18: Root resorption

Shanon Patel, Conor Durack, Domenico Ricucci, Abdulaziz A. Bakhsh

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Dental resorption is defined as the loss of dental hard tissues as a result of clastic activities.[84] Root resorption in the primary dentition is indeed a physiologic process except if it occurs prematurely.[21,22] It is not yet completely understood how this process occurs, although it is believed that it is regulated by cytokines and transcription factors, which are also involved in bone remodeling.[54,125] On the other hand, resorption of permanent dentition is a pathologic process that, if left untreated, may result in premature loss of the affected teeth.

Depending on its location in relation to root surface, root resorption may be classified as external and internal.[4,107] Internal root resorption (IRR) was reported as early as 1830.[18] The etiology and pathogenesis of IRR have not been completely demonstrated.[64,88] Diagnosis of IRR is often a concern to the clinician because it is often confused with external cervical resorption (ECR). An inaccurate diagnosis may result in inappropriate treatment in certain cases.[51,52,83,87,88]

General histologic features

Bone resorption is a process regulated by motile, multinucleated giant cells called osteoclasts. They are formed by the fusion of mononuclear precursor

Telegram: @dental_k

www.konkur.in

cells of the monocyte-macrophage lineage derived from the spleen or bone marrow; osteoblasts and osteocytes, on the other hand, are derived from skeletal precursor cells.[72,103] Osteoclasts are recruited to the site of injury or irritation by the release of many proinflammatory cytokines. To perform their function, osteoclasts must attach themselves to the bone surface. On contact with mineralized extracellular matrices, the actin cytoskeleton of an actively resorbing osteoclast is reorganized to produce an organelle-free zone of sealing cytoplasm (clear zone) associated with the osteoclast's cell membrane; this enables the osteoclast to achieve intimate contact with the hard tissue surface.[91] The clear zone surrounds a series of fingerlike projections (podosomes) of cell membrane, known as the *ruffled border*, beneath which bone resorption occurs. The resorptive area within the clear zone therefore is isolated from the extracellular environment, creating an acidic microenvironment for the resorption of hard tissues.

Odontoclast cells are morphologically similar to osteoclasts but they are responsible of resorbing dental hard tissue (Fig. 18.1).[44] Odontoclasts differ from osteoclasts in that they are smaller, have fewer nuclei, and have smaller sealing zones, possibly as result of differences in their respective resorption substrata.[66] Osteoclasts and odontoclasts resorb their target tissues in a similar manner.[91] The two cells have similar enzymatic properties,[79] show similar cytologic features, and create resorption depressions, termed *Howship lacunae*, on the surface of the mineralized tissues (see Fig. 18.1).[91] Odontoclasts are polarized in relation to dental tissue and have a ruffled border, located inside a clear zone, that is in intimate contact with their dental substratum.[60,91]

www.konkur.in

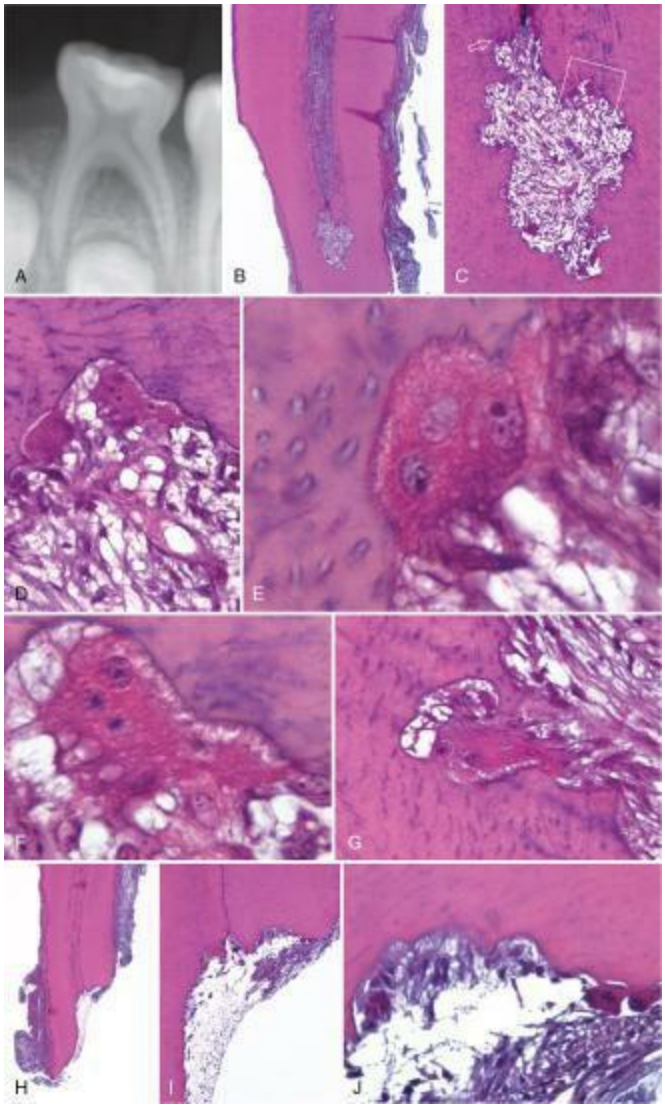

FIG. 18.1 Light microscopy images of a deciduous tooth showing both physiologic and pathologic (inflammatory) resorption. **A,** Tooth 7.5 in a 9-year-old boy. Extensive exposure of a mesial pulp horn occurred during caries excavation, and pulp capping was performed. The patient was brought to the dental office 4 months after the treatment because of severe spontaneous pain. The radiograph shows radiolucencies on both apices and interradicularly. The parents did not accept any treatment and requested extraction. **B,** Longitudinal section taken on a mesiodistal plane, passing approximately at the center of the mesial root. (Hematoxylin-eosin [H&E] stain; original magnification ×25.) **C,** Detail of the resorption area apically in **B** (original magnification ×100). **D,** Magnification of the area demarcated by the rectangle in **C.** Two odontoclasts are present in an area of dentin being resorbed, surrounded by fibroblasts and inflammatory cells (original magnification ×400). **E,** High-power view of the area indicated by the *arrow* in **C.** An odontoclast is in close contact with the dentin in a Howship lacuna. Its cytoplasm appears vacuolated and shows a more intense staining

Telegram: @dental_k

www.konkur.in

reaction than the cytoplasm of the adjacent cells (original magnification ×1000). **F,** High-power view of the upper odontoclast in **D.** The characteristic ruffled border can be distinguished (original magnification ×1000). **G,** Howship lacuna with an odontoclast in another area (original magnification ×400). **H–J,** Progressive magnification of the mesial root apex. The resorption process may be physiologic at this level (original magnification ×16, ×100, and ×400).

Set of radiograph and stained micrographs marked A through J shows the different views of inflammatory cells along with vesicles in connective tissue at the mesial root apex.

At high-power magnification, the cytoplasm of the odontoclasts appears vacuolated and shows a more intense staining reaction than the cytoplasm of the adjacent cells. Where odontoclasts are in contact with the tooth surface, the characteristic brush border can be seen, but the hematoxyphilic zone lining the lacunae is absent.[44] When odontoclasts are observed with an electron microscope, the most striking features are the large number of mitochondria and vacuoles in the cytoplasm and the scarcity of endoplasmic reticulum. An abundance of cytoplasmic ribosomes can be seen. The nucleoli are fairly large and centrally located in the nucleus. Close to the nucleus, the Golgi apparatus appears as a narrow zone of fine canals. Where the odontoclasts are in contact with the tooth surface, the ruffled border (corresponding to the brush border) may be observed with the light microscope. The ruffled border consists of cytoplasmic folds that create a system of canals extending 2 to 3 μm into the cytoplasm. In undecalcified sections, mineral crystals could be observed in these canals.[44]

Although both mononuclear dendritic cells and multinucleated osteoclasts share a common hematopoietic lineage, they have previously been accounted for as immunologic defense cells. Recent studies have indicated that immature dendritic cells also function as osteoclast precursors and have the potential to transdifferentiate into osteoclasts.[104] Because dendritic cells are present in the dental pulp, it is possible they also may function as precursors of odontoclasts.

From a molecular signaling perspective, the osteoprotegerin (OPG)/receptor activator of nuclear factor κB ligand (RANKL)/RANK transcription factor system[23] that controls clastic functions during bone remodeling has also been identified in root resorption.[111] The system is

Telegram: @dental_k

www.konkur.in

responsible for the differentiation of clastic cells from their precursors by means of complex cell-cell interactions with osteoblastic stromal cells. Similar to periodontal ligament (PDL) cells that are responsible for external root resorption,[114] the human dental pulp has recently been shown to express OPG and RANKL messenger ribonucleic acids (mRNAs).[112] OPG, a member of the tumor necrosis factor superfamily, has the ability to inhibit clastic functions by acting as a decoy receptor that binds to RANKL and reduces its affinity for RANK receptors on the surface of clastic precursors. This results in inhibition of the regulation of clastic cell differentiation. Thus, it is possible that the OPG/RANKL/RANK system may be actively involved in the differentiation of odontoclasts during root resorption.

We know that osteoclasts do not adhere to nonmineralized collagen matrices.[108] It has been suggested that the presence of a noncollagenous, organic component in dentin (odontoblast layer and predentin) prevents (internal) resorption of the root canal wall, and precementum prevents (external) resorption of the external root surface.[117,119] Similar to osteoclasts, odontoclasts may bind to extracellular proteins containing the arginine-glycine–aspartic acid (RGD) sequence of amino acids by means of integrins.[100] The latter are specific surface adhesion glycoprotein membrane receptors containing different α and β subunits. In particular, $\alpha_v\beta_3$ integrin plays a key role in the adhesion of clastic cells.[76] Extracellular matrix proteins containing the RGD peptide sequence, particularly osteopontin, present on the surface of mineralized tissues and serve as binding sites of clastic cells.[58] The osteopontin molecule contains different domains, with one domain binding to apatites in the denuded dentin and another domain binding to integrin receptors in the plasma membranes of clastic cells. Thus, osteopontin serves as a linker molecule that optimizes the attachment of a clastic cell to mineralized tissues, mediating the rearrangement of its actin cytoskeleton.[30] It has been speculated that the lack of RGD peptides in predentin reduces the binding of odontoclasts, thereby conferring resistance of the canal walls to IRR.

Once the clastic cells have established contact with the cementum, any subsequent resorption is self-limiting unless the bound cells are subject to continued stimulation.[4] Therefore, in addition to the precipitating events discussed previously, progressive root resorption requires a source of

Telegram: @dental_k

www.konkur.in

stimulation for the resorbing cells. Stimulating factors vary and are related to the site and type of resorption, in addition to the cause of the predisposing damage to the predentin or precementum. Examples include persistent pressure and forces associated with continued orthodontic treatment; persistent impacted teeth; untreated cysts, granulomas, and tumors; endodontic inflammation and/or infection; and periodontal inflammation and/or infection.[45]

External inflammatory resorption

Introduction

External inflammatory resorption (EIR) affects the outer surface of the root and is usually a consequence to dental luxation[2] and avulsion[13] injuries. It is a progressive condition with a potentially precipitous onset, and it is capable of advancing rapidly, such that an entire root surface may be resorbed within a few months if the tooth is left untreated.[5,13] It also affects teeth diagnosed with chronic periapical periodontitis (Figs. 18.2–18.5).[62]

Telegram: @dental_k

www.konkur.in

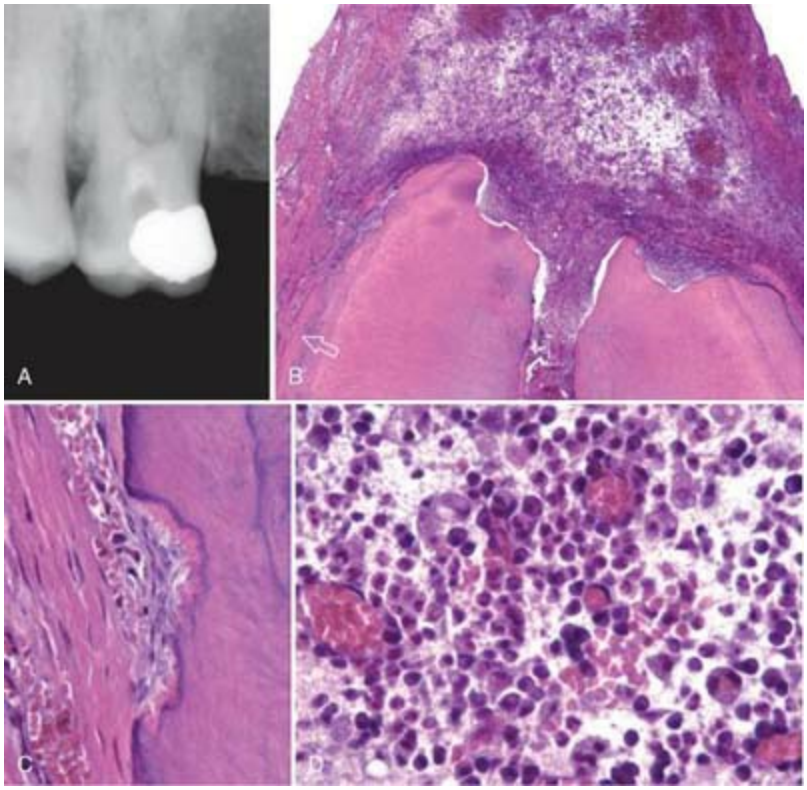

FIG. 18.2 External apical inflammatory resorption. **A,** Maxillary first molar in a 46-year-old female patient that was causing severe pain. The radiographs revealed material in the pulp chamber, a large distal caries, and apical radiolucencies. The tooth was extracted. **B,** Palatal root apex extracted with the pathologic tissue attached. Note the ingrowth of granulation tissue into the foramen and the massive resorption of the apical profile. Also note the resorption of lacunae on the left radicular profile. (H&E stain; original magnification ×25.) **C,** High magnification of the area of the external radicular profile indicated by the *arrow* in **B.** A resorption lacuna can be seen in the cementum. (H&E stain; original magnification ×400.) **D,** View from the center of the apical periodontitis lesion showing severe concentration of chronic inflammatory cells (mostly plasma cells) (original magnification ×400).

A) Radiograph shows a large nearly circular patch on one side of the crown in first molar of the upper jaw. Beside this, the molar has less-density patch on the other side of crown, at the center, and close to the root apices.

B) Stained micrograph shows an arrow pointing toward two tissue protuberances near the root apex on left and inflammation with oval cells at the tip.

C) Stained micrograph shows enlarged view of the protuberance that has connective tissue and different-sized dark cells.

D) Stained micrograph shows tissue having multi-chamber oval and circular

FIG. 18.4 External apical inflammatory resorption. **A,** Mesial root of a mandibular first molar extracted with a periapical lesion attached. This section passes through the canal and the foramen. Extensive resorption of the foramen has occurred, and a calcification can be seen more coronally. Note that the tissue in the apical canal and in the resorptive defect appears structured and continuous with the apical periodontitis lesion. A thick biofilm can be discerned layering the root canal walls more coronally. (Taylor's modified Brown & Brenn stain; original magnification ×25.) **B,** Palatal root of a maxillary first molar extracted with the periapical lesion attached. A cyst cavity is present in the body of the lesion. Resorption of the foramen is present, and a portion of the right dentin wall has been replaced by bone *(arrowheads).* (H&E stain; original magnification ×25.)

A) Stained micrograph shows root tip of a molar with the absorption of surrounding inflammatory tissue in the root canal. The canal also has white deposition along with granular cells and an oval patch along the canal walls.

B) Stained micrograph shows the resorption of tissue in the root canal along with a lesion near the root apex.

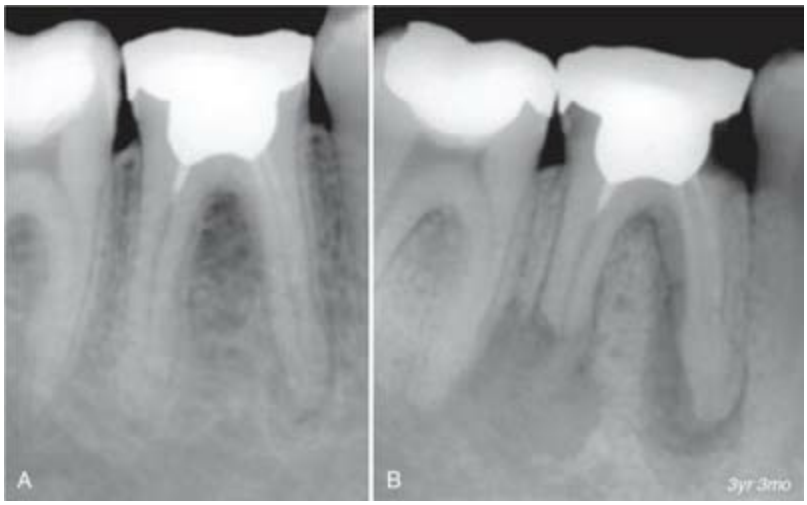

FIG. 18.5 Apical resorption. **A,** 22-year-old male patient complained of pain on chewing. This was caused by a molar that had been treated endodontically 1 year earlier. A radiograph showed obturation material only at the root canal orifices and a periapical radiolucency on the mesial root. Endodontic retreatment was recommended, but the patient declined this treatment. **B,** The patient returned 3 years and 3 months later because of an abscess that was causing severe pain. A radiograph disclosed destructive mesial caries and large periapical radiolucencies on both roots, along with resorption of the whole apical third of the distal root.

A) Radiograph shows porous tissue at the bifurcation of root system in a tooth.

B) Radiograph taken after 3 years 3 months shows large radiolucent patches extending in and along the root apices.

After luxation injuries, EIR ranges from almost 5%[2] to 18%.[32] It affects 30% of replanted avulsed teeth.[10,11] EIR is the most common form of external resorption root resorption after luxation and avulsion injuries.[32]

Treatment of EIR should be carried out as soon as it is diagnosed, and it is mainly based on effective removal of the infected necrotic pulp.[37] The earlier the diagnosis, management, and treatment of EIR, the better the prognosis of the affected tooth.[35]

The diagnosis of EIR in clinical situations is based solely on the radiographic demonstration of the process.[3] In some cases, the initial radiographic signs of EIR can be visualized as early as 2 weeks after replantation of avulsed teeth.[13] However, the limitations of conventional radiographic imaging in dentistry have been well reported. The diagnostic yield of radiographs is reduced by adjacent anatomic noise,[19,50,61,94] geometric distortion,[50] and compression of three-dimensional (3D) structures onto a two-dimensional (2D) shadowgraph.[31,82,116] These limitations may result in late diagnosis of EIR after dental trauma.

In a prospective study including up to 637 permanent luxated teeth in 400 patients for 10 years, Andreasen and Vestergaard Pedersen[2] reported that no cases of EIR after concussion injuries and only one case after subluxation injuries, which represented only 0.5% of the total number of subluxated teeth. Six percent of extrusively luxated teeth and 3% of laterally luxated teeth developed EIR. However, EIR was a healing complication in 38% of intrusive luxation injuries.[2] Crona-Larsson et al.[32] also reported a higher prevalence of EIR after more severe luxation injuries, with 60% of extrusively luxated teeth and 22% of intruded teeth affected by the complication. They reported EIR to be a much more frequent occurrence after lateral luxation (16.7%) and subluxation injuries (3.8%) relative to the findings of Andreasen and Vestergaard Pedersen.

Etiology and pathogenesis of external inflammatory

Telegram: @dental_k

www.konkur.in

resorption

Normally, permanent teeth are resistant to resorption.[118,119,120] It is generally accepted that odontoclasts do not bind to the nonmineralized layers covering the external root surface and the root canal wall (i.e., the precementum and predentin, respectively).[4,53,118,119,120] Similarly, it has been shown that, between episodes of physiologic resorption, the surface of bone is impervious to osteoclastic activity because it is covered by a layer of nonmineralized collagen fibrils, to which the osteoclast is incapable of binding.[29]

Traumatic dental injuries (e.g., intrusion, lateral luxation, and avulsion) and subsequent replantation often result in contusion injuries to the PDL.[4] Damage to the precementum, with a resultant breach in its integrity, is the precipitating factor in all types of external resorption.[4,6] In the subsequent wound healing process, necrotic PDL tissue remnants are excavated and removed by macrophages and osteoclasts.[39] A critical factor is that the precementum may be stripped from the root surface during the injury and the damaged cementum and bone may also be phagocytosed, resulting in exposure of the underlying dentine to osteoclastic and odontoclastic activity.[39] External root resorption may ensue, but the precise type depends on the severity of the initial injury, the stage of root development, and the pulp status of the affected tooth.[4,6] Once the clastic cells have established contact with the cementum or dentine, any subsequent resorption is self-limiting unless the cells are subject to continued stimulation.[9] As already mentioned, odontoclasts do not adhere to the nonmineralized layers covering the external root surface.[4,53,118,119,120] Therefore, damage to the precementum with a resultant breach in the integrity of these layers is the precipitating factor in all types of ERR.[4,6] Damage to the precementum and underlying tooth structure allow circulating odontoclasts to bind to the underlying mineralized dentine and cementum.[118]

The pathogenesis of EIR can be explained as follows. Contusion injuries to the PDL, after a traumatic dental injury (TDI) involving the periodontal structures, initiate wound healing, during which osteoclasts and macrophages are attracted to the site of the injury to remove the damaged tissue. The initial injury causes a breach in the integrity of the protective precementum. This permits odontoclasts to bind to and resorb the underlying mineralized

Telegram: @dental_k

www.konkur.in

cementum and dentine in a manner similar to the development of surface resorption.[6] However, EIR differs from surface resorption in that it is a progressive event that relies on microbial stimulation from the infected necrotic pulp of the affected tooth for its progression.[9] Therefore, it is more commonly associated with tooth avulsions[10,11] and moderate to severe luxation injuries, which have the potential to compromise pulp vitality.[2] If the strength of the initial osteoclast attack is sufficient to expose patent dentinal tubules beneath the cementum, a communication is created between the pulp space and the external root surface and adjacent periodontal tissues.[9,14] Microbes and/or their toxins (e.g., lipopolysaccharide, muramyl dipeptide, and lipoteichoic acid),[15] located in the root canal and the dentinal tubules, diffuse through the tubules and directly stimulate the resorbing osteoclasts. The resorption process intensifies and accelerates.[7] The resorbed mineralized tissue is replaced by granulation tissue, which ultimately invades the pulp space if the process continues.[15]

Pressure on the root surface during orthodontic treatment[63] and from impacted teeth,[124] cysts,[106] and tumors[65] may also denude the protective precementum from the root surface and therefore initiate ERR.

Histologic appearance

The histologic appearance of EIR is characterized by saucer- or bowl-shaped areas of resorption in both the cementum and dentine, with concomitant inflammation in the adjacent periodontal membrane. Howship lacunae are a common feature of the resorption cavities, and histologic sections show that the lacunae sometimes are occupied by odontoclasts. The inflammatory reaction in the periodontal membrane appears intense and consists of a mixed-cell infiltrate that includes plasma cells, lymphocytes, and polymorphonuclear leucocytes in a granulation tissue matrix. Proliferation of capillaries in the areas of inflammation is also a feature.[14] EIR can be identified histologically 1 week after experimental replantation of teeth.[8]

Clinical features

The tooth in question will not respond to sensibility testing and in advanced cases may be associated with signs of pulpitis or apical periodontitis such as

Telegram: @dental_k

www.konkur.in

discoloration, sinus tract, and/or tenderness to percussion and/or palpation.

Radiographic features

As mentioned, diagnosis of EIR is based solely on radiographic demonstration of the process.[3,13] EIR is characterized radiographically by radiolucent, concave, and sometimes ragged bowl-shaped excavations along the root surface, with corresponding and associated radiolucencies in the adjacent alveolar bone. Complete loss of the lamina dura is seen in the area of the resorption.[14] The initial radiographic signs of EIR can often be seen as early as 3 to 4 weeks after a TDI involving the periodontal tissues,[14] and if it will develop, EIR is always seen within 1 year after the injury.[7]

EIR can have a rapid onset and aggressive progression, such that complete resorption of an entire root can occur within 3 months. The diagnostic potential of a number of radiographic imaging systems has been investigated, with varying degrees of success.

Conventional intraoral radiographic imaging (digital or film based) is currently the clinical reference standard for the detection of ERR after luxation and avulsion injuries.[41,42] However, it has been well documented that this form of imaging is an inadequate method of detecting simulated ERR, especially when the cavity sizes are small.[3] Clinical studies have also demonstrated that conventional radiography grossly underestimates the extent of inflammatory root resorption.[40]

Clinical studies directly comparing the ability of intraoral radiographs and cone beam computed tomography (CBCT) to detect and diagnose EIR are limited. One clinical study reported that CBCT is superior to conventional radiography in diagnosing and determining the extent of nonspecific inflammatory resorption on root surfaces.[40] D'Addazio et al.[36] compared the ability of CBCT and periapical radiography to detect simulated external resorption cavities of about 2 mm in diameter in a human ex vivo model. Although both imaging modalities were 100% sensitive in the detection of the lesions, only CBCT could accurately assess the position of the defects on the root surface and their relationship to the root canal, even though multiple angled periapical radiographs of the test teeth were available to the examiners.

Telegram: @dental_k

www.konkur.in

Management

In cases were the tooth is treatable, root canal treatment will be able to help in arresting the resorption and therefore prevent further progression of the resorption. This would create an environment conducive to hard tissue repair of the damaged root surface.[33,34,37] Therefore, it is essential to initiate root canal treatment as soon as radiographic signs of EIR are identified.[35] An exception to this is replanted teeth with closed apices; in these cases, root canal treatment should be carried out 7 to 10 days after replantation, even if there are no radiographic signs of EIR.[42] The earlier the resorption is diagnosed and treated, the better the prognosis is for the affected tooth. Failure to diagnose and treat the condition may result in tooth loss.

Effective chemomechanical debridement of the root canal space is fundamental to the success of the root canal treatment and the inhibition and cessation of EIR.[34,37] In principle, the specific root canal protocol used is irrelevant, as long as the biologic objectives are met. Long-term dressing of the root canal with calcium hydroxide may be beneficial in the treatment of established EIR; however, this protocol should be used judiciously because of the associated risk of root fracture.[12]

In many cases the EIR is extensive, rendering the tooth unsalvageable and requiring extraction.

Follow-up and prognosis of external inflammatory resorption

Healing of EIR is characterized radiographically by cessation of the resorption process, resolution of the radiolucency in the adjacent bone, and reestablishment of the PDL space.[13] As mentioned previously, in untreated cases, EIR can progress so rapidly that an entire root can be resorbed within 3 months.[13,34] The prognosis is especially poor for untreated immature teeth.[13]

External cervical resorption

Introduction

ECR manifest mainly in the cervical region and it may invade root dentin in

Telegram: @dental_k

www.konkur.in

any direction and to a varying degree. ECR generally develops immediately apical to the epithelial attachment of the tooth. In healthy teeth with a normal periodontal attachment, this is in the tooth's cervical region, a feature that gave rise to the name. However, in teeth that have developed gingival recession and lost periodontal support and/or have developed a long junctional epithelium, the resorptive defect may arise at a more apical location.

ECR has also been referred to as invasive cervical resorption,[56] supraosseous extracanal invasive resorption,[43] peripheral inflammatory root resorption,[48] and subepithelial external root resorption.[109] The authors of this chapter prefer the term ECR because it describes the nature and location of the lesions.

Etiology and pathogenesis

The exact etiology and pathogenesis of ECR have not been fully elucidated. It is widely accepted that the resorptive process is the same for ECR as it is for any other type or resorption: a breach in the protective nonmineralized layers must exist to allow the clastic cells to bind to the underlying dentine, and the same cells must be stimulated to perpetuate the process. However, in ECR only some of the factors that predispose the root surface to clastic activity have been identified.

The anatomic profile of the cementoenamel junction (CEJ) is variable, and the junction between the enamel and the cementum in this region is not contiguous in all teeth. This may lead to exposed areas of unprotected dentin, which are vulnerable to osteoclastic activity, in the cervical region of some teeth.[78]

Mavridou et al.[69] investigated the potential predisposing factors using a two-step approach. The first step was an interview with the patient to obtain a complete information on their dental and medical history, the second step was a thorough clinical investigation of the patient with a combination of periapical radiograph and 3D CBCT scans.

Of the 347 teeth examined, 59% were multifactorial. From these multifactorial cases, 38% had 2 predisposing factors, and 17% and 3% had 3 and 4 factors, respectively.

Orthodontics was the most common appearing factor (45.7%) followed by

Telegram: @dental_k

www.konkur.in

trauma (28.5%), parafunctional habits (23.2%), poor oral hygiene (22.9%), malocclusion (17.5%), and extraction of neighboring tooth (14%).

Combination of orthodontics with previous dental trauma was the most common combination (17.6%); this was followed by orthodontics along with parafunctional habits (13%), orthodontics with extraction of neighboring tooth (12%), extraction of neighboring tooth along with occlusal overloading and poor oral health (5%), malocclusion with poor oral health (3%), and malocclusion along with parafunctional habits (2.7%).

Of the cases examined, ECR was located on 29% of maxillary central incisors, 14% in maxillary canines, 14% in mandibular molars, and 14% maxillary premolars. ECR was less frequently seen in mandibular canines (3%), mandibular centrals (1%), and mandibular lateral (1%).[69]

Histologic appearance

The histologic profile of ECR is similar to that of other forms of resorption, with certain unique features reflecting the invasive nature of the process.

Recently, histologic analysis has revealed that ECR lesion is a mechanism of a three-stage process. Initially, the ECR starts at the cementum apical to the gingival epithelium (i.e., the initiation stage). In the second stage of the resorption (i.e., the resorption phase), the resorptive lesion invades the tooth structure in a 3D manner towards the pulp space. However, the pulp is protected by a pericanalar resorption-resistant sheet which prevents the resorption lesion from penetrating the pulp space. This layer has a fluctuating thickness of 210 μm and consists of predentin, dentin, and occasionally bonelike tissue. At the last advanced stage (i.e., the repair stage), bonelike tissue is deposited into the resorption cavity in which repair takes place (Fig. 18.6).[70]

www.konkur.in

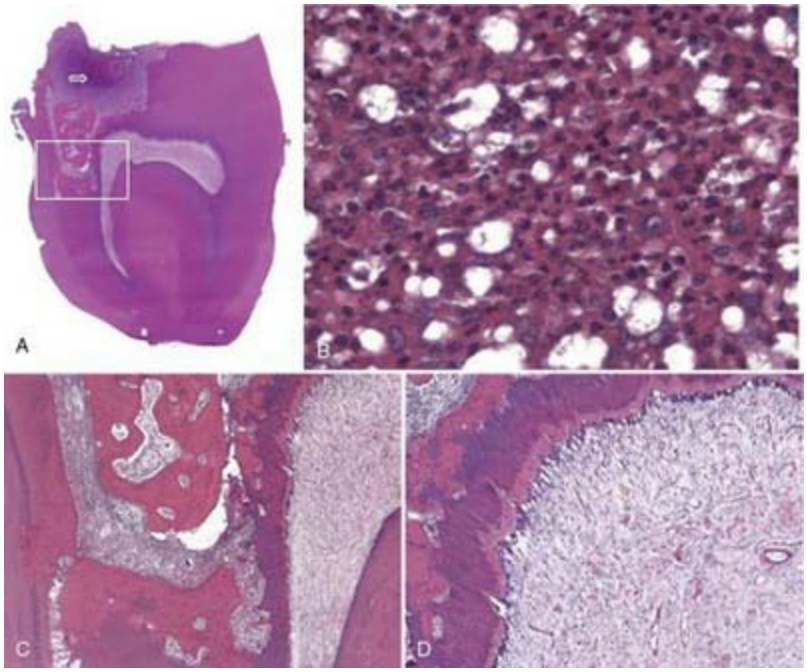

FIG. 18.6 External cervical resorption with replacement. **A,** Asymptomatic mandibular third molar. ECR was diagnosed on a radiograph taken for neighboring teeth. The tooth was extracted. Overview of the tooth (H&E stain; original magnification ×2). **B,** High power view of the resorptive area occupied by granulation tissue indicated by the *arrow* in **A**. Severe concentration of acute and chronic inflammatory cells (original magnification ×400). **C,** Detail of the area demarcated by the *rectangle* in **A**. The large area of resorbed dentin has been partly repaired with bonelike tissue. Note the thin layer of dentin remaining. No inflammatory changes can be observed in the adjacent pulp (original magnification ×25). **D,** Detail from **C**. Normal appearance of dentin, predentin, and odontoblast layer. Absence of inflammation (original magnification ×50).

Set of four stained micrographs marked A through D shows the deposition of hard tissue in place of the resorption cavity of third molar.

In a case study investigating the presence of hypoxia with ECR, Mavridou et al.[71] reported that histologic analysis showed that hypoxia does exist. Hypoxia inducible factor 1a-positive odontoblast was found within the apical area of the resorption (Figs. 18.7 and 18.8).

www.konkur.in

Clinical features

The clinical features of ECR are variable (Figs. 18.9 and 18.10). The process is very often quiescent and asymptomatic, especially in the earlier stages, and absence of clinical signs and symptoms is very common; the diagnosis is commonly made as a result of a chance radiographic finding. A pink or red discoloration may develop at the cervical region of the tooth; when present, this often is the feature that alerts the patient or clinician to the possible existence of a problem. The discoloration is due to the fibrovascular granulation tissue occupying the resorptive defect, which has a reduced thickness of enamel and dentin at its peripheries because of the loss of hard tissue. The granulation tissue imparts a pink hue to the tooth, through the thinned enamel and dentin, in the region of the resorption.[84] The granulation tissue may perforate the enamel or dentin at the gingival margin, giving the appearance of mild gingival hyperplasia. The discoloration, sometimes referred to as a “pink spot,” can be quite subtle and is often a chance finding by the patient, the dentist or, increasingly, the dental hygienist. However, it is a relatively rare feature of ECR. Furthermore, it must occur at a site where it is readily identifiable (e.g., labial surface of an anterior tooth) to be noticed. Loss of periodontal attachment may occur in the region of the resorption, and probing of the resorptive defect or the associated periodontal pocket causes the granulation tissue to bleed profusely.[87]

www.konkur.in

resorption: a review. *J Endod* 35:616–625, 2009.)

As the process progresses, perforation of the root canal wall and bacterial contamination of the pulp may occur. The affected tooth may develop pulpitis and the associated clinical symptoms. Pulp necrosis and chronic periapical periodontitis may eventually develop. Clinical signs and symptoms may be the first indication of a problem with the affected tooth; they may include tooth discoloration, spontaneous localized pain, tenderness on mastication, tenderness to percussion, tenderness to palpation over the apical region of the tooth, a draining sinus, and/or buccal sulcus swelling.

Radiographic features

There is no usual radiographic appearance of ECR. The lesion may have well-defined or irregular margins in the cervical aspect of the tooth.

The radiographic appearance of ECR depends on the location, the extent of invasion, and the relative proportions of fibro-osseous and fibrovascular tissue occupying the resorptive cavity. All ECR defects present as a radiolucency of varying radiodensity, often in but not confined to the cervical region of the affected tooth or teeth (Figs. 18.11 and 18.12; also see Figs. 18.9 and 18.10).

presented with a long story of pain on chewing and with cold stimuli. Recently the pain had become continuous and severe. The maxillary first molar, which had a mesial amalgam restoration, did not respond to sensitivity tests. A radiograph showed a periapical radiolucency on the palatal root. After removal of the restorative materials, a crack line involving the pulp chamber floor was diagnosed, and the tooth was extracted. **B,** Some pathologic tissue remained attached to the palatal root apex at extraction. A longitudinal section passing at the center of the canal demonstrated vital connective tissue in the apical third. (H&E stain; original magnification ×16.) **C,** Detail of the canal in **B.** Note the connective tissue with vessels and relatively few inflammatory cells, in addition to the resorption lacunae on the root canal walls (original magnification ×1000). **D,** High-power view of the area of the canal wall indicated by the upper *arrow* in **C.** Note the resorption lacuna with odontoclasts (original magnification ×1000). **E** and **F,** Progressive magnification of the area of the canal wall indicated by the lower *arrow* in **C.** Note the Howship lacuna housing clastic cells. Predentin is present in some areas of the wall, but it is absent in the areas with active resorption (original magnification ×400 and ×1000).

Set of radiograph and stained micrographs marked A through F shows the vesicles and inflammatory cells along with predentin on the root canal.

The margins of the lesion may vary from poorly to well defined, depending on the depth of the defect and the proportion and distribution of osseous inclusions in the lesion. Although lesions with irregular margins are more common, some ECR defects may have smooth and/or well-defined margins.

Despite its often cervical location, ECR may commence apical to this region, reflecting the position of the epithelial attachment of the affected tooth. In teeth with a normal periodontal attachment, the invasive nature of the process may result in the lesion extending some distance apical and/or coronal to the cervical location where it started. Furthermore, the tissue destruction at the site of onset may sometimes be minimal and/or not evident on conventional radiographs due to its location on the root surface. In these instances, the lesion may appear to have originated at a location where significant tissue destruction, evident radiographically, has occurred. This may be some distance from the actual point of origin. This feature has come to light only since the advent of assessment of ECR with CBCT.

The radiographic features of ECR are very similar to those of IRR (discussed later), and differentiating between them, especially in the absence of clinical signs, may be challenging. It is useful to trace the outline of the

Telegram: @dental_k

www.konkur.in

root canal walls as they approach and pass through the resorption defect on the radiograph. In cases of ECR, the outline of the canal wall should be visible and intact and should maintain its course as it passes through the defect. This is due to the fact that the resorptive lesion lies on the external surface of the root and is not in communication with the root canal; it is merely superimposed on the defect radiographically. In cases of IRR, it should be possible to trace the outline of the root canal through the resorptive defect because the defect is an extension of the root canal wall and is continuous with it.[46] Although this is a useful diagnostic feature, it does have some shortcomings. First, the outline of the root canal wall may be obscured by calcified tissue in the resorptive defect (ECR or IRR). Second, when ECR has resulted in extensive tissue destruction, perforation of the root canal wall may have allowed communication between the canal wall and the external defect.

Parallax radiographs should always be used to obtain further information about the nature of the resorptive process. In addition to a paralleled periapical radiograph, another radiograph should be taken with a shift (parallax) in the horizontal angulation of the x-ray tube in relation to the image receptor. In cases of ECR, the position of the resorptive defect moves relative to the root canal. If the lesion is located palatally/lingually, the defect moves in the same direction as the x-ray tube shift. If the lesion is located buccally, it moves in the opposite direction. This is sometimes referred to as the “same lingual, opposite buccal” (SLOB) rule. In contrast, internal resorptive defects maintain their position relative to the root canal because the defects are an extension of the root canal system.

CBCT has allowed 3D assessment of the nature, position, and extent of the resorptive defect, eliminating diagnostic confusion and providing essential information about the restorability and subsequent management of the tooth. CBCT is particularly useful if the clinician is not sure whether the ECR cavity has perforated the root canal wall (and thus for determining the need for root canal treatment). A CBCT scan eliminates the need for exploratory treatment. In an ex vivo study, Vaz de Souza et al.[113] compared the diagnostic efficacy of two CBCT scanners with periapical radiograph for the detection and classification of simulated ECR lesions. Examiners were asked to classify and identify the root surface(s) that ECR extended to with

Telegram: @dental_k

www.konkur.in

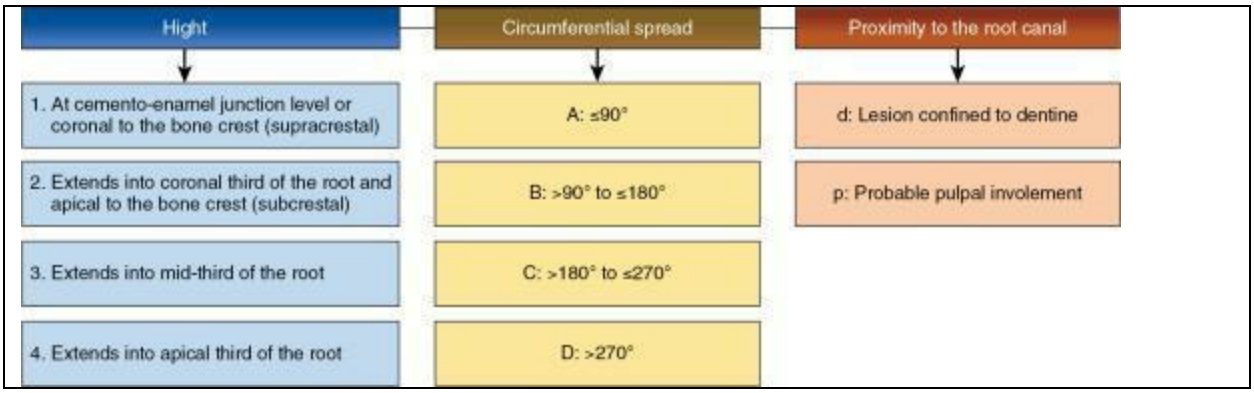
periapical radiograph and CBCT. Identification of the lesion according to the tooth surface was successful in 89.1% Morita CBCT, 87.8% Kodak CBCT, and 49.4% periapical radiograph cases. According to Heithersay classification, ECR was classified correctly in 71.4% Kodak CBCT, 70% Morita CBCT, and 32% periapical radiograph.

A clinical study by Patel et al.[83] comparing the ability of conventional radiographs and CBCT to diagnose and to differentiate accurately between IRR and ECR showed that CBCT was significantly more accurate (100%) than periapical radiographs at diagnosing the presence and nature of the root resorption. These researchers also concluded that the correct treatment plan should incorporate the additional information provided by CBCT.[83]

Recently, Patel et al.[86] suggested a 3D classification that accounts for the lesion height, circumferential spread, and proximity to the root canal. The aim of the classification is to ensure accurate diagnosis and communication of ECR between clinicians (Table 18.1).

Table 18.1

Three-Dimensional Classification of External Cervical Resorption



Management

The fundamental treatment objectives in ECR are to excavate the resorptive defect, halt the resorptive process, restore the hard tissue defect with an esthetic filling material, and prevent and monitor the tooth for recurrence. Effective management of ECR depends on accurate assessment of the true nature and accessibility of the lesion.

Telegram: @dental_k

www.konkur.in

Preoperative CBCT scans can help in assessing the extent of the defect and aid in good treatment planning. Also, treatment options could be confidently discussed with the patient and "exploratory" treatment may be avoided.[97,98]

Small lesions have the most favorable outcome where typically the pulp is not involved. These lesions are considered as Heithersay class 1 and class 2.[55] Surgical access to the site of resorption is gained by raising a mucoperiosteal flap, the dimensions of which should allow visualization of the full extent of the defect. Once access has been achieved, the resorptive cavity is excavated. Fibrovascular granulomatous tissue is readily removed with a hand excavator. However, defects containing significant amounts of fibro-osseous tissue (especially when the latter is contiguous with the adjacent dentin) require discriminate removal of the tissue with ultrasonic instruments. It may be extremely difficult to differentiate between sound dentin and fibro-osseous deposits; therefore, use of the surgical operating microscope is essential. Frequent intraoperative radiographs may be necessary to ensure accurate removal of unwanted, hard resorptive tissue and to prevent unnecessary removal of sound dental tissue.

Once the resorptive tissue has been removed, the cavity may be treated with a 90% aqueous solution of trichloroacetic acid; this causes coagulation necrosis of the resorptive tissue without damaging the periodontal tissue.[55] The acid also penetrates and treats small channels of resorption that are not accessible to mechanical instrumentation.[87] Once the defect has been excavated and treated with trichloroacetic acid, any undermined dentin or enamel at the peripheries of the cavity is removed with a bur in a high-speed turbine, and the cavity is restored with an esthetically acceptable restorative material, such as composite resin or glass ionomer cement. Biodentine may prove to be a particularly suitable material for restoring these defects[28,80] because it may combine acceptable esthetics with the ability to support PDL attachment.

Once the cavity has been restored, the mucoperiosteal flap is replaced and secured in position. If perforation of the root canal wall has occurred, root canal treatment should be carried out. Access to the root canal system should be gained under a rubber dam before the resorptive defect is assessed. The root canal should be prepared in the area of the defect as normal, using saline as an irrigant. A tapered gutta-percha (GP) point then should be placed in the

Telegram: @dental_k

www.konkur.in

canal to maintain its patency during the excavation and restoration of the resorptive defect and to provide a barrier against which the final restoration can be condensed. The rubber dam is removed, and surgical treatment of the resorptive defect can be carried out as described, without any risk of the resorptive debris entering the root canal system. After repositioning of the mucoperiosteal flap, root canal treatment can be completed in the normal manner, without fear of extrusion of infected tissue, irrigants, or medicaments into the periodontal tissues.

One of the treatment modalities of ECR is internal repair of the lesion, which does not require any surgical procedure.[85] This treatment option is indicated when the resorptive defect is close to or has just perforated the pulp chamber, and external surgical flap is not accessible and/or result in excessive removal of sound tooth structure. The internal repair is preferred in cases where the entry point is small, intraosseous, and apical to the epithelial junction.

Root canal treatment in such cases might be indicated if the defect was close to the pulp. Endodontic treatment could be done in one visit. After completion of the endodontic treatment, the access cavity should be extended to encompass the ECR lesion. The ECR and endodontic access cavity may be restored with a direct plastic restoration such as composite resin or glass-ionomer cement. Alternatively, Biodentine could be used as a dentine substitute, over which a thin layer of glass ionomer cement and/or composite resin may be placed.[90,99]

The treatment of ECR depends on the severity, extent, and location of the resorptive defect and the restorability of the tooth. Heithersay[55] developed a four-stage classification system for ECR based on the depth of penetration of the resorption in a buccolingual and apicocoronal direction. He examined the prognosis of treatment in 101 cases of ECR in 94 patients using the nonsurgical protocol referred to previously and related the success rates for treatment to the classification of the lesion.[55] He reported a 100% success rate for class I and class II lesions, a 77.8% success rate for class III lesions, and a 12.5% success rate for class IV lesions. This emphasizes the poorer outcome that can be expected for more advanced cases. A major limitation of the Heithersay classification is that it is valid only if the ECR lesion is confined to the proximal aspect of the tooth, because lesions are assessed on

Telegram: @dental_k

www.konkur.in

2D radiographs. If the ECR lesion is located on and/or extends to the labial and/or buccal (proximal) aspects of the tooth, the true nature of lesion cannot be accurately assessed with radiographs.[81,87]

Internal root resorption

Introduction

IRR is a form of root resorption that originates in and affects the root canal wall.[6] It is further classified as either inflammatory or replacement. The replacement type is associated with the deposition of mineralized tissue in the root canal space after the initial loss of dentin (initial dentin loss is a feature of both types).[6] Because their characteristics are largely similar, the two types of IRR are discussed together.

Etiology and pathogenesis of internal root resorption

Damage to the outermost protective odontoblast layer and the predentin of the canal wall results in exposure of the underlying mineralized dentin to odontoclasts, which subsequently leads to IRR (Fig. 18.14).[108,118]

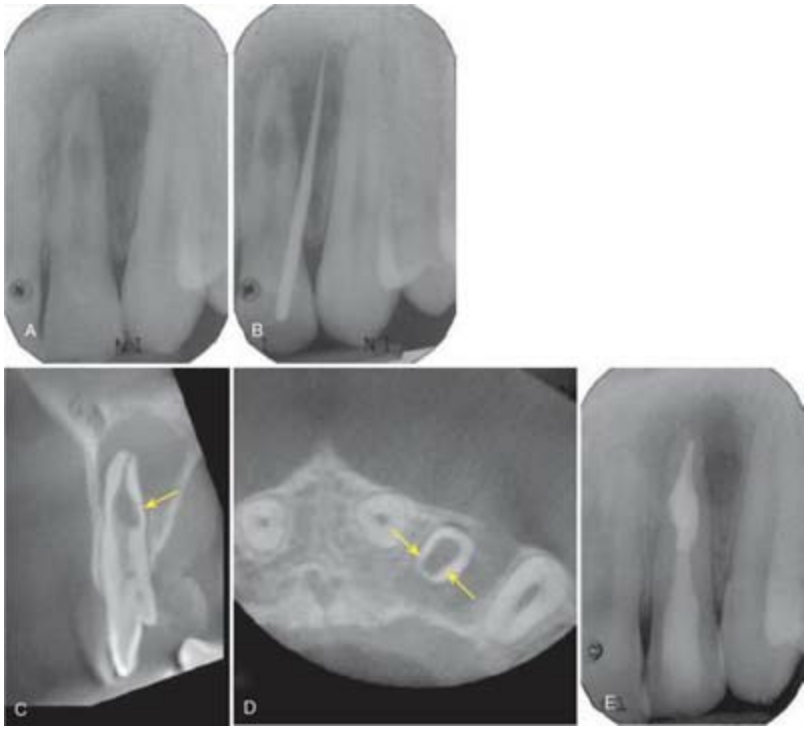

FIG. 18.14 **A** and **B,** Parallax views of the maxillary left lateral incisor showing internal root resorption with necrosis. A gutta-percha point has been used to track the sinus. The reconstructed sagittal **(C)** and axial **(D)** slices from a CBCT scan reveal that the lesion has resorbed the palatal aspect of the root *(arrows)* and has nearly perforated the root wall. **E,** The tooth has been obturated with gutta-percha using a thermoplasticized technique.

Set of five radiographs marked A through E shows the healing of radiolucent root canal and patch near the apex using gutta-percha.

Source: (From Patel S, Ricucci D, Durack C, Tay F: Internal root resorption: a review. *J Endod* 36:1107–1121, 2010.)

The exact cause or type of injury that causes such damage is not completely understood. Several etiologic factors have been expressed for the loss of predentin, including trauma, caries and periodontal infections, excessive heat generated during restorative procedures on vital teeth, calcium hydroxide procedures, vital root resections, anachoresis, orthodontic treatment, cracked teeth, or simply idiopathic dystrophic changes in normal pulps.[7,17,26,92,115] In a study of 25 teeth with internal resorption, trauma was found to be the most common predisposing factor, responsible for 45% of the cases examined.[27] The suggested etiologies in the other cases were inflammation as a result of carious lesions (25%) and carious/periodontal

Telegram: @dental_k

www.konkur.in

lesions (14%). The cause of the internal resorption in the remaining teeth was unknown. Other reports in the literature support the view that trauma[7,119,121] and pulpal inflammation/infection[52,121] are the major contributory factors in the initiation of internal resorption.

As previously mentioned, damage to the odontoblast layer and predentin of the canal wall is a prerequisite for initiation of IRR.[119] However, progression of IRR depends on bacterial stimulation of the clastic cells involved in hard tissue resorption. Without this stimulation, the resorption is self-limiting.[119]

For IRR to continue, the pulp tissue apical to the resorptive lesion must have a viable blood supply; this provides clastic cells and their nutrients, and the infected necrotic coronal pulp tissue provides stimulation for those clastic cells (see Fig. 18.14).[107] Bacteria may enter the pulp canal through dentinal tubules, carious cavities, cracks, fractures, and lateral canals. In the absence of a bacterial stimulus, the resorption is transient and may not advance to the stage that can be diagnosed clinically and radiographically. Therefore, the pulp apical to the site of resorption must be vital for the resorptive lesion to progress (see Fig. 18.14). If left untreated, internal resorption may continue until the inflamed connective tissue filling the resorptive defect degenerates, advancing the lesion in an apical direction. Ultimately, if left untreated, the pulp tissue apical to the resorptive lesion undergoes necrosis and the bacteria infect the entire root canal system, resulting in apical periodontitis.[95]

Histologic appearance

Wedenberg and Zetterqvist[121] reported on the histologic nature of IRR. The authors specifically examined the histologic, enzyme histochemical, and scanning electron micrographic (SEM) features of the resorptive process in a small sample of primary and secondary teeth extracted due to progressive IRR. The histologic and enzyme histochemical profiles were identical for the two groups, but the resorptive process appeared to occur more rapidly in the primary teeth. The pulpal tissue was populated to varying degrees in all teeth with an inflammatory infiltrate composed predominantly of lymphocytes and macrophages, with some neutrophils. The connective tissue in the pulp spaces was less vascular than healthy pulpal tissue and resembled periodontal membrane connective tissue with relatively more cells and fibers. The odontoblast layer and predentin were absent from the affected dentinal walls,

Telegram: @dental_k

www.konkur.in

which were populated by large, multinucleated odontoclasts occupying resorption lacunae. The odontoclasts showed evidence of active resorption (see Fig. 18.14). They were accompanied by mononuclear cells, believed to be odontoclast precursors, which populated the connective tissue adjacent to the site of resorption. Both types of cell displayed tartrate-resistant acid phosphatase (TRAP) activity.

Interestingly, the root canal wall was incompletely lined with a mineralized tissue resembling bone or cementum in all of the examined teeth.[121] Furthermore, islands of calcified tissue of a similar nature occupied the pulpal space in three of the cases. Islands of mineralized tissue occupying the root canal space are the defining feature of internal replacement resorption.[6] The authors suggested that deposition of this mineralized tissue is likely to be part of a coupling process, at the end of a period of resorption, in which osteoblasts are attracted to the affected site and participate in bone formation.[121]

Clinical features

The clinical features of IRR largely depend on the histologic status of the affected pulp, the extent of the hard tissue destruction caused by the resorptive process, and the position of the resorptive cavity in the root canal space. In the active stages of resorption, bacterial contamination of vital pulpal tissue may cause an acute inflammatory response, leading to clinical symptoms of pulpitis. With the onset of pulpal necrosis and an established bacterial colonization of the root canal space, clinical signs and symptoms associated with acute or chronic apical periodontitis may develop. Sinus tract(s) may occur and may be associated with suppuration in the periapical tissues or possibly at the site of a perforation of the root canal wall caused by the hard tissue destruction. Extensive resorption of the coronal pulp may result in a pink or red discoloration visible through the crown of the affected tooth; this is caused by granulomatous tissue extending into and occupying the resorptive defect.[67] Although often reported as a common clinical indicator of the process, these pink spots actually are rare in cases of IRR. They may occur relatively more frequently in cases of ECR, but they are not very common with that resorption type, either. Often the affected tooth is asymptomatic, and clinical signs are absent.

www.konkur.in

Radiographic features and diagnosis

The diagnosis of any type of root resorption depends on radiographic demonstration of its presence. Two-dimensional radiographs make the detection and differentiation of the various types of resorption challenging. Both IRR and ECR could have similar features which makes differentiation and diagnosis from a two-dimensional shadowgraph difficult.[51,84,88,107] Gartner et al.[46] reported that lesions of IRR present radiographically as radiolucencies of uniform density that have a smooth outline and are symmetrically distributed over the root of the affected tooth (Fig. 18.15). The authors further reported that the outline of the root canal wall should not be traceable through the resorption defect because the root canal wall balloons out. Other authors have described IRR lesions as oval, circumscribed radiolucencies in continuity with the root canal wall.[77] Although certain cases of IRR may have some or all of these radiographic features, many do not; each case should be assessed individually before a diagnosis is made.

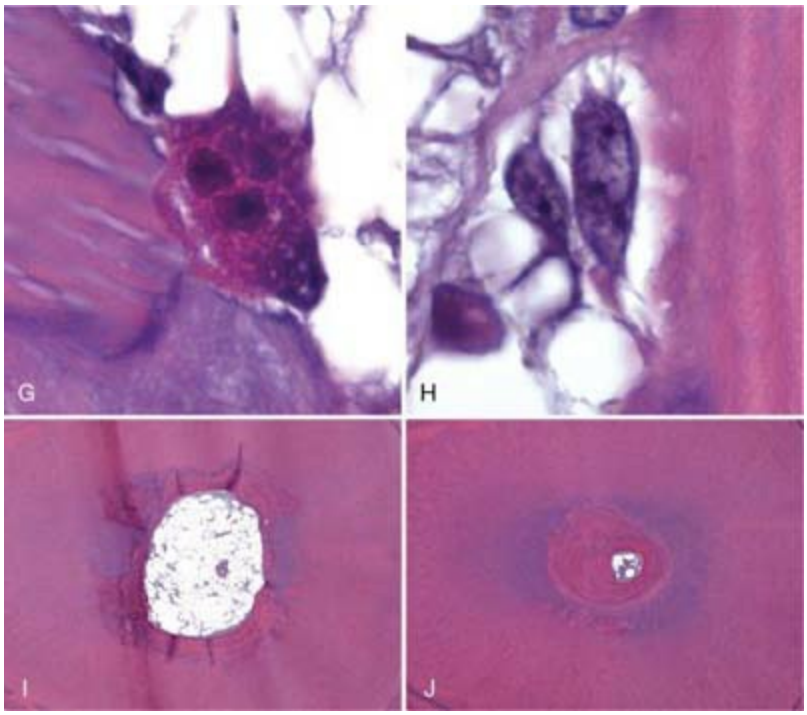

FIG. 18.15 Light microscopy images of a tooth with internal (root canal) replacement resorption. The tooth belonged to a 44-year-old male patient who was referred to the first author for management of a perforated root. The tooth was asymptomatic on examination, but there was a history of previous trauma. **A,** Radiograph of a maxillary central incisor with a radiolucent lesion in the middle third of the root canal. The radiolucent lesion appears to be mottled, which suggests internal root resorption with metaplasia. **B,** Clinical radiograph of the tooth after extraction, taken at a 90-degree angle, showing the continuity of the resorptive lesion with the canal space. **C,** Cross section taken approximately at the level of *line 1* in *B.* The low-magnification overview shows that the dentin around the root canal had been replaced by an ingrowth of bone tissue, and the root appears to have been perforated on the distopalatal aspect. (H&E stain; ×8.) **D,** Higher magnification of *C.* (H&E stain; ×16.) **E,** High magnification of the area demarcated by the rectangle in *D.* The intraradicular dentin has been resorbed. (H&E stain; ×100.) **F,** High-magnification view taken from the right part of *C,* showing that the resorbed dentin has been replaced by lamellar bone. Osteocytes are present in lacunae between the lamellae. A characteristic cross section of an osteon can be seen on the right *(open arrows),* with concentric lamellae surrounding a vascular structure. (H&E stain; ×100.) **G,** High-magnification view of the area indicated by the left open *arrow* in *E.* A multinucleated resorbing cell (odontoclast) can be seen in a dentinal lacuna, indicating active resorption of the dentinal wall. (H&E stain; ×1000.) **H,** High-magnification view of the bone surface indicated by the right *arrow* in *E.* The large cells are osteoblast-like cells. Once they produced mineralized tissue, they were embedded in the bone lacunae, assuming the characteristics of

Telegram: @dental_k

www.konkur.in

osteocytes. (H&E stain; ×1000.) **I,** Cross section taken approximately at the level of *line 2* in *B.* The root canal is still large at this level and is surrounded by a relatively thin layer of newly formed bone. (H&E stain; ×16.) **J,** Cross section taken approximately at the level of *line 3* in *B.* At this level the root canal appears consistently narrowed by a dense layer of newly formed bone. (H&E stain; ×16.)

Set of radiograph and micrographs marked A through F shows the development of concentric circles around the root canal.

Set of four micrographs marked G through J shows the deposition of multinucleated cells resulting in the reduction of root canal.

Source: (From Patel S, Ricucci D, Durack C, Tay F: Internal root resorption: a review. *J Endod* 36:1107–1121, 2010.)

