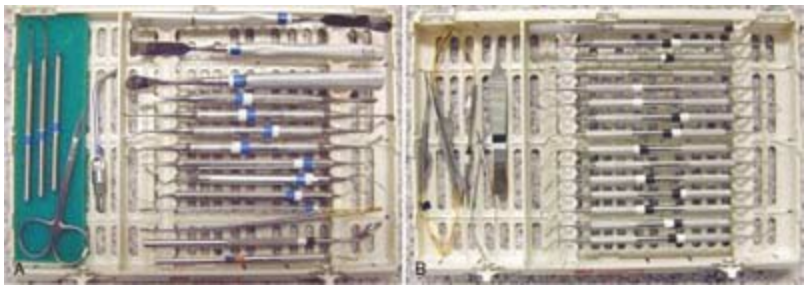

FIG. 11.12 **A,** Basic tray setup for initial surgical access. Surgical instruments shown are distributed by Hu-Friedy ([HF] Chicago), CK Dental Specialities ([CKDS] Orange, CA), EIE ([EIE]), and G. Hartzell & Son ([GHS]). *Left to right* (left section of tray): Small round micromirror (CKDS); medium oval micromirror (CKDS); handle for microscalpel (CKDS); scissors (S18 [HF]); surgical suction tip (GHS). *Top to bottom* (main section of tray): Carr #1 retractor (EIE); Carr #2 retractor (EIE); TRH-1 retractor (HF); periosteal elevator (HF); Ruddle R elevator (EIE); Ruddle L elevator (EIE); Jacquette curette (SJ 34/35 [HF]); spoon curette (CL 84 [HF]); scaler (7/8 [HF]); surgical forceps (TP 5061 [HF]); mouth mirror (HF); periodontal probe (HF). **B,** Instrument tray for root-end filling and suturing. *Left to right* (left section of tray): Two Castroviejo needle holders (Roydent Dental Products, Rochester Hills, MI); Castroviejo scissors (S31 [HF]); micro–tissue forceps (TP 5042 [HF]). *Top to bottom* (main section of tray): Cement spatula (HF); Feinstein super plugger (F1L); microexplorer (CX-1 [EIE]); endoexplorer (DG-16 [EIE]); right Super-EBA Placing & Plugging instrument (MRFR [HF]); left Super-EBA Placing & Plugging instrument (MRFL [HF]); small anterior microburnisher and plugger (HF); small left microburnisher and plugger (HF); small right microburnisher and plugger (HF); medium anterior microburnisher and plugger (HF); medium left microburnisher and plugger (HF); medium right microburnisher and plugger (HF); large anterior microburnisher and plugger (HF); large left microburnisher and plugger (HF); large right microburnisher and plugger (HF).

Periradicular surgery can be performed without the benefit of enhanced magnification and illumination; however, those who use microscopes, endoscopes, and orascopes report dramatically improved visualization and control of the surgical site.[39,92,280,350] Studies reporting the highest surgical success rates and those cited previously in this chapter all involved some form of enhanced magnification and illumination as part of the standard operating protocol. A systematic review and meta-analysis found that the outcome for endodontic surgery performed with high magnification and illumination (microscope or endoscope) was significantly higher than surgery performed with loupes only or no magnification.[482]

Local anesthesia for surgery

Local anesthesia for surgical root canal procedures differs from that for nonsurgical root canal treatment, primarily in the need for localized hemostasis in addition to profound local anesthesia. In fact, use of a local anesthetic with a vasoconstrictor may be the single most important local

Telegram: @dental_k

www.konkur.in

measure to help control hemorrhage and provide a clear surgical field. Otherwise, the same regional block and local infiltration techniques used for nonsurgical treatment are used for surgical root canal procedures. Infiltration of the surgical site with a local anesthetic containing 1:50,000 epinephrine is the technique of choice to obtain vasoconstriction and hemostasis.[280] The local anesthetic is first slowly deposited in the buccal root apex area of the alveolar mucosa at the surgical site and extended two or three teeth on either side of the site. Usually palatal or lingual infiltration is also required, although this requires a much smaller amount of local anesthetic than the primary buccal infiltration. After the injections for anesthesia, the surgeon should wait at least 10 minutes before making the first incision.

Long-acting local anesthetics (e.g., 0.5% bupivacaine with 1:200,000 epinephrine) have been shown to reduce postoperative pain and analgesic use after surgical removal of impacted third molars.[125,204] However, use of a local anesthetic with 1:200,000 epinephrine may result in greater blood loss during surgery.[234,493] To maximize postoperative analgesia and minimize intraoperative bleeding, a local anesthetic can be used with higher epinephrine concentrations (1:100,000 or 1:50,000) for the primary surgical anesthesia and supplemented with one cartridge of long-acting local anesthetic immediately after surgery. Long-lasting local anesthetics are particularly beneficial in mandibular surgery but much less so for surgery in the maxillary arch.

Every effort must be made to ensure profound local anesthesia before surgery begins. Usually a minimum of 10 to 20 minutes is required from the time of injection to the start of surgery to ensure both profound local anesthesia and adequate vasoconstriction for hemostasis. The patient should be asked about the usual signs of soft-tissue anesthesia, and a sharp explorer can be used to test the surgical area for sensation. Even when the surgeon pays careful attention to local anesthetic technique, a patient sometimes has inadequate anesthesia or loss of anesthesia during the surgical procedure. Providing supplemental infiltration anesthesia is difficult after a full-thickness flap has been reflected. A supplemental block injection may be useful for mandibular teeth and maxillary posterior teeth. In the maxillary anterior area, a palatal approach to the anterior middle superior nerve may be helpful. The key to this approach is slow injection of approximately 1 mL of

Telegram: @dental_k

www.konkur.in

local anesthetic in the area of the first and second maxillary premolars midway between the gingival crest and the palatal midline. An intraosseous injection also may be used to regain lost anesthesia, but even when it is effective, the area of local anesthesia often is smaller than desired for a surgical procedure. As a last resort, the procedure can be terminated short of completion and the patient can be rescheduled for surgery under sedation or general anesthesia.

Surgical access

The goals of periradicular surgery are to access the affected area, remove the diseased tissue, evaluate the root circumference and root canal system, and place a biocompatible seal in the form of a root-end filling that can stimulate regeneration of the periodontium. The formation of new cementum on the surgically exposed root surface and on the root-end filling material is essential to regeneration of the periodontium.

Successful endodontic surgery requires the surgeon to use several conceptual elements in planning the procedure. A vision of the immediate postoperative surgical end point (i.e., replacement of the reflected tissues) is essential for designing each phase of the surgery. Visualization of a three-dimensional image of the surgical procedure allows the surgeon to anticipate and prepare for unusual circumstances. In surgical root canal treatment, once a procedure is started, it must be completed uninterrupted within a limited time; this is a paramount difference between nonsurgical and surgical root canal treatment. For this reason, it is absolutely essential that the surgeon plan the procedure thoroughly and include alternative plans of action that anticipate unusual findings during the process of discovery.

Several general principles are important for designing the access to a diseased region: (1) the surgeon must have a thorough knowledge of the anatomic structures in relation to each other, including tooth anatomy; (2) the surgeon must be able to visualize the three-dimensional nature of the structures in the soft and hard tissue (this reduces unnecessary tissue damage); (3) the trauma of the surgical procedure itself must be minimized, which includes the preservation of the tooth and supporting structures; and (4) the tissue and instruments must be manipulated within a limited space with the aim of removing diseased tissues and retaining healthy tissues.

Telegram: @dental_k

www.konkur.in

Soft-tissue access

In designing the soft-tissue access window to the diseased tissue, the surgeon must take into consideration various anatomic features, such as frenum-muscle attachments, the width of attached gingiva, papillary height and width, bone eminence, and crown margins. The supraperiosteal blood vessels of the attached gingiva extend from the alveolar mucosa and run parallel to the long axis of the teeth, lying in the reticular layer superficial to the periosteum.[172] A vertical, rather than an angled, releasing incision severs fewer vessels,[325] reducing the possibility of hemorrhage. Also, the blood supply to the tissue coronal to the incision is not compromised,[477] which prevents localized ischemia and sloughing of these tissues. Ultimately, the result is less bleeding during the procedure and enhanced healing. For these reasons, an angled releasing incision is contraindicated in periradicular surgery.

Vertical incision

The general principles for placement of a vertical relieving incision are as follows:

1. The incision should be made parallel to the supraperiosteal vessels in the attached gingiva and submucosa (Fig. 11.25).
2. No cuts should be made across frenum and muscle attachments.
3. Frenum and muscle attachments should not be located in the reflected tissue, if possible.
4. The incision should be placed directly over healthy bone.
5. The incision should not be placed superior to a bony eminence.
6. The dental papilla should be included or excluded but not dissected.
7. The incision should extend from the depth of the vestibular sulcus to the midpoint between the dental papilla and the horizontal aspect of the buccal gingival sulcus.

Telegram: @dental_k

www.konkur.in

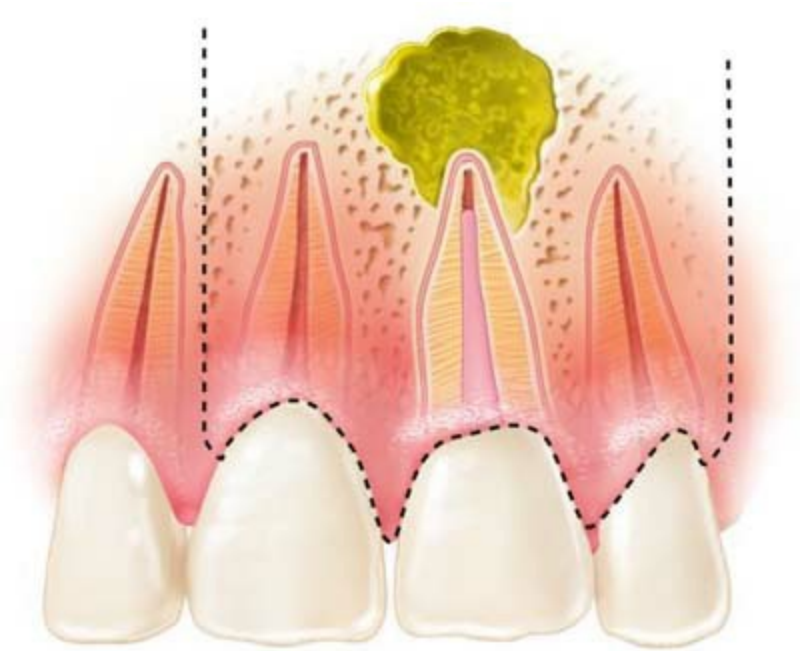

FIG. 11.25 Intrasulcular incision with two vertical releasing incisions (rectangular flap).

An illustration of interior of mouth shows a lesion on the apical foramen of tooth at the center, with a dashed rectangular flap drawn parallel to supraperiosteal vessels covering the junction of the submucosa and the attached gingiva.

Horizontal incision

Three types of horizontal incisions can be used to gain access to a surgical site in hard tissue:

- *An intrasulcular incision that includes the dental papilla.* This incision extends from the gingival sulcus through the PDL fibers and terminates at the crestal bone of the alveolar bone proper. The incision then passes in a buccolingual direction adjacent to each tooth of the dental papilla and includes the midcol region of each dental papilla. Thus the entire dental papilla is completely mobilized.
- *An intrasulcular incision that excludes the dental papilla (papillary-based incision,* Fig. 11.26). This technique consists of a shallow first incision at the base of the papilla and a second incision directed to the crestal bone.

Telegram: @dental_k

www.konkur.in

- *An incision made in the attached gingiva (a submarginal or Ochsenbein-Luebke flap).*[322] With this technique, at least 2 mm of attached gingiva must be retained to prevent mucogingival degeneration.[296] Consequently, the incision must be placed at least 2 mm from the depth of the gingival sulcus. Extensive periodontal probing should be done to establish the depth of the gingival sulcus before the incision is made. The average width of the attached gingiva is 2.1 to 5.1 mm in the maxilla and 1.8 to 3.8 mm in the mandible.[10,199,341,563] It is widest over the central and lateral incisors, narrows over the canine and the first premolar, and then widens over the second premolar and the first molar. These variances were similar for both the maxilla and mandible.[517] Overall, this incision technique has a narrow margin of safety. It generally is recommended for use in the maxilla, especially where the aesthetics of existing crown margins are a concern.

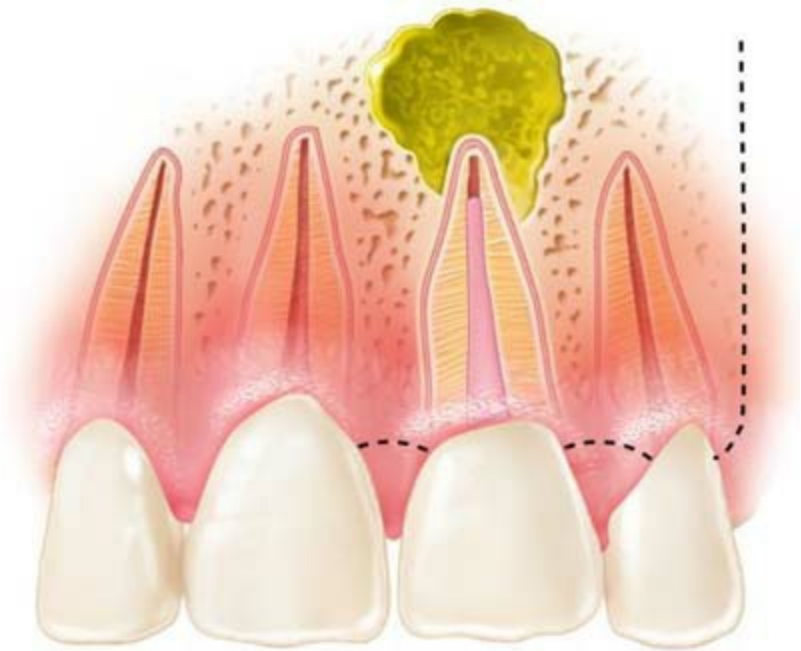

FIG. 11.26 Papillary-based incision with one vertical releasing incision.

An illustration of interior of mouth shows a lesion on the apical foramen of tooth at the center, with first incision at the base of papilla and second incision directed to the crestal bone.

Telegram: @dental_k

www.konkur.in

Studies have compared the incision techniques that include and exclude the dental papilla in patients with healthy marginal periodontal conditions.[554,555,557] These researchers found that the papilla base incision resulted in rapid, recession-free healing. In contrast, complete mobilization of the papilla led to a marked loss of papilla height. The authors suggested that use of the papilla base incision in aesthetically sensitive regions could help prevent papilla recession and surgical cleft, or double papilla.

Flap design

Combinations of vertical and horizontal incisions are used to achieve various flap designs (Figs. 11.27 and 11.28). The full mucoperiosteal and limited mucoperiosteal are the two major categories of flap design used during periradicular surgery, the main differentiating feature being the position of the horizontal incision. In each case the entire body of soft tissue is reflected as one unit and includes the alveolar mucosa, the gingival tissues, and the periosteum. The number and position of the vertical relaxing incisions therefore governs the major variation in design:

1. Full mucoperiosteal (intrasulcular incision including the dental papilla or papillary based) (see Figs. 11.27 and 11.28):
    a. Triangular: one vertical relieving incision
    b. Rectangular: two vertical relieving incisions
    c. Trapezoidal: two angled vertical relieving incisions
    d. Horizontal: no vertical relieving incision
2. Limited mucoperiosteal (Figs. 11.29 and 11.30):
    a. Curve submarginal (semilunar)
    b. Freeform rectilinear submarginal (Ochsenbein-Luebke)

Tissue reflection

Elevation and reflection of the entire mucoperiosteal complex, maintaining the microvasculature in the body of the tissue flap, increases hemostatic control during surgery. Tissue reflection should begin from the vertical releasing incision at the junction of the submucosa and the attached gingiva (Figs. 11.31 and 11.32). By initiating the reflection process at this point, damage to the delicate supracrestal root-attached fibers is avoided. Using a flap reflection technique that reduces reflective tissue forces in the

Telegram: @dental_k

www.konkur.in

intrasulcular incisional wound and avoids curettage of the root surface conserves the root-attached tissues and helps prevent apical down-growth of epithelium and loss of soft-tissue attachment.[222] Force should be applied such that the periosteum and superficial tissues are reflected as a complete unit. Using a gentle rocking motion, the surgeon initially should reflect the tissue in a horizontal direction.[213] The underlying bone of the cortical plate is irregular, and it is critical to avoid damaging the fragile tissues during elevation.

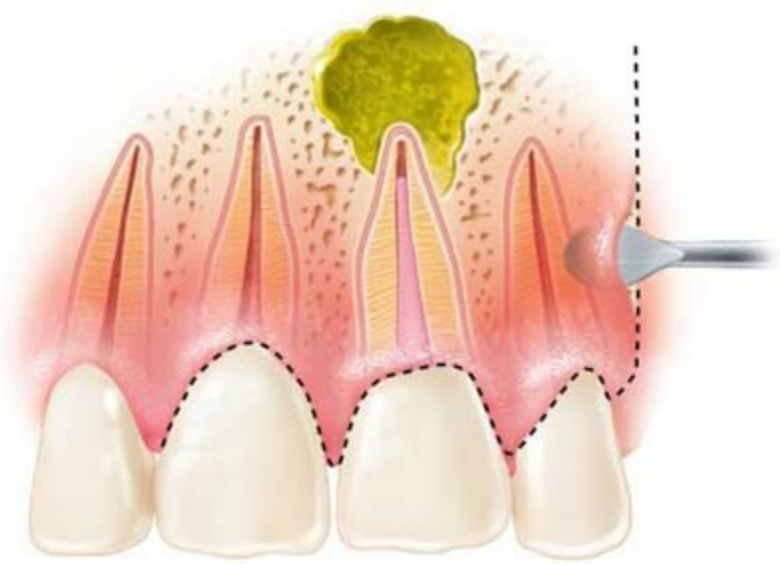

FIG. 11.31 Elevator placed in the vertical incision for the first step in undermining flap reflection.

www.konkur.in

FIG. 11.32 Continuation of reflection of full-thickness flap.

An illustration of maxillary jaw shows a lesion present at the apical foramen of second tooth from the right, with a retractor placed above an elevator placed in the vertical incision.

The operator should take great care not to slip during the tissue reflection process by using an appropriate instrument stabilized with adequate finger support. Slipping can result not only in a puncture of the immediate overlying tissue but also in damage to the surrounding structures.

As space permits, the elevator should be directed coronally, undermining the attached gingiva. As the interdental papilla is approached, a narrower instrument may be required to undermine and gently elevate the tissue in this region, to avoid crushing the delicate free gingival tissues. This process should be continued gradually until the osseous tissues overlying the diseased tooth structure have been adequately exposed. Generally, elevation of the flap 0.75 cm apical to the estimated apex of the root should allow adequate space to perform the surgical procedure.

No single instrument is essential for the flap elevation procedure, because every instrument has both advantages and disadvantages. Surgeons should familiarize themselves with the various instruments available.

Tissue retraction

After the tissue is reflected, it must be retracted to provide adequate access for bone removal and root-end procedures. The main goals of tissue

Telegram: @dental_k

www.konkur.in

retraction are to provide a clear view of the bony surgical site and to prevent further soft-tissue trauma. Accidental crushing of the soft tissues leads to more postoperative swelling and ecchymoses.[222,223]

The general principles of retraction are as follows: (1) retractors should rest on solid cortical bone; (2) firm but light pressure should be used; (3) tearing, puncturing, and crushing of the soft tissue should be avoided; (4) sterile physiologic saline should be used periodically to maintain hydration of the reflected tissue; and (5) the retractor should be large enough to protect the retracted soft tissue during surgical treatment (e.g., prevent it from becoming entangled in the bone bur). No one retractor suffices for all surgical procedures, therefore the surgeon should have a selection of retractors available for the various situations that arise during surgery. If difficulty is encountered in stabilizing the retractor, a small groove can be cut into the cortical plate to support it.

Hard-tissue access

Two biologic principles govern the removal of bone for hard-tissue access to diseased root ends: (1) healthy hard tissue must be preserved, and (2) heat generation during the process must be minimized.

Temperature increases above normal body temperature in osseous tissues are detrimental. Heating osseous tissue to 117° to 122°F (47° to 50°C) for 1 minute significantly reduces bone formation and is associated with irreversible cellular damage and fatty cell infiltration.[161,338] Two critical factors determine the degree of injury: how high the temperature increases and how long it remains elevated. As the temperature rises above 104°F (40°C), blood flow initially increases. It stagnates at 198°F (46°C) applied for 2 minutes. Heating osseous tissue to 133°F (56°C) deactivates alkaline phosphatase.[422,423] Studies using animal bone have shown that at temperatures above 109°F (42.5°C), for every 1°C elevation in temperature, the exposure time for the same biologic effect decreases by a factor of approximately 2.[158-161] Temperatures above 117°F (47°C) maintained for 1 minute produce effects similar to those at 118°F (48°C) applied for 30 seconds. This correlation means that the decisive exposure time declines quickly as the temperature increases. Temperatures above 127°F (53°C) applied for less than 1 second can adversely affect osteogenesis.[158-161]

Telegram: @dental_k

www.konkur.in

Several factors determine the amount of heat generated during bone removal, including the shape and composition of the bur, the rotational speed, the use of coolant, and the pressure applied during cutting.

The round bur has the best shape for removing osseous tissue, and it should be used with a gentle brushstroke action.[519] This type of bur also readily allows access of coolant to the actual cutting surfaces. Studies comparing the heat generated with round and fissure burs found more favorable results with the round burs.[85,111,216,338,360] Cutting with round burs produced a wound site with less inflammation, which is more favorable for rapid wound healing. Although fissure-type burs cut efficiently on the sides, the tip of the bur is very inefficient because it allows no coolant access. The net result is increased inflammation and a reduced healing response.

Use of a diamond bur to remove osseous tissue is inefficient and slows ultimate wound healing. Because of its larger surface area, more of a diamond bur is in contact with the bone tissue. As a result, less coolant reaches the cutting surface, and the bur has a greater tendency to become clogged with residual bone fragments. The net effect is greater heat generation, increased inflammation, and reduced healing.[85,586]

Use of a coolant during bone cutting is essential. If an appropriate irrigant is not used, temperatures can exceed those known to impair bone healing[274]; histologically, healing can be delayed up to 3 weeks.[169] It also is critical that the coolant reach the cutting surface. Temperatures can rise above 212°F (100°C) when excess pressure is applied during cutting; this burrows the bur into the bone, where little or no irrigant can reach the cutting tip,[519] hence the recommendation for a gentle brush-stroke technique.[213] Favorable results are obtained with these provided the surgeon follows the basic tenet of minimizing heat generation: using a round fluted bur with coolant and a brushstroke technique. A high-speed handpiece that exhausts air from the base rather than the cutting end is recommended to reduce the risk of air embolism (Fig. 11.33).

Periradicular curettage and biopsy

Most periradicular lesions originate in the pulp and can be classified histopathologically as granulomas or cysts.[53,58,292,295,297,359,367,382,488] Histologically, such lesions consist mainly of granulation tissue associated with angiogenesis, fibroblasts, connective tissue fibers, and inflammatory cells. Foreign material, cholesterol clefts,[365,370] and stimulated strands of epithelium also may be present. The stimulated epithelium can form into a stratified, squamous epithelium–lined cystic cavity.[366] These periradicular lesions (granulomas and cysts) are inflammatory lesions that develop in response to irritation caused by intraradicular and extraradicular microorganisms associated with the root canal system[363,368] or by foreign materials forced into the periradicular tissues.[600]

An important aspect of periradicular surgery is the removal of diseased tissue associated with the root apex. Because a large portion of this tissue is reactionary, the focus of surgical root canal treatment is removal of the irritant or diseased tissues. Histologically, an inflammatory periradicular lesion is similar to healing granulation tissue. If the irritant can be readily

Telegram: @dental_k

www.konkur.in

identified and successfully eliminated, it is not always necessary to completely curette all the inflamed periradicular tissues during surgery.[306] This is especially true when complete removal might result in injury to neural or vascular tissues. In addition to removing diseased tissue, periradicular curettage provides visibility and accessibility to facilitate treatment of the apical root canal system or the removal of foreign materials in the periradicular tissues.

The need for a histopathologic assessment of all tissues removed from the body cannot be overstated. Although only a small percentage of periradicular lesions are associated with pathoses other than a periradicular cyst or granuloma, all lesions must be diagnosed definitively because of the potential gravity of the few rare diseases associated with periradicular lesions.[12,121,185,383,409]

The technical aspect of removing soft tissue from the bony crypt varies among surgeons and clinical settings. Various bone and periodontal curettes are available for this purpose, and no one instrument suffices for all cases. Regardless of the instrument selected, the basic principles are the same. A sharp instrument is always preferable to a blunt instrument. The soft-tissue lesion first should be peeled away from the osseous crypt, starting at the lateral borders. This can be accomplished efficiently by using the curette with the concave surface facing the internal wall of the osseous crypt. Once the soft-tissue lesion has been separated from the osseous crypt to the point where the crypt changes its convexity, the curette can be used in a scraping manner to remove the remainder of the lesion from the medial wall of the osseous defect.

Localized hemostasis

Localized hemostasis during periradicular surgery is essential to successful management of the resected root end. Appropriate hemostasis during surgery minimizes surgical time, surgical blood loss, and postoperative hemorrhage and swelling.[213] The hemostatic agents used during endodontic surgery are intended to control bleeding from small blood vessels or capillaries. Localized hemorrhage control not only enhances the visibility and assessment of the root structure but also ensures the appropriate environment for

Telegram: @dental_k

www.konkur.in

placement of the current root-end filling materials and minimizes root-end filling contamination.

Many hemostatic agents have been advocated for use during surgery, and the action of these agents, their ability to control bleeding, and their effect on healing vary considerably. They generally aid coagulation by inducing rapid development of an occlusive clot, either by exerting a physical tamponade action or by enhancing the clotting mechanism and vasoconstriction (or both). No one local hemostatic agent is ideal; each has disadvantages. Therefore further investigation is indicated to find the ideal local hemostatic agent.

Preoperative considerations

A thorough review of the patient's body systems and medical history increases the likelihood of detecting an undiagnosed condition that might affect hemostasis during periradicular surgery. Review of the patient's medications, both prescribed and OTC drugs, is essential. Many OTC drugs can affect the clotting mechanism. The patient's vital signs (i.e., blood pressure, heart rate, and respiratory rate) should be assessed. Vital signs also can be used to monitor anxious patients. An increase in blood pressure and heart rate above a patient's known normal values indicates increased stress or poorly controlled hypertension. Easing the patient's anxiety before surgery reduces the possible hemostatic-potentiating effect of elevated cardiac output during surgery.[156] Anxiety and stress can be alleviated with planning, sedation, and profound local anesthesia.

Local hemostatic agents

Collagen-based materials

Various collagen-based hemostatic agents are available for use as local hemostatic agents. The principal differences are in the microstructure and density of the collagen. Collagen can act as a mild allergen, but the problem of allergenization and unwanted tissue reaction does not occur when highly purified animal collagen is used.[49] The mechanisms by which collagen products help achieve hemostasis involves stimulation of platelet adhesion, platelet aggregation and release reaction,[270,271] activation of factor XII

Telegram: @dental_k

www.konkur.in

(Hageman factor),[335,336] and mechanical tamponade by the structure that forms at the collagen-blood wound interface. Collagen shows minimal interference in the wound healing process, with a limited foreign body reaction.[215] It does not increase the incidence of infection and only slightly delays early bone repair.[246] Osseous regeneration in the presence of collagen typically proceeds uneventfully, without a foreign body reaction.[168]

Collagen-based materials can be difficult to apply to the bony crypt because they adhere to wet surfaces, particularly instruments and gloves.[466] Several collagen-based products are commercially available. They include CollaCote (Integra Life Sciences, Plainsboro, NJ) (Fig. 11.34, *A*), CollaStat (American Medical Products Corp, Eatontown, NJ), Hemocollagene (Septodont, United Kingdom) and Instat (Ethicon, Somerville, NJ). These materials act in essentially similar ways, and the surgical area undergoes a similar healing pattern.[485,504] Overall, studies of wound healing with collagen-based hemostatic agents have shown favorable results.

FIG. 11.34 **A,** Absorbable collagen (CollaCote) is a convenient, biocompatible packing material for localized hemostasis. **B,** Cotton pellets impregnated with racemic epinephrine (Racellet) also may be used for localized hemostasis.

www.konkur.in

with epinephrine built-in dispenser contains 3 grams (approx. 450) size 3 pellets.

Surgicel

Surgicel (Ethicon) is a chemically sterilized material prepared through oxidation of regenerated alpha cellulose (oxycellulose). The basic element of Surgicel is polyanhydroglucuronic acid, which is spun into threads and then woven into gauze. Surgicel has a pH of 3. If the material is maintained in the wound for up to 120 days, a pH this low could slow healing.[408] It is primarily a physical hemostatic agent, which acts as a barrier to blood and then becomes a sticky mass that serves as an artificial coagulum. It does not enhance the clotting cascade through adhesion or aggregation of platelets. Surgicel is retained in the surgical wound,[373] and healing is retarded, with little evidence of resorption of the material at 120 days.[57] Use of Surgicel in extraction sockets resulted in greater postoperative pain compared with a control in a split mouth–designed study.[408]

Gelfoam

Gelfoam (Pharmacia, Peapack, NJ) is a gelatin-based sponge that is water insoluble and biologically resorbable. It stimulates the intrinsic clotting pathway by promoting platelet disintegration and the subsequent release of thromboplastin and thrombin.[164] The initial reaction to Gelfoam in the surgical site is a decrease in the rate of healing. Extraction sockets containing Gelfoam showed a greater inflammatory cell infiltrate, marked reduction in bone ingrowth, and a foreign body reaction at 8 days.[74] However, these effects were transitory and did not impair long-term bone healing.[392]

Bone wax

Historically, bone wax has been advocated for controlling both hemostasis and debris in the bony crypt during periradicular surgery.[480] It is a nonabsorbable product composed of 88% beeswax and 12% isopropyl palmitate. Healing with bone wax is best described as poor. The bony crypt typically contains fibrous connective tissue and has no bony or hematopoietic tissue. Bone wax retards bone healing and predisposes the surgical site to

Telegram: @dental_k

www.konkur.in

infection[117,378] by producing a chronic inflammatory foreign body reaction[35] and impairing the clearance of bacteria.[263] The use of bone wax can no longer be recommended because it impairs healing and several good alternatives are available.[589]

Ferric sulfate

Ferric sulfate (Cut-Trol, Ichthys Enterprises, Mobile, AL), a necrotizing agent with an extremely low pH, is one of the few products investigated for use in periradicular surgery. In studies using a rabbit model, Lemon and colleagues[301] and Jeansonne and colleagues[256] reported hemostatic control for 5 minutes and near normal healing with only a mild foreign body reaction, provided the surgical wound was adequately curetted and irrigated with saline. Failure to remove ferric sulfate from the surgical wound site resulted in severely impaired healing, a foreign body-type reaction, and, in some cases, abscess formation. The possibility of acute inflammation and necrosis of the surrounding soft tissue with careless use of this solution should not be underestimated.[298] A similar product, Monsel solution (ferric subsulfate), has been used to control local hemostasis in dermatologic procedures. However, the popularity of this solution has declined because application to wound sites has resulted in tissue necrosis for up to 2 weeks,[130] differences in the degree of epidermal maturation, and tattoo formation.[536]

Calcium sulfate

Calcium sulfate has been used as a substitute bone graft material to fill bone defects since the late 1800s. The presence of calcium sulfate in an osseous wound does not inhibit bone formation.[574] It is gradually removed from the site of implantation regardless of whether new bone has formed.[110] Use of calcium sulfate during periradicular surgery does not significantly affect healing, and deposition of cementum and osseous healing proceed normally.[27] As a hemostatic agent, calcium sulfate acts as a physical barrier. The material is placed in the bony crypt, allowed to set, and then partly carved away to allow access to the root end.[283] The remaining material lines the crypt walls, preventing bleeding. When the root-end filling has been placed and all extraneous root-end filling material removed, the residual calcium sulfate can be removed or left in situ.

Telegram: @dental_k

www.konkur.in

Epinephrine pellets

Epinephrine, a sympathomimetic-amine vasoconstrictor, is frequently used to control hemorrhage during oral surgery.[82,283] All granulation tissue should be removed from the root apex area prior to placement of the epinephrine pellet to assure direct contact with bone.[282] Vasoconstrictive amines exert their effects by binding to and interacting with adrenergic receptors in various body tissues. When epinephrine is bound to $alpha_1$- and $alpha_2$-adrenergic receptors, a powerful vasoconstricting effect results. Racemic epinephrine cotton pellets (Racellet #3; Pascal Co., Bellevue, WA) contain an average of 0.55 mg of racemic epinephrine hydrochloride per pellet, half of which is the pharmacologically active L-form. Racellets (see Fig. 11.31, *B*) provide good localized hemostasis in periradicular surgery.[558]

Two concerns arise with the use of Racellets in the surgical site: the cardiovascular impact of the additional epinephrine and the retention of cotton fibers in the wound, resulting in impaired wound healing.[213,265] A study by Vickers and coworkers[558] examined the cardiovascular effects of epinephrine pellets and concluded that no evidence existed of cardiovascular changes (blood pressure and pulse) compared with saline-saturated pellet controls. These authors hypothesized that the vasoconstrictive effect on the capillaries is localized and immediate and that little or no systemic uptake of epinephrine occurred.

Although the cardiovascular effect appears to be of little concern, retention of cotton fibers in the surgical site could result in inflammation and impaired wound healing. Therefore due diligence on the part of the surgeon is paramount when epinephrine pellets are used. Each pellet applied during surgery must be accounted for, and the bony crypt should be lightly curetted to remove any embedded cotton fibers before the wound is closed. The retention of cotton fibers in the crypt can be eliminated by substituting CollaCote saturated with 10 drops of 2.25% racepinephrine inhalation solution.[567] As previously noted, CollaCote is biocompatible and does not interfere with wound healing.

Cautery/electrosurgery

Telegram: @dental_k

www.konkur.in

Cautery stops the flow of blood through coagulation of blood and tissue protein, leaving an eschar that the body attempts to slough.[537] The effect of cautery in the bony crypt during periradicular surgery has not been studied to date. However, the effect of electrosurgery on alveolar bone has been studied in periodontal surgery. Tissue destruction was greater in areas exposed to electrosurgery and healing was delayed compared with surgical sites not exposed to electrosurgery. Twelve hours after surgery, a more extensive inflammatory reaction and greater destruction of periosteum were noted with electrosurgery.[36] At 24 hours, many empty lacunae were observed in the bone associated with electrosurgery, and this necrosis was even more extensive by 48 hours. At 96 hours the electrosurgical connective tissue wounds were still lined by coagulum, whereas the scalpel wound was beginning to repair.[381] The detrimental effect of applying heat to bone is proportional to both temperature and the duration of application.

Management of the root end

Management of the resected root end during periradicular surgery is critical to the overall success of a case. The aim of surgery should be to create an environment conducive to regeneration of the periodontium—that is, healing and regeneration of the alveolar bone, PDL, and cementum overlying the root end and root-end filling material. The key to regeneration is the presence of appropriate inducible cell types, growth factors, and specific substances necessary for mineralization. Failure to create an environment conducive to this process results in tissue repair rather than regeneration and possibly less-than-ideal healing.

Determination of the need for root-end resection and filling

The basis for periradicular surgery is twofold. The first objective is to remove the etiologic factor; the second is to prevent recontamination of the periradicular tissues once the etiologic agent has been removed.

Etiologic factors typically can be categorized as intraradicular or extraradicular bacteria,[254,287,367,491,540,541,559,580] intraradicular or extraradicular chemical substances, or extraradicular physical

Telegram: @dental_k

www.konkur.in

factors.[370,496,497] The etiology cannot always be determined with complete certainty; frequently, a number of factors are involved.[98] However, most cases involve some form of bacterial participation (e.g., bacteria within apical ramifications). The only definitive means of eradicating such an irritant is physical removal through root-end resection. The rationale for root-end resection in such cases is to establish access to and remove the diseased tissues. This ensures that the optimum environment for wound healing is established.

As mentioned, the second objective of periradicular surgery is to prevent recontamination of the tissues after removal of the etiologic agent. It follows, then, that if the remainder of the canal system cannot be verified to be irritant free, then a root-end filling should be placed to seal any remaining irritants within the canal system, thus preventing recontamination of the periradicular tissues.

Root-end resection

Two main principles dictate the extent of the root-end resection. First, the cause (or causes) of an ongoing disease process must be removed; this includes removal of the diseased tissue and, when indicated, reduction of an apically fenestrated root. Second, adequate room must be provided for inspection and management of the root end.

The anatomy of each tooth root is complex. The surgeon must understand the anatomy of the apical third of the root to determine the extent of a root-end resection. Approximately 75% of teeth have canal aberrations (e.g., accessory or lateral canals) in the apical 3 mm of the tooth.[131,481] An apical resection of approximately 3 mm should include most accessory and lateral canals and thus eliminate most residual microorganisms and irritants (Fig. 11.35). When roots with more than one main canal are resected, isthmus tissue may be present, and the preparation should be modified to include the isthmus area (Fig. 11.36).

Telegram: @dental_k

www.konkur.in

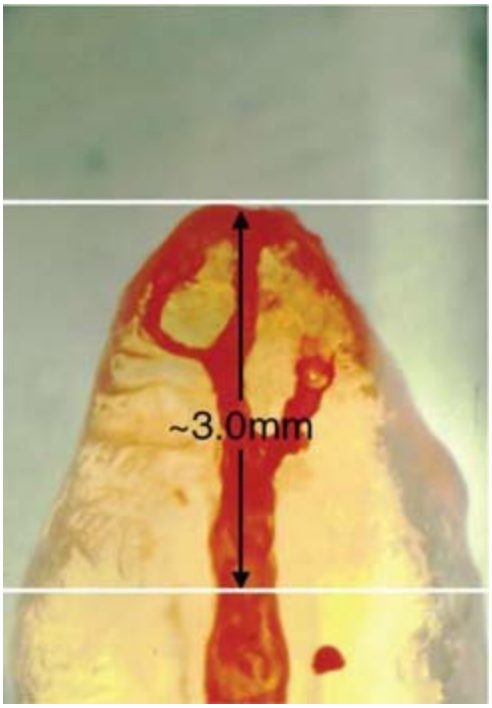

FIG. 11.35 Cleared section of a typical single-canal root that was injected with dye to demonstrate apical accessory canals. Most of the apical ramifications can be eliminated with a 3-mm resection.

www.konkur.in

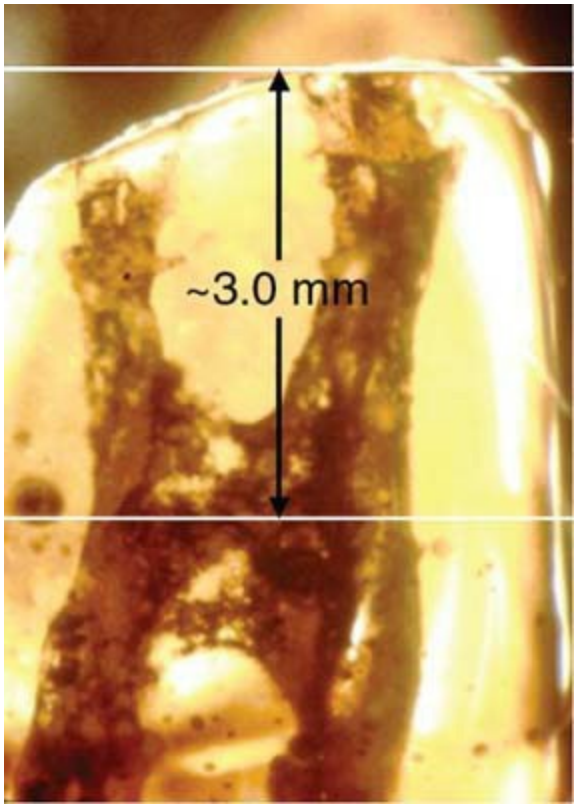

FIG. 11.36 Cleared section of a mesiobuccal (MB) root in a maxillary first molar. Root resection at the recommended 3-mm level exposes isthmus tissue connecting the MB-1 and MB-2 canals.

A cleared section of tooth shows a double headed arrow labeled as approximately 3 millimeters covering isthmus tissue linked to mesiobuccal cannal 1 and 2.

If the root apex is close to the buccal cortical plate, apical fenestration can occur, leading to persistent symptoms, especially tenderness to palpation over the root apex.[72] Reduction of an apically fenestrated root apex below the level of the surrounding cortical bone allows remodeling of the bone over the tooth structure. The buccal root of the maxillary first premolar often is closest to the buccal cortical plate.

The surgeon's convenience as a rationale for root-end resection depends on the individual case and the surgeon's abilities. The basic principle of the dental surgeon's convenience should be modified by the desire to minimize the trauma of the surgical procedure itself, including the preservation of tooth and supporting structures. Access to and visibility of the periradicular root structures historically has determined the extent of root-end resection. The

Telegram: @dental_k

www.konkur.in

surgeon must be able to inspect the resected root end, prepare a root-end cavity, and place a root-end filling. Enhanced visualization equipment (e.g., microscopes, endoscopes, and orascopes) have reduced the need to resect large amounts of the root to gain adequate visualization and access.[91,94,228,280,440,441,448,486] In some cases part of the root must be resected to gain access to the entire soft-tissue lesion, an additional palatally positioned root (e.g., maxillary premolars), or foreign material in the periradicular tissues.

A major consideration in determining the extent of root-end resection is the presence of anatomic structures such as the mental foramen or mandibular canal.[355,410-412] The surgeon should position the resection of the root to avoid possible damage to these structures.

Angle of resection

Enhanced magnification and illumination techniques have eliminated the need to create a beveled root surface in most cases.[94,441] From a biologic perspective, the most appropriate angle of root-end resection is perpendicular to the long axis of the tooth (Figs. 11.37 and 11.38). The rationale for a perpendicular root-end resection is based on several anatomic parameters. First, a perpendicular resection approximately 3 mm from the anatomic apex is more likely to include all the apical ramifications in that region of the tooth.[339] Second, as the angle of resection increases, the number of dentinal tubules that communicate with the periradicular region and the root canal system increases significantly; therefore the probability that irritants from within the canal system will gain access to the healing tissues also rises as the resection angle increases.[181,523] Third, extending the root-end cavity preparation beyond the coronal extent of the root surface is simpler if the root-end resection is perpendicular to the long axis of the tooth.[195] Finally, with a perpendicular root-end resection, the stress forces exerted in the apical region are more evenly distributed; this may reduce the propagation of apical fractures and provide a better environment for apical healing.[470]

An illustration of a tooth shows a triangular flap exposing the root of tooth with a horizontal green line drawn in the apical region.

Root-end surface preparation

As with all phases of endodontic surgery, the goal is to produce a resected root end with optimum conditions for the growth of cementum and subsequent regeneration of the PDL across the resected root end. Two important aspects of this process are the surface topography of the resected root end and chemical treatment of the resected root end. Healthy cementum on the root end is required for successful regeneration of periodontal tissues.[22] A number of substances found in cementum stimulate the migration, growth, and attachment of periodontal fibroblasts. Cementum extracts also activate fibroblast, protein, and collagen synthesis, which is necessary to reestablish a functional PDL.[52,471,562]

Resected root-end surface topography

The conventional axiom for surface preparation of the resected root end has been to produce a smooth, flat root surface without sharp edges or spurs of root structure that might serve as irritants during the healing process. However, little information exists on whether smooth root ends heal differently or more quickly than rough root ends after root-end resection. A study investigating the effect of the surface topography of resected root ends on human PDL fibroblast attachment found no significant difference in fibroblast attachment to the root ends prepared with various instruments.[584] However, with a smooth resected root-end surface, the surgeon is better able to detect surface cracks and anatomic variations.[357] Given that human PDL fibroblast attachment to a smooth surface was not impaired, it would seem appropriate to produce as smooth a surface as possible to facilitate inspection of the resected root end. A smooth root end therefore should be considered advantageous.

Different types of burs tend to produce different patterns on the resected root surface.[212] Several studies have compared the root-end surface after resection.[357,377,585] Generally, crosscut fissure burs in both high-speed and low-speed handpieces produced the roughest and most irregular surfaces.

Telegram: @dental_k

www.konkur.in

Morgan and Marshall[357] compared the surface topography of root-end resection with a #57 straight fissure bur (Midwest Dental Products, Des Plains, IL), a Lindeman bone bur (Brasseler USA, Savannah, GA), and the Multi-Purpose bur (Dentsply Maillefer, Ballaigues, Switzerland), then finished with a either a multifluted carbide finishing bur (Brasseler USA) or an ultrafine diamond finishing bur (Brasseler USA). The Multi-Purpose bur produced the smoothest, most uniplanar resected root-end surface with the least amount of shattering. Regardless of the type of bur used, smearing and shredding of the gutta-percha across the root face occurred only when the handpiece was moved across the root face in reverse direction in relation to the bur's direction of rotation.[585] Burs that produce a smooth surface also tend to cut with less vibration and chatter, resulting in greater patient comfort.

Root-end conditioning

Root surface conditioning removes the smear layer and provides a surface conducive to mechanical adhesion and cellular mechanisms for growth and attachment. It exposes the collagenous matrix of dentin and retains biologically active substances, such as growth factors, in the dentin proper. Experimental studies have shown that demineralized dentin can induce the development of bonelike mineralized tissue.[42,43,241,550,597] Some contend that root surface conditioning produces a biocompatible surface conducive to periodontal cell colonization without compromising the vitality of the adjacent periodontium.

Three solutions have been advocated for root surface modification: citric acid, tetracycline, and ethylenediamine tetra-acetic acid (EDTA). All three solutions have enhanced fibroblast attachment to the root surface in vitro. However, citric acid is the only solution tested in an endodontic surgical application.

Citric acid traditionally has been the solution of choice. Periodontists have used an aqueous solution of citric acid (pH 1) for 2 to 3 minutes to etch diseased root surfaces to facilitate formation, new attachment, and cementogenesis.[434-438] Craig and Harrison[114] examined the effect of citric acid demineralization of resected root ends on periradicular healing. They found that 1- or 2-minute applications of 50% citric acid (pH 1) resulted in demineralized root ends and earlier complete healing than in the

Telegram: @dental_k

www.konkur.in

nondemineralized root ends. However, the periodontal literature has questioned the benefit of etching dentin surfaces with low pH agents. At a low pH, adjacent vital periodontal tissues may be compromised. Also, extended application (3 minutes) has been shown to discourage alveolar bone growth.[60,62]

EDTA, a solution with a neutral pH that endodontists have used as a canal irrigant, has been shown to be equally effective at exposing collagen fibers on dentin surfaces.[64] Unlike the lower pH solution, EDTA does not adversely affect the surrounding tissues.[63]

A series of studies that examined the effect of EDTA and citric and phosphoric acids in a periodontal application showed that application of 15% to 24% EDTA for approximately 2 minutes produces the optimum root surface.[59,61,64] These researchers concluded that EDTA, at neutral pH, was able to selectively remove mineral from a dentin surface, exposing a collagenous matrix. Citric and phosphoric acids, which have a low pH, appeared not only to remove the mineral component but also to denature the collagenous matrix.

Tetracycline has been shown to remove the dentin smear layer, leaving clean, open tubules, with application times as short as 30 seconds.[327] A histologic evaluation of new attachment in periodontally diseased human roots treated with tetracycline hydrochloride showed a trend for greater connective tissue attachment after tetracycline treatment of roots.[13] Studies comparing the effect of a 3-minute application of either EDTA (pH 7.3) or tetracycline HCl (pH 1.8) showed no significant difference in the treated tooth surfaces.[37] However, EDTA has been shown to be more favorable to human PDL cell attachment.[601]

Although the root surface conditioning effects of citric acid, EDTA, and tetracycline are well documented in the periodontal literature, this treatment has not translated into significant gains in periodontal attachment in periodontally diseased teeth.[330] Currently, only citric acid has been assessed as a root-end conditioning agent. In an animal model, citric acid was shown to enhance periradicular healing. Nonetheless, its effect and the effect of other root-end conditioning agents on the outcome of human periradicular surgery have not been established. Based on periodontal research, it would appear that if a root surface conditioning agent were to be used during

Telegram: @dental_k

www.konkur.in

periradicular surgery, EDTA might be the most appropriate solution. However, the manufacturer (personnel communication, Dr. Torabinejad) has advised against the use of EDTA when MTA is used as a root-end filling material, because it may interfere with the hard tissue–producing effect of MTA.

Root-end cavity preparation

The root-end cavity preparation is a crucial step in the establishment of an apical seal. The goal is to make a cavity in the resected root end that is dimensionally sufficient for placement of a root-end filling material and at the same time avoid unnecessary damage to the root-end structures. The ideal preparation is a class I cavity prepared along the long axis of the tooth to a depth of at least 3 mm (Figs. 11.39 and 11.40). The surgical procedure is most likely to be successful if the remaining canal system has been thoroughly cleaned and shaped to eliminate microorganisms and irritants.[178,449] Traditionally, a microhandpiece with a rotating bur has been used for this purpose. However, with the advent of ultrasonic tips designed specifically for this purpose (Fig. 11.41), root-end preparations now are most often performed with the ultrasonic technique.[91] Clinical evidence is emerging to support the benefit of an ultrasonic root-end preparation when compared to traditional bur preparation, especially in molar surgery.[132]

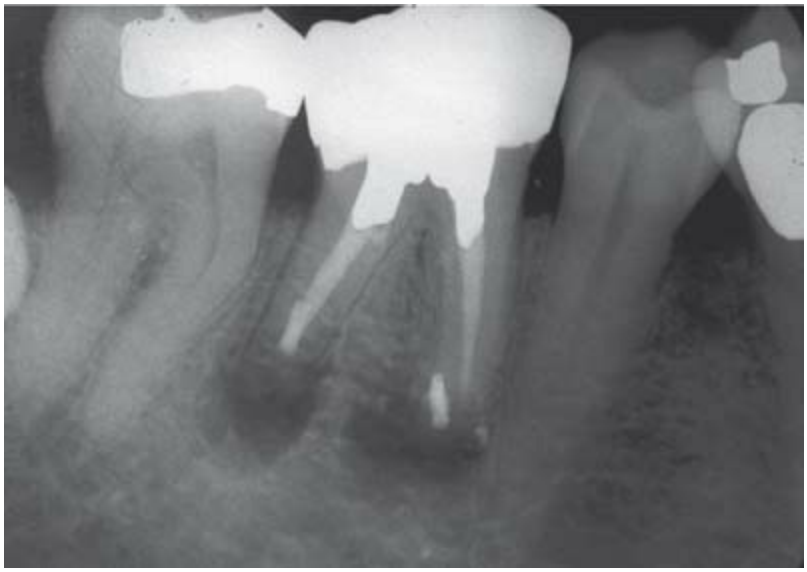

FIG. 11.40 Error in root-end cavity preparation: ultrasonic preparation did not follow the long axis of the mesial root and therefore did not allow for proper sealing of this root. Healing is unlikely.

Radiograph shows a teeth with black spots at the apical foramen.

Telegram: @dental_k

www.konkur.in

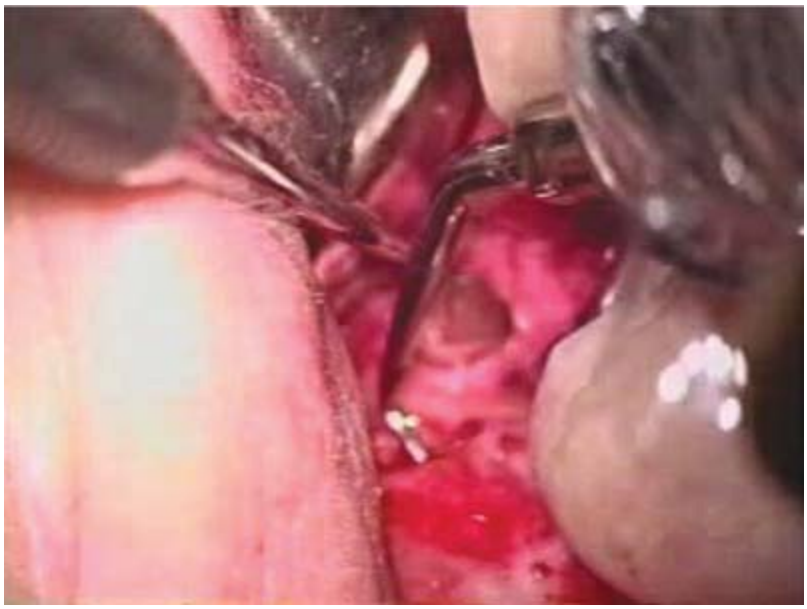

FIG. 11.41 Ultrasonic tip in use. Preparation along the long axis of the root is possible using tips designed for each area of the mouth. In this case, the tip is properly positioned for root-end cavity preparation of a maxillary first premolar but is dangerously close to the lip because of improper retraction. Heat generated by an ultrasonic tip can cause a thermal burn, which may result in scar tissue formation.

Close-up view shows tip placed very close to lip near the maxillary first premolar.

Ultrasonic root-end preparation techniques have several advantages over the microhandpiece method. Less osseous tissue must be removed to gain proper access to the resected root end. Also, the surgeon is better able to produce a more conservative preparation that follows the long axis of the tooth and remains centered in the canal. The risk of root-end perforation is reduced, partly because of enhanced manipulation of the instrument. In addition, ultrasonic root-end techniques produce a more consistent, deeper cavity preparation that requires less beveling of the root.[95,304,347,592] Ultrasonic apical preparation generates significantly less smear layer compared with burs alone[205]; root-end preparation with a bur produces a heavy smear layer at all levels of preparation.[214]

The major concern with ultrasonic root-end preparation is the potential for

Telegram: @dental_k

www.konkur.in

creating root fractures as a result of the ultrasonic vibration (Fig. 11.42).

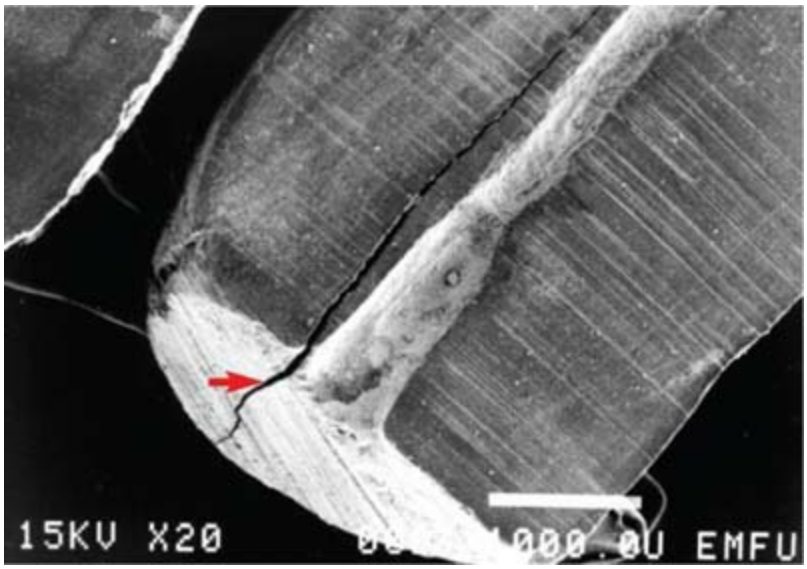

FIG. 11.42 Scanning electron microscope image of a root end prepared in vitro with an ultrasonic device at high-power setting. A distinct fracture line can be seen *(red arrow).* Root-end preparation with ultrasonic devices should be done at low power and with water coolant.

Microscopic image of apical region of a tooth shows a red arrow pointing at a vertical black line depicting root fracture.

Ultrasonic root-end preparation and apical fractures

Several studies have investigated the fracture-inducing potential of ultrasonic root-end preparation techniques. This is possibly the most controversial question that arises in relation to the use of ultrasonic root-end preparation tips. Three types of root-end fractures have been described: intracanal fractures (originating from the root canal system and extending into the dentin), extracanal fractures (originating on the root surface and extending into the dentin), and communicating fractures (extending from the root surface to the root canal system).[425] This classification system is not universally used in studies of root-end cavity preparation; therefore it is difficult to establish the significance, if any, of one type of fracture over another. When a strain gauge was used to measure root deformation, ultrasonic root-end preparation was shown to produce significantly greater

Telegram: @dental_k

www.konkur.in

strain, on average, than that generated by a microhandpiece. However, this did not translate into an increase in cracks observed on the resected surface of roots after root-end cavity preparation.[48,303,375,425] Several other in vitro studies that used different models to assess root-end fractures conversely concluded that ultrasonic root-end preparation does induce apical fractures.[2,184,299,354,469] Thus the degree to which apical fractures are induced during ultrasonic root-end cavity preparation is difficult to determine from in vitro studies.

On the other hand, in an in vivo study[358] and cadaver-based studies[86,207] designed to replicate the clinical scenario, root fractures were not attributed to ultrasonic use. In these studies, ultrasonic root-end preparation did not induce a significant number of root-end fractures. Several explanations may account for the differences observed in these studies. The surrounding tissues in cadaver and clinical subjects may disperse the ultrasonic energy away from the root tip. Thermal energy produced during ultrasonic preparation may have been controlled more adequately in some studies than in others. The power setting used on the ultrasonic unit may have been in the low range; a low power setting has been shown to produce fewer fractures in an in vitro setting[176,299] and is therefore recommended for clinical use.

Significance of ultrasonic tip design

Different types of ultrasonic tips are available for root-end preparation (Figs. 11.43 and 11.44), including tips of varying lengths and diameters constructed of stainless steel. These tips are left uncoated or are coated with diamond or zirconium nitride. Tips with a curvature of 70 degrees or greater are more susceptible to fracture under continuous loading, and fracture typically occurs at the bend.[573] Coating of ultrasonic tips undoubtedly improves the cutting efficiency compared with uncoated stainless steel tips; this translates into significantly less time required to prepare a root-end cavity.[200,405] In the coated tips, the diamond coating appears to be the most aggressive and requires the least amount of time to produce a root-end cavity preparation.[253] Furthermore, the type of tip (i.e., stainless steel, diamond coated, or zirconium nitride coated) appears to have little effect on the number or types of fractures that can be induced in the root end during root-end preparation.[76,200,253,375,425] The cavity walls of root-end preparations formed

Telegram: @dental_k

www.konkur.in

by stainless steel tips typically have cleaner canal walls than those formed by coated root-end preparation tips. Stainless steel tips appear to produce less superficial debris and smear layer. Coated root-end preparation instruments typically produce a heavily abraded, debris-covered cavity wall surface.[76,610] However, overall the quality of the coated-tip preparation has been suggested to be superior.[405]

FIG. 11.43 Ultrasonic tips (Obtura Spartan) are available in a wide variety of configurations for use in different areas of the mouth. Most new tips have a special coating (zirconium nitride or diamond) that improves cutting efficiency.

www.konkur.in

FIG. 11.44 Ultrasonic tip with diamond coating and irrigation port (DENTSPLY Tulsa Dental Specialties).

Close-up of ultrasonic top with a drop-shaped hollow space in handle as irrigation port.

Temperature changes induced by ultrasonic instruments

The importance of heat generation and temperature changes has already been discussed. All ultrasonic surgical tips should have an irrigation port. Use of an ultrasonic instrument in the periradicular tissues without adequate irrigation results in an extreme temperature increase in the tissues, although this specific effect has not been demonstrated during root-end preparation. Scaling without irrigation can increase the temperature in dentin as much as 95°F (35°C) above the baseline temperature[290]; such an increase can injure pulpal and periodontal tissues.[380]

Bonded root-end fillings

Root-end cavity preparation for bonded root-end filling materials requires a change in the standard root-end cavity preparation technique. A shallow, scalloped preparation of the entire root surface should be made using a round or oval bur; the preparation should be at least 1 mm at the deepest concavity.[26,453] An ultrasonic preparation can be made into the root canal system, but this may not be necessary. The root-end filling material is placed

Telegram: @dental_k

www.konkur.in

in a dome fashion and bonded to the entirety of the resected root end (Fig. 11.45).

FIG. 11.45 **A,** Immediate postoperative radiograph of a bonded root-end filling in a maxillary first premolar. **B,** Follow-up radiograph at 20 months showing good periradicular healing.

Set of two radiographs are marked A and B as follows:

A) Radiograph shows radiopaque bud attached to the crown of the tooth with a gray spot present at the root of tooth.

B) Radiograph shows disappearance of gray spot at the apical root of the tooth with root end filling in place depicted as a radiopaque region.

Root-end filling materials

The ideal root-end filling material seals the contents of the root canal system within the canal, preventing egress of any bacteria, bacterial by-products, or toxic material into the surrounding periradicular tissues. The material should be nonresorbable, biocompatible, and dimensionally stable over time. It should be able to induce regeneration of the PDL complex, specifically cementogenesis over the root-end filling itself. Finally, the handling properties and working time should be such that the endodontic surgeon can place a root-end filling with sufficient ease.

Telegram: @dental_k

www.konkur.in

Many materials have been used as root-end fillings, including gutta-percha, polycarboxylate cements, silver cones, amalgam, Cavit (3M ESPE, St. Paul, MN) zinc phosphate cement, gold foil, and titanium screws. However, this section focuses on root-end filling materials discussed in the literature within the past 10 years that are in common clinical use. These materials are zinc oxide–eugenol (ZOE) cements (IRM and Super-EBA), glass ionomer cement, Diaket, composite resins (Retroplast), resin–glass ionomer hybrids (Geristore), and mineral trioxide aggregate (ProRoot-MTA), and bioceramics.

Zinc oxide–eugenol cements

Zinc oxide powder and eugenol liquid can be mixed to form a paste that is compacted into a cavity preparation. Use of this material dates back to the 1870s. Eugenol is released from ZOE mixtures, although this declines exponentially with time and is directly proportional to the liquid-powder ratio.[243] When ZOE comes in contact with water, it undergoes surface hydrolysis, producing zinc hydroxide and eugenol. This reaction continues until all the ZOE in contact with the free water is converted to zinc hydroxide.[243-245] Eugenol can have a number of effects on mammalian cells, depending on the concentration and length of exposure. These effects include cell respiration depression, macrophage and fibroblast cytotoxicity, depressed vasoconstrictor response, inhibition of PG, and suppressing or enhancing effects on the immune response.[139,349,561] Other materials have been added to the basic ZOE mixture in an effort to increase the strength and radiopacity and reduce the solubility of the final material. Commercially available ZOE materials include intermediate restorative material (IRM; Dentsply Caulk, Milford, DE) and Super-EBA (Bosworth Company, Skokie, IL).

Intermediate restorative material

IRM consists of a powder containing greater than 75% zinc oxide and approximately 20% polymethacrylate mixed in equal parts with a liquid that contains greater than 99% eugenol and less than 1% acetic acid. IRM seals better than amalgam and is not affected by the liquid-powder ratio or root-end conditioning agents.[116,407] IRM appears to be tolerated in the periradicular tissue, but it has no dental hard-tissue regenerative capacity. The response is similar to that seen with other ZOE-based materials.[221,329,417-420] In vitro,

Telegram: @dental_k

www.konkur.in

IRM prevents adherence of enamel matrix proteins.[463]

Super-EBA

Super-EBA consists of a powder containing 60% zinc oxide, 34% aluminum oxide, and 6% natural resins. It is mixed in equal parts with a liquid that contains 37.5% eugenol and 62.5% o-methoxybenzoic acid. Super-EBA is available in two forms, fast set and regular set. Other than the setting time, the properties of the two forms appear to be the same.[593] Super-EBA has radiopacity[484] and sealing effects similar to those of IRM and is less leaky than amalgam.[232,388] The leakage pattern of Super-EBA does not appear to be affected by root-end conditioning or finishing techniques.[174,469] When Super-EBA and IRM were finished with a carbide finishing bur in a high-speed handpiece, marginal adaptation was better than with ball burnishing, which was equal to burnishing with a moistened cotton pellet.[170] The environment of the periradicular wound may affect the long-term stability of Super-EBA, which has been shown to disintegrate over time in an acid pH environment.[30]

Biologically, Super-EBA is well tolerated in the periradicular tissues when used as a root-end filling. However, it has no capacity to regenerate cementum. Bone healing has been demonstrated at 12 weeks, with some fibrous tissue persisting. Super-EBA root-end fillings show a basophilic-stained line adjacent to the filling material, which may indicate hard-tissue formation.[404,418,419,542] Collagen fibers appear to grow into the cracks of the material,[396] but the significance of this is unknown. Super-EBA has limited antibacterial effect.[101] The cytotoxicity of Super-EBA is similar to that of amalgam and IRM.[102,605] The incidence of persistent disease after endodontic surgery in which Super-EBA was used as a root-end filling material ranges from 4% to 20%. In comparative studies in which amalgam was also used as a root-end filling material, the use of Super-EBA always resulted in less persistent disease. The follow-up period for these studies ranged from 0.5 to 4.6 years.[147,326,397,448,518,565]

Glass-ionomer cements

Glass-ionomer cement (GIC) consists of aqueous polymeric acids, such as polyacrylic acid, plus basic glass powders, such as calcium aluminosilicate.

Telegram: @dental_k

www.konkur.in

GIC sets by a neutralization reaction of aluminosilicate, which is chelated with carboxylate groups to cross-link the polyacids; a substantial amount of the glass remains unreacted and acts as reinforcing filler. GICs can be either light or chemically cured. Silver has been incorporated into GIC to improve the physical properties, including compressive and tensile strength and creep resistance. Both forms of GIC have been suggested as an alternative root-end filling material.[44,415,416]

The seal and marginal adaptation of light-cured GIC are superior to those with chemical-cured GIC. The seal achieved with GIC generally is better than that with amalgam and similar to that with IRM.[105,106,252,444,520,591] Long-term surface changes can occur in silver-GIC that may affect the stability of silver-GIC in the periradicular tissues.[55] GICs are susceptible to attack by moisture during the initial setting period, resulting in increased solubility and decreased bond strength.[188,508,596] Contamination with moisture and blood adversely affected the outcome when GIC was used as a root-end filling material; this occurred significantly more often in unsuccessful cases.[602] The cytotoxicity of chemical- and light-cured GIC does not differ significantly from that of Super-EBA or amalgam.[102,394] The tissue response to GIC is considerably more favorable than to amalgam and similar to that with ZOE-based materials.[100,104,133,416] In a comparative clinical study using amalgam or GIC for root-end filling, healing was evaluated clinically and radiographically after 1 and 5 years.[261,602] No difference was seen in healing capacity between the two materials. The overall success rate in both groups was 90% at 1 year and 85% at 5 years. This study showed that the 5-year follow-up result can be predicted in more than 95% of the cases at the 1-year follow-up. These authors concluded that GIC is a valid alternative to amalgam for use as an apical sealant after root-end resection and that it provides equally good long-term clinical results.[261,602]

Diaket

Diaket (ESPE GmbH, Seefeld, Germany) a polyvinyl resin initially intended for use as a root canal sealer, has been advocated for use as a root-end filling material.[587] It is a powder consisting of approximately 98% zinc oxide and 2% bismuth phosphate mixed with a liquid consisting of 2.2-dihydroxy-5.5

Telegram: @dental_k

www.konkur.in

dichlorodiphenylmethane, propionylacetophenone, triethanolamine, caproic acid copolymers of vinyl acetate, and vinyl chloride vinyl isobutylether. Leakage studies comparing Diaket to other commonly used root-end filling materials have shown it to have a superior sealing ability.[190,264,313,571] Its sealing ability has not been directly compared to that of MTA. When Diaket was used as a root canal sealer, biocompatibility studies showed that it was cytotoxic in cell culture[276] and generated long-term chronic inflammation in osseous[502] and subcutaneous tissues.[393] However, when mixed at the thicker consistency advocated for use as a root-end filling material, Diaket has shown good biocompatibility with osseous tissues.[379,587] Histologically, a unique tissue barrier has been observed to form across the Diaket at the resected root end, the nature of which is unknown. This tissue resembles an osteoid or cementoid type of matrix with a close approximation of periodontal tissue fibers, suggesting a regenerative response to the root-end filling material.[587] In animal studies Diaket has shown a better healing response than resected gutta-percha in uninfected teeth[590] and a healing response similar to that with MTA. However, no cementum formation was evident.[433] This material is no longer available in the United States.

Composite resins and resin-ionomer hybrids

Composite resin materials have some desirable properties and may be considered for use as root-end filling materials. Generally, when assessed for sealability, composite resins perform well in vitro studies. Composite resins also tend to leak less than amalgam, Super-EBA, IRM, and GICs.[126,344,345,520] However, blood contamination during the bonding process reduces bond strength and increases leakage.[353,560] Marginal adaptation varies, depending on the conditions and the bonding agents.[17] Certain components of composite resins and dentin-bonding agents can have a cytotoxic effect on cells; this effect varies, depending on the agent and its concentration.[80,217,428,429,514] Studies have shown that once the composite resin sets, cells can grow on its surface.[328,362,402,604] The healing response of the periradicular tissues to composite resins in general appears to be very diverse, ranging from poor to good[25,542]; this may depend on the type of material used. Two composite resin–based materials, Retroplast (Retroplast

Telegram: @dental_k

www.konkur.in

Trading, Rørvig, Denmark) and Geristore (Den-Mat, Santa Maria, CA), have been advocated for use as root-end filling materials.

Retroplast

Retroplast is a dentin-bonding composite resin system developed in 1984 specifically for use as a root-end filling material. The formulation was changed in 1990, when the silver was replaced with ytterbium trifluoride and ferric oxide. Retroplast is a two-paste system that forms a dual-cure composite resin when mixed. Paste A is composed of Bis-GMA/TEGDMA 1:1, benzoyl peroxide N,N-di-(2-hyydroxyethyl)-p-toluidine, and butylated hydroxytoluene (BHT). This is mixed in equal parts with paste B, which is composed of resin ytterbium trifluoride aerosil ferric oxide. A Gluma-based dentin bonding agent is used to adhere the material to the root-end surface. The working time is 1½ to 2 minutes, and the radiopacity (due to the ytterbium trifluoride content) is equivalent to 6 mm of aluminum.

Only limited information is available on the physical and chemical properties of Retroplast, although a number of human clinical studies have been published.[22,25,361, 451-455,457-460] In all cases the material appeared to be well tolerated and promoted a good healing response. There is evidence that Retroplast promotes hard-tissue formation at the root apex, and some have suggested that this is a form of cementum. In a limited number of case reports, Retroplast root-end fillings have demonstrated regeneration of the periodontium with a cementum layer over the root-end restoration.[22,453,454] The healing response in these cases showed deposition of minimal cementum and the insertion of new Sharpey's fibers. The PDL fibers also entered the newly formed adjacent alveolar bone, indicating that tissue regeneration, including cementogenesis, may occur on composite material, consequently forming a biologic closure of the root canal.[25] In an investigation of 388 cases comparing root-end fillings of Retroplast or amalgam, radiographic healing after 1 year was as follows: with Retroplast, 74% showed complete healing, 4% showed fibrous healing, 15% were uncertain, and 7% were failures; with amalgam, 59% showed complete healing, 3% showed fibrous healing, 30% were uncertain, and 8% were failures.[453] Complete healing occurred significantly more often after root-end filling with Retroplast. The number of immediate postoperative complications did not differ significantly

Telegram: @dental_k

www.konkur.in

between the composite and the amalgam groups. A more recent clinical study of 351 cases reported a complete healing rate of 80% to 89%.[459] A 10-year follow-up of 34 of these cases showed complete healing in 33 of the cases.[458]

Resin-ionomer suspension (Geristore) and compomer (Dyract)

The resin-ionomer suspension and compomer group of materials attempts to combine the various properties of composite resins and glass ionomers. Geristore and Dyract (Dentsply, Tulsa, OK) have been investigated for use as root-end filling materials, although the available published literature on both is limited. These two materials require light activation and resin-dentin bonding agents to attach to the tooth.

Geristore has been recommended both as a root-end filling material[93] and for use in restoring subgingival surface defects such as root surface caries, external root resorption lesions, iatrogenic root perforations, and subgingival oblique fractured roots. Clinical evaluation of Geristore as a restorative material for root caries and cervical erosions showed it to be an acceptable material.[183,372,475,548] When it is used for surgical repair of root perforations and as an adjunct to GTR, the results have been favorable in isolated case reports.[3,4,47,440,487] Geristore's dual-curing paste/paste formulation is a hydrophilic Bis-GMA with long-term fluoride release. Light activation for 40 seconds cures the material to approximately 4 mm. However, the top layer is harder until the material achieves uniform hardness at 1 day after activation.[512] In vitro leakage assessment of Geristore and Dyract indicates that the materials leak less than root-end fillings made of IRM, amalgam, or Super-EBA.[65,209] Geristore has a leakage pattern similar to that of MTA.[474] An acid pH significantly reduces dye leakage of Geristore.[446] These materials are less sensitive to moisture than conventional GIC; however, dry environments produce stronger bonds.[99] The effect of blood contamination during the bonding phase in a clinical scenario is unknown. Geristore appears to have the potential to allow regeneration of the periradicular tissue. In one study, PDL and gingival fibroblasts attached to Geristore, and the attachment improved with time and cell proliferation.[87] Studies investigating epithelial and connective tissue adherence to Geristore found clinical and histologic evidence of cellular attachment when the material was placed in subgingival cavities.[150,151,475] However, the healing response in the periradicular region

Telegram: @dental_k

www.konkur.in

is best described as unpredictable. In a study in dogs, 10 of the 18 root end–filled teeth developed abscesses. The author attributed this to the technical difficulty of placing Geristore root-end filling. However, a small number of specimens developed cementum on the root-end fillings. The cemental covering was never greater than 25% of the root-end filling surface, which was considerably less than the amount of cementum developed on both white and gray MTA.[315]

Mineral trioxide aggregate

MTA (ProRoot MTA; DENTSPLY Tulsa Dental Specialties), a material developed specifically as a root-end filling,[529] has undergone numerous in vitro and in vivo investigations comparing its various properties to Super-EBA, IRM, and amalgam. In vitro sealing ability and biocompatibility studies comparing root-end filling materials have shown MTA to be superior to other commonly used materials.[277,300,527,530,531,533-535] When various in vitro leakage models were used, MTA prevented leakage as well as composite resin and GIC.[6,129,171,591] However, the setting and subsequent leakage of MTA are not affected by the presence of blood.[527] Torabinejad and colleagues[535] developed the original product (gray MTA). The main constituents of this material are calcium silicate ($CaSiO_4$), bismuth oxide (Bi_2O_3), calcium carbonate ($CaCO_3$), calcium sulfate ($CaSO_4$), and calcium aluminate ($CaAl_2O_4$). Hydration of the powder produces a colloidal gel that solidifies into a hard structure consisting of discrete crystals in an amorphous matrix. The crystals are composed of calcium oxide, and the amorphous region is composed of 33% calcium, 49% phosphate, 2% carbon, 3% chloride, and 6% silica.[529] In a study comparing the setting time, compressive strength, radiopacity, and solubility of MTA to those of amalgam, Super-EBA, and IRM, MTA was found to be less radiopaque than amalgam but more radiopaque than Super-EBA and IRM.[529] MTA had the longest setting time (2 hours, 45 minutes) and the lowest compressive strength at 24 hours after mixing (40 MPa), although compressive strength increased to 67 MPa at 21 days after mixing. The solubility of MTA after setting was similar to that of amalgam and Super-EBA. Initially MTA has a pH of 10.2, which rises to 12.5 3 hours after mixing.[529] The pH has been reported to be approximately

Telegram: @dental_k

www.konkur.in

9.5 at 168 hours after mixing.[152] MTA is less cytotoxic than amalgam, Super-EBA, or IRM root-end fillings.[531] Endodontic surgery studies in dogs and monkeys have reported less periradicular inflammation and cementum deposition immediately adjacent to the root-end filling material.[27,173,236,528,532] Holland and colleagues[236,237] theorized that the tricalcium oxide in MTA reacts with tissue fluids to form calcium hydroxide, resulting in hard-tissue formation.

The importance of the presence of cementum-like tissue adjacent to MTA cannot be understated. Cementum deposition is essential to regeneration of the periodontal apparatus.[310] Augmentation of new cementum across the root end and root-end restoration is essential for ideal healing of the periodontium. A layer would also enhance the integrity of the apical barrier, making it more resistant to penetration by microorganisms; in effect, establishing a biologic barrier.[22] This is seen most frequently in sections where MTA was used as the filling material. MTA appears to be able to induce cementoblastic cells to produce hard tissue. Cementogenesis in the presence of MTA has been evaluated by assessment of the expression of osteocalcin (OCN), cell growth, and the morphology of cementoblast-like cells.[522] Scanning electron microscope (SEM) analysis indicated that cementoblasts could attach to and grow on MTA. In addition, strong expression of the OCN gene was seen after application of MTA. MTA can also increase the production of both proinflammatory and antiinflammatory cytokines from osteoblasts. The clinical significance of this reaction is not known. The effect of MTA on periradicular tissues is probably partly due to these reactions.

In a human outcomes assessment study comparing ProRoot MTA to IRM, the rate of persistent disease with MTA was 16% at 12 months and 8% at 24 months.[103] The rate of persistent disease with IRM was 24% at 12 months and 13% at 24 months. These authors concluded that the use of MTA as a root-end filling material resulted in a high success rate that was not significantly better than that obtained with IRM. A prospective clinical trial using MTA as a root-end filling material along with current microsurgical techniques reported 89% clinical success, with follow-up time ranging from 4 to 72 months.[468]

A variation of the original formula of gray MTA has been introduced. This material, which is a cream white color, is often called white MTA. The

Telegram: @dental_k

www.konkur.in

chemical composition of white MTA is very similar to that of the original. White and gray ProRoot-MTA materials differ by less than 6% in any one component. Both are fine powders with a mean particle size of approximately 10 μm (the range in particle size is approximately 0.1 to 100 μm). The radiopacity of both materials is equivalent to approximately 3.04 mm of aluminum.[45] When white MTA was implanted in the subcutaneous connective tissue of rats, the results were similar to those reported for gray MTA.[238] One study compared the tissue reaction evoked by the two materials when used as root-end fillings in canines.[315] The only statistically significant difference observed was for the presence of macrophages or multinucleated giant cells adjacent to material. Gray MTA had more samples with mild to moderate infiltration of macrophages or multinucleated giant cells, and white MTA had more samples with no macrophages and/or multinucleated giant cells adjacent to the material. All other parameters assessed were essentially the same.

Bioceramics

Bioceramics are a relatively new and potentially promising addition to the group of materials available for root-end filling. In vitro testing of EndoSequence Root Repair Material (ERRM; Brasseler USA) demonstrates biocompatibility and antimicrobial activity that is similar to MTA.[107,122,317,323] ERRM is composed of calcium silicates, monobasic calcium phosphate, and zirconium oxide.[107] The material is hydrophilic, radiopaque, and has high pH. ERRM is available as a putty and a syringable paste. Because this is a relatively new material, long-term clinical studies are not yet available.

Overview of root-end filling materials

Many different materials have been advocated for use as root-end filling materials, and each has specific advantages and disadvantages. However, from the biologic perspective of regeneration of the periradicular tissues, MTA, followed by Retroplast, appears to have a clear advantage over the other available materials. Bioceramic materials may join this group but require more clinical testing. Retroplast and other composite resin–based

Telegram: @dental_k

www.konkur.in

filling materials require meticulous hemostasis and a dry surgical field for optimum results. The most commonly cited disadvantage of MTA is its handling properties. Even when properly prepared, MTA is more difficult to place in the root-end cavity than most other materials. Several devices have been modified or developed specifically for use with MTA (Fig. 11.46; also see Figs. 11.19–11.23). Typical clinical cases showing the surgical procedures described in the previous sections are presented in Figs. 11.47–11.49.

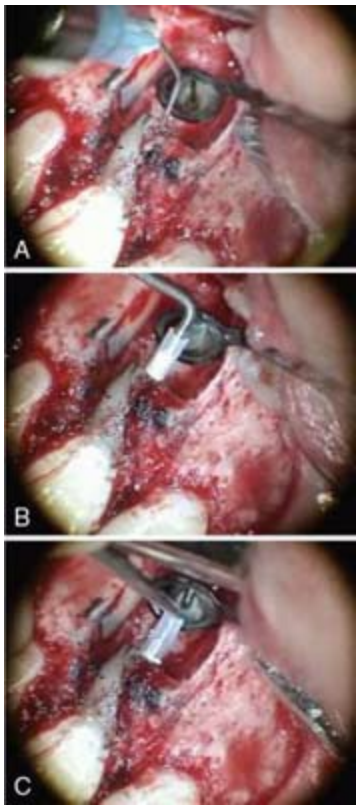

FIG. 11.46 **A,** Stropko syringe used to dry a root-end preparation before placement of the root-end filling material. **B,** Clinical use of an MTA delivery system (Dentsply Tulsa Dental). The device is loaded with MTA and placed over the root-end preparation. **C,** Pressing the plugger into the sleeve delivers the filling material to the root-end cavity preparation. The filling material then is compacted with microcondensers, and additional filling material is placed as needed.

Set of three photographs showing interior of mouth, marked A through C depict use of devices in MTA.

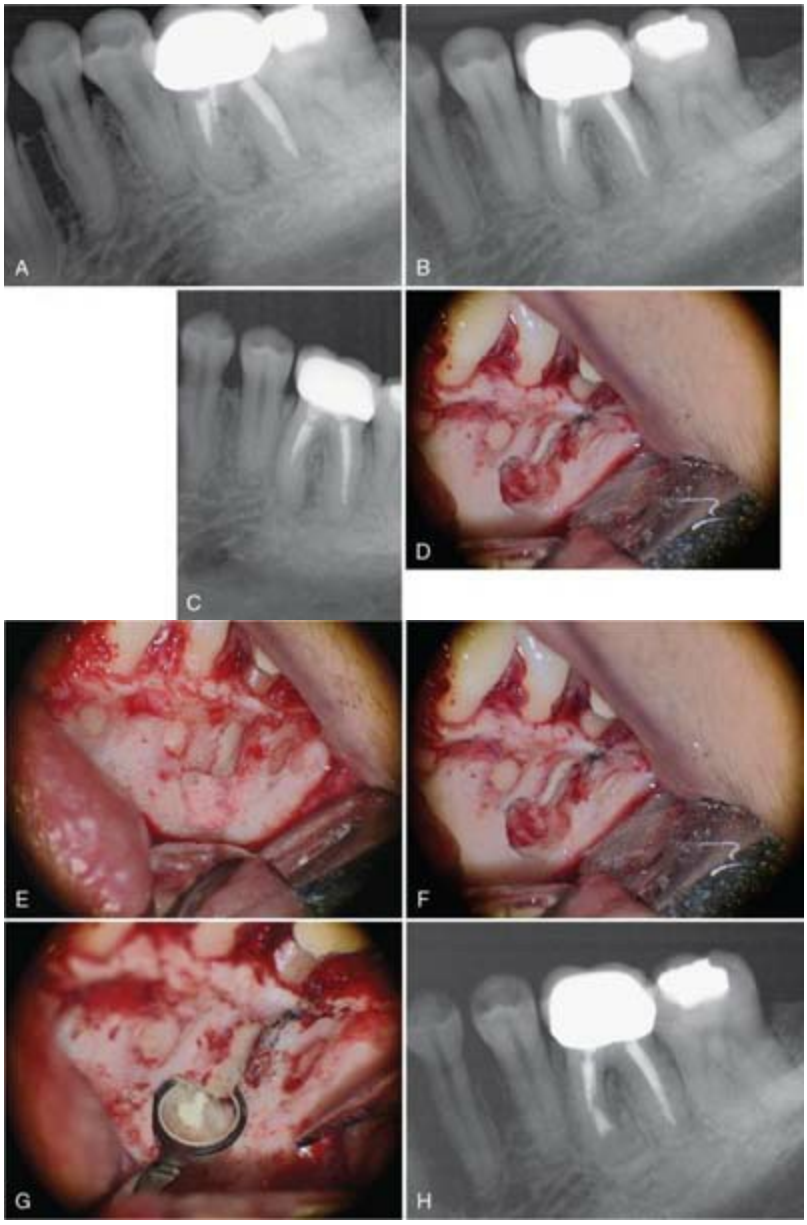

FIG. 11.47 **A,** Preoperative radiograph (mesial angle) of a left mandibular first molar. Periradicular disease and symptoms had persisted after nonsurgical retreatment by an endodontic resident. The mesial canals were completely obstructed at the midroot level. The preoperative evaluation included three periapical radiographs, two different horizontal angulations, and one vertically positioned radiograph. **B,** Straight view preoperative radiograph. **C,** Vertical periapical view preoperative radiograph. **D,** Osteotomy and root resection perpendicular to the long axis of the root were performed; a partial bony dehiscence over the mesial root can be seen. **E,** Racellets were packed into the bony crypt to establish hemostasis. **F,** The Racellets were removed (one usually is left in the deepest part of the crypt during root-end preparation and filling), and the root end was

Telegram: @dental_k

www.konkur.in

beveled perpendicular to the long axis of the root. Methylene blue dye can be useful for identifying the root outline and locating any cracks. Ultrasonic root-end preparation was completed to a depth of 3 mm, connecting the MB and ML canals. **G,** Mineral trioxide aggregate root-end filling was placed and inspected. The bony crypt was then gently curetted to initiate bleeding and to remove any remnants of hemostatic materials. The flap was repositioned, and a radiograph was taken. **H,** An immediate postoperative radiograph confirmed the depth and density of the root-end filling and the absence of any foreign objects. Note that calcium sulfate and bone grafting material was placed in the osseous defect and over the root because of the large buccal dehiscence, although this is not routinely required in these cases.

Set of radiographs and photographs marked A to H depict surgical treatment of left mandibular first molar for periradicular disease.

Source: (Courtesy Dr. Vince Penesis.)

FIG. 11.48 **A,** Preoperative radiograph of a maxillary left central incisor showing evidence of previous surgery but no apparent root-end filling. Because of the short root length and inadequate band of keratinized gingiva, an intrasulcular incision and full-thickness triangular mucoperiosteal flap design were selected. **B,** The root was minimally

Telegram: @dental_k

www.konkur.in

resected, and the root-end cavity was prepared ultrasonically. **C,** Mineral trioxide aggregate was placed and condensed into the root-end cavity preparation. **D,** The root-end filling was inspected before the flap was repositioned and sutured. **E,** Immediate postoperative radiograph. **F,** The 6-month follow-up radiograph showed good initial periradicular healing.

Set of radiographs and photographs marked A to H depict surgical treatment of maxillary left central incisor as follows:

A) Radiograph shows a radiolupency in the apical region of tooth on the left depicting short root length.

B) Close-up of interior of mouth shows diamond coated micromirror placed in the cavity at the root of affected tooth, with flap held by retractor.

C) Close-up of interior of mouth shows a dot of MTA being filled in the hollow cavity.

D) A micromirror is held near the cavity.

E) Radiograph shows a blur spot at the root of affected tooth.

F) Radiograph shows filling extending the canal of till the root of the tooth.

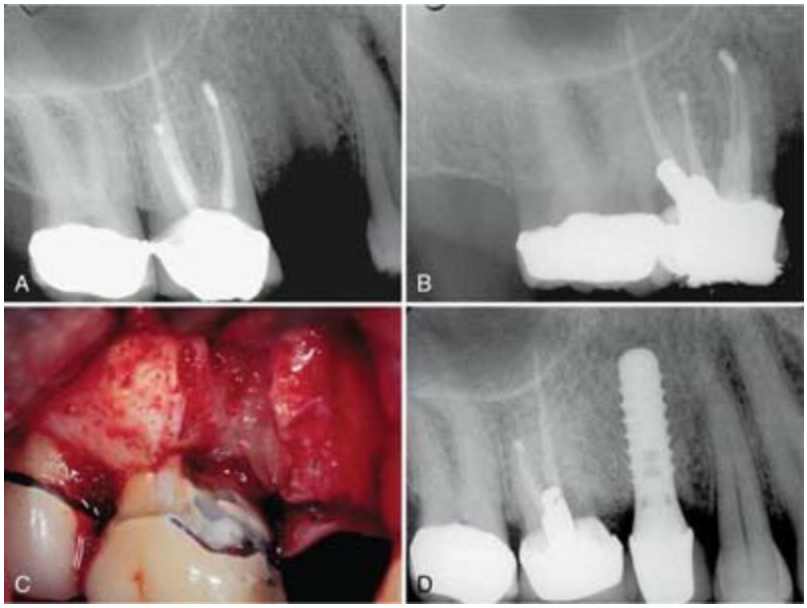

FIG. 11.49 **A,** A maxillary right first molar that was sensitive to percussion and tender to palpation over the MB root. Periodontal

Telegram: @dental_k

www.konkur.in

probing revealed a deep, narrow bony defect on the facial aspect of the MB root. The presence of a vertical root fracture was confirmed visually using magnification and methylene blue dye. The maxillary right second premolar had been recently extracted because of a vertical root fracture. **B,** A bonded amalgam core buildup was placed in the DB and P canals, and Geristore was placed in the MB canal system. **C,** The MB root was resected, and methylene blue dye was used to help define the extent of the fracture. **D,** At the 3-year follow-up visit, a new crown had been fabricated for the molar, and the premolar had been replaced with an implant.

Set of three radiographs and a photograph marked A through depict steps involved in surgical treatment of maxillary right first molar.

Closure of the surgical site and selection of suture material

Closure of the surgical site

The surgical site should be closed only after careful visual and radiographic inspection of the area. Before suturing, a radiograph should be taken with the flap held loosely in place to detect any foreign objects in the crypt or adhering to the flap. This image is also important for confirming the depth and density of the root-end filling. The osteotomy site then is gently curetted and irrigated with sterile saline or water to remove any remnants of hemostatic agents and packing materials. Some bleeding is encouraged at this point, because the blood clot forms the initial scaffold for subsequent healing and repair. If indicated, grafting materials or barriers may be placed at this time. Slight undermining of the unreflected soft tissue adjacent to the flap facilitates the placement of sutures. The flap is then repositioned and gently compressed with a piece of chilled, sterile moist cotton gauze to express excess blood and tissue fluids.

For the common flap designs discussed in this chapter, the corners are first identified and sutured in place with a single interrupted suture. Interrupted sutures are initially passed through the free portion of the flap approximately 2 to 3 mm from the edge and then connected to the attached tissue. The suture is secured with a simple surgeon’s knot, which is positioned away from the incision line. The center of the flap then is located and sutured with

Telegram: @dental_k

www.konkur.in

either an interrupted or a sling suture. A continuous locking suture technique may be used to close a submarginal (Ochsenbein-Luebke) flap.[288] The primary advantage of a continuous suture technique is the ease of suture removal compared with multiple interrupted sutures. The disadvantages are possible difficulty with precise control of tension in each area, and the fact that the entire suture may loosen if one suture pulls through the flap. A sling suture is commonly used for the central tooth in the surgical site to close a full-thickness intrasulcular (rectangular or triangular) flap. The tension on this type of suture can be varied slightly to allow some control of the apicocoronal positioning of the flap. Interrupted sutures then are placed as needed.

When suturing is complete, chilled, sterile moist cotton gauze is again placed over the flap and pressure is applied for 5 minutes. Pressure to the area provides stability for the initial fibrin stage of clot formation and reduces the possibility of excessive postoperative bleeding and hematoma formation under the flap. The iced gauze also supports hemostasis. Final inspection of the area should confirm that all soft-tissue margins have been closely approximated and bleeding has been controlled. An additional injection of long-acting local anesthetic may be administered at this time, although care must be taken not to inject it directly under the newly repositioned flap. The patient is given a cold compress and instructed to hold it on the face in the surgical area, on for 20 minutes and then off for 20 minutes, for the rest of the day. The patient is also given verbal and written postoperative instructions, including after-hours contact information (Fig. 11.50). The patient should sit in an upright position for approximately 15 minutes and the surgical site should be inspected one more time before the patient is discharged.

Care of Your Mouth After Endodontic Surgery

1. Apply an ice pack to your face next to the surgery area (on for 20 minutes and off for 20 minutes) for the next 5 to 6 hours to help decrease postoperative swelling. Swelling is usually greatest the day after surgery and may be at its worst 2 or 3 days after surgery.

2. Take all medications as directed. Approximately 45 minutes should be allowed for you to feel the effect of pain medication.

3. Clean your mouth as usual (brushing, flossing, etc.) in all areas except the surgical site. Modify cleaning procedures of the teeth in the area of the surgical site to keep from disturbing the area. Do not rinse vigorously during the first 24 hours following surgery. Continue using the prescribed mouth rinse twice a day until after you return to have the sutures removed.

4. Minor oozing of blood from the surgical site may occur in the first 24 hours after surgery. This will produce a pink tinge in the saliva and is not a cause for concern. However, if bleeding is excessive, please contact our office. You may apply pressure to the area with a tea bag or moist cotton gauze.

5. Sutures have been placed and will need to be removed at your next appointment. Please do not lift or pull on your lip to examine the surgical site during the first 2 to 3 days because this may disturb the healing process.

6. A soft diet is recommended for the first 2 or 3 days. Try to avoid foods that are hot, spicy, or hard to chew. It is very important that you drink plenty of fluids (nonalcoholic). This will help your mouth heal.

7. Avoid cigarettes and all other tobacco products.

8. A slight increase in body temperature may occur during the first 24 hours following surgery. This is normal. Infection after endodontic surgery is not typical but can occur. If an infection develops, it usually occurs 2 to 3 days after the surgery. Signs of an infection include sudden increase in pain or swelling, feverish feeling, sore glands in the neck area, and a general flulike feeling. If you think an infection has developed, please contact the office immediately.

If you have any questions, please contact the office during normal office hours at 312-XXX-5555. If you are experiencing problems after office hours, you may contact Dr. _____ at: 312-XXX-1212.

FIG. 11.50 Example of postoperative instructions. Written instructions provide an essential reference for the patient, because verbal instructions often are difficult to remember after surgery. The instructions may be modified as needed; it is important to provide instructions that the patient can understand. For example, the readability of these instructions is at approximately the eighth-grade level using the Flesch-Kincaid Grade Level scale.

A specimen titled, Care of Your Mouth After Endodontic Surgery, reads eight points as follows:

1. Apply an ice pack to your face next to the surgery area (on for 20 minutes and off for 20 minutes) for the next 5 to 6 hours to help decrease postoperative swelling. Swelling is usually greatest the day after surgery and may be at its worst 2 or 3 days after surgery.

2. Take all medications as directed. Approximately 45 minutes should be allowed for you to feel the effect of pain medication.

Selection of the suture material

The properties of an ideal suture material for periradicular surgery include pliability for ease of handling and knot tying, a smooth surface that discourages bacterial growth and wicking of oral fluids, and a reasonable cost. Suture material in size 5-0 is most commonly used, although some clinicians prefer slightly larger (4-0) or smaller (6-0) suture. Sutures smaller than 6-0 tend to cut through the relatively fragile oral tissues when tied with the tension required to approximate the wound margins. Silk suture material has commonly been used in dental surgery for decades and is both inexpensive and easy to handle. However, silk tends to support bacterial growth and allows for a wicking effect around the sutures. For these reasons, other materials are preferable to silk.[92]

Resorbable suture materials (plain gut and chromic gut) are not routinely used for periradicular surgery, although this material may be indicated if the patient will be unavailable for the regular suture removal appointment (48 to 96 hours after surgery) or if the suture will be used in areas of the mouth where access is difficult. The primary problem with resorbable suture materials is the variable rate of resorption—that is, sutures may weaken and dissolve too soon or, more commonly, may remain in the incision area for longer than desired. Gut suture materials are packed in isopropyl alcohol. The handling properties of gut sutures can be improved by immersion in sterile water for 3 to 5 minutes before use.[430]

Suture materials with a smooth Teflon or polybutilate coating (e.g., Tevdec and Ethibond, respectively) are particularly well suited for use in periradicular surgery. Synthetic monofilament suture materials (e.g., Supramid and Monocryl) are also commonly used. These materials are easy to handle and do not promote bacterial growth or wicking of oral fluids to the same extent as silk. Gortex (expanded PTEE-Teflon) sutures have many desirable properties but are more expensive than the previously mentioned materials.

Tissue adhesives such as cyanoacrylate and fibrin glues may hold promise for wound closure after periradicular surgery.[113,196,403,599] Although the currently available research is insufficient to recommend these adhesives as a routine replacement for more traditional suture materials, future applications

Telegram: @dental_k

www.konkur.in

in periradicular surgery are possible.

Guided tissue regeneration and endodontic surgery

The amount and location of bone adjacent to the root structures affect the prognosis of periradicular surgery. Kim and Kratchman[282] propose a six-category classification system to assist in predicting surgical prognosis and determining the need for bone grafting and barrier techniques. Class A (no lesion), class B (small periapical lesion), and class C (large periapical lesion without periodontal communication) all represent situations that are favorable for healing without supplemental grafting or barriers. Class D (similar to class C with independent periodontal pocketing), class E (endodontic-periodontal communication to the apex), and class F (apical lesion with complete loss of buccal bone) represent situations with a more guarded prognosis and usually require concurrent use of bone grafting and barrier techniques. Figs. 11.51–11.63 are examples of cases that required GTR.

FIG. 11.51 **A,** Preoperative periapical radiograph of tooth #19. **B,** Clinical image demonstrating periodontal defect along the facial aspect of the mesial root. **C,** Immediate postsurgical radiograph. BioOss xenograft material was placed. **D,** The 19-month follow-up radiograph showed good periradicular healing.

Set of four radiographs are marked A through D as follows:

A) Radiograph shows mandibular left first molar shows a gray spot at the apex of distal root.

B) Radiograph shows two black spots, with one each placed at the apex of root.

C) Radiograph shows elimination of spots from apex, with a mild spot on the apex of root.

D) Radiograph shows elimination of spots from apex of root.

An apicomarginal defect[141] or a localized bony defect distinguished by a total deficiency of alveolar bone over the entire root length has a significant adverse effect on the outcome, reducing the rate of complete healing by approximately 20% or more when compared to teeth with an isolated endodontic-only lesion.[233,279,499] The presence of a periradicular lesion 15 mm or greater in diameter has also been linked to a poorer prognosis.[233] Advanced periodontitis with deep pocket formation has been associated with chronic periradicular inflammation after endodontic surgery and subsequent

Telegram: @dental_k

www.konkur.in

failure of the root-end surgery.[450] The cause of failure has been identified as in-growth of nonosteogenic tissues into the periradicular surgical site and down-growth of epithelial tissue along the root surface. Successful treatment may depend more on controlling epithelial proliferation than root-end management. GTR techniques have been advocated for use in such cases.[206,547]

The basic principle of guided tissue and bone regeneration is that different types of cells repopulate a wound at different rates during healing. The soft-tissue cells are considerably more motile than the hard-tissue cells, therefore they tend to migrate into the wound more quickly during healing. A barrier interposed between the gingival tissue and the exposed root surfaces and supporting alveolar bone prevents colonization of the exposed root surface by gingival cells. This encourages selective repopulation of the root surface by PDL cells. The use of an absorbable barrier theoretically would allow PDL cells and other cells with osteogenic potential to repopulate the defect, resulting in new connective tissue attachment and bone formation. Dahlin and coworkers[119,120] demonstrated that in monkeys, a significant increase in osseous healing occurs when membranes are used in through-and-through bone defects in periradicular surgery of the lateral maxillary incisors. The use of resorbable GTR membranes in endodontic surgery with buccal apicomarginal type defects also has been shown to enhance regeneration of the periodontium and surrounding bone in dogs.[149] This type of matrix barrier promoted greater amounts of connective tissue and alveolar bone and minimized the formation of junctional epithelium.

Several case reports have discussed the use of GTR techniques in conjunction with endodontic surgery.[5,32,81,123,154,273,337,414,421,432,515,544,549,607] These studies largely have reported favorable outcomes in cases involving large periradicular lesions, through-and-through bone defects, and repair of a surgical perforation or loss of the buccal cortical plate adjacent to the root.

Pecora and colleagues[400] compared the healing of 20 large periradicular defects (>10 mm diameter) with and without the use of nonresorbable membrane. They reported that at 12 months after surgery, the sites in which membranes had been used had healed more quickly and that the quality and quantity of the regenerated bone was superior. One study evaluated

www.konkur.in

periradicular and periodontal healing in cases involving apicomarginal defects when GTR (Bio-Oss and Bio-Gide membrane; Osteohealth Co., Shirley, NY) was performed in conjunction with periradicular surgery. At 12 months after surgery, 86% were considered healed both clinically and radiographically. It was concluded that GTR should be considered as an adjunct to periradicular surgery in cases of apicomarginal defects.[142] However, use of a resorbable membrane when a standard apical osteotomy is performed and the buccal bone over the remainder of the root is intact has no beneficial effect on healing.[186]

Several different types of membranes are available. They can be grouped into two broad categories, nonresorbable and resorbable (Table 11.1). Resorbable membranes are generally better suited for endodontic uses because a second surgical procedure is not required to remove the membrane.

Table 11.1

Examples of Membrane Materials

Composition	Trade Name/Manufacturer
NONRESORBABLE	
Polytetrafluoroethylene	Gortex (WL Gore & Associates Inc, Flagstaff, AZ) TefGen FD (Lifecore Biomedical, Chaska, MN) Bicon Barrier Membrane (Bicon, Boston, MA) Cytoflex (Unicare Biomedical, Laguna Hills, CA)
RESORBABLE	
Laminar bone	Lambone (Pacific Coast Tissues Bank, Los Angeles, CA)
Polylactic acid	Guidor* This product was used extensively in early research with very favorable results (Guidor USA) Atrisorb (CollaGenex Pharmaceuticals, Newtown, PA)
Polyglactic acid	Vicyl Mesh (Ethicon, Somerville, NJ)
Polylactic acid, polyglycolic acid, and trimethylene carbonate	Resolut (WL Gore & Associates Inc, Flagstaff, AZ)

Collagen	Biomend (Zimmer Dental, Carlsbad, CA) Bio-Guide (Osteohealth, Shirley, NY) Bicon Resorbable Collagen Membrane (Bicon, Boston, MA)

*No longer available.

Membranes frequently require support so that the membrane does not collapse into the defect itself. Support for the membrane may be provided by using either a titanium-tented membrane or a graft material. Graft materials have two main functions: to act as a mechanical substructure that supports the membrane and the overlying soft tissues and to serve as a biologic component that enhances bone formation. Bone graft materials (Table 11.2) can be categorized as osteoconductive or osteoinductive. An osteoconductive material provides a framework into which bone can grow. The pore size of the material is similar to that of normal bone, and the material eventually is absorbed and remodeled. An osteoinductive material stimulates the production of new bone cells such that healing occurs more quickly. The BMP family has been investigated extensively for use in this role. A combination of osteoconductive and osteoinductive materials also can be used for bone grafts.

Table 11.2

Examples of Bone Graft Materials

Graft Type	Description	Product/Manufacturer or Source
Autogenous graft	Obtained from patient's own body	Ramus, chin, iliac crest
Allograft	Demineralized freeze-dried human bone (DFDBA)	Osteofil (Regeneration Technologies, Alachua, FL) Grafton (Osteotech, Eatontown, NJ) Dynagraft (GenSci, Toronto, Ontario, Canada) Opteform (Exactech, Gainesville, FL) Puros (Zimmer Dental, Carlsbad CA)

		MTF DeMin Bone (DENTSPLY Friadent CeraMed, Lakewood, CO)
Xenograft	Inorganic bovine/porcine bone particles	BioOss (Osteohealth, Shirley, NY) OsteoGraf (DENTSPLY Friadent CeraMed, Lakewood, CO)
Ceramic/synthetic grafts	Calcium sulfate, calcium phosphate/hydroxyapatite, bioactive glass	CapSet (Lifecore Biomedical, Chaska, MN) OsteoSet (Wright Medical Technology, Arlington, TN) HTR (Bioplant HTR, Kerr Corporation, West Collins, CA) Biogran (3i, Palm Beach Gardens, FL) Norian SRS (Synthes, West Chester, PA) NovaBone-C/M (NovaBone Products, LLC, Sales and Manufacturing, Alachua, FL) PerioGlas (NovaBone Products, LLC, Sales and Manufacturing, Alachua, FL)
Bioactive proteins	Bone morphogenic proteins (BMPs)	Experimental
Combination graft	Allograft, xenograft, or ceramic/synthetic grafts plus bioactive protein	PepGen P15 (DENTSPLY Friadent CeraMed, Lakewood, CO)

The use of GTR techniques raises several additional issues that should be discussed with the patient before surgery. These include the cost of the additional material, the origin of the material (synthetic, animal, or human), the need to manage the wound for a longer period, and potential postoperative complications related specifically to these techniques and materials. Discussion of the composition of the materials to be used is very important, because some patients may have concerns based on religious or ethical grounds. The surgeon must discuss all the ramifications of using these materials with the patient before beginning the procedure, because it is not

Telegram: @dental_k

www.konkur.in

always possible to predict before surgery when grafting materials may be needed.

If GTR techniques are to be used during periradicular surgery, a resorbable membrane should be chosen and a protocol should be followed (see Figs. 11.62 and 11.63):

1. The membrane is extended to cover 2 to 3 mm of bone peripheral to the margins of the crypt; it should be supported with a bone substitute graft material so that it does not collapse into the crypt or onto underlying tooth structures.
2. Tissue closure techniques should ensure total tissue coverage of the membrane. The traditional postoperative compression is eliminated, because this would collapse the membrane onto the underlying structures.
3. Smoking is contraindicated with GTR techniques because it consistently has been shown to affect the outcome adversely.[73,324,445,525,538,539]

Ridge preservation

With the growing use of dental implants for the replacement of missing teeth, clinicians should be aware of ridge preservation strategies, even if they do not place implants.[308] As an example, ridge preservation should be considered when a tooth is determined to have a vertical root fracture during an exploratory surgical procedure and is extracted. In this situation, there is often a complete absence of the buccal bony plate, and simple extraction of the tooth would predispose the patient to a loss of ridge height and width, thereby complicating future implant placement. GTR with graft and barrier placement (as previously described) at the time of extraction may be indicated to create a more favorable site for future implant placement.[31,251,342,608] An atraumatic extraction technique is desirable, as one of the goals is to preserve the maximum amount of existing bone. Periotomes are particularly useful for this type of bone-preserving extraction technique.