IRR can occur at any location in the root canal system and may manifest radiographically as a radiolucency with variable shape, radiodensity, outline, and symmetry in relation to the root canal. Internal inflammatory root resorption lesions are more likely be uniformly radiolucent, whereas in internal replacement (metaplastic) root resorption, the defect has a somewhat mottled or clouded appearance as a result of the radiopaque nature of the calcified material occupying the lesion (Fig. 18.16).[88] ECR lesions may contain predominantly granulomatous tissue, predominantly calcified tissue, or a mixture of the two; therefore, they may have a radiodensity similar to either type of internal resorption, which complicates the clinical differentiation of the disease process. As noted by Gartner et al.,[46] the best practice is to trace the outline of the root canal wall as it approaches and leaves the resorption defect. An IRR cavity is continuous with the normal root canal walls because it is essentially an extension of them. As such, in teeth with single canals affected by IRR, the canal walls should not be traceable through the defect. This is in contrast to ECR, in which the lesion lies buccal or palatal/lingual to the defect and is consequently superimposed on the canal system when viewed on conventional radiographs. In this situation the canal walls should maintain their normal course as they pass through the resorption defect, allowing them to be traced through it. However, it should be noted that in teeth with multiple canals, a canal that has been unaffected by IRR may be superimposed onto the IRR resorption defect on conventional radiographs. When the guidelines outlined by Gartner

Telegram: @dental_k

www.konkur.in

et al.[46] are used, this may lead to misdiagnosis

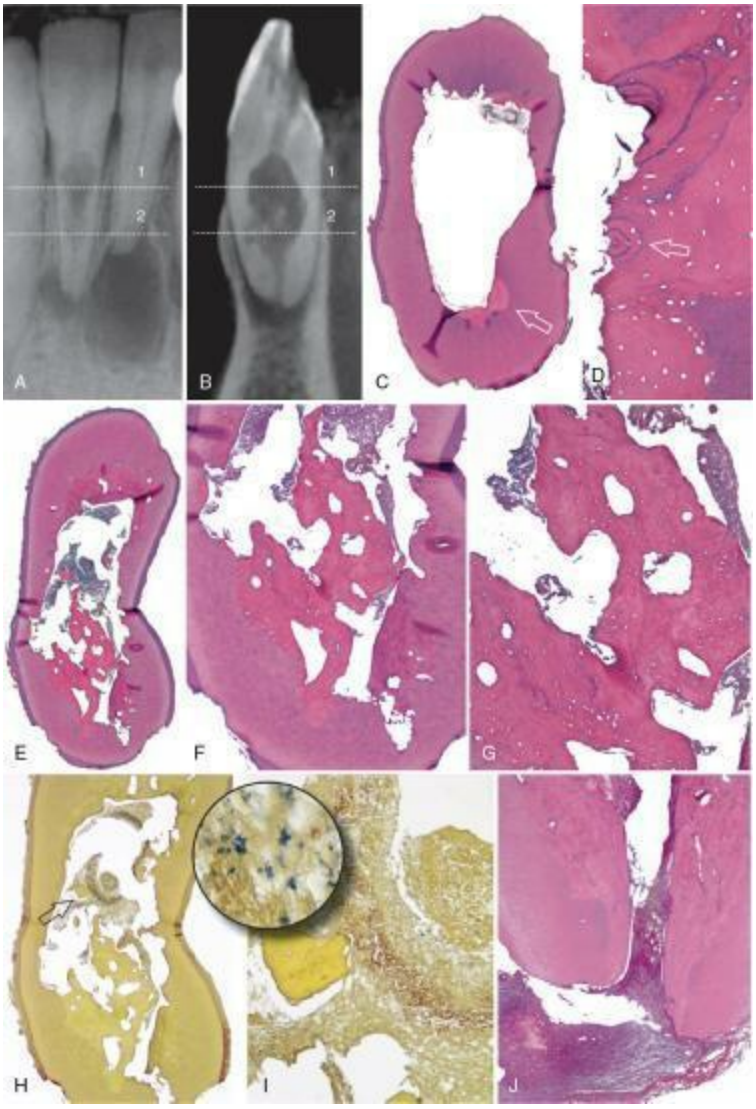

FIG. 18.16 Light microscopy images of a variant of internal (root canal) replacement resorption with tunneling resorption. The lower right lateral incisor belonged to a 39-year-old former boxer who had suffered a jaw fracture in a boxing match in his early twenties and was placed in intermaxillary fixation. The patient developed symptoms 20 years later and complained of pain associated with his lower incisors. **A,** Radiograph of the mandibular right incisors. The lower right central incisor had asymptomatic apical periodontitis associated with a necrotic and infected pulp. The lower right lateral incisor showed a large area of internal root resorption. The tooth did not respond to sensitivity tests. **B,** Sagittal CBCT slice shows some calcified tissue in the resorptive defect. **C,** Cross section taken at the level of *line 1* in *A* and *B.* The overview shows that the canal was apparently empty at this level. stain; ×6.) **D,** High magnification of the area indicated by the *arrow* in *C.* Lamellar bone filling an area of previous resorption. Note the osteon structure *(arrow).* (H&E stain; ×100.) **E,** Cross section taken at the level of line 2 in *A* and *B.* Overview shows that the canal lumen was partly occupied by necrotic remnants, partly by bonelike tissue. (H&E stain; ×8.) **F,** High magnification of the lower part in *E.* (H&E stain; ×50.) **G,** Higher magnification of *F.* Bone trabeculae are surrounded by necrotic debris. (H&E stain; ×100.) **H,** Cross section taken from the same area as that in *E*. (Taylor's modified Brown & Brenn [TBB] stain; ×16.) **I,** High magnification of the area indicated by the *arrow* in *H.* A fragment of bonelike tissue can be seen surrounded by bacteria-colonized necrotic tissues. (TBB stain; ×100; inset ×1000.) **J,** Longitudinal section passing approximately through the center of the root apex. Dentin walls have been resorbed and replaced by a bonelike tissue. (H&E stain; ×16.).

Set of radiographs and stained micrographs marked A through J shows the deposition of bonelike tissue around the root canal at the center of right incisor.

Source: (From Patel S, Ricucci D, Durack C, Tay F: Internal root resorption: a review. *J Endod* 36:1107–1121, 2010.)

Parallax radiographs must always be used to obtain further information about the resorptive process. In addition to a paralleled periapical radiograph, a radiograph should be taken with a shift in the horizontal angulation of the x-ray tube in relation to the image receptor. IRR lesions maintain their position relative to the root canal system on the angled view. ECR lesions move in the same direction as the x-ray tube shift if they are lingually/palatally positioned and move in the opposite direction if they are buccally located.[46] This diagnostic technique, coupled with tracing of the root canal/pulp chamber outline through the lesion, have been the most reliable aids in the differential diagnosis of IRR when conventional radiography is used. However, as discussed previously, the amount of information available from conventional radiographic imaging is limited. This can lead to misdiagnoses and incorrect treatment in the management of IRR and invasive cervical resorption.

The use of CBCT as a diagnostic and treatment planning tool in the management of IRR has been reported in the literature.[20] Information such as the position, extent, and dimensions of an IRR lesion, in addition to the presence of any associated perforation, can be obtained from a CBCT scan.

Telegram: @dental_k

www.konkur.in

The same scan can differentiate between ECR and IRR, removing any doubt about the diagnosis that may have arisen with the conventional radiographic examination.

Management

Once a diagnosis of IRR has been made, the extent of the hard tissue destruction must be assessed, and a clinical decision must be made about the prognosis of the affected tooth. If the affected tooth is salvageable and has a reasonable prognosis, root canal treatment is necessary. As with any infected tooth, the main purpose of the root canal treatment is to remove the intraradicular bacteria and disinfect the root canal space. If the resorptive process is still active, the treatment serves an adjunctive purpose, which is to eliminate the vital apical tissue that is sustaining and stimulating the resorbing cells.

The nature of the resorptive process in cases of IRR presents the endodontist with unique operative challenges. In teeth with active resorption, profuse bleeding from the granulomatous and inflamed pulpal tissues may impair visibility in the initial stages of treatment and may provide a stubborn source of mild hemorrhage when attempts are made to dry the canal after chemomechanical preparation. Furthermore, the irregularly concave nature of resorption defects makes them inaccessible to direct mechanical debridement.

Chemomechanical debridement of the root canal

Teeth usually have unique morphologic features of root canal that harbor microorganisms in infected teeth. Endodontic instruments and passively delivered irrigants fail to penetrate into these secluded spaces and niches.[75,96,101] The use of ultrasonic instruments to aid the penetration of endodontic irrigants has been shown to improve the removal of organic debris and biofilms from the root canal space.[24] Given the inaccessibility of IRR defects to normal instrumentation and passive irrigation, ultrasonic activation of irrigants should be considered an essential step in the treatment of these cases (see Fig. 18.14). However, even when this adjunctive measure is used, microbes may persist in confined areas after chemomechanical debridement.[24] As such, an intracanal antibacterial medicament should be used to further reduce the microbial load and improve the disinfection of the

Telegram: @dental_k

www.konkur.in

root canal space.[101] Calcium hydroxide is an antibacterial, interappointment, endodontic medicament that has been shown to eradicate bacteria persisting in the root canal space after root canal treatment.[25,102] Also, when used in conjunction with sodium hypochlorite, it potentiates the effect of that irrigant in the removal of organic debris from the root canal system.[1,110] Based on this evidence the authors advocate the use of calcium hydroxide as an intracanal, antibacterial medicament to supplement the conventional chemomechanical debridement of the root canal system.[88]

Obturation

One of the fundamental objectives of endodontic treatment is to fill the disinfected root canal space completely with an appropriate material. In IRR, the hard tissue defects caused by the resorptive process are challenging to fill adequately. To obturate the resorptive defect, the root-filling material must be able to flow. GP is widely regarded as the gold standard filling material in endodontics. It can plasticize when pressure is applied, and it becomes flowable with the application of heat. Gencoglu et al.[47] examined the ability of different obturation systems and techniques to fill the defects in artificially created internal resorptive cavities ex vivo. They found that Obtura II (ObII) and Microseal (MS) thermoplastic GP systems produced significantly better fills in simulated resorptive cavities than did Thermafill, soft core systems (SCS), and cold lateral condensation (CLC). In a similar study Goldberg et al.[49] demonstrated that the Obtura II system filled simulated resorptive defects statistically better than CLC, Thermafill, and a hybrid technique. Gencoglu et al.[47] reported that the Obtura II and MS systems produced fills with greater GP–to-sealer (GP/sealer) ratios than did the other techniques examined. These findings were corroborated in the study by Goldberg et al.[49]

Because root canal sealers shrink on setting[122] and dissolve and degrade to varying degrees in the presence of moisture,[73] fillings with higher GP/sealer ratios reduce the risk of void formation and leakage of contaminants into the root canal system, with potentially positive benefits for the treatment outcome.

Stamos and Stamos[105] and Wilson and Barnes[123] reported on cases of internal resorption in which the Obtura system was successfully used to

Telegram: @dental_k

www.konkur.in

obturate the canal. In light of the evidence presented, the Obtura and MS systems apparently can be expected to produce the best technical results for obturating canals with IRR.

When choosing the appropriate materials and methods for filling resorptive defects of IRR, the clinician first must establish the presence and extent of any perforations in the wall of the affected root. This information can be readily obtained from an appropriate CBCT scan. If perforation has occurred, mineral trioxide aggregate (MTA) should be considered the material of choice to repair the root wall. MTA is biocompatible,[74] has superior sealing properties when used as a retrograde filling material,[16] and has proved effective in the repair of lateral and furcal root perforations in animal studies.[68] Furthermore, the material is well tolerated in the periapical tissues, and when used as a root-end filling material in the absence of infection, it supports almost complete regeneration of the adjacent periodontium.[93] These are desirable properties in the context of perforation repair because of the very real possibility of unintentional extrusion of the material when a perforating internal resorptive defect is repaired in an orthograde manner. However, the flow properties of MTA are significantly poorer than those of heated GP. Its use as an effective filling material in IRR depends on adequate ultrasonic activation of the material to disperse it into the recesses of the defect.[20] Use of a dental operating microscope and the correct equipment to deliver the material are essential.

A hybrid technique to obturate canals affected by perforating internal resorption also may be used. In these cases, the canal apical to the resorption defect is filled with GP. The GP can then be used as a barrier against which the MTA can be packed. Hsiang-Chi Hsien et al.[57] successfully used this technique to treat a perforating IRR defect in a maxillary incisor. Jacobovitz and De Lima[59] described a case in which a maxillary central incisor with a large, perforating internal resorption defect had a poor prognosis and initially was designated for extraction. The tooth subsequently was successfully treated in an orthograde manner with white MTA and GP.[59]

Clinical situations arise in which a perforating resorptive defect causes extensive dental hard tissue destruction that fails to respond to or is not amenable to repair with an orthograde approach. Surgical treatment may be needed in these cases. For the reasons discussed already, MTA would be the

material of choice to repair these perforations. In cases that have not already been treated in a nonsurgical manner, the operator first must access the root canal as for orthograde treatment. A well-fitting, tapered GP point or an appropriately sized finger spreader is then positioned in the canal to occlude it and to provide a barrier against which the MTA can be packed once surgical access to the defect has been gained. The barrier also prevents inadvertent deposition of the MTA into the apical third of the canal. The perforation is then exposed surgically and repaired with the MTA. The canal can be shaped, disinfected, and obturated with thermoplasticized GP once the MTA has set.

If the resorptive process has caused sufficient tissue destruction to render the tooth unrestorable, extraction is the most appropriate treatment option. If the tooth has been weakened by the disease process to the extent that fracture of the tooth root is likely, the patient may elect to have the tooth extracted. The presence of a perforating resorptive defect is certainly not a contraindication to treatment, but a perforation of significant size will have a bearing on the decision to surgically treat or extract the tooth. CBCT is an invaluable component of the clinician's armamentarium in the treatment of IRR.[38] A CBCT scan gives the clinician a 3D view of the tooth, the resorptive defect, and the adjacent anatomy. The clinician thus has the information necessary to determine a prognosis for the tooth and/or its amenability to surgical repair. If extraction of the affected tooth is indicated, the scan may be used as a diagnostic and treatment planning tool for provision of a dental implant–retained prosthesis. Bhuva et al.[20] described a case in which CBCT was used as a treatment planning tool in the successful treatment of a case of IRR. As mentioned previously, CBCT has been found to be highly accurate in revealing the nature of the resorptive lesion, and this leads to the selection of the most suitable treatment plan.

Summary

- More research is needed for understanding of the etiology and pathogenesis of different types of root resorption (Table 18.2).
- New ECR classification provides a better description of the lesion in a three-dimensional manner.

Telegram: @dental_k

www.konkur.in

- The earlier the detection of root resorption, the better the prognosis and the outcome.
- CBCT is an excellent diagnostic tool for the confirmation of the presence of ECR and IRR and also in appreciation of the true nature of these conditions.

Table 18.2

Characteristic Key Features of Root Resorption

	INTERNAL		EXTERNAL			
Resorption Type	**Inflammatory**	**Replacement**	**Inflammatory**	**Replacement**	**Cervical**	**Surface**
Clinical finding	Discoloration, symptoms of irreversible pulpitis and/or apical periodontitis	Discoloration, Symptoms of irreversible pulpitis and/or apical periodontitis	Discoloration, symptoms of apical periodontitis	May exhibit a metallic percussion sound. Mobility not expected	Probable periodontal defect, symptoms of (ir)reversible pulpitis	None
Clinical appearance	Pink spot (rare), or sign of pulpitis/apical periodontitis.	Pink spot (rare), or sign of pulpitis/apical periodontitis.	Healthy, or sign of pulpitis/apical periodontitis.	Healthy	±pink spot, or sign of pulpitis/apical periodontitis.	Healthy
Location on root	Anywhere	Anywhere	Anywhere	Anywhere	Cervical third initially but can be seen in mid and apical third in advanced cases	Adjacent to impacted tooth, cyst or tumour. Apical in orthodontic treated teeth
Pulp sensitivity	Maybe +ve in partially vital cases, or −ve in advance necrotic cases	Maybe +ve in partially vital cases, or −ve in advance necrotic cases	−ve	+ve	Usually +ve, −ve in advanced necrotic cases	+ve
Radiological appearance	Symmetrical oval shaped (ballooning) enlargement of root canal	Oval shaped enlargement of root canal with cloudy and/or mottled canal wall	Asymmetrical bowl shaped periradicular or periapical radiolucencies	Asymmetrical bony replacement of root surface and loss of PDL space	(A) symmetrical radiolucent (early), or radiopaque (advanced) appearance. Lesion moves on parallax views	Blunted root apex. Asymmetrical loss of root
Root canal	Canal expands into lesions	Canal expands into lesions	Intact in early EIR, perforation in advanced cases	Intact	Intact, but perforation in advanced cases	Intact

EIR, External inflammatory resorption; *PDL*, periodontal ligament.

19: Management of endodontic emergencies

Fabricio B. Teixeira, Gary S.P. Cheung*

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Emergency classifications

The proper diagnosis and effective management of acute dental pain are possibly the most rewarding and satisfying aspects of providing dental care. An endodontic emergency is defined as pain or swelling caused by various stages of inflammation or infection of the pulpal or periradicular tissues. The cause of dental pain originates typically from caries, deep or defective restorations, or traumatic injuries. Sometimes occlusion-related issues such as cracks can also mimic acute dental pain (Fig. 19.1). Bender[9] stated that patients who manifest severe or referred pain almost always had a previous history of pain with the offending tooth. Approximately 85% of all dental emergencies arise as a result of pulpal or periapical disease, which would necessitate either extraction or endodontic treatment to relieve the symptoms.[43,75] It has also been estimated that about 12% of the United States population experienced a toothache in the preceding 6 months.[71]

FIG. 19.1 **A,** Patient complained of acute pain on biting at the upper left molar (tooth #15). **B,** Clinical thermal tests revealed pulpal necrosis and a preoperative radiograph taken (periapical lesions noted). **C,** The tooth was split in half.

A) Close-up view shows occlusal view of two teeth with cracks.

B) Radiograph shows two teeth. The tooth on left has radiolucent spot in the pulp chamber. The gum line has porous tissue.

C) Close-up view shows a probe being pointed out at the fracture in tooth that

Telegram: @dental_k

www.konkur.in

has cracks on it.

Determining a definitive diagnosis can sometimes be challenging and even frustrating for clinicians, but a methodical, objective, and subjective evaluation is imperative before developing a proper treatment plan. Unfortunately, on the basis of the diagnosis, there are conflicting opinions on how to best clinically manage various endodontic emergencies. Surveys obtained from board-certified endodontists in 1977,[25,26] 1990,[34] and 2009[69] proposed to define seven conditions as endodontic emergencies. However, due to terminology changes, five clinical presentations are presently considered legitimate emergencies:

1. Symptomatic irreversible pulpitis with normal apical tissues
2. Symptomatic irreversible pulpitis with symptomatic apical periodontitis
3. Necrotic pulp with symptomatic apical periodontitis
4. Necrotic pulp with fluctuant intraoral swelling
5. Necrotic pulp with diffuse facial swelling

There are other endodontic emergencies such as traumatic dental injuries, previously endodontic treated teeth with either symptomatic apical periodontitis or acute apical abscess, and endodontic flare-ups that may occur between treatment sessions. Of course, there are also many types of facial pain that have a nonodontogenic origin; these are described in detail in Chapter 4.

There have been several changes in the determined clinical management of endodontic emergencies over the years. Many of these treatment modifications have occurred because of the more contemporary armamentarium and materials as well as new evidence-based research and the presumption of empirical clinical success.

Emergency endodontic management

Because pain is both a psychological and biologic entity, the management of acute dental pain must take into consideration both the physical symptoms and the emotional status of the patient. The patient's needs, fears, and coping

Telegram: @dental_k

www.konkur.in

mechanisms must be compassionately understood. This assessment and the clinician's ability to build rapport with the patient are critical factors in the comprehensive success of the patient's management.[9,33,54,99]

The methodical steps for determining an accurate diagnosis, based on evaluation of the patient's chief complaint, review of the medical history, and the protocols used for an objective and subjective diagnosis, are described in detail in Chapter 1. Once it has been determined that endodontic treatment is necessary, it is incumbent on the clinician to take the proper steps necessary to manage the acute dental emergency.

The clinician has a responsibility to inform the patient of the recommended treatment plan and to advise the patient of the treatment alternatives, the risks, and benefits that pertain, and the expected prognosis under the present circumstances. Given this information, the patient may elect extraction over endodontics or possibly request a second opinion. The treatment plan should never be forced on a patient. The informed course of treatment is made jointly between the patient and the clinician.

In the event of an endodontic emergency, the clinician must determine the optimal mode of treatment according to the diagnosis. Treatment may vary depending on the pulpal or periapical status, the intensity and duration of pain, and whether there is diffuse or fluctuant swelling. Paradoxically, as discussed later, the mode of therapy that we tend to choose has been directed more from surveys of practicing endodontists rather than from controlled clinical studies or research investigations.

Teeth with vital pulps

Teeth with vital pulps can have one of the following presentations:

- *Normal.* The teeth are asymptomatic with no objective pathoses.
- *Reversible pulpitis.* There is a reversible sensitivity to cold or osmotic changes (i.e., sweet, salty, and sour).
- *Irreversible pulpitis.* The sensitivity to temperature changes is more intense and with a longer duration.

Reversible pulpitis

Reversible pulpitis can be induced by caries, exposed dentin, recent dental

Telegram: @dental_k

www.konkur.in

treatment, and defective restorations. Conservative removal of caries, protection of dentin, and a proper restoration will typically resolve the symptoms. However, the symptoms from exposed dentin, specifically from gingival recession and cervically exposed roots, can often be difficult to alleviate. Topical applications of desensitizing agents and the use of certain dentifrices have been helpful in the management of dentin hypersensitivity; the etiology, physiology, and management of this are discussed in Chapter 13.

Irreversible pulpitis

The diagnosis of irreversible pulpitis can be subcategorized as asymptomatic or symptomatic. *Asymptomatic* irreversible pulpitis pertains to a tooth that has no symptoms, but has deep caries or tooth structure loss that, if left untreated, will cause the tooth to become symptomatic or nonvital. On the other hand, the pain from *symptomatic* irreversible pulpitis is often an emergency condition that requires immediate treatment. These teeth exhibit intermittent or spontaneous pain and are sensitive to thermal triggers. Exposure to extreme temperatures, especially cold, will elicit intense and prolonged episodes of pain, even after the source of the stimulus is removed.

In 1977,[25,26] 187 board-certified endodontists responded to a survey to determine how they would manage various endodontic emergencies. Ten years later, 314 board-certified endodontists responded to the same questionnaire in order to determine whether there had been any changes in how these emergencies were managed.[34] The clinical management of emergency treatment of a tooth with symptomatic irreversible pulpitis with or without normal periapical tissues seemed to be reasonably similar by removing the inflamed pulp tissue either by pulpotomy or complete instrumentation.[83] In a similar survey conducted in 2009,[69] most respondents stated that they would clean to the level of the “apex,” as confirmed with an electronic apex locator; this suggests a change in the management of endodontic cases based on the advent of a more contemporary armamentarium. In general, there is a trend toward more cleaning and shaping of the canal when symptomatic irreversible pulpitis presents with a normal periapex, compared with performing just pulpectomies as described in the 1977 survey. None of the individuals surveyed in the 1990 or 2009 poll

Telegram: @dental_k

www.konkur.in

stated that they would manage these emergencies by establishing any type of drainage by trephining the apex, making an incision, or leaving the tooth open for an extended period of time.

In addition, for vital teeth, the 1977 survey did not even broach the concept of completing the endodontics in one visit, whereas in the 1988 study about one third of the respondents indicated that they would complete these vital cases in a single visit and the response rose to 79% in the most recent survey. Since the early 1980s, there seems to have been an increase in the acceptability of providing endodontic therapy in one visit, especially in cases of vital pulps, with most studies revealing an equal number, or fewer, flare-ups after single-visit endodontic treatment.[27,86,91,96,98,106] However, this has not come without controversy, with some studies showing otherwise,[118] contending that there is more posttreatment pain after single-visit endodontics, and possibly a lower long-term success rate. Unfortunately, time constraints at the emergency visit often make the single-visit treatment option not practical.[4]

If root canal therapy is completed at a later date, medicating the canal with calcium hydroxide has been suggested to reduce the chances of bacterial growth in the canal between appointments in most studies.[20] One randomized clinical study showed that a dry cotton pellet was as effective in relieving pain as a pellet moistened with camphorated monochlorophenol (CMCP), metacresylacetate (cresatin), eugenol, or saline.[45] Sources of infection, such as caries and defective restorations, should be completely removed to prevent recontamination of the root canal system between appointments.[45] The concept of single- versus multiple-visit endodontics is described in greater detail in Chapter 17.

For emergency management of vital teeth that are not initially sensitive to percussion, occlusal reduction has not been shown to be beneficial.[22,34] However, the clinician should be cognizant of the possibility of occlusal interferences and prematurities that might cause tooth fracture under heavy mastication. In vital teeth in which the inflammation has extended periapically, which will present with pretreatment pain to percussion, occlusal reduction has been reported to reduce posttreatment pain.[34,82,97]

Antibiotics are not recommended for the emergency management of irreversible pulpitis (see Chapters 15 and 17),[59,107] as placebo-controlled

Telegram: @dental_k

www.konkur.in

clinical trials have demonstrated that antibiotics have no effect on pain levels in patients with irreversible pulpitis.[80]

Most endodontists and endodontic textbooks recommend the emergency management of *symptomatic* irreversible pulpitis to involve the initiation of root canal treatment,[20,34,44,69,111] with complete pulp removal and total debridement of the root canal system. Unfortunately, in an emergency situation, the allotted time necessary for this treatment is often an issue. Given the potential time constraints and inevitable differences in skill level between clinicians, it may not be feasible to complete the total canal cleaning at the initial emergency visit. Subsequently, especially with multirooted teeth, a pulpotomy (removal of the coronal pulp) has been advocated for emergency treatment of irreversible pulpitis.[17,44,103] In a clinical study of various emergency procedures, it has been demonstrated that this treatment is highly effective for alleviating acute dental pain due to irreversible pulpitis.[17] A randomized clinical trial showed that pulpotomy was an excellent alternative for emergency relief of pain.[32] These findings were similar to the results seen in a recent study,[5] which reported more pain relief after pulpotomy as compared to the root canals treatment.

To assist the clinician in assessing the level of difficulty of a given endodontic case, the American Association of Endodontists (Chicago, IL) has developed the “AAE Endodontic Case Difficulty Assessment Form and Guidelines” (Fig. 19.2). This form is intended to make case selection more efficient, more consistent, and easier to document, as well as to provide a more objective ability to determine when it may be necessary to refer the patient to another clinician who may be better able to manage the complexities of the case. Haug et al. evaluated the impact of the case difficulty on endodontic mishaps in an undergraduate student clinic. They emphasized the importance and relevance of case difficulty assessment. Their results showed that the American Association of Endodontists (AAE) case difficulty assessment form is a valuable tool to predict potential mishaps and the number of treatment visits.[46]

Guidelines for Using the AAE Endodontic Case Difficulty Assessment Form

The AAE designed the Endodontic Case Difficulty Assessment Form for use in endodontic curricula. The Assessment Form makes case selection more efficient, more consistent and easier to document. Dentists may also choose to use the Assessment Form to help with referral decision making and record keeping.

Conditions listed in this form should be considered potential risk factors that may complicate treatment and adversely affect the outcome. Levels of difficulty are sets of conditions that may not be controllable by the dentist. Risk factors can influence the ability to provide care at a consistently predictable level and impact the appropriate provision of care and quality assurance.

The Assessment Form enables a practitioner to assign a level of difficulty to a particular case.

LEVELS OF DIFFICULTY

MINIMAL DIFFICULTY	Preoperative condition indicates routine complexity (uncomplicated). These types of cases would exhibit only those factors listed in the MINIMAL DIFFICULTY category. Achieving a predictable treatment outcome should be attainable by a competent practitioner with limited experience.
MODERATE DIFFICULTY	Preoperative condition is complicated, exhibiting one or more patient or treatment factors listed in the MODERATE DIFFICULTY category. Achieving a predictable treatment outcome will be challenging for a competent, experienced practitioner.
HIGH DIFFICULTY	Preoperative condition is exceptionally complicated, exhibiting several factors listed in the MODERATE DIFFICULTY category or at least one in the HIGH DIFFICULTY category. Achieving a predictable treatment outcome will be challenging for even the most experienced practitioner with an extensive history of favorable outcomes.

Review your assessment of each case to determine the level of difficulty. If the level of difficulty exceeds your experience and comfort, you might consider referral to an endodontist.

The AAE Endodontic Case Difficulty Assessment Form is designed to aid the practitioner in determining appropriate case disposition. The American Association of Endodontists neither expressly nor implicitly warrants any positive results associated with the use of this form. This form may be reproduced but may not be amended or altered in any way.

AAE Endodontic Case Difficulty Assessment Form

Criteria and Subcriteria	Minimal Difficulty	Moderate Difficulty	High Difficulty
A. PATIENT CONSIDERATIONS			
Medical history	☐ No medical problem (ASA Class 1*)	☐ One or more medical problems (ASA Class 2*)	☐ Complex medical history/serious illness/disability (ASA Classes 3-5*)
Anesthesia	☐ No history of anesthesia problems	☐ Vasoconstrictor intolerance	☐ Difficulty achieving anesthesia
Patient disposition	☐ Cooperative and compliant	☐ Anxious but cooperative	☐ Uncooperative
Ability to open mouth	☐ No limitation	☐ Slight limitation in opening	☐ Significant limitation in opening
Gag reflex	☐ None	☐ Gags occasionally with radiographs/treatment	☐ Extreme gag reflex which has compromised past dental care
Emergency condition	☐ Minimum pain or swelling	☐ Moderate pain or swelling	☐ Severe pain or swelling
B. DIAGNOSTIC AND TREATMENT CONSIDERATIONS			
Diagnosis	☐ Signs and symptoms consistent with recognized pulpal and periapical conditions	☐ Extensive differential diagnosis of usual signs and symptoms required	☐ Confusing and complex signs and symptoms; difficult diagnosis ☐ History of chronic oral/facial pain
Radiographic difficulties	☐ Minimal difficulty obtaining/interpreting radiographs	☐ Moderate difficulty obtaining/interpreting radiographs (e.g., high floor of mouth, narrow or low palatal vault, presence of tori)	☐ Extreme difficulty obtaining/interpreting radiographs (e.g., superimposed anatomical structures)
Position in the arch	☐ Anterior/premolar ☐ Slight inclination (<10°) ☐ Slight rotation (<10°)	☐ 1st molar ☐ Moderate inclination (10-30°) ☐ Moderate rotation (10-30°)	☐ 2nd or 3rd molar ☐ Extreme inclination (>30°) ☐ Extreme rotation (>30°)
Tooth isolation	☐ Routine rubber dam placement	☐ Simple pretreatment modification required for rubber dam isolation	☐ Extensive pretreatment modification required for rubber dam isolation
Morphologic aberrations of crown	☐ Normal original crown morphology	☐ Full coverage restoration ☐ Porcelain restoration ☐ Bridge abutment ☐ Moderate deviation from normal tooth/root form (e.g., taurodontism, microdens) ☐ Teeth with extensive coronal destruction	☐ Restoration does not reflect original anatomy/alignment ☐ Significant deviation from normal tooth/root form (e.g., fusion, dens in dente)
Canal and root morphology	☐ Slight or no curvature (<10°) ☐ Closed apex <1 mm diameter	☐ Moderate curvature (10-30°) ☐ Crown axis differs moderately from root axis. Apical opening 1-1.5 mm in diameter	☐ Extreme curvature (>30°) or S-shaped curve ☐ Mandibular premolar or anterior with 2 roots ☐ Maxillary premolar with 3 roots ☐ Canal divides in the middle or apical third ☐ Very long tooth (>25 mm) ☐ Open apex (>1.5 mm in diameter)
Radiographic appearance of canal(s)	☐ Canal(s) visible and not reduced in size	☐ Canal(s) and chamber visible but reduced in size ☐ Pulp stones	☐ Indistinct canal path ☐ Canal(s) not visible
Resorption	☐ No resorption evident	☐ Minimal apical resorption	☐ Extensive apical resorption ☐ Internal resorption ☐ External resorption
C. ADDITIONAL CONSIDERATIONS			
Trauma history	☐ Uncomplicated crown fracture of mature or immature teeth	☐ Complicated crown fracture of mature teeth ☐ Subluxation	☐ Complicated crown fracture of immature teeth ☐ Horizontal root fracture ☐ Alveolar fracture ☐ Intrusive, extrusive or lateral luxation ☐ Avulsion
Endodontic treatment history	☐ No previous treatment	☐ Previous access without complications	☐ Previous access with complications (e.g., perforation, non-negotiated canal, ledge, separated instrument) ☐ Previous surgical or nonsurgical endodontic treatment completed
Periodontal-endodontic condition	☐ None or mild periodontal disease	☐ Concurrent moderate periodontal disease	☐ Concurrent severe periodontal disease ☐ Cracked teeth with periodontal complications ☐ Combined endodontic/periodontic lesion ☐ Root amputation prior to endodontic treatment

*American Society of Anesthesiologists (ASA) Classification System:
Class 1: No systemic illness. Patient healthy.
Class 2: Patient with mild degree of systemic illness, but without functional restrictions, e.g., well-controlled hypertension.
Class 3: Patient with severe degree of systemic illness which limits activities, but does not immobilize the patient.
Class 4: Patient with severe systemic illness that immobilizes and is sometimes life threatening.
Class 5: Patient will not survive more than 24 hours whether or not surgical intervention takes place.
www.asahq.org/clinical/physicalstatus.htm

FIG. 19.2 The American Association of Endodontists *(AAE)* Endodontic Case Difficulty Assessment Form and Guidelines, developed to assist the clinician in assessing the level of difficulty of a given endodontic case and to help determine when referral may be necessary.

AAE Endodontic Case Difficulty Assessment Form and Guidelines are shown along with AAE logo at the upper left corner.

The first panel shows patient information including its name, address, city/state/zip, and phone. To the right, the information under the heading disposition is as follows: treat in office (Yes or no each with blank check boxes), refer patient number, date.

The second panel shows guidelines for using the AAE Endodontic Case Difficulty Assessment Form

The AAE designed the Endodontic Case Difficulty Assessment Form for use

www.konkur.in

in endodontic curricula. The Assessment Form makes case selection more efficient, more consistent and easier to document. Dentists may also choose to use the Assessment Form to help with referral decision making and record keeping.

Conditions listed in this form should be considered potential risk factors that may complicate treatment and adversely affect the outcome. Levels of difficulty are sets of conditions that may not be controllable by the dentist. Risk factors can influence the ability to provide care at a consistently predictable level and impact the appropriate provision of care and quality assurance.

The Assessment Form enables a practitioner to assign a level of difficulty to a particular case.

Levels of difficulty are as follows:

Minimal difficulty: Preoperative condition indicates routine complexity (uncomplicated). These types of cases would exhibit only those factors listed in the minimal difficulty category. Achieving a predictable treatment outcome should be attainable by a competent practitioner with limited experience.

Moderate difficulty: Preoperative condition is complicated, exhibiting one or more patient or treatment factors listed in the moderate difficulty category. Achieving a predictable treatment outcome will be challenging for a competent, experienced practitioner.

High difficulty: Preoperative condition is exceptionally complicated, exhibiting several factors listed in the moderate difficulty category or at least one in the high difficulty category. Achieving a predictable treatment outcome will be challenging for even the most experienced practitioner with an extensive history of favorable outcomes.

Review your assessment of each case to determine the level of difficulty. If the level of difficulty exceeds your experience and comfort, you might consider referral to an endodontist.

Text at the bottom reads, The AAE Endodontic Case Difficulty Assessment Form is designed to aid the practitioner in determining appropriate case disposition. The American Association of Endodontists neither expressly nor implicitly warrants any positive results associated with the use of this form. This form may be reproduced but may not be amended or altered in any way.

The continuation of AAE Endodontic Case Difficulty Assessment Form shows three sections as follows: A) Patient considerations, B) Diagnostic and treatment considerations, C) Additional considerations. Each section has list of queries under criteria and subcriteria, minimal difficulty, moderate difficulty, and high difficulty columns.

www.konkur.in

Pulpal necrosis with symptomatic apical periodontitis

Over the years, the proper methodology for the emergency endodontic management of necrotic teeth has been controversial. In a 1977 survey of board-certified endodontists,[25,26] it was reported that, in the absence of swelling, most respondents would completely instrument the canals, keeping the file short of the radiographic apex. However, when swelling was present, the majority of those polled in 1977 preferred to leave the tooth open, with instrumentation extending beyond the apex to help facilitate drainage through the canals. Years later and again validated in a 2009 study, most respondents favored complete instrumentation regardless of the presence of swelling. Also, it was the decision of 25.2% to 38.5% of the clinicians to leave these teeth open in the event of diffuse swelling; 17.5% to 31.5% left the teeth open in the presence of a fluctuant swelling. However, as discussed later, there is currently a trend toward not leaving teeth open for drainage. There is also another trend: when treatment is done in more than one visit, most endodontists will use calcium hydroxide as an intracanal medicament.[69]

Care should be taken not to push necrotic debris beyond the apex during root canal instrumentation, as this has been shown to promote more posttreatment discomfort.[15,34,95,104] Crown-down instrumentation techniques have been shown to remove most of the debris coronally rather than pushing it out the apex. The use of positive-pressure irrigation methods, such as needle-and-syringe irrigation, also poses a risk of expressing debris or solution out of the apex.[12,23] Improvements in technology, such as electronic apex locators and use of the limited cone-beam computed tomography (CBCT) have facilitated increased accuracy in determining working length measurements.[74] An increased number of clinicians now use these devices.[62,69] Moreover, new negative-pressure irrigation systems may allow for a more thorough canal debridement with less apical extrusion of debris.[18,75]

The attenuation of postoperative pain in patients with this specific condition has continuously been evaluated in the literature. An outcome study indicated that the use of a negative apical pressure irrigation device significantly reduces the postoperative pain levels in comparison to conventional needle irrigation.[3] A randomized clinical trial demonstrated

Telegram: @dental_k

www.konkur.in

final irrigation with 20 mL sterile cold (2.5°C) saline solution delivered to the working length with a sterile, cold (2.5°C) EndoVac microcannula (Kerr Endo, Orange Country, CA) for 5 minutes.[116] They concluded that cryotherapy reduced the incidence of postoperative pain and the need for medication in patients presenting with a diagnosis of necrotic pulp and symptomatic apical periodontitis.

Trephination

In the absence of swelling, trephination is the surgical perforation of the alveolar cortical plate to release, from between the cortical plates, the accumulated inflammatory and infective tissue exudate that causes pain. Its use has been historically advocated to provide pain relief in patients with severe and recalcitrant periradicular pain.[25,26] The technique involves an engine-driven perforator entering through the cortical bone and into the cancellous bone, often without the need for an incision,[19] in order to provide a pathway for drainage from the periradicular tissues. Although more recent studies have failed to show the benefit of trephination in patients with irreversible pulpitis with symptomatic apical periodontitis[77] or necrotic teeth with symptomatic apical periodontitis,[82] there remain some advocates who recommend trephination for managing acute and intractable periapical pain.[51] The clinician should understand that local anesthesia may be difficult for cases with acute inflammation or infection.[55] Extreme care must be taken when carrying out a trephination procedure to guard against inadvertent and possibly irreversible injury to the tooth root or surrounding structures, such as the mental foramen, intra-alveolar nerve, or maxillary sinus.

Necrosis and single-visit endodontics

Although single-visit endodontic treatment for teeth diagnosed with irreversible pulpitis is not contraindicated,[2,91,93,98,119] performing single-visit endodontics on necrotic and previously treated teeth is not without controversy. In cases of necrotic teeth, although research[27] has indicated that there may be no difference in posttreatment pain if the canals are filled at the time of the emergency versus a later date, some studies[105,112] have questioned the long-term prognosis of such treatment, especially in cases of symptomatic apical periodontitis. Several studies,[28,66] including a CONSORT

Telegram: @dental_k

www.konkur.in

(Consolidated Standards of Reporting Trials) meta-analysis,[92] have shown no difference in outcome between single-visit and two-visit treatments. The concept of single- versus multi-visit endodontics is further discussed in Chapters 5 and 17.

Pulpal necrosis with acute apical abscess

Swelling

Tissue swelling may be associated with an acute apical abscess at the time of the initial emergency visit, or it may occur as an inter-appointment flare-up or as a postendodontic complication. Swellings may be localized or diffuse, fluctuant or firm. Localized swellings are confined within the oral cavity, whereas a diffuse swelling, or cellulitis, is more extensive, spreading through adjacent soft tissues and dissecting tissue spaces along fascial planes.[100]

Swelling may be controlled by establishing drainage through the root canal or by incising the fluctuant swelling. As discussed later and in Chapter 15, antibiotics may be recruited when there are systemic manifestations of the infection, such as fever and malaise. The principal modality for managing swelling secondary to endodontic infections is to achieve drainage and remove the source of the infection.[41] When the swelling is localized, the preferred avenue is drainage through the root canal (Fig. 19.3). Complete canal debridement and disinfection[42,114] are paramount for success regardless of observable drainage, because the presence of any bacteria remaining within the root canal system will compromise the resolution of the acute infection.[73] In the presence of persistent swelling, gentle finger pressure to the mucosa overlying the swelling may help facilitate drainage through the canal. Once the canals have been cleaned and allowed to dry, calcium hydroxide as the intracanal medicament[69] should be placed and the access properly sealed.[20,34,44]

www.konkur.in

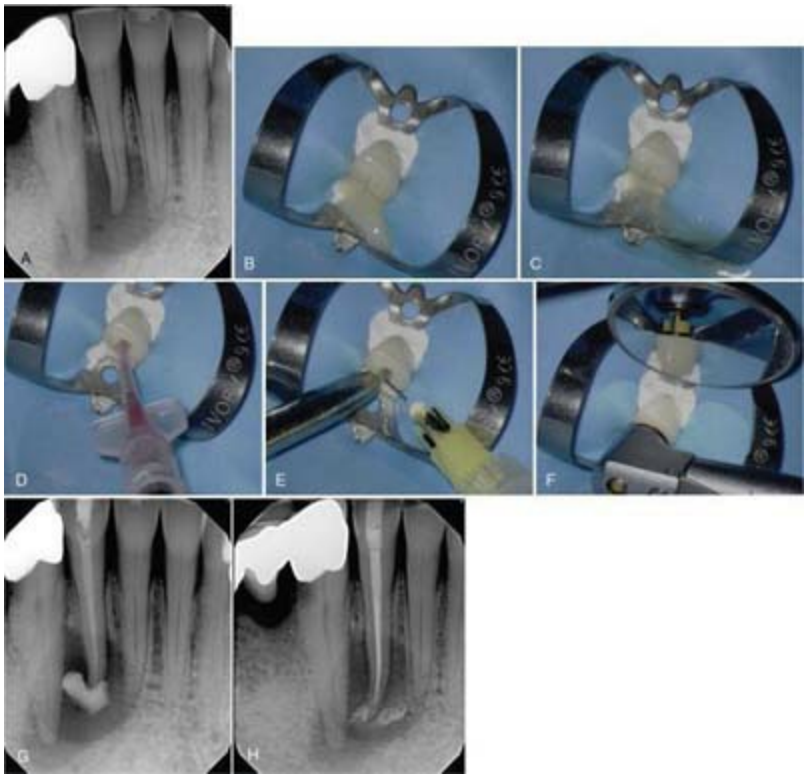

FIG. 19.3 Drainage of pus through the root canal. **A,** Acute apical abscess arising from the lower right lateral incisor with radiographic radiolucency. **B,** Initial drainage through the canal. **C,** Persistent drainage through the canal. **D,** Aspiration of the content with a plastic suction tip. **E,** Irrigation with NaOCl. **F,** Mechanical debridement. **G,** Placement of calcium hydroxide. **H,** Obturation of root canals during second visit.

Set of eight illustrations depicts steps involved in the removal of pus from tooth through root canal.

Fascial space infections

If bacteria from the infected root canal gain entry into the periradicular tissues and the immune system is unable to suppress the invasion, an otherwise healthy patient eventually shows signs and symptoms of an acute apical abscess, which can, in turn, evolve to cellulitis. Clinically, the patient experiences swelling and mild to severe pain. Depending on the relationship of the apices of the affected tooth to the muscular attachments, the swelling may be localized to the vestibule or extend into a fascial space. The patient may also have systemic manifestations, such as fever, chills,

Telegram: @dental_k

www.konkur.in

lymphadenopathy, headache, and nausea. Because the reaction to the infection may occur quickly, the involved tooth may or may not show radiographic evidence of a widened periodontal ligament space. In most cases, the tooth elicits a positive response to percussion, and the periradicular area is tender to palpation. The tooth now becomes a *focus of infection* because it leads to periradicular infection and secondary spread to the fascial spaces of the head and neck, resulting in cellulitis and systemic signs and symptoms of infection.

In such cases, treatment may involve incision for drainage, root canal treatment, or extraction to remove the source of the infection. Antibiotic therapy may be indicated in patients with compromised host resistance, the presence of systemic symptoms, or fascial space involvement. Fascial space infections of odontogenic origin are infections that have spread into the fascial spaces from the periradicular area of a tooth, the focus of infection. They are *not* examples of the theory of focal infection, which describes the dissemination of bacteria or their products from a distant focus of infection. Preferably, this is an example of the local spread of infection from an odontogenic source.

Fascial spaces are potential anatomic areas that exist between the fascia and underlying organs and other tissues. During infection, these spaces are formed as a result of the spread of purulent exudate. The spread of infections of odontogenic origin into the fascial spaces of the head and neck is determined by the location of the root end of affected tooth to its overlying buccal or lingual cortical plate and the relationship of the apex to the attachment of a muscle (Fig. 19.4, *A*). For example, if the source of the infection is a mandibular molar whose apices lie closer to the lingual cortical plate and *above* the attachment of the mylohyoid muscle of the floor of the mouth, the purulent exudate may break through the lingual cortical plate and into the *sublingual* space. However, if the apices lie *below* the attachment of the mylohyoid muscle, the infection may spread into the *submandibular* space.

vestibule (posterior tooth). **C,** Mandibular buccal vestibule (anterior tooth). **D,** Mental space. **E,** Submental space. **F,** Sublingual space. **G,** Submandibular space. **H,** Maxillary buccal vestibule. **I,** Buccal space. **J,** Submasseteric space. **K,** Temporal space. **L,** Pterygomandibular space. **M,** Parapharyngeal spaces. **N,** Cervical spaces. **O,** Canine (infraorbital) and periorbital space.

A) Open mouth with labels as follows: Buccinator muscle, mylohyoid muscle, and platysma muscle.

B) Tooth near buccinator muscle has a cloud of unusual cells on the left extending from the root canal.

C) Tooth shows the unusual growth of cells above mentalis muscle.

D) The cloud changes its shape and dislocates next to mentalis muscle.

E) The cloud further moves above platysma muscle.

F) The infectious tissue move on the right side of tooth.

G) Front view shows infectious tissue extending from the root canal above platysma muscle.

H) Enlarged view shows the infectious tissue close to buccinators muscle.

I) An arrow from the molar tooth of mandible leads to infectious tissue along buccinator muscle below masseter muscle and Ramus of the mandible.

J) The infectious tissue is present in-between masseter muscle and Ramus of the mandible below the parotid gland.

K) Front view of face with labels as follows: Temporalis muscle, superficial temporal space, deep temporal space, lateral pterygoid muscle, pterygomandibular space, submasseteric space, medial pterygoid muscle, and masseter muscle.

L) The infectious tissue from tooth moves below medial pterygoid muscle.

M) The infectious tissue lies in between superior constrictor muscle and medial pterygoid muscle.

N) Side view of neck and lower face with labels as follows: Alar fascia, prevertebral space, retropharyngeal space, and danger space (space 4).

O) Front view upper face with labels as follows: Periorbital space, orbicularis oculi muscle, and canine space.

As described by Hohl and colleagues,[53] the fascial spaces of the head and

Telegram: @dental_k

www.konkur.in

neck can be categorized into four anatomic groups:

- The mandible and below
- The cheek and lateral face
- The pharyngeal and cervical areas
- The midface

Swellings of and below the mandible include six anatomic areas or fascial spaces:

- The buccal vestibule
- The body of the mandible
- The mental space
- The submental space
- The sublingual space
- The submandibular space

The *mandibular buccal vestibule* is the anatomic area amid the buccal cortical plate, the overlying alveolar mucosa, and the buccinator muscle (posterior) or the mentalis muscle (anterior) (see Fig. 19.4, *B* and *C*). In this case, the source of the infection is a mandibular posterior or anterior tooth in which the purulent exudate breaks through the buccal cortical plate, and the apex or apices of the involved tooth lie above the attachment of the buccinator or mentalis muscle, respectively.

The *space of the body of the mandible* is the potential anatomic area between the buccal or lingual cortical plate and its overlying periosteum. The source of infection is a mandibular tooth in which the purulent exudate has broken through the overlying cortical plate but not yet perforated the overlying periosteum. Involvement of this space can also occur as a result of a postsurgical infection.

The *mental space* (see Fig. 19.4, *D*) is the potential bilateral anatomic area of the chin that lies between the mentalis muscle superiorly and the platysma muscle inferiorly. The source of the infection is an anterior tooth in which the purulent exudate breaks through the buccal cortical plate, and the apex of the tooth lies below the attachment of the mentalis muscle.

The *submental space* (see Fig. 19.4, *E*) is the potential anatomic area

Telegram: @dental_k

www.konkur.in

between the mylohyoid muscle superiorly and the platysma muscle inferiorly. The source of the infection is an anterior tooth in which the purulent exudate breaks through the lingual cortical plate, and the apex of the tooth lies below the attachment of the mylohyoid muscle.

The *sublingual space* (see Fig. 19.4, *F*) is the potential anatomic area between the oral mucosa of the floor of the mouth superiorly and the mylohyoid muscle inferiorly. The lateral boundaries of the space are the lingual surfaces of the mandible. The source of infection is any mandibular tooth in which the purulent exudate breaks through the lingual cortical plate, and the apex or apices of the tooth lie above the attachment of the mylohyoid muscle.

The *submandibular space* (see Fig. 19.4, *G*) is the potential space between the mylohyoid muscle superiorly and the platysma muscle inferiorly. The source of infection is a posterior tooth, usually a molar, in which the purulent exudate breaks through the lingual cortical plate and the apices of the tooth lie below the attachment of the mylohyoid muscle. If the submental, sublingual, and submandibular spaces are involved at the same time, a diagnosis of Ludwig angina is made. This life-threatening cellulitis can advance into the pharyngeal and cervical spaces, resulting in airway obstruction.

Swellings of the lateral face and cheek include four anatomic areas or fascial spaces:

- The buccal vestibule of the maxilla
- The buccal space
- The submasseteric space
- The temporal space

Anatomically, the *buccal vestibular space* (see Fig. 19.4, *H*) is the area between the buccal cortical plate, the overlying mucosa, and the buccinator muscle. The superior extent of the space is the attachment of the buccinator muscle to the zygomatic process. The source of infection is a posterior maxillary tooth in which the purulent exudate breaks through the buccal cortical plate, and the apex of the tooth lies below the attachment of the buccinator muscle.

The *buccal space* (see Fig. 19.4, *I*) is the potential space between the

Telegram: @dental_k

www.konkur.in

lateral surface of the buccinator muscle and the medial surface of the skin of the cheek. The superior extent of the space is the attachment of the buccinator muscle to the zygomatic arch, whereas the inferior and posterior boundaries are the attachment of the buccinator to the inferior border of the mandible and the anterior margin of the masseter muscle, respectively. The source of the infection can be either a posterior mandibular or maxillary tooth in which the purulent exudate breaks through the buccal cortical plate, and the apex or apices of the tooth lie above the attachment of the buccinator muscle (i.e., maxilla) or below the attachment of the buccinator muscle (i.e., mandible).

As the name implies, the *submasseteric space* (see Fig. 19.4, *J*) is the potential space between the lateral surface of the ramus of the mandible and the medial surface of the masseter muscle. The source of the infection is usually an impacted third molar in which the purulent exudate breaks through the lingual cortical plate, and the apices of the tooth lie very close to or within the space.

The *temporal space* (see Fig. 19.4, *K*) is divided into two compartments by the temporalis muscle. The *deep temporal space* is the potential space between the lateral surface of the skull and the medial surface of the temporalis muscle; the *superficial temporal space* lies between the temporalis muscle and its overlying fascia. The deep or superficial temporal spaces are involved indirectly if an infection spreads superiorly from the inferior pterygomandibular or submasseteric spaces, respectively.

Swellings of the pharyngeal and cervical areas include the following fascial spaces:

- The pterygomandibular space
- The parapharyngeal spaces
- The cervical spaces

The *pterygomandibular space* (see Fig. 19.4, *L*) is the potential space between the lateral surface of the medial pterygoid muscle and the medial surface of the ramus of the mandible. The superior extent of the space is the lateral pterygoid muscle. The source of the infection is mandibular second or third molars in which the purulent exudate drains directly into the space. In addition, contaminated inferior alveolar nerve injections can lead to infection of the space.

Telegram: @dental_k

www.konkur.in

The *parapharyngeal spaces* comprise the lateral pharyngeal and retropharyngeal spaces (see Fig. 19.4, *M*). The *lateral pharyngeal space* is bilateral and lies between the lateral surface of the medial pterygoid muscle and the posterior surface of the superior constrictor muscle. The superior and inferior margins of the space are the base of the skull and the hyoid bone, respectively, and the posterior margin is the *carotid space*, or sheath, which contains the common carotid artery, internal jugular vein, and the vagus nerve. Anatomically, the *retropharyngeal space* lies between the anterior surface of the prevertebral fascia and the posterior surface of the superior constrictor muscle and extends inferiorly into the retroesophageal space, which extends into the posterior compartment of the mediastinum. The pharyngeal spaces usually become involved as a result of the secondary spread of infection from other fascial spaces or directly from a peritonsillar abscess.

The cervical spaces comprise the pretracheal, retrovisceral, danger, and prevertebral spaces (see Fig. 19.4, *N*). The *pretracheal space* is the potential space surrounding the trachea. It extends from the thyroid cartilage inferiorly into the superior portion of the anterior compartment of the mediastinum to the level of the aortic arch. Because of its anatomic location, odontogenic infections do not spread to the pretracheal space. The *retrovisceral space* comprises the retropharyngeal space superiorly and the retroesophageal space inferiorly. The space extends from the base of the skull into the posterior compartment of the mediastinum to a level between vertebrae C6 and T4. The *danger space* (i.e., space 4)[29,38] is the potential space between the alar and prevertebral fascia. Because this space is composed of loose connective tissue, it is considered an actual anatomic space extending from the base of the skull into the posterior compartment of the mediastinum to a level corresponding to the diaphragm. It is not unknown for odontogenic infection to spread into this space, if left untreated and undiagnosed.[36] The consequence can be fatal. The *prevertebral space* is the potential space surrounding the vertebral column. As such, it extends from vertebra C1 to the coccyx. A retrospective study showed that 71% of cases in which the mediastinum was involved arose from the spread of infection from the retrovisceral space (21% from the carotid space and 8% from the pretracheal space).[70]

Telegram: @dental_k

www.konkur.in

Swellings of the midface consist of four anatomic areas and spaces:

- The palate
- The base of the upper lip
- The canine spaces
- The periorbital spaces

Odontogenic infections can spread into the areas between the palate and its overlying periosteum and mucosa and the base of the upper lip, which lies superior to the orbicularis oris muscle, even though these areas are not considered actual fascial spaces. The source of infection of the palate is any of the maxillary teeth in which the apex of the involved tooth lies close to the palate. The source of infection of the base of the upper lip is a maxillary central incisor in which the apex lies close to the buccal cortical plate and above the attachment of the orbicularis oris muscle.

The *canine*, or *infraorbital, space* (see Fig. 19.4, *O*) is the potential space between the levator anguli oris muscle inferiorly and the levator labii superioris muscle superiorly. The source of infection is the maxillary canine or first premolar in which the purulent exudate breaks through the buccal cortical plate, and the apex of the tooth lies above the attachment of the levator anguli oris muscle. There is a chance for the infection to spread from the infraorbital space into the cavernous sinus in the cranium via the valveless veins of the face and anterior skull base.[29]

The *periorbital space* (see Fig. 19.4, *O*) is the potential space that lies deep to the orbicularis oculi muscle. This space becomes involved through the spread of infection from the canine or buccal spaces. Infections of the midface can be very dangerous because they can result in *cavernous sinus thrombosis*, a life-threatening infection in which a thrombus formed in the cavernous sinus breaks free, resulting in blockage of an artery or the spread of infection. Under normal conditions, the angular and ophthalmic veins and the pterygoid plexus of veins flow into the facial and external jugular veins. If an infection has spread into the midfacial area, however, edema and the resultant increased pressure from the inflammatory response cause the blood to back up into the cavernous sinus. Once in the sinus, the blood stagnates and clots. The resultant infected thrombi remain in the cavernous sinus or

Telegram: @dental_k

www.konkur.in

escape into the circulation.[85,122]

Management of abscesses and cellulitis

The two most essential elements of effective patient management for the resolution of an odontogenic infection are correct diagnosis and removal of the cause. When endodontic treatment is possible and preferred, in an otherwise healthy patient, chemomechanical preparation of the infected root canals and incision for drainage of any fluctuant periradicular swelling usually provide immediate improvement of the clinical signs and symptoms. The majority of cases of endodontic infections can be treated effectively without the use of systemic antibiotics. The appropriate treatment is the removal of the cause of the inflammatory condition.

Antibiotics are still prescribed in clinical situations for which they are typically not indicated.[35] The evidence clearly showed that they are *not* recommended for irreversible pulpitis, symptomatic apical periodontitis, draining sinus tracts, after endodontic surgery, to prevent flare-ups, or after incision for drainage of a localized swelling (without cellulitis, fever, or lymphadenopathy).[31,52,80,94,118] When the ratio of risk to benefit is considered in these situations, antibiotic use may put the patient at risk for side effects of the antimicrobial agent and select for resistant microorganisms. Analgesics (not antibiotics) are indicated for controlling the pain.

Antibiotics in conjunction with appropriate endodontic treatment are recommended for progressive or persistent infections with systemic signs and symptoms such as fever (over 100°F or 37°C), malaise, cellulitis, unexplained trismus, and progressive or persistent swelling (or both) (Fig. 19.5). In such cases, antibiotic therapy is indicated as an adjunct to debridement of the root canal system, which is a reservoir of microorganisms. In addition, aggressive incision for drainage is indicated for any infection marked by cellulitis. The incision for drainage is indicated whether the cellulitis is indurate or fluctuant. It is essential to provide a pathway of drainage to prevent further spread of the abscess or cellulitis. An incision for drainage allows decompression of the increased tissue pressure associated with edema and provides significant pain relief. Furthermore, the incision provides a draining pathway not only for bacteria and their products but also

Telegram: @dental_k

www.konkur.in

for the inflammatory mediators associated with the spread of cellulitis.

FIG. 19.5 **A,** Preoperative radiograph. **B,** Cellulitis.

A) Radiograph shows circular dark patch at the root tips of first molar. The crown is radiopaque with radiolucency near the neck.

B) Close-up view shows the front view of a patient's face with swelling on right buccal region.

A minimum inhibitory concentration of antibiotic may not reach the source of the infection because of decreased blood flow and because the antibiotic must diffuse through the edematous fluid and pus. Drainage of edematous fluid and purulent exudate improves circulation to the tissues associated with an abscess or cellulitis, providing better delivery of the antibiotic to the area. Placement of a drain may not be indicated for localized fluctuant swellings if complete evacuation of the purulent exudate is believed to have occurred.

For effective drainage, a vertically oriented stab incision is made through the mucoperiosteum in the most dependent site of the swelling. The incision must be long enough to allow blunt dissection using a curved hemostat or periosteal elevator under the periosteum for drainage of pockets of inflammatory exudate (Fig 19.6). A rubber dam drain or a Penrose drain is indicated for any patient with a progressive abscess or cellulitis to maintain an open pathway for drainage. A more detailed description is given later.

B) A dental instrument is placed on the inflamed mass.

C) A dental instrument is pressed into the inflamed mass.

D) Milky fluid along with blood is being released from the inflamed mass.

Patients with cellulitis should be followed daily to ensure that the infection is resolving. The best practical guide for determining the duration of antibiotic therapy is the clinical improvement of the patient. When clinical evidence indicates that the infection is certain to resolve or is resolved, antibiotics should be administered for no longer than 1 or 2 days more.

Endodontic treatment should be completed as soon as possible after the incision for drainage. The drain can usually be removed 1 or 2 days after improvement. If no significant clinical improvement occurs, the diagnosis and treatment must be reviewed carefully. Consultation with a specialist and referral may be indicated for severe or persistent infections. Likewise,

Telegram: @dental_k

www.konkur.in

patients requiring extraoral drainage should be referred to a clinician trained in the technique.

Incision for drainage

Although a recent study concluded that establishing drainage from a localized soft-tissue swelling may not result in the immediate relief of pain,[11] this procedure is sometimes necessary. This can be accomplished through the *incision for drainage* of the area.[81] Incision for drainage is indicated whether the cellulitis is indurated or fluctuant,[100] and it is used when a pathway for drainage is needed to prevent further spread of infection. The incision for drainage allows decompression from the increased tissue pressure associated with edema and can provide significant pain relief for the patient; noteworthy is that often pain decreases when the soft tissues swell due to the relief of pressure within the bone. The incision also provides a pathway not only for bacteria and bacterial by-products but also for the inflammatory mediators that are associated with the spread of cellulitis.

The basic principles of incision for drainage are as follows:

- Anesthetize the area.
- Make a vertically oriented incision at the site of greatest fluctuant swelling.
- Dissect gently, through the deeper tissues, and thoroughly explore all parts of the abscess cavity, eventually extending to the offending roots that are responsible for the pathosis. This will allow compartmentalized areas of inflammatory exudates and infection to be disrupted and evacuated.
- To promote drainage, the wound should be kept clean with warm saltwater mouth rinses. Intraoral heat application to infected tissues results in a dilation of small vessels, which subsequently intensifies host defenses through increased vascular flow.[42,100]
- A drain should be placed to prevent the incision from closing too early. One type of drain is ½-inch iodoform gauze, which is comfortable and less traumatic to the patient (Fig. 19.7). The patient should be seen the following day to remove the drain.

Telegram: @dental_k

www.konkur.in

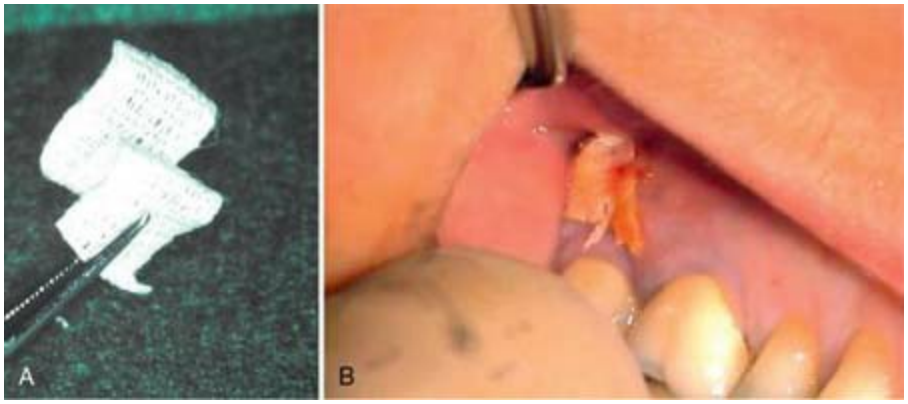

FIG. 19.7 **A,** Iodoform gauze cut to proper length. **B,** Iodoform gauze drain after 24 hours.