Intentional replantation

Telegram: @dental_k

www.konkur.in

Intentional replantation may be an option when surgical access is limited or presents unacceptable risks. Mandibular second molars are a common example for this technique because of the typically thick overlying buccal bone, shallow vestibular depth, and proximity of the root apices to the mandibular canal (Fig. 11.64). However, any tooth that can be atraumatically removed in one piece is a potential candidate for intentional replantation. Contraindications include teeth with flared or moderately curved roots and the presence of periodontal disease. Vertical root fracture has often been considered a contraindication,[401] although some investigators have demonstrated moderate success using a dentin-bonded resin and intentional replantation for the treatment of teeth with root fractures.[226,268,506] The prognosis was generally better for incisors and for teeth with fractures less than two thirds of the root length. Clinical success after 1 year was about 89% and decreased to 59% at 5 years.[226]

www.konkur.in

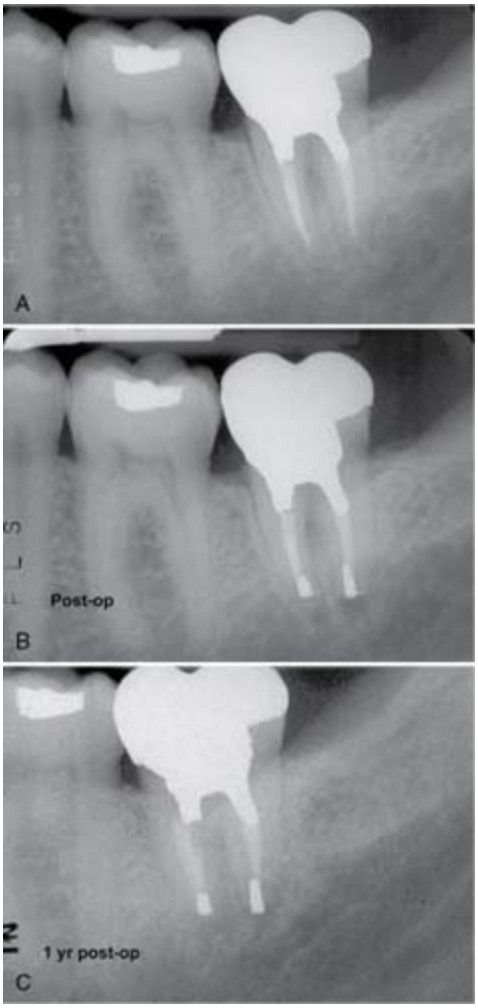

FIG. 11.64 Intentional replantation. **A,** Preoperative radiograph of a mandibular left second molar. The tooth was persistently sensitive to percussion and biting after nonsurgical retreatment. **B,** Radiograph of the tooth immediately after extraction, root-end preparation and filling, and replantation. **C,** At the 1-year follow-up visit, the tooth was asymptomatic and showed good periradicular healing.

Set of three radiographs are marked A through C as follows:

A) Radiograph of mandibular left second molar shows blur, narrow lines of canals.

B) Radiograph shows two radiopaque spots present at the bottom of the root.

C) Radiograph shows healing of tooth post treatment depicted as increase in radiopaque region of tooth.

Source: (Courtesy Dr. Matt Davis.)

The tooth should be extracted with minimal trauma to the tooth and socket.

Telegram: @dental_k

www.konkur.in

Ideally, elevators are not used and the root surface is not engaged with the forceps. All instruments and materials for root-end preparation and filling should be arranged before extraction to minimize extraoral working time. The root surface must be kept moist by wrapping the root with gauze soaked in a physiologic solution, such as Hank's Balanced Salt Solution. After root-end preparation and filling (as described previously in this chapter), the tooth is replanted and the buccal bone is compressed. The patient may be instructed to bite on a cotton roll or other semisolid object to help position the tooth properly in the socket. Occlusal adjustment is indicated to minimize traumatic forces on the tooth during the initial stage of healing. A splint may be applied, but this is often not necessary. The patient should eat a soft diet and avoid sticky foods, candy, and chewing gum for at least 7 to 10 days. Based on clinical observations and several animal model studies, the prognosis for successful healing after replantation is most closely related to avoiding trauma to the PDL and cementum during extraction and minimizing extraoral time.[21,23,391]

Postoperative care

As previously noted, NSAIDs are generally the preferred class of drugs for managing postoperative pain.[9,41,54,143] Ibuprofen (400 to 800 mg) or an equivalent NSAID typically is given before or immediately after surgery and can be continued for several days postoperatively as needed. When additional pain relief is required, a narcotic such as codeine, hydrocodone, or tramadol may be added to the standard NSAID regimen. This strategy may result in a synergistic effect, and therefore greater pain relief, than would be expected with the separate analgesic value of each drug.[148] A useful short-term approach to the management of moderate to severe pain is a "by the clock" alternating schedule of an NSAID and an acetaminophen/narcotic combination.[250,348] Pain after periradicular surgery is typically only mild to moderate. Postoperative pain usually is managed quite well with NSAIDs only, especially when the previously recommended strategy of preoperative NSAID therapy and a long-acting local anesthetic is combined with a minimally traumatic surgical approach.

Sutures are commonly removed 2 to 4 days after surgery.[92,213] This

Telegram: @dental_k

www.konkur.in

recommendation is based on the current understanding of wound healing and the desire to remove any potential irritants from the incision area as soon as possible. Local anesthesia is rarely required, although application of a topical anesthetic may be helpful, especially to releasing incisions in nonkeratinized mucosa. Sharp suture scissors or a #12 scalpel blade can be used to cut the sutures before they are removed with cotton pliers or tissue forceps. A transient bacteremia can be expected after suture removal, even when a preprocedural chlorhexidine mouth rinse is used.[79] Antibiotic coverage should be considered only for patients at high risk of developing bacterial endocarditis.

If healing is progressing normally at the suture removal appointment, the patient does not need to be seen again in the office until the first scheduled recall examination, typically 3 to 12 months after surgery. However, phone contact with the patient approximately 7 to 10 days after suture removal is recommended to confirm the absence of problems. Patients with questionable healing at the suture removal appointment should be reevaluated in the office in 7 to 10 days or sooner if necessary.

Management of surgical complications

Although serious postoperative surgical complications are rare, the clinician should be prepared to respond to patient concerns and recognize when additional treatment may be necessary. Careful case evaluation, adherence to a minimally traumatic surgical technique, and proper patient management, as described previously in this chapter, should result in a low incidence of postoperative complications. Even so, some patients experience mild to moderate postoperative pain, swelling, ecchymosis, or infection. In a prospective study of 82 patients undergoing endodontic surgical treatment, Tsesis and coworkers[545] reported that 76.4% were pain free 1 day after surgery and 64.7% did not report any swelling. Only 4% of the patients in this study experienced moderate pain, and this sequela was closely related to the presence of presurgical symptoms. Postoperative pain typically peaks the day of surgery and swelling reaches its maximum 1 to 2 days after surgery.[294] As previously noted, good evidence supports the use of prophylactic NSAID therapy and a long-acting local anesthetic to reduce the magnitude and

Telegram: @dental_k

www.konkur.in

duration of postoperative pain.

Patients should be advised that some postoperative oozing of blood is normal, but significant bleeding is uncommon and may require attention. Most bleeding can be controlled by applying steady pressure for 20 to 30 minutes, typically with a piece of moist cotton gauze or a tea bag. Bleeding that persists requires attention by the clinician. Pressure to the area and injection of a local anesthetic containing 1:50,000 epinephrine are reasonable first steps. If bleeding continues, it may be necessary to remove the sutures and search for a small severed blood vessel. When located, the blood vessel can be crushed or cauterized to control bleeding. Cauterization may be performed with a heat source commonly used for warm obturation techniques. Local hemostatic agents, as previously described, may also be used. Occasionally, a patient may require hospitalization and surgical intervention to control bleeding, but this is an extremely rare event. Extraoral ecchymosis (Fig. 11.65) occurs when blood seeps through the interstitial tissues; although it may be alarming to the patient and clinician, this condition is self-limiting and does not affect the prognosis.[281] Moist heat applied to the area may be helpful, although complete resolution of the discoloration may take up to 2 weeks. Heat should not be applied to the face during the first 24 hours after surgery.

Telegram: @dental_k

www.konkur.in

FIG. 11.65 Postoperative ecchymosis can be alarming to the patient but resolves spontaneously within 7 to 14 days.

Lateral view of a patient's face shows purple blue bruise below the eye and a yellow patch present below cheek on the mandibular region.

Sinus exposure during surgical root canal procedures on maxillary posterior teeth is not uncommon. Postoperative antibiotics and decongestants are often recommended[16,29,281,568]; however, this practice is controversial, and no evidence supports the routine use of antibiotics and decongestants in these cases. Walton[576] makes a persuasive argument that antibiotics are not routinely indicated for the management of sinus exposures during periradicular surgery when primary closure of the oral-antral communication is possible. Further support for this position is provided by other clinicians who have observed excellent healing and minimal complications after sinus exposure during periradicular surgery.[291,456,579] Clinical judgment should guide the use of antibiotics and decongestants on a case-by-case basis until more conclusive evidence on this practice is available.

No reliable data are available to provide an accurate estimate of the likelihood of paresthesia after surgical root canal treatment. The incidence of

Telegram: @dental_k

www.konkur.in

paresthesia after third molar removal is estimated to be 1% to 4.4%[443]; however, most reported cases of paresthesia after third molar extraction involved the lingual nerve, which is rarely encountered in mandibular periradicular surgery. The incidence of damage to the inferior alveolar nerve after third molar surgery is approximately 1.3%, with only about 25% of these cases resulting in permanent injury.[551] Unless the nerve is resected during surgery, most patients can be expected to return to normal sensation within 3 to 4 months. If the paresthesia does not show signs of resolving within 10 to 12 weeks, referral and evaluation for possible neuromicrosurgical repair should be considered.[167,431] Robinson and Williams[443] presented a useful method for charting and documenting paresthesias. The area of altered sensation is determined by pinching the skin or mucosa with cotton pliers; alternatively, a pinprick can be applied with a sharp instrument. The area of paresthesia is noted with a series of marks on a diagram of the face and mouth. This method provides a graphic and chronologic record of the paresthesia.

Summary

Periradicular surgery today bears little resemblance to the surgical procedures commonly performed as recently as the 1990s. Enhanced magnification and illumination, microsurgical instruments, ultrasonics, new materials for hemostasis, root-end filling, and GTR, and a greater understanding of the biology of wound healing and the etiology of persistent periradicular disease all have contributed to the rapid evolution of periradicular surgery. With proper case selection and operator skill, periradicular surgery can be considered a predictable, cost-effective alternative to extraction and tooth replacement.

12: Regenerative endodontics

Anibal Diogenes, Stéphane Simon, Alan S. Law

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Overview of regenerative dentistry

Advancements in tissue engineering are dramatically changing medicine and dentistry. Tissue engineering is an interdisciplinary field that applies the principles of engineering and the life sciences toward restoring, maintaining, or replacing biologic function. It involves the interplay between stem cells, growth factors, and scaffolds (biologic matrices). It has become increasingly clear that the intentional manipulation of these three factors can lead to the regeneration of tissue function that would not otherwise take place if repair had taken place without intervention.[68] This relatively young field was first applied to medicine with many examples of regenerative medicine approaches used in the clinical practice.[175,222,306] Although the inclusion of tissue engineering in dentistry is more recent, it is also fundamentally changing the way clinicians are treating patients while providing a fertile research field that fosters future advancements and therapies.

Most of the history of dentistry is marked by the evolution of dental materials and techniques tailored to the replacement of lost or diseased tissues with inert materials. This prosthetic replacement of missing dental tissues has prevailed in dentistry since the primordial examples of dental treatments in ancient civilizations.[23,86,145,193,320] In contrast, the goal of regenerative dentistry is to induce biologic replacement of dental tissues and their supporting structures. The potential for regenerative dentistry is in large part due to advancements in biologic therapies that apply principles of tissue engineering with the spatial and temporal assembly of stem cells, growth factors, and scaffolds to achieve the functional regeneration of a missing tissue.

The foundations of regenerative endodontics date back to more than a century ago with the first attempts of vital pulp therapy with the goal of

Telegram: @dental_k

www.konkur.in

maintaining the physiologic function of an injured pulp.[71] Phillip Pfaff in 1756 performed the first reported pulp capping procedure. He concluded that the exposed injured pulp had the potential of repair if the tissue was further irritated with a caustic agent or heated instruments to promote the cauterization of the pulp stomps.[98,113] It was not until 1920 when Datwyler introduced zinc eugenol–based cement as a direct pulp capping agent.[125] Next, D.W. Herman introduced calcium hydroxide as a biocompatible agent to be used in both vital and nonvital therapies in 1921. In 1960 Professor Nygaard-Østby evaluated a revascularization method for reestablishing a pulp-dentin complex in permanent teeth with pulpal necrosis (see later).[220,221] Over the past several decades, the scope and clinical application of regenerative dental procedures have continuously advanced to now include guided tissue regeneration (GTR) or guided bone regeneration (GBR) procedures and distraction osteogenesis,[56,114] the application of platelet-rich plasma (PRP) for bone augmentation,[117] Emdogain for regeneration of periodontal tissues and pulp,[7,55] recombinant human bone morphogenic protein (rhBMP) for augmentation of bone,[61] and clinical trials on the use of fibroblast growth factor 2 (FGF-2) for periodontal tissue regeneration.[171] The potential of regenerative procedures in endodontics has been emphasized by elegant studies demonstrating the regeneration of pulp and dentin using scaffold materials and stem cells.[105,142,144,146,147,251] Thus regenerative dental procedures are emerging as a vital, evolving field of dental care, creating a paradigm shift in many dental specialties, including endodontics.[208] This chapter will review the current status of regenerative endodontic procedures (REPs) with an emphasis on biologic principles and the advantages and limitations of currently available clinical procedures.

Overview of regenerative endodontics

The developing dentition is at risk for pulpal necrosis due to trauma, caries, and developmental dental anomalies such as dens evaginatus.[17-19,67,77,243,244,325] It is important to note that full radicular maturation occurs up to 3 years after the eruption of a tooth in the oral cavity,[204] and the loss of pulp vitality during this period arrests further root development, rendering these teeth susceptible to premature tooth loss. This untoward event in young

Telegram: @dental_k

www.konkur.in

patients with mixed dentition can have devastating consequences that include: altered maxillary and mandibular bone development, interferences with phonics, breathing, and mastication, and importantly, there is a severe detrimental psychosocial effect on young patients.[158,287]

Immature teeth diagnosed with pulp necrosis have been traditionally treated with apexification procedures using either long-term calcium hydroxide treatment[65,66] or immediate placement of a mineral trioxide aggregate (MTA) apical plug.[315] Although these treatments often result in the resolution of signs and symptoms of pathosis, they provide little to no benefit for continued root development.[39] The process of root maturation includes root elongation, apical closure, and further root thickening (Fig. 12.1). This process is mediated through epithelial-mesenchymal interactions between the Hertwig root sheath (HERS) and the apical papilla.[317] Throughout this process, the pulp-dentin complex is formed at the expense of the apical papilla as stem cells migrate and differentiate forming odontoblasts and fibroblasts, reducing the apical papilla size as the root matures (see Fig. 12.1). Unfortunately, this elaborate developmental process can be disrupted by untoward events such as trauma and infection. Thus immature teeth treated with these procedures are considered in a state of "arrested development," and no further root growth, normal pulpal nociception, and immune defense should be expected.

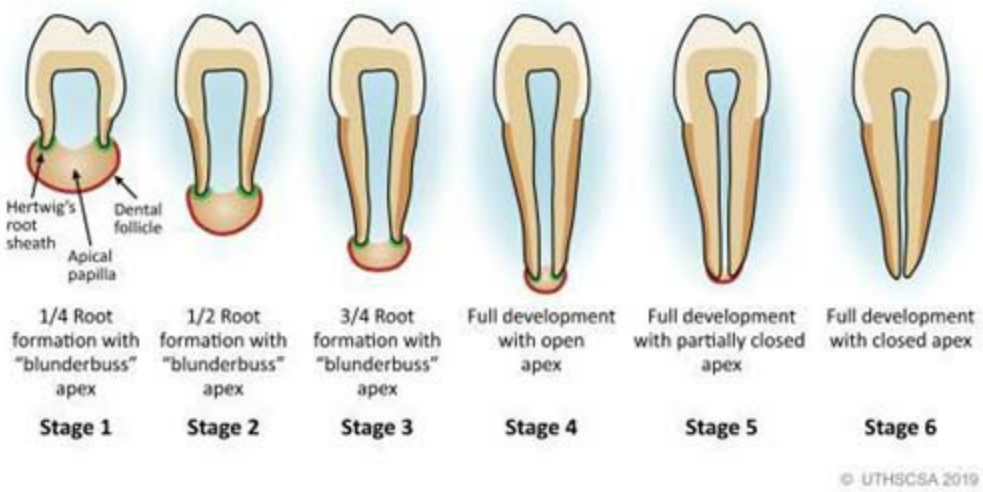

FIG. 12.1 Schematic drawing demonstrating the different stages of root development and the subsequent reduction of the apical papilla

Telegram: @dental_k

www.konkur.in

and Hertwig root sheath.

Lateral cutaway diagram of tooth is labeled from left to right as Hertwig's root sheath, apical papilla and dental follicle. The stages of root development are marked from left to right as:

Stage 1: One-fourth root formation with "blunderbuss" apex.

Stage 2: Half root formation with "blunderbuss" apex.

Stage 3: Three-fourth root formation with "blunderbuss" apex.

Stage 4: full development with open apex.

Stage 5: full development with partially closed apex.

Stage 6: Full development with closed apex.

REPs have been defined as biologically based procedures designed to replace damaged structures such as dentin, root structures, and cells of the pulp-dentin complex.[208] This new treatment modality has emerged as a treatment alternative for these teeth that, in addition to healing of apical periodontitis, aims to promote normal pulpal physiologic functions. These include continued root development, immune competency,[24] and normal nociception, as seen in some published cases.[77] Thus the ultimate goal of these procedures is to regenerate the components and normal function of the pulp-dentin complex to promote tooth longevity and function.

Regenerative endodontics has its foundation on the seminal work by Dr. Nygaard-Østby more than 50 years ago.[226] He hypothesized that a blood clot could be the first step in the healing of a damaged dental pulp, similar to the role of the blood clot in the healing process observed in other areas (e.g., alveolar bone following extraction). To test the hypothesis that the presence of a blood clot within a root canal system promotes healing, mature teeth diagnosed with either vital or necrotic pulp received pulp space débridement followed by foraminal enlargement, medicament dressing for the necrotic cases, evoked intracanal bleeding, and a kloroperka obturation placed coronal to the formed blood clot. Patients (n = 17) were followed for various time periods (17 days to 3.5 years), and then the treated tooth was extracted and the newly formed tissues were histologically examined. The outcomes were similar for all teeth: (1) resolution of symptoms of inflammation related to

Telegram: @dental_k

www.konkur.in

foraminal enlargement and overinstrumentation in as early as 17 days, (2) resolution of signs and symptoms of pathosis for the necrotic cases, and in certain cases, (3) radiographic evidence of apical closure. For the histologic analysis, it was observed that there was ingrowth of connective tissue into the canal space and varied levels of mineralized tissue found along the canal walls as well as "islands" of mineralized tissue embedded within the newly formed tissue (see Fig. 12.1). Because dental pulp is a type of connective tissue with a rich supply of fibroblasts, this general finding was quite promising. However, the inclusion of undesired cell types (e.g., cementoblasts) and the lack of desired cell types (e.g., odontoblasts) indicate that this protocol did not lead to complete histologic regeneration of dental pulp. Despite its shortcomings, this pioneer study laid the foundation for the subsequent studies in the field of regenerative endodontics.

In 1966 a study was published reporting that disinfection could be established primarily with interappointment medication with polyantibiotic mixes (three different formulations used in five cases).[245] The investigators did not purposely evoke intracanal bleeding in this study but instrumented canals short of what they believed to be vital tissue determined by visualization of tissue and pain sensation upon instrumentation. Resolution of signs and symptoms of disease and continued root development was seen for all reported cases. It represented the first reported case where polyantibiotic pastes were used in immature necrotic teeth for disinfection and to promote root development. Five years later, another study was published that included the use of antibiotics in the disinfection protocol and the intentional promotion of intracanal bleeding.[221] Resolution of symptoms and continued root development was a common finding. However, histology of the extracted teeth demonstrated that connective tissue was formed in 28 out of 35 teeth, whereas cellular cementum was formed in 18 out of 35 teeth. Again, these protocols generated acceptable clinical outcomes (e.g., healing of apical periodontitis, lack of symptoms) with only partial evidence of dental pulp phenotype. Collectively, these findings laid the foundation for contemporary regenerative endodontics, demonstrating that repair could take place following root canal disinfection in immature teeth.

The emergence of the field of regenerative endodontics was catalyzed in the early 2000s with the publication of two remarkable case reports.[27,149]

Telegram: @dental_k

www.konkur.in

Since then, there has been an exponential increase in published cases reporting unprecedented clinical outcomes such as resolution of signs and symptoms of apical periodontitis, continued root development, and, in certain cases, normal nociceptive responses to vitality testing.[77,130,173] Among the many published cases, there are two randomized clinical trials[185,211] that, despite limited sample sizes, support the hypothesis that patients with otherwise limited treatment options benefit from these procedures.[297] Importantly, the field of regenerative endodontics has seen a dramatic increase in knowledge gained from translational basic science studies evaluating the interplay of the tissue-engineering components (stem cells, growth factors, and scaffolds) applied to the clinical need and challenges.

Preclinical studies on regenerative endodontics

Applying the principles of tissue engineering to the development of REPs requires research on the correct spatial assembly of distinct stem cells, growth factors/morphogens, and scaffolds to form a functional pulp-dentin complex.[131,142,144,176] In this section, we will review each of these critical components in turn.

Stem cells

Stem cells are defined as a distinct subpopulation of undifferentiated cells with the ability of self-renewal and differentiation into cell lineages of their tissue of origin.[203] They can be classified as pluripotent or multipotent cells. Pluripotent stem cells have the capacity of becoming specialized cells belonging to all three germ layers. Embryonic stem cells are the best example of pluripotent cells. There is a significant body of research on embryonic stem cells, but ethical, legal, and medical (tissue-rejection) issues can render these cell types unsuitable for clinical applications.[208] True pluripotent stem cells can be found only in the developing embryo, and the harvesting of these cells requires destruction of the embryo, hence the legal and ethical concerns with such practice. Yamanka and colleagues reported the groundbreaking finding that somatic cells can be transformed into pluripotent stem cells,

Telegram: @dental_k

www.konkur.in

namely induced pluripotent stem cells (iPSCs).[225] The use of iPSCs does not have the same legal and ethical concerns as the use of embryonic stem cells, but there are still concerns regarding their inherent pluripotent capacity and lack of proliferative control. These cells tend to form teratomas after implantation into a host, a true testament of their high proliferative and differentiation capacities, but making their use in clinical applications challenging, requiring that differentiation into single phenotypically differentiated cells occurs in vitro prior to implantation.[165] On the other hand, all adult mesenchymal stem cells (MSCs) are more restricted in their capacity to differentiate, forming tissues only of mesenchymal origin, and therefore are classified as multipotent.[50] These cells can be found compartmentalized within tissues in "stem cell niches." The mesenchymal tissues (e.g., bone, dental pulp, periodontal ligament) appear to have an enriched population of adult stem cells.[50] These cells were first found in bone marrow decades ago and characterized as self-renewing and plastic-adherent and formed cell colonies with a fibroblastic appearance.[100,101] They were initially called stromal stem cells but later received the now widely accepted terminology "mesenchymal stem cells."[50] It is worth mentioning this terminology is not unanimous, and the characteristics or criteria that define a "stem cell" remain controversial.[51] Nonetheless, most undifferentiated progenitor cells found in the orofacial region are considered MSCs.[83]

Different populations of adult stem cells have been identified in tissue compartments in the oral region. These include stem cells of the apical papilla (SCAPs),[279] inflammatory periapical progenitor cells (iPAPCs),[184] dental follicle stem cells (DFSCs),[205] dental pulp stem cells (DPSCs),[124] periodontal ligament stem cells (PDLSCs),[261] bone marrow stem cells (BMSCs),[100] tooth germ progenitor cells (TGPCs),[285] salivary gland stem cells (SGSCs),[260] stem cells from human exfoliated deciduous teeth (SHEDs),[201] oral epithelial stem cells (OESCs), gingiva-derived mesenchymal stem cells (GMSCs),[156] and periosteal-derived stem cells (PSCs) (Fig. 12.2).[326] Although stem cells have been identified in most oral tissues, the stem cells more likely to be involved in REPs are localized around the periapical region. These include SCAPs, PDLSCs, BMSCs, iPAPCs, and DPSCs (if vital pulp is still present apically).

The apical papilla and its residing stem cells (SCAPs) were first characterized in 2006.[279] The apical papilla (Fig. 12.3) is a dense reservoir of undifferentiated MSCs with great proliferative and odontogenic

Telegram: @dental_k

www.konkur.in

differentiation capacity and are directly involved in root formation during development.[140,246,317] Furthermore, the close proximity of the apical papilla to the apices of teeth in continuum with the root canal space makes this rich source of stem cells readily available for regenerative endodontic therapeutics through autologous cell transfer without the necessity to harvest and manipulate these cells exogenously. The iPAPCs represent another important potential source of stem cells for regenerative endodontics in teeth with well-established apical periodontitis.[58,184] These cells appear to be largely localized in the vasculature within apical granulomatous tissues. Lastly, PDLSCs and BMSCs should be also considered as stem cells sources for regenerative procedures because the action of mechanical disruption of the apical tissue (evoked bleeding) could also trigger the release of these cells, albeit their relative abundance is believed to be significantly less than SCAPs and iPAPCs.

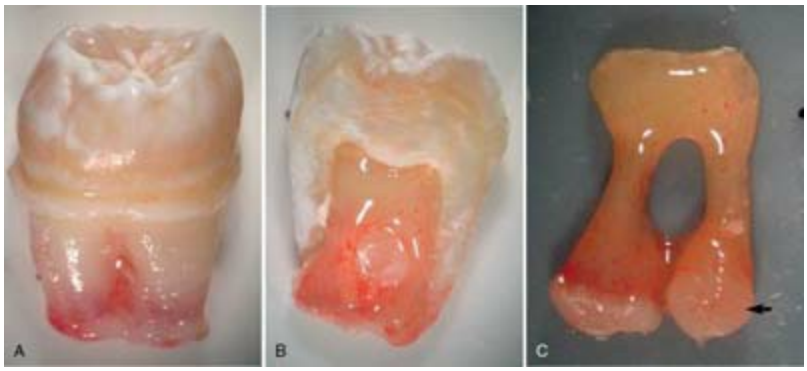

FIG. 12.3 Dissection of an immature permanent tooth indicating the extent of the apical papilla (**A–C**). Note that this structure is likely lacerated during the evoked bleeding step of revascularization cases and thus cells from this structure, including mesenchymal stem cells of the apical papilla (SCAPs), are likely to be delivered into the root canal space. *Arrow* in **C** denotes junction of apical papilla and dental pulp.

A) Lateral close up of a tooth shows crown, neck and roots covered in a sheath of white transopaque membrane.

B) Lateral close up of a tooth shows part of crown and outline of the lower tooth covered in a sheath of white transopaque membrane. A part of root canals is exposed with a circular scar formed between them.

In 2011 a study was conducted to evaluate the presence of MSCs following the evoked-bleeding step in regenerative procedures.[191] It was found that there is a substantial influx of MSCs into root canals during regenerative procedures resulting in an increase greater than 700-fold in the expression of MSC markers (Fig. 12.4). In addition, the cells could be harvested from clinical samples and examined under confocal microscopy (Fig. 12.5). This was the first demonstration that REPs are stem cell–based therapies.[77] Although this study did not evaluate whether the MSCs detected in REPs are derived from the apical papilla, it was assumed that these cells were SCAPs because the evoked-bleeding step lacerated the apical papilla. However, these MSCs are a heterogeneous population of cells that could come from any of the periradicular tissues after the mechanical step of evoking bleeding into the root canal system.

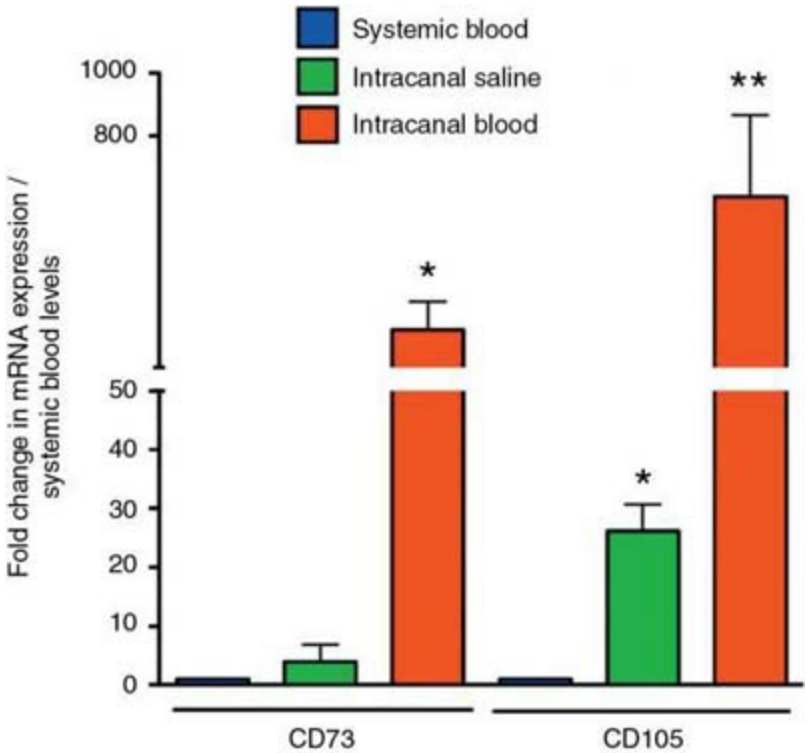

FIG. 12.4 Evoked-bleeding step in endodontic regenerative procedures in immature teeth with open apices leads to significant

www.konkur.in

increase in expression of undifferentiated mesenchymal stem cell markers in the root canal space. Systemic blood, saline irrigation, and intracanal blood samples were collected during second visit of regenerative procedures. Real-time RT-PCR was performed by using RNA isolated from each sample as template, with validated specific primers for target genes and 18S ribosomal RNA endogenous control. Expression of mesenchymal stem cell markers CD73 and CD105 was upregulated after the evoked-bleeding step in regenerative procedures. Data were normalized to the housekeeping gene 18S levels and presented as mean ± standard deviation fold increase in relation to systemic blood levels for each gene and analyzed with one-way analysis of variance with Bonferroni post hoc test (n = 8; *P <.05; **P <.01; n.s., not statistically significant).

Plot shows cluster of differentiation 73 and cluster of differentiation 105 against fold change in mRNA expression and systemic blood levels. The horizontal axis has three bars of systematic blood, intracanal saline and intracanal blood under cluster of differentiation 73 and 105 each. The segmented vertical axis ranges from 0 to 50 in increments of 10 and 800 to 1000. The data is as follows:

Cluster of differentiation 73:

Systemic blood: 1, intracanal saline: 4, intracanal blood: 50 (lower vertical axis) : 100 (upper vertical axis).

Cluster of differentiation 105:

Systemic blood: 1, intracanal saline: 25, intracanal blood: 50 (lower vertical axis) : 600 (upper vertical axis).

The delivery of substantial concentrations of MSCs into the root canal space, despite advanced apical periodontitis or abscess, points to an impressive survival capacity of these cells. In these clinical presentations, low oxygen tension, low pH, and high concentration of endotoxins and inflammatory mediators are expected. Indeed, the finding of high concentrations of the immune cell marker CD14 in those clinical samples indicates that there was still a substantial chronic inflammatory exudate present at the apical region of those teeth. These findings raise the question of how MSCs such as SCAPs can survive during apical periodontitis where a complex microflora, an array of inflammatory mediators, immune cells, and presumably low oxygen tension are commonly encountered. The biologic reason for this apparent resilient survival, despite challenging conditions, may be explained by the relatively low density of blood vessels in the apical papilla in comparison with the adjacent dental pulp, whereas the dental follicle surrounding the apical papilla is highly vascularized and may act as a capillary bed to supply nutrients to SCAPs.[77] Indeed, the apical papilla was found to remain vital despite complete pulpal necrosis and advanced apical periodontitis in animal model of endodontic infection in rodents[290] and dogs.[229] Further evidence of this survival capacity was shown in a clinical case when an apical papilla was harvested through the canal space with a Hedstrom file. This tissue was processed for immunohistochemistry, and

Telegram: @dental_k

www.konkur.in

cells were cultured and found to be multipotent and expressing all recognized marked of MSCs.[59] The cells cultured from the apical papilla of that patient with a history of apical abscess due to pulp necrosis for more than 1 year showed greater mineralization potential than apical papilla cells cultured from healthy extracted third molars.[59] Interestingly, it has been demonstrated that hypoxic environments enhance the proliferation, survival, and angiogenic potential of dental stem cells[4,21,84,305] and that similar enhancing effects were observed when dental stem cells were exposed to bacterial by-products or antigens.[84,308] Thus it appears that SCAPs and surrounding stem cells are equipped to survive and maintain their potential for differentiation in adverse conditions such as apical periodontitis and apical abscesses. Nonetheless, stem cells delivered into root canals after bleeding is evoked from the periradicular tissues are likely from various apical sources or niches, and not restricted to the apical papilla.

A clinical study in 2014 evaluated the intracanal transfer of undifferentiated MSCs from the apical region in adult patients through evoked bleeding.[58] A substantial increase in MSC markers could be detected in intracanal blood samples compared with systemic blood using quantitative real-time polymerase chain reaction (qRT-PCR). In addition, cells were cultured from the intracanal blood sample from tooth #8 in a 35-year-old female patient diagnosed with pulp necrosis and symptomatic apical periodontitis. The cells cultured were adherent to plastic, formed single colonies, coexpressed MSC markers, had high proliferative rates, and differentiated into a mineralizing phenotype.[58] This study supports that apical lesions contain a substantial number of undifferentiated cells and that these cells could participate in an intracanal regenerative or reparative process. Indeed, these procedures have been attempted in adults with fully formed teeth and published as case report[232,318,331] and case series.[252] Although significant root development is not expected in mature roots, it can be argued that regaining nociception and immune defense, a tooth regains surveillance and reparative functions, respectively. However, further evidence is needed to compare the predictability and the long-term success and survival of mature teeth treated with a regenerative approach versus conventional root canal therapy. Regardless of the clinical outcome of current techniques, evidence strongly supports the presence of apical undifferentiated cells in mature teeth

Telegram: @dental_k

www.konkur.in

in adults, opening the possibility for future biologic-based therapies for all patients and not only children with immature teeth.

The dental pulp can be viewed as a core of innervated and vascularized loose connective tissue surrounded by a layer of odontoblasts. The major cell type of this core region is the fibroblast. Together with blood vessels, lymphatics, and neurons, this core tissue is embedded in an extracellular matrix consisting of collagen and other fiber types (see also Chapter 13). DPSCs can be found throughout the dental pulp but are known to accumulate in the perivascular region and the cell-rich zone of Hohl adjacent to the odontoblastic layer.[96,262] Thus DPSCs from both sources are believed to be active participants in the process of reparative dentinogenesis. These cells are recruited to the site of injury following a gradient of chemotactic agents released by resident immune cells and from the damaged dentin.[1,270] The reparative dentin formed by these cells is distinct from the primary, secondary, and reactionary dentin that has been lost.[8,324] It is often called "osteodentin" when found to be disorganized and atubular and having cellular inclusions.[302] This process of cellular repair is known to be enhanced by bioactive materials (e.g., MTA and Biodentine).[168] These materials are known to increase the inherent mineralizing potential of the dental pulp when used in both indirect and direct pulp applications. These biologic events form the basis of contemporary vital pulp therapies that include direct pulp capping and pulpotomies with well-documented high success rates.[137,188,266] However, the physiologic process of tertiary dentinogenesis requires a vital pulp and the resolution of the etiology (e.g., caries or trauma). This process becomes disrupted when the pulp succumbs to injury, resulting in liquefaction necrosis of the dental pulp. Regeneration or repair in this case is only possible with the recruitment or delivery of autologous stem cells to the canal space following adequate disinfection.[77]

Odontoblasts are one of the most specialized cells of the pulp-dentin complex with dentinogenic, immunogenic, and possibly sensorial functions.[40,82,85] Identification of odontoblasts in the intact pulp-dentin complex is easily achieved based on their location and their distinct morphologic characteristics (i.e., columnar polarized cell body with cellular projections into the dentinal tubules). However, identification and characterization of an odontoblast-like cell are far more challenging. One of

Telegram: @dental_k

www.konkur.in

the main reasons for this is that these cells lack a primary odontoblast morphology and unique markers that could be used for identification.[139] Indeed, many markers used for the identification of odontoblast-like cells are also expressed in other mineralizing cell types such as osteoblasts. For example, both odontoblasts-like cells and osteoblasts are similar in the formation of mineralized nodules and in the expression of several proteins such as dentin sialoprotein (DSP), although DSP levels are nearly 400 times greater in odontoblasts than osteoblasts.[309] Measuring only one or two characteristics of a cell might not conclusively identify whether the cell is a true odontoblast. Even among odontoblasts, the phenotype varies in cells located in the apical (squamous shape) versus coronal (tall columnar) pulpal tissue. Importantly, molecular studies have identified many of the genes selectively expressed in odontoblasts.[189,227,228] Lastly, an intermediate filament protein called “nestin” has been shown to be preferentially expressed in odontoblasts or odontoblast-like cells when in the active secretory function. Nestin expression could be used in conjunction with other markers to better identify odontoblast-like cells.[2,3] This knowledge is expected to aid future studies characterizing the conditions necessary for mesenchymal cells of multiple origins to differentiate into odontoblast-like cells. It is likely that definitive cellular identification depends upon both the morphology of the cell and an assessment of the expression of multiple genes.

At least five different types of postnatal MSCs, in addition to DPSCs, have been reported to differentiate into odontoblast-like cells, including SHEDs,[201] SCAPs,[140] iPAPCs,[184] dental follicle progenitor cells (DFPCs),[205] and bone marrow mesenchymal stem cells (BMMSCs).[26] As stated previously, overinstrumentation into the periradicular tissues followed by bleeding into the canal space results in a robust influx of cells with MSC markers in fully mature teeth, similarly to that seen in immature teeth.[58,191] Thus it appears that MSCs from the apical region can be delivered into the root canal spaces in both immature and mature teeth. However, there is growing evidence that MSCs have decreased proliferative and differentiation potential with aging.[166,215] Further research is required to elucidate the age limit for the use of autologous dental-derived stem cells, but these findings suggest that regenerative procedures may be applicable to mature fully formed teeth in adults. Thus it is recognized that more research and development are required

Telegram: @dental_k

www.konkur.in

to make regenerative procedures more predictable for immature teeth and that these procedures may transition to be applicable to fully formed teeth.

Growth factors/morphogens

Dentin is composed of collagen fibers (90%, collagen type I) and noncollagenous matrix molecules (proteoglycans, phosphoproteins, and phospholipids). The collagen fibers act as a grid or matrix, and this structure behaves as a scaffold upon which mineralization can occur. Dentin phosphoprotein (DPP) and DSP are the most abundant dentin-specific proteins among the noncollagenous proteins of organic matrix.[46] DSP resembles other sialoproteins such as bone sialoprotein, but its precise function is still unclear; it may have a role in matrix mineralization.[126] Both DSP and DPP are a part of the small integrin-binding, ligand N-linked glycoproteins (SIBLINGs) which include dentin matrix acidic phosphoprotein 1 (DMP-1), bone sialoprotein, osteopontin, osteocalcin, and osteonectin. These proteins are only a small part of the whole cocktail of noncollagenous proteins which form components of the dentin.[119]

Research on dentin structure and composition has highlighted that the matrix contains some components that may be important in regulating tissue due to their bioactive properties. Based on this, dentin is currently considered a reservoir of growth factors and cytokines.[32,270,274–276] These growth factors/cytokines are secreted by the odontoblasts during primary dentinogenesis, becoming sequestered and trapped or “fossilized” into the dentin matrix after biomineralization (Table 12.1). However, they may become solubilized by demineralization of the matrix, by bacterial acid (caries decay), chemical treatment (ethylenediaminetetraacetic acid [EDTA] rinsing solution, calcium hydroxide or acid etching for bonded restorations), or by restorative materials such as MTA and Biodentine (Fig. 12.6).[272,292]

www.konkur.in

Growth Factors in Dentin Matrix	
Transforming growth factor beta-1 (TGF-β1)	Cassidy et al. (1997)[53]
Transforming growth factor beta-2 (TGF-β2)	Cassidy et al. (1997)[53]
Transforming growth factor beta-3 (TGF-β3)	Cassidy et al. (1997)[53]
Bone morphogenic protein 2 (BMP-2)	Thomadakis et al. (1999)[289a]
Bone morphogenic protein 4 (BMP-4)	About et al. (2000)[3]
Bone morphogenic protein 7 (BMP-7)	Thomadakis et al. (1999)[289a]
Insulin-like growth factor-1 (IGF-I)	Finkelman et al. (1990)[95]
Insulin-like growth factor-2 (IGF-II)	Finkelman et al. (1990)[95]
Hepatocyte growth factor (HGF)	Tomson et al. (2013)[292a]
Vascular endothelial growth factor (VEGF)	Roberts-Clark and Smith (2000)[242a]
Adrenomedullin (ADM)	Musson et al. (2010)[208a]

Other growth factors and their receptors have been shown to be present at the enamel organ–dental papilla interface by immunohistochemistry and in situ hybridization during tooth development and have been implicated in odontoblast differentiation:

- Growth hormone (GH) plays a paracrine and/or autocrine role in dental development.[329]
- Insulin-like growth factor beta-1 (IGF-β1) and beta-2 (IFG-β2)[31,157]
- Transforming growth factor beta-1 (TGF-β1), TGF-β2, and TGF-β3[69,288] and bone morphogenic protein 2 (BMP-2), BMP-4, and BMP-6[303] play a role in the polarization and the differentiation of odontoblasts.[31] Notably in adult pulp, TGF-β1 plays an important role in the regulation of the inflammatory response and tissue regenerative processes.[183]

The dental pulp has well-recognized regenerative potential observed in the process of reparative dentinogenesis.[207,271] In this process, dentin-derived growth factors are believed to play a key role to be deciphered into the regulation of progenitor cell recruitment, cell proliferation, and differentiation of new dentin-secreting cells.[183,270] Indeed, the differentiation of new odontoblast-like cells has also been reported following pulp capping with fibroblast growth factor (FGF), TGF-β1 (Li et al. 2014), and BMP-7.[118,183]

The sequestration of these growth factors in the dentin matrix and their subsequent “fossilization” during the mineralization process appear key to the

Telegram: @dental_k

www.konkur.in

pulp healing process where their release from the matrix may be responsible for various signaling events. These growth factors are extremely potent and have a variety of cell signaling properties. However, their precise localization in the dentin[273] and their various biologic roles remain to be elucidated.

It is possible to imagine opportunities for therapeutic stimulation, inducing a targeted release of these proteins. For example, treatment of dentin with EDTA solution has been shown to dissolve the mineral phase, liberating growth factors that orchestrate the stimulation of progenitors or stem cell differentiation.[104,105,110,270,274,276] Etching with orthophosphoric acid, used for conditioning the dentin in bonding procedures, also promotes demineralization of the dentin and liberation of biologic factors.[81,93] For a long time, calcium hydroxide has been used as a protective lining, especially beneath amalgams fillings, or as a canal disinfection medication. It has been shown to have the ability to release bioactive components from the dentin, including growth factors.[123] Unlike dentin-etching acids which have only brief contact with the dentin, calcium hydroxide remains in place beneath restorations or in canals, allowing for a gentle and continued dissolution, thus releasing growth factors; its action is prolonged and potentially controllable depending on the form of the product. Lastly, calcium hydroxide, a by-product of the use of MTA and Biodentine, appears to underlie release of bioactive dentin-derived growth factors by these two bioactive materials.[292] Thus clinicians may take advantage of potent growth factors stored within dentin with the use of chemical treatments and materials that promote the release of these factors (see Fig. 12.6).

Morphogens

It is also important to keep in mind that a second level of regulation exists during dental development (and thus during pulp regeneration process)—transcription factors. Notably, Msx1 is expressed in polarized preodontoblasts, whereas Msx2 is present in mature odontoblasts.[31] Protein and transcripts for Msx1 have been identified in the pulp mesenchyme at early stages of tooth development and their concentrations decreased at the bell stage.[63] The expression of these transcription factors is under the control of growth factors, and they can ultimately have broad-ranging effects. Significantly, BMP-4 upregulates Msx1 and Msx2 expression. In turn,

Telegram: @dental_k

www.konkur.in

transcription factors regulate further growth factor expression; for example, Msx1 upregulates BMP-4 synthesis in the mesenchyme and Msx2 regulates Runx2 and osteocalcin gene expression during odontogenesis.[37,38]

Growth factors and transcription factors are central to the cascade of molecular and cellular events during tooth development and are responsible for many of the temporospatial morphologic changes observed in the developing tooth germ. For these reasons, they are also likely involved in the regeneration process.

It is also important to consider the nature of the signaling process between the injurious agent and the pulp cells. Bacteria and their toxins are key candidates in the direct stimulation of pulp cells.[82] Lipopolysaccharides (LPS) and other bacterial toxins initiate intrapulpal inflammatory processes by activation of Toll-like receptors (e.g., TLR4 activation by LPS).[76,280] Importantly, both progenitor and dental stem cells have been shown to express these receptors.[40,41,133,134,291,330] Thus stem cells within the dental pulp or periradicular tissues are equipped to detect microorganisms. Exposure of these cells to microbial antigens has been shown to directly modulate the proliferation and differentiation potential of these cells.[134,135,190] A study demonstrated that SCAPs differentiation into odontoblast-like cells was blocked when these cells were in contact with a previously infected dentin, resulting in osteoblastic differentiation instead.[308] This study showed that microbial factors can alter the ultimate differentiation fate of stem cells, reinforcing the notion that the microenvironment in which these cells are found dictates their final phenotype. Lastly, cytokines commonly found in the inflammatory milieu (including that of the dental pulp) have a profound effect on stem cells. For example, it has been recently shown that tumor necrosis factor-α (TNF-α) stimulates differentiation of dental pulp cells toward an odontoblastic phenotype via mitogen-activated protein (MAP) kinase pathway activation and p38 phosphorylation.[233,267] Therefore stem cell fate within the dental pulp is ultimately dictated by a complex cascade of intracellular signaling pathways activated by agents released from microorganisms, dentin, and immune cells.

Interestingly, morphogens are not the only naturally occurring factors found in within teeth. Several growth factors have also been evaluated for their ability to trigger the differentiation of selected MSC populations into

Telegram: @dental_k

www.konkur.in

odontoblast-like cells (Table 12.2). Interestingly, several case studies have reported that patients taking long-term corticosteroids often present with dramatic reduction of the radiographic size of the pulp chamber and up to a fivefold increase in the thickness of the predentin layer.[216,217,283] Although these patients were medically complex patients (e.g., renal failure) taking multiple drugs, the use of corticosteroids appeared to be associated with the observed increased activity of human odontoblasts. Furthermore, these unexpected "side-effects" were also observed in a retrospective study evaluating the association of pulp calcifications and the long-term use of statins.[236] These incidental effects of commonly prescribed medications were further evaluated in translational studies that have extended this general observation by demonstrating that the application of dexamethasone or statins greatly increased the differentiation of human dental pulp cells into odontoblast-like cells.[139,224] This was particularly evident when dexamethasone was combined with 1,25-dihydroxyvitamin D_3.[139] Merely changing the composition of growth factors completely altered the differentiation of these cells, with the same population of cells able to express markers of odontoblasts, chondrocytes, or adipocytes, depending on their exposure to different combinations of growth factors.[309] Such findings emphasize the importance of growth factors in guiding the differentiation of these cells. Other studies have evaluated growth factors administered alone or in various combinations for promoting differentiation of odontoblast-like cells.

Several of the approaches using compounds later found to have growth factor–like effects have immediate clinical implications. First, it is unlikely that a single growth factor will result in maximal differentiation, so combinations of growth factors may be required for evaluation in clinical trials. Related to this point, many of the studied growth factors (e.g., dexamethasone, insulin) are drugs already approved for human use in other medical/dental applications. Second, the demonstration that statins promote the differentiation of an odontoblast-like phenotype suggests that patients clinically taking statins may also have narrowing of the pulp chamber space, similar to the findings previously described for corticosteroids. This would be an important future area of research. Third, clinicians have long used demineralized human bone to augment healing after surgical procedures.[240] Demineralized human bone is thought to contain a natural combination of

Telegram: @dental_k

www.konkur.in

appropriate growth factors and scaffolds, thereby providing an appropriate environment for osteoblast differentiation or function. Extending this concept, several research groups have demonstrated that demineralized human dentin has significant benefit for promoting the differentiation of odontoblast-like cells. Importantly, translational studies in regenerative endodontics have demonstrated that irrigation of dentin with 17% EDTA increases the survival of stem cells[194,300] and odontoblastic differentiation,[106,194] possibly due to the release of bioactive molecules from dentin.[270] Collectively these findings suggest that EDTA irrigation of the dentinal walls as part of a REP could result in improved clinical outcomes.

Scaffolds

An important component of tissue engineering is a physical scaffold.[176,214] Tissues are organized as three-dimensional structures, and appropriate scaffolding is necessary to (1) provide a spatially correct position of cell location and (2) regulate differentiation, proliferation, or metabolism while promoting nutrient and gaseous exchanges. It is known that extracellular matrix molecules control the differentiation of stem cells,[238,239,321] and an appropriate scaffold might selectively bind and localize cells, contain growth factors,[107] and undergo biodegradation over time.[327] Thus a scaffold is far more than a simple lattice to contain cells but instead can be viewed as the "blueprint" of the engineered tissue.

Scaffolds can be classified as either natural or synthetic. Examples of natural scaffolds include collagen,[211,213] glycosaminoglycans, hyaluronic acid (HA), demineralized or native dentin matrix,[28,57,127,212] and fibrin.[107] On the other hand, examples of synthetic scaffolds include poly-L-lactic acid (PLLA),[74] polyglycolic acid (PGA), polylactic-coglycolic acid (PLGA),[87] polyepsilon caprolactone,[322] hydroxyapatite/tricalcium phosphate,[16] bioceramics, and hydrogels such as self-assembly peptide hydrogels.[109] The great majority of currently published REPs involve evoked bleeding and the formation of a blood clot to serve as a scaffold.[77,173] Although it relatively straightforward because it does not require ex vivo manipulation, this simplistic approach is not without challenges. The blood clot is often difficult to achieve, and it does not have many of the properties of the ideal scaffold.

Telegram: @dental_k

www.konkur.in

These properties include easy delivery, adequate mechanical properties, controllable biodegradation, and incorporation of growth factors.[107] In addition, the blood clot contains a great number of hematopoietic cells, which eventually undergo cell death releasing their toxic intracellular enzymes in the microenvironment that may be detrimental to stem cell survival.

Another approach for creating a scaffold involves the use of autologous PRP. It requires minimal ex vivo manipulation, being fairly easy to prepare in a dental setting. PRP is rich in growth factors, degrades over time, and forms a three-dimensional fibrin matrix.[20,148,223] Platelet-rich fibrin (PRF) is an alternative to PRP because it has a three-dimensional architecture conducive with stem cell proliferation and differentiation and contains bioactive molecules.[73,75] These autologous scaffolds have been used successfully in regenerative cases.[173] However, it should be emphasized that, despite their reported use, there are some drawbacks to their clinical use; they require collection of intravenous blood that can be challenging in children, the diversity and concentration of growth factors within PRP and PRF preparations are not controllable, and they lack temporal degradation control and the mechanical strength to support a coronal restoration. Thus, despite some desirable characteristics, other scaffold alternatives to PRP and PRF should be carefully considered.

Hydrogels are a class of scaffolds composed of three-dimensional hydrophilic polymers that absorb water or tissue fluids up to several times their weight.[94,109] These water-swollen materials are easily injectable in their colloidal form, undergoing gelation by chemical (e.g., changes in pH and osmolarity) and/or physical (e.g., temperature change) cues. These materials are highly tunable and biocompatible and can be designed to resemble naturally occurring extracellular matrices.[319] They are of particular interest for regenerative endodontics because they can be easily injected into narrow root canal spaces and be modified to deliver chemotactic and angiogenic agents to drive stem cell homing and supportive angiogenesis.[77,121] Hydrogels made of self-assembly peptides (e.g., Puramatrix)[54] show great potential to be used in endodontic tissue engineering because their sequence includes short peptide sequences, similar to those naturally occurring in tissues, enhancing cell attachment and proliferation.[111] Similarly, fibrin-based scaffolds have been shown to have excellent properties that they may

Telegram: @dental_k

www.konkur.in

be well suited for use in regenerative endodontics. These scaffolds have the potential to be functionalized because they can be loaded with growth factors or dentin matrix protein extracts that promote in vitro and in vivo proliferation and proper differentiation of stem cells.[103,311] In addition, fibrin is a natural scaffold that already is used in medicine (e.g., surgical fibrin glue) and could potentially be adopted for use in REPs.

Decellularized human and animal tissues have been used as scaffolds for many decades in regenerative medicine and dentistry.[116] An adequate decellularization procedure is needed to obtain a suitable ECM scaffold from native tissues. It should minimize the loss or damage of the extracellular matrix (ECM) components and maximize the removal of the cellular component to reduce the immunologic responses.[116,316] There are many examples of decellularized tissues that have been approved by the US Food and Drug Administration (FDA) to be used as scaffolds, including dermal allograft (Alloderm), human peripheral nerves (Avance Nerve Graft, Axogen), porcine small intestine submucosa (SurgiSIS, Cook Biotech), porcine urinary bladder (MatriStem, Acell), and porcine heart valves (Syntergraft, Cryolife).[12,44] Unfortunately, these scaffolds do not share the intricate ultrastructure and molecular composition of the dental pulp. A study demonstrated that human dental pulp from extracted healthy third molars can be successfully decellularized and used as a scaffold.[277] SCAPs, when seeded in the decellularized dental pulp scaffold, proliferated in three dimensions and differentiated into odontoblast-like cells extending cellular processes into dentinal tubules (Fig. 12.7).[277] This study introduced the concept that harvested dental pulp, from otherwise discarded extracted molars, could be made into scaffolds for use in regenerative endodontics, similarly to many other tissues currently available for tissue specific regeneration in medicine. The results of this study have been confirmed by another study that evaluated the use of decellularized swine dental pulp in REPs.[14] The authors demonstrated that the decellularized scaffold allowed for cell proliferation in vitro and that its implantation into pulpectomized teeth in dogs favored the recruitment of apical stem cells resulting in the formation of a vascularized pulplike tissue with expression of an odontoblastic marker (i.e., DSP).[14] Collectively, these studies demonstrated that, similarly to other tissues, dental pulp could be decellularized and used as scaffold for regenerative purposes.

Telegram: @dental_k

www.konkur.in

This allograft approach is further facilitated by the readily available source of this tissue because millions of healthy third molars are extracted and discarded every year in the United States alone. Alternatively, dental pulp from animals such as swine could be used as the source of a xenograft scaffold.

Delivery system

Even with selection of the appropriate cell source, growth factors, and scaffold, the resultant mixture must be delivered in a spatially appropriate fashion into the space of the root canal system. For example, nearly all cells of the body are within 0.1 to 1 mm of a blood vessel to maintain adequate diffusion of oxygen and nutrients.[122,136] This represents a challenge still to be overcome in the currently performed REPs that recruit stem cells[58,191] to a canal space devoid of lateral vascularity and several millimeters away from apical blood vessels. If one were to inject cells, in a cell-based approach, along the entire coronal-apical extent of a root canal system, the vast majority of cells would be expected to succumb to tissue hypoxia. Interestingly, it has been demonstrated that, under hypoxic conditions, stem cells proliferate faster and release greater levels of angiogenic factors such as vascular endothelial growth factor 1 (VEGF-1) that promote targeted angiogenesis into the engineered space.[21] Thus an alternative approach would be to inject a scaffold with chemotactic factors into the root canal. This approach is called

Telegram: @dental_k

www.konkur.in

cell homing because cells are attracted to the scaffold along with supportive blood vessels in a progressive manner;[170] instead of being abruptly delivered to an avascular space (i.e., similar to the current revascularization procedures), the cell-homing approach can be applied in a cell-free[108] (no cells implanted along the chemotactic factors) (Fig. 12.8) or cell-based approach (cells are delivered in the chemotactic-containing scaffold).[77,208] Because dental pulp can be approximated as a loose connective tissue core surrounded by a layer of odontoblasts, the spatial arrangement of cells and growth factors within the scaffold may be particularly important to promote odontogenesis without having complete calcification of the root canal system. Complete recapitulation of the pulp-dentin complex architecture requires additional research effort.

Translational studies

Several elegant studies in regenerative endodontics have used various translational methodologies, including evaluation of clinical samples,[59,191] organotype root canal models,[194,300] tooth slice models,[74,120,251] whole tooth culture,[178,286] and animal models.[106,170,212,213,295,296] These studies have been crucial to provide a strong scientific foundation for the field of regenerative endodontics while allowing for clinical treatment protocol optimization, and the development of new treatment strategies such as inclusion of scaffold and growth factors in regenerative procedures.[211,219]

A study demonstrated that new dentin and pulplike tissue could be generated in human root segments implanted subcutaneously in immunocompromised mice.[141] In this study, root segments had one of the openings sealed with MTA to mimic the coronal restoration of regenerative endodontic cases. The canal space was filled with either SCAPs or DPSCs in

Telegram: @dental_k

www.konkur.in

a PLGA-based scaffold. The implants were harvested 3 months later and processed for immunohistochemical analysis. The results indicated that there was a dramatic circumferential apposition of dentinlike material along the dentinal walls. The new mineralized tissue was lined with polarized cells expressing odontoblastic markers. In addition, the dentinlike tissue was largely atubular and displayed cellular inclusions similar to the histologic presentation of osteodentin. Importantly, the cells from the engineered pulp were positive for human mitochondria demonstrating that they were originated from the implanted human stem cells and not from the host (mouse). Lastly, the root segments that were implanted without stem cells had only connective tissue that did not resemble a pulplike tissue nor had mineralized tissues and odontoblast-like cells. Thus a pulp-dentin complex could be engineered in human roots implanted subcutaneously in immunodeficient mice.

Complete pulpal regeneration in dogs has been accomplished by Nakashima and colleagues.[142] In this elegant study, dental pulp was removed via sterile pulpectomy procedure, followed by placement of sorted CD105+ DPSCs in a collagen gel to the midroot. The remaining coronal part of the canal was back-filled with the collagen gel containing the chemotactic factor stromal-derived factor 1 (SDF-1). Subsequent histology demonstrated formation of new pulp tissue with innervation, vascularization, and odontoblast-like cells lining the dentinal walls. In addition, the engineered pulp had protein and RNA expression similar to the native dental pulp.[142]

In another important study, mobilized DPSCs were generated by selecting DPSCs that migrated towards a concentration gradient of granulocyte colony-stimulating factor (G-CSF). These selected cells were implanted in a collagen gel into pulpectomized root canals.[143] Complete pulpal regeneration was observed, with evidence of new dentin formation, blood vessels, and innervation in the engineered tissue (Fig. 12.9). The impressive results with this cell-based approach have laid the foundation for the use of this technology in emerging clinical trials using stem cell transplantation.[215]

www.konkur.in

It is noteworthy that all the demonstrations of pulp regeneration in animal models were in root canals without history of infection and pulpal necrosis.[142-144,251] Previously infected root canals must be adequately disinfected to suppress chronic inflammation that is detrimental to regeneration.[62] However, many irrigants and medicaments have detrimental effects on stem cell survival and differentiation.[79] Several studies using organotype root canal models and animal models evaluated the combination and concentrations of irrigants and medicaments that allowed for stem cells proliferation and differentiation.[15,177,194,300,310,312] Furthermore, emerging studies demonstrated that bacterial antigens have a robust effect on the terminal differentiation of stem cells guiding these to a greater osteogenic as opposed to an odontoblastic phenotype.[40,308] Thus adequate disinfection, resolution of inflammation, and the detoxification of residual microbial antigens appear to be limiting factors in complete pulpal regeneration, despite exciting results from current advances in dental pulp tissue engineering.[79]

Summary of basic research on regenerative endodontics

Regeneration of a functional pulp-dentin complex relies on the foundation of tissue engineering and can be viewed as a function of the spatially correct delivery of appropriate stem cells and growth factors embedded within a scaffold. Although considerable research has used in vitro cell culture methods to identify key factors regulating the differentiation of odontoblast-like cells, it should be noted that emerging studies conducted in animal models are quite promising for regeneration of this pulp tissue. Preclinical studies involving surgical placement of a human tooth filled with human stem cell/growth factor/scaffold combination into immunocompromised mice[74,106,251] have permitted histologic analysis of neovascularization as well as the differentiation and mineralization activity of newly formed odontoblasts. The use of human cells in a mouse model permits histologic confirmation that the resulting odontoblast-like cells were of human origin. These novel findings provide strong evidence that either human SCAP or DPSC cell sources, on a PLGA scaffold, were able to regenerate a vascularized tissue that had histologic evidence of odontoblast-like cell differentiation and the spatially appropriate formation of dentinlike material onto the root canal walls. Although no specific growth factors were added to

Telegram: @dental_k

www.konkur.in

this mixture, it is important to note that the root canal walls were treated with 17% EDTA, an irrigant known to expose endogenous growth factor proteins embedded in the dentinal walls.[332] This and other related studies provide strong impetus for clinical translational research evaluating various potential regenerative endodontic therapies.

Clinical studies on regenerative endodontics

To date, most case reports, case series, and retrospective studies published in regenerative endodontics have not fully incorporated the tissue-engineering concepts described. Instead, most of these reports present cases with variations of revascularization techniques.[77] These procedures were initially performed empirically with a strong focus on disinfection and the intentional bleeding into the root canal. However, it became obvious that these procedures were in fact stem cell–based procedures with all the three components of the tissue-engineering triad present: stem cells,[58,191] growth factors,[32] and scaffolds.[27,173,293] Important preclinical studies previously described in this chapter have provided the foundational framework for a paradigm shift. This shift represents a clear departure from the traditional "disinfect the canals at all cost" to "disinfection while creating a microenvironment conducive for tissue engineering." Varied terminologies have been given to these procedures that include revascularization,[27] revitalization,[155,181,186,195,299] and maturogenesis.[5,115,210] Of these terms, the most popularly used has been revascularization. This term is largely based on the trauma literature observation that immature teeth could become "revascularized" after trauma. However, revascularization is a term better used for the reestablishment of the vascularity of an ischemic tissue, such as the dental pulp of an avulsed tooth. From this perspective, a focus on revascularization would ignore the potential importance of growth factors and scaffolds that are required for histologic recapitulation of the pulp-dentin complex. Although we appreciate that angiogenesis and the establishment of a functional blood supply are a key requirement in the maintenance and maturation of a regenerating tissue, it is noteworthy that some of the published cases report positive responses to pulp sensitivity tests such as cold or electric pulp test.[77] In addition, histologic analysis of human teeth treated

Telegram: @dental_k

www.konkur.in

with these procedures revealed the rich presence of innervation that includes nociceptors.[24,179] This is evidence that a space that was previously vacant (débrided root canal) may become populated with an innervated tissue supported by vascularity. Furthermore, studies that performed histologic analyses of the tissue formed following these procedures in patients revealed the presence of ectopic bone formation, periodontal ligament, and cementum in addition to vascularized loose connective tissue.[30] However, odontoblast-like cells and newly formed tissue resembling dentin have also been found in certain cases.[24,234,263] Taken together, the core concepts of tissue engineering distinguish a regenerative treatment philosophy from a revascularization philosophy derived from certain trauma cases (which only occur in a low percentage of replanted teeth). Lastly, there have been a number of reports of procedures performed with intentional manipulation of the principles of tissue engineering such as use of autologous PRP,[9,112,151,237,293] PRF,[206,210] and exogenous growth factors and scaffolds.[173] Thus, instead of using different terms for each variant of these procedures, we will refer to them simply as REPs that include past, present, and future procedures that aim to the functional regeneration of the pulp-dentin complex.

Clinical procedures related to regenerative endodontics

There are several challenges clinicians face when presented with an incompletely formed root in need of endodontic treatment.[77] Because the apex is not fully developed and often has a blunderbuss shape, cleaning and shaping of the apical portion of the root canal system can be difficult. The process is further complicated by the presence of thin, fragile dentinal walls that may be prone to fracture during instrumentation or obturation. In addition, the open apex increases the risk of extruding material into the periradicular tissues. Traditionally an immature tooth with an open apex is treated by apexification, which involves creating an apical barrier to prevent extrusion. In many cases, this entails an involved, long-term treatment with $Ca(OH)_2$, resulting in the formation of a hard-tissue apical barrier.[65,66,99] However, a disadvantage of the traditional apexification procedures is that the short-term or long-term use of $Ca(OH)_2$ has the potential to reduce root strength.[29,80,163,250,269,304,323] This finding is consistent with a large case

Telegram: @dental_k

www.konkur.in

series using the traditional apexification protocol; it showed that a major reason for tooth loss following apexification was root fracture.[65,152] In a retrospective study, the use of calcium hydroxide in apexification procedures resulted in the fracture of 23% of the teeth treated during the follow-up period of up to 18 months.[152] The advent of one-step apexification, by creation of artificial barriers (i.e., apical plugs) using materials such as MTA,[196,197,314,315] has greatly decreased the number of appointments and time to completion. Importantly, the one-step apexification has been shown to have as high success rate as apexification with calcium hydroxide in resolving apical periodontitis (both symptoms and radiographic presentation).[297] However, apexification procedures do not generally result in further root development.[39] A primary advantage of REPs in these cases is the greater likelihood there will be an increase in root length and root wall thickness, in addition to the possible regain of vitality responses. In addition to managing the open apex, REPs have been shown to be beneficial in cases of root resorption promoting the arrestment of the resorptive process and repair of the resorbed root (Fig. 12.10).[164,254,301]

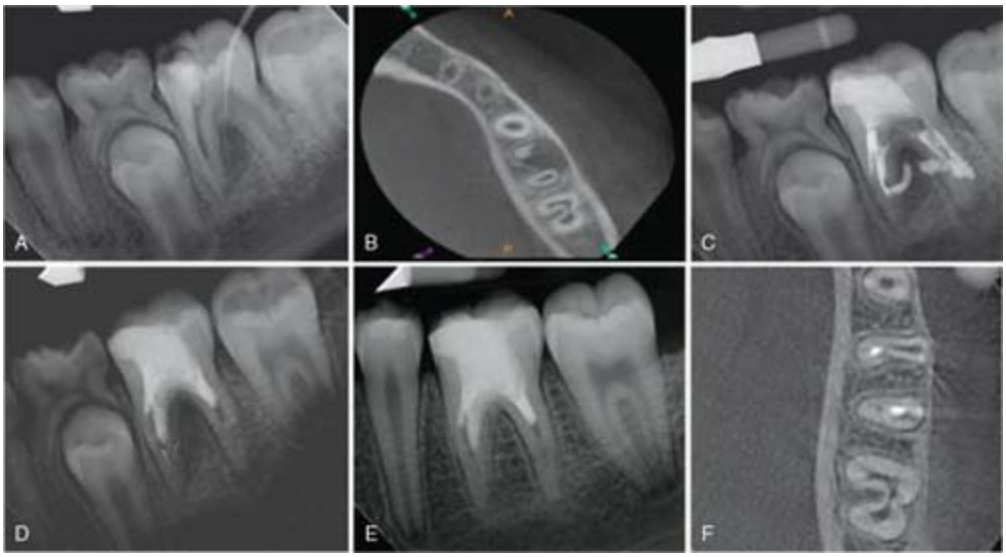

FIG. 12.10 An 11-year-old female was referred for evaluation of tooth #19 diagnosed with pulp necrosis and chronic apical abscess traced with a gutta-percha cone as seen in the periapical (PA) radiograph (**A**). A small-volume CBCT revealed resorption in mesial and distal roots (**B**). The canals were disinfected and medicated with Vitapex (**C**). Four weeks later, the patient was asymptomatic and tooth #19 and the sinus

There have been numerous published cases of REPs. Investigators and clinicians have used a variety of medicaments to disinfect the canal space.[77] Between 51% and 80% of the cases included the use of a triple antibiotic paste (TAP) (a 1:1:1 mixture of ciprofloxacin/metronidazole/minocycline), whereas 20% to 37% used $Ca(OH)_2$ as an intracanal medicament.[77,173]

The development of the TAP was led in large part by Hoshino and colleagues.[258,259] They demonstrated the effectiveness of combinations of antibiotics (and in particular the high efficacy of the combination of ciprofloxacin, metronidazole, and minocycline) in eradicating bacteria from the infected dentin of root canals.[258] Astute practitioners realized that the TAP could be a valuable adjunct for revascularization procedures because it could be used to create an environment favorable for the ingrowth of vasculature and regenerative cells by reducing or eradicating bacteria in the canal space of teeth with necrotic pulps and incompletely formed apices. The

Telegram: @dental_k

www.konkur.in

efficacy of the TAP in disinfecting necrotic root canal systems has been demonstrated in a preclinical model.[313] In this dog study, 60 teeth were accessed and infected by sealing dental plaque and sterile saline on a cotton pellet into the pulp chamber for 6 weeks. By the end of this period, each premolar was radiographically confirmed to have apical periodontitis. The canals were then sampled at three time points: before and after irrigation with 1.25% NaOCl, and 2 weeks after the delivery of the TAP into the root canal system using a Lentulo spiral. Before irrigation, all of the teeth had positive cultures for anaerobic bacteria, with a mean colony-forming unit (CFU) count of 1.7×10^8. After irrigation with 1.25% NaOCl, 10% of the teeth sampled cultured bacteria free. The mean CFU count was 1.4×10^4, or an approximate 10,000-fold reduction in viable bacteria. After dressing with the TAP for 2 weeks, 70% of the teeth sampled cultured bacteria free. The mean CFU count was only 26, which is approximately another 1000-fold drop in bacteria. These findings were confirmed in another related dog study.[289] This study provides strong support for the effectiveness of the TAP in disinfection of immature teeth with apical periodontitis.

As stated previously, calcium hydroxide has been the second most used intracanal medicament in published cases. This application represents a new use of a long established intracanal medicament in endodontics. Although $Ca(OH)_2$ appears to be less effective against some intracanal bacterial species than antibiotic paste formulations,[22,249] its use is associated with lower cytotoxicity to stem cells,[15,247] release of important bioactive growth factors from the treated dentin,[128] and greater survival and proliferation of stem cells in presence of the conditioned dentin.[113] In addition, the relatively short-term use of this medicament in regenerative procedures does not appear sufficient to reduce fracture resistance.[323] Another factor to consider when choosing an intracanal medicament is the ability to remove the medicament from the canal space. One study that addressed this question incorporated radioactive tracers in both calcium hydroxide paste (Ultracal; Ultradent, Inc.) and TAP (Champs Pharmacy; San Antonio, TX).[36] The radiolabeled medicaments were placed in extracted teeth with standardized root canals. After 28 days of incubation, canal spaces were irrigated with a standardized protocol using different techniques. Surprisingly, greater than 80% of the TAP could not be removed from the tooth (Fig. 12.11), and it was found not in the canal lumen but

Telegram: @dental_k

www.konkur.in

greater than 350 μm into the dentinal tubules. In contrast, greater than 80% of calcium hydroxide was removed (see Fig. 12.11) with the remaining medicament present in superficially within dentin.[36] This is an important finding, given that drugs remaining within dentin are likely to have an effect on the fate of stem cells in contact with the treated dentin. Another study revealed that TAP, when used at concentrations typically used in case reports (1 g/mL), and removed with standardized irrigation protocol, resulted in no SCAP survival.[15] In contrast, dentin treated with calcium hydroxide promoted SCAP survival and proliferation, and dentin treated with TAP at a 1 mg/mL had no effect on SCAP survival (Fig. 12.12). The ultimate success of REPs relies on maximizing disinfection and detoxification of the root canal system while minimizing detrimental effect on survival and differentiation of stem cells. Therefore it is imperative that the choice of medicament and concentration must also be antimicrobial. The concentration of 1 mg/mL of TAP, approximately 1000 times less concentrated than commonly used in the form as paste, has been tested for its antimicrobial efficacy in a randomized clinical trial using qRT-PCR to detect residual bacteria.[22] In that study, this concentration of TAP resulted in significantly less measurable bacteria than a mixture of calcium hydroxide and chlorhexidine.[22] This clinical study confirmed the findings of many in vitro studies demonstrating that the effective antibacterial concentration of either triple or double antibiotic is 1 to 10 mg/mL.[150,154,177,249,284] It is important to mention that at the concentration of 1 to 10 mg/mL in aqueous medium, the antibiotic formulation is a solution. Despite this solution being effective clinically,[22] its placement and bioavailability over 2 to 4 weeks is more challenging than in a paste form. However, this concentration can be easily used if combined with a macrogol and propylene glycol pasty vehicle as first described by Hoshino and colleagues to facilitate placement and enhance dentinal tubule penetration.[64,138,259] Alternatively, the use of a hydrogel solution has been investigated and methylcellulose found to be a suitable vehicle for delivery of lower concentration of antibiotic mixtures,[284] and it can be combined with a radiopaque agent to allow for radiographic confirmation of its adequate placement.[307] Lastly, resorbable drug delivery systems are being developed to allow for localized and controlled drug release of predefined concentrations of drugs that are known to be

Telegram: @dental_k

www.konkur.in

antibacterial while less detrimental to the microenvironment and cells involved in the regenerative process.[10,42,162] Thus clinicians must carefully evaluate the advantages and disadvantages of each intracanal medicament while observing the ideal therapeutic concentration.[79]

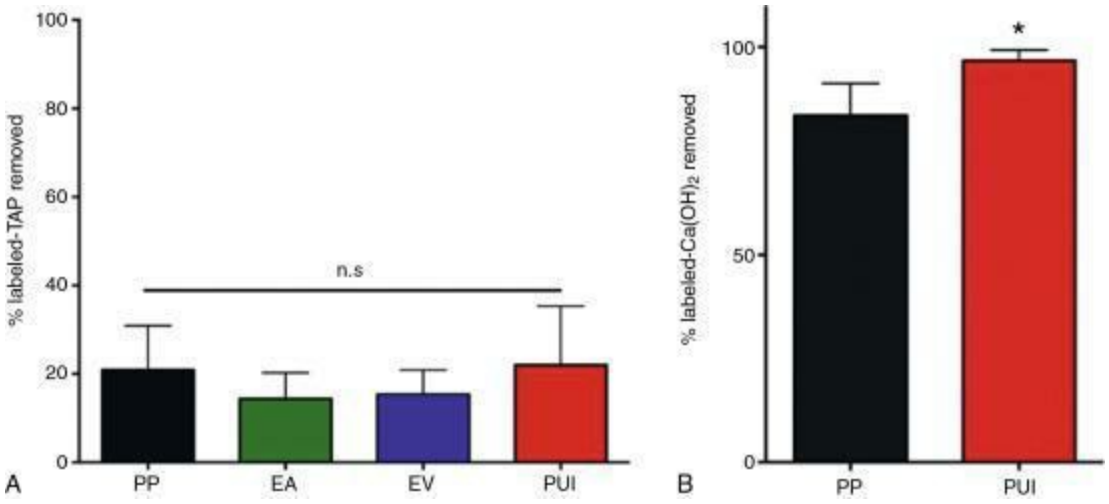

FIG. 12.11 TAP remains in dentin, whereas most $Ca(OH)_2$ is eliminated after endodontic irrigation. Radiolabeled TAP or $Ca(OH)_2$ was placed within canals of standardized root segments and incubated for 28 days at 37°C. The canals were flushed with standardized volumes of EDTA and saline using either positive pressure with a side-vented needle (PP) or positive pressure with ultrasonic activation of irrigants (PUI). There was no difference in labeled TAP removal among groups with only approximately 20% of the medicament being removed by the irrigation protocols (**A**). In contrast, >80% of $Ca(OH)_2$ was removed, with more efficient removal observed in canals irrigated with PUI (**B**). Data are presented as the mean percentage of total radiolabeled medicament removal ± standard error of the mean. *P <.05 tested by the Student t test (n = 12/group).

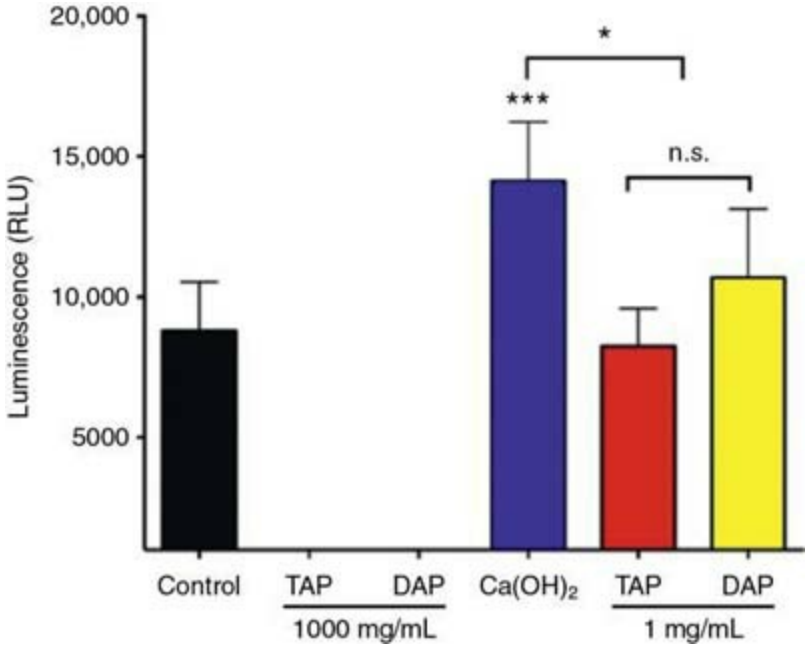

FIG. 12.12 Dentin conditioning for 7 days with medicaments used in REPs has a profound effect on SCAP survival. Standardized dentin disks were treated for 7 days with TAP or double antibiotic paste (DAP) (concentrations of 1000 mg/mL or 1 mg/mL), $Ca(OH)_2$ (Ultracal), or sterile saline (control). SCAP in a Matrigel scaffold (BD Biosciences; Bedford, MA) was seeded into the lumen of the disks after the medicaments were removed and cultured for 7 days. Cell viability (survival) was determined using a luminescent assay. SCAP culture on dentin treated with TAP or DAP at the concentration of 1000 mg/mL resulted in no viable cells. Conversely, dentin conditioning with TAP or DAP at the concentration of 1 mg/mL supported cell viability with no difference from untreated dentin disks (control). Greater survival and proliferation were detected in the group treated with $Ca(OH)_2$. Data are presented as mean ± standard deviation of relative luminescence units (n = 12/group). *P <.05; ***P <.001; n.s., no statistical difference as tested by 1-way analysis of variance.

Regardless of the intracanal medicament used, REPs have common features. Most of these published procedures reported minimal to no instrumentation.[77] This might be due, at least in part, to the concern of further weakening fragile dentinal walls and the difficulty of mechanically debriding canals of such large diameters. Due to the lack of mechanical debridement, clinicians relied on copious irrigation for maximum antimicrobial and tissue dissolution effects.[77] Canals were then medicated for a period that varied from days to several weeks. At the second visit, if signs and symptoms of diseased had subsided, the medicament was removed, the canal was dried, and intracanal bleeding was evoked in most, but not all, cases.[77] In most cases a coronal plug of MTA was placed over the blood clot or a collagen-based internal matrix, followed by a bonded coronal restoration.[173] Each of these steps will be discussed later in light of the current American Association of Endodontists (AAE) considerations for REPs.

Overview of clinical regenerative endodontic procedures

To date, most published clinical studies on REPs are composed of case reports and case series, and fewer retrospective cohort study[13,60,152,198,265,278] and prospective randomized clinical trials[185,211] on regenerative endodontics treatment are available. Although case series do not provide definitive evidence to support a given treatment modality, they do have the advantage of being conducted in actual patients and thus provide a higher level of evidence than preclinical studies. Although techniques for regenerative endodontics have varied in published case reports and case series,[77] there

Telegram: @dental_k

www.konkur.in

have been some consistent features worth noting. Nearly all reported cases involve patients 8 to 18 years old and teeth with immature apices with exception of published cases performed in mature, fully formed teeth.[132,151,209,252–255] Thus the patient age appears to be an important factor in case selection because some studies suggest that younger patients have a greater healing capacity or stem cell regenerative potential. Another important factor related to age is the stage of root development because the large diameter of the immature (open) apex may foster the ingrowth of tissue into the root canal space and may be indicative of a rich source of mesenchymal stem cells of the apical papilla (SCAP; see Figs. 12.2 and 12.3). These tissues are likely lacerated during the evoked-bleeding step and constitute a likely source of MSCs delivered into the root canal space. Indeed, a clinical study comparing outcomes in REPs found that greater root development was detected in the younger patient group, particularly with apices measuring more than 1 mm on the periapical radiographs.[90] Another consistent finding reported in nearly every case is the lack of instrumentation of the dentinal walls related to concerns about the potential fracture of these thin, incompletely developed roots. The lack of instrumentation would be expected to have the benefit of avoiding generation of a smear layer that could occlude the dentinal walls or tubules. On the other hand, the lack of instrumentation could result in remaining bacterial biofilms within dentinal tubes. This is particularly an issue in immature teeth due to large patent dentinal tubules that are more prone to bacterial penetration.[161] This is an issue that has not been evaluated in many cases, but the lack of canal wall instrumentation (and subsequent identification of bacteria in the apical dentin) has been suggested as a reason for failure of a regeneration case.[187] It is important to emphasize that these procedures are marked by robust disinfection protocols. Sodium hypochlorite, either alone or in combination with other irrigants, has been used to disinfect the canal space in most cases.[173] In a majority of cases, a combination of triple antibiotic (minocycline, metronidazole, and ciprofloxacin) was left in the canal space for a period of days to weeks, so the disinfection protocol was primarily a chemical method rather than the chemomechanical approach used in conventional nonsurgical endodontic therapy.[77] In most cases a blood clot was formed in the canal and might serve as a protein scaffold, permitting

Telegram: @dental_k

www.konkur.in

three-dimensional ingrowth of tissue.[77,173] However, it should be noted that few published cases included the use of PRP or platelet-rich fibrin (PRF)[148] and the use of exogenous scaffolds such as collagen type 1[211] and hydroxyapatite.[219]

Nearly all of these reports noted continued thickening of the root walls and subsequent apical closure. Examples of increased root length and thickening of root walls following REPs are seen in Figs. 12.13–12.16. Because of the lack of histology in most clinical cases, it should be recognized that radiographic findings of continued root wall thickness do not necessarily indicate that dentin was formed. Based on histologic results from preclinical studies, it is possible that the radiographic appearance of increased root wall thickness might be due to ingrowth of cementum, bone, or a dentinlike material. Histologic evidence from human extracted teeth following REPs suggests that regenerated pulp tissue may be in the canal space[263] and that the mineralized tissue along the dentinal walls appear to be cementum-like or osteodentin.[195,199,256] It should also be noted in some of the case reports that, although the teeth were nonresponsive to pulp testing, the authors suggested that vital tissue was identified in the apical portion of the canal space. In these cases, necrotic tissue was removed until bleeding was observed, then the canals were disinfected with antibiotic paste or $Ca(OH)_2$.[77] One could argue that by leaving vital pulp tissue in the apical segment of the canal, the resulting progression of root formation is more similar to apexogenesis than revascularization. Although the biologic process may differ between the revascularization and apexogenesis cases presented in these case reports, the goals of the procedures are similarly advantageous and significant. In both procedures, there is healing of the periradicular tissues and a progression of root development in a tooth that would otherwise have had a progression of pulpal and periradicular pathosis.

FIG. 12.15 Regenerative endodontic case illustrating treatment delivered to a 9-year-old male patient with a diagnosis of pulpal necrosis secondary to trauma and periradicular chronic apical abscess on tooth #9 seen on preoperative periapical radiograph (**A**) with sinus track tracing with a gutta-percha cone **(A1),** and with CBCT (**B**). The patient was asymptomatic and has draining facial sinus tract. The tooth was treated with a regenerative procedure using double antibiotic paste (DAP), a mixture of ciprofloxacin and metronidazole for 1 month. At the second appointment, the sinus tract had resolved. Then, the tooth was isolated, and the double antibiotic paste was removed by irrigation with 20 mL 17% EDTA. Intracanal bleeding was evoked from the apical tissues using a precurved #25 hand-file extending approximately 2 mm beyond the root apex. A Collaplug barrier was placed at the mid-root level, then covered with 3-mm white MTA. Fuji II LC glass ionomer was used as a coronal seal of the MTA. The access was then restored with a composite resin and polished (**C**). At the 1-year follow-up, the patient was asymptomatic, responsive to electrical pulp test (EPT), periodontal probings were no greater than 3 mm, and the tooth exhibited grade I mobility without coronal discoloration. Importantly there was appreciable root maturation in addition to resolution of apical radiolucency seen on CBCT (**D**) and periapical radiograph (**E**).

treatment delivered to a 9-year-old female patient with a diagnosis of previously initiated endodontic therapy (pulpectomy) due to pain from pulpal inflammation on #29. Bilateral examination revealed presence of a talon cusp (dens evaginatus) which may have been the etiology of pulpal inflammation on #29. Radiographic examination revealed large periapical radiolucency on a periapical radiograph (**A**) and cone-beam computed tomography (CBCT) (**B**). The tooth was treated with a regenerative procedure using double antibiotic paste as an intracanal medicament for 48 days. On the second visit, the tooth was isolated, and the double antibiotic paste removed by saline irrigation followed by a final rinse with 17% EDTA. The canal was dried and bleeding was evoked followed by placement of an internal matrix of Collaplug 3–4 mm below the CEJ. Mineral trioxide aggregate (MTA) was then placed over it and the tooth was restored with Fuji II LC and Build It. There was complete resolution of apical radiolucency on 1-month recall (**C**), appreciable root development at 5 months recall (**D**) and complete root maturation seen at 1-year recall on both periapical radiograph and CBCT (**E** and **F**, respectively). Greater root maturation is observed at 2.5 years recall periapical radiograph (**G**) and CBCT (**H** and **I**). In addition, the tooth responded to EPT on the 1- and 2.5-year recall visits.

A retrospective study has compared the radiographic changes in 48 revascularization cases to 40 control cases.[39] Although published revascularization cases have been treated with varying clinical protocols, they can be grouped by method of canal disinfection—namely, TAP, $Ca(OH)_2$ treatment, or formocresol treatment. This study applied a mathematic image-correction procedure that permitted the comparison of nonstandardized radiographs with subsequent statistical analysis of radiographic outcomes. The percent change in root dimensions was first compared in two negative control groups (nonsurgical root canal treatment [NSRCT] and MTA apexification) predicted to have little to no change in root dimensions.[39] This provides an internal test that the mathematic analysis was appropriate. The results indicate that these two negative control groups had minimal measured changes in root width (Fig. 12.17) or root length (Fig. 12.18), with the anticipated finding that instrumentation with files of greater taper resulted in a slight but detectable loss of apical root wall width. The results indicated that revascularization treatment with either the TAP or $Ca(OH)_2$ medicament produced significantly greater increases in root length compared with either the MTA or NSRCT control groups. Treatment with the TAP produced significantly greater increases in root wall thickness compared with the MTA and NSRCT control groups. Treatment with $Ca(OH)_2$ resulted in significantly greater change in root wall thickness compared with the NSRCT group, but no differences were observed between these medicaments and the MTA apexification group. Finally, the TAP produced significantly greater differences in root wall thickness compared with either the $Ca(OH)_2$ or formocresol groups. In general, the formocresol group showed the smallest improvement in root length and wall thickness. Secondary analyses indicated that a 12- to 18-month recall is probably the minimal time to judge radiographic evidence of root development, although later time points (36 months) often demonstrate continued root development. Jeeruphan et al. (2012) used a similar method to measure changes in root length and width following apexification versus revascularization.[152] They reported that teeth treated with revascularization showed a significantly greater percentage

Telegram: @dental_k

www.konkur.in

increase in root length (14.9%) compared with teeth treated by either MTA apexification (6.1%) or calcium hydroxide apexification. They also reported that the revascularization protocol produced significantly greater percentage increases in root width (28.2%) compared with teeth treated by either MTA apexification (0.0%) or calcium hydroxide apexification. In addition to measuring changes in root dimensions, the authors reported a survival (defined as retention of the tooth in the arch at the time of the postoperative recall) rate of 100% at an average of 14 months after revascularization treatment. This compared favorably with survival rates of 95% for MTA apexification and 77% for calcium hydroxide apexification. Although prospective randomized clinical trials with standardized radiographic assessment are clearly required, the results of this retrospective study are consistent with a robust outcome of revascularization procedures, particularly when medicated with either a TAP or a $Ca(OH)_2$ medicament.

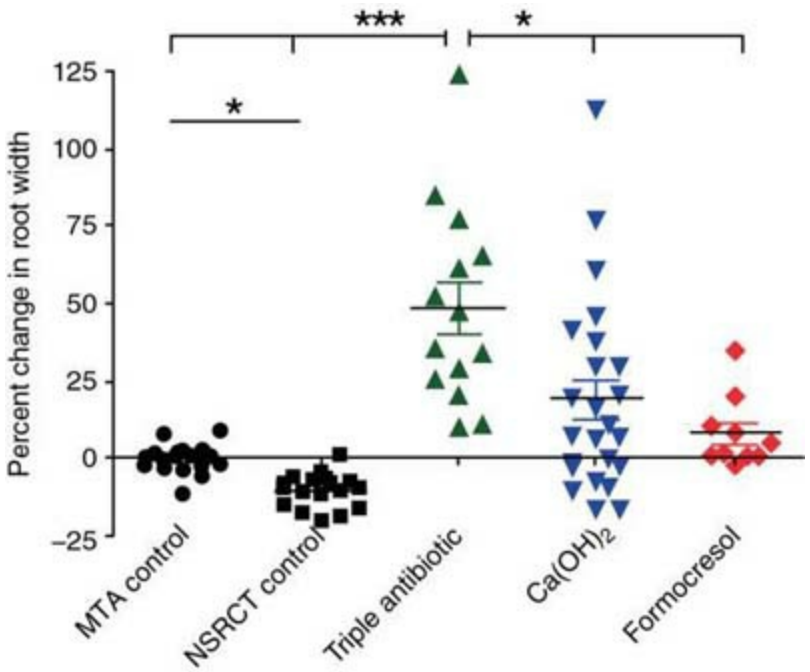

FIG. 12.17 Retrospective analysis of the percentage of change in dentinal wall thickness from preoperative image to postoperative image, measured at the apical third of the root (position of apical third defined in the preoperative image) in 40 control patients and in 48 patients following a revascularization procedure. *, *P* <.05 for each *P* <.05; ***, *P* <.001 versus mineral trioxide aggregate (MTA) apexification control group and NSRCT control group. *P* <.05 versus

Example of a revascularization protocol

Based on current research, several considerations can be reviewed when considering a protocol for revascularization treatment. The first issue is case selection; the best available evidence indicates that this treatment should be considered for the incompletely developed permanent tooth that has an open apex and is negative to pulpal responsiveness testing. Although the ultimate goal of this approach may include a tissue engineering–based method of pulpal regeneration in the fully developed permanent tooth, it should be recognized that current revascularization protocols have not been developed or evaluated for these more challenging cases. Informed consent should include the number of appointments (at least two), the possible adverse effects (primarily potential staining of the crown), the potential lack of response to treatment and alternative treatments, and possible posttreatment symptoms. Because the canal space will not be accessible following revascularization, teeth requiring retention in the canal space for the restoration are not good candidates for REPs. One reason for clinical staining of the crown and any root structure above the gingival margin appears to be due to the presence of minocycline.[169,235,241] This can be minimized by using a delivery system that restricts the drug below the cementoenamel junction (CEJ)[241] or the use of medication that does not contain minocycline such as double antibiotic mixture (ciprofloxacin and metronidazole) or calcium hydroxide. The use of MTA (ProRoot, Dentsply Tulsa Dental, Tulsa, OK), in both gray- and white-form variants,[33,43,48] may also cause tooth discoloration, which can also be reduced but not completely eliminated by a walking bleach technique.[43] Importantly, newer tricalcium silicate materials such as Biodentine and Endosequence BC Root Repair Material-Putty (ES) have

Telegram: @dental_k

www.konkur.in

substantially less discoloration potential, while promoting greater proliferation of SCAPs and differentiation into odontoblastic-like cells than MTA in an in vitro regenerative endodontics model.[200] This is particularly important because these nonstaining materials can be placed above the CEJ, favoring the formation of mineralized tissues in the cervical region of teeth, where ferrule and resistance to fracture are important factors. Importantly, because MTA promoted greater osteoblastic potential than the other tested biomaterials, it is recognized as the best-suited material to be used in MTA plugs and endodontic microsurgeries when bone formation and repair is the desired outcome.[200] Alternative treatments that should be discussed with the patient and guardian would include MTA apexification, no treatment, or extraction.

At the first appointment (Fig. 12.19, *A–E*), the treatment alternatives, risks, and potential benefits should be described to the patient and guardian after collecting clinical information and establishing pulpal and apical diagnoses. Following informed consent, the tooth is anesthetized, isolated, and accessed. Minimal instrumentation should be accomplished perhaps with the use of Hedstrom files circumferentially "brushing" the canal walls without major dentin removal. In addition, an appropriately sized file should be placed in the root canal system and radiographed to determine working length is important. Next, the root canal system should be copiously and slowly irrigated. Because of its proven efficacy as a canal disinfectant and a tissue dissolution agent, sodium hypochlorite (NaOCl) has been the irrigant of choice in most the revascularization case reports.[77] However, studies have demonstrated that treatment of dentin with NaOCl results in an indirect cytotoxic effect on stem cells.[194,300] Importantly, minimal deleterious effect was seen with the use of 1.5% NaOCl followed by 17% EDTA. Thus lower concentration (1.5%) of NaOCl followed by EDTA should be considered as the standard irrigation for REPs.[194] Moreover, the use of chlorhexidine should be limited or avoided because it does not have tissue dissolution capability and has also been shown to be cytotoxic to stem cells. However, if chlorhexidine is used, its cytotoxicity can be largely avoided by adding an inactivation step with a solution of L-alpha-lecithin followed by 17% EDTA.[310] Because canal disinfection relies considerably on chemical irrigants, it is important to place the needle into the apical third and irrigate

Telegram: @dental_k

www.konkur.in

using needles with a closed end and side-port vents (e.g., Max-I-Probe needles), together with a slow rate of infusion, to help to reduce any irrigants passing through the open apex. There is evidence that negative pressure can be beneficial and it should be considered in these procedures.[70] In addition, ultrasonic activation of solutions has been shown to promote greater tissue dissolution in addition to accelerating the release of growth factors from the dentinal walls.[312] Thus ultrasonic activation should be considered, particularly in the last visit for both sodium hypochlorite and the final EDTA irrigation.

prior to the appointment. First appointment: (**A**), Clinical examination revealed a pain upon percussion and palpation. A working length file was placed into the root canal system (**B**). The tooth was slowly irrigated with 20 mL of 1.5% sodium hypochlorite (NaOCl) followed by 20 mL of saline using a Max-I-Probe needle inserted to the apical third (**C**). The canals were dried and medicated with calcium hydroxide paste (Ultracal) (**D**). The patient returned asymptomatic 1 month later. The tooth was isolated, accessed, and the medicament removed by slow irrigation with 1.5% NaOCl followed by 17% EDTA. After the canal was adequately dried, intracanal bleeding was achieved by lacerating the apical tissues (**E**). Blood clotting was observed after approximately 10 minutes **(F).** CollaPlug was placed below the CEJ (**G**) to serve as a matrix to position the white mineral trioxide aggregate coronal to the blood clot (**H**). The tooth was then sealed with a layer of Fuji IX (**I**), etched and restored with a composite (**J**). A final radiograph was taken (**K**). The tooth responded to electrical pulp tested at the 1-year recall, and demonstrated apical closure and moderate dentinal wall thickening (**L**).

The root canal system is then dried with sterile paper points, and the antimicrobial medicament is delivered into the root canal space. The best available evidence would support the use of either an antibiotic mixture (TAP or double antibiotic paste [DAP]) at the concentration of 1 to 10 mg/mL or $Ca(OH)_2$. TAP and $Ca(OH)_2$ have been shown to be effective (see Figs. 12.13 and 12.14). The TAP has the advantage of being a very effective antibiotic combination against endodontic microorganisms; its efficacy is supported by its use in many published cases.[77,173] However, this combination is not approved by the FDA and carries a potential for minocycline staining of the crown. Thus, when performing REPs on teeth in esthetic areas, practitioners should consider the use of calcium hydroxide or eliminating minocycline from the antibiotic paste, sealing the coronal dentin with a dentin-bonding agent or composite. After antimicrobial medicament is placed, the tooth is then sealed with a sterile sponge and a temporary filling (e.g., Cavit), and the patient is discharged for 3 to 4 weeks.

At the second appointment (see Fig. 12.19, *F–M*), the patient is evaluated for resolution of any signs or symptoms of an acute infection (e.g., swelling, sinus tract pain) that may have been present at the first appointment. The antimicrobial treatment is repeated if resolution has not occurred. In most reported cases, the acute signs and symptoms resolved after treatment with the intracanal medicament.[77] Because revascularization-induced bleeding will be evoked at this appointment, the tooth should not be anesthetized with a local anesthetic containing a vasoconstrictor. Instead, 3% mepivacaine can be used, which will facilitate the ability to trigger bleeding into the root canal system. Following isolation and reestablishment of coronal access, the tooth should be copiously and slowly irrigated, possibly together with gentle agitation with a small hand file to remove the antimicrobial medicament, followed by ultrasonic activation of the irrigant with the tip 2 to 3 mm away from the apical foramen. When choosing an irrigant at the second appointment, it is worth considering irrigants such as NaOCl and chlorhexidine may be cytotoxic to stem cells either directly[89] or indirectly

Telegram: @dental_k

www.konkur.in

after dentin has been exposed to the irrigants.[194,300,310] It has been demonstrated that exposure of dentin to 5% to 6% sodium hypochlorite leads to decreased stem cell survival and odontoblastic differentiation. This indirect effect is likely related to various deleterious effects of sodium hypochlorite on the dentin matrix leading to reduced cell attachment[242] and a decrease in dentin matrix-derived growth factors such as TGF-β1.[270,332] Thus it is prudent to continue to use sodium hypochlorite at the concentration of 1.5% on the second visit. Lastly, irrigation with 17% EDTA may be advantageous because it has been shown to release growth factors from dentin and promote stem cell survival and differentiation.[312,332] In addition, Galler et al. (2011), using dentin cylinders transplanted into immunocompromised mice, showed that DPSCs seeded onto EDTA-conditioned dentin differentiated into odontoblast-like cells and had cellular processes extending into the dentin.[106] On the other hand, stem cells differentiated into osteoclasts/odontoclasts, causing resorption on the dentinal walls if dentin was previously treated with 5% sodium hypochlorite. Thus the use of 17% EDTA as the last irrigant promotes attachment, proliferation, and odontoblastic differentiation of stem cells that could further increase with the use of passive ultrasonic irrigation.[312]

After drying the canal system with sterile paper points, a file is placed a few millimeters beyond the apical foramen, and the apical tissue is lacerated with bleeding preferably coronal to the CEJ. A small piece of Colla-Plug (Zimmer Dental, Carlsbad, CA) may be placed over the clot to serve as an internal matrix and prevent the restorative materials from being displaced into the canal space upon placement. Approximately 2 to 3 mm of a bioactive hydraulic cement such as Biodentine, ES, or MTA should be placed as coronal as possible while leaving enough chamber space for a glass ionomer and composite restoration. Although MTA has been used in many of the case reports and may have many desirable properties,[230,231,294,298] it is associated with severe discoloration, making it unsuitable to be used in these procedures.[160,172,174,180] Alternatively, Biodentine or ES putty could be used because there have been encouraging studies demonstrating that they induce stem cell proliferation and odontoblastic differentiation.[178,192,200,328] Indeed, Biodentine[11,282,293] and ES putty[45] have been successfully used in REPs and appear better suited materials due to the reduced risk of discoloration.

www.konkur.in

In addition to follow-up visits in the first several months after REPs to assess for signs of healing, a 12- to 18-month recall should be considered as a reasonable time point to radiographically assess apical healing and root development.[39]

The following box summarizes the steps in a REP. Importantly, these considerations are based on the best available evidence and are likely to change as the field progresses (Box 12.1).

Box 12.1

Treatment Procedures for Regenerative Endodontics

First treatment visit for regenerative endodontics:

1. Informed consent, including explanation of risks and alternative treatments or no treatment.
2. After ascertaining adequate local anesthesia rubber dam isolation is obtained.
3. The root canal systems are accessed and working length is determined (radiograph of a file loosely positioned at 1 mm from root end).
4. The root canal systems are slowly irrigated first with 1.5% NaOCl (20 mL/canal, 5 min) and then irrigated with saline (20 mL/canal, 5 min), with irrigating needle positioned approximately 1 mm from root end.
5. Canals are dried with paper points.
6. Calcium hydroxide or an Antibiotic Paste or solution (combined total of 1–10 mg/mL) is delivered to canal system
7. Access is temporarily restored

Final (second) treatment visit for regenerative endodontics (Typically 2–4 weeks after the first visit):

1. A clinical exam is first performed to ensure that that there is no moderate to severe sensitivity to palpation and percussion. If such sensitivity is observed, or a sinus tract or swelling is noted, then the treatment provided at the first visit is repeated.
2. After ascertaining adequate local anesthesia with 3% mepivacaine (no

Telegram: @dental_k

www.konkur.in

epinephrine) rubber dam isolation is obtained.
3. The root canal systems are accessed; the intracanal medicament is removed by irrigating with 17% ethylenediaminetetraacetic acid (EDTA) (30 mL/canal, 5 min) and then a final flush with saline (5 mL/canal, 1 min).
4. The canals are dried with paper points.
5. Bleeding is induced by rotating a precurved K-file size #25 at 2 mm past the apical foramen with the goal of having the whole canal filled with blood at least to the level of the cementoenamel junction, but preferably coronal to it.
6. Once a blood clot is formed, a premeasured piece of Collaplug (Zimmer Dental Inc., Warsaw, IN) is carefully placed on top of the blood clot, preferably above the cementoenamel junction, to serve as an internal matrix for the placement of approximately 2 mm of a tricalcium silicate biomaterial such as Biodentine (Septodont) or Endosequence BC Root Repair Material-Putty (ES) (Brasseler).
7. A (3 mm) layer of glass ionomer layer (e.g., Fuji IX, GC America, Alsip, IL; or other) is flowed gently over the bioactive coronal barrier and light cured for 40 s.
8. A bonded reinforced composite resin restoration is placed over the glass ionomer.
9. The case needs to be followed-up at 3 months, 6 months, and yearly after that for a total of 4 years.

Clinical measures of treatment outcomes

The goal of conventional endodontic therapy is to maintain or restore the health of periradicular tissues by preventing or healing apical periodontitis. The goals of regenerative procedures extend beyond the goals of conventional endodontic therapy and include continued root development and reestablishment of pulpal vitality while aiming to achieve the functional recapitulation of a healthy pulp-dentin complex. As mentioned earlier, contemporary REPs are being modified and evolving towards accomplishing these additional objectives that are not achievable with conventional nonsurgical root canal therapy. Accordingly, the definition of success for REPs includes multilevel goals that are not mutually exclusive. This

Telegram: @dental_k

www.konkur.in

multilevel approach should be focused on three levels of outcomes: patient-centered, clinician-centered, and scientist-centered outcomes (Fig. 12.20).

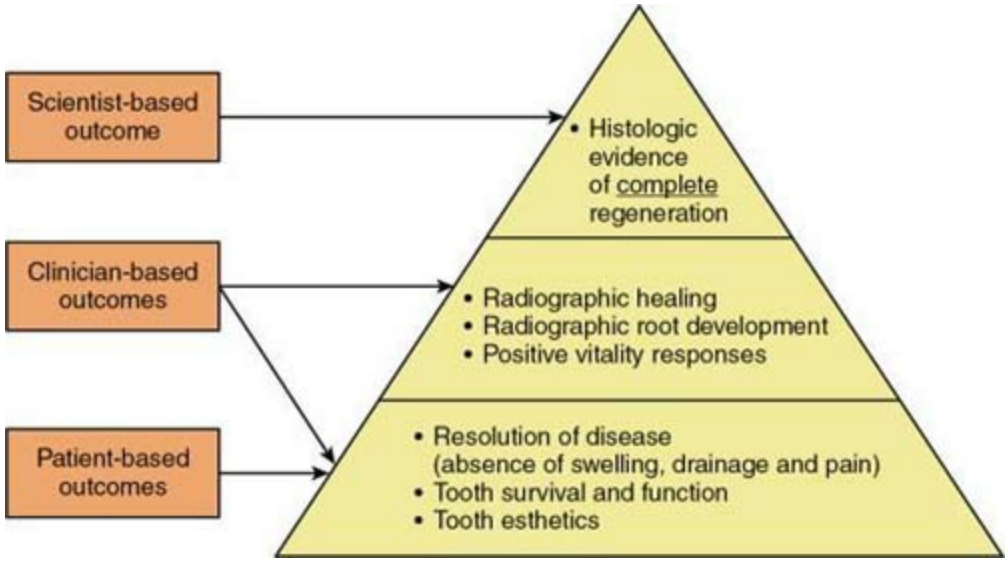

FIG. 12.20 Trilevel outcome assessment pyramid. Regenerative endodontic procedures must be assessed and evaluated in a systematic manner, acknowledging that there are different levels of possible outcomes that carry different meanings and value for patients, clinicians, and scientists. The patient-centered outcomes represent the base of this pyramid, symbolizing the fundamental importance of achieving healing, reestablishment of function, and patient satisfaction and overall well-being.

A three-level pyramidal diagram shows different levels of possible outcomes. Scientist-based outcome leads to histologic evidence of complete regeneration, clinician-based outcomes lead to radiographic healing, radiographic root development and positive vitality responses; and patient-based outcomes lead to resolution of disease (absence of swelling, drainage and pain), tooth survival and function and tooth esthetics.

Source: (Modified from Diogenes A, Ruparel NB, Shiloah Y, Hargreaves KM: Regenerative endodontics: a way forward, *JADA* 147(5):372–380, 2016.)

Patient-centered outcomes

It is well established that the primary goal of endodontics is the prevention and healing of pulpal and periradicular inflammation (i.e., resolution of signs and symptoms of disease). Unfortunately, there has been too much emphasis

Telegram: @dental_k

www.konkur.in

on radiographic assessment while often ignoring the benefit and improvement in the quality of life given to the patient. Clinical studies focusing on patient-centered outcomes in endodontics report that the greatest benefit of endodontic therapy was alleviation of pain and psychological discomfort[202] and improvement in quality of life.[129] Unfortunately, a tooth could be considered a failed treatment if any radiographic finding is detected by a clinician despite the benefit that the treatment has brought to the patient. Not surprising, the definition of clinical success has been a controversial topic in endodontics throughout the history of the specialty, but it has been largely based on lack of symptoms and a strict radiographic criteria,[34,35,102,281] or even dependent on the absence of cultivable microorganisms.[47] This radiographic criteria of success have been present in endodontics for decades and exemplify the disconnect between the expectations of patients, clinicians, and scientists. This disconnect is not unique to endodontics but found in all fields of dentistry and medicine. Patients are the primary stakeholders of their own well-being status, providing feedback on treatment effectiveness, and thus advancing the development of therapies that promote the overall population health. For patients undergoing regenerative procedures, their primary expectation is that teeth are disease free (i.e., no symptoms) and functional (i.e., survival) and have acceptable esthetics.[78]

A recent metanalysis of published REPs and apexification procedures revealed that the success defined as healing of apical periodontitis was found in approximately 91% and 95% for REPs and apexification procedures without statistically significant difference between the two treatment modalities.[297] Likewise, there was no difference in survival rate between REPs and apexification procedures, 98% and 97%, respectively. As pointed out in this metanalysis, most included studies were case series and retrospective studies. Additional randomized clinical trials with large sample sizes and adequate follow-up (>2 years) and recall rates are required to improve the quality of the pooled data. It is important to highlight that this lack of higher-quality studies is not restricted to REPs, but it is also true for apexification procedures. Therefore so far there have not been studies that demonstrated a meaningful difference between REPs and apexification in healing of apical periodontitis and survival rates, with the latter impacted by the often-found short follow-up periods in the current published studies.

Telegram: @dental_k

www.konkur.in

Collectively, currently published studies support that both procedures demonstrate equally acceptable clinical outcomes for healing and survival addressing two of the three patient-centered outcomes.

Esthetics is considered a patient outcome because it is a personal perception. Tooth discoloration has been identified as an adverse event associated with many published REPs.[160,218,235] Tooth discoloration has two primary sources in these procedures: intracanal medicament and coronal barrier material. As discussed previously in this chapter, the undesirable staining that has marked the initial generations of these procedures can be greatly minimized, or completely eliminated, with the use of medicaments that do not contain minocycline and alternative tricalcium silicate biomaterial with lesser staining risk than MTA, such as Biodentine or ES, in esthetic zones.[49,167] In addition, the use of a dentin-bonding agent to seal the dentinal tubules in the pulp chamber is beneficial also to minimizing any possible discoloration from the coronal plug material.[6,169] Therefore a clinician's choice of medicaments and materials has the potential to greatly impact this important patient-centered outcome.

Clinician-centered outcomes

Because the well-being of our patient is the paramount goal of every clinician, we must first ascertain that the patient-centered outcomes (i.e., no symptoms, functional survival, and acceptable esthetics). In addition, clinicians use objective and subjective clinical testing to assess radiographic evidence of healing and continued root development and responses to sensibility tests (i.e., vitality testing).

Continued root development is another desirable outcome of REPs. This is normally evaluated by the clinician upon radiographic evaluation. A total of four possible radiographic outcomes regarding root development can be found (Fig. 12.21). These outcomes range from: type 4—no change; type 3—closing of apical opening without change in elongation/thickening; type 2—root elongation/thickening without closure of the apical opening; and type 1—elongation/thickening and closure of the apex (most desirable outcome). Many published case reports and case series provided initial subjective evidence that REPs promoted radiographic healing and continued root development, until a retrospective study used a quantitative methodology to

Telegram: @dental_k

www.konkur.in

assess root development, comparing to apexification procedures. In this initial study, REPs were found to promote significantly greater root elongation and thickening compared with no changes seen with apexification procedures.[39] The methodology used in this study was adopted by other studies finding similar results.[13,153,159,211] Furthermore, this methodology was later revised and modified to assess changes in radiographic root area.[97] Despite being designed to digitally align radiographs taken in a nonstandardized manner to allow for quantitative measurements, there are instances in which the discrepancy in angulation and acquired image dimension ratios exceed the capacity of the software to perform adequate correction.[159] As a viable alternative, volumetric analysis of acquired cone-beam computed tomography (CBCT) images has been proposed[91] as a method to three-dimensionally quantify changes in root development. This methodology has been used in two studies, both demonstrating that REPs promoted an increase in total root volume.[24,198] A recent randomized prospective study used acquired CBCT volumes to quantify and characterize the type of development detected in cases treated with REPs (n = 69) and apexification procedures (n = 34). In this study, REPs promoted the average root growth of greater than 0.24 mm in approximately 82.6% of the teeth, whereas teeth treated with apexification had no changes in root development. Interestingly, teeth with dental anomaly (i.e., dens invaginatus) as etiology of disease showed more desirable outcome patterns (type 1 and type 2; see Fig. 12.21), whereas trauma was associated with less development and greater incidence of the less desirable type 4 and type 3 outcome patterns (see Fig. 12.21). These data agree with previous case series and retrospective studies that included trauma as the main etiology for less desirable outcomes[13,257] compared with other studies that included less trauma cases.[153] Therefore these studies suggest that trauma negatively affects root development following REPs. Even though more studies are required to establish the correlation of trauma with less desirable outcomes in REPs, these observations agree with different lines of evidence demonstrating that development can be halted if trauma disrupts the interaction between the apical papilla and the HERS.

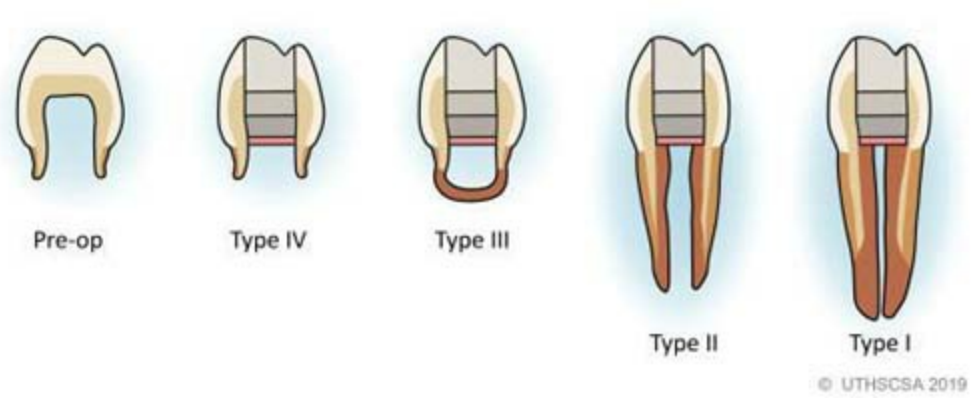

FIG. 12.21 Schematic illustrating the different possible outcomes in root development following regenerative endodontic procedures. Type I shows root development and narrowing of the apical foramen. Type II shows root development but failure of apex closure. Type III shows no root development but closure of the apical foramen. Type IV shows no developments and failure to apex closure.

Lateral diagrams of tooth show five stages of root development as labeled from pre-operative stage to type one.

Vitality responses have been reported in approximately 50% of the published cases.[77] Responses to electric pulp tester (EPT) are more commonly reported than cold responses. These responses to vitality testing (with either cold or EPT), as well as the lack of signs and symptoms of pathosis, suggest the presence of functioning tissue in the canal space. Vitality responses, in addition to continued root development, are a very desirable outcome because "normal" nociception is protective and suggests immune competence of the vascularized tissue. However, the lack of response to sensitivity tests in absence of signs and symptoms of disease should not be interpreted as failure, because there have been several reports of cases demonstrating healing of apical periodontitis and appreciable root development in the absence of a positive response to vitality testing. Histologic examination of teeth treated with REPs has revealed the presence of nerve fibers in a well-vascularized loose connective tissue.[179,199] A recent histologic study of a tooth treated successfully with REPs revealed that this innervation includes nociceptors, thus lending evidence that functional free nerve endings are regenerated following these procedures.[24] These free nerve endings are attracted to the "regenerated" pulp space by a process called axonal targeting that is likely mediated by cellular and noncellular

Telegram: @dental_k

www.konkur.in

processes.[25,72,88]

The significance of reinnervation is the newly formed tissues within the canal space likely transcend the expected physiologic responses to noxious stimuli and infections. It is known that several species of amphibians including salamanders have the capacity of full limb regeneration. Interesting, this amazing regenerative capacity, which has been studied by researchers for decades, is completely lost if the limb is denervated.[92] This concurrent loss of innervation and regenerative potential suggests that peripheral nerves have a pivotal role in regeneration. Further research is required to establish regenerative role in the pulp-dentin complex. Nonetheless, the appropriate innervation of the newly formed pulplike tissue must represent a major goal of these procedures. Lastly, the presence of reinnervation may not always be detected with sensitivity tests that are prone to false-positive and false-negative responses[182] in addition to variations in the thickness and apical extent of coronal barrier and restorations.

Scientist-based outcomes: Regeneration or repair?

Scientific outcomes that are not directly related to the well-being of the patient or the clinical success according to clinician-based outcome measures can be of high importance. These outcomes require scientific methodology to be evaluated and focus on important scientific questions, promoting further research and bring advancements to the field. A good example of a scientist-based outcome is the nature of the tissue formed, including the identification of cellular components, formed following REPs. Undoubtedly, there is considerable debate on whether REPs promote true regeneration or repair.[268] This has strong scientific merit, but it is directly related to the clinical success of a case. Histologic evaluation of teeth that were previously treated with REPs but later extracted due to recurring trauma and fractures suggests that the newly formed tissue does not resemble the lost dental pulp, and formed tissues include ectopic bone, cementum, and periodontal ligament, in addition to commonly found components of the dental pulp complex such as fibroblasts, blood vessels, and nerves.[30,195,199,264]

A recent histologic study evaluated the scientist-based outcomes of two REP cases with different clinical outcomes.[24] One case was considered a clinical failure due to recurrent caries and resorption, despite the noticed

Telegram: @dental_k

www.konkur.in

continued root development resulting in extraction and histologic examination, which revealed the presence of inflammatory infiltrate absence of odontoblast-like cells and the predominant presence of cementum and bone as newly mineralized tissues. The other case was considered a clinical success for 6 years and was extracted only for orthodontic reasons. In addition to the typical ectopic mineralized tissues, odontoblast-like cells were found and newly formed tubular dentin (Fig. 12.22).[24] In addition, this study characterized the innervation found in the tissue as containing peptidergic nociceptors (i.e., expressing calcitonin gene related peptide) (Fig. 12.23). This is the first study that used laser confocal microscopy to identify cellular components and mineralized matrix in teeth treated with REPs.[24] The results of this study are surprising and suggest that, when sophisticated methods are used, further characterization can be achieved, revealing that at least a partial regeneration of components of the pulp-dentin complex is possible. It has been suggested that the current scientist-based status of REPs could be described as guided endodontic repair (GER) because the tissues are not fully regenerated but demonstrate the result of an intentional and directed repair that was not previously thought possible.

Summary

The field of regenerative endodontics is rapidly advancing. This progress is based on the principles of tissue engineering, namely the spatial delivery of appropriate cells, scaffolds, and growth factors. Similar to most rapidly developing fields, the preclinical area of research has outpaced translational

Telegram: @dental_k

www.konkur.in

clinical studies. Preclinical studies have identified several MSC sources capable of differentiating into odontoblast-like cells, as well as candidate scaffolds and growth factors capable of guiding this development. The initial preclinical animal studies indicate that using all three components of the tissue-engineering triad (stem cells, growth factors, and scaffolds) can result in complete regeneration of the pulp-dentin complex. There is a delicate balance between disinfection of the root canal system and the interplay of these three components that warrants more research. It is likely that this combined approach of in vitro and in vivo preclinical research will greatly advance our understanding of the conditions necessary to regenerate a functional pulp-dentin complex.

The translational nature of regenerative endodontic research is allowing for changes to take place in clinic practice in a relatively short time. This crosstalk between basic and clinical sciences is largely fueled by the realization that all three components of the tissue-engineering triad are already present in revascularization procedures: stem cells, scaffold (blood clot), and growth factors (from dentin and blood). Preclinical studies that evaluated the effect of irrigants[194,300,310] and medicaments[15,248] on the survival of stem cells, release of growth factors from dentin,[270] and odontoblastic differentiation[52,106] are shaping the future generations of regenerative procedures. Furthermore, the incorporation of other scaffolds such as PRP, PRF, and gelatin sponges have been used in the clinic practice with encouraging results.[173] Discussion about the requirements of an appropriate scaffold and growth factor was begun in the 1960s by Nygaard-Østby,[221] who had no access to our contemporary instruments, materials, and the entire knowledge base of tissue engineering. Although clinical revascularization procedures do not constitute the ideal regenerative treatment, it is important to note that they do generate a scaffold (fibrin) and growth factors (from platelets and access to proteins embedded in the dentinal walls), and the clinical outcome results in continued radiographic root development of the immature permanent tooth with a diagnosis of pulpal necrosis. Thus REPs provide a treatment of high clinical value in cases with an otherwise poor prognosis. Histologic analyses of REPs conducted in patients or animals suggest that the increase in root dimensions is often due to deposition of cementum-like material, osteodentin, dentin, or bone.

Telegram: @dental_k

www.konkur.in

Future clinical research will likely focus on further translating basic research findings into improved regenerative procedures. For example, the formation of a cementum-like material on the dentinal walls may lead to studies evaluating benefits of REPs for overall tooth resistance to fracture. In addition, it is clear that the multipotent nature of many MSC types could contribute to the finding of cementum deposition. Controlled differentiation of stem cells into odontoblasts is an important area of research and amenable to tissue-engineering concepts. The development of delivery systems that permit structural reinforcement of the cervical area (or ideally, the pulp chamber) might provide clinical opportunities to regenerate lost tooth structure, thereby permitting natural teeth to be retained instead of possible fracture or extraction. Finally, the ultimate and long-term goal for REPs should be to treat the fully formed permanent tooth. Although this situation is more complex than the immature tooth with an open apex and a ready source of stem cells, it provides the unique potential of saving the natural dentition while restoring the sensory, immunologic, and defensive properties of the pulp-dentin complex.

Morphologic zones of the pulp

The pulp-dentin complex

The dental pulp and dentin function as a unit and the odontoblasts represent a crucial element in this system. The odontoblasts are located in the periphery of the pulp tissue, with extensions into the inner part of dentin. Dentin would not exist unless produced by odontoblasts, and the dental pulp is dependent upon the protection provided by the dentin and enamel. Likewise, integrated dynamics of the pulp-dentin complex imply that impacts on dentin may affect the pulpal components and that disturbances in the dental pulp will in turn affect the quantity and quality of the dentin produced.

Odontoblast layer

The outermost stratum of cells of the healthy pulp is the odontoblast layer (Figs. 13.1 and 13.2). This layer is located immediately subjacent to the predentin. The odontoblast processes, however, pass on through the predentin into the inner part of dentin. Consequently, the odontoblast layer is actually composed of the cell bodies of odontoblasts. In addition, capillaries, nerve fibers, and dendritic cells may be found among the odontoblasts.

In the coronal portion of a young pulp that is actively secreting collagen, the odontoblasts assume a tall columnar form.[63] The odontoblasts vary in height; consequently, their nuclei are not all at the same level and are aligned in a staggered array, often described as a palisade appearance. This organization makes the layers appear to be three to five cells in thickness even though there is only one actual layer of odontoblasts. Between adjacent odontoblasts there are small intercellular spaces approximately 30 to 40 nm in width. Odontoblast cell bodies are connected by tight and gap junctional complexes.[29 63,162] Gap junctions are formed by connexin proteins[115] that permit cell-to-cell passage of signal molecules.

The odontoblast layer in the coronal pulp contains more cells per unit area than in the radicular pulp.[245] Whereas the odontoblasts of the mature coronal pulp are usually columnar, those in the midportion of the radicular pulp are more cuboidal.[63] Near the apical foramen, the odontoblasts appear as a squamous layer of flattened cells. Because fewer dentinal tubules per unit area are present in the root than in the crown of the tooth, the odontoblast cell bodies are less crowded and are able to spread out laterally.[245] During maturation and aging, there is a continued ongoing crowding in the odontoblast layer, particularly in the coronal pulp, due to narrowing of the pulp space. Apoptosis of odontoblasts seems to adjust for this limited space during development.[257]

There is a series of specialized cell-to-cell junctions (i.e., junctional complexes), including desmosomes (i.e., zonula adherens), gap junctions (i.e., nexuses), and tight junctions (i.e., zonula occludens) that connect adjacent odontoblasts. Spot desmosomes located in the apical part of odontoblast cell bodies mechanically join odontoblasts together. The numerous gap junctions provide permeable pathways through which signal molecules can pass between cells (Fig. 13.3) to synchronize secretory activity that produces relatively uniform predentin layers (see Fig. 13.2). These junctions are most numerous during the formation of primary dentin. Gap junctions and desmosomes have also been observed joining odontoblasts to the processes of fibroblasts in the subodontoblastic area. Tight junctions are found mainly in the apical part of odontoblasts in young teeth. These structures consist of linear ridges and grooves that close off the intercellular

Telegram: @dental_k

www.konkur.in

space. However, tracer studies suggest direct passage of small elements from subodontoblastic capillaries to predentin and dentin between the odontoblasts.[359] It appears that tight junctions determine the permeability of the odontoblast layer when dentin is covered by enamel or cementum by restricting the passage of molecules, ions, and fluid between the extracellular compartments of the pulp and predentin.[29] During cavity preparation, these junctions are disrupted, thereby increasing dentin permeability.[380,381]

Cell-poor zone

Telegram: @dental_k

www.konkur.in

Immediately subjacent to the odontoblast layer in the coronal pulp, there is often a narrow zone approximately 40 μm in width that is relatively free of cells (see Fig. 13.1) and hence is called the *cell-free layer of Weil*. It is traversed by blood capillaries, unmyelinated nerve fibers, and the slender cytoplasmic processes of fibroblasts (see Fig. 13.2). The presence or absence of the cell-poor zone depends on the functional status of the pulp.[63] It may not be apparent in young pulps, where dentin forms rapidly, or in older pulps, where reparative dentin is being produced.

Cell-rich zone

In the subodontoblastic area, there is a stratum containing a relatively high proportion of fibroblasts compared with the more central region of the pulp (see Fig. 13.1). It is much more prominent in the coronal pulp than in the radicular pulp. Besides fibroblasts, the cell-rich zone may include a variable number of immune cells like macrophages and dendritic cells but also undifferentiated mesenchymal stem cells (MSCs).

On the basis of evidence obtained in rat molar teeth, it has been suggested[128] that the cell-rich zone forms as a result of peripheral migration of cells populating the central regions of the pulp, commencing at about the time of tooth eruption. Migration of immunocompetent cells out of and into the cell-rich zone has been demonstrated as a result of antigenic challenge.[428] Although cell division within the cell-rich zone is rare in normal pulps, the death of the odontoblasts triggers a great increase in the rate of mitosis. Because odontoblasts are postmitotic cells, irreversibly injured odontoblasts are replaced by cells that migrate from the cell-rich zone onto the inner surface of the dentin.[100] This mitotic activity is probably the first step in the formation of a new odontoblast layer.[74,261,263,345] Studies implicate stem cells as a source for these replacement odontoblasts.[353]

Pulp proper

The pulp proper is the central mass of the pulp (see Fig. 13.1). It consists of loose connective tissue and contains the larger blood vessels and nerves. The most prominent cell in this zone is the fibroblast.

www.konkur.in

Cells of the pulp

Odontoblast

Because odontoblasts are responsible for dentinogenesis, both during tooth development and aging, the odontoblast is the most characteristic and specialized cell of the dentin-pulp complex. During dentinogenesis, the odontoblasts form dentin and the dentinal tubules, and their presence within the tubules makes dentin a living responsive tissue.

Dentinogenesis, osteogenesis, and cementogenesis are in many respects quite similar, and odontoblasts, osteoblasts, and cementoblasts have many characteristics in common. Each of these cells produces a matrix composed of collagen fibrils, noncollagenous proteins, and proteoglycans that are capable of undergoing mineralization. The ultrastructural characteristics of odontoblasts, osteoblasts, and cementoblasts are likewise similar in that each exhibits a highly ordered rough endoplasmic reticulum (RER), a prominent Golgi complex, secretory granules, and numerous mitochondria. In addition, these cells are rich in RNA, and their nuclei contain one or more prominent nucleoli. These are the general characteristics of protein-secreting cells.

The most significant differences among odontoblasts, osteoblasts, and cementoblasts are their morphologic characteristics and the anatomic relationship between the cells and the mineralized structures they produce. Whereas osteoblasts and cementoblasts are polygonal to cuboidal in form, the fully developed odontoblast of the coronal pulp is a tall columnar cell.[63,245] In bone and cementum, some of the osteoblasts and cementoblasts become entrapped in the matrix as osteocytes or cementocytes, respectively. The odontoblast, on the other hand, leaves behind a cellular process to form the dentinal tubule, and the cell body resides outside the mineralized tissue. Lateral branches between the major odontoblast processes interconnect[180,258] through canaliculi, just as osteocytes and cementocytes are linked through the canaliculi in bone and cementum. This provides a pathway for intercellular communication and circulation of fluid and metabolites through the mineralized matrix.

The ultrastructural features of the odontoblast have been the subject of numerous investigations. The cell body of the active odontoblast has a large nucleus that may contain up to four nucleoli (Fig. 13.4). The nucleus is

Telegram: @dental_k

www.konkur.in

situated at the basal end of the cell and is contained within a nuclear envelope. A well-developed Golgi complex, centrally located in the supranuclear cytoplasm, consists of an assembly of smooth-walled vesicles and cisternae. Numerous mitochondria are evenly distributed throughout the cell body. RER is particularly prominent, consisting of closely stacked cisternae forming parallel arrays that are dispersed diffusely within the cytoplasm. Numerous ribosomes closely associated with the membranes of the cisternae mark the sites of protein synthesis. Within the lumen of the cisternae, filamentous material (probably representing newly synthesized protein) can be observed.

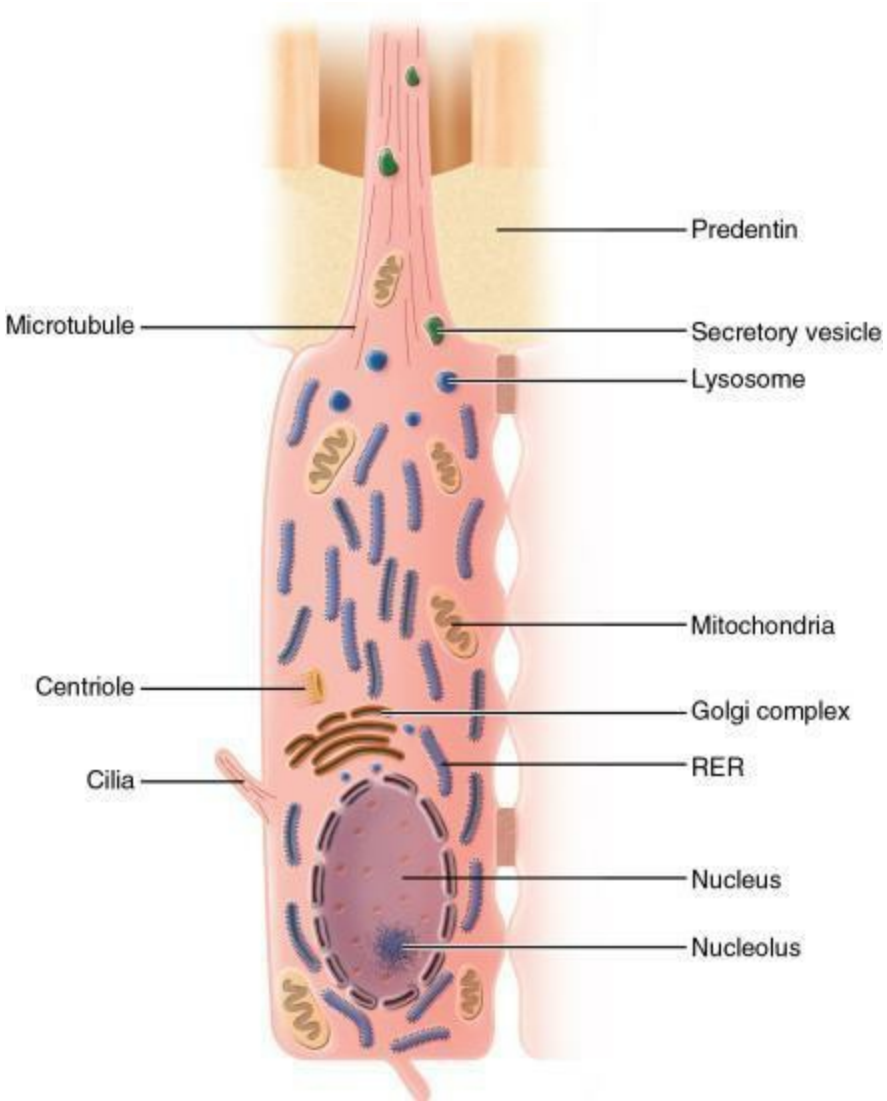

FIG. 13.4 Diagram of a fully differentiated odontoblast. *RER,* Rough

endoplasmic reticulum.

Differentiated odontoblast with labels as follows: Predentin, secretory vesicle, lysosome, mitochondria, Golgi complex, RER, nucleus, nucleolus, cilia, centriole, and microtubule.

The odontoblast appears to synthesize mainly type I collagen,[212,408] although small amounts of type V collagen have been found in the extracellular matrix (ECM). In addition to proteoglycans[39,85,125] and collagen,[212,224] the odontoblast secretes dentin sialoprotein[41] and phosphophoryn,[41,70] a highly phosphorylated phosphoprotein involved in extracellular mineralization.[41,78] Phosphophoryn is unique to dentin and is not found in any other mesenchymal cell types.[78] The odontoblast also secretes both acid phosphatase and alkaline phosphatase. The latter enzyme is closely linked to mineralization, but the precise role of alkaline phosphatase in dentinogenesis is not completely understood. Acid phosphatase, a lysosomal enzyme, may be involved in digesting resorbed material from the predentin matrix.[89]

In contrast to the active odontoblast, the resting or inactive odontoblast has a decreased number of organelles and may become progressively shorter.[63,245] These changes can begin with the completion of root development and eruption when dentin production shifts from primary to secondary dentin.

Direct actions of odontoblasts on dental nerves and vice versa have been proposed based on the excitability of odontoblasts, the differential expression of receptors for neuropeptides on odontoblasts (Fig. 13.5), the demonstration of the thermosensitive transient receptor potential (TRP) ion channels, and the finding that all nine voltage-gated sodium channels are variably expressed on odontoblasts in developing, mature, and aging rat teeth.[53,72,84,109,236,237] In addition, a possible function of odontoblast in immune regulation has been proposed by the finding of innate immune components in the odontoblast layer.[387] Hence the odontoblasts should be capable of recognizing and differentially responding to bacterial components, thereby serving immune and pulp-dentine barrier functions.

Odontoblast process

A dentinal tubule forms around each of the major odontoblastic processes. The odontoblast process occupies most of the space within the tubule and coordinates the formation of peritubular dentin.

Microtubules and microfilaments are the principal ultrastructural components of the odontoblast process and its lateral branches.[112,160] Microtubules extend from the cell body out into the process.[112] These straight structures follow a course that is parallel with the long axis of the cell and impart the impression of rigidity. Although their precise role is unknown, theories as to their functional significance suggest that they may be involved in cytoplasmic extension, transport of materials, or the provision of a structural framework. Occasionally, mitochondria can be found in the process where it passes through the predentin.

The plasma membrane of the odontoblast process closely approximates the

Telegram: @dental_k

www.konkur.in

wall of the dentinal tubule. Localized constrictions in the process occasionally produce relatively large spaces between the tubule wall and the process. Such spaces may contain collagen fibrils and fine granular material that presumably represents ground substance (see also The Pulpal Interstitium and Ground Substance in this chapter). The peritubular dentin matrix within the tubule is lined by an electron-dense limiting membrane called the *lamina limitans*.[265,361,405] A narrow space separates the limiting membrane from the plasma membrane of the odontoblast process, except for the areas where the process is constricted.

In restoring a tooth, the removal of enamel and dentin often disrupts odontoblasts.[42,46,74,81,206,262] It would be of considerable clinical importance to establish the extent of the odontoblast processes in human teeth, because with this knowledge the clinician would be in a better position to estimate the impact of the restorative procedure on the underlying odontoblasts. However, the extent to which the process penetrates into dentin has been a matter of considerable controversy. It has long been thought that the process is present throughout the full thickness of dentin. Although ultrastructural studies using transmission electron microscopy have described the process as being limited to the inner third of the dentin,[49,113,361,405] it should be noted that this could possibly be the result of shrinkage occurring during fixation and dehydration. Other studies employing scanning electron microscopy have described the process extending further into the tubule, often as far as the dentoenamel junction (DEJ),[132,181,343,419] but it has been suggested that what has been observed in scanning electron micrographs is actually the lamina limitans.[361,362,405]

In an attempt to resolve this issue, monoclonal antibodies directed against microtubules were used to demonstrate tubulin in the microtubules of the process. Immunoreactivity was observed throughout the dentinal tubule, suggesting that the process extends throughout the thickness of dentin.[343] However, a study employing confocal microscopy found that odontoblast processes in rat molars do not extend to the outer dentin or DEJ, except during the early stages of tooth development.[49] It is likely that the walls of tubules contain many proteins originally derived from odontoblasts that no longer remain at that site. Because dentin matrix has no turnover, these antigens remain fixed in place. From a clinical perspective, it is important to

Telegram: @dental_k

www.konkur.in

remember that these processes in the tubules represent appendages from living odontoblasts in the pulp, which explains why the dentin must be considered a vital tissue, the destruction of which will affect the pulp.

The odontoblast is considered to be a fixed postmitotic cell in that once it has fully differentiated, it apparently cannot undergo further cell division. If this is indeed the case, the life span of the odontoblast coincides with the life span of the viable pulp. However, its metabolic activity can be dynamically altered (described under the heading Pulpal Repair).

Relationship of odontoblast structure to secretory function

Studies using radiolabeled chemicals have shed light on the functional significance of the cytoplasmic organelles of the active odontoblast.[407,408] In experimental animals, intraperitoneal injection of a collagen precursor (e.g., ^{3}H-proline) was followed by autoradiographic labeling of the odontoblasts and predentin matrix (Fig. 13.6).[408] Rapid incorporation of the isotope in the RER soon lead to labeling of the Golgi complex in the area where the procollagen was packed and concentrated into secretory vesicles. Radiolabeled vesicles passed along their migration pathway until they reach the base of the odontoblast process. Here they fused with the cell membrane and released their tropocollagen molecules into the predentin matrix by the process of exocytosis.

Telegram: @dental_k

www.konkur.in

FIG. 13.6 Autoradiograph demonstrating odontoblasts and predentin in a developing rat molar 1 hour after intraperitoneal injection of ^{3}H-proline.

Autoradiograph shows odontoblast cells extending toward dentin. Four horizontal layers with different patterns have scattered tiny dots throughout.

It is now known that collagen fibrils precipitate from a solution of secreted tropocollagen and that the aggregation of fibrils occurs on the outer surface of the odontoblast plasma membrane. Fibrils are released into the predentin and increase in thickness as they approach the mineralized matrix. Whereas fibrils at the base of the odontoblast process are approximately 15 nm in diameter, fibrils in the region of the calcification front have attained a diameter of about 50 nm.

Similar tracer studies[407] have elucidated the pathway of synthesis, transport, and secretion of the predentin proteoglycans. The protein moiety of these molecules is synthesized by the RER of the odontoblast, whereas sulfation and addition of the glycosaminoglycan (GAG) moieties to the protein molecules take place in the Golgi complex. Secretory vesicles then transport the proteoglycans to the base of the odontoblast process, where they are secreted into the predentin matrix. Proteoglycans, principally chondroitin sulfate, accumulate near the calcification front. The role of the proteoglycans is speculative, but mounting evidence suggests that they act as inhibitors of calcification by binding calcium. It appears that just before calcification, the

Telegram: @dental_k

www.konkur.in

proteoglycans are removed, probably by lysosomal enzymes secreted by the odontoblasts.[86]

Pulp fibroblast

Fibroblasts are the most numerous cells of the pulp. They appear to be tissue-specific cells capable of giving rise to cells that are committed to differentiation (e.g., odontoblast-like cells) if given the proper signal. These cells synthesize type I and III collagen, as well as proteoglycans and GAGs. Thus they produce and maintain the matrix proteins of the ECM. Because they are also able to phagocytose and digest collagen, fibroblasts are responsible for collagen turnover in the pulp.

Although distributed throughout the pulp, fibroblasts are particularly abundant in the cell-rich zone. The early differentiating fibroblasts are polygonal and appear to be widely separated and evenly distributed within the ground substance. Cell-to-cell contacts are established between the multiple processes that extend out from each of the cells. Many of these contacts take the form of gap junctions that provide for electronic coupling or chemical signaling from one cell to another. In terms of ultrastructure, the organelles of the immature fibroblasts are generally in a rudimentary stage of development, with an inconspicuous Golgi complex, numerous free ribosomes, and sparse RER. As they mature, the cells become stellate in form, and the Golgi complex enlarges, the RER proliferates, secretory vesicles appear, and the fibroblasts take on the characteristic appearance of protein-secreting cells. In addition, collagen fibrils accumulate along the outer surface of the cell body. With an increase in the number of blood vessels, nerves, and collagen fibers, there is a relative decrease in the number of fibroblasts in the pulp.

Many fibroblasts of the pulp are characterized by being relatively undifferentiated. A more modern term for these undifferentiated cells is MSC. MSC derived from different tissues appear to be tissue specific and are responsible for maintenance of specific tissue functions. However, MSC share some common characteristics, as they are able to differentiate into other cell lineages when given the proper signals. Like MSC from bone and adipose tissues, pulpal MSC proliferate well in culture (Fig. 13.7), and when stimulated they have neurogenic, adipogenic, chondrogenic, and osteogenic

Telegram: @dental_k

www.konkur.in

differentiation potential.[282] Many pulpal cells seem to remain in a relatively undifferentiated modality, compared with fibroblasts of most other connective tissues.[138] This perception has been supported by the observation of large numbers of reticulin-like fibers in the pulp. Reticulin fibers have an affinity for silver stains and are similar to the argyrophilic fibers of the pulp. However, in a careful review, it appears that actual reticulin fibers may not be present in the pulp; instead the previously described fibers are actually *argyrophilic collagen fibers*.[15] The fibers apparently acquire a GAG sheath, and it is this sheath that is impregnated by silver stains. In the young pulp, the nonargyrophilic collagen fibers are sparse, but they progressively increase in number as the pulp ages.

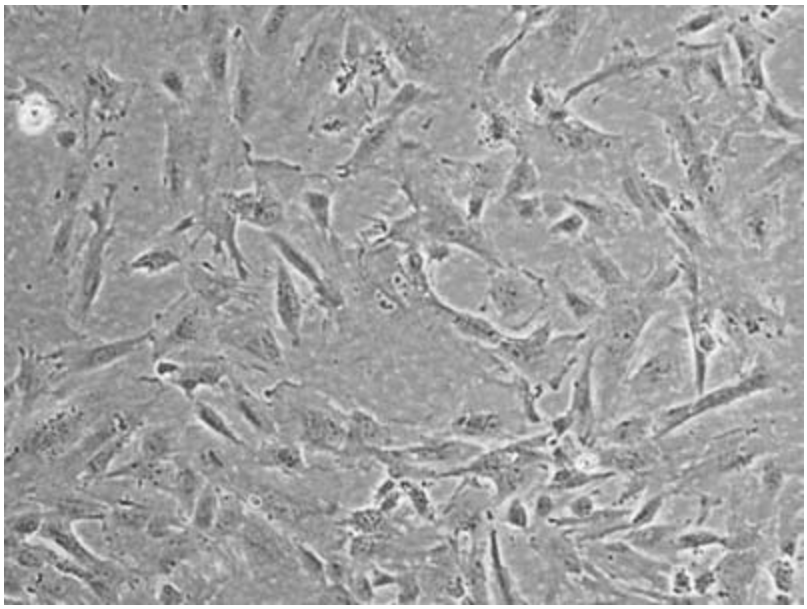

FIG. 13.7 Morphology of cultured pulpal cells. Many of the cells will have mesenchymal stem cell characteristics.

Electron micrograph of cultured pulpal cells shows the network of undifferentiated fibroblast-like cells that have stellate and spindle shapes.

Many experimental models have been developed to study wound healing in the pulp, particularly dentinal bridge formation after pulp exposure or pulpotomy. One study[100] demonstrated that mitotic activity preceding the differentiation of replacement odontoblasts appears to occur primarily among perivascular fibroblasts.

Telegram: @dental_k

www.konkur.in

Pulpal fibroblasts seem to take active part in signaling pathways in the dental pulp. For example, fibroblast growth and synthesis are stimulated by neuropeptides; in turn, fibroblasts produce nerve growth factor (NGF) and proinflammatory cytokines during inflammation.[32,415,420] NGF plays an important role not only in tooth development but also in regulating neuronal and possibly odontoblast responses to injury via activation of similar neurotrophin receptors expressed on both cell types (see also Plasticity of Intradental Nerve Fibers in this chapter).[415]

Macrophage

Macrophages are monocytes that have left the bloodstream, entered the tissues, and differentiated into various subpopulations. The different subpopulations can be studied by their antigenic properties in immunohistochemical studies. Many are found in close proximity to blood vessels. A major subpopulation of macrophages is active in endocytosis and phagocytosis. Because of their mobility and phagocytic activity, they are able to act as scavengers, removing extravasated red blood cells, dead cells, and foreign bodies from the tissue. Ingested material is destroyed by the action of lysosomal enzymes. Another subset of macrophages participates in immune reactions by processing antigen and presenting it to memory T cells.[287] The processed antigen is bound to class II major histocompatibility complex (MHC) molecules on the macrophage, where it can interact with specific receptors present on naive or memory T cells (Fig. 13.8).[135] Such interactions are essential for T-cell–dependent immunity. Similar to fibroblasts, macrophages take an active part in the signaling pathways in the pulp. When activated by the appropriate inflammatory stimuli, macrophages are capable of producing a large variety of soluble factors, including interleukin (IL) 1, tumor necrosis factor (TNF), growth factors, and other cytokines. One study showed that a subset of macrophages express lymphatic markers, indicating a link between macrophages and lymphatic function and development.[19]

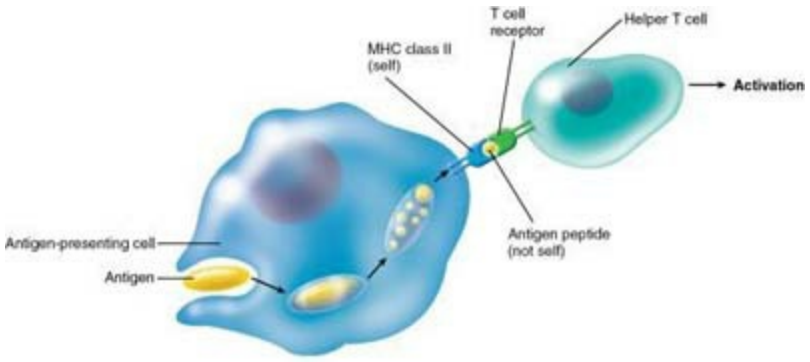

FIG. 13.8 Function of major histocompatibility complex *(MHC)* class II molecule-expressing cells. They act as antigen-presenting cells that are essential for the induction of helper T-cell-dependent immune responses.

Diagram of major histocompatibility complex with labels as follows: Antigen, antigen-presenting cell, MHC class II (self), antigen peptide (not self), T cell receptor, helper T cell, and activation.

Dendritic cell

Dendritic cells are accessory cells of the immune system. Similar cells are found in the epidermis and mucous membranes, where they are called *Langerhans cells*.[175,286] Dendritic cells are primarily found in lymphoid tissues, but they are also widely distributed in connective tissues, including the pulp (Fig. 13.9).[325] These cells are termed *antigen-presenting cells* and are characterized by dendritic cytoplasmic processes and the presence of class II MHC complexes on their cell surface. In the normal pulp they are mostly located in the periphery of the coronal pulp close to the predentin, but they migrate centrally in the pulp after antigenic challenge.[428] They are known to play a central role in the induction of T-cell–dependent immunity. Like antigen-presenting macrophages, dendritic cells engulf protein antigens and then present an assembly of peptide fragments of the antigens and MHC class II molecules. It is this assembly that T cells can recognize. Then the assembly binds to a T-cell receptor and T-cell activation occurs (see Fig. 13.8). Fig. 13.10 shows a cell-to-cell contact between a dendritic-like cell and a lymphocyte.

Lymphocyte

Telegram: @dental_k

www.konkur.in

Hahn and colleagues[135] reported finding T lymphocytes in normal pulps from human teeth. T8 (suppressor) lymphocytes were the predominant T-lymphocyte subset present in these samples. Lymphocytes have also been observed in the pulps of impacted teeth.[205] The presence of macrophages, dendritic cells, and T lymphocytes indicates that the pulp is well equipped with cells required for the initiation of immune responses.[175,325] B lymphocytes are scarcely found in the normal uninflamed pulp.

Mast cell

Mast cells are widely distributed in connective tissues, where they occur in small groups in relation to blood vessels. Mast cells are seldom found in the normal pulp tissue, although they are routinely found in chronically inflamed pulps.[325] The mast cell has been the subject of considerable attention because of its dramatic role in inflammatory reactions. The granules of mast cells contain heparin, an anticoagulant, and histamine, an important inflammatory mediator, as well as many other chemical factors.

Metabolism

The metabolic activity of the pulp has been studied by measuring the rate of oxygen consumption and the production of carbon dioxide (CO_2) or lactic acid.[26,97,98,99,137,326] An investigation employed an oxygen-sensitive microelectrode inserted into a rat incisor pulp with a micromanipulator, and the authors reported that odontoblasts consumed O_2 at the rate of 3.2 ± 0.2 mL/min/100 g of pulp tissue.[425]

Because of the relatively sparse cellular composition of the pulp, the rate of oxygen consumption is low in comparison with that of most other tissues. During active dentinogenesis, metabolic activity is much higher than after the crown is completed. As would be anticipated, the greatest metabolic activity is found in the region of the odontoblast layer, and the lowest is found in the central pulp, where most of the nerves and blood vessels are located.[25]

In addition to the usual glycolytic pathway, the pulp has the ability to produce energy through a phosphogluconate (i.e., pentose phosphate) shunt type of carbohydrate metabolism,[99] a metabolic pathway that permits tissues

Telegram: @dental_k

www.konkur.in

to function under varying degrees of ischemia. This could explain how the pulp manages to withstand periods of low perfusion resulting from vasoconstriction induced by epinephrine-containing infiltration anesthesia.[193]

Several commonly used dental materials (e.g., eugenol, zinc oxide and eugenol, calcium hydroxide, silver amalgam) inhibit oxygen consumption by pulp tissue, indicating that these agents may be capable of depressing the metabolic activity of pulpal cells.[98,174] One study[137] found that application of orthodontic force to human premolars for 3 days resulted in a 27% reduction in respiratory activity in the pulp. This study utilized carbon-14-labeled succinic acid in the medium. As cells metabolize succinic acid, they produce $^{14}CO_2$ that can be trapped and quantitated by a liquid scintillation counter.[137] This technique requires only a few milligrams of tissue.

The pulpal interstitium and ground substance

The interstitium consists of the interstitial fluid and the interstitial (extracellular) matrix and occupies the extracellular and extravascular space. It is amorphous and generally regarded as a gel rather than a solid. Its constituents are similar in all tissues, but their relative amount varies. The major structural component of the interstitium is collagen (Fig. 13.11). The network of collagen fibers also supports the other components of the interstitium, the proteoglycans, hyaluronan, and elastic fibers. The two former components represent the GAGs of the interstitial matrix.

Telegram: @dental_k

www.konkur.in

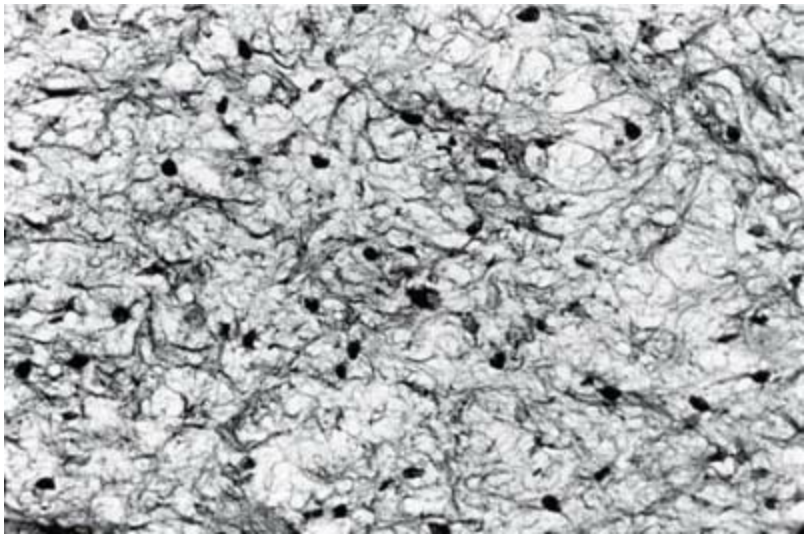

FIG. 13.11 Delicate network of pulpal collagen fibers as demonstrated by the Pearson silver impregnation method.

Electron micrograph of pulpal collagen fibers hold connective tissues together with scattered circular and irregular cells.

Because of its content of polyanionic polysaccharides, the interstitium is responsible for the water-holding properties of connective tissues and acts as a molecular sieve in regulating the diffusion of substances through this space.[411]

Connective tissue consists of cells and fibers, both embedded in ground substance or ECM. Cells that produce connective tissue fibers also synthesize the major constituents of the ECM. Whereas the fibers and cells have recognizable shapes, the ECM is described as being amorphous. It is generally regarded as a gel rather than a solid. Nearly all proteins of the ECM are glycoproteins.[242] Proteoglycans are an important subclass of glycoproteins.[125] These molecules support cells, provide tissue turgor, and mediate a variety of cell interactions. They have in common the presence of GAG chains and a protein core to which the chains are linked. Except for heparan sulfate and heparin, the chains are composed of disaccharides. The primary function of GAG chains is to act as adhesive molecules that can bond to cell surfaces and other matrix molecules.

Fibronectin is a major surface glycoprotein that, together with collagen, forms an integrated fibrillary network that influences adhesion, motility, growth, and differentiation of cells. Laminin, an important component of

Telegram: @dental_k

www.konkur.in

basement membranes, binds to type IV collagen and cell surface receptors.[120] Tenascin is another substrate adhesion glycoprotein.

In the pulp, the principal proteoglycans include hyaluronic acid dermatan sulfate, heparan sulfate, and chondroitin sulfate.[132] The proteoglycan content of pulp tissue decreases approximately 50% with tooth eruption.[224] During active dentinogenesis, chondroitin sulfate is the principal proteoglycan, particularly in the odontoblast and predentin layer, where it is somehow involved with mineralization; with tooth eruption, hyaluronic acid and dermatan sulfate increase, and chondroitin sulfate decreases greatly.

The consistency of a connective tissue (e.g., the pulp) is largely determined by the proteoglycan components of the ground substance. The long GAG chains of the proteoglycan molecules form relatively rigid coils constituting a network that holds water, thus forming a characteristic gel. Hyaluronic acid in particular has a strong affinity for water and is a major component of ground substance in tissues with a large fluid content, such as Wharton jelly of the umbilical cord. The water content of the young pulp is very high (approximately 90%), so the ground substance forms a cushion capable of protecting cells and vascular components of the tooth.

Ground substance also acts as a molecular sieve in that it excludes large proteins. Cell metabolites, nutrients, and wastes pass through the ground substance between cells and blood vessels. In some ways, ground substance can be likened to an ion exchange resin, because the polyanionic chains of the GAGs bind cations. In addition, osmotic pressures can be altered by excluding osmotically active molecules. Thus proteoglycans can regulate the dispersion of interstitial matrix solutes, colloids, and water, and (in large measure) they determine the physical characteristics of a tissue, such as the pulp.

Degradation of ground substance can occur in certain inflammatory lesions that have a high concentration of macrophage lysosomal enzymes. Proteolytic enzymes, hyaluronidases, and chondroitin sulfatases of lysosomal and bacterial origin are examples of the hydrolytic enzymes that can attack components of the ground substance. The pathways of inflammation and infection are strongly influenced by the state of polymerization of the ground substance components.

Telegram: @dental_k

www.konkur.in

Hyaluronan

Another major structural component of the interstitial matrix is hyaluronan. It is an unbranched, random-coil molecule from repeating nonsulfated disaccharide units and is found in the interstitium as free molecules or bound to cells, possibly via the connection to fibronectin.[209] Its large molecular weight together with its protein structure accounts for its unique properties. It has a high viscosity even at low concentration, exhibits exclusion properties, and has a strong affinity for water.

Hyaluronan is one of several types of GAGs in the pulp.[221,242] The hyaluronan receptor-1 is expressed on lymphatic vessels and also on immune cells in the dental pulp.[19] Hyaluronan is removed from the tissue by the lymphatics and metabolized in the lymph nodes[103] and by endothelial cells in the liver.[136,304]

Elastic fibers

Elastic fibers constitute an elastin core and a surrounding microfibrillar network and provide elasticity to the tissue.[295] The amount of elastin in the interstitial matrix in most tissue is small. There is no evidence for elastic fibers in the matrix in the pulp.[136,304]

The inflamed interstitium

Hyaluronidases, chondroitin sulfatases, and matrix metalloproteinases (MMPs) are examples of the enzymes that can attack components of the interstitium.

During infection and inflammation, the physical properties of the pulp tissue may then be altered due to production of such degrading enzymes.[147,324] In addition to their own damaging effect, they may also pave the way for the deleterious effects of bacterial toxins, increasing the magnitude of the damage.[179]

The pathways of inflammation and infection are strongly influenced by the particular composition of the interstitium in every tissue and its degradation by either host or microbial enzymes.

www.konkur.in

Connective tissue fibers of the pulp

Two types of structural proteins are found in the pulp: collagen and elastin. Elastin fibers are confined to the walls of arterioles and, unlike collagen, are not a part of the ECM.

A single collagen molecule, referred to as *tropocollagen*, consists of three polypeptide chains, designated as either α-1 or α-2 depending on their amino acid composition and sequence. In the human pulp, the amount of collagen is reported to be 26% to 32% of dry weight in premolars and molars.[383] Type I and type III collagen represent the major subtypes of collagen in the pulp, and type I is found in thick striated fibrils throughout the pulp tissue.[210,342] The different combinations and linkages of chains making up the tropocollagen molecule have allowed collagen fibers and fibrils to be classified into a number of types:

- Type I collagen is found in skin, tendon, bone, dentin, and pulp.
- Type II collagen is found in cartilage.
- Type III collagen is found in most unmineralized connective tissues. It is a fetal form found in the dental papilla and the mature pulp. In bovine pulp, it constitutes 45% of the total pulp collagen during all stages of development.[383]
- Types IV and VII collagen are components of basement membranes.
- Type V collagen is a constituent of interstitial tissues.
- Type VI collagen is a heterotrimer of three distinct chains, α 2 (VI) and α 3 (VI), and is widely distributed in low concentrations in soft tissues at interfibrillar filaments.

Type I collagen is synthesized by odontoblasts and osteoblasts; fibroblasts synthesize types I, III, V, and VII collagen.

In collagen synthesis, the protein portion of the molecule is formed by the polyribosomes of the RER of connective tissue cells. The proline and lysine residues of the polypeptide chains are hydroxylated in the cisternae of the RER, and the chains are assembled into a triple-helix configuration in the smooth endoplasmic reticulum. The product of this assembly is termed *procollagen,* and it has a terminal unit of amino acids known as the *telopeptide of the procollagen molecule*. When these molecules reach the

Telegram: @dental_k

www.konkur.in

Golgi complex, they are glycosylated and packaged in secretory vesicles. The vesicles are transported to the plasma membrane and secreted by way of exocytosis into the extracellular milieu, thus releasing the procollagen. Here the terminal telopeptide is cleaved by a hydrolytic enzyme, and the tropocollagen molecules begin aggregating to form collagen fibrils. It is believed that the GAGs somehow mediate aggregation of tropocollagen. The conversion of soluble collagen into insoluble fibers occurs as a result of cross-linking of tropocollagen molecules. The transcription factor SOX9 is strongly expressed in normal dental pulp tissue and reduced in inflamed pulp.[232] The factor seems to promote collagen synthesis and seems to be important for ECM balance.

The presence of collagen fibers passing from the dentin matrix between odontoblasts into the dental pulp has been reported in fully erupted teeth.[29] Larger collagen fiber bundles are much more numerous in the radicular pulp than in the coronal pulp. The highest concentration of these larger fiber bundles is usually found near the apex (Fig. 13.12).[371]

The trigeminal system

Innervation

Pain is a subjective phenomenon involving not only sensory physiologic responses, but also emotional, conceptual, and motivational aspects of behavior. The existence of peripheral “nociceptive” (pain-detecting) sensory neurons forms the basis for pain, and pain sensations of varying qualities and intensities are evoked by activation of the intradental nerves innervating teeth. Noxious stimuli in teeth are transmitted in primary afferent neurons located in the trigeminal ganglion via second-order neurons in the brain stem to the brain (Fig. 13.13) (see also Chapter 4 and later in this chapter). Transmission of sensory information consists of a cascade of events involving input, processing, and sensing,[335] so the control of dental pain should be based on an understanding of the origin of pain signals and the complex modulation that may take place locally and at higher levels. The sensory system of the pulp appears to be well suited for signaling potential damage to the tooth. The tooth is innervated by a large number of myelinated and unmyelinated axons. The number of axons entering a human premolar may reach 2000 or more, and each axon can arborize to form multiple points of innervation.[92,171,172]

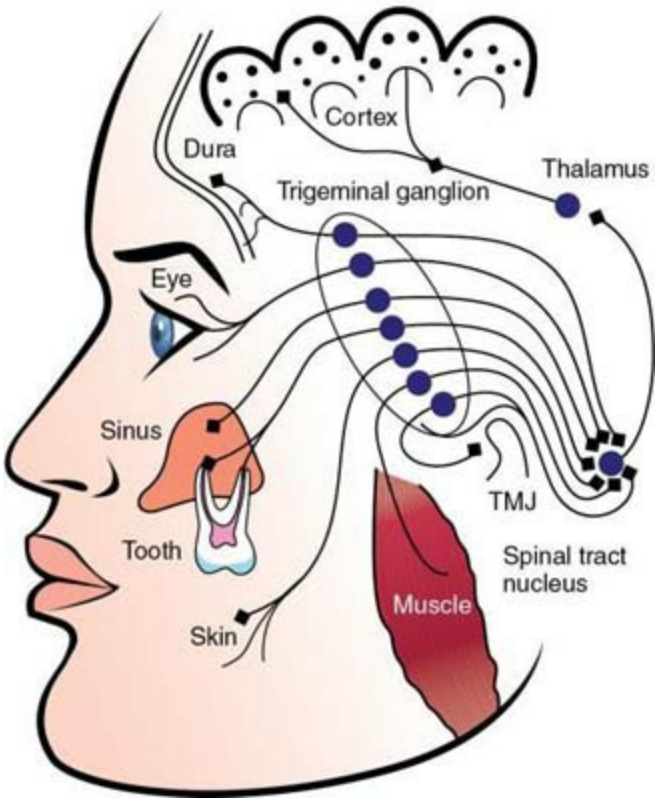

FIG. 13.13 Schematic drawing illustrating the convergence of sensory information from teeth to higher brain centers. *TMJ,* Temporomandibular joint.

Lateral view of face shows branches from eye, sinus, tooth, skin, muscle near spinal tract nucleus and, TMJ converged and leading to thalamus, trigeminal ganglion, dura, and cortex.

Regardless of the nature of the sensory stimulus (i.e., thermal, mechanical, chemical, electric [e.g., pulp tester]), almost all afferent impulses generated from pulp tissue result in the sensation of pain. However, when the pulp is weakly stimulated by an electric pulp tester under carefully controlled experimental conditions, a nonpainful sensation (i.e., prepain) has been reported.[252] Thus not all afferent neurons that innervate the pulp are nociceptors. The innervation of the pulp includes both *afferent neurons,* which conduct sensory impulses, and *autonomic or efferent neurons,*[165] which provide neurogenic modulation of the microcirculation, inflammatory reactions,[150] and perhaps regulate dentinogenesis.[47]

The sympathetic innervation of teeth derives from the superior cervical ganglion (SCG).[8,307] Postganglionic sympathetic nerves travel with the

Telegram: @dental_k

www.konkur.in

internal carotid nerve, join the trigeminal nerve at the ganglion, and supply teeth and supporting structures via the maxillary and mandibular division of the trigeminal nerve.[244] Sympathetic fibers appear with blood vessels at the time the vascular system is established in the dental papilla.[106] In the adult tooth pulp, sympathetic fibers form plexuses, usually around pulpal arterioles (Fig. 13.14). Stimulation of these fibers results in constriction of the arterioles and a decrease in blood flow.[1,82] The sympathetic neuron terminals contain the classic neurotransmitter, norepinephrine (NE), and neuropeptide Y (NPY) (see Neuropeptides later in this chapter). NPY is synthesized in sympathetic neurons and supplied to terminals by axonal transport. By contrast, NE is mainly produced locally in the terminals. Compared with the sensory nerves, these fibers are most often located in deeper parts of the pulp proper, but fibers have also been found in close relation to odontoblasts.[1,166]

The presence of parasympathetic cholinergic nerves in dental tissues has been and is still controversial, although it has been concluded that there is absence of parasympathetic vasodilation in the cat dental pulp.[292,329] It has been reported that the neuropeptide vasoactive intestinal polypeptide (VIP) is localized in the parasympathetic neurons.[229,230] The origin of VIP-containing fibers in the pulp is uncertain insofar as no form of surgical denervation has resulted in complete loss of these fibers from the dental pulp.[397]

Sensory nerve fibers are usually classified according to their diameter, conduction velocity, and function (Table 13.1). The pulp contains two types of sensory nerve fibers: myelinated (A fibers) and unmyelinated (C fibers). It has been shown that there is some functional overlap between pulpal A and C fibers, as both fiber types can be nociceptors.[165,171,172,251,272] The A fibers include both A-β and A-δ fibers. The A-β fibers may be slightly more sensitive to stimulation than the A-δ fibers, but functionally these fibers are grouped together in the dental pulp, because both innervate the dentinal tubules, and both are stimulated by dentinal fluid movement (Fig. 13.15). Approximately 90% of the A fibers in dental pulp are A-δ fibers.[251] Table 13.2 summarizes the principal characteristics of the main sensory fibers.

Telegram: @dental_k

www.konkur.in

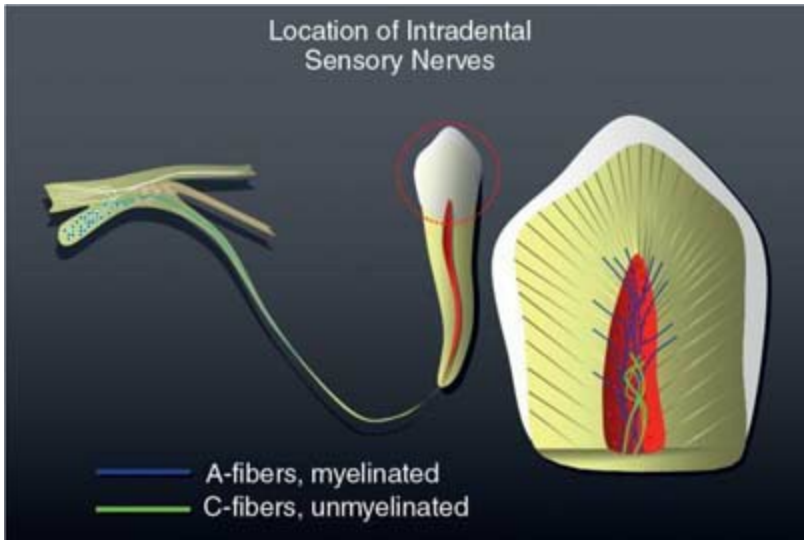

FIG. 13.15 Schematic drawing illustrating the location of A and C fibers in the dental pulp. Myelinated A fibers are located in the periphery of the pulp, penetrating the inner part of dentin. Unmyelinated C fibers are located in the deeper part of the pulp proper.

Location of intradental sensory nerves in crown of tooth is shown. To the right, pulp in the crown area has a mesh of myelinated A-fibers and unmyelinated C-fibers.

Table 13.1

Classification of Nerve Fibers

Type of Fiber	Function	Diameter (μm)	Conduction Velocity (m/s)
A-α	Motor, proprioception	12–20	70–120
A-β	Pressure, touch	5–12	30–70
A-γ	Motor, to muscle spindles	3–6	15–30
A-δ	Pain, temperature, touch	1–5	6–30
B	Preganglionic autonomic	<3	3–15
C dorsal root	Pain	0.4–1	0.5–2
Sympathetic	Postganglionic sympathetic	0.3–1.3	0.7–2.3

Table 13.2

Characteristics of Sensory Fibers

Telegram: @dental_k

www.konkur.in

Fiber	Myelination	Location of Terminals	Pain Characteristics	Stimulation Threshold
A-δ	Yes	Principally in region of pulp-dentin junction	Sharp, pricking	Relatively low
C	No	Probably distributed throughout pulp	Burning, aching, less bearable than A-δ fiber sensations	Relatively high, usually associated with tissue injury

During the bell stage of tooth development, "pioneer" nerve fibers enter the dental papilla following the path of blood vessels.[106] Although only unmyelinated fibers are observed in the dental papilla, a proportion of these fibers are probably A fibers that have lost or not developed their myelin sheath. Myelinated fibers are the last major structures to appear in the developing human dental pulp.[11] The number of nerve fibers gradually increases, and branching occurs as the fibers approach dentin. During the bell stage, very few fibers enter the predentin.[106]

The sensory nerves of the pulp arise from the trigeminal nerve and pass into the radicular pulp in bundles by way of the foramen in close association with arterioles and venules (Fig. 13.16). Each of the nerves entering the pulp is invested within Schwann cells, and the A fibers acquire their myelin sheath from these cells. With the completion of root development, the myelinated fibers appear grouped in bundles in the central region of the pulp (Fig. 13.17). Most of the unmyelinated C fibers entering the pulp are located within these fiber bundles; the remainder is situated toward the periphery of the pulp (see Fig. 13.15).[313] It should be noted that single neurons branch and innervate the pulps of multiple teeth in animal studies.[157] Assuming a similar innervation pattern in humans, such organization may contribute to the poor localization of dental pain and may also allow neurogenic vasodilation and inflammatory reactions to occur in an area of tissue wider than that affected by the original insult (Fig. 13.18). This phenomenon, also known as the axon reflex,[328] was first demonstrated in rat teeth and later confirmed in cat teeth where stimulation of a second premolar caused neurogenic inflammation in the canine tooth.[157,199] An alternative explanation to this clinical observation is that the pulp has a relatively low density of proprioceptors, and thus patients have difficulty identifying the inflamed tooth until the inflammation reaches the periradicular tissue, which is highly innervated with proprioceptors. This is discussed in greater detail in Chapter 4.

www.konkur.in

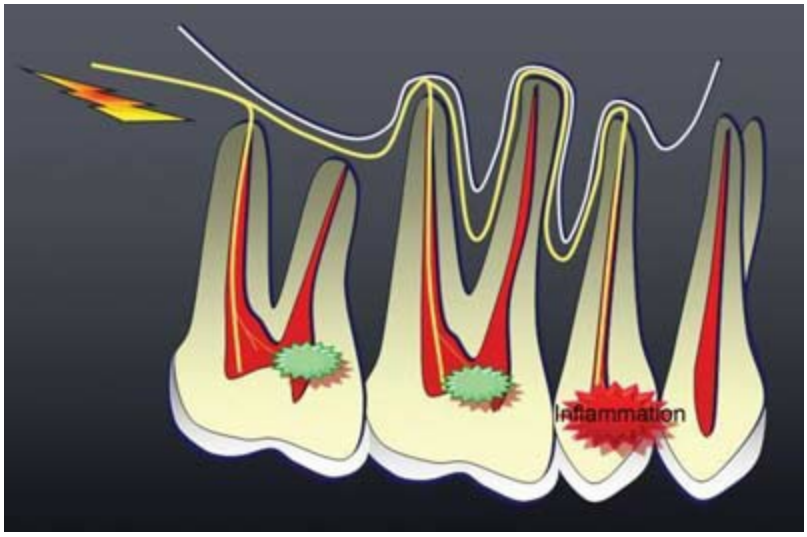

FIG. 13.18 Branches of a single nerve fiber may innervate more than a single tooth. Nerve fiber activation in one tooth may thus result in neurogenic inflammation in adjacent teeth innervated by the same axon. The mechanism is known as the axonal reflex. This phenomenon may also contribute to the poor localization of pain reported by patients.

A branch of nerve fiber enters three teeth through root canals, resulting in the inflammation in the crown of the third tooth.

In the human premolar, the number of unmyelinated axons entering the tooth at the apex reached a maximal number shortly after tooth eruption.[172] At this stage, an average of 1800 unmyelinated axons and more than 400 myelinated axons were found, although in some teeth fewer than 100 myelinated axons were present. Five years after eruption, the number of A fibers gradually increased to more than 700. The relatively late appearance of A fibers in the pulp may help to explain why the electric pulp test tends to be unreliable in young teeth, as A fibers are more easily electrically stimulated than C fibers.[110]

A quantitative study of axons 1 to 2 mm coronal to the root apex of fully developed human canine and incisor teeth[172] reported a mean of about 360 myelinated axons in canines and incisors, whereas there were 1600 to 2200 unmyelinated axons. However, this does not reflect the actual number of neurons supporting a single tooth, because multiple branching of the axons may occur in the peripheral tissues. Overall, approximately 80% of the axons were unmyelinated fibers.[171,172]

The nerve bundles pass upward through the radicular pulp together with

Telegram: @dental_k

www.konkur.in

blood vessels. Once they reach the coronal pulp, they fan out beneath the cell-rich zone, branch into smaller bundles, and finally ramify into a plexus of single-nerve axons known as the *plexus of Raschkow* (Fig. 13.19). Full development of this plexus does not occur until the final stages of root formation.[92] It has been estimated that each axon entering the pulp sends at least eight branches to the plexus of Raschkow. There is prolific branching of the fibers in the plexus, producing a tremendous overlap of receptor fields.[145,272,273,274,278] It is in the plexus that the A fibers emerge from their encircling Schwann cells and branch repeatedly to form the subodontoblastic plexus. Finally, terminal axons pass between the odontoblasts as free nerve endings (see Figs. 13.19–13.21). The extent to which dentin is innervated has been the subject of numerous investigations.[43,46,47,50,92,219] With the exception of the innervation of dentinal tubules, discussed later in this chapter, the bulk of dentin is devoid of sensory nerve fibers. This offers an explanation as to why pain-producing agents (e.g., potassium chloride) do not always elicit pain when applied to exposed dentin. Similarly, application of topical anesthetic solutions to dentin does not decrease its sensitivity. Hence a high concentration of lidocaine solution is needed to block the response of intradental nerves to mechanical stimulation of the dentin.[4]

One investigator[133] studied the distribution and organization of nerve fibers in the dentin-pulp border zone of human teeth. On the basis of their location and pattern of branching, several types of nerve endings were described (Fig. 13.22). Some fibers were found running from the subodontoblastic nerve plexus toward the odontoblast layer. However, these fibers do not reach the predentin; they terminate in extracellular spaces in the cell-rich zone, the cell-poor zone, or the odontoblast layer. Other fibers extend into the predentin and run through a dentinal tubule in close association with an odontoblast process. Most of these intratubular fibers extend into the dentinal tubules for only a few micrometers, but a few may penetrate as far as 100 μm (see Figs. 13.19 and 13.20). The area covered by a

Telegram: @dental_k

www.konkur.in

single such terminal complex often reaches thousands of square micrometers.[133,273]

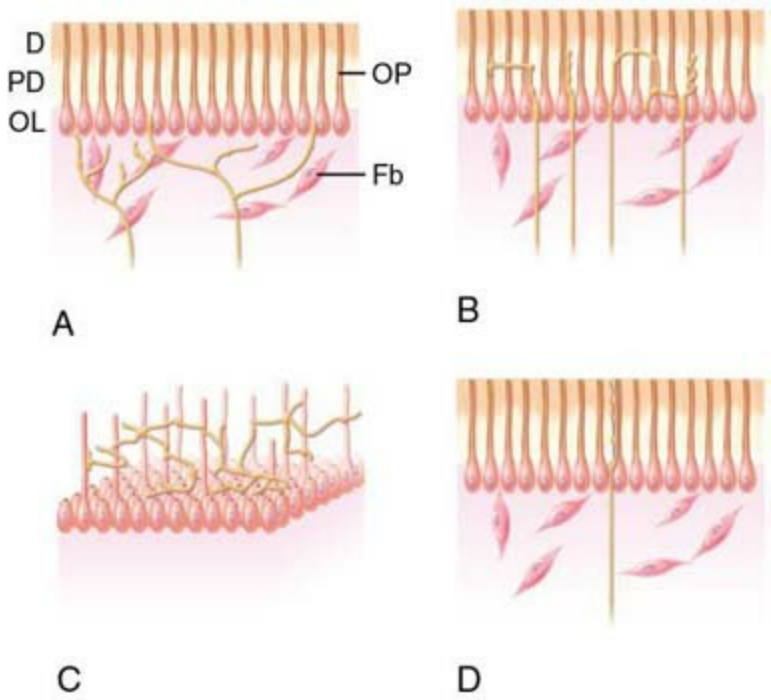

FIG. 13.22 Schematic drawing showing distribution of nerve fibers in the dentin-pulp border zone. **A,** Fibers running from the subodontoblastic plexus to the odontoblast layer. **B,** Fibers extending into the dentinal tubules in the predentin. **C,** Complex fibers that branch extensively in the predentin. **D,** Intratubular fibers extending into the dentin. *D,* Dentin; *Fb,* fibroblast; *OL,* odontoblast layer; *OP,* odontoblast process; *PD,* predentin.

Four drawings marked A through D explain the organization and branching pattern of nerve fibers in tooth.

Intratubular nerve endings are most numerous in the area of the pulp horns, where as many as 40% of the tubules may contain fibers.[47,219] The number of intratubular fibers decreases in other parts of the dentin, and in root dentin only about 1% of dentinal tubules contain fibers. This notion has been challenged in a study that stained pulps for protein gene-product 9.5, a specific marker for nerves.[235] In that study, root dentin appeared to be as well innervated as coronal dentin. The anatomic relationship between the odontoblast processes and sensory nerve endings has led to much speculation

Telegram: @dental_k

www.konkur.in

as to the functional relationships between these structures, if any.[46] When present, nerve fibers lie in a groove or gutter along the surface of the odontoblast process, and toward their terminal ends they twist around the process like a corkscrew. The cell membranes of the odontoblast process and the nerve fiber are closely approximated and run closely parallel for the length of their proximity, but they are not synaptically linked.[162]

Although it may be tempting to speculate that the odontoblasts and their associated nerve axons are functionally interrelated and that together they play a role in dentin sensitivity, there is a paucity of evidence supporting this hypothesis. If the odontoblast were acting as a classic receptor cell,[†] it would have chemical, electric, or mechanical communication with the adjacent nerve fiber. However, researchers have been unable to find classic anatomic structures (e.g., synaptic junctions) that could functionally couple odontoblasts and nerve fibers together. With regard to the membrane properties of odontoblasts, it has been reported that the membrane potential of the odontoblast is low (−24 to −30 mV),[202,231] and that the cell does not respond to electric stimulation.[292,413] It would appear that the odontoblast does not possess the properties of an excitable cell. Further, the sensitivity of dentin is not diminished after disruption of the odontoblast layer.[38,220] It is still possible that odontoblasts could modulate neuronal function via alteration in sodium channel activity or the release of paracrine factors that diffuse to the closely approximated nerve terminal.

Another study showed that a reduction in pulpal blood flow (PBF), induced by stimulation of sympathetic fibers leading to the pulp, results in depressed excitability of pulpal A fibers.[83] The excitability of C fibers is less affected than that of A fibers by a reduction in blood flow.[370]

Of clinical interest is the evidence that nerve fibers of the pulp may be resistant to necrosis[83,260] because their cell bodies are found in ganglia outside the pulp. Because nerve bundles in general are more resistant to autolysis than other tissue elements, even in degenerating pulps, C fibers might still be able to respond to noxious stimulation. It may be that C fibers remain excitable even after blood flow has been compromised in the diseased pulp, as C fibers are often able to function in the presence of hypoxia.[370] This may explain why instrumentation of the root canals of apparently nonvital teeth sometimes elicits pain. On the other hand, histologic studies on nonvital

Telegram: @dental_k

www.konkur.in

teeth failed to demonstrate high levels of innervation, leading to the suggestion that pain may be due to the transfer of noxious chemicals to terminals located in periapical tissues.[260]

Steps and mechanisms in pain perception

When activated by a stimulus sufficient to cause tissue damage or release of inflammatory mediators, nerve endings in the pulp and periradicular tissues begin to send bursts of messages to the central nervous system (CNS) that may eventually be perceived as pain. The anatomic pathway for this transmission of information has been fairly well established, and it is tempting to view the perception of pain of orofacial origin as a simple graded response to the intensity of the stimulus. However, researchers have come to realize that the pain system is a complex, multilevel system that begins with the *detection* of tissue-damaging stimuli in the periphery, the *processing* of that input at the level of the medullary spinal cord, and the *perception* of what is felt as pain in higher brain regions such as the cerebral cortex (Fig. 13.23). After a noxious stimulus is detected in the periphery, there is ample opportunity for a great deal of endogenous and possibly exogenous modification of the message prior to its ultimate perception. The clinician deals with all three levels of the pain system in diagnosing and treating odontalgia, and a practitioner with a basic understanding of each level will be able to recognize therapeutic opportunities and apply effective pain control methods.

Telegram: @dental_k

www.konkur.in

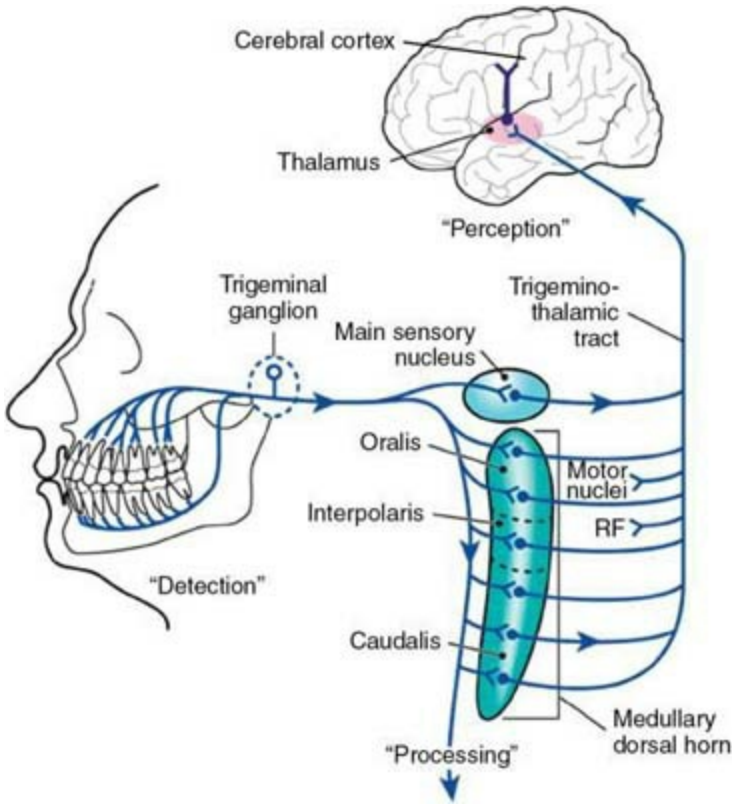

FIG. 13.23 Schematic diagram of the pathway of transmission of nociceptive information from the orofacial region. The trigeminal pain system is a complex multilevel system that begins with the *detection* of tissue damaging stimuli in the periphery, the *processing* of that input at the level of the medullary spinal cord, and the final *perception* of what is felt as pain in the cerebral cortex. There is growing appreciation for the concept that once a noxious stimulus is detected in the periphery, there is the opportunity for a great deal of modification of the message prior to ultimate perception. *RF,* Reticular formation.

Damaged tissue is detected in the lower face, after which trigeminal ganglion leads to processing in medullary dorsal horn and main sensory nucleus. Labels in medullary dorsal horn are as follows: oralis interpolaris, and caudalis. Motor nuclei and RF along with main sensory nucleus are collectively leading to trigeminothalamic tract followed by perception in brain. Two labels in brain are cerebral cortex and thalamus.

Detection: The first step in pain perception

Various types of peripheral neurons are found in the trigeminal system, including large-diameter, heavily myelinated Aα, Aβ, and Aγ fibers associated with motor, proprioception, touch, pressure, and muscle spindle

Telegram: @dental_k

www.konkur.in

stretch functions. But it is the smaller, less myelinated Aδ and yet smaller and unmyelinated C fibers that conduct information likely to be perceived as pain. These two classes of pain-sensing nerve fibers, or *nociceptors*, are both found in the tooth pulp, but there are three to eight times more unmyelinated C fibers than A-δ fibers.[42,46,172,376] It should be noted that this classification system is based purely on the size and myelination of the neurons and does not necessarily indicate function. For example, another class of pulpal C fibers are the postganglionic sympathetic efferents found in association with blood vessels, where they regulate PBF[2,190,305,306] and may also influence the activity of peripheral nociceptors (for reviews, see Perl[302] or Hargreaves[139]). Because most pulpal sensory fibers are nociceptive, their terminal branches are free nerve endings, and physiologic stimulation by any modality (temperature, hyperosmotic fluids) results in the perception of pure pain, which can be difficult for patients to localize. Under experimental conditions, electrical stimulation can result in a *prepain* sensation that is also difficult to localize. Once inflammation has extended to the periodontal ligament, which is well endowed with Aβ discriminative touch receptors, the localization of pain is more predictable with light mechanical stimuli such as the percussion test.

In the normal uninflamed pulp and periradicular tissues, a noxious stimulus causes depolarization of nociceptors sufficient to generate action potentials by means of the opening of voltage-gated sodium channels (Na_v). After generation of an action potential, not only is information sent to the CNS, but also in an *antidromic* fashion (i.e., in the reverse direction of the impulse, also termed as an axon reflex). In this way, proinflammatory neuropeptides such as substance P (SP), calcitonin gene-related peptide (CGRP), neurokinins, and the classic neurotransmitter, glutamate, are released from afferent terminals in the pulp and periradicular tissues, even including neighboring teeth (see Fig. 13.18).

Neuropeptides

Of immense importance in pulp biology is the presence of neuropeptides in pulpal nerves.[43,47,50,356] Pulpal nerve fibers contain neuropeptides such as CGRP (see Figs. 13.16 and 13.20),[42] SP,[273,291] NPY (see Fig. 13.14),

Telegram: @dental_k

www.konkur.in

neurokinin A (NKA),[12] and VIP.[233,396] In rat molars, the largest group of intradental sensory fibers contains CGRP. Some of these fibers also contain other peptides, such as SP and NKA.[43,46] Release of these peptides can be triggered by numerous stimuli, including tissue injury,[12] complement activation, antigen-antibody reactions,[286] or antidromic stimulation of the inferior alveolar nerve.[288,291] Once released, vasoactive peptides produce vascular changes that are similar to those evoked by histamine and bradykinin (BK) (i.e., vasodilation).[288] In addition to their neurovascular properties, SP and CGRP contribute to inflammation and promote wound healing.[32,374] The release of CGRP can be modified by sympathetic agonists and antagonists,[117,140] offering the promise of using such agonists to treat dental pain. This latter point is important because clinicians use sympathetic agonists every day—the vasoconstrictors present in local anesthetic solutions may have direct effects on inhibiting dental nerve activity. Local anesthetic reduction in pain may be due to the actions of both the local anesthetic and the vasoconstrictor.[139,140] In cats, capsaicin acutely activates and chronically blocks the *transient receptor potential subtype V1* (TRPV1)-expressing classes of C and A-δ nociceptors in the pulp.[165] In addition, the chronic application of capsaicin ointment to skin has been shown to relieve pain in patients, suggesting that clinical trials evaluating chronic application of capsaicin for treating pulpal or periradicular pain may be of value.

It has been reported[251,291] that mechanical stimulation of dentin produces vasodilation within the pulp, presumably by causing the release of neuropeptides from intradental sensory fibers (neurogenic inflammation).[291] Electric stimulation of the tooth has a similar effect.[154] The pulpal concentrations of CGRP, SP, and NKA are elevated in painful human teeth over healthy control teeth extracted for orthodontic reasons.[12] These peptides are also elevated in pulps beneath advancing carious lesions.[316,317]

Pulp testing

The electric pulp tester delivers a current sufficient to overcome the resistance of enamel and dentin and stimulate the sensory A fibers at the dentin-pulp border zone. Smaller C fibers of the pulp do not respond to the conventional pulp tester because significantly more current is needed to

Telegram: @dental_k

www.konkur.in

stimulate them.[272] Bender and associates[17] found that in anterior teeth, the optimal placement site of the electrode is the incisal edge, as the response threshold is lowest at that location and increases as the electrode is moved toward the cervical region of the tooth.

Cold tests using CO_2 snow or liquid refrigerants and heat tests employing heated gutta-percha or hot water activate hydrodynamic forces within the dentinal tubules, which in turn excite the intradental A fibers. C fibers are generally not activated by these tests unless they produce injury to the pulp. It has been shown that cold tests do not injure the pulp.[110] Heat tests have a greater potential to produce injury, but if the tests are used properly, injury is not likely.

Sensitivity of dentin

The mechanisms underlying dentin sensitivity have been a subject of interest for many years. How are stimuli relayed from the peripheral dentin to the sensory terminals located in the region of the dentin-pulp border zone? Converging evidence indicates that movement of fluid in the dentinal tubules is the basic event in the arousal of dentinal pain.[36,38,268,392,394,395] It now appears that pain-producing stimuli, such as heat, cold, air blasts, and probing with the tip of an explorer, have in common the ability to displace fluid in the tubules.[36,251] This is referred to as the *hydrodynamic mechanism of dentin sensitivity*. The hydrodynamic theory suggests that dentinal pain associated with stimulation of a sensitive tooth ultimately involves mechanotransduction. Classical mechanotransducers have been recognized on pulpal afferents, providing a mechanistic support to this theory.[151] Thus fluid movement in the dentinal tubules is translated into electric signals by receptors located in the axon terminals innervating dentinal tubules. Using single-fiber recording techniques, a positive correlation was found between the degree of pressure change and the number of nerve impulses leaving the pulp (Figs. 13.24 and 13.25).[251,271,391] Thus the outward fluid movements (negative pressure) produce a much stronger nerve response than inward movements.[251,394]

Graph plots number of impulses in 5 seconds against pressure in mm Hg. The vertical axis ranges from 0 near the base to 400 at the top. The horizontal axis ranges from negative 400 (near the base) to positive 400. The data points are as follows: (negative 480, 320), (negative 400, 230), (negative 300, 120), (negative 200, 70), (negative 150, 20), (negative 110, 0), (positive 110, 0), (positive 150, 0), (positive 200, 0), (positive 250, 5), (positive 400, 10), and (positive 500, 20). All data are approximate.

Source: (From Vongsavan N, Matthews B: The relationship between the discharge of intradental nerves and the rate of fluid flow through dentine in the cat, *Arch Oral Biol* 52:643, 2007.)

In experiments on humans, brief application of heat or cold to the outer surface of premolar teeth evoked a painful response before the heat or cold could have produced temperature changes capable of activating sensory receptors in the underlying pulp.[271,377] The evoked pain was of short duration: 1 or 2 seconds. The thermal diffusivity of dentin is relatively low, yet the response of the tooth to thermal stimulation is rapid, often less than 1 second. Evidence suggests that thermal stimulation of the tooth results in a rapid movement of fluid into the dentinal tubules. This results in activation of the sensory nerve terminal in the underlying pulp. Presumably, heat expands the fluid within the tubules faster than it expands dentin, causing the fluid to

Telegram: @dental_k

www.konkur.in

flow toward the pulp, whereas cold causes the fluid to contract more rapidly than dentin, producing an outward flow. It is speculated that the rapid movement of fluid across the cell membrane of the axon terminal activates a mechanosensitive receptor, similar to how fluid movement activates hair cells in the cochlea of the ear. All axon terminals have membrane channels through which charged ions pass, and this initial receptor current, if sufficient, can trigger voltage-gated sodium channels to depolarize the cell, leading to a barrage of impulses to the brain. Some ion channels are activated by voltage, some by chemicals, and some by mechanical pressure.[251,268,273] In the case of pulpal nerve fibers that are activated by hydrodynamic forces, pressure would be transduced, gating mechanosensitive ion channels.

The dentinal tubule is a capillary tube with an exceedingly small diameter.[‡,113] The physical properties of capillarity are significant because fluid force increases as the diameter is reduced. If fluid is removed from the outer end of exposed dentinal tubules by dehydrating the dentinal surface with an air blast or absorbent paper, capillary forces produce a rapid outward movement of fluid in the tubule (Fig. 13.26). According to Brännström,[36] desiccation of dentin can theoretically cause dentinal fluid to flow outward at a rate of 2 to 3 mm/s. In addition to air blasts, dehydrating solutions containing hyperosmotic concentrations of sucrose or calcium chloride can produce pain if applied to exposed dentin.

Telegram: @dental_k

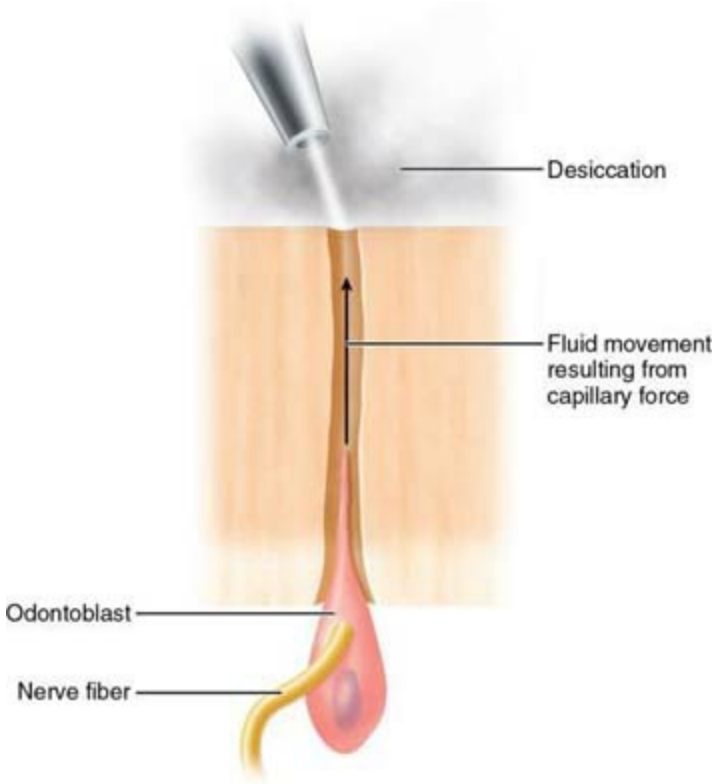

FIG. 13.26 Diagram illustrating movement of fluid in the dentinal tubules resulting from the dehydrating effect of a blast of air from an air syringe.

Pulp of tooth undergoing desiccation with labels as follows: Nerve fiber, odontoblast, and fluid movement resulting from capillary force.

Investigators have shown that it is the A fibers rather than the C fibers that are activated by hydrodynamic stimuli (e.g., heat, cold, air blasts) applied to exposed dentin.[270,278] However, if heat is applied long enough to increase the temperature of the dentin-pulp border by several degrees Celsius, then C fibers may respond, particularly if the heat produces injury. It seems that the A fibers are mainly activated by a rapid displacement of the tubular contents.[268] Slow heating of the tooth produced no response until the temperature reached 111°F (43.8°C), at which time C fibers were activated, presumably because of heat-induced injury to the pulp. These C fibers are called *polymodal nociceptors* because they contain numerous receptors that confer the ability to detect and respond to many different types of stimuli.[273,274] Capsaicin, the pungent active ingredient in hot peppers, is known to simulate C fibers and a subset of A-δ fibers.[165] Capsaicin activates

Telegram: @dental_k

www.konkur.in

a receptor termed the “TRP, subtype vanilloid 1” or TRPV1.[59] The TRPV1 receptor is expressed primarily on a major subclass of nociceptors and responds to heat (>110°F [>43°C]), certain inflammatory mediators, and acid (pH < 6). Thus TRPV1 has been considered a molecular integrator of polymodal noxious stimuli.[283] The ability of the TRPV1 antagonist, capsazepine, to inhibit acid-, heat-, and capsaicin-activated trigeminal neurons[225] has led to the development of new drugs (i.e., TRPV1 antagonists) for the treatment of pulpal pain. Eugenol is known to activate and ultimately desensitize TRPV1, and this may explain the anodyne action of zinc oxide eugenol temporary restorations.[422]

It has also been shown that pain-producing stimuli are more readily transmitted from the dentin surface when the exposed tubule apertures are open[159,173] and the fluid within the tubules is free to flow outward.[173,251,394] For example, acid treatment of exposed dentin to remove the smear layer opens the tubule orifices and makes the dentin much more responsive to stimuli such as air blasts and probing.[159,274]

Perhaps the most difficult phenomenon to explain is dentinal pain associated with light probing of dentin. Even light pressure of an explorer tip can produce strong forces.[§] These forces have been shown to mechanically compress dentin and close open tubule orifices with a smear layer that causes sufficient displacement of fluid to excite the sensory receptors in the underlying pulp (Fig. 13.27).[55,56] Considering the density of the tubules in which hydrodynamic forces would be generated by probing, multiple nerve endings would be simultaneously stimulated when a dental explorer is scratched across dentin. Another newly suggested explanation is that the nerves innervating teeth are special in nature and that low-threshold mechanoreceptors are signaling nociceptive input in teeth.[105] Similar low-threshold mechanoreceptors convey tactile sensation in skin. The authors used the term low-threshold “algoneurons” for these nerves. This theory is not in conflict with the hydrodynamic theory but may help to explain the sensation of pain felt after weak mechanical stimuli like air puffs and water spray.

Source: (From Camps J, Salomon JP, Meerbeek BV, et al: Dentin deformation after scratching with clinically relevant forces, *Arch Oral Biol* 48:527, 2003.)

Another example of the effect of strong hydraulic forces that are created within the dentinal tubules is the phenomenon of odontoblast displacement. In this reaction, the nuclei and cell bodies of odontoblasts are displaced upward in the dentinal tubules, presumably by a rapid movement of fluid in the tubules produced when exposed dentin is desiccated, as with the use of an air syringe or cavity-drying agents (Fig. 13.28).[206] Such cellular displacement results in the destruction of odontoblasts, because cells thus affected soon undergo autolysis and disappear from the tubules. Displaced odontoblasts may eventually be replaced by stem cells that migrate from the cell-rich zone of the pulp, as discussed later in the chapter.

Telegram: @dental_k

www.konkur.in

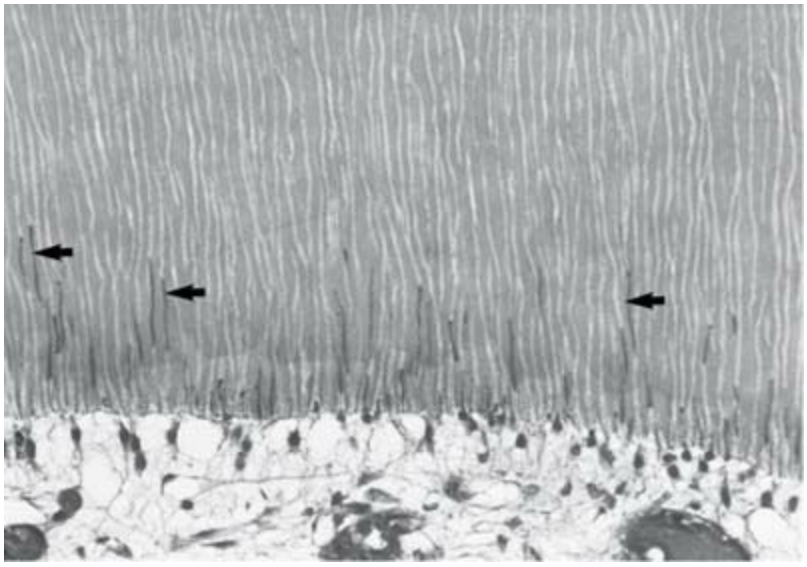

FIG. 13.28 Odontoblasts *(arrows)* displaced upward into the dentinal tubules.

Micrograph shows dark thread-like structures in dentin layer of tooth.

The hydrodynamic theory can also be applied to an understanding of the mechanism responsible for hypersensitive dentin.[37,38] There is controversy regarding whether exposed dentin is simply sensitive or becomes truly hypersensitive.[273,274,278] Growing evidence indicates that new sodium channels responsible for activating nerves are expressed in nerve tissue exposed to inflammation.[121,139,314] An increase in the density of sodium channels or their sensitivity may contribute to dentinal hypersensitivity. Hypersensitive dentin is also associated with the exposure of dentin normally covered by cementum or enamel. The thin layer of cementum is frequently lost as gingival recession exposes cementum to the oral environment. Cementum is subsequently worn away by brushing, flossing, or using toothpicks. Once exposed, the dentin may respond to the same stimuli to which any exposed dentin surface responds (e.g., mechanical pressure, dehydrating agents). Although the dentin may at first be very sensitive, within a few weeks the sensitivity usually subsides. This desensitization is thought to occur as a result of gradual occlusion of the tubules by mineral deposits, thus reducing hydrodynamic forces. In addition, deposition of reparative dentin over the pulpal ends of the exposed tubules probably also reduces sensitivity, because reparative dentin is less innervated by sensory

Telegram: @dental_k

www.konkur.in

nerve fibers.[45] However, some hypersensitive dentin does not spontaneously desensitize, so hypersensitivity may be caused by either inflammatory changes in the pulp or mechanical changes in the patency of dentinal tubules.

Currently, the treatment of hypersensitive teeth is directed toward reducing the functional diameter of the dentinal tubules to limit fluid movement. Four possible treatment modalities[293,378] can accomplish this objective:

1. Formation of a smear layer on the sensitive dentin by burnishing the exposed root surface[159,273,274]
2. Application of agents, such as oxalate compounds, that form insoluble precipitates within the tubules[159,298]
3. Application of agents such as hydroxyethyl methacrylate (HEMA) with or without glutaraldehyde that are thought to occlude tubules with precipitated plasma proteins in dentinal fluid[331]
4. Application of dentin bonding agents to seal off the tubules[309]

Dentin sensitivity can be modified by laser irradiation, but clinicians must be concerned about its effect on the pulp.[353,363]

Peripheral sensitization

Following repeated noxious stimuli, both A and polymodal C fiber nociceptors undergo a process of sensitization manifested by three obvious changes in response patterns. First, firing thresholds may decrease, so that previously non-noxious stimuli may trigger discharges, contributing to the sensation of pain *(allodynia).* Second, after-discharges may occur, so that noxious stimuli may produce an even greater increase in the perceived intensity of pain *(hyperalgesia).* And third, firing may occur spontaneously, contributing to the development of spontaneous pain. These changes are often seen in endodontic pain patients and may be explained in part by the effects of chemical mediators released into inflamed pulp and periradicular tissues. Such mediators include substances produced from damaged tissues, agents of vascular origin, and peptides released from the nerve fibers themselves (Table 13.3). Other mechanisms of peripheral sensitization are listed in Box 13.1.

Hyperalgesia and allodynia

Three characteristics of hyperalgesia are (1) spontaneous pain, (2) a decreased pain threshold, and (3) an increased response to a painful stimulus.[139] The peripheral mechanisms for these symptoms include a decrease in firing threshold, an increase in responsiveness to noxious stimuli, and development of spontaneous discharges of nociceptors. All three of these characteristics can be seen in patients experiencing inflammatory pain of pulpal origin (Table 13.4). It is recognized that hyperalgesia can be produced by sustained inflammation, as in the case of sunburned skin. Clinical observation has shown that the sensitivity of dentin often increases when the underlying pulp becomes acutely inflamed, and the tooth may be more difficult to anesthetize. This is due in part to the upregulation of tetrodotoxin-resistant (TTX-resistant) sodium channels in inflamed neural tissue.[121,139] NGF also seems to play an important role in hyperalgesia.[303] NGF regulates chronic inflammatory hyperalgesia by controlling gene expression in sensory neurons,[279] including genes involved in inflammatory hyperalgesia in the dental pulp.[75] Although a precise explanation for hyperalgesia is lacking, apparently localized elevations in tissue pressure and inflammatory mediators that accompany acute inflammation play an important role.[153,156,351,367,384] Clinically, we know that when the pulp chamber of a painful tooth with an abscessed pulp is opened, drainage of exudate soon produces a reduction in the level of pain. This suggests that mechanical stimuli may contribute substantially to pain during inflammatory hyperalgesia.

From Hargreaves KM, Swift JQ, Roszkowski MT, et al: Pharmacology of peripheral neuropeptide and inflammatory mediator release, *Oral Surg Oral Med Oral Pathol* 78:503, 1994.

From a clinical point of view, *thermal allodynia* is the term that best describes a patient whose chief complaint is, “I have pain when I drink cold beverages.” *Mechanical allodynia* is involved when the chief complaint is “It now hurts when I bite on this tooth.” These previously nonnoxious stimuli now cause the perception of pain. Hyperalgesia is manifested in endodontic pain patients when noxious stimuli (e.g., refrigerant sprays or CO_2 snow used in the cold test) produce much more pain than they would in teeth with normal pulp tissues. Spontaneous pain involves episodes of pain that seem to be unprovoked. All these changes can be partly explained by sensitization of peripheral nerve endings in the pulp and periradicular tissues.

Many silent nerve fibers are present in the normal pulp[273,274] and are termed *silent* because they are not excited by ordinary external stimuli. Once they are sensitized through pulpal inflammation, they begin to respond to hydrodynamic stimuli.[47,273,274,278] This phenomenon may provide an additional mechanism for dentin hypersensitivity. The molecular mechanisms of this activation are not known in detail but involve the upregulation of numerous genes and their products.[12,46,121]

Inflammatory mediators

Among the best characterized of the inflammatory mediators are the prostaglandins (PGs), which are derived from arachidonic acid via the action of the cyclooxygenase (COX) enzyme systems. The human COX enzyme is known to exist in at least two forms, COX-1 and COX-2. COX-1 is constitutively expressed and produces PGs that are involved in basic housekeeping functions such as cytoprotection in the stomach, regulation of blood flow in the kidneys, and the formation of thromboxane A_2. The formation of thromboxane A_2 can ultimately lead to platelet aggregation; therefore inhibition of thromboxane A_2 should decrease platelet aggregation. COX-2 is inducible, synthesized in inflamed tissues (including dental pulp),[267] and is important in the production of the proinflammatory PGs as well as the vasodilating prostacyclin (PGI_2). Although they do not produce

Telegram: @dental_k

www.konkur.in

pain if applied alone, PGs are known to sensitize peripheral nociceptors, which increases the algogenic (pain-producing) properties of serotonin and BK.[77,126] The exact mechanism by which PGs increase neuronal excitability is not clear, but there is a growing body of evidence to suggest that they activate the PG E receptor subtypes EP2 and EP3 in the trigeminal system[299] and exert their effects by regulating the activity of certain ion channels,[401] including voltage-gated sodium channels (for a review, see England[88]). For example, application of prostaglandin E_2 (PGE_2) to isolated dorsal root ganglion neuronal somata more than doubles the responsiveness of certain sodium channels found predominantly on nociceptors—channels thought to be relatively resistant to lidocaine.[9,122] When administered to rats before an inflammatory insult, ibuprofen, a nonselective COX inhibitor, has been shown to block the increased expression of $Na_v1.7$ and $Na_v1.8$.[129,130] Therefore if the concentrations of PGs in inflamed pulp and periradicular tissues can be decreased with nonsteroidal antiinflammatory drugs (NSAIDs) or corticosteroids, postoperative pain may be relieved; in addition, more profound local anesthesia may be achieved in patients with hyperalgesia of pulpal origin.[142,163,259] It is interesting to note that sensory neurons themselves are a source of PGs; during inflammation, the levels of PGE_2 appear to increase in dorsal root ganglia and spinal cord, suggesting that NSAIDs also have a central site of action (discussed in Chapter 6).[240,412]

BK is a proinflammatory mediator derived from circulating plasma proteins and also causes direct activation of nociceptive neurons, resulting in pain. Increased levels of BK have been demonstrated in the inflamed dental pulp,[211] and the presence of growth factors associated with inflammation (e.g., NGF) have been reported to cause an increase in the expression of mRNA encoding B1 and B2 receptors in primary cultures of rat trigeminal ganglia,[368] as well as other receptors such as TRPV1 and TRPA1.[75,170] The TRPV1 is the “capsaicin receptor”; it plays a key role in mediating inflammatory pain. TRPA1 is expressed on capsaicin-sensitive neurons[75] and interacts with TRPV1.[320] BK likely increases the excitability of nociceptive neurons through its action on TRPV1 and TRPA1 (for review, see Tominaga et al.[364]).

Cytokines are a diverse group of regulatory proteins synthesized and

Telegram: @dental_k

www.konkur.in

secreted by a variety of cell types, such as leukocytes, neurons, and glia. In particular, TNF-α and the interleukins IL-1β, IL-6, and IL-8 are thought to play a role in the neuroplastic changes that occur in nociceptors innervating inflamed tissues, leading to hyperalgesia.[201] Application of TNF-α rapidly sensitizes TRPV1,[185] contributing to activation of the capsaicin-sensitive class of nociceptors. All of these are thought to exist in the inflamed pulp (for review, see Fouad[102]) and are thought to act at least in part by causing increased release of prostanoids.[354]

Painful pulpitis

From the foregoing, it is apparent that pain associated with the stimulation of the A fibers does not necessarily signify that the pulp is inflamed or that tissue injury has occurred. Clinically, pain produced by A fibers in response to the hydrodynamic mechanism has a sharp or bright quality as contrasted with the dull, boring, or throbbing pain associated with C fibers. A fibers have a relatively low threshold of excitability to external stimuli,[251,272] and painful pulpitis is more likely to be associated with nociceptive C fiber activity indicative of pulpal tissue injury.[272–274,278] The clinician should carefully examine symptomatic teeth to rule out the possibility of hypersensitive dentin, cracked or leaky fillings, or fracture lines—each of which may initiate hydrodynamic forces—before establishing a diagnosis of reversible or irreversible pulpitis (see also Chapters 1 and 22).

Pain associated with an inflamed or degenerating pulp may be either provoked or spontaneous. The hyperalgesic pulp may demonstrate a lowered threshold of pain by responding to stimuli that usually do not evoke pain (allodynia), or the pain may be exaggerated and persist longer than normal (hyperalgesia).[6] On the other hand, the tooth may commence to ache spontaneously in the absence of any external stimulus.[139] Spontaneous, unprovoked pain generally indicates a pulp that is seriously damaged and generally will not respond to noninvasive therapy.