A) Rectangular piece of gauze having a fold is held by forceps.

B) Close-up view of the gauze absorbing the drain above the gum line of teeth.

A diffuse swelling may develop into a life-threatening medical emergency. Because the spread of infection can traverse between the fascial planes and muscle attachments, vital structures can be compromised and breathing may be impeded. Two examples are Ludwig angina and cervical fasciitis.[36] It is imperative that the clinician is in constant communication with the patient to ensure that the infection does not worsen and that medical attention is provided as necessary. Antibiotics and analgesics should be prescribed, and the patient should be monitored closely for the next several days or until there is an improvement. Individuals who show signs of toxicity, elevated body temperature, lethargy, central nervous system (CNS) changes, or airway compromise should be referred to an oral surgeon or medical facility for immediate care and intervention.

Symptomatic teeth with previous endodontic treatment

The emergency management of teeth with previous endodontic treatment may be technically challenging and time-consuming. This is especially true in the presence of extensive restorations, including posts and cores, crowns, and bridgework. However, the goal remains the same as for the management of necrotic teeth: remove contaminants from the root canal system and establish

Telegram: @dental_k

www.konkur.in

patency to achieve drainage. Gaining access to the periapical tissues through the root canals may require removal of posts and obturation materials, as well as negotiating blocked or ledged canals. Failure to complete root canal debridement and achieve periapical drainage may result in continued painful symptoms, in which case a trephination procedure or apicoectomy may be indicated. The ability, practicality, and feasibility to adequately retreat the root canal system must be carefully assessed before the initiation of treatment, as conventional retreatment might not be the optimal treatment plan. This is further discussed in Chapter 10.

Leaving teeth open

On rare occasions, canal drainage may continue from the periapical spaces (Fig. 19.8). In these cases, the clinician may opt to step away from the patient for some time to allow the drainage to continue and hopefully resolve on the same treatment visit.[111]

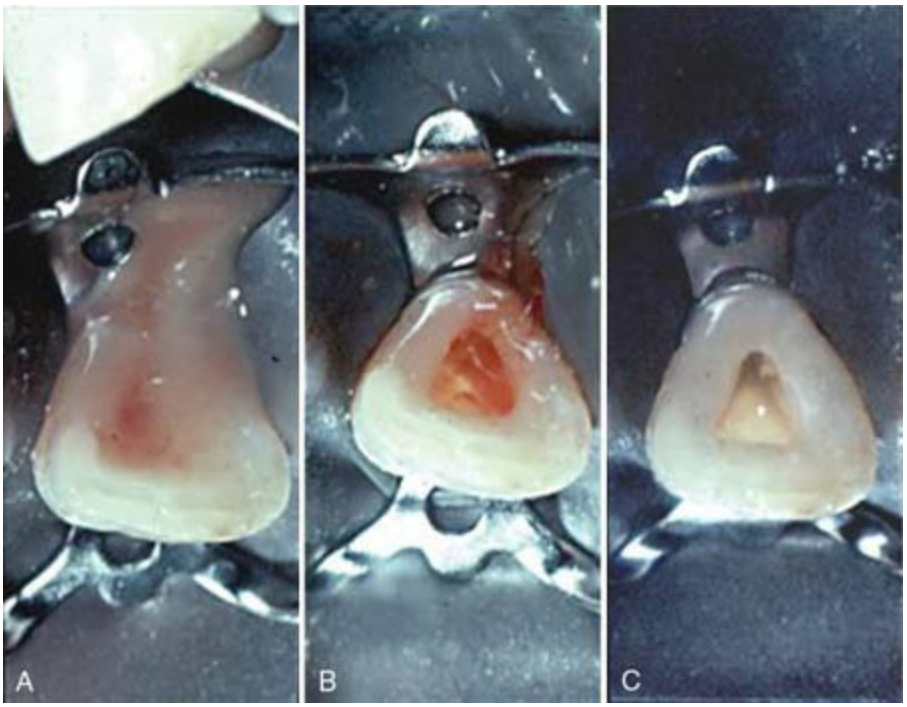

FIG. 19.8 Nonvital infected tooth with active drainage from the periapical area through the canal. **A,** Access opened and draining for 1 minute. **B,** Drainage after 2 minutes. **C,** Canal space dried after 3 minutes.

A) Tooth isolated by rubber dam clamp shows accumulated reddish fluid below the enamel.

B) Isolated tooth shows cavity at the center filled with yellowish red fluid.

C) Isolated tooth shows cavity at the center.

Historically, in the presence of acutely painful necrotic teeth with no swelling or diffuse swelling, 19.4% to 71.2% of surveyed endodontists would leave the tooth open between visits.[25,26] However, the more current literature makes it clear that this form of treatment would impair uneventful resolution and create a more complicated procedure.[6,8,120] For this reason, *leaving teeth open between appointments is not recommended*. Foreign objects have been found in teeth left open for drainage (Fig. 19.9). There has even been a documented case report of a foreign object being found to enter the periapical tissues through a tooth that had been left open for drainage.[103] In addition, leaving a tooth open provides an opportunity for oral microorganisms to invade and colonize the root canal system if the tooth is left open for an extended period.

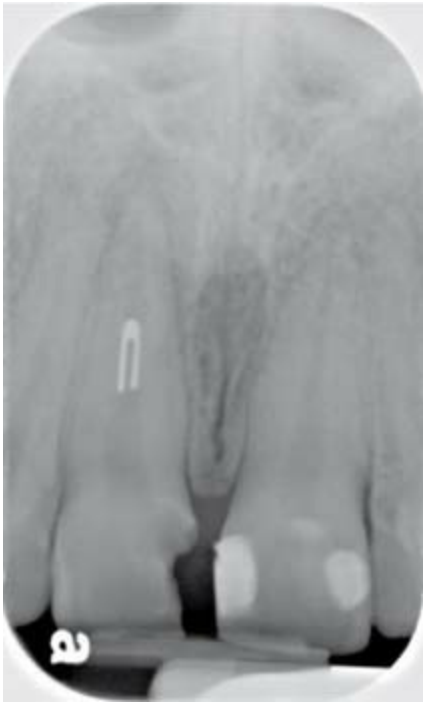

FIG. 19.9 Foreign object in tooth left open to drain. Patient used a sewing needle to clear out food particles that were blocking the canal

www.konkur.in

and broke the needle in the tooth.

Radiograph shows inverted U shaped radiopaque line in the root canal and split end above the neck region of tooth, marked a. The adjacent tooth shows radiopaque spots on the sides of crown.

Systemic antibiotics for endodontic infections

A hundred years ago, infectious diseases were the major recognized causes of death in the world. The advent of antibiotics resulted in a significant decline in the incidence of life-threatening infections and heralded a new era in the therapy of infectious diseases, but the enthusiasm generated turned out to be premature. Over the years, microbial evolutionary responses to the selective pressure exerted by antibiotics have resulted in microbial species resistant to virtually every known antibiotic agent.[47] The rapid emergence of resistant microbial strains comes as a consequence of the astonishing power of natural selection among microorganisms. If a given member of a microbial community possesses genes of resistance against a certain antibiotic and the community is persistently exposed to the drug, the resistant microorganism is selected to emerge and multiply to the detriment of the susceptible portion of the community. Passing on the genes responsible for resistance via plasmids and quorum sensing[47] has also been shown to encourage the survival of the microbial community. The emergence of multidrug-resistant strains of several bacterial species capable of causing life-threatening infections has been reported.[47,72,90,108,121] Antibiotic resistance among obligately anaerobic bacteria is increasing, with resistance to penicillins, clindamycin, and cephalosporins noted at community hospitals and major medical centers.[48,49]

Among oral bacteria, there have been reports on emerging resistance to commonly used antibiotics. Resistance has been found in *Fusobacterium nucleatum* strains for penicillin, amoxicillin, and metronidazole, in *Prevotella intermedia* for tetracycline and amoxicillin, and in *Aggregatibacter actinomycetemcomitans* for amoxicillin and azithromycin.[64,115] Macrolides (erythromycin and azithromycin) have presented decreased activity against *Fusobacterium* and nonpigmented *Prevotella* species.[50,64,65] Production of beta-lactamase by oral bacteria has also been reported, with the most

Telegram: @dental_k

www.konkur.in

prominent beta-lactamase-producing bacteria belonging to the anaerobic genus *Prevotella*.[10,13,30,39,115] Kuriyama and colleagues[64] revealed that beta-lactamase production was detected in 36% of the black-pigmented *Prevotella* and 32% of the nonpigmented *Prevotella* species isolated from pus samples of oral abscesses. Susceptibility of *Prevotella* strains to several cephalosporins, erythromycin, and azithromycin has been found to correlate with amoxicillin susceptibility; amoxicillin-resistant strains can be similarly resistant to these other antibiotics.[64] This finding suggests that there is little value in the use of oral cephalosporins and macrolides in managing endodontic abscesses, mainly when penicillin-resistant strains are evident. Other enzyme-producing oral anaerobic species include strains of *F. nucleatum, Propionibacterium acnes, Actinomyces* species, and *Peptostreptococcus* species.[13,30,39,115] Facultative bacteria such as *Capnocytophaga* and *Neisseria* species have also been detected among the beta-lactamase producers.[39] Bacteria that produce beta-lactamases protect not only themselves but also other penicillin-susceptible bacteria present in a mixed community by releasing free beta-lactamase into the environment.[13]

Overuse and misuse of antibiotics have been considered the primary cause for the emergence of multidrug-resistant strains. Improper use of antibiotics includes use in cases with no infection, wrong choice of the agent, dosage or duration of therapy, and excessive consumption in prophylaxis.[88,89] Antibiotics are used in clinical practice far more often than necessary. Antibiotic therapy is warranted in about 20% of the individuals who are seen for clinical infectious disease, but they are prescribed up to 80% of the time. To complicate matters further, in up to 50% of cases, recommended agents, doses, or duration of therapy are incorrect.[69]

The appalling rise in the frequency of multidrug resistance among leading pathogens should cause great concern and incite a commitment to act carefully and responsibly. A single erroneous use of antibiotics can be a significant contribution to the current scenario of increasing microbial resistance. Diseases that were effectively treated in the past with a given antibiotic may now require the use of another drug, usually more expensive and potentially more toxic, to achieve effective antimicrobial treatment. Unfortunately, even the new prescription may not be valid.

Antibiotics are defined as naturally occurring substances of microbial

Telegram: @dental_k

www.konkur.in

origin or similar synthetic (or semisynthetic) elements that have antimicrobial activity in low concentrations and inhibit the growth of or kill selective microorganisms. The purpose of antibiotic therapy is to aid the host defenses in controlling and eliminating microorganisms that temporarily have overwhelmed the host defense mechanisms.[88] Based on the earlier discussion, it becomes clear that the most critical decision in antibiotic therapy is not so much *which* antibiotic should be employed but *whether* antibiotics should be used at all.[87] One should bear in mind that antibiotics are beneficial drugs classically employed to treat or help treat infectious disease and provide prophylaxis in carefully selected cases.

The majority of infections of endodontic origin are treated without the need for antibiotics. As mentioned, the absence of blood circulation in a necrotic pulp prevents antibiotics from reaching and eliminating microorganisms present in the root canal system; therefore, the source of infection is often unaffected by systemic antibiotic therapy. Antibiotics can, however, help impede the spread of the disease and development of focal infections in medically compromised patients and provide a valuable adjunct for managing selected cases of endodontic infection. In addition to the indications for systemic antibiotics discussed earlier for acute abscesses and cellulitis, antibiotics are also prescribed for prophylaxis in medically compromised patients during routine endodontic therapy, in some cases of persistent exudation not resolved after revision of intracanal procedures, and after the replantation of avulsed teeth.

Selection of antibiotics in clinical practice is either empirical or based on the results of microbial sensitivity tests. For diseases with known microbial causes, empirical therapy may be used. This is especially applicable to infections of endodontic origin because culture-dependent antimicrobial analyses of anaerobic bacteria can take too long to provide results about their susceptibility to antibiotics (7 to 14 days). Therefore, it is preferable to opt for an antimicrobial agent whose spectrum of action includes the most commonly detected bacteria. Most of the bacterial species involved with endodontic infections, including abscesses, are susceptible to penicillins,[7,57,61,65] which make them first-line drugs of choice. Because the use of antibiotics is restricted to severe infections or prophylaxis, it seems prudent to use amoxicillin, a semisynthetic penicillin with a broad spectrum

Telegram: @dental_k

www.konkur.in

of antimicrobial activity and one that is well absorbed in the alimentary canal. In more severe cases, including life-threatening conditions, combining amoxicillin with clavulanic acid or metronidazole may be required to achieve optimum antimicrobial effects as a result of the extended spectrum of action to include penicillin-resistant strains.[65] In patients allergic to penicillins or cases refractory to amoxicillin therapy, clindamycin is indicated. Clindamycin has potent antimicrobial activity against oral anaerobes.[61,63,65,67]

The risk/benefit ratio should always be evaluated before prescribing antibiotics. Appropriately selected patients will benefit from systemically administered antibiotics. Restrictive and conservative use of antibiotics is highly recommended in endodontic practice. Indiscriminate use (including cases of reversible or irreversible pulpitis) is contrary to sound clinical practice, as it may cause a selective overgrowth of intrinsically resistant bacteria, predisposing patients to secondary and super-infections, rendering drugs ineffective against potentially fatal medical infectious diseases.

Analgesics

As a more thorough description of pain medications can be found in Chapter 6, the following information is merely a summary of pain control using analgesics. Because pulpal and periapical pain involve inflammatory processes, the first choice of painkillers is nonsteroidal antiinflammatory drugs (NSAIDs).[69] However, no pain medication can replace the efficacy of thoroughly cleaning the root canal system to rid the tooth of the source of infection.[40]

Aspirin has been used as an analgesic for more than 100 years. In some cases, it may be more effective than 60 mg of codeine[21]; its analgesic and antipyretic effects are equal to those of acetaminophen, and its antiinflammatory effect is more potent.[24] However, aspirin's side effects include gastric distress, nausea, and gastrointestinal ulceration. In addition, its analgesic effect is inferior to that of ibuprofen, 400 mg. When NSAIDs and aspirin are contraindicated, such as in patients for whom gastrointestinal problems are a concern, acetaminophen is the preferred nonprescription analgesic. A recommended maximum daily dose of 4 g of acetaminophen is

Telegram: @dental_k

www.konkur.in

currently in force, and a further reduction of this dosage has been proposed to reduce the chance of acetaminophen-related liver toxicity.[68,101]

For moderate to severe pain relief, ibuprofen, an NSAID, is superior to aspirin (650 mg) and acetaminophen (600 mg) with or without codeine (60 mg). Also, ibuprofen has fewer side effects than the combinations with an opioid.[21,58] The maximal dose of 3.2 g in 24 hours should not be exceeded. Patients who take daily doses of aspirin for its cardioprotective benefit can take occasional doses of ibuprofen; however, it would be prudent to advise such patients to avoid regular doses of ibuprofen.[1] These patients would gain more relief by taking a selective cyclooxygenase (COX)-2 inhibitor, such as diclofenac or celecoxib.

Because of their antiinflammatory effect, NSAIDs can suppress swelling to a certain degree after surgical procedures. The good analgesic effect combined with the additional antiinflammatory benefit make NSAIDs, especially ibuprofen, the drug of choice for acute dental pain in the absence of any contraindication to their use. Ibuprofen has been used for more than 30 years and has been thoroughly evaluated.[24] If the NSAID alone does not have a satisfactory effect in controlling pain, then the addition of an opioid may provide additional analgesia. However, in addition to other possible side effects, opioids may cause nausea, constipation, lethargy, dizziness, and disorientation.

Laboratory diagnostic adjuncts

Chapter 15 discusses culturing techniques and indications. Because the results of culturing for anaerobic bacteria usually require at least 1 to 2 weeks, it is not considered routine in the management of an acute endodontic emergency. Thus, in an endodontic emergency, antibiotic treatment, *when indicated* (see Chapter 19), should begin immediately, because oral infections can progress rapidly.

Flare-ups

An endodontic flare-up is defined as an acute exacerbation of a periradicular pathosis after the initiation or continuation of nonsurgical root canal

www.konkur.in

treatment.[3] The incidence may be from 2% to 20% of cases.[56,78,84,117] A meta-analysis of the literature, using strict criteria, showed the flare-up frequency to be about 8.4%.[113] Endodontic flare-ups are more prevalent among females under the age of 20 years and may occur more in maxillary lateral incisors; in mandibular first molars, when there are large periapical lesions; and in the retreatment of previous root canals.[109] The presence of pretreatment pain may also be a predictor of potential posttreatment flare-ups.[56,110,117] Fortunately, there is no decrease in the endodontic success for cases that had a treatment flare-up.[60]

Endodontic flare-ups may occur for a variety of reasons, including preparation beyond the apical terminus, over-instrumentation, pushing dentinal and pulpal debris into the periapical area,[41] incomplete removal of pulp tissue, overextension of root canal filling material, chemical irritants (such as irrigants, intracanal medicaments, and sealers), hyper occlusion, root fractures, and microbiologic factors.[102] Although many of these cases can be pharmacologically managed (see Chapter 19), refractory cases may require periapical surgery, reentry into the tooth, the establishment of drainage either through the tooth or via trephination, or, at a minimum, adjustment of the occlusion.[21,97,102] The prophylactic use of antibiotics to decrease the incidence of flare-ups has been met with some controversy. Whereas earlier investigators[79] found that antibiotic administration before treatment of necrotic teeth reduced the incidence of flare-ups, more recent studies found antibiotic use either less effective than analgesics or not to affect in reducing interappointment emergencies or posttreatment symptoms.[94,110,117]

Cracked and fractured teeth

Described in detail in Chapters 1 and 22, cracks and incomplete fractures can be challenging to locate and diagnose, but their detection can be an essential component in the management of an acute dental emergency. In the early stages, cracks are small and difficult to discern. Removal of filling materials, applications of dye solutions, selective loading of cusps, transillumination, and magnification are helpful in their detection (Fig. 19.10). As the crack or fracture becomes more extensive, it can become easier to visualize. Because cracks are difficult to find and their symptoms can be so variable, the name

Telegram: @dental_k

www.konkur.in

cracked tooth syndrome has been suggested,[16] even though it is not indeed a syndrome. Cracks in vital teeth often exhibit a sudden and sharp pain, especially during mastication. Cracks in nonvital or obturated teeth tend to have more of a “dull ache” but can still be sensitive to mastication.

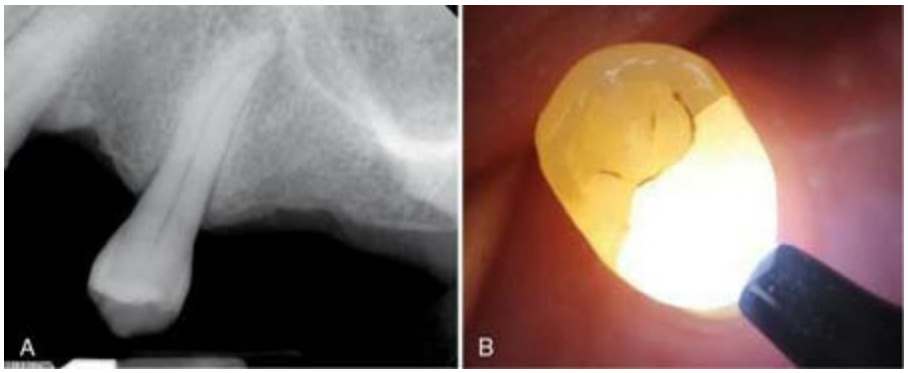

FIG. 19.10 **A,** Preoperative radiograph. **B,** Transillumination.

A) Radiograph shows posterior view of tooth with radiolucent root canal and tip.

B) Close-up view shows illuminated occlusion view of tooth.

The determination of the presence of a crack or fracture is paramount because the prognosis for the tooth may be directly dependent on the extent of the crack or the longitudinal fracture. Management of cracks in vital teeth may be as simple as a bonded restoration or a full coverage crown. However, even the best efforts to manage a crack may be unsuccessful, often requiring endodontic treatment or extraction. Fractures in nonvital or obturated teeth may be more challenging. In addition, it must be determined whether the crack or fracture was the cause of pulpal necrosis and whether there has been an extensive periodontal breakdown. If so, the prognosis for the tooth is generally poor; thus, extraction is recommended (Fig. 19.11).

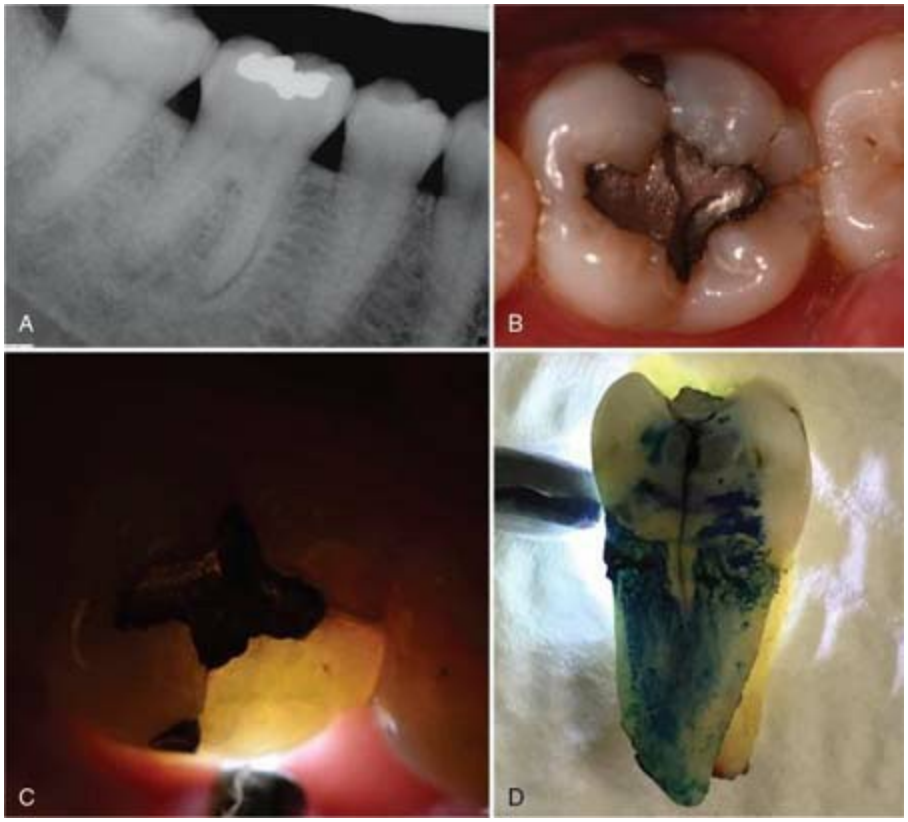

FIG. 19.11 **A,** Preoperative radiograph. **B,** Clinical view. **C,** Transillumination. **D,** Extracted tooth showing the extension of the stained longitudinal fracture.

A) Radiograph shows four teeth with less-density tissue on gum line. The first molar has white patch on the crown and the pulp is partially radiolucent.

B) Close-up view shows filled cavity of tooth that has cracks inside.

C) The cavity of tooth being examined under light shows soft tissue.

D) Extracted tooth stained in blue has fracture extending from the crown below the neck region.

Summary

The management of endodontic emergencies is an essential part of dental practice. It can often be a disruptive part of the day for the clinician and staff, but it is an invaluable solution for the distressed patient. Methodical diagnosis and prognostic assessment are imperative, with the patient being informed of the various treatment alternatives.

20: Managing iatrogenic events

Yoshitsugu Terauchi, Tara F. Renton

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

An iatrogenic event is defined as a procedure “induced inadvertently by a

Telegram: @dental_k

www.konkur.in

physician or surgeon" (Merriam-Webster dictionary). This is true for dentistry as well, with cases of endodontic malpractice being among the most prevalent in dentistry.[70,132,293] These occurrences are not limited to the United States, with other countries reporting similar percentages of endodontic malpractice claims.[257]

Although iatrogenic accidents cannot be prevented with absolute certainty, their occurrences can be greatly reduced with the aid of the "Three Ts": training, technique, and technology. Incumbent with the first (training) is expertise with the other two factors, especially regarding technology and, more specifically, the dental operating microscope (DOM) together with cone-beam computed tomography (CBCT).[12,182,272] They have proven themselves indispensable in treatment planning based on the diagnosis,[272] locating canals including complex anatomical spaces and periapical pathosis,[12,160,180,183,197,291,322,347] removing separated instruments,[324,346] repairing perforations,[268] preventing iatrogenic accidents,[182,364] and enhancing the delivery of quality care.[174] The superior visualization with the aid of CBCT imaging permits more accurate clinical evaluations including the identification of the canal root morphology that cannot be visualized with the DOM,[48] and allowing for a precise assessment of the challenge and the appropriate treatment plan for its resolution. Illumination and magnification along with the 3D imaging are indispensable for all of the treatment scenarios that follow, which are therefore assumed to be performed with the DOM and CBCT imaging, which has proven as accurate as direct visualization.[13]

Sodium hypochlorite

Often happening without warning, the progression of events following sodium hypochlorite (NaOCl) extrusion into periradicular tissues is both rapid and startling to witness. In addition to the physical outcomes, the experience is likely to leave the patient wary of both the procedure and practitioner.

Although the properties and methods of delivering NaOCl are covered in Chapter 8, the gravity of the consequences of its misuse merits a brief highlight. NaOCl is an effective irrigating solution in concentrations ranging from 0.5% to 6%[149,373] and is able to disrupt the biofilm,[58] dissolve necrotic

tissues,[211] and remove organic components of the smear layer.[20] However, it is extremely cytotoxic, irrespective of the tissue it contacts,[231] with concentrations as low as 0.01% lethal to fibroblasts in vitro.[138] NaOCl injection into vital tissue initiates hemolysis and ulceration, damages endothelial and fibroblast cells, and inhibits neutrophil migration.[107,109] A study investigating the physical effects of NaOCl on bone ex vivo found degradation of the organic matrix collagen and no sign of living cellular contents (Fig. 20.1).[163]

FIG. 20.1 Femur shaft cross sections (**A**) untreated bone section; (**B**) saline-treated bone; (**C**) sodium hypochlorite (NaOCl)-treated bone section. Grossly, NaOCl caused significant changes in cancellous structure, leaving large structural craters of apparent demineralization.

Three cross-sections of femur shaft are marked A through C.

A) It has wet cavity with few holes and stretched connective tissue along the periphery.

B) The cavity has dried perforated layer.

C) The cavity shows the complete degradation of collagen cells with large number of irregular chambers.

Source: (From Kerbl FM, DeVilliers P, Litaker M, Eleazer PD: Physical effects of NaOCl on bone: an ex vivo study. *J Endod* 38:357, 2012.)

The majority of reported NaOCl complications appear to be due to an inaccurate working length, iatrogenic widening of the radicular foramen, lateral perforation of the root, or wedging of the irrigation needle.[171,316] The pattern of facial distention is comparable to that encountered with a cervicofacial emphysema (discussed later), dissecting fascial spaces in a similar fashion, with the concomitant tissue destruction magnifying the effect and impeding recovery. This swelling is further exacerbated by the presence

Telegram: @dental_k

www.konkur.in

of effervescing agents such as hydrogen peroxide, potentiating the effect of the hypochlorite and amplifying soft-tissue involvement.[23,186] The initial patient reaction to the fluid insult is severe and immediate pain, with marked edema or bruising that may continue to extend over the injured side of the face, cheek, or lips (Fig. 20.2). There may be spontaneous and profuse hemorrhaging from the canal space, and, in the case of maxillary posterior teeth, the patient may report periorbital pain,[24,107] chlorine taste, or irritation of the throat.[80] The amount that has been expressed into the periradicular area, the spatial location of the fluid introduction, and the proximity to sensitive anatomic structures will dictate the severity and duration of the reaction. Paresthesia, either transient[24] or permanent,[255] can occur, especially if interventional treatment is not rendered immediately. In addition to sensory deprivation, motor nerve dysfunction secondary to irreversible chemical damage has been reported (Fig. 20.3).[236] In this case, there was distinct loss of upper lip and cheek function, with problems in the musculature. In mandibular teeth, extension into the submandibular, submental, or sublingual regions can compromise the airway, compelling immediate hospitalization and surgical intervention to avert a life-threatening episode.[35]

FIG. 20.2 **A,** Clinical presentation 3 days following the extrusion of sodium hypochlorite (NaOCl) during treatment of the maxillary right canine. The patient had difficulty opening her right eye, and the swelling had extended to the submandibular/sublingual regions on the

Upon realizing that an extrusion event has occurred, it is imperative that the clinician cease further treatment and immediately engage in measures targeted at diminishing the effect of the chemical; ignoring the event reduces outcomes.[187,255] Treatment protocols are empirical and are predicated on cause and severity. With the emphasis on pain control, local anesthetics and analgesics can be administered, along with cold compresses, in an effort to moderate swelling and edema. Directed at diluting the effect of the extrusion, it has been suggested that the clinician immediately irrigate the canal with normal saline to encourage bleeding, both diluting the irritant and removing it from the site of the injury.[80,206] In addition, clinicians may immediately irrigate the canal and periradicular areas of the extrusion with saline, using a negative pressure irrigation device with the cannula placed at the radicular foramen. In one report, the subsequent reaction was short lived with this approach.[267]

After one day, warm compresses are substituted for the cold, and warm oral rinses are prescribed to stimulate the local microcirculation. Antibiotics are usually prescribed, and their administration commensurate with the severity of hard- and soft-tissue destruction and necrosis; milder cases can be treated with oral medications, whereas severe presentations are better controlled and modulated in a hospital setting with intravenous routes of delivery. The use of corticosteroids is equivocal; the control of the spreading edema must be balanced with the increased risk of infection. The patient should be monitored closely; a marked increase in the size or extent of the swelling or signs of impending airway obstruction mandate immediate referral to the hospital or a maxillofacial surgeon for more aggressive treatment and management. Lastly, reassuring patients that recovery, despite

Telegram: @dental_k

www.konkur.in

their current appearance, is usually complete and uneventful, will ease their anxiety. They should be informed as to why it occurred and what to expect during their recovery. Recovery should be monitored and documented daily until the resolution is imminent.

Prevention involves attention to detail and an appreciation for fluid dynamics. In summary, the clinician should do the following:

- Establish an accurate working length and avoid over-instrumentation/enlargement of the radicular foramen.
- If irrigating using positive pressure, employ a small side-vented needle placed no closer than 2 mm from the working length. Express the fluid slowly and observe that it is venting through the access cavity.[34]
- Carefully assess the canal integrity for signs of perforation or other large portals of fluid egress.
- Avoid wedging the needle tip in the canal space or inserting it beyond the working length.
- Confirm the identity of the solution prior to injection or irrigation.[124]

Instrument separation

The introduction of nickel titanium (NiTi) rotary instruments into endodontics revolutionized the way the root canal system is instrumented. However, with the advent of rotary NiTi files, there has also been a perceived increase in the occurrence of separated instruments,[101,281] with some reports indicating that separation of NiTi rotary instruments occurs more frequently than hand instruments.[343] On radiographic examination, separated instruments can usually be discerned by the distinct radiopacity within the canal. However, if the canal with a separated instrument is subsequently obturated with radiopaque materials, it may not be visualized on the radiograph. Upon removal of filling materials from the canal, a separated instrument may be visualized under the DOM or become apparent on radiographs for the first time (Fig. 20.4).

Set of photographs and radiographs marked G through K shows the healing of cavity along one side of the root canal near bifurcation in tooth.

Causes of instrument separation

A common cause of instrument separation is improper use.[101,285] Typical examples of improper use include inadequate access, overuse of the instrument, too much radicular pressure during instrumentation,[287,339] and the continuous use of a large instrument in a curved canal.[127,251] Additional contributing factors are operator experience,[229,331] rotational speed,[66,194] canal curvature (radius),[195,251] instrument design and technique,[39,177] torque setting,[102] manufacturing process,[4] the type of NiTi alloys used,[106] the type of rotational motion (continuous rotations vs. reciprocating motions),[235] the type of tooth,[64,218,299] and absence of a glide path.[233] Based on these factors, it is not surprising that the reported incidence of separated NiTi files ranges from 0.4% to 23%.[4,6,240,253,288,317]

Separated instruments seem to occur more frequently in molars than in anterior teeth, especially in mandibular molars. This high incidence of instrument fracture in molars may be related to accessibility to the canal, diameter of the root canal, and root canal curvature.[64,218,299] Endodontists have reported the incidence of instrument separation to be about 5%.[4,229] The clinician must inform the patient of the instrument separation and treatment options as well as potential complications of both the separated instrument retention and its attempted removal.

Endodontic instruments fracture as a result of cyclic fatigue or torsional fatigue[60] or a combination of both types of fatigue.[285,297,345] Cyclic fatigue is

Telegram: @dental_k

www.konkur.in

caused by repetitive compressive and tensile stresses acting on the outer portion of a file rotating in a curved canal, leading to cyclic failure without previous signs of plastic deformation.[229] Torsional failure occurs when the tip of the instrument binds but the shank of the file (driven by the handpiece) continues to rotate.[285] Shear fracture of the material then occurs when the maximum strength of the material is exceeded.[179] Clinically, cyclic fatigue seems to be more prevalent in curved root canals, whereas torsional failure might happen even in a straight canal.[55,372] Cyclic-fatigued instruments are reported to become less resistant to torsional fatigue failure,[168] whereas the use of rotary instruments at a high torque setting is reported to increase the risk of cyclic fatigue failure.[101] In general, smaller sized instruments with smaller tapers are more resistant to cyclic fatigue and more susceptible to torsional fatigue, while larger sized instruments with greater tapers tend to be opposite to those types of fatigue. Therefore smaller instruments should be used to shape the canal where cyclic fatigue is expected to occur. Interestingly, the use of reciprocal motions (as opposed to rotational motions) is reported to extend the life span of an instrument[69,371] and increase cyclic fatigue resistance.[235] It is recommended that instruments be used in a reciprocating motion when either torsional or cyclic fatigue is expected to occur while shaping a severely curved canal and that the instruments used to prepare such curved root canals be discarded after use to prevent instrument fracture.

Management of separated instruments

The management of separated instruments includes nonsurgical orthograde (mechanical or chemical) or surgical approaches. The mechanical removal involves the use of tools dedicated to separated instrument removal such as extractors, wire loops, post removal systems, ultrasonics, and laser irradiation (see also Chapter 10). The chemical removal involves the use of chemical solvents for instrument corrosion and electrochemical process for instrument dissolution. Surgical approaches include radicular surgery, intentional replantation, root amputation, or hemisection, which are in general considered relatively invasive due to the amount of dentin loss.

For a nonsurgical approach in removing a separated file, various methods and devices have been developed (see also Chapter 10). When a separated

Telegram: @dental_k

www.konkur.in

instrument extends above the root canal orifice, it can often be easily removed with a hemostat, Steiglitz forceps, a modified Castroviejo needle holder,[96] or a Perry plier.[357] A spoon excavator or a Caulfield retriever, or EndoCowboy (Koehrer Medical Engineering, Neuss, Germany) can also be used to engage and remove the separated instrument with coronally directed pressure. In the event that a hand file can bypass the separated instrument, a "braiding technique" can be used whereby several Hedström files are inserted along the bypassed instrument, the files are twisted to grasp the separated instrument, and it is then extracted as one unit. When a fractured instrument is below the canal orifice and cannot be bypassed, one basic method for removing the separated instrument requires the exposure of approximately 2 mm of the coronal portion of the separated file. This allows the use of an extracting device for engaging the file, securing it, and removing it. The Masserann kit (Micro-Mega, Besancon, France) is a popular system for the removal of separated instruments located within the straight part of the canal. This kit involves the use of trephine burs to expose the coronal portion of the separated instrument and for creating a space for an extractor. An extractor is then used to grasp and remove the separated instrument. The limitation of this system is that it cannot be used for cases involving separated instruments located beyond the midroot or in a curved canal, as this technique involves a considerable amount of dentin sacrifice that can weaken the root structure and increase the risk of perforation.[369] An alternative to the Masserann kit is the Endo Safety System.[359] This system differs from the Masserann kit in that it uses smaller diameter trephine burs and the extractor has its own unique mechanism for grasping instruments. The Endo Extractor (Brasseler Inc., Savannah, GA) can also be used in these types of cases. This system consists of a trephine bur to expose the coronal portion of the separated instrument and a hollow tube extractor that is threaded over the exposed portion of the separated instrument and bonded to it with cyanoacrylate adhesive.[110] The Canal Finder System (FaSociété Endo Technique, Marseilles, France) or the EndoPuls System (EndoTechnic, San Diego, CA) provides a different approach to a separated instrument. The system is composed of a handpiece and files that are designed exclusively for the system.[189] The system produces a vertical movement with a maximum amplitude of 1 to 2 mm, which decreases when the speed increases.[147] This vertical movement of the

Telegram: @dental_k

www.konkur.in

file will also help bypass an instrument fragment. The flutes of the file can mechanically engage with the separated instrument, and with the vertical vibration, the instrument fragment can be loosened or even retrieved.[148] The mechanical movement of the file can get aggressive, so the clinician must use caution to avoid root perforation, especially in a curved canal. These systems are technique sensitive and therefore results can vary between cases.

Ultrasonic instruments are very effective for the removal of separated instruments.[54,212,280] However, it is important to realize that separated NiTi files tend to fracture repeatedly when ultrasonics ia continuously applied to them, whereas stainless steel instruments are more resistant and are more easily removed with ultrasonics than NiTi instruments.[280,324,354] Small ultrasonic instruments allow continuous and improved vision of the field of operation. The use of ultrasonics, especially when performed under the DOM, enhances both preparation and removal procedures and can provide safety and accuracy in the process.[218,324,353] The ultrasonic tip is placed on the staging platform between the exposed portion of the separated file and the canal wall, and it is vibrated around it in a counterclockwise direction, applying an unscrewing force to the separated file. This technique will help with removing most rotary separated instruments that have a clockwise cutting action. If it is known that the separated file has a counterclockwise cutting action, then a clockwise rotation will be necessary. The energy applied will aid in loosening the file, and occasionally the file will suddenly exit out of the canal.

However, the use of ultrasonics does have some drawbacks. Upon ultrasonic activation, a separated file can be accidentally extruded into the bone, either radicularly or through a perforation when ultrasonics i applied to the top of the separated file or from the outer wall to the side of it. In addition, the ultrasonic activation of a separated instrument has been reported to separate into small fragments from the original fragment while troughing around it.[53] Smaller file fragments can easily get pushed into a more radicular level if they are pushed on the top by ultrasonics, making it more difficult to remove them due to the additional procedure, which would eventually increase the risk of perforation and extra dentin sacrifice, especially in the apical third or beyond the curve. At the same time, smaller file fragments can be considered easier and faster to remove than longer file fragments if they

Telegram: @dental_k

www.konkur.in

are visible simply because shorter file fragments requires less dentin sacrifice to loosen it than longer ones. On the other hand, such long instruments as separated at the shaft can also be easily removed as they can simply be grasped with a plier or forceps around the orifice and pulled out.[254] If the coronal end of the long file fragment is out of reach of the plier or the forceps, it will not be as easy. It all depends on how the separated instruments are managed to be successful in removing them as there are many variables involved in the procedures that affect the success in instrument retrieval.

The success rate for removing separated files varies from 33% to 95%[6,64,253,279,354] with the time required for using ultrasonic techniques varying between 3 and over 60 minutes.[8,212,331] The variations in success rates are due to the location of fractured instruments, the diameter of the root canal,[299] the degree of canal curvature,[8,252,313] the radius of curvature,[8,251] operator experience,[8,331] operator fatigue, and the length of the separated instrument.[330] Visualization and accessibility to the separated instrument play a major role in file retrieval.[64] In general, the success rate for removal is high for separated files located before the canal curvature, moderate for those located at the curvature, and low for those located beyond the curvature.[195,358] The success rate is also more favorable when the canal curvature is less and the radius of curvature is longer.[8] The combination of ultrasonic techniques and microscopes typically improves success rates in file removal.[64,100,218,354]

It has been recommended that removal attempts of separated instruments from root canals should not exceed 45 to 60 minutes because the success rates may drop with increased treatment time.[324] The reduced success rate could be related to operator fatigue or overenlargement of the canal, which compromises the integrity of the tooth and increases the risk of perforation. Any case where the separated instrument can be visualized under the DOM may be considered less challenging to manage.

It would be the worst-case scenario if the separated file was decided to be retained only after a lot of dentin was sacrificed and the canal perforation occurred during the instrument retrieval attempts. Hence it is in the best interests of both the patient and the clinician to make an accurate diagnosis and a predictable treatment plan using CBCT to prevent any procedural mishaps. In other words, separated instrument removal attempts should be

Telegram: @dental_k

www.konkur.in

made only after the preparation is completed based on the treatment plan that always includes surgical interventions and the retention of the separated instrument, as the separated file can be incorporated as part of the obturation and kept under observation.[92,97,253,314]

Conditions for separated instrument removal attempts

Root canal preparations for separated instrument removal followed by removal attempts can be made in either a dry or a wet environment. Dry conditions provide better visibility when using the DOM, preventing fewer additional procedural accidents.[281,313,324,353] For this reason, the root canal preparations for instrument removal should be conducted in a dry condition. However, heat generation by ultrasonics is inevitable,[115,134,181,199,299,313,324,353] and a temperature rise above 10°C on the external root surface can damage the periodontal tissues.[85,325] In addition, the separated instrument will be susceptible to secondary fracture when ultrasonic tips are in contact with the file.[332,353] Therefore it is recommended that pulsing and in/out motions be used to prevent the secondary fracture as well as the temperature rise during ultrasonic activation in preparation. At the same time, the ultrasonic tip should be activated at the lowest possible power setting.[42,88,200,353] Only after the loosening of the separated instrument is confirmed in preparation, the removal attempts can be made in a wet condition with a fluid to take advantage of cavitation and acoustic stream, which facilitates instrument removal. Ethylenediaminetetraacetic acid (EDTA) solution or oil with the lowest surface tension is recommended as the fluid for this purpose as EDTA solution removes hard-tissue debris produced during ultrasonic removal attempts and the oil enhances lubrication together with both cavitation and acoustic stream to remove the separated instrument.

Root canal preparation techniques

Root canal preparation for visible instrument retrieval

In the root canal preparation stage for instrument retrieval, the goal is to make the separated instrument “dance” by enlarging the canal and loosening it with ultrasonics based on the diagnosis and the treatment plan whether ultrasonic

Telegram: @dental_k

www.konkur.in

oscillation or the loop is used to get the separated instrument out in the instrument retrieval stage. The majority of separated instruments are NiTi,[317] with the mean length of separated instruments being 2.5 to 3.5 mm.[157] Many NiTi rotary instruments used have a.04 to.08 taper range with a tip size of #20 to #30, resulting in a coronal diameter of about 0.30 to 0.58 mm. If the coronal diameter of the separated instrument is smaller than 0.45 mm, then a #3 modified Gates Gliden bur (#3 MGG bur from the Terauchi File Retrieval Kit [TFRK] [DELabs Santa Barbara, CA]) should be used to enlarge the canal to the separated instrument, followed by the micro-trephine bur (MT bur) (DELabs for exposing the coronal portion of the separated instrument, with less risk than ultrasonics for secondary fracture of the separated instrument (see Fig. 20.20, *A* and *D*).[331,332] The inner diameter of the micro-trephine bur is 0.45 mm and it is then used, in a counter clockwise rotation, with the intent of unscrewing the separated instrument. This bur should be used at 600 rpm in wet conditions; if the rotational speed exceeds 600 rpm, unintentional ledge formation may occur, especially in a curved canal greater than 15 degrees.

If the coronal diameter of the separated instrument is larger than 0.45 mm or the canal curvature is greater than 15 degrees, then a larger NiTi rotary instrument, with tip size 0.15 mm (three sizes) larger than the coronal diameter of the separated instrument, should be used to enlarge the canal coronal to the separated instrument, followed by ultrasonic instruments to expose the coronal semicircular portion.

First, a few drops of mineral based oil with lubricant additives is placed into the canal on the separated file to facilitate the separation of it from the canal wall, and then excess oil is removed with paper points or mild airblows for the visible root canal preparation with ultrasonic tips. The mineral oil almost instantly permeates the spaces between the canal walls and the tightly wedged file fragment and separates them just like loosening a rusty tightened screw from the metal plate (Fig. 20.5). Then the spoon tip with the concave portion facing the separated file (TFRK-6/12, DELabs) (see Fig. 20.20, *B1*, *C2*, and *D*) will be introduced into the thin gap between the separated file and the inside curve of the canal to create one quarter space of the circle (90-degree semicircular space) that is approximately one third of the separated file length. Second, the straight tip (TFRK-S, DELabs) (see Fig. 20.20, *B2*,

Telegram: @dental_k

www.konkur.in

C2, and *D*) is introduced to expand the space to complete the 180-degree semicircular space on the inside curve until the separated file gets loosened. When the depth of the space created is longer than one third of the file length and the semicircular space is greater than 180 degrees, the separated file will most likely get loosened (Fig. 20.6). The ultrasonic tip used for this purpose should be as thin as possible, allowing the clinician to both visualize the operative field and prevent both overenlargement of the canal wall and pushing the separated instrument radicularly (Fig. 20.7). In addition, the ultrasonic tip should always be applied to the area on the inner canal curve being extended in the radicular direction (Fig. 20.8) where the outer canal wall is in contact with the separated instrument to prevent secondary fracture, not where the outer canal wall is not in contact with the separated file (see Fig. 20.8, *H*).[332] If the ultrasonic tip is placed in the space outside the curve and ultrasonic energy is given to the separated instrument from the outer curve, the force applied will redirect the separated instrument in an apical direction (see Fig. 20.8, *D* and *E*), eventually pushing it more apically and making the instrument retrieval more difficult, whereas the force applied from the inner curve to the separated instrument will consequently reorient the separated instrument in a coronal direction (see Fig. 20.8, *F* and *G*). In most cases, the coronal one third of the separated file is the main portion engaged in the canal wall with more stress leaning toward the outer wall. This portion can get less resistant to mechanical force for disengagement when the mineral based oil injected permeates the tiny interfacial space between them to loosen the separated file. Therefore cutting the inner dentin wall contacting the coronal third of the separated file should typically be enough to disengage it (Fig. 20.9). For example, if the separated file fragment is 3 mm long, the 180-degree semicircular space needs to be extended radicularly about 1 mm on the inside curve to help the ultrasonic tip loosen it. Due to the force directed from the inner wall to the fragment during this ultrasonic preparation phase, the separated file may come out accidentally by ultrasonic activation at any moment (Fig. 20.10, *A*). However, a fatigued separated instrument is already extremely susceptible to secondary fracture by ultrasonic activation.[332,353] For this reason it is safer to create a semicircular space on the inner wall instead of troughing around it, and both pulsing and pecking motions should be applied to it while ultrasonics is activated to prevent

Telegram: @dental_k

www.konkur.in

instrument fracture and temperature rise, especially in dry conditions.[85,325,332,353] The depth of the semicircular space created on the inner curve must be not only longer than one third of the fragment length but also evenly the same length along the canal walls to allow the disengagement of the separated instrument. If the separated instrument is not loosened after the space creation, the depth of this space should be extended in a radicular direction until it is loosened. In general the longer the file fragment is, the more preparation time is needed to loosen it. The separated instrument must be seen "dancing," "not flexing," before making instrument retrieval attempts. The difference between the separated instrument dancing and flexing is that the separated instrument is considered dancing when it is seen moving from one place to another place, whereas it is still considered flexing when seen moving from one place to another and getting back to the original place (Fig. 20.11).

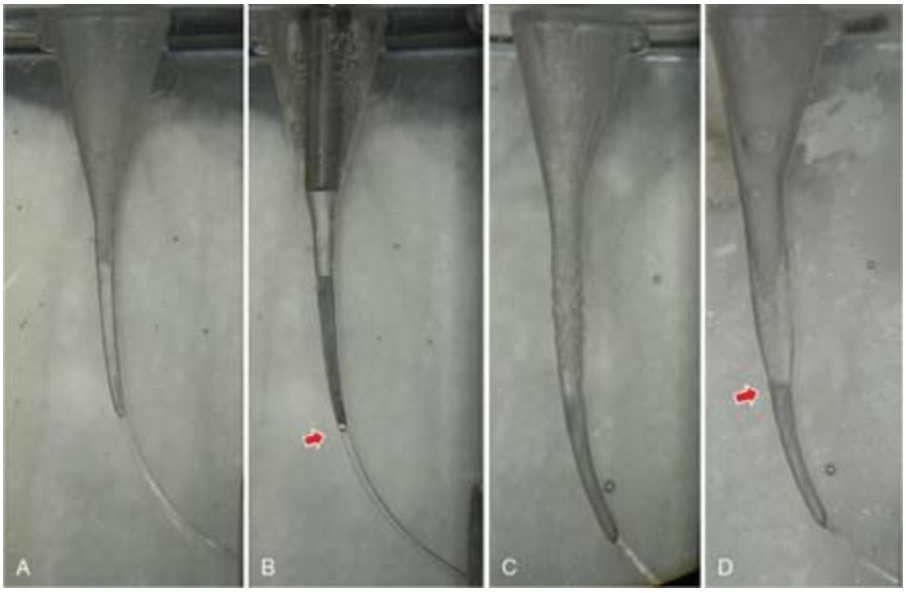

FIG. 20.5 **A,** Separated file covered with debris. **B,** Mineral oil immediately permeated the spaces between the canal walls and the separated file revealing the surface of the file and broke through the entire file. **C,** Separated file covered with debris. **D,** Water did not permeate those spaces at all.

activation during a preparation phase. **B,** EDTA solution is put into the canal to take advantage of cavitation and acoustic streaming effects for instrument retrieval. **C,** Ultrasonics must be activated within the space created. **D,** Separated file is removed from the canal with ultrasonics in the presence of EDTA solution or oil.

Set of figures marked A through D shows the steps involved in removing the conical spiral piece from the root canal by using endosonic file and blue-colored EDTA solution.

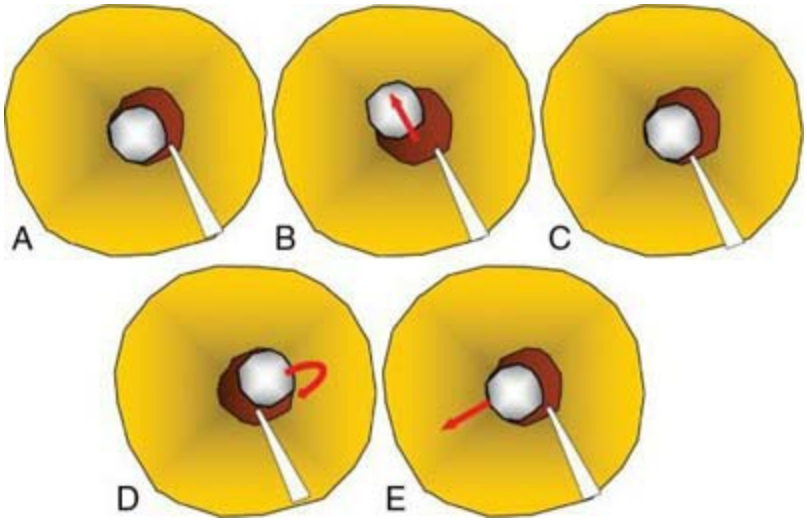

FIG. 20.11 **A**, Separated file in the canal with the space created on the inner wall *(right side)*. **B**, Separated file shifted to a different place in the space created *(red arrow)*. This movement shows the separated file is "dancing." **C**, Separated file in the canal with the space created on the inner wall *(right side)*. **D**, Separated file flexing to a different place *(red arrow)*. **E**. Separated file returning to the original place *(red arrow)*. This movement shows the separated file is "flexing."

Set of five figures marked A through E shows a circular separated file in the canal located at lower left, upper left, lower left, central right, and its original position, respectively.

Root canal preparation for nonvisible instrument retrieval

When the separated file is not visible beyond the curve, the mineral oil should be present all the time during the procedure to help it loosen the file fragment while preparing the root canal for instrument retrieval with ultrasonics. The key to success in loosening the separated file in non-visible

Telegram: @dental_k

www.konkur.in

status is to get a sticky feeling with ultrasonic tips in the space on the inner canal wall. The ultrasonic tip used in this situation should be thin and sharp enough to feel the tiny gap between the inner canal wall and the separated instrument. First, a thin spoon-shaped tip (TFRK-6/12, DELabs) or a customized sword-shaped tip (any ultrasonic tip converted into a sword-shaped tip or a “Katana” tip) is precurved and placed in the space to grope for a sticky feeling while obtaining a tactile sensation on the fingers holding the handpiece (Fig. 20.12). If a larger sized tip is used, the tip will most likely hit on the top of the separated instrument before being placed into the gap between the fragment and the inner wall. It is also very typical to hear a clicking sound and get a sticky feeling when a sharp ultrasonic tip shifts from the separated file to the canal wall into the gap. When it is placed in the gap with a sticky feeling, a radiograph should be taken with the ultrasonic tip in it to confirm its position. Then the tip is activated in it to create a 90-degree semicircular space. The ultrasonic tip is simply activated directly on the file fragment from the inner curve in both pecking and pulsing motions to prevent secondary fracture and breakage of the tip without creating a 180-degree semicircular space or expanding the space laterally as it is impossible to do so in nonvisible status. The intensity of ultrasonic activation should be as low as practical for the same reasons. As this conservative root canal preparation continues with ultrasonic oscillation directed to the separated instrument from the inner wall, any dentin walls contacting the separated file will be eliminated by indirect ultrasonic oscillation transferred to it from the vibrating tip, which will eventually result in loosening it (Fig. 20.13). When the sticky feeling is lost from the ultrasonic tip or the separated file emerges from the nonvisible curve with ultrasonics, the root canal preparation for instrument retrieval can be considered complete, and then the instrument retrieval attempts should be made from this point (Fig. 20.14). The advantage of this conservative preparation technique is the clinician can be minimally invasive in preparation, while the disadvantage of this technique is that it is unpredictable when to make the separated instrument dance and the secondary fracture or breakage can occur if it is performed aggressively. It also requires the patience to be successful in loosening the fragment in this technique as it is not predictable.

FIG. 20.14 **A,** Separated file beyond the severe curve in relation to the file placed in the mesiobuccal (MB) canal. **B,** Thin ultrasonic tip placed in the gap between the inner wall and the separated file. **C,** Separated file is not visible in the MB. **D,** Separated file coming out of the canal. **E,** Removal of the separated file confirmed on a radiograph. **F,** Retrieved separated file along with the original file

Set of radiographs and photographs marked A through F shows the removal of a piece of the separated file left out in the canal in the mid root of tooth and the piece further placed close to original file.

When the separated file is found to be loose beyond the radicular foramen, it is not necessary to prepare the canal for its retrieval because it is not engaged in the canal wall, but it just lies in the radicular extent of the canal space (Fig. 20.15). The separated file in this status can be simply irrigated out of the canal using saline with ultrasonic irrigation devices such as ProUltra PiezoFlow (Dentsply, Tulsa, OK) and GentleWave (Sonendo, Inc, Laguna Hills, CA) (Fig. 20.16).

Instrument retrieval techniques

Use of ultrasonic oscillation

Once the root canal preparation for instrument retrieval is completed, it is

Telegram: @dental_k

www.konkur.in

important to confirm that the canal wall is smooth from the separated file to the coronal extent, with no overhangs on the outside canal wall. A retrospective study and the author's empirical findings show that when the separated instrument is shorter than 3 mm or between 3.1 and 4.4 mm with the curvature smaller than 30 degrees, the clinician will most likely be able to retrieve it with ultrasonics alone.[330] Then the canal is rinsed with the silicone based oil or EDTA solution and is filled with it up to the cavosurface, "not just in the root canal alone," in order to take advantage of cavitation and acoustic streaming for instrument retrieval in wet conditions (see Fig. 20.10, *B*). The ultrasonic tip placed is continuously activated at a power setting that is about 5% higher than it was in the preparation stage with short up-and-down strokes within the space created on the inner curve until the separated instrument is removed, which is typically completed in 10 seconds (see Fig. 20.10, *C* and *D*) (Fig. 20.17). If the separated instrument didn't come out of the canal in 10 seconds, there are three possibilities of the failure; the first one is that the space between the ultrasonic tip and the outer canal wall might be smaller than the diameter of the separated instrument (Fig. 20.18) or this space might be closed during the ultrasonic retrieval attempts, the second one is that the separated instrument might be pushed on the top back into the original position or from the outer wall by the ultrasonic tip (see Fig. 20.18, *F*), and the third one is that the amount of the fluid filled in the canal at the time of the ultrasonic removal attempts might not be sufficient enough to let the separated file flow out of the canal with the aid of acoustic streaming and cavitation (Fig. 20.19). If any of those possibilities is not applicable to the case and the instrument retrieval attempts were not successful with ultrasonics in wet conditions, or when the separated instrument is longer than 4.5 mm or between 3.1 and 4.4 mm with the curvature greater than 30 degrees, the loop (Yoshi Loop, DELabs) (Fig. 20.20, *C1*, *C2*, and *D*) should be used to retrieve the separated instrument.[330]

The kit includes a GG-3M, TFRK-MT, TFRK-6 ultrasonic tip, TFRK-12 ultrasonic tip, TFRK-S ultrasonic tip, Yoshi loop, TFRK- GPR, and TFRK-ME, High Speed Polishing Point (HSPP), NiTi GT #70/.12 Rotary File (GT70.12).

A) Two instruments have rod with flattened end.

B1) A conical rod with oval end.

B2) A wide conical rod with sharp end.

C1) A tubular instrument has wing-shaped end with wide base and a thin protruding tube at the center.

C2) A spiral shaped instrument.

D) Pack of Terauchi File Retrieval Kit.

Longer separated instruments, especially around a severe curve, are apt to be touching all over the canal walls, which creates more friction as it is reoriented in a coronal direction and makes it more resistant to instrument retrieval with ultrasonics alone, requiring more mechanical force to pull it out of the canal. This is why the loop is necessary to retrieve those types of separated instruments.

Use of the loop

It requires at least 0.4-mm-diameter space to place the loop in the canal, and the coronal portion of the separated instrument needs to be peripherally exposed by at least 0.7 mm to be grasped by the Yoshi loop (Fig. 20.21, *A*), The loop size must be adjusted to fit the coronal diameter of the separated file using an endodontic explorer, such as a DG16 Endo Explorer (Hu-Friedy, Chicago, IL) (see Fig. 20.21, *G*). The tip of a DG16 is placed in the loop and the loop is contracted around it. The apical portion of the DG16 is used to make the loop size smaller and the coronal portion is used to make it larger

Telegram: @dental_k

www.konkur.in

when the loop is tightened around it. The loop is then pre-bent to 45 degrees instead of 90 degrees to both facilitate the placement of the loop over the separated instrument and be minimally invasive as bending it to 90 degrees requires more room compared to 45 degrees (see Fig. 20.21, *E* and *F*). The loop is then brought into the canal and placed over the exposed portion of the separated file as the loop is pushed back to 90 degrees upon it (see Fig. 20.21, *B* and *C*). Subsequently, the loop is tightened over the separated instrument by sliding down the handle. The separated instrument will be retrieved by pulling the loop out of the canal in various directions with a swaying motion to dislodge it from the canal walls (see Figs. 20.21, *D* and 20.20, *C2*). A couple of pull motions in several directions will usually dislodge the file fragment and complete the case for separated file removal.

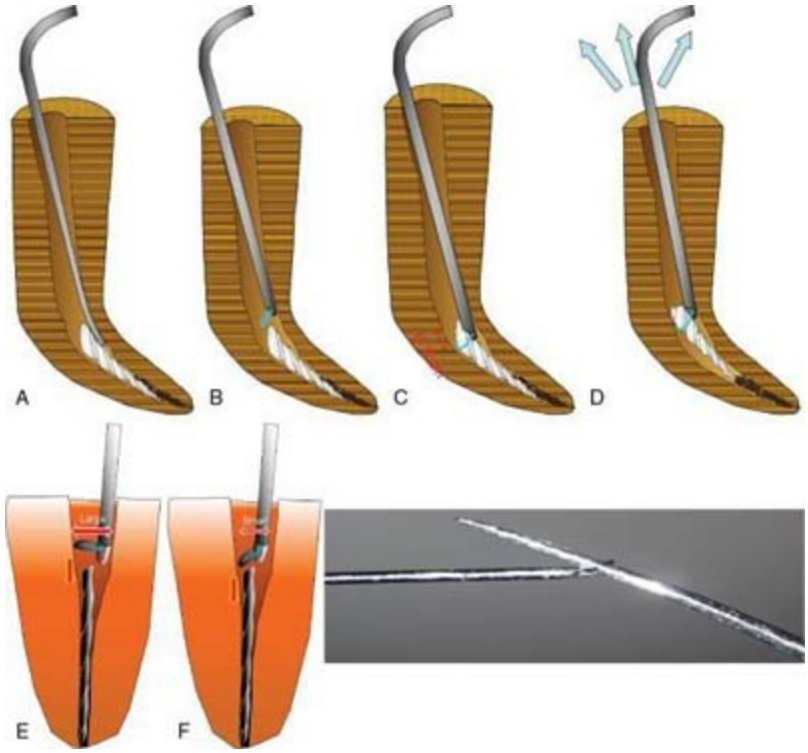

FIG. 20.21 **A,** Coronal portion of the separated file should be exposed at least 0.7 mm above the bottom of the space created around it. A #40 plugger should be placed in the space to assess the available space prior to the placement of the loop. **B,** Approaching the separated file with the loop bent to 45 degrees against it. **C,** Loop is pushed back to 90 degrees as it is placed over the separated file. Removal with the loop requires the diameters of the loop device (0.4 mm) and the separated instrument and a depth of at least 0.7 mm. **D,** Separated file

is pulled out with the loop device in various directions. **E,** Loop prebent to 90 degrees occupying more room in the canal. **F,** Loop pre-bent to 45 degrees requiring minimum room in the canal. **G,** Loop size is adjusted using an endodontic explorer.