Plasticity of intradental nerve fibers

It has become apparent that the innervation of the tooth is a dynamic process in which the number, size, and cytochemistry of nerve fibers can change

because of aging,[104,227,356] tooth injury,[43,46,47,50] and dental caries.[316] For example, in rats, nerve fibers sprout into inflamed tissues surrounding sites of pulpal injury, and the content of CGRP and SP increases in these sprouting fibers.[43,46,47,50,54] When inflammation subsides, the number of sprouts decreases. Fig. 13.29 compares the normal distribution of CGRP-immunoreactive sensory fibers in an adult rat molar with those beneath a shallow cavity preparation. The innervational pattern in normal and inflamed teeth is governed by neuronal growth factors. Neurotrophic and target-derived factors regulate neuronal structure, survival, and function, and are important for the maintenance of neuronal phenotype characteristics. During development, all dental fibers appear to require NGF and express its receptor, tropomyosin receptor kinase A (TrkA),, at some stages,[249] whereas in adult teeth the large trigeminal neurons are potentially dependent only on dental pulp–derived, glial cell line–derived neurotrophic factor (GDNF); the smaller trigeminal neurons remain dependent on NGF.[204,311] This suggests that GDNF may function as a neurotrophic factor for the subset of larger neurons supporting the tooth, which apparently mediate mechanosensitive stimuli, whereas NGF is suggested to support neurons responsible for nociception.[264] NGF is the most extensively investigated among the trophic factors.[213] Binding of target-derived NGF is dependent on specific TrkA receptors located on the axonal surface, with subsequent internalization and transport to the cell body, where the effects are mediated.

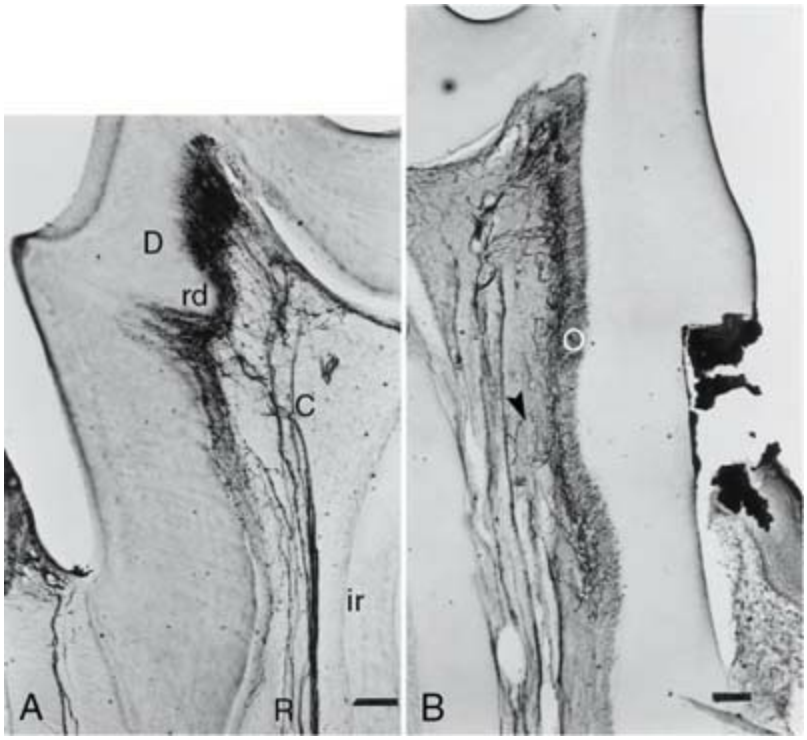

FIG. 13.29 **A,** Normal distribution of calcitonin gene–related peptide (CGRP)-immunoreactive sensory fibers in adult rat molar. Nerve fibers typically are unbranched in the root *(R)*, avoid interradicular dentin *(ir)*, and form many branches in coronal pulp *(C)* and dentin *(D)*. Nerve distribution is often asymmetric, with endings concentrated near the most columnar odontoblasts (in this case on the left side of the crown). When reparative dentin *(rd)* forms, it alters conditions so that dentinal innervation is reduced. **B,** Shallow class I cavity preparation on the cervical root of a rat molar was made 4 days earlier. Primary odontoblast *(O)* layer survived, and many new CGRP-immunoreactive terminal branches spread beneath and into the injured pulp and dentin. Terminal arbor can be seen branching *(arrowhead)* from a larger axon and growing into the injury site. Scale bar: 0.1 mm.

Two electron micrographs marked A and B compare the location and branching pattern of CGRP in the molar tooth of adult rat.

Source: (From Taylor PE, Byers MR and Redd PE: Sprouting of CGRP nerve fibers in response to dentin injury in rat molars, *Brain Res* 461:371–376, 1988.)

Regulation of neural changes during inflammation seems to be a function of NGF expression.[48,54] NGF receptors are found on intradental sensory fibers and Schwann cells.[46] Evidence indicates that NGF is synthesized by fibroblasts in the coronal subodontoblastic zone (i.e., cell-rich zone),

Telegram: @dental_k

www.konkur.in

particularly in the tip of the pulp horn.[46] Maximal sprouting of CGRP- and SP-containing nerve fibers corresponds to areas of the pulp with increased production of NGF.[54] Fig. 13.30 shows the expression of NGF-mRNA in a pulp horn subjacent to cavity preparation.

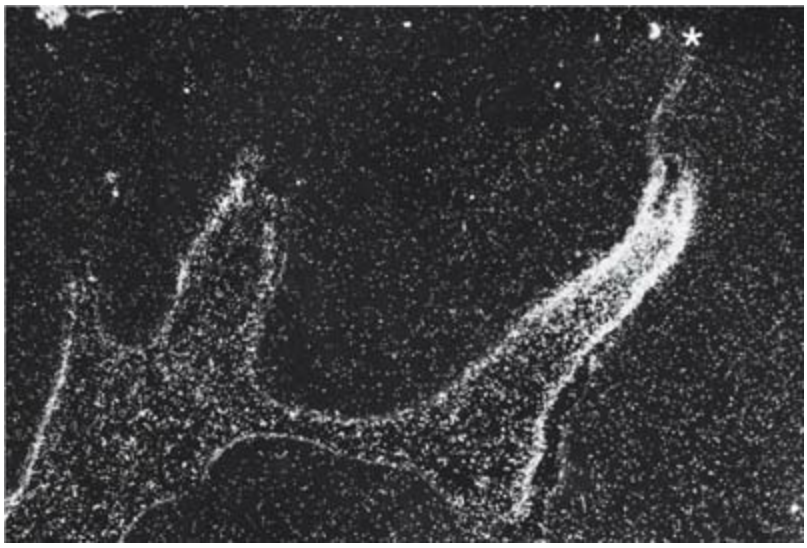

FIG. 13.30 NGF-mRNA is upregulated in the mesial pulp horn 6 hours after cavity preparation.

Electron micrograph shows two pulp horns in tooth where one pulp horn is large and extended toward the crown with a U-shaped mark at the top.

Source: (From Byers MR, Wheeler EF, and Bothwell M: Altered expression of NGF and p75 NGF-Receptor mRNA by fibroblasts of injured teeth precedes sensory nerve sprouting, *Growth Factors* 6:41–45, 1992.)

It has been suggested that neuroimmune interactions take place in the dental pulp, because a coordinated increase of pulpal nerves and immune cells has been demonstrated.[175,325] In addition, recruitment of immunocompetent cells has been demonstrated in the dental pulp after electrical tooth stimulation.[67,108] Similar responses have been seen in periapical bone in rats with radicular pulpitis.[198] Neurogenic inflammation is generally thought to enhance healing, because denervated teeth show poorer healing following pulp exposures than innervated teeth.[43,51]

Another consideration in the neural response to inflammation is the possibility of a change in the distribution and activity of voltage-gated

Telegram: @dental_k

www.konkur.in

sodium channels. In particular, mice lacking the gene for $Na_v1.7$ show reduced painlike behaviors when treated with a variety of proinflammatory agents.[275] Also implicated in the altered firing characteristics of nociceptors innervating inflamed tissues are the sodium channels that are resistant to TTX, the biotoxin found in the tetraodon pufferfish. The two main TTX-R sodium channels are $Na_v1.8$ and $Na_v1.9$, and both have been shown to be increased twofold to fourfold in inflamed dental pulp collected from patients with a diagnosis of irreversible pulpitis.[403,409] When exposed to PGE_2, neurons isolated from dorsal root ganglia cells have been shown to increase TTX-resistant sodium channel currents within minutes,[122] indicating an increased activation of existing channels, rather than de novo protein synthesis. These sodium channels are relatively resistant to lidocaine,[319] and this may explain the difficulty in achieving profound anesthesia in inflamed tissues (see also Chapter 6).[142]

Tissue injury and deafferentation

When a peripheral nerve is cut or crushed, an interruption of the afferent input to the CNS occurs, which is called *deafferentation.* It would be logical to assume that the result of deafferentation would be anesthesia of the formerly innervated area, but occasionally other symptoms may occur, which may surprisingly include pain. Following nerve injury, a dramatic shift in transcription of neuropeptides, receptors, and sodium channels has been documented. The bidirectional contact between the nerve cell and the peripheral target tissue is lost, and the neurons change into a state of either regeneration or neuronal cell death. The impact on neurons in the trigeminal ganglion is dependent on the injury site. A peripheral injury has less effect than a more centrally located one. However, even a small pulp exposure induces neuronal changes, both in the trigeminal ganglion and at the second-order neuronal level in the brain stem.[44,398] Because each single-rooted tooth contains about 2000 nerve fibers,[171,172] extirpation of the pulp is shown to cause both neurochemical and degenerative changes of their cell bodies in the trigeminal ganglion.[131,188,340] The central projection of these nerves to the spinal nucleus of the trigeminal nerve is also affected,[372] and there is evidence for transsynaptic changes[336,340] that are reflected in the sensory

Telegram: @dental_k

www.konkur.in

cortex. Even larger responses would be expected from tooth extraction, where both periodontal ligament and pulpal innervation are destroyed.

When an axon is severed peripherally, a complete degeneration of the cell bodies may not always occur.[399] Attempted regeneration by axonal sprouting may result in altered expression of various receptors, resulting in sensitivity to NE (via increased adrenergic receptor activity)[284] or acetylcholine (ACh) (via increased cholinergic receptor activity),[73] sensitizing sensory neurons to autonomic activity. In addition, dorsal horn neurons, deprived of their normal sensory input, may begin to respond to other nearby afferents. Thus normal inhibitory influences are reduced, and a widening of the sensory receptive field is produced, which can produce central sensitization (see Central Sensitization later in this chapter). *Phantom tooth pain* is another term often used synonymously with pain following deafferentation. Different reports suggest an incidence of persistent pain following pulpectomy to be in the range of 3% to 6%.[243,389]

Following tissue injury or tissue inflammation, extensive changes occur in the gene expression of sensory ganglion neurons and, by way of transsynaptic mechanisms, in their central projections (Fig. 13.31).[46,107,188,340] One example is the upregulation of inducible gene transcription factors such as c-*fos*[44] and different subsets of sodium channels.[119] This is thought to result in alterations in threshold properties and the size of receptor fields. C-*fos* is not normally expressed in neurons in the brain stem, but chronic pulpitis causes prolonged increases in c-*fos* expression is some brain stem neurons (see Fig. 13.31).[44]

certain patients may complain of vague, poorly described pain for months following endodontic treatment. If their pulpitis caused sprouting of periapical nerves,[50,51,54,198] then these nerves may have taken part in transport of peripheral signaling molecules to the cell body by way of retrograde axoplasmic flow.[43,54] This could induce changes in the expression of many genes, resulting in central sensitization[6,42] that may require many months to correct.[75] Reports of nerve sprouting in human inflamed pulps have been confirmed in different studies.[316,318,325] Such reactions might contribute to increases in dentin sensitivity as well as expansion of receptive fields.[273,274,278] Sprouting of sympathetic fibers has also been reported,[149] but the timing appears to be different. The functional implications and how these relate to pain mechanisms are unknown, but it has been suggested that these reactions are involved in healing and nociception following pulpal inflammation.[117,149,150]

Processing: The second step in pain perception

The medullary dorsal horn

After activation of peripheral nociceptors, nerve impulses in the form of action potentials convey information about the intensity (encoded by firing frequency), quality (encoded by type of neuron activated), and temporal features (encoded by onset, duration, and offset of depolarization) of the peripheral stimuli to the CNS. In the trigeminal pain system, these action potentials arrive at the trigeminal spinal tract nuclear complex located in the medulla.[143,218,329] Three distinct subnuclei can be found in this complex. Named for their anatomic position, they are the *subnuclei oralis*, *interpolaris*, and *caudalis* (see Fig. 13.23). Although the more rostral subnuclei (oralis and interpolaris) receive some nociceptive input from oral tissues,[71] most such input is received at the level of the subnucleus caudalis.[238,335] Because of its organizational similarity to the dorsal horn of the spinal cord (which receives nociceptive input from the somatosensory system), the subnucleus caudalis has been termed the *medullary dorsal horn*.

Components of the medullary dorsal horn

The medullary dorsal horn relays information to higher centers in the brain

www.konkur.in

and serves as the site of much potential processing of the signals from primary afferent sensory nerve fibers. Output from this region can be increased (hyperalgesia), decreased (analgesia), or misinterpreted (referred pain). Understanding the functional components involved in such processing not only helps explain some of these clinical phenomena but also allows evaluation of potential therapeutic modalities currently under investigation. Functional components include the central terminals of primary nociceptors (Aδ and C fiber afferents), the second-order projecting neurons, interneurons, the terminals of descending neurons, and glial[246] cells (for review, see Hargreaves[139]).

Primary afferent fibers (whose cell bodies are located in the trigeminal ganglion) transmit signals to projection neurons via the release of transmitters such as the excitatory amino acid, glutamate, and the neuropeptide, SP. Receptors for these neurotransmitters are found on postsynaptic membranes and include the N-methyl-d-aspartate receptor (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPA) classes of glutamate receptors and the neurokinin 1 (NK1) class of SP receptors. Antagonists to these receptors have been shown to reduce hyperalgesia in animal studies.[60] In a human clinical trial using an oral surgery model, the AMPA/kainate antagonist, LY293558, was shown to be antihyperalgesic.[119] NK1 antagonists have shown promising results in animal studies, but in general, they have displayed limited analgesic efficacy in humans.[158]

The cell bodies of the second-order (projection) neurons in the trigeminal pain system are found in the medullary dorsal horn; their processes cross the midline and project rostrally to the thalamus via the trigeminothalamic tract (Fig. 13.32). From the thalamus, third-order neurons relay information to the cerebral cortex via a thalamocortical tract. Once signals have reached the cortex, the input may be perceived as pain. Evidence exists that referred pain is caused by convergence of afferent input from different areas onto the same projection neurons.

Telegram: @dental_k

www.konkur.in

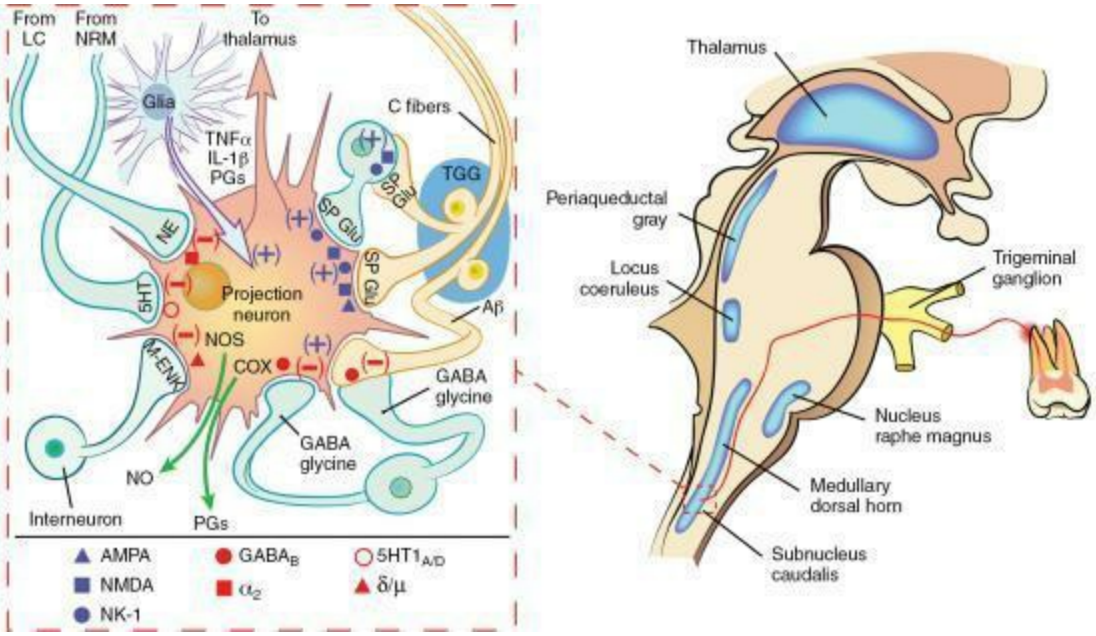

FIG. 13.32 Schematic diagram of the perception and modulation of orofacial pain. Activation of primary afferent fibers (in this example from an inflamed maxillary molar) leads to the entry of a nociceptive signal that is conveyed across a synapse in the subnucleus caudalis of the trigeminal spinal nucleus. The second-order neuron projects to the thalamus; the information is then relayed to the cortex. A great deal of processing of nociceptive input can occur at the level of the medullary dorsal horn (MDH). The *inset* depicts a typical wide dynamic range (WDR) projection neuron and its relationship with other components of the MDH. Primary afferent fibers release the excitatory amino acid, glutamate—which binds and activates either AMPA or NMDA receptors —and substance P—which activates NK-1 receptors on the WDR neuron or excitatory interneurons. Descending fibers from the locus coeruleus *(LC)* and nucleus raphe magnus *(NRM)* secrete serotonin *(5HT)* and norepinephrine *(NE)*, respectively, which inhibit transmission. Release of γ amino butyric acid *(GABA)*, the amino acid, glycine, and endogenous opioid peptides such as met-enkephalin *(M-ENK)* also inhibit transmission of nociceptive information. Projection neurons may have autocrine or paracrine effects by the synthesis and release of prostaglandins *(PGs)* and nitric oxide *(NO)* via the action of cyclooxygenase *(COX)* and nitric oxide synthase *(NOS)*, respectively. Glial cells can modulate nociceptive processing by the release of cytokines such as tumor necrosis factor α *(TNF-α)* and interleukin 1 β *(IL-1β)*. The + sign indicates an excitatory action, whereas the—sign denotes an inhibitory action. *AMPA,* α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; *NK,* neurokinin; *NMDA, N*-methyl-d-aspartate; *SP,* substance P; *TGG,* trigeminal ganglion.

Telegram: @dental_k

www.konkur.in

dorsal horn, subnucleus caudalis, locus coeruleus, periaqueductal gray, and thalamus. An inset from subnucleus caudalis shows projection of neuron and associated components.

Approximately 50% of subnucleus caudalis neurons are estimated to receive convergence of sensory input from cutaneous and deep structures.[335] In one study of a cat, a single nucleus caudalis neuron received input from sensory neurons innervating the cornea, the skin overlying the maxilla, a maxillary premolar tooth, and a mandibular canine and premolar tooth on one side.[339] Subnuclei oralis and interpolaris also receive converging input from orofacial and muscle afferents.[338] This would explain the clinical observation of patients who perceive pain in a particular tooth that actually originates from either a different tooth or structure (see also Chapter 4). In such cases, anesthetizing the tooth suspected by the patient would afford no relief. However, if an anesthetic is delivered selectively to the suspected primary source of pain, the patient's discomfort should greatly diminish.[285] Likewise, if the source of a perceived toothache were located in a muscle of mastication, palpation of that muscle should aggravate the pain.[417]

In the medullary dorsal horn, local circuit interneurons have the potential to affect the transmission of nociceptive input from primary afferents to projection neurons. Depending on the transmitter released, these neurons have the ability to enhance or diminish the signal. Typically, excitatory interneurons release glutamate or SP, whereas inhibitory interneurons release the amino acid, glycine, or γ amino butyric acid (GABA).[218,337]

The terminals of neurons that descend from brain structures such as the locus coeruleus and nucleus raphe magnus tend to inhibit nociceptive transmission at the level of the medullary dorsal horn.[14] These terminals release a variety of neuroeffective agents, including the endogenous opioid peptides (EOPs). The EOPs, similar in three-dimensional structure to many of the exogenous opiates from which their name derives, are released in response to nociceptive input and act to suppress the pain system. The EOPs likely are partly responsible for the placebo effect seen in pain control studies, because this effect can be reversed by administration of the opioid antagonist, naloxone.[141,216]

The final component of the medullary dorsal horn complex to be considered is the glial cell population. Historically considered to be solely

Telegram: @dental_k

www.konkur.in

supportive in function, they are now recognized to play an important role in the pain processing system.[308,404] Following nociceptive input from primary afferents, glia release cytokines such as TNF-α and IL-1, as well as certain PGs that may facilitate the activity of projection neurons. Glial modulating agents have been shown to be effective in experimental models of neuropathic pain,[355] and NSAIDs potentially could exert part of their analgesic mechanism by acting at this level.

Central sensitization

Central sensitization can be defined as an increased responsiveness of central nociceptive neurons to peripheral stimulation that occurs in addition to *peripheral sensitization* of the primary afferent nociceptors. Central sensitization is thought to be a major cause of hyperalgesia and allodynia.[208] Clinical trials implicate central sensitization in patients reporting pain due to irreversible pulpitis. In one survey of nearly 1000 patients, 57% of patients with irreversible pulpitis reported mechanical allodynia (pain due to percussion).[294] This appears to be due at least in part to central sensitization, as both the ipsilateral (pulpitis) tooth and a contralateral (normal) tooth demonstrated mechanical allodynia to a force transducer.[187] Thus central sensitization contributes to a spread of endodontic pain, and the clinical application of bite force transducers may provide a novel method for diagnosing pain mechanisms.[186,187]

Different studies shed light on the molecular mechanisms involved in central sensitization (for review, see Cousins and Power[64] and Hargreaves[139]), but the process is generally initiated by a barrage of nociceptive impulses from peripheral C fibers. The level and duration of pain prior to endodontic intervention have been cited in several studies as predictors of postoperative endodontic pain,[369,400] and this may be due to such a prolonged and intense input from C nociceptors. Any reduction of such a barrage should limit the occurrence of central sensitization and the development of pain of longer duration after tissue injury (including surgical and nonsurgical endodontic procedures). The use of long-acting local anesthetics following tonsillectomies and third molar extractions has been shown to provide pain relief far beyond the duration of the peripheral tissue anesthesia.[127,169]

Telegram: @dental_k

www.konkur.in

A reduction in the chemical mediators of inflammation at the level of the medullary dorsal horn also should reduce sensitization of second-order neurons. Decreasing the synthesis of proinflammatory PGs, cytokines, nitric oxide (NO), or the use of drugs that block the receptors of such agents probably will become accepted pharmacotherapy in the future. For example, application of an inflammatory agent to the tooth pulp of rat maxillary molars results in an increased receptive field of Aβ touch receptors on the face. This can be blocked by pretreatment with a glutamate NMDA receptor antagonist, indicating that such centrally acting drugs may offer highly efficacious means of treating odontogenic pain.[60] A similar investigation implicated NO synthesis at the level of the subnucleus caudalis in the development of tactile hypersensitivity following dental injury.[423] Reduction in NO synthase levels may also provide protection from central sensitization.[239,253]

Perception: Thalamus to cortex

The final anatomic step in the trigeminal pain pathway relies on neurons that leave the thalamus and extend to the cerebral cortex (see Fig. 13.23). The patient actually perceives a stimulus as painful at the cortical level. It is interesting to note (but likely of no surprise to the experienced clinician) that a disproportionately large portion of the sensory cortex in humans is devoted to input from orofacial regions.[300]

It is becoming increasingly obvious that higher-order (i.e., cortical) perceptual processes have a profound effect on the ultimate state of pain the patient experiences (for a review, see Yaksh[418]). Memories of previous pain experiences provide a framework by which similar new experiences are judged and serve to shape the patient's response to a given stimulus. In the field of dentistry, the anxiety level of the patient at the time of treatment has been shown to affect not only the patient's response to pain experienced during treatment,[79,414] but also the tendency of the patient to recall the experience as painful or unpleasant even 18 months after treatment.[114] The clinician should do everything possible to control a patient's anxiety level prior to endodontic treatment. One simple pretreatment method is to provide patients with positive written information regarding the control of pain during their endodontic treatment. In a placebo-controlled clinical trial, 437 endodontic patients were given one of five informative paragraphs to read

Telegram: @dental_k

www.konkur.in

prior to treatment. One of the paragraphs contained positive information about pain during treatment. Patients completed questionnaires following treatment that evaluated their dental anxiety and dental fear. Subjects given positive information were shown to be less fearful of pain during endodontic therapy.[386] Along with a positive and caring attitude, pharmacologic intervention may help reduce anxiety. Nitrous oxide has been shown to be effective in a dental setting,[76] but it may interfere with radiography procedures during endodontic therapy. In a placebo-controlled clinical trial in patients undergoing the extraction of impacted third molars, 0.25 mg of oral triazolam (a benzodiazepine) provided comparable anxiolysis to intravenous diazepam titrated to a typical clinical endpoint.[178] Of course, the patient so medicated must be provided transportation to and from the dental office, and the potential drug-drug interactions with other centrally acting agents such as opioids, barbiturates, and alcohol must be considered. One interaction that should be considered is the capacity of grapefruit juice to prolong the half-life of triazolam.[221] It has been shown that furanocoumarins in grapefruit juice inhibit cytochrome P450 3A4,[296] which is the enzyme responsible for the metabolism of triazolam in the liver. Patients should be told not to take oral triazolam with grapefruit juice.

Vascular supply

Blood from the dental artery enters the tooth by way of arterioles having diameters of 100 μm or less. These vessels pass through the apical foramen or foramina with nerve bundles. Smaller vessels may enter the pulp by way of lateral or accessory canals. They are richly innervated by autonomic and sensory nerves, and the regulation of blood flow seems to be dominated by neuronal control (Fig. 13.33).[2,20,191,289,365]

The arterioles course up through the central portion of the radicular pulp and give off branches that spread laterally toward the odontoblast layer, beneath which they ramify to form a capillary plexus (Fig. 13.34).[200] As the arterioles pass into the coronal pulp, they fan out toward the dentin, diminish in size, and give rise to a capillary network in the subodontoblastic region (Fig. 13.35).[358] This network provides the odontoblasts with a rich source of metabolites.

Capillary blood flow in the coronal portion of the pulp is nearly twice that in the root portion.[195] Moreover, blood flow in the region of the pulp horns is greater than in all other areas of the pulp.[254] In young teeth, capillaries commonly extend into the odontoblast layer, thus ensuring an adequate supply of nutrients for the metabolically active odontoblasts (Fig. 13.36). In the subodontoblastic capillaries, fenestrations are observed in the vessel wall.[312] These fenestrations are thought to promote rapid transport of fluid and metabolites from the capillaries to the adjacent odontoblasts. The average capillary density is about 1400/mm^2, which is greater than in most other tissues of the body.[393]

Blood passes from the capillary plexus, first into postcapillary venules (see Figs. 13.35 and 13.37) and then into larger venules.[200] Venules in the pulp have unusually thin walls, and the muscular layer is discontinuous,[70] which may facilitate the movement of fluid in or out of the vessel. The collecting venules become progressively larger as they course to the central region of the pulp. The largest venules have a diameter that may reach a maximum of 200 μm, which is considerably larger than the arterioles of the pulp.

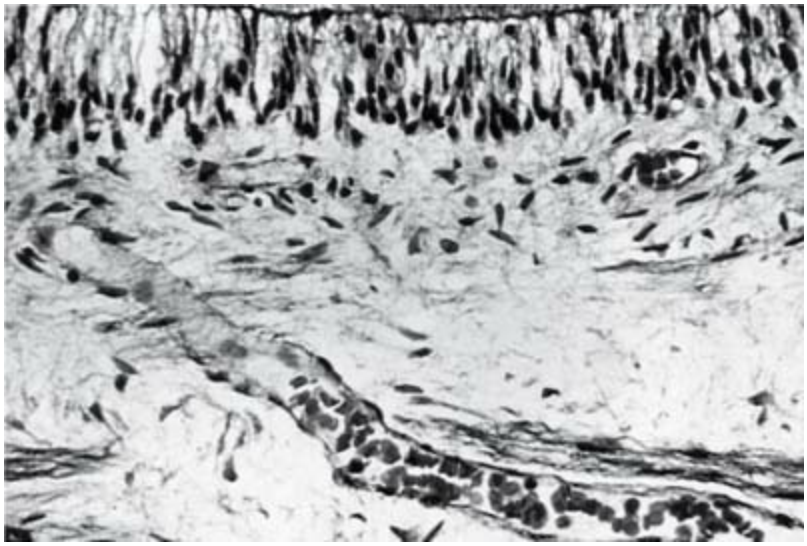

FIG. 13.37 Postcapillary venule draining blood from subodontoblastic capillary plexus.

Electron micrograph shows narrow channel of postcapillary venule with blood cells in pulp below odontoblast layer.

The resting PBF is relatively high averaging 0.15 to 0.60 mL/min/g tissue.[250,367] Blood volume represents about 3% of pulpal wet weight,[31] approximately the same as in mammary tumor tissue.[410] As would be anticipated, PBF is greater in the peripheral layer of the pulp (i.e., the subodontoblastic capillary plexus)[200] where the oxygen consumption has been shown to be higher than in the central pulp.[26]

Changes in PBF can be measured through dentin using laser Doppler flowmeters. Sensitivity to movement requires that they are stabilized in an occlusal stent or a modified rubber dam clamp.[95,327] Because up to 80% of the Doppler signal originates from periodontal tissue, it is helpful to cover periodontal tissues with a black rubber dam.[146] Laser Doppler flowmetry can be used to detect revascularization of traumatized teeth.[80,90] Although measurement of PBF would be an ideal tool for determining pulp vitality, the use of laser Doppler and other techniques is limited due to sensitivity, specificity, reproducibility, and costs.

Regulation of pulpal blood flow

Under normal physiologic conditions, pulpal vascular tone is controlled by neuronal, paracrine, and endocrine mechanisms that keep the blood vessels in

Telegram: @dental_k

www.konkur.in

a state of partial constriction. The PBF is also influenced by vascular tone in neighboring tissues. Vasodilatation in these tissues has been shown to cause a drop in PBF due to reduction in local arterial pressure of the teeth and thereby reduced pulpal perfusion pressure.[366] The "stealing" of dental perfusion pressure makes the dental pulp vulnerable in clinical situations with inflammatory processes in the adjacent tissues, as in gingivitis and periodontitis. There is no autoregulation of PBF as it follows passively changes in systemic blood pressure.[189]

Neuronal regulation of blood flow is extensive in the pulp. There is little or no vasoconstrictor tone of sympathetic origin in the dental pulp during resting conditions,[167,365] but a neuronal vasodilator tone caused by release of sensory neuropeptides has been demonstrated (Fig. 13.38).[21,20]

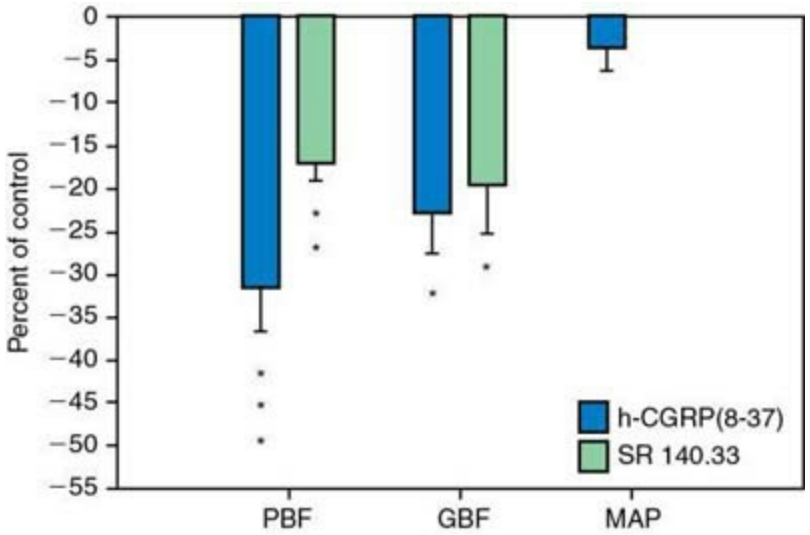

FIG. 13.38 Effect of antagonist infusion of h-*CGRP(8-37)* (calcitonin gene–related peptide inhibitor) and *SR* 140.33 (substance P inhibitor) on basal pulpal blood flow *(PBF)* and gingival blood flow *(GBF)*. *MAP,* Mean arterial pressure. ***, p <0.001, **, p <0.005, *, p <0.05, as compared with control recordings before antagonist infusion.

Bar graph plots percent of control against PBF, GBF, and MAP on the horizontal axis. The vertical axis ranges from 0 to negative 55 from bottom to top. The data are as follows. PBF: h-CGRP(8-37): negative 32, SR 140.33: negative 18, GBF: h-CGRP(8-37): negative 24, SR 140.33: negative 20, and h-CGRP(8-37): negative 4.

Telegram: @dental_k

www.konkur.in

gingival blood flow in ferrets, *Arch Oral Biol* 45:537, 2000.)

There are α-adrenergic receptors in the pulp,[164] and stimulation of the cervical sympathetic trunk causes vasoconstriction and fall in PBF that can be partially reversed by α-receptor blockade.[191,365] NPY, colocalized with NE in pulpal sympathetic nerve fibers, also contributes to vasoconstriction in the pulp.[82,197]

Increase in PBF is observed after electrical tooth stimulation and is caused by the release of sensory neuropeptides followed by vasodilatation.[20,155,183] CGRP released from sensory nerve fibers is mainly responsible for the observed vasodilatation.[20,21]

Glutamate, present in CGRP negative sensory afferent nerve fibers in the pulp, also has a vasodilatory effect when applied in the pulp during experimental conditions.[426]

There is evidence for sympathetic modulation of sensory neuropeptide release in the dental pulp[140]; presynaptic adrenoceptors are found on the sensory nerve terminals and attenuate the release of vasodilators from the sensory nerves.[35,183]

Muscarinic receptors have been identified in the pulp,[33] and the parasympathetic neurotransmitter ACh causes vasodilatation and increases blood flow in the tissue.[424] The vasodilation evoked by ACh has been demonstrated to be partly dependent on NO production.

VIP, which coexists with ACh in postganglionic neurons, is found in the dental pulp[382,397] and has been demonstrated to cause vasodilatation and increase in PBF in cats.[289]

On the other hand, Sasano and coworkers[329] failed to demonstrate parasympathetic nerve-evoked vasodilatation in the cat dental pulp, leaving pulpal vascular responses to parasympathetic neurotransmitters with some uncertainty.

Local control of blood flow

The microvascular bed in the dental pulp has the ability to regulate hemodynamics in response to local tissue demands. Endothelin-1 is located in the endothelium of pulpal vasculature,[58] and close intraarterial infusions of endothelin-1 reduce PBF.[22,118,424] However, endothelin-1 does not seem to

Telegram: @dental_k

www.konkur.in

influence blood vessel vascular tone under basal, resting conditions.[22]

The endothelium in pulpal blood vessels modulates vascular tone by release of vasodilators such as prostacyclin and NO. A basal synthesis of NO provides a vasodilator tone on pulpal vessels.[20,226] The shear forces that blood flow exerts on endothelial cells seem to regulate the release of NO.[77]

Adenosine is released from ischemic and hypoxic tissue and is probably important in the metabolic regulation of blood flow in periods of low pulpal oxygen tension. When applied from the extraluminal side of the vessel wall, adenosine mediates vasodilatation in pulpal vessels.[424]

Humoral control of blood flow

Evidence for humoral control of PBF exists and takes place when vasoactive substances transported by the bloodstream reach the receptors in the pulp tissue. Angiotensin II is produced by activation of the renin/angiotensin system and exerts a vasoconstrictive basal tone on pulpal blood vessels.[22] The angiotensin II receptors, AT1 and AT2, have been identified in rat pulp.[348]

Similarly to the effect of NE released from sympathetic nerve fibers in the pulp, epinephrine released from the adrenal medulla will cause vasoconstriction due to activation of α-adrenergic receptors in the pulp. Another catecholamine, dihydroxyphenylalanine (DOPA), also induces vasoconstriction in pulpal arterioles when applied intraarterially.[424]

Fluid drainage

Interstitial fluid, which accumulates in the tissue during normal conditions through net filtration out of the blood vessels or during inflammation where the net filtration is increased, must be removed in order to maintain normal fluid balance. In most tissues in the body, the lymphatic vessels drain excess fluid from the peripheral tissue and return it into the blood vessel system. In addition, the lymphatic system is important because it transports captured antigen and presents it in the lymph nodes. The existence of lymphatics in the pulp has been a matter of debate because it is difficult to distinguish between blood and lymphatic vessels by ordinary microscopic techniques without specific lymphatic markers.

Several specific lymphatic markers have now been applied, and

Telegram: @dental_k

www.konkur.in

contradictory conclusions have been drawn. One of the markers tested is vascular endothelial growth factor receptor (VEGFR-3), known to be expressed by lymphatic endothelial cells in adult tissue.[114,242] The receptor expression was reported in human and mouse pulp tissue, but to identify lymphatic vessels use of more than one lymphatic marker is recommended. VEGFR-3 has recently been demonstrated in blood vessels and on various immune cells and is not specific to lymphatic vessels.[30,390] However, other studies have failed to demonstrate lymphatic markers in the pulp [116,247] and one study showed lymphatic vessel endothelium receptor-1 (LYVE-1) staining in immune cells in human pulp, but not in vascular structures (Fig. 13.39). The same observation was done in a characterization of the lymphatic system of the mouse head.[228] The authors showed that lymphatic vessels were found in the mandibular canal. We have demonstrated lymphatic vessels in the mandibular canal in rats starting below the molars (Fig. 13.40). Taken together, we can conclude that the pulp is not supplied with draining lymphatic vessels.

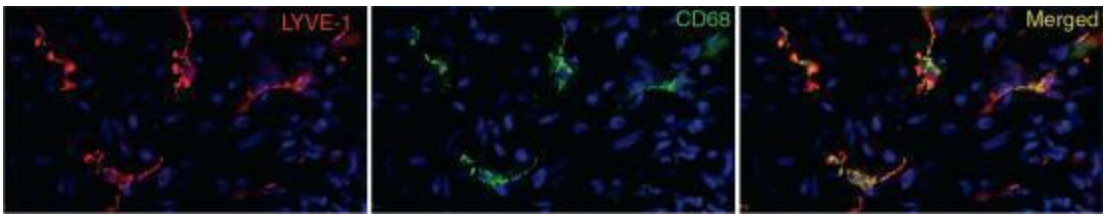

FIG. 13.39 Immune cells in normal human pulp are immunopositive to *LYVE-1*, known as a lymphatic vessel marker. The *CD68*$^{+}$*/LYVE-1*$^{+}$ cells derive from the monocytic lineage of cells. Immunostaining demonstrated the lack of *LYVE-1*$^{+}$ lymphatic vessels in the pulp.

Set of three confocal images show the presence of LYVE-1, CD68, and merged cells, respectively, in the tooth pulp.

Transcapillary fluid exchange

In all tissues in the body, the fluid transport between the blood vessels and the interstitial space is regulated by differences in colloid osmotic and hydrostatic pressures in the plasma and the interstitium, and by properties in the capillary membrane (Fig. 13.41). From the interstitium excess fluid is transported back to the blood circulation through the lymphatic system. The pulp seems to be an exception along with, for example, the brain and bone marrow, as lymphatic vessels are not detected in the tissue (see the previous section). During normal conditions, a steady state is achieved as the fluid filtered into the interstitial space equals the amount of fluid transported out of the same compartment. Using radioisotopes, the interstitial fluid volume in the pulp was measured and averaged 0.6 ± 0.03 mL/g wet weight,[31] demonstrating that as much as 60% of the extracellular fluid in dental pulp is located outside the vascular system. Measurements of interstitial fluid

Telegram: @dental_k

www.konkur.in

pressure in the pulp with the micropuncture method have given values that range from 6 to 10 mm Hg,[20,152] but higher values measured with different methods have also been reported.[40,385,392]

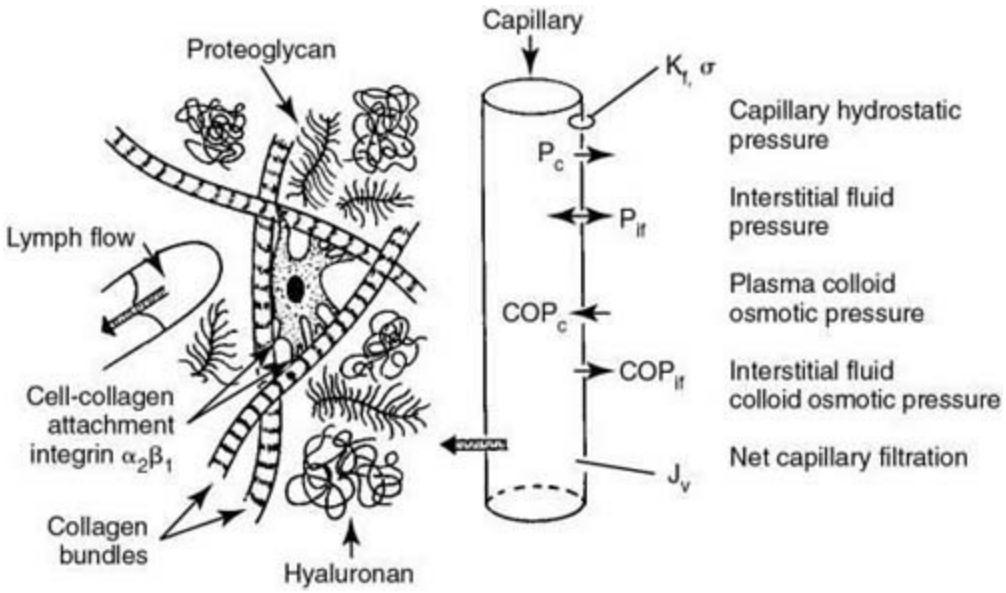

FIG. 13.41 Interstitial structure and pressures that govern transcapillary fluid transport. K_f, Capillary filtration coefficient; σ, capillary reflection coefficient for plasma proteins.

Capillary with labels as follows: K sub f, alpha, capillary hydrostatic pressure (P sub c), interstitial fluid pressure (P sub i f), plasma colloid osmotic pressure (COP sub c), interstitial fluid colloid osmotic pressure (COP sub i f), and net capillary filtration (J sub v). Labels associated with neuron are as follows: Hyaluronan, collagen bundles, cell-collagen attachment integrin alpha sub 2 beta sub 1, lymph flow, and proteoglycan.

Source: (From Wiig H, Rubin K, Reed RK: New and active role of the interstitium in control of interstitial fluid pressure: potential therapeutic consequences, *Acta Anaesthesiol Scand* 47:111, 2003.)

Colloid osmotic pressure (COP) measurements in interstitial fluid isolated from rat incisors have shown a relatively high pulpal COP, reaching 83% of plasma COP.[31] The high value may imply that the normal permeability of pulpal vessels to plasma proteins is relatively high or the drainage of plasma proteins is ineffective.

Because lymphatic vessels are lacking inside the pulp, excess interstitial fluid and proteins must be transported out of the pulp by other transport

Telegram: @dental_k

www.konkur.in

routes in order to achieve a steady-state situation. Two possibilities exists: (1) transport of fluid in the interstitial compartment toward the apical part of the pulp and furthermore out of the apex, and (2) a combination of fluid reabsorption into pulpal blood vessels in addition to transport of protein-rich fluid toward the apex.

Circulation in the inflamed pulp

Inflammation in the pulp takes place in a low-compliance environment composed of rigid dentinal walls. *Compliance* is defined as the relationship between volume (V) and interstitial pressure (P) changes: $C = \Delta V/\Delta P$. Consequently, in the low-compliant pulp, an increase in blood or interstitial volume will lead to a relatively large increase in the hydrostatic pressure in the pulp. The acute vascular reactions to an inflammatory stimulus are vasodilatation and increased vascular permeability, both of which will increase pulp interstitial fluid pressure[153,156,365,384] and may tend to compress blood vessels and counteract a beneficial blood flow increase (Fig. 13.42).

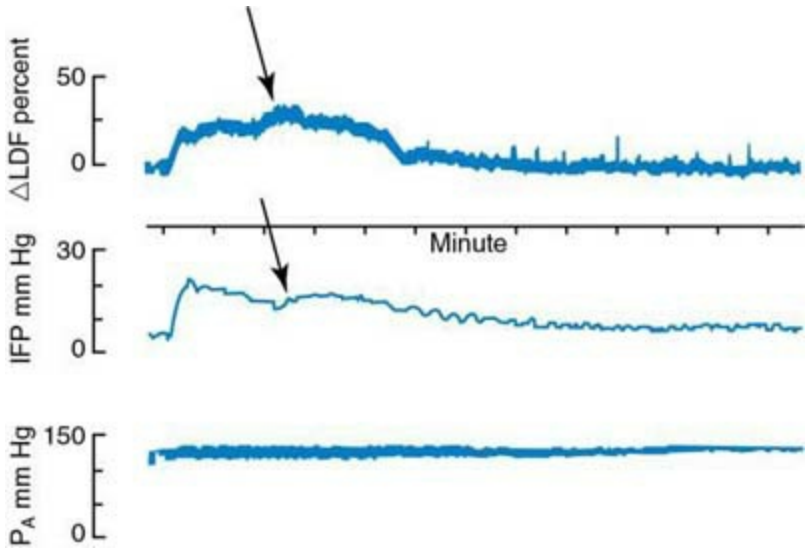

FIG. 13.42 Original simultaneous recordings of percent change in pulpal blood flow *(*ΔLDF%), interstitial fluid pressure *(IFP)*, and systemic blood pressure *(P_A* mm Hg) in a cat during electrical tooth stimulation. Note that when IFP is first decreasing after an initial rise, the pulpal blood flow reaches its maximal level *(arrows),* demonstrating compression of vessels in the first phase.

Three graphs compare the recordings of uppercase delta LDF percent, IFP,

Telegram: @dental_k

www.konkur.in

and P sub A in mm Hg against minutes. In LDF, the LDF reading originates from 0, reaches a height at 30, slops down to 0 and oscillates throughout. IFP reading originates from 0, reaches a height at 27, slopes down to 24 (when LDF increases), oscillates, and terminates at 8. P sub A originates from 110 and remains almost constant throughout. All data are approximate.

Source: (Courtesy Dr. K.J. Heyeraas.)

Classical studies have demonstrated that an increase in intrapulpal tissue pressure promoted absorption of tissue fluid back into the circulation, thereby reducing the pressure.[153,156] This observation can explain why pulpal tissue pressure in inflamed pulps may persist in local regions for long observation periods,[367] contradicting the old concept of a wide, generalized collapse of pulpal venules and cessation of blood flow (pulpal strangulation theory).

The delivery of dental restorative procedures may lead to substantial increases or decreases in PBF, depending on the precise procedure and time point sampled.[191] Vasoactive mediators are locally released upon an inflammatory insult, and in the pulp, PGE_2, BK, SP, and histamine have all been demonstrated to increase PBF after application.[194,290] In contrast, serotonin (5-HT) is released primarily from the platelets, and given intraarterially, it has been shown to reduce PBF.[196,424]

Acute inflammation in the dental pulp induces an immediate rise in blood flow and can reach a magnitude of up to nearly 200% of control flow followed by increased vascular permeability.[154,156]

A common outcome of pulpal inflammation is development of tissue necrosis. One study found circulatory dysfunction developed in the pulp after exposure to lipopolysaccharide (LPS) from gram-negative bacteria.[31]

In addition, the inflammatory cytokines IL-1 and TNF-α are elevated in the inflamed pulp. When the endothelium is exposed to endotoxin, it expresses cytokines, chemokines, and thromboxane A2. The latter has been demonstrated to be produced in the pulp exposed to LPS[287] and induces vasoconstriction. The set of changes in endothelial function have been called *endothelial perturbation* and were first described in endothelial cells exposed to endotoxin or to cytokines such as IL-1, TNF-α, and IL-6.[24,276] The activated endothelium also participates in procoagulant reactions that promote fibrin clot formation.[352] A reduced pulpal perfusion due to

Telegram: @dental_k

www.konkur.in

endothelial perturbation might be the consequence of bacterial infection impairing pulpal defense mechanisms and promoting necrosis. Downregulation of vascular endothelial growth factor (VEGF) expression in stromal cells and reduced microvessel density have been observed in human dental pulps with irreversible pulpitis.[10] VEGF is an essential proangiogenic factor, and the reduced microvessel density might also lead to reduced pulpal perfusion and contribute to development of pulpal necrosis.

Vascular permeability

Increased vascular permeability takes place as a result of acute inflammation, and vascular leakage has been demonstrated in the pulp after release of inflammatory mediators such as PG, histamine, BK, and the sensory neuropeptide, SP.[184,194,241]

LPS and lipoteichoic acid from gram-negative and gram-positive bacteria, respectively, cause upregulation of VEGF in activated pulpal cells.[34,360] VEGF increases vascular permeability,[93,334] and it is likely that it also causes leakage in pulpal vessels. It is a potent agent, because its ability to enhance microvascular permeability is estimated to be 50,000 times higher than that of histamine.[341] Cytokines such as IL-1 and TNF-α are released into the pulp interstitial fluid during inflammation[31] and upregulate VEGF mRNA gene expression in pulpal fibroblasts.[61]

The resulting increased vascular permeability allows increased transport of proteins through the capillary vessel wall and results in increased COP in the tissue. In acute pulpitis induced by LPS, it has been shown that COP in the pulp can reach the level of plasma COP, meaning that a protein transport barrier between plasma and interstitium can be eliminated.[31]

The lack of lymphatic vessels in the pulp may in this situation disfavor the pulps ability to recover and reestablish a normal COP since the transport of proteins is dependent on a pressure difference for fluid transport out of the pulp. Lack of lymphatic vessel for transport of protein-rich fluid may make the pulp more vulnerable to development of necrosis after severe pulpitis.

Clinical aspects

The influence of posture on PBF has been observed in humans.[95] Significantly greater PBF was measured when subjects changed from an

Telegram: @dental_k

www.konkur.in

upright to a supine position. The supine position increases venous return from all tissues below the level of the heart, thereby increasing cardiac output and producing a transient increase in systemic blood pressure. The increase in blood pressure stimulates baroreceptors that reflexively decrease sympathetic vasoconstriction to all vascular beds, thereby increasing peripheral blood flow. Patients with pulpitis often report an inability to sleep at night because they are disturbed by throbbing tooth pain. In addition to the lack of distractions normally present during the day, the following mechanism may be operative in patients with inflamed pulps. When these patients lie down at the end of the day, their PBF probably increases due to the cardiovascular postural responses described earlier. This may increase their already elevated pulpal tissue pressure,[153,156,351,367,384] which is then sufficient to activate sensitized pulpal nociceptors and initiate spontaneous pulpal pain. Thus the "throbbing" sensation of toothache was previously considered as an effect of the pulsation in the pulp that follows heart contractions (systole), but a study investigating the rhythm of toothache and the patient pulse showed lack of synchrony between the two parameters.[256] The authors raised an alternative hypothesis: that the throbbing quality is not a primary sensation but rather an emergent property, or perception, whose "pacemaker" lies within the CNS.

Pulpal repair

The inherent healing potential of the dental pulp is well recognized. As in all other connective tissues, repair of tissue injury commences with débridement by macrophages, followed by proliferation of fibroblasts, capillary buds, and the formation of collagen. Local circulation is of critical importance in wound healing and repair. An adequate supply of blood is essential to transport immune cells into the area of pulpal injury and to dilute and remove deleterious agents from the area. It is also important to provide fibroblasts with nutrients from which to synthesize collagen. Unlike most tissues, the pulp has essentially no collateral circulation, making it theoretically more vulnerable than most other tissues. In the case of severe injury, healing would be impaired in teeth with a limited blood supply. It seems reasonable to assume that the highly cellular pulp of a young tooth, with a wide-open apical foramen and rich blood supply, has a much better healing potential than an

Telegram: @dental_k

www.konkur.in

older tooth with a narrow foramen and a restricted blood supply.

Dentin can be classified as primary, secondary, or tertiary, depending on when it was formed. *Primary dentin* is the regular tubular dentin formed before eruption, including mantle dentin. *Secondary dentin* is the regular circumferential dentin formed after tooth eruption, whose tubules remain continuous with that of primary dentin. *Tertiary dentin* is the irregular dentin that is formed in response to abnormal stimuli, such as excess tooth wear, cavity preparation, restorative materials, and caries.[65,66] In the past, tertiary dentin has been called *irregular dentin, irritation dentin, reparative dentin,* and *replacement dentin*. Much of the confusion was caused by a lack of understanding of how tertiary dentin is formed.

If the original odontoblasts that made *secondary dentin* are responsible for focal tertiary dentin formation, that particular type of tertiary dentin is termed *reactionary dentin*.[345] Generally, the rate of formation of dentin is increased, but the tubules remain continuous with the secondary dentin.[349] However, if the provoking stimulus caused the destruction of the original odontoblasts, the new, less tubular, more irregular dentin formed by newly differentiated odontoblast-like cells is called *reparative dentin*. In this dentin, the tubules are usually not continuous with those of secondary dentin. Initially, the newly formed cells tend to be cuboidal in shape, without the odontoblast process that is necessary to form dentinal tubules. They seem to form in response to the release of growth factors that were bound to collagen during the formation of secondary dentin.[94,315,345] The loss of the continuous layer of odontoblasts exposes unmineralized predentin that is thought to contain both soluble and insoluble forms of TGF-β, insulin-like growth factor (IGF)-1 and IGF-2, bone morphogenetic proteins (BMPs), VEGF, and other growth factors that attract and cause proliferation and differentiation of MSC to form reparative dentin and new blood vessels. During caries progression, bacterial acids may solubilize these growth factors from mineralized dentin, liberating them to diffuse to the pulp, where they could stimulate reactionary dentin formation. This is also thought to be the mechanism of action of calcium hydroxide during apexification treatment. Despite its high pH, calcium hydroxide has a slight demineralizing effect on dentin and has been shown to cause the release of TGF-β.[344] TGF-β and other growth factors stimulate and accelerate reparative dentinogenesis. Attempts have been made to apply

Telegram: @dental_k

www.konkur.in

growth factors to dentin to allow it to diffuse through the tubules to the pulp.[322,323,346] Although this has been successful, the remaining dentin thickness must be so thin that this approach may not be practical from a therapeutic perspective. Others have inserted deoxyribonucleic acid (DNA)-sequenced BMP-7 into retroviruses to transfect ferret pulpal fibroblasts to stimulate increased BMP-7 production. Although this was successful in normal pulps,[322] it was unsuccessful in inflamed pulps.[321] Specific amelogenin gene splice products, A + 4 and A − 4, adsorbed onto agarose beads and applied to pulp exposures, induced complete closure and mineralization of the root canal in rat molars.[124] The regulation of peritubular dentin formation is not fully understood. Some have claimed that this is a passive process resulting in occlusion of the tubules over time, but it has also been claimed that this is a mechanism under odontoblast control. If odontoblasts could be stimulated to form excessive peritubular dentin by the application of an appropriate biologic signaling molecule to the floor of cavity preparations, the tubules of the remaining dentin could be occluded, rendering this dentin impermeable and protecting the pulp from the inward diffusion of noxious substances that might leak around restorations.[297] These are examples of how molecular biology may be used in future restorative dentistry.

The term most commonly applied to irregularly formed dentin is *reparative dentin,* presumably because it frequently forms in response to injury and appears to be a component of the reparative process. It must be recognized, however, that this type of dentin has also been observed in the pulps of normal, unerupted teeth without any obvious injury.[281]

It should be recalled that secondary dentin is deposited circumpulpally at a slow rate throughout the life of the vital tooth.[349] In contrast, when a carious lesion has invaded dentin, the pulp usually responds by depositing a layer of tertiary dentin over the dentinal tubules of the primary or secondary dentin that communicate with the carious lesion (Fig. 13.43). Similarly, when occlusal wear removes the overlying enamel and exposes the dentin to the oral environment, tertiary dentin is deposited on the pulpal surface of the exposed dentin. Thus the formation of tertiary dentin allows the pulp to retreat behind a barrier of mineralized tissue.[375]

Source: (From Trowbridge HO: Pathogenesis of pulpitis resulting from dental caries, *J Endod* 7:52, 1981.)

Compared with primary or secondary dentin, tertiary dentin tends to be less tubular, and the tubules tend to be more irregular with larger lumina. In some cases, particularly when the original odontoblasts are destroyed, no tubules are formed. The cells that form reparative dentin are often cuboidal and not as columnar as the primary odontoblasts of the coronal pulp (Fig. 13.44). The quality of tertiary dentin (i.e., the extent to which it resembles primary or secondary dentin) is quite variable. If irritation to the pulp is relatively mild, as in the case of a superficial carious lesion, then the tertiary dentin formed may resemble primary dentin in terms of tubularity and degree of mineralization. On the other hand, dentin deposited in response to a deep carious lesion may be relatively atubular and poorly mineralized, with many areas of interglobular dentin. The degree of irregularity of this dentin is

Telegram: @dental_k

www.konkur.in

probably determined by numerous factors, such as the amount of inflammation present, the extent of cellular injury, and the state of differentiation of the replacement odontoblasts.

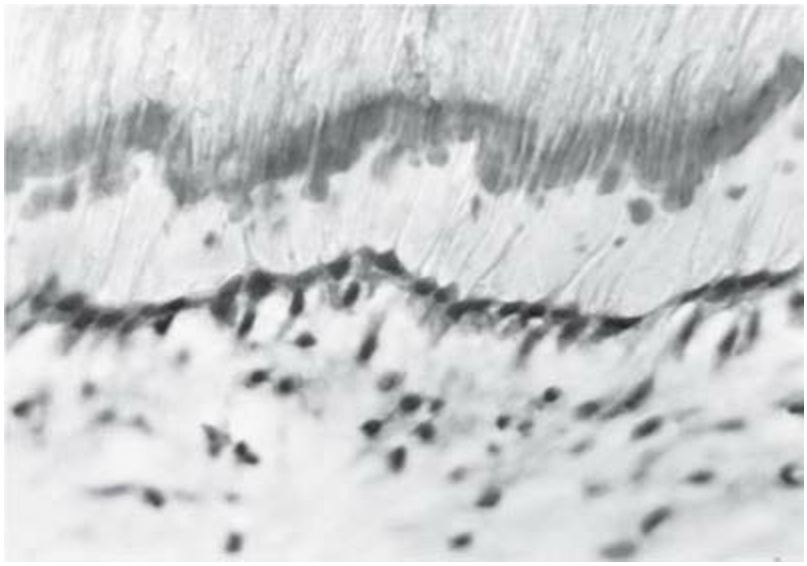

FIG. 13.44 Layer of cells forming reparative dentin. Note the decreased tubularity of reparative dentin compared with the developmental dentin above it.

Electron micrograph shows reparative dentin cells in odontoblast layer of tooth resulting in diminishing of columnar cells.

The poorest quality of reparative dentin is usually observed in association with marked pulpal inflammation.[65,375] In fact, the dentin may be so poorly organized that areas of soft tissue are entrapped within the dentinal matrix. In histologic sections, these areas of soft-tissue entrapment impart a Swiss-cheese appearance to the dentin (Fig. 13.45). As the entrapped soft tissue degenerates, products of tissue degeneration are released that further contribute to the inflammatory stimuli assailing the pulp.[375]

Telegram: @dental_k

www.konkur.in

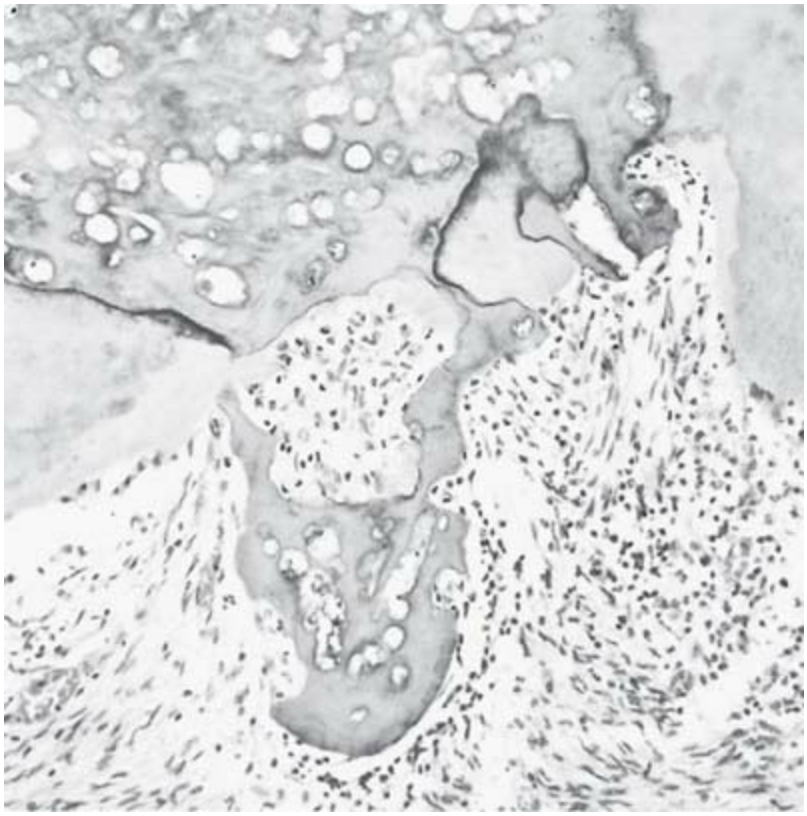

FIG. 13.45 Swiss-cheese type of reparative dentin. Note the numerous areas of soft-tissue inclusion and infiltration of inflammatory cells in the pulp.

Electron micrograph shows an irregular reparative dentin in pulp depicted as transparent irregular circles.

It has been reported that trauma caused by cavity preparation that is too mild to result in the loss of primary odontoblasts does not lead to reparative dentin formation, even if the cavity preparation is relatively deep.[74] This has been confirmed in both rat[52] and human teeth.[261] However, chronic pulpal inflammation associated with deep caries produces reparative dentin. This reparative dentin is formed by new odontoblast-like cells. For many years, it has been recognized that destruction of primary odontoblasts is soon followed by increased mitotic activity within fibroblasts of the subjacent cell-rich zone. It has been shown that the progeny of these dividing cells differentiate into functioning odontoblasts.[100] Investigators[421] have studied dentin bridge formation in healthy teeth of dogs and found that pulpal fibroblasts appeared to undergo dedifferentiation and revert to undifferentiated MSC (Fig. 13.46). The similarity of primary odontoblasts to

Telegram: @dental_k

www.konkur.in

replacement odontoblasts was established by D'Souza and colleagues.[78] They were able to show that cells forming reparative dentin synthesize type I (but not type III) collagen, and they are immunopositive for dentin sialoprotein.

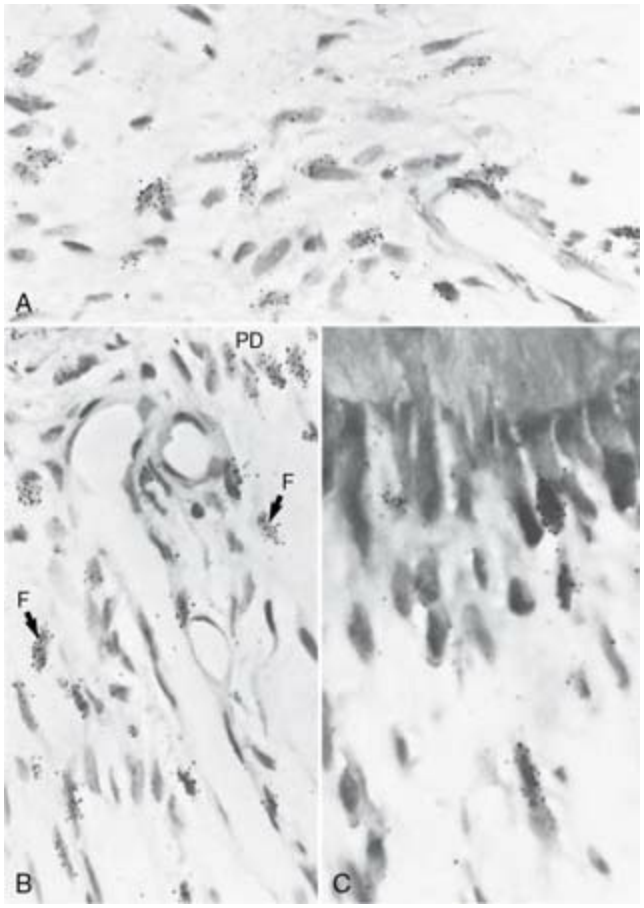

FIG. 13.46 Autoradiographs from dog molars illustrating uptake of ^{3}H-thymidine by pulp cells preparing to undergo cell division after pulpotomy and pulp capping with calcium hydroxide. **A,** Two days after pulp capping. Fibroblasts, endothelial cells, and pericytes beneath the exposure site are labeled. **B,** By the fourth day, fibroblasts *(F)* and preodontoblasts adjacent to the predentin *(PD)* are labeled, which suggests that differentiation of preodontoblasts occurred within 2 days. **C,** Six days after pulp capping, new odontoblasts are labeled, and tubular dentin is being formed. (Titrated thymidine was injected 2 days after the pulp capping procedures in [**B]** and [**C]**.)

Set of three radiographs marked A through C shows the development of columnar odontoblast cells below the dentin layer in molar tooth of dog.

Telegram: @dental_k

www.konkur.in

periodontal tissue during wound healing and regeneration, *Bull Tokyo Dent Coll* 21:181, 1980.)

Destruction of primary odontoblasts can occur from cutting cavity preparations dry,[81,206] from bacterial products such as endotoxins shed from deep carious lesions,[18,402] or from mechanical exposure of pulps.[262] Such pulpal wounds do not heal if the tissue is irreversibly inflamed.[65] Local fibroblast-like cells divide, and the new cells then differentiate into new odontoblasts. Recalling the migratory potential of ectomesenchymal cells from which the pulpal fibroblasts are derived, it is not difficult to envision the differentiating odontoblasts moving from the subodontoblastic zone to the area of injury to constitute a new odontoblast layer. Activation of antigen-presenting dendritic cells by mild inflammatory processes may also promote osteoblast/odontoblast-like differentiation and expression of molecules implicated in mineralization. Recognition of bacteria by specific odontoblast and fibroblast membrane receptors triggers an inflammatory and immune response within the pulp tissue that would also modulate the repair process.[123]

Although many animal studies have shown dentin bridge formation in healthy pulps following pulp capping with adhesive resins,[65] such procedures fail in normal human teeth.[62]

When small mechanical pulp exposures are inadvertently made in healthy teeth, the recommendation has been to place a small, calcium hydroxide–containing dressing on the wound. After setting, the surrounding dentin can be bonded using a no-rinse, self-etching primer adhesive.[177] Calcium silicate cements like mineral trioxide aggregate (MTA) have also been recognized to promote hard-tissue formation, and available information indicates that the dentin bridge formed under these cements is more dense and has fewer defects compared with traditional calcium hydroxide–containing dressings.[3,5,266,373]

The formation of atubular “fibrodentin” is another potential product of newly differentiated odontoblasts, provided that a capillary plexus develops beneath the fibrodentin.[15] This is consistent with the observation that the newly formed dentin bridge is composed first of a thin layer of atubular dentin on which a relatively thick layer of tubular dentin is deposited.[65,100]

Telegram: @dental_k

www.konkur.in

The fibrodentin was lined by cells resembling mesenchymal cells, whereas the tubular dentin was associated with cells closely resembling odontoblasts.

Researchers have also studied reparative dentin formed in response to relatively traumatic experimental class V cavity preparations in human teeth.[349] They found that seldom was reparative dentin formed until about the 30th postoperative day. The rate of dentin formation was 3.5 μm/day for the first 3 weeks after the onset of dentinogenesis, after which it decreased markedly. By postoperative day 132, dentin formation had nearly ceased. Assuming that most of the odontoblasts were destroyed during traumatic cavity preparation, as was likely in this experiment, the 30-day delay between cavity preparation and the onset of reparative dentin formation is thought to reflect the time required for the proliferation, migration, and differentiation of new replacement odontoblasts.

Does reparative dentin protect the pulp, or is it simply a form of scar tissue? To serve a protective function, it would have to provide a relatively impermeable barrier that would exclude irritants from the pulp and compensate for the loss of developmental dentin. The junction between developmental and reparative dentin has been studied using a dye diffusion technique, which demonstrated the presence of an atubular zone situated between secondary dentin and reparative dentin (Fig. 13.47).[96] In addition to a dramatic reduction in the number of tubules, the walls of the tubules along the junction were often thickened and occluded with material similar to peritubular matrix.[332] Taken together, these observations would indicate that the junctional zone between developmental and reparative dentin is an atubular zone of low permeability. Moreover, the accumulation of pulpal dendritic cells was reduced after reparative dentin formation, which may indicate the reduction of incoming bacterial antigens.[325]

FIG. 13.47 Diffusion of dye from the pulp into reparative dentin. Note atubular zone between reparative dentin (RD) and primary dentin on the left.

Autoradiograph shows the longitudinal view of highly dense dentin layer on the left, followed by a blank narrow zone, and wide zone of sparse tubules on the right.

Source: (From Fish EW: *Experimental investigation of the enamel, dentin, and dental pulp,* London, 1932, John Bale Sons & Danielson.)

Periodontally diseased teeth have smaller root canal diameters than teeth that are periodontally healthy.[207] The root canals of such teeth are narrowed by the deposition of large quantities of reactionary dentin along the dentinal walls.[333] The decrease in root canal diameter with increasing age, in the absence of periodontal disease, is more likely to be the result of secondary dentin formation.

One study showed that in a rat model, frequent scaling and root planing resulted in reparative dentin formation along the pulpal wall subjacent to the instrumented root surface.[148] However, given that normal rat root dentin is only 100 μm thick, these procedures are probably more traumatic to the pulp

Telegram: @dental_k

www.konkur.in

in the rat model than in humans, where normal root dentin is more than 2000 µm thick.

Not uncommonly, the cellular elements of the pulp are largely replaced by fibrous connective tissue over a span of five decades. It appears that in some cases, the pulp responds to noxious stimuli by accumulating large fiber bundles of collagen, rather than by elaborating reparative dentin (Fig. 13.48). However, fibrosis and reparative dentin formation often go hand in hand, indicating that both are expressions of a reparative potential. In periodontally diseased teeth, the pulp tissue is found to be the site of an enhanced process of collagenous fibrosis associated with an inflammatory infiltrate.[57]

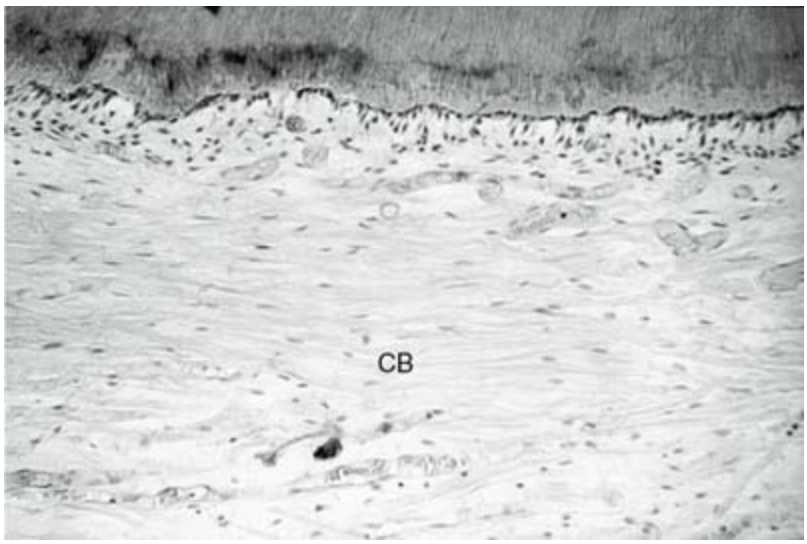

FIG. 13.48 Fibrosis of dental pulp showing replacement of pulp tissue by large collagen bundles *(CB)*.

Micrograph shows diffused collagen fibers replacing the cells in pulp below odontoblasts.

With the expanding knowledge of tooth regeneration and biologic mechanisms of functional dental tissue repair, current treatment strategies are beginning to give way to evolving fields such as tissue engineering and biomimetics. Pulpal stem cells in scaffolds have been shown to produce pulplike tissues with tubular-like dentin,[89] and in animal models, root perforations have been treated with scaffolds of collagen, pulpal stem cells, and dentin matrix protein 1, resulting in organized matrix similar to that of

Telegram: @dental_k

www.konkur.in

pulpal tissue.[310]

Studies investigating new possibilities for regeneration of the pulp/dentin complex are now frequently reported and are described in detail in Chapter 12. A first interesting case report, which has been followed up by others, has led to new strategies for treatment of necrotic immature roots (Fig. 13.49).[13] In the future, the field of pulpal repair will probably develop rapidly, and new treatment strategies will appear.

FIG. 13.49 Immature tooth with a necrotic infected canal with apical periodontitis. The canal is disinfected with copious irrigation with sodium hypochlorite and an antibiotic paste. Seven months after treatment, the patient is asymptomatic, and the apex shows healing of the apical periodontitis and some closure of the apex.

Pre-operative radiograph shows open root canal with a radiolucent patch at the root tip and porous tissue surrounding the root.

Radiograph after 7 month recall shows partially filled root canal.

Pulpal calcifications

Telegram: @dental_k

www.konkur.in

The calcification of pulp tissue is a common occurrence. Although estimates of the incidence of this phenomenon vary widely, it is safe to say that one or more pulp calcifications are present in at least 50% of all teeth. In the coronal pulp, calcification usually takes the form of discrete, concentric pulp stones (Fig. 13.50), whereas in the radicular pulp, calcification tends to be diffuse (Fig. 13.51).[379] There is no clear evidence as to whether pulp calcification is a pathologic process related to various forms of injury or a natural phenomenon. The clinical significance of pulp calcification is that it may hinder root canal treatment.

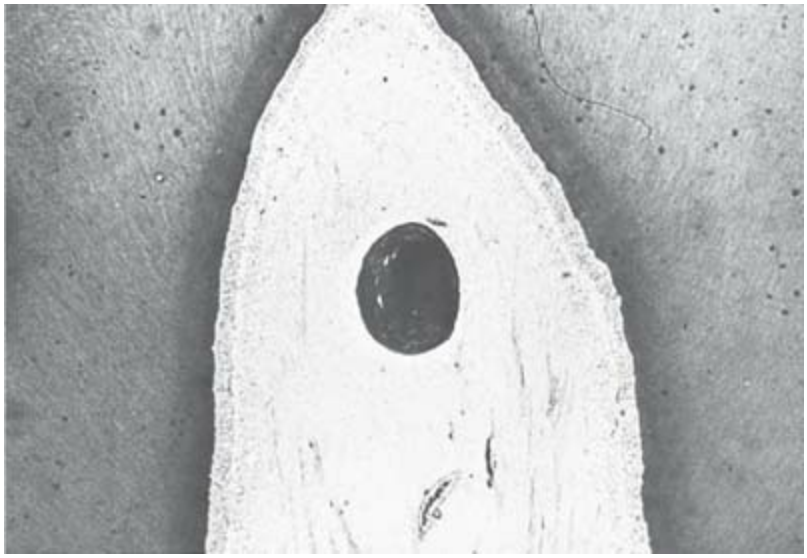

FIG. 13.50 Pulp stone with a smooth surface and concentric laminations in the pulp of a newly erupted premolar extracted in the course of orthodontic treatment.

Micrograph shows a round dark stone in the pulp.

Telegram: @dental_k

www.konkur.in

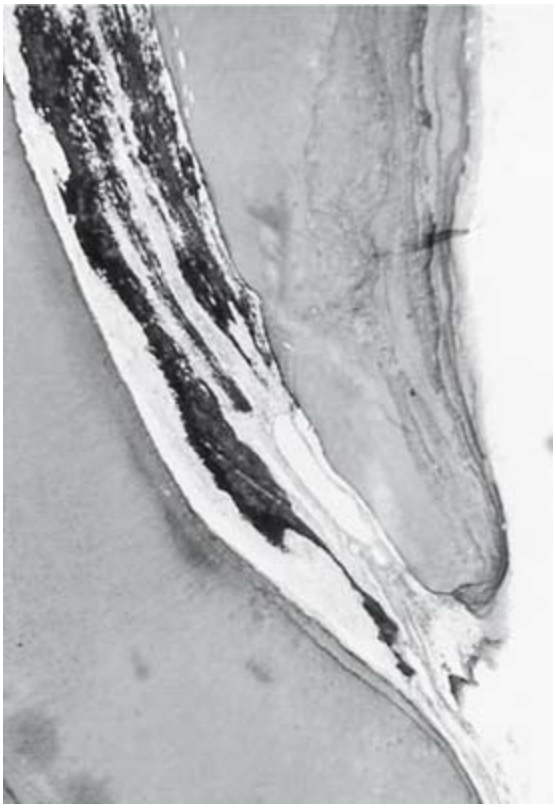

FIG. 13.51 Diffuse calcification near the apical foramen.

Micrograph shows the root apex of tooth with diffused calcification in the canal.

Pulp stones (denticles) range in size from small, microscopic particles often seen in association with the wall of arterioles to accretions that occupy almost the entire pulp chamber (Fig. 13.52). The mineral phase of pulp calcifications has been shown to consist of typical carbonated hydroxyapatite.[379] Histologically, two types of stones are recognized: (1) those that are round or ovoid, with smooth surfaces and concentric laminations (see Fig. 13.50), and (2) those that assume no particular shape, lack laminations, and have rough surfaces (Fig. 13.53). Laminated stones appear to grow by the addition of collagen fibrils to their surface, whereas unlaminated stones develop by way of the mineralization of preformed collagen fiber bundles. In the latter type, the mineralization front seems to extend out along the coarse fibers, making the surface of the stones appear fuzzy (Fig. 13.54). Often these coarse fiber bundles appear to have undergone hyalinization, thus resembling old scar tissue.

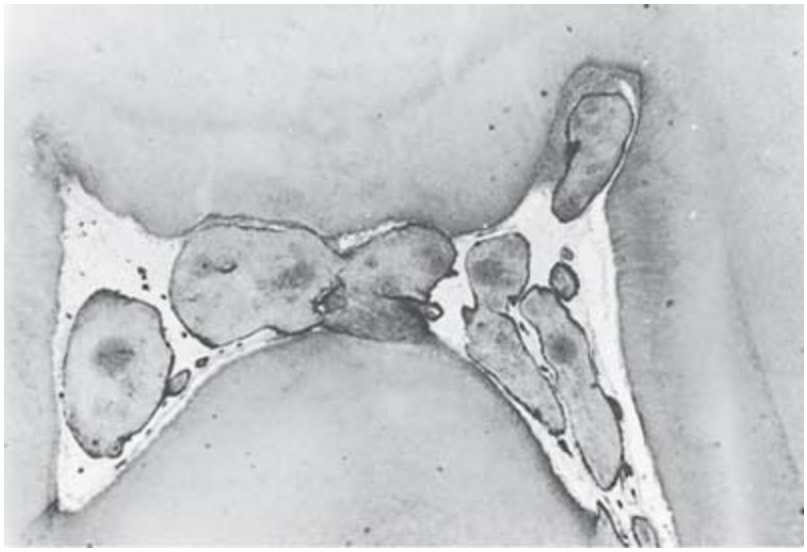

FIG. 13.52 Pulp stones occupying much of the pulp chamber.

Pulp chamber of tooth is filled with irregular and large stones. One stone is present in the pulp horn on the right.

FIG. 13.53 Rough surface form of pulp stone. Note hyalinization of collagen fibers.

Magnified image shows roughly oval and irregular structure of pulp stone.

Telegram: @dental_k

www.konkur.in

FIG. 13.54 High-power view of a pulp stone from Fig. 13.53, showing the relationship of mineralization fronts to collagen fibers.

Highly magnified view shows half pulp stone surrounded by collagen fibers.

Pulp stones may also form around epithelial cells (i.e., remnants of Hertwig epithelial root sheath). Presumably the epithelial remnants induce adjacent MSC to differentiate into odontoblasts. Characteristically these pulp stones are found near the root apex and contain dentinal tubules (see Fig. 13.19).

The cause of pulpal calcification is largely unknown. Calcification may occur around a nidus of degenerating cells, blood thrombi, or collagen fibers. Many authors believe that this represents a form of dystrophic calcification. In this type of calcification, calcium is deposited in tissues that are degenerating. Calcium phosphate crystals may be deposited within the cells themselves. Initially this takes place within the mitochondria because of the increased membrane permeability to calcium resulting from a failure to maintain active transport systems within the cell membranes. Thus degenerating cells serving as a nidus may initiate calcification of a tissue. In the absence of obvious tissue degeneration, the cause of pulpal calcification is enigmatic. It is often difficult to assign the term *dystrophic calcification* to

Telegram: @dental_k

www.konkur.in

pulp stones because they so often occur in apparently healthy pulps, suggesting that functional stress need not be present for calcification to occur. Calcification in the mature pulp is often assumed to be related to the aging process, but in a study involving 52 impacted canines from patients between 11 and 76 years of age, there was a constant incidence of concentric denticles for all age groups, indicating no relation to aging.[281] Diffuse calcifications, on the other hand, increased in incidence to age 25 years; thereafter they remained constant in successive age groups.

At times, numerous concentric pulp stones with no apparent cause are seen in all the teeth of young individuals. In such cases, the appearance of pulp stones may be ascribed to individual biologic characteristics (e.g., tori, cutaneous nevi).[281]

Although soft-tissue collagen does not usually calcify, it is common to find calcification occurring in old hyalinized scar tissue in the skin. This may be due to the increase in the extent of cross-linking between collagen molecules (because increased cross-linkage is thought to enhance the tendency for collagen fibers to calcify). A relationship may exist between pathologic alterations in collagen molecules within the pulp and pulpal calcification.

Calcification replaces the cellular components of the pulp and may possibly hinder the blood supply, although concrete evidence for this strangulation theory is lacking. Idiopathic pulpal pain was classically attributed to the presence of pulp stones. Modern knowledge of mechanisms of nociceptor activation coupled with the observation that pulp stones are so frequently observed in teeth lacking a history of pain have largely discounted this hypothesis. Therefore from a clinical perspective, it would be unlikely that a patient's unexplained pain symptoms are due to pulpal calcifications, no matter how dramatic they may appear on a radiograph.

Luxation of teeth as a result of trauma may result in calcific metamorphosis, a condition that can, in a matter of months or years, lead to partial or complete radiographic obliteration of the pulp chamber. The cause of radiographic obliteration is excessive deposition of mineralized tissue resembling cementum or, occasionally, bone on the dentin walls, also referred to as *internal ankylosis* (Fig. 13.55). Histologic examination invariably reveals the presence of some soft tissue, and cells resembling cementoblasts can be observed lining the mineralized tissue. This calcific

Telegram: @dental_k

www.konkur.in

metamorphosis of the pulp has also been reported in replanted teeth of the rat.[280]

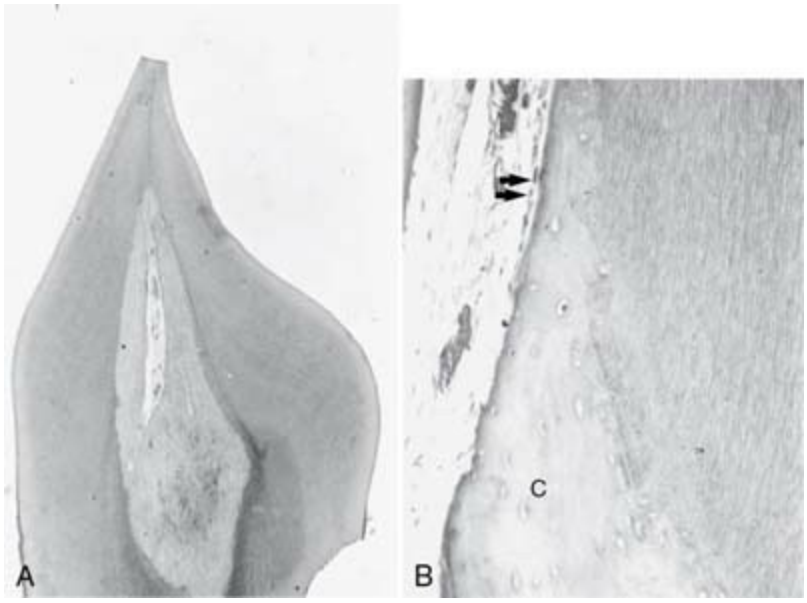

FIG. 13.55 **A,** Calcific metamorphosis of pulp tissue after luxation of tooth as a result of trauma. Note presence of soft-tissue inclusion. **B,** High-power view showing cementoblasts *(arrows)* lining cementum *(C)*, which has been deposited on the dentin walls.

A) Pulp shows deposition of calcium in root canal.

B) Arrows point toward the cementoblasts in pulp close to the dentin layer.

Clinically, the crowns of teeth affected by calcific metamorphosis may show a yellowish hue compared with adjacent normal teeth. This condition usually occurs in teeth with incomplete root formation. Trauma results in the disruption of blood vessels entering the tooth, thus producing pulpal infarction. The wide periapical foramen allows connective tissue from the periodontal ligament to proliferate and replace the infarcted tissue, bringing with it cementoprogenitor and osteoprogenitor cells capable of differentiating into either cementoblasts or osteoblasts or both.

When calcific metamorphosis is noted on a patient's radiograph, it is sometimes suggested that the tooth be treated endodontically because the pulp is expected to be secondarily infected, and endodontic therapy should be performed while the pulp canal is still large enough to instrument. In a classic

Telegram: @dental_k

www.konkur.in

study of luxated teeth, Andreasen[7] found that only 7% of the pulps that underwent calcific metamorphosis exhibited secondary infection. Because the success rate for nonsurgical endodontic therapy, not only in general[406] but also for obliterated teeth,[68] is considered high, prophylactic intervention does not seem to be warranted.

Age changes

Continued formation of secondary dentin throughout life gradually reduces the size of the pulp chamber and root canals, although the width of the cementodentinal junction appears to stay relatively the same.[111,349] However, due to continuous cement application, the distance from the apical constriction to the radiographic apex may increase (Fig. 13.56).[388] The progressive sclerosis of dentin starting apically also has endodontic implications, as it makes dentine almost impermeable to bacterial invasion (see Fig. 13.56).[347] In addition, certain regressive changes in the pulp appear to be related to the aging process. There is a gradual decrease in the cellularity and a concomitant increase in the number and thickness of collagen fibers, particularly in the radicular pulp. The thick collagen fibers may serve as foci for pulpal calcification (see Fig. 13.53). The odontoblasts decrease in size and number, and they may disappear altogether in certain areas of the pulp, particularly on the pulpal floor over the bifurcation or trifurcation areas of multirooted teeth.

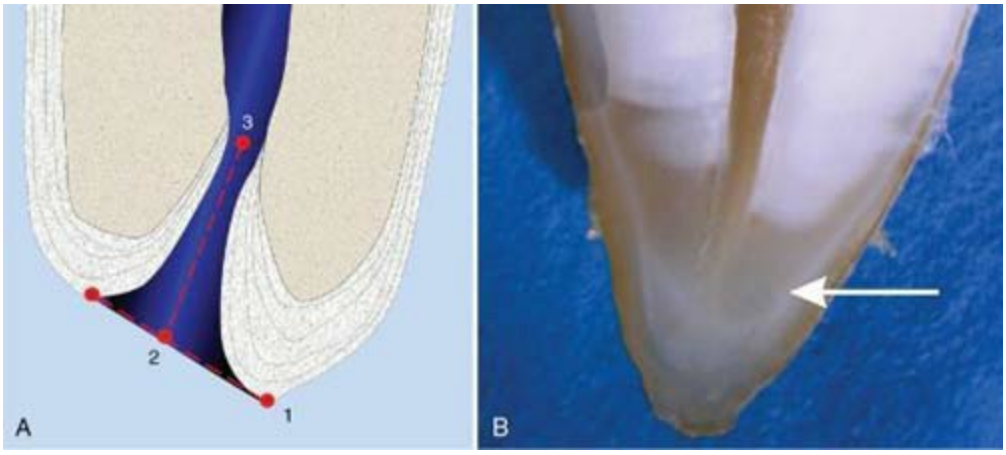

FIG. 13.56 Anatomical structures in the apical area. **A**, Cementum

Telegram: @dental_k

apposition during life will change the apical anatomical landmarks. Number *1* denotes the radiographic apex, *2* the apical foramen (major) and *3* the apical constriction (the minor apical foramen) representing the transition between the pulpal and periodontal tissues. The line that goes through *1* and *2* is often denoted the anatomical apex. **B**, Age-related sclerosis, making the dentinal tubules impermeable to bacteria, is a progressive event starting in the apical area *(white arrow)*.

A) Three points in the root canal near the apex are marked 1 through 3.

B) Root apex shows the loss of normal tissues at the apex comparatively rest of the structure in root.

With age there is a progressive reduction in the number of nerves[104] and blood vessels.[23,25] Evidence also suggests that aging results in an increase in the resistance of pulp tissue to the action of proteolytic enzymes,[427] hyaluronidase, and sialidase,[25] suggesting an alteration of both collagen and proteoglycans in the pulps of older teeth. The main changes in dentin associated with aging are an increase in peritubular dentin, dentinal sclerosis, and the number of dead tracts.[¶,349] Dentinal sclerosis produces a gradual decrease in dentinal permeability as the dentinal tubules become progressively reduced in diameter.[357]

†A receptor cell is a non–nerve cell capable of exciting adjacent afferent nerve fibers. Synaptic junctions connect receptor cells to afferent nerves.

‡To appreciate fully the dimensions of dentin tubules, understand that the diameter of the tubules (about 1 μm) is much smaller than that of red blood cells (about 7 μm). The thickness of coronal dentin is about 3 mm, so each tubule is 3000 μm long but only 1 μm in diameter. Thus each tubule is 3000 diameters long.

Telegram: @dental_k

www.konkur.in

[§]A force of 44 cM (44 g) applied to an explorer having a tip 40 μm in diameter would produce a pressure of 2437 MPa on the dentin.[55] This is far in excess of the compressive strength of dentin, listed as 245 MPa, as evidenced by the shallow grooves lined by smear layers created in dentin using this force.[56]

[¶]The term *dead tract* refers to a group of dentinal tubules in which odontoblast processes are absent. Dead tracts are easily recognized in ground sections because the empty tubules refract transmitted light, and the tract appears black in contrast to the light color of normal dentin.

14: Pulp reactions to caries and dental procedures

Ashraf F. Fouad, Linda G. Levin

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

The dental pulp is a dynamic tissue that responds to external stimuli in a variety of ways. However, there are certain unique features of the dental pulp response that distinguish it from other connective tissues in the body. These include the pulp's exposure to dental caries, a very prevalent chronic infectious disease, its encasement in an unyielding environment after complete tooth maturation, and the paucity of collateral circulation render it susceptible to injury and complicate its regeneration. Moreover, the pulp is endowed with a rich neurovascular supply that promotes the effects of inflammation and may lead to rapid degeneration and necrosis. The treatment of dental caries and other tooth pathosis often involves the cleaning and shaping of the enamel and dentin, the hardest tissues in the body, thus adding to the irritation of the pulp. In this chapter, the response of the pulp to all these variables will be discussed and recent advances in our understanding of dental procedures and their effects on the pulp will be presented.

Pulp reaction to caries

Dental caries is a localized, destructive, and progressive infection of dentin, which, if left unchecked, can result in pulp necrosis and potential tooth loss. Both bacterial by-products and products from the dissolution of the organic and inorganic constituents of dentin mediate the effects of dental caries on the pulp. Three basic reactions tend to protect the pulp against caries: (1) decreases in dentin permeability due to dentin sclerosis, (2) tertiary dentin formation, and (3) inflammatory and immune reactions in the pulp.[143] These responses occur concomitantly and their robustness is highly dependent on the aggressive nature of the advancing lesion.

Bacterial proteolytic enzymes, toxins, and metabolic by-products have been thought to be initiators of pulp reactions, yet the buffering capacity of dentin and dentinal fluid likely attenuate these stimulatory effects. This protective function is significantly reduced when the remaining dentin thickness (RDT) is minimal.[267] When the pulp is exposed, bacterial metabolites, toxins, and cell wall components induce inflammation. In initial to moderate lesions, current evidence suggests that acidic by-products of the carious process act indirectly by degrading the dentin matrix, thereby liberating bioactive molecules previously sequestered during dentinogenesis. Once liberated, these molecules resume their role in dentin formation, this time being stimulatory for *tertiary* dentinogenesis.[268] This theory is supported by the findings that demineralized dentin matrix implanted at the site of pulp exposure can induce dentinogenesis.[300] Furthermore, placement of purified dentin matrix proteins on exposed dentin or exposed pulp stimulates tertiary dentin formation, indicating that these molecules can act directly or across intact dentin.[269,299]

Recent evidence suggests several candidate molecules for stimulation of reparative dentinogenesis. Transforming growth factor-β1 (TGF-β1), TGF-β3, insulin-like growth factors I (IGF-I) and II, platelet-derived growth factor (PDGF), bone morphogenetic protein-2 (BMP-2), and angiogenic growth factors such as vascular endothelial growth factor (VEGF) have been shown to be stimulatory for dentinogenesis in vitro.[259] The TGF-β superfamily in particular seems to be important in the signaling process for odontoblast differentiation as well as primary and tertiary dentinogenesis. As the

Telegram: @dental_k

www.konkur.in

predominant isoform, TGF-β1 is equally distributed in the soluble and insoluble fractions of dentin matrix.[43] During the carious dissolution of dentin, it is believed that the soluble pool of TGF-β1 can diffuse across intact dentin while the insoluble pool is immobilized on insoluble dentin matrix and serves to stimulate odontoblasts, much like membrane-bound TGF-βs during odontogenesis.[267,270]

Despite the research interest in tertiary dentinogenesis, it is neither the first nor necessarily the most effective defense against invading pathogens. A combination of an increased deposition of intratubular dentin and the direct deposition of mineral crystals into the narrowed dentin tubules to decrease dentin permeability is the first defense to caries and is called *dentin sclerosis*. The combination of increased deposition of intratubular dentin and tubule occlusion by precipitated crystals results in an effective decrease in dentin permeability underneath the advancing carious lesion.[229] In vitro studies with cultured tooth slices implicate TGF-β1 as a central player in the increased deposition of intratubular dentin.[266] The deposition of whitlockite crystals in the tubular lumen most likely results from a similar stimulation of vital associated odontoblasts, possibly in combination with precipitation of mineral released during the demineralization process (Fig. 14.1).[171,296]

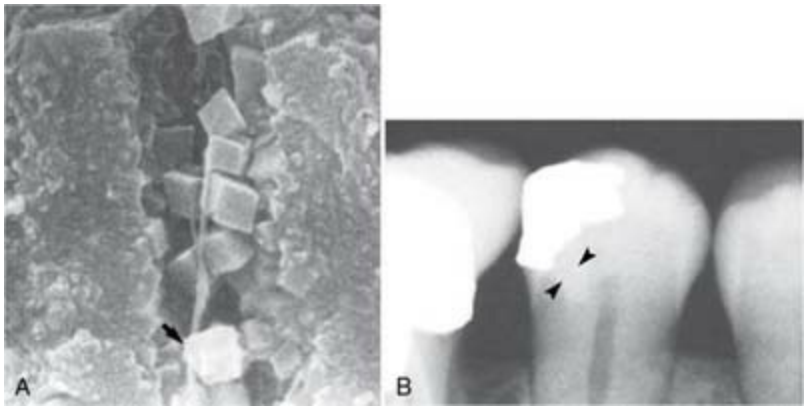

FIG. 14.1 **A,** Whitlockite crystals occlude the dentinal tubules in sclerotic dentin. **B,** Dentinal sclerosis is radiographically apparent beneath a deep class II lesion.

A) Micrograph shows a deep canal at the center with cube-like structures.

B) Radiograph shows a white spot of sclerosis at the top right of root canal below an extremely radiopaque patch.

Telegram: @dental_k

www.konkur.in

The formation of tertiary dentin occurs over a longer period than does that of sclerotic dentin, and its resultant character is highly dependent on the stimulus. Mild stimuli activate resident quiescent odontoblasts whereupon they elaborate the organic matrix of dentin. This type of tertiary dentin is referred to as *reactionary dentin* and can be observed when initial dentin demineralization occurs beneath the noncavitated enamel lesion.[164] Mediators present during the carious process induce a focal upregulation of matrix production by resident odontoblasts. The resultant dentin is similar in morphology to physiologic dentin and may only be apparent due to a change in the direction of the new dentinal tubules (Fig. 14.2). In the aggressive lesion, the carious process may prove cytocidal to subjacent odontoblasts and require repopulation of the disrupted odontoblast layer with differentiating progenitors. The organization and composition of the resultant matrix are a direct reflection of the differentiation state of the secretory cells. This accounts for the heterogeneity of *reparative dentin*, where the morphology can range from organized tubular dentin to more disorganized irregular *fibrodentin*. Fibrodentin, due to its irregular configuration and tissue inclusions, is more permeable than physiologic dentin (Fig. 14.3).[310]

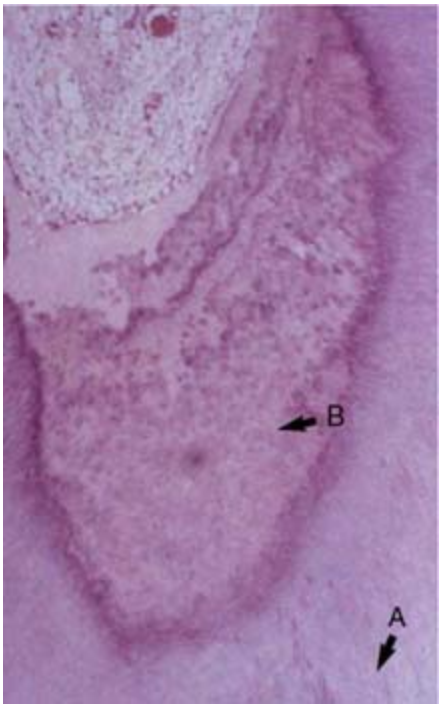

FIG. 14.3 Tertiary dentin. The strong stimulus of the impinging infection is cytocidal for odontoblasts. The resultant dentin is irregular with soft-tissue inclusions. Intact secondary dentin is depicted by *arrow A,* and tertiary dentin is designated by *arrow B*.

Stained micrograph shows a magnified view of reparative dentin consisting of the matrix of disorganized cells.

While dentin can provide a physical barrier against noxious stimuli, the pulp immune response provides humoral and cellular challenges to invading pathogens. In the progressing carious lesion, the host immune response increases in intensity as the infection advances. It has been shown that titers of T helper cells, B-lineage cells, neutrophils, and macrophages are directly proportional to lesion depth in human teeth.[126] The disintegration of large

Telegram: @dental_k

www.konkur.in

amounts of dentin, however, is not necessary to elicit a pulp immune response. This is supported by the observation that a pulp inflammatory response can be seen beneath noncavitated lesions and noncoalesced pits and fissures.[36]

The early inflammatory response to caries is characterized by the focal accumulation of chronic inflammatory cells (Fig. 14.4). This is mediated initially by odontoblasts and later by dendritic cells. As the most peripheral cell in the pulp, the odontoblast is positioned to encounter foreign antigens first and initiate the innate immune response. Pathogen detection in general is accomplished via specific receptors called pattern recognition receptors (PRRs).[128] These receptors recognize pathogen associated molecular patterns (PAMPs) on invading organisms and initiate a host defense through the activation of the NF-κB pathway.[106] One class of the PAMP recognition molecules is the Toll-like receptor (TLR) family. Odontoblasts have been shown to have an increased expression of certain TLRs in response to bacterial products. Under experimental conditions, odontoblast expression of TLR3, 5, and 9 was increased in response to lipoteichoic acid while lipopolysaccharide increased TLR2 and 4 expression.[71,114,204] It was also shown that TGF-β1 inhibits the expression of TLR2 and 4 by odontoblasts in response to gram-positive and -negative bacteria.[114] Once the odontoblast TLR is stimulated by a pathogen, proinflammatory cytokines, chemokines, and antimicrobial peptides are elaborated by the odontoblast resulting in recruitment and stimulation of immune effector cells as well as direct bacterial killing.[80,82,138]

Telegram: @dental_k

www.konkur.in

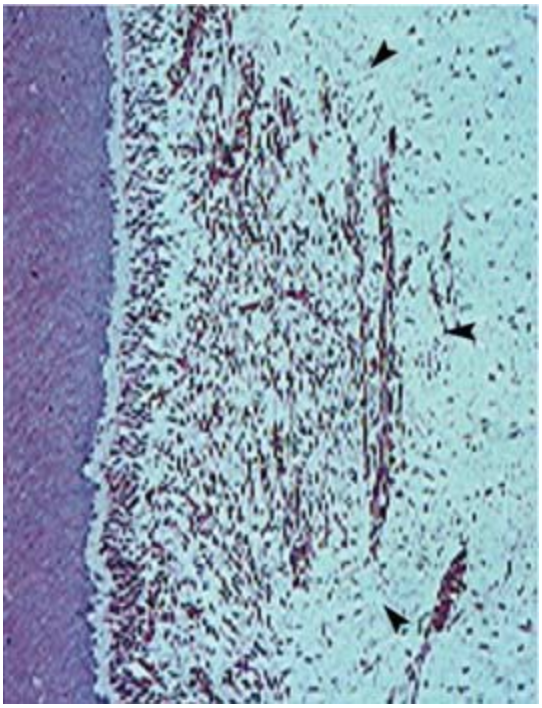

FIG. 14.4 The early pulpal response to caries is represented by a focal accumulation of chronic inflammatory cells *(arrowheads)*. Note that peripheral to the inflammation the pulpal parenchyma is relatively unaffected.

Stained micrograph shows pulp layer with high density of cells toward the odontoblasts.

Many cells produce chemokines at low levels constitutively. Unstimulated odontoblasts express genes coding for CCl2, CXCL12, and CXCL14, three genes known to code for factors chemotactic for immature dendritic cells.[44] They also produce CCL26—a natural antagonist for CCR1, CCR2, and CCR5—which are chemokines normally produced by monocytes and dendritic cells.[324] Stimulation with bacterial cell wall constituents has been shown to upregulate the expression of multiple chemokine genes, including CXCL12, CCL2, CXCL9, CX3CL1, CCL8, CXCL10, CCL16, CCL5, CXCL2, CCL4, CXCL11, and CCL3, as well as 9 chemokine receptor genes, including CXCR4, CCR1, CCR5, CX3CR1, CCR10, and CXCR3, suggesting that odontoblasts sense pathogens and express factors that recruit immune effector cells (Fig. 14.5).[44,81,113,165] These data suggest a scenario whereby stimulated odontoblasts express high levels of chemokines, such as IL-8 (CXCL8), that act in concert with the release of formerly sequestered growth

Telegram: @dental_k

www.konkur.in

factors from carious dentin, which induce a focal increase in dendritic cell numbers with additional release of chemotactic mediators.[83,270] The subsequent influx of immune effector cells is composed of lymphocytes, macrophages, and plasma cells. This cellular infiltrate is accompanied by localized capillary sprouting in response to angiogenic factors as well as coaggregation of nerve fibers and HLA-DR-positive dendritic cells.[316,317]

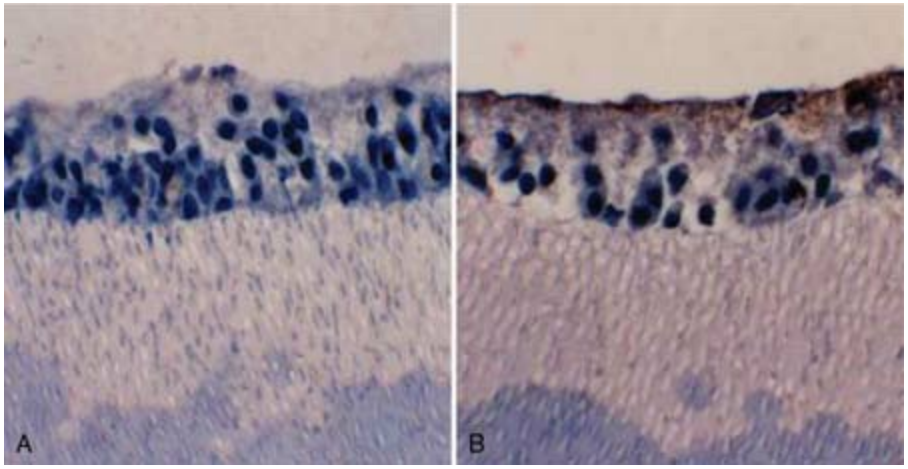

FIG. 14.5 Odontoblasts exposed to lipopolysaccharide (LPS) in an in vitro culture model express IL-8 as evidenced by immunostaining with anti-IL-8 antibodies. **A,** Control cultures not exposed to LPS (negative control). **B,** Immunostaining for IL-8 in cultures exposed to LPS.

Set of two stained micrographs marked A and B shows the changes in odontoblasts with abnormal periphery in B micrograph.

As the carious lesion progresses, the density of the chronic inflammatory infiltrate and well as that of dendritic cells in the odontoblast region increases. Pulp dendritic cells are responsible for antigen presentation and stimulation of T lymphocytes. In the uninflamed pulp, they are scattered throughout the pulp. With caries progression, they aggregate initially in the pulp and subodontoblastic regions then extend into the odontoblast layer and eventually migrate into the entrance to tubules beside the odontoblast process (Fig. 14.6).[318] There are two distinct populations of dendritic cells that have been identified in the dental pulp. CD11c+ is found in the pulp/dentin border and subjacent to pits and fissures. F4/80+ dendritic cells are concentrated in the perivascular spaces in the subodontoblastic zone and inner pulp.[324]

Telegram: @dental_k

www.konkur.in

CD11c+ dendritic cells express TLRs 2 and 4 and are CD205 positive. F4/80+ dendritic cells have migratory ability. As they migrate from the central pulp, they increase in size and become CD86 positive. In vitro studies have suggested that the secretion of GM-CSF and osteopontin by dendritic cells and macrophages represents a mechanism whereby they contribute to odontoblast differentiation.[255]

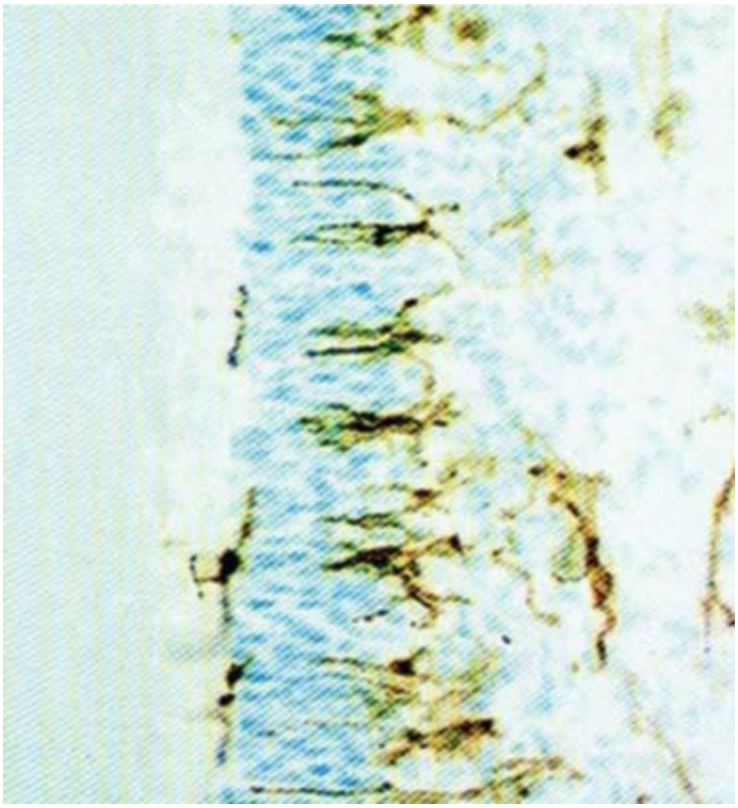

FIG. 14.6 Dental caries stimulates the accumulation of pulpal dendritic cells in and around the odontoblastic layer.

Micrograph shows several branched dendritic cells in odontoblastic layer extending toward the dentin layer.

Source: (Reprinted with permission from Mats Jontell.)

Evidence suggests that odontoblasts also play a role in the humoral immune response to caries. IgG, IgM, and IgA have been localized in the cytoplasm and cell processes of odontoblasts in human carious dentin, suggesting that these cells actively transport antibodies to the infection front.[211] In the incipient lesion antibodies accumulate in the odontoblast layer

Telegram: @dental_k

www.konkur.in

and with lesion progression can be seen in the dentinal tubules. Eventually, this leads to a focal concentration of antibodies beneath the advancing lesion.[210]

In the most advanced phase of carious destruction, the humoral immune response is accompanied by immunopathologic destruction of pulp tissue. In animal studies where monkeys were hyperimmunized to BSA, there was an observed increase in pulp tissue destruction subsequent to antigenic challenge across freshly cut dentin.[22] Odontoblasts also appear to be involved in the production of innate antimicrobial molecules such as human beta defensin-2 (HBD2). IL-1 and TNF-α as well as bacterial LPS were responsible for significant increases in HBD2 in response to caries.[113] In sum, it appears that the odontoblasts play a central role in orchestrating local and chemotactic inflammatory responses to dental caries (Fig. 14.7).

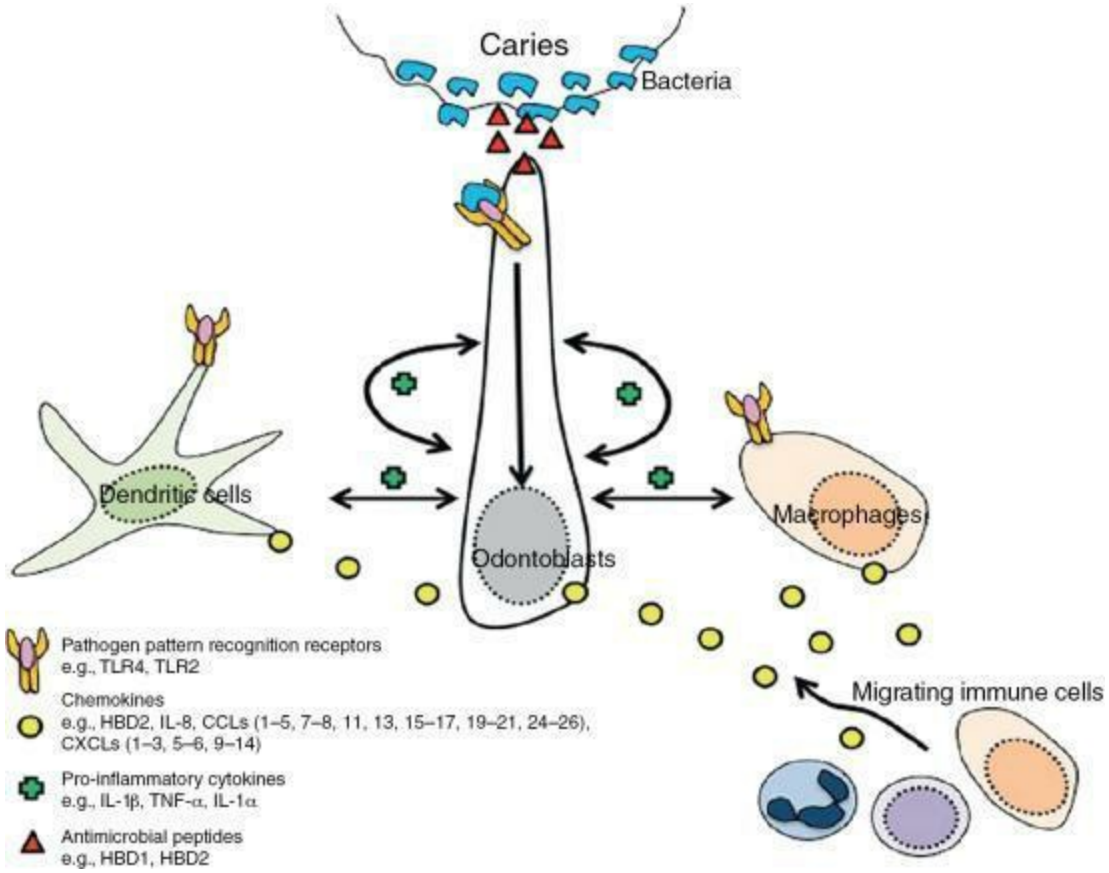

FIG. 14.7 Innate immunity in the odontoblast layer (ODL). Bacterial components from caries activate cytokine/chemokine release from odontoblasts, dendritic cells, and/or macrophages via Toll-like

Telegram: @dental_k

www.konkur.in

receptors *(TLRs)*. Proinflammatory cytokines released from these cells act as autocrine and paracrine signals to amplify cytokine responses including antimicrobial peptide, cytokine, and chemokine production. The release of chemokines creates a migration gradient for immune cells to ODL while antimicrobial peptides reduce bacterial load.

Diagram explains innate immunity in the odontoblast layer. Labels are as follows: Odontoblasts, macrophages, dendritic cells, and migrating immune cells. Examples of pathogen pattern recognition receptors are TLR4, TLR2. Examples of chemokines are HBD2, IL-8, CCLs (1–5, 7–8, 11, 13, 15–17, 19–21, 24–26), CXCLs (1–3, 5–6, 9–14). Examples of pro-inflammatory cytokines are IL-1 beta, TNF-alpha, IL-1 alpha. Examples of antimicrobial peptides are HBD1, HBD2.

Pulp exposure in primary and immature permanent teeth can lead to a proliferative response or *hyperplastic pulpitis*. Exuberant inflammatory tissue proliferates through the exposure and forms a “pulp polyp” (Fig. 14.8). It is presumed that a rich blood supply facilitates this proliferative response. Conventional root canal therapy or therapeutic pulpotomy would be indicated in these cases.

FIG. 14.8 A proliferative response to caries in a young tooth, typically referred to as proliferative pulpitis, hyperplastic pulpitis, or pulp polyp.

Close-up view shows abnormal growth of large mass surrounded by a cavity in place of the tooth.

Neurogenic mediators

Neurogenic mediators are involved in the pulp response to irritants and like immune components they can mediate pathology as well as the healing response. External stimulation of dentin causes the release of proinflammatory neuropeptides from pulp afferent nerves.[38,139] Substance P (SP), calcitonin gene-related peptide (CGRP), neurokinin A (NKA), neurokinin Y (NKY), and vasoactive intestinal peptide (VIP) are released and affect vascular events such as vasodilatation and increased vascular permeability. This results in a net increase in tissue pressure that can progress to necrosis in extreme and persistent circumstances. Stimulation of sympathetic nerves in response to the local release of mediators such as norepinephrine, neuropeptide Y, and ATP has been shown to alter pulp blood flow (PBF). Receptor field studies as well as anatomic studies have shown sprouting of afferent fibers in response to inflammation.[38]

Neuropeptides can act to modulate the pulp immune response. It has been demonstrated that SP acts as a chemotactic and stimulatory agent for macrophages and T lymphocytes. The result of this stimulation is increased production of arachidonic acid metabolites, stimulation of lymphocytic mitosis, and production of cytokines. CGRP demonstrates immunosuppressive activity, which is evidenced by a diminution of Class II antigen presentation and lymphocyte proliferation.

SP and CGRP are mitogenic for pulp and odontoblast-like cells, thereby initiating and propagating the pulp healing response.[294] CGRP has been shown to stimulate the production of bone morphogenic protein by human pulp cells. The result of such stimulation has been postulated to induce tertiary dentinogenesis.[40] SP appears to increase in the dental pulp and periodontal ligament as a result of acutely induced occlusal trauma,[47] which may be related to the pain associated with concussion traumatic injury.

It was shown that there may be gender differences in CGRP production in the dental pulp.[31,175] In one study, serotonin (a peripheral pronociceptive mediator) induced a significant increase in capsaicin-evoked CGRP release in

Telegram: @dental_k

www.konkur.in

dental pulps obtained from female and not male patients.[175] This interplay of inflammatory mediators may explain some of the gender differences in clinical presentation with dental pain.

It was also recently shown that these neurotropic factors are not only present in dentin matrix but may be released and may aid in trigeminal neurite growth during regenerative procedures of the dental pulp.[13,313]

Correlation between clinical symptoms and actual pulp inflammation

From a clinical perspective, it would be most helpful to the clinician to be able to diagnose pulp conditions from a profile of symptoms with which a patient presents. If symptoms are not conclusive, a number of objective tests should aid the clinician in reaching a definitive diagnosis of the pulp pathological status. In actuality, such combinations of subjective and objective findings are frequently insufficient in reaching definitive diagnosis of the status of the dental pulp. This is particularly true in cases of vital inflamed pulp, where it is difficult for the practitioner to determine clinically whether the inflammation is reversible or irreversible.

Many practitioners rely on painful symptoms to determine the status of the pulp. Several studies have examined this question in some detail. Several classic studies were performed in which the subjective and objective clinical findings related to carious teeth were recorded prior to extracting the teeth and examining them histologically. The underlying hypothesis in these studies was that the more severe the clinical symptoms, the more intense pulp inflammation and destruction was evident histologically. These studies showed that in the vital pulp, clinical symptoms generally did not correlate with histopathological findings.[105,189,262] Furthermore, carious pulp exposure was associated with severe inflammatory response or liquefactive necrosis, regardless of symptoms (Fig. 14.9). These histological changes ranged in extent from being present only at the site of the exposure to deep into the root canals.[262] In a few studies, prolonged or spontaneous severe symptoms were associated with chronic partial or total pulpitis, or pulp necrosis.[68,262] However, in these as well as in other studies, it was common to find cases with evidence of severe inflammatory responses including partial necrosis

Telegram: @dental_k

www.konkur.in

histologically, but with little or no clinical symptoms—the so-called "painless pulpitis."[68,105,189,262] Moreover, the frequency of nerve fibers,[252] and the vascularity[253] in inflamed pulp does not correlate with clinical symptoms in primary and permanent teeth. It has been reported that the incidence of painless pulpitis that leads to pulp necrosis and asymptomatic apical periodontitis is about 40% to 60% of all pulpitis cases.[188] More recently, one study[248] documented the clinical and histopathological findings and showed that the clinical diagnosis of normal pulp/reversible pulpitis match the histologic diagnosis in 96.6% of the time and of irreversible pulpitis 84.4%, respectively. They also noted that the inflammation and bacterial infection was often localized to the coronal pulp when the tooth responded as irreversible pulpitis. This is critical for vital pulp therapy (VPT), as the radicular pulp is maintained in that procedure. However, this study was retrospective, based on one dentist's subjective definitions of reversible and irreversible pulpitis with no standardization of testing. Asymptomatic irreversible pulpitis was not included. Moreover, cases with signs and symptoms of symptomatic irreversible pulpitis and normal periapex respond well to emergency pulpotomy[77] and to VPT with a tricalcium silicate.[166]

FIG. 14.9 Histological photomicrograph of a molar with carious pulp exposure. The exposure had been capped but had failed and the patient presented with symptoms. The photomicrograph shows an area

www.konkur.in

of necrosis and extensive inflammation throughout the coronal pulp.

Stained micrograph shows dead tissue in the crown of tooth.

Objective clinical findings are essential for determining the vitality of the pulp and whether the inflammation has extended into the periapical tissues. Lack of response to electric pulp testing is generally indicative that the pulp has become necrotic.[247,262] Thermal pulp testing is valuable in reproducing a symptom of thermal sensitivity, and in allowing the practitioner to assess the reaction of the patient to a stimulus and the duration of the response. However, pulp testing cannot determine the degree of pulp inflammation.[68,262] These studies show that irreversible pulp inflammation can be diagnosed with some certainty only in cases where, in addition to being responsive to pulp testing, the pulp develops severe spontaneous symptoms. Pulp necrosis could be predictably diagnosed by a consistent negative response to pulp tests, preferably to both cold and electrical tests to avoid false responses.[234,235] Recent studies show the accuracy of traditional pulp testing to be about 82% to 84%.[179]

The lack of correlation between the histological status of the pulp and clinical symptoms may be explained by recent advances in the science of pulp biology. In the last few decades, studies have shown that numerous molecular mediators may act in synchrony to initiate, promote, and/or modulate the inflammatory response in the dental pulp. The nature and quantity of these inflammatory mediators cannot be determined from histological analysis, without the use of very specialized staining techniques and molecular assays. Many of these molecular mediators tend to reduce the pain threshold, either directly by acting on peripheral nerve cells or through promoting the inflammatory process. Thus a number of these mediators were shown to be elevated in human pulp diagnosed with painful pulpitis. These mediators include prostaglandins,[53,251] the vasoactive amine bradykinin,[163] tumor necrosis factor alpha,[151] neuropeptides such as SP,[32] CGRP and neurokinin A,[14] and catecholamines.[207] In fact, it was even shown that when patients have painful pulpitis, the crevicular fluid related to the affected teeth has significantly increased neuropeptides compared to the levels in

Telegram: @dental_k

www.konkur.in

contralateral teeth.[14]

It has also been determined that peripheral opioid receptors are present in the dental pulp,[127] and these could play a role in helping us understand why many cases with irreversible pulpitis are asymptomatic. As noted before, carious teeth are frequently not associated with significant symptoms. However, they still have significant amount of inflammation. The pulp in teeth with mild to moderate caries has increased neuropeptide Y,[73] and its Y1 receptor,[74] compared to that in normal teeth. Neuropeptide Y is a neurotransmitter for sympathetic nervous system and is thought to act as a modulator of neurogenic inflammation. Likewise, the levels of VIP, although not its receptor VPAC1, seemed to increase in the pulp of moderately carious teeth.[72]

With recent advances in molecular biology, efficient detection of hundreds of molecular mediators simultaneously by their gene expression has become a reality. Current research seeks to examine which genes are specifically expressed or upregulated in the pulp, in response to the carious lesion. In this regard, preliminary studies have shown that various cytokines and other inflammatory mediators are upregulated underneath a carious lesion, in a manner that correlates with the depth of caries.[184] Gene microarrays have been used in several studies to obtain an accurate mapping of candidate genes that show elevated expression in inflamed pulp and the odontoblastic cell layer.[185,216,217] In addition, research has revealed the differential expression of microRNAs (miRNAs) in healthy and diseased dental pulp,[326] and the increase in viral microRNA in inflamed pulp, to correlate with levels of inflammatory mediators.[325] miRNAs are noncoding RNA molecules that regulate gene expression in complex inflammatory responses and may eventually assist in clinical predictions of pulp status. Therefore more accurate chair-side diagnostic methods are potentially feasible to develop; particularly, sampling can be made from crevicular fluid, dentinal fluid, or the pulp directly. For this reason, more research is needed to determine the key mediators that would predict survival or degeneration of the dental pulp in difficult diagnostic cases.

Dentin hypersensitivity and its management

Telegram: @dental_k

www.konkur.in

Dentin hypersensitivity is a special situation in which a significant, chronic, pulp pain arises, which does not seem to be associated with irreversible pulp pathosis, in most cases. Dentin hypersensitivity is characterized by brief sharp pain arising from exposed dentin in response to stimuli (typically thermal, evaporative, tactile, osmotic or chemical) that cannot be ascribed to any other form of dental defect or pathology.[111] Facial root surfaces in canines, premolars, and molars are particularly affected, especially in areas of periodontal attachment loss. Dentin hypersensitivity may be related to excessive abrasion during tooth brushing, periodontal disease, or erosion from dietary or gastric acids,[2,3,49] and may be increased following scaling and root planning.[49,308] The dentin is hypersensitive most likely due to the lack of protection by cementum, loss of smear layer by acidic dietary fluids, and the hydrodynamic movement of fluid in dentinal tubules.[5,35] The degree of inflammation in the pulp in cases of dentin hypersensitivity is not well characterized because the condition is usually not severe enough to warrant tooth extraction or endodontic therapy. However, patent dentinal tubules are present in areas of hypersensitivity (Fig. 14.10)[320] and may result in increased irritation and localized reversible inflammation of the pulp at the sites involved.

The application of neural modulating agents such as potassium nitrate,[183] or tubule blocking agents such as strontium chloride, oxalates, or dentin bonding agents (Fig. 14.11),[5,224] usually alleviates the condition, at least temporarily. However, the placement of passive molecules or crystals may provide only temporary relief, thus there has been the need to provide biocompatible materials that bond to the root surface, in order to provide a more lasting solution. One such material was a calcium sodium phosphosilicate bioactive glass,[172] which was developed into a commercial product (SootheRx, NovaMin Technology Inc., Alachua, FL). Another product uses a combination of a calcium oxalate and an acid-etched bonding material to seal the dentinal tubules (BisBlock, Bisco Inc., Schaumberg, IL). A concern has been raised that the acidic pH during etching may cause dissolution of the oxalate crystals, thus interfering with the effectiveness of the material,[315] However, one study found that BisBlock and two other products (Seal&Protect, Dentsply DeTrey GmbH, Konstanz, Germany, and Vivasens, Ivoclar Vivadent AG, Schaan, Liechtenstein) were effective compared to placebo, several weeks after treatment,[220] In the long term, the development of smear layer, such as from tooth brushing, dentin sclerosis, reactionary dentin, and the blockage of tubules with large endogenous macromolecules, are all thought to reduce the problem[225] (illustrated by Dentin Hypersensitivity animation at www.PathwaysofthePulp.com). A practice-based randomized clinical trial compared the effectiveness of non-desensitizing toothpaste (Colgate Cavity Protection Regular, Colgate-Palmolive, United States), with desensitizing toothpaste (Colgate Sensitive Fresh Stripe, Colgate-Palmolive, United States) and a professionally applied desensitizing agent (Seal and Protect, Dentsply, United States).[95] The findings showed a significant reduction of dentin hypersensitivity in the desensitizing therapies compared to the non-desensitizing group. In fact, the reduction was much more significant than that obtained by the professionally applied desensitizing agent over a 6-month period. Contemporary desensitizing agents that have been found to be effective include nano-hydroxyapatite,[66] laser treatment, HEMA and glutaraldehyde primer, 3% oxalate, or home products containing 8% arginine/NaF or 5% potassium nitrate.[93]

Pulp reactions to local anesthetics

An intact PBF is critical for maintaining the health of the dental pulp. Because the dental pulp is enclosed in a rigid chamber and is supplied by few arterioles through the apical foramina, it cannot benefit from collateral circulation or volumetric changes that compensate for changes in blood flow in other soft tissues. Furthermore, reduction in blood flow has the compounding effect of reducing the clearance of large molecular weight toxins or waste products,[223] resulting in irreversible pulp pathosis. Vasoconstrictors are added to local anesthetics to enhance the duration of anesthesia. However, vasoconstrictors in local anesthetics could negatively impact the health of the pulp if they reduce blood flow, particularly if the pulp is inflamed preoperatively. Earlier studies have documented that

Telegram: @dental_k

www.konkur.in

vasoconstrictors in local anesthetics do reduce PBF in experimental animals when administered by infiltration and nerve block (Fig. 14.12),[142] and that this effect was more severe with periodontal ligament injections (Fig. 14.13).[141] More recently, clinical trials were conducted in which subjects were given infiltration of different local anesthetics with or without epinephrine at a concentration of 1:100,000 and the PBF was measured by the laser Doppler flowmetry. In groups that received the epinephrine, there were consistently significant reductions in PBF,[6,51,198] even if the infiltration was palatal to maxillary premolars.[237] Interestingly, in one study the reduction in PBF with epinephrine infiltration was more that the reduction in gingival blood flow, and did not return to baseline values after 1 hour of injection.[6] Similar reductions in PBF were reported when inferior alveolar nerve block injections of lidocaine and 1:100,000 or 1:80,000 epinephrine were administered.[209] It is important to note a limitation of studies using laser Doppler flowmetry, which is that a large proportion of the signal measured may be from sources other than the dental pulp.[236,271] Thus the monitoring of minor changes in PBF should be interpreted with caution, particularly if the rubber dam or a similar barrier was not used.[104] Human studies showed that intraosseous anesthesia reduced PBF in molars by 60% after 1 minute, which returned to normal within 45 minutes. A similar reduction was not observed for the blood flow in canines.[309] Taken together, these findings suggest that local anesthesia with vasoconstrictors may compromise the inflamed pulp's ability to recover from inflammation, particularly if it is severely inflamed or if the tooth is subjected to extensive restorative procedures or acute trauma, and if the anesthetic is delivered via a periodontal ligament or an intraosseous route.

Intrapulpal anesthesia is often used as a last resort, when pulp anesthesia is insufficient during root canal therapy. The effect of intrapulpal anesthesia on the pulp in these cases is not considered, as the pulp will be removed. However, occasionally VPT is indicated. One study has shown that intrapulpal anesthesia can be used in these cases, with no clinical differences on follow-up of over 24 weeks between the groups that did or did not receive intrapulpal anesthesia, and when given, in the groups where the anesthetic

Telegram: @dental_k

contained or did not contain epinephrine.[287] However, clearly this injection would have to be performed with caution.

Pulp reactions to restorative procedures

A large body of literature exists on the effects of restorative procedures on the dental pulp. This topic understandably, has been important for practicing dentists for many years. Restorative procedures are performed primarily to treat an infectious disease, dental caries, which itself causes significant irritation of the pulp. They may also be performed to help restore missing teeth, correct developmental anomalies, and address fractures, cracks, failures of previous restorations, or a myriad of other abnormalities. One key requirement of a successful restorative procedure is to cause minimal additional irritation of the pulp so as not to interfere with normal pulp healing. When pulp vitality is to be maintained during a restorative procedure, then a provisional diagnosis of reversible pulpitis rather than irreversible pulpitis must preexist. Therefore it would be most desirable to perform a minimally traumatic restorative procedure, which would not potentially convert the diagnosis to irreversible pulpitis. As was discussed previously, irreversible pulpitis may present clinically with severe spontaneous postoperative pain, but it may also be asymptomatic, leading to the asymptomatic demise of the pulp. The additive effects of restorative procedures are particularly critical in borderline cases, such as those of moderately symptomatic teeth with deep caries but no pulp exposure. There are still many factors whose influence on the response of the dental pulp to cumulative effects of caries, microleakage, restorative procedures, and materials is not well understood. It is generally accepted that the effects of pulp insults, be they from caries, restorative procedures, or trauma, are cumulative. That is, with each succeeding irritation, the pulp has a diminished capacity to remain vital. As a part of informed consent, the clinician is often faced with the task of outlining possible risks of restorative treatment. One study addressed the fate of pulps beneath single unit metal-ceramic (MC) crowns or MC bridge abutments.[50] Patients who had received either treatment were invited to attend a recall appointment that involved both clinical and radiographic examinations. One hundred and twenty-two teeth

Telegram: @dental_k

www.konkur.in

with preoperatively vital pulps treated with single unit MC crowns and 77 treated as bridge abutments were examined. The mean observation period was 14 years for the former and 15.6 years for the latter. Pulp necrosis had occurred in 15.6% of the teeth treated with single unit crowns, while 32.5% of the pulps in the bridge retainer groups had become necrotic. There was a significantly higher percentage of pulp necrosis in anterior teeth that served as bridge abutments (54.5% of anterior abutment teeth examined). In general, however, the available evidence indicates that the effects of dental procedures on the pulp depend on the following factors.

The degree of inflammation of the pulp preoperatively

As stated previously, the dental pulp is compromised in its ability to respond to external irritants because it is enclosed in a noncompliant environment, and because it lacks collateral circulation. Thus the more severe the pulp is inflamed, the less it will be able to respond to further irritation, such as in the form of restorative procedures.[160]

Most research studies designed to evaluate the effects of restorative procedures (or materials) on the pulp are conducted on human or experimental animal teeth with normal pulp tissue. Furthermore, many of the animal research projects have been performed on anesthetized animals without the use of local anesthesia, which as stated previously, reduces PBF. Therefore the results of these studies may not reveal the true clinical effects of these procedures when the pulp is already inflamed by the carious lesion and PBF is reduced by local anesthetic with vasoconstrictors. In a study that evaluated the response of the pulp to capping procedures as a function of duration of exposure, it was shown that the pulp responds favorably to exposures of up to 24 hours after exposure, but not as favorably after longer periods of exposure to oral environment.[60] It may be that the longer exposure periods lead to the formation of a bacterial biofilm, which is difficult for the pulp immune responses to eliminate, and/or the extension of the infection so deep into the pulp to preclude healing. This is relevant in cases of aseptic mechanical exposures or teeth where the pulp is exposed by traumatic injuries for a brief duration. In these cases, the pulp usually responds favorably to VPT procedures.[7] Models of standardized pulp inflammation with chronic caries are not commonly used in determining the effects of

Telegram: @dental_k

www.konkur.in

dental procedures. Older clinical studies show an unfavorable long-term outcome of capping cases with carious pulp exposures[18,115]; however, newer studies in which tricalcium silicates were used show more favorable results in these cases.[28,166,186,230]

In the absence of severe spontaneous symptoms or pulp exposure, as indicated previously, the clinician currently cannot determine accurately the degree of preoperative pulp inflammation. Thus every effort should be done to minimize added irritation during restorative procedures, as it is possible that excessive irritation could convert the inflammatory status of the pulp from a reversible to an irreversible condition. In addition, the patient should always be advised of the possibility of pulp degeneration and the importance of follow-up.

The amount of physical irritation caused by the procedure

Physical irritation during restorative procedures such as from heat, desiccation, or vibration may adversely affect the dental pulp.

Heat

Restorative procedures such as cavity or crown preparation or curing of resins during direct fabrication of provisional restorations[288] may cause significant increases in pulp temperatures. It has been shown using primate models that an intrapulpal temperature rise of 10°C causes irreversible pulp pathosis in 15%, and a 20°C rise caused pulp abscess formation in 60% of teeth evaluated.[322] Several other older studies documented burns or severe inflammation in the pulp when cavity or crown preparations were performed without coolants (Figs. 14.14–14.16). However, a more recent study in which gradual controlled heat application over a large area of the intact occlusal surface of human unanesthetized teeth was employed, failed to corroborate these earlier findings.[15] In this study, an increase of intrapulpal temperature of about 11°C followed by 2- to 3-month evaluation did not show any clinical or histological changes in the pulp of any of the teeth evaluated. A heat increase in rat pulp tissue to 42°C and in vitro raised heat shock protein-70, which are known to be tissue protective, caused changes in alkaline phosphatase and gap junction proteins, that were reversed to normalcy a few

Telegram: @dental_k

www.konkur.in

hours later.[9] By contrast, heat applied in deep cavity preparations, prepared atraumatically in human teeth, in another study, caused histologic changes that were dependent on the proximity of the heat source to the pulp.[208] It was common in that study to see a loss of odontoblasts or their aspiration into the dentinal tubules. In cases where the cavity floor was less than 0.5 mm from the pulp, areas of coagulation necrosis could be seen, although the patients remained asymptomatic for the 1-month duration of the study. The measurement of heat in the tooth being prepared in areas other than the site of tooth preparation, occasionally shows reduction in temperature,[96] presumably because of the poor conductive properties of dentin and the cooling effect of compressed air of the high-speed hand-piece. Furthermore, cavity and crown preparations include several other irritating stimuli, such as desiccation, severance of odontoblastic processes, vibration, and smearing of bacterial irritants onto the surface of dentin. Therefore taken together, these findings suggest that the transient increase in temperature to levels relevant to modern dental procedures on its own may not be the culprit in inducing pulp changes. Rather, the synergistic application of excessive heat with other irritation factors and its proximity to the pulp may induce pathological changes.

Desiccation

Desiccation during cavity and crown preparation has long been known to cause aspiration of odontoblastic nuclei into dentinal tubules and pulp inflammation.[33] One study showed that as little as 30 seconds of continuous air drying of class V cavities in human molars with uninflamed pulp caused significant displacement of odontoblastic nuclei, pulp inflammation and even areas of necrosis related to the areas that were dried.[59] However, another study showed that the effects of desiccation are transient and that within 7 to 30 days, there is autolysis of the aspirated cells and formation of reactionary dentin.[34] The pulp, in cases with aspirated odontoblasts following desiccation for 1 minute, was not sensitive to clinical scraping with an explorer. The sensitivity was restored with rehydration of the cavities and was increased in other cases where pulp inflammation was induced by microbial

Telegram: @dental_k

www.konkur.in

contamination.[168] In this study, despite the lack of sensitivity in desiccated cavities, neural elements were seen histologically to be pushed into the tubules, like the odontoblastic nuclei. The disruption of the odontoblastic layer and peripheral neural elements in the pulp with desiccation was also observed in a rat model using axonal transport of radioactive protein.[39] One clinical observational study showed that air cooling without water during crown and bridge preparations caused minimal damage to the pulp clinically or radiographically.[174]

Biological and chemical irritation

Dental caries is clearly a disease in which microorganisms and their virulence factors constantly irritate the pulp, even at the early stages, long before pulp exposure.[36] However, despite the elimination of visible caries during cavity preparation, the cavity floor is undoubtedly left with some contamination by caries bacteria. While the rubber dam should be used with any cavity preparation to prevent cavity contamination with salivary microorganisms, the use of water coolants allows the cavity to be contaminated with bacteria from water lines. Concerns about residual cavity contamination prompted some to use cavity disinfection with some caustic chemicals. Chemicals such as hydrogen peroxide, sodium hypochlorite, or calcium hydroxide solutions have been proposed for this purpose, although they may exert a toxic effect.[56] An earlier study showed that the amounts of residual bacteria following adequate restoration are not significant.[190] Once dentin is exposed, there is a constant outward flow of dentinal fluid that minimizes the inward flow of any noxious agents.[310] This may aid in the reduction of irritation from residual microbial factors in dentinal tubules.

In contemporary practice, most chemical irritation during restorative procedures results from the application of etching agents, especially strong acids, in the form of total dentin etch, particularly if capping of exposed pulp is performed.[98,219] Etching is performed to remove the smear layer, to promote physical adhesion of bonding agents to dentin by forming resin tags in the dentinal tubules, and to permeate the newer unfilled resin primers into the unmineralized surface layer of collagen to form the so-called “hybrid layer.”

If the cavity is relatively superficial and is adequately sealed with a

Telegram: @dental_k

www.konkur.in

restorative resin, then the etching of dentin is probably not detrimental to the pulp because of the narrow diameter of dentinal tubules and their low density in peripheral dentin.[30] In fact, one study documented that histological evidence of bacteria in human cavities restored with composite was significantly less if the cavity had been etched with phosphoric acid than if it was etched with 17% EDTA or nonetched.[197] Pulp inflammation in this study was not correlated with the etching treatments, but with bacterial presence; thus in cases of etching with phosphoric acid, if bacteria were also present, severe pulp inflammation and necrosis could be seen.

Self-etching formulations have become popular because they eliminate the separate etching step involved in total-etch procedures. Some have speculated that the bonding of self-etching systems may be poorer than total-etch systems because of the weaker acidity of the acidic primers of self-etching systems compared to total-etch systems.[30] However, studies have shown no significant differences between the two adhesive systems in long-term in vitro bond strength, postoperative sensitivity,[232] long-term in vivo degradation,[153] or long-term in vitro bond strength.[11] One clinical study showed no differences between the two systems with respect to bacterial leakage and the inflammatory response in the pulp.[202] The most important variable that affected the pulp in this study was the amount of bacterial leakage with either system.

Other factors that may contribute to pulp irritation during resin placement from chemical/biologic irritants include unpolymerized monomer and polymerization shrinkage. Higher concentrations of monomeric resin components were shown to exert an inhibitory effect on T-lymphocytes and spleen cells,[132] as well as monocytes/macrophages[162,240,241,261] in vitro. These components may leach directly into the pulp in deep cavities and cause chemical irritation.[118] Shrinkage during polymerization of composites may induce internal stresses on dentin and create voids that allow microleakage. Shrinkage of resins is estimated to range from 0.6% to 1.4% and should be minimized during placement by incremental curing and possibly starting the restoration with flowable resins.[30]

Recent studies have shown that salivary or dentin matrix-based metalloproteinases or salivary esterases may be released during etching and may degrade the collagen in the hybrid layer, thereby degrading the

Telegram: @dental_k

www.konkur.in

dentin/composite bone.[116,182] In vitro and in vivo research showed that this detrimental effect could be reduced and the stability of the hybrid layer maintained with the use of chlorhexidine, galardin, benzalkonium chloride, or quaternary ammonium methacrylates.[182]

In summary, the available evidence indicates that chemicals involved in modern restorative procedures may irritate the pulp if placed directly on an exposure, if there is microbial leakage along the tooth/restoration interface, or if there is degradation of the hybrid layer that seals the restoration dentin interface.

The proximity of the restorative procedures to the dental pulp and the surface area of dentin exposed

It has been known for several decades that, as the carious lesion progresses towards the pulp, particularly when the RDT is less than 0.5 mm, there is an increasingly severe pulp reaction, with a greater likelihood of the pulp undergoing irreversible pathosis.[245] The diameter and density of dentinal tubules increase closer to the pulp (Fig. 14.17). Based on the dentinal tubule density at the DEJ (about 65,000/mm^2) and the pulp (about 15,000/mm^2),[90,94] it was estimated that the area occupied by tubule lumina at the DEJ was 1% of the total surface area at the DEJ and 22% at the pulp.[225] Thus it is not surprising that several studies have shown that pulp inflammation in response to restorative procedures increases with the reduction in RDT.[1,61,196] One study examined the differential effects on the rat pulp of the preparation method, RDT, coolant, drill speed, conditioning with EDTA, and filling materials.[195] Subsequent to the cavity preparations a tooth slice was obtained and maintained ex vivo as an organ culture for up to 2 weeks. The results showed that the RDT was the most important factor on pulp injury.

With the passage of time following cavity preparation, there is a reduction in the permeability of RDT.[227] This may be due to the rapid deposition of reactionary dentin, the migration of large proteins into the tubules, and/or the diminution of tubule diameter as dentin becomes more sclerotic. Using a primate model, it was shown that the basic rate of secondary dentin deposition was about 0.8 µm/day and that this rate increased to an average of 2.9 µm/day following restorative procedures. Interestingly, in this study, dentin deposition was also more rapid next to shallow cavities than deep cavities[312]; however, another study showed that total reactionary dentin

Telegram: @dental_k

www.konkur.in

deposited was thicker in deeper and wider cavities.[194]

Clinically, it has been observed that postoperative sensitivity is common with many restorative procedures. Following resin composite restorations on patients, it was shown that postoperative sensitivity was related to the depth of the cavity but not to the presence or absence of liners or bases.[302]

In addition to the depth and/or the width of a large cavity preparation, a crown preparation exposes more dentinal tubules to microbial or chemical irritation. During crown fabrication, there are added irritation factors such as the length of time of preparation, impression techniques, and the imperfect adaptation of temporary restorations that cause microleakage during the temporization period. Due to the precise engineering requirements of some restorations, some providers may be inclined to reduce the coolant during crown preparations steps, such as finalizing the finishing lines. However, crown preparations without coolants have been shown to dramatically reduce PBF in an animal model (Fig. 14.18).[143] Air coolant appears to be adequate, at least in part.[174] In general, long-term outcome studies have documented that the incidence of pulp necrosis following crown placement ranges from 10% to 50%.[50,85,303]

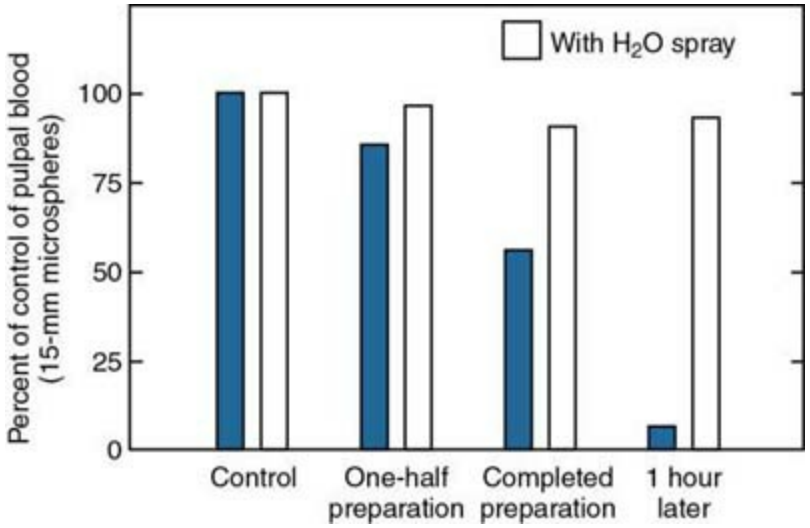

FIG. 14.18 Effects of crown preparation in dogs, with and without water and air spray (at 350,000 rpm) on pulpal blood flow. The permeability of dentin and the odontoblastic layer between the area being restored and the pulp

The permeability of dentin plays an important role in the ingress of potential irritants to the pulp. It is clear from research done in the last three decades that dentin is not uniformly permeable and that permeability depends on factors such as the location within the same tooth, the age of the patient, and the presence of pathological conditions such as dental caries. Fundamentally, the permeability of dentin depends on the collective sum of permeability of individual tubules at a specific site in the tooth. The tubular diameter increases from about 0.6 to 0.8 μm close to the DEJ to about 3 μm at the pulp.[222] Given that bacterial cells are about 0.5 to 1 μm in diameter, it is evident that in deep cavity preparations, particularly when total-etch procedures are employed, bacteria can migrate through the remaining dentin into the pulp.

With age, the width of peritubular dentin increases, causing reduction in tubular lumen or sclerosis. Caries causes demineralization in superficial dentin, which is associated with remineralization and the formation of caries crystals within the tubules of inner undemineralized dentin (Fig. 14.19). This causes a decrease in permeability in dentin subjacent to the carious lesion[224] and could be considered a protective mechanism, as it may delay the progress of the carious lesion.

It was shown that irritation from cavity preparation increased the permeability of the odontoblastic cell layer only at the site of the cavity preparation.[125,297] In addition to the physical barrier to permeability and the production of reactionary or reparative dentin, the odontoblastic layer may, in fact, contribute to the host response of the dental pulp by expressing important inflammatory mediators[165,218] or recognize bacteria through TLRs.[29,71,80,131]

Telegram: @dental_k

www.konkur.in

The age of the patient

Resting PBF, as well as the changes in PBF in response to cold application, decreases with age.[121] Age may also be associated with a reduction in pulp neuropeptides.[91] However, studies show no differences between young and old pulp in the regenerative capacity of odontoblast-like cells, nor in the presence of cells positive for class II major histocompatibility complex, heat shock protein 25 or nestin, when subjected to cavity preparation.[137] An examination of normal, young versus old human pulp showed that young pulp had an increased expression of biological factors related to cell differentiation, proliferation, and the immune response; however, older pulp had increased factors related to apoptosis.[293] Nevertheless, PBF in anterior teeth measured with laser Doppler flowmetry showed that it correlates with systolic blood pressure, but not with age, sex, or tooth type.[140] Taken together, these analyses cannot translate to the pulp's ability to deal with irritation and its sequelae. Thus the net result of the ability of the pulp to cope with external stimulation or irritation in humans with advancing age is not clear.

Pulp reactions to restorative materials

The effects of restorative materials on the dental pulp have been investigated and seem to relate directly to the permeability of the associated dentin. The degree of dentin permeability, however, is often variable and is governed by several factors, including age and caries status.[284] The most important variable in dentin permeability to restorative materials is the thickness of the dentin between the floor of the cavity preparation and the pulp.[1]

Given the importance of dentin permeability, there are direct effects of any given restorative material on the pulp that is governed by the composition of the material and associated eluted or degraded products. Unbound components of resin materials and preparative agents such as acid etchants can affect the subjacent pulp by inducing an inflammatory response.[93,98,239] The indirect effects of desiccation and/or demineralization of dentin as well as the direct effects of the material itself when in contact with pulp tissue mediate this inflammatory response. Studies have shown that the certain cytotoxic components of resin monomers (e.g., triethylene glycol

Telegram: @dental_k

www.konkur.in

dimethacrylate and 2-hydroxyethyl methacrylate) readily penetrate dentin.[87] Similarly, eugenol and components of Ledermix (triamcinolone and demeclocycline) have been shown to pass through dentin into the subjacent pulp.[117,120] In vivo data show that these chemicals have an effect on the pulp; however, the effect seems to be short lived and, in the absence of bacteria, reversible.[23]

The mechanisms whereby restorative materials exert an injurious effect on the dental pulp are varied. Evidence exists that supports direct and, in some instances, prolonged cytotoxicity, stimulation of hypersensitivity reactions, or impairment of the host immune response to bacteria.[258] Some of the components of resin restorations are released at cytotoxic levels after polymerization is completed, leading to chronic stimulation and a resultant prolonged inflammatory response.[86] Furthermore, even subtoxic concentrations of certain agents are capable of eliciting allergic reactions in humans.[119] Primates hyperimmunized with BSA showed significant pulp damage with repeated antigenic challenge in class V cavity preparations, suggesting a role for antigen-antibody complex–mediated hypersensitivity in tissue destruction.[26] In a separate study, exposure to dentin primers elicited a delayed-type hypersensitivity reaction in guinea pigs.[136] These studies, taken together, present a compelling argument for immune-mediated pulp tissue damage subsequent to exposure to restorative materials. Foreign body reactions have also been described in pulps containing extruded globules of resin material.[123,124] Histological examination of such pulps shows macrophages and giant cells surrounding the resin particles. Lastly, resin monomers have been shown to decrease the activity of immunocompetent cells in a dose-dependent manner in in vitro functional assays.[132] While all these effects are documented, their extent and therefore morbidity on the dental pulp is speculative and doubtless does not act solely to effect pulp demise. As previously noted, most restorative materials are placed adjacent to pulps that are previously compromised by bacterial insult and that disease, debridement, and restoration of the tooth have cumulative effects on the dental pulp.

Although pulp irritation is largely considered to be a negative sequela, the irritant potential of certain restorative materials is central to their usefulness in restorative dentistry. Calcium hydroxide is one of the oldest and most

Telegram: @dental_k

www.konkur.in

widely used medicaments for stimulation of dentinal bridge formation subsequent to microscopic or gross pulp exposure. The low-grade pulp irritation that it induces is important for dentinal bridge formation in exposures.[64,260] The degree of inflammation is dependent on the preparation of calcium hydroxide used. Aqueous suspensions of calcium hydroxide applied to exposed pulps cause superficial necrosis of pulp tissue followed by low-grade inflammatory changes. Within 30 days, the tissue subjacent to the necrotic zone has reorganized and resumed normal architecture. Hard setting calcium hydroxide preparations as well as mineral trioxide aggregates (MTAs) are effective in eliciting dentinal bridge formation with a much smaller to nonexistent necrotic zone.[108] This is preferable in vital pulp therapies such as the Cvek pulpotomy where maintenance of the maximum amount of vital pulp tissue is desirable and the extent of pulp inflammation is minimal (Fig. 14.20).[63] The irritation potential of calcium hydroxide across intact dentin is dependent on factors such as the RDT and permeability. Application of calcium hydroxide to intact dentin appears to induce sclerosis by promoting crystal precipitation within the tubules accompanied by reductions in permeability.[192] However, more recent findings show that calcium hydroxide over intact dentin does not exert a significant clinical advantage and may be lost due to the action of leakage or dentinal fluid.[62]

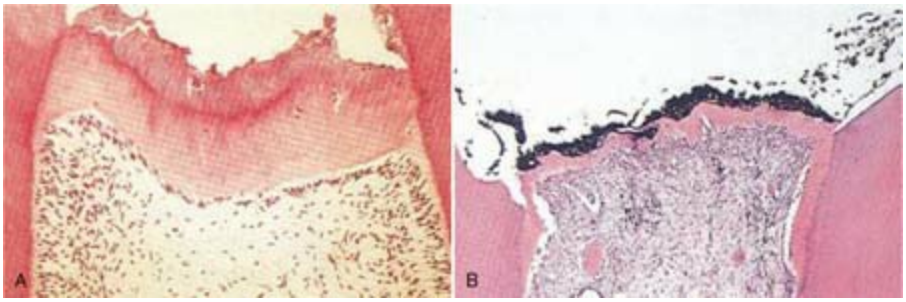

FIG. 14.20 Calcium hydroxide produces an inflammatory response that stimulates dentinal bridge formation. The dentin bridge forms lower in the tooth with calcium hydroxide paste **(A)** versus hard setting calcium hydroxide **(B)**.

Set of two stained micrographs marked A and B shows the formation of calcium hydroxide paste and calcium hydroxide hard tissue in tooth, respectively.

Telegram: @dental_k

www.konkur.in

While the irritation potential of calcium hydroxide plays a role in its effectiveness, the high pH of this material can act to liberate bioactive molecules from dentin. Numerous authors have demonstrated that dentin matrix proteins like TGF-β1 and adrenomedullin are liberated by both calcium hydroxide and MTA.[97,291] Once liberated, they are able to facilitate hard tissue formation yet again. This offers another explanation for the ability of these materials to induce hard tissue formation in vivo. Acid etching or the use of chelating agents such as EDTA represent a common step in the placement of bonded restorations. The etching process removes minerals and exposes collagen fibrils. As with a high pH, sequestered bioactive molecules are released and can act on pulp cells. These include growth factors and metalloproteinases, which can be inductive for healing but can also degrade the bond of the restoration.[228] EDTA has been shown to be even more effective at extracting noncollagenous proteins from dentin than either calcium hydroxide or MTA, but less so than citric acid.[97,291]

Investigations into the pulp response to glass ionomer materials have shown that both the lowered pH of the material and the release of high concentrations of fluoride can inflict damage to pulp tissues.[135] In direct contact with pulp cells, glass ionomers are toxic.[155] Direct pulp capping studies have shown it to be inferior to calcium hydroxide.[67,112] When applied to intact dentin and in the absence of bacteria, there is a transient inflammatory response and reparative dentin is formed.[57]

In addition to the direct chemical effects of restorative materials, there are indirect factors that contribute to pulp irritation. The technique sensitivity of certain materials predisposes them to faulty bonds to tooth structure that can translate to dentin hypersensitivity, recurrent disease, and pulp inflammation or necrosis. Much attention has been given to the interface created between resin-bonded materials and dentin. During the etching process, the more highly mineralized peritubular dentin is preferentially dissolved, leaving free collagen fibrils and opening lateral tubular branches.[98,99,191] Applied resin infiltrates the exposed collagen mesh creating a layer 5 to 10 μm thick referred to as the hybrid layer.[199] This layer, along with the resin permeating exposed tubules, forms the bond between the resin and dentin. If the preparation is too dry, the collagen fibrils collapse and the resin cannot effectively permeate the mesh, which results in a defective bond. As the

Telegram: @dental_k

www.konkur.in

optimal degree of hydration of the preparation surface can vary from material to material, resin restoration placement is technique-sensitive. This same principle is applicable to the practice of bonding fractured tooth fragments where the segment has become dehydrated while outside of the mouth. Current protocols recommend rehydration of the segment prior to bonding, thus increasing the mechanical and, presumably, the microbial seal.[84] This is particularly important with a complicated crown fracture where the pulp protection by intact dentin is absent.

Some restorative materials rely on their medicinal properties as well as their ability to seal a cavity preparation. Materials containing zinc oxide and eugenol (ZOE) fall into this category. ZOE is used for a variety of purposes in dentistry largely because of its anesthetic and antiseptic properties. It has been shown to block the transmission of action potentials in nerve fibers and to suppress nerve excitability in the pulp when applied to deep excavations.[295] In addition, ZOE has good adaptation to dentin and inhibits bacterial growth on cavity walls. These properties have made it a favored material for temporary fillings, but not long-term restorations, as ZOE temporaries have been shown to leak after only a few weeks in situ.[323]

Direct pulp capping with bioceramics

The direct capping of pulp exposures is indicated in pulps that were previously healthy and exposed by trauma or dental restorative procedures and, more recently, for pulp exposure where the diagnosis is reversible pulpitis.[4,279,283] This is particularly true in the cariously exposed immature permanent tooth, where maintenance of pulp vitality is crucial to further tooth development. Although calcium hydroxide has historically been the preferred dressing agent on mechanically exposed pulps, the use of MTA, Biodentine, and other bioceramic formulations has recently been proposed, even on carious pulp exposures.[17,28,109,186] Prospective animal studies and human case reports have evaluated the ability of MTA to allow for the formation of a reparative dentin bridge and to maintain continued pulp vitality.[79,89,148] Although the results are generally favorable, one concern is of tooth discoloration in cases where the gray MTA formulation is used on anterior teeth. Recent studies have indicated that newer bioceramic materials show

Telegram: @dental_k

www.konkur.in

less potential for discoloration when used as pulp capping materials.[149]

The bioceramic that has been most intensely studied for pulp capping is MTA. In one clinical study, MTA was used as a pulp capping material for carious pulp exposures.[28] Forty patients, ages 7 to 45, who were diagnosed with reversible pulpitis had caries removed using a caries detection dye and sodium hypochlorite for hemostasis. The treatment was performed in two visits to allow the MTA to set up and to confirm pulp sensibility to pulp tests in the second visit. Success was determined radiographically, with subjective symptoms, pulp testing with cold, and continued root formation on immature teeth. Outcomes were measured over a period of up to 9 years postoperatively and showed an overall success rate of 97%, with all the teeth in the immature root group showing success. In another clinical study in which dentists and students participated in the treatment, pulp capping of carious pulp exposures was compared between MTA and calcium hydroxide.[186] At follow-up, 122 cases of patients of mean age of 40 years were available. The success with MTA was 78% and, with calcium hydroxide, success was 60%, a difference that was statistically significant. Within the parameters of these studies, it seems that white MTA is a suitable capping agent for pulp exposures of healthy or reversibly inflamed pulps, including cases with asymptomatic carious exposures. Randomized trials and consensus reports have shown that tricalcium silicates are significantly better than calcium hydroxide as pulp capping agents in carious pulp exposure.[69,157] However, given that the prognosis of root canal therapy in this last category has been shown to be predictably high in many studies, the patient needs to be educated carefully of the options, and consent must be documented.

As previously mentioned, other calcium silicate-based materials are gaining popularity as pulp capping agents and appear to have similar properties and effects as MTA.[12,205] Biodentine deserves special reference because, in addition to the biocompatibility, it has physical properties that are very similar to dentin.[41,154] Studies show no differences between MTA, Biodentine, and other tricalcium silicates like NeoMTA Plus as pulp capping or pulpotomy agents.[134,206,290]

The use of hemostatic agents and

Telegram: @dental_k

www.konkur.in

disinfectants on direct pulp exposures

There is still debate as to whether the outcomes of pulp capping for exposure depends on the toxicity of medicaments and materials placed on vital pulp tissues, the ability of these materials to induce mineralization, or their ability to seal the cavity from further bacterial ingress. It is likely a combination of these factors, as was shown in the recent clinical trial with MTA mentioned before.[28] Another factor in the prognosis of direct pulp caps is the ability to control hemorrhage at the exposure site.[273] Given the difficulty in creating a bacteria-free operating environment during tooth preparation, the ideal hemostatic agent also would have the ability to kill bacteria.

One study compared the effects of two hemostatic/disinfectant agents on the healing of experimental pulp exposures created in human third molar teeth and capped with calcium hydroxide.[264] Pulp exposures were made in 45 maxillary wisdom teeth scheduled for extraction for orthodontic reasons. Teeth were randomly assigned to receive hard-setting calcium hydroxide pulp caps after a 30-second surface treatment with one of three agents: 0.9% saline, 2% chlorhexidine, or 5.25% sodium hypochlorite. Although the 7-day saline specimens showed slightly less inflammatory response, there were no statistically significant differences between the groups with respect to all dependent measures over the course of the study. Complete healing was seen in 88% of all specimens at 90 days.

The pulps in these teeth were previously uninjured, and the exposures were made in a clean environment. Carious pulp exposure frequently reveals an inflamed pulp in which it is difficult to stop the bleeding. The original study by Bogen et al. proposed applying a cotton pellet with 5.25% to 6% sodium hypochlorite for 1 to 10 minutes for hemostasis.[28]

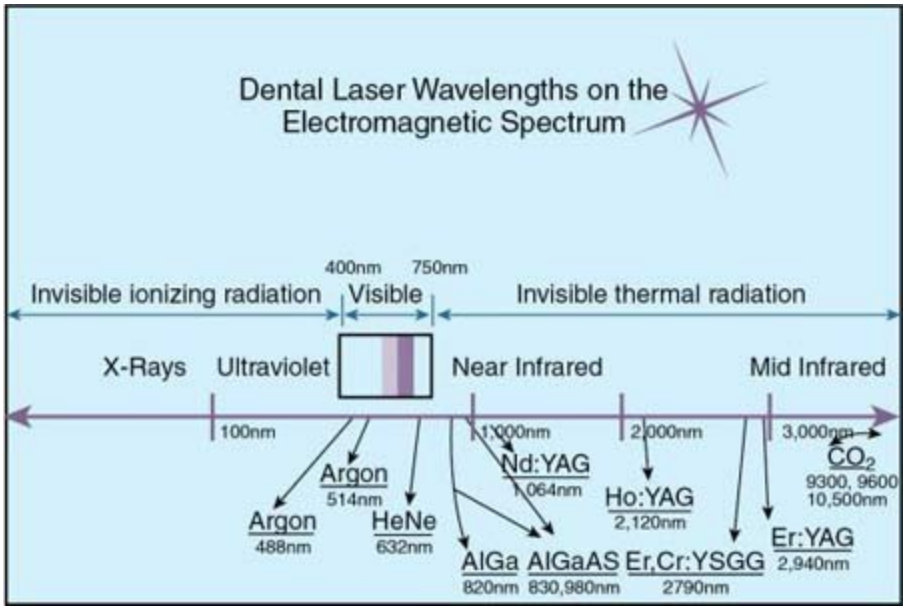
Pulp reactions to laser procedures

Numerous studies have been published on the effect of using lasers on enamel, dentin, and pulp. Laser use on hard tissue has been a popular area of research because of the potential benefits of efficiency, reduced sensitivity, disinfection, and precision. There are several different types of laser technologies available that depend on the wavelength, active medium, emission mode, delivery system, power output, and duration of application.

Telegram: @dental_k

www.konkur.in

The main types available in dentistry today are shown in Fig. 14.21. The CO_2 laser is historically the oldest type used on soft tissues and thus has been the most studied. It has the longest wavelength (10,600 nm). It cannot be delivered in an optic fiber and thus must be used in a hollow tubelike wave guide in continuous gated-pulse mode. This means that the operator does not feel a solid resistance when using this laser. Er:YAG, Nd:YAG, or Ho:YAG lasers all have an active medium of a solid crystal of yttrium-aluminum-garnet, which is impregnated in erbium, neodymium, or holmium, respectively. Er:YAG has a wavelength of 2940 nm and is delivered using a solid optic fiber. It has a high affinity for water and hydroxyapatite, which means it can be used for removal of caries and cutting dentin with coolant. It can also be used on soft tissue. The Ho:YAG laser has a wavelength of 2120 nm, has a high affinity for water but not to tooth structure, and thus is used primarily for soft-tissue surgery. Nd:YAG laser is also delivered fiberoptically, has a wavelength of 1064 nm, and has been used extensively in dentistry because it has a high affinity for water and pigmented tissues and offers good hemostasis; therefore it is used extensively in surgery.[54] In addition, there are some low power output lasers such as HeNe or helium neon (632 nm), and GaAlAs or gallium-aluminum-arsenide (diode; semiconductor) (720 to 904 nm) lasers that have been used in laser Doppler flowmetry and in treating dentin hypersensitivity.[144]



Telegram: @dental_k

www.konkur.in

FIG. 14.21 Currently available dental wavelengths on the electromagnetic spectrum. Note all of the wavelengths are nonionizing.

In dental laser wavelengths on the electromagnetic spectrum, the invisible ionizing and invisible thermal radiation extend toward the left and right of visible region (400 to 750 nanometers), respectively. The visible region marks argon at 488, argon at 514, HeNe at 632 nanometers. Region from near infrared to mid infrared shows AlGa at 820, AlGaAS at 830, 980, ND: YAG at 1,064, Ho: YAG at 2,120, Er,Cr: YSGG at 2790, Er:YAG at 2490, and CO2 at 9300, 9600, and 10, 500 nanometers.

In order to summarize the available data, a discussion of the application of lasers for two specific purposes will follow.

Lasers in the prevention, diagnosis, and treatment of caries

Laser irradiation of deep susceptible pits and fissures may reduce the incidence of dental caries. Once caries develops, some lasers may be effective in removing the carious lesion and sparing undemineralized dentin because of their differential absorption by water and hydroxyapatite. Furthermore, if caries exposes the pulp in young teeth, particularly those with immature apex, lasers may be able to effectively excise coronal infected pulp in pulpotomy because of their hemostatic and antibacterial properties. All these potential uses prompted a large number of investigations on the effectiveness of lasers in these applications.

Some clinicians have proposed using lasers to enhance adhesion of pit and fissure sealants; however, this was shown to not add any advantage following acid-etching—a necessity for adhesion.[177] Laser fluorescence is used by the DIAGNOdent and DIAGNOdent pen, which are laser devices that have been introduced for the diagnosis of non-cavitated caries. Although these devices initially showed some promising results,[178] more recent work shows that they are best used as adjunctive devices to radiography and visual examination.[8,55,156]

Laser ablation of superficial carious lesions may be more conservative than bur preparation. A recent controlled clinical trial supports this tenet, when

Telegram: @dental_k

www.konkur.in

free-running pulsed Nd:YAG laser was used to ablate superficial pit and fissure caries in third molars scheduled for extraction (Fig. 14.22).[103] In this study, there were no histologic differences in the pulp response between the two groups.

From the perspective of the effects on the pulp, most laser applications that are employed in cutting or modifying cavities in dentin or acting directly on the pulp tissue are important. Earlier studies showed reduced permeability of dentin in vitro with an XeCl excimer laser (a laser with a relatively short wavelength of 308 nm in the ultraviolet range).[272] The apparent fusion of tubules in superficial layers of dentin was shown to occur with CO_2, Nd:YAG, and Er:YAG lasers in vitro.[314] The pulp responses to Nd:YAG and CO_2 lasers were not favorable. It was shown that Nd:YAG, and to a lesser degree CO_2 lasers, may be associated with charring and significant inflammation in the pulp compared with Er:YAG laser (Fig. 14.23).[289,314] More recently, it was reported that water cooling was necessary for laser ablation as it is for high-speed bur preparations.[45] Studies have shown that Er:YAG laser appears to induce similar responses in the pulp to those seen

Telegram: @dental_k

www.konkur.in

with high-speed bur preparations, at the level of light microscopy analysis.[78,285,286,314] However, the findings with electron microscopy were different: it was reported that while shallow cavities ablated in rat molars using Er:YAG lasers did not show changes from base-line using light microscopy and transmission electron microscopy showed disruption and degeneration of pulp peripheral nerve endings and of myelin sheath in the immediate postoperative period (Fig. 14.24).[122] This may explain the reduced sensitivity that accompanies laser cavity preparations. Thus in summary, it does not appear that the use of lasers provides predictable advantages in cavity preparation compared with traditional methods at this time.

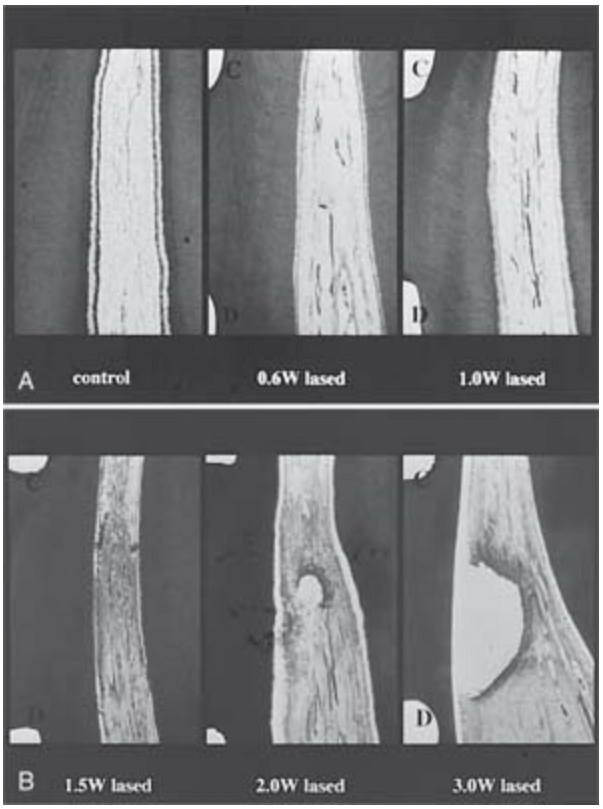

FIG. 14.23 **A** and **B,** Histopathologic picture of Nd:YAG laser specimen with an increasing power. There is direct relationship between the degree of pathologic changes and the increasing power of the laser. In fact, 1.5 W and the greater power cause permanent damage to the pulp.

www.konkur.in

For pulpotomy procedures, such as in primary teeth, permanent teeth with immature apex, or pulps that are exposed due to fracture and treated promptly, the lasers, particularly CO_2 lasers, may be useful in achieving precise surgical excision of coronal pulp and immediate hemostasis. A controlled clinical study showed that CO_2 laser pulpotomy was comparable to traditional methods in experimental pulpotomies of primary teeth scheduled for extraction for orthodontic reasons.[75] However, an animal study in which CO_2 and Nd:YAG lasers were compared revealed poor response with both lasers compared with calcium hydroxide.[133] An animal study using Er:YAG laser showed that the results are dependent on the power settings, in that lower energy delivered with this laser produced favorable results.[145]

Lasers in the treatment of dentin hypersensitivity

Earlier studies have shown effectiveness ranging from 5% to 100% of low output lasers on dentin hypersensitivity.[144] One author reported a reduction of hypersensitivity in 73% of mild cases, 19% of moderate cases, and 14% of severe cases after 4 months, using a GaAlAs laser.[144] Low output lasers do not have any effects on the morphology of enamel or dentin but are thought to cause transient reduction in action potential mediated by pulp C-fibers, but not Aδ-fibers,[311] although this finding was not consistent.[214] Nd:YAG lasers have also been used in dentin hypersensitivity. Because of the higher power output, these lasers cause superficial occlusion of dentinal tubules of up to 4 μm,[173] in addition to action potential blockage within the pulp in vitro or in experimental animals.[213,214] However, a placebo-controlled clinical trial has shown that both Nd:YAG and placebo caused significant reduction in dentin hypersensitivity for up to 4 months postoperatively, but were not different from each other.[167] More recent clinical trials show that while lasers are useful for managing hypersensitivity, they do not appear to be better than less costly and more readily available alternatives.[88,301]

Pulp reactions to vital bleaching techniques

Vital bleaching techniques employ the use of strong oxidizing agents,

Telegram: @dental_k

www.konkur.in

namely, 10% carbamide peroxide and hydrogen peroxide, to bleach the enamel of teeth with vital pulp. There have been concerns about the potential for pulp irritation during these procedures because of the long amount of time during which the chemicals are in contact with the teeth, particularly if dentin with open tubules or cracks are present. Histologic or histochemical analysis of the pulp following bleaching for up to 2 weeks showed minor inflammatory changes in the pulp of the bleached teeth that were reversible.[10,92] One clinical report documented that if 16% carbamide peroxide was used, gingival irritation was evident; however, no changes in pulp vitality or in symptoms were noted. Even in patients who develop symptoms post-operatively, these tend to be reversible and can be prevented by treating the teeth with fluorides and by correcting restorative deficiencies preoperatively.[201] Clinical symptoms are likely to be due to increases in neuropeptides, such as SP, in the pulp.[46] An earlier clinical trial showed that vital bleaching using 10% carbamide peroxide in a custom tray for 6 weeks was safe for the pulp health for up to 10 years postoperatively, although the bleaching effectiveness may decline with time.[250] In one recent clinical study premolars scheduled for orthodontic extraction had 38% H_2O_2 bleaching gel with and without a halogen light source applied. There were no histologic effects on the dental pulp at 2 to 15 days after bleaching.[146] When the study was performed on incisors with the same treatment for 45 minutes, areas of coagulation necrosis could be seen in the pulp.[58] Therefore caution should be exercised when this caustic agent is used for extended bleaching.

Light activation of bleaching agents is widely used. In conjunction with a source of peroxide moieties, the light emission results in both thermal and photo catalysis of the bleaching agent, thereby releasing hydroxyl radicals and facilitating the whitening process.[169,176] The light sources can be halogen light or diode lasers, and they are reported to speed the bleaching process, allowing shade improvement over a shorter period. Some of these techniques, however, have been shown to generate sufficient heat to result in a rise in pulp tissue temperature, increasing the risk of thermal tissue damage. To this point, comparisons of bleaching with and without light activation report a higher incidence of tooth sensitivity in the light-activated bleaching group.[147] Pretreatment with a desensitizing gel of 5% nitrate potassium/2% sodium fluoride was effective in one study in reducing postoperative sensitivity after

Telegram: @dental_k

www.konkur.in

light-activated bleaching.[246]

Pulp reactions to periodontal procedures

In an intact non-traumatized nontraumatized existence throughout life because it is insulated from microbial irritation in the oral cavity. Periodontal disease causes attachment loss, which exposes the root surface to the oral cavity. Occasionally, pulp inflammation secondary to severe periodontitis is observed.[161] Some reports have described bacterial infiltration through dentinal tubules of exposed root surface causing mild inflammatory changes in the pulp (Fig. 14.25).[159] However, in a case report of 25 teeth that were extracted in a patient with extensive periodontal disease, none of the pulp tissue had significant inflammatory changes.[292] It is much more common for pulp necrosis, or for failure of healing of periapical lesions, to present clinically with signs of periodontal disease than for periodontal disease to cause pulp pathosis. Primary endodontic, secondary periodontal pathosis is particularly evident if a perforation occurs in the pulp chamber or coronal third of the root during endodontic treatment and is not promptly treated, in cases of cracked teeth/vertical root fractures or in cases of congenital tooth defects such as palatal groove defects. Thus it is more likely for microbial irritants to move outward from a necrotic pulp to cause periodontal breakdown than for them to move inward from a periodontal pocket to cause irreversible pathosis in the vital pulp. The reasons for this observation are not fully understood. However, if the assumption is that bacteria may migrate through patent dentinal tubules in these situations, as is shown in Fig. 14.25, then it may be that the outward dentinal fluid flow in teeth with vital pulp contribute to the resistance to ingress of bacteria in sufficient amounts to cause a clinically significant disease process. Once the pulp degenerates, dentinal fluid flow no longer exists. Thus microbial irritants from the pulp may promote pocket formation and periodontal bone loss,[129] and the prognosis of endodontic and periodontal treatment may be related,[130] as the microbial factors may pass across dentin more readily.

Periodontal scaling and root planning may result in removal of cementum and exposure of dentin to the oral cavity. Frequently, this treatment results in dentin hypersensitivity, as discussed previously. In theory, periodontal disease and its treatment should be associated with increased incidence of pulp pathosis. In an older study, investigators induced periodontal disease in

Telegram: @dental_k

www.konkur.in

a primate model using ligatures and compared the effects on the pulp of periodontal disease with or without scaling.[24] In teeth with periodontal disease, mild chronic inflammatory changes were observed in 29% of the teeth and could be seen in areas of the pulp related to bone loss. One of 40 teeth developed pulp necrosis. In teeth that received scaling, a similar percentage of 32% developed the same mild inflammation and none developed pulp necrosis. In a later clinical study,[25] 52 periodontitis patients who had 672 teeth with vital pulp were followed up and maintained every 3 to 6 months for 4 to 13 years (mean 8.7 years). Of those teeth, 255 were bridge abutments. The results showed a significantly higher chance of pulp complications in teeth that were bridge abutments than teeth that were not abutments (15% vs. 3%; $P < .01$). Considering that both types of teeth had similar degrees of periodontal disease, the authors concluded that prosthodontic treatment is associated with pulp involvement more frequently than periodontal disease and its treatment. Another histologic analysis of 46 teeth with varying degrees of periodontal disease and coronal restorations reached a similar conclusion.[65] Furthermore, two comprehensive reviews of the topic concluded that while the potential exists for periodontal disease and its treatment to cause pulp pathosis, particularly if large lateral or accessory canals are exposed, this occurrence is rare.[102,254]

Mechanical irritants: Orthodontic movement

The most conspicuous pulp change observed in response to orthodontic forces is hemodynamic. Both human and animal studies have confirmed that both lateral and intrusive forces result in an increase in PBF.[158,203,212] Furthermore, blood flow alterations are not confined to the tooth in active movement. Observed increases in blood flow are seen in teeth adjacent to the focus of movement forces, implying that directed forces on one tooth could shunt blood to proximal vessels, supplying other oral structures including teeth. If orthodontic forces are extreme, circulatory interruptions can occur, resulting in pulp necrosis.[37]

Biochemical, biologic, and histological studies of the effects of orthodontic movement have confirmed that metabolic as well as inflammatory changes can result. The dental pulp tissue respiration rate is depressed after short-term

Telegram: @dental_k

www.konkur.in

application of orthodontic force.[100] Biochemical and molecular markers confirm that apoptosis and necrosis of pulp cells are also increased subsequent to movement.[233] However, it was shown that the inflammatory mediators IL-1α and TNF-α show minor increases in the pulp during orthodontic movement, compared to the increase in periodontal tissues.[27] Histological examination of pulps in teeth subjected to intrusive forces showed vascular congestion and dilatation as well as vacuolization of the odontoblastic layer.[276–278] Most, if not all, of these effects are due to circulatory changes, and the consensus is that they are transient provided that the movement forces are not excessive.[152] It was recently shown, however, that pulp necrosis of teeth that were undergoing orthodontic treatment and had also been traumatized prior to that is significantly increased compared to teeth that had either of these conditions but not the other, particularly in lateral incisors and if the traumatized tooth had pulp canal obliteration.[19,20] As noted previously, SP appears to increase in the dental pulp as a result of acutely induced occlusal trauma.[47] Also, CGRP increases under the influence of orthodontic forces.[48] One area of growing interest with respect to orthodontic forces is their role in the pathogenesis of cervical invasive root resorption (CIRR). Studies that have categorized the potential etiology of CIRR have documented that the history of orthodontic treatment is the most cited associated factor.[107,181] However, longitudinal observational or case control studies that show a stronger relationship between CIRR and orthodontic treatment are lacking.

Pulp reactions to orthodontic surgery

It has been known for decades that osteotomies in the maxilla or mandible may cause disruption in the blood supply to teeth in the area of the surgery, with resultant inflammation and/or necrosis.[16,150,200,231] Occasionally, the teeth affected show postoperative manifestations common with traumatic injuries, such as pulp canal obliteration.[305] Animal studies have shown that if a safe distance of 5 to 10 mm is maintained between the site of the surgery and the teeth, minimal disruption occurs.[70,319] A number of studies have documented, using laser Doppler flowmetry, actual reduction in PBF immediately following maxillary Le Fort I osteotomy,[215,242,257] particularly if

Telegram: @dental_k

www.konkur.in

segmental osteotomy is performed.[76] In most cases, the blood flow is regained within months of the surgery. A modification of the Le Fort I osteotomy technique has been described in which the Le Fort I sectioning is combined with a horseshoe palatal osteotomy to spare any disruption to the descending palatine artery.[101] An examination of PBF of maxillary teeth using laser Doppler flowmetry as well as the responsiveness to electric pulp testing showed significant differences between the two surgical techniques in the postoperative recovery values (Fig. 14.26). In cases where the surgery did not disrupt the palatine artery, the PBF in the anterior teeth consistently increased without disruption in the post-operative period. A recent systematic review concluded that following a Le Fort I osteotomy, there is a decrease in pulpal vascularity and neurosensory response but only in the early postoperative period (1 to 10 days), and that this is likely a temporary effect.[243]

It should also be noted that occasionally, teeth are traumatized during endotracheal intubation for surgery that requires general anesthesia, when the surgery itself is not related to the jaws or teeth.[265]

Biomechanical irritation: Parafunctional habits

Occlusal loading of teeth effects deformation to varying degrees.[187] While enamel is largely resistant to flexure, the underlying dentin demonstrates considerable elastic and viscoelastic characteristics. As a result, defects in enamel secondary to cracks, decay, and/or restorative preparation allow cusp flexure with subsequent pulp responses, presumably due to dentinal fluid flow secondary to compression and microleakage.[110] The magnitude of the pulp response is dictated by the degree and chronicity of dentinal deformation.

Multiple factors influence the degree of tooth deformation during occlusal loading. Investigators have noted that preparation geometry has a direct impact on cuspal flexure. The width of the occlusal isthmus relative to the facio-lingual dimension of the tooth as well as the ablation of marginal ridges directly impact the degree of cusp flexure.[221,244,304] MOD preparations have been shown to cause a 50% reduction in cusp stiffness and resistance to fracture. Physical properties of the restorative material can also play a part in cusp flexure. Studies have shown that polymerization shrinkage of certain resin composites can induce an inward deflection of cusps with resultant stresses on tooth structure.[306,307]

Symptomology from cusp flexure can result from two primary sources. It has been theorized that cusp flexure results in dentin deformation, thus promoting dentinal fluid flow that activates nerve endings in the odontoblast layer of the tooth. This is supported in part by an in vitro study, which found that dentinal fluid flow could be induced by occlusal loading of restored

Telegram: @dental_k

www.konkur.in

teeth.[110] A second source of pulp pain is bacterial microleakage created by a gap at the restoration/dentin interface that is repeatedly opened during cycles of occlusal loading. If repeated cuspal flexure gives rise to a crack, dentinal exposure to bacteria and their by-products is even greater. It is likely that in vivo, both dentinal fluid flow and bacterial access to dentinal surfaces work together to produce inflammation that is often manifested by thermal as well as biting sensitivity for the patient. In the instance of parafunctional habits, this is often combined with concussive periodontal forces to the periodontium that induce acute periradicular periodontitis, mobility, and radiographic changes.

On the cellular level, studies have shown increased levels of SP after experimentally induced occlusal trauma.[47] SP is a modulator of both sensory and immune function in the dental pulp. Alterations in physiologic levels of this mediator could result in disruptions in the pain response as well as secondary stimulation of prostaglandin E2. Furthermore, the immunostimulatory ability of neuropeptides could initiate and maintain a chronic pulp inflammation, possibly leading to necrosis. While animal studies have suggested that pulp necrosis is a possible sequela to chronic occlusal trauma, there are no controlled clinical studies that confirm this.

Dentinal cracks expose tubules that are not occluded by a smear layer and therefore offer a direct portal to the subjacent pulp. When dentinal tubules are freely exposed, there is an outward flow of dentinal fluid driven by relatively high pulp tissue pressures. Dentinal fluid is composed of proteins such as fibrinogen and serum albumin, which can coagulate and effectively block the tubule lumen, thereby limiting fluid egress and resultant dentin hypersensitivity. This phenomenon can occur within 2 days. As this serves as a short-term protective mechanism for the pulp, dentinal sclerosis and tertiary dentin formation can ultimately provide greater protection for the pulp and reduction of symptoms. Clinical interventions include the application of materials that occlude the tubules and extracoronal restorations to prevent the propagation of cracks. Cracks were also shown to harbor bacterial biofilms that can add to the irritation and inflammation of the pulp and induce periodontal pocket formation in cases with cracked teeth.[249]

Pulp reactions to implant placement and

Telegram: @dental_k

www.konkur.in

function

Osseointegrated implants are now a common option for the replacement of missing teeth. The placement of implants requires multifaceted preoperative radiographic techniques, including intraoral, tomographic, cephalometric, and panoramic imaging.[298] This ensures that implant placement fully rests in bone and does not compromise neighboring structures, including teeth. The lack of attention to the three-dimensional anatomy of the site of implant placement and the orientation of neighboring teeth may lead to the implant perforating the root and devitalizing the pulp.[180,281] The same could occur during procedures of maxillary sinus floor augmentation.[21]

It is usually recommended that implants not be placed directly at a site where a periradicular lesion, particularly one with signs of purulence, exists, as microbial irritants may interfere with osseointegration.[238] However, some data suggest that immediate implant placement in sites that have been adequately debrided is successful.[42] One systematic review corroborated this finding, provided that adequate preoperative, intraoperative, and postoperative antimicrobial measures are utilized.[52]

Case reports have also claimed that teeth with periradicular lesions may reduce the success of neighboring implants even if adequate endodontic treatment is performed.[280] To address this issue, a study was reported in which implants were placed to replace premolars in dogs and periradicular lesions were likewise induced, some of which were treated nonsurgically or with surgical and nonsurgical treatment.[263] The results showed that the presence of treated or untreated periradicular lesions did not affect the long-term osseointegration of implants that were already osseointegrated. Clinical cases with complete resolution of periapical lesions that also involve neighboring implants, following adequate endodontic treatment, have been published.[170,256,275]

15: Microbiology of endodontic infections

José F. Siqueira JR., Isabela N. Rôas

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Apical periodontitis is essentially an inflammatory disease of microbial etiology primarily caused by infection of the root canal system.[217] Although chemical and physical factors can induce periradicular inflammation, a large body of scientific evidence indicates that endodontic infection is essential to the progression and perpetuation of the different forms of apical periodontitis.[18,91,123,273] Endodontic infection develops in root canals devoid of host defenses, as a consequence of either pulp necrosis (as a sequel to caries, trauma, periodontal disease, or invasive operative procedures) or pulp removal for treatment.

Microorganisms other than bacteria have been detected in association with endodontic infections, including fungi, archaea, and viruses.[54,194,254,261,291] However, given their high prevalence, dominance, organization, and pathogenicity, bacteria can be regarded as the major microorganisms implicated in the pathogenesis of apical periodontitis. In advanced stages of the endodontic infectious process, bacterial structures resembling biofilms are

Telegram: @dental_k

www.konkur.in

commonly observed adhering to the canal walls.[124,164,245] Consequently, apical periodontitis has been included in the roll of biofilm-related oral diseases.[256] Bacteria colonizing the root canal system enter in contact with the periradicular tissues via apical/lateral foramina or root perforations. As a consequence of the encounter between bacteria and host defenses, inflammatory changes take place in the periradicular tissues and give rise to the development of apical periodontitis. Depending on several bacterial and host-related factors, apical periodontitis can be symptomatic (acute) or asymptomatic (chronic).

The ultimate goal of endodontic treatment is either to prevent the development of apical periodontitis or, in cases where the disease is already present, to create appropriate conditions for periradicular tissue healing. The intent is to preserve the tooth and associated periradicular tissues in healthy conditions. Because apical periodontitis is an infectious disease, the rationale for endodontic treatment is to eradicate the occurring infection or prevent microorganisms from infecting or reinfecting the root canal or the periradicular tissues. The cardinal principle of any health care profession is the thorough understanding of disease etiology and pathogenesis, which provides a framework for effective treatment. In this context, understanding the microbiologic aspects of apical periodontitis is the basis for sound endodontic practice and sets the stage for an evidence-based therapeutic approach. This chapter focuses on diverse aspects of endodontic microbiology, including pathogenetic, taxonomic, morphologic, and ecologic issues.

Apical periodontitis as an infectious disease

The first recorded observation of bacteria in the root canal dates back to the 17th century and the Dutch amateur microscope builder Antony van Leeuwenhoek (1632–1723). He reported that the root canals of a decayed tooth “were stuffed with a soft matter” and that “the whole stuff” seemed to be alive.[44] At that time, the role of Leeuwenhoek’s “animalcules” in disease causation was unsuspected. It took almost 200 years until his observation was confirmed and a cause-and-effect relationship between bacteria and apical periodontitis was suggested. This occurred specifically in 1894, when

Telegram: @dental_k

www.konkur.in

Willoughby Dayton Miller, an American dentist working at the laboratory of Robert Koch in Berlin, Germany, published a milestone study reporting on the association between bacteria and apical periodontitis after an analysis of samples collected from root canals.[119] By means of bacterioscopy of the canal samples, he found bacterial cells in the three basic morphologies known at the time: cocci, bacilli, and spirilla (or spirochetes) (Fig. 15.1). Morphologically, the endodontic microbiota was clearly different in the coronal, middle, and apical parts of the root canal. Spirochetes were found in high frequencies in abscessed cases, and a pathogenic role was suspected for these bacteria. Most of the bacteria Miller observed under light microscopy could not be cultivated using the technology available at that time. Those bacteria were conceivably anaerobic bacteria, which were only successfully cultivated about 50 to 100 years later with the advent of anaerobic culture techniques. However, it is now widely recognized that a large number of bacterial species living in diverse environments still remain to be cultivated by current technology,[6,154,155] and the root canal is no exception (discussed later in this chapter). Based on his findings, Miller raised the hypothesis that bacteria were the causative agents of apical periodontitis.

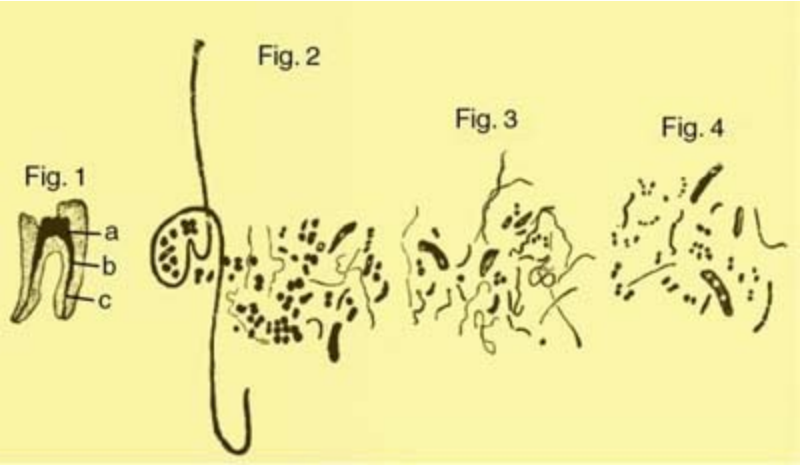

FIG. 15.1 Drawings from Miller's classic paper showing different bacterial forms in a root canal sample observed by microscopy.

Set of four hand drawings are marked figure 1 to 4 as follows:

Figure 1: Diagram of tooth shows three labels marked a to c.

Figure 2: Irregularly spherical shape of bacteria.

www.konkur.in

Figure 3: Rod-shaped bacteria.

Figure 4: Spirally twisted bacteria.

Approximately 70 years after Miller's classic study, his assumptions were confirmed by an elegant study from Kakehashi et al.[91] These authors investigated the response of exposed dental pulps to the oral cavity in conventional and germ-free rats. Histologic evaluation was performed and revealed that pulp necrosis and apical periodontitis lesions developed in all conventional rats; however, the exposed pulps of germ-free rats not only remained vital but also repaired themselves with hard-tissue formation. Dentin-like tissue sealed the exposure area and isolated the pulps again from the oral cavity.

The important role of bacteria in the etiology of apical periodontitis was further confirmed by Sundqvist's study.[273] This author applied advanced anaerobic culturing techniques to the evaluation of bacteria occurring in the root canals of teeth whose pulps became necrotic after trauma. Bacteria were found only in the root canals of teeth exhibiting radiographic evidence of apical periodontitis, confirming the infectious cause of this disease. Anaerobic bacteria accounted for more than 90% of the isolates. Findings from the Sundqvist's study also demonstrated that in the absence of infection, the necrotic pulp tissue itself and stagnant tissue fluid in the root canal do not induce or perpetuate apical periodontitis lesions.

Möller et al.[123] also provided strong evidence about the microbial causation of apical periodontitis. Their study on monkeys demonstrated that only devitalized pulps that were infected induced apical periodontitis lesions, whereas devitalized and noninfected pulps showed an absence of significant pathologic changes in the periradicular tissues. In addition to corroborating the importance of microorganisms for the development of apical periodontitis, this study also confirmed that necrotic pulp tissue per se is unable to induce and maintain an apical periodontitis lesion.

Bacteria causing apical periodontitis are primarily organized in biofilms colonizing the root canal system. Bacterial agglomerations resembling what is known nowadays as biofilms had been observed by several morphologic studies,[124,210,245] but it was not until the study by Ricucci and Siqueira[164] that the high prevalence of bacterial biofilms was consistently disclosed and a

Telegram: @dental_k

www.konkur.in

strong association with primary and posttreatment apical periodontitis was reported (see the section Spatial Distribution of the Endodontic Microbiota for a further discussion of biofilms in endodontic infections).

Routes of root canal infection

Under normal conditions, the pulpodentin complex is sterile and isolated from the oral microbiota by overlying enamel and cementum. In the event that the integrity of these natural layers is breached (e.g., as a result of caries, trauma-induced fractures and cracks, restorative procedures, scaling and root planning, attrition, abrasion) or naturally absent (e.g., because of gaps in the cementum coating at the cervical root surface), the pulpodentin complex is exposed to the oral environment. The pulpodentin complex is then challenged by bacteria present in caries lesions, saliva bathing the exposed area, or dental plaque formed on the exposed area. Bacteria from subgingival biofilms associated with periodontal disease may also have access to the pulp via dentinal tubules at the cervical region of the tooth and lateral or apical foramina. Bacteria and other microorganisms may also have access to the root canal any time during or after endodontic intervention, emphasizing the need for maintaining strict asepsis during treatment and promoting an adequate coronal seal.

Whenever dentin is exposed, the pulp is put at risk of infection as a consequence of the permeability of normal dentin dictated by its tubular structure (Fig. 15.2).[140] Dentinal tubules traverse the entire width of the dentin and have a conical conformation, with the largest diameter located near the pulp (mean, 2.5 μm) and the smallest diameter near the enamel or cementum (mean, 0.9 μm).[58] The smallest tubule diameter is entirely compatible with the cell diameter of most oral bacterial species, which usually ranges from 0.2 to 0.7 μm. One might assume that once exposed, dentin offers an unimpeded pathway for bacteria to reach the pulp via tubules. However, it has been demonstrated that bacterial invasion of dentinal tubules occurs more rapidly with a nonvital pulp than with a vital pulp.[128] With a vital pulp, outward movement of dentinal fluid and the tubular contents (including odontoblast processes, collagen fibrils, and the sheathlike lamina limitans that lines the tubules) influence dentinal permeability and can

Telegram: @dental_k

www.konkur.in

conceivably delay intratubular invasion by bacteria. Because of the presence of tubular contents, the functional or physiologic diameter of the tubules is only 5% to 10% of the anatomic diameter seen by microscopy.[117] Other factors such as dentinal sclerosis, tertiary dentin, smear layer, and intratubular deposition of fibrinogen also reduce dentin permeability and thereby limit or even impede bacterial progression to the pulp via dentinal tubules.[142] Host defense molecules, such as antibodies and components of the complement system, may also be present in the dentinal fluid of vital teeth and can assist in the protection against deep bacterial invasion of dentin.[3,133,134] As long as the pulp is vital, dentinal exposure does not represent a significant route of pulpal infection, except when dentin thickness is considerably reduced or when the dentin permeability is significantly increased.

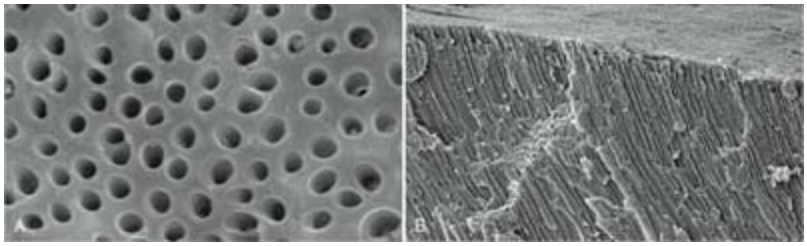

FIG. 15.2 **A,** Scanning electron micrographs of dentin showing tubules in cross-sectional view (magnification ×850). **B,** Longitudinal view (magnification ×130).

A) Scanning electron micrograph shows round hollow spaces on the surface.

B) Scanning electron micrograph shows slanting, fine, longitudinal lines.

Most of the bacteria in the carious process are nonmotile; they invade dentin by repeated cell division, which pushes cells into tubules. Bacterial cells may also be forced into tubules by hydrostatic pressures developed on dentin during mastication.[118] Bacteria inside tubules under a deep carious lesion can reach the pulp even before frank pulpal exposure.[85] As previously mentioned, it has been assumed that the pulp will not be easily infected if it is still vital. The few bacteria that reach the pulp may not be significant, because the vital pulp can eliminate such a transient infection and rapidly clear or remove bacterial products. This efficient clearance mechanism tends to prevent injurious agents from reaching a high enough concentration to

Telegram: @dental_k

www.konkur.in

induce significant inflammatory reactions.[141] On the other hand, if the vitality of the pulp is compromised and the defense mechanisms are impaired, even a small amount of bacteria may initiate pulpal infection.

Direct exposure of the dental pulp to the oral cavity is the most obvious route of endodontic infection. Caries is the most common cause of pulp exposure, but bacteria may also reach the pulp via direct pulp exposure as a result of iatrogenic restorative procedures or trauma. The exposed pulp tissue comes in direct contact with oral bacteria from carious lesions, saliva, or plaque accumulated onto the exposed surface. Almost invariably, exposed pulps will undergo inflammation and necrosis and become infected. The time elapsed between pulp exposure and infection of the entire canal is unpredictable, but it is usually a slow process.[35]

The egress of bacteria and their products from infected root canals through apical, lateral, or furcation foramina, dentinal tubules, and iatrogenic root perforations can directly affect the surrounding periodontal tissues and give rise to pathologic changes in these tissues. Conceptually, bacteria in subgingival plaque biofilms associated with periodontal disease could reach the pulp by the same pathways intracanal bacteria reach the periodontium and could thereby exert harmful effects on the pulp. It has been demonstrated that although degenerative and inflammatory changes of different degrees may occur in the pulp of teeth with associated periodontal disease, significant pulpal necrosis only develops if the periodontal biofilm reaches the apical foramen, leading to irreversible damage to the main blood vessels that penetrate through this foramen (Fig. 15.3).[102] After the pulp becomes necrotic, periodontal bacteria can invade the root canal system via apical foramina, lateral canals, and exposed dentinal tubules.

Telegram: @dental_k

www.konkur.in

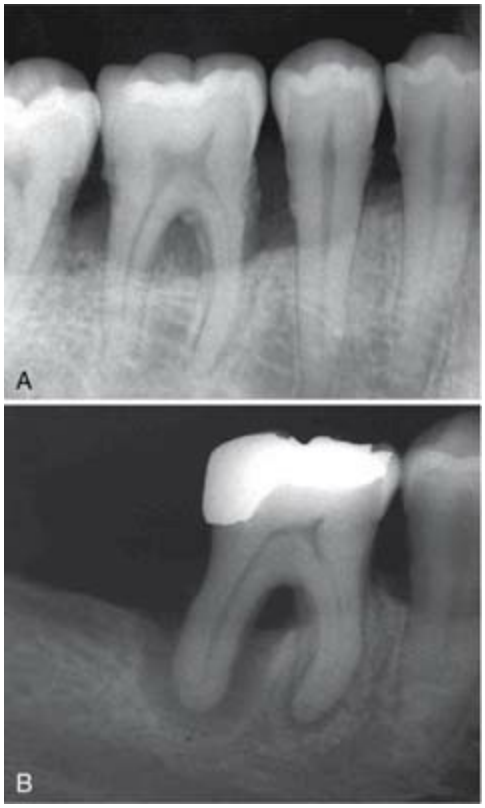

FIG. 15.3 Periodontal disease **(A)** mostly affects the pulp vitality when the subgingival biofilm reaches the apical foramen **(B)**.

A) Radiograph of four teeth shows blur radiolupency in the pulp horn.

B) Radiograph of a teeth shows gray patch surrounding the apical foramen with dentine depicted as radiopaque.

In the past, it was claimed that bacteria could reach the pulp by anachoresis.[72] Theoretically, bacteria can be transported in the blood or lymph to an area of tissue damage, where they leave the vessel, enter the damaged tissue, and establish an infection.[61,170] However, there is no clear evidence showing that this process represents a route for root canal infection. Bacteria could not be recovered from unfilled root canals of cats when the bloodstream was experimentally infected, unless the root canals were overinstrumented during the period of bacteremia, with resulting injury to periodontal blood vessels and blood seepage into the canal.[40] Another argument against anachoresis as a route for pulpal infection comes from the study by Möller et al.,[123] who induced pulpal necrosis in monkeys' teeth and reported that all cases of aseptic necrosis remained bacteria-free after 6 to 7

Telegram: @dental_k

www.konkur.in

months of observation.

Bacteria have been isolated from traumatized teeth with necrotic pulps with apparently intact crowns.[273,306] Although anachoresis has been suggested to be the mechanism through which these traumatized teeth become infected,[72] current evidence indicates that the main pathway of root canal infection in these cases is dentinal exposure due to enamel cracks.[111,112] Macro- and microcracks in enamel can occur in most teeth (not only traumatized teeth) and do not necessarily end at the enamel-dentin junction; they can extend deep into the dentin.[112] A large number of dentinal tubules are exposed to the oral environment by a single crack. Cracks can be clogged with plaque biofilm and provide portals of entry for bacteria. If the pulp remains vital after trauma, bacterial penetration into tubules is counteracted by the dentinal fluid and tubular contents, as discussed earlier, and pulpal health is not usually jeopardized. But if the pulp becomes necrotic as a consequence of trauma, it loses the ability to protect itself against bacterial invasion, and regardless of dentin thickness, dentinal tubules may become true avenues through which bacteria reach and colonize the necrotic pulp.

Whatever the route of bacterial access to the root canal, necrosis of pulp tissue is a prerequisite for the establishment of primary endodontic infections. To reiterate: If the pulp is vital, it can protect itself against bacterial invasion and colonization. If the pulp becomes necrotic as a sequel to caries, trauma, operative procedures, or periodontal disease, then it can be easily infected.

Another situation in which the root canal system is devoid of host defenses relates to cases in which the pulp was removed for treatment. Microbial penetration in the canal can occur during treatment, between appointments, or even after root canal obturation. The main causes of microbial introduction into the canal *during treatment* include residual dental plaque biofilm, calculus, or caries on the tooth crown; leaking rubber dam; contaminated endodontic instruments (e.g., after touching with the fingers); and contaminated irrigant solutions or other solutions of intracanal use (e.g., saline solution, distilled water, citric acid). Bacteria can also enter the root canal system *between appointments* by leakage through the temporary restorative material; breakdown, fracture, or loss of the temporary restoration; fracture of the tooth structure; and in teeth left open for drainage. Bacteria can penetrate the root canal system even *after completion of the root canal*

Telegram: @dental_k

www.konkur.in

obturation by leakage through the temporary or permanent restorative material; breakdown, fracture, or loss of the temporary/permanent restoration; fracture of the tooth structure; recurrent decay; or delay in the placement of the permanent restoration.[227]

Mechanisms of microbial pathogenicity and virulence factors

Pathogenicity is a term that refers to the ability of a microorganism to cause disease. The degree of pathogenicity of a microorganism is referred to as *virulence*. Microbial secreted products, structural cellular components, and strategies that contribute to pathogenicity are regarded as *virulence factors*. One example of bacterial strategy that contributes to pathogenicity is the ability to form biofilms, which confers protection against host defenses, microbial competitors, and antimicrobial agents. Some microorganisms routinely cause disease in a given host and are called *primary pathogens*. Other microorganisms cause disease only when host defenses are impaired and are called *opportunistic pathogens*. Bacteria that make up the normal resident microbiota are usually present as harmless commensals and live in balance with the host. One of the greatest beneficial effects of human microbiota is probably the tendency to protect the host from exogenous infections by excluding other microorganisms. Nevertheless, in certain situations, the balance may be disturbed by a decrease in the normal level of resistance, and then the commensal bacteria are usually the first to take advantage. Most bacteria involved with endodontic infections are normal inhabitants of the oral microbiota that exploit changes in the balance of the host–bacteria relationship, becoming opportunistic pathogens.

The bacterial species involved with the pathogenesis of primary apical periodontitis may have participated in the early stages of pulp inflammation and necrosis, or they may have gained entry into the root canal space any time after pulpal necrosis. In the former situation, involved bacteria are usually those present in the advanced front of caries lesions and from saliva bathing the affected area. Bacteria in caries lesions form authentic biofilms adhered to dentin (Fig. 15.4). Diffusion of bacterial products through dentinal tubules induces pulp inflammation long before the tissue is exposed. After

Telegram: @dental_k

www.konkur.in

frank exposure, the surface of the pulp tissue can be colonized and covered by bacteria present in the caries biofilm. The exposed pulp tissue enters in direct contact with bacteria and their products and responds with severe inflammation. Some tissue invasion by the involved bacteria may occur. Bacteria in the forefront of infection have to survive the attack from the host defenses and at the same time acquire nutrients to keep themselves alive. In this bacteria–pulp clash, the pulp invariably is "defeated" and becomes necrotic, so bacteria move forward and "occupy the territory"—that is, they colonize the necrotic tissue. These events advance through tissue compartments, coalesce, and move toward to the apical part of the canal until virtually the entire root canal is necrotic and infected (Fig. 15.5). At this stage, involved bacteria can be regarded as the early root canal colonizers or pioneer species.

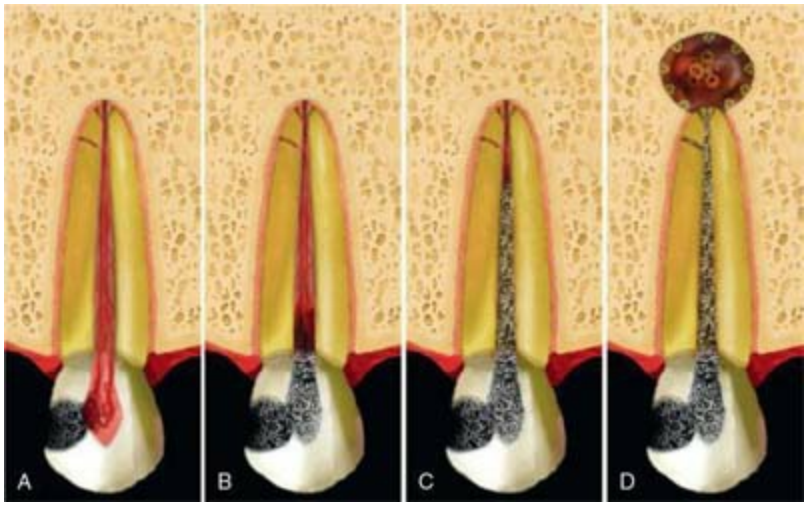

FIG. 15.5 Dynamics of pulp response from caries exposure **(A)** to pulp inflammation **(B)** to pulp necrosis **(C)** to apical periodontitis formation **(D)**.

Set of four illustrations marked A through D shows changes in pulp brought about on caries exposure depicted as necrosis of pulp moving from crown to root.

Early colonizers play an important role in the initiation of the apical periodontitis disease process. Moreover, they may significantly modify the environment, making it conducive to the establishment of other bacterial groups. These new species may have access to the canal via coronal exposure or exposed dentinal tubules, establish themselves, and contribute to a shift in the microbiota. Rearrangement in the proportions of the pioneer species and latecomers occurs, and, as the environment changes, some early colonizers may even disappear. With the passage of time, the endodontic microbiota becomes more and more structurally and spatially organized.

Some virulence attributes required for pathogens to thrive in other sites may be of no value for bacteria that reach the root canal after necrosis—for instance, the ability to evade host defenses. This is because latecomers face no significant opposition from host defenses, which are no longer active in the canal after necrosis. Although colonization may appear an easy task for late colonizers, other environmental factors (e.g., interaction with pioneer species, oxygen tension, nutrient availability) will determine whether new species entering the canal will succeed in establishing themselves and join the early colonizers to make up a dynamic mixed community in the root canal. Ultimately, the root canals of teeth with radiographically detectable apical

Telegram: @dental_k

www.konkur.in

periodontitis lesions harbor both early colonizers that managed to stay in the canals and late colonizers that managed to adapt to the new environmental conditions.[234]

Periradicular inflammation can be observed, even before the frontline of intracanal bacterial infection reaches the apical foramen.[8,124,265,307] Bacteria exert their pathogenicity by wreaking havoc on the host tissues through direct or indirect mechanisms. Bacterial virulence factors that cause direct tissue harm include those that damage host cells or the intercellular matrix of the connective tissue. Secreted bacterial products, such as enzymes, exotoxins, heat-shock proteins, and metabolic end products, are the main examples.[234] Furthermore, bacterial structural components, including lipopolysaccharide (LPS), peptidoglycan, lipoteichoic acid (LTA), fimbriae, flagella, outer membrane proteins and vesicles, lipoproteins, DNA, and exopolysaccharides, can act as modulins by stimulating the development of host immune reactions capable not only of defending the host against infection but also of causing severe tissue destruction (Fig. 15.6).[80,234,287] For instance, inflammatory and noninflammatory host cells are stimulated by bacterial components to release proinflammatory cytokines that are involved in bone resorption characteristically observed in apical periodontitis.[201] Another example of indirect damage is pus formation in acute apical abscesses, which results from the destruction of the connective extracellular matrix by oxygen-derived free radicals and lysosomal enzymes released by polymorphonuclear leukocytes in response to bacteria.[285] Although direct damage caused by bacterial products may certainly be involved in the pathogenesis of apical periodontitis, bacterial indirect destructive effects seem to be more significant in this regard.[201]

www.konkur.in

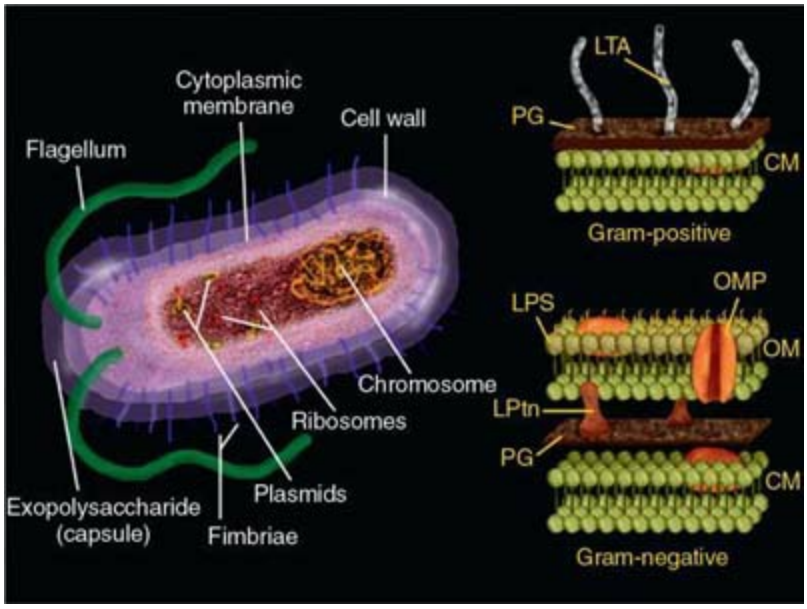

FIG. 15.6 Bacterial cell and its structural components that can act as virulence factors. *Right:* A detailed scheme of the bacterial cell walls from gram-positive and gram-negative bacteria. *CM,* Cytoplasmic membrane; *LPS,* lipopolysaccharide (endotoxin); *LPtn,* lipoproteins; *LTA,* lipoteichoic acid; *OM,* outer membrane; *OMP,* outer membrane protein; *PG,* peptidoglycan.