Set of four illustrations marked A through D shows the process of removal of separated file from the root apex by using loops on endodontic explorer, followed by two illustrations marked E and F that depict the separated file moving back to the root apices due to large and small loops. The last illustration marked G shows a sharp conical rod placed on the tip of endodontic explorer.

Surgical approaches for the management of separated instruments represent a second category of procedures for dealing with this iatrogenic event (see also Chapter 11). Surgical approaches should be considered in the following situations[201]:

- As a last resort if other nonsurgical approaches fail, posttreatment disease develops, and the tooth is strategically important to retain
- As a first approach when periradicular pathosis is present at the time of instrument separation, especially if the separated instrument is found in the apical third of the canal coexistent, presumably with persistent extraradicular infection
- As a first approach when the radicular portion of the separated instrument is already outside the root, when an orthograde approach is unsuccessful, or when a significant amount of dentin must be sacrificed for instrument removal

Prognosis

When an endodontic instrument separates in a canal during cleaning and shaping procedures, and if it hinders adequate cleaning of the canal, then the prognosis may be affected. Moreover, attempts to remove a separated instrument from a curved canal may cause additional complications such as excessive removal of dentin structure, secondary instrument fracture, root perforation, or even root fracture.[134,286,313,317] However, there are cases in which the prognosis is not compromised, depending on what stage of instrumentation the file fracture occurred, the preoperative diagnosis of the pulp and periradicular tissues, and whether or not the separated file can be

Telegram: @dental_k

www.konkur.in

removed or bypassed.[317] The presence of a separated instrument per se in a canal or outside the root does not necessarily condemn the case to postoperative disease. Rather, it is the residual presence of any infected tissue that determines the prognosis. The closer the root canal preparation is to the terminus at the time of instrument separation, the better the outcome will be.[339] It has been suggested that instrument separation occurring in a later stage of canal instrumentation, especially if it is at the apex, has the best prognosis because the canal is probably well debrided and may be relatively free from microorganisms.[338] If the preoperative canal is not infected, and no radicular periodontitis is associated with the root, then the presence of the separated instrument should not affect the prognosis[63] and the separated instrument can be incorporated into root canal filling materials. If the separated file can be removed predictably without sacrificing a significant amount of dentin, the prognosis will not be reduced. In other words, the treatment prognosis depends more on the removal of microbial infection than on instrument removal.

Ledge formation

Ledges may be created as a result of instrumentation causing radicular transportation, which also causes zipping of the canal and possible canal perforation (Fig. 20.22). The *Glossary of Endodontic Terms* of the American Association of Endodontists[10] defines a ledge as “an artificial irregularity created on the surface of the root canal wall that impedes the placement of an instrument to the apex of an otherwise patent canal.” Canal transportation[10] is defined as “the removal of canal wall structure on the outside curve in the radicular half of the canal due to the tendency of files to restore themselves to their original linear shape during canal preparation.” The presence of a ledge hinders adequate shaping and cleaning of the canal in the areas radicular to the ledge. Consequently, there is a possible causal relationship between ledge formation and an unfavorable endodontic treatment outcome.[61,62,118,125,133,159,215,377]

C) Root canal has wide apex.

D) Root canal has an accessory branch near the apex.

Causes of ledge formation

Ledge formation can occur during biomechanical preparation of the canal system, especially when the canals are more curved. There are a number of factors associated with ledge formation, such as the instrumentation technique, instrument type, root canal curvature, tooth type, working length, master radicular file size, clinician's level of expertise, and canal location. Failure to precurve the instruments, the inability to achieve a proper glide path to the apex, and forcing large files into curved canals are perhaps the most common reasons for ledge formation.[153] The incidence of ledge formation was reported to increase significantly when the curvature of the canal was greater than 20 degrees; more than 50% of the canals in the study were ledged when the canal curvature was greater than 30 degrees.[118] Jafarzadeh[156] described 14 possible causes of ledge formation (Box 20.1).

Box 20.1

14 Possible Causes of Ledge Formation

Telegram: @dental_k

www.konkur.in

1. Not extending the access cavity sufficiently to allow adequate access to the radicular part of the root canal[61,125,153,159,185,352]
2. Loss of instrument control if endodontic treatment is attempted via a proximal surface cavity or through a proximal restoration[153]
3. Incorrect assessment of the root canal direction[61,159,185]
4. Incorrect root canal length determination[61,159,185]
5. Forcing the instrument into the canal wall[356]
6. Using a noncurved stainless steel instrument that is too large for a curved canal[61,153,159,250,352]
7. Failing to use the instruments in sequential order[61,125,159,185]
8. Rotating the file excessively at the working length[125,356]
9. Inadequate irrigation or lubrication during instrumentation[352]
10. Over-relying on chelating agents[356]
11. Attempting to retrieve separated instruments[61,159,185]
12. Removing root filling materials during endodontic retreatment[61,159,185]
13. Attempting to negotiate calcified root canals[61,159,185]
14. Inadvertently packing debris in the radicular portion of the canal during instrumentation[61,352]

Management of ledge formation

Once a canal is ledged, the endodontic treatment becomes difficult and the prognosis may be compromised. When a ledge is formed, early recognition of its location, using radiographs including CBCT and magnification, will facilitate its management.[125] The canal is usually “straightened” at the point where the file stops negotiating the curve, and there is suddenly a looser feeling of the file within the canal, with no more tactile sensation of the tip of the instrument binding in the canal. If the radiograph reveals that the tip of the instrument deviates away from the canal curvature, then it is highly likely that a ledge formation has occurred on the canal wall. The tip of the instrument placed in the canal should appear at the midpoint of the root on the radiographs because the canal is always in the center of the single-canaled root. If there are more than two canals in one root, then it is natural that the instrument placed in the canal appears off-center, which makes it essential to refer to CBCT for the number of the canals in the root before the

Telegram: @dental_k

www.konkur.in

instrumentation is initiated (Fig. 20.23).

When a ledge formation is identified, the shortest file possible that can reach the working length should be selected to bypass the ledge. Shorter

Telegram: @dental_k

www.konkur.in

instruments have more stiffness and allow the clinician's fingers to be placed closer to the tip of the instrument, which consequently provides greater tactile sensation and more control over the instrument.[156] It usually requires determination, perseverance, and patience to bypass a ledge once it is formed.[61] The successful management of a ledge depends on whether both the ledge and the orifice of the original pathway can be visualized, reached, or felt with instruments.[191] Any case where the ledge can be visualized under the DOM may be considered less complex to treat. Cases in which the ledge is not directly visible are more difficult to treat, as tactile sensation and negotiation require patience and experience.[61] However, 3D radiographic images obtained from CBCT reveal the locations and the directions of both the ledge and the original pathway to the canal terminus as the ledge always forms on the outer wall of the curved root canal in the straight line direction from the access. CBCT helps the clinician locate the entrance of the original pathway to the radicular foramen. First the ledge needs to be recognized under the DOM and both the ledge and the original canal need to be located on the 3D radiographic images. The maximum curvature of the root apical to the ledge can be identified on the axial view of CBCT as it is exactly the same as what is seen under the DOM. The maximum curvature can be located simply by viewing the axial slices from the coronal aspect before the ledge to the radicular aspect past the ledge in parallel with the coronal straight line to the ledge, and then a sagittal slice or a coronal slice is cut over the center of the curved root on the axial slice with the maximum curvature. On the sagittal view or the coronal view, the relationship between the ledge and the original pathway can be recognized, and with this view, the entrance to the original canal can be measured to locate its position under the DOM in reference to the ledge and the orifice from several reference points to it as the original canal is always in the center of the single-canaled root and the ledge is always in the straight line. CBCT without doubt, compared to 2D radiography, provides additional information for making an accurate diagnosis and therefore helps the clinician manage the ledge formation with a more predictable outcome and negotiate the original canal.[232,331]

Bypassing a ledge

Telegram: @dental_k

www.konkur.in

Using hand instruments

Based on the information from CBCT, the original pathway can be predictably identified and opened up under the DOM using micro-hand instruments. In addition, the ledge can always be visualized under the DOM as it is created in the straight-line direction. In addition, caries detector dye (Kuraray America, Inc., NY) or methylene blue dye can stain the orifice of the original pathway to locate it in comparison with dentin wall. Small hand files dedicated to microscopic use (such as the micro-Opener with #10/.06 taper) may help flare the orifice of the original pathway on the inner wall of the root canal coronal to the ledge (Fig. 20.24, *A*). The micro-Opener is available only in 16 mm and is short enough to provide tactile sensation and better control. However, in some cases a longer instrument is required to reach the ledge present in the radicular third of a long canal. In these instances, a hand instrument holder such as an EndoHandle (Venta, Logan, UT) may help the clinician easily negotiate the canal radicular to the ledge. Any hand files can be attached to the handle for microscopic use. Other hand instruments are available specifically for this purpose (TFRK microexplorer instrument [TFRK-ME] or Gutta-Percha Removal Instrument [TFRK-GPR, DELabs] and ELES instrument [DenMat Lompoc, CA]) that are long enough to reach the ledge formed in the radicular third. Both instruments are made of stainless steel. The TFRK-ME has a 0.1 mm biconical tip with a.08 taper for the first 1-mm portion from the radicular end and a.06 taper for the next 10-mm portion, which gives the instrument more stability in push-pull motions than a.02 tapered K-file. The TFRK-ME is precurved to the original pathway in the radicular 2 to 3 mm and pecked with to explore the narrow original canal on the opposite side of the canal wall with the ledge (Fig. 20.25), while the ELES and the TFRK-GPR are used to reduce the ledge in push-pull motions as the 0.2 mm diameter tip portion of the ELES with a.06 taper is coated with fine diamond particles on the tip portion (Fig. 20.26) and the TFRK-GPR has a sharp conical tip. They can be used in sequence to widen the orifice of the original pathway, which results in reducing or removing the ledge. The maximum diameter of the TFRK-ME and the TFRK-GPR is 0.78 mm, which provides stability and maintains a high visibility under the DOM when it is precurved, whereas the maximum diameter of the ELES instrument is 0.68 mm, which provides more flexibility and more visibility, even around

Telegram: @dental_k

www.konkur.in

a curve, to facilitate the widening the orifice of the original pathway without worsening the ledge. Once the first TFRK-ME or any other micro-hand file has successfully bypassed the ledge, subsequently the ELES or the TFRK-GPR instrument or the same micro-instrument can be used in a push-pull motion to enlarge and reestablish the original pathway (Fig. 20.27), followed by hand instruments (such as ProTaper S1 and S2 hand instruments, DENTSPLY Sirona Tulsa Dental Specialties, Tulsa, OK) to both shape and reduce the ledge. S1 and S2 ProTaper Gold files (DENTSPLY Sirona Tulsa Dental Specialties) can also be precurved with ease and used as hand files in short pumping motions for the same purposes after the preliminary enlargement of the original pathway with those micro-hand instruments (Fig. 20.28).

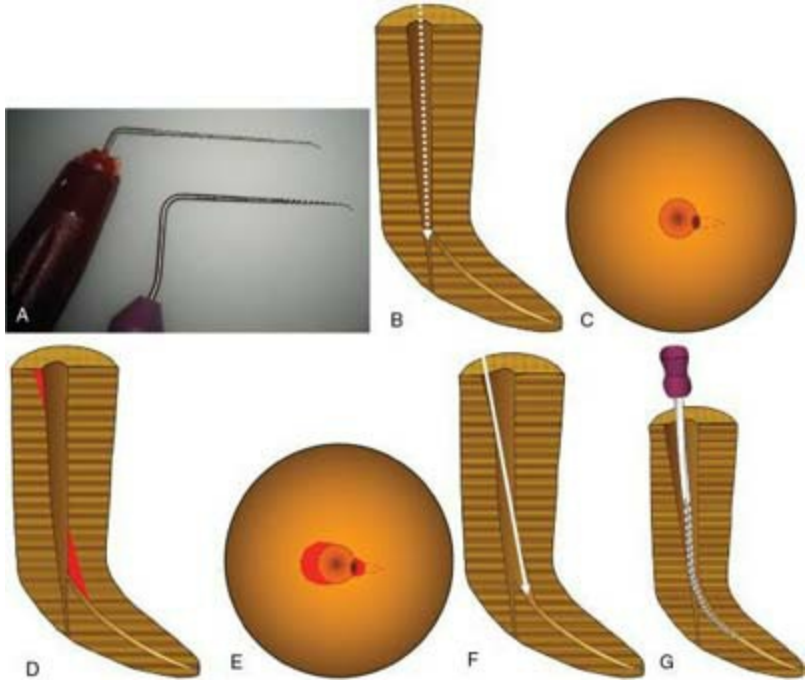

FIG. 20.24 **A,** Precurved microinstruments such as EndoHandle with a precurved #25 Hedstrom File (Venta Endo, Logan, UT) and micro-Opener (Dentsply Sirona) to explore a ledged canal for the original pathway and to reduce irregularities over the ledge. **B,** Ledge is formed with perforation in a radicular straight direction. **C,** Microscopic view showing the ledged canal in the center and a narrow access to the original pathway on the right side. **D,** The canal orifice as well as the access to the original pathway needs to be flared in an anticurvature direction *(red portions)*. **E,** Microscopic view showing red portions to be removed for easy access to the original pathway. **F,** Access to the

center of the root. **B,** Cone-beam computed tomography (CBCT) image in sagittal view showing the original canal *(red arrow)* in the center of the root while the ledge *(white arrow)* turns away in the straight line in the mesial root. **C,** CBCT image in coronal view showing the MB and the ML canals merge into one canal *(red arrow)* in the apical third. **D1** and **D2,** Consecutive CBCT images in axial view showing the MB canal and the ML canal *(white arrows)* join into one oval canal *(red arrow)*. **E,** Magnification of the MB canal showing a separated file *(red arrow)*. **F,** Retrieved separated files from the mesial root and the distal root. **G,** Interoperative radiograph showing removal of the two separated files. **H,** Placement of a small file into the MB canal reveals a perforation on the outer wall in the straight line form from the orifice on the interoperative radiograph. **I,** Ledge *(red arrow)* and the original pathway *(white arrow)* were identified in the MB canal under the DOM based on the axial view of CBCT and the orifice of the original canal was enlarged with a precurved #10/.06 micro-opener with short push-pull strokes. **J,** Placement of a precurved small hand file (ProTaper S1) reveals it in the original canal reaching the working length on the interoperative radiograph. **K,** Placement of the final shaping file into the MB canal confirms it in the original canal reaching the working length without transportation on the interoperative radiograph. **L,** Postoperative radiograph shows root canal fillings with mineral trioxide aggregate (MTA) including the ledged canal with the perforation. **M,** Three-month postoperative radiograph shows a dissolving periapical lesion.

Set of eight radiographs and two blurred photographs marked A through I shows the removal of separated files from mesial and distal roots of first molar in the lower jaw, followed by the formation of ledge canal along with original pathway in the root near the apex.

Set of four radiographs marked J through M shows the filling of root canals along with ledge in first molar of lower jaw and development of hard tissue in place of the radiolucent patch at the root apex.

As an alternative technique to bypass the ledge when the clinician wishes to use K files without using the DOM, precurving of a #8 or #10 hand file is a critical step. The small file should have a distinct curve at the tip. This file should be used initially to negotiate and explore the original pathway of the canal to the radicular foramen.[61,153,352] A rubber stopper with a directional indicator pointed in the direction of the original pathway should be set in the instrument.[153] A slight rotation of the file combined with a “pecking” motion can often help advance the instrument to the full working length of the canal.[153,352] If this technique is unsuccessful, the clinician should flare the

Telegram: @dental_k

www.konkur.in

canal coronal to the ledge in an anticurvature direction to obtain wider straight-line access to the original pathway of the canal, followed by a smaller K-file with the tip precurved to bypass the ledge (see Fig. 20.24).

Using ultrasonic tips

Small diameter ultrasonic tips improve both cutting efficiency and visibility with the added benefit of reducing the need for sacrificing sound dentin in bypassing or removing the ledge.[192] The only drawback to the thinner tips could be that they are more prone to fracture during ultrasonic activation.[351] Therefore thinner ultrasonic tips should be activated in a pulsing and pecking fashion at the lowest possible power setting to prevent fracture, overextending the ledge, and heat generation as ultrasonics may get very aggressive in cutting.[282]

The use of longer ultrasonic tips may also facilitate bypassing or reducing the ledge in the radicular third as long as it is performed under the DOM. The entrance to the original canal just coronal to the ledge can be quickly enlarged with small diameter ultrasonic tips if it can be visualized under the DOM or felt with a sticky feeling from the micro-hand instruments (Fig. 20.29). First, an appropriate size of a small diameter ultrasonic tip (such as TFRK-S, DELabs and ET25, Satelec Corp, Merignac Cedex, France) is selected and precurved in the direction of the original canal. Then it is simply placed into the orifice of the original pathway in a radicular direction and activated in pecking and short push-pull motions at the same time, which will automatically enlarge the opening of the true canal in a few seconds so that files can consecutively be placed into the original canal for root canal preparation. Once the orifice of the original pathway gets wide enough for file insertion, negotiation files need to be placed into the canal to establish patency and to smooth out the irregularities on the canal wall that may have been created with ultrasonics, followed by root canal preparation with NiTi rotary or hand files (Fig. 20.30).

established with a precurved micro-opener followed by a precurved ProTaper S1. **G,** Postoperative radiograph showing the completed root fillings including the original canal and the ledged canal with perforation *(red arrows)*. **H,** Three-month follow-up showing healing in progress. **I,** Six-month follow-up showing nice periapical healing. **J,** A series of 6-month postoperative CBCT images in axial view from the apical third to the radicular foramen (**J1** to **J3**) reveals root fillings in both the original canal and the ledged canal with nice periapical healing. **K,** A pair of 6-month postoperative CBCT images in sagittal view (**K1** and **K2**) shows nice periapical healing compared to the preoperative CBCT images. **L,** Six-month CBCT image in coronal view also shows nice periapical healing.

Set of seven radiographs and three photographs marked A through E 3 shows a radiolucent patch at the root apex and the filled root canals extended beyond the apex in second molar of the upper jaw, which undergo removal and resulting in the restoration of original canal without filling.

Set of ten radiographs marked F through L shows the fillings in root canals including ledge resulting in thee healing of radiolucent patches at the root apex of second molar in the upper jaw.

Using rotary instruments

Before using rotary instruments to bypass the ledge, the canal should be enlarged to the area coronal to the ledge for better visualization of the original pathway and then the orifice of the original pathway must be located and opened. Precurved smaller diameter rotary files with smaller tapers such as PathFiles (Dentsply Sirona, Ballaigues, Switzerland) and Race 10 (FKG Dentaire, La Chaux-de-Fond, Switzerland) are also beneficial for negotiating beyond a ledge. First, the radicular 2 to 3 mm of the file is precurved to the original pathway based on the coronal or the sagittal view of CBCT and is rotated at 100 rpm or with 90° CW/30° to 60° CCW reciprocating motions at 150 rpm in short up-and-down motions as it is brought slowly into the canal and moved radicularly (Fig. 20.31). If a ledge or sharp radicular curvature is encountered, the instrument is withdrawn about 1 mm and immediately reinserted. This allows the precurved tip to move to a different orientation within the canal as it is reinserted. This may require one or two withdrawals and re-insertions to negotiating the original canal. This procedure is followed in sequence by the next larger rotary files to preliminarily enlarge the original pathway and reduce the ledge prior to the conventional root canal preparation

Telegram: @dental_k

www.konkur.in

with NiTi rotary instruments.

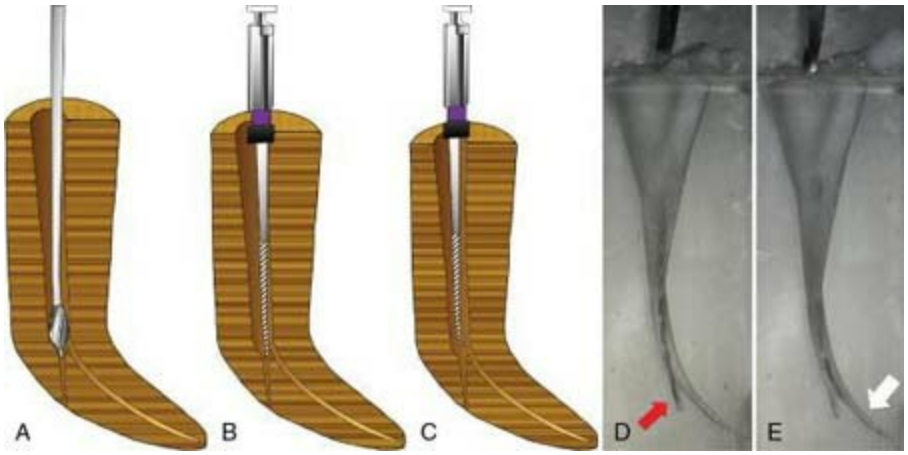

FIG. 20.31 **A,** Canal coronal to the ledge is enlarged with a #3 GG bur. **B,** Small straight rotary file (#10/.02 or #10/.04) rotating at 300 RPM or faster will not get into the original pathway. **C,** Small precurved rotary file rotating at 100 RPM or 150 RPM with 90-degree clockwise and 30-degree counterclockwise reciprocating motions will most likely get into the original pathway. **D,** Small precurved rotary file rotating at 300 RPM ended up going into the ledged canal *(red arrow)*. **E,** Small precurved rotary file rotating at 100 RPM was able to get into the original canal *(white arrow)*.

Set of three illustrations and two radiographs marked A through E shows 3 GG bur and rotatory files inserted into either ledged canal or original canal of the root.

Potential complications of removal or bypassing a ledge

During ledge removal or bypassing a ledge, complications can occur, including root fracture, root perforation, worsening the ledge, and instrument separation. Since a ledge is likely to form around a curve, attempts to bypass or eliminate it may often involve dentin sacrifice, which may eventually compromise the integrity of the tooth and increase the risk of perforation or root fracture. Care should be taken not to remove excessive root structure or overstress the instruments during the ledge management. If a ledge cannot be bypassed with any of the techniques described earlier, and if signs or symptoms of the periradicular lesion persist, then the treatment options are limited to either the use of GentleWave, which applies advanced fluid

Telegram: @dental_k

www.konkur.in

dynamics, acoustics, and tissue dissolution chemistry to clean and disinfect the entire root canal system, regardless of any anatomic complexities (including the original pathway beyond the ledge), leading to success in eliminating infection from the canal system without shaping them where traditional instruments cannot access[301,302,349] or surgical intervention such as periradicular surgery or intentional replantation.[153]

Prevention of ledge formation

Glide path preparation helps clinicians prevent mishaps such as ledge formation and canal transportation as it guarantees that the root canal diameter is sufficiently large to receive the first shaping instrument.[27,234] Precurving the instruments and not forcing them into the canal is one of the most important considerations in the prevention of ledge formation.[153]

NiTi reciprocating instrumentation shows a lower frequency of procedural errors such as ledge formation and instrument separation even in the hands of novice clinicians, compared to K-file/NiTi rotary instrumentation.[73,128,202,283,328] The use of NiTi files and instruments with noncutting tips helps to maintain original root canal curvatures.[153] The concept of use of these instruments is that the rounded tip does not cut into the wall but will slip alongside it.[152,153] In addition to the tip design, flexibility of an instrument also plays an important role in keeping the instrument centered in the canal, with NiTi instruments favored over stainless steel instruments.[143,150,223] The use of novel NiTi alloy instruments with new heat treatment methods such as the Controlled Memory alloy technology (Coltene/Whaledent AG) and the GOLD alloy technology (Dentsply Maillefer, Ballaigues, Switzerland) show less canal transportation and more canal centering ability than conventional NiTi alloy instruments.[135,227,244,348]

Prognosis

A ledge in a canal is analogous to any intracanal obstruction that hinders the cleaning and shaping of the root canal to the radicular terminus. The presence of a nonnegotiated ledge may have a similar prognosis as a canal with a retained separated instrument. If the ledge can be bypassed or eliminated, and if the canal beyond the ledge can be cleaned without excessive enlargement

Telegram: @dental_k

www.konkur.in

or perforation, then the prognosis should not be that greatly reduced.[338,339] Therefore the prognosis in general for such a case depends not only on the efficacy of the disinfection process but also on the host response to remaining debris or biofilms (bacteria) that are traditionally not removed with conventional root canal therapy (Fig. 20.32).[74]

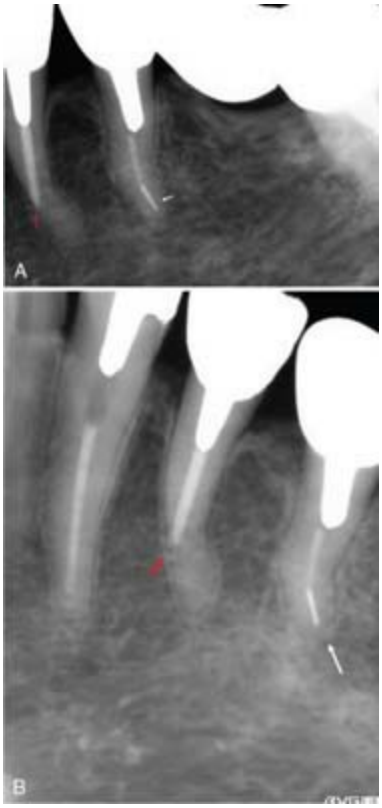

FIG. 20.32 **A,** Radiograph taken in 2010 for evaluation of the ledge *(red arrow)* in the mandibular left first premolar and the separated file *(white arrow)* in the mandibular left second premolar showing no radiographic periapical pathosis and both of the teeth were asymptomatic. **B,** Radiograph taken in 2019 for evaluation of those teeth showing the same without any sign of periapical pathosis *(red and white arrows)*.

Set of two radiographs marked A and B shows ledge canal and separated file in two different teeth of lower jaw.

Radicular extrusion of root canal filling

Telegram: @dental_k

www.konkur.in

materials

The extrusion of root filling materials beyond the radicular foramen or the perforation site may occur either when the canal is obturated or during the removal of obturation materials. Radicularly extruded materials such as obturating materials, necrotic pulp tissue, bacteria, medicaments, and irrigants have been associated with posttreatment inflammation and flare-up or the lack of radicular healing.[213,295,305,335] In vivo histologic studies show the most favorable histologic outcome when the root filling material remains within the radicular constriction. When gutta-percha is extruded into the periradicular tissue, there can be a severe inflammatory reaction.[265] However, other types of materials, such as ProRoot mineral trioxide aggregate (MTA) (DENTSPLY Sirona Tulsa Dental Specialties) and EndoSequence BC Sealer (Brasseler, Savannah, GA), are more biocompatible[1,57,111,117,167] and do not seem to produce much periradicular inflammation if extruded beyond the root of the tooth.[93,312]

Studies show that almost all instrumentation techniques or types of NiTi instruments promote the radicular extrusion of debris including root filling materials.[7,144,329,336] Furthermore, gutta-percha and Resilon filling materials obtained from teeth associated with refractory radicular periodontitis have indicated the presence of bacterial biofilm and *E. faecalis*.[122,214,223,296] Another study stressed the possibility of gutta-percha–centered *E. faecalis* biofilm as well as the role of tissue fluids such as saliva and serum in the biofilm formation.[108] *E. faecalis* adheres well to gutta-percha with and without canal sealers, with the biofilm formation more effective when it is in contact with serum in periradicular tissues. Because bacterial biofilm is considered the primary cause of chronic and recurrent endodontic infections,[341] it is crucial to keep gutta-percha filling materials within the canal system as much as possible to both prevent potential periradicular periodontitis and obtain the optimal results.[26,83,289]

Uncontrolled obturation can cause the extrusion of root canal filling materials into the maxillary sinus[86] or into the territory of the inferior alveolar nerve (IAN).[246] The systematic review shows most of the nerve injury cases with lateral condensation fully recovered over time, compared with none of the cases with vertical condensation that recovered.[273] Serious

Telegram: @dental_k

www.konkur.in

complications such as maxillary sinusitis, aspergillosis infection, paresthesia, dysesthesia, and similar neural complications may occur after extruding the root filling materials including a core carrier of an obturator into such sensitive areas.[30,173,203]

Endodontic-related paresthesia can be caused mechanically, thermally, chemically, or a combination of these via the passage of endodontic materials into the vicinity of the major nerves such as the IAN or its branches.[3,249] When the IAN is injured, the pain is not only located in the immediate periradicular area but may radiate and refer to the surrounding or distant structures.[222] Inflammation caused by mechanical irritation is likely to persist until the extruded materials are removed, and it may become permanent secondary to the mechanical, thermal, or chemical insult.[136] These extruded materials include root canal irrigants, sealers, and paraformaldehyde-containing pastes.[350] Most extrusion cases with resin-based sealers showed full recovery from nerve injuries (62%), but only 27% of those with paraformaldehyde based sealers showed full recovery.[273] The use of paraformaldehyde-containing pastes is not recommended for endodontic obturation[210,249] because paraformaldehyde is a polymeric hydrate of formaldehyde that releases formaldehyde gas and may cause permanent damage to the nerve when it is in contact with water.[114] On the other hand, extrusion of endodontic materials, even into the inferior alveolar canal, will not always result in altered sensation.[246] The possible explanation for this is that some extruded root canal sealants demonstrate their neurotoxic properties only when they come into direct contact with the individual fascicles through the pathway created by over-instrumentation, whereas they are less harmful to the sensory nerves when they are outside the epineurium.

Significantly higher or lower pH materials than those of body fluids (around 7.35) are also likely to cause cellular necrosis of tissues when they are in direct contact with these materials. The clinician must also consider the pH of some of the routinely used endodontic and related dental materials. It has been reported that an alkaline pH of root canal sealers could neutralize the lactic acid from osteoclasts and prevent dissolution of mineralized components of teeth; therefore root canal sealers, especially calcium silicate–based cements or sealers, can contribute to hard tissue formation by activating alkaline phosphatase.[321] Commonly used endodontic medicaments

Telegram: @dental_k

www.konkur.in

are as follows[47,105,245,258,303]:

Formocresol: pH 12.45 +/− 0.02
NaOCl: pH 11 to 12
Calcium hydroxide (Calyxl): pH 10 to 14
ProRoot MTA: pH 11.7 to 7.12 at 3 hours to 28 days
Endosequence BC Sealer: pH 10.31 to 11.16 at 3 hours to 240 hours
MTA Fillapex: pH 9.68 to 7.76 at 3 hours to 168 hours
AH plus: pH 7.81 to 7.17 at 3 hours to 240 hours
Sealapex: pH 9.72 to 9.63 at 3 hours to 24 hours
Antibiotic-corticosteroid paste (Ledermix): pH 8.13
Pulp Canal Sealer: 8.07 to 7.55 at 3 hours to 24 hours
Eugenol: pH 4.34 +/−0.05
Iodoform paste: pH 2.90 +/−0.02

Neural damage from those higher or lower pH materials may be permanent and can cause neuropathic pain (i.e., dysesthesia) or anesthesia.

Orbital pain and headache may occur secondary to the local compression of overextended material into the maxillary sinus.[365] Sinus infection caused by zinc-oxide-eugenol–based filling materials extruded into the maxillary sinus is often associated with aspergillus growth and biofilms (Fig. 20.33).[21,22,112,175,274] Although aspergillosis of the paranasal sinuses is a relatively rare finding in non-immunocompromised patients, it is known as an opportunistic infection.[166] Many studies have demonstrated that maxillary sinus aspergillosis is generally caused by extruded root canal filling material containing zinc oxide and formaldehyde.[21,22,175,188,319] However, even those extruded materials that are not considered toxic[315] may cause an additional foreign body reaction.

Telegram: @dental_k

www.konkur.in

FIG. 20.33 Maxillary sinus aspergillosis. **A,** Preoperative radiograph showing a lesion associated with the palatal root, from which the extrusion of the root filling materials occurred in the maxillary sinus. **B,** Cone-beam computed tomography (CBCT) image in sagittal view showing the relation between mucositis on the maxillary sinus floor and the gutta-percha filling materials. **C,** CBCT image in axial view showing the relation between mucositis on the mesial wall of the maxillary sinus and the extruded root filling materials. **D,** CBCT image in coronal view showing the relation between the palatal root and the extruded root filling materials. **E,** Postoperative radiograph of orthograde root canal retreatment on the maxillary left first molar showing the mesiobuccal, distobuccal, and palatal root canals were adequately filled without overextension of the filling materials. **F,** Aspergillus was found on the filling materials retrieved from the maxillary sinus.

Set of five radiographs and a specimen marked A through F shows the tooth with maxillary sinus undergoing filling in root canals along with mesial, distal and palatal root, followed by the extraction of filling materials that has aspergillus on it.

The systematic review shows nerve injuries caused by overextruded endodontic materials were reported to be 72% for the first or the second mandibular molars followed by the second mandibular premolars (19%), and none in maxillary teeth.[273]

Causes of extrusion of obturation materials beyond the

Telegram: @dental_k

www.konkur.in

radicular foramen

The extrusion of obturation material that was thought to be the cause of endodontic failure is reported to be as low as 3%,[311] with the majority of causes thought to be more from coronal leakage. However, several researchers have seen a higher frequency of failure and unhealed periradicular lesions in cases where the root filling material had extruded beyond the radicular foramen without filling small anatomical spaces within the root canal system and harboring biofilms on the surface of the extruded material.[26,30,40,239,296] Overextension of the root canal filling materials occurs mainly for lack of material control.[43,126] The degree of extrusion of obturation materials into periradicular tissues depends on the techniques used for root canal preparation and obturation,[266] which include accidental over-instrumentation and incorrect canal working length measurement. Caution should also be taken when obturating a canal with open apices and larger minor foramen diameters, which are often found in cases with radicular inflammatory resorption. Warm vertical compaction techniques produce a homogeneous obturation that adapts well to the canal walls[290,362] but may result in the extrusion of gutta-percha filling into the periradicular tissues and may damage them mechanically and thermally.[43] Carrier-based obturation was also found to have more radicular extrusion of gutta-percha when compared with warm vertical compaction.[184] The type of canal shaping may also be a contributing factor. The canal shape created with the Profile GT system is more prone to extrusion of gutta-percha when obturated with the carrier-based technique than the canal shape created using Profile 0.06 instruments. The Profile GT system created a more parallel preparation coronally and a tapered preparation radicularly, whereas the Profile 0.06 system created a preparation with uniform taper from the apex to its most coronal extent.[266] Therefore possibly the more continuously tapered the canal shape is, the less obturation material is extruded beyond the radicular foramen.

When endodontic retreatment is performed, irritants in the form of root filling materials can be extruded into the periradicular tissues.[7,144,329] Techniques involving push-pull filing strokes usually create a greater mass of debris than those involving some sort of rotational motions.[5,38,94,165,205,254]

www.konkur.in

Management of obturation materials extruded beyond the radicular foramen

Nonsurgical management of extrusion of obturation materials

Methods to remove the gutta-percha filling material from the root canal include the use of heat-carrying instruments, ultrasonics, solvents, and rotary or reciprocating or hand files. Mechanized methods to remove filling materials are faster but may possibly be no different from manual methods in terms of the amount of remaining material in the root canal.[129,164,269,270,327] Heat-carrying instrument may damage the periradicular tissues if the removal attempts extend beyond the radicular foramen. The complete removal of gutta-percha from the root canal system has proven difficult.[129,327,368] Poorly compacted gutta-percha obturation can easily be removed in large masses of gutta-percha root fillings with micro-hand instruments under the DOM or Hedström files in combination with solvents such as chloroform,[59,154] although the extruded portion of root canal fillings will often remain in the periradicular tissue (Fig. 20.34).[59] The relative ease of gutta-percha removal suggests a failure of previous endodontic treatment, possibly related to poor obturation compaction or canal shaping, which resulted in both radicular extrusion and failure of the radicular seal. Comparatively, well-filled canals with radicular extrusion do not appear to have a significant failure rate.[15,154] On the other hand, the extrusion of the MTA root filling material into the periradicular tissues does not appear to negatively affect the periradicular healing due to the high biocompatibility and antibacterial properties that the calcium silicate–based cement possesses,[196,326] compared to gutta-percha filling materials (Fig. 20.35). Hence the MTA root filling extruded into periapical tissues does not have to be removed.

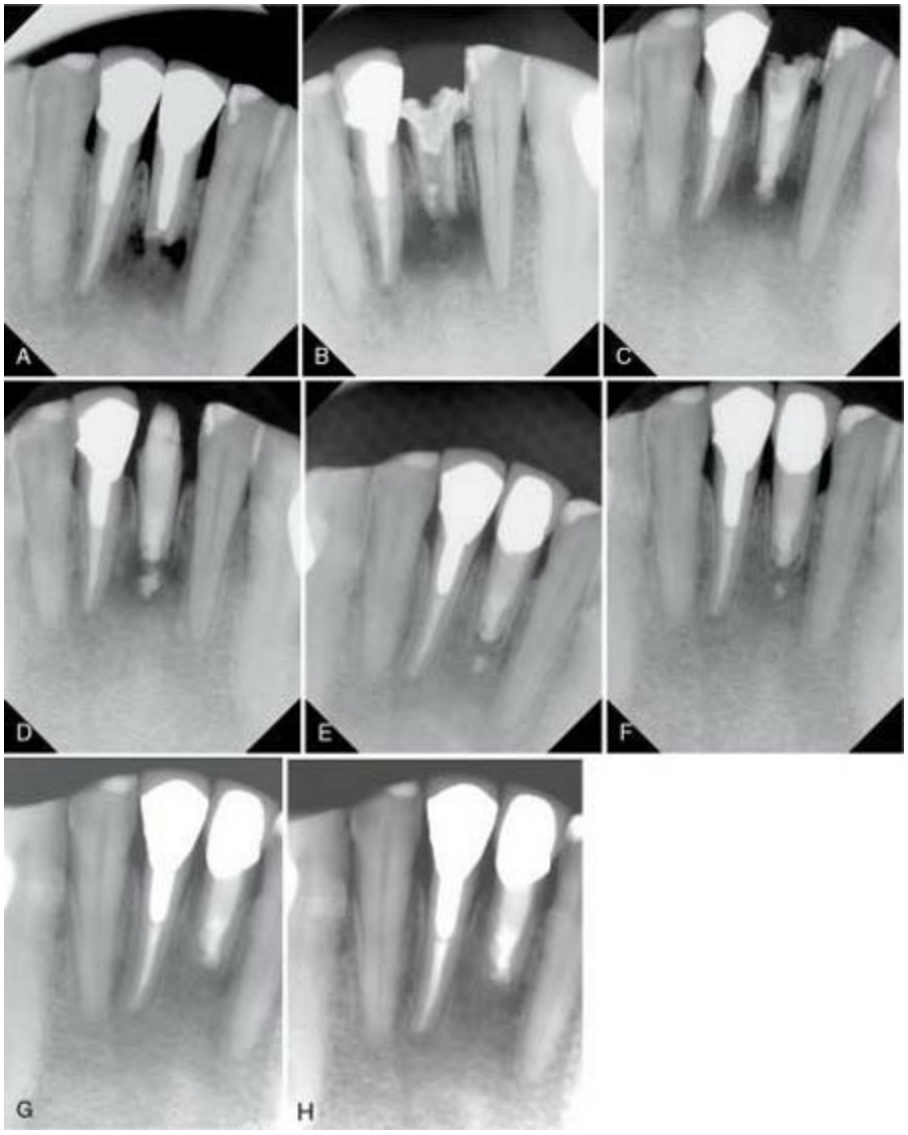

FIG. 20.35 **A,** Preoperative radiograph showing a large periradicular lesion associated with the root of the mandibular left incisor. **B,** Interoperative radiograph showing the cast post and the root filling in the canal was mechanically removed. Calcium hydroxide was placed as an intracanal dressing on the first appointment. **C,** Postoperative radiograph on the second appointment showing the canal was obturated with mineral trioxide aggregate (MTA), which resulted in overextension of the material into the periradicular tissues. **D,** Six-month postoperative radiograph showing the significantly reduced size of the lesion. **E,** One-year postoperative radiograph showing a nice periradicular healing with hard tissues formed on the radicular end of the MTA filling, resulting in a longer root aside from a residual of the MTA root filling extruded into the periradicular tissues. **F,** Three-year postoperative radiograph showing the tooth has maintained healthy periradicular tissues with the extruded MTA filling reduced in size. **G,** Twelve-year postoperative radiograph showing the tooth has

Telegram: @dental_k

www.konkur.in

maintained healthy periradicular tissues with the extruded MTA filling completely dissolved in the bone. **H,** Sixteen-year postoperative radiograph showing the tooth has maintained healthy periradicular tissues with healthy lamina dura surrounding the root.

Set of eight radiographs marked A through H shows the restoration of less-density tissue at the root tip of incisor that half root.

When gutta-percha is overextended into the periradicular space, removal can be attempted by inserting a new Hedström file, usually a #15 or #20, into the radicular obturation, using a gentle clockwise rotation to a depth of 0.5 to 1 mm beyond the radicular constriction. The file is then slowly and firmly withdrawn with no rotation, thereby engaging and removing the overextended material.[207] This technique works frequently, but care must be taken not to force the instrument, or further extrusion of the gutta-percha or separation of the file may result. The overextended radicular portion of the gutta-percha should not be softened with heat or solvent, because this application can decrease the likelihood of the Hedström file engaging the obturation, hindering its retrieval.[318] In addition, care should be taken not to overextend the file into the area of the IAN canal, which could cause irreversible damage to the associated nerves.

The use of rotary NiTi files that are specifically designed for gutta-percha removal with active tips and more aggressive cutting may not be superior to conventional files.[348,349] Hand instrumentation may be associated with longer times to remove root filling materials than rotary/reciprocation systems. However, no iatrogenic errors were reported with hand instrumentation.[269,270,271] Hand instruments used for the removal of root fillings include H and K-files, Micro-debriders (DENTSPLY Maillefer, Ballaigues, Switzerland), EGPR-L/R/U/D (Den-Mat Holdings LLC, Lompoc, CA), and the TFRK gutta-percha removal instrument (TFRK-GPR, DELabs). Single-file systems such as the self-adjusting file (SAF) (ReDent-Nova, Ra'anana, Israel), Hyflex EDM "one file" (EDM) (Coltene/Whaledent, Alstatten, Switzerland), WaveOne Gold (WOG) (Dentsply Sirona, Ballaigues, Switzerland), RECIPROC blue (VDW, Munich, Germany), and XP Shaper (XP) (FKG, La Chaux de Fonds, Switzerland) have improved mechanical properties that can potentially make them suitable for gutta-percha removal. The XP is a minimal taper file that can expand beyond its

Telegram: @dental_k

www.konkur.in

core size to adapt to the anatomy of the root canal space and may be more efficient in removing root filling materials than other single-file systems as it provides more space for the debris to be displaced.[16,304] The XP has been reported to provide a shorter operation time and showed the optimum results without any added untoward events when operated at a higher speed (3000 rpm) when compared to other single-file systems.[16] A full rotation motion may also be a more suitable cutting motion in root filling removal than a reciprocating motion.[16] Rotary retreatment files may be more advantageous in the amount of debris extrusion when compared with manual techniques using Hedström files with chloroform,[124,337] although all instrumentation techniques resulted in some radicular extrusion.[146,310] The literature shows more debris extrusion produced by instruments used with a reciprocating movement than instruments used with a continuous rotary movement.[44,45,51,336,340] Likewise, the rotary XP shaper instrument has been reported to extrude a significantly smaller amount of debris compared with reciprocating Reciproc Blue instruments because of its expanding snake-like structure, which may be ideal to mechanically remove root fillings extruded into periradicular tissues (Fig. 20.36). Furthermore, a combination of both rotary instruments for initial quick removal of gutta-percha and hand instruments to refine and complete the cleaning of the canal, especially in the radicular third of the root, shows the better protocol for obtaining clean canal walls during endodontic retreatment.[28,151] It has been reported that the use of a solvent after mechanical retreatment procedures may enhance root filling removal.[50] The use of a solvent, such as chloroform, may help to dissolve the gutta-percha root fillings remaining in both the periradicular tissues and the root canal system after mechanical removal attempts using a micro-hand instrument or an efficient rotary single-file system such as the XP (Fig. 20.37 *D–G*). In addition, chloroform has been reported to be capable of reducing the intracanal levels of *Enterococcus faecalis*.[79,209] However, when chloroform is used during the early stages of gutta-percha removal, more filling material will remain in the canal and some of it may be extruded beyond the radicular foramen.[146,198] Although the carcinogenicity of chloroform in humans is suspect, chloroform is regarded as a safe and effective endodontic solvent when used carefully.[56,204]

minimally invasive irrigant such as saline. **G,** Extruded gutta-percha filling material can also be braided out with those expandable rotary files with caution not to break them or not to damage the inferior alveolar nerve if close to it.

Set of seven illustrations marked A through G shows the changes in extruded gutta-percha extended beyond the root tip of tooth.

Unlike rotary instruments, the EGPR-L/R/U/D hand instruments and the GPR instrument are 30 mm in length, allowing them to remove obturation materials not only from the radicular third of the canal but also from the periradicular tissues through the radicular foramen. The micro-debriders are designed to be used in conjunction with a DOM. They have a Hedström cutting configuration with a standard.02 taper in sizes 20 and 30 with 16 mm of cutting flutes, which may not be long enough to reach the gutta-percha filling material beyond the radicular foramen. Another option to reach the root fillings extruded into the radicular tissues is to use an Endo Handle (Vento Endo, Logan, UT) which is designed to be used under the DOM with a pre-bent 30-mm hand file attached to the locking chamber.

First, a small hole must be created between the canal wall and the gutta-percha filling with a small diameter ultrasonic tip to facilitate the root filling removal with the hand gutta-percha removal instrument placed into the hole. It is ideal to remove the root filling in one large piece from the periradicular tissues. Care should be taken not to push the root filling materials in a radicular direction with those micro-instruments especially for a canal with large radicular foramen. Then the gutta-percha filling is scraped and taken out from the canal wall with the micro-instrument.

The EGPR instrument has a tiny projection on one side of the tip for scraping and engaging the gutta-percha filling left on the canal wall. The overall diameter of the tip is 0.3 mm and the length of the projection is 0.1 mm. This hand instrument works like a scraper on the canal wall. When the radicular portion of the EGPR comes down to the bottom of the hole created, the projection is directed to the gutta-percha filling so that it can be hooked on the projection pressed against it. Then the gutta-percha filling should come apart in large pieces from the canal wall (see Fig. 20.37, *A–C*).

On the other hand, the TFRK-GPR instrument has a tiny conical harpoon-shaped tip that is sharp and small enough to sneak into a narrow space on the

Telegram: @dental_k

www.konkur.in

canal wall and hook the gutta-percha on the rim on the return stroke. The tip portion of this instrument has a.40 taper with the minimum tip diameter of 0.1 mm and the maximum diameter of 0.3 mm with a 0.2-mm diameter shank supporting the tip portion. The 0.1-mm gap between the 0.3-mm and the 0.2-mm diameters works practically as a tiny circular projection over the shank portion that can hook a mass of gutta-percha fillings. The conical tip with the maximum diameter of the shank portion being 0.6 mm makes it possible to place the instrument into the canal beyond the curve just like a Hedström file. The gutta-percha filling can also be hooked by pressing the projecting rim against it, and then should be removed in large pieces from the canal wall.

When a small amount of gutta-percha filling remains on the inside curve or in the radicular third of the canal after the mechanical removal attempts, chloroform should be filled in the canal and the GPR instrument can be used to agitate it in short push-and-pull motions in the canal, or even outside the canal if root filling is extruded beyond the radicular foramen, to actively dissolve the residual root filling. The mean percent total values of residual material ranged from 43.9% to 0.02%, with the vast majority of studies reporting values less than 10%.[275]

Management of tissue damage caused by extrusion of root canal filling materials

When root canal filling material extends into the periradicular spaces, tissue damage may occur. The majority of these cases are managed by nonsurgical methods such as analgesics, cold packs, corticosteroids, and antibiotics.[90] Dexamethasone is a corticosteroid that has been widely used in dentistry, and it seems to decrease periradicular inflammation caused by a foreign body[210] with minimal side effects.[65] If the tissue damage is extended to the IAN or maxillary sinus, then a different approach may be necessary.

Sinus perforation

There is a close proximity of maxillary premolars and molars to the sinus, and the apices of these teeth can be less than 2 mm from the floor of the sinus.[78] Pathologic destruction of the sinus floor may predispose a maxillary sinus communication,[294] producing an oroantral communication,[98,190,278,355]

Telegram: @dental_k

www.konkur.in

also known as an OAC. In general, exposure of the sinus lumen is well tolerated,[155,238] with no overt repercussions on healing. One investigator[355] found no significant difference in the healing of the mucosa in patients with and without intraoperative perforations and regeneration of the membrane, complete with cilia, in approximately 5 months following complete removal.[25] However, introduction of foreign materials during the access or apical resection/manipulation can initiate thickening of the sinus mucosa with symptoms of maxillary sinusitis.[84]

Conventional radiographs appear to be of limited value in predicting the potential for OAC, with the position of the root tip, periapical lesion, or outline of the lesion not statistically significant in that respect.[224] In contrast, a CBCT survey of the intended surgical field is much more informative, providing accurate measurements of the osseous thickness, distance to the sinus floor, and presence of pathosis.[33]

Maxillary sinus complications secondary to the extrusion of root canal filling material need to be managed differently. Approximately 10% of all patients with chronic sinusitis are found to have an aspergilloma.[120,193] It has been suggested that root canal treated teeth with overextension of the root canal sealer into the maxillary sinus might be the main cause for aspergillosis in healthy patients.[21,22] Surgical intervention is usually the most predictable method for removing extruded root canal filling material and allowing for adequate healing secondary to IAN or sinus complications.[333]

Inferior alveolar nerve injury

Sensory nerves are extremely sensitive to physical, radiation, chemical, thermal and ischemic damage. Despite their capacity to heal, if the injury causes sufficient damage, then persistent posttraumatic sensory neuropathy will result. The presenting symptoms of sensory neuropathy include; a neuropathic area within the dermatome where the surgery or injury took place,[259] allodynia (pain to touch or cold), hyperpathia (continued pain or altered sensation after stimulus removed), hyperalgesia (increased pain to a painful stimulus for example exaggerated response to sharp blunt discrimination test despite ongoing numbness). Additional clinical symptoms may include ongoing, spontaneous and/ or elicited altered sensation

Telegram: @dental_k

www.konkur.in

(paraesthesia or dysesthesia), a tingling or formication (ants crawling on the skin), burning or shooting pain or electric shock. The sensory deficit to mechanical function indicates damage to larger myelinated fibers, whereas sensor deficit to noxious and thermal stimuli indicates damage to small diameter afferent fibers of the spinothalamic tract.[256]

Clinicians must use appropriate medical language and not refer to sensory neuropathy as 'paraesthesia' which is a clinical sign and not a diagnosis. Generally, neurologists refer to either hypoesthetic (predominantly anesthetic [numb] with reduced mechanosensory function) or hyperesthetic (ongoing, spontaneous and/or elicited pain or dysesthesia) sensory neuropathies. Posttraumatic neuropathic pain (PTNP) is a recognized neurologic diagnosis (ICOP).[154a]

Iatrogenic trigeminal nerve injuries remain significant and complex clinical problems. The impact on the patient of posttraumatic sensory neuropathy can be functionally and psychologically severe, particularly when painful and iatrogenic. The trigeminal nerve underpins our very existence, providing sensory protection to our eyes, nose, mouth and brain. Thus the affective and emotional reaction to the threat or experience of trigeminal pain is thus proportionally immense. Altered sensation and pain in the orofacial region may interfere with speaking, eating, kissing, shaving, applying make-up, tooth brushing and drinking—in fact, just about every social interaction we take for granted. Thus these injuries have a significant negative effect on the patient's quality of life and the iatrogenesis of these injuries lead to significant psychological effects.[308] The management of patients with posttraumatic sensory neuropathy is complex and 'curative' treatment is unavailable, thus prevention of these injuries is paramount. Trigeminal nerve injury is the most challenging consequence of contemporary dental surgical procedures with significant medical-legal repercussions (see also Chapter 27).[46] An approximate estimation places the incidence if IAN injury at 5%, with approximately one third of these patients afflicted with neuropathies, including neuropathic pain.[262] Common causes of injury to the IAN are listed in Box 20.2.[258]

Box 20.2

Common Causes of Damage to the Inferior Alveolar

Telegram: @dental_k

www.konkur.in

Nerve

1. Local anesthetic injections
2. Third molar surgery
3. Implants
4. Endodontics (extrusion of the materials used in endodontic treatment, overinstrumentation, elevated temperatures)
5. Ablative surgery
6. Trauma
7. Orthognathic surgery

The highest incidence of reported damage to the inferior alveolar and lingual nerves is associated with third molar extractions.[18,140,141] Local anesthesia was the second most common cause of nerve injury, and its exact mechanism can be confusing. It may be physical (needle damage, epineural/perineural hemorrhage) or chemical (local anesthetic contents). Reports have implicated certain local anesthetics of high concentrations (prilocaine 4% and articaine 4%) with IAN neuropathies (see also Chapter 6).[17,131,142,248] A relatively small percentage of IAN injury cases (8%) are associated with an endodontic procedure.[261]

IAN damage has been suggested to occur in up to 1% of mandibular premolars that receive root canal treatment.[87] In one retrospective study examining cases of paraesthesia related to endodontic treatment of mandibular premolars, the incidence was 0.96% (8/832).[172] In a survey of 2338 patients, 7% sustained chronic neuropathic pain after a single endodontic procedure.[170] Most reports of endodontic-related nerve injuries are case reports with very little analysis of the clinical impact for the patient, risk factors, or management issues. To date, there are four case series reports on inferior alveolar nerve injuries (IANIs) related to root canal treatment (RCT) including 61 cases,[246] eight cases,[172] four cases,[292] and one case series reported on the treatment of 11 cases.[121] These case series predominantly focus on the outcomes surgical exploration and irrigation of damage nerves.

The mechanisms of sensory neuropathy are complex, and they are likely not only due to mechanical damage including perforation or compression. Pogrel[247] concluded that the severity of the injury was proportional to the

Telegram: @dental_k

www.konkur.in

process by which the injury was created, and these processes included scalpel blade wounding/transection, crushing, and stretching damages. These would be analogous to the dissection and reflection of the flap, improper retraction location/application, and postoperative edema. However, endodontics is complicated with use of chemicals and fillers that provide additional risk of nerve injury. It is likely that chemical (pH of dental materials), ischemia, hemorrhage (the iron in hemoglobin irritates nerve tissue), and thermal factors may compound the nerve injury resulting in persistent neuropathy. Compression of peripheral sensory nerves over 6 hours can evoke nerve fiber atrophy.[298] Ischemia alone without direct nerve damage will cause sufficient neural inflammation and damage to cause permanent nerve injury within only 6 hours.[230] The IAN may be damaged when an increase in temperature proximal to the IAN is greater than 10°C.[87] The type of sealer cement used may influence the symptoms of IAN damage.[216]

The three primary factors responsible for IAN damage during endodontic treatment are as follows:

1. Chemical toxicity and mechanical pressure produced by leakage of sealers into areas close to the mandibular canal are other potential mechanisms for nerve injury related to endodontic procedures, with the IAN and mental nerve being most affected. Cytotoxic materials employed either in the preparation (e.g., irrigation liquids, intracanal medicaments)[2,109] or the obturation of the canal space[277] as the materials most commonly associated with these complications are those containing paraformaldehyde.[3] In addition, most endodontic materials have very high pH levels, resulting in immediate nerve damage likely to be permanent (Fig. 20.38).[37]
2. Mechanical factors: repeated insertions of endodontic instruments through the apex into the IAN and surrounding tissues[70]
3. Thermal factors: inappropriate/prolonged heat application[89]

Risk assessment for the prevention of endodontic nerve injury

Preoperative assessment is crucial in prevention of nerve injury related to endodontics (Box 20.3). Prevention is the key to successful treatment. Damage, either directly to the IAN or to the vessel(s) that nourish it, will result in sensory events that may be transient or permanent. Pretreatment radiographic assessment using periapical images is mandatory; in critical cases, CBCT may be more appropriate and precise in establishing proximity (Fig. 20.39). Assessment should include the following:

- Proximity of the apex of the tooth to the IDC. Lower molar teeth where root apices are is close proximity to the Inferior dental canal and or mental foramen. Mandibular second molars are most commonly associated with this population, but cases involving treatment of mandibular first molars and premolars have also been

Telegram: @dental_k

www.konkur.in

reported.[172] Careful consideration should also focus on the distance between the root apices and the mandibular canal. For mandibular first molars, this distance varies between 1 and 4 mm, and for mandibular second and third molars, the distance can be less than 1 mm.[334] With mandibular premolars, the proximity of a mental foramen should always be considered.[219] In addition, a study using CBCT has shown that the mesiobuccal root apex of maxillary second molars is frequently in very close proximity with the sinus floor (see Fig. 20.39).[228]

- Tilotta-Yasukawa and colleagues (2006) determined the proximity of the apex of the premolars and molars in relation to the mandibular canal, as well as the relationship between the IAN and its corresponding artery, with the goal of understanding how endodontic filling material spreads through the bone to penetrate the mandibular canal. They observed that the distance between the dental apex and the mandibular canal was more variable (and generally greater) for the first molar than for the second and third molars (1 to 4 mm vs. <1 mm [35 cases in 40 mandibles examined]). The presence of bone between the apices and the IAN canal does not necessarily protect against injury to the nerve. Research has provided an enlightening explanation to this puzzle (Figs. 20.40–20.42).[334] Using fresh cadaver specimens (mandibles), researchers examined the true anatomic relationship among the root apices, IAN, and the artery. They drew the following conclusions:
  - There was never any compact layer of cortical bone surrounding the mandibular nerve sheath. In some cases, a slightly denser cancellous bone was found, but it was replete with multiple perforations that would not afford significant resistance to penetration.[137]
  - The proximity of the IAN canal to the apices of the second molars was < 1 mm, and it was more variable (1 to 4 mm) with first molars. This could explain the higher percentages of paresthesias reported with these teeth.
  - The mandibular artery ran along the superomedial side of the IAN up to the first molar, and then crossed on the upper side

Telegram: @dental_k

www.konkur.in

until the mental foramen. Perforation of this vessel, with the concomitant hemorrhage exerting pressure on the pedicle, could feasibly produce a paresthetic event via the resulting ischemia.[71]

- Only with root apices in direct contact with the IAN canal were extrusions able to penetrate the nerve. If cancellous bone was interspersed between the apices and pedicle, the spread of the extrusion through the trabeculations remained at the periphery of the sheath.
- The low density of trabeculations and presence of numerous vacuoles provided an avenue for the diffusion of extruded irrigation fluids and obturation materials toward the IAN bundle. In a tooth with apical resorption, the foramen is frequently enlarged[363]; these two factors in concert could explain the occurrence of sensory symptoms in the absence of clinical or radiographic signs of overexpression or close proximity to the mandibular nerve.

- Predisposing radiological factors that may indicate a higher risk of an adverse incident during root canal treatment or cause an extrusion of endodontic filler/hypochlorite accident
  - Resorption defects where extent is not identified, such as internal/external communicating with root canal and external surface of the root
  - Suspicion of a perforation communicating with the external root surface
  - Root fracture where there could be a potential communication of the root canal with external root surface
  - Sclerosed root canal
  - Dens invaginatus
  - Presence and the diameter of bone lesions of endodontic origin may also influence the occurrence of paraesthesia, especially when associated with the premolars and lower molars.[176]

Box 20.3

Key Points for Prevention of Nerve Injury Related to Endodontics

- Aways assess the proximity of the tooth apex to the inferior alveolar nerve (IAN).
- Always assess additional risk factors in root morphology and bone factors contributing to leakage of chemicals adjacent to the IAN.
- Take all the steps to minimize the apical breach during endodontic treatment if any of the previous risk factors exists. This will allow leakage of high pH chemicals into the IAN, rendering permanent chemical damage to the IAN.

Telegram: @dental_k

www.konkur.in

- Consider immediate extraction of the tooth and generous lavage of the socket along with adjunctive medical treatment (described in this chapter) if the patient develops sensory neuropathy within 3 days of endodontic treatment.