On the left, cross-sectional diagram of bacterial cell shows labels for cell wall, cytoplasmic membrane, exopolysaccharide (capsule), chromosome, ribosomes, plasmids, flagellum, and fimbriae. On the right, gram-positive cells are shown to have a thick peptidoglycan layer between cytoplasmic membrane, and lipoteichoic acid present on peptidoglycan layer while gram negative cells are shows to have a outer membrane and peptidoglycan layer connected by lipoproteins. The outer membrane lipopolysaccharide and outer membrane proteins while peptidoglycan layer is followed by cytoplasmic membrane.

Apical periodontitis is a multifactorial disease that is resultant of the interplay of many host and bacterial factors. Few if any of the putative endodontic pathogens are individually capable of inducing all of the events involved in the pathogenesis of the different forms of apical periodontitis. Therefore, the process requires an integrated and orchestrated interaction of the selected members of the mixed endodontic microbiota and their respective virulence attributes.[295] LPS, which is exclusive of gram-negative bacteria, has been detected in high concentrations in canals of teeth with large and/or symptomatic apical periodontitis, and in conditions of persistent exudation.[38,64,84,88,205,206] Although LPS has been widely studied and quoted

Telegram: @dental_k

www.konkur.in

as an important virulence factor with regard to the pathogenesis of apical periodontitis,[39,127] many other bacterial mediators are also expected to contribute to disease causation. For instance, some cases of primary infections and many cases of secondary/persistent infections may harbor exclusively gram-positive bacteria, which indicates that the involvement of other factors must not be overlooked. Indeed, LTA, which is exclusive of gram-positive bacteria, has been detected in all teeth with posttreatment apical periodontitis.[10] Many bacterial secreted products have been detected in endodontic infections.[79,152,153] Therefore, the pathogenesis of different forms of apical periodontitis and even the same form in different individuals is unlikely to follow a stereotyped course with regard to the bacterial mediators involved.[218]

Spatial distribution of the endodontic microbiota

Mounting evidence indicates that apical periodontitis, like caries and periodontal diseases, is also a biofilm-related disease. Morphologic studies have shown that the root canal microbiota in primary infections is dominated by bacterial morphotypes that include cocci, rods, filaments, and spirilla (spirochetes) (Fig. 15.7). Fungal cells are sporadically found (Fig. 15.8).[210,245] Although planktonic bacterial cells suspended in a fluid phase and enmeshed in necrotic pulp tissue can be observed in the main root canal, most bacteria colonizing the root canal system usually grow in sessile multispecies biofilms adhered to the dentinal walls (Fig. 15.9).[124,165,245] Lateral canals, apical ramifications, and isthmuses connecting main canals may also be clogged with bacterial biofilms (Figs. 15.10 and 15.11).[160,163,290]

Bacterial cells at the bottom of the endodontic biofilm structure are often seen penetrating the dentinal tubules (Fig. 15.12). Dentinal tubule infection occurs in 70% to 80% of the teeth evincing apical periodontitis lesions.[116,148] A shallow penetration is more common, but in some teeth bacterial cells are observed reaching approximately 300 μm deep (Fig. 15.13).[245] Dividing bacterial cells are frequently seen within tubules (see Fig. 15.13),[245] indicating that they are alive and probably derive nutrients from degrading odontoblastic processes, denatured collagen, bacterial cells that die during the course of infection, and intracanal fluids that enter the tubules by capillarity.

Several putative endodontic pathogens have been shown to be capable of penetrating dentinal tubules in vitro, including *Porphyromonas endodontalis, Porphyromonas gingivalis, Fusobacterium nucleatum, Actinomyces israelii, Propionibacterium acnes, Enterococcus faecalis, Candida albicans*, and streptococci.[112,146,223,246,299] A clinical study isolated and identified bacteria present in root dentin at different depths, and the most common isolates belonged to the genera *Prevotella, Porphyromonas, Fusobacterium, Veillonella, Peptostreptococcus, Eubacterium, Actinomyces,* lactobacilli, and streptococci.[148] Using immunohistologic analysis, Matsuo et al.[116] observed the occurrence of *F. nucleatum, Pseudoramibacter alactolyticus, Eubacterium nodatum, Lactobacillus casei*, and *Parvimonas micra* inside dentinal tubules from the canal walls of extracted teeth with apical periodontitis.

Whereas bacteria present as planktonic cells in the main root canal may be easily accessed and eliminated by instruments and antimicrobial substances used during endodontic treatment, those organized in biofilms attached to the canal walls or located into isthmuses, recesses, lateral canals, and dentinal tubules are definitely more difficult to reach,[290] and may require special therapeutic strategies to be eradicated.

Biofilm and community-based microbial pathogenesis

Individual microorganisms proliferating in a habitat give rise to *populations*. Such populations often occur as microcolonies in the environment. Populations interact with one another to form a *community*. The community and habitat are part of a larger system called an *ecosystem*, which is defined as a functional self-supporting system that includes the microbial community and its environment.

It has been recognized that the dental plaque biofilms associated with

Telegram: @dental_k

www.konkur.in

caries and periodontal diseases represent sophisticated communities that exert functions essential for the biofilm architecture and physiology, with consequent pathogenetic implications. Evidence indicates that apical periodontitis can also develop as a result of collaborative activities of a biofilm community established in the root canal system.

For many endogenous infections in the human body, the community, instead of a single species, has been regarded as the unit of pathogenicity. This community-as-pathogen concept is based on a holistic approach to understand the group behavior of bacteria in mixed infections, and assumes that the whole is more than the simple sum of its parts. Factors such as the composition (types of species), abundance (proportion of each species), interactions (synergism), and virulence factors will act in concert to define the collective pathogenicity of a certain community and determine the disease outcome.

Community profiling studies revealed that bacterial composition of the endodontic microbiota differs consistently between individuals suffering from the same disease (Fig. 15.14).[30,113,184,251] This indicates that apical periodontitis has a heterogeneous etiology, where multiple bacterial combinations can play a role in disease causation. Interindividual variability is even more pronounced when different geographic locations are studied.[60,113,184,244] Moreover, community structure differs significantly between different disease forms (e.g., asymptomatic apical periodontitis vs. acute apical abscess),[196,200,251] suggesting existence of a pattern associated with each form.

Biofilm and bacterial interactions

The community-forming ability can be regarded as essential for microbial survival in virtually all environments. Indeed, the majority of microorganisms in nature invariably grow and function as members of metabolically integrated communities, or biofilms.[33,115] *Biofilm* can be defined as a sessile multicellular microbial community characterized by cells that are firmly attached to a surface and enmeshed in a self-produced matrix of extracellular polymeric substance (EPS), mostly composed of polysaccharide but also proteins and nucleic acids (Fig. 15.15).[33,45,75] The ability to form biofilms has been regarded as a virulence factor,[75] and biofilm infections account for an estimated 65% to 80% of bacterial infections that affect humans in the developed world.[32] Given its importance in varied aspects, biofilm properties have been extensively studied not only in medical microbiology but also in different sectors of industrial and environmental microbiology.

www.konkur.in

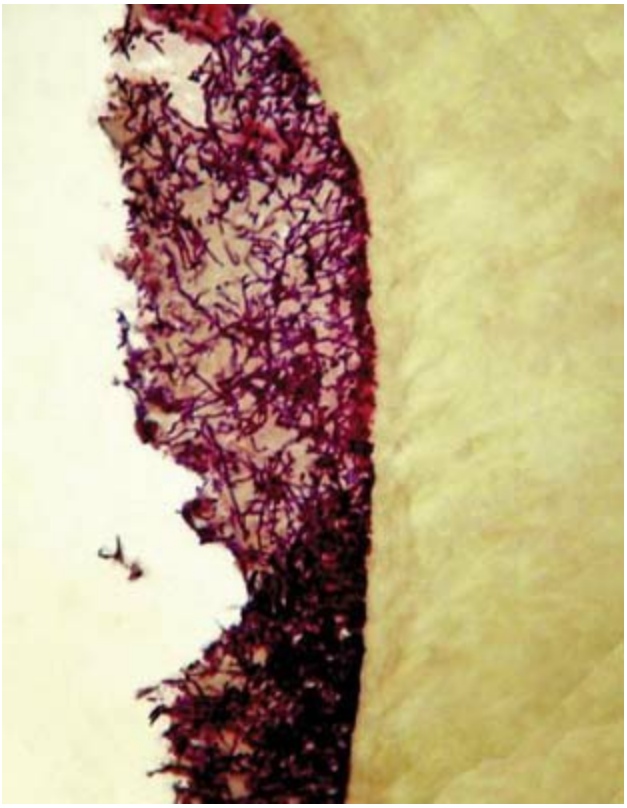

FIG. 15.15 Mixed bacterial biofilm adhered to the tooth surface (Brown and Brenn staining, magnification ×1000).

A micrograph shows a purple blue layer of stain present to the left of wall of tooth.

As a community, biofilms are composed of populations or microcolonies (±15% by volume) that are embedded and nonrandomly distributed in the EPS matrix (±85% by volume) and separated by water channels.[34,45,263,267] Dental biofilms can reach up to 300 or more cell layers in thickness.[263] Individual microcolonies may consist of a single bacterial species, but more frequently are composed of several different species in a mixed community.

The EPS matrix is not only important physically as part of the scaffold that determines the biofilm structure, but it is also biologically active and can retain nutrients, water, and essential enzymes within the biofilm.[5] The matrix also protects the biofilm community from exogenous threats and may participate in adherence to the surfaces.

In most biofilms in nature, bacterial populations arise from surface colonization by planktonic (unattached) bacterial cells. Floating bacteria approach to the surface to be colonized and attach to host proteins and/or

Telegram: @dental_k

www.konkur.in

coaggregate with previously bound bacteria. This process may occur in canals that are frankly exposed to the oral cavity and filled with saliva. However, biofilm formation in the root canal system in most circumstances, especially as a sequel to caries, is expected to occur in a different way. As the caries biofilm reaches the pulp, the latter becomes inflamed and necrotic, and the biofilm advances in apical direction. Therefore, biofilm formation on the root canal walls in most cases occurs gradually as the pulp becomes necrotic and the infectious process advances towards the apical canal.[256]

Bacterial interactions in biofilms lead to changes in growth rate, gene expression, and protein production. Genes expressed by cells in biofilms can differ by 20% to 70% from those expressed by the same cells growing in planktonic culture.[17,135,203] Thus, bacteria in biofilms adopt a radically different phenotype compared with their planktonic counterparts. Within biofilms, some bacteria also use sophisticated systems of cell-cell communication (quorum sensing) to coordinate gene expression. Phenotypic heterogeneity in biofilms is also observed as a result of exposure of microcolonies to a variety of gradients (e.g., oxygen tension, pH, type and amount of nutrients, cell density), which contribute to form diverse microenvironments throughout the biofilm structure.

Biofilm resistance to antimicrobial agents

From a clinical standpoint, the biofilm increased resistance to antimicrobial agents is of special concern. Bacterial cells arranged in biofilms are considered more resistant to antibiotics than the same cells grown in planktonic state. The antibiotic concentration required to kill bacteria in the biofilm is about 100 to 1000 times higher than that needed to kill the same species in planktonic state.[114]

Several possible mechanisms help explain the biofilm resistance to antimicrobials: (a) the biofilm structure may restrict penetration of antimicrobial agents[266]; (b) starved bacteria entering the stationary phase in biofilms are much less susceptible to antimicrobials than rapidly-growing cells[75]; and (c) presence of a subpopulation of specialized survivor cells known as persisters.[94]

www.konkur.in

Apical periodontitis as a biofilm-related disease

Numerous morphologic studies have reported the occurrence of bacterial agglomerations on the root canal walls resembling structures that later were defined as biofilm.[23,124,163,166,167,204,245] However, the strongest evidence about the association of bacterial biofilms with apical periodontitis came from a histobacteriologic study by Ricucci and Siqueira.[164] These authors evaluated the prevalence of biofilms in the apical root canal system of untreated teeth with primary apical periodontitis and treated teeth with posttreatment disease and looked for associations between biofilms and clinical/histopathologic conditions. Some of the most important findings of their study are as follows:

1. Intraradicular biofilms were generally observed in the apical segment of approximately 80% of the root canals of teeth with primary or posttreatment apical periodontitis.
2. Morphology of endodontic biofilms differed consistently from individual to individual (e.g., thickness, morphotypes, bacterial cells/extracellular matrix ratio).
3. Dentinal tubules underneath biofilms were often invaded by bacterial cells from the bottom of the biofilm community.
4. Biofilms were also commonly seen covering the walls of apical ramifications, lateral canals, and isthmuses.
5. Bacterial biofilms were more frequent in root canals of teeth with large apical periodontitis lesions. Because it takes time for apical periodontitis to develop and become radiographically visible, one can surmise that large lesions represent a longstanding pathologic process caused by an even “older” intraradicular infection. In longstanding infectious processes, involved bacteria may have had enough time and conditions to adapt themselves to the environment and set a mature and organized biofilm community. The fact that the apical root canal of teeth with large lesions harbors a large number of bacterial cells and species almost always organized in biofilms may help explain the concept that treatment outcome is influenced by

Telegram: @dental_k

www.konkur.in

lesion size.[31,131]

6. The prevalences of intraradicular biofilms in teeth associated with apical cysts, abscesses, and granulomas were 95%, 83%, and 69.5%, respectively. Biofilms were significantly associated with epithelialized lesions. Because apical cysts develop as a result of epithelial proliferation in some granulomas,[107] it may be anticipated that the older the apical periodontitis lesion, the greater the probability of it becoming a cyst. Similar to teeth with large lesions, the age of the pathologic process may also help explain the high prevalence of biofilms in association with cysts.
7. Extraradicular biofilms were infrequent; they occurred in only 6% of the cases. Except for one case, they were always associated with intraradicular biofilms. All cases showing an extraradicular biofilm exhibited clinical symptoms.
8. Bacteria were also seen in the lumen of the main canal, ramifications, and isthmuses as flocs and planktonic cells, either intermixed with necrotic pulp tissue or possibly suspended in a fluid phase. Bacterial flocs are sometimes regarded as “planktonic biofilms” and may originate from growth of cell aggregates/coaggregates in a fluid or they may have detached from biofilms.[76]

Ricucci and Siqueira[164] also used the following criteria available in the literature to establish a causal link between biofilms and a given infectious disease[76,139,164]:

1. Infecting bacteria are adhered to or associated with a surface.
2. Direct examination of the infected tissue shows bacteria forming clusters or microcolonies encased in an extracellular matrix.
3. The infection is generally confined to a particular site and although dissemination may occur, it is a secondary event.
4. The infection is difficult or impossible to eradicate with antibiotics in spite of the responsible microorganisms being susceptible to killing in the planktonic cell state.
5. Ineffective host clearance is evident, as suggested by the location of bacterial colonies in areas of the host tissue associated with host

Telegram: @dental_k

www.konkur.in

inflammatory cells. Accumulation of polymorphonuclear neutrophils and macrophages surrounding bacterial aggregates/coaggregates in situ considerably increases the suspicion of biofilm involvement with disease causation.

6. Elimination or significant disruption of the biofilm structure and ecology leads to remission of the disease process.

Based on findings from the Ricucci and Siqueira's study,[164] apical periodontitis can be considered to fulfill four of the six criteria. Bacterial agreggates/coaggregates are observed adhered to or at least associated with the dentinal root canal walls (criterion 1). Bacterial colonies are often seen encased in an amorphous extracellular matrix (criterion 2). Endodontic biofilms are frequently confined to the root canal system, in only a few cases extending to the external root surface, but dissemination through the lesion never occurred (criterion 3). In the great majority of cases, biofilms are directly faced by an accumulation of inflammatory cells, especially polymorphonuclear neutrophils (criterion 5).

As for criterion 4, it is widely known that intraradicular endodontic infections cannot be effectively treated by systemic antibiotic therapy, even though most endodontic bacteria in the planktonic cell state are susceptible to currently used antibiotics.[15,65,96] The lack of efficacy of systemic antibiotics against intraradicular infections is mainly because the drug does not reach endodontic bacteria that are located in the avascular pulp necrotic space. The recognition of biofilms as the main mode of bacterial establishment in the root canal system further strengthens the explanations for the lack of antibiotic effectiveness against endodontic infections. Finally, there is a clear potential for fulfillment of criterion 6, because biofilms are frequently observed in canals of treated teeth with posttreatment apical periodontitis,[167] whereas teeth with a successful outcome show no biofilm infection of the root canal.[158] In addition, canals that exhibit negative cultures at the time of filling have a better treatment outcome.[52,296]

Methods for microbial identification

The endodontic microbiota has been traditionally investigated by culture

Telegram: @dental_k

www.konkur.in

methods. Culture is the process of propagating microorganisms in the laboratory by providing them with the required nutrients and proper physicochemical conditions, including temperature, moisture, atmosphere, salt concentration, and pH.[260] Essentially, culture analyses involve the following steps: sample collection and transport, dispersion, dilution, cultivation, isolation, and identification.[274] Endodontic samples are collected and transported to the laboratory in a viability-preserving, nonsupportive, anaerobic medium. They are then dispersed by sonication or vortex mixing, diluted, distributed onto various types of agar media, and cultivated under aerobic or anaerobic conditions. After a suitable period of incubation, individual colonies are subcultivated and identified on the basis of multiple phenotype-based aspects, including colony and cellular morphology, gram-staining pattern, oxygen tolerance, comprehensive biochemical characterization, and metabolic end-product analysis by gas-liquid chromatography. The outer cellular membrane protein profile is examined by gel electrophoresis, fluorescence under ultraviolet light, and susceptibility tests to selected antibiotics may be needed for identification of some species.[50] Marketed packaged kits that test for preformed enzymes have also been used for rapid identification of several species. Isolated colonies can also be identified by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS)[303] or 16S rRNA sequencing.[250]

Culture analyses of endodontic infections have provided a substantial body of information about the etiology of apical periodontitis, composition of the endodontic microbiota in different clinical conditions, effects of treatment procedures in bacterial elimination, and susceptibilities of endodontic bacteria to antibiotics. Advantages and limitations of culture methods are listed in Box 15.1; some important limitations of culture methods make a comprehensive analysis of the endodontic microbiota difficult to achieve.

Box 15.1

Advantages and Limitations of Culture Methods

Advantages	Limitations
Broad-range nature, identification of unexpected species	Impossibility of culturing a large number of extant bacterial species

Telegram: @dental_k

www.konkur.in

Allow quantification of all major viable cultivable microorganisms in samples Allow determination of antimicrobial susceptibilities of isolates Physiologic studies are possible Pathogenicity studies are possible Widely available	Not all viable bacteria can be recovered Once isolated, bacteria require identification using a number of techniques Misidentification of strains with ambiguous or aberrant phenotypic behavior Low sensitivity Strict dependence on the mode of sample transport Samples require immediate processing Costly, time consuming, and laborious, as for cultivation of anaerobes Specificity is dependent on experience of microbiologist Extensive expertise and specialized equipment needed to isolate anaerobes Takes several days to weeks to identify most anaerobes

The difficulties in culturing or identifying many microbial species are of special concern. Unfortunately, not all microorganisms can be cultivated under artificial conditions, and this is simply because the nutritional and physiologic needs of most microorganisms are still unknown. Investigations of many environments using culture-independent methods have revealed that the large majority of microbial members of these systems still remain to be cultivated.[6,302] Furthermore, 40% to 80% of bacterial species composing the microbiota associated with diverse human sites, including the oral cavity, represent unknown and still uncultivated bacteria.[1,2,42,47,99,143,151,268]

That a given species has not been cultivated does not imply that this species will remain indefinitely impossible to cultivate. Myriad obligate anaerobic bacteria were uncultivable in the early 1900s, but further developments in anaerobic culturing techniques have to a large extent helped to solve this problem. It must be assumed that no single method or culture medium is suitable for isolating the vast diversity of microorganisms present in most environments.[69] Because we remain relatively unaware of the requirements for many bacteria to grow, identification methods not based on

Telegram: @dental_k

www.konkur.in

cultivability are required.

In some situations, even the successful cultivation of a given microorganism does not necessarily mean that this microorganism can be successfully identified. Culture-dependent identification is based on phenotypic traits observed in reference strains, with predictable biochemical and physical properties under optimal growth conditions. However, many phenotype-related factors can lead to difficulties in identification and even to misidentification.[16,20,240,282] As a consequence, phenotype-based identification does not always allow an unequivocal identification.

To sidestep the limitations of culturing, tools and procedures based on molecular biology have become available and have substantially improved the ability to achieve a more realistic description of the microbial world without the need for cultivation (Fig. 15.16). Molecular technology has also been applied to reliably identify cultivated bacteria, including strains with ambiguous or aberrant phenotypic behavior, rare isolates, poorly described or uncharacterized bacteria, and newly named species.[21,46,149,231,264,280] The 16S rRNA gene (or 16S rDNA) has been the most widely used gene for bacterial identification, while the 18S rRNA gene of fungi and other eukaryotes has also been used extensively to identify these organisms.

www.konkur.in

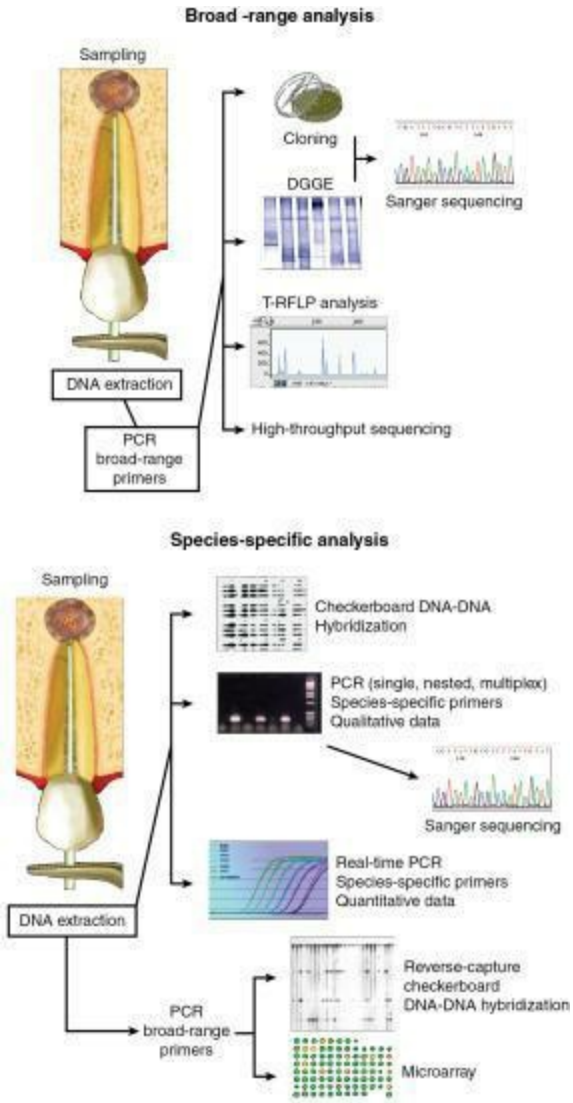

FIG. 15.16 Molecular biology methods used (or with potential to be used) in the study of endodontic infections. The choice for a particular technique will depend on the type of analysis to be performed. Some methods can be used for detection of target microbial species or groups and others for a broader analysis of the microbiota.

Set of two illustrations compares two types of molecular biology methods including broad-range and species-specific analysis. In broad range analysis, DNA is extracted from sample and PCR is conducted using broad-range primers for cloning, DGGE, T-RFLP analysis, and pyrosequencing. Cloning and DGGE is collectively used for sequencing.

In species-specific analysis, DNA is extracted from sample following two purposes:

1. In PCR, broad-range primers are used in generating reverse-capture checkerboard DNA-DNA hybridization and microarray; and

Telegram: @dental_k

www.konkur.in

2. Checkerboard DNA-DNA hybridization; PCR (single, nested, multiplex) utilize species-specific primers, used to deduce qualitative data for sequencing; and real-time PCR using species-specific primers to generate qualitative data.

Data from 16S rRNA gene sequences can be used for accurate and rapid identification of known and unknown bacterial species, using techniques that do not require cultivation. The 16S RNA gene of virtually all bacterial species in a given environment, including still uncultivated and uncharacterized bacteria, can be amplified by polymerase chain reaction (PCR) using broad-range (or universal) primers that are complementary to conserved regions of this gene. Sequencing of the variable regions flanked by the broad-range primers will provide information for accurate bacterial identification. Primers or probes that are complementary to variable regions can also be designed to detect specific target species directly in clinical samples.

Many molecular methods for the study of microorganisms exist; the choice of a particular approach depends on the questions being addressed.[240] Broad-range PCR followed by cloning and Sanger sequencing can be used to unravel the breadth of bacterial diversity in a given environment. High-throughput (or “next-generation”) sequencing (HTS) approaches permit DNA sequencing from samples to a far deeper coverage and higher throughput in comparison with the traditional Sanger sequencing approach[82,294]; even low-abundant components of the bacterial community can be disclosed by HTS approaches. In addition to HTS, bacterial community structures can be analyzed and compared by fingerprinting techniques such as denaturing gradient gel electrophoresis (DGGE) and terminal restriction fragment length polymorphism (T-RFLP). Fluorescence in situ hybridization (FISH) can measure the abundance of target species and provide information on their spatial distribution in tissues. Among other applications, DNA-DNA hybridization arrays (checkerboard techniques, DNA microarrays), species-specific single PCR, nested PCR, multiplex PCR, and quantitative real-time PCR can be used to survey large numbers of clinical samples for the presence of target species. Quantitative real-time PCR can also be applied to the study of the antibacterial effectiveness of treatment procedures by quantifying all bacteria or certain groups before and after treatment. Variations in PCR

Telegram: @dental_k

www.konkur.in

technology can also be used to type microbial strains. As with any other method, molecular methods have their own advantages and limitations (Box 15.2).

Box 15.2

Advantages and Limitations of Molecular Biology Methods

Advantages	Limitations
Detect both cultivable and as-yet-uncultivated species or strains	Most assays are qualitative or semiquantitative (exception: real-time PCR)
High specificity and accurate identification of strains with ambiguous or aberrant phenotypic behavior	Most assays only detect one species or a few different species at a time (exceptions: broad-range PCR, checkerboard, microarray)
Detect species directly in clinical samples	Most assays detect only the target species and fail to detect unexpected species (exception: broad-range PCR)
High sensitivity	Some assays can be laborious and costly (e.g., broad-range PCR)
Rapid; most assays take no more than minutes to a few hours to identify a microbial species	Biases in broad-range PCR introduced by homogenization procedures, preferential DNA amplification, and differential DNA extraction
Do not require carefully controlled anaerobic conditions during sampling and transportation	Hybridization assays using whole genome probes detect only cultivable species
Can be used during antimicrobial treatment	Can be very expensive
Anaerobic handling and expertise not required	
Samples can be stored frozen for later analysis	
DNA can be transported easily between laboratories	
Detect dead microorganisms

The five generations of endodontic microbiology studies

Telegram: @dental_k

www.konkur.in

Microbiologic studies for identification of the species participating in endodontic infections can be chronologically divided into five generations on the basis of the different strategic approaches used.[255] These generations are detailed in Table 15.1.

Table 15.1

Generations of Studies for Microbiologic Identification in Endodontic Infections

Study Generation	Identification Method	Nature	Description and Findings
First	Culture	Open ended (broad range)	Revealed many cultivable species in association with apical periodontitis
Second	Molecular methods (e.g., PCR and its derivatives, original checkerboard assay)	Closed ended (species specific)	Target cultivable bacteria Confirmed and strengthened data from first generation Allowed inclusion of some culture-difficult species in the set of candidate endodontic pathogens
Third	Molecular methods (e.g., PCR-cloning-sequencing, T-RFLP)	Open ended (broad range)	Allowed a more comprehensive investigation of the bacterial diversity in endodontic infections Not only cultivable species but also as-yet-uncultivated and uncharacterized bacteria were identified
Fourth	Molecular methods (e.g., PCR, microarrays, reverse-capture checkerboard)	Closed ended (species specific)	Target cultivable and as-yet-uncultivated bacteria Large-scale clinical studies to investigate prevalence and association of species/phylotypes with endodontic infections
Fifth	Molecular methods (high-throughput sequencing platforms, such as Roche 454 GS-FLX pyrosequencing, Illumina MiSeq and HiSeq)	Open ended (broad range)	Permit a deep-coverage and more comprehensive analysis of the diversity of endodontic infections

PCR, Polymerase chain reaction.

Impact of molecular methods in endodontic microbiology

Telegram: @dental_k

www.konkur.in

Culture studies (first generation) identified a set of species thought to play an important role in the pathogenesis of apical periodontitis.[11,209,276] Further, not only have findings from culture-based methods been confirmed, but they have also been significantly supplemented with those from culture-independent molecular biology techniques, which constitute the other four generations of endodontic microbiology studies.[236] Molecular methods have confirmed and strengthened the association of many cultivable bacterial species with apical periodontitis and have also revealed new suspected endodontic pathogens.[232] The list of candidate pathogens has expanded to include culture-difficult species or as-yet-uncultivated bacteria that had never been found in endodontic infections by culture. The results from molecular studies impact remarkably on the knowledge of bacterial diversity in endodontic infections. More than 400 different bacterial species have been detected in different types of endodontic infections.[236] Of these, about 45% were exclusively reported by molecular biology studies, compared with 32% detected by culture studies alone.[236] Twenty-three percent of the total bacterial species richness have been detected by application of both culture and molecular studies (Fig. 15.17). As a consequence, it becomes quite evident that the knowledge about the composition of the endodontic microbiota has been refined and redefined by molecular methods.[232]

Telegram: @dental_k

www.konkur.in

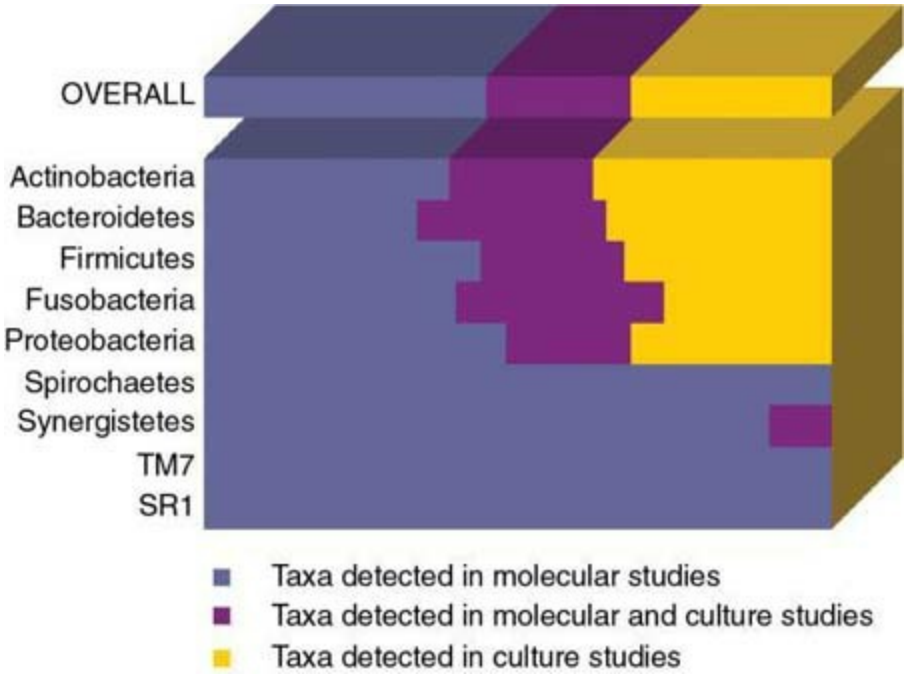

FIG. 15.17 Percentage distribution of bacterial species/phylotypes found in endodontic infections according to the detection method. Data refer to the percentage of species or phylotypes overall or in each of the nine phyla that have endodontic representatives.

Percentage distribution of bacterial species are given as follows in increasing percentage:

Overall, actinobacteria, bacteriodetes, firmicutes, fusobacteria, and proteobacteria: Taxa detected in molecular studies; taxa detected in culture studies; and taxa detected in molecular and cultural studies.

Taxa detected only in molecular studies: Spirochaetes, TM7, and SR 1.

Synergistetes are majorly detected by molecular studies with a minor portion detected by molecular and culture studies.

Note: All data is approximate.

Types of endodontic infections

Endodontic infections can be classified according to the anatomic location as intraradicular or extraradicular infection. *Intraradicular infection* is caused by microorganisms colonizing the root canal system and can be subdivided into three categories according to the time microorganisms entered the root canal system: *primary infection*, caused by microorganisms that initially

Telegram: @dental_k

www.konkur.in

invade and colonize the necrotic pulp tissue (initial or "virgin" infection); *secondary infection,* caused by microorganisms not present in the primary infection but introduced in the root canal at some time after professional intervention (i.e., *secondary* to intervention); and *persistent infection,* caused by microorganisms that were members of a primary or secondary infection and in some way resisted intracanal antimicrobial procedures and were able to endure periods of nutrient deprivation in treated canals. *Extraradicular infection* in turn is characterized by microbial invasion of the inflamed periradicular tissues and is a sequel to the intraradicular infection. Extraradicular infections may be dependent on or independent of the intraradicular infection.

Diversity of the endodontic microbiota

The terms *microbiota* and *microbiome* have been used interchangeably in many texts, while others have used some confounding definitions. Here, we refer to *microbiome* as a collection of genomes from all the microorganisms in a given site, and *microbiota* as all the microorganisms in a site. Microbiota should replace terms such as *flora* and *microflora,* which perpetuate an outdated classification of microorganisms as plants.[41] *Diversity* refers to the number of different species present (richness) and their relative abundance (evenness) in a given ecosystem.[87]

The oral cavity harbors one of the highest accumulations of microorganisms in the human body. Even though viruses, archaea, fungi, and protozoa can be found as constituents of the oral microbiota, bacteria are by far the most dominant inhabitants of the oral cavity. Culture-independent studies (microscopy and molecular biology technologies) have shown that over 40% to 60% of the oral microbiota still remains to be cultivated and fully characterized.[2,42,262] A high diversity of bacterial species has been revealed in the oral cavity by culturing approaches,[125] but application of molecular biology methods to the analysis of the bacterial diversity has revealed a still broader and more diverse spectrum of extant oral bacteria.[144] More than 1000 bacterial species/phylotypes have been found in studies of the human oral microbiome,[42] but advanced HTS studies have indicated that this number may still have been largely underestimated.[4,71,93] Anaerobic

Telegram: @dental_k

www.konkur.in

culture and molecular biology techniques have demonstrated that, at a broader taxonomic level, endodontic bacteria fall into nine phyla—namely, Firmicutes, Bacteroidetes, Spirochaetes, Fusobacteria, Actinobacteria, Proteobacteria, Synergistetes, TM7, and SR1 (Fig. 15.18).[126,156,177,195–197,233,236] However, data from studies using HTS technology reveal that several other bacterial phyla may have been overlooked by previous identification techniques, including Tenericutes, Acidobacteria, Deinococcus-Thermus, Chloroflexi, and Cyanobacteria.[63,83,86,95,105,200,213,219,220,224,286,289,309] Members of these less common phyla are usually low-abundant components of the endodontic bacterial communities, only detected because of deep sequencing coverage. Fungi and archaea are types of microorganisms that have been only occasionally found in endodontic infections.

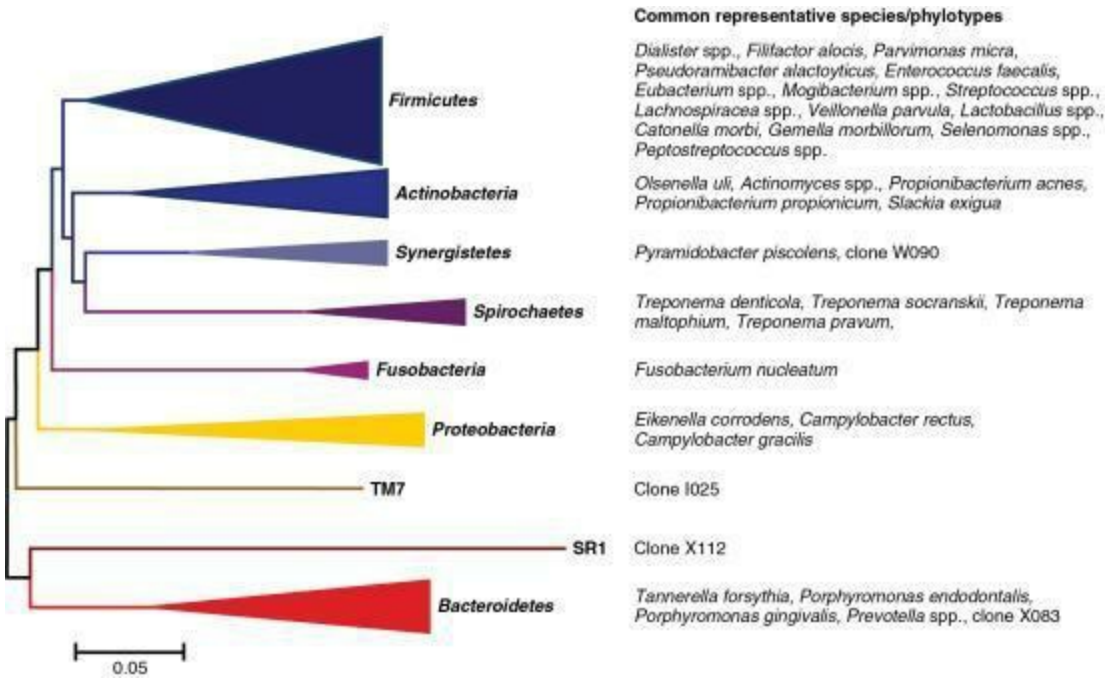

FIG. 15.18 Bacterial phyla with their respective endodontic representatives. *Right:* Example species or phylotypes for each phylum.

Phylogenetic tree shows bacteriodetes and SR1 leading to a node connecting TM 7, which further connects to node linked to proteobacteria. Together theory are linked to fusobacteria, which leads to three sub-classes: Firmicutes linked to actinobacteria and a combination of synergistetes and spirochaetes.

Telegram: @dental_k

www.konkur.in

Endodontic infections develop in a previously sterile place that does not contain a normal microbiota. Any species found has the potential to be an endodontic pathogen or at least play a role in the ecology of the endodontic microbial community. Culture and molecular studies of endodontic infections are cross-sectional in nature and consequently reveal only prevalence of species; thus, only association can be inferred. A role in causation of apical periodontitis is usually surmised on the basis of both frequency of detection and potential pathogenicity (in animal models or association with other human diseases), and several species have emerged as candidate endodontic pathogens. The following sections discuss specific aspects of each type of endodontic infection.

Primary intraradicular infection

Microbial diversity

Primary intraradicular infection develops in the necrotic pulp tissue of untreated teeth and is the cause of primary apical periodontitis (Fig. 15.19). Participating bacteria may be involved in earlier stages of pulp invasion (usually via caries) that culminated in inflammation and further necrosis, or they can be latecomers that took advantage of the environmental conditions in the root canal after pulp necrosis.

Telegram: @dental_k

www.konkur.in

FIG. 15.19 Apical periodontitis due to primary intraradicular infection. The dental pulp is necrotic and the lesion size is usually directly proportional to the complexity of the microbiota involved.

Radiograph shows a gray patch present at the apical foramen in the root.

Primary infections are characterized by a mixed (multispecies) community conspicuously dominated by anaerobic bacteria. The number of bacterial cells may vary from 10^3 to 10^8 per root canal.[19,130,197,249,273,292] Second- to fourth-generation molecular studies have disclosed a mean of 10 to 20 species/phylotypes per infected canal.[126,156,177,232,251] However, these numbers may be even higher based on fifth-generation HTS studies.[83,105,200,219] Canals of teeth with associated sinus tracts may exhibit a number of species close to the top of this range.[177] The size of apical periodontitis lesion has been shown to be proportional to the number of bacterial species (richness) and cells (density or load) in the root canal.[177,250,273] A molecular study[177] demonstrated that the number of taxa per canal was clearly in direct proportion to the lesion size: small lesions (<5 mm) harbored about 12 taxa, lesions from 5 to less than 10 mm harbored 16 taxa, and lesions over 10 mm harbored about 20 species. Some canals

Telegram: @dental_k

www.konkur.in

associated with large lesions may harbor even more than 40 taxa.[177] Therefore, the larger the lesion, the higher the bacterial diversity and density in the canal.

The most prevalent named bacterial species detected in primary infections, including acute abscess cases, belong to diverse genera of gram-negative (i.e., *Fusobacterium*, *Dialister*, *Porphyromonas*, *Prevotella*, *Tannerella*, *Treponema*, *Pyramidobacter*, *Campylobacter*, and *Veillonella*) and gram-positive (*Parvimonas*, *Filifactor*, *Pseudoramibacter*, *Streptococcus*, *Propionibacterium*, *Olsenella*, and *Actinomyces*) bacteria.[14,55,56,66,74,96,126,156,177,179,183,195,196,232,250,252,253,273,275,293] Bacterial prevalence in primary infections may vary from study to study as a function of several factors, such as sensitivity and specificity of the detection and identification methods, sampling technique, geographic location, and accuracy or divergence in clinical diagnosis and disease classification. Even so, the species most frequently detected are expected to be the same in most well-conducted studies. Figs. 15.20–15.22 display the most frequently detected species associated with asymptomatic apical periodontitis, symptomatic apical periodontitis, and acute apical abscesses, as revealed by studies from the authors' group using a highly sensitive molecular biology technique (nested PCR).

Approximately 40% to 66% of the endodontic microbiota in primary infections is composed of species still uncultivated.[126,156,196] As for their abundance in these infections, as-yet-uncultivated phylotypes corresponded to about 40% of the clones sequenced.[196] Molecular studies investigating the breadth of bacterial diversity in infected root canals have disclosed the occurrence of uncultivated phylotypes belonging to several genera, including *Dialister*, *Prevotella*, *Solobacterium*, *Olsenella*, *Fusobacterium*, *Treponema*, *Eubacterium*, *Megasphaera*, *Veillonella*, and *Selenomonas*, as well as phylotypes related to the family *Lachnospiraceae* or the TM7 and Synergistetes phyla.[126,156,175,176,188,195,196,199,233,243] Some uncultivated phylotypes can even be among the most prevalent bacteria in primary intraradicular infections, and others may be associated with pain.[196] *Bacteroidaceae* sp. HOT-272 (synonym, Bacteroidetes oral clone X083) is one of the most prevalent phylotypes found in endodontic infections.[177–179,241] Detection of as-yet-uncultivated phylotypes in samples from endodontic infections suggests that they can be previously unrecognized bacteria that play a role in the pathogenesis of different forms of apical periodontitis. The fact that they have not yet been cultivated and phenotypically characterized does not mean that they are not important.[238]

Symptomatic infections

Symptomatic apical periodontitis and acute apical abscesses are typical examples of endodontic infections causing severe symptoms. In these cases, the infection is located in the canal, but it has also reached the periradicular tissues and, in abscessed cases, can spread to other anatomic spaces. Acute apical abscesses are caused by bacteria that egress from the infected root canal and invade the periradicular tissues to establish an extraradicular infection and evoke purulent inflammation. Clinically, the disease leads to

Telegram: @dental_k

www.konkur.in

pain or swelling and has the potential to diffuse to sinuses and fascial spaces of the head and neck to form a cellulitis or other complications (Fig. 15.23). The microbiota involved in endodontic abscesses is mixed and dominated by anaerobic bacteria (see Fig. 15.22).[37,96,100,169,196,237,239,251] Direct comparisons using molecular technology revealed an average of 12 to 18 taxa per abscess case, compared with 7 to 12 taxa present in root canals of teeth with asymptomatic lesions.[196,251] Uncultivated phylotypes constitute approximately 40% of the taxa found in abscesses (richness) and collectively represent more than 30% of the 16S rRNA gene sequences retrieved in clone libraries (abundance).[196] The total number of bacterial cells in acute apical abscesses has been shown to vary from 10^4 to 10^9.[96,103,305]

Whereas microbial causation of apical periodontitis is well established, there is no strong evidence disclosing specific involvement of a single species with any particular sign or symptom of apical periodontitis. Some gram-negative anaerobic bacteria have been suggested to be involved with symptomatic lesions,[66,70,185,196,273,288,308] but the same species may also be present in somewhat similar frequencies in asymptomatic cases.[14,56,74,90,183,252,253] Thus, factors other than the mere presence of a given putative pathogenic species may play a role in the etiology of symptomatic endodontic infections.[214,221,239] These factors include: differences in virulence ability among strains of the same species, bacterial interactions resulting in synergistic effects among species in mixed infections, overall number of bacterial cells (overall infectious load), counts and relative abundance of specific pathogenic species (specific infectious load), environmental cues regulating expression of virulence factors, host resistance, and concomitant herpesvirus infection. Association of some or all of these factors is likely to determine the occurrence and intensity of symptoms.[214,221]

Molecular studies using DGGE, T-RFLP, or HTS analysis have revealed that the structure of the endodontic bacterial communities in symptomatic teeth, including abscess cases, is significantly different from that of asymptomatic teeth.[196,200,251] Differences are represented by different dominant species in the communities and larger numbers of species in symptomatic cases. Differences in the type and load of dominant species and the resulting bacterial interactions may affect virulence of the whole bacterial community. The counts of some specific pathogenic species have been shown to be important for the community pathogenicity in abscesses. Molecular studies have shown that the levels of *Porphyromonas endodontalis, Prevotella baroniae, Tannerella forsythia, Treponema denticola,* and *Streptococcus* species were significantly higher in samples from abscesses than in asymptomatic teeth.[183,202] In addition, different species combinations may result in different outcomes because of the network of interactions.[186] The possibility exists that bacterial interactions result in communities that are more or less aggressive and consequently can cause host responses of corresponding intensity. This is consistent with the concept that the entire bacterial community is the unit of pathogenicity.

Geographic influence

Findings from laboratories in different countries are often different regarding the prevalence of the species involved in endodontic infections. Although these differences may be attributed to technical issues, a geographic influence in the composition of the root canal microbiota has been suspected. Studies using molecular biology techniques directly compared the prevalence of candidate endodontic pathogens in endodontic samples from patients residing in distinct geographic locations and observed significant differences.[13,171,226] Analysis of the bacterial community profiles of the microbiota associated with endodontic infections from different countries also revealed a geography-related pattern, with several species being exclusive for each location and others shared by the locations showing great differences in prevalence.[113,244] The factors that can lead to differences in the composition of the endodontic microbiota and the impact of these differences on therapy, particularly in abscess cases requiring systemic antibiotic therapy, remain elusive.

Microbial ecology and the root canal ecosystem

A root canal with necrotic pulp provides a space for bacterial colonization and affords bacteria a moist, warm, nutritious, and anaerobic environment, which is by and large protected from the host defenses because of lack of an active blood circulation in the necrotic pulp tissue. Also, the root canal walls are nonshedding surfaces conducive to persistent colonization and formation of complex communities. The necrotic root canal might be considered a fertile environment for bacterial growth, with colonization not being a difficult task for most oral bacterial species. Although a large number of bacterial species (about 100 to 200) can be found in the oral cavity of a particular individual,[144] only a limited assortment of these species (about 10 to 20) is consistently selected out for growth and survival within a root canal containing necrotic pulp tissue from the same individual. This indicates that ecologic determinants operate in the necrotic canal and dictate which species will succeed in colonizing this previously sterile environment. The major ecologic factors that determine the composition of the root canal microbiota include oxygen tension, type and amount of available nutrients, and bacterial interactions. Other factors such as temperature, pH, and receptors for

Telegram: @dental_k

www.konkur.in

adhesins may also be involved.

The root canal infection is a dynamic process, and different bacterial species apparently dominate at different stages.[281] Shifts in the composition of the microbiota are largely due to changes in environmental conditions, particularly in regard to oxygen tension and nutrient availability. In the initial phases of the pulpal infectious process, facultative bacteria predominate.[51] After a few days or weeks, oxygen is depleted within the root canal as a result of pulp necrosis and consumption by facultative bacteria. Further oxygen supply is interrupted with loss of blood circulation in the necrotic pulp. An anaerobic milieu develops and is highly conducive to the survival and growth of obligate anaerobic bacteria. With the passage of time, anaerobic conditions become even more pronounced, particularly in the apical third of the root canal; as a consequence, anaerobes will dominate the microbiota, outnumbering facultative bacteria (Fig. 15.24).

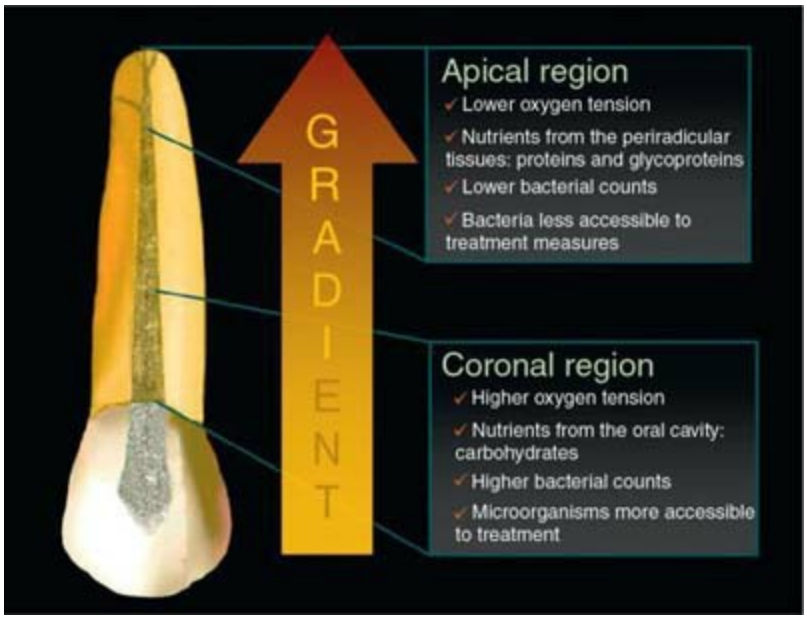

FIG. 15.24 Ecologic conditions in different areas of the root canal. A gradient of oxygen tension and nutrients (type and availability) is formed. Consequently, the microbiota residing in different parts can also differ in diversity, density, and accessibility to treatment procedures.

An upward arrow marked to the right of a tooth shows gradient divided into two regions as follows:

Telegram: @dental_k

www.konkur.in

Apical region:

• Lower oxygen tension.

• Nutrient from the periandicula tissues: proteins and glycoproteins.

• Lower bacterial counts.

• Bacteria less accessible to treatment measures.

Coronal region:

• Higher oxygen tension.

• Nutrients from the oral cavity: carbohydrates.

• Higher bacterial counts.

• Microorganisms more accessible to treatment.

The main sources of nutrients for bacteria colonizing the root canal system include (1) the necrotic pulp tissue, (2) proteins and glycoproteins from tissue fluids and exudate that seep into the root canal system via apical and lateral foramina, (3) components of saliva that may coronally penetrate into the root canal, and (4) products of the metabolism of other bacteria. Because the largest amount of nutrients is available in the main canal, which is the most voluminous part of the root canal system, the highest numbers of bacteria (particularly fastidious anaerobic species) are expected to be located in this region. Bacterial species that can best utilize and compete for nutrients in the root canal system will succeed in colonization.

In addition to being influenced by variations in oxygen levels, shifts in the composition of the microbiota colonizing the root canal system can also be dependent upon the dynamics of nutrient utilization. Saccharolytic species dominate the very early stages of the infectious process but are soon outnumbered by asaccharolytic species, which will dominate later stages. Even though the necrotic pulp tissue can be regarded as a finite source of nutrients to bacteria (given the small volume of tissue that is progressively degraded), induction of periradicular inflammation guarantees a sustainable source of nutrients, particularly in the form of proteins and glycoproteins present in the exudate that seep into the canal. At this stage of the infectious process, bacteria that have a proteolytic capacity or establish a cooperative

Telegram: @dental_k

www.konkur.in

interaction with those that can utilize this substrate in the metabolism, start to dominate.[278] Therefore, as the infectious process reaches the stage of induction of periradicular inflammation, proteins become the principal nutrient source, particularly in the apical part of the canal, favoring the establishment of anaerobic species that utilize peptides or amino acids in their metabolism (see Fig. 15.24).

Because primary endodontic infections are usually characterized by mixed communities, different bacterial species are in close proximity with one another, and interactions become inevitable. Thus, establishment of certain species in the root canal is also influenced by interactions with other species. In this regard, early colonizers play an important role in dictating which species will live along with them in the community. Bacterial interactions can be positive or negative. Positive interactions enhance the survival capacity of the interacting bacteria and enable different species to coexist in habitats where neither could exist alone. For instance, interbacterial nutritional interactions are important ecologic determinants that result in higher metabolic efficiency of the whole community. Nutritional interactions are mainly represented by food webs, including utilization of metabolic end products from one species by another and bacterial cooperation for the breakdown of complex host-derived substrates. Moreover, one species can provide growth conditions favorable to another—for example, by reducing oxygen tension in the environment and favoring the establishment of anaerobes, or by releasing proteinases that can provide protection from host defenses. Negative interactions in turn act as feedback mechanisms that limit population densities. Examples include competition (for nutrients and space) and amensalism (or antagonism, when one species produces a substance that inhibits another species, e.g., bacteriocins).

Many species adhere directly to host surfaces, whereas other species adhere to bacteria already attached to the surface. The latter is called *coaggregation* and is a highly specific phenomenon with regard to the partners involved.[98] A given pair of species can attach to each other by means of specific receptor-adhesin interactions, which are usually lectin-like interactions (attachment of a specific protein on the surface of one species to a specific carbohydrate on the surface of the other). Coaggregation can favor colonization of host surfaces and also facilitate metabolic interactions

Telegram: @dental_k

www.konkur.in

between the partners. Coaggregation has been demonstrated for several pairs of bacterial taxa found in endodontic infections.[97]

Other microorganisms in endodontic infections

Fungi

Fungi are eukaryotic microorganisms that may colonize the oral cavity, especially *Candida* species, but they have been only occasionally detected in primary intraradicular infections.[49,101,122,248] Fungi are more frequently detected in canals of teeth with posttreatment disease (discussed later).

Archaea

Archaea consist of a highly diverse group of prokaryotes distinct from bacteria. Members of this domain have been traditionally recognized as extremophiles, but some of these microorganisms have also been found to flourish in nonextreme environments, including the human body.[48] No member of the *Archaea* domain has been described as a human pathogen. Several studies have failed to detect archaea in samples from primary endodontic infections.[180,181,242] However, other studies have reported on the detection of these organisms, including a *Methanobrevibacter oralis*–like phylotype, in some cases.[136,137,291,293] Because archaea have not been consistently detected in infected root canals, their role, if any, in the pathogenesis of apical periodontitis is questionable.

Viruses

Viruses are inanimate particles composed of a nucleic acid molecule (DNA or RNA) and a protein coat. On their own, they have no metabolism. In order to replicate the viral genome, they need to infect living cells and use the cell's machinery; as a consequence, they cannot prosper in the necrotic root canal. Viruses have been detected in root canals only in teeth with vital pulps. A study found the human immunodeficiency virus (HIV) in vital pulps of HIV-seropositive individuals.[62] Another study reported the occurrence of some herpesviruses in normal and inflamed vital pulps.[104]

Apical periodontitis lesions, in turn, are characterized by dense accumulations of viable immune and connective tissue cells. Sabeti and Slots

Telegram: @dental_k

www.konkur.in

first reported on the occurrence of herpesviruses in these lesions.[190–193] It was hypothesized that herpesviruses might be implicated in the pathogenesis of apical periodontitis as a direct result of virus infection and replication or as a result of virally induced impairment of local host defenses, which would favor the overgrowth of pathogenic bacteria in the very apical part of the root canal.[261] Bacterial challenge emanating from the canals might cause an influx of virus-infected cells into the periradicular tissues. Reactivation of herpesviruses by tissue injury induced by bacteria would evoke impairment of host immune response in the periradicular microenvironment, changing the potential of local defense cells to mount an adequate response against infectious agents. In addition, herpesviruses may directly stimulate inflammatory cells to release proinflammatory cytokines.[120,301]

Herpesviruses have been found in samples from symptomatic apical periodontitis lesions,[191,193] abscesses,[27,54] large lesions,[192,193] and lesions from HIV-positive patients.[194] Most studies reported on the occurrence of herpesviruses in samples of apical periodontitis, but this cannot be necessarily interpreted as active infection. Herpesvirus-infected inflammatory cells may be attracted to the periradicular tissues in response to bacterial infection. Once these cells accumulated in the area, herpesviruses can be easily detected. While more consistent information is not available, the role of herpesviruses in the pathogenesis of apical periodontitis, if any, cannot be ascertained.

Persistent/secondary endodontic infections

As defined earlier in this chapter, persistent intraradicular infections are caused by microorganisms that resisted intracanal antimicrobial procedures and survived in the treated canal. Involved microorganisms are usually remnants of a primary infection. The secondary infection, in turn, is caused by microorganisms that at some time entered the root canal system secondary to clinical intervention. The moment can be during treatment, between appointments, or even after root canal filling. In any circumstance, if penetrating microorganisms manage to adapt themselves to the new environment, surviving and flourishing, a secondary infection is established. Species involved can be oral species or not, depending on the source of

Telegram: @dental_k

www.konkur.in

secondary infection.

Persistent and secondary infections are for the most part clinically indistinguishable. Exceptions include infectious complications (such as an apical abscess) arising after the treatment of noninfected vital pulps or cases in which apical periodontitis was absent at the time of treatment but present on the follow-up radiograph. Both situations are typical examples of secondary infections. Both persistent and secondary infections can be responsible for several clinical problems, including persistent exudation ("wet" canal), persistent symptoms, interappointment flare-ups, and failure of the endodontic treatment, characterized by a posttreatment apical periodontitis lesion.

Persistent/secondary infections and treatment failure

Intraradicular infections, either persistent or secondary, can be regarded as the major causes of posttreatment apical periodontitis (Fig. 15.25). Other causes include extraradicular infections (discussed later in this chapter) and non-microbial factors, for which there is only weak evidence coming from case reports and speculation.[129] The major role of persistent/secondary infections in treatment failure is supported by two strong evidence-based arguments. First, it has been demonstrated that there is an increased risk of adverse treatment outcome when bacteria are present in the canal at the time of obturation.[52,297] Second, virtually all root canal–treated teeth evincing persistent apical periodontitis lesions have been demonstrated to harbor an intraradicular infection.[106,108,150,167,173,198,230,277] Based on these arguments, studies investigating bacteria remaining in the root canals at the obturation stage disclose species that have the potential to influence the treatment outcome *(predicting the outcome).* On the other hand, studies dealing with the microbiota of root canal–treated teeth with apical periodontitis show the association of species with treatment failure, because the microorganisms detected are likely to be the cause of posttreatment disease *(outcome established).*

Telegram: @dental_k

www.konkur.in

FIG. 15.25 Posttreatment apical periodontitis lesions in root canal–treated teeth. In inadequately treated canals, the microbiota is similar to primary infections. In cases apparently well treated, fewer species are found. Regardless of treatment quality, persistent or secondary intraradicular infections are the main causative agents of endodontic treatment failure.

Radiograph of two teeth shows a lesion present in between apical and coronal region depicted as a radiolucent patch.

Bacteria at the root canal obturation stage

Diligent antimicrobial treatment may still fail to completely eliminate bacteria from the infected root canal system.[235] This is mostly because persisting bacteria are located in areas inaccessible to treatment procedures,[247] although resistance to some substances have been suggested as cause of bacterial persistence.[57,300] Whatever the cause of persistence, bacterial diversity and density in infected canals are substantially reduced after treatment. Root canal samples positive for bacterial growth after chemomechanical procedures, followed or not by intracanal medication, have

Telegram: @dental_k

www.konkur.in

been shown to harbor one to five bacterial species per case, and the number of persistent bacterial cells usually varies from 10^2 to 10^5 per sample.[9,22,130,174,,228,229,292]

No single species has been significantly found to persist after treatment procedures. Gram-negative bacteria, which are common members of primary infections, are usually eliminated. Exceptions include some anaerobic rods, such as *F. nucleatum* and *Prevotella* species, which are among the species found in postinstrumentation or postmedication samples.[22,67,147,197,249,258,309] Most studies on this subject have clearly revealed that when bacteria resist treatment procedures, gram-positive bacteria are more frequently present. Gram-positive facultatives or anaerobes often detected in these samples include streptococci, *P. micra, Propionibacterium* species, *P. alactolyticus, Actinomyces* species, lactobacilli, *E. faecalis*, and *Olsenella uli*.[22,24–26,29,67,145,147,179–181,197,225,228,229,258,279] This supports the notion that gram-positive bacteria can be more resistant to antimicrobial treatment measures and have the ability to adapt to the harsh environmental conditions in instrumented and medicated root canals. As-yet-uncultivated bacteria have also been detected in posttreatment samples,[138,197] indicating that they may also resist antimicrobial treatment.

Bacteria persisting in the root canal after chemomechanical procedures or intracanal medication will not always maintain an infectious process. This statement is supported by evidence that some apical periodontitis lesions healed even after bacteria were isolated from the canal at the obturation stage.[52,258] There are some possible explanations[235]:

- Residual bacteria may die after obturation because of toxic effects of the filling material, access denied to nutrients, or disruption of bacterial ecology.
- Residual bacteria may be present in quantities and virulence subcritical to sustaining periradicular inflammation.
- Residual bacteria remain in locations of the root canal system where access to periradicular tissues is denied.

Bacteria that resist intracanal procedures and are present in the canal at the time of obturation can influence the outcome of the endodontic treatment

Telegram: @dental_k

www.konkur.in

provided they do the following[235]:

- Have the ability to withstand periods of starvation, scavenging for low traces of nutrients or assuming a dormant state or a state of low metabolic activity (viable but noncultivable -VBNC), to prosper again when the nutrient source is reestablished.
- Resist treatment-induced disturbances in the ecology of the bacterial community, including disruption of quorum-sensing systems, food webs, genetic exchanges, and disorganization of protective biofilm structures.
- Reach a critical population density (load) necessary to inflict damage to the host.
- Have unrestrained access to the periradicular tissues through apical/lateral foramina or iatrogenic root perforations.
- Possess virulence attributes that are expressed in the modified environment and reach concentrations adequate to directly or indirectly induce damage to the periradicular tissues.
- In this context, the host resistance to infection is also an important and decisive counteracting factor.

Microbiota in root canal–treated teeth

The microbiota in root canal–treated teeth with apical periodontitis exhibits decreased diversity in comparison to primary infections. In addition, canals apparently well treated harbor less species than canals with inadequate treatment; the latter can exhibit similar species richness to untreated canals.[150,184,198,230,] The bacterial density in treated teeth with posttreatment disease varies from 10^3 to 10^7 per canal.[19,145,182,207,] Likewise, inadequately treated canals are expected to have a higher bacterial density than well-treated canals.

Several culture and molecular biology studies have revealed that *E. faecalis* is the most frequent species in root canal–treated teeth, with prevalence values in some studies reaching more than 90% of cases (Fig. 15.26).[121,150,173,182,187,207,230,277,312] Rôças et al.[187] reported that root canal–treated teeth are about nine times more likely to harbor *E. faecalis* than cases of primary infections. This suggests that other members of a mixed bacterial

Telegram: @dental_k

www.konkur.in

consortium commonly present in primary infections can inhibit this species, and that the bleak environmental conditions within obturated root canals do not prevent its survival. The fact that *E. faecalis* has been commonly recovered from teeth treated at multiple visits or left open for drainage[257] suggests that this species is a secondary invader capable of colonizing the canal and resisting treatment. In other words, *E. faecalis* may cause secondary infections that later become persistent. *E. faecalis is* considered a transient species in the oral cavity; its source may be food.[311]

For a given microorganism to survive in root canal–treated teeth, it has to resist intracanal disinfection procedures and adapt to the harsh environmental conditions caused by treatment. The ability of *E. faecalis* to penetrate dentinal tubules, sometimes to a deep extent (Fig. 15.27),[73,223] can enable it to escape the action of endodontic instruments and irrigants used during chemomechanical preparation.[73,222] Moreover, its ability to form biofilms in root canals can be important for its resistance to and persistence after intracanal antimicrobial procedures.[43] *Enterococcus faecalis* is also resistant to calcium hydroxide.[73] Finally, environmental cues can regulate gene expression in *E. faecalis*, affording this bacterium the ability to adapt to varying (and adverse) conditions.[89] Indeed, *E. faecalis* can enter a VBNC state,[109] which is a survival mechanism adopted by several bacteria when exposed to unfavorable environmental conditions.[110] In the VBNC state, bacteria lose the ability to grow in culture media but maintain viability and pathogenicity and sometimes can resume division when optimal environmental conditions are restored. *E. faecalis* has the capacity to recover from a prolonged starvation state in obturated canals,[208] suggesting that viable cells of this species, entombed at the time of canal obturation, may provide a long-term nidus for subsequent infection.

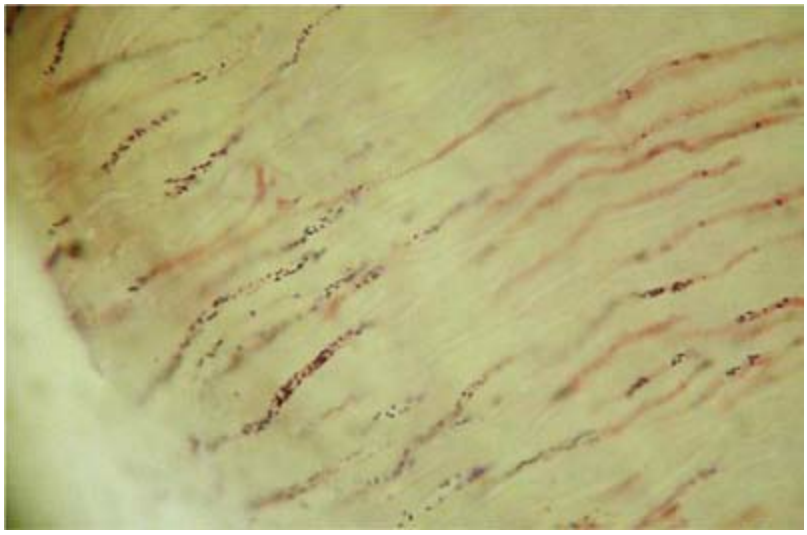

FIG. 15.27 Dentinal tubule infection by *Enterococcus faecalis* in a dog's tooth after experimental infection. Notice that cells invaded the entire extent of some tubules up to the cementum (Brown and Brenn staining, ×1000).

Radiograph shows curvy pink and blue lines on a dull background.

Taken together, all these properties help explain the significantly high prevalence of *E. faecalis* in root canal–treated teeth. Although association of this species with posttreatment disease is suggested by cross-sectional studies and supported by the species attributes that allow it to survive under unfavorable environmental conditions, causation is unproved. In fact, the following findings from studies carried out in independent laboratories have questioned the status of *E. faecalis* as the main causative agent of endodontic failures:

- Despite being easily cultivated, *E. faecalis* is not detected in all studies evaluating the microbiota of root canal–treated teeth with posttreatment disease.[28,188]
- In many studies that detected *E. faecalis*, it was rarely one of the most dominant species in the microbiota of retreatment cases.[81,172,184,198,]
- *E. faecalis* is found in similar prevalence in root canal–treated teeth with or without apical periodontitis.[92,312]

Other bacteria found in endodontically treated teeth with apical

periodontitis include *Streptococcus* species and some fastidious anaerobic species, such as *P. alactolyticus*, *Propionibacterium* species, *Filifactor alocis*, *Dialister* species, *Tannerella forsythia*, *P. micra*, and *Prevotella* species (Fig. 15.28).[7,68,81,121,150,172,182,184,198,230,233,277,309,310] Uncultivated phylotypes correspond to 55% of the taxa detected in treated canals, and collectively they can also be in high proportions, corresponding to about half of the 16S rRNA gene sequences retrieved in clone libraries.[198] Detection of uncultivated phylotypes helps explain why culture studies fail to detect bacteria in some treated root canals.

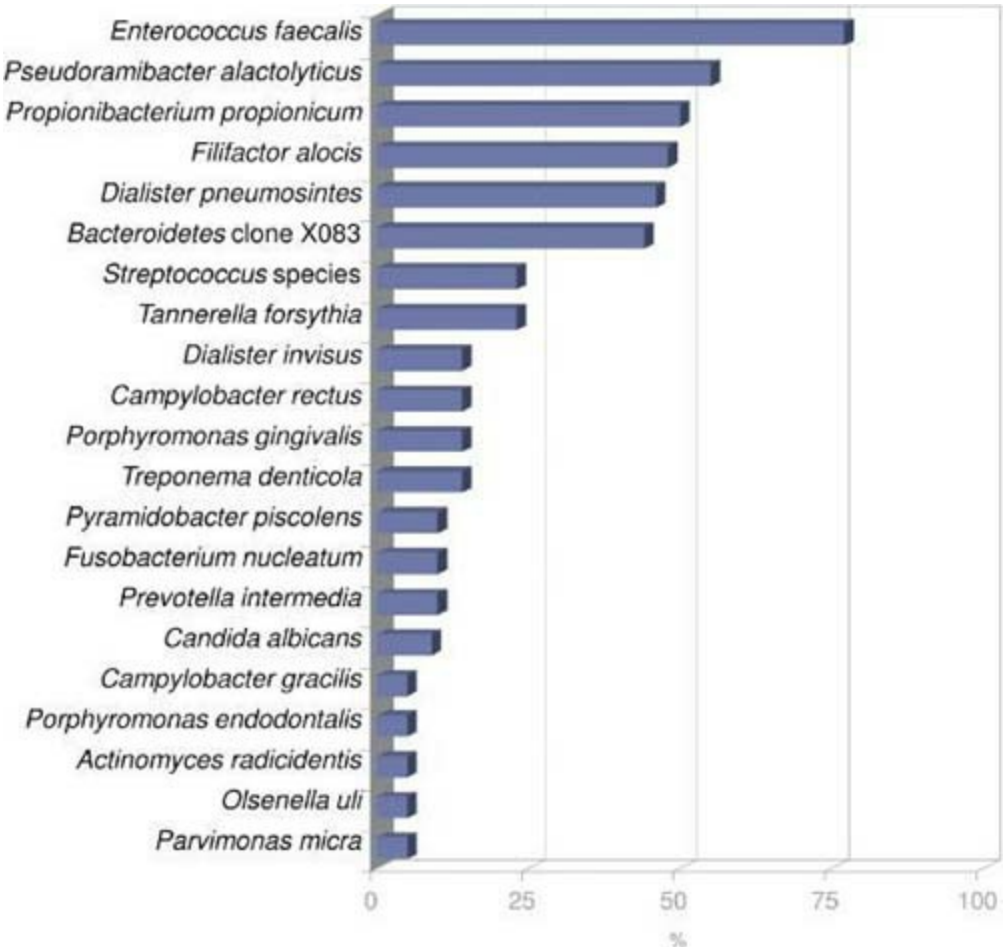

FIG. 15.28 Prevalence of microorganisms detected in root canal–treated teeth with posttreatment disease.

Horizontal bar chart shows percentage distribution of bacterial species found in root canal–treated teeth with posttreatment disease are marked in the decreasing order from top to bottom as follows:

Telegram: @dental_k

www.konkur.in

50 to 75 percent: Enterococcus faecalis and Psueodoramibacter alactolyticus.

25 to 50 percent: Propionibacterium propionicum; Folifactor alocis; Dialister pneumosintes; and Bacteriodetes clone X 083.

0 to 25 percent: Streptococcus species; Tannerella forsythia; Dialister invisus; Campylobacter rectus; Porphyromonas gingvalis; Treponema denticola; Pyramidobacte pisclens; Fusobacterium nucleatum; Prevotella intermedia; Candida albicans; Campylobacter gracilis; Porphromonas endodontalis; Actinomyces radicidentis; Olsenella uli; and Parvimonas micra.

Source: Data from the authors' findings using a taxon-specific polymerase chain reaction assay.

The bacterial community profiles in treated cases vary from individual to individual, indicating that distinct bacterial combinations can play a role in treatment failure (Fig. 15.29).[184,198,220,309] Molecular findings indicate that the microbiota of root canal–treated teeth with apical periodontitis is more complex than previously demonstrated by culture studies.

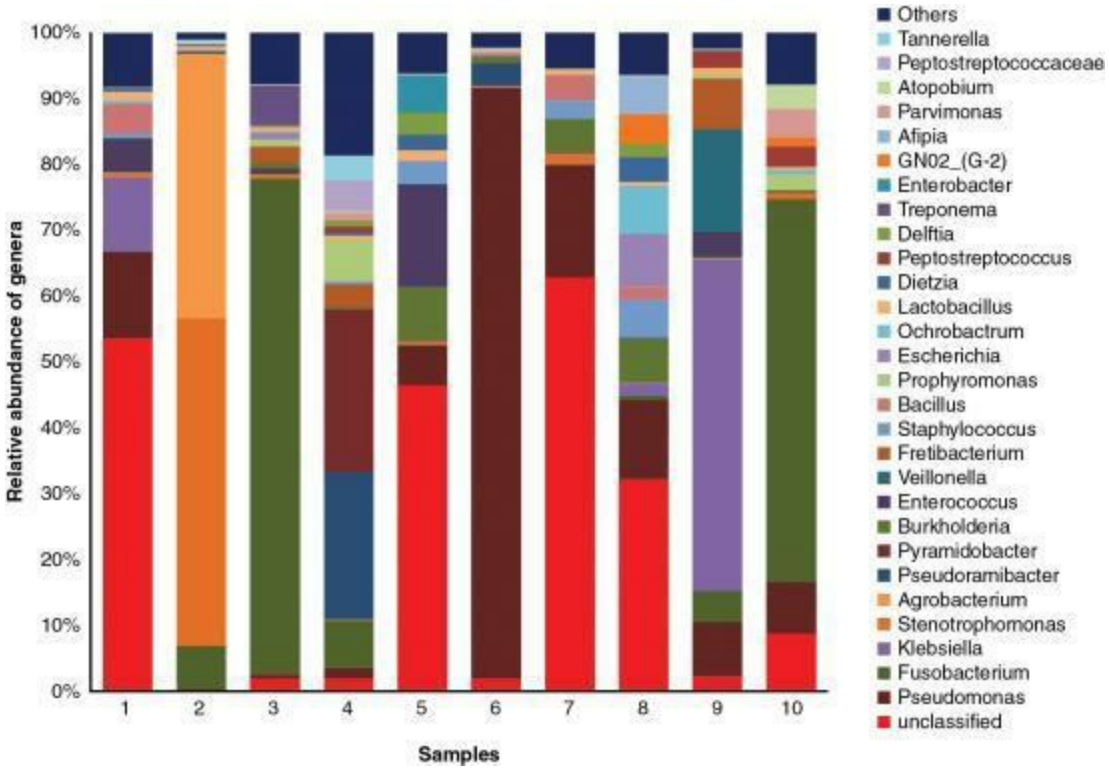

FIG. 15.29 Interindividual variability in bacterial diversity (richness and abundance) at the genus levels in cryopulverized apices from teeth with posttreatment apical periodontitis. Notice that no two samples are

the same in terms of bacterial composition.

Stacked bar chart of samples against relative abundance of genera (in percentage) shows the sample-wise data as follows:

Sample 1: Majority of population is unclassified.

Sample 2: Majority population is of Agrobacterium and Stenotrophomonas.

Sample 3: Majority population is of Fusobacterium.

Sample 4: Mixed population of Fusobacterium, Pseudomonas; Peptostreptococcus.

Sample 5: Mixed population of Delftia; Fusobacterium; Treponema; with majority as unclassified.

Sample 6: 80 percent population is of pyramidobacter.

Sample 7: 60 percent of population is unclassified; remaining contains pyramidobacter, Afipia; Parvimonas; and others.

Sample 8: 30 percent is unclassified; remaining is a mixed population.

Sample 9: 40 percent is Klebsiella; remaining is a mixed population of Veillonella; fusobacterium; pseudomonas; Fretibacterium; Peptostreptococcus; and other.

Sample 10: 50 percent of fusobacterim; remaining is a mixed population.
Note: All data is approximate.

Source: (Based on data from Siqueira JF Jr, Antunes HS, Rôças IN, Rachid CT, Alves FR. Microbiome in the apical root canal system of teeth with post-treatment apical periodontitis. *PLoS One* 11:e0162887, 2016)

Fungi are only occasionally found in primary infections, but *Candida* species have been detected in root canal–treated teeth in up to 18% of the cases.[28,49,121,122,145,150,230,277] Fungi gain access to root canals via contamination during endodontic therapy (secondary infection) or they overgrow after inefficient intracanal antimicrobial procedures that cause an imbalance in the primary endodontic microbiota.[254] *Candida albicans* is by far the most commonly detected fungal species in root canal–treated teeth. This species has several properties that can be involved in persistence following treatment, including its ability to colonize and invade dentin[211,212,246] and resistance to calcium hydroxide.[298,300]

Extraradicular infections

Apical periodontitis lesions are formed in response to intraradicular infection and by and large constitute an effective barrier against spread of the infection to the alveolar bone and other body sites. In most situations, apical periodontitis inflammatory lesions succeed in preventing bacteria from invading the periradicular tissues. Nevertheless, in some specific circumstances, bacteria can overcome this defense barrier and establish an extraradicular infection. The most common form of extraradicular infection is the acute apical abscess, characterized by purulent inflammation in the periradicular tissues in response to a massive egress of virulent bacteria from the root canal. Extraradicular infections in the form of biofilm covering the outer root surface, along with complex bacterial arrangements in the apical canal system, are commonly observed in cases of chronic abscesses (with sinus tract) and "wet canals"(persistent exudation).[157,159] Extraradicular biofilm, adhered to the external root surface around the apical foramina, and apical actinomycosis, characterized by cohesive actinomycotic colonies in the lesion body (Fig. 15.30),[78,132,161,168,] have been regarded as possible extraradicular causes of posttreatment apical periodontitis.

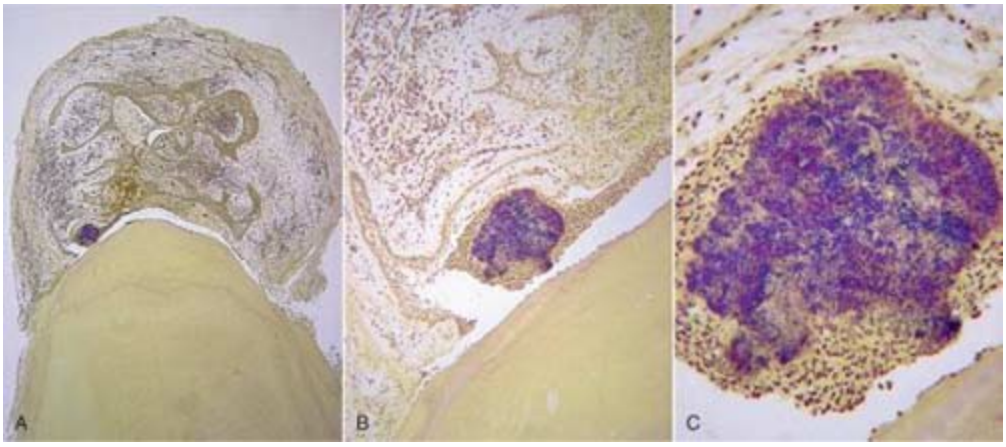

FIG. 15.30 Bacterial aggregate in an epithelialized apical periodontitis lesion, suggestive of actinomycosis. This case presented a severe flare-up in the past, but the tooth was asymptomatic at the time of extraction. **A,** Section not passing through the canal; note cyst cavity and bacterial aggregation on the left (magnification ×25). **B,** Detail of area with colony (magnification ×100). **C,** Higher magnification of colony, which is surrounded by neutrophils (magnification ×400).

An extraradicular infection can develop as follows[216]:

- It can be a result of direct advance of some bacterial species that overcome host defenses concentrated near or beyond the apical foramen, an extension of the intraradicular infectious process, or bacterial penetration into the lumen of a cyst that is in direct communication with the apical foramen ("bay" cyst). The borderline between the infecting endodontic microbiota and the host defenses is often located intraradicularly, short of or at the apical foramen. In some cases, however, bacteria may reach the periradicular tissues, and the borderline is then situated extraradicularly, beyond the boundaries of the apical foramen (Fig. 15.31). In the latter situation, the whole infectious process is a continuum composed of an intraradicular and an extraradicular segment, in which the former usually fosters the latter (see Fig. 15.31). It has been suggested that in some cases, the extraradicular segment may become independent of the intraradicular component of the infectious process.[168]
- It can result from bacterial persistence in the apical periodontitis lesion after remission of an acute apical abscess. The acute apical abscess is for the most part clearly dependent on the intraradicular infection; once the intraradicular infection is properly controlled by root canal treatment or tooth extraction and drainage of pus is achieved, the extraradicular infection is handled by the host defenses and usually subsides. Nonetheless, it should be appreciated that in some rare cases, bacteria that have participated in acute apical abscesses may persist in the periradicular tissues following resolution of the acute response and establish a persistent extraradicular infection associated with chronic periradicular

Telegram: @dental_k

www.konkur.in

inflammation, sometimes resulting in an actively draining sinus tract.

- It can be a sequel to apical extrusion of debris during root canal instrumentation (particularly after overinstrumentation). Bacteria embedded in dentinal chips can be physically protected from the host defense cells and therefore can persist in the periradicular tissues and sustain periradicular inflammation. In addition, large bacterial flocs ("planktonic biofilms") may be located in the apical canal and be extruded during root canal procedures; once in the periapical tissues, they can induce or maintain inflammation (Fig. 15.32).[161] The virulence and quantity of the extruded bacteria, as well as the host's ability to deal with infection, will be decisive factors dictating whether an extraradicular infection will develop or not as a result of apical extrusion of debris.

Source: (From Ricucci D, Lopes WP, Loghin S, Rocas IN, Siqueira JF Jr. Large bacterial floc causing an independent extraradicular infection and posttreatment apical periodontitis: a case report. *J Endod* 44:1308, 2018.)

Conceivably, the extraradicular infection can be dependent on or independent of the intraradicular infection.[215] Independent extraradicular infections are those that are no longer fostered by the intraradicular infection and can persist even after successful eradication of the latter. For an

Telegram: @dental_k

www.konkur.in

extraradicular infection to be classified as independent of the intraradicular infection, a comprehensive analysis of the apical canal should demonstrate absence of infection. So far, only a few cases have been reported that fulfill this requirement.[161,168]

It is still controversial whether asymptomatic apical periodontitis lesions can harbor bacteria for very long beyond initial tissue invasion.[12] Studies using culture-dependent[270,284,304] or culture-independent molecular biology methods, such as checkerboard hybridization,[59,272] FISH,[271] clone library analysis,[77] and HTS,[189] have reported the extraradicular occurrence of several bacterial species, especially anaerobes, in teeth that did not respond favorably to the root canal treatment. Because of the cross-sectional nature of the studies, it is not possible to infer if the extraradicular bacteria were transient or established therein. Apart from a discussion about whether contamination can be effectively prevented during surgical sampling of apical periodontitis lesions, these studies did not evaluate the bacteriologic conditions of the apical part of the root canal either. This makes it difficult to ascertain whether those extraradicular infections were dependent on or independent of an intraradicular infection. Actually, findings from a study evaluating both the resected root ends and the apical periodontitis lesions from treated teeth suggested that the large majority of cases of extraradicular infections are maintained by a concomitant apical root canal infection.[269]

Extraradicular biofilms are infrequent in untreated teeth with apical periodontitis, and when present they are virtually always associated with intraradicular biofilms; the occurrence of a sinus tract is usually indicative of the presence of an extraradicular biofilm.[159,164] The high success rate of nonsurgical root canal treatment[36,162,259] suggests that, in the occasional cases it is present, the extraradicular infection component may not suffice to maintain apical periodontitis provided the intraradicular infection is properly managed. This is consistent with the concept of dependent infection. Even in root canal–treated teeth with recalcitrant lesions in which a higher incidence of extraradicular bacteria has been reported, a high rate of healing following retreatment[53,259] suggests that the major cause of posttreatment disease is located within the root canal system, characterizing a persistent or secondary intraradicular infection.[108,121,150,167,184,230,277,309,310]

www.konkur.in

Periradicular tissues consist of cementum, periodontal ligament, and alveolar bone. *Cementum* is a mineralized, avascular connective tissue and consists of three different types. Acellular afibrillar cementum covers the teeth at and along the cementoenamel junction. Acellular extrinsic fiber cementum is confined to the coronal half of the root. Cellular intrinsic fiber cementum is present on the apical half of the root where no acellular extrinsic fiber cementum has been laid down.[198] Many growth factors, such as insulin-like growth factor-1 (IGF-1), fibroblast growth factors (FGFs), epidermal growth factor (EGF), bone morphogenetic proteins (BMPs), transforming growth factor-β (TGF-β), and platelet-derived growth factor (PDGF), are contained

Telegram: @dental_k

www.konkur.in

in the cementum matrix.[50,91,170] These growth factors may be released under certain conditions, as they have been shown to be associated with cementoblast proliferation, migration, and differentiation during cementum wound healing.[91]

The *periodontal ligament* is a soft, specialized connective tissue that connects the cementum to the alveolar bone. Periodontal ligament contains heterogeneous cell populations and extracellular matrix (ECM).[149,198] The cells of the periodontal ligament include osteoblasts, fibroblasts, epithelial cell rests of Malassez (ERM), macrophages, cementoblasts, and undifferentiated mesenchymal cells (stem cells).[198] Fibroblasts, osteoblasts, and epithelial cells are differentiated cells that have retained the ability to undergo limited cell divisions and proliferation upon stimulation by appropriate signals. Multipotent mesenchymal stem cells of the periodontal ligament are capable of differentiating into cementoblast-like cells and periodontal ligament cells as well as osteoblasts.[115,188,243] The ECM of the periodontal ligament consists of collagen fibers, fibronectin, elastin, other noncollagenous proteins, and proteoglycans. The ECM serves as stratum for cell adhesion and promotes cell spreading and cytoskeletal organization. The collagen fibers (Sharpey fiber) of the periodontal ligament connect the tooth with the alveolar bone. The periodontal ligament is highly vascularized and innervated. The tissue apical to the dentinocemental junction should be considered as part of the periodontal ligament because cementum is not a normal component of the pulp tissue.

ERM, the remnants of the Hertwig epithelial root sheath that disintegrates after tooth development, are present in the periodontal ligament near the root surface in all teeth after root formation. [217,218] They are nests of epithelial cells connected as a network and surrounded by a basal lamina.[198,240] ERM are quiescent in normal periodontal ligament[198] but can be stimulated to proliferate in apical periodontitis.[163] They are believed to be the cellular source that when properly stimulated can form radicular cysts in certain apical periodontitis lesions.[163,206]

Alveolar bone or *alveolar process* is that part of bone of the jaws housing the sockets for the teeth. It consists of outer cortical plate, a central spongy or cancellous bone, and bone lining the sockets.[198] Bone matrix contains growth factors, IGFs, TGF-β, BMPs, FGF, and PDGF.[43,261] These growth factors are

Telegram: @dental_k

www.konkur.in

essential for osteoblast progenitor cell proliferation, migration, and differentiation during bone wound healing.[166]

The response of the periradicular tissues to various injuries is similar to that of other connective tissues elsewhere in the body. The response is manifested as an inflammatory reaction regulated by both innate and adaptive immune mechanisms. Although microbial infection of the pulp in the root canals is the primary cause of apical periodontitis,[122,184,190] the pathologic changes of the periapical tissues in apical periodontitis are usually not directly caused by microbes themselves, but rather by their toxins, noxious metabolic by-products, and disintegrated pulp tissue in the root canal system. These irritants are capable of inducing both innate and adaptive immune responses. The subsequent immunoinflammatory responses are diverse and can involve changes in microvasculature, transmigration of blood-borne cells and plasma proteins out of the blood circulation into the tissue space, and activation of sensory nerves. In addition, endothelial cells, mast cells, platelets, fibroblasts, neutrophils, macrophages, dendritic cells, innate and adaptive immune cells, immunoglobulins, inflammatory mediators, proinflammatory cytokines, chemokines, and neuropeptides are also involved in the inflammatory response. Apical periodontitis can be protective or destructive, depending on the dynamic interaction between microbial insult and the host's defenses in the periapical tissues.[176] Unfortunately, the bacterial biofilm formed in the root canal system with necrotic pulp is protected from host's defenses and antibiotic therapy because of a lack of blood circulation in the root canal system. Consequently, any attempt of wounded periradicular tissues to repair/regenerate is futile, because bacterial toxins and noxious metabolic by-products in the root canal system continuously egress into the periapical area and irritate the periapical tissues. Emerging lines of evidence suggest that under most conditions, bacterial biofilms in the complex root canal system can be greatly reduced, but not eliminated, by conventional endodontic procedures such as mechanical instrumentation, antiseptic irrigation, and intracanal medication. If microbes in the root canal system are effectively eliminated or entombed within the root canal by filling material, and the root canal system is adequately sealed and protected from coronal microleakage, then periradicular tissues have the ability to restore their original structures by means of a repair/regeneration

Telegram: @dental_k

www.konkur.in

process. Nevertheless, the presence of posttreatment apical periodontitis may be due to persistent microbial biofilms in the root canal,[190,224] and this recognition has spurred considerable research into treating biofilms (see Chapters 14 and 15).

Apical periodontitis

Prevalence

Epidemiologic study of apical periodontitis documents that the prevalence of apical periodontitis varies among patients aged 20 to 30 (33% prevalence of apical periodontitis), 30 to 40 (40%), 40 to 50 (48%), 50 to 60 (57%), and older than 60 years of age (62%).[79,209] Most studies on the prevalence of apical periodontitis are from European and Scandinavian countries.[73,120,247] According to a survey by the American Dental Association in 2005–06, an estimated 15.1 million root canal treatments were performed annually in the United States alone.[10] Apical periodontitis is a prevalent health problem.[74]

Etiology

The etiology, pathogenesis, and histopathology of apical periodontitis are similar to that of marginal periodontitis (see also Chapter 25). Both diseases are caused by bacterial infection and involve pathologic changes of alveolar bone, periodontal ligament, and cementum. Marginal periodontitis affects coronal periodontal tissues, whereas apical periodontitis affects apical periodontal tissues. Bone loss is one of the characteristic features in both diseases: crest bone is lost in marginal periodontitis, and apical bone undergoes resorption in apical periodontitis.

Apical periodontitis can be caused by both exogenous and endogenous factors. Exogenous factors include microbes and their toxins and noxious metabolic by-products, chemical agents, mechanical irritation, foreign bodies, and trauma. Endogenous factors include the host's metabolic products, such as urate and cholesterol crystals,[194] as well as cytokines or other inflammatory mediators.[263] These irritants can activate nonantigenic pathway or antigenic pathway to induce innate and adaptive immunoinflammatory

Telegram: @dental_k

www.konkur.in

responses, respectively.

Infection of the pulp tissue caused by caries or other pathways is the primary cause of apical periodontitis.[122,190,224] The classic study by Kakehashi and colleagues[122] demonstrated that pulp necrosis and periradicular inflammation developed in conventional rats when the pulps of teeth were surgically exposed to oral microorganisms. However, in germ-free laboratory rats, no pulp necrosis and periradicular inflammation occurred even when the pulps of teeth were surgically exposed to the oral environment and packed with sterile food debris. A similar response occurs in humans. Using bacterial culturing, it has been demonstrated that traumatized human teeth with intact crowns and necrotic pulps *without bacterial contamination* did not show radiographic evidence of periapical bone destruction. In contrast, if bacteria were isolated from traumatized teeth with intact crowns and necrotic pulps, then radiographic evidence of periradicular bone destruction was observed.[272] Similar important findings have been replicated in nonhuman primate experiments. When the pulps of intact vital teeth were intentionally devitalized under aseptic conditions and left in the root canals with bacteria-tight, sealed coronal restoration for 6 months to 1 year, no periradicular inflammatory reaction was observed.[161,184] Taken together, there is considerable evidence that bacteria constitute a major etiologic factor in the development of apical periodontitis.

Bacterial toxins (e.g., lipopolysaccharide [LPS], lipoteichoic acid [LTA]) and noxious metabolic by-products that egress from the root canal system into the periapical tissues are capable of inducing a periapical immunoinflammatory reaction.[55,57,67,236,322] These irritants can activate the innate immune system via receptors that recognize the stereotypic pathogen-associated molecular patterns (PAMPs) that are found in the structure of these toxins. Different classes of microbes express different molecular patterns that are recognized by different pattern recognition receptors (PRRs) or Toll-like receptors (TLRs) on host cells, such as phagocytes, dendritic cells, and B lymphocytes.[1,177,178] PRRs or TLRs are encoded in the germline. In mammalian species, there are at least 10 TLRs, and each appears to have a distinct function in innate immune recognition.[178] For example, LPS can stimulate sensory nerve fibers to release calcitonin gene–related peptide (CGRP) and substance P (SP)[64,110] to cause vasodilation and increased

Telegram: @dental_k

www.konkur.in

vascular permeability. LPS and lipoproteins can also activate TLRs on dendritic cells to stimulate T-lymphocyte differentiation.[5] Certain subtypes of TLRs recognize the common shared structural features of various toxins (i.e., PAMPS). Because the TLRs are synthesized before an infection, they are classified as part of the innate immune system.

Apical periodontitis can be caused either by entry into the periapical tissues of bacterial toxins, enzymes, and noxious metabolic by-products or by direct invasion of the periapical tissues by microbes originating from the root canal system. It is important to differentiate between apical inflammation and apical infection. *Apical inflammation* is the periapical tissue reaction to irritants emerging from the root canal system that manifests as vasodilation, increased vascular permeability, and exudation. In contrast, *apical infection* is due to the physical presence of pathogenic microorganisms in the periapical tissues that subsequently produce tissue damage. There can be infection without inflammation, for instance, in a severely immunocompromised patient. There can also be inflammation without infection, such as in a myocardial infarct, cerebral infarct, and physical or chemical injury.[171] In diseases caused by infection, bacteria are usually present in the involved tissues or organs,[305] such as acute necrotizing gingivitis, marginal periodontitis, actinomycosis, tuberculosis, and bacterial bronchitis. Although apical periodontitis is primarily an infectious disease, bacteria are usually not present in the periapical tissues but in the root canal system,[145,190,307] except in certain types of apical periodontitis associated with abscess formation,[207,302,314] or with a draining sinus tract,[93,207,312] or extraradicular endodontic infection.[271,296] One major current hypothesis is that apical periodontitis is triggered by entry into the periapical tissues of bacterial toxins, enzymes, and noxious metabolic by-products.[280] The mere presence of bacterial contamination in some apical periodontitis lesions does not necessarily denote a periradicular infection. Periapical infection is related to both virulence and the number and specific combinations of microorganisms and the host's immune defense in the periapical tissues. Bacteria may be temporarily present in the inflamed periradicular tissues only to be killed by the host's defense mechanisms when the focus of infection in the root canal system is effectively eliminated by mechanical instrumentation, antiseptic irrigation, and intracanal medication. For instance, the majority of apical

Telegram: @dental_k

www.konkur.in

periodontitis lesions with abscess formation or draining sinus tracts heal satisfactorily after nonsurgical root canal treatment without the need for systemic antimicrobial therapy.[209]

Primary root canal infection in untreated root canals is a polymicrobial mix with approximately equal proportions of gram-positive and gram-negative bacterial species, dominated by obligate anaerobes (see Chapter 15).[273,275] In root-filled teeth with apical periodontitis, gram-positive microorganisms, with a relatively equal distribution of facultative and anaerobic species, appear to dominate other microorganisms.[182,276] A high prevalence of *E. faecalis* is frequently observed in filled root canals associated with persistent apical periodontitis.[97,127,182,213,254] These issues are described in greater detail in Chapter 15.

Physical (overinstrumentation, overfilling) and chemical (irrigants, intracanal medication, root canal filling materials) insults,[240] as well as traumatic injury[11,12] to the periapical tissues, can also cause apical periodontitis, depending on the severity of injury and cytotoxicity of the chemicals. Foreign bodies, such as root canal filling materials, have been shown to cause persistent periapical inflammation.[136,193,211,324] However, the possibility of bacterial contamination in foreign body–induced apical periodontitis lesions was not carefully ruled out in many studies, therefore it is possible that the foreign bodies might serve as carriers for the microorganisms. In addition, foreign bodies have the odd property of favoring infection,[325] as they can lower the infectious dose of bacteria and cause granulocytes to develop phagocytic defect or loss of ammunition.[326] Although most root canal filling materials are not inert and are capable of inducing certain degrees of inflammation, in general they are biocompatible and well tolerated by periapical tissues.[99,102]

It has also been demonstrated histologically that periodontal disease could cause inflammatory pulpal and periapical disease.[146]

Infection: A conflict between host and parasites

Every infection is a race between the capabilities of the microorganism to

Telegram: @dental_k

www.konkur.in

multiply, spread, and cause disease and the ability of the host to control and finally eliminate the microorganisms.[305] The host has physical barriers—surface epithelium, enamel, and dentin—as well as innate and adaptive immune defenses to prevent establishment of infection. Nevertheless, microbes also possess weapons, leading to inhibition of phagocytosis, inhibited lysosomal function, reduced killing by phagocytes, inactivation of complement system and immunoglobulins, and specific mechanisms that permit invasion of the host's physical barriers.[305] Infection of a tissue can manifest different histopathologic features as a result of specific host-microbe interactions that occur. Many infections are asymptomatic in more than 90% of individuals.[305] For instance, pulp necrosis and chronic apical periodontitis caused by root canal infection are usually asymptomatic, and patients are often surprised to find out that this infection has been present for a sufficient time to lead to destruction of periapical bone. There is no simple correlation between infection and clinical symptoms of apical periodontitis, except in cases of symptomatic apical periodontitis and acute apical abscess.

Pathogenesis

It is a general belief that the development of apical periodontitis follows total pulp necrosis. This belief is based on (1) the pulpal strangulation theory due to a generalized increase in pulpal interstitial pressure inside the uncompromised pulp space during pulpal inflammation that causes collapse of venules and cessation of blood flow[99] and (2) animal and human studies that concluded that uncontaminated necrotic pulps that are intentionally devitalized or accidentally traumatized are generally incapable of inducing periapical inflammation unless they are infected.[161,184,272] However, if the vital pulps become infected due to caries or other pathways, periapical inflammation can develop even when inflamed, but vital tissue is still present in the apical portion of the root canal.[159,224] Most of our information related to the histopathology of apical periodontitis comes from analysis of longstanding, chronic human lesions caused by caries or from time-course studies of development of apical periodontitis induced by artificial root canal infection in animals. In these instances, the moment of transition from pulpitis to apical periodontitis was not captured. In fact, apical periodontitis

Telegram: @dental_k

www.konkur.in

has been demonstrated to be a direct extension of apical pulpitis into the periapical tissues before total pulp necrosis caused by root canal infection (Fig. 16.1).[138,159,160,222,223,279] For example, Kovacevic and colleagues[138] studied the transition from pulpitis to apical periodontitis in dogs' teeth by artificial exposure of pulps to the oral cavity and observed that pulpitis was coupled with an acute apical periodontitis. Similarly, Kimberly and Byers[131] demonstrated that periapical changes, including sprouting of nerve fibers, appeared 3 to 5 weeks following establishment of irreversible pulpitis subsequent to pulp exposure lesions in animals. Yamasaki and coworkers[321] and Stashenko and colleagues[266] also showed that periapical inflammatory infiltrates, increased osteoclast numbers, and bone destruction were apparent well in advance of total pulpal necrosis, with vital pulp tissue still present in the apical portion of the root canal. The biologic basis for these observations appears to hinge on the apical development of pulpal infection/inflammation leading to the diffusion of many inflammatory mediators, proinflammatory cytokines, chemokines, and bacterial toxins into the periapical area prior to total pulpal necrosis.

Source: (Courtesy Dr. Domenico Ricucci, Rome, Italy.)

When pulps are infected/inflamed, many innate and adaptive immune cells are activated and release elevated amounts of various inflammatory mediators, including cytokines, chemokines, and neuropeptides. As the pulpal inflammation spreads, the inflammatory mediators begin to alter the pathobiology of the periapical tissues, manifesting as vasodilation, increased vascular permeability, infiltration of immunoinflammatory cells, and bone resorption. Clinically, the observable changes on radiographic examination of apical periodontitis are widening of the periodontal ligament space or development of apical osteolytic lesions due to bone resorption. The loss of bone is mainly caused by activated osteoclasts. Many cytokines, such as interleukin (IL)-1, IL-6, IL-11, IL-17, and tumor necrosis factor α (TNF-α), are found to have the ability to induce osteoclast progenitor cell differentiation and activation.[27,263] The inflammation-induced bone resorption in the periapical tissues is accompanied by recruitment of immunoinflammatory cells that essentially build a defensive line against the spread of microbial invasion from the root canal.[176]

The pathogenesis of apical periodontitis involves innate and adaptive immune responses as well as sensory nerve response in the periapical tissues. Immunoinflammatory cells present in human periradicular lesions consist of lymphocytes, macrophages, plasma cells, neutrophils, dendritic cells, and natural killer (NK) cells with the former two types as the majority.[156,175] The characteristic features of innate and adaptive immunity are summarized in Table 16.1.

Innate immune response

Specificity of innate immune response

In recent years, the concept of the nonspecific nature of innate immunity has changed since identification of a network of germline-encoded receptors, PRRs, which recognize specific molecular motifs of microorganisms.[5,6,178] PRRs can be expressed on the cell surface (macrophages, dendritic cells, neutrophils, NK cells, B cells), in intracellular compartments, or secreted into the blood and tissue fluids.[118] There are numerous microbial constitutive and conserved products such as PAMPs also noted earlier. Importantly, the PRRs of the innate immune system recognize PAMPs.[5,178]

Telegram: @dental_k

www.konkur.in

The specificity of innate immunity is due to the recognition of PAMPs of microorganisms by PRRs, such as TLRs of the host's cells. Activation of PRRs triggers numerous host responses, including opsonization, activation of complement and coagulation cascades, phagocytosis, activation of proinflammatory signaling pathways, and induction of apoptosis.[118] For example, TLR4/CD14 is the receptor for the gram-negative bacterial LPS. TLR4-mutated C3H/HeJ mice (LPS hyporesponsive) have reduced response to gram-negative bacteria and are highly susceptible to infection by *Salmonella typhimurium* or *Neisseria meningitidis*.[51] Importantly, there is a reduced expression of IL-1 and IL-12 and decreased periradicular bone destruction in TLR-4 deficient mice when teeth are subjected to pulpal exposures and infection with a mixture of four anaerobic pathogens: *Prevotella intermedia*, *Fusobacterium nucleatum*, *Streptococcus intermedius* (G+), and *Peptostreptococcus micros* (G+).[108] In addition, LPS is shown to be capable of inducing pain via direct activation of TLR4/CD14 expressed on nociceptive sensory neurons.[304] Thus, the TLR4 PRR receptor is importantly involved in odontogenic infections.

Components such as LTA of gram-positive bacterial cell walls can also stimulate innate immunity in a way similar to LPS. TLR2 plays a major role in detecting gram-positive bacteria and is involved in the recognition of a variety of microbial components, including LTA, lipoproteins, and peptidoglycan. The importance of TLR2 in the host defense against gram-positive bacteria has been demonstrated using TLR2-deficient ($TLR2^{-/-}$) mice, which were found to be highly susceptible to challenge with *Staphylococcus aureus* or *Streptococcus pneumoniae*.[69,281] LTA also stimulates leukocytes to release inflammatory mediators, including TNF-α, IL-1β, IL-6, IL-8, and prostaglandin (PG) E2, which are known to play a role in various phases of the inflammatory response. All of these inflammatory mediators have been detected in periapical samples, and each has a well-known tissue-damaging effect by activating various host responses.

The innate immune response to bacterial infection induces expression of proinflammatory cytokines (IL-1, IL-6, IL-8, IL-17, TNFα, IFN-γ), chemokines (CXCR1, CXCR2, TGF-β), and costimulators, which are essential for activation and influence of the nature of adaptive immune response.[5,177] The innate immune system is capable of recognizing non-self

Telegram: @dental_k

www.konkur.in

and self-antigens, whereas the adaptive immune system is not; thus, many autoimmune diseases are disorders of adaptive immunity.[177]

Nonspecific innate immune response

The primary nonspecific innate immune defense mechanism in apical periodontitis is phagocytosis of microbes by specialized phagocytes such as polymorphonuclear leukocytes (PMNs) and macrophages. This type of immune response does not require specific recognition of invaders by phagocytes. Tissue inflammation leads to the recruitment of PMNs from the blood circulation into the periradicular tissue. Activated PMNs exhibit an abrupt increase in oxygen consumption, the well-known respiratory burst, resulting in the release of oxygen radicals, a family of extremely destructive, short-lived substances that destroy nearby microorganisms and host cells.[17] Phagocytized microbes or foreign particles are exposed to a toxic environment containing specific azurophil granules and oxygen-derived free radicals and are eventually degraded.[200] PMNs also possess an extracellular killing mechanism via neutrophil extracellular traps (NETs), which are extracellular structures composed of chromatin with specific proteins from the neutrophilic granules. Upon activation (e.g., by IL-8, LPS, bacteria, fungi, activated platelets), neutrophils start a cellular program called *apoptosis* that leads to their death and the formation of NETs, which have antimicrobial activities.[33,80] Besides their role in the innate immunity as professional phagocytes, macrophages also serve as APC by expressing MHC (major histocompatibility complex) class II molecules that interact with antigen-specific clones of T-helper lymphocytes. Circulating monocytes are the precursors of both tissue macrophages and many dendritic cell subsets.[1,129,244] The details of the immunologic activities of neutrophils and macrophages in periapical pathosis are described in Chapters 13 and 14.