Operative techniques to minimize nerve injuries

Surgical endodontic procedures need to be designed to minimize trauma to nerves including the IAN, mental nerve, and mental foramen. Although the mental foramen is most often located apically to the second premolar,[217,241,242,243] it can vary in anterior-posterior locations,[162,220] coronal-apical locations,[95] and number.

Careful presurgical assessment via radiographs and CBCT provides critical information on the size, location, and spatial relation of the planned surgery to nearby trigeminal nerves.[32] Before exiting the mandibular canal, the nerve often loops anteriorly, then superior and posteriorly in the apical portion of the premolar region.[119] If an apical procedure is planned in an area commensurate with this anatomic variant, then CBCT is warranted and strongly advised.

Controlled reflection of the tissue overlying the suspected location of the foramen will diminish the incidence of transection. Cautious reflection of the flap will reveal evidence of tissue “funneling” at its base (Fig. 20.43); this is the telltale sign of the exiting nerve bundle.[221] This exiting tissue, upon discovery, can be marked with a dot of gentian violet or methylene blue dye. By highlighting it in this fashion, the surgeon can avoid unintentional impingement with a retractor. The tissues should be minimally distended and the underside of the flap kept well hydrated.

Source: (From Tilotta-Yasukawa F, Millot S, El Haddioui A, et al: Labiomandibular paresthesia caused by endodontic treatment: an anatomic and clinical study. *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 102:e47, 2006.)

Prevention of over instrumentation: Every attempt should be undertaken to confine the instrumentation and irrigation processes to within the canal space; damage from extrusions can be chemical or mechanical in origin,[292] and toxic products can easily diffuse through the trabecular spaces and vacuoles surrounding the nerve bundle. This latency in diffusion, and the potential onset of paresthetic symptoms, dictates close monitoring for 72 hours postoperatively in cases where extrusion is apparent.[246]

Prevention of over filling with beyond apex extrusion of filler or treatment chemicals: Any tooth requiring endodontic therapy, which is in close proximity to the IAN canal, should require special attention, including: NaOCl (as irrigation) and calcium hydroxide (as sealant; calcium hydroxide medicaments breach the canal roof, precipitating a vascular bleed resulting in hemoglobin irritation of the nerve due to the iron content).[31,87]

Prevention of thermal injury: Imprudent heat application during

Telegram: @dental_k

www.konkur.in

thermoplastic compaction of gutta-percha may also lead to IAN injury.[31]

The clinician must be aware and record any events that may indicate operative nerve injury, including extreme pain during LA IDB, canal instrumentation, irrigation, medication, or filling; and sudden and profuse hemorrhage arising from the apex of the tooth

Appropriate postoperative periapical radiographs must be taken, in accordance with endodontic clinical guidance, to check for any extrusion of dressing or filling materials into the inferior dental canal or around the mental foramen.

Home check should be undertaken, particularly for high-risk cases, to assess signs of persistent or new neuropathy.

Management of nerve injuries

The priority in management of patients with iatrogenic nerve injuries is for them to understand what has happened, the likely prognosis and possible support, and medical or surgical interventions. Management should be holistic and of the patient with the nerve injury and not just the neuropathy itself.[261] Pain, functional problems, and psychological impact should be assessed using questionnaires.[82] Grötz and colleagues[121] reported on 11 patients with endodontic-associated neuropathy and their management, reporting that the neurologic findings were dominated by hypoaesthesia and dysesthesia, with 50% of patients reporting pain. Initial x-rays showed root filling material in the area of the mandibular canal. Nine cases were treated with apicectomy and decompression of the nerve: in two cases, extraction of the tooth was necessary; only one patient reported persistent pain after surgery.

It is important to recognize that IANI can occur due to local anesthetic block injections and the clinician can often discriminate between endodontic and local anesthesia-caused nerve injuries by careful questioning and careful clinical neurologic assessment. Mapping of the neuropathic area will discriminate between inferior dental block (IDB) and endodontic nerve injury (Figs. 20.44 and 20.45).[49]

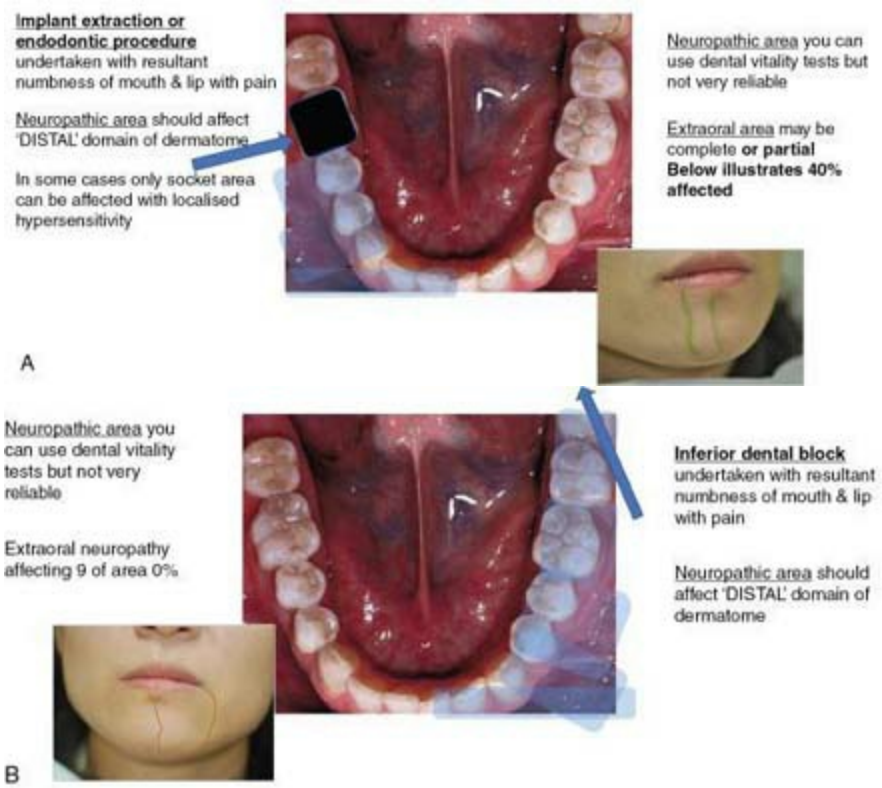

FIG. 20.45 **A,** Nerve injury proximal to endodontically treated tooth. Cause = endo. **B,** Inferior dental block nerve injury initially will cause neuropathy of the whole dermatome.

A) Close-up view of lower jaw shows highlighted teeth in lower right side. Text reads: Implant extraction or endodontic procedure undertaken with resultant numbness of mouth & lip with pain.

Neuropathic area should affect 'DISTAL' domain of dermatome. In some cases only socket area can be affected with localized hypersensitivity. Neuropathic area you can use dental vitality tests but not very reliable. Extraoral area may be complete or partial Below illustrates 40 percent affected. Close-up view of lower mouth highlights the region with U-shaped outline below lower right teeth.

B) Close-up view of lower jaw shows highlighted teeth in lower left side. Text reads: Neuropathic area you can use dental vitality tests but not very reliable. Extraoral neuropathy affecting 9 of area 0 percent. Inferior dental block undertaken with resultant numbness of mouth and lip with pain. Neuropathic area should affect 'DISTAL' domain of dermatome. Close-up view of lower mouth highlights the region with wide U-shaped outline below left right teeth.

Diagnosis is based upon the signs and symptoms described earlier in this section. Posttraumatic sensory neuropathy is a clinical diagnosis and

Telegram: @dental_k

www.konkur.in

knowledge of the preoperative risk along with the posttreatment radiographs should be sufficient in confirming the diagnosis. Further radiographic assessment, especially CBCT, may be useful in revealing the extent of location of extruded materials in relation to the mandibular canal or the maxillary sinus) but is unlikely to improve treatment outcome.[31,103,113] Chemical nerve injury may not be obvious radiographically: If the patient is suffering from neuropathy after the local anesthetic has worn off and the postoperative radiographs confirm that there is no radiopaque material in the canal, chemical nerve injury may be presumed

Transient paresthesia may occur in cases where a protracted surgical procedure, inadvertent stretching, or excessive postoperative edema has occurred. Appropriate reevaluation appointments include neurosensory testing and mapping the outline of the sensory deficit. Return of sensation within the first few weeks indicates a neuropraxia and may indicate prognosis but cannot predict full recovery. It is not possible to distinguish between temporary or permanent nerve injuries early postoperatively, thus treatment must be based upon the patient's symptom severity, the extent of neuropathy, and the evidence of injury (recent treatment and radiographic overfill). Timing of intervention is paramount and ideally high-risk patients should be followed up for 24 to 60 hours post endo to check for onset of symptoms of neuropathy.

Assessment

The patient must be assessed for pain, functional limitations, and psychological impact. Further confirmation of the neuropathic area and mechanosensory testing is important to establish the extent and symptoms of the neuropathy. The patient must be assessed holistically, including their history of the event and if it is related to the initiation of pain.[261] Ensure that the pain history excludes preexisting neuropathic pain, including the following:

- Severe pain during procedure (funny bone pain)
- High-level postsurgical pain (indicative of nerve injury)
- Ongoing pain, altered sensation, and/or numbness
- Functional problems

Telegram: @dental_k

www.konkur.in

- Psychological issues. Important questions about the mechanism and duration of the neuropathy will drive the timing and type of management.[260]

Necessary investigations include:

- Radiological: LCPA; CBCT necessary posttrauma
- Neurosensory to confirm that the presence of a neuropathy and distribution correlates with potential nerve injury
- Diagnostic local anesthesia blocks may be useful in evaluating the potential of some peripheral pain management strategies when medical management is unsuccessful.

Recent developments of medical resonance neurography may enhance the ability of the clinician to assess the trigeminal nerve injury early postoperatively, allowing for earlier surgical intervention, if required.[375]

Immediate intervention

If nerve section or severe injury is known or suspect, likely due to scalpel or drill, then immediate repair must be undertaken. If the transected ends are closely approximated following the injury, either naturally or surgically, proliferating axons will attempt to bridge the gap and, if they find a perineural tube to populate, gradually restore function. However, in cases where the gap is beyond a critical length, a neuroma may develop at the proximal end. Neuromas consist of dense fibrous tissue intermingled with nerve fascicles, with a disproportionate proliferation of unmyelinated fibers. Treatment, if initiated within 3 months of the initial event, often entails resection of the neuroma and repair by tension-free anastomosis or nerve grafting.

Early intervention

If the patient exhibits neuropathic signs during instrumentation (severe neuralgia) or after the local anesthesia has worn off, posttreatment radiographs should be reevaluated to observe the possibility of any obturation material extending into the IAN canal. Devine et al.[72] reported that there may

Telegram: @dental_k

www.konkur.in

be delayed development of sensory neuropathy, usually 2 to 3 days, likely due to chemical leakage through the treated tooth apex, resulting in chemical nerve injury which will not be apparent on a posttrreatment radiograph. Three months after the IAN injury, permanent central and peripheral changes occur within the nervous system subsequent to injury, which are unlikely to respond to surgical treatment intervention.[367]

There is a strong correlation between duration, origin, significance of the injury, and the prognosis for resolution of the paresthesia. The longer the irritation persists, either chemical of mechanical, the more fibers are involved in a degenerative process and the more likely the paresthesia will become permanent.[284] If injury to the nerve is demonstrated by postoperative neuropathy and posttreatment radiographs (not for chemical leakage) confirm the presence of a significant extrusion or overinstrumentation into the IAN canal, management entails the surgical removal of the offending material as soon as possible if the patient is symptomatic.[246,258,262]

Management should be performed by immediate removal of endodontic materials within 24 to 48 hours via periapical surgery, tooth extraction, or surgical debridement, whichever will be the most effective option with the least potential damage to the IAN.[75,178,246,258] If the patient wishes to retain the treated tooth and overfill is present in the inferior dental canal (IDC), then immediate mandibular buccal corticotomy under general anesthesia may be advised, with removal of overfill and hours of neural lavage with saline.[245a]

However, in spite of the best efforts to eliminate the causative agent, the symptoms may persist because of the associated chemical damage to the nerve. If sensory improvement has not been evident after 2 months, with or without repair during interventional surgery, then the prognosis for recovery is poor, and steps should be taken to alleviate the patient's concerns through counseling and systemic medications for chronic pain.[261]

Counseling and medical therapeutic management are indicated within 48 hours for injuries caused by endodontic treatment or local anesthetic injections.[99]

Watch and wait?

If the patient presents with a minimal neuropathic area which is tolerable and hyposensitive (nonpainful) then intervention may not be justified. Decisions

Telegram: @dental_k

www.konkur.in

about intervention have to be based on the patient's understanding of the risks and benefits. Although the prognosis in the case of the IAN damage caused by resorbable or inert material is favorable, as it is dissolved over time, the toxicity of the material, whether chemical or pH, may cause permanent damage if left in place.[222] In addition, pressure from the material on the IAN may be caused by a hematoma or inflammatory, which can also contribute to temporary or permanent IAN damage.[90,222] The prognosis of the IAN damage depends on the severity of the direct injury to the nerve, the toxicity of the irritant, the amount and speed of its resorption, and how rapidly the causative agent is removed.[222,226,246] Because the paresthesia can be of both a mechanical and a chemical nature, removal of the excess material might not be sufficient if the nerve fibers have already undergone degeneration from a chemical irritant. Nevertheless, paresthesia caused by an instant irritation of the nerve, like a minor overinstrumentation or swelling from infection or minor inflammation, usually subsides within days. If no signs of healing are observed within 3 to 6 months, the chances of healing are considered much lower, although normal sensory function might still return after this time.[113,334]

If the opportunity for immediate repair or early decompression has been missed, then the patient must be treated therapeutically, which may include medical and psychological interventions.

Psychological interventions may include counseling, mindfulness, acceptance, and commitment as well as cognitive behavioral therapies for patients with nerve injuries, which is very effective (there is limited evidence for success of this treatment for endodontic-related IANIs, but evidence does support psychological therapies for chronic pain and IANIs).[261]

Early medical management to minimize acute surgical neural inflammation using protocols undertaken for other acute sensory nerve injuries (Gatot, Tovi, 1986; Grötz et al., 1998). Steroids may maximize recovery of peripheral nerve injury (evidenced in spinal nerve injuries) using prednisolone (15 mg for 5 days, 10 mg for 5 days, and 5 mg for 5 days) and high-dose nonsteroidal antiinflammatory drugs (NSAIDs) (600 mg ibuprofen) as long as the patient has no contraindications to NSAIDs (gastric or peptic ulceration or allergy to NSAIDs) and a timely referral is made to an appropriately trained oral or maxillofacial microsurgeon. If the opportunity

Telegram: @dental_k

www.konkur.in

for early repair is missed, long-term therapeutic pain management will be necessary.[197a] Vitamin B complex and magnesium supplements may have some beneficial effects for neural recovery. Antibiotics are not recommended for nerve injuries unless infection related neuropathy is suspected but, in these cases, the tooth should be endodontically treated or extracted.

Regarding late medical management of chronic pain associated with endodontic treatment. Oshima[225] reported that 16 out of 271 patients presenting with chronic orofacial pain were diagnosed with chronic neuropathic tooth pain subsequent to endodontic retreatment. Most of these patients were treated for maxillary teeth. Seventy percent of the patients responded to tricyclic antidepressant therapy, which highlights the importance of establishing whether the patient has neuropathic pain. In Renton and Yilmaz's study,[261] all the patients presented too late for surgical decompression or it was not indicated. Thus two patients were managed with oxcarbazepine for neuralgic pain elicited with touch or cold and with topical clonazepam intraorally to manage the severe gingival discomfort. Two patients were prescribed topical 5% lidocaine patches (12 hours on nocte and 12 hours off daily) for debilitating mechanical allodynia in the extraoral dermatome of the IAN, causing pain and functional problems. This is a treatment used successfully for patients with chronic orofacial pain, particularly those with mechanical or cold allodynia of the face.

Recommendations for the treatment of neuropathic pain are reported; Medical guidance is provided by Alonso-Ezpeleta et al.[9] Surgical intervention using direct repair or allograft cadaveric grafts has limited impact on trigeminal neuropathic pain,[376] and other interventions for neuropathic pain have been summarized.[77] Overall, the management of neuropathic pain remains unsatisfactory in that the side effects of medications are significant. Recent reports of Botoxin A and Lidocaine patches may improve the patients' quality of life with a low evidence base, but most importantly, acknowledgement and holistic support for the patient with iatrogenic nerve injuries must not be underestimated, and the prevention of these nerve injuries is paramount.

Cervicofacial subcutaneous emphysema

Telegram: @dental_k

www.konkur.in

Subcutaneous emphysema is defined as the penetration of air or other gases beneath the skin and submucosa, resulting in soft-tissue distention. A specific type, termed *cervicofacial subcutaneous emphysema* (CFSE), is a relatively rare occurrence and may be limited to traumatic, iatrogenic, or spontaneous events.

The first recorded instance was reported by Turnbull in 1900.[342] It details the account of a musician inducing CFSE by playing his bugle immediately after the extraction of a mandibular tooth; the subsequent swelling resolved a few days after he ceased playing the instrument. Indeed, most early reports of CFSE usually follow tooth extractions and were the result of activities the patient engaged in that raised intraoral pressures.[300] With the introduction of air-driven handpieces, there was an increased risk of CFSE.[11,67,370] Although tooth extraction, especially of mandibular third molars, remains the most commonly reported reason for CFSE,[53,67,145,276,366,370] it can also result from restorative treatment,[52,104,158,320,344] periodontal surgery,[99,309] crown and bridge treatments,[116,374] and root canal therapy.[29,149,161,237,323,344,361]

Compressed air, delivered through an air syringe, a high-speed handpiece, or a combination of the two during the operative procedure is associated with 71% of the cases.[139] A more recent study[14] reviewing 47 computed tomography (CT)–documented cases of CFSE found the exclusive cause was the high-speed handpiece in 66% of these patients. Other means of introducing air into the facial spaces include the following:

- Use of the dental laser (Er:YAG) in the gingival pocket: compressed air is used to cool the tip but is of sufficient pressure to dissect the sulcular wound.[208]
- Hydrogen peroxide beyond the canal space: most often reported when the fluid is introduced through a perforation in the canal[29] or overinstrumented apex.[161]
- Lack of rubber dam isolation: a compressed air syringe was implemented to increase visibility in these molar retreatments, with air infiltration through the gingival sulcus.[76,169]
- Barotrauma secondary to Boerhaave syndrome: spontaneous rupture of the distal esophagus as a result of intractable vomiting, causing an increase in intraluminal esophageal pressure.[123]

Telegram: @dental_k

www.konkur.in

The deposition of air beyond the canal space is a function of both the diameter of the canal at the apex[81] and the position of the syringe tip.[307] An air emphysema has the potential to spread along the facial planes in a similar manner (Figs. 20.46 and 20.47). Air entering the parapharyngeal and retropharyngeal spaces can lead to soft-tissue infections,[91] airway compromise,[263] optic nerve damage,[41] and even death.[68,264] The majority of the cases, however, present as a soft, skin-colored swelling without redness that occurs during or shortly after the dental appointment. The cervicofacial swelling is always associated with crepitus (a crunchy feeling to the tissues upon palpation), which may not be palpable before a latency period of several hours. The more serious presentation of pneumomediastinum is characterized by dyspnea with a brassy voice, chest or back pain, and Hamman sign (a bubbling or crunching sound caused by air or movement accompanied by cardiac pulsation).[130] Secondary complications such as pyogenic mediastinitis or necrotizing fasciitis must be considered, and appropriate means taken to evaluate and manage them (blood cultures, broad-spectrum intravenous antibiotics).[76] Differential diagnosis should include an allergic reaction (more pronounced dermal signs prior to cardiac/respiratory symptoms), hematoma (a rapid accumulation of fluid without initial discoloration and without crepitation), and angioneurotic edema (a defined, circumscribed area of edema, often preceded by a burning sensation in the mucous membranes or skin).[99]

FIG. 20.46 **A,** Facial presentation after the rubber dam was removed. **B,** Close-up view reveals marked distention of the left suborbital region,

Telegram: @dental_k

www.konkur.in

with ptosis of the eye and loss of the nasolabial fold. There was marked crepitus upon palpation, but the patient was pain-free. **C,** She was placed on an antibiotic regime, as per the protocol, 2 days after the incident, the emphysema has resolved and the tissues are normal in color and texture.

A) Close-up view shows the front view of face with swollen under eye and soft tissue on left eye lid.

B) Close-up view shows the left side of patient's face with swollen under eye and soft tissue on left eye lid.

C) Close-up view shows the normal left eye of patient.

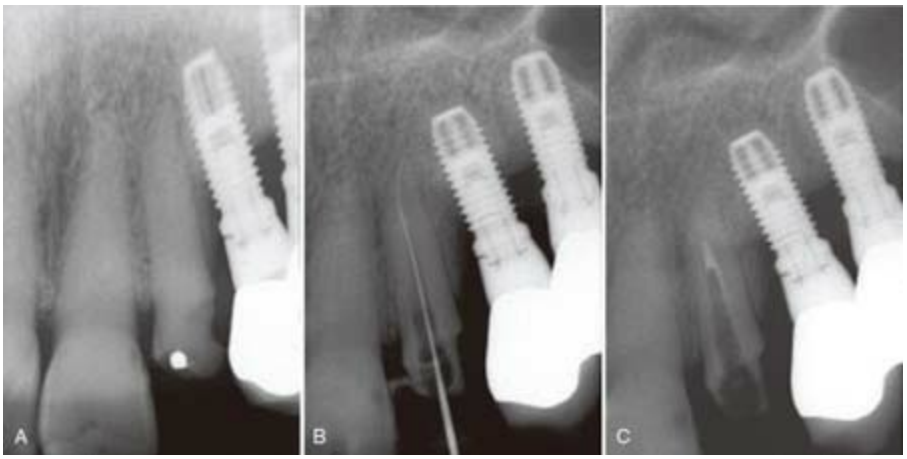

FIG. 20.47 **A,** Preoperative radiograph tooth #10[158]; dystrophic calcification has obliterated the pulp chamber and the coronal half of the canal space. **B,** A #10 file inserted to estimated working length; the file is actually through a facial perforation of the root at the radicular extent of the ultrasonic excavation. Repeated drying of the canal space using an air syringe forced air through the perforation site and precipitated the emphysema seen in Fig. 20.26, *A* and *B*. **C,** The radicular perforation site was sealed with mineral trioxide aggregate (MTA) before the canal space was obturated. The tooth has remained asymptomatic since the incident.

Three radiographs are marked A through C.

A) The central tooth has a radiopaque circular spot and broken edge on one side of the crown.

B) The tooth has radiolucent patch extending from the crown to below the chamber and a file is properly inserted into the tooth.

Telegram: @dental_k

www.konkur.in

C) The tooth has radiolucent crown and root canal. The root tip is filled.

Treatment is largely empirical and is dependent on the extent of the CFSE. Antibiotics are usually prescribed due to the nonsterility of the air supply and the possibility of necrotic debris or microorganisms forced into surrounding tissues.[263] Administration of 100% oxygen via a non-rebreather mask is reported to hasten the resolution of the emphysema because the oxygen, which replaces the trapped air, is more readily absorbed at the site.[169] More severe presentations warrant hospitalization with intravenous antibiotics, where the extent and regression of the CFSE can be closely monitored using CT scans and complications can be managed more effectively.[36] Resolution, barring any severe complications, is characteristically rapid and uneventful, with the patients returning to their normal appearance within 4 to 7 days. A reevaluation of the cause of the emphysema should be examined and corrected before treatment resumes, especially in instances of a perforation.

From an endodontic perspective, minimizing compressed air at the site, from either a high-speed handpiece or an air syringe, is key to preventing this consequence. Isolation with a rubber dam, the use of paper points or high-volume aspiration for drying canal spaces, and avoiding the use of hydrogen peroxide during the procedure will also reduce the risk of introducing or entrapping air beneath the overlying tissues. For endodontic microsurgery, the use of a rear-exhausting high-speed handpiece for root resection as well as ultrasonics for root end preparation would decrease the likelihood of precipitating a CFSE during root end procedures.[19]

21: The role of endodontics after dental traumatic injuries

Bill Kahler*

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Telegram: @dental_k

www.konkur.in

Telegram: @dental_k

www.konkur.in

A traumatic injury to the tooth results in damage to many dental and periradicular structures, making the management and consequences of these injuries multifactorial. Knowledge of the interrelating healing patterns of these tissues is essential. This chapter concentrates on the role of the dentinopulpal complex in the pathogenesis of disease subsequent to dentinal trauma and how treatment of this complex can contribute to favorable healing after an injury.

Unique aspects of dental trauma

Most dental trauma occurs in the 7- to 12-year-old age group and is mainly due to falls and accidents near home or school.[28,165] It occurs primarily in the anterior region of the mouth, affecting the maxillary more than the mandibular jaw.[33] Serious accidents, such as automobile crashes, can affect any tooth and can occur in all age ranges. In many cases, after a traumatic dental injury, endodontic treatment is provided to caries-free, single-rooted, young permanent teeth. If quick and correct treatment for these teeth is provided after injury, the potential for a successful endodontic outcome is very good.

Telegram: @dental_k

www.konkur.in

Most common types of dental trauma

Crown fractures

Most crown fractures occur in young, caries-free anterior teeth.[109,128] This makes maintaining or regaining pulp vitality essential. Luckily, vital pulp therapy supports a good prognosis in these situations if correct treatment and follow-up procedures are carefully followed.

Crown-root fractures

Crown-root fractures are first treated periodontally to ensure that there is a sufficient and good margin to allow restoration. If the tooth can be maintained from a periodontal point of view, then the pulp is treated as for a crown fracture.

Root fractures

A surprisingly large number of pulps in root-fractured teeth will survive this rather dramatic injury. In almost every case, the apical segment stays vital, and in many cases, the coronal segment stays vital or regains vitality subsequent to the injury. If the coronal segment permanently loses vitality, it should be treated as an immature permanent tooth with nonvital pulp. *The apical segment rarely needs treatment.*

Luxation injuries and avulsion

Luxation injuries and avulsion often result in pulp necrosis and damage to the cemental protective layer of the root. The potential complication of pulp infection in a root that has lost its cemental protective layer makes these injuries potentially catastrophic. Correct emergency and follow-up evaluation, which may include timely endodontic treatment, is critical.

Follow-up after dental trauma

The reader is referred to Chapter 1 for specific descriptions of pulp tests, but a few general statements about pulp tests on traumatized teeth may be helpful in trying to interpret the results.

Telegram: @dental_k

www.konkur.in

For decades, controversy has surrounded the validity of thermal and electric tests on traumatized teeth. Only generalized impressions may be gained from these tests following a traumatic injury. They are in reality sensitivity tests for nerve function and do not indicate the presence or absence of blood circulation within the pulpal space. It is assumed that subsequent to traumatic injury, the conduction capability of the nerve endings and/or sensory receptors is sufficiently deranged to inhibit the nerve impulse from an electrical or thermal stimulus. This makes the traumatized tooth vulnerable to false-negative readings from such tests.[146]

Teeth that give a response at the initial examination cannot be assumed to be healthy and to continue to give a response over time. Teeth that yield no response cannot be assumed to have necrotic pulps because they may give a response at later follow-up visits. It has been demonstrated that it may take as long as 9 months for normal blood flow to return to the coronal pulp of a traumatized fully formed tooth. As circulation is restored, the responsiveness to pulp tests returns.[81]

The transition from a negative response to a positive response at a subsequent test may be considered a sign of a healing pulp. The repetitious finding of responses may be taken as a sign of a healthy pulp. The transition from a response to no response may be taken as an indication that the pulp is probably undergoing degeneration, and therefore an intervention in the form of endodontic treatment might be indicated. The persistence of no response would suggest that the pulp has been irreversibly damaged, but even this is not absolute.[39]

Thermal and electrical pulp tests of all anterior teeth (canine to canine) of the maxillary and mandibular jaws should be performed at the time of the initial examination and carefully recorded to establish a baseline for comparison with subsequent repeated tests in later months. These tests should be repeated at 2 to 4 and 6 to 8 weeks; at 3, 6, and 12 months; and at yearly intervals after the trauma (according to the guidelines of the American Association of Endodontists). The purpose of the tests is to establish a trend as to the physiologic status of the pulps of these teeth. Particularly in traumatized teeth, carbon dioxide snow (CO_2, −78°C) or dichlorodifluoromethane (−40°C) placed on the incisal third of the facial surface gives more accurate responses than a water-ice pencil (Fig. 21.1).[79,80]

Telegram: @dental_k

www.konkur.in

The intense cold seems to penetrate the tooth and covering splints or restorations and reach the deeper areas of the tooth. Neither the dry ice nor the dichlorodifluoromethane spray forms ice water, which could disperse over adjacent teeth or gingiva to give a false-positive response. In trauma evaluation, there is no question that using water-ice pencils should be avoided because of this. Dichlorodifluoromethane spray is a very inexpensive alternative to CO_2 snow; its coldness elicits much more reliable responses than water-ice. The electrical pulp test relies on electrical impulses directly stimulating the nerves of the pulp. These tests have limited value in young teeth but are useful when the dentinal tubules are closed and do not allow dentinal fluid to flow in them. This situation is typical of teeth in elderly patients or in traumatized teeth that are undergoing premature sclerosis. In these situations, the thermal tests that rely on fluid flow in the tubules cannot be used, and the electrical pulp test becomes important.

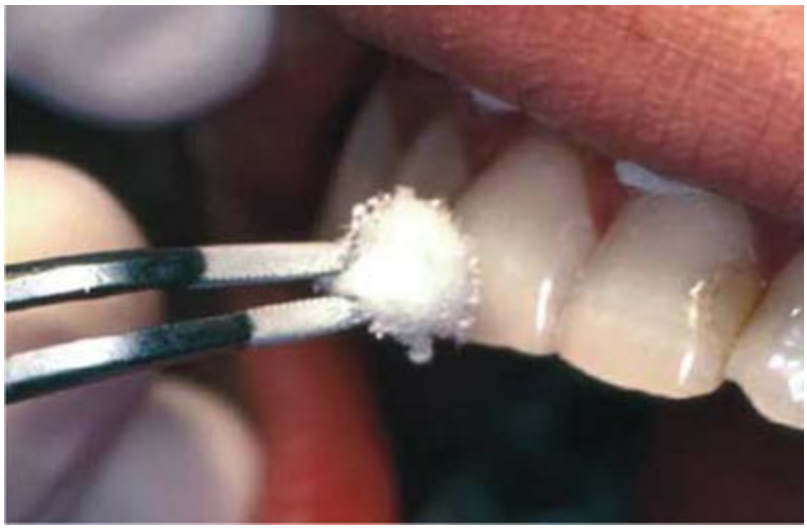

FIG. 21.1 Dichlorodifluoromethane (−40°F [−40°C]) gas is sprayed on a cotton pellet and then placed on the incisal edge of the maxillary incisor.

Close-up view shows gloved hands placing the cotton pellet using forceps on the upper front tooth.

Laser Doppler flowmetry (LDF) was introduced in the early 1970s for measurement of blood flow in the retina.[102] The technique has also been used to assess blood flow in other tissue systems, such as the skin and renal cortex.

Telegram: @dental_k

www.konkur.in

It uses a beam of infrared (780 to 820 nm) or near-infrared (632.8 nm) light that is directed into the tissue by optical fibers. As light enters the tissue, it is scattered by moving red blood cells and stationary tissue cells. Photons that interact with moving red blood cells are scattered, and the frequency shifts according to the Doppler principle. Photons that interact with stationary tissue cells are scattered but not Doppler shifted. A portion of the light is returned to a photodetector, and a signal is produced (Fig. 21.2).

FIG. 21.2 Laser Doppler machine.

DRT4, Laser Doppler Monitor manufactured by moor instruments shows a display at the center with controls on left and right.

Source: (Courtesy Moor Instruments, Devon, United Kingdom.)

Attempts have been made to use LDF technology for pulp vitality diagnosis in traumatized teeth because this would provide a more accurate reading of the vitality status of the pulp.[136,196,197] Studies have shown promising results, indicating that laser Doppler can detect blood flow more consistently and earlier than the standard vitality tests would be expected to render a response. In a study on young dogs, laser Doppler was able to correctly detect blood flow as early as 2 to 3 weeks after avulsion of an immature tooth and at the same time indicate no flow in those that would remain necrotic.[197]

Presently the cost of an LDF machine limits its use in private dental

Telegram: @dental_k

www.konkur.in

offices; these are used primarily in hospitals and teaching institutions.

Radiographic examinations

Radiographic imaging is essential for thorough examination, diagnosis, and management of dentoalveolar trauma. Imaging may reveal root fractures, subgingival crown fractures, tooth displacements, bone fractures, root resorptions, and embedded foreign objects. A single radiograph, even a panoramic image, is insufficient to properly diagnose just about any dental trauma case. In its 2020 guidelines for the management of traumatic dental injuries, and in the current recommendations on its interactive website (www.dentaltraumaguide.org), the International Association of Dental Traumatology (IADT) has recommended taking at least four different radiographs for almost every injury[44a,64,75a]: a direct 90-degree on the axis of the tooth, two with different vertical angulations, and one occlusal film (Fig. 21.3).

Telegram: @dental_k

www.konkur.in

FIG. 21.3 An occlusal film of a luxation injury of central incisors. Both were diagnosed to be laterally luxated with apical translocation. Note that the left central is completely obliterated and has a history of being luxated some years prior.

Radiograph shows two large oval patches extending from the gum line and roots of incisors.

Multiple radiographs increase the likelihood of diagnosing root fractures, tooth displacement, and other possible injuries. However, two-dimensional (2D) imaging methods have well-known inherent limitations, and their lack of three-dimensional (3D) information may prevent proper diagnosis and adversely affect long-term treatment outcomes. The interpretation of an image can be confounded by a number of factors, including the regional anatomy and superimposition of both the teeth and surrounding dentoalveolar structures. As a result of superimposition, periapical radiographs reveal only limited aspects (i.e., a 2D view) of the true 3D anatomy.[52,142] In addition, there is often geometric distortion of the anatomic structures imaged with conventional radiographic methods.[4] These problems can be overcome by using cone-beam computed tomography (CBCT) imaging techniques, which produce accurate 3D images of the teeth and surrounding dentoalveolar structures and have shown promise in improving the clinician's ability to properly diagnose luxation injuries, alveolar fractures, root fractures, and root resorption (Fig. 21.4).[50,51]

Telegram: @dental_k

www.konkur.in

Telegram: @dental_k

www.konkur.in

FIG. 21.4 **A,** Panoramic radiograph taken on a patient with past history of dentoalveolar trauma. Tooth #9 appeared to have arrested root development with a periapical radiolucency. **B,** Sagittal view of tooth #9 of same patient from CBCT imaging. This revealed that tooth #9 had arrested root development, a large periapical radiolucency, and extensive root resorption along the palatal surface that was *not* evident on the panoramic image. **C,** Periapical radiograph of tooth #9 with extensive complicated crown fracture. The clinical examination revealed the crown fracture extended subgingivally on the palatal aspect. **D,** Sagittal view of tooth #9 of same patient from CBCT imaging. This revealed that the apical extent of the fractured palatal portion extended just apical to the crest of bone. The correct diagnosis of this injury was complicated crown-root fracture. **E,** Periapical radiograph of teeth #8, #9 revealed crown fractures. **F,** Sagittal view of tooth #9 of same patient from CBCT imaging. This revealed that tooth #9 suffered a lateral luxation displacement injury with extensive concomitant alveolar fracture. The necessary treatment of repositioning and splinting was apparent. **G,** Periapical radiograph of tooth #9 following dentoalveolar trauma. Tooth #8 was avulsed and tooth #9 appeared to be severely intruded. **H,** Sagittal view of tooth #9 of same patient from CBCT imaging. This revealed the labial position of tooth #9. **I,** Periapical radiograph of tooth #8 revealed a lateral luxation injury. **J,** Sagittal view of tooth #8 from CBCT imaging. The extensive tooth displacement and concomitant alveolar are evident. **K,** Periapical radiograph of teeth #8 to #10, that had recently been splinted in an emergency room. This image revealed that these teeth were not

Telegram: @dental_k

www.konkur.in

properly repositioned before splinting, evidenced by the spaces along each root. **L,** Axial view of maxillary anterior region of same patient from CBCT imaging. This revealed that teeth #8 to #10 are labially displaced. **M,** Sagittal view of tooth #10 of same patient revealed how severe the displacement was. Following consent and local anesthesia, the splint was removed and teeth #8 to #10 were repositioned and resplinted.

Six radiographs marked A through F.

A) It shows radiolucent edge of central incisor along with dark patches at the root apices. One tooth is missing in the upper right quadrant and few teeth are missing in the lower left quadrant.

B) Incisor has a large dark patch at the root apex followed by porous tissue above.

C) Two incisors at the center have space in-between. Tissue above root apices show large marrow spaces with some dark patches.

D) Tooth has fracture in crown, indicated by radiolucent regions.

E) Close-up view of two central incisors. Both have broken crown edges and wedge-shaped radiolucency.

F) Tooth shows radiopaque lateral edges of the crown.

Seven radiographs are marked G through M.

G) It shows tooth little above the root tip of adjacent incisor. Gum line is completely radiolucent.

H) It has displaced tooth along the arch.

I) It shows three incisors with a tooth-like structure at the top. The central incisor has radiolucent curved patch at the root apex.

J) The central incisor with radiolucency at the root apex.

K) Three incisors that appear little smaller and locate slightly below the teeth arch.

L) Teeth arranged in inverted U-shaped structure. The teeth at the center are situated away from their original position.

M) Incisor shows an oval radiolucent patch near the root apex and radiopaque patch at the one side of crown.

In instances of soft-tissue laceration, it is advisable to radiograph the

Telegram: @dental_k

www.konkur.in

injured area before suturing to be sure that no foreign objects have been embedded. A soft-tissue radiograph with a normal-sized film briefly exposed at reduced kilovoltage should reveal the presence of many foreign substances, including tooth fragments (Fig. 21.5).

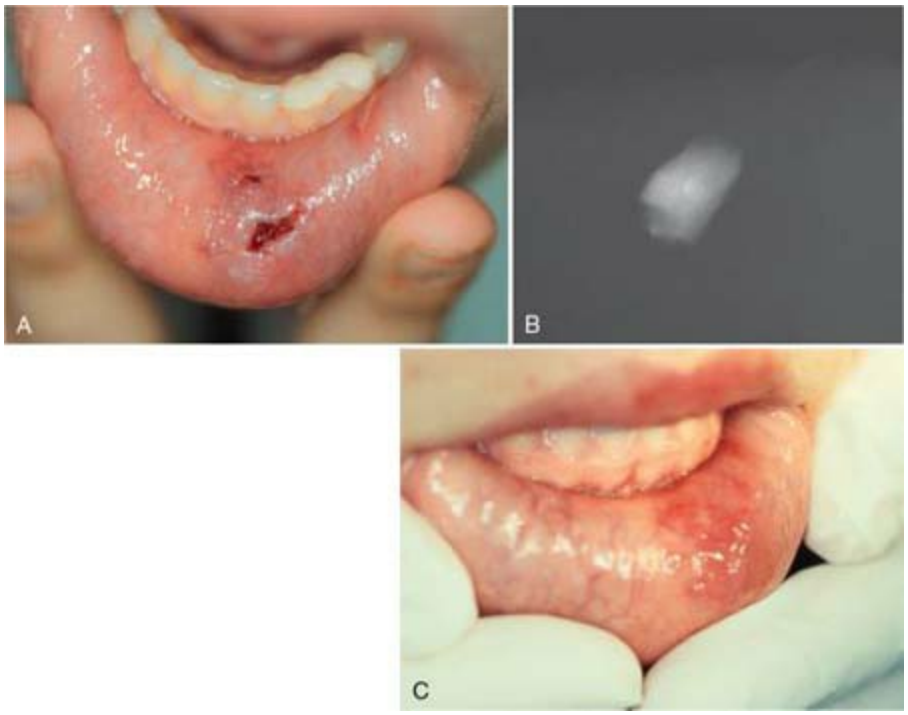

FIG. 21.5 Patient sustained complicated crown fractures on the left lower incisors and later on the canine tooth. **A,** An emergency pulp capping; Band-Aid composite was placed on the teeth. Six days later the patient was referred to the clinic because of a poorly healed laceration on the lip. **B,** Radiograph of the lip revealed a portion of the lateral crown still in the lip. The patient was anesthetized and the crown removed. **C,** Healing was quick and uneventful.

A) Close-up view of lower lip with a deep wound that shows clotted blood surrounded by inflammation.

B) Radiograph shows a radiopaque crown in the dark background.

C) Close-up view of gloved hands stretches the lower lip that shows slight inflamed tissue in place of the wound.

Cone-beam computed tomography and dentoalveolar trauma

Telegram: @dental_k

www.konkur.in

CBCT is accomplished by using a rotating gantry to which an x-ray source and detector are fixed (see Chapter 2). A divergent pyramidal or cone-shaped source of ionizing radiation is directed through the middle of the area of interest onto an area x-ray detector on the opposite side of the patient. The x-ray source and detector rotate around a fixed fulcrum within the region of interest. During the exposure sequence, hundreds of planar projection images are acquired of the field of view (FOV) in an arc of at least 180 degrees. In this single rotation, CBCT provides precise, essentially immediate, and accurate 3D radiographic images. Because CBCT exposure incorporates the entire FOV, only one rotational sequence of the gantry is necessary to acquire enough data for image reconstruction.

CBCT has been suggested as an adjunct imaging tool when the true nature of the dentoalveolar root fracture and dental injuries cannot be confidently diagnosed from a conventional examination and radiographs.[13,50,134,143] However, it has been repeatedly demonstrated that the use of CBCT provides improved diagnostic images in cases of dentoalveolar injury.[37,38,50,51,52,66,71,123,134,142,143] Perhaps the use of CBCT imaging for dentoalveolar injuries could be considered “best practice” and is recommended for most serious injuries (Fig. 21.6).[69]

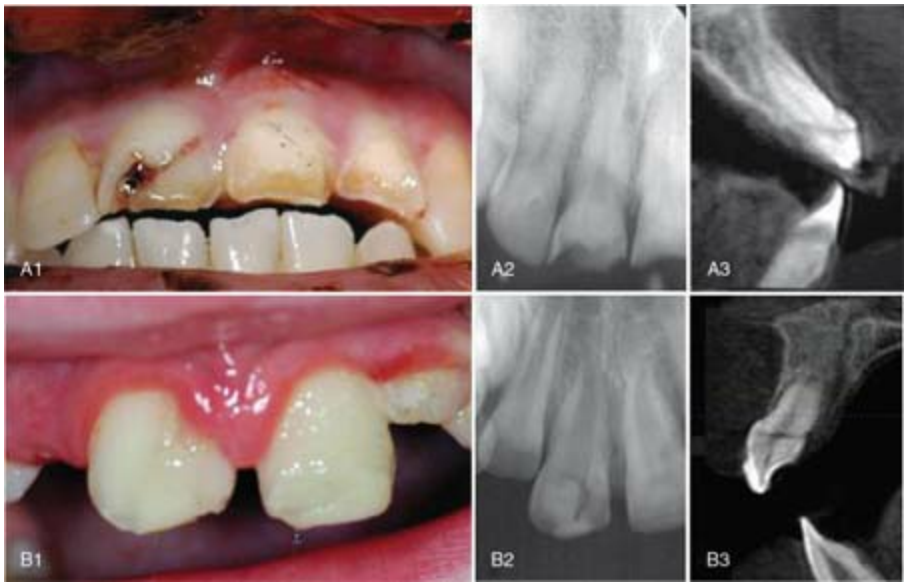

FIG. 21.6 **A1,** A clinical photograph of a maxillary right central incisor that sustained a crown-root fracture. **A2,** A periapical radiograph that failed to show the extent of the crown-root fracture. **A3,** A CBCT image

revealed the extent of the crown-root fracture. **B1,** A clinical photograph of a right maxillary central incisor that had sustained a crown fracture that was restored with composite resin by the referring dentist. **B2,** A periapical radiograph revealed a vertical fracture in the crown and the coronal third of the root. An area of bone loss just below the alveolar crest on the mesial aspect of the root suggested further injury. **B3,** A CBCT image revealed the further injury as a transverse root fracture.

A1) Close-up view of teeth shows cracks on crowns of front three teeth. The right central incisor has brown filling.

A2) Radiograph shows three teeth where the central tooth has chipped crown.

A3) Close-up view of the chipped crown shows wide empty space in-between.

B1) Close-view of upper jaw shows front incisors with wide space in-between and the surrounding.

B2) Radiograph shows the central tooth with radiolucent root canal and radiolucent triangular fracture on the crown.

B3) Radiograph shows wide black space adjacent to incisor. The crown of incisor is broken from one side.

Source: (Reproduced from Andreasen FM, Kahler B: Diagnosis of acute dental trauma: the importance of standardized documentation: a review, *Dent Traumatol* 31:340, 2015.)

Root resorption

Because the development and progression of root resorption occur without clinical signs or symptoms, their early detection is challenging. Therefore the definitive diagnosis of root resorption depends on its radiographic demonstration, which in turn is limited by the diagnostic accuracy of the imaging device used to determine its presence (see Chapter 18).[143] The radiodensity of the root requires that a significant amount of root substance be removed to cause enough contrast on the radiograph to allow it to be detected. Thus only resorptive defects on the mesial or distal aspects of the root can be predictably detected after some time; the facial and palatal or lingual aspects are much harder to see. To overcome these difficulties, it is essential to take as many different horizontal-angled radiographs as feasible in cases of suspected root resorption. Early detection of small resorption defects has been shown to be poor with conventional dental radiographs, and

Telegram: @dental_k

www.konkur.in

the extent of the resorptive defect is grossly underestimated compared with CBCT.[38,66,71]

The available literature supports the use of CBCT as a diagnostic tool to assess the true nature of teeth diagnosed with root resorption to improve diagnosis and aid management. This should ultimately improve the prognosis of teeth with root resorption that require endodontic management (see Fig. 21.4, *A*, *B*).[143]

Horizontal (transverse) root fractures

There is a significant risk of misdiagnosing the true location of a root fracture in anterior teeth when intraoral radiography is used because of the possibility of the oblique course of the fracture line in the sagittal plane. It has been shown that horizontal root fracture can be detected sooner using CBCT than with periapical views, and the fracture can be assessed in coronal, axial, and cross-sectional views (see Fig. 21.4, *C*, *D*).[117] Compared with conventional radiographs, CBCT increased the accuracy of diagnosing the actual nature of horizontal root fractures.[37,134]

Luxation injuries

As previously mentioned, conventional intraoral radiography provides poor sensitivity in the detection of minimal tooth displacements and root and alveolar fractures.[123] CBCT has significantly improved the ability to accurately diagnose traumatic injuries and has the potential to overcome most of the technical limitations of the plain-film projection (see Fig. 21.4, *E*–*M*).[37,38,50,51,66,71,123,134,143]

Crown fractures

As already mentioned, the primary aim from an endodontic point of view is to maintain pulp vitality after crown fractures.

Crown infraction

Crown infraction can be defined as an incomplete fracture of or a crack in the enamel, without loss of tooth structure.[21]

Telegram: @dental_k

www.konkur.in

Biologic consequences

Crown infractions are injuries that carry little danger of resulting in pulp necrosis. Meticulous follow-up over a 5-year period is the most important endodontic preventive measure in these cases. If, at any follow-up examination, the reaction to sensitivity tests changes, or if, on radiographic assessment, signs of apical or periradicular periodontitis develop or the root appears to have stopped development or is obliterating, endodontic intervention should be considered.

Uncomplicated crown fracture

Uncomplicated crown fracture can be defined as fracture of the enamel only or the enamel and dentin without pulp exposure.[21]

Incidence

Uncomplicated crown fracture is likely to be the most commonly reported dental injury. It is estimated to account for at least one third to one half of all reported dental trauma.

Biologic consequences

Uncomplicated crown fractures are also injuries that have little danger of resulting in pulp necrosis. In fact, the biggest danger to the health of the pulp is through iatrogenic causes during the esthetic restoration of these teeth.

Treatment

There are two key issues in the treatment of crown fractures. First, all exposed dental tubules need to be closed as soon as reasonably possible. If the broken-off piece is not available or if it is not possible to reattach it and there is no time to do a full composite restoration at the time of the emergency appointment, a composite Band-Aid or temporary coverage should be placed on all exposed dentin. This prevents any ingress of bacteria into the tubules and reduces the patient's discomfort. The second issue is the remaining dentin thickness. Several studies have confirmed that if the remaining dentin is more than 0.5 mm thick, the tooth can be restored with the restoration of choice, including etching and bonding, and no special

Telegram: @dental_k

www.konkur.in

attention needs to be given to the pulp.[4,54,70,137,173] However, if the remaining dentin is less than this thickness, a protective layer of hard-setting calcium hydroxide in the deepest part of the dentin exposure does reduce, if not completely prevent, reactive inflammation of the underlying pulp, which is a significantly different reaction compared with the negative reaction to composite bonding systems.[4,54,70,137,173]

Complicated crown fracture

A *complicated crown fracture* involves enamel, dentin, and pulp (Fig. 21.7).[21]

FIG. 21.7 Complicated crown fracture involving enamel, dentin, and pulp.

1) Close-up view shows upper jaw where half-crown of right incisor is broken horizontally. The crown of left incisor is broken diagonally.

2) Close-up view shows horizontal and diagonal cracks under dental mirror in right and left incisor, respectively.

Incidence

Complicated crown fractures occur in 0.9% to 13% of all dental injuries.[47,153,175]

Biologic consequences

A crown fracture involving the pulp, if left untreated, always results in pulp necrosis.[116] However, the manner and time sequence in which the pulp becomes necrotic allow a great deal of potential for successful intervention to

Telegram: @dental_k

www.konkur.in

maintain pulp vitality. The first reaction after the injury is hemorrhage and local inflammation (Fig. 21.8).

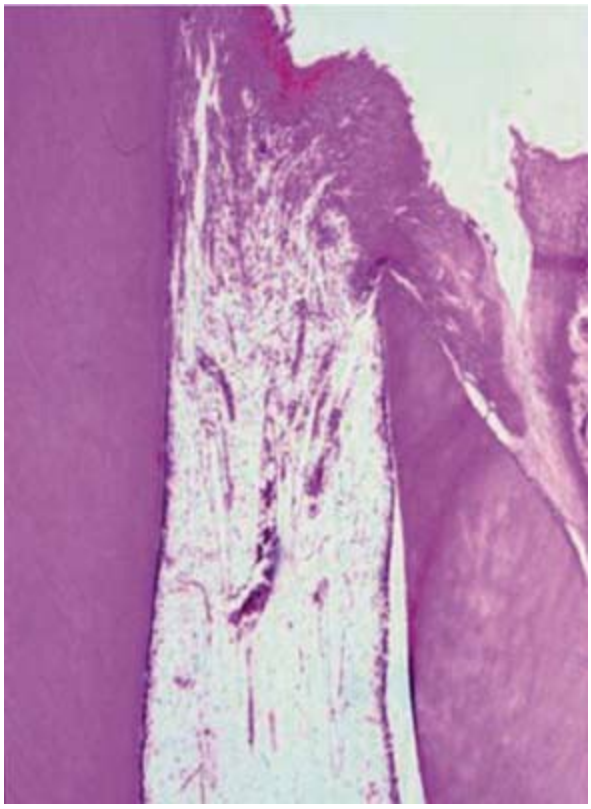

FIG. 21.8 Histologic appearance of the pulp within 24 hours of a traumatic exposure. The pulp proliferated over the exposed dentinal tubules. There is approximately 1.5 mm of inflamed pulp below the surface of the fracture.

Stained micrograph of the inflamed pulp shows proliferated cells in canal with a tinge of purple.

Subsequent inflammatory changes are usually proliferative but can be destructive over time. A proliferative reaction is favored in traumatic injuries because the fractured surface is usually flat, allowing salivary rinsing with little chance of impaction of contaminated debris. Unless impaction of contaminated debris is obvious, it is expected that in the first 24 hours after the injury, a proliferative response with inflammation extending not more than 2 mm into the pulp will be present (see Fig. 21.8).[57,60,90] In time, the bacterial challenge results in local pulpal necrosis and a slow apical progression of the pulpal inflammation (Fig. 21.9).

Telegram: @dental_k

www.konkur.in

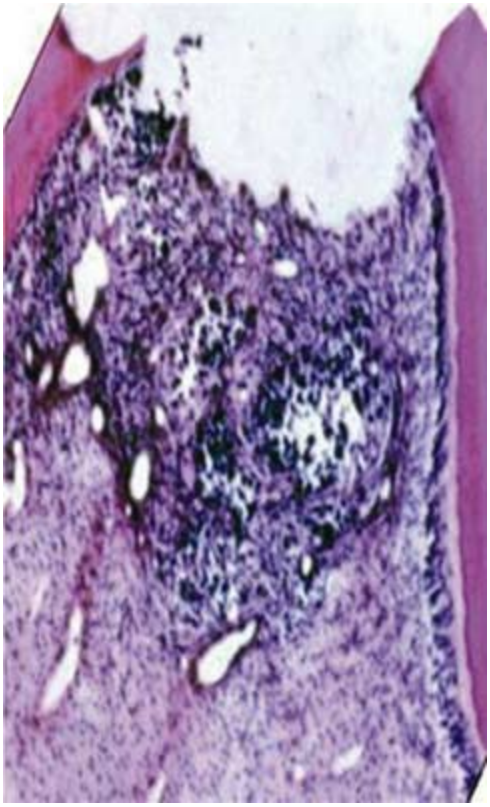

FIG. 21.9 Histologic appearance of the pulp days after a traumatic exposure. Superficial necrosis above a zone of inflamed pulp is seen.

Stained micrograph of partial pulp necrosis shows normal cell nuclei at the bottom. At the top, porous connective tissue has white and dark patches with granules.

Treatment

Treatment options for complicated crown fracture are (1) vital pulp therapy, comprising pulp capping, partial pulpotomy, or full pulpotomy; and (2) pulpectomy. The choice of treatment depends on the stage of development of the tooth, the time between trauma and treatment, concomitant periodontal injury, and the restorative treatment plan.

Stage of development of the tooth

Loss of vitality in an immature tooth can have catastrophic consequences. Root canal treatment on a tooth with a blunderbuss canal is time consuming

Telegram: @dental_k

www.konkur.in

and difficult. It is probably more important that necrosis of an immature tooth leaves it with thin dentinal walls that are susceptible to fracture both during and after the apexification procedure.[118] Every effort must be made to keep the tooth vital, at least until the apex and cervical root have completed their development.

Removal of the pulp in a mature tooth is not as significant as in an immature tooth because a pulpectomy in a mature tooth has an extremely high success rate.[164] However, it has been shown that under optimal conditions, vital pulp therapy (rather than removal) can be carried out successfully on a mature tooth.[133,193] Therefore this form of therapy can be an option under certain circumstances, even though a pulpectomy is the treatment that affords the most predictable success.

In an immature tooth, vital pulp therapy should always be attempted if at all feasible because of the tremendous advantages of maintaining the vital pulp.

Time between trauma and treatment

For 48 hours after a traumatic injury, the initial reaction of the pulp is proliferative, with no more than a 2-mm depth of pulpal inflammation (see Fig. 21.9). After 48 hours, chances of direct bacterial contamination of the pulp increase, with the zone of inflammation progressing apically[60]; as time passes, the likelihood of successfully maintaining a healthy pulp decreases.

Concomitant attachment damage

A periodontal injury compromises the nutritional supply of the pulp. This fact is particularly important in mature teeth, in which the chance of pulp survival is not as good as for immature teeth.[18,68]

Restorative treatment plan

Unlike in an immature tooth, in which the benefits of maintaining vitality of the pulp are so great, pulpectomy is a viable treatment option in a mature tooth. As pointed out, if performed under optimal conditions, vital pulp therapy after traumatic exposures can be successful. If the restorative treatment plan is simple and a composite resin restoration will suffice as the permanent restoration, this treatment option should be given serious

Telegram: @dental_k

www.konkur.in

consideration. If a more complex restoration is to be placed (e.g., a crown or bridge abutment), pulpectomy may be the more predictable treatment method.

Vital pulp therapy: Requirements for success

Vital pulp therapy has an extremely high success rate if the following requirements can be met (also see Chapter 24).

- *Treatment of a noninflamed pulp*. Treatment of a healthy pulp has been shown to be an important requirement for successful therapy.[174,183] Vital pulp therapy of the inflamed pulp yields an inferior success rate,[174,183] so the optimal time for treatment is in the first 24 hours when pulp inflammation is superficial. As time between the injury and therapy increases, pulp removal must be extended apically to ensure that noninflamed pulp has been reached.
- *Bacteria-tight seal*. This requirement can be considered the most critical factor for successful treatment.[174] Challenge by bacteria during the healing phase causes failure (see also Chapter 15).[53] If the exposed pulp is effectively sealed from bacterial leakage, successful healing of the pulp with a hard-tissue barrier will occur independent of the dressing placed on the pulp and after more extended time periods between accident and treatment.[54,88]
- *Pulp dressing*. Calcium hydroxide has traditionally been used for vital pulp therapy. Its main advantage is that it is antibacterial[46,163] and disinfects the superficial pulp. Pure calcium hydroxide causes necrosis of approximately 1.5 mm of pulp tissue, which removes superficial layers of inflamed pulp if present (Fig. 21.10).[135] The high pH (12.5) of calcium hydroxide causes a liquefaction necrosis in the most superficial layers.[156] The toxicity of calcium hydroxide appears to be neutralized as the deeper layers of pulp are affected, causing a coagulative necrosis at the junction of the necrotic and vital pulp, resulting in only mild irritation. This mild irritation initiates an inflammatory response, and in the absence of bacteria,[156] the pulp will heal with a hard-tissue barrier (Fig. 21.11).[155,156] Hard-

Telegram: @dental_k

www.konkur.in

setting calcium hydroxide does not cause necrosis of the superficial layers of pulp; it has also been shown to initiate healing with a hard-tissue barrier.[172,180]

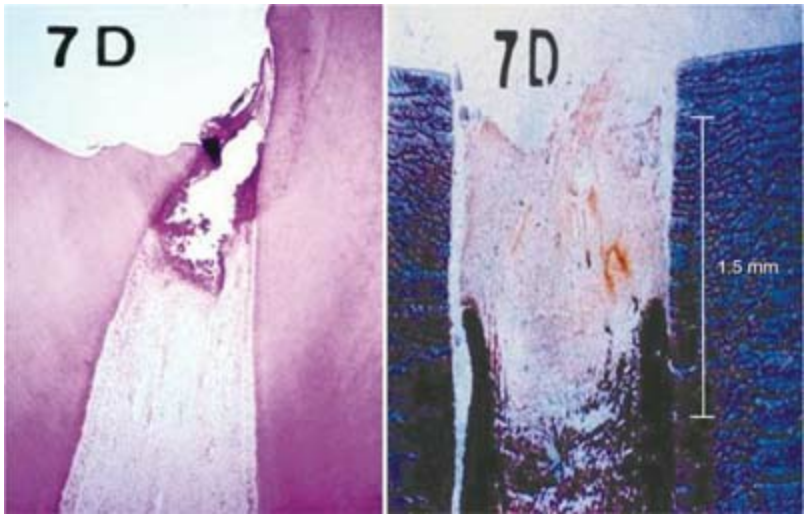

FIG. 21.10 Pulp necrosis of 1.5 mm as a result of the high pH of calcium hydroxide.

1) Stained micrograph after 7 days of traumatic exposure shows a white deposition in the root canal.

2) Micrograph after 7 days shows 1.5 millimeter pulp necrosis as bundle of delicate and proliferated collagen fibers. The bottom area has black deposition.

hydroxide. **C,** Radiographic appearance of the hard-tissue barrier *(arrow)*.

B) Close-up view of tooth shows cavity with a brown deposition at the center.

C) Radiograph shows tooth with radiolucent root canal and a curved radiopaque line in the crown that also has a radiopaque patch at the tip.

The major disadvantage of calcium hydroxide is that it does not seal the fractured surface. Therefore an additional material must be used to ensure that bacteria do not challenge the pulp, particularly during the critical healing phase.

Many materials, such as zinc oxide eugenol,[30,183] tricalcium phosphate,[98] and composite resin,[29] have been proposed as medicaments for vital pulp therapy. None to this date have afforded the predictability of calcium hydroxide used in conjunction with a well-sealed coronal restoration.[70,122,161,173] In a dog study, for example, pulps capped directly with various adhesive agents showed moderate to severe inflammatory reactions, with progressive extension of tissue necrosis with time and total absence of continuous hard-tissue bridge formation.[122] Application of a calcium hydroxide–based material was characterized by inflammatory cell infiltration, limited tissue necrosis, and partial to complete hard-tissue bridging.[122] In a similar study on human teeth in vivo, it was found that Scotchbond Multi-Purpose Plus (3M, St. Paul, MN) caused inflammatory changes when applied directly to exposed pulp tissue; however, direct capping with Dycal followed by sealing with Scotchbond Multi-Purpose Plus showed favorable results in pulp tissue.[173]

Currently, bioceramic materials are considered the pulp capping agents of choice.[5] Mineral trioxide aggregate (MTA), a first-generation bioceramic material, has been shown to be a good pulp capping agent.[72,139,141,195] It has a high pH, similar to that of calcium hydroxide, when unset[177] and after setting creates an excellent bacteria-tight seal.[178] It is also hard enough to act as a base for a final restoration.[177] Yet MTA does not enjoy the same popularity as calcium hydroxide as a pulp capping agent in the treatment of traumatic exposures due to a prolonged setting time and discoloration of the

Telegram: @dental_k

www.konkur.in

crown because of the bismuth oxide filler in the material.