Adaptive/specific immune response

Continuous or severe infections at levels beyond the defense capacity of innate immunity are mediated by adaptive immunity, which is much more specific toward exogenous antigens. Adaptive immunity possesses the ability to memorize and respond to repeated exposure to the same antigen. The specificity of adaptive immunity is regulated at genetic levels in B and T

Telegram: @dental_k

www.konkur.in

lymphocytes through a complex process leading to the generation of molecules that recognize and bind to foreign or self-antigens. These molecules are specific receptors on T cells (T-cell antigen receptors or TCRs) and on B cells (B-cell antigen receptors or BCRs; also termed *immunoglobulins*). TCRs on T cells interact with antigens that are presented by antigen presenting cells (APC) expressing MHC II molecules along with other accessory molecules, whereas BCRs on B cells interact with antigens directly. BCRs may be secreted in the blood circulation or in the tissues as antibodies. The variable region of both TCR and BCR proteins are rearranged at the genomic level via genetic recombination of the V(D)J segments. The estimated total diversity after this recombination for TCR is approximately 10^{21} and for BCR is approximately 10^{15} that generates the repertoire of different individual T- and B-cell clones.[1,119] Each T- or B-cell clone generated in the bone marrow carries a specific TCR and BCR. They undergo a positive and negative selection process through which most clones are deleted via apoptosis because they bind to self-antigens. This initial "negative screening" process reduces the potential for autoimmune disorders. Only those that do not interact with self-antigens are released into the lymphatic system and blood circulation. The naive T cells circulate back and forth between the lymphatic system and blood circulation until they encounter foreign antigens presented by APC. About 97% of T cells undergo apoptosis, and only a small percentage of these cells are exported to the periphery as mature T cells.[1]

The interaction between TCR and the antigen peptide/MHC complex and co-stimulators activates T cells, leading to the synthesis of T-cell growth factor, IL-2, and its receptor that causes T-cell clonal expansion/proliferation. Some of these T cells differentiate into armed, effector T cells, and others become memory cells. There are a number of T-cell subpopulations, categorized by their functions: (1) T helper cells (T_H), (2) T regulatory cells (T_{reg}), (3) T suppressor cells (T_S), and (4) T cytotoxic (cytolytic) (T_C) cells.[1,60,301] Some of them can be distinguished by their cell surface markers, cytokine profiles, or transcriptional factors. See also Chapter 14 for additional details.

The development of CD4 T_H cells involves the encounter of APCs in association with class II MHC. All tissue cells express MHC class I, but only

Telegram: @dental_k

www.konkur.in

certain cells express class II MHC. Class II MHC–expressing cells constitute the body's population of APCs and consist of (1) dendritic cells, (2) macrophages, (3) B cells, (4) vascular endothelial cells, and (5) epithelial cells. The former three are considered "professional" APCs, because they are dedicated to this function. The latter two APCs are quiescent under normal conditions but can be induced to express class II MHC when exposed to elevated concentrations of IFN-γ.[1,119]

Dendritic cells and macrophages phagocytose foreign antigens, whereas B cells utilize the membrane-bound immunoglobulin to bind and internalize antigens. Other APCs endocytose foreign antigens into the cytoplasm for antigen processing and the processed antigens are partially degraded into small peptides. Many of them are 10 to 30 amino acids long and capable of binding onto the newly synthesized class II MHC molecules before the antigen/class II MHC complex is transported to the surface of cells and presented to TCRs of $CD4^+$ T cells.

Although controversial, evidence has suggested that $CD8^+$ T_S and $CD8^+$ CTLs represent distinct subpopulations of $CD8^+$ T cells. T_S are MHC class I–restricted $CD8^+/CD28^-$ T_S cells, which act on APC by a contact-dependent manner, rendering them tolerogenic to T_H cells. They inhibit the proliferation of T_H cells.[53,327] T cytotoxic cells ($CD8^+T_C$), also known as *cytolytic T lymphocytes* (CTLs), are a subset of T cells that kill target cells expressing MHC-associated peptide antigens. The majority of T_C cells express CD8 and recognize antigens degraded in the cytosol and expressed on the cell surface in association with class I MHC molecules of the target cells. Functional T_C acquire specific membrane-bound cytoplasmic granules, including a membrane pore-forming protein called *perforin* or *cytolysin* and enzymes called *granzymes*.[1]

Upon antigen stimulation, naive CD4 T cells can proliferate and differentiate into T_H0 cells, which are subsequently committed to develop into T_H1 or T_H2 cells.[1] Monocytoid DC (dendritic cell) (DC1) induces T_H1-type responses; plasmacytoid DC (DC2) selectively induces T_H2 responses. Each subset of T_H cells has distinct functions and cytokine profiles. T_H1 cells develop from T_H0 activated by IL-12 and IFN-γ and mainly produce IL-2,

Telegram: @dental_k

www.konkur.in

interferon (IFN)-γ, and TNF-α, which activate macrophages. T_H2 cells develop from T_H0 activated by IL-4 and IL-10 and produce IL-4, IL-5, IL-10, and IL-13, which activate B cells to make antibody. T_H0 can also develop into T_H17 under the activation of IL-6 and TGF-β and produce IL-17, a powerful proinflammatory cytokine. Macrophages, dendritic cells, and T cells produce antiinflammatory cytokine, IL-10. Overall, T_H1 and T_H2 have mutually inhibitory effects.[1]

The role of B cells in adaptive immunity is mainly the production of antibodies that constitute the host humoral immune response. The V(D)J gene recombination occurs in both heavy and light (κ and λ) chains. A recombinase system, which is an enzymatic complex consisting of several enzymes—including recombination activating gene 1 and 2 (RAG-1, RAG-2), terminal deoxynucleotidyl transferase (TdT), DNA ligase IV, Ku proteins, and XRCC4—is essential for successful recombination. This recombinase system is also used for TCR recombination. Mature IgM/IgD coexpressing B cells undergo isotype switching via a process called *switch recombination* after encountering antigen. The rearranged V(D)J gene segment recombines with a downstream C region gene (γ, ε, or α), and the intervening DNA sequence is deleted. This gives rise to other classes of immunoglobulins (IgG, IgE, IgA) besides IgM. In addition to isotype switching, activated B cells also undergo somatic mutation in the V region gene, leading to affinity maturation of antibodies and alternative splicing of VDJ RNA to membrane or secreted immunoglobulin mRNA. A large quantity of antibody is secreted when B cells terminally differentiate into plasma cells.[1,119] The ability of antigens to selectively stimulate the differentiation of plasma cells supports the clinical finding that plasma cells isolated from periapical lesions secrete antibodies specific for the particular bacteria found in the adjacent root canal system.

The immune response and the role of lymphocyte subpopulations in apical periodontitis lesions were investigated by employing lymphocyte-deficient rodents as study models. T-cell deficiency appears to accelerate bone loss at the early phase of apical periodontitis lesions (2 weeks) but does not affect the overall course of lesion development.[282,306] Using RAG-2 SCID mice (both T- and B-cell-deficient), it was found that approximately a third of the RAG-2 mice developed endodontic abscesses, whereas no immunocompetent

Telegram: @dental_k

www.konkur.in

controls had abscesses.[284] In another study, specific RAG-2 knockout (k/o) mice were used to determine which immune element was important for the defense mechanism in endodontic infection. The results demonstrated that B cells, but not T cells, played a pivotal role in preventing dissemination of endodontic infection.[109] Therefore, both T and B cells mediate the observed immune responses in apical periodontitis lesions.

Neurogenic inflammation

Certain primary afferent sensory nerve fibers, upon stimulation by various irritants, release neuropeptides, which cause vasodilation, protein extravasation, and recruitment/regulation of immune cells such as macrophages, neutrophils, mast cells, and lymphocytes. This phenomenon is termed *neurogenic inflammation*.[29,32] Pivotal neuropeptides in the induction of neurogenic inflammation are calcitonin gene-related peptide (CGRP) for vasodilation, and SP for the induction of protein extravasation. Neuropeptides and their receptors are widely distributed throughout the body. During inflammation, there is a sprouting of afferent fibers[41,42] and local increases in inflammatory mediators that trigger neuropeptide release, leading to neurogenic inflammation.[29,46] Besides the cardinal functions of the key neuropeptides that cause the first sign of inflammation—vasodilation and increased vascular permeability—the role of these neuropeptides in the process of inflammation is now known to be far more complex. In the development of chronic apical periodontitis lesions, neuropeptides are also involved in immune regulation, bone resorption, and wound healing. At sufficient concentrations, SP increases the secretion of IL-1, TNF-α, and IL-6 from macrophages and stimulates T-lymphocyte proliferation and enhances antigen-induced IFN-γ production by T cells.[264] Certain neuropeptides, such as SP, up-regulate immune and inflammatory responses, whereas other neuropeptides, such as CGRP, vasoactive intestinal peptide (VIP), and neuropeptide Y (NPY), inhibit inflammatory responses. Synergistic interactions among neuropeptides, such as CGRP and other inflammatory mediators, eicosanoids, and bradykinin, suggest a complex interplay between these molecules in the immune response.[86,219,264]

In chronic apical periodontitis lesions, specific receptors for SP and CGRP are expressed in certain immune cells, including macrophages and

Telegram: @dental_k

www.konkur.in

lymphocytes. Both CGRP and VIP may play a role in inhibiting bone resorption by suppressing osteoclastic functions. The level of VIP in apical periodontitis lesions is inversely related to lesion size. Osteoclast cell culture studies have demonstrated that the presence of greater concentrations of VIP leads to a decrease in their ability to form lacunae of osseous resorption, causing rapid cytoplasmatic contraction and reduced cell mobility. VIP exerts an effect on macrophages to block the production of TNF-α, IL-6, and IL-12, suggesting that VIP could have a role in controlling growth of apical periodontitis lesions.[46]

The major innate and adaptive immune responses and neurogenic inflammation in the pathogenesis of apical periodontitis caused by root canal infection are illustrated in Fig. 16.2.

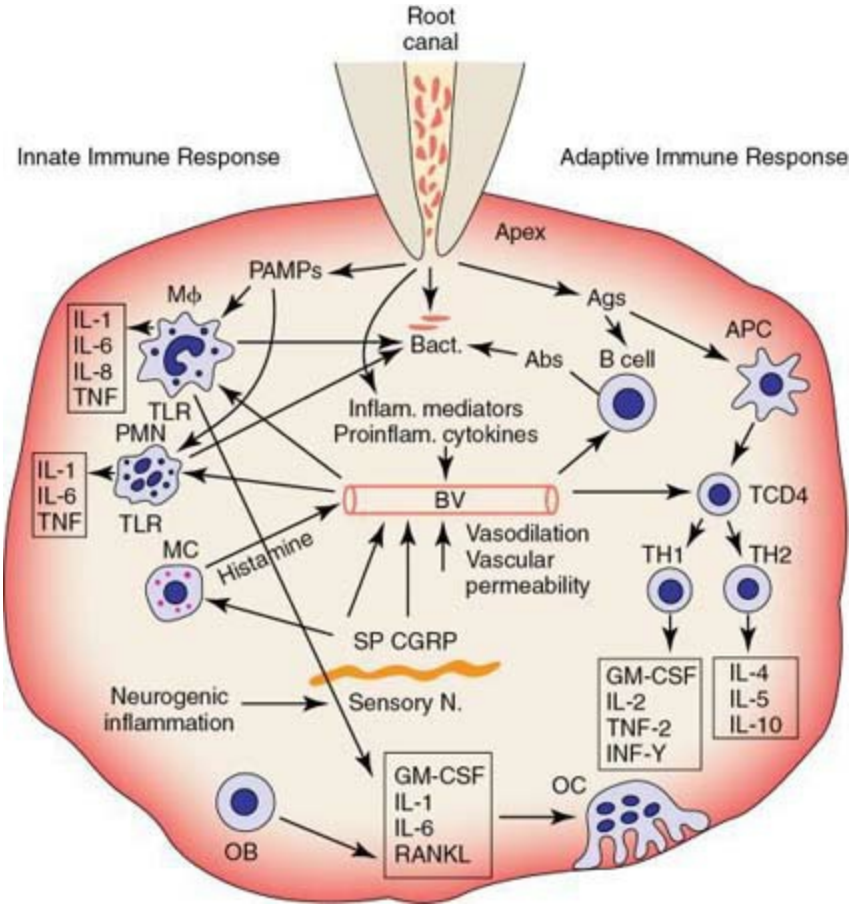

FIG. 16.2 Major innate and adaptive immune responses and neurogenic inflammation in the pathogenesis of apical periodontitis. *APC,* Antigen presenting cell; *BV,* blood vessels; *CGRP,* calcitonin gene–related peptide; *GM-CSF,* granulocyte/monocyte colony-

stimulating factor; *INF*, interferon-*r*; *MC,* mast cell; *Mφ,* macrophage; *OB,* osteoblast; *OC,* osteoclast; *PAMPs,* pathogen-associated molecular patterns; *PMN,* polymorphonuclear leukocyte; *RANKL,* receptor activator of nuclear factor κB ligand; *TLR,* Toll-like receptor; *TNF*, tumor necrosis factor.

A schematic diagram shows innate immune response and adaptive immune response caused by root canal infection.

Innate immune response: PAMPs leads to TLR in PMN and TLR in M phi followed by IL-1, IL-6, IL-8, TNF. PMN further leads to bacteria along with IL-1, IL-6, and TNF, whereas M phi leads to bacteria as well as GM-CSF, IL-1, IL-6, RANKL from OB that further leads to OC during neurogenic inflammation. Beside this, SP CGRP leads to MC and BV. MC along with histamine further leads to BV. BV ultimately leads to Mm phi and PMN.

Adaption immune response: Ags from apex leads to APS and B cell. APS further leads to TCD4 further leads to TH1 and TH2. TH1 leads to GM-CSF, IL-2, TNF-2, INF-Y and TH2 leads to IL-4, IL-5, IL-10. SP CGRP from sensory nerve leads to BV through vasodilation vasculator permeability that further leads to TCD4 and B cell followed by Abs then bacteria from root canal infection. Inflam. mediators proinflam. cytokines leads to BV.

Diagnosis

Correlation between clinical and histologic findings

Clinical diagnosis of inflammatory periapical disease is mainly based on clinical signs or symptoms, duration of disease, pulp tests, percussion, palpation, and radiographic findings (see also Chapter 1). In contrast, a histologic diagnosis is a morphologic and biologic description of cells and ECM of diseased tissues. The clinical diagnosis represents a provisional diagnosis of disease based on signs, symptoms, and testing results, whereas the histologic diagnosis is a definitive diagnosis of the disease.

Apical periodontitis can be symptomatic or asymptomatic. Similar to pulpitis, apical periodontitis is not always symptomatic or painful.[241,242,248] Although many inflammatory mediators (histamine, bradykinin, prostaglandins) and proinflammatory cytokines (IL-1, IL-6, TNF, nerve growth factor [NGF]), as well as neuropeptides (SP, CGRP), are capable of

Telegram: @dental_k

www.konkur.in

sensitizing and activating nociceptors of sensory nerve fibers,[99,100] other mediators such as endogenous opioids and somatostatin released by inflammatory cells during inflammation are able to inhibit firing of sensory nerve fibers.[105,246] Activation of nociceptors of sensory nerve fibers may also be related to concentrations of inflammatory mediators. The complexity of these findings supports the clinical observation that there is no good correlation between clinical symptoms and histopathologic findings of apical periodontitis.[30,164] For example, many teeth with apical periodontitis are free of symptoms. In addition, pain is mediated at molecular level and hard to identify histologically.[21]

Correlation between radiographic and histologic findings

Radiography is designed to detect pathologic changes at tissue and not cellular level. Even using sensitive imaging systems such as ultrasound, cone-beam computed tomography, and other imaging technologies, it is impossible to detect the presence of inflammatory cells or other subtle changes in the periapical tissues. Using conventional radiographic and histologic methods in the same cadavers, evidence of inflammation was often observed in the periapical tissues of endodontically treated teeth with histologic examination but not with normal radiographic examination.[19,39,88] It has also been demonstrated that lesions localized in the cancellous bone may not be visible radiographically unless they involve cortical bone (see also Chapter 2).[23,25,112] In addition, radiographic images are unable to differentiate apical granuloma and apical cyst.[144,225,278] Accordingly, radiographic findings and histopathologic features of apical periodontitis have a poor correlation. Histologic examination remains the gold standard of diagnosis of inflammatory periapical lesions. Cone beam computed tomography is more sensitive than conventional periapical radiography to detect periapical osteolytic lesions.[212]

The absence of clinical symptoms and negative periapical radiographic findings of endodontically involved teeth does not necessarily indicate absence of apical periodontitis.[19] By the same token, clinical success of endodontically involved teeth (i.e., absence of signs and symptoms and

Telegram: @dental_k

www.konkur.in

negative periapical radiographic findings) after nonsurgical root canal therapy does not necessarily imply complete histologic healing of periapical lesions. Thus, currently available diagnostic methods used in endodontics, such as clinical symptoms, percussion, palpation, pulp sensibility tests (cold, heat, electric), and radiographic imaging are not sensitive enough to provide accurate diagnosis of inflammatory periapical lesions. Until we have more advanced and sophisticated clinical diagnostic technologies, we will continue to face the problem of clinical diagnosis of inflammatory periapical lesions. Nevertheless, the treatment of various types of apical periodontitis lesions is basically the same: nonsurgical root canal therapy.

Histopathology

Histopathology focuses on cellular biology of diseased tissues and organs. Biochemical disorders occur inside the cells before histologically observable morphologic changes of cell injury. Cell death (protein denaturation) occurs before observable morphologic changes of cell necrosis. Gene transformation or mutation occurs before observable morphologic changes of neoplastic cells.[171]

Based on etiology, clinical signs and symptoms, and duration of the disease process, the World Health Organization (WHO) classifies disease of periapical tissues into many categories.[318] There are also many classifications of inflammatory periradicular disease in several endodontic textbooks[113,209,293] and by the American Board of Endodontists, depending on clinical manifestations and histologic appearances. In addition, the American Association of Endodontists held a consensus conference on diagnostic terms in the fall of 2008. Traditionally, there has been a lack of consensus on clinical diagnostic terminology of pulpal and periapical disease in the endodontic community because of the paucity of studies with high levels of evidence. This chapter will focus on pathobiology of apical periodontitis.

The histopathologic analysis of a diseased tissue or organ only shows structural changes of cells and ECM at the time the tissue or organ is removed. Therefore, it does not represent the complete kinetics or spectrum of disease development. Histologic classification of apical periodontitis is

Telegram: @dental_k

www.konkur.in

based on types of cells participating in inflammatory responses in the periapical tissues in this chapter. In general, inflammation can be divided into acute and chronic responses, depending on types of cells present at the site of injured tissue.[141,171,259,310] Acute inflammatory response is characterized by participation of neutrophilic leukocytes and chronic inflammatory response by participation of macrophages and lymphocytes. However, many factors, such as severity of tissue injury, specific etiology, host's resistance, and particular tissue involved, can modify the course and morphologic variations as well as cell biology of both acute and chronic inflammatory responses.[141,171] Acute and chronic inflammatory responses are in fact not rigid phases of a single programmed event but two overlapping responses with partially different triggering mechanisms and programs.[171] Sometimes apical periodontitis may be associated with abscess formation. *Abscess* is a localized collection of purulent exudate in a tissue.[141] The development of an abscess in apical periodontitis lesions is probably caused by colonization of a combination of specific pyogenic pathogens in the inflamed periapical tissues.[35,207,274,302] Abscess begins as a furious battle between highly virulent pathogens and an army of neutrophilic leukocytes. The pathogens produce massive toxins to kill neutrophils. As neutrophils attack the pathogens, they secrete lysosomal enzymes that digest not only the dead cells but also some live ones. Many neutrophils die fighting against pathogens. The resulting purulent exudate is poorly oxygenated and has a low pH. The bactericidal ability of leukocytes appears to be impaired because of the deprivation of oxygen and interference of respiratory burst. The purpose of respiratory burst is to generate bactericidal agents.[17,171] However, the phagocytic activity of leukocytes is not impaired in anaerobic conditions.[171] To avoid confusion between histologic and clinical diagnosis, readers are encouraged to read the chapters related to clinical examination, radiographic interpretation, and clinical diagnosis of inflammatory periapical disease (see Chapters 1, 2, and 5).

Acute apical periodontitis

The development of acute apical periodontitis largely reflects the innate immune response and is the first line of active defense against irritants from

Telegram: @dental_k

www.konkur.in

the root canal. Acute apical periodontitis is an immediate defense reaction to irritants and does not require exquisite specificity and memory. Characteristic features of acute apical periodontitis are similar to the typical acute inflammatory reaction in all connective tissues and consist of vasodilation, increased vascular permeability, and transmigration of leukocytes from the blood vessels into perivascular tissue space. The beneficial actions of acute inflammation are (1) infiltration of leukocytes to the injured tissue to phagocytose and kill microbial agents; (2) accumulation and activation of humoral factors such as immunoglobulins, complement factors, plasma proteins, and innate immune cytokines (IL-1, TNF) in the injured tissue to recruit more neutrophils and macrophages; and (3) neutralization or degradation of bacterial toxins and their harmful metabolic by-products.[141,171]

Cell biology

The inflammatory response is a dynamic interaction between host defense mechanisms and microbial insults. The interlacing activation and control pathways of cellular and humoral components involved in the inflammatory response are complex. The cells involved—neutrophils, monocytes/macrophages, platelets, mast cells, T lymphocytes, B lymphocytes, NK cells, dendritic cells, endothelial cells, fibroblasts, eosinophils, and basophils—each have numerous functions that are activated and modulated by a multiplicity of biochemical messengers.[1,141,171] *Cell activation* means that the cell acquires the ability to perform one or more new functions or to perform normal functions at a higher rate[1]; it often results in transcription of new genes and synthesis of new proteins.[1]

Mast cells

Histamine stored in the cytoplasmic granules of mast cells is the mediator that first appears in acute inflammation to induce vasodilation and increased vascular permeability; mast cells are the designated triggers of acute inflammation. They are widely distributed in perivascular tissue spaces and originate in the bone marrow from precursor cells. Mature mast cells contain numerous cytoplasmic granules, which are the source of vasoactive mediators. The preformed histamine is released by mast cell degranulation

Telegram: @dental_k

www.konkur.in

and can be triggered by (1) physical stimuli such as cold, heat, and mechanical trauma; (2) binding of IgE-specific antigen to mast cells and membrane-bound IgE antibodies; (3) binding of complement components (C3a and C5a) to their complementary receptors on mast cells; and (4) stimulation by neuropeptide (SP) and cytokines (IL-1, IL-8).[1,32,141,171] In addition, activated mast cells secret cytokines (TNF-α, IL-1, IL-3, IL-4, IL-5, IL-6, IL-13), prostaglandins, and leukotrienes to enhance inflammatory defense mechanisms.[1,40,129]

Endothelial cells

Endothelial cells are important players in the inflammatory response. Without the participation of endothelial cells, the host is unable to deliver its cellular and humoral defense components from the circulating blood to the site of tissue injury. Inflammatory mediators, complement components, proinflammatory cytokines, nitric oxide, neuropeptides, and bacterial toxins can all affect endothelial cells, resulting in vasodilation and increased vascular permeability.[1,141,171] IL-1 and TNF released by activated macrophages and NK cells can stimulate endothelial cells to express intercellular adhesion molecules (ICAMs), such as ICAM-1, ICAM-2, ICAM-3, vascular cell adhesion molecule (VCAM), and platelet endothelial cell adhesion molecule (PECAM), which enhance leukocyte adhesion to endothelial cells and transmigration through the blood vessels.[1,141,153,171] IL-1, TNF, and LPS also can activate endothelial cells to synthesize chemokine (IL-8), a potent chemotactic mediator for neutrophils.[1]

Polymorphonuclear neutrophilic leukocytes

Polymorphonuclear neutrophilic leukocytes (PMNs) are the principal effector cells in acute apical periodontitis. They are derived from bone marrow hematopoietic stem cells. Neutrophils have a lobulated nucleus and contain primary or azurophil (elastase and myeloperoxidase) and secondary or specific (lysozyme and other protease) granules in their cytoplasm.[129,141,171] Neutrophils are only present in the blood circulation. They are the first leukocytes to transmigrate through the blood vessels into perivascular tissue space and then are directed toward the wound or irritants, peaking at 24 to 48 hours. The transmigration of neutrophilic leukocytes from the blood vessels

Telegram: @dental_k

www.konkur.in

into perivascular space involves complex cellular and molecular biology. Following vasodilation and increased vascular permeability, leukocyte margination, rolling, capture, and activation in the blood vessel and then transmigration through the blood vessel are mediated by an intricate interaction of cell adhesion molecules expressed on leukocytes (L-selectin, integrins) and on endothelial cells (P- and E-selectins, ICAM, VCAM, PECAM-1). Neutrophil rolling is mediated by interaction between leukocyte selectin ligands and P-selectins on endothelial cells. Leukocyte sticking is mediated by interaction between leukocyte integrins and ICAMs and VCAMs on endothelial cells. Leukocyte transmigration is mediated by interaction between PECAM-1 on both leukocytes and endothelial cells.[171] Chemokines (IL-8) increase the affinity of leukocyte integrins for their ligands on endothelial cells.[1] Once transmigrating through the junction between endothelial cells and basement membrane into the perivascular tissue space, neutrophilic leukocytes are directed toward stimuli by chemotactic factors or chemotaxins, such as bacterial products (fLMP), C3a, C5a, leukotriene B4 (LTB4), platelet-activating factor (PAF), fibrinopeptides, dead cells, and chemokines (IL-8) by receptor-mediated mechanisms.[1,141,171,259]

Neutrophils can be activated by bacteria and PAMPs (also known as the TLRs, described earlier). They can also be stimulated by IL-1, TNF, and chemokines produced by activated macrophages and NK cells to enhance the phagocytic activity of infectious agents and synthesis of defensins, which are broad-spectrum antibiotics.[1] Neutrophilic leukocytes are terminally differentiated cells and short lived—within hours to a few days. Most neutrophilic leukocytes in acute inflammatory response die as a result of apoptosis or programmed cell death. The apoptotic neutrophils are phagocytosed by macrophages.[92,141,171] However, some neutrophilic leukocytes die after a furious battle against microbial infection and release intracellular proteolytic lysosomal enzymes, oxygen-derived active metabolites, nitric oxide, proinflammatory cytokines, eicosanoids, and matrix metalloproteinases into tissue to intensify inflammation and tissue damage.[141,171] The release of lysosomal enzymes by neutrophils and macrophages can also occur by lysosomal suicide due to rupture of phagolysosome in the cytosol, regurgitation during phagocytosis of irritants, or frustrated phagocytosis of indigestible foreign bodies. [141,171] The main

Telegram: @dental_k

www.konkur.in

effector functions of neutrophilic leukocytes are phagocytosis, killing of microbes, and release of inflammatory mediators (including proinflammatory cytokines) to recruit more leukocytes to prevent spread of infection.

Macrophages

Macrophages make their appearance as a second wave in acute apical periodontitis within 48 to 96 hours. Macrophages are blood-borne but have a counterpart in the connective tissue.[171] Blood monocytes transmigrate through the blood vessel into the tissues and become macrophages. Mature macrophages have an irregular-shaped nucleus and contain abundant lysosomes and many phagocytic vesicles (phagosomes). Monocytes use mechanisms similar to neutrophils to adhere to endothelial cells in high endothelial venule–expressing adhesion molecules for mononuclear leukocytes (ICAM for macrophages and VCAM for lymphocytes); they then transmigrate through the blood vessel and are directed toward the site of tissue injury by chemotactic factors.[171]

Macrophages can be activated by bacteria, PAMPs, and interferon-γ (INF-γ) and produce numerous products: lysosomal enzymes, coagulation factors, bioactive lipids, reactive oxygen species, chemokines, cytokines/growth factors, and angiogenesis factors.[141,171,259] Macrophages are the most dynamic and versatile leukocytes. The main functions of macrophages are numerous. They include phagocytosis of microbes and foreign bodies, production of inflammatory mediators, initiation of the immune response, cleanup operation of necrotic cells and tissue, induction of systemic effects (fever, acute phase reaction, cachexia), synthesis of molecules or cytokines affecting cell and vascular growth in wound healing, as well as antibacterial and antiviral defenses.[171] Tissue macrophages are not terminally differentiated cells and are able to undergo mitosis. Their life span is from several weeks to months.

Activated neutrophilic leukocytes and macrophages are capable of phagocytizing and killing pathogens. They recognize microbes through TLRs and receptors for the Fc fragment of immunoglobulin IgG as well as complement component C3b on their cell surface. C3b opsonization and antibody coating of microbes enhance recognition and phagocytosis of pathogens by activated neutrophilic leukocytes and macrophages.[1,141,171]

Telegram: @dental_k

www.konkur.in

Activated neutrophilic leukocytes are effective in phagocytosing and killing extracellular microbes, whereas macrophages activated by IFN-*r* produced by NK cells and T_H1 cells are more effective in phagocytosing and killing intracellular microbes.[1] Killing of phagocytosed microbes by neutrophilic leukocytes and macrophages is mediated through oxygen-dependent and oxygen-independent mechanisms. Oxygen-dependent mechanisms are more effective in killing all kinds of bacteria than oxygen-independent mechanisms.[1,141,259] The effector molecules of an oxygen-dependent system are hydrogen peroxide, superoxide anion, hydroxyl radical, singlet oxygen, and hypochlorite. An oxygen-independent system is also important in killing microbes and is dependent on lysozymes, defensins, and lactoferrin contained in phagocyte granules.[1,141,171,259] Some antimicrobial peptides and other oxygen-independent mechanisms possessed by phagocytes are specialized for killing of certain groups of microbes.[1,259]

Microbes phagocytosed by phagocytes are enclosed in membrane-bound phagosomes in the cytosol. The phagosomes fuse with lysosomes to form phagolysosomes. Irritants such as microbes, foreign protein antigens, and dead cells inside the phagolysosome are destroyed or degraded by proteolytic enzymes stored in lysosomes.[1] There are also granules that are fused with the nascent phagosome and release their contents into the phagosome. Some of these granules have direct antimicrobial action, such as defensins and the bactericidal permeability-increasing protein azurocidin. Others are proteases, such as elastase and cathepsins, lactoferrin, and peroxidase myeloperoxidase. Lysosomal enzymes, reactive oxygen intermediates, and nitric oxide released by neutrophils and macrophages indiscriminately kill not only bacteria but also tissue cells. Much of periapical tissue damage that occurs during acute inflammation can be attributed to release of proteolytic lysosomal enzymes and MMPs from disintegrated neutrophilic leukocytes and macrophages rather than to bacteria and their toxins.[1,171]

Platelets

Platelets normally circulate in the blood but also play an important role in inflammation. They are small cytoplasmic fragments derived from the megakaryocyte.[129] Platelets are essential for blood clotting, hemostasis, and fibrinolysis. Platelets produce vasoactive amines (PAF, serotonin),

Telegram: @dental_k

www.konkur.in

chemokines, and growth factors (PGDF, FGF, TGF) during inflammation.[171]

Natural killer cells

NK cells are also players in acute apical periodontitis. They are a subset of lymphocytes found in blood and lymphoid tissues. NK cells are derived from the bone marrow hematopoietic stem cells but lack the specific T-cell receptor for antigen recognition.[1] NK cells also possess TLRs for microbial constitutive and conserved products. The effector functions of NK cells are to lyse virus-infected cells without expressing class 1 MHC molecules and to secret IFN-*r* to activate macrophages. Antibody-coated cells, cells infected by viruses, some intracellular bacteria, and IL-2 released by activated macrophages can activate NK cells. Viruses have been isolated in apical periodontitis lesions.[228,260] NK cells kill target cells by antibody-dependent cell-mediated cytotoxicity because NK cells express receptor for the Fc fragment of IgG.[1] NK cells provide a link between the innate and adaptive immune systems.[118]

Inflammatory mediators

Numerous biochemical mediators are involved in the acute innate inflammatory response. They are mainly derived from plasma and inflammatory cells. The main biologic functions of inflammatory mediators are to cause vasodilation and increased vascular permeability and recruit inflammatory cells, mainly neutrophilic leukocytes and macrophages from blood circulation to the site of tissue injury. Some mediators can also cause tissue damage. The major mediators involved in vascular changes, cell recruitment, and tissue damage in the acute inflammatory response are listed in Table 16.2.

CGRP, Calcitonin gene–related peptide; *fMLP,* formyl-methionyl-leucyl-phenylalanine; *ICAMs*, intercellular adhesion molecules; *IL,* interleukin; *LPS,* lipopolysaccharide; *PAF,* platelet activation factor; *PECAM*, platelet endothelial cell adhesion molecule; *NK cell,* natural killer cell; *TNF,* tumor necrosis factor; *VCAM*, vascular cell adhesion molecule.

Data from Kumar V, Abbas AK, Fausto N, et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders; Slauson DO, Cooper BJ: *Mechanisms of disease*, ed 3, St Louis, 2002, Mosby; Majno G, Joris I: *Cell, tissues, and disease*, ed 2, Oxford, 2004, Oxford University Press; Abbas AK, Lichtman, Pober JS: *Cellular and molecular immunology*, ed 5, Philadelphia, 2003, Saunders.

All listed inflammatory mediators have been shown to be present in apical periodontitis.[289,290] Bradykinin is the product of kinin-system activation; fibrinopeptides, the products of blood-clotting system activation; and fibrin degradation products, the products of fibrinolytic-system activation. Kinin, fibrinolytic, and clotting systems are initiated by activated Hageman factor (coagulation factor XII). Prostaglandins and leukotrienes are the products of arachidonic acid metabolism. Activated phospholipase A2 splits cell membrane phospholipid molecules into arachidonic acid and platelet activating factor. Arachidonic acid molecules can be processed along two pathways: the cyclooxygenase pathway, which leads to production of prostaglandins and thromboxanes, and the lipoxygenase pathway, which produces leukotrienes.[141,171]

Complement components, such as C3a, C3b, C5a, C5b, and C5–C9, are products of the complement cascade, which can be activated by two pathways. The classic pathway is initiated by activation of C1 by multimolecular aggregates of IgG or IgM antibody complexed with specific antigen. The alternate pathway is activated by microbial cell components (LPS, teichoic acid) and plasmin. C3a and C5a are anaphylatoxins that stimulate mast cells and basophils to release histamine. They also cause phagocytes to release lysosomal enzymes. C3b is an opsonin and can coat

Telegram: @dental_k

www.konkur.in

bacteria to enhance phagocytosis by phagocytes. In addition, C3b can also bind to antibody bound to antigen or microbes. C5a is a strong chemotaxin for neutrophils. C5b-C9 is a membrane attack complex and able to cause cell lysis if activated on the host cell and bacterial cell membrane.[141,171]

Besides inflammatory mediators, the inflammatory response is also dependent upon the timing and extent of various cytokine and chemokine secretions. IL-1, TNF, IL-6, IL-12, and IFN-γ are present in the acute inflammatory response.[1,94] IL-6 is produced by activated mononuclear phagocytes, endothelial cells, and fibroblasts in response to microbial infection and other cytokines, such as IL-1 and TNF. IL-6 stimulates the synthesis of acute-phase proteins by hepatocytes.[1] The major source of IL-12 is activated mononuclear phagocytes and dendritic cells. IL-12 provides a link between innate and adaptive immune responses.[1] IFN-*r* is produced by activated NK cells, T_H1 cells, and cytotoxic T cells and can activate macrophages and enhance their microbial killing ability. IL-1β and TNF are associated with apical bone resorption during chronic apical periodontitis.[263]

Chemokines are a large family of structurally homologous cytokines that stimulate leukocyte movement and regulate the transmigration of leukocytes from the blood vessel to tissue space.[1] They are produced by leukocytes, endothelial cells, and fibroblasts. The secretion of chemokines is induced by microbial infection, TNF, and IL-1.[1,94,249] Different types of leukocytes express different chemokine receptors.[1]

Neuropeptides are released via axon reflexes of afferent sensory neurons in response to various stimuli. Neuropeptides, as mediators of the inflammatory process, are described in detail in the Neurogenic Inflammation section of this chapter. Inflammatory mediators such as histamine, kinins, prostaglandins, and proinflammatory cytokines are capable of sensitizing and activating sensory nerves to release neuropeptides.[32,100,221,235]

Histopathology

The acute inflammatory response is practically immutable in all vascularized living tissues, largely due to the programmed actions of the innate immune system. Initially, blood vessels are engorged by a local infiltration of inflammatory cells, mainly activated neutrophilic leukocytes and some

Telegram: @dental_k

www.konkur.in

macrophages in the apical periodontal ligament of the infected/inflamed root canal. In addition, sprouting of sensory nerve fibers has been shown early in the inflamed periapical tissues.[42,131] Several studies have also demonstrated the presence of inflamed vital pulp tissue with intact nerve fibers in the apical portion of the root canal in association with apical periodontitis.[159,222,223,321] This explains the clinical observation that a patient may experience some pain if an instrument is introduced into the canal short of the apex in some teeth with apical periodontitis lesions. Acute apical periodontitis with abscess formation may show localized collection of dead and live neutrophilic leukocytes, disintegrating tissue cells, and dead and live pyogenic pathogens (Fig. 16.3).

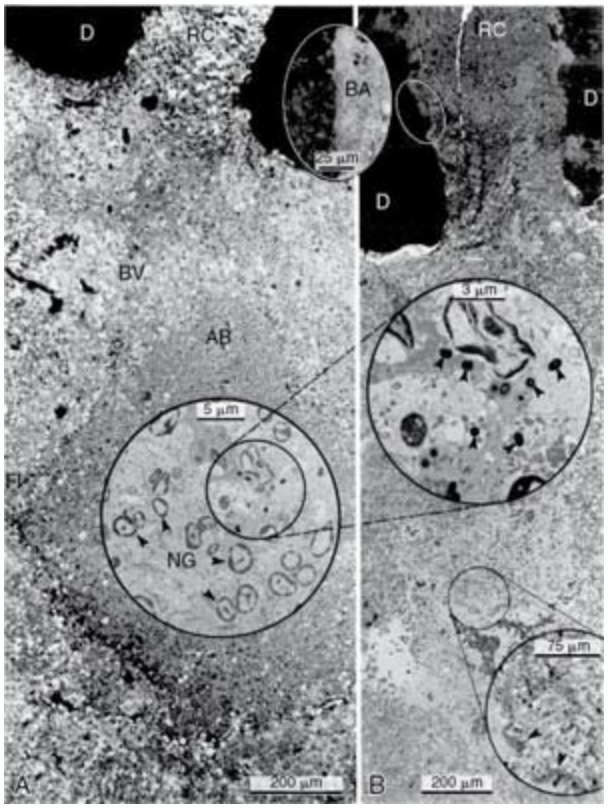

FIG. 16.3 Structure of a secondary periapical abscess. **A,** Axial section of an abscessed apical periodontitis. The microabscess *(AB)* contains a focus of neutrophils (*NG* inset in **A**). Note the phagocytosed bacteria in one of the neutrophils (further magnified in large inset in **B**). A secondary abscess forms when bacteria (*BA* in oval inset) from the apical root canal *(RC)* advance into the chronic apical periodontitis lesion (**B**). lower inset). BV, Blood vessels; *D,* dentin. (**A,** Magnification: ×130; **B,** magnification: ×100; oval inset, magnification: ×400; inset in **A**, magnification: ×2680; upper inset in **B**, magnification: ×4900; lower inset in **B**, magnification: ×250.)

A) Electron micrograph depicted on the scale of 200 micrometers shows D, RC, inset of BA, AB, and NG. NG has irregular and oval shaped cells. NG and BA are depicted on the scale of 5 and 25 micrometers, respectively.

B) Electron micrograph depicted on the scale of 200 micrometers shows two insets. The first inset, NG, on the scale of 3 micrometers has large irregular structure with a nucleus in it along with small circular and oval cells in the surrounding. Another inset depicted on the scale of 75 micrometers has normal cells.

Source: (From Nair PNR: Apical periodontitis: a dynamic encounter between root canal infection and host response, *Periodontol 2000* 13:121, 1997.)

In primary acute apical periodontitis, apical bone destruction is usually not observed by conventional periapical radiography because the duration of acute response is short, and activated neutrophilic leukocytes and macrophages are not able to resorb bone. Only osteoclasts are capable of resorbing bone, and they have to differentiate from bone marrow mesenchymal stem cells. However, in a rat model experiment, Stashenko and colleagues[266] showed histologically that periapical inflammatory cell infiltration increases osteoclast numbers, and that bone destruction was apparent well in advance of total pulpal necrosis. Bacteria are usually not present in acute apical periodontitis lesions.

Clinical features

As discussed earlier, there is no correlation between clinical and radiographic findings and histologic appearance of inflammatory periapical disease. Teeth with acute apical periodontitis are usually symptomatic and painful to bite and percussion, which results from mechanical allodynia and hyperalgesia.[99,128] Pain is induced by sensitization and activation of nociceptors of sensory nerve fibers by inflammatory mediators, proinflammatory cytokines, nerve growth factor, and pressure.[99,128] Sprouting of sensory nerve fibers in inflamed periapical tissues could also increase receptive field size in teeth with apical periodontitis.[41,42] If acute

Telegram: @dental_k

www.konkur.in

apical periodontitis is associated with abscess formation, intraoral or extraoral swelling may develop. Radiographic examination usually does not show periapical bone destruction of the involved tooth in acute apical periodontitis, although occasional slight widening of the apical periodontal ligament space and loss of the apical lamina dura of the involved tooth may be present.

Outcomes

The fundamental purpose of the acute inflammatory response is to restore the structural and functional integrity of damaged tissue by eliminating irritants as soon as possible.[141,171,310] Tissue damage can also occur in acute inflammation by release of lysosomal enzymes, toxic oxygen radicals, and nitric acid from disintegrated neutrophilic leukocytes and macrophages into tissue.[171] Depending on the dynamic interaction between host defenses and microbial insults, acute apical periodontitis can result in (1) restitution of normal periapical tissues if irritants are immediately eliminated by root canal therapy, (2) abscess formation if massive invasion of periapical tissues by highly pyogenic pathogens occurs, or (3) progression to chronic apical inflammation if irritants continue to persist.

If purulent exudate in apical abscess can be evacuated through the root canal (or through incision and drainage when indicated) during root canal therapy, the patient usually experiences an immediate relief of acute pain. In most cases, if the source of infection in the root canal is eliminated by root canal therapy, the abscess will heal by reabsorption of the pus by periapical tissues. Phagocytes will kill bacteria in the abscess. The continued influx of leukocytes stops because the chemotactic stimuli have been removed, and the existing neutrophilic leukocytes die of apoptosis. Finally, macrophages move in to clean up necrotic neutrophilic leukocytes and disintegrated tissue cells. However, if bacterial virulence and numbers of pathogens overwhelm the host's defenses, the abscess may break through the cortical bone, periosteum, and oral mucosa or facial skin to develop an intraoral or extraoral draining sinus tract. Sometimes, the uncontrolled abscess may spread along the fascial planes of the face and neck to develop serious cellulitis (see also Chapter 19).[147,240]

Chronic apical periodontitis

If pathogens in the root canal are not eliminated, the acute apical periodontitis may progress to become a chronic apical periodontitis. Chronic apical periodontitis is characterized by the persistence of inflammatory stimuli, adaptation of the host's response to stimuli, presence of adaptive immune responses, and initiation of the repair process.[141,171,259,310] Chronic inflammation is good news and bad news. The good news is that the host's defenses are able to maintain an active defense against the invading microorganisms and toxins; the bad news is that the host response is inadequate to eliminate these factors.[171]

Chronic apical periodontitis is a form of adaptive immune response that requires exquisite specificity and memory. The adaptive immune response enhances bacterial killing compared with the innate immune response. Traditionally, the terms *chronic apical periodontitis* and *periapical granuloma* are used interchangeably. A granuloma is a focal area of *granulomatous inflammation*, which is a histologic term for a chronic inflammatory reaction.[141,171,305] Granulomatous inflammation is characterized by the presence of activated macrophages with modified epithelioid cells in diseases such as tuberculosis, leprosy, syphilis, cryptococcosis, sarcoidosis, rheumatic fever, and foreign body granuloma.[104,141,171,315] The presence of poorly digestible irritants (nonantigenic or antigenic), T cell–mediated immunity to irritants, or both appears to be necessary for granuloma formation.[1,141,171] A granuloma is relatively avascular,[141,171] whereas a chronic apical periodontitis is very vascular. Histologically, some but not all chronic apical periodontitis lesions may show some features of granulomatous inflammation,[141,171] so the terms *apical granuloma* and *chronic apical periodontitis* should not be used interchangeably. A *granuloma* is best considered a histologic term used to describe a specific form of chronic inflammation such as foreign body granuloma or immune granuloma.[141,171]

The foreign body reaction is a specific subtype of chronic inflammation.[141,171,310] Foreign materials such as root canal filling materials, paper points, cotton fibers, and surgical sutures can trigger a foreign body giant cell granuloma.[136,193,324] If activated macrophages are unable to engulf

Telegram: @dental_k

www.konkur.in

large indigestible foreign particles, they can fuse to form giant cells on the surface of the particles and continuously release lysosomal enzymes, inflammatory mediators, and proinflammatory cytokines as a result of frustrated phagocytosis. Giant cells appear to be at least as active metabolically as a regular macrophage.[171] In addition, foreign bodies can favor infection in several ways, as they can be a source of bacterial biofilm[54,203] and they lower the infectious dose of bacteria to induce infection. For example, if a small, sterile plastic cage is implanted under the skin of a guinea pig, as few as 100 *S. aureus* are sufficient to infect the tissue, whereas even 10^9 bacteria (i.e., a million-fold increase in dose) fail to produce an abscess in normal guinea pig skin.[326] Finally, foreign bodies can make the infection hard to treat because bacteria in biofilms can switch on appropriate genes and cover themselves with a thick layer of biopolymer that is resistant to both host defense mechanisms and antimicrobial agents.[121,171]

Cell biology

Macrophages and lymphocytes

Macrophages and lymphocytes are the primary players in asymptomatic apical periodontitis.[4,55,82,125,135,269,270,291,323] Lymphocytes are blood-borne and have counterparts in the connective tissue.[171] Macrophages play a dual role in host defenses. In the innate immune response, activated macrophages phagocytose microbes, dead cells, and foreign bodies and produce inflammatory mediators and proinflammatory cytokines to enhance the host defense against stimuli. In the adaptive immune response, activated macrophages function as APCs. They phagocytose and present the processed foreign antigens in association with MHC to T cells. Thus, activated macrophages are effector cells of adaptive immune response.

Lymphocytes are the only cells in the body capable of specifically recognizing and distinguishing different antigenic determinants; they are responsible for the two defining characteristics of the adaptive immune response: specificity and memory. The functions of lymphocytes were described earlier in the section on the adaptive immune response.

Dendritic cells

Telegram: @dental_k

www.konkur.in

Dendritic cells play a vital role in asymptomatic apical periodontitis. They have been shown to be present in apical periodontitis lesions in rats.[123,208] Dendritic cells are accessory immune cells derived from bone marrow hematopoietic stem cells and may be related to the mononuclear phagocyte lineage.[1] They function as APC for naive T lymphocytes and are important for the initiation of adaptive immune responses to protein antigen.[1] Activated dendritic cells produce IL-12, which is a key inducer of cell-mediated immunity.

Osteoclasts

Periapical bone destruction is a hallmark of asymptomatic apical periodontitis. During the chronic stage of apical periodontitis, both osteoclast and osteoblast activity decrease,[308] so the periapical osteolytic lesion remains stationary. Based on magnified radiographic and automated image analysis, periapical bone destruction was observed at 7 days after the pulps of experimental teeth were exposed to oral microorganisms in animal studies. A period of rapid bone destruction took place between 10 and 20 days, with slower bone resorption thereafter.[308] The stationary phase of bone resorbing activity was correlated to asymptomatic apical periodontitis.[308] Increased expression of bone resorptive cytokines such as IL-1, IL-6, and TNF was related to the period of active bone resorption.[309] T_H cells appear to outnumber T_S cells during the active stage of periapical bone destruction in induced rat periapical lesions, but T_S cells dominate T_H cells during the stationary stage of bone destruction.[267]

Bone resorption is caused by osteoclasts and involves a cross-talk among osteocytes, osteoblasts, and osteoclasts.[215] The formation of osteoclasts involves differentiation of the osteoclast precursors from mesenchymal stem cells in bone marrow. Several cytokines and growth factors, such as granulocyte/macrophage colony-stimulating factor (GM-CSF), RANKL (receptor activator of nuclear factor κB ligand), osteoprotegerin (OPG), IL-1, IL-6, TNF, as well as prostaglandins, bradykinin, kallidin, and thrombin, have been shown to mediate osteoclast progenitor cell differentiation.[27,43,68,152,157,186,215,216,283] Parathyroid hormone is capable of stimulating osteoblasts to synthesize GM-CSF and RANKL. Bone stromal

Telegram: @dental_k

www.konkur.in

cells and T cells also produce RANKL. Osteoclast progenitor cells express receptor activator of nuclear factor κB (RANK). Osteoprotegerin (OPG), a decoy receptor for RANKL secreted by osteoblasts, negatively regulates the differentiation of osteoclasts by absorbing RANKL and reducing its ability to activate the RANK pathway.[129,215] RANKL activates the RANK pathway on osteoclast progenitor cells, resulting in differentiation of these cells along the osteoclast lineage. Proinflammatory cytokines, IL-1, TNF, and IL-6 also mediate the differentiation of osteoclast progenitor cells to osteoclasts. The differentiation of the mononuclear osteoclast progenitor cells terminates with fusion to latent multinucleated osteoclasts, which are finally activated to become bone-resorbing osteoclasts. The mature osteoclasts then attach to mineralized bone surface after osteoblasts have primed the unmineralized bone surface and released chemotactic factor to attract osteoclasts.[196,215] Osteoclasts attach to bone by the vitronectin receptor (integrin superfamily), expressed preferentially in the sealing zone. Vitronectin has binding sites for the arginine-glycine-aspartic amino acid (RDG) sequences present in many ECM proteins, including osteopontin, bone sialoprotein, and fibronectin, on the surface of the exposed mineralized bone.[84] When bound to bone ECM, osteoclasts develop a ruffled border. Inside the ruffled border, osteoclasts use ATP to drive H^+ pumps, leading to the acidification of the extracellular compartment. They subsequently secrete proteolytic lysosomal enzymes and carbonic anhydrase to degrade both the mineralized and unmineralized components of bone.[18,20,31,283] (See Fig. 16.5 for the mechanism of bone resorption by osteoclasts in apical periodontitis.)

The resorption of root cementum or dentin in apical periodontitis lesions is less well understood than resorption of bone. Bone is constantly remolding (resorption and deposition) through physiologic and functional processes and thus is much easier to study. In contrast, cementum and dentin are more stable. The cells responsible for dental hard-tissue resorption are called *odontoclasts*.[229] It has been shown in ultrastructure and gene expression studies that odontoclasts and osteoclasts are similar.[230,231] Therefore, it is believed that the cellular mechanisms of bone, cementum, and dentin resorption are similar.[231] Nevertheless, little is known about how the precursors of the odontoclasts appear and what causes odontoclast differentiation and activation to resorb dentin and cementum. Bone resorption

Telegram: @dental_k

www.konkur.in

by osteoclasts in apical periodontitis is illustrated in Fig. 16.4.

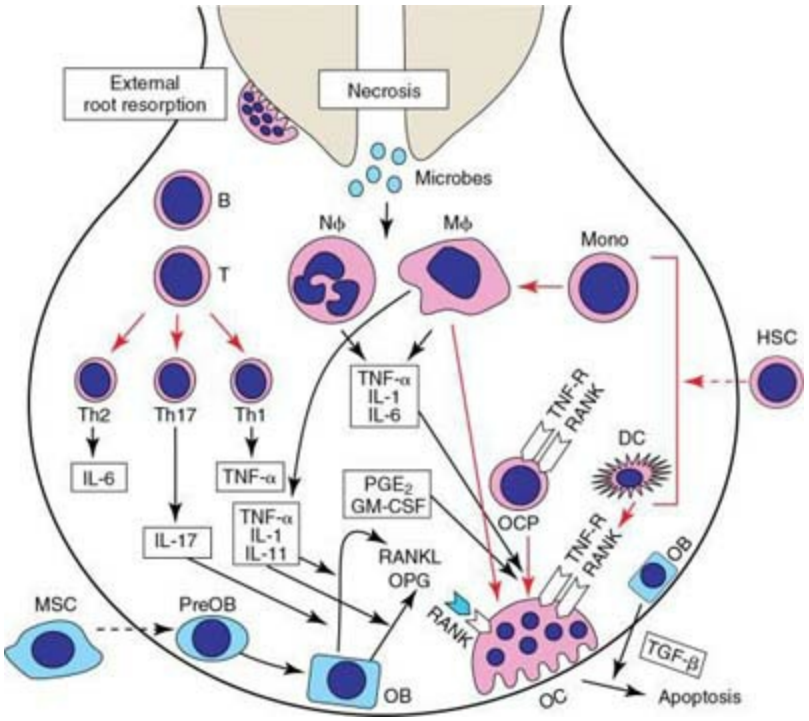

FIG. 16.4 Bone resorption by osteoclasts in apical periodontitis. *DC,* Dendritic cell; *GM-CSF,* granulocyte/monocyte colony-stimulating factor; *HSC,* hematopoietic stem cell; *IL*, interleukin; *Mφ,* macrophage; *MSC,* mesenchymal stromal cell; *Nφ,* neutrophil; *OB,* osteoblast; *OC,* osteoclast; *OCP,* osteoclast precursor; *OPG,* osteoprotegerin; *PGE,* prostaglandin E; *RANK,* receptor activator of nuclear factor κB; *RANKL,* receptor activator of nuclear factor κB ligand; *TGF*-β, transforming growth factor-β; *TNF*, tumor necrosis factor.

The process of bone resorption is as follows:

Microbes from necrosis lead to N phi and M phi, which leads to TNF-alpha, IL-1, IL-6. They along with PGE sub 2, GM-CSF, TNF-R and RANK in OCP as well as DC, lead to OC. OC and OB in the presence of TGF-beta cause apoptosis. HSC leads to mono and DC. Mono further leads to M phi. Two cells on the left below the text external root resorption, B and T, lead to Th2, Th17, and Th1. Th2 further leads to IL-6, Th17 further leads to iL-17, and Th1 leads to TNF-alpha. IL-17 along with TNF-alpha, IL-1, and IL-11 collectively leads to RANKL and OPG from OB. MSC leads to PreOB further leads to OB.

Epithelial cell rests of malassez

ERM are present in the periodontal ligament of all teeth. Proliferation of ERM is evident in approximately 52% of inflammatory periapical lesions collected from extracted teeth.[192] It is a form of pathologic (inflammatory) hyperplasia. This type of hyperplasia is caused by stimulation of growth factors and cytokines produced during the inflammatory response. Hyperplasia is a self-limiting process and is reversible when the causative stimulus is eliminated.[141,171,259] During periapical inflammation, innate and adaptive immune cells and stromal cells (e.g., activated macrophages, neutrophilic leukocytes, NK cells, T cells, fibroblasts) in the periapical tissues produce many inflammatory mediators (e.g., prostaglandin, histamine), proinflammatory cytokines (e.g., IL-1, IL-6, TNF), and growth factors (e.g., PDGF, EGF, keratinocyte growth factor [KGF], FGF). These inflammatory mediators, proinflammatory cytokines,[38,49,90,179,233] and growth factors[81,114,165,183,204,287] are capable of stimulating epithelial cell rests to proliferate (Fig. 16.5). The extent of cellular proliferation appears to be related to the degree of inflammatory cell infiltration.[222,223]

proliferation of epithelial cell rests in apical periodontitis. *EGF,* Epidermal growth factor; EO, eosinophil; *ERM*, epithelial cell rests of Malassez; *FGF,* fibroblast growth factor; *KGF*, keratinocyte growth factor; *IGF,* insulin-like growth factor; *IL*, interleukin; *Mφ,* macrophage; *OC,* osteoclast; *PMN,* polymorphonuclear leukocyte; *TGF,* transforming growth factor; *TNF*, tumor necrosis factor.

Radiograph shows a large dark patch under the tooth. An enlarged view of the dark patch has fibroblast under OC. Fibroblast in the presence of KGF, EGF, and IGF leads to ERM. M phi (IL-1, TNF, PGs, TGF), TH2 (IL-6), EO (TGF-alpha), and TH1 (TNF) also lead to ERM. The lower right corner has PMN.

Source: (From Lin LM, Huang GT-J, Rosenberg P: Proliferation of epithelial cell rests, formation of apical cysts, and regression of apical cysts after periapical wound healing, *J Endod* 33:908, 2007.)

Fibroblasts

Fibroblasts are important cells in chronic inflammation and wound healing. They are derived from undifferentiated mesenchymal cells and exist in all connective tissues. They synthesize and secret proteoglycans, glycoproteins, and precursor molecules of various types of collagens and elastin.[126] In chronic inflammation, fibroblast migration and proliferation are triggered by multiple growth factors (TGF-β, PDGF, EGF, FGF) and the fibrogenic cytokines, IL-1 and TGF-α, produced by activated platelets, macrophages, endothelial cells, and inflammatory cells.[141,171] In turn, activated fibroblasts produce an array of cytokines such as IL-1, IL-6, and GM-CSF, which influence leukocyte development. Fibroblasts stimulated by inflammation also produce matrix metalloproteinase to degrade the proteins that comprise the ECM.[171,298]

Fibrovascular granulation tissue is also a prominent feature of chronic apical periodontitis as a repair process. Migration and proliferation of endothelial cells from preexisting capillaries and venules into the site of chronic inflammation is called *neovascularization*. It is mediated by angiogenesis factors, such as vascular endothelial growth factor (VEGF) and TGF-β, produced by activated macrophages, platelets, and endothelium.[171,259] Neovascularization supplies oxygen and nutrients for the support of metabolically active macrophages and fibroblasts during wound healing.

Telegram: @dental_k

www.konkur.in

Inflammatory mediators

Many inflammatory mediators present in symptomatic apical periodontitis are also expressed in asymptomatic apical periodontitis. In addition, several different cytokines and growth factors are secreted by cells such as activated macrophages, lymphocytes, dendritic cells, and fibroblasts, in the chronic/adaptive inflammatory response described earlier.

Histopathology

Macrophages and lymphocytes are predominant cells in asymptomatic apical periodontitis lesions (Fig. 16.6). Occasionally, foamy macrophages and giant cells are seen, especially associated with cholesterol crystal deposits, which are products of disintegrated cell membranes. Cholesterol crystals are present in approximately 18% to 44% of all apical periodontitis lesions.[36,297] Bone resorption is a hallmark of asymptomatic apical periodontitis. Multinucleated osteoclasts may sometimes be seen in resorptive Howship lacunae. Proliferation of epithelial cell rests is often present in asymptomatic apical periodontitis lesions. ERM proliferate in three dimensions and form irregular strands or islands of epithelium, which are often infiltrated by varying degrees of inflammatory cells (see Fig. 16.6, *B*). A key feature of asymptomatic apical periodontitis is a proliferation of fibrovascular granulation tissue that is an attempt to prevent further spread of infection/inflammation and to repair wounded periapical tissues.

www.konkur.in

periodontitis. Using a scanning electron microscope, Simon and associates[252] observed that projections, depressions, and fibers of cementum were haphazardly arranged in root canal infection under scanning electron microscopy. There was an increase of mineralized projections, cementum lacunae, and surface resorptions and a decrease in fibers. All these changes may provide a more favorable condition for attachment of bacterial biofilm on the apical external root surface in extraradicular infection.

It is a general belief that asymptomatic apical periodontitis lesions are usually devoid of innervation, so local anesthesia may not be necessary if teeth with asymptomatic apical periodontitis require root canal therapy. However, light and transmission electron microscopic studies have demonstrated that teeth with chronic apical periodontitis were well innervated (Fig. 16.7).[158,174] This explains why instruments accidentally introduced into inflamed periapical tissues without local anesthesia can cause the patient pain.

External root resorption that involves cementum or both cementum and dentin usually occurs in asymptomatic apical periodontitis lesions.[148,303] Fortunately, cementum and dentin appear to be less readily resorbed than bone by inflammatory processes.[95] However, the radiographic presence of root "blunting" should be interpreted by the astute clinician as evidence for resorption of dentin and cementum, and the working length of the instrumentation and obturation phases of nonsurgical endodontic treatment should be adjusted by a corresponding amount.

Using light and transmission electron microscopy and microbiologic culturing, bacteria have been shown to be present in many asymptomatic apical periodontitis lesions.[2,117,296,311] Inadvertent contamination is a major concern when culturing bacteria from these lesions. Under meticulous transmission electron microscopic examination, Nair[189] was unable to observe bacteria in most asymptomatic apical periodontitis lesions. If bacteria are present in the inflamed periapical tissues, they are usually found inside the phagocytes (Fig. 16.8).[159] Importantly, the mere presence of bacteria in the inflamed periapical tissues (colonization) does not necessarily imply periapical infection. Bacteria have to be able to establish an infectious process, such as survival and tissue destruction, in the inflamed periapical tissues to be considered as etiologic factors for the resulting infection. Most apical periodontitis lesions are not infected; nonsurgical root canal therapy of teeth with apical periodontitis can achieve a high success rate, provided root canal infection is controlled.

Clinical features

Involved teeth are usually asymptomatic and show an ill-defined or well-defined periapical radiolucent lesion radiographically. Chronic apical periodontitis lesion with abscess formation always shows a draining sinus tract. Occasionally, the sinus tract from an apical abscess may drain along the root surface and opens into the gingival sulcus. This leads to the development of a deep, narrow pseudopocket that often mimics a periodontal pocket or a vertical root fracture (see Chapter 25 for details).

Outcomes

Chronic apical periodontitis may result in (1) regeneration or repair of the periapical tissues after root canal therapy, (2) acute exacerbation, (3)

Telegram: @dental_k

www.konkur.in

development of an abscess with an intraoral or extraoral draining sinus tract, or (4) development of a serious cellulitis.

Chronic apical periodontitis with cyst formation

The radicular cyst is unique because no cysts in the body have similar pathogenesis. It is believed that the radicular cyst is likely formed by inflammatory proliferation of epithelial cell rests in the inflamed periodontal ligament in chronic apical periodontitis lesions.[163,195,206,285] The radicular cyst is a pathologic cavity completely lined by nonkeratinized stratified squamous epithelium of variable thickness in a three-dimensional structure in an apical periodontitis lesion. A radicular cyst can be a “pocket cyst” (i.e., attached to the apical foramen) or a “true cyst” (no attachment to the root structure),[191,251] but it cannot form by itself. Therefore, a radicular cyst should not be considered a separate disease entity from chronic apical periodontitis. A radicular cyst (pocket or true) is classified as an inflammatory and not an abnormal developmental or a neoplastic lesion in the WHO *Histological Typing of Odontogenic Tumors, Jaw Cysts and Allied Lesions*.[139] The prevalence of radicular cysts in apical periodontitis lesions from extracted teeth ranges from 15% to 20%.[192]

Cell biology

In addition to the presence of all chronic inflammatory cells, the epithelial cells are the most prominent cell type found in chronic apical periodontitis with cyst formation. ERM can be considered unipotent or restricted-potential stem cells. They can be stimulated to divide symmetrically and asymmetrically into basal cells (stem cells) and suprabasal squamous cells of lining epithelium of radicular cysts.[163] Many theories about apical cyst formation have been proposed. The nutritional deficiency theory assumes that when islands of epithelium keep growing, the central cells of the epithelial island will move farther away from their source of nutritional supply and undergo necrosis and liquefaction degeneration. The products accumulated attract neutrophils and granulocytes into the necrotic area. Microcavities then

Telegram: @dental_k

www.konkur.in

coalesce to form a cyst cavity lined by stratified squamous epithelium.[285] The abscess theory postulates that when an abscess is formed in connective tissue, epithelial cells proliferate and line the abscess cavity because of their inherent tendency to cover exposed connective-tissue surface.[195,206] The theory of merging of epithelial strands proposes that proliferating epithelial strands merge in all directions to form a three-dimensional sphere-like structure composed of fibrovascular connective tissue, with varying degrees of inflammatory cells trapped, that gradually degenerates due to lack of blood supply. This leads to formation of a cyst cavity.[163] Regardless of how a radicular cyst (pocket or true) is formed, it is likely caused by inflammatory proliferation (hyperplasia) of epithelial cell rests in the apical periodontitis lesions.

It has been speculated that radicular cyst expansion is caused by increased osmotic pressure in the cyst cavity,[288] but this hypothesis overlooks the cellular aspects of cyst growth and the biochemistry of bone destruction.[75,179] Radicular cyst expansion is likely caused by degradation of fibrous connective tissue capsule by MMPs, which are produced by activated neutrophils, fibroblasts, and macrophages[286] and bone resorption. The ERM have also been shown to be capable of secreting a bone resorbing factor.[28] Most inflammatory mediators and proinflammatory cytokines that stimulate proliferation of epithelial cell rests also mediate bone resorption in apical periodontitis lesions.

Inflammatory mediators

Mediators are basically similar to those present in chronic apical periodontitis.

Histopathology

Two types of cysts have been described in chronic apical periodontitis lesions. The pocket cyst's lumen opens into the root canal of the involved tooth (Fig. 16.9).[191,192,251] The true cyst is completely enclosed by a lining epithelium, and its lumen has no communication with the root canal of the involved tooth (Fig. 16.10).[191,192,251] Apical cysts are lined by hyperplastic, nonkeratinized stratified squamous epithelium of variable thickness, which is

Telegram: @dental_k

www.konkur.in

separated from the fibrovascular connective tissue capsule by a basement membrane. Both the lining epithelium and the connective tissue capsule are usually infiltrated with inflammatory cells,[224,245] indicating that inflammatory cells are attracted to these tissues by chemotactic irritants, either in the root canal system or in the periapical tissues. In nonproliferating epithelium, there is less inflammatory cell infiltration.[47,240] Occasionally, mucous cell metaplasia or ciliated respiratory-type cells are present in cystic epithelial lining.[201] The epithelial cells of lining epithelium do not show any characteristic features of neoplastic changes, such as pleomorphism, lack of polarity, nuclear enlargement, large nucleoli, abnormal nuclear/cytoplasmic ratio, hyperchromatism, or abnormal mitosis. Unlike odontogenic keratocysts and calcifying odontogenic cysts, the basal cells of radicular cystic lining epithelium are incapable of proliferation by themselves without stimulation of growth factors or cytokines released by innate and adaptive immune cells during periapical inflammation. The lumen of cysts may contain inflammatory exudates, cholesterol crystals, clear fluid, or bacterial colonies (Figs. 16.11 and 16.12).[192,224]

Clinical features

The involved tooth is usually asymptomatic. Periapical osteolytic lesions of endodontically involved teeth may sometimes show a well-demarcated radiolucency surrounded by a rim of radiopaque border radiographically.

Outcomes

There is no direct evidence demonstrating whether chronic apical periodontitis with cyst formation (pocket and true) can or cannot regress after nonsurgical root canal therapy. Unfortunately, apical cysts cannot be diagnosed clinically and can only be diagnosed after surgical biopsy or extraction of teeth with apical periodontitis. Clinical outcome studies have shown that after proper nonsurgical root canal therapy, teeth with apical periodontitis lesions heal in 78% of cases.[258] Therefore, it is speculated that some cysts, especially pocket cysts, may heal after nonsurgical root canal therapy.[191] Apical true cysts are less likely to heal after nonsurgical root canal therapy because of their self-sustaining nature; surgical intervention is necessary.[191] Nonetheless, similar to the periapical pocket cyst, a periapical true cyst is also formed within an apical periodontitis lesion and is not a

Telegram: @dental_k

www.konkur.in

neoplastic lesion. Any disease caused by inflammation/infection should be able to heal if the causative irritant/irritants are removed, unless the irritant/irritants are neoplasm-inducing agents or a carcinogen.

Chronic apical periodontitis with reactive bone formation: Focal condensing osteitis

Chronic apical periodontitis with reactive bone formation is analogous to chronic osteomyelitis with proliferative periostitis. The etiology and pathogenesis of these two diseases are not well understood. It is generally believed that both lesions are caused by a long-term, low-grade inflammation/infection or a high resistance of local tissue to inflammation/infection.[201,218] Instead of bone resorption, the inflammation induces reactive bone formation of alveolar trabecular or spongy bone around the periapex of endodontically involved teeth.

Cell biology

As described previously, during the chronic stage of apical periodontitis, both osteoclast and osteoblast activity decrease.[308] However, in chronic apical periodontitis with reactive bone formation, osteoblasts appear to be stimulated to produce more bone. It is not clear what factor/factors stimulate osteoblasts to produce more bone mass. It could be due to increased expression of growth factors/cytokines, such as TGF-β, BMP, PDGF, and transcription factor Cbfa1 (core-binding factor family).[129]

Histopathology

There is an excessive apposition of bone mass without bone resorption in the apical area. As the bone marrow spaces become smaller and obliterated, the bone resembles compact bone that is infiltrated by a small number of lymphocytes. The compact bone has few lacunae, and many of them are empty of osteocytes. It has many prominent resting and reversal lines, similar to an idiopathic osteosclerosis or a Pagetoid appearance.[47,201,218]

Clinical features

Telegram: @dental_k

www.konkur.in

The lesion is usually observed in young patients, and the mandibular first molar is most commonly involved. The teeth often have gross carious lesions and can be vital or nonvital. They are usually asymptomatic. Radiographically, the lesion may have a well-defined or ill-defined radiopaque mass associated with the apex of an endodontically involved tooth. The lamina dura around the root apex is usually intact.

Outcomes

Most chronic apical periodontitis lesions with reactive bone formation demonstrate healing after nonsurgical root canal therapy. The excessive compact bone in most cases will be remodeled to normal appearance.[72]

Periapical lesions of nonendodontic origin

Many periapical lesions are not of endodontic origin and should be considered in the differential diagnosis of apical periodontitis. These lesions include (but are not limited to) trauma,[11,12] foreign bodies,[136,193,324] host metabolic by-products,[194] advanced periodontal disease,[146] fibro-osseous lesions, and benign and malignant tumors.[201] A complete description of these lesions is beyond the scope of this chapter; the interested reader is encouraged to seek the cited references.

Extraradicular endodontic infection

Extraradicular endodontic infection implies that bacteria have established an infectious process outside the root canal system in the periapical area.[257,271,296] Extraradicular endodontic infection can only be diagnosed after surgical biopsy or microbiologic sampling or molecular detection of therapy-resistant periapical lesions during apical surgery. The method of sample collection should be carefully reviewed, because contamination is a problem in bacteriologic study of apical periodontitis lesions during apical surgery.

Extraradicular endodontic infection can be a part of intraradicular infection or an independent entity without an intraradicular component. To be considered an independent extraradicular infection, the presence of pathogens

Telegram: @dental_k

www.konkur.in

in the root canal system must be completely ruled out, because intraradicular bacteria pose more potential problems than extraradicular bacteria in periapical inflammation. Bacteria in the complex root canal system are well protected from root canal treatment procedures (i.e., mechanical instrumentation, antiseptic irrigation, intracanal medication), host defenses, and antimicrobial therapy because of a lack of blood circulation and areas resistant to access (e.g., isthmi; see Chapter 8). The independent extraradicular infection probably does not occur often and is usually associated with apical actinomycosis.[98,277] Bacteria have been observed as biofilm on the apical external root surface.[257,295] In addition, viruses have also been isolated from apical periodontitis lesions.[154,228,260] If microbiologic root canal cultures are not completely reliable (because bacteria may remain in the complex root canal system),[232] then interpretation of independent extraradicular infections as endodontic treatment failures should be carefully evaluated.

Although virulence and number of pathogens, and the host's immune defense mechanisms. determine whether extraradicular infection will develop or not, the development of extraradicular infection is still not fully understood. In order for planktonic pathogens to establish infection in the periapical tissues, most likely the host's immune defense mechanisms have to be compromised. What are the predisposing factors to extraradicular infection? How are planktonic bacterial cells able to evade the host's powerful defenses in order to colonize and establish an infectious process in the periapical tissues? Are all extraradicular infections resistant to nonsurgical root canal therapy? The preponderance of evidence does not support the consistent presence of an independent periapical infection in endodontic infections.

Apical periodontitis and systemic diseases

Information concerning apical periodontitis and systemic diseases is limited. Clinical and radiographic studies have shown that there is a greater prevalence of periapical lesions in diabetics than in nondiabetics.[24] Type 2 diabetes mellitus (DM) is significantly associated with an increased prevalence of apical periodontitis.[239] Other findings demonstrated that type 2

Telegram: @dental_k

www.konkur.in

diabetes is associated with increased risk of a poor response by the periradicular tissues to odontogenic pathogens.[34] In rodent models, diabetic conditions enhance the development of periradicular lesions and increase mortality.[76,116,134] Mice deficient in P/E-selectin are shown to be more prone to infection-mediated early-onset periodontal disease.[202]

Genetic polymorphisms may also play a role in the individual's response to various diseases. Haplotype analyses have indicated that a variant of the IL-1β gene was likely to be most important for early-onset periodontitis risk.[65] In a Chinese male population, it was reported that the polymorphisms of *IL1A*+4845 and *IL1B*-511 might play an important role in determining generalized aggressive periodontitis susceptibility. A possible combined effect of the polymorphism of *IL1B*-511 and smoking on this type of periodontitis susceptibility was suggested.[155] In a study on patients from Chile, the heterozygous inheritance of the *IL1B*+3954 gene was found significantly higher in periodontitis cases than in control patients. The prevalence of a positive genotype (at least one allele of the two variants present at each locus) is significantly higher in cases (26%) than in controls (10%) and significantly associated with periodontitis, irrespective of smoking status and periodontitis severity.[167] Those displaying high-producer *IL6* genotype, intermediate and high-producer *IL1B* genotypes, and low-producer *TNFA* genotype tend to exhibit symptomatic dental abscesses.[56]

Apical periodontitis was once considered a focus of infection, and the microorganisms from the focus could disseminate through blood circulation to remote parts of the body, where secondary disease occurred.[111] Even though bacteremias do occur during root canal treatment of teeth with apical periodontitis when instrumentation is carried through the apical foramen into the periapical tissues, the incidence and magnitude of bacteremias is not clinically significant for a healthy person and in fact appears to be lower than that observed by flossing.[22,61,62] Microorganisms in the blood circulation are rapidly eliminated by the host's humoral and cellular defense components within minutes.[22,62] However, bacteremia may pose a potential danger to immunocompromised patients or patients with congenital heart valve disease.[61] No good correlation between apical periodontitis and coronal heart disease and rheumatoid arthritis has been observed.[44,187] There is insufficient evidence to support that apical periodontitis could serve as a focus of

Telegram: @dental_k

www.konkur.in

infection and cause significant systemic diseases.[71,210]

Genetic and systemic disease risk factors of persistent apical periodontitis

Genetic risk factors

Genetic polymorphism in the population plays an important role in the variation of the susceptibility and development of diseases among individuals. Knowledge on the polymorphism of key genes that are involved in disease development will help us to understand and establish prevention or treatment strategies for the diseases. Because of the completion of the Human Genome Project, many advanced molecular technologies have been developed including high-throughput screening and sequencing, which further help gather the information on polymorphism in human populations. There are different types and causes of genetic polymorphisms. Single nucleotide polymorphisms (SNPs) that have a single base variation resulting from insertion or deletion of a base are considered the most common type of genetic polymorphism.[45]

Occurrence of SNP within the coding region of a gene may produce an altered protein, which may lead to altered function (termed functional SNPs). Occurrence of SNP within the promoter region of a gene may alter gene regulation, which may cause reduction/inhibition or overexpression of gene expression. Functional SNPs alter amino acid sequence or interfere with the transcriptional factor binding, whereas nonfunctional SNPs do not affect the regulation of protein expression. Many SNPs have no effect on cell function, but some could predispose people to disease or influence their response to drugs. Besides SNPs, there are single amino-acid polymorphisms (SAAPs or SAPs) of proteins, which may result from RNA editing independent of SNPs.[319]

A genetic polymorphism is defined as alleles or variants that appear in at least 1% of the population. The 1% cutoff excludes mutations that may have occurred in a single family. In most polymorphisms, one allele dominates and appears with < 99% frequency (for example, 65%) in the population. In a biallelic situation, some authors term the dominant allele as normal (N-allele

Telegram: @dental_k

www.konkur.in

or allele 1) and it occurs in < 99%, whereas the rarer allele (R-allele or allele 2) is present in >1% in the population.[237,256] It has been long known that genetic polymorphisms are associated with increased severity of inflammatory diseases.[101] Both endodontic and periodontic diseases are mainly an infectious disease caused by microbial infection. They share common features in terms of inflammation and bone resorption. Studies have implicated association of periodontitis or apical periodontitis with several gene polymorphisms such as *IL-1, IL-6, IL-8, Fc*γR, TNF receptor superfamily member 1B (*TNFRSF1B*), (selenoprotein S) *SEPS1*, and *MMPs*.[8,48,132,137,180,181,320]

It has long been observed that the proinflammatory cytokine interleukin-1 *(IL-1)* genotype is a severity factor in adult periodontal disease.[137] The specific periodontitis-associated IL-1 genotype has a variant in the *IL-1B* gene that is associated with high levels of IL-1 production. Gene polymorphism studies suggest that the frequency of *IL-1*β genotypes (*IL-1*β +3953 restriction fragment length biallelic polymorphism) is increased in patients with advanced adult periodontitis compared to early and moderate combined, and to healthy controls.[87] A more recent study showed that IL-1β levels in gingival crevicular fluid is increased with severity of disease and correlates well with clinical signs of incipient disease.[265] This suggests that some individuals, when challenged by bacterial accumulations, may respond with a higher level of inflammatory activities, therefore leading to more severe periodontitis. Both FcγRIIa (CD32) and FcγRIIIb (CD16) influence polymorphonuclear leukocyte phagocytic function and therefore their polymorphisms may also influence inflammatory disease development. It was reported that the *Fc*γR IIIb-NA2 allotype represents a risk factor for recurrence of adult periodontitis,[132] and the *Fc*γRIIIa-158V allele and possibly *Fc*γRIIIb-NA2 may be associated with severity of chronic periodontitis in a Japanese population,[133] whereas the *Fc*γRIIa-H/H131 genotype may be associated with chronic periodontitis risk (and disease severity) in Caucasian smokers.[320] *Fc*γRIIIa and *Fc*γRIIIb genotypes may impose an additional risk of periodontal bone loss in a German population.[180]

The polymorphisms of two other genes involved in inflammation, *SEPS1* and *TNFRSF1B*, have been found to be involved in determining host individual susceptibility to aggressive periodontitis, and there is the potential

Telegram: @dental_k

www.konkur.in

association between *IL-6* and *Fc*γR polymorphisms and the aggressive periodontitis in a Caucasian-Italian population.[234]

The genetic polymorphisms have been involved in the development of apical periodontitis reports. Two genetic conditions—carriage of allele H131 of the *Fc*γRIIa gene and a combination of this allele with allele NA2 of the *Fc*γRIIIb gene—have been reported to be associated with posttreatment apical periodontitis,[256] whereas polymorphism in the *Fc*γRIIIa does not influence the patient's response to endodontic treatment of teeth with apical periodontitis in a Brazilian population.[255] So far there has been only one report on *IL-1* polymorphism association with apical periodontitis in an American population.[185] In this study, patients with persistent apical periodontitis showed an increased prevalence in the genotype composed of allele 2 of *IL-1*β polymorphism when compared with those who experienced complete healing after acceptable root canal therapy (70.6% vs. 24.6%). This outcome suggests that specific genetic markers associated with IL-1β production may predict increased susceptibility to persistent apical periodontitis. An earlier paper that studied a Brazilian population did not find an association between IL1 polymorphism and persistent apical periodontitis; however, allele 1 (for *IL-1A* and *IL-1B*) was always detected higher in diseased than in healthy/healing individuals, although not statistically significant.[256] The lack of statistical difference could be due to small sample size or different population pools.

The polymorphism of the IL-8 gene, a potent chemokine that attracts neutrophils to the site of infection, has also been shown to influence the development of different forms of apical periodontitis.[8] *IL8/CXCL8-251 T* allele, which is associated with higher production of IL8/CXCL8, is also associated with a higher risk of developing acute suppurative form of apical periodontitis. *IL8/CXCL8-251 A* allele, which is associated with lower production of IL8/CXCL8, is associated with the chronic nonsuppurative form of apical periodontitis. SNP of other inflammation-associated genes, MMP2 and MMP3, also show influence on periapical lesion formation.[181] Thus, markers in MMP3 and MMP2 genes could also help predict host susceptibility to developing periapical lesions and the healing response. It is clear that genetic polymorphisms are involved in pathogenesis of apical periodontitis.[140]

www.konkur.in

Systemic disease risk factors

Many systemic diseases have been linked to periodontal disease[130,205] because they contribute to either a decreased host's resistance to infection or dysfunction in the connective tissue of periodontium, increasing patient susceptibility to immuno-inflammation-induced destruction.[16] However, the similar systemic diseases do not appear to link to apical periodontitis, possibly because periodontitis is an open lesion and apical periodontitis is a closed lesion.

DM, a systemic disease, has been well documented to be associated with a high prevalence of apical periodontitis.[24,77,116,168,173,238] DM is a chronic disorder of carbohydrate, fat, and protein metabolism, and a defective or deficient insulin secretory response.[141] Hyperglycemia is characteristic of DM and has profound effects on cell metabolisms, especially endothelial cells such as increased polyol pathway flux, increased formation of advanced glycation end products, hyperglycemia-induced activation of protein kinase C, and increased hexosamine pathway flux.[37] The tissue most frequently affected by hyperglycemia is microvasculature, whereby endothelial cells are not able to transport intracellular glucose effectively.[37] Because of damage to vasculature (atherosclerosis), blood circulation, innate and adaptive immuno-inflammatory mechanism, and phagocyte function are impaired,[37,141] thus leading to pulp necrosis and predisposition to pulpal infection and subsequent apical periodontitis.[24]

Sickle cell anemia is the prototype of hereditary globinopathies, characterized by the production of structurally abnormal hemoglobulin.[141] The red blood cells are sickle shaped. Accumulation of distorted red cells could cause vasoocclusion, which could lead to anoxia, infarcts, and necrosis of tissue.[103] The occurrence of asymptomatic pulp necrosis in clinically intact permanent teeth has been reported.[14,126,250] Pulp necrosis could predispose to pulpal infection and apical periodontitis because of a lack of defense mechanism.

Sjögren syndrome is a chronic, systemic autoimmune disorder.[201] It involves salivary glands resulting in xerostomia. The lack of salivary cleansing action predisposes the patient to dental caries. If the caries is not prevented or treated early, it would impose risk of pulpal infection and apical

Telegram: @dental_k

www.konkur.in

periodontitis.

Radiation therapy of head and neck malignant lesions is associated with a high occurrence of caries.[107] If untreated, the radiation caries could lead to pulpal infection and subsequent apical periodontitis. It has been shown that a radiation dose 66 to 72.2 Gy (gray) in the head and neck region was associated with a high prevalence of caries and apical periodontitis because of a change in microflora favorable for carious development.[106]

However, there is no clear-cut direct causation or mechanism between systemic disease risk factors and the incidence or persistence of apical periodontitis without prior caries and pulp infection.

Wound healing of apical periodontitis

Periapical wound healing after nonsurgical root canal therapy

Understanding wound healing is as important as knowing the pathogenesis of disease, because satisfactory wound healing is the ultimate goal of treatment. If we are able to understand the mechanisms of periapical wound healing, we can design treatment approaches that maximize favorable conditions for wound healing to occur, such as effective disinfection of the root canal system in nonsurgical root canal therapy, control of periapical inflammation by medication, or incorporation of growth factors in bone grafts in surgical endodontic therapy (see also Chapters 13 and 22).

Wound healing begins as soon as inflammation starts. When irritants (microbial and nonmicrobial) in the canal systems or in the periapical tissues are eliminated by nonsurgical or surgical endodontic therapy, inflammatory mediators are no longer produced in the periapical tissues because of the reduction of inflammatory cells. Inflammatory mediators already present are inactivated by the body's control mechanisms to prevent an inflammatory reaction from going unchecked. This process precedes wound healing. Although a great deal of information is known about what turns on the inflammation, relatively little is known about what turns off the inflammatory system after elimination of irritants. Examples of host antiinflammatory control mechanisms are (1) enzyme destruction of inflammatory activators;

Telegram: @dental_k

www.konkur.in

(2) natural inhibitors of inflammatory mediators (opioids, somatostatin, glucocorticoids); (3) relative balance between intracellular levels of cyclic AMP (adenosine monophosphate) and cyclic GMP (guanosine monophosphate); (4) the antiphlogistic role of histamine; (5) inhibitors of the complement system[298]; and (6) antiinflammatory cytokines, such as IL-4, IL-10, IL-13, and TGF-β.[96,199] In addition, the major cellular inducer of inflammation, neutrophilic leukocytes, undergo apoptosis,[92] and the major cellular player of wound healing, macrophages, secrete antiinflammatory molecules such as lipoxins, resolvins, and protectins.[141,171,199]

The process of wound healing is tightly regulated by cell-to-cell cross-talk, cell-to-ECM interactions, and cell surface receptors, as well as the temporal and spatial expression of a variety of cytokines, growth factors, and neuropeptides and apoptosis (Table 16.3).[32,89,92,268,313] All these cellular and humoral factors operate together in either an antagonistic or synergistic manner and are precisely orchestrated during wound healing. This results in a highly organized response permitting regeneration of the original tissue architecture. Wound healing appears to be a programmed event. Much information concerning the pathogenesis of apical periodontitis has been gained from animal studies.[78,122,292] Although studies of wound healing of teeth with apical periodontitis after nonsurgical root canal therapy and endodontic surgery are available in a few animal experiments and a human study,[13,150,151] no studies of wound healing of apical periodontitis lesions with cyst formation after nonsurgical root canal therapy exist in the literature.

Table 16.3

Important Growth Factors/Cytokines in Wound Healing

Cytokines	Major Source	Target Cells and Major Effects
EGF	Macrophages, platelets, fibroblasts	Epithelial cells, fibroblasts, endothelial cells
FGF	Macrophages, endothelial cells	Endothelial cells (angiogenesis), mesenchymal cells
TGF-α	Macrophages, platelets, keratinocytes	Angiogenesis, fibroblasts

Telegram: @dental_k

www.konkur.in

TGF-β	Macrophages, platelets	Similar to EGF
PDGF	Macrophages, platelets, endothelial cells	Chemoattractant for macrophages, fibroblasts
VEGF	Macrophages, epithelial cells	Angiogenesis
IGF	Fibroblasts, epithelial cells	Granulation tissue formation, reepithelialization
CSF	Multiple cells	Macrophages, granulation tissue formation
SP, CGRP	Sensory nerve	Endothelial cells, fibroblasts, keratinocytes

CGRP, Calcitonin gene–related peptide; *CSF,* colony-stimulating factor; *EGF,* epidermal growth factor; *FGF,* fibroblast growth factor; *IGF,* insulin-like growth factor; *PDGF,* platelet-derived growth factor; *TGF,* transforming growth factor; *VEGF,* vascular endothelial growth factor.

Modified from Majno G, Joris I: *Cell, tissues, and disease*, ed 2, Oxford, 2004, Oxford University Press; Slauson DO, Cooper BJ: *Mechanisms of disease*, ed 3, St Louis, 2002, Mosby; Werner S, Grose R: Regulation of wound healing by growth factors and cytokines, *Physiol Rev* 83:835, 2003.

Wound healing of apical periodontitis lesions after proper nonsurgical root canal therapy follows the general principle of wound healing of connective tissues elsewhere in the body, with the formation of fibrovascular granulation tissue, removal of necrotic tissue and dead bacteria by activated macrophages, and finally repair or regeneration of the wounded tissue. Healing of apical periodontitis lesions is largely accomplished by regeneration and to some degree by repair. Local tissue resident cells involved in periapical wound healing are osteocytes, osteoblasts, and bone marrow mesenchymal stem cells in alveolar bone and stem cells in the periodontal ligament.[243] During periapical wound healing, many unwanted hyperplastic cells (e.g., endothelial cells, fibroblasts, epithelial cells) are deleted by apoptosis,[63,89,92] and the ECM is remodeled by metalloproteinases. Pathologic processes such as extensive fibrosis do not occur often, and the damaged periapical tissues can be restored mostly to their original structure by the process of regeneration.

Mesenchymal stem cells have immunomodulatory and antiinflammatory properties.[3,169,253] Recently, mesenchymal stem cells were shown to play an important role as prohealing and immunosuppressive agents in the pathogenesis of inflammatory periapical lesions.[15] During periapical

Telegram: @dental_k

www.konkur.in

inflammation, proinflammatory cytokines such as IL-1β and TNFα are capable of inhibiting osteogenic differentiation from mesenchymal stem cells.[143] However, during periapical wound healing, mesenchymal stem cells are capable of inhibiting immune response and producing antiinflammatory cytokines.[15]

The temporal and spatial relationship between alveolar bone, cementum, and periodontal ligament during periapical wound healing after nonsurgical root canal therapy cannot be clearly delineated. Nevertheless, wound healing appears to recapitulate the embryonic morphogenesis of damaged tissues or organs in many instances. The process of periapical wound healing after nonsurgical root canal therapy may be similar to wound healing following guided tissue regeneration in periodontal therapy: regeneration of new cementum, new alveolar bone, and new periodontal ligament.[70,294] Both nonsurgical root canal therapy and guided tissue regeneration therapy in periodontal disease are intended to remove irritants and provide a favorable microenvironment conducive to regeneration of periodontal tissues damaged by apical periodontitis and marginal periodontitis, respectively.

During periapical wound healing, the cells of viable periodontal ligament from adjacent root surfaces proliferate to cover the root surfaces in which the periodontal ligament was damaged by apical periodontitis and removed by macrophages. Proteins derived from the Hertwig epithelial root sheath (i.e., enamel matrix proteins) are required for cementoblast differentiation from ectomesenchymal stem cells in the dental follicle during tooth development.[262] However, the cells of the Hertwig epithelial root sheath are absent in mature teeth.[198,240] Nevertheless, the ECM and growth factors of cementum (i.e., IGF-1, FGFs, EGF, BMP, TGF-β, PDGF) sequestered after cemental resorption in mature teeth are capable of inducing proliferation, migration, attachment, and differentiation of multipotent stem cells in the periodontal ligament into cementoblast-like cells and produce cementoid tissue on the root surface denuded of periodontal ligament.[50,91,243] This is similar to reparative dentin formation by pulp stem cells in vital pulp therapy where growth factors such as TGF-β are released from dentin matrix binding sites by capping materials, such as calcium hydroxide or mineral trioxide aggregate.[197,227,300] Root resorption that involves cementum or both cementum and dentin can only be repaired by cementoid tissue, because

Telegram: @dental_k

www.konkur.in

multipotent stem cells of the periodontal ligament are incapable of differentiating into odontoblasts that produce dentin.[243]

Bone has a remarkable capacity for regeneration in response to injury. During periapical wound healing, the osteoprogenitor cells lining the surfaces of endosteum—stimulated by TGF-β, BMPs, IGFs, PDGF, VEGF, and cytokines released by stromal cells, osteoblasts, platelets, and bone matrix after bone resorption—can undergo proliferation and differentiation into osteoblasts and produce bone matrix.[7,166] The osteoprogenitor cells in the inner layer of periosteum beneath the oral mucosa—stimulated by TGF-β, BMPs, IGFs, PDGF, and VEGF—are also capable of proliferation and differentiation into osteoblasts and produce bone matrix.[126,166] If both buccal and lingual/palatal cortical bone plates are destroyed by large apical periodontitis lesions, it is possible that the lesion may be repaired with fibrous scar tissue formation because of extensive destruction of the periosteum beneath the oral mucosa.[13] Accordingly, a guided tissue regeneration procedure using membrane barriers and bone grafts may be recommended to prevent ingrowth of fibroblasts from periosteum or submucosa into the bony defect and to enhance periapical wound healing if periapical surgery is necessary.[58,59] The cellular and molecular mechanisms of excess scar tissue formation in periapical wound healing are not completely understood. Growth factors/cytokines may play an important role in regulating fibroblast gene expression and excess scar tissue formation.[299]

The newly regenerated periodontal ligament will finally undergo remodeling into a mature periodontal ligament, with one group of collagen fibers (Sharpey fibers) inserted into the newly formed cementum and another group of collagen fibers inserted into the newly formed alveolar bone. Thereby, regeneration of damaged periapical tissues, cementum, periodontal ligament, and alveolar bone is completed.

Periapical wound healing after surgical endodontic therapy

The mechanism of periapical wound healing after nonsurgical and surgical endodontic therapy is similar, but the kinetics of healing of the periapical wound after endodontic surgery is faster than nonsurgical endodontic

Telegram: @dental_k

www.konkur.in

therapy.[142] In surgical endodontic therapy, a clinician removes irritants, such as necrotic cells, tissue debris, and bacteria in the periapical lesions, which is called *surgical debridement*.[162,171] In contrast, in nonsurgical endodontic therapy, activated macrophages perform bacterial killing and cleanup of periapical lesions, which is called *biologic debridement*.[171] Surgical debridement is very effective and of course quite rapid, whereas biologic debridement takes time. Surgical treatment may result in more rapid periapical bone healing, but also may imply a higher risk of late failure compared to nonsurgical endodontic therapy.[142] However, endodontic surgery is more invasive. The distinctive difference between nonsurgical and surgical endodontic therapy is that the goal of nonsurgical endodontic therapy is to remove primary microbial etiology from the root canal system, and the goal of surgical endodontic therapy is often to seal microbial etiology within the root canal system by root-end filling in most cases (see also Chapter 22).

Can radicular cysts in apical periodontitis lesions regress after nonsurgical endodontic therapy?

Based on histology and cell biology, no studies have ever shown that apical true cysts are different from apical pocket cysts. It was suggested that pocket cysts in apical periodontitis lesions might regress after nonsurgical root canal therapy by the mechanism of apoptosis or programmed cell death, based on molecular cell biology.[163] In contrast, apical true cysts may be less likely to heal after nonsurgical root canal therapy because of their self-sustaining nature.[191] Histologically, inflammatory cell infiltration is always present in the lining epithelium or fibrous connective tissue capsule of apical true cysts.[191,223,224] This indicates there is continued presentation of irritants (such as bacteria)—present in the root canal system, the periapical tissues, or the lumen of cysts—to attract inflammatory cells to the cystic lining epithelium or fibrous connective tissue capsule.[223,224] It is not known if epithelial cells of apical true cysts alone are capable of acting as autocrine cells and secreting growth factors to sustain their own survival. It is important to realize that the apical true cyst is completely different from the odontogenic keratocyst, which is self-sustaining because it is a neoplastic lesion. Biologically, it is unlikely that the hyperplastic epithelial cells of inflammatory apical true cysts

Telegram: @dental_k

www.konkur.in

would suddenly transform into cells that behave like self-sustaining neoplasms. Any disease caused by infection should be able to regress after removal of its causative irritant(s), unless the irritants themselves are neoplasm-inducing agents or carcinogens, such as some viruses and human malignant tumors.[171,305] From pathogenesis, histology, and molecular cell biology, apical true cysts are similar to pocket cysts. Accordingly, apical true cysts, similar to pocket cysts, may be able to regress after nonsurgical root canal therapy by the mechanism of apoptosis if root canal infection is effectively under control.[163] This prediction is consistent with the high level of healing observed after nonsurgical root canal treatment.

In apical periodontitis lesions with cyst formation, the cysts have to regress before the periapical tissues can be restored to their original architecture. It is not known what matrix serves as a scaffold for endothelial cells, fibroblasts, and osteoblasts to migrate into the lumen of regressing cysts after nonsurgical root canal therapy. Complete regression of radicular cysts after nonsurgical root canal therapy could be due to any of several possible scenarios. Regression of radicular cysts and regeneration of bone may occur concurrently, or during regression of radicular cysts, part of the cystic lining epithelium could disintegrate due to apoptosis of local epithelial cells. Together with degradation of the basal lamina by MMPs, this could allow a fibrous connective tissue capsule to grow into the lumen of radicular cysts. Eventually, the cystic lining epithelium will completely regress or become remnants of epithelial cell rests remaining in the periodontal ligament.

Taken together, our knowledge of apical cyst formation and healing offers tantalizing clinical implications and clearly supports the conclusion that more studies are required to understand the complex mechanisms of regression of inflammatory apical cysts, both pocket and true.

Factors influencing periapical wound healing after endodontic therapy

Local and systemic factors may affect periapical wound healing. Infection will complicate and prevent wound healing, foreign bodies can impair wound healing,[193,324] and nutrition can also affect wound healing.[316] Diabetes was reported to reduce the likelihood of healing of apical periodontitis lesions

Telegram: @dental_k

www.konkur.in

after nonsurgical root canal therapy.[77] Impaired nonspecific immune response and disorders of the vascular system appeared to have a significant influence on the success rate of nonsurgical root canal therapy on teeth with apical periodontitis.[172] However, immunocompromised patients, such as HIV patients, responded as well as counterpart patients after nonsurgical endodontic therapy.[52,85,214] Although smoking has not been shown to be associated with increased incidence of apical periodontitis and prognosis of nonsurgical root canal therapy,[26,66] smoking may increase complications of periapical surgery, such as pain and swelling.[83]

Patients receiving radiotherapy of jaws and bisphosphonate therapy have a risk of developing osteonecrosis of jawbones,[220,226,317] so nonsurgical root canal therapy is recommended for these patients.[124,157] However, for endodontic surgery, the guidelines of the American Association of Oral and Maxillofacial Surgeons position paper on bisphosphonate-related osteonecrosis of the jaws are highly recommended.[9] For asymptomatic patients who have taken an oral bisphosphonate for less than 3 years and have no clinical risk factors, endodontic surgery is not contraindicated.[9] Nevertheless, the patient's physician should be consulted. Any kind of surgical procedure should be avoided for patients receiving intravenous bisphosphonate.[9] To prevent the complication of osteonecrosis, if patients are going to receive radiation of jaws or bisphosphonate therapy, nonsurgical or surgical endodontic therapy should be completed before the initiation of radiation or bisphosphonate therapy.[9]

www.konkur.in

Context of evaluating endodontic outcomes

The development of medical and dental practices has been guided by prevailing philosophies and consensus of expert opinions. The foundations of modern endodontics were shaken when Billings[97] brought the apparent relationship between oral sepsis and bacterial endocarditis to the attention of dentistry and medicine. He had strengthened the concept further from Miller,[134] who had coined the term *focus of infection* to highlight a possible link between "mouth germs" and systemic disease. The disastrous consequences of the focal infection era were sealed when Hunter[96] delivered his famous address at McGill University. Fears of fatal oral sepsis from deficient root canal treatments led to widespread extraction of pulpless teeth. Endodontics virtually disappeared from many dental schools, whereas in some areas, treatment was restricted to anterior teeth. The focal infection theory reigned for about 50 years[83] until around 1940.

The discipline of endodontics was rescued by individual, diligent practitioners in Europe and the United States who meticulously recorded their treatments, as well as their outcomes, to demonstrate the effectiveness of the procedures in controlling root canal infection. It was through these individual endeavors of merit that the reputation of endodontic procedures was restored and the discipline granted its specialist status in 1952 in the United States.[59]

Toward the 1990s, the improvements in general health and longer survival of Western populations as well as their teeth, coupled with the rising costs of health care for longer-living individuals, prompted a host of reevaluations of the altered economic burdens on society. Among them, the *cost-effectiveness of treatment procedures* for management of diseases loomed large. Thus began the era of evidence-based medicine and dentistry, with its emphasis on costs, benefits, and outcomes of treatment. Attempts to pool outcome data for greater power brought with it the realization that studies originating from

Telegram: @dental_k

www.konkur.in

different centers varied in diverse ways, leading to very heterogeneous data that challenged formal attempts at drawing definitive conclusions. Characterization of data types and its quality prompted calls for standardization of approaches in measuring outcomes to enable more meaningful pooling.

Because of the better established science of evidence assessment, a modern revisitation of the "focal infection era"[94] did not lead to the same threat to the endodontic discipline that was evident at the beginning of the 20th century. In fact, it was suggested as an opportunity to secure research funding for assessing and managing the importance of dental care on systemic health.

Interestingly, the modern threat to endodontics was posed by the cost-economic pressures exerted on treatment planning decisions centering on the question of whether to "save the tooth" or extract it with replacement by an implant-supported crown.[238] Once again, the science of evidence-based practice has helped to avert irrational treatment recommendations leaning toward extraction of savable teeth.[54,100,103]

Types of disease and their treatment

The statement, "Endodontists provide endodontic treatment to manage endodontic disease" is a gross oversimplification that masks important subtleties in recognition of the nature of the diseases and how best to address them. Endodontists manage inflammation of the specialized connective tissues within and surrounding the teeth; more specifically, they deal with inflammation that generally commences in the pulp tissue and progresses to the periradicular tissues via portals of communication that convey the neurovascular supply. Incipient or established pulpitis may be managed by vital pulp therapy when judged reversible, largely because a sufficient body of pulp tissue remains healthy and unaffected. More advanced pulpitis that approaches the foramina into the periodontal ligament may require root canal treatment. When pulpal inflammation, necrosis, or infection encroaches on the apical periodontal ligament, root canal treatment is required. Apical periodontitis that persists despite technically adequate root canal treatment may require root canal retreatment, periradicular surgery, or extraction to manage the source of the persistent disease. *Endodontic treatment* is therefore a collective and nonspecific term for a range of procedures directed at

Telegram: @dental_k

www.konkur.in

managing the spread of pulpal inflammation or infection. Endodontic treatment encompasses the following procedures:

1. Vital pulp therapy (indirect pulp therapy, direct pulp capping, pulpotomy, regenerative pulp therapy)
2. Nonsurgical root canal treatment
3. Nonsurgical root canal retreatment
4. Surgical retreatment

The ideal outcome for endodontic treatment consists of the controlled reduction of inflammation, accompanied by healing through regeneration, although sometimes repair may follow instead. Unfortunately, none of the involved tissues are within the direct sight of the clinician, hidden as they are by their housings of hard tooth structure or alveolar bone and their gingival/mucosal coverings. Consequently, surrogate measures must be employed to evaluate the presence or absence of the disease process and its resolution. The evaluation process is further complicated by the lack of direct correlation between measures of the disease process and its clinical manifestation.

What are surrogate outcome measures?

Signs of acute inflammation are classically described in the “triple response” exhibited by mechanically injured skin, which includes altered color (redness), texture/contour (swelling), and sensation (pain), which are directly accessible and viewable. These changes have a direct correlation with histopathologic and molecular alterations. Chronic inflammation does not necessarily exhibit the same highly visible signs and symptoms of its histopathologic character. When hidden from view, as are pulpal and periradicular tissues, the task of recognizing the presence or absence of chronic inflammation is even more challenging. The clinician is therefore left with indirect or associated (proxy) changes by which to judge the presence or absence of disease; these are called “surrogate” measures. Some of these may have to be inferred through associations, some may be directly visualized, and others are only indirectly “viewable” through various imaging techniques (such as radiography). The process therefore calls upon the clinician to

Telegram: @dental_k

www.konkur.in

assimilate various sources of information to form a judgment about the presence or absence of disease.

Types of outcome measures

In its broadest sense, an outcome measure for a treatment intervention may constitute any consistently anticipated and measurable consequence of the treatment. The prepared shape of the root canal system, bacterial load reduction, and technical quality of the root filling may all be regarded as outcome measures by this definition. But the ultimate *clinical* measure of a treatment outcome is assessing the prevention and resolution of disease.

The outcome of endodontic treatment may be assessed in four dimensions as in other medical disciplines.[9] The first dimension is physical/physiologic and related to presence or absence of pulpal/periapical health/disease, pain, and function. The second dimension assesses longevity or tooth survival. The third dimension relates to economics and assesses direct and indirect costs. Finally, the fourth dimension examines psychologic aspects involving perceptions of oral health–related quality of life (OHRQoL) and aesthetics.

What is the purpose of evaluating outcomes?

Apart from the importance of developing a solid foundation of evidence-based practice, it is important to evaluate treatment outcomes for a number of reasons.

Effectiveness of procedures

First, treatment procedures must be effective. Otherwise, there is no reason to recommend them to patients as a treatment option. The patient must be properly informed as to the risks, benefits, and potential outcomes of the offered treatment. The availability of pooled outcome data and consensus guidelines offers both patients and endodontists reassurance and confidence in the validity and predictability of the offered procedure. However, the pooled average outcome data may not pertain if the clinician does not have the requisite experience, skill, and personal outcomes matching at least these average figures of performance. Personal outcome data offer the patient more precise measures for comparison and expectation. It also aids practitioners in

Telegram: @dental_k

www.konkur.in

refining their technique and knowledge to further improve their outcomes and, ultimately, to help improve the overall pooled data.[34] The treating clinician must assess his or her own personal outcome data and personal expectation of success. If the clinician is uncertain of a result or feels that the outcome could be enhanced by treatment from another clinician, then referral to someone else more qualified is paramount.

Factors affecting outcomes

Pooling data (that is preferably homogeneous) offers the potential to evaluate and prioritize the factors that exert a dominant influence on outcomes. In this way, protocols for treatment may be improved in a progressive fashion, bringing about the perfect meld of technical, clinical, and biologic insight necessary for the highest performance and most predictable outcome. Evaluation of factors affecting treatment outcomes arguably provides the strongest influence for making changes that will improve the clinical outcomes. Weighing the relative importance of individual factors should help to identify the key biologic factors at play and how best to manage them from a clinical or technical perspective.