Recently, newer-generation bioceramic materials (e.g., BioDentine) have come to the market that have similar positive properties as MTA but not the disadvantages described previously. They set quickly enough for a one-visit procedure and do not discolor the tooth.[198] These materials are now considered superior to calcium hydroxide as the capping agent for traumatic pulp exposures.

Treatment methods

Pulp capping

Pulp capping implies placing the dressing directly on the pulp exposure without any removal of the soft tissue.[29]

Indications.

There are few indications for pulp capping when traumatic pulp exposures are treated. The success rate of this procedure (80%),[77,148] compared with partial pulpotomy (95%),[57] indicates that a superficial pulp cap should not be considered after traumatic pulp exposures. The lower success rate is not difficult to understand because superficial inflammation develops soon after the traumatic exposure. If the treatment is at the superficial level, a number of inflamed (rather than healthy) pulps will be treated, lowering the potential for success. In addition, a bacteria-tight coronal seal is much more difficult to attain in superficial pulp capping because there is no depth to the cavity to aid in creating the seal, as there is with a partial pulpotomy.

It must be acknowledged that the studies suggesting that an inflamed pulp is contraindicated for an attempt at pulp capping were performed in the 1970s with amalgam as the standard coronal restoration. From a microleakage perspective, as amalgam leaks and calcium hydroxide washes out in the presence of moisture as the reasons for the poor results, then it may be poor coronal seal, rather than the inflamed pulp, that leads to failure in these cases. More recent studies suggest that with the bioceramic as the pulp cap, the inflamed pulp is not the impediment as previously thought, but rather that the seal seems to be the major factor for success. Thus this material used as a base in these situations may provide more leeway for capping the inflamed

Telegram: @dental_k

www.konkur.in

pulp.

However, in a situation of a traumatic pulp exposure of a tooth (injuries in which most patients are young [large pulps]), the patient typically presents for treatment within 48 hours because of sensitivity and esthetic concerns. Therefore the pulpal inflammation is usually only superficial. In these cases, it may be prudent to remove the superficial layer of inflammation and place a bioceramic agent for pulp capping.

Partial pulpotomy

Partial pulpotomy implies the removal of coronal pulp tissue to the level of healthy pulp. Knowledge of the reaction of the pulp after a traumatic injury makes it possible to accurately determine this level. This procedure is commonly called the *Cvek pulpotomy*.

Indications.

As for pulp capping.

Technique.

Administration of an anesthetic (possibly without a vasoconstrictor), rubber dam placement, and superficial disinfection are performed. A 1- to 2-mm-deep cavity is prepared into the pulp, using a high-speed handpiece with a sterile diamond bur of appropriate size and copious water coolant (Fig. 21.12).[85] A slow-speed bur or spoon excavator should be avoided. If bleeding is excessive, the pulp is amputated deeper until only moderate hemorrhage is seen. Excess blood is carefully removed by rinsing with sterile saline, and the area is dried with a sterile cotton pellet. Use of 5% sodium hypochlorite (NaOCl; bleach) has been recommended to rinse the pulpal wound.[54] The bleach causes chemical amputation of the blood coagulum; removes damaged pulp cells, dentin chips, and other debris; and provides hemorrhage control with minimal damage to the “normal” pulp tissue underneath.

Telegram: @dental_k

www.konkur.in

FIG. 21.12 Cvek partial pulpotomy. **A,** The fractured teeth are cleaned and disinfected; a rubber dam is placed. **B,** Cavities are prepared at high speed with a round diamond bur 1 to 2 mm into the pulpal tissue. **C,** Calcium hydroxide on a plugger **(D)** is placed on the soft tissue of the pulp. **E,** Care is taken to avoid smearing the walls of the preparation with the calcium hydroxide. **F,** Cavity preparations are filled with glass ionomer cement. The exposed dentin is etched **(G)** and then covered with composite resin **(H)**. **I,** Radiograph 6 months later shows formation of hard-tissue barriers in both teeth *(arrows)*.

Eight close-up view show four teeth isolated by rubber dam clamps. The close-up views are accompanied by a radiograph.

A) Second tooth on right has a blood stain in the fracture. Third tooth has a fracture with a tiny spot.

B) Both second and third teeth show deep cavities at the center with accumulated fluids.

C) The cavity of third tooth is being filled by using plugger.

D) The cavities of both second and third tooth are partially filled with calcium hydroxide.

E) It is similar to D, except that the image is clearer and the color of the rubber

clamp is changed.

F) The cavities are completely filled with calcium hydroxide and they appear as smooth surface.

G) Both teeth are covered with plastic material.

H) The plastic covers are removed and teeth have no cavities.

I) Radiograph of both teeth shows normal appearance with partially radiopaque region in the pulp.

Source: (Courtesy Dr. Alessandra Ritter, Chapel Hill, NC.)

Care must be taken not to allow a blood clot to develop because this would compromise the prognosis.[57,155] Calcium hydroxide is carefully placed on the pulp stump. If the pulp size does not permit additional loss of pulp tissue, a commercial hard-setting calcium hydroxide can be used.[159] The prepared cavity is filled with a material with the best chance of a bacteria-tight seal such as a glass ionomer cement to a level flush with the fractured surface. The material in the pulpal cavity and all exposed dentinal tubules are etched and restored with bonded composite resin. Alternatively, after hemostasis has been obtained, the pulp can be capped with MTA, covered with a lining material, and then restored with composite restoration. However, this has been to shown to cause discoloration of the tooth.[35]

Follow-up.

The follow-up is the same as for pulp capping. Emphasis is placed on evidence of maintenance of responses to sensitivity tests and radiographic evidence of continued root development (Fig. 21.13).

Telegram: @dental_k

www.konkur.in

FIG. 21.13 Continued root development after partial pulpotomy. **A,** Radiograph of immature tooth with a complicated crown fracture. **B,** At the time of placement of calcium hydroxide after partial pulpotomy *(arrow)*. **C,** Follow-up radiograph confirming that the pulp maintained vitality and the root continued to develop.

Three radiographs of two teeth are marked A through C.

A) Left tooth has fracture at the edge of crown followed by radiolucency with a radiopaque patch. The canal root canal is wide and radiolucent.

B) Left tooth has hard-density tissue in the pulp.

C) Crown of left tooth shows radiopaque edge at the site of fracture.

Prognosis.

This method affords many advantages over pulp capping. Superficial inflamed pulp is removed during preparation of the pulpal cavity. Calcium hydroxide disinfects dentin and pulp and removes additional pulpal inflammation. Most important, space is provided for a material that can achieve a bacteria-tight seal to allow pulpal healing with hard tissue under optimal conditions. In addition, coronal pulp remains, which allows sensitivity testing to be carried out at the follow-up visits. The prognosis is extremely good (94% to 96%).[57,78]

Full pulpotomy

Full pulpotomy involves removal of the entire coronal pulp to a level of the root orifices. This level of pulp amputation is chosen arbitrarily because of its anatomic convenience. Because inflamed pulp sometimes extends past the canal orifices into the root pulp, many mistakes are made that result in

Telegram: @dental_k

www.konkur.in

treatment of an inflamed rather than a noninflamed pulp.

Indications.

Full pulpotomy is indicated when it is anticipated that the pulp is inflamed to the deeper levels of the coronal pulp. Traumatic exposures after more than 72 hours and carious exposure of a young tooth with a partially developed apex are two examples of cases in which this treatment may be indicated. Because of the likelihood that the dressing will be placed on an inflamed pulp, full pulpotomy is contraindicated in mature teeth. In the immature tooth, benefits outweigh risks for this treatment form only with incompletely formed apices and thin dentinal walls.

Technique.

The procedure begins with administration of an anesthetic, rubber dam placement, and superficial disinfection, as for pulp capping and partial pulpotomy. The coronal pulp is removed as in partial pulpotomy but to the level of the root orifices. A calcium hydroxide dressing, a bacteria-tight seal, and a coronal restoration are carried out as for partial pulpotomy.

Follow-up.

Follow-up is the same as for pulp capping and partial pulpotomy. A major disadvantage of this treatment method is that sensitivity testing is not possible, owing to the loss of coronal pulp, so radiographic follow-up is extremely important to assess for signs of apical periodontitis and to ensure the continuation of root formation.

Prognosis.

Because cervical pulpotomy is performed on pulps that are expected to have deep inflammation and the site of pulp amputation is arbitrary, many more mistakes are made that lead to treatment of the inflamed pulp. Consequently the prognosis, which is in the range of 75%, is poorer than for partial pulpotomy.[82] Because of the inability to evaluate pulp status after full pulpotomy, some authors have recommended pulpectomy routinely after the roots have fully formed (Fig. 21.14). This philosophy is based on the pulpectomy procedure having a success rate in the range of 95%, whereas if

Telegram: @dental_k

www.konkur.in

apical periodontitis develops, the prognosis of root canal treatment drops significantly to approximately 80%.[158,164]

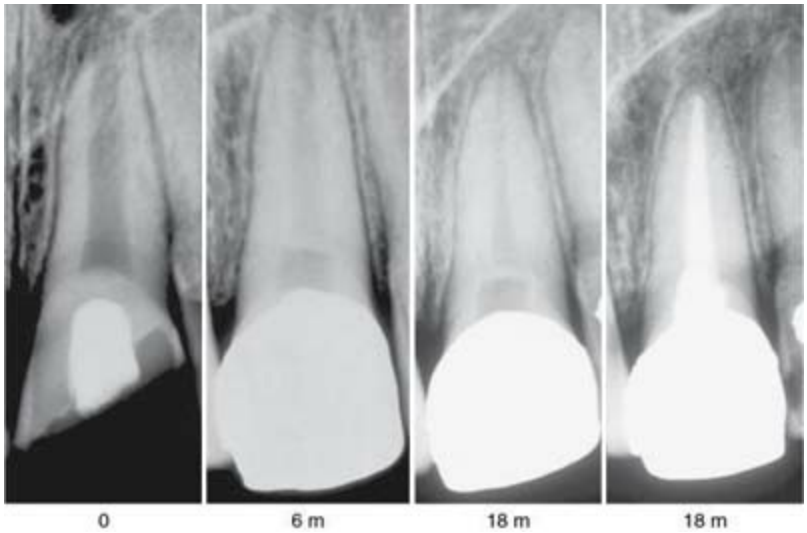

FIG. 21.14 Successful pulpotomy followed by a pulpectomy at 18 months.

Radiograph, marked 0, shows tooth with half-crown fractured diagonally with a radiopaque spot. The root canal is radiolucent.

Radiograph after 6 months shows partial radiopaque crown including fracture site with comparatively radiolucent root canal in tooth. There is a hard-density barrier below the pulp.

Radiograph after 18 months shows more radiopaquicity than that of the radiograph after 6 months.

Another radiograph after 18 months shows filled root canal and crown.

Source: (Courtesy Dr. Leif Tronstad, Oslo, Norway.)

Pulpectomy

Pulpectomy implies removal of the entire pulp to the level of the apical foramen.

Indications.

Pulpectomy is indicated in a complicated crown fracture of mature teeth if conditions are not ideal for vital pulp therapy or if it is foreseeable that

Telegram: @dental_k

www.konkur.in

restoring the tooth would require placement of a post. This procedure is no different from root canal treatment of a vital nontraumatized tooth.

Treatment of the nonvital pulp

Immature tooth: Apexification

Indications.

Apexification should be performed in teeth with open apices and thin dentinal walls in which standard instrumentation techniques cannot create an apical stop to facilitate effective root canal filling.

Biologic consequences.

A nonvital immature tooth presents a number of difficulties for adequate endodontic treatment. The canal is often wider apically than coronally, necessitating the use of a filling technique with softened filling material to mold it to the shape of the apical part of the canal. Because the apex is extremely wide, no barrier exists to stop this softened material from moving into and traumatizing the apical periodontal tissues. In addition, the lack of apical stop and extrusion of material through the canal might result in a canal that is underfilled and susceptible to leakage. An additional problem in immature teeth with thin dentinal walls is their susceptibility to fracture, both during and after treatment.[58]

These problems are overcome by stimulating the formation of a hard-tissue barrier to allow for optimal filling of the canal and by reinforcing the weakened root against fracture, both during and after apexification.[120,176]

Technique

Disinfection of the canal.

In most cases, nonvital teeth are infected,[36,160] so the first phase of treatment is to disinfect the root canal system to ensure periapical healing.[46,61] The canal length is estimated with a parallel preoperative radiograph, and after access to the canals has been prepared, a file is placed to this estimated length. When the length has been confirmed radiographically,

Telegram: @dental_k

www.konkur.in

very light filing (because of the thin dentinal walls) is performed with copious irrigation with 0.5% NaOCl.[62,169] A lower strength of NaOCl is used because of the increased danger of placing the agent through the apex in immature teeth. The increased volume of irrigant used compensates for this lower concentration of NaOCl. An irrigation needle that can passively reach close to the apical length is useful in disinfecting the canals of these immature teeth. The canal is dried with paper points and a creamy mix of calcium hydroxide (toothpaste thickness) spun into the canal with a Lentulo spiral instrument (Fig. 21.15). Additional disinfecting action of calcium hydroxide is effective after its application for at least 1 week,[163] so continuation of treatment can take place any time after 1 week. Further treatment should not be delayed more than 1 month because the calcium hydroxide could be washed out by tissue fluids through the open apex, leaving the canal susceptible to reinfection.

FIG. 21.15 Creamy mix of calcium hydroxide on a Lentulo spiral instrument ready for placement into the canal.

A long filament of calcium hydroxide paste oozes out from Lentulo spiral instrument.

Hard-tissue apical barrier

Traditional method.

Telegram: @dental_k

www.konkur.in

Formation of the hard-tissue barrier at the apex requires a similar environment to that required for hard-tissue formation in vital pulp therapy: a mild inflammatory stimulus to initiate healing and a bacteria-free environment to ensure that inflammation is not progressive.

As with vital pulp therapy, calcium hydroxide is used for this procedure.[58,91,99] Calcium hydroxide is packed against the apical soft tissue with a plugger or thick point to initiate hard-tissue formation. This step is followed by backfilling with calcium hydroxide to completely fill the canal. The calcium hydroxide is meticulously removed from the access cavity to the level of the root orifices, and a well-sealing, temporary filling is placed in the access cavity. A radiograph is taken; the canal should appear to have become calcified, indicating that the entire canal has been filled with the calcium hydroxide (Fig. 21.16). Because calcium hydroxide washout is evaluated by its relative radiodensity in the canal, it is prudent to use a calcium hydroxide mixture without the addition of a radiopaquer, such as barium sulfate. These additives do not wash out as readily as calcium hydroxide, so if they are present in the canal, evaluation of washout is impossible.

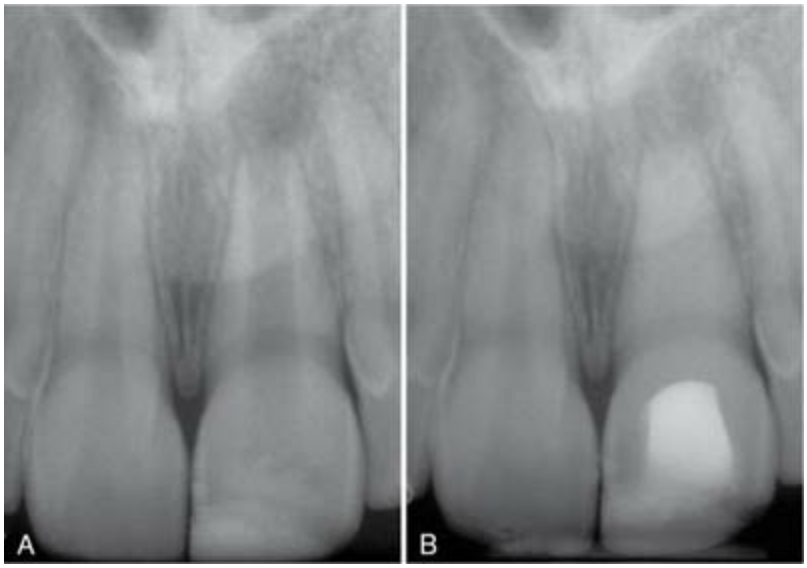

FIG. 21.16 **A** and **B,** Root canal that "disappears" after placement of a thick mix of pure calcium hydroxide and then over time washes out again.

At 3-month intervals, a radiograph is exposed to evaluate whether a hard-tissue barrier has formed and if the calcium hydroxide has washed out of the canal. This is assessed to have occurred if the canal can be seen again radiographically. If no washout is evident, the calcium hydroxide can be left intact for another 3 months. Excessive calcium hydroxide dressing changes should be avoided if at all possible because the initial toxicity of the material is thought to delay healing.[125]

When completion of a hard-tissue barrier is suspected, the calcium hydroxide should be washed out of the canal with NaOCl. A file of a size that can easily reach the apex can be used to gently probe for a stop at the apex. When a hard-tissue barrier is indicated radiographically and can be probed with an instrument, the canal is ready for filling.

Bioceramic barrier.

The creation of a physiologic hard-tissue barrier, although quite predictable, takes anywhere from 3 to 18 months with calcium hydroxide. The disadvantages of this long time period are that the patient is required to present for treatment multiple times and the tooth may fracture during treatment before the thin, weak roots can be strengthened. In addition, one study has indicated that long-term treatment with calcium hydroxide may weaken the roots and make them even more susceptible to fracture.[24] However, this is not conclusive because another more recent study showed that calcium hydroxide did not weaken teeth over time when compared with positive and negative controls and that fracture. Therefore fracture may be more related to the stage of root development rather than calcium hydroxide use.[115]

Bioceramic material has been used to create a hard-tissue barrier quickly after disinfection of the canal (see earlier in the section Traditional Method) (Fig. 21.17). Calcium sulfate is pushed through the apex to provide a resorbable extraradicular barrier against which to pack the bioceramic material. The material is mixed and packed into the apical 4 to 5 mm of the

Telegram: @dental_k

www.konkur.in

canal. Historically, a wet cotton pellet was placed against the bioceramic material and left for at least 6 hours and this is now not considered necessary as long as the bioceramic material does not dry out. The canal is filled with thermoplasticized gutta-percha. The cervical canal is then reinforced with composite resin to below the marginal bone level (described later; also see Fig. 21.17).

FIG. 21.17 Apexification with mineral trioxide aggregate. **A,** The canal is disinfected with light instrumentation, copious irrigation, and a creamy mix of calcium hydroxide for 1 month. **B,** Calcium sulfate is placed through the apex as a barrier against which the mineral trioxide aggregate (MTA) is placed. **C,** A 4-mm MTA plug is placed at the apex. **D,** The body of the canal is filled with the Resilon obturation system. **E,** A bonded resin is placed below the cementoenamel junction (CEJ) to strengthen the root.

Five radiographs are marked A through E.

A) It shows a spiral instrument being inserted into the root canal of tooth through its crown that has a black large hole.

B) It shows slightly dense tissue at the place of the hole in the tooth. The root has a globular hard tissue at the tip.

C) The one-fourth root canal of tooth is filled at the tip.

D) The half root canal of tooth is filled.

E) Tooth shows filled root canal with radiopaquicity in place of the black hole.

Source: (Courtesy Dr. Marga Ree. Purmerend, Netherlands.)

A number of case reports have been published using this apical barrier technique,[83,101,131] and it has steadily gained popularity with clinicians. Numerous reports attest to the efficacy of this technique.[48,114]

Telegram: @dental_k

www.konkur.in

Filling the root canal.

Because the apical diameter is larger than the coronal diameter of most of these canals, a softened filling technique is indicated in these teeth (see Chapter 9). Care must be taken to avoid excessive lateral force during filling, owing to the thin walls of the root. If the hard-tissue barrier was produced by long-term calcium hydroxide therapy, it consists of irregularly arranged layers of coagulated soft tissue, calcified tissue, and cementum-like tissue (Fig. 21.18). Included also are islands of soft connective tissue, giving the barrier a "Swiss cheese" consistency.[40,56] Because of the irregular nature of the barrier, it is not unusual for cement or softened filling material to be pushed through it into the apical tissues during filling (Fig. 21.19). Formation of the hard-tissue barrier might be some distance short of the radiographic apex because the barrier forms wherever the calcium hydroxide contacts vital tissue. In teeth with wide, open apices, vital tissue can survive and proliferate from the periodontal ligament a few millimeters into the root canal. Filling should be completed to the level of the hard-tissue barrier and not forced toward the radiographic apex.

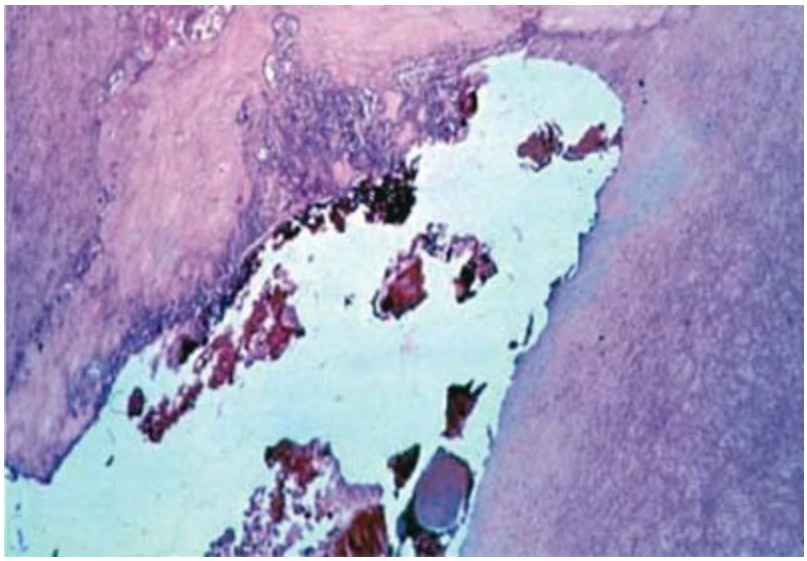

FIG. 21.18 Histologic appearance of hard-tissue barrier after calcium hydroxide apexification. The barrier is composed of cementum and bone with soft-tissue inclusions.

Radiograph shows filled root canal and radiolucent patch in the neck region of tooth.

Reinforcement of thin dentinal walls.

The apexification procedure has become a predictably successful procedure (see the section Prognosis),[76,91] but thin dentinal walls still present a clinical problem. Should secondary injuries occur, teeth with thin dentinal walls are more susceptible to fractures that render them unrestorable.[65,179] It has been reported that approximately 30% of these teeth will fracture during or after endodontic treatment.[120] Consequently, some clinicians have questioned the advisability of the apexification procedure and have opted for more radical treatment procedures, including extraction followed by extensive restorative procedures, such as dental implants. However, this approach cannot be considered in children or young adults because facial growth has not been completed. Studies have shown that intracoronal bonded

Telegram: @dental_k

www.konkur.in

restorations can internally strengthen endodontically treated teeth and increase their resistance to fracture.[84,118] Thus, after root filling, the material should be removed to below the marginal bone level and a bonded resin filling placed (see Fig. 21.17).

Follow-up.

Routine recall evaluation should be performed to determine success in the prevention or treatment of apical periodontitis. Restorative procedures should be assessed to ensure that they in no way promote root fractures.

Prognosis.

Periapical healing and the formation of a hard-tissue barrier occur predictably with long-term calcium hydroxide treatment (79% to 96%).[58,120] However, long-term survival is jeopardized by the fracture potential of the thin dentinal walls of these teeth. It is expected that the newer techniques of internally strengthening the teeth described earlier will increase their long-term survivability.

Pulp revascularization/regenerative endodontic treatment.

Regeneration of a necrotic pulp has been considered possible only after avulsion of an immature permanent tooth that was reimplanted within 40 minutes (discussed later). The advantages of pulp revascularization lie in the possibility of further root development and reinforcement of dentinal walls by deposition of hard tissue, thus strengthening the root against fracture (see also Chapter 12). After reimplantation of an avulsed immature tooth, a unique set of circumstances exists that allows regeneration to take place. The young tooth has an open apex and is short, which allows new tissue to grow into the pulp space relatively quickly. The pulp is necrotic but usually neither degenerated nor infected, so it acts as a matrix into which the new tissue can grow. It has been experimentally shown that the apical part of a pulp may remain vital and after reimplantation proliferate coronally, replacing the necrotized portion of the pulp.[30,140,167] Because in most cases the crown of the tooth is intact and caries free, bacterial penetration into the pulp space through cracks[127] and defects will be a slow process. The race between new tissue growth and infection of the pulp space favors the new tissue.[14]

Telegram: @dental_k

www.konkur.in

Traditionally, regeneration of pulp tissue in a necrotic infected tooth with apical periodontitis was thought to be impossible.[138] Regeneration/repair can occur when the canal is effectively disinfected, a matrix into which new tissue can grow is provided, and coronal access is effectively sealed.[30,105] There have been many studies in the past few years aimed at making the procedure more predictable both in healing of apical periodontitis and in promoting pulp and not nonspecific connective tissue (see Chapter 12). A clinical protocol can be found in the AAE "Clinical Considerations for a Regenerative Procedure." However, although there is the potential for further root maturation, a prospective study has shown that increases in root width and length are variable in a cohort of predominantly traumatized teeth (Fig. 21.20).[112]

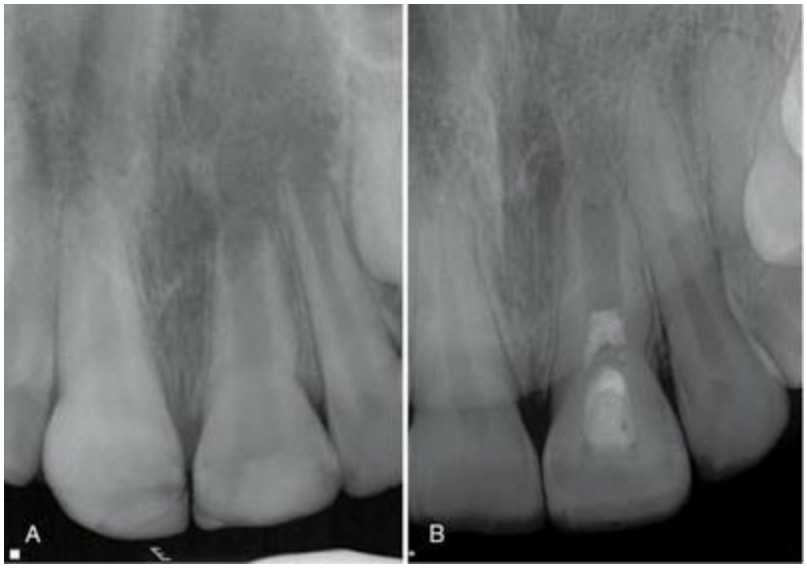

FIG. 21.20 **A,** Preoperative radiograph showing an immature incisor (tooth #9) that sustained an uncomplicated crown fracture where pulp necrosis developed as shown by cessation of root development when compared with tooth #8. **B,** A 6-year review radiograph showing the tooth after treatment with a regenerative endodontic protocol. There were no signs of infection (primary goal). Calcific material at the apex is present indicating apical closure. A quantitative analysis as described by Bose et al.[44] reports a 1.9% increase in root length and a 5% increase in canal wall width (secondary goal). The tooth was responsive to electric pulp testing in a comparable range to tooth #8 (tertiary goal).

Radiograph A shows ninth tooth with wide radiolucent root canal.

Telegram: @dental_k

www.konkur.in

Radiograph B shows two radiopaque patches, one in the crown and the other at the beginning of root.

In regenerative endodontic procedures there are three outcome measures for success. The primary goal is the elimination of symptoms and the evidence of bony healing. The secondary goal is increased root wall thickness and/or increased root length, which is considered desirable but perhaps not essential. The tertiary goal is a positive response to vitality testing (which if achieved, could indicate a more organized vital pulp tissue).[1] It is known that results are variable for these objectives and true regeneration of the pulp/dentin complex is not achieved. Repair derived primarily from the periodontal and osseous tissues has been shown histologically.[34,132]

Disinfection of the canal involved no mechanical preparation, but copious irrigation with NaOCl was performed, followed by placement of an intracanal mixture of antibiotics consisting of equal amounts of ciprofloxacin, metronidazole, and minocycline, to a final concentration of 1 to 5 mg/mL.[1,103] The minocycline in the triantibiotic paste causes unacceptable discoloration of the teeth[113]; this has led to many studies on eliminating or replacing this antibiotic in the paste or eliminating the tripaste. Alternatively, calcium hydroxide can be used as an intracanal medicament rather than an antibiotic paste. Furthermore, Biodentine when used as an intracanal barrier results in less crown discoloration then when MTA is used. Avoiding discoloration of the crown is a patient-centered outcome.

Studies are underway to find a synthetic matrix that can act as a more predictable scaffold for new ingrowth of tissue than the introduction of a blood clot into the canal.[121,194] Studies are also underway on stem cells and growth factors aimed at a more predictable production of odontoblasts and thus pulp cells. It is hoped that with the concept of tissue engineering, namely stem cells, scaffolds, and signaling molecules, that true pulp regeneration is an achievable goal.[121] The procedure described here can be attempted in most cases and has been recommended as treatment of choice for immature teeth with incomplete root formation, although teeth with near or complete root formation may be more suited for conventional endodontic therapy or MTA barrier techniques.[121] If there are no signs of regeneration or continued signs of infection, the more traditional treatment methods for treatment of

Telegram: @dental_k

www.konkur.in

immature teeth can be initiated.

Mature tooth

Conventional endodontic therapy is recommended for mature teeth with closed apex.

Crown-root fracture

Crown-root fracture is a periodontal rather than an endodontic challenge. The tooth must be treated periodontally to enable a well-sealed coronal restoration. This could be accomplished by simple gingivectomy if the extent of the root component of the fracture is large. Alternatively, the tooth could be orthodontically or surgically extruded such that the exposed surface of the root fracture is treatable. Once the feasibility of the coronal restoration is ensured, the particular crown fracture is treated as previously described.

Root fracture

Root fracture implies fracture of the cementum, dentin, and pulp. These injuries are relatively infrequent, occurring in less than 3% of all dental injuries.[199] Immature teeth with vital pulps rarely sustain horizontal root fractures.[10] When a root fractures horizontally, the coronal segment is displaced to a varying degree, but generally the apical segment is not displaced. Because the apical pulpal circulation is not disrupted, pulp necrosis in the apical segment is extremely rare. Permanent pulpal necrosis of the coronal segment, requiring endodontic treatment, occurs in approximately 25% of cases.[11,12,107]

Diagnosis and clinical presentation

The clinical presentation of a root fracture is similar to that of luxation injuries. The extent of displacement of the coronal segment is usually indicative of the location of the fracture and can vary from none, simulating a concussion injury (apical fracture), to severe, simulating an extrusive luxation (cervical fracture).

Radiographic examination for root fractures is extremely important.

Telegram: @dental_k

www.konkur.in

Because root fractures are usually oblique (facial to palatal; Fig. 21.21), one periapical radiograph may easily miss it. It is imperative to take at least three angled radiographs (45 degrees, 90 degrees, and 110 degrees) so that at least at one angulation, the x-ray beam passes directly through the fracture line to make it visible on the radiograph (Fig. 21.22).

B) Two fracture marks are visible on the right incisor with receding gum line.

C) One light and one wide dark fracture mark is visible on the right incisor.

Treatment

Emergency treatment involves repositioning the segments into close proximity as much as possible. In the case of severe displacement of the coronal segment, its apical extension is frequently lodged in (if not

Telegram: @dental_k

www.konkur.in

perforating through) the cortical bone facial to the tooth. Forcing the crown facially is not possible, and the two segments will not be properly aligned. The only way to accomplish reapproximation of the two segments is to release the coronal segment from the bone by gently pulling it slightly downward with finger pressure or extraction forceps and, once it is loose, rotating it back to its original position (Fig. 21.23). The traditionally recommended[147] splinting protocol has been changed from 2 to 4 months with rigid splinting to a flexible splint to adjacent teeth for 2 to 4 weeks.[23,69,110] If a long time has elapsed between the injury and treatment, repositioning of the segments close to their original position probably will not be possible; this compromises the long-term prognosis for the tooth.

Healing patterns

Investigators[26] have described four types of responses to root fractures.

1. *Healing with calcified tissue.* Radiographically, the fracture line is discernible, but the fragments are in close contact (Fig. 21.24, *A*).
2. *Healing with interproximal connective tissue.* Radiographically, the

Telegram: @dental_k

www.konkur.in

fragments appear separated by a narrow radiolucent line, and the fractured edges appear rounded (see Fig. 21.24, *B*).

3. *Healing with interproximal bone and connective tissue*. Radiographically, the fragments are separated by a distinct bony ridge (see Fig. 21.24, *C*).
4. *Interproximal inflammatory tissue without healing*. Radiographically, a widening of the fracture line and/or a developing radiolucency corresponding to the fracture line becomes apparent (see Fig. 21.24, *D*).

The first three healing patterns are considered successful. The teeth are usually asymptomatic and respond positively to sensitivity testing. Histologically, healing can be derived from pulpal and periodontal tissues (Fig. 21.25 for healing with calcified tissue; Fig. 21.26 for healing with interproximal connective tissue).[97]

Telegram: @dental_k

www.konkur.in

B) Close-up view shows reddish-yellow front teeth. The lateral incisor has circular deep patch.

The fourth type of root fracture response is typical when the coronal segment loses its vitality. The infective products in the coronal pulp cause an inflammatory response and typically radiolucencies are at the fracture line (see Fig. 21.24, *D*).[26]

Treatment of complications

Coronal root fractures

Historically it had been thought that fractures in the cervical segment had a poor prognosis, and extraction of the coronal segment was recommended. Research does not support this treatment; in fact, if these coronal segments are adequately splinted, chances of healing do not differ from those for midroot or apical fractures (Fig. 21.28).[199] However, if the fracture occurs at the level of or coronal to the crest of the alveolar bone, the prognosis is extremely poor.

FIG. 21.28 Internal root resorption in the root fracture area; tooth was diagnosed with compound midroot fracture. **A,** Coronal portion was repositioned and then splinted to the lateral incisor with a composite splint. **B,** At 6-month recall, the pulp responded normally to cold, but an internal root-resorptive defect was noted on radiograph. No treatment was indicated, because the pulp did respond normally to vitality tests. **C,** At 42-month recall, the tooth was still asymptomatic, and the pulp still responded to vitality tests. The resorptive defect had healed, and signs of dystrophic calcifications were evident in the apical and coronal

Telegram: @dental_k

www.konkur.in

segments.

Set of three radiographs, marked A through C, compare the fracture in the mid-root of tooth after 6 and 42 month recall.

If reapproximation of the fractured segments is not possible, extraction of the coronal segment is indicated. The level of fracture and length of the remaining root are evaluated for restorability. If the apical root segment is long enough, gentle orthodontic eruption of this segment can be carried out to enable fabrication of a restoration.

Midroot and apical root fractures

Permanent pulpal necrosis occurs in 25% of root fractures.[56,108] Initially it is likely that in many cases the pulp in the coronal segment will become necrotic after the injury; however, because of a very large apical opening in the coronal segment, revascularization is possible if the segments are well reapproximated. In most cases, permanent necrosis occurs in the coronal segment, with only the apical segment remaining vital. Therefore endodontic treatment is indicated in the coronal root segment unless periapical pathology is seen in the apical segment. In most cases the pulpal lumen is wide at the apical extent of the coronal segment, and long-term calcium hydroxide treatment or an MTA apical plug is indicated (see the section Apexification). The coronal segment is filled after a hard-tissue barrier has formed apically in the coronal segment and periradicular healing has taken place.

In rare cases in which both the coronal and apical pulp are necrotic, treatment is more complicated. Endodontic treatment through the fracture is extremely difficult. Endodontic manipulations, medicaments, and filling materials all have a detrimental effect on healing of the fracture site. If healing of the fracture has been completed and is followed by necrosis of the apical segment, the prognosis is much improved.

In more apical root fractures, necrotic apical segments can be surgically removed. This is a viable treatment if the remaining coronal root segment is long enough to provide adequate periodontal support. Removal of the apical segment in midroot fractures leaves the coronal segment with a compromised attachment.

Follow-up

Telegram: @dental_k

www.konkur.in

After the splinting period is completed, follow-up is as for all dental traumatic injuries: at 3, 6, and 12 months and yearly thereafter for at least 5 years.

Prognosis

The following factors influence repair:

1. The degree of dislocation and mobility of the coronal fragment are extremely important in determining outcome.[10,22,108,170,199] Increased dislocation and coronal fragment mobility result in a poorer prognosis.
2. Immature teeth are seldom involved in root fractures, but in the unlikely event they are, the prognosis is good.[22,106]
3. The quality of treatment is vital to successful repair. The prognosis improves with quick treatment, close reduction of the root segments, and semirigid splinting for 2 to 4 weeks.[23]

Complications include pulp necrosis and root canal obliteration. Pulp necrosis can be treated successfully[56,108] by treating the coronal segment with calcium hydroxide to stimulate hard-tissue barrier formation. Root canal obliteration is common if the root segment (coronal or apical) remains vital.

Luxation injuries

Definitions

The types of luxation injury can be defined as follows:

1. *Concussion* implies no displacement, normal mobility, and sensitivity to percussion.
2. *Subluxation* implies sensitivity to percussion, increased mobility, and no displacement.
3. *Lateral luxation* implies displacement labially, lingually, distally, or incisally.
4. *Extrusive luxation* implies displacement in a coronal direction.

Telegram: @dental_k

www.konkur.in

5. *Intrusive luxation* implies displacement in an apical direction into the alveolus.

Definitions 1 through 5 describe injuries of increasing magnitude in terms of intensity of the injury and subsequent sequelae.

Incidence

Luxation injuries as a group are the most common of all dental injuries, with a reported incidence ranging from 30% to 44%.[63]

Treatment

Teeth that are concussed or subluxated do not need any immediate treatment. Responses to vitality tests should be investigated and noted. Even after mild injury, such as subluxation, the pulp might be unresponsive to vitality tests for several weeks if not months.[166] When the pulp is unresponsive initially after the trauma, patients should be recalled on a regular basis and monitored for any additional signs of infection of the root canal (discussed later).

Teeth with lateral and extrusive luxation should be repositioned as soon as possible. In lateral luxation, the apex might be perforating the facial bone plate, and the tooth must be slightly and gently pulled down to loosen the hold before it is repositioned in its original position. Current IADT guidelines call for 2 weeks of physiologic splinting in cases of extrusion luxation and 4 weeks for lateral luxation. A decision on root canal therapy follows the guidelines for avulsion (discussed later). If the tooth has a fully formed apex and was diagnosed to have moved into (if not through) the cortical plate (apical translocation), there is a good likelihood of the pulp being devitalized; therefore endodontic treatment should be initiated as early as 2 weeks after the injury. If the apex is still not fully formed, waiting for signs of revascularization is strongly recommended.

Permanent teeth that are intruded are not likely to spontaneously reerupt, especially if the apex is fully formed.[119] Alternative treatment, such as orthodontic extrusion or immediate surgical repositioning, should be considered. If orthodontic extrusion is planned for an intruded tooth, it should be initiated as soon as possible and should not be delayed longer than 2 to 3 weeks after the trauma. Only a few studies have evaluated the true efficacy of

Telegram: @dental_k

www.konkur.in

this approach. One study[189] using a dog model indicated that severely intruded teeth showed signs of ankylosis as early as 11 to 13 days after the trauma, despite initiation of orthodontic movement 5 to 7 days after the injury.

For the surgical approach, one study[55] (using a dog model) concluded that "a careful immediate surgical repositioning of a severely intruded permanent tooth with complete root formation has many advantages with few disadvantages." Another investigation,[67] a retrospective study of 58 intruded human teeth, indicated that surgical repositioning resulted in a predictable outcome, with only five of the teeth lost over the observation period. However, it was also observed that less surgical manipulation positively influenced the healing. If an intruded tooth is immediately reimplanted, it should be splinted for at least 4 weeks, but in most cases the splint needs to be left on the tooth longer.

Biologic consequences

Luxation injuries result in damage to the attachment apparatus (periodontal ligament and cemental layer), the severity of which depends on the type of injury sustained (concussion least, intrusion most). The apical neurovascular supply to the pulp is also affected to varying degrees, resulting in an altered or nonvital tooth.

Healing can be favorable or unfavorable. Favorable healing after a luxation injury occurs if the initial physical damage to the root surface and the resultant inflammatory response to the damaged external root surface are again covered with cementum. An unfavorable response occurs when there is direct attachment of bone to the root, with the root ultimately being replaced by bone.

There are two resorption responses in which the pulp plays an essential role:

1. In *external* inflammatory root resorption, the *necrotic infected pulp* provides the stimulus for periodontal inflammation in the ligament space. If the cementum has been damaged, the inflammatory stimulators in the pulp space are able to diffuse through the dentinal tubules and stimulate an inflammatory response over large areas of

Telegram: @dental_k

www.konkur.in

the periodontal ligament. Because of the lack of cemental protection, the periodontal inflammation includes root resorption in addition to the expected bone resorption.

2. With *internal* inflammatory root resorption, the inflamed pulp is the tissue involved in resorbing the root structure. The pathogenesis of internal root resorption is not completely understood. Here it is thought that coronal necrotic infected pulp provides a stimulus for a pulpal inflammation in the more apical parts of the remaining vital pulp.[10] If the internal root surface has lost its precemental protection during an injury, internal root resorption occurs in the area adjacent to the inflamed pulp. Thus both the necrotic infected pulp and the inflamed pulp contribute to this type of root resorption.

External root resorption

Caused by an injury (alone) to the external root surface.

If an injury harms the attachment, the by-products of this mechanical damage stimulate an inflammatory response. The healing response depends on the extent of the initial damage.

Localized injury: Healing with cementum.

When the injury is localized (e.g., after concussion or subluxation injury), mechanical damage to the cementum occurs, resulting in a local inflammatory response and a localized area of root resorption. If no further inflammatory stimulus is present, periodontal healing and root surface repair occur within 14 days (Fig. 21.29).[86] The resorption is localized to the area of mechanical damage, and treatment is not required because it is free of symptoms and not even visualized radiographically in most cases. However, in a minority of cases, small radiolucencies can be seen on the root surface if the radiograph is taken at a specific angle. It is important to avoid misinterpreting these cases as progressive. The pulp is not involved. If the pulp responds to sensitivity tests, this is a clue that no treatment should be performed. A wait-and-see attitude can allow spontaneous healing to take place. It is important to realize that in the initial stages, radiolucency could be followed by spontaneous repair, and endodontic treatment should *not* be

Telegram: @dental_k

www.konkur.in

initiated.

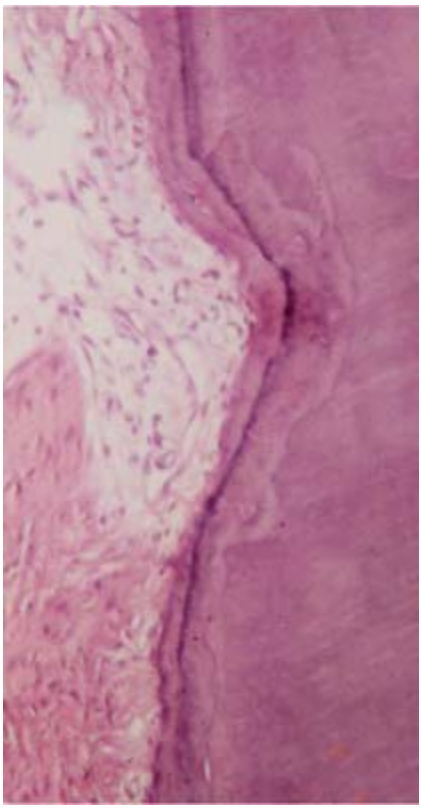

FIG. 21.29 Histologic section showing previous root resorptive defect healed with new cementum and periodontal ligament.

Stained micrograph shows delicate connective tissue with dark spots on the left of vertical line that extends toward the right at the center.

Diffuse injury: Healing by replacement resorption.

When the traumatic injury is severe (e.g., intrusive luxation or avulsion with extended dry time), involving diffuse damage on more than 20% of the root surface, an abnormal attachment can occur after healing takes place.[126] The initial reaction, as always, is inflammation in response to the severe mechanical damage to the root surface. After the initial inflammatory response, a diffuse area of root surface devoid of cementum results. Cells in the vicinity of the denuded root now compete to repopulate it. Often cells that are precursors of bone, rather than the slower-moving periodontal ligament cells, move across from the socket wall and populate the damaged root. Bone

Telegram: @dental_k

www.konkur.in

comes into contact with the root without an intermediate attachment apparatus. This phenomenon is termed *dentoalveolar ankylosis*.[126] Ankylosis results in failure of the tooth to erupt, leading to infraposition in the developing dentition and a high-pitch sound to percussion. However, the ankylosis and replacement resorption that follows cannot be reversed and can be considered a physiologic process because bone resorbs and reforms throughout life. Thus root is resorbed by osteoclasts, but in the reforming stage, bone is laid down instead of dentin, slowly replacing the root with bone. This process is termed *replacement resorption* (Fig. 21.30).[8,19] However, in these traumatic cases, the resorptive phase includes the root being "replaced" with bone (Fig. 21.31). An alternative term of "osseous replacement" has been used.[186]

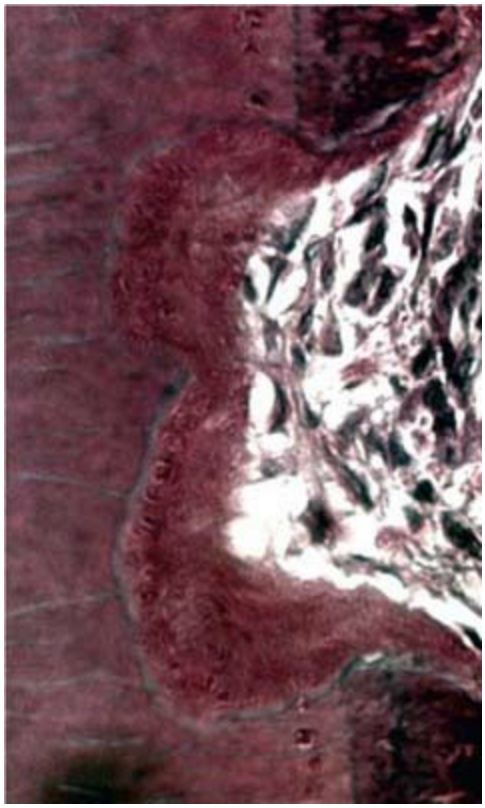

FIG. 21.30 Histologic appearance of replacement resorption. There is direct contact between bone and root structure. Resorptive defects are seen in the bone and root tissue, which is the normal physiologic process of bone turnover. The resorptive defects are filled by new bone and additional areas resorbed. In this way the entire root is replaced by bone at a rate dependent on the metabolic rate of the patient.

Micrograph shows inflammatory superficial root resorption.

FIG. 21.31 Radiographic appearance of replacement resorption. The root acquires the radiographic appearance of the surrounding bone (without a lamina dura). Note that radiolucencies typical of active inflammation are not present.

Radiograph of tooth shows filled root canal and squarish dark patch on the crown.

Treatment.

Treatment strategies for limiting the effect of the traumatic injury to the periodontal structures are outside the scope of this chapter. However, in general they involve minimizing the initial inflammatory response to the injury. The initial inflammation is destructive in nature and increases the surface area of root to be covered in the healing phase.[25] The smaller the surface area to be covered by new cementum, the higher the chances of favorable repair.

Telegram: @dental_k

www.konkur.in

A study has indicated that if Ledermix, a drug combining corticosteroid and tetracycline, is placed in the root canal immediately after a severe trauma in which replacement resorption is expected, favorable healing occurs at a very high rate.[45] In a more recent study, it was shown that triamcinolone (the corticosteroid portion of the Ledermix paste) was as effective as Ledermix at inhibiting external root resorption.[49] Both of these studies were done on young dogs and need to be replicated in human studies.

Caused by an injury to the external root surface and inflammatory stimulus in the root canal.

Recognized inflammatory stimuli that cause root resorption are pressure, pulp space infection, and sulcular infection. This chapter focuses on pulp space infection.

Consequences of apical neurovascular supply damage

Pulp canal obliteration (calcification).

Pulp canal obliteration is common after luxation injuries (see Fig. 21.27). The frequency of pulp canal obliteration appears inversely proportional to pulp necrosis. The exact mechanism of pulp canal obliteration is unknown. It has been theorized that the sympathetic/parasympathetic control of blood flow to the odontoblasts is altered, resulting in uncontrolled reparative dentin.[10,20] Another theory is that hemorrhage and blood clot formation in the pulp after injury form a nidus for subsequent calcification if the pulp remains vital.[10,20] One study[16] found that pulp canal obliteration could usually be diagnosed within the first year after injury and was more frequent in teeth with open apices (>0.7 mm radiographically), those with extrusive and lateral luxation injuries, and those that had been rigidly splinted.[16]

Pulp necrosis.

The factors most important for the development of pulp necrosis are the type of injury (concussion least, intrusion most) and the stage of root development (mature apex more than an immature apex).[15] Pulp necrosis will most likely to lead to infection of the root canal system, with problematic consequences.

Telegram: @dental_k

www.konkur.in

Pulp space infection.

Pulp space infection in conjunction with damage to the external root surface results in periradicular root and bone resorption and continues in its active state as long as the pulpal stimulus (infection) remains. When the root loses its cemental protection, lateral periodontitis with root resorption can result (Fig. 21.32). CBCT imaging can show the extent of the resorption (Fig. 21.33).

FIG. 21.32 Inflammatory root resorption caused by a pulp space infection. Note the radiolucencies in the root and surrounding bone.

Radiograph shows two teeth. The first tooth has chipped crown at the edge and wedge-shaped radiolucency in the root canal. The second tooth has radiolucent root canal with a dark patch on one side.

FIG. 21.33 **A,** Periapical radiograph of tooth #9 of a 16-year-old boy showing a mature tooth 6 months after avulsion and replantation within 5 minutes. Inflammatory root resorption is occurring as endodontic treatment was not commenced. **B** and **C,** CBCT sagittal images taken same day as the periapical radiograph. **D,** CBCT axial images.

Four radiographs are marked A through D.

A) It shows 9th tooth with two fused radiopaque patches in the root canal. 10th tooth has filled root canal

B) 9th tooth shows partially filled root canal extending from the crown.

C) Tooth shows a radiolucent oval near the root apex.

D) Teeth arch shows tooth on the left with radiopaque central cavity.

To have pulp space infection, the pulp must first become necrotic. Necrosis occurs after a fairly serious injury in which displacement of the tooth results in severing of the apical blood vessels. In mature teeth, pulp regeneration cannot occur, and usually by 3 weeks, the necrotic pulp becomes infected. (For details of the typical bacterial contents of a traumatized necrotic pulp, the reader is referred to Chapter 15 or to Bergenholtz.[36]) Because a serious injury is required for pulp necrosis, areas of cemental covering of the root usually are also affected, resulting in loss of its protective (insulating) quality. Now bacterial toxins can pass through the dentinal tubules and stimulate an inflammatory response in the periodontal ligament. The result is resorption of the root and bone. The periodontal infiltrate consists of granulation tissue with lymphocytes, plasma cells, and polymorphonuclear leukocytes. Multinucleated giant cells resorb the denuded root surface, and this continues until the stimulus (pulp space bacteria) is removed (Fig. 21.34).[181] Radiographically, the resorption is observed as progressive radiolucent areas

Telegram: @dental_k

www.konkur.in

of the root and adjacent bone (see Fig. 21.32).

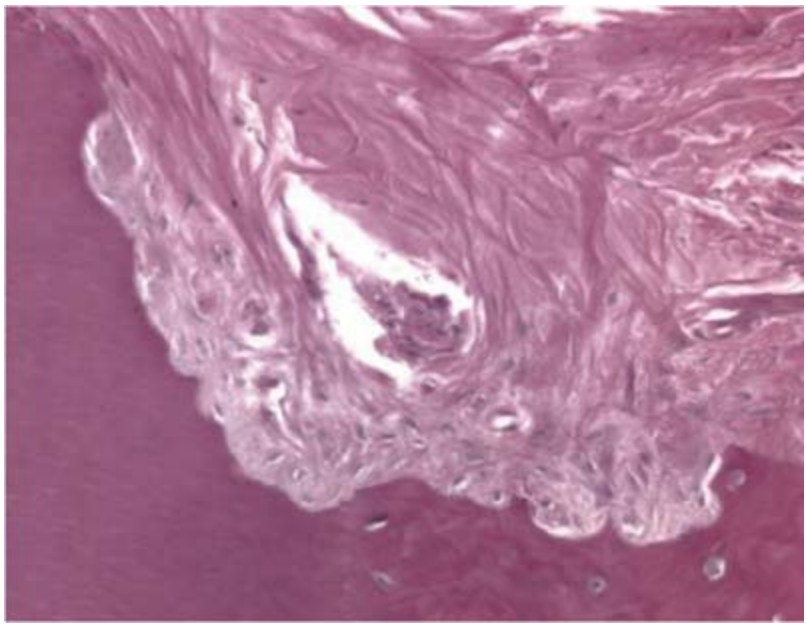

FIG. 21.34 Histologic appearance of multinucleated osteoclasts (dentinoclasts) resorbing the dentin of the root.

Stained micrograph shows large multinucleated cells scattered in the bone cavity consisting of dense fibroblastic cells.

Treatment.

Assessing attachment damage caused by the traumatic injury and minimizing the subsequent inflammation should be the focus of the emergency visit. The clinician's attention to pulp space infection should ideally be 7 to 10 days after the injury.[187,188] Root canal disinfection removes the stimulus to the periradicular inflammation, thus the resorption will stop.[86,187,188] In most cases a new attachment will form, but if a large area of root is affected, replacement resorption can result by the mechanism already described. Again, treatment principles include prevention of pulp space infection or elimination of the bacteria if they are present in the pulp space.

1. Prevention of pulp space infection
    a. *Reestablish the vitality of the pulp*. If the pulp stays vital, the canal will be free of bacteria, and external inflammatory root

Telegram: @dental_k

www.konkur.in

resorption will not occur. In severe injuries in which vitality has been lost, it is possible under some circumstances to promote revascularization of the pulp. Revascularization is possible in young teeth with incompletely formed apices if the teeth are replaced in their original position within 60 minutes of the injury (Fig. 21.35).[59] If the tooth has been avulsed, soaking it in doxycycline for 5 minutes or covering the root with minocycline powder before replantation has been shown to double or triple the revascularization rate.[59,150] However, even under the best conditions, revascularization fails to occur on many occasions, and a diagnostic dilemma results. If the pulp revascularizes, external root resorption will not occur, and the root will continue to develop and strengthen. If the pulp becomes necrotic and infected, the subsequent external inflammatory root resorption that develops could result in loss of the tooth in a very short time. At present, the diagnostic tools available cannot detect a vital pulp in this situation before approximately 6 months after successful revascularization. This period of time is obviously unacceptable because by that time the teeth that have not revascularized could be lost to the resorption process. Recently the laser Doppler flowmeter or the pulse oximeter has been shown to have diagnostic potential for the detection of revascularization in immature teeth (see Fig. 21.2). These devices appear to detect the presence of vital tissue in the pulp space by 4 weeks after the traumatic injury.[197]

b. *Prevent root canal infection by initiating root canal treatment at 7 to 10 days*. In teeth with closed apices, revascularization cannot occur. These teeth should be endodontically treated within 7 to 10 days of the injury, before the ischemically necrosed pulp becomes infected.[187,188] Endodontic treatment is extremely difficult so soon after a serious traumatic injury. It is beneficial to start the endodontic treatment with chemomechanical preparation, after which an intracanal dressing with a creamy mix of calcium hydroxide is placed (see Fig. 21.15).[187] Then, the clinician can fill the canal at his or her

Telegram: @dental_k

www.konkur.in

convenience after periodontal healing of the injury is complete, approximately 1 month after the instrumentation visit. There appears to be no necessity for long-term calcium hydroxide treatment in cases in which the endodontic treatment is started within 10 days of the injury.[187]

2. *Eliminate pulp space infection*. When root canal treatment is initiated later than 10 days after the accident or if active external inflammatory resorption is observed, the preferred antibacterial protocol consists of microbial control followed by long-term dressing with calcium hydroxide.[188] Calcium hydroxide can effect an alkaline pH in the surrounding dentinal tubules (Fig. 21.36), kill bacteria, and neutralize endotoxin, a potent inflammatory stimulator.

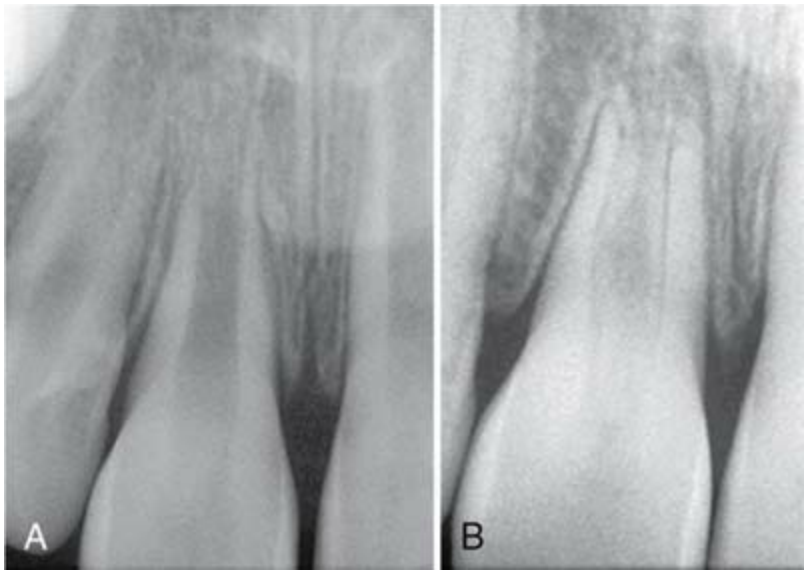

FIG. 21.35 Revascularization of immature root. A tooth with an open apex was replanted soon after the avulsion. The checkup radiograph 12 years later confirms that regrowth has taken place into the pulp chamber. It appears that a bone plug has grown in, and new periodontal ligament has formed, with a lamina dura within the pulp canal.

Two radiographs are marked A and B.

A) The central tooth has open root tip and radiolucency extended below the neck region.

B) The tooth has radiopaque root canal and a partial radiolucent patch (oval-

shaped) in the root.

Source: (Courtesy Dr. Cecilia Bourguignon, Paris, France.)

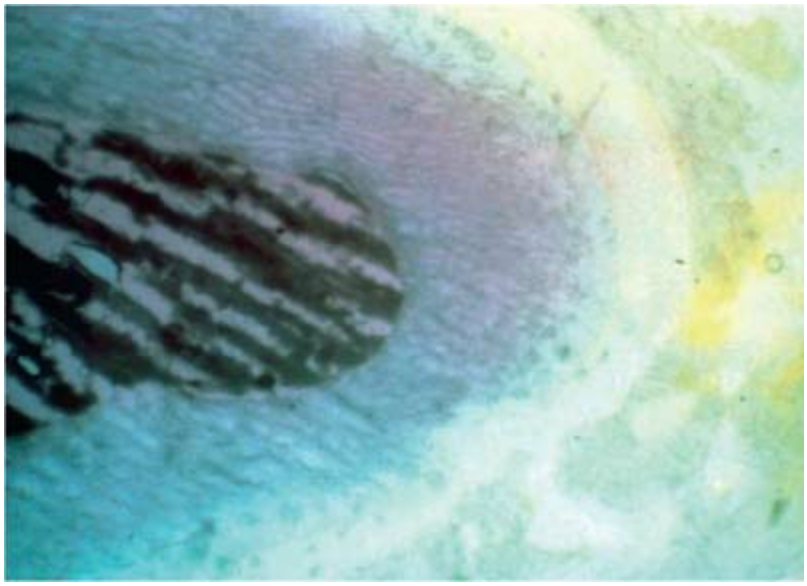

FIG. 21.36 High pH of calcium hydroxide. The root was filled with calcium hydroxide and then cut in cross section. A pH indication shows the high pH in the canal and surrounding root, whereas the surrounding tissue is a neutral pH.

Root apex shows oblique black lines surrounded by pinkish blue color, which is further followed by a white margin and then greenish-pink color with a tinge of yellow on one side.

The first visit consists of the microbial control phase, with cleaning and shaping of the canal and the placement of either a corticosteroid/antibiotic material or a creamy mix of calcium hydroxide using a Lentulo spiral. The patient is seen in approximately 1 month, at which time the canal is filled with a dense mix of calcium hydroxide. Once filled, the canal should appear radiographically to be calcified because the radiodensity of calcium hydroxide in the canal is usually similar to that of the surrounding dentin (see Fig. 21.16). A radiograph is then exposed at 3-month intervals. At each visit the tooth is tested for symptoms of periodontitis. In addition to stopping the resorptive process, calcium hydroxide washout is assessed. Because the root surface is so radiodense as to make assessment of healing difficult, the

Telegram: @dental_k

www.konkur.in

adjacent bone healing is assessed. If adjacent bone has healed, it is assumed that the resorptive process has stopped in the root as well; then the canal can be obturated with the permanent root filling material (Fig. 21.37).

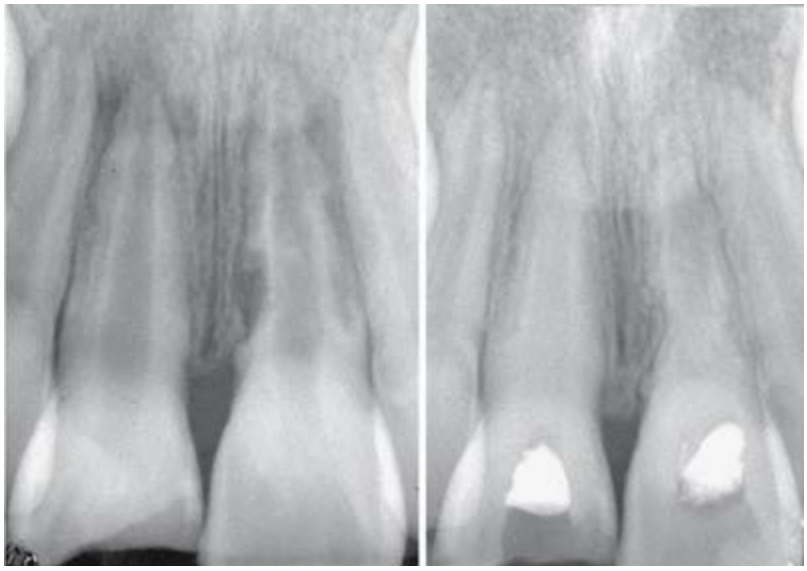

FIG. 21.37 Healing of external inflammatory root resorption after calcium hydroxide treatment. The radiolucencies seen before treatment have disappeared with the reestablishment of the lamina dura.

Radiograph on the left shows one tooth with chipped crown and wedge-shaped radiolucency in root canal. The adjacent tooth has radiolucent root canal with dark patches on both side and receding gum line.

Internal root resorption

Internal root resorption is rare in permanent teeth. Internal resorption is characterized by an oval-shaped enlargement of the root canal space.[21] External resorption, which is much more common, is often misdiagnosed as internal resorption.

Etiology.

Internal root resorption is characterized by resorption of the internal aspect of

Telegram: @dental_k

www.konkur.in

the root by multinucleated giant cells adjacent to the granulation tissue in the pulp (Fig. 21.38). Chronic inflammatory tissue is common in the pulp, but only rarely does it result in resorption. There are different theories on the origin of the pulpal granulation tissue involved in internal resorption. The most logical explanation is that it is inflamed pulp tissue caused by an infected coronal pulp space. Communication between the coronal necrotic tissue and the vital pulp is through appropriately oriented dentinal tubules (see Fig. 21.38).[191] One investigator[191] reported that resorption of the dentin is frequently associated with deposition of hard tissue resembling bone or cementum and not dentin. He postulates that the resorbing tissue is not of pulpal origin but is “metaplastic” tissue derived from the pulpal invasion of macrophage-like cells. Others[171] concluded that the pulp tissue was replaced by periodontium-like connective tissue when internal resorption was present. In addition to the requirement of the presence of granulation tissue, root resorption takes place only if the odontoblastic layer and predentin are lost or altered.[181]

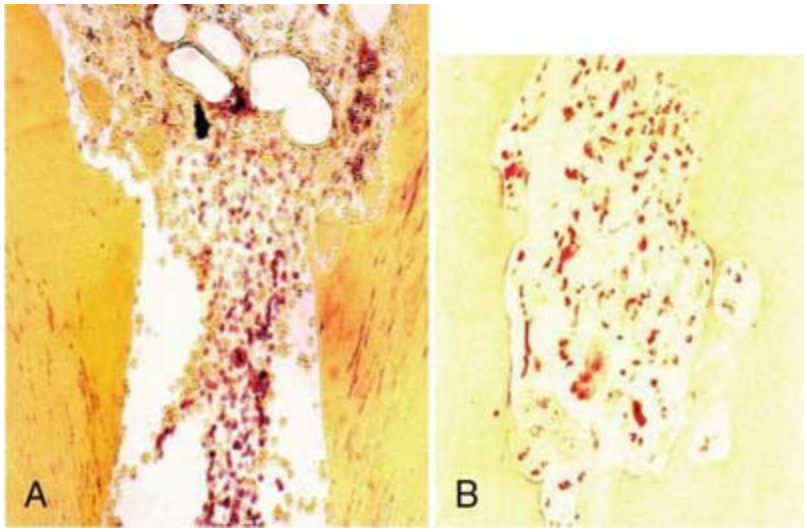

FIG. 21.38 Histologic appearance of internal root resorption. **A,** Section stained with Brown and Brenn. Bacteria are seen (in the dentinal tubules) communicating between the necrotic coronal segment and the apical granulomatous tissue and resorbing cells. **B,** An area of active internal root resorption.

Telegram: @dental_k

www.konkur.in

B) Stained micrograph shows irregular light patch with scattered dark cells.

Source: (Courtesy Dr. Leif Tronstad, Oslo, Norway.)

Reasons for the loss of predentin adjacent to the granulation tissue are not obvious. Trauma frequently has been suggested as a cause.[157,192] Another reason for the loss of predentin might be extreme heat produced when cutting on dentin without an adequate water spray. The heat presumably would destroy the predentin layer, and if later the coronal aspect of the pulp becomes infected, the bacterial products could initiate the typical inflammation in conjunction with resorbing giant cells in the vital pulp adjacent to the denuded root surface. Internal root resorption has been produced experimentally by the application of diathermy.[191]

Clinical manifestations.

Internal root resorption is usually asymptomatic and is first recognized clinically through routine radiographs. For internal resorption to be active, at least part of the pulp must be vital. The coronal portion of the pulp is often necrotic, whereas the apical pulp that includes the internal resorptive defect can remain vital. Therefore a negative sensitivity test result does not rule out active internal resorption. It is also possible that the pulp becomes nonvital after a period of active resorption, giving a negative sensitivity test, radiographic signs of internal resorption, and radiographic signs of apical inflammation. Traditionally, the pink tooth has been thought to be pathognomonic of internal root resorption. The pink color is due to the granulation tissue in the coronal dentin undermining the crown enamel. The pink tooth can also be a feature of invasive cervical resorption, which must be excluded before a diagnosis of internal root resorption is made. Invasive cervical resorption has been described and classified by Heithersay[92,93,94] by the extent of the resorptive lesion into the root, which initiates at the external cervical aspect of the tooth. Simple elimination of the resorptive tissue is ineffective in arresting its progress. Total removal or inactivation of the resorptive tissue is essential if recurrence (or concurrence) is to be avoided. Concurrence indicates the incomplete removal of the resorptive tissue at the time of treatment and recurrence is the reestablishment of the resorptive process. The reason for recurrence or concurrence is probably due to the

Telegram: @dental_k

www.konkur.in

invasive nature of the resorptive tissue whereby small infiltrative channels are created within the dentin, and these may interconnect with the periodontal ligament in positions more apical to the main resorptive defect. The use of trichloroacetic acid has been shown to be effective.[94]

Radiographic appearance.

The usual radiographic presentation of internal root resorption is a fairly uniform radiolucent enlargement of the pulp canal (Figs. 21.39 and 21.40). Because the resorption is initiated in the root canal, the resorptive defect includes some part of the root canal space, so the original outline of the root canal is distorted.

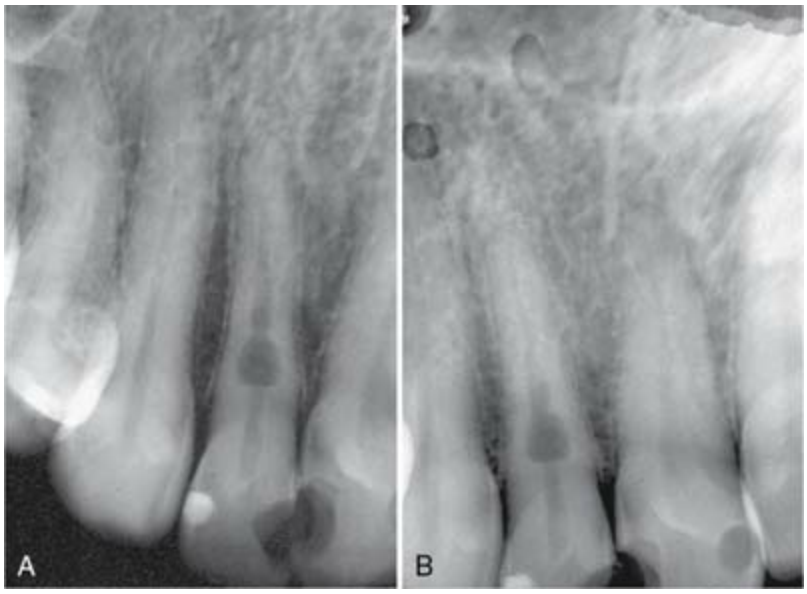

FIG. 21.39 Angled radiographs to show internal resorption. Radiographs from two different horizontal projections depict **(A)** the lesion within the confines of the canal on both views and **(B)** the adjacent bone intact on both views.

Radiograph A shows four teeth. The third tooth has a dark patch on the root canal. The crowns of both third and fourth teeth are broken at the connected site.

Radiograph B shows the third teeth with squarish dark patch below the neck region on the root canal. The fourth tooth has a round dark patch in the crown.

Telegram: @dental_k

www.konkur.in

Histologic appearance.

Like that of other inflammatory resorptive defects, the histologic picture of internal resorption is granulation tissue with multinucleated giant cells (see Fig. 21.37). An area of necrotic pulp is found coronal to the granulation tissue. Dentinal tubules containing microorganisms and communicating between the necrotic zone and the granulation tissue can sometimes be seen (see Fig. 21.38).[162,181,188,191] Unlike external root resorption, the adjacent bone is not affected with internal root resorption.

Treatment.

Treatment of internal root resorption is conceptually very easy. Because the resorptive defect is the result of the inflamed pulp and the blood supply to the tissue is through the apical foramina, endodontic treatment that effectively removes the blood supply to the resorbing cells is the treatment approach. After adequate anesthesia has been obtained, the canal apical to the internal defect is explored, and a working length short of the radiographic apex is used. The apical canal is thoroughly cleaned and shaped to ensure that the blood supply to the tissue resorbing the root is cut off.

By completion of the root canal instrumentation, it should be possible to obtain a blood-free and dry canal with paper points. Calcium hydroxide is spun into the canal to facilitate the removal of the tissue in the irregular defect at the next visit. At the second visit, the tooth and defect are filled with a warm gutta-percha technique (Fig. 21.41).

FIG. 21.41 **A,** Internal root resorption in a maxillary premolar with a history of trauma 7 years before the diagnosis (patient's head slammed against side window during an automobile accident). **B,** Three-year follow-up radiograph after endodontic treatment.

Telegram: @dental_k

www.konkur.in

Radiograph A shows upper premolar with radiolucent patch in-between the root and two radiopaque patches on the crown. The adjacent tooth has radiolucent root canal.

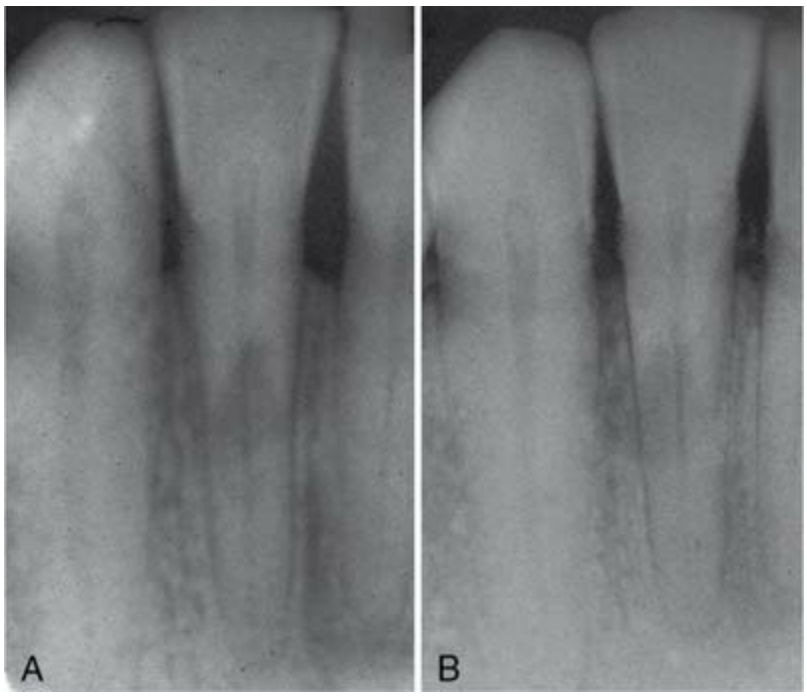
Radiograph B shows upper premolar with two radiopaque patches on the crown. The adjacent tooth has filled root canal.

Diagnostic features of external versus internal root resorption

It is often very difficult to distinguish external from internal root resorption, so misdiagnosis and incorrect treatment may result. The following sections present a list of typical diagnostic features of each resorptive type.

Radiographic features.

A change of angulation of x-rays should give a fairly good indication of whether a resorptive defect is internal or external. A lesion of internal origin appears close to the canal, whatever the angle of the x-ray (see Fig. 21.39). A defect on the external aspect of the root moves away from the canal as the angulation changes (Fig. 21.42). By using the buccal object rule, it is usually possible to distinguish whether the external root defect is buccal or lingual-palatal.



Telegram: @dental_k

www.konkur.in

FIG. 21.42 External root resorption. Radiographs from two different horizontal projections depict movement of the lesion to outside the confines of the root canal.

Radiograph A shows three teeth. The central tooth has a radiolucent patch below the neck region in the root. Radiograph B shows the central tooth with a radiolucent patch on one side of the canal.

With internal resorption, the outline of the root canal is usually distorted, and the root canal and radiolucent resorptive defect appear contiguous (see Fig. 21.40). When the defect is external, the root canal outline appears normal and can usually be seen "running through" the radiolucent defect (Fig. 21.43).

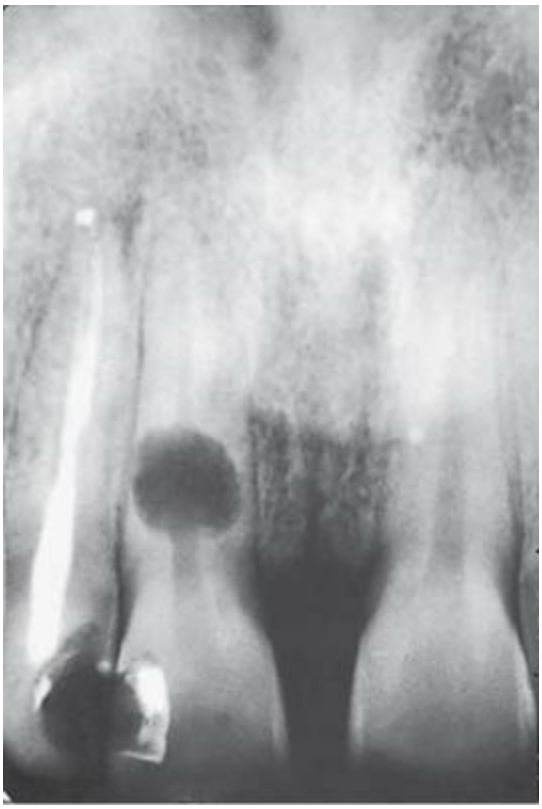


FIG. 21.40 A maxillary incisor with internal root resorption. Uniform enlargement of the pulp space is apparent. Outline of the canal cannot be seen in the resorptive defect.

Radiograph shows a round dark patch on the lateral side of crown in first tooth and another round patch in the root canal of second tooth.

Telegram: @dental_k

www.konkur.in

FIG. 21.43 **A,** Periapical radiograph of invasive cervical root resorption in tooth #8 and #9 in a 68-year-old female where the only known trauma was a fall onto bitumen aged 7 years when hit by a car. These teeth are diagnosed as having Heithersay Grade IV invasive cervical resorptive lesions which can be confirmed by CBCT imaging. **B** and **C,** CBCT coronal images. **D,** CBCT sagittal image of tooth #8. **E,** CBCT axial image. The outline of the canal is evident in Panels A, B, D, and E. The pulp does not appear exposed due to the anticlastic properties of predentin.

Five radiographs are marked A through E.

A) 8th tooth has a large oval-shaped dark patch. 9th tooth has a small dark patch on one side of the root canal.

B) 8th tooth has clear dark patch extended from dentin to the middle of root. 9th tooth is radiopaque.

C) 8th and 9th tooth show a dark patch on the right and at the center, respectively.

D) 8th tooth has a radiolucent root canal along with a large patch on the left.

E) 8th tooth has a U-shaped radiolucency. 9th tooth has a squarish radioluceny.

Invasive cervical resorption maybe accompanied by resorption of the bone in addition to the root (Fig. 21.44); radiolucencies can be apparent in the root and the adjacent bone. Internal root resorption does not involve the bone, and

Telegram: @dental_k

www.konkur.in

as a rule the radiolucency is confined to the root (see Fig. 21.39). On rare occasions, if the internal defect perforates the root, the bone adjacent to it is resorbed and appears radiolucent on the radiograph.

FIG. 21.44 Tooth #9 exhibiting invasive cervical resorption in a 31-year-old male. The tooth was injured 3 years prior after a fall from a scooter and was root filled and restored with a post crown. The resorption commences in the cervical external root and extends deeper into the root consistent with a Heithersay Grade III invasive cervical resorptive lesion. A resorptive defect is also present in the adjacent bone.

Radiograph shows central tooth with filled root canal. There is a radiolucent patch near the gum line.

Vitality testing.

External inflammatory resorption in the apical and lateral aspects of the root involves an infected pulp space, so no response to sensitivity tests supports the diagnosis. However, because invasive cervical resorption does not involve the pulp, a normal response to sensitivity testing is usually associated with this type of resorption. Internal root resorption usually occurs in teeth

Telegram: @dental_k

www.konkur.in

with vital pulps and responses to sensitivity testing. In teeth that exhibit internal root resorption, it is common to register a nonresponse to sensitivity testing because often the coronal pulp has been removed or is necrotic, and the active resorbing cells are more apical in the canal. In addition, the pulp might have become necrotic after active resorption took place.

Pink spot.

With apical and lateral external root resorption, the pulp is nonvital, so the granulation tissue that produces the pink spot is not present in these cases. For invasive cervical (Fig. 21.45) and internal root resorption, the pink spot due to the granulation tissue undermining the enamel is a possible sign.

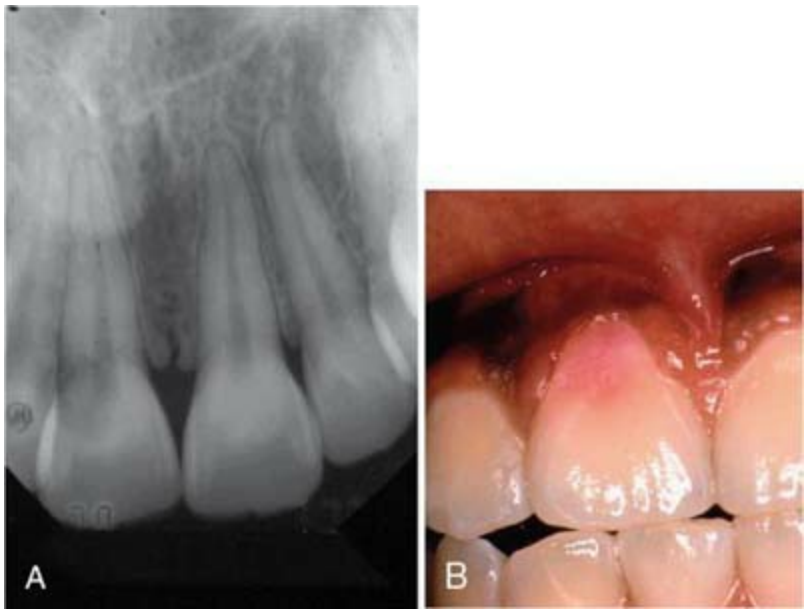

FIG. 21.45 Pink spot of invasive cervical root resorption. **A,** Radiographic appearance. **B,** Clinical appearance.

A) Radiograph shows a round radiolucent patch on the crown close to the gum line.

B) Close-up view shows a pink stain on the tooth.

Transient apical breakdown.

A variation on internal resorption, noted especially after luxation injuries to more mature teeth, is transient apical internal resorption. Disruption of the

Telegram: @dental_k

www.konkur.in

neurovascular bundle at the apex may result in inflammatory mediators that allow osteoclastic changes at the apex to accommodate vascular derived repair followed by remodeling of the apex when the resorptive processes resolve. Teeth considered to show a combination of color changes, altered or V-notched apical radiographic changes, and altered pulp sensibility over time may have “transient apical breakdown” (TAB) for which no treatment other than observation is necessary.[9]

Summary of possible diagnostic features

- External inflammatory root resorption due to pulp infection.
  - *Apical:* No response of the pulp to thermal or electric stimuli, with or without a history of trauma.
  - *Lateral:* History of trauma, no response of the pulp to thermal or electric stimuli, lesion moves on angled x-rays, root canal visualized radiographically overlying the defect, bony radiolucency also apparent.
- Invasive cervical resorption. Often a history of trauma (maybe forgotten, or its long-term risks not appreciated by the patient); positive pulp sensitivity test; lesion located at the attachment level of the tooth; lesion moves on angled x-rays; root canal outline is undistorted and can be visualized radiographically; crestal bony defect associated with the lesion; pink spot possible. CBCT imaging more reliably illustrates the extent of the resorption throughout the root (see Fig. 21.43).
- Internal root resorption. History of trauma, crown preparation, or pulpotomy; responsive pulp to thermal or electric stimuli likely, may occur at any location along the root canal (not only attachment level); lesion stays associated with the root canal on angled x-rays, radiolucency contained in the root without an adjacent bony defect; pink spot possible.

Most misdiagnoses of resorptive defects are made between invasive cervical and internal root resorptions. The diagnosis should always be confirmed as treatment proceeds. If root canal therapy is the treatment of choice for an apparent internal root resorption, the bleeding within the canal

Telegram: @dental_k

www.konkur.in

should cease quickly after pulp extirpation because the blood supply of the granulation tissue is the apical blood vessels. If bleeding continues during treatment, and particularly if it is still present at the second visit, the source of the blood supply is external, and treatment for perforating external resorption should be carried out. On obturation, it should be possible to fill the entire canal from within in internal resorption. Failure to achieve this should make the clinician suspicious of an external lesion that perforates the root. Finally, if the blood supply of an internal resorption defect is removed on pulp extirpation, any continuation of the resorptive process on recall radiographs should alert the clinician to the possibility that an external resorptive defect was misdiagnosed.

Clinical management of the avulsed tooth

Favorable healing after an avulsion injury requires quick emergency intervention followed by evaluation and possible treatment at decisive times during the healing phase. The urgency of the emergency visit and the multidisciplinary nature of follow-up evaluations require that both the public and clinicians from many dental disciplines be knowledgeable about the treatment strategies involved.

Consequences of tooth avulsion

Tooth avulsion results in attachment damage and pulp necrosis. The tooth is "separated" from the socket due mainly to tearing of the periodontal ligament that leaves viable periodontal ligament cells on most of the root surface. In addition, small and localized cemental damage occurs from the crushing of the tooth against the socket.

If the periodontal ligament left attached to the root surface does not dry out, the consequences of tooth avulsion are usually minimal.[19,168] The hydrated periodontal ligament cells will maintain their viability and repair after replantation, with minimal destructive inflammation as a by-product. Because the areas of the crushing injury are localized, inflammation stimulated by the damaged tissues will be correspondingly limited, and favorable healing with new replacement cementum is likely to occur after the initial inflammation subsides (see Fig. 21.29).

Telegram: @dental_k

www.konkur.in

If excessive drying occurs before replantation, the damaged periodontal ligament cells elicit a severe inflammatory response over a diffuse area on the root surface. Unlike the situation described earlier, in which the area to be repaired after the initial inflammatory response is small, here a large area of root surface is affected that must be repaired by new tissue. The slower-moving cementoblasts cannot cover the entire root surface in time, and it is likely that in certain areas, bone will attach directly onto the root surface. In time, through physiologic bone recontouring, the entire root will be replaced by bone. As earlier noted, this has been termed *replacement resorption* (see Figs. 21.30 and 21.31).[25,184]

Pulpal necrosis always occurs after an avulsion injury. Although a necrotic pulp itself is not of consequence, the necrotic tissue is extremely susceptible to bacterial contamination. If revascularization does not occur or effective endodontic therapy is not carried out, the pulp space inevitably becomes infected. The combination of bacteria in the root canal and cemental damage on the external surface of the root results in an external inflammatory resorption that can be very serious and can lead to rapid loss of the tooth root (see Figs. 21.32 and 21.33).[181]

The consequences after tooth avulsion appear to be directly related to the severity and surface area of the inflammation on the root surface and resultant damaged root surface that must be repaired. Treatment strategies should always be considered in the context of limiting the extent of the periradicular inflammation, thus tipping the balance toward favorable responses (cemental) rather than unfavorable ones (replacement resorption or inflammatory resorption).

Treatment objectives

Treatment is directed at avoiding or minimizing resultant inflammation due to the two main consequences of the avulsed tooth: attachment damage and pulpal infection.

Attachment damage as a direct result of the avulsion injury cannot be avoided. However, considerable additional damage can occur to the periodontal ligament in the time that the tooth is out of the mouth (primarily because of drying). Treatment is directed at minimizing this damage (and the resultant inflammation) so that the fewest possible complications result.

Telegram: @dental_k

www.konkur.in

When severe additional damage cannot be avoided and replacement resorption of the root is considered certain, steps are taken to slow the replacement of the root by bone to maintain the tooth in the mouth for as long as possible.

In the open apex tooth, all efforts are made to promote revascularization of the pulp, thus avoiding pulp space infection. When revascularization fails (in the open apex tooth) or is not possible (in the closed apex tooth), all treatment efforts are made to prevent or eliminate toxins from the root canal space.

Clinical management

Emergency treatment at the accident site

Replant if possible, or place in an appropriate storage medium. As mentioned, damage to the attachment apparatus that occurred during the initial injury is unavoidable but usually minimal. However, all efforts must be made to minimize necrosis of the remaining periodontal ligament while the tooth is out of the mouth. Pulpal sequelae are not a concern initially and are dealt with at a later stage of treatment.

The single most important factor to ensure a favorable outcome after replantation is the speed with which the tooth is replanted.[21,27] Of utmost importance is the prevention of drying, which causes loss of normal physiologic metabolism and morphology of the periodontal ligament cells.[27,168] Every effort should be made to replant the tooth within the first 15 to 20 minutes.[32] This usually requires emergency personnel at the site of the injury with some knowledge of treatment protocol. The clinician should communicate clearly with the person at the site of the accident. Ideally this information should have been given at an earlier time; for example, as an educational offering to school nurses or athletic trainers. Failing this, the information can be given over the phone. The aim is to replant a clean tooth with an undamaged root surface as gently as possible, after which the patient should be brought to the office immediately. If doubt exists that the tooth can be replanted adequately, the tooth should quickly be stored in an appropriate medium until the patient can get to the dental office for replantation. Suggested storage media, in order of preference, are milk, saliva (either in the vestibule of the mouth or in a container into which the patient expectorates),

Telegram: @dental_k

www.konkur.in

physiologic saline, and water.[100] Water is the least desirable storage medium because the hypotonic environment causes rapid cell lysis and increased inflammation on replantation.[42,43]

Cell culture media in specialized transport containers, such as Hanks Balanced Salt Solution (HBSS), have shown superior ability to maintain the viability of the periodontal ligament fibers for extended periods.[186] Presently they are considered impractical because they need to be present at the accident site before the injury occurs. However, if we consider that more than 60% of avulsion injuries occur close to home or school,[89] it seems reasonable to assume that it would be beneficial to have these media available in emergency kits at these sites. It would also be advantageous to have them in ambulances and in the kits of emergency response personnel who are likely to treat the more serious injuries in which teeth might otherwise be sacrificed to a more serious life-threatening situation.

Management in the dental office

Emergency visit.

Prepare socket, prepare root, replant, construct a functional splint, and administer local and systemic antibiotics.

Recognizing that a dental injury might be secondary to a more serious injury is essential. The attending dental clinician is likely to be the first health care provider the patient sees after a head injury, so ruling out any injuries to the brain (e.g., concussion) and/or central nervous system (CNS) in general is paramount. If on examination a CNS injury is suspected, immediate referral to the appropriate expert is the first priority, above and beyond the dental injury. Once a CNS injury has been ruled out, the focus of the emergency visit is the attachment apparatus. The aim is to replant the tooth with a minimum of irreversibly damaged cells (that will cause inflammation) and the maximal number of periodontal ligament cells that have the potential to regenerate and repair the damaged root surface.

Diagnosis and treatment planning

If the tooth was replanted at the site of injury, a complete history is taken to assess the likelihood of a favorable outcome. The position of the replanted

Telegram: @dental_k

www.konkur.in

tooth is assessed and adjusted if necessary. On rare occasions, the tooth may be gently removed to prepare the root to increase the chances of a favorable outcome (discussed later).

If the patient presents with the tooth out of the mouth, the storage medium should be evaluated and the tooth placed in a more appropriate medium if required. HBSS is presently considered the best medium for this purpose. Milk or physiologic saline is also appropriate for storage purposes.

The medical and accident histories are taken, and a clinical exam is carried out, with emphasis on questions about when, how, and where the injury occurred.

The clinical examination should include an examination of the socket to ascertain whether it is intact and suitable for replantation. The socket is gently rinsed with saline, and when it has been cleared of the clot and debris, its walls are examined directly for the presence, absence, or collapse of the socket wall. The socket and surrounding areas, including the soft tissues, should be radiographed. Three vertical angulations are required for diagnosis of the presence of a horizontal root fracture in adjacent teeth.[21] The remaining teeth in both the upper and lower jaws should be examined for injuries, such as crown fractures. Any soft-tissue lacerations should be noted and, if tooth fragments are missing, explored. A photograph prior to any treatment is beneficial especially if legal concerns or insurance claims are involved.[13]

Preparation of the root

Preparation of the root depends on the maturity of the tooth (open versus closed apex) and on the dry time of the tooth before it was placed in a storage medium. A dry time of 60 minutes is considered the point where survival of root periodontal ligament cells is unlikely.

Extraoral dry time less than 60 minutes

Closed apex

The root should be rinsed of debris with water or saline and replanted in as gentle a fashion as possible.

Telegram: @dental_k

www.konkur.in

If the tooth has a closed apex, revascularization is not possible,[59] but because the tooth was dry for less than 60 minutes (replanted or placed in appropriate medium), the chance for periodontal healing exists. Most importantly, the chance of a severe inflammatory response at the time of replantation is lessened. A dry time of less than 15 to 20 minutes is considered optimal, and periodontal healing would be expected.[19,32,168]

A continuing challenge is the treatment of the tooth that has been dry for more than 20 minutes (periodontal cell survival is assured) but less than 60 minutes (periodontal cell survival unlikely). In these cases, logic suggests that the root surface consists of some cells with the potential to regenerate and some that will act as inflammatory stimulators.

Open apex

Gently rinse off debris, if available, soak in doxycycline for 5 minutes or cover with minocycline, and replant.

In an open apex tooth, revascularization of the pulp and continued root development are possible (see Fig. 21.35). Investigators[59] found in monkeys that soaking the tooth in doxycycline (1 mg in approximately 20 mL of physiologic saline) for 5 minutes before replantation significantly enhanced complete revascularization (Fig. 21.46, *A*). This result was confirmed later in dogs by other investigators.[150,197] A study found that covering the root with minocycline (Arestin, OraPharma, Warminster, PA), which attaches to the root for approximately 15 days, further increased the revascularization rate in dogs (see Fig. 21.46, *B*).[150] Although animal studies do not provide us with a prediction of the rate of revascularization in humans, it is reasonable to expect that the same enhancement of revascularization that occurred in two animal species also will occur in humans.[31] As for a closed apex tooth, the open apex tooth is gently rinsed and replanted.

Extraoral dry time more than 60 minutes

Telegram: @dental_k

www.konkur.in

Closed apex

Remove the periodontal ligament by placing in acid for 5 minutes, soak in fluoride, and replant.

When the root has been dry for 60 minutes or more, survival of the periodontal ligament cells is not expected.[27,168] In such cases the root should be prepared to be as resistant to resorption as possible (attempting to slow the osseous replacement process). These teeth should be soaked in acid for 5 minutes to remove all remaining periodontal ligament and thus remove the tissue that would initiate the inflammatory response on replantation. The tooth can then be soaked in 2% stannous fluoride for 5 minutes and replanted.[41,159] A few years ago, studies were published that indicated that an enamel matrix protein, Emdogain (Straumann USA, Andover, MA), could be beneficial in teeth with extended extraoral dry times, not only to make the root more resistant to resorption but also, possibly, to stimulate the formation of new periodontal ligament from the socket.[74,104] Unfortunately, more recent studies have shown that the positive effect of Emdogain is only temporary, and most of these teeth start to resorb after a few years.[154]

If the tooth has been dry for more than 60 minutes and no consideration is given to preserving the periodontal ligament, the endodontics may be performed extraorally. In the case of a tooth with a closed apex, no advantage exists to this additional step at the emergency visit. However, in a tooth with an open apex, endodontic treatment performed after replantation involves a long-term apexification procedure. In these cases, completing the root canal treatment extraorally, in which a seal in the blunderbuss apex is easier to achieve, may be advantageous. When endodontic treatment is performed extraorally, it must be performed aseptically with the utmost care to achieve a root canal system that is thoroughly disinfected.

Open apex

Replant? If yes, treat as with closed apex tooth. Endodontic treatment may be performed out of the mouth.

Because these teeth are in young patients in whom facial development is usually incomplete, many pediatric clinicians consider the prognosis to be so poor and the potential complications of an ankylosed tooth so severe, they recommend that these teeth not be replanted. Considerable debate exists as to

Telegram: @dental_k

www.konkur.in

whether it would be beneficial to replant the root even though it will inevitably be lost due to osseous replacement. If the patients are followed carefully and the root submerged by decoronation procedure at the appropriate time,[8,73,130] the height, and, more important, the width of the alveolar bone will be maintained, allowing for easier permanent restoration at the appropriate time when the child's facial development is complete.

Preparation of the socket

The socket should be left undisturbed before replantation.[21] Emphasis is placed on removal of obstacles in the socket to facilitate replacement of the tooth into the socket.[87] It should be lightly aspirated if a blood clot is present. If the alveolar bone has collapsed or may interfere with replantation, a blunt instrument should be inserted carefully into the socket in an attempt to reposition the wall.

Splinting

A splint that allows for physiologic movement of the tooth during healing and that is in place for a minimal period results in a decreased incidence of ankylosis.[4,17,87] Flexible (physiologic) fixation for 1 to 2 weeks is recommended.[4,6,7] Composite and wire splints where the wire diameter is no greater than 0.4 mm is considered to be a flexible splint.[124] The splint should allow movement of the tooth, should have no memory (so the tooth is not moved during healing), and should not impinge on the gingiva and/or prevent maintenance of oral hygiene in the area. Many splints satisfy the requirements of an acceptable device.[111] Fishing line has recently been recommended as a splinting material and, when bonded with resin modified glass ionomer cement, reduces the amount of iatrogenic damage to enamel when the splint is removed.[75a,111] A new titanium trauma splint (TTS) has recently been shown to be particularly effective and easy to use (Fig. 21.47).[190] After the splint is in place, a radiograph should be exposed to verify the positioning of the tooth and as a preoperative reference for further treatment and follow-up. When the tooth is in the best possible position, adjusting the bite to ensure that it has not been splinted in a position causing

Telegram: @dental_k

www.konkur.in

traumatic occlusion is important. One week is sufficient to create periodontal support to maintain the avulsed tooth in position.[185] Therefore the splint should be removed after 1 to 2 weeks. The only exception is with avulsion in conjunction with alveolar fractures, for which 4 to 8 weeks is the suggested time of splinting.[185]

FIG. 21.47 Titanium trauma splint (TTS) in place.

Close-up view of upper jaw shows TTS holding the teeth. The central incisors have a cavity filled with fluid in the gum line.

Management of the soft tissues

Soft-tissue lacerations of the socket gingiva should be tightly sutured. Lacerations of the lip are fairly common with these types of injuries. The clinician should approach lip lacerations with some caution; a plastic surgery consult might be prudent. If these lacerations are sutured, care must be taken to clean the wound thoroughly beforehand because dirt or even minute tooth fragments left in the wound affect healing and the esthetic result.

Adjunctive therapy

Systemic antibiotics given at the time of replantation and before endodontic

Telegram: @dental_k

www.konkur.in

treatment are effective in preventing bacterial invasion of the necrotic pulp and therefore subsequent inflammatory resorption.[87] Tetracycline has the additional benefit of decreasing root resorption by affecting the motility of the osteoclasts and reducing the effectiveness of collagenase.[151] The administration of systemic antibiotics is recommended, beginning at the emergency visit and continuing until the splint is removed.[87] For patients not susceptible to tetracycline staining, the antibiotic of choice is doxycycline twice daily for 7 days at the appropriate dosage for patient age and weight.[151,152] Penicillin V 1000 mg as a loading dose, followed by 500 mg 4 times daily for 7 days, has also been shown to be beneficial. The bacterial content of the sulcus also should be controlled during the healing phase. In addition to stressing to the patient the need for adequate oral hygiene, the use of chlorhexidine rinses for 7 to 10 days is helpful.

As stated previously, there is a benefit in removal of the pulp contents at the emergency visit and placing Ledermix or corticosteroid into the root canal.[45,49] The medicament was able to shut down the inflammatory response after replantation and inhibit the spread of dentinoclasts to allow for more favorable healing compared with those teeth that did not have the medicament.[144,145]

The need for analgesics should be assessed on an individual case basis. The use of pain medication stronger than nonprescription nonsteroidal antiinflammatory drugs (NSAIDs) is unusual. The patient should be sent to a physician for consultation regarding a tetanus booster within 48 hours of the initial visit.

Second visit

The second visit should take place 1 to 2 weeks after the trauma. At the emergency visit, emphasis was placed on the preservation and healing of the attachment apparatus. The focus of the second visit is the prevention or elimination of potential irritants from the root canal space. These irritants, if present, provide the stimulus for the progression of the inflammatory response, bone and root resorption. Also at this visit, the course of systemic antibiotics is completed; the chlorhexidine rinses can be stopped. At this appointment the splint is removed; the tooth might still have class I or class II mobility after splint removal, but all indications are that it will continue to

Telegram: @dental_k

www.konkur.in

heal better without the splint.[4]

Endodontic treatment

Extraoral time less than 60 minutes

Closed apex

Initiate endodontic treatment after 1 to 2 weeks. When endodontic treatment is delayed or signs of resorption are present, provide long-term calcium hydroxide treatment before obturation.

No chance exists for revascularization of teeth with closed apices; therefore endodontic treatment should be initiated at the second visit 7 to 10 days later.[18,59] If therapy is initiated at this optimum time, the pulp should be necrotic without (or with minimal) infection.[129,187] Endodontic therapy with an effective interappointment antibacterial agent[187] over a relatively short period (1 to 2 weeks) is sufficient to ensure effective disinfection of the canal.[163] Long-term calcium hydroxide treatment should always be considered if the injury occurred more than 2 weeks before initiation of the endodontic treatment or especially if radiographic evidence of inflammatory resorption is present.[187]

The root canal is thoroughly cleaned and shaped, irrigated, and then filled with calcium hydroxide. The canal is obturated when a radiographically intact periodontal membrane can be demonstrated around the root (see Fig. 21.37). Calcium hydroxide is an effective antibacterial agent[46,163] and favorably influences the local environment at the resorption site, theoretically promoting healing.[182] It also changes the environment in the dentin to a more alkaline pH, which may slow the action of the resorptive cells and promote hard-tissue formation.[182] However, changing of the calcium hydroxide should be kept to a minimum (not more than every 3 months) because it has a necrotizing effect on the cells attempting to repopulate the damaged root surface.[125]

Calcium hydroxide is considered the material of choice in the prevention and treatment of inflammatory root resorption, but it is not the only medicament recommended in these cases. Some attempts have been made not

Telegram: @dental_k

www.konkur.in

only to remove the stimulus for the resorbing cells but also to affect them directly. The antibiotic-corticosteroid paste Ledermix is effective in treating inflammatory root resorption by inhibiting the spread of dentinoclasts[144,145] without damaging the periodontal ligament; however, its ability to diffuse through the human tooth root has been demonstrated,[2] and its release and diffusion are enhanced when it is used in combination with calcium hydroxide paste.[3]

Open apex

Avoid endodontic treatment and look for signs of revascularization. At the first sign of an infected pulp, initiate apexification procedure.

Teeth with open apices have the potential to revascularize and continue root development; initial treatment is directed toward reestablishing the blood supply.[59,150,196] The initiation of endodontic treatment is avoided if at all possible, unless definite signs of pulp necrosis are present (e.g., periradicular inflammation). An accurate diagnosis of pulp vitality is extremely challenging in these cases. After trauma, a diagnosis of necrotic pulp is particularly undesirable because infection in these teeth is potentially more harmful due to cemental damage accompanying the traumatic injury. External inflammatory root resorption can be extremely rapid in these young teeth because the tubules are wide and allow irritants to move freely to the external surface of the root.[59,196]

Patients should be recalled every 3 to 4 weeks for pulp vitality testing. Studies indicate that thermal tests with carbon dioxide snow (−78°C) or dichlorodifluoromethane (−40°C) placed at the incisal edge or pulp horn are the best methods of sensitivity testing, particularly in young permanent teeth.[79,80,140] One of these two tests must be included in the pulp vitality testing. Reports confirm the superiority of the laser Doppler flowmeter in the diagnosis of revascularization of traumatized immature teeth[197]; however, the cost of such an instrument precludes its use in the average dental office. Radiographic signs (apical breakdown and/or signs of lateral root resorption) and clinical signs (pain on percussion and palpation) of pulp pathosis are carefully assessed. At the first sign of pathosis, endodontic treatment should be initiated, and after disinfection of the root canal space, an apexification procedure should be carried out.

Telegram: @dental_k

www.konkur.in

Extraoral time more than 60 minutes

Closed apex

Teeth with closed apices are treated endodontically in the same way as teeth that had an extraoral time of less than 60 minutes.

Open apex (if replanted)

If endodontic treatment was not performed out of the mouth, initiate apexification procedure.

The chance of revascularization in these teeth is extremely poor,[184,188] so no attempt is made to revitalize them. An apexification procedure is initiated at the second visit if root canal treatment was not performed at the emergency visit. If endodontic treatment was performed at the emergency visit, the second visit is a recall visit to assess initial healing only.

Temporary restoration

Effectively sealing the coronal access is essential to prevent infection of the canal between visits. Recommended temporary restorations are reinforced zinc oxide eugenol cement, acid etch composite resin, or glass ionomer cement. The depth of the temporary restoration is critical to its sealability. A depth of at least 4 mm is recommended, so a cotton pellet should not be placed; the temporary restoration is placed directly onto the calcium hydroxide in the access cavity. Calcium hydroxide should be removed from the walls of the access cavity before the temporary restoration is placed because calcium hydroxide is soluble and washes out when it comes into contact with saliva, leaving a defective temporary restoration.

After initiation of the root canal treatment, the splint is removed. If time does not permit complete removal of the splint at this visit, the resin tacks are smoothed so as not to irritate the soft tissues; the remaining resin is removed at a later appointment.

At this appointment, healing is usually sufficient to allow a detailed clinical examination of the teeth surrounding the avulsed tooth. Pulp vitality tests, reaction to percussion and palpation, and periodontal probing measurements should be carefully recorded for reference at follow-up visits.

Telegram: @dental_k

www.konkur.in

Root filling visit

This visit should take place at the clinician's convenience or after long-term calcium hydroxide therapy, when an intact lamina dura is traced.

If the endodontic treatment was initiated 1 to 2 weeks after the avulsion and a thorough examination confirms normality, filling of the root canal at this visit is acceptable. Long-term use of calcium hydroxide is also a proven option for these cases. If endodontic treatment was initiated more than 2 weeks after the avulsion or active resorption is visible, the pulp space must first be disinfected before root filling. Traditionally, the reestablishment of a lamina dura (see Fig. 21.37) is a radiographic sign that the canal bacteria have been controlled. When an intact lamina dura can be traced throughout, root filling can take place.

The canal is cleaned, shaped, and irrigated under strict asepsis (i.e., a rubber dam). After completion of cleaning and shaping, the canal can be filled.

Permanent restoration

Much evidence exists that coronal leakage caused by defective temporary and permanent restorations results in a clinically relevant amount of bacterial contamination of the root canal after root filling.[149] Therefore the tooth should receive a permanent restoration as soon as possible. The depth of restoration is important for a tight seal, so the deepest restoration possible should be made. A post should be avoided if possible. Because most avulsions occur in the anterior region of the mouth where esthetics is important, composite resins combined with dentin bonding agents are recommended in these cases.

Follow-up care

Follow-up evaluations should take place at 3 months, 6 months, and yearly for at least 5 years. If replacement resorption is identified (see Fig. 21.31), a more closely monitored follow-up schedule is indicated. In the case of inflammatory root resorption (see Figs. 21.32 and 21.33), a new attempt at disinfection of the root canal space by standard retreatment might reverse the process. Teeth adjacent to and surrounding the avulsed tooth or teeth may

Telegram: @dental_k

www.konkur.in

show pathologic changes long after the initial accident, so these teeth, too, should be tested at follow-up visits and the results compared with those collected soon after the accident.

Late complications

The IADT and AAE guidelines as stated previously recommend 5-year follow-up after the initial trauma. Heithersay[95,96] wrote a series on the "life cycles of traumatized teeth" discussing follow-up of cases of up to 51 years post injury. Resorption is a common posttraumatic sequelae presenting many years after this initial trauma. Changes in the color of the crown also need to be monitored as either a need for bleaching of the tooth or a change in the condition of the tooth such as intracanal calcification. This chapter has presented many concepts and treatment approaches at the time of trauma. However, it is important to consider that there can be either unfortunate events over time that need secondary management or failure in diagnosis that is apparent years later when signs and symptoms of infection or resorption and inappropriate or poor treatment were performed at the time of injury (Figs. 21.48 and 21.49; see also Fig. 21.43).

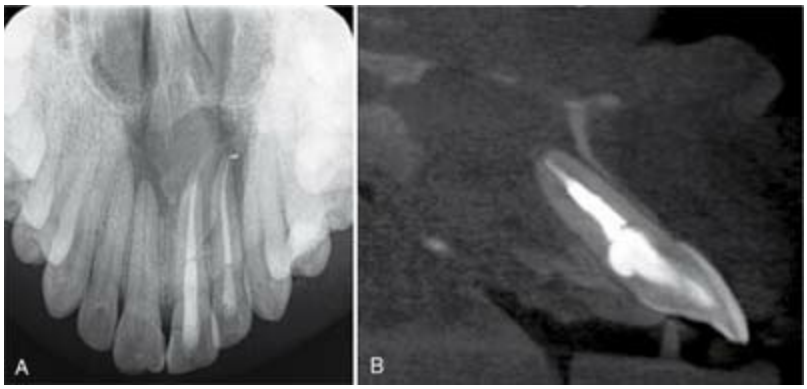

FIG. 21.48 **A,** An occlusograph showing root fillings in teeth #9 and #10 in a 44-year-old male 25 years after the teeth had been traumatized. Symptoms and infection returned after endodontic treatment and surgical correction was required. **B,** CBCT imaging revealed internal resorption within the canal.

A) Radiograph shows upper jaw with filled root canals with a radiolucent line at the center in left incisors. There is a large radiolucent patch at the root apices of incisors.

Telegram: @dental_k

B) Radiograph shows fading filling in the root apices and crown.

FIG. 21.49 **A,** An occlusograph showing extensive periapical radiolucencies associated with the maxillary incisor teeth in a 23-year-old male. The patient sustained a traumatic injury when he was 8 years of age. Tooth #8 has extruded gutta-percha through the open apex indicating either a failed apexification procedure or poor obturation of the canal due to the open apex. Tooth #9 has an open apex indication pulp necrosis likely occurred at or soon after the traumatic injury but no treatment was undertaken. **B,** CBCT imaging revealing the immature root formation of tooth #9 and periapical lesion. Surface resorption on the palatal cervical root is suggestive of a prior palatal luxation injury.

A) Radiograph shows upper jaw where eighth root has filled root canal and ninth tooth has open and wide radiolucent canal. Seventh and eighth teeth have a radiolucent patch.

B) Radiograph of eighth tooth shows radiolucent root canal, which narrows down toward the crown and widens toward the root tip.

Dentoalveolar trauma to the primary dentition

The classification of injuries to the primary dentition is the same as the permanent dentition, although management may be different. Consideration must be given to the risk of damage to the developing permanent teeth. Furthermore, there may also be behavioral issues of the child that require different approaches in patient care. Instances where care is required to minimize risk to the permanent dentition include intrusive injuries when the intruded root is close to the developing permanent tooth. It is generally not

Telegram: @dental_k

www.konkur.in

advisable to replant an avulsed primary tooth. However, most luxation injuries heal spontaneously, so conservative treatment for preschool children is recommended. Immediate treatment is advised for complicated crown fractures, crown-root fractures, root fractures when the coronal fragment is displaced, extrusive luxations, and alveolar fractures.[75,130]

22: Chronic cracks and fractures

Louis H. Berman, Aviad Tamse

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

The presence of cracks or fractures in teeth can be difficult to diagnose and clinically manage. They may present with no symptoms or the symptoms may be vague or specific. Symptoms alone are often insufficient for making a definitive diagnosis and the radiographic interpretation can be inconclusive. Although the clinical management of the crack or fracture depends on its extent, often the extent of the crack or fracture cannot be clinically determined.

According to the 2016 version of the American Association of Endodontists (AAE) *Glossary of Endodontic Terms*, a *crack* is defined as "a thin surface disruption of enamel and dentin, and possibly cementum, of unknown depth or extension." A *fracture* is defined as "a split or break in bone, cartilage or tooth structure. When involving tooth structure, it is a disruption of the enamel and/or dentin and/or cementum that is assumed to be of greater depth than a crack, of unknown depth or extension, visible or not visible clinically or radiographically, and with separated or unseparated segments."[3a]

Telegram: @dental_k

www.konkur.in

Impact trauma

Traumatic injury to the tooth can be accompanied with a fracture in the crown or root system. These types of traumatic fractures mainly occur in the anterior segment of the mouth and are elaborated on in Chapter 21). In contrast, the cracks and fractures described in this chapter are often not associated with a traumatic event. These cracks and fractures are frequently the result of an accumulating, unobserved trauma resulting from either normal or excessive occlusal forces that are repetitively applied[22,35,46,48,71,72,91] without the patient's awareness. Specifically discussed in this chapter will be crown originating fractures and longitudinal fractures in the roots.

Diagnostic challenge

Three categories of cracks and fractures are discussed in this chapter: crown originating fractures, split teeth, and vertical root fractures (VRFs). Each is often undiagnosed or misdiagnosed for a relatively long time.[16,19,81] The astute clinician can usually diagnose a pulpitis, apical periodontitis, or an abscess after appropriate diagnostic tests and clinical assessments are performed. However, because of the wide variety of clinical presentations from cracks and fractures, the diagnosis is less straightforward.[16,18,79] To complicate the diagnosis, most cracks and fractures exhibit no radiographic manifestation in the early stages, depriving the dentist of one of the most objective diagnostic tools.

Symptoms from a crack or fracture may be slight and present for *several months* before an accurate diagnosis is made,[5,16,19] which may be frustrating for both the patient and the dentist, and often causes the patient to develop a subsequent loss of trust and confidence in the dentist. The final diagnosis is typically reached at a relatively late stage of these conditions, often after complications have already occurred. Complications may include a subsequent fracture of the tooth or cusp or significant periradicular bone loss associated with a VRF as seen by radiographic examination (see also Chapter 2). For this reason, this chapter emphasizes the *early diagnosis* of these conditions. The collection of signs and symptoms associated with cracks and fractures may be confusing; the clinician should consider these as indicators

Telegram: @dental_k

www.konkur.in

during the examination and diagnostic process.

Fracture mechanics

Fracture mechanics is the field of biomechanics concerned with the propagation of *cracks* in a given material until the formation of the final catastrophic *fracture*.[7,53] Many terms have been loosely used in the dental literature to describe the clinical entities that are the subject of this chapter.[5,9,18,36] Here, the term *crack* will be used in the biomechanical sense: a *partial discontinuity* in a material that may propagate and eventually lead to a complete discontinuity, also known as a *fracture*.[7,53] In this context, a cusp may be described as *cracked*, a condition that may continue over time into a *fractured cusp*. A *cracked tooth* generally presents in a longitudinal direction, along the long axis of the root. It may be so called until a final fracture occurs that separates the tooth into two parts, a condition termed a *split tooth*. Similarly, microcracks may appear in the radicular dentin of an endodontically treated tooth, and these cracks may propagate with time until a *vertical root fracture* occurs, at which point the full thickness of the dentinal wall shows discontinuity: a through-and-through fracture. Such a fracture may be *incomplete*, involving one wall of the root, or *complete*, separating the root into two parts (Fig. 22.1).[81]

FIG. 22.1 Complete vertical root fracture. A cross section of a mesial root of a mandibular molar with a complete vertical root fracture. The fracture is in the buccolingual plane and extends from the buccal convexity of the root to its lingual convexity.

Cracked and fractured cusps

Definition

A *cracked cusp* is characterized by a crack between a cusp and the rest of the tooth structure, to the extent of allowing microscopic flexure upon mastication. This crack typically does not involve the pulp. With time, the crack may propagate, eventually resulting in a *fractured cusp*.[5]

Diagnosis

Patient history

In the case of a cracked cusp, the patient history is the most important tool for making a diagnosis. The patient will likely complain about pain when chewing, to the extent of not being able to chew on the side on which the crack occurred.[18,36,70] The patient will also often state that the condition existed for a relatively long period of time and that his or her dentist could not find the source or visualize any radiographic findings to suggest a cusp fracture.[3,16,48] When asked whether the pain is sharp or dull, patients will typically report a sharp pain that makes them immediately stop chewing on that side. The diagnostic challenge is attempting to determine which cusp of which tooth is involved, as patients often have difficulties determining the specific location of the discomfort.[16,18,36,70] Because the pain has a pulpal origin, the patient's proprioception may not be accurate, as no periodontal ligament is involved. Occasionally, the masticatory pain may radiate to nondental locations on the same side of the face,[16,48,72] as also described in Chapter 4.

Clinical manifestation

Early manifestation.

The typical characteristic of a cracked cusp is generally a sharp pain upon

Telegram: @dental_k

www.konkur.in

chewing, although the affected tooth may not be sensitive, or only selectively sensitive, to percussion.[71] The tooth is vital, and its response to a cold stimulus may be normal; but with time, this response may resemble a reversible pulpitis, which may be either localized or referred to other odontogenic or nonodontogenic locations.[16,48,72]

Cracked cusps are often associated with extensive occlusal restorations,[3,29,72,79] which may undermine and weaken the cusp and predispose it to initiating or perpetuating a crack from occlusal forces. Nevertheless, a cracked cusp may also be present in intact nonrestored teeth or teeth that are minimally restored.[13,71]

Late manifestation.

With time, a crack under a cusp may propagate and result in a fractured cusp. If the fracture line occurs supragingivally, the fractured cusp will simply separate from the tooth. However, if the fracture line extends subgingivally, gingival fibers or the periodontal ligament will often retain the fractured cusp. Initially, it may be possible to move the cusp by wedging a sharp explorer into the fracture line, making the fractured cusp more visible. Often, from continued mastication, a localized and more acute pain may develop secondary to the movement of the fractured fragment on the underlying tooth structure. The pulpal pain that is typical at an earlier stage (the cracked cusp) will typically resolve once a complete fracture occurs. However, with the resulting tooth structure having exposed dentin (or even a pulp exposure), a resulting reversible or irreversible pulpitis may ensue.

Diagnosis

A cracked cusp may be diagnosed, to a large extent, on the basis of the patient history. To locate the affected tooth, a *biting test* should be performed using a Tooth Slooth (Professional Results, Laguna Niguel, CA) or a similar device (Fig. 22.2).[9,12] The device is composed of a small pyramid with a flattened top that is placed on a selective cusp, while the wider part of the device is applied to opposing teeth while the patient occludes. The application of these forces to a cracked cusp will generate a sharp pain, which may occur upon pressure or released.[3,35,44] The patient will typically state that this sensation has reproduced the sensation of their chief complaint.

Telegram: @dental_k

www.konkur.in

FIG. 22.2 The Tooth Slooth device. Application for a bite test: the tip of the pyramid is touching the tested cusp while the wide base is supported by multiple contacts.

Close-up view shows tooth slooth examining the grayish premolar in lower jaw.

Magnification with such devices as loupes or an operating microscope can be helpful when looking for a crack. If the tooth does not have an extensive intracoronal restoration, *transillumination* may also assist in revealing the crack line. If the tooth has a large restoration, the removal of the restoration may facilitate the effective use of this diagnostic tool (Fig. 22.3). The light source should be intense but with small dimensions; it is applied to the tooth at the area of the suspected cusp fracture, with the lights of the dental unit, microscope, and room extinguished. The light penetrates the tooth structure up to the crack, leaving the part beyond the crack relatively dark (see Fig. 22.3).

Telegram: @dental_k

www.konkur.in

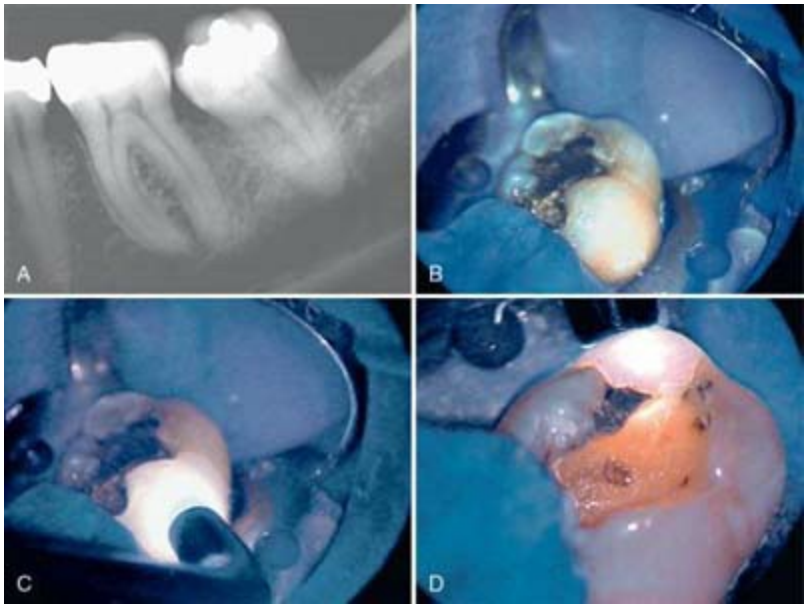

FIG. 22.3 Transillumination for the detection of a cracked cusp/tooth. An intense but small light source is applied to the suspect tooth, preferably in relative darkness. The light is transmitted through the tooth structure but is reflected from the crack plane, leaving the area behind the crack in darkness.

A) Radiograph shows right tooth with radiolucent root canals. Large part of the crown is radiopaque. Adjacent tooth has irregular radiopaque patch on the crown.

B) Tooth is isolated using rubber dam clamp and the cavity of tooth is filled with grey material.

C) Tooth is examined using light source.

D) Tooth shows the removal of upper enamel layer on one side of the cusp. The soft and tissue with a dark patch are visible.

Once the crack propagates, resulting in a fractured cusp, the diagnosis becomes more objective, as the fractured cusp will either be missing or can be moved by wedging an explorer into the fracture line (Fig. 22.4).

www.konkur.in

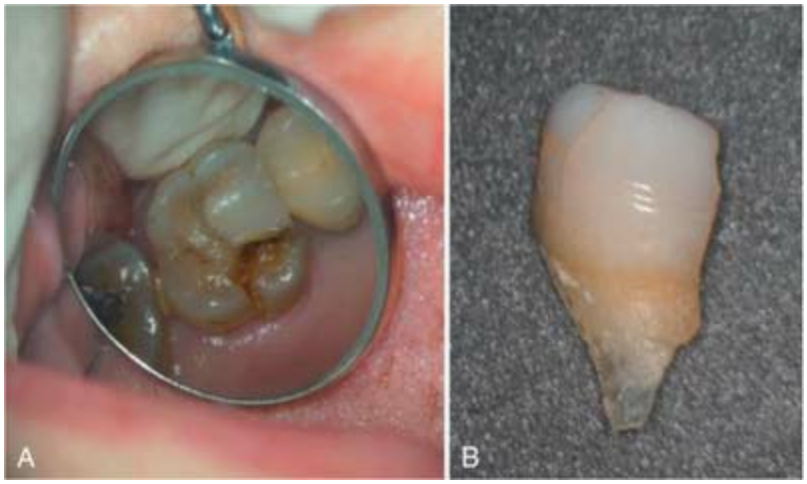

FIG. 22.4 A fractured cusp. **A,** The mesiopalatal cusp of a maxillary first right molar was fractured. The fractured cusp was movable and was retained by the periodontal ligament. **B,** The cusp was removed, and the tooth was considered restorable. It was treated with root canal treatment and a crown.