Value for prognostication

Prognostication, which could be defined as the prediction, projection, prophesizing, or foretelling the likely outcome of treatment, is not often well defined in endodontics. The overall prognosis of a tooth depends on the interaction among three individual and often independent variables, including endodontic, periodontal, and restorative prognoses. Each has a set of subsidiary factors that must be considered to derive an overall prognosis. Finally, the tooth in question must be considered from a strategic perspective, relative to its position in the dental arch and the contribution it makes in the dynamic occlusion.

A deeper analysis of the factors affecting outcomes as prognostic indicators is merited in order to clarify the degree of complexity inherent to the problem. A comparison may be made with the randomized controlled trial of a drug as a treatment intervention. The drug therapy is delivered as a clearly prescribed and standardized dose regimen delivered by specified timings to effect an anticipated blood or target tissue concentration for a

Telegram: @dental_k

www.konkur.in

specified duration. Data recording is confined to compliance with the prescription and possibly to the checking of actual blood levels achieved as well as the final outcome effect.

In stark contrast, a surgical intervention, regardless of any standardization of the described procedural protocol, is subject to enormous variation in its delivery dependent on interpretation and execution of the protocol by each operator. To add to the levels of complexity and variation, surgical protocols are often multistep, sequential procedures, each prospective step dependent on the previous for its efficacy. Even characterizing and accurately recording any variations in treatment protocols becomes a challenge because many aspects and steps must be documented. This leads to the next challenge, that of demonstrating compliance with the accuracy of such complex data gathering. Furthermore, it becomes important from an analytic perspective to not only consider the effect of individual steps (factors) alone but also any interactive effect between the multiple steps inherent in the procedure. Even when such comprehensive prospective outcome data are available, utilizing these data to individually calculate the prognosis in a particular scenario may be challenging. Clinically, there may be two distinct ways to estimate prognosis: (1) to apply heuristic principles and intuitively gauge the effect of dominant factors or, at the other end of the spectrum, (2) to mathematically input comprehensive data into an algorithmic model to calculate the estimated outcome. An even more sophisticated approach may be to use mathematical modeling to calculate iterations on variations within the system. At present, the evidence base is insufficient to allow such a sophisticated approach.

It therefore follows that evaluating outcomes and the factors that affect them are fundamental to the creation of a suitable data foundation for future application to endodontic prognostication. The endodontic treatment option is in competition with other alternative therapies and therefore for the discipline to survive and thrive, a suitable blend of efficacy, efficiency, utility, predictability, and cost-effectiveness data must be generated for its principal therapies. Achievement of such a goal will require a diligent and conscientious collection of data from many sources. Analyses of such powerful datasets will ultimately yield proper insight into outcomes of the procedures we use. Coupled with biologic insight of the problem, it will become possible to derive new therapeutic solutions necessary to deliver

Telegram: @dental_k

www.konkur.in

them.

Outcome measures for endodontic treatment

Before determining the success or failure of an endodontic procedure, the parameters as to what is considered a success or a failure have to be discussed. These are termed the *outcome measures* of the procedures.

Outcome measures for vital pulp therapy procedures

The techniques used to maintain the vitality and health of pulps in teeth with extensive caries or those with traumatic/mechanical exposures include (1) indirect pulp capping with one-step or stepwise caries excavation, (2) direct pulp capping of exposed pulps, and (3) partial/full pulpotomy procedures for more extensively involved pulps. The surrogate outcome measures adopted in studies include (1) clinical success (pulp sensitivity to cold test and absence of pain, soft-tissue swelling, sinus tract, periradicular radiolucency, or pathologic root resorption), (2) patient satisfaction, (3) adverse events (pain, swelling, tooth fracture), and (4) tooth extraction.[89,136] Although not providing a specific follow-up strategy, the quality guidelines of the European Society of Endodontology (ESE)[61] suggests “initial review at no longer than 6 months and thereafter at further regular intervals.” They also provide the criteria for judging the favorable outcome of vital pulp therapy (Table 17.1). There are substantial differences in the criteria adopted in published clinical studies on outcomes of vital pulp therapy[89,136] with few studies adopting all of the criteria. The frequency of radiologic review adopted in published studies also varies substantially, with some recommending the first review at 1 month followed by subsequent 3 monthly reviews.[172,242] The relative benefit of acquired information versus unnecessary radiation to patients has been questioned.[66] An initial assessment at 6 to 12 weeks, followed by a review 6 and 12 months after treatment, seems to have been accepted and is recommended. Some studies reported up to 10 years follow-up on case series demonstrating lower success rates, inferring the possibility of slow spread of pulpal inflammation and late failures. The conclusion is that longer follow-up periods are merited.

Table 17.1

Criteria for Assessing the Outcome of Pulp Therapy

Quality Guidelines for Endodontic Treatment: Consensus Report of the European Society of Endodontology (2006)	Guidelines on Pulp Therapy for Primary and Immature Permanent Teeth (American Academy of Pediatric Dentistry, 2014)
1. Normal response to pulp sensitivity tests (when feasible) 2. Absence of pain and other symptoms 3. Radiologic evidence of dentinal bridge formation 4. Radiologic evidence of continued root formation in immature teeth 5. Absence of clinical and radiographic signs of internal root resorption and apical periodontitis	1. Tooth vitality maintained 2. Absence of posttreatment signs or symptoms such as sensitivity, pain, or swelling 3. Occurrence of pulp healing and reparative dentin formation 4. Absence of radiographic evidence of internal or external root resorption, periapical radiolucency, abnormal calcification, or other pathologic changes 5. Teeth with immature roots should show continued root development and apexogenesis

The process at each review consists of obtaining a history of symptoms, coupled with an examination to determine the presence or absence of tenderness to palpation of adjacent soft tissues, tenderness to pressure and percussion of the tooth, signs of radiographic pulpal, periapical changes, and responses to pulp tests. The accuracy of pulp tests may be limited in pulpotomized teeth because of the distance of the remaining pulp tissue from the tooth's surface. In the case of pulp capping and pulpotomy, additional tests include radiographic verification of the presence of the calcific barrier (Fig. 17.1) and its integrity by removal of the dressing and direct probing. Although an initial examination at 6 weeks has been suggested, this can be modified for the radiographic assessment. If there is no evidence of complete bridge formation, the treatment is considered failed and root canal treatment should be considered. In addition, in the case of incompletely formed roots there should be radiographic evidence of continued root development (Fig. 17.2).

Outcome measures for nonsurgical root canal treatment and retreatment

Root canal treatment may be employed either to prevent or resolve periapical disease. Given that periapical lesions develop as a result of the *interaction* between bacteria (and their by-products) and the host defenses, it is clear that prevention or resolution of the disease process depends on preventing or terminating this interaction.

Prevention of apical periodontitis applies to the clinical situation where it is judged that the pulp is irreversibly inflamed, necrotic, or infected to the extent that vital pulp therapy would not resolve the problem, which therefore requires pulpectomy. The implication is that the procedure demands asepsis as a prime requirement. The precise technical details of the protocol may not be so important, as long as they are focused on effective and aseptic removal of the pulp tissue. This is validated by the high chance of retaining periapical health (judged by conventional radiography), regardless of the clinical protocol used.[153]

Once the periapical lesion has become established, the challenge is a different one because the purpose now is to remove the bacterial biofilm and to effect switching off of the periapical host response. The challenge seems to be greater still if the periapical lesion is larger as it is associated with a more diverse infection. A number of approaches (protocols) have been used to achieve this general aim. The periapical healing process that occurs after root canal treatment is less clear. Nevertheless, ideal healing would eventually result in regeneration and the formation of cementum over the apical termini, isolating the root canal system from the periapex (Fig. 17.3), but this is not an inevitable result. Incomplete removal of the infection will reduce but not eliminate the periradicular inflammatory reaction, and in fact this is generally what happens.[147] This implies that residual infection in the apical anatomy is typical following completion of root canal treatment and that an ongoing interaction continues between the residual infection, root filling material, and host defenses, which plays a definitive role in determining the final healing outcome.

Telegram: @dental_k

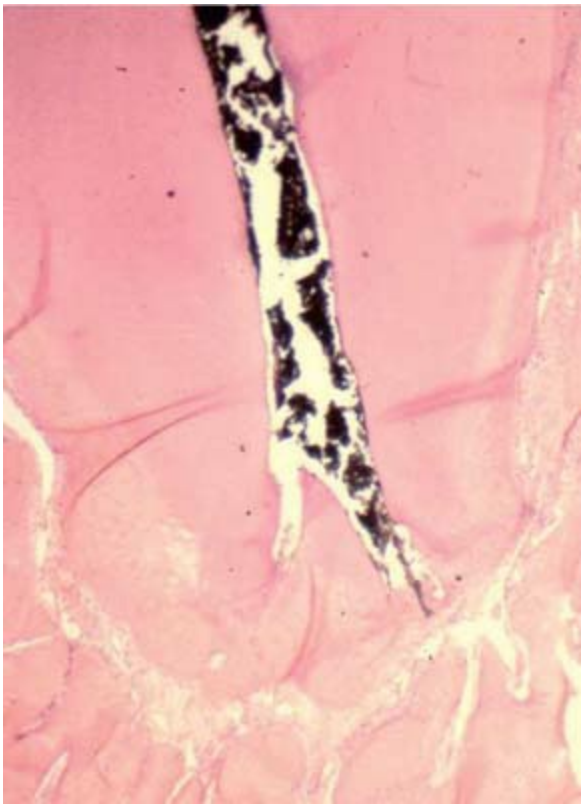

FIG. 17.3 Low-power view of healing by cementum formation when Sealpex is used (black particles are residual Sealapex and root filling material).

Microscopic image shows black residues extending to one end in the root.

Source: (Courtesy Prof. M. Tagger.)

The culture test has been used during root canal treatment as an interim measure of the efficacy of the chemomechanical procedure; however, it has fallen out of favor in contemporary practice for a variety of reasons.[139] The outcome measures that quantitate healing subsequent to root canal treatment are the absence of clinical signs and symptoms of persistent periapical disease.[17,18] The definitive outcome measure (in conjunction with the absence of signs and symptoms), however, is periapical healing, because the treatment is aimed at resolution of periapical disease (Fig. 17.4).[152] Clinical judgment of the outcome of treatment is based on the absence of signs of infection and inflammation, such as pain, tenderness to pressure/percussion of the tooth, tenderness to palpation of the related soft tissues, absence of swelling and sinus tract, and radiographic demonstration of reduction in the

Telegram: @dental_k

www.konkur.in

size of the periapical lesion (if sufficient time has lapsed), with a completely normal development of the periodontal ligament space. Although the majority of periapical lesions heal within 1 year, healing may continue for up to 4 years or longer.[229]

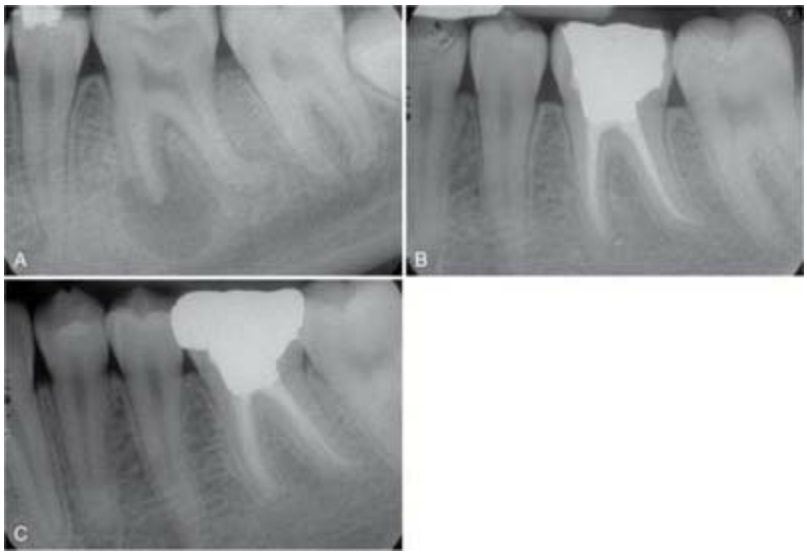

FIG. 17.4 Resolution of periapical disease after root canal treatment of the mandibular left molar with preoperative periapical radiolucency associated with mesial and distal roots **(A)**, delayed healing caused by extruded filling material from the distal canal **(B)** and nearing complete healing as extruded material is resorbed **(C)**.

Three radiographs marked A through C as follows:

A) A less-density patch at the root tip of canal in first molar.

B) The first molar shows filled crown and root canals. The tissue is less-dense below the gum line and inside the roots.

C) The first molar has less-density tissue below the gum line on one side of the molar tooth.

Absence of signs and symptoms of periapical disease with radiographic evidence of a persistent periapical radiolucency may indicate either fibrous repair (Fig. 17.5) or persistent chronic inflammation or infection. Only time and acute exacerbation would identify the latter, whereas the former should remain asymptomatic.

Telegram: @dental_k

www.konkur.in

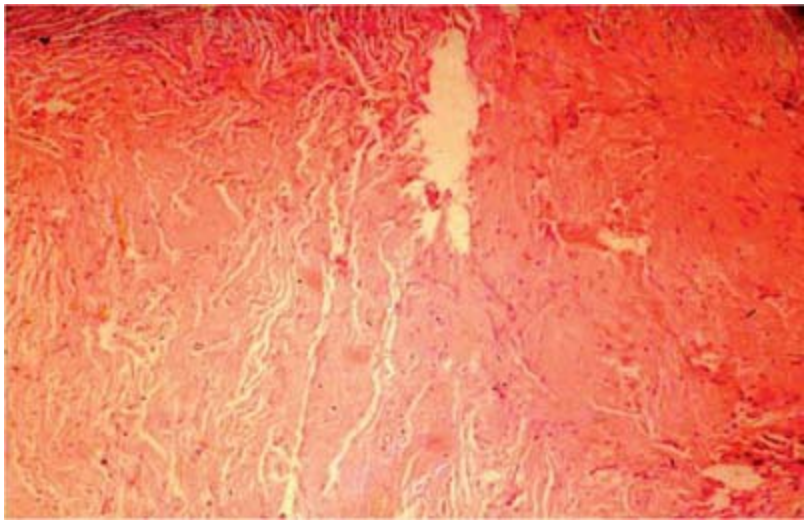

FIG. 17.5 Histologic view of fibrous periapical healing.

A large light scar with fibers is shown in the dark background.

Longevity measures include survival of the root canal fillings or treatment[118,228,236] and tooth retention or survival.[111,149,190] The term *functional retention* was coined by Friedman in 2004[69] to mean retention of the tooth in the absence of signs and symptoms regardless of the radiographic presence of a lesion. The term *functionality* should further and more specifically cover the functional utility of the tooth—that is, some patients may complain that despite the absence of specific signs and symptoms of infection or inflammation, they find it impossible to use the tooth because it "feels" weak.

Modern definitions of health embrace a broader spectrum of measures including psychological well-being.[116] Instruments to assess these aspects have been developed in general medicine and adapted for application to dentistry, such as the Oral Health Related Quality of Life instrument.[55,87,115] There is no definitive instrument for measuring these aspects in endodontics as yet. Studies published so far have mainly adapted versions of the Oral Health Impact Profile (OHIP).

The periapical status of root-treated teeth has traditionally been assessed using two-dimensional conventional radiographic imaging. The use and limitations of two-dimensional radiographic images for assessing treatment outcome has been reviewed thoroughly and is reported to suffer from low sensitivity, particularly in the posterior parts of the mouth.[98] The

Telegram: @dental_k

www.konkur.in

development of digital imaging technology[80] brought the possibility of image manipulation, including digital subtraction,[50,158,243,259] densitometric analysis,[156] correction of gray values,[32] and the manipulation of brightness and contrast.[75] However, none of these approaches has addressed the main deficiencies of accurately elucidating and quantitating the actual existence or progression of periapical bone loss.

Cone-beam computed tomography (CBCT), a new three-dimensional imaging technique requiring only 8% of the effective dose of conventional computed tomography,[119] has been proposed as a means of overcoming the problem of superimposition of tissue layers and structures. The diagnostic values of periapical radiography and CBCT were compared on dogs' teeth using histology as the comparative method of determining apical periodontitis 180 days after root canal treatment.[44] CBCT was found to be significantly more accurate in detecting minor bone lesions compared with two-dimensional radiology.[44,174] Other evidence to support the superior sensitivity of CBCT is available from studies using a variety of simulated defects created in bone in pig[226] or human[165,221] jaws. Although the validity of clinical outcome data derived using conventional radiographic techniques has been questioned,[256] the *routine use* of CBCT is not recommended[62,91,197] owing to its higher radiation dosage.[5,91] The use of CBCT, which may be more sensitive for detection of periapical healing,[114,167] may give lower healing rates and longer durations to complete healing.

Many studies consider the treatment successful only when both radiographic and clinical criteria are satisfied.[69] It has been documented that a small proportion of cases present with persistent symptoms despite complete radiographic resolution of the periapical lesion.[176] Comparison of success rates estimated with or without clinical examination revealed no[93] or only a very small difference (1%).[150]

The widely accepted definition for endodontic success and failure by Strindberg[229] embraces both radiographic and clinical findings (Table 17.2). Friedman and Mor[69] preferred the terms *healed*, *healing*, and *diseased* instead of *success* and *failure* because of the potential of the latter to confuse patients. The "healed" category corresponds to "success" as defined by Strindberg,[229] whereas "healing" corresponds to "success" as defined by

Telegram: @dental_k

www.konkur.in

Bender and colleagues (see Table 17.2).[17,18]

Table 17.2

Criteria for Determination of Periapical Status

Strindberg (1956)	Bender et al. (1966, a and b)	Friedman and Mor (2004)
Success	**Success**	**Healed**
Clinical: No symptoms *Radiographic:* The contours, width, and structure of the periodontal margin were normal OR The periodontal contours were widened mainly around the excess filling	*Clinical:* Absence of pain/swelling; disappearance of fistula; no loss of function; no evidence of tissue destruction *Radiographic:* An eliminated or arrested area of rarefaction after a posttreatment interval of 6 months to 2 years	*Clinical:* Normal presentation *Radiographic:* Normal presentation
Failure		**Diseased**
Clinical: Presence of symptoms *Radiographic:* A decrease in the periradicular rarefaction OR Unchanged periradicular rarefaction OR An appearance of new rarefaction or an increase in the initial rarefaction		Radiolucency has emerged or persisted without change, even when the clinical presentation is normal OR Clinical signs or symptoms are present, even if the radiographic presentation is normal

www.konkur.in

some reason, be repeated OR The tooth was extracted prior to the 3-year follow-up owing to the unsuccessful treatment of another root of the tooth		radiolucency

The long duration of the periapical healing process coupled with the reduced recall rates at longer follow-up periods has provided opportunity for setting the thresholds of success at either complete healing or partial healing (reduced lesion size). The success criteria used for complete resolution have been described either as "strict"[152] or "stringent,"[69] whereas the criteria established for reduction in periapical radiolucency size has been described as either "loose"[152] or "lenient."[69] The frequency of adoption of these two thresholds has been similar in previous studies; the expected success rates using "strict" criteria would be expected to be lower than those based on "loose" criteria. The literature finds differences that vary from 4% to 48%.[153]

A periapical index (PAI) consisting of five points on the scale was devised for measuring the periapical status and used in some studies.[157,159] However, the studies only reported the increase or decrease in mean scores for the clinical factors under investigation coupled with the proportion of successful cases. This approach precluded direct comparison of their data with studies reporting conventional dichotomized outcomes. Other studies using the index dichotomized the scores into "healthy" (PAI 1 or 2) or "diseased" (PAI 3 to 5) categories,[160] thus allowing the data to be compared directly with the more traditionally used binary outcomes of success or failure. In this system of designation, given that the PAI score 2 represents periodontal ligament widening, it effectively signals adoption of the "loose" threshold. The longitudinal follow-up[86] of 14 cases presenting with widened apical periodontal ligament (PAI score at 2) for 10 years revealed unfavorable future healing in only a small proportion of the cases (28%, 4/14).

Outcome measures for periapical surgery

Nonsurgical root canal treatment alone may fail to resolve apical periodontitis in a small proportion of cases because it may not allow access to the infection

Telegram: @dental_k

www.konkur.in

or resolution of the cause of the infection (i.e., root fracture or crestal bone communication to the periapical infection). Where the cause is microbial persistence, the infection may be localized intraradicularly (in the apical canal anatomy [Fig. 17.6] or in the apical dentinal tubules [Fig. 17.7] or extraradicularly [Fig. 17.8]). In these instances, a surgical approach to the periapex may be required in addition to the nonsurgical approach to removing such microbes (see Fig. 17.7).

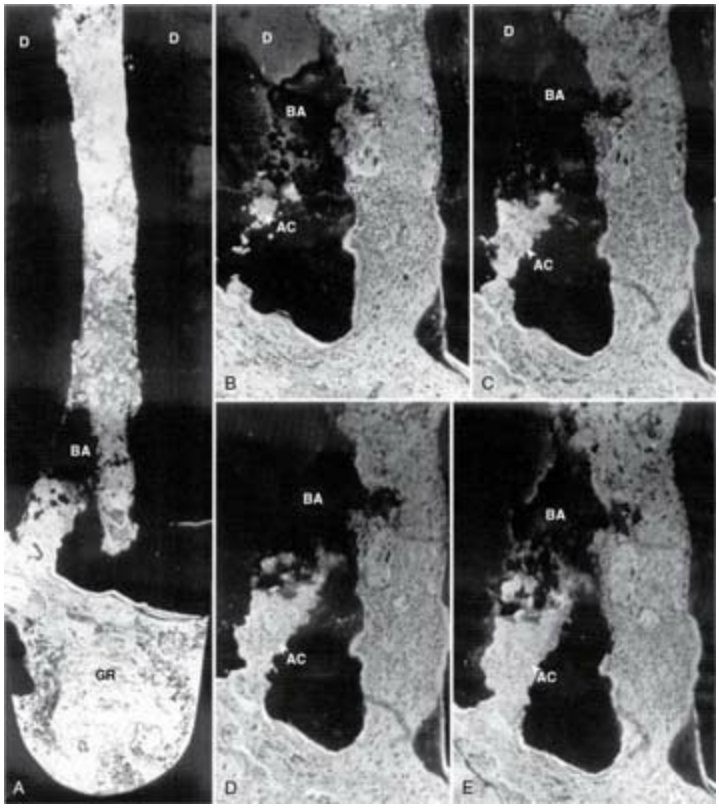

FIG. 17.6 Axial sections through the surgically removed apical portion of the root with a therapy-resistant periapical lesion *(GR)*. Note the cluster of bacteria *(BA)* visible in the root canal. Parts (**B**)–(**E**) show serial semithin sections taken at varying distances from the section plane of **(A)** to reveal the emerging **(B)** and gradually widening **(C–E)** profiles of an accessory root canal *(AC)*. Note that the accessory canal is clogged with bacteria *(BA)*. Original magnification: **A,** ×52; **B–E,** ×62.

Five radiographs marked A through E show bacterial colonies above GR in the radiograph A and increasing accessory canal below BA from radiograph B to E.

The success of periapical surgery has been assessed with the same clinical and radiographic criteria as for nonsurgical root canal treatment. However, the radiographic criteria for successful periapical healing are different from those for nonsurgical root canal treatment (Table 17.3; Figs. 17.9–17.11).[140,186] Moreover, periodontal attachment loss in the form of marginal gingival recession is an additional criterion for measuring the outcome of periapical surgery.

FIG. 17.9 **A,** A maxillary right central incisor having undergone periapical surgery. **B,** Incomplete periapical healing at 1 year postoperatively. Complete healing at 3 **(C)** and 4 years **(D)** postoperatively.

Four radiographs are marked A through D.

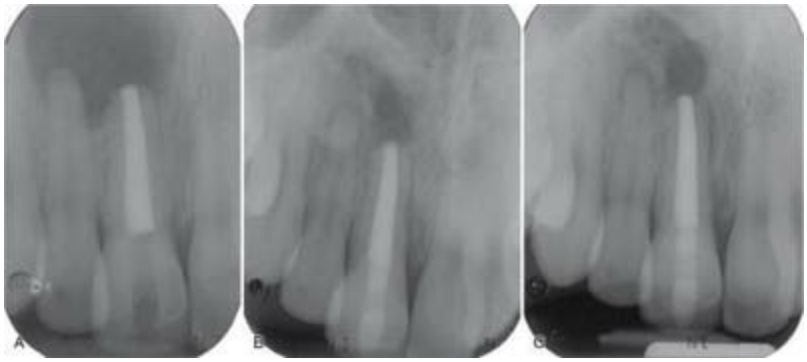

FIG. 17.11 Example of uncertain healing. Periapical radiographs of a maxillary left central incisor taken immediately after periapical surgery **(A)**, at 2 years postoperatively **(B)**, and at 3 years postoperatively **(C)**.

Three radiographs are marked A through C.

A) It has a large dark patch around the root apices of two teeth.

B) It has a triangular dark patch at the root tip of one tooth.

C) It has a circular dark patch at the root tip of one tooth.

Table 17.3

Classification of Periapical Healing Following Apical Surgery

COMPLETE HEALING
Reformation of a Periodontal Space With
Normal width and lamina dura to be followed around the apex Slight increase in width of apical periodontal space but less than twice the width of noninvolved parts of the root Tiny defect in the lamina dura (maximum 1 mm) adjacent to the root filling
Complete Bone Repair With
Bone bordering the apical area does not have the same density as surrounding noninvolved bone No apical periodontal space can be discerned
Incomplete Healing (Scar Tissue)
The Rarefaction Has Decreased in Size or Remained Stationary With
Bone structure recognized within the rarefaction The irregular periphery of the rarefaction and demarcation by a compact bone border The rarefaction located asymmetrically around the apex

Telegram: @dental_k

www.konkur.in

Angular connection between the rarefaction and the periodontal space
An Isolated Scar Tissue in the Bone With Findings Above
Uncertain Healing
The Rarefaction Has Decreased in Size With
The size larger than twice the width of the periodontal space Lamina-dura like bone structures around the border A circular or semicircular periphery Symmetric location around the apex as a funnel-shaped extension of the periodontal space Bone structure discernible within the bony cavity A collar-shaped increase in width of lamina dura coronal to the radiolucency
Unsatisfactory Healing (Failures)
The rarefaction has enlarged or is unchanged If a case still demonstrated "uncertain healing" 4 years postoperatively, the treatment should be considered a failure[186]

From Rud J, Andreasen JO: A study of failures after endodontic surgery by radiographic, histologic and stereomicroscopic methods, *Int J Oral Surg* 1:311-328, 1972; Molven O, Halse A, Grung B: Observer strategy and the radiographic classification of healing after endodontic surgery, *Int J Oral Maxillofac Surg* 16:432-439, 1987.

Now that the parameters have been discussed as to the variables that need to be considered when assessing healing or nonhealing outcomes, the following discussion will describe the expected outcomes of the various endodontic procedures.

Outcomes of vital pulp therapy procedures

The vital pulp therapy procedures discussed in this chapter include those for managing extensive caries with a high risk of pulpal exposure or pulps exposed through caries or traumatic injuries.

Indirect pulp capping (one-step versus stepwise excavation)

The most conservative management for extensive caries is indirect pulp capping using either the one-step or the stepwise excavation approach. The stepwise excavation approach with initial partial caries removal was advocated to reduce the risk of pulpal exposure and is generally considered to be associated with poorer outcomes. The clinical outcomes of the one-step or

Telegram: @dental_k

www.konkur.in

stepwise approaches have been compared in three randomized controlled trials on permanent teeth with deep caries.[19,113,121,122] Stepwise excavation was found to be associated with a lower rate of pulp exposure and higher chance of long-term clinical success than the one-step excavation approach (Table 17.4).[19,113] Maltz and colleagues,[121,122] however, found the contrary, and they attributed the low long-term clinical success rate of the stepwise approach to patients being noncompliant in returning for scheduled completion of treatment. Interestingly, comparison of the cost-effectiveness of the one-step versus the stepwise excavation techniques using health-economic modeling involving simulated treatment of a molar tooth with deep caries in a 15-year-old patient revealed that the one-step procedure accrues lower long-term costs as well as longer tooth retention and pulp vitality.[200]

Meta-analyses of data from studies[19,20,65,81,89,113,120-122, 141] listed in Table 17.4 revealed that the weighted pooled success rate for indirect pulp capping using the one-step approach (81.7%; 95% confidence interval [CI]: 72.7%, 90.6%) (Fig. 17.12) was similar to that for the stepwise approach (81.9%; 95% CI: 72.1%, 91.7%) (Fig. 17.13).

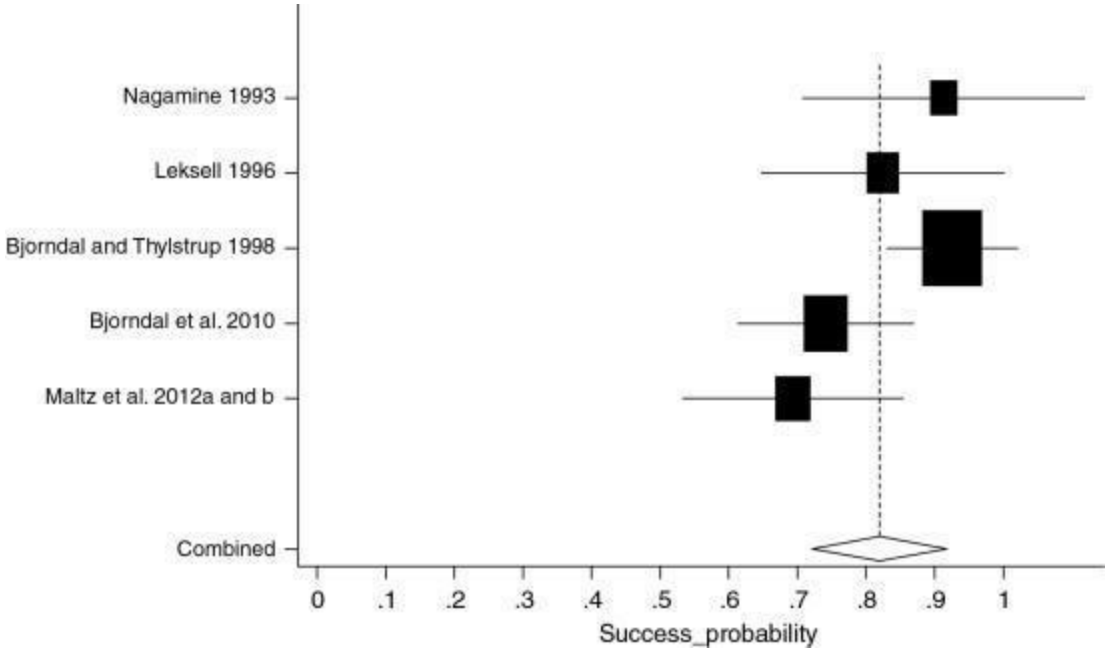

FIG. 17.13 Forest plot showing individual study and weighted pooled probabilities of success for stepwise indirect pulp capping.

Forest plot shows individual study against success probability.

The horizontal axis is marked 0 to 1 with increment of 0.1. The approximate data are as follows: Combined: 0.7 5 to 0.9, Maltz et al. 2012a and b: 0.7, Bjorndal et al. 2010: 0.7 3, Bjorndal and Thylstrup 1998: 0.9 2, Leksell 1996: 0.8 2, and Nagamine 1993: 0.9 2.

Calcium hydroxide cement was the preferred lining material for the pulpal surface, whereas zinc oxide–eugenol–based cement was the preferred base material in most studies. Recently, resin-modified-glass-ionomer liner has also been used, but the type of lining material did not influence the outcome (see Table 17.4). The age of patients, the presence of preoperative pain, and pulpal exposure during excavation were significant negative prognostic factors.[19]

Direct pulp capping

Direct pulp capping is performed on teeth with pulp exposures caused by caries, caries excavation, or traumatic injuries. Most studies investigating the clinical outcome of direct pulp capping on permanent teeth had excluded teeth with signs and symptoms of irreversible pulpitis and apical pathosis (Table 17.5). Saline, sodium hypochlorite, and chlorhexidine have been

Telegram: @dental_k

www.konkur.in

reportedly used to irrigate the exposed pulp and to achieve hemostasis. Calcium hydroxide paste and mineral trioxide aggregate (MTA) were the commonly used capping materials (see Table 17.5).

CH, Calcium hydroxide; *GIC*, glass ionomer; *MTA*, mineral trioxide aggregate; *NaOCl*, sodium hypochlorite; *RCT*, randomized controlled trial.

A meta-analysis of data from studies[12,19,21,64,65,72,88,90,92,128,132,133,193,207,254] listed in Table 17.5 revealed the weighted pooled success rate to be 70.1% (95% CI: 59.9%, 80.2%) (Fig. 17.14). The patient's age and sex; tooth location and type; pulp exposure type, size, and its location; and the restoration type, size, and quality did not have a significant influence on success. Although the outcome of direct pulp capping of teeth with immature versus mature apices has not been systematically compared in individual studies, indirect comparison of pooled data from different studies[1] revealed that teeth with immature roots were associated with significantly more successful outcomes.

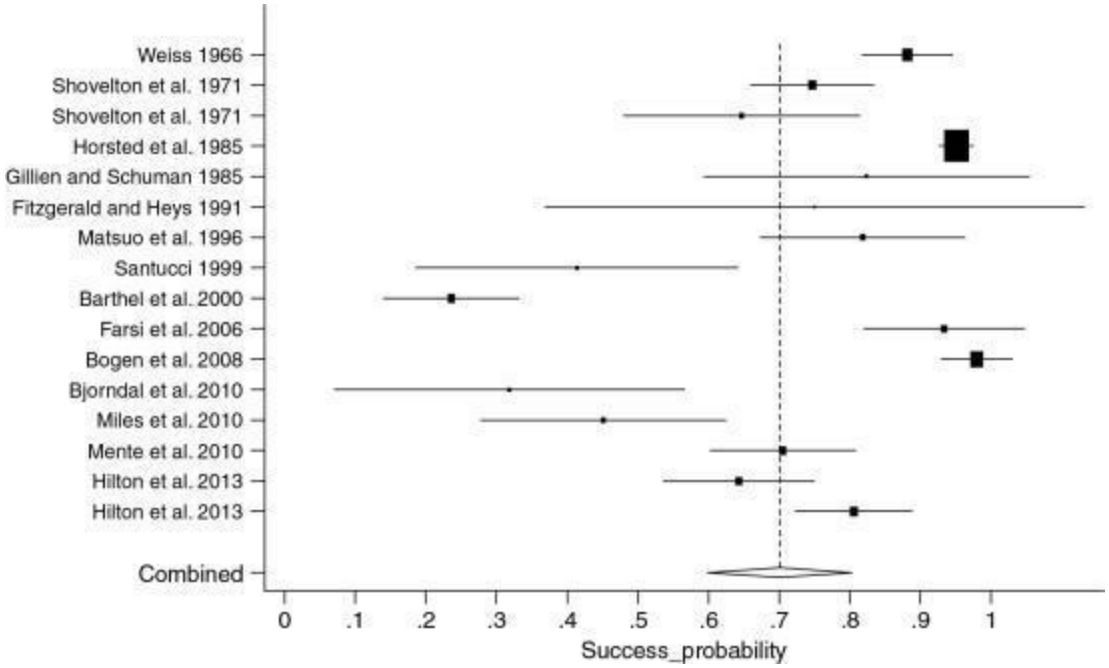

FIG. 17.14 Forest plot showing individual study and weighted pooled probabilities of success for direct pulp capping.

Forest plot shows individual study against success probability.

The horizontal axis is marked 0 to 1 with increment of 0.1. The approximate data are as follows: Combined: 0.6 to 0.8, Hilton et al. 2013: 0.8 1, Hilton et al. 2013: 0.6 4, Mente et al. 2010: 0.7, Miles et al. 2010: 0.3 1, Bjorndal et al.

www.konkur.in

2010: 0.3 2, Bogen et al. 2008; 1, Farsi et al. 2006: 0.9 2, Barthel et al. 2000: 0.2 4, Santucci 1999: 0.4, Matsuo et al. 1996: 0.8, Fitzgerald and Heys 1991: 0.7 4, Gillien and Schuman 1985: 0.8 1, Shovelton et al. 1971: 0.6 3, Shovelton et al. 1971: 0.7 6, and Weiss 1966: 0.9 2.

The type of capping material was another significant prognostic factor,[90,197,207] with MTA performing superiorly to calcium hydroxide in a randomized controlled trial[90] and in a systematic review.[1]

Pulpotomy

Earlier studies on the outcome of *partial pulpotomy* (specifying varying degrees of coronal pulp removal) had only included teeth with vital traumatic pulp exposures; however, more recent studies have also included teeth with carious pulp exposures. Teeth with spontaneous or severe pain and signs and symptoms of apical pathosis were excluded (Table 17.6). On the other hand, the outcomes of *full pulpotomies* (completely removing the coronal pulp and retaining the radicular pulp) had only been investigated in teeth with carious exposures (Table 17.7). Saline irrigation has been preferred for achieving hemostasis, whereas calcium hydroxide, and more recently, MTA, were the preferred pulp capping materials (see Table 17.6).

Summary of prognostic factors for vital pulp therapy

In summary, vital pulp therapy performed under guideline standards with optimal coronal seal achieved promising long-term success in teeth with carious, mechanical, or traumatic exposures of healthy pulps.

The most important factors affecting the outcome of vital pulp therapy are preexisting health of the pulp, adequate removal of infected hard or soft tissues, careful operative technique to avoid damage to residual tissues, and elimination of microbial leakage around the final restoration. It can be difficult to gauge the health of the residual pulp as it is a matter of subjective assessment and relies on experience in pulp diagnosis. The degree of pulp bleeding upon exposure is a more reliable tool to judge the status of the pulp than the preoperative clinical signs and symptoms. Continued bleeding after 10 minutes, even after rinsing with sodium hypochlorite solution, may suggest that the residual pulp was still heavily inflamed and a complete pulpectomy may be a more effective treatment modality. Removal of infected tissue is a matter of subjective experience but may be aided by various dyes. The final factor relies on the correct choice of restorative material and its adequate manipulation to prevent leakage.

Factors such as the age and health of the patient, the size and nature (carious or traumatic) of pulp exposure and its duration of exposure to the oral environment (up to 48 hours) do not in themselves compromise outcomes of vital pulp therapy.

Outcomes of nonsurgical root canal treatment

In contrast to other areas of endodontics, the number of studies and extent of investigation of nonsurgical root canal treatment is more comprehensive, yielding a much greater insight even though the quality and scope of the research does not always reach the highest levels.

A systematic review and meta-analysis of the factors affecting primary root canal treatment outcome conducted by the authors revealed the following: the mean success rate was 83% when vital pulpectomy was performed (Fig. 17.17), which reduced to 72% when the root canal treatment procedure was used to eradicate the established infection associated with a periapical lesion (Fig. 17.18).

Factors affecting periapical health or healing following root canal treatment

The factors influencing the maintenance of periapical health or periapical healing of preexisting lesions following root canal treatment may be broadly classified into patient factors (age, sex, general health, tooth anatomy, preoperative pulpal and periapical status), treatment factors (operator variables, canal enlargement, irrigation, medication, culture test, and obturation), and restorative factors. Some factors had a profound impact on success rates, whereas others showed a negligible effect. Patient factors characterizing the nature of the disease showed the most significant effect (periapical status), whereas most of the treatment factors were found to exert a less significant effect; exceptions were the apical extent of root canal treatment relative to the root canal terminus. In addition, the quality of the postoperative restorative care also exerted a profound influence on the outcome of treatment.

Patient factors

Patient's age and sex consistently had no significant effect on outcome, whereas some specific health conditions (diabetes,[54,67] compromised immune response[123]) apparently had a significant influence. The evidence for the effect of host immune response characterized by the general health of the patient is, however, weak. Emerging evidence indicates that the host response measured by polymorphisms of various genes involved in periapical healing may have an effect on outcomes (Table 17.8).[142,183,212,213] The importance of the host response to maintenance of periapical health or periapical healing was also supported by the statistically significant clustering effect of multiple teeth within the same patient in a prospective study.[150]

SNP, Single nucleotide polymorphism.

The widespread perception that single-rooted teeth with less complicated anatomy should benefit with more predictable and favorable outcomes proves to be untrue. Having accounted for potential confounding factors such as the presence of periapical disease, tooth type does not seem to exert a strong influence on success rates. This would appear to be counterintuitive but may be explained by the logical inference that canal complexities in the apical anatomy probably play a more dominant role than other complexities, such as the number and curvature of canals.

The presence and size of a periapical lesion seem to have the most negative effect on periapical health/healing; it therefore follows that these factors must be accounted for when analyzing the influence of any other factor. The profound change in success rates once a periapical lesion becomes established is interesting, as it is correlated with the establishment of infection in the apical canal anatomy. This seems to suggest that once the apical canal complexities become infected, it may be much more difficult to eradicate the infection. The negative influence of large periapical lesions has a reasonable biologic explanation: the diversity of bacteria (by number of species and their relative abundance) is greater in teeth with larger periapical lesions.[230] An endodontic infection is more likely to persist in canals with a higher number of bacteria present preoperatively.[27] In addition, larger lesions may represent longer-standing root canal infections that may have penetrated deeper into dentinal tubules and accessory anatomy in the complex canal system[206] where mechanical and chemical decontamination procedures may not be so effective. Larger lesions may also represent cystic transformation.[145] Finally, the host response may also play a part, as patients with larger lesions may innately respond less favorably to residual bacteria.[147] This speculation may crystallize into distinct questions for further biologic research into the nature of interactions among host, bacterial infection, and treatment intervention.

Telegram: @dental_k

www.konkur.in

Most of the other investigated preoperative factors (pain, tooth tenderness to percussion, soft-tissue tenderness to palpation, soft-tissue swelling and sinus tract, periodontal probing defect of endodontic origin, root resorption) are in fact different clinical manifestations of periapical disease.[254] They may therefore act as surrogate measures or complement "presence and size of periapical lesion" in measuring the effect of severity of periapical disease within a broad continuous spectrum. Of these, only presence of preoperative pain,[68] sinus tract,[150] swelling,[150] and apical resorption[229] have been found to be significant prognostic factors that have been associated with significantly reduced success rates in root canal treatment.

The biologic explanation for the negative impact of sinus tract and swelling, either in the acute or chronic form, on periapical healing is interesting, as both represent suppuration and the proliferation of microbiota into the periapical tissues, with the inference being that the host tissues must have become locally overwhelmed. The precise reasons for reduced success rates under these conditions remain unclear but must somehow be related to the nature of the host-microbial interaction.

Treatment factors

Operator.

Although the impact of operator qualification and skill has not been specifically investigated, systematic review has shown that the involved clinicians may be grouped into undergraduate students, general practitioners, postgraduate students, and specialists. Studies show a clear trend in superior outcomes by greater experience and training. Clearly, technical skills play an important role, but this is difficult and often impossible to quantify. In addition, the technical abilities must be augmented by the overall understanding of the biologic issues and the quest for superior treatment by the operator. If clinicians do not feel that they can provide optimal treatment, it is incumbent upon them to refer the patient to a more qualified practitioner.

Isolation.

The use of rubber dams in modern root canal treatment is widely accepted, and the justification seems almost empirical. One study on retreatment[244]

Telegram: @dental_k

www.konkur.in

analyzed the influence of rubber dam use compared to cotton roll isolation and found significantly higher success rates with the former approach. Another study reported a significantly higher success rate of root canal–treated teeth[76] when a rubber dam was employed during post placement compared to when it was not. Perhaps as a consequence, the principal justification for rubber dam use is based on medicolegal implications of root canal instrument ingestion or aspiration by the patient.[61]

Magnification and illumination.

Endodontists have repeatedly reinforced the value of magnification and illumination during root canal treatment,[166] but a systematic review failed to draw any objective conclusions on their influence as no article was identified in the current literature that satisfied their inclusion criteria.[46] A prospective study investigated this factor,[150] but researchers found only an insignificant influence on the final outcome. Use of a microscope may sometimes assist location of the second mesiobuccal canal in maxillary molars, but this only made a small difference to the success rates associated with mesiobuccal roots, when a periapical lesion was present.[150] The true benefit of a microscope can only be verified through a randomized controlled trial. However, canal negotiation with less tooth structure removal and fewer procedural accidents is favorable and seems intuitively more consistent with the use of superior magnification and illumination.

Mechanical preparation: Size, taper, extent, and procedural errors.

The root canal system may be mechanically prepared to a requisite size and taper[199] using a variety of instruments of different cutting designs, tips, tapers, and materials of construction. Their efficacy is often tested in laboratory studies, and the instruments and their utility may have well-characterized properties.[95] Investigation of the influence of the type of instrument used for canal enlargement has been undertaken in one nonrandomized prospective study, but the outcome is likely subjective because of many factors, including the protocol adopted for teaching technical skills.[150] In this study, the better success rates for hand or rotary NiTi instruments compared with stainless steel instruments[150] were

Telegram: @dental_k

www.konkur.in

attributable to the fact that tactile skills training was achieved through a preliminary focus on the use of stainless steel files to develop tactile sensitivity and consistency. Only on demonstration of this competency did the trainees progress to NiTi instruments. More importantly, such senior students may also have had a better understanding of the biologic rationale for root canal treatment. The ability to gain and maintain apical patency as well as to avoid procedural errors was better instilled in the senior students, whereas in selected cases, NiTi instruments appear capable of achieving the same in primary root canal treatment undertaken by undergraduates.[175]

A key tenet of the ESE[61] guidelines is that root canal debridement must be extended to the terminus of the canal system, which is expressed variously as extension to the "apical constriction," or to "0.5 to 2 mm from the radiographic apex," or to the "cementodentinal junction." This guideline is broadly supported by the fact that outcome of treatment is compromised by canal obstruction or failure to achieve patency to the canal terminus.[150,216,229] Ng and colleagues[150] reported a twofold reduction in the success of treatment when the patency to the canal terminus was not achieved. It could be speculated that the lack of mechanical negotiability of canals may be due to the presence of obstructions caused by "denticles," tertiary dentine, acute branching or a fine plexus of apical canals, or dentine/organic debris.

The continued debate on the optimal size of apical preparation remains topical in the absence of definitive evidence; the findings from relevant in vitro and clinical studies have been previously reviewed.[15] So far, four clinical outcome studies have considered this issue or have systematically investigated the effect of apical size of canal preparation on treatment outcome.[93,102,150,188,223,229] One randomized controlled trial revealed that enlargement of the canal to three sizes larger than the first apical binding file was adequate[188] (the mean final size was ISO #30). The observational studies[95,150,229] had not designed their investigation with apical canal size as their principal focus and neither had they found a statistically significant influence from this factor; nevertheless, they all reported the same inverse trend of decreasing success rates with an increase in size of apical preparation. It was speculated that canal preparation to larger apical sizes may compromise treatment success by generation of more apical dentine debris, which in the absence of an adequate irrigation regimen serves to block

Telegram: @dental_k

www.konkur.in

apical canal exits that may still be contaminated with bacteria. Continued generation of dentine debris, in the absence of sufficient irrigation, may lead to what is termed *dentine mud,* which ultimately creates a blockage. The impatient or neophyte clinician fails to resist the temptation to force the instrument back to length, resulting in the classically described procedural errors of apical transportation, canal straightening, and perforation. An alternative mechanism is required to explain the higher failures in initially large canals; it is likely that immature roots present a different debridement challenge, where the canal shape is not amenable to planing of the main portions of the canal by conventional instruments. Perhaps an intracanal brush may be a more suitable cleaning device in such teeth. The findings from these studies therefore do not concur with views that more effective bacterial debridement may be achieved with larger apical preparations.[33,164,184]

The issue of apical preparation size should be considered together with that of the size and taper of the rest of the canal preparation. Again, there is a paucity of sufficient direct evidence for the influence of degree of canal taper on root canal treatment outcome. The ESE guidelines[63] recommend only that canal preparation should be tapered from crown to apex without stipulating any particular degree of taper. Three studies have analyzed the influence of canal preparation taper on primary treatment and retreatment outcome, although again, none had focused their investigation primarily on this factor.[93,150,220] Smith and coworkers,[220] using loose criteria for determination of success, found that a “flared” preparation (wide taper) resulted in a significantly higher success rate compared with a “conical” preparation (narrow taper); the exact degree of taper was not reported and the effects of other treatment and nontreatment parameters were not controlled. In contrast, Hoskinson and associates[93] and Ng and colleagues,[150] using strict criteria, did not find any significant difference in treatment outcome between narrow (0.05) and wide (0.10) canal tapers. The controlled use of stainless steel instruments in a step-back technique may create 0.05 (1 mm step-back) or 0.10 (0.5 mm step-back) tapers, although, of course, uncontrolled use of such instruments may generate a variety of shapes. Ng and colleagues[150] also compared these (0.05 and 0.10) preparation tapers with 0.02, 0.04, 0.06, and 0.08 tapers (generally achieved by using greater taper nickel-titanium

Telegram: @dental_k

www.konkur.in

instruments) and found no significant effect on treatment outcome. They cautioned that their investigation of the influence of canal preparation taper without randomization could be influenced by the initial size of the canal, the type of instrument used, and operator experience.

Triangulation of the data on the effects of canal preparation size and taper on treatment outcome may intuitively lead to the conclusion that as far as current best evidence indicates, it is not necessary to overenlarge the canal to achieve periapical healing. An apical preparation size of ISO 30 with a 0.05 taper for stainless steel instrumentation or 0.06 taper for NiTi instrumentation is sufficient. Precisely what biologic and hydrodynamic mechanisms underpin such sufficiency is more difficult to define based on available evidence. Although a number of laboratory studies[4,84,112] have investigated the interaction between canal dimensions and irrigation or obturation dynamics, the precise physical, chemical, or biologic mechanisms that ultimately enable periapical healing remain unknown, although collaborations with fluid dynamics specialists[84] and (micro)biologists[82] may ultimately yield a clearer picture.

Procedural errors during root canal preparation include canal blockage, ledge formation, apical zipping and transportation, straightening of canal curvature, tooth or root perforation at the pulp chamber or radicular level, and separation of instruments. Instrument separation during treatment has been found to reduce the success rate significantly[150,229]; however, the reported prevalence of instrument separation was low (0.5% to 0.9%) in these studies, precluding an analysis of causative factors. A case-control study[225] revealed no significant difference in success rates between periapically involved teeth with or without retained separated instruments. The stage of canal debridement at which instrument separation occurred and the justification for their retention may have implications on the outcome. The coronoapical location of a separated instrument and whether the instrument was successfully bypassed were found to have no effect on treatment outcome.

Irrigant.

Different chemical agents have been used as irrigants for root canal treatment, singly or in various combinations, both in clinical practice and in the studies reviewed. They have included water, saline and solutions of local

Telegram: @dental_k

www.konkur.in

anesthetic, sodium hypochlorite, iodine, chloramine, sulfuric acid, EDTA, hydrogen peroxide, organic acid, Savlon, urea peroxide, and Biosept (a quaternary ammonium compound).[153] Most of the studies had used sodium hypochlorite as an irrigant,[153] regardless of whether it was primary treatment or retreatment. This is consistent with the ESE guidelines[61] for irrigation, which recommend a solution possessing disinfectant and tissue-dissolving properties.

One prospective study[150] systematically investigated the effect of the irrigant on the success rates of root canal retreatment, which, although not a randomized controlled trial, revealed interesting new findings on the effects of irrigants. Even though a higher concentration of sodium hypochlorite made negligible difference to treatment outcome, the additional use of other specific irrigants had a significant influence on success rates.[150] The finding of a lack of improvement in periapical healing with the use of a higher concentration NaOCl solution is consistent with previous clinical/microbiologic findings.[29,41] Comparing 0.5% to 5.0% NaOCl solution for irrigation, it was found that the concentration of solution, per se, did not appear to increase the proportion of teeth rendered culture-negative[29] or associated with greater periapical healing.[41] As iodine and sodium hypochlorite are both halogen-releasing agents and attack common key protein groups,[129] the finding that the additional use of 10% povidone-iodine for irrigation had no additional influence on treatment success was as expected. Surprisingly, however, the additional use of 0.2% chlorhexidine solution for irrigation was found to reduce the success of treatment significantly.[150] This finding was in complete contrast to previous reports[211,252] on its equivalent or superior in vivo antibacterial efficacy when compared with sodium hypochlorite solution. The use of chlorhexidine as a final irrigant following sodium hypochlorite irrigation had been recommended[107] and was justified on several grounds, including its substantivity in root dentin (i.e., prolonged antibacterial effect),[185] relative lack of toxicity,[117] and broad-spectrum efficacy.[130] Not until recently has alternate irrigation with sodium hypochlorite and chlorhexidine solution raised serious concerns because of their interaction product. The interaction product is thought to be an insoluble precipitate containing para-

Telegram: @dental_k

www.konkur.in

chloroaniline, which is cytotoxic and carcinogenic.[14,24] Apart from mutually depleting the active moiety in the two solutions for bacterial inactivation, the precipitate may cause persistent irritation to the periapical tissue and block dentinal tubules and accessory anatomy, possibly explaining the observed lower success rate when chlorhexidine was used as an additional irrigant.

Ng and associates[150] also found that the additional use of EDTA had a profound effect on improving radiographically observed periapical healing associated with root canal treatment (OR = 1.5 [1.1, 2.0]). In contrast, the observed synergistic effect of sodium hypochlorite and EDTA had been previously demonstrated in terms of bacterial load reduction[26] but not periapical healing. The long-term (≥2 years) outcome of their cases stratified by canal disinfection protocols[25] did not support their microbiologic findings. Their reported success rate for alternate irrigation with sodium hypochlorite and EDTA solutions (67%) was low when compared to the success rate for irrigation using saline (91%), 0.5% sodium hypochlorite (92%), or 5% sodium hypochlorite (86%) solutions.[162] The reported outcome data were unexpected, as preobturation negative bacterial culture was achieved in all cases. Given the complexity of their study design (clinical and microbiologic), their sample size was restricted to 11 to 15 teeth per group, limiting their outcome data. The synergistic effect of the two disinfectants has been attributed to the chelating properties of the sodium salts of EDTA, and their roles have been reviewed by Zehnder.[261] EDTA solution assists negotiation of narrow or sclerosed canals by demineralization of root dentine and helps in the removal of compacted debris from noninstrumented canal anatomy. It may also facilitate deeper penetration of sodium hypochlorite solution into dentine by opening dentinal tubules and removing the smear layer from the instrumented surface. Lastly, it may help detach or break up biofilms adhering to root canal walls.[85]

Medicament.

Most previous treatment outcome studies have not standardized the type of root canal medicament used in the interappointment period, but the use of several different medicaments has been reported. The list was consistent with that recommended in the ESE guidelines for a medicament with disinfectant properties and included calcium hydroxide, creosote, and iodine solutions.[153]

Telegram: @dental_k

www.konkur.in

However, there is an absence of studies investigating the influence of this factor on treatment outcome.

The use of a mixture of calcium hydroxide and chlorhexidine has been tested based on the speculation that the mixture would be more effective against *E. faecalis.*[13,78,198]

Root canal bacterial culture results prior to obturation.

In the past, in various centers of endodontic excellence, completion of root canal treatment by obturation would only be acceptable after a negative culture test was obtained from the canal, confirming the absence of bacteria in the part of the root canal system that could be sampled.[23,70,143] This practice has fallen out of clinical favor because of the perceived predictability and good prognosis of root canal treatment without microbiologic sampling. Sampling procedures are considered to be lengthy, difficult, and often inaccurate, requiring laboratory support and having low benefit-to-cost ratio.[138,139] A preobturation negative culture result may increase treatment success twofold (Fig. 17.19). One large study[201] helped contribute to the demise of the canal-culture test; however, even this study showed a 10% difference in success in favor of the negative culture test when periapical disease was present. The outcome is even worse when a positive culture test result combines with the presence of a periapical lesion.

CH, Calcium hydroxide; *CP*, camphorated phenol; *CMCP*, camphorated monochlorophenol; *NaOCl*, sodium hypochlorite; *PP*, paper point sample; *r culture*, culture test before obturation.

The effect of the "mechanical preparation" of the canal(s) on the microbiota has been tested using only water or saline as the irrigant. Taken collectively, the studies show that negative cultures were achieved on a weighted pooled average in 31% of the cases (range 0% to 79%). When sodium hypochlorite (concentration range 0.5% to 5%) irrigation supplemented the "mechanical preparation," the frequency of negative cultures immediately increased to a weighted pooled average of 52% (range 13% to 95%) (see Table 17.9).

Most studies report culture reversals during the interappointment period when active antibacterial dressing is not used in the root canal system between appointments. The reversals are due to regrowth of residual bacteria or recontamination by bacteria from coronal restoration leakage. When active interappointment antibacterial dressing is used, negative cultures in the subsequent visit were achieved on average in 71% of cases (range 25% to 100%) (see Table 17.9).

Effect of persistent bacteria on root canal treatment outcome.

The bacteria present in preobturation cultures have included *Enterococcus*, *Streptococcus*, *Staphylococcus*, *Lactobacillus*, *Veillonella*, *Pseudomonas*, *Fusobacterium* species, and yeasts. Studies have been variable as to the relationship between individual species and treatment failure. Although the overall failure rate for cases with positive cultures was 31%, teeth testing positive for *Enterococcus* species had a failure rate of 55%, and teeth with positive cultures for *Streptococcus* species had 90% failures.[70] In another study, good-quality root canal treatment on 54 teeth with asymptomatic periapical disease gave an overall success rate of 74%, but teeth with positive cultures for *Enterococcus faecalis* achieved a success rate of only 66%.[231] The success rate for teeth with no bacteria was 80%, whereas that for teeth with bacteria in the canal before obturation was 33%. These associations cannot be regarded as direct cause-and-effect associations, but they further emphasize the need to determine a relationship between microbial diversity and treatment outcome.

A monkey-model study[63] used a four- or five-strain infection to test the effect of debridement and obturation procedures on outcome. When bacteria remained after chemomechanical debridement, 79% of the root canals were associated with nonhealed periapical lesions, compared with 28% when no bacteria were found to remain. Combinations of several residual bacterial species were more frequently related to nonhealed lesions than were single strains. When no bacteria remained at the end of chemomechanical debridement, healing occurred independently of the quality of the root filling. In contrast, when bacteria remained in the canal system, there was a greater correlation with nonhealing associated with poor-quality root fillings than in technically well-performed fillings. In root canals where bacteria were found after removal of the root filling, 97% had not healed, compared with 18% for those root canal systems with no bacteria detected upon removal of root filling. The study emphasizes the importance of reducing bacteria below detection limits before permanent root filling in order to achieve optimal healing conditions for the periapical tissues. It also reinforces the view that obturation does indeed play a role when residual infection is present.

Regardless of the technique used for obtaining a sample for a canal culture, the presence of a negative culture seems to have a positive impact on

Telegram: @dental_k

www.konkur.in

treatment outcome. The association of specific species with treatment failure is not well established but the identity of the small group of species isolated from positive cultures is relatively constant and may hold answers to treatment resistance and failure. However, it is important to understand that there are many other factors that can influence root canal treatment outcome.

Root filling material and technique.

The interrelationship among the core root filling material, sealer (for filling the gaps between the core material and canal surface), and technique for their placement complicates the investigation of the effect of obturation and technique on treatment outcome. In previous studies on treatment outcome, the most commonly used core root filling material was gutta-percha with various types of sealer or gutta-percha softened in chloroform (chloropercha).[153] The sealers used may be classified into zinc oxide–eugenol–based, glass ionomer–based, and resin-based types.[153] Materials such as Resilon, SmartSeal, and MTA have been adopted but have not significantly penetrated the market, except for the use of MTA in surgical repairs or repairs for immature apices. In any case, there is no evidence to show that the nature of root filling material and the technique used for placement has any significant influence on treatment outcome.

Apical extent of root filling.

Of the many intraoperative factors associated with success and failure of root canal treatment, the apical extent of the root canal filling material has been the most frequently and thoroughly investigated. In these previous studies, the apical extent of root fillings has been classified into three categories for statistical analyses: more than 2 mm short of radiographic apex (short), 0 to 2 mm within the radiographic apex (flush), and extended beyond the radiographic apex (long).[153] The apical extent of root filling was found to have a significant influence on the success rates of treatment, regardless of the periapical status.[150,153] Flush root fillings were associated with the highest success rates, whereas long root fillings were associated with the lowest success rates.

Most previous retrospective studies could not distinguish between the effects of apical extent of instrumentation versus the apical extent of

Telegram: @dental_k

www.konkur.in

obturation; however, the London Eastman study[150] was able to separate the effect of these two factors and found them both to independently and significantly affect periapical healing. The factors correlated with each other, consistent with the fact that canals are normally filled to the same extent as canal preparation.

Extrusion of cleaning, medication, or filling materials beyond the apical terminus into the surrounding tissues may result in delayed healing or even treatment failure due to a foreign body reaction.[105,146,218,260] Magnesium and silicon from the talc-contaminated extruded gutta-percha were found to induce a foreign body reaction, resulting in treatment failure.[146] An animal study has shown that large pieces of subcutaneously implanted gutta-percha in guinea pigs were well encapsulated in collagenous capsules, but fine particles of gutta-percha induced an intense, localized tissue response.[218] The inference that perhaps extrusion of large pieces of gutta-percha may not impact periapical healing was not supported by data from previous studies.[150,153] The discrepancy may possibly be accounted for by bacterial contamination of the extruded gutta-percha in the clinical data.

The radiographic evidence of “sealer puffs” extruding through the main apical foramina and lateral/accessory canals has been pursued with vigor by some endodontists based on the undaunted belief of its value as “good practice.” Their perception is that this represents a measure of root canal system cleanliness, and they ardently argue that healing would follow, albeit with some delay. The published evidence on the effects of sealer extrusion into the periapical tissues has been contradictory. Friedman and colleagues[68] found that extrusion of a glass ionomer-based sealer significantly reduced success rates. In contrast, Ng and associates[150] reported that extrusion of a zinc oxide–eugenol based–sealer had no significant effect on periapical healing. The discrepancy may be attributed to the difference in sealer type and the duration of treatment follow-up. The radiographic assessment of the presence or resorption of sealer may be complicated by the radiolucent property of its basic components and the insufficient sensitivity of the radiographic method used to detect small traces of it.[150] It is possible that, in some cases, the radiographic disappearance of extruded sealer may simply be due to resorption of the radio opaque additive, barium sulfate, or its uptake by macrophages, still resident in the vicinity.[146]

Telegram: @dental_k

www.konkur.in

Extruded glass ionomer–based[68] zinc oxide–eugenol–based,[98] silicone-based[98] sealers or endomethasone[22] were not found to be resorbed/absorbed by periapical tissues after 1 year. Traces of calcium hydroxide–based sealer (Sealapex) could still be detected after 3 years.[194] In the latter study, treatments were carried out on primary molar teeth and the canals were obturated with Sealapex without gutta-percha. With longer duration of follow-up, complete resorption of extruded zinc oxide–eugenol–based sealers (Procosol, Roth Elite)[8] and a resin-based sealer (AH Plus, Dentsply/DeTrey, Konstanz, Germany)[194] was demonstrated in 69% and 45% of the cases after 4 and 5 years, respectively. Ng and associates[150] advanced two explanations for the difference between the effect of extruded core gutta-percha and the zinc oxide–eugenol sealer: the latter is antibacterial and may kill residual microorganisms, whereas it is also more soluble and readily removed by host cells compared to gutta-percha.

Quality of root filling.

Another much investigated parameter of obturation in retrospective studies has been the radiographic measure of the "quality of root filling." The rationale for complete obturation of the root canal system is to prevent recontamination by colonization from the residual infection or newly invading bacteria. Both are supposedly prevented by a "tight" seal with the canal wall and an absence of voids within the body of the material. Quality of root filling may therefore be regarded either as poor root-filling technique or as a surrogate measure of the quality of the entire root canal treatment, because good obturation relies on properly executed preliminary steps in canal preparation. A systematic review[153] reported that the criteria for judging the quality of root fillings have not been well defined in previous studies.[43,93,216] An unsatisfactory root filling has been defined as "inadequate seal," "poor apical seal," or "radiographic presence of voids." Nevertheless, satisfactory root fillings were found to be associated with significantly higher success rates than unsatisfactory root fillings.[153]

Acute exacerbation during treatment.

The causes for interappointment "flare-up" or pain have not been precisely determined, and several hypothetical mechanisms involving chemical,

Telegram: @dental_k

www.konkur.in

mechanical, or microbial injury to the periradicular tissues, as well as psychological influences, have been suggested as contributory to postpreparation pain or swelling.[202,203] Although these factors have not been specifically studied in the context of periapical healing, acute "flare-ups" during treatment were not found to be significantly associated with periapical healing in two studies.[102,216] In contrast, the London Eastman study[150] found that pain or swelling occurred in 15% of cases after chemomechanical debridement and was found to significantly reduce success as measured by periapical healing. This interesting finding may be explained by the hypothesis that "flare-ups" were caused by extrusion of contaminated material during canal preparation. Such material may elicit a foreign body reaction or (transient) extraradicular infection, resulting in treatment failure in a proportion of such cases. Alternatively, acute symptoms may be the result of incomplete chemomechanical debridement at the first appointment, leading to a shift in canal microbial ecology favoring the growth of more virulent microorganisms, leading to further postpreparation pain and treatment failure. The exact biologic mechanisms of failure in these cases remain obscure and warrant further investigation.

Number of treatment visits.

The number of treatment visits for completing root canal treatment and its effect on periapical healing remains an ongoing controversy. Generally, the argument for single-visit treatment centers around better patient acceptability and cost-effectiveness versus the preference of multiple-visit treatments based on biologic rationale.[224] The premise for multiple-visit treatments has been that primary debridement is not completely effective in eliminating all the adherent bacterial biofilm,[147] and the residual bacteria may multiply and recolonize the canal system.[25,29] Therefore the proponents consider it desirable to use the interappointment period to dress the canal with a long-lasting or slow-release antibacterial agent capable of destroying or incapacitating residual bacteria, as well as to take the opportunity to gauge the initial periapical response before root filling. Calcium hydroxide has served in this capacity for many years because of its ability to dissolve organic tissue, kill bacteria, detoxify antigenic material, and act as a slow-release agent because of its low solubility-product in an aqueous

Telegram: @dental_k

www.konkur.in

environment. However, its antibacterial ability has come under close scrutiny, with advocates suggesting that the material is not suitable for this purpose.[195] A final resolution to this debate is awaited based on robust clinical evidence. Most of the published randomized controlled trials found no significant influence of healing attributable to number of treatment visits, but they all lacked robust statistical power.

The debate about the merits of single- or multiple-visit treatments will continue unabated given the respective strengths of the motivational drivers among the opposing groups. The issue may only be resolved by properly documented, large randomized controlled trials (which are currently unavailable) because undocumented variables (i.e., operator skill, biologic or technical case complexity, and patient compliance) would continue to bias the outcome.

Post root canal treatment restorative factors

Effect of quality and type of restoration.

The placement of a coronal restoration after root canal obturation is the final step in the management of teeth undergoing root canal treatment. It has been shown to have a major influence on endodontic outcomes. Teeth with satisfactory coronal restorations were found to have significantly better periapical healing compared with those with unsatisfactory restorations (OR = 3.31; 95% CI: 1.07, 10.30).[153] The term *satisfactory restorations* has been defined as a restoration with no evidence of marginal discrepancy, discoloration, or recurrent caries with absence of a history of decementation.[93,182]

Given that one of the roles of coronal restorations is to prevent postoperative root canal reinfection via coronal leakage, the criteria for unsatisfactory restoration given by Hoskinson and colleagues[93] could not infer coronal leakage when the inner core was still intact. Consequently, the London Eastman study[150] adopted a different classification and definition for unsatisfactory restorations in order to illustrate obvious and potential coronal leakage more accurately. The two groups of unsatisfactory restorations were defined as those with (1) obvious signs of exposed root filling and (2) potential leakage indicated by marginal defects and history of decementation.

Telegram: @dental_k

www.konkur.in

It is perhaps this strategy that contributed to the finding of a profound effect (OR = 10.7; 95% CI: 3.7, 31.5) of coronal leakage on the endodontic outcome.

A number of investigations have been performed based on comparisons between the types of post root canal treatment restorations, including permanent versus temporary restorations,[43,68,150] crown versus acrylic restorations,[43,68,150,216] presence versus absence of posts,[68,150] and nonabutment versus abutment.[150,216] Teeth that had been permanently restored were associated with significantly higher success rates than their temporarily restored counterparts in some studies[43,68] but not in others.[38,150] The type of permanent restoration[43,68,150,216] was found to have no significant influence on the outcome of treatment.

It has often been recommended that it would be wise to provide a subseal over the root filling in case of loss of a permanent or temporary restoration; the subseal would be glass ionomer (GIC) or zinc oxide–eugenol cement.[196] The placement of a GIC or zinc oxide–eugenol (IRM) cement lining coronal to the gutta-percha filling and underneath the permanent core in order to provide an additional antibacterial coronal seal was found in a prospective study to have no beneficial effect on treatment success.[150]

In summary, the preceding findings overall support the ESE guidelines[61] that an adequate restoration should be placed after root canal treatment to prevent subsequent bacterial recontamination. Therefore the provision of a good-quality coronal restoration, regardless of type, should be considered the final part of the root canal treatment procedure following obturation.

Use of root treated teeth as abutments for prostheses and occlusal contacts.

Mechanical stress on restorations is a function of the role of individual teeth in the occlusal scheme. The pattern of occlusal loading both in static and dynamic occlusion is dictated by whether the teeth are involved as single units or abutments (bridge/denture) and whether they have holding or guiding contacts. It is reasonable to expect that bridge and denture abutments may be placed under unfavorable loads, as may last-standing teeth in the dental arch.[127] These teeth may therefore be expected to have lower success rates because of a potential increase in the development of cracks and fractures due

Telegram: @dental_k

www.konkur.in

to fatigue. This observation has been confirmed for teeth functioning as bridge abutments compared with those restored as individual units following root canal treatment.[216]

Summary of factors influencing periapical healing following nonsurgical root canal treatment

The following factors are considered as having a major impact on periapical health subsequent to root canal treatment:

- Presence (Fig. 17.20) and size (Fig. 17.21) of periapical lesion
- Patency at the canal terminus (achieving patency significantly increased the chance of success twofold)[150]
- Apical extent of chemomechanical preparation in relation to the radiographic apex (Fig. 17.22)
- Outcome of intraoperative culture test (see Fig. 17.19)
- Iatrogenic perforation (if present, reduces the odds of success by 30%)[150]
- Quality of root canal treatment judged by the radiographic appearance of the root filling (Fig. 17.23)
- Quality of the final coronal restoration (Fig. 17.24)

horizontal axis and 10.2.

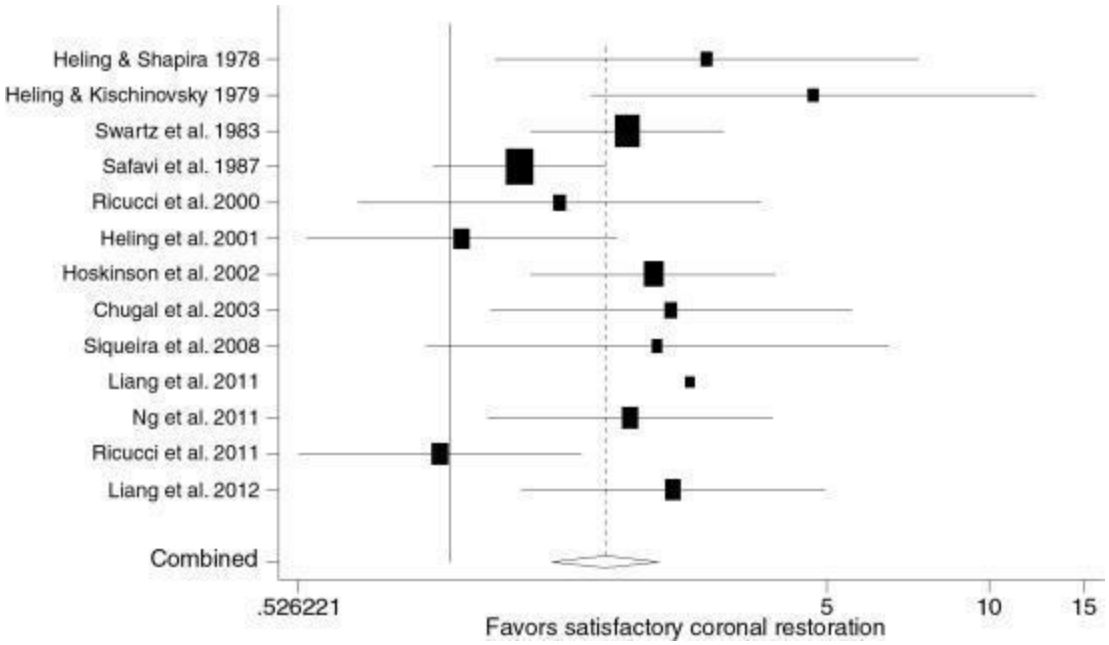

FIG. 17.24 Forest plot showing pooled and individual study's odds ratio (OR) of periapical health for teeth undergoing root canal treatment with satisfactory versus unsatisfactory coronal restoration at follow-up (pooled OR = 1.9; 95% CI: 1.5, 2.5).

Forest plot shows combined and individual study against Logor_satrest_unsatrest.

The horizontal axis is marked at 0.5 2 6 2 2 1, 5, 10, and 15. The vertical axis is marked from bottom to top as follows: Combined, Liang et al. 2012, Ricucci et al. 2011, Ng et al. 2011, Liang et al. 2011, Siqueira et al. 2008, Chugal et al. 2003, Hoskinson et al. 2002, Heling et al. 2001, Ricucci et al. 2000, Safavi et al. 1987, Swartz et al. 1983, Heling & Kischinovsky 1979, Heling & Shapira 1978. The data points for all studies lie in-between near one-fourth length of the horizontal axis and 5 (three-fourth length of the horizontal axis).

The following factors are considered as having minimal impact on root canal treatment outcome:

- Age of patient
- Gender of patient
- Tooth morphologic type

Telegram: @dental_k

www.konkur.in

- Specific root canal treatment protocol and technique (preparation, irrigation, and obturation material and technique)

Contemporary improvements in mechanical and chemical canal preparation have not resulted in an increase in the success rate for root canal treatment over the past century (Fig. 17.25). This observation may be explained by the currently available techniques not being effective in eliminating the infection in the apical canal anatomy.

J) Forest plot shows combined and individual study against Probability of success—loose.

The horizontal axis ranges from 0 (near origin) to 1 in the increments of 0.1. The approximate data are as follows: Combined: 0.8 9, Ng et al. 2011: 0.8 9, Witherspoon et al. 2008: 0.9 1, Siqueira et al. 2008: 0.9 5, Penesis et al. 2008: 0.8 2, Zmener and Pameijer 2007: 0.9 3, Sari and Duruturk 2007: 0.9 1, Molander et al. 2007: 0.9, Conner et al. 2007: 0.8 3, Negishi et al. 2005: 0.8 4, Huumonen et al. 2003: 0.7 8, Cheung and Chan 2003: 0.4 9, Peters and Wesselink 2002: 0.9 7, Benenati and Khajotia 2002: 0.9, Pettiett et al. 2001: 0.6, Peak et al. 2001: 0.8 3, Heling et al. 2001: 0.6 4, Deutsch et al. 2001: 0.9 2, and Weiger et al. 2000: 0.9 2.

It is notable that all factors that have a strong influence on periapical health after root canal treatment are associated in some way with a persistent root canal infection. Further improvements in root canal treatment outcomes may therefore be achieved by understanding the nature of the root canal infection (especially apically) and the manner in which the microbiota is altered or eliminated during root canal treatment.

Factors affecting tooth survival following root canal treatment

Telegram: @dental_k

www.konkur.in

A systematic review and meta-analysis has shown that 93% of endodontically treated teeth survive at 2 years postoperatively; but this survival reduced to 88% at 10 years following treatment (Fig. 17.26). The most common reasons for such tooth loss were due to problems of endodontic origin, tooth/root fracture, or restoration failure.[149,151] Consistent with the studies on periapical healing, the considerations affecting the survival of endodontically treated teeth may be divided into patient, intraoperative, and restorative factors.

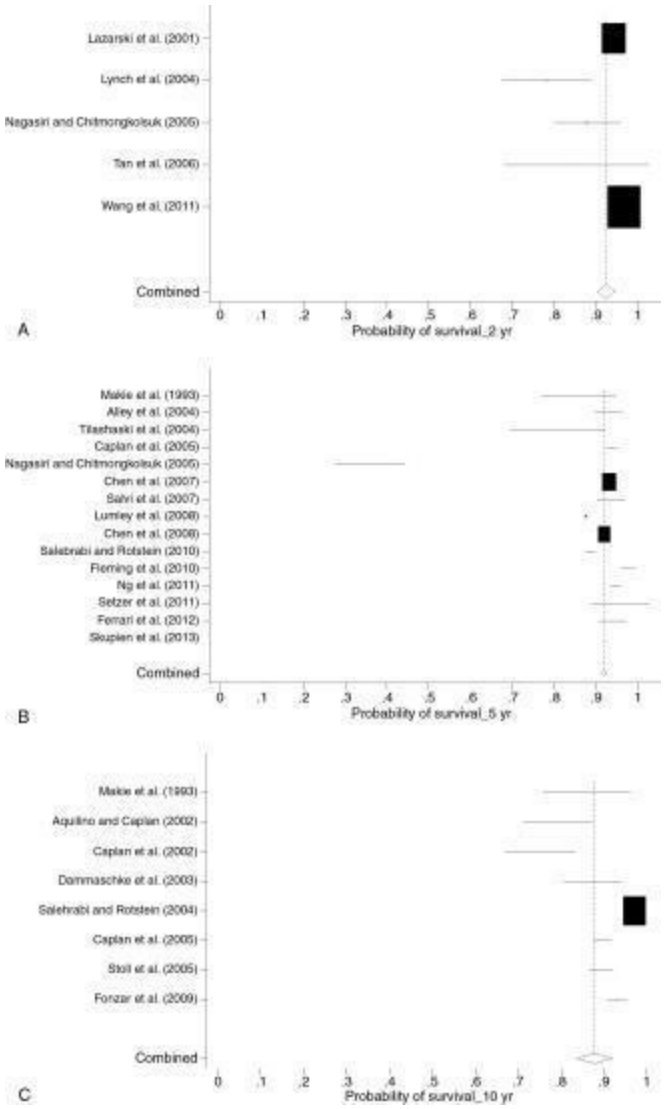

FIG. 17.26 Forest plot showing pooled and individual study's probability of 2-year (pooled probability = 0.93; 95% CI: 0.90, 0.95) **(A)**, 5-year (pooled probability = 0.92; 95% CI: 0.91, 0.93) **(B)**, and 10-year (pooled probability = 0.88; 95% CI: 0.84, 0.92) **(C)** survival of teeth undergoing root canal treatment.

Patient factors

Ng and colleagues[151] found that teeth in patients suffering from diabetes or receiving systemic steroid therapy had a higher chance of being extracted after root canal treatment. The negative influence of diabetes on tooth survival is consistent with the report by Mindiola and associates,[135] whereas the influence of steroid therapy had never been reported previously. It may be argued that patients with diabetes are more susceptible to periodontal disease[74] or have a lower success rate of root canal treatment[67] because of being immunologically compromised. However, the researchers reported that over 50% of such teeth were extracted due to persistent pain. Some of these observations may be explained by the presence of neuropathy, a debilitating painful complication of diabetes.[57] It is interesting to note that systemic steroid therapy is often prescribed to control such chronic pain.[39,51,101]

Tooth morphologic type and location

Tooth types (i.e., location within the arch) may vary with respect to their

Telegram: @dental_k

www.konkur.in

susceptibility to tooth fracture, a common reason for tooth loss after endodontic treatment. Ng and coworkers[149] found that tooth type had a significant influence on survival. Maxillary premolars and mandibular molars were found to have the highest frequency of extraction, with tooth fracture being the most common reason. The observation is consistent with previous reports on fracture incidence of maxillary premolars and mandibular molars.[56,109] The factors "proximal contacts" and "terminal (last standing) teeth" were found to affect tooth survival considerably,[149,151] but they were significantly correlated with molar teeth. Most of the extractions of terminal teeth or teeth with one or fewer proximal contacts were due to tooth fracture.[151] The observation may be explained by the unfavorable distribution of occlusal forces and higher nonaxial stress on terminal teeth and those with fewer than two proximal contacts. Other possible reasons for their higher rate of loss are (1) failure of root canal treatment in a terminal tooth may be accepted more willingly because of little perceived aesthetic value and (2) clinicians may be less likely to offer further treatment on terminal molar teeth due to difficult access. Therefore when restoring molar teeth, the favorable distribution of occlusal forces must be considered, especially on teeth with one or fewer adjacent teeth or on terminal teeth.

Preoperative conditions of teeth

The presence of preoperative periapical lesions, which is the most significant prognostic factor for periapical healing, was found to have no significant influence on tooth survival.[151] On the other hand, the presence of preoperative periodontal probing defects of endodontic origin, preoperative pain, and preoperative sinus tracts were found to reduce tooth survival.[151] These observations are consistent with a previous report that the mere presence of a persistent periapical lesion was not a sufficient reason for dentists and patients to opt for further treatment, either retreatment or extraction.[180] The negative impact of preoperative pain on survival outcome highlights the importance of accurate pain diagnosis. In some instances, the pain may have been of nonendodontic origin and therefore would persist after treatment.[176] In other instances, preoperative pain of endodontic origin may persist following treatment, as a result of peripheral or central sensitization. Therefore effective pain diagnosis and management for patients presenting

Telegram: @dental_k

www.konkur.in

with preoperative pain are crucial.

The presence of preoperative cervical resorption and perforation was also found to significantly reduce tooth survival.[151] This was as expected because tooth fracture and reinfection due to leakage through the resorption and perforating defects are likely sequelae in such cases. In the presence of reinfection, clinicians are more inclined to suggest extraction due to the intuitive perception of poor long-term prognosis of such teeth.

Treatment factors

Considering all of the intraoperative factors, the "lack of patency at apical foramen" and the "extrusion of gutta-percha root filling" were found to be the most significant intraoperative factors in reducing tooth survival.[151] In the presence of persistent problems and knowing that the treatment objective of cleaning to the canal terminus could not be achieved, patients and dentists may be more likely to opt for extraction sooner than later.

Restorative factors

Protection of teeth with crowns or cast restorations has not been shown to influence periapical healing; however, the placement of good cores had a positive effect on endodontic outcome. In contrast, placement of crowns or cast restorations was found to improve tooth survival.[149,151,189] This suggests that crowns and cast restorations help prevent tooth fracture, whereas the mere placement of a satisfactory core is sufficient to prevent reinfection after endodontic treatment. Unfortunately, the study was not able to investigate the interrelationship between tooth morphologic type, the extent of tooth tissue loss after treatment, or the type of final restoration. Although the clinical inference from these findings is that cast restorations should preferably be placed on all teeth after root canal treatment, this is probably a gross exaggeration of the true need. On the basis of laboratory[178] and clinical findings,[144] posterior teeth with compromised marginal ridges (mesial or distal), together with heavy occlusal loading evidenced by faceting, may benefit from full coverage restorations. The restoration design should attempt to preserve as much remaining tooth tissue as possible; the implication is that the so-called nonaesthetic but technically demanding partial veneer onlays and partial coverage crowns would be the restorations of choice for root-

Telegram: @dental_k

www.konkur.in

treated teeth. In anterior teeth, the missing tooth tissue may often be adequately replaced with composite restorative materials. A crown is only indicated when tooth structure or aesthetics become compromised.

The use of cast post and cores for retention of restorations have also been found to reduce tooth survival.[149,151] It may be speculated that the presence of a post has different effects on anterior versus posterior teeth as they are subjected to different directions and amount of occlusal force. It has been reported that only 12% of the extracted teeth with cast post and cores were incisors or canines. Therefore the inference is that the use of such retention should be particularly avoided in premolar and molar teeth. Alternative treatment options should be considered for molar or premolar teeth lacking sufficient tooth structure.

Ng and colleagues[151] observed that teeth functioning as prosthetic abutments had poorer survival rates; however, the number of teeth (n = 94) in the study that functioned as abutments was too small a sample to be considered statistically significant. As previously described, the explanation may reside in the excessive and unfavorable distribution of occlusal stresses on abutment teeth. If possible, root-treated teeth should be avoided as abutments for prostheses or in provision of occlusal guidance in excursive movements.

Summary of factors influencing the survival of teeth following root canal treatment

The following conditions have been found to significantly improve tooth survival following root canal treatment:

- Nonmolar teeth (Fig. 17.27)
- Teeth with both mesial and distal adjacent teeth (Fig. 17.28)
- Teeth not located as the distal-most tooth in the arch[151]
- Teeth (molar) with cast restorations after treatment (Fig. 17.29)
- Teeth not requiring cast post and core for support and retention of restoration[111,151]
- Teeth not functioning as abutments for fixed prosthesis[3,111,191,151]
- Absence of preoperative deep periodontal probing defects, pain, sinus tract, or perforation[151]

www.konkur.in

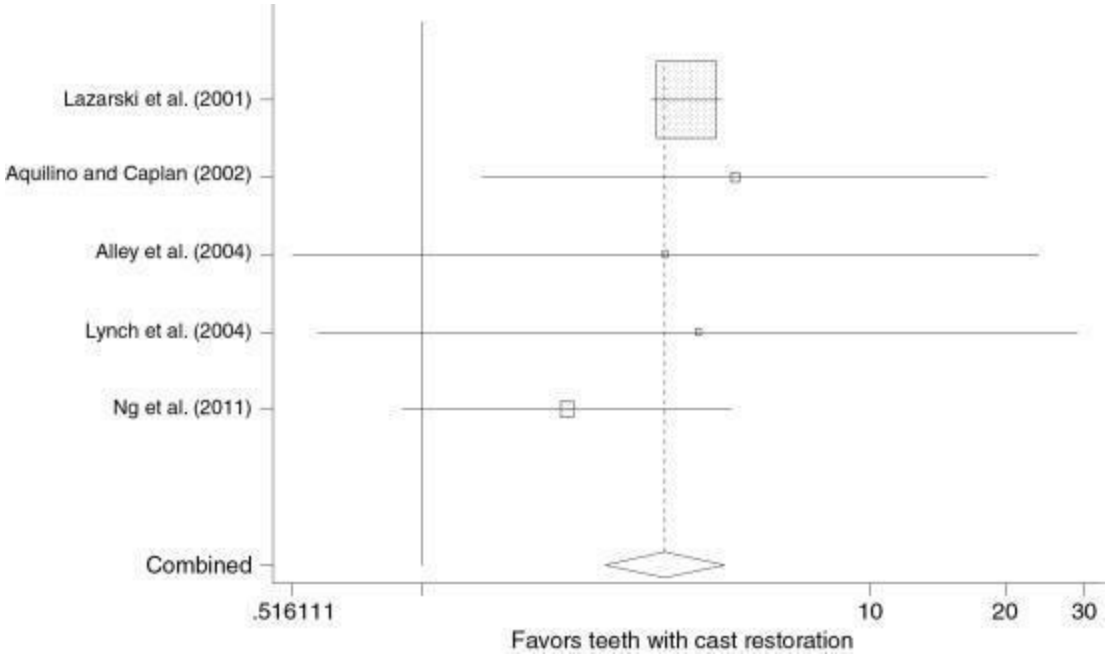

FIG. 17.29 Forest plot showing pooled and individual study's odds ratio (OR) of survival probability for teeth restored with cast versus plastic restoration (pooled OR = 3.5; 95% CI: 2.6, 4.7).

Forest plot shows combined and individual study against Logor_crown_nocrown.

The horizontal axis is marked at 0.5 1 6 1 1 1, 10, 20, and 30. The vertical axis is marked from bottom to top as follows: Combined, Ng et al. (2011), Lynch et al. (2004), Alley et al. (2004), Aquilino and Caplan (2002), and Lazarski et al. (2001). The data points for all studies lie in between lie near and at the center of horizontal axis.

In addition, it is important to ensure favorable distribution of occlusal forces when designing restorations for endodontically treated teeth.

Impact of root canal treatment on quality of life

The impact of root canal treatment on the OHRQoL of patients has been evaluated using the short form (OHIP-14) or the modified version (OHIP-17) of the Oral Health Impact Profile (OHIP-14) (Table 17.10).[219] The distinctly positive impact of root canal treatment was apparent, regardless of cultural background of the patient group or the measure used.[55,73,87,115] As expected, physical pain, psychological discomfort (feeling tense), and disability (difficulty in relaxing) were the most improved domains following treatment.

Table 17.10

The OHIP-14 and Modified Oral Health Impact Profile Instrument (OHIP-17)

OHIP-#	Item Question
OHIP-1	Have you had trouble pronouncing words because of your teeth and mouth?
OHIP-2	Have you felt that your sense of taste has worsened because of your teeth or mouth?
OHIP-3	Have you had painful aching in your mouth?
OHIP-4	Have you found it uncomfortable to eat any foods because of your teeth or mouth?
OHIP-5*	Have you had to alter the temperature of the foods that you eat because of your teeth or mouth?
OHIP-6	Have you been self-conscious because of your teeth or mouth?
OHIP-7	Have you felt tense because of your teeth or mouth?
OHIP-8	Has your diet been unsatisfactory because of your teeth or mouth?
OHIP-9	Have you had to interrupt meals because of your teeth or mouth?
OHIP-10	Have you found it difficult to relax because of your teeth or mouth?
OHIP-11*	Have you found it difficult to fall asleep because of your teeth or mouth?
OHIP-12*	Have you ever been awakened by problems with your teeth or mouth?
OHIP-13	Have you been embarrassed because of your teeth or mouth?
OHIP-14	Have you been irritable with other people because of your teeth or mouth?
OHIP-15	Have you had difficulty doing your usual jobs because of problems with your teeth or mouth?
OHIP-16	Have you felt that life in general was less satisfying because of your teeth or mouth?
OHIP-17	Have you been totally unable to function because of your teeth or mouth?

OHIP-14 contains all the items except those with an asterisk (*).

outcomes of endodontic treatment, *J Endod* 28:819-827, 2002.

Outcome of nonsurgical retreatment

When root canal treatment fails to resolve periapical disease, it is often considered appropriate to retreat the tooth using conventional approaches first, especially when the previous treatment is technically deficient (Fig. 17.30). This requires removal of the previous root-filling material and any other material placed for restorative reasons. Correction of any procedural errors may also be required, if possible. All materials must be removed in their entirety to ensure delivery of antibacterial agents to all surfaces of the root canal dentin (see Fig. 17.30). The periapical healing rates of root canal retreatment are generally perceived to be lower compared to primary treatment for the following reasons:

- Obstructed access to the apical infection
- A potentially more resistant microbiota

FIG. 17.30 Tooth with technically deficient root canal treatment **(A)**; having undergone (**B** and **C**) root canal retreatment.

Three radiographs are marked A through C.

A) Four teeth are shown. The third tooth has incomplete root canals. The

Telegram: @dental_k

www.konkur.in

crown has a radiopaque patch.

B) Third tooth is undergoing root canal treatment.

C) Third tooth has filled root canals and radiopaque crown.

The outcomes from a range of studies show that the mean weighted success rate of nonsurgical root canal retreatment is 66% (Figs. 17.31 and 17.32), which is about 6% lower than in the case of primary treatment on teeth with apical periodontitis.[148,150] However, it has also been shown that the survival rate of teeth having undergone nonsurgical root canal retreatment may be similar to that for primary root canal treatment.[151]

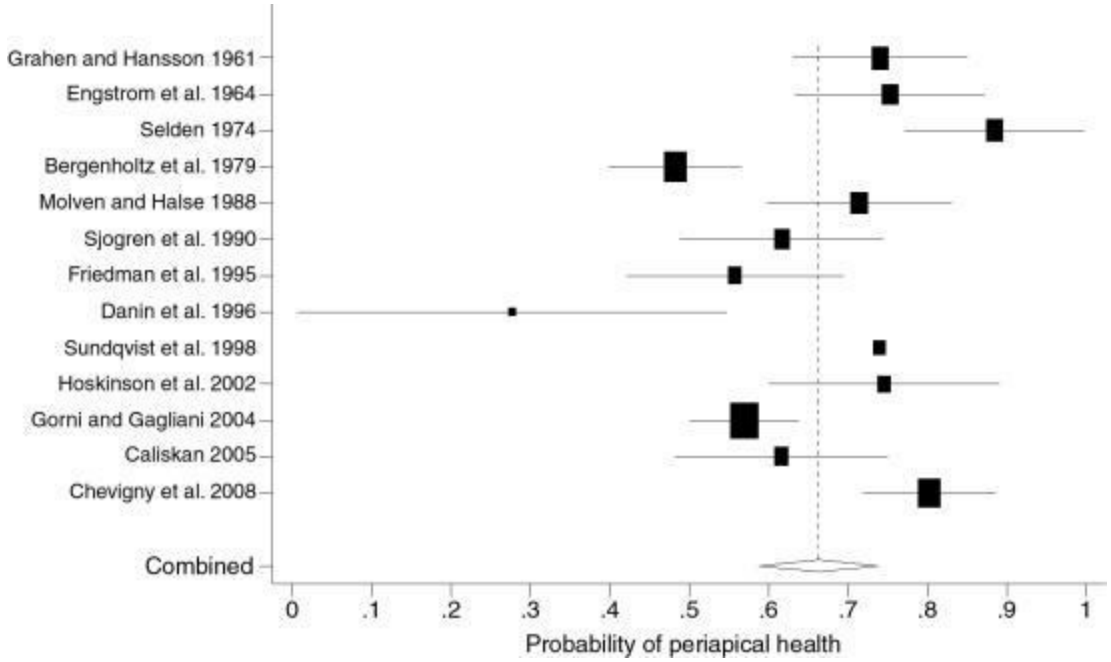

FIG. 17.31 Forest plot showing pooled and individual study's probability of complete periapical healing following root canal retreatment.

Forest plot shows combined and individual study against pr_success_pa.

The horizontal axis ranges from 0 (near origin) to 1 in the increments of 0.1. The approximate data are as follows: Combined: 0.5 9 to 0. 7 3, Chevigny et al. 2008: 0.8, Caliskan 2005: 0.6 1, Gorni and Gagliani 2004: 0.5 8, Hoskinson et al. 2002: 0.7 2, Sundqvist et al. 1998: 0.7 2, Danin et al. 1996: 0.2 8, Friedman et al. 1995: 0.5 7, Sjogren et al. 1990: 0.6, Molven and Halse 1988: 0.7, Bergenholtz et al. 1979: 0.4 9, Selden 1974: 0.8 9, Engstrom et al. 1964: 0.7 8, and Grahen and Hansson 1961: 0.7 7.

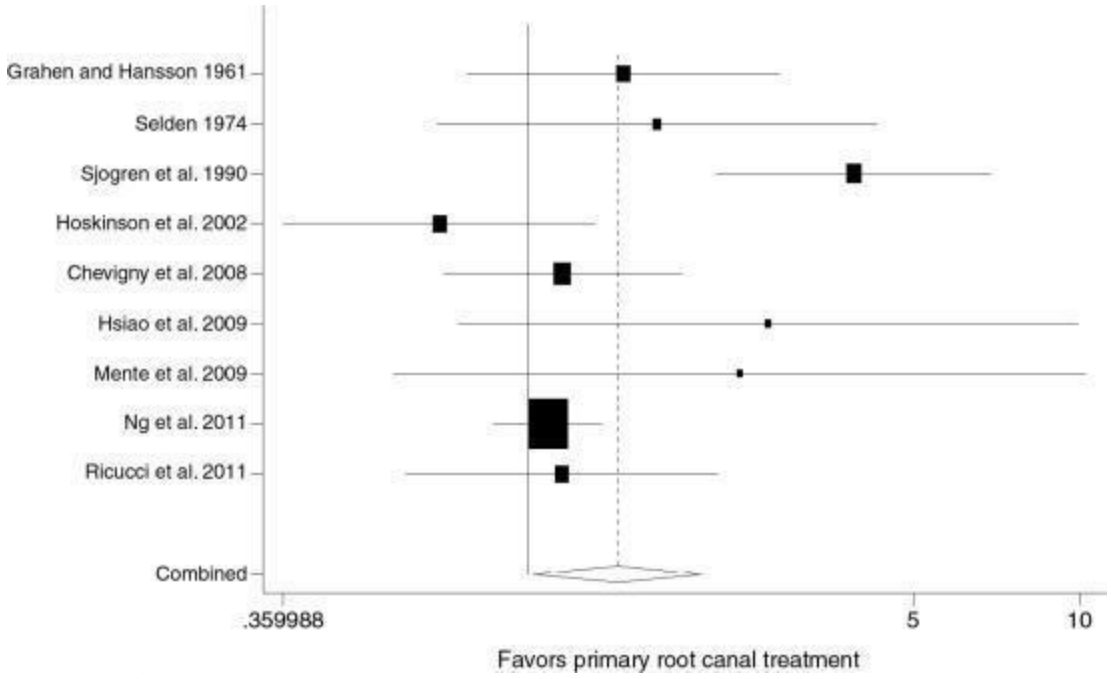

FIG. 17.32 Forest plot showing pooled and individual study's odds ratio of periapical health for teeth with preoperative periapical radiolucency undergoing primary root canal treatment versus root canal retreatment (pooled OR = 1.5; 95% CI: 1.0, 2.1).

Forest plot shows combined and individual study against Logor_pa1st_pa2nd.

The horizontal axis is marked at 0.3 5 9 9 8 8, 5, and 10. The vertical axis is marked from bottom to top as follows: Combined, Ricucci et al. 2011, Ng et al. 2011, Mente et al. 2009, Hsiao et al. 2009, Chevigny et al. 2008, Hoskinson et al. 2002, Sjogren et al. 1990, Selden 1974, and Grahen and Hansson 1961. The data points for all studies lie in between one-fourth length of the horizontal axis to the point 5.

The factors affecting outcomes of periapical health and tooth survival following root canal retreatment are otherwise identical to those affecting primary root canal treatment. Of the potential prognostic factors unique to retreatment cases, the most significant factor influencing the outcome of treatment is the ability to remove or bypass preexisting root-filling material or separated instruments during retreatment. This is understandable because it would have a direct impact on the ability to achieve canal patency and canal disinfection at the apical terminus.[150]

Outcome of surgical retreatment

Factors affecting periapical health or healing following periapical surgery and root-end filling

There are a number of published systematic reviews on the prognostic factors for periapical surgery with apical filling.[45,47,48,155,204,205,239-241,250] The major limitations of this pooled data include the variable length of time for evaluating success following treatment as well as the radiographic criteria used to assess healing. An unpublished meta-analysis[130] of data from the studies listed in Table 17.11 reveals that the weighted pooled probability of success from periapical surgery with retrograde restorations, based on complete radiographic healing, is 67.5% (95% CI: 62.9%, 72.0%) (Fig. 17.33). The trend shows higher success rates reported in more recent studies. This observation is consistent with the much higher pooled success rate of 92% (95% CI: 86%, 95%) revealed in the meta-analysis of prospective outcome data of surgical endodontic treatments performed by a “modern” technique (using magnification, root-end resection with minimal or no bevel, retrograde cavity preparation with ultrasonic tips, and modern retrograde root canal filling materials).[240,241] In congruence with these findings, Setzer and colleagues reported that the pooled success rate of treatment using a microsurgical approach (94%; 95% CI: 89%, 98%) was more favorable than traditional root-end surgery (59%; 95% CI: 55%, 63%).[205] However, the studies included in the latter meta-analysis differed in design, case selection, duration after treatment, and the provision of preoperative nonsurgical treatment, which may bias the higher success rate of the contemporary treatment.

C, Clinical; *DPT*, dental pantomogram; *Pa*, periapical; *PAI*, periapical index; *R*, radiographic; *RCT*, randomized controlled trial.

The unpublished meta-analysis[130] stratified by duration following treatment reveals that the pooled probability of success based on complete healing plateaued after 2 years postoperatively, being 51% (95% CI: 42%, 60%) after 6 months, 68% (95% CI: 63%, 73%) after 12 months, 76% (95% CI: 67%, 84%) after 24 months, 74% (95% CI: 52%, 95%) after 48 months,

Telegram: @dental_k

www.konkur.in

and 74% (95% CI: 66%, 82%) after more than 48 months. It is therefore advisable to follow up on cases that have undergone periapical surgery for a minimum period of 2 years and up to 4 years, as suggested in quality guidelines.[61]

The factors having a major impact on outcome of periapical surgery with retrograde cavities and fillings in teeth with preoperative periapical radiolucencies revealed in the (as yet) unpublished meta-analyses[130] of data from studies listed in Table 17.11 are as follows:

- Small (≤5 mm) versus large (>5 mm) periapical lesion (risk ratio = 1.2; 95% CI: 1.1, 1.3)
- Periapical lesion involving one versus both cortical plates (risk ratio = 1.2; 95% CI: 1.0, 1.5)
- Absence versus presence of previous surgery (risk ratio = 1.2; 95% CI: 1.1, 1.3)
- Using magnification versus without the use of magnification during surgery (risk ratio = 1.5; 95% CI: 1.3, 1.8)
- Root-end resection with minimum versus obvious bevel (risk ratio = 1.3; 95% CI: 1.2, 1.4)
- Use of ultrasonic tip versus bur for retro-cavity preparation (risk ratio = 1.3; 95% CI: 1.2, 1.4)
- Use of retro-filling material with mineral trioxide aggregate (MTA) cement, super ethoxybenzoic acid (EBA) cement, or intermediate restorative material (IRM) versus amalgam; the use of MTA resulted in a similar outcome to SuperEBA (risk ratio = 1.0; 95% CI: 0.99, 1.1) or IRM (risk ratio = 1.1; 95% CI: 0.98, 1.1); SuperEBA and IRM were associated with significantly higher chances of success than amalgam (risk ratio = 1.2; 95% CI: 1.1, 1.3) as the retro-filling material

The preoperative presence of signs or symptoms (risk ratio = 1.2; 95% CI: 1.1, 1.3),[249] periodontal status (risk ratio = 2.1; 95% CI: 1.1, 3.8),[222] and quality of the coronal restoration (risk ratio = 1.6; 95% CI: 1.2, 2.1)[249] have also been revealed as significant prognostic factors by individual studies.

The following factors have minimal effect on surgical retreatment[43]:

Telegram: @dental_k

www.konkur.in

- Age of patient
- Gender of patient
- General health of patient
- Tooth type
- Quality of the preexisting root canal filling, as judged radiographically
- Histologic diagnosis of the biopsied periapical lesion (cyst or granuloma)

The use of guided periodontal tissue regenerative membrane or grafting material has been advocated for cases with through-and-through defects (missing buccal and palatal cortical plates), but there are conflicting reports as to their benefits.[53,162,170,232-234,237,249] The unpublished meta-analyses[130] of data from these studies did not reveal a significant influence of such approaches on the periapical healing outcome.

Factors affecting periodontal incisional wound healing

Periodontal attachment level after periapical surgery is an additional physical outcome measure compared to nonsurgical root canal treatment. Studies have compared the effect of different soft-tissue incision techniques (e.g., intrasulcular with or without involving interproximal papilla, submarginal, papilla-base).[106,245-247] As expected, all concluded that negligible marginal recession could be achieved by adopting a flap design that avoided reflection of the interproximal papilla.

The improvement in outcomes of periapical surgery has been attributed to modern surgical techniques plus greater biologic awareness of clinicians.[205,250] In addition, and perhaps even more importantly, case selection may be more critical in excluding potential failures, inferring that prognostication may have improved.

Factors affecting tooth survival following periapical surgery and root-end filling

Unlike nonsurgical root canal treatment, the outcome measure of tooth survival had only been adopted by one study[253] on surgical cases at the time of this writing. The reported median survival time for first-time surgery was

Telegram: @dental_k

www.konkur.in

92.1 months (95% CI: 40.9, 143.4) and that for resurgery was 39.1 months (95% CI: 6.1, 72.1).[253] The failure events, however, included tooth extraction and clinical and radiographic signs of periapical disease after treatment.

Impact of periapical surgery on quality of life

The impact of periapical surgery on the patient's quality of life has only been evaluated using a questionnaire including three domains: physical function (chewing, talking, sleeping, daily routine, and work), physical pain, and other physical symptoms (swelling, bleeding, nausea, bad taste/breath).[49] It was concluded that the papilla-base incision flap design resulted in a lower impact on physical pain and other symptoms within the first week postoperation. The impact on physical pain has also been explored by two other studies[35,36]; both reported the postoperative pain was of relatively short duration, with the intensity peaking at 3 to 5 hours postoperatively and progressively decreasing with time with no significant influencing factors identified.

Concluding remarks

The procedures used to maintain pulp vitality and for prevention and treatment of periapical disease are able to achieve excellent outcomes. The outcome data and potential prognostic factors should be considered during treatment options appraisal and planning. Despite the fact that most important prognostic factors are beyond the control of clinicians, optimal outcomes for individual cases may still be achieved by performing the procedure to guideline standards. From a health and economic perspective, conventional root canal treatment is a highly cost-effective treatment as a first-line intervention to extend the life of the tooth with a preoperative periapical lesion.[103,171] If a root canal treatment subsequently fails, nonsurgical and surgical retreatments are also more cost-effective than replacement with a prosthesis.[103,171] Ultimately, all sources of evidence must be assessed for biasing influences based on the local cultures, expertise, treatment predilection, and funding sources.