A) Close-up view shows the fractured tooth with brown stains using tooth mirror.

B) Extracted tooth having orange surface and transparent root.

Etiology

Extensive intracoronal restorations may be a predisposing factor for cracked and fractured cusps.[3,29,72,79] Otherwise, the etiology of these conditions is similar to that of cracked teeth (see Cracked and Split Teeth, Etiology).

Treatment planning

Cracked cusp

Treatment should consist of protecting the affected cusp from occlusal forces, both to prevent pain while chewing and to prevent the propagation of the crack into a full fracture. This can be facilitated with restorative treatment and an occlusal evaluation. Full-coverage crown or onlay is recommended,[5,16,40] although bonded composite restorations have also been proposed.[28,65] One should keep in mind that if the cracked cusp is not protected, the tooth may eventually fracture, complicating the treatment or

Telegram: @dental_k

www.konkur.in

even compromising the salvageability of the tooth. If the fracture plane extends apically into the root, the tooth may potentially become nonrestorable.[5,9,12] Endodontic treatment is indicated only if signs and symptoms of pulpal pathosis are observed. In addition, if the removal of the cracked cusp and associated restoration will result in little or no remaining coronal tooth structure, then elective root canal treatment may be necessary for prosthetic reasons. When such a treatment plan is selected, one should also perform an occlusal reduction of the tooth as soon as possible to remove the tooth from active occlusion. The patient should be instructed to be careful when chewing until the tooth is restored with a crown.

Fractured cusp

The treatment of a fractured cusp depends on the amount of tooth structure remaining. If the missing cusp is limited in size, then the conservative restoration of a bonded composite resin may be indicated to cover the exposed dentin. In contrast, when a larger fragment has fractured and is either removed or missing, a full crown or an onlay may be necessary.

In certain cases, when cracked cusps are found in intact teeth or in teeth with no extensive restoration, it is difficult to predict the direction in which the crack is propagating. Therefore, in these cases, when considering endodontic and restorative treatment, the patient should be advised as to the potential decrease in prognosis, as described later.

Cracked and split teeth

Definition

As previously described, a *cracked tooth* has “a thin surface disruption of enamel and dentin, and possibly cementum, of unknown depth or extension.” It exhibits a crack that incompletely separates the tooth crown into two parts. If the crack is allowed to propagate longitudinally, the tooth will eventually fracture into two fragments, resulting in a *split tooth*. The American Association of Endodontists describes a split tooth as “a continuation of a crack or vertical root fracture whereby the fractured segments are completely separated longitudinally; it may occur buccal-lingually or mesial-distally; it may cause an isolated periodontal defect(s) or sinus tract; it may be

Telegram: @dental_k

www.konkur.in

radiographically evident."

Diagnosis

Patient history

In cases of a cracked tooth, the patient history may be similar to that of a cracked cusp; there may be a sharp pain upon mastication and prolonged inability of the dentist to diagnose the source of the pain.[16,19] Similar to a cracked cusp, the diagnosis of a cracked tooth is often made on the basis of the patient history alone. Often it is challenging for the practitioner to determine the location of the offending tooth. With time, the patient may report that he or she *used to have* a sharp pain and now experiences great sensitivity to cold stimuli; the patient may even report, at a later stage, that the pain has subsided. These observations are consistent with pulpitis or pulp necrosis, which may develop in the affected tooth over time.[13]

Clinical manifestation

Early manifestation.

Cracked teeth may have extensive restorations with a weakened crown, or they may have minimal or no restorations. A cracked tooth begins with a crack in the clinical crown, which may gradually propagate in an apical direction.[3,5,28,48] Such cracks typically run in the mesiodistal direction, often splitting the crown into the buccal and lingual fragments. In the early stages, the tooth may be vital and painful to mastication. The pain may be sharp, to the extent that the patient is unable to chew on the affected side. This condition may persist for an extended period of time.[16,18,19] The pain may be localized or referred to any tooth, maxillary or mandibular, on the same side of the mouth.[16,48,72] No radiographic manifestations are present at these early stages, as the crack is microscopic and runs perpendicular to the x-ray beam. The affected tooth may or may not be sensitive to percussion at this point, and pulp testing may be normal or indicative of increased sensitivity to cold stimuli.

Late manifestation.

Telegram: @dental_k

www.konkur.in

The late manifestation of a cracked tooth may include pulp involvement and potentially the loss of pulp vitality[13] or apical propagation of the fracture resulting in a split tooth. In one investigation,[13] 27 nonvital molar and premolar teeth that had minimal or no restorations or caries were studied. Upon extraction, these teeth were examined under a surgical operating microscope or using micro–computed tomography (CT) analysis. In all of these teeth, a longitudinal crack was observed, which extended to the pulp and often to an external surface of the root. Although the study had a limited sample size, the clinician should understand the potentially poor prognosis from cracked teeth, especially when the crack is suspected to be the *cause* of pulp necrosis ("fracture necrosis") (Fig. 22.5).[13]

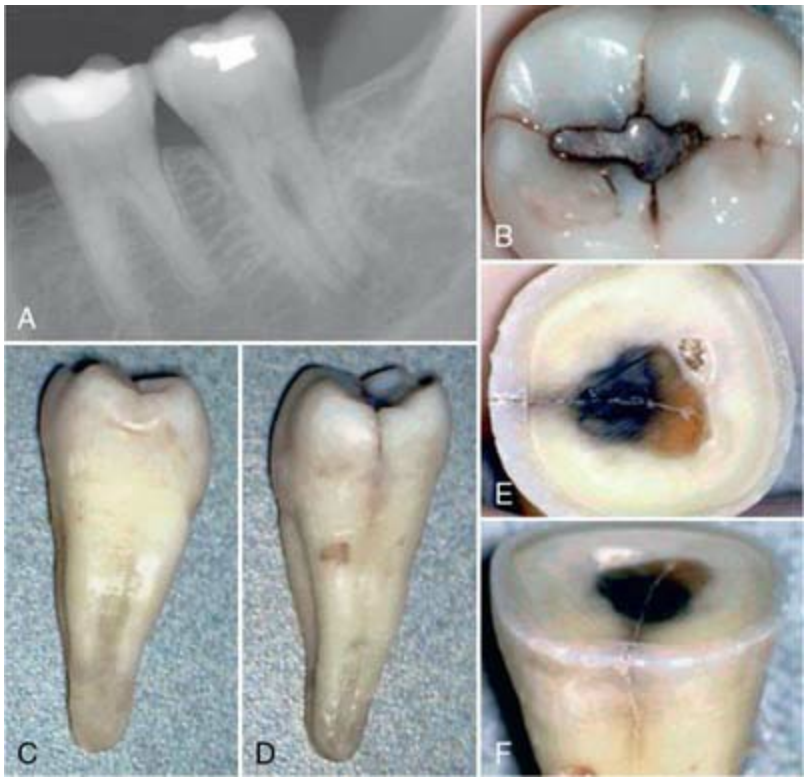

FIG. 22.5 A case of fracture-induced necrosis. A tooth with minimal or no restoration or caries is unlikely to become nonvital. **A,** This radiograph of a mandibular second molar shows a restoration that is distant from the pulp chamber, yet the tooth is nonvital and symptomatic. **B,** On occlusal examination, a slight crack is observed on the distal marginal ridge. **C,** After extraction, the mesial aspect of the crown and root shows no indication of a fracture. **D,** However, the distal aspect of the crown and coronal root shows the fracture. **E** and **F,**

Telegram: @dental_k

www.konkur.in

When the crown is sectioned, the crack can be observed to extend well into the pulp chamber.

A) Radiograph shows two teeth with radiopaque patches on the crown. The pulp chamber is depressed.

B) Occlusal view of tooth shows silver filling in the cavity with black lines in pits.

C) Tooth has smooth surface. The root tip is less dense.

D) Tooth with a dark spot below the neck region.

E) Tooth shows a cavity and a brown spot. The cavity has blackish residue and brown tissue.

F) Tooth with a dark hole. The lateral side of tooth has a vertical line.

Pulp involvement occurs more often in cases of centrally located cracks than in cracks with a more buccal or lingual location (i.e., extending from marginal ridge to marginal ridge through the central fossa).[18,91] These centrally located cracks commonly affect the roof of the pulp chamber at a later stage. Consequently, pulp vitality may be compromised and later lost due to bacterial penetration through the crack. The sharp pain upon mastication that is typical of the early stage may disappear once pulp vitality is lost. Consequently, apical periodontitis in an apparently intact molar may be a late manifestation of an untreated case of a cracked tooth.[13] When pulp necrosis occurs, the radiographic manifestation may be an apical radiolucency, which is undistinguishable from that of apical periodontitis (see Fig. 22.5).

A crack may propagate over time through the pulp chamber and into the root, resulting in a complete fracture that separates the tooth into two parts, a condition termed *split tooth*. This is defined in the AAE *Glossary of Endodontic Terms* as a longitudinal fracture ("a root fracture extending in the axial plane within the tooth") that becomes "a continuation of a crack or vertical root fracture whereby the fractured segments are completely separated longitudinally."[3a] When this split occurs, the resulting parts of the tooth may be movable by wedging a sharp explorer into the fissure.[5,9] Given time and masticatory forces, more evident movement of the parts may be observed. The radiographic presentation at such a late stage may eventually

Telegram: @dental_k

www.konkur.in

develop into a diffuse radiolucency surrounding the root. At this late stage, narrow isolated deep periodontal pockets may be present.[9] However, such pockets are typically located mesially or distally and, if adjacent teeth are present, they will be difficult if not impossible to detect.

Cracked and split teeth may present with a large and variable collection of signs and symptoms that are potentially confusing.[16,18,79] Only by being aware of the *process* leading from early to late manifestations can clinicians interpret these signs and symptoms and identify the specific point they are encountering on the potential timeline of this process.

A *definitive* combination of factors, signs, and symptoms that when collectively observed allows the clinician to conclude the existence of a specific disease state is termed a *syndrome*. However, given the multitude of signs and symptoms that cracked roots can present with, it is often difficult to achieve an objective definitive diagnosis. For this reason, the terminology of *cracked tooth syndrome*[18] should be avoided.

Diagnosis

Early detection of a cracked or split tooth is imperative to resolve the patient's symptoms as well as increasing the prognosis. However, the use of the Tooth Slooth device (see Fig. 22.2) may or may not provide as clear a result for a symmetrically cracked tooth, as each of the parts of the tooth may be rather stable. Asking the patient to chew on a cotton roll[9] or on the tip of a cotton-tip applicator placed at a particular site may reproduce the symptoms. Nevertheless, this method may not indicate whether the source is a maxillary or mandibular tooth and may need further measures to pinpoint the involved tooth. *Magnification* using either loupes or an operating microscope can be helpful for detecting a fracture line. In addition, dyes, such as methylene blue or tincture of iodine, which are applied either to the outer surface of the crown or to the dentin after the removal of an existing intracoronal restoration, can be helpful for visualizing the crack (see Fig. 22.3). Transillumination can also be applied to the suspected tooth and, if the tooth has no restorations, this method may yield an impressively straightforward diagnosis (see Fig. 22.3). Anesthetizing the suspected tooth, followed by asking the patient to chew again on the cotton roll, may further confirm the diagnosis and finally differentiate the origin as a mandibular or maxillary

Telegram: @dental_k

www.konkur.in

tooth. At a later stage, when splitting of the tooth has occurred, wedging of a sharp explorer into the fracture line will provide a clear diagnosis of a split tooth.

In general, the diagnosis of a crack in a tooth can be difficult. When there are signs and symptoms of a pulpitis or necrosis, it is incumbent upon the clinician to determine the source that initiated the signs and symptoms. In the case of a problematic tooth with no apparent reason for a pulpitis or necrosis, like a tooth with minimal or no caries, restoration, or trauma, a crack or fracture must be considered.[13] In some cases, an objective diagnosis may not be possible; however, with the possibility of a crack or fracture, the patient should be advised of a potential decrease in the endodontic or restorative prognosis.[5,12]

Etiology

Masticatory forces are the cause of cracked teeth.[22,35,46,48,71,72,91] Thus, the dietary habit of chewing on coarse food has been proposed as a contributing factor.[22,91] Bruxism or clenching of the teeth as well as occlusal prematurities are also frequent causes of cracked teeth.[18,22,35,46,48,71,72,91] For this reason, certain teeth may be more prone to developing cracks, such as mandibular second molars and maxillary premolars.[18] Masticatory habits such as chewing ice may also predispose teeth to cracks. The term *fatigue root fracture*, proposed by Yeh,[91] encompasses all of these causes.

In certain cases, traumatic injuries, such as a severe upward blow to the mandible (e.g., during a car or sports accident) can also cause a tooth crack or fracture. Another potential cause is the unexpected chewing of a hard object (e.g., a cherry pit or an un-popped corn kernel in popcorn). The occlusal forces applied by the first molars are as high as 90 kg,[46] which, when fully applied to a small surface area, may damage the tooth structure. However, in most cases, a tooth crack can be attributed to no specific cause other than normal or excessive masticatory forces.[22,35,46,48,71,72,91]

Treatment planning

Cracked tooth

Telegram: @dental_k

www.konkur.in

When a cracked tooth is either suspected or determined, the patient should be informed that the prognosis is reduced and is sometimes questionable.[5,9,12] Protecting a tooth from the propagation of a crack and improving comfort while chewing are the principal goals in the treatment of cracked teeth. Both goals can often be immediately achieved by placing an orthodontic band around the tooth[3,9,16] or by placing a provisional crown. These procedures allow the clinician to evaluate the extent of pulp involvement by checking whether the pulpal symptoms subside in response to the intervention.[3,9,16]

Protecting the tooth from further splitting forces by the placement of a permanent crown is essential in these cases.[3,5,9,16,40] Unfortunately, a crown alone is often not sufficient to resolve symptoms, and endodontic treatment may be considered prior to the placement of the permanent crown, depending on the pulpal symptoms.[9]

A root canal treatment followed by a permanent crown has the benefit of immediately eliminating the long-lasting, painful symptoms as well as early protection from occlusal forces that may cause propagation of a cracked tooth to become a split tooth. Nevertheless, when 127 cracked teeth with reversible pulpitis were treated with a crown alone, 20% of these teeth converted to irreversible pulpitis within 6 months and required root canal treatment.[52] In contrast, none of the other teeth needed a root canal over a 6-year evaluation period.[52] However, it should also be understood that varying percentages of crowned teeth, cracked or noncracked, may also require endodontic treatment, merely from the trauma of the crown preparation. By comparison, it has been shown that when suspected cracked teeth were restored with resin bonded restorations, only 7% required subsequent endodontic treatment or extraction.[65]

After removal of an intracoronal restoration or when penetrating the dentin to prepare for endodontic access, one may observe discoloration along the crack in the dentin. Once the access cavity has been completed, the pulp chamber floor and the distal and mesial walls of the pulp chamber should be carefully inspected to check for the presence and extent of any cracks. Upon evaluating 245 restored teeth, cracks were observed preoperatively in 23.3% of the teeth; however, when the restorations were removed, 60% of these teeth were found to have cracks.[1] Methylene blue dye may be helpful in this type of examination. If a crack is found that reaches from the mesial wall,

Telegram: @dental_k

www.konkur.in

through the floor of the pulp chamber and into the distal wall, then the prognosis for the tooth is poor, and extraction should be considered (see Fig. 22.5).[5,9,12] If the crack does not reach the pulp chamber or is limited to the coronal parts of the mesial or distal wall, the subsequent protection of the tooth with a crown may save the tooth. Nevertheless, as mentioned previously, the patient should be advised that the treatment success may be compromised and that long-term follow-up will be required.[5,9,12]

Given that such cracks occasionally occur in teeth with minimal or no restorations and that all of the pain may cease once the pulp is removed, it may be tempting to limit the final restoration to an intracoronal amalgam or composite restoration. This temptation should be resisted by all means, as the forces that caused the crack are still present, and the apical propagation of the crack and loss of the tooth is still likely.

Split tooth

When the tooth is split either through its entire length or obliquely (Fig. 22.6), extraction is typically the only treatment option.[5,9] However, if the fracture line is such that the split results in large and small segments, and if the removal of the small fragment preserves enough tooth structure that is restorable, then retention and restoration of the tooth may be considered.[5] If this is a consideration, the patient should be aware that periodontal crown lengthening may be necessary. Proper interdisciplinary management of cases like this is imperative so as to ensure that the prognosis is evaluated and maximized.

Vertical root fracture

Definition

A *vertical root fracture* is defined in the AAE *Glossary of Endodontic Terms* as a longitudinal fracture "in the root whereby the fractured segments are incompletely separated; it may occur buccal-lingually or mesial-distally; it may cause an isolated periodontal defect(s) or sinus tract; it may be radiographically evident"[3a] (Figs. 22.7–22.9; see also Fig. 22.1). Previous definitions described VRFs as initiating from the apical root and traveling coronally, or only as a result of endodontic treatment. In the latest edition of the AAE *Glossary of Endodontic Terms*, these stipulations have been removed. It is differentiated from a split root in that segments associated with the fracture are not completely separated.

Diagnosis

Patient history

In the case of a VRF, a patient may complain of pain or sensitivity related to or adjacent to a specific tooth. Sensitivity and discomfort while chewing are also common complaints.[81] Swelling may occasionally occur in the area. There is often a long history of failing to diagnose the cause of the pain and discomfort. A history of repeated clinical and radiographic examinations that revealed no cause for the pain is also common in VRF cases. After recent endodontic retreatment, if the symptoms remain and the dentist is unable to determine the cause of the symptoms, the patient may lose confidence in the dentist. Often retreatment or surgical retreatment may have been attempted to reveal the accurate diagnosis.[1] Unfortunately, such ineffective treatment attempts may only worsen the dentist-patient relationship.

Clinical manifestations

Telegram: @dental_k

www.konkur.in

Susceptible teeth and vertical root fracture location.

VRFs are commonly associated with endodontically treated teeth with or without a post.[5] Nevertheless, VRFs can also occur in teeth with no previous root canal treatment.[22] The most susceptible sites and tooth groups are the maxillary and mandibular premolars, mesial roots of the mandibular molars, mesio-buccal roots of the maxillary molars, and mandibular incisors.[82] However, VRFs may occasionally occur in other teeth and roots as well. VRFs may progress in the bucco-lingual direction in these teeth and roots, which are typically narrow mesiodistally and wide buccolingually.[41] However, VRFs may also propagate diagonally, thus affecting the mesial or distal aspect of the root (see Fig. 22.7). VRFs may be initiated at any root level.[5] They may also be initiated at the apical part of the root and propagate coronally (see Fig. 22.8, *C*). Some VRFs originate at the coronal-cervical part of the root and extend apically (see Fig. 22.8, *A*), and in other cases a VRF may be initiated as a midroot fracture (see Figs. 22.8, *B* and 22.9, *C* and *D*).

FIG. 22.7 Diagonal vertical root fracture (VRF) in a molar. A lingual view of a right first mandibular molar revealing a diagonal VRF in the mesial root.

The root fractures in the two root canals of molar are shown from two different angles. The lateral sides of crown in both views have smooth silver surface.

Source: (Courtesy Dr. R. Ganik.)

It is commonly believed that VRFs begin as microcracks in the area of the root canal surface of the radicular dentin and gradually propagate outward until the full thickness of the radicular dentin is fractured.[5,10,21,57,88] Other studies[14,17,51,77,92] have shown that microcracks can also be initiated at the outer surface of the root and propagate inward. Therefore, the correlation between microcracks in the radicular dentin and the formation of VRFs should be further investigated.

Early manifestation.

In the early stages of a VRF, there may be pain or discomfort on the affected side of the tooth. In particular, the tooth may feel uncomfortable and sensitive

Telegram: @dental_k

www.konkur.in

upon chewing, although this pain is often of a dull nature, as opposed to the sharp pain typical of a cracked cusp or tooth with a vital pulp. As the fracture and subsequent infection progresses, swelling often occurs, and a sinus tract may be present. Noteworthy is that the location of a sinus tract associated with a VRF is more coronal than a sinus tract that is typically associated with a case of a chronic apical abscess (Fig. 22.10).[80,82] These signs and symptoms are frequently similar to those encountered from nonhealing root canal treatment.[58,87] In the early stages, radiographic findings are unlikely because (1) the root canal filling may obstruct the detection of the fracture (Fig. 22.11, *A*), and (2) the bone destruction (which still has limited mesiodistal dimensions) may be obstructed by the superimposed root structure (Fig. 22.12).

from the gum line to mid-root.

Source: (Surgical image courtesy Dr. Devora Schwartz-Arad, Ramat-Hasharon, Israel.)

Often in a case of a VRF, there is the presence of a deep, narrow, and isolated periodontal pocket. This presentation may be inconsistent with the surrounding periodontal status.[80,82,86] This specific type of periodontal defect occurs secondary to the bony dehiscence caused by the VRF and is substantially different in its presentation from the pockets caused by advanced periodontitis (discussed later).

Late manifestation.

A longstanding VRF is easier to detect. The major destruction of the alveolar bone adjacent to the root has already occurred, allowing the VRF to be more likely revealed in a periapical radiograph (see Fig. 22.6, *B*). One of the most typical radiographic signs is a *J-shaped* or *halo radiolucency*, which is a confluence of periapical and periradicular bone loss (i.e., bone loss apically combining with the bone loss on the side of the root, extending coronally) (Fig. 22.13).[83,84] In addition, the pocket now approximating the fracture, which was initially tight and narrow, may become wider and easier to detect. In longstanding cases in which the bone destruction is extensive, the VRF may result in a split root whereby the segments of the root separate, resulting in radiographic evidence clearly revealing an objective split root (Fig. 22.14).

A) Radiograph shows left tooth with a large radiolucent patch at the root tip and half-filled root canal.

B) Radiograph shows V-shaped radiolucent region in-between the root canal. The adjacent tooth has filled root canals and fractures.

Diagnosis

Importance of early diagnosis.

Accurate and timely diagnosis is crucial in VRF cases, allowing the extraction of the tooth or root before extensive damage to the alveolar bone occurs. Early diagnosis is particularly important when implants are a potential part of the future restorative process; when an extraction is performed at an early stage, the uncomplicated placement of an implant is more likely. When the tooth is extracted after extensive damage has already occurred, bone regeneration procedures may be required,[43] adding additional cost and time to the restoration process.

The American Association of Endodontists stated in 2008[5] that a sinus tract and a narrow, isolated periodontal probing defect associated with a tooth that has undergone a root canal treatment, with or without post placement, can be considered pathognomonic for the presence of a VRF.

However, the combination of the following two factors makes the early

Telegram: @dental_k

www.konkur.in

diagnosis difficult: (1) many of the clinical symptoms associated with VRFs mimic apical periodontitis or periodontal disease, and (2) the narrow and tight pocket associated with early stages of VRF is difficult to detect using rigid probes (see the Vertical Root Fracture Pockets section), especially when the pocket is interproximal. Consequently, a delay in the accurate diagnosis —or a misdiagnosis of a VRF—may often occur.

Misdiagnosis of vertical root fractures.

Certain cases of longstanding VRFs are so discernible that no dentist should miss the diagnosis (see Fig. 22.14). Nevertheless, two retrospective case series, one by Fuss et al.[33] and another by Chan et al.,[22] reported that general practitioners often misdiagnose VRFs. The teeth that were extracted in these studies had often been diagnosed as endodontic failures or refractive periodontal pockets, only to realize after extraction that in some of them the actual cause was a VRF.

Vertical root fracture pockets.

The pockets that are typical of the early stages of VRFs differ substantially from the deep pockets associated with advanced periodontal disease. The deep pockets associated with periodontal disease develop as a result of the bacterial biofilm that initially accumulates at the cervical areas of the tooth and the destructive host response to these bacteria.[39] Therefore, deep periodontal pockets are typically wider coronally and easier to probe. This pocket anatomy allows an easy insertion of a rigid periodontal probe (Fig. 22.15). These types of periodontal pockets typically present with the deeper part of the pocket at the mesial or distal aspects of the tooth. In addition, periodontal disease often affects groups of teeth rather than an isolated location of a single tooth.

Telegram: @dental_k

www.konkur.in

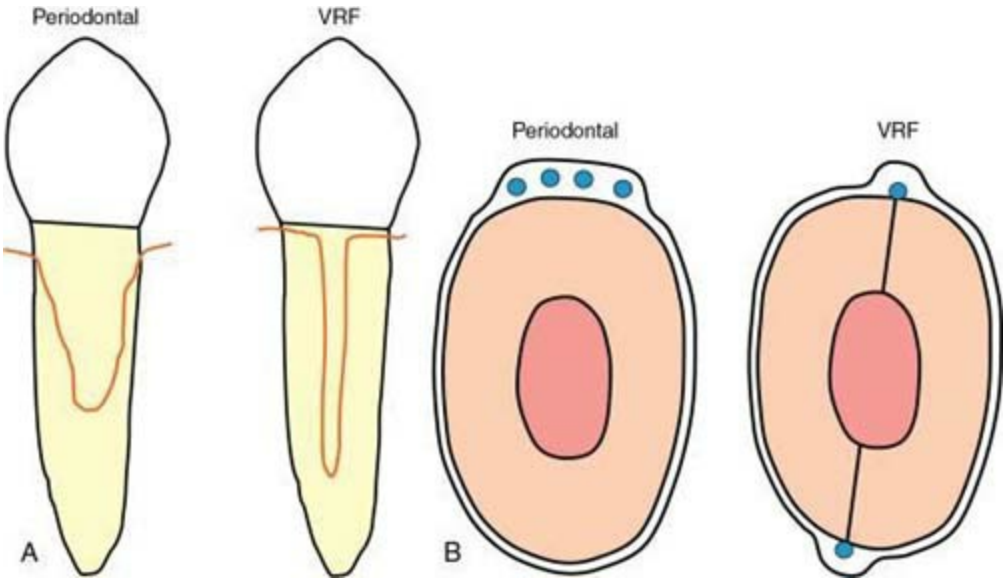

FIG. 22.15 Vertical root fracture *(VRF)* pocket. **A,** Periodontal pockets *(left)* are wide coronally, whereas VRF pockets *(right)* are narrow and deep. **B,** Periodontal pockets *(left)* are loose and allow probing at various sites, whereas VRF pockets *(right)* are narrow and tight. If not checked carefully at every millimeter of the sulcus, an early VRF pocket can easily be missed. Note that periodontal pockets appear more commonly in the proximal sides of the root, whereas VRF pockets are more common on the buccal or lingual sides.

A) Tooth has a nearly bell-shaped periodontal pocket extending below the neck region to the midway of root. Another tooth has a narrow U-shaped VRF pocket extending at the base of crown to three-fourth length of root.

B) Tooth with periodontal pocket has four spheres at the top. Another tooth with VRF pocket has two spheres, one at the top and the other at the base.

The pockets associated with VRFs develop due to bacterial penetration into the fracture, triggering a destructive host response that occurs in the periodontal ligament along the entire length of the fracture. These bacteria may leak from an infected root canal[88]; however, when the VRF extends to the cervically exposed root, the microbes in the fracture may also originate from the oral cavity. In the early stages, the periodontal ligament is affected and destroyed along the longitudinal opening of the fracture, initially with a limited resorption to the adjacent bone. This permits the penetration of a periodontal probe. The pocket associated with a VRF is typically isolated and present only in a limited area adjacent to the affected tooth. This pocket is often located at the buccal or lingual convexity of the tooth. In the early

Telegram: @dental_k

www.konkur.in

stages, the pocket is deep but has a narrow coronal opening (see Fig. 22.15). The insertion of a probe first requires the detection of the coronal opening; often, light pressure is necessary for the insertion of the probe. Because the pocket is narrow, probe insertion may result in the blanching of the surrounding tissue (Fig. 22.16). This is specially the case when a more flexible plastic probe is used, as its coronal part is thicker than an equivalent metal probe (Fig. 22.17; also see Fig. 22.16). Therefore, the pocket associated with the early stages of a VRF is quite different from a typical periodontal pocket. This difference has been widely recognized, and terms such as *osseous defect*[28] and *probing defect*[5] have been used to emphasize the point. Nevertheless, these pockets do possess enough unique features to justify them being specifically termed a *VRF pocket*.

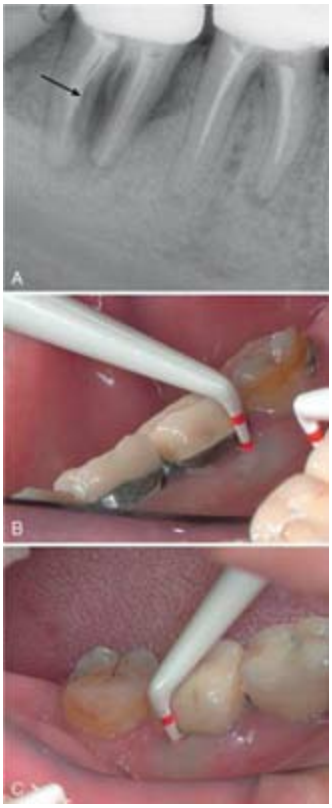

FIG. 22.16 Tight vertical root fracture (VRF) pockets. **A,** The distal root of a second right mandibular molar with a VRF. VRF pockets were found on both the lingual **(B)** and the buccal **(C)** sides. VRF pockets are tight, so inserting a probe into these pockets causes pressure blanching of the surrounding tissues.

A) Radiograph shows two teeth. Second right molar has filled radiopaque root

www.konkur.in

canals with a wavy line extended from below the neck region to above the root tip. The tissue in-between both root canals has less-density.

B) Close-up view of teeth shows probe pressing the white gum line of tooth. The bases of crown are covered with silver strips.

C) Close-up view shows the probe inserting into the gum close to the molar.

Rigid metal periodontal probes may be ineffective in probing VRF pockets in the early stages of a VRF. Given that the pocket is deep, narrow, and tight, the bulge and obstruction of the tooth's crown may prevent the insertion of a metal probe into the pocket (see Fig. 22.17). A flexible probe should be used instead, such as a probe available from Premier Dental Products (Plymouth Meeting, PA) (see Fig. 22.17) or a similar device. This type of flexible probe should be included on every endodontic examination tray and is an essential tool when checking for potential VRF pockets.

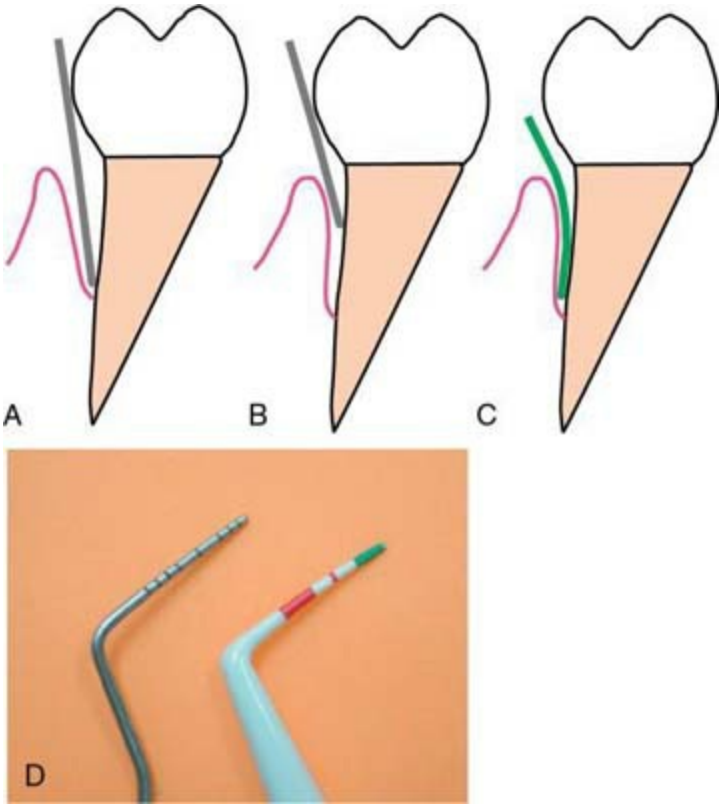

FIG. 22.17 Rigid versus flexible probes. **A,** In a loose periodontal pocket, a rigid metal probe can easily reach the depth of the pocket. **B,** In a tight, early-stage vertical root fracture (VRF) pocket, a rigid probe may be of limited value, as the bulge of the crown often prevents the

Telegram: @dental_k

www.konkur.in

insertion of the probe into the tight, deep pocket. **C,** A flexible probe **(D)** is more likely to detect VRF pockets at an early stage.

A) Probe reaches the midway of the root into the pocket.

B) Probe reaches the one-fourth part of the root at the top of pocket.

C) Probe is curved and reaches deep into the pocket.

D) Two L-shaped probes are shown.

Tamse et al.[82] reported the presence of a typical VRF pocket in 67% of the VRF cases reported. However, because the early detection of such pockets is technique sensitive and because traditional metal probes were used in the aforementioned study, the incidence of these pockets may in fact be higher than reported. When a typical VRF pocket is present on the convex surfaces of the root, on the buccal or lingual aspects, it is likely that the root has a VRF. In contrast, when such a pocket is located at the furcation of a molar, the pocket may indicate either a VRF or a sinus tract from an apical abscess that drained at a point of least resistance at the furcation area. In cases with a furcation pocket, when a VRF diagnosis cannot be conclusively determined, a positive healing response to the elimination of infection (by periodontal therapy or initiating root canal treatment if necessary) may differentiate between these two types of pathoses.

Coronally located sinus tract.

Sinus tracts that originate from a chronic apical abscess are typically detected at the site of least bone resistance, against the apical part of the root or in the area of the junction of the attached gingiva and the oral mucosa. Sinus tracts that are associated with a VRF pocket are often found in a more coronal position, as the source is not from a periapical lesion (see Fig. 22.10).[81]

In four clinical retrospective case series, coronally located sinus tracts were found in 13% to 35% of these cases.[59,80,82,86] As in the case of a VRF pocket, if the sinus tract is located at the furcation of a molar, this observation does not necessarily indicate a VRF, as periapical abscesses from re-infected root canal treatment can also drain in this coronal location.

Radiographic features.

Telegram: @dental_k

www.konkur.in

A definitive VRF diagnosis can sometimes be made based on the radiographic appearance of a thin radiolucent line extending longitudinally down the root.[73] Such lines, however, are difficult to detect and are commonly not seen in routine periapical radiographs because either the root canal filling has “masked” the fracture line or the angulation of the x-ray beam is not optimal for discerning the fracture (Fig. 22.18; also see Fig. 22.11). Rud and Omnell[73] claimed that it was possible to observe fracture lines in 35.7% of cases, but many of these cases were not true VRF instances. In clinical practice, it is still rare to observe a VRF on a radiograph, especially when only a single periapical radiograph is exposed. Such an observation requires the x-ray beam to align with the plane of the fracture as well as the fracture line not being superimposed over the radiopaque root filling. Therefore, two or three periapical radiographs should be exposed from different horizontal angulations when a fracture is suspected (Fig. 22.19; also see Fig. 22.18).[81] In most VRF cases, the clinician must make subjective *interpretations* or *predictions* based on the various patterns of periradicular bone destruction which, unfortunately, are also shared by other periodontal and endodontic-like lesions.[59,76,89]

FIG. 22.18 Radiography of an empty canal: a clinical case. The right maxillary lateral incisor underwent a root canal treatment a few years ago. The patient complained about occasional pain on the palatal side. The tooth was sensitive to percussion and palpation on the palatal side. Radiography revealed a periapical radiolucency **(A).** An isolated, deep, and narrow pocket was found on the palatal side of the root. Both the patient and the referring dentist were reluctant to extract the tooth, assuming that the pocket could potentially be a sinus tract, and decided on retreatment. A radiograph taken with a file during the process **(B)** could have missed essential information that was obscured by the file,

Telegram: @dental_k

www.konkur.in

which was an evident vertical root fracture **(C).**

Three radiographs are marked A through C.

A) Lateral incisor has a filled root canal with a bulge at the center. The tissue near root tip is less dense.

B) Lateral incisor has zigzag pattern of filling in radiolucent root canal. The tissue near root tip is less dense.

C) Lateral incisor has a slant vertical line in radiolucent root canal extended from below the neck to three-fourth of the root.

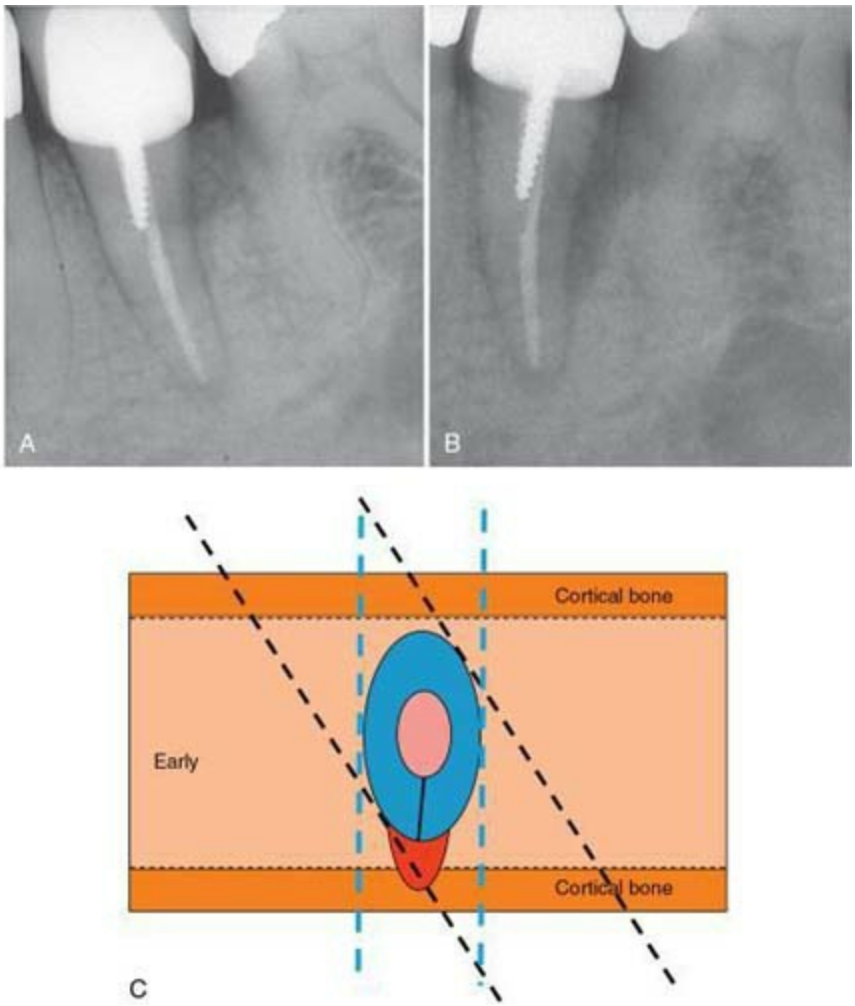

FIG. 22.19 Diagonal radiographs for detection of vertical root fracture (VRF). **A,** Orthoradial radiograph: very limited bone loss is seen. **B,** A different horizontal angulation reveals a radiolucent lesion along the root. **C,** Schematic presentation. Although a radiograph in an

Telegram: @dental_k

www.konkur.in

orthoradial direction *(blue lines)* cannot pick up the radiolucency along the root, diagonal angulation *(black lines)* may do so, as in **B.**

A) Radiograph shows the central tooth with filled root canal. The filling is comparatively less radiopaque from mid to tip of the root.

B) Radiograph shows the oblique space in the mid of the root canal. The tissue along the one side of root has less density.

C) Early detection shows the U-shaped outgrowth from tooth penetrates in the cortical bone. The tooth is placed inside two vertical parallel blue lines and two black diagonal lines.

In the early stages of a VRF, no radiolucent bone lesions may be observed[20] (see Fig. 22.12), which may be the reason why VRFs often remain undetected, delaying diagnosis and treatment. Rud and Omnell[73] correlated the direction of the fracture, the degree of bone destruction, and the radiographic appearance, and emphasized that the extent of bone destruction around a fractured root depends on the location of the root fracture and the time elapsed since the inception of the fracture. The significance of time was confirmed by Meister et al.,[59] who demonstrated that immediate radiographic detection is difficult due to the time required for bone resorption to occur or for the fractured segments to separate and be radiographically visible. In a study of the patterns of bone resorption in 110 VRF cases, Lustig et al.[58] found that in 72% of patients with either chronic signs and symptoms (i.e., pertaining to a sinus tract, osseous defect, or mobility) or acute exacerbations, there was greater bone loss recorded compared to patients for whom a VRF diagnosis was made at an early stage.[58]

Despite the difficulty of diagnosing *early stage* VRFs in endodontically treated teeth, there are often several radiographic signs associated with *later stages* that are strong indicators of VRF.

The J-shaped or halo radiographic appearance of bone loss, a combination of periapical and periradicular radiolucencies, was associated with a high probability of a VRF in a double-blind radiographic study involving 102 endodontically treated maxillary premolars (see Fig. 22.13).[83] An angular resorption of the crestal bone along the root on one or both sides, without the involvement of the periapical area, mimicking a “periodontal radiolucency” (see Fig. 22.13), was found in 14% of the cases. Tamse et al.[84] also reported

Telegram: @dental_k

www.konkur.in

the radiographic appearance of “halo” and “periodontal” radiolucencies in vertically fractured mesial roots of mandibular molars (37% and 29%, respectively). In that study, the use of these two variables, combined with bifurcation involvement (63%) and the presence of an amalgam dowel (67%), predicted fracture in 78% of the cases. Others have reported similar findings.[24,63] Despite the different sample sizes, study designs, and objectives, the most common radiographic feature in these studies was a lateral radiolucency appearing longitudinally along the root and a halo appearance.

Osseous radiolucency adjacent to the root.

The type of periradicular radiolucency associated with a VRF is not and should not be interpreted as a thickening of the PDL. Instead, it represents a substantial destruction of the cortical plate of the alveolar bone (see Fig. 22.12).[58] In the case of a VRF in the bucco-lingual plane, often the bone resorption is limited at early stages, and any associated radiolucency may be obscured by the superimposition of the root (see Fig. 22.12). As the bone loss increases, the radiolucency becomes greater than the dimensions of the root, allowing it to be detected more clearly in the previously mentioned manner (see Fig. 22.12). As the VRF progresses to an intermediate stage, radiographs taken at different horizontal angulations may detect bone resorption (see Fig. 22.19), whereas a single radiograph may not (see Figs. 22.12 and 22.19). This radiographic feature should be differentiated from a split tooth, in which the fracture plane is typically mesiodistal, with the bone resorption occurring in the earlier stages on the mesial or distal aspects of the root.

Radiograph of empty canal.

As mentioned previously, the direct clinical detection of an early stage VRF from a periapical radiograph is unlikely, especially when there has been endodontic treatment. Because most VRFs are in the bucco-lingual plane, the radiopaque obturation often obstructs the view of the hairline radiolucency of the fracture (see Fig. 22.11). When a VRF is suspected, one may initiate root canal retreatment, removing the root obturation, and exposing radiographs at two or three different horizontal angulations. The detection of a hairline radiolucency may provide a more definitive diagnosis of a VRF (see Fig.

Telegram: @dental_k

www.konkur.in

22.18).[81]

Cone-beam computed tomography in vertical root fracture diagnosis.

Modern cone-beam computed tomography (CBCT) has a much smaller radiation dose compared to traditional medical spiral CT imaging, thus rendering CBCT a reasonable diagnostic tool for use in selected endodontic cases.[6,31,32,66]

One of the unique features of CBCT is its ability to study the suspected tooth and associated bone in an axial plane (i.e., the horizontal sectioning of the root). Axial views may provide detailed information regarding the cross-sectional appearance of the tooth and its surrounding bone (Fig. 22.20). Considering the resolution of the current CBCT devices, the width of an unseparated fracture may be too small to be detectable (see Fig. 22.20) (SEDENTEXCT guidelines[31]). Traditional planar, periapical radiographs are also of limited value for the *early* detection of VRFs. More specifically, bone damage or separation of the fragments is only radiographically evident at a relatively late stage. Several studies suggested that the detection of early-stage VRFs by a CBCT scan set to an axial view may be possible.[42,43,60] Yet such detection may greatly depend on the resolution of the machine (i.e., the voxel size). At a voxel size of 0.3 mm, the detection of early, unseparated VRFs is not reliable; however, when smaller voxel sizes were used in these in vitro studies, the reliability greatly increased.[42,43,60] Although the detection level of a fracture is thought to be the width of twice the voxel size of the CBCT imaging, there is presently no literature available to support this theory. Therefore, given that the smallest voxel size currently available for a CBCT device is about 0.075 mm, CBCT imaging would not be able to visualize a root fracture unless the fracture width was greater than 0.15 mm. It should also be noted that the intracanal presence of gutta-percha or a metal post often causes artifacts that make it extremely difficult to discern a VRF.[60]

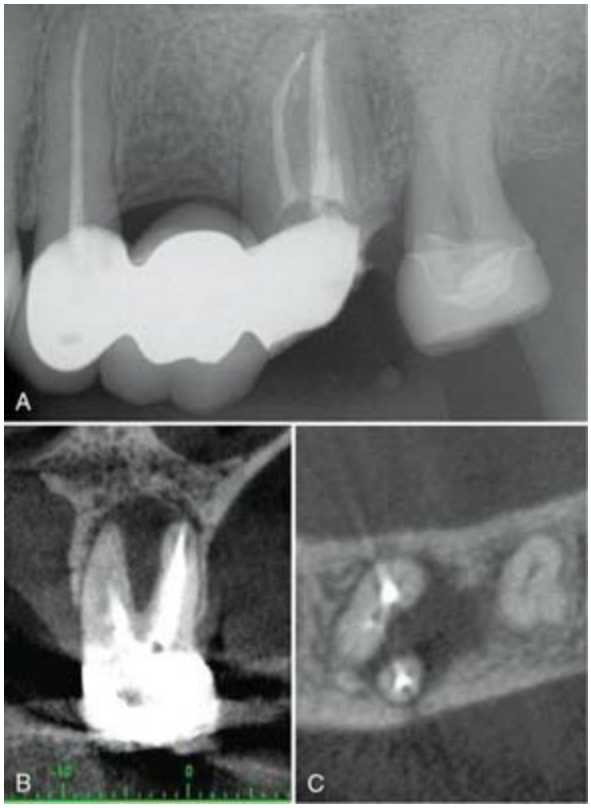

FIG. 22.20 **A,** Periapical radiograph of maxillary left first molar. **B,** Cone beam computed tomography (CBCT) coronal view revealing bone loss between the buccal and palatal roots, suggestive of a vertical root fracture. **C,** CBCT axial view revealing bone loss between the buccal and palatal roots, suggestive of a vertical root fracture.

Set of four radiographs, marked A through D, shows periapical, front, and transverse views of vertical root fracture in left first molar of upper jaw.

Source: (Courtesy Dr. R. Granik.)

Although the width of early VRFs may still be below the detection level of many CBCT devices, the *early destruction of the bone* along the suspected fracture may be visible in the cancellous bone (i.e., with an axial view) at relatively early stages, whereas this early bone destruction would not be detectable in traditional two-dimensional periapical radiographs; such bone resorption may help to establish a VRF diagnosis (see Fig. 22.20).

With likely increased resolution in the near future, CBCT may become a more important diagnostic tool for the detection of VRFs. For the present, neither the most updated Joint Position Statement of the American Association of Endodontists and American Academy of Oral and

Telegram: @dental_k

www.konkur.in

Maxillofacial Radiology (2010), nor the European Society of Endodontology position statement on the use of CBCT in endodontics (2014) recommend the use of CBCT for a definitive diagnosis of VRF.[6,32]

Improvements of CBCT imaging—such as achieving a better signal-to-noise ratio, obtaining a smaller voxel size, and by applying advanced algorithms to segment fracture lines—may promise the potential to enhance the ability to detect early-stage VRFs in the future.

Exploratory surgery.

When clinical and radiographic evaluations are equivocal in detecting a suspected VRF, exploratory surgery may be indicated. In the presence of a bony lesion, especially a bony dehiscence, the raising of a full-thickness flap and removal of the granulation tissue may help to facilitate the visualization of a VRF (Fig. 22.21; also see Fig. 22.12).[81] The bone resorption pattern associated with a VRF is most often seen as a bony dehiscence, with the greater bone destruction being present on the buccal cortical plate located over the offending root. In a small percentage of the cases, a fenestration can be seen.[58] Furthermore, it has been shown that the longer a VRF-related infection persists, the greater the resulting periradicular bone destruction.[58]

Etiology

VRFs may arise from a series of factors, some of which are natural whereas others are iatrogenic, arising from dental procedures such as endodontic treatment and restorative procedures. The most common dental procedure contributing to VRFs is endodontic treatment.[11]

Most VRFs occur in endodontically treated teeth.[11,24] VRFs usually do not occur during the actual obturation of the root canal, but rather long after the procedure has been completed.[82]

The etiology of VRFs is multifactorial,[34,80] arising in the presence of one or more predisposing factors, the repeated functional or parafunctional occlusal loads which may eventually lead, over months or even years, to the

development of a VRF. Predisposing factors may include natural influences, such as the anatomy of the root, or iatrogenic causes, such as the excessive forces during root canal instrumentation, excessive tooth structure removal, or excessive obturation pressure.

Natural predisposing factors

Shape of root cross section.

One of the common anatomic features shared by teeth that typically develop VRFs is an oval cross section of the root, with a bucco-lingual diameter being larger than the mesiodistal diameter.[37,41] These teeth include the maxillary and mandibular premolars, the mesial roots of the mandibular molars, and the mandibular incisors (Fig. 22.22, *A* and *B*). Such anatomy is easily observed in the axial plane of a CBCT scan (see Fig. 22.22, *A* and *B*). The fracture in these teeth typically starts in the bucco-lingual plane, specifically at the highest convexity of the oval root (see Fig. 22.22, *A* and *B*).[21,81] This conclusion, derived from large case series, is also supported by finite element analysis.[65] Such analysis clearly demonstrated strain concentration on the inner side of the remaining dentin wall at the highest convexity point (i.e., the buccal and lingual sides of the oval roots) (Fig. 22.23).[55,56]

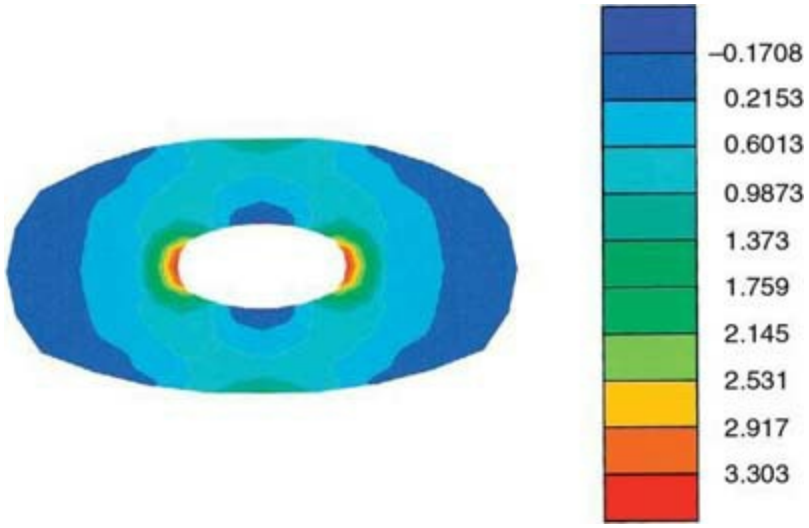

FIG. 22.23 Finite element analysis of the strain distribution in an oval root. Note the strain concentration on the inner side of the highest convexity of the remaining dentin wall. Red and orange represent areas of higher strains than blue areas.

Multicolored horizontal tooth shows oval root where left and right sides have higher strain in a range of 3.3 0 3 to 0.9 8 7 3. The top and bottom sides of the root have strain in the range of 0.2 1 5 3 to negative 0.1 7 0 8.

Source: (From Lertchirakarn V, Palamara J, Messer HH: Patterns of vertical fractures: factors affecting stress distribution in the root canal, *J Endod* 29:523, 2003.)

Occlusal factors.

Excessive occlusal loads or concentration of such loads may be another natural predisposing factor for VRFs. Load concentrations, such as those caused by occlusal prematurities in maxillary premolars, and excessive

Telegram: @dental_k

www.konkur.in

occlusal forces, specifically in the case of mandibular second molars, are good illustrations.[18] In combination with other natural and iatrogenic predisposing factors, excessive occlusal loads may, over time, lead to VRFs.

Preexisting microcracks.

Preexisting microcracks may be present in the radicular dentin, likely resulting from repeated forces of mastication or occlusal parafunction.[15,64] Such fractures were also recently reported by Barreto et al.,[10] who found these microcracks present in 40% of intact maxillary incisors and canines.

Iatrogenic predisposing factors

Root canal treatment.

VRFs mostly appear in endodontically treated teeth[5,81]; therefore, endodontic treatment per se may be considered an iatrogenic predisposing factor. Teeth were once thought to be more susceptible to fracturing after endodontic treatment because of a decrease in hydration.[44] However, later studies found no difference in the properties of dentin, as a material, after endodontic procedures.[47,76]

Although the physical characteristics of dentin, as a material, may not be compromised by endodontic treatment, the radicular dentin, as a structure, may be compromised by the accumulative or combined effect of several natural or iatrogenic factors associated with the endodontic treatment and the restoration of endodontically treated teeth. This may be the reason for the often-reported association of VRF with endodontically treated teeth.

It is incumbent for the clinician to recognize this effect and take efforts to minimize any steps that may contribute to the development of a root fracture during endodontic treatment.

Excessive root canal preparation.

Excessive root canal preparation may be a predisposing factor for VRF development.[90] In one study, cracks detected by transillumination were more frequent when the same teeth were subjected to a gradually increasing endodontic canal preparation.[90] To reduce the risk of VRFs, less invasive methods may be considered, such as minimally invasive endodontic

www.konkur.in

instrumentation (see also Chapter 8).[61,67]

Microcracks caused by rotary instrumentation.

Shemesh et al.[77] and others[2,10,14,17,45,78,92] observed that root canal preparation using nickel-titanium rotary and reciprocating files often results in microcracks in the remaining radicular dentin (Fig. 22.24). This finding, which was originally noted for single rooted teeth, has been further supported by Yoldas et al.,[92] who studied microcrack formation from rotary files in the mesial roots of mandibular molars. Each of the rotary file systems examined in this study caused frequent microcracks in the dentin, whereas both hand instrumentation with files and the self-adjusting file (see Chapter 8) did not cause such cracks.

FIG. 22.24 Typical bucco-lingual fracture that includes the isthmus in a maxillary premolar with two canals.

Tooth shows a deep horizontal line with two circular structures on buccal and lingual sides.

A finite element analysis by Kim et al.[51] supports and may explain these findings. These researchers and others reported that rotary files induce strain on the dentin, as measured in the surface layers of the root dentin, which likely exceeds the elasticity of the dentin, causing subsequent microcracks.[2,10,14,17,45,77,78,92] Additional stress, either from root obturation with lateral compaction[10,77] or by nonsurgical endodontic retreatment,[78]

Telegram: @dental_k

www.konkur.in

caused some of the microcracks to propagate and become through-and-through fractures that were indistinguishable from VRFs.[10,77,78]

The relationship of these various findings to the subsequent clinical creation of a VRF has yet to be confirmed. In any event, considering the basic principles of fracture mechanics, the creation of microcracks should at least be considered as a potential predisposing factor.

Uneven thickness of remaining dentin.

The instrumentation of root canals often results in uneven thickness of the remaining dentin, particularly when curved canals are straightened by instrumentation.[68] Uneven dentin thickness can also occur upon excessive instrumentation of the mesial roots of the mandibular molars or first maxillary premolars, which may exhibit a distal or mesial concavity, respectively, that is not detectable in a common planar, periapical radiograph (see Fig. 22.22, *C* and *D*). These areas, which have been referred to as "danger zones,"[30] may be characterized by a decrease in the remaining dentin thickness in which the application of internal strain may potentially lead to a fracture. The anatomic groove that is often found on the palatal side of the buccal root of maxillary bifurcated premolars is another example of such a hidden danger zone (see Fig. 22.22, *E*–H).[49]

Lingual access, which is commonly used in incisors, may also result in a thinner buccal wall in the apical area as compared with the lingual wall. This phenomenon may be especially pronounced when thick, and thus rigid, instruments are used excessively. When lateral compaction was applied ex vivo in a similar case, the strain concentration was recorded on the thinner buccal side of the apical part of the tooth.

The use of flexible nickel-titanium files and minimally invasive instrumentation may reduce such risks (see also Chapter 8).

Methods of obturation.

Certain obturation techniques, such as lateral compaction, involve the application of internal pressure with a spreader, which may cause strains[27,74] and subsequent propagation of microcracks into fractures across the full dentin thickness.[10,77] Other obturation methods may create less pressure, such as thermoplasticized gutta-percha, and may reduce the risk of VRFs (see

Telegram: @dental_k

www.konkur.in

Chapter 9).

Type of spreader used.

The use of a more rigid and thick stainless-steel hand spreader may lead to increased strain in the radicular dentin and can result in an increased incidence of root fracture.[27,74] The introduction of more flexible finger spreaders, which have smaller diameter, may greatly reduce such risks.[27] Among the finger spreaders, devices composed of nickel-titanium allow insertion with less force than stainless-steel finger spreaders.[75] The nickel-titanium spreaders also allow a further reduction in the strain induced in the radicular dentin during obturation compared to traditional stainless-steel finger spreaders.[69]

Post design.

Post selection, design, and seating have a significant effect on the strain distribution in the root. Excessively long or thick posts are considered a predisposing factor for VRFs.[23,25,62] The use of posts carries an inherent risk of root fracture, particularly if excessive dentin is removed during preparation. Posts should only be used when essential for core retention and should be avoided whenever sufficient coronal tooth structure is available for the secure retention of the crown.[4,38]

Crown design.

When considering endodontically treated teeth, crowns with a ferrule margin (i.e., supported by a sound tooth structure all around and beyond the gingival margins of the core) provide better strain distribution than similar restorations that are supported by the post and core alone.[4] This design may help to avoid yet another potential predisposing factor for VRFs.[26]

Even though endodontic treatment may be necessary because of pulpal pathosis, the impact of each of the iatrogenic predisposing factors should be minimized as much as possible, as they are likely to have a cumulative deleterious effect in perpetuating VRFs.

Treatment planning

Telegram: @dental_k

www.konkur.in

Prevention is the key to managing VRFs. There are many predisposing factors and iatrogenic causes of these fractures, all of which should be minimized as much as clinically possible. Whereas VRFs may be present in teeth subjected to endodontic retreatment, they are rarely present in teeth that have never undergone endodontic treatment.[22] Therefore, comprehensive clinical, radiographic, and periodontal examination is imperative when evaluating any tooth that is planned for endodontic treatment or retreatment. A flexible periodontal probe is mandatory in such examinations.

When a VRF is determined to be present, extraction of the affected tooth or root is recommended as soon as possible. Any delay may increase the potential for additional periradicular bone loss and potentially compromise the placement of an endosseous implant. Attempts to "repair" a fracture by filling the crevice with a variety of restorative materials have been reported; however, none of these repairs is considered a reliable long-term solution.[8,50,54,85]

There are additional clinical and radiographic examples that can be seen of VRFs in Figs. 22.25 and 22.26.

Summary

Because of the wide variety of different types of cracks and fractures in teeth, there may be a myriad of symptoms and presentations that may appear at different stages of the crack or fracture development, making their diagnosis often difficult. The awareness that many of these symptoms represent *stages in an evolving process* may make their interpretation easier for the clinician.

The extensiveness of a crack may directly alter the prognosis assessment and treatment plan for a given tooth; the presence of a fracture may lead to the demise of a tooth and may compromise the periradicular bone. Therefore, developing a diagnosis, prognosis assessment, and treatment plan for teeth with suspected cracks and fractures is essential, with an emphasis on early detection. In addition, endodontic and restorative procedures should focus on minimizing any offending and predisposing factors that may perpetuate cracks and fractures.

Special features of endodontically treated teeth

Once endodontic therapy is completed, the tooth must be adequately restored. Indeed, given the large impact that poor or missing restorations have on the survival of endodontically treated teeth, one could make the argument that the restoration is actually the last step of endodontic therapy. However, it is important to realize that endodontically treated teeth are structurally different from nontreated vital teeth. Major changes following treatment include altered tissue physical characteristics, loss of tooth structure, and possibly discoloration. Research has analyzed these tissue modifications at different levels, including tooth composition, dentin microstructure, and tooth macrostructure. These studies indicate that it is critical to understand the implication of such features on tooth biomechanics, as they will largely influence the restorative approach and means (Table 23.1). Additional in vitro studies dealing with the complexity of the nonvital tooth substrate are reported in the literature; ultimately, clinical studies have documented the global effect of these changes on the long-term survival of endodontically treated teeth.

Table 23.1

Specific Tissue Modifications and Possible Clinical Implications Following Loss of Vitality or Endodontic Treatment

Alteration Level	Specific Changes	Possible Clinical Implication

	and content	
Dentin structure	Elasticity modulus and behavior Tensile and shear strength Microhardness	Increased tooth fragility
Tooth macrostructure	Resistance to deformation Resistance to fracture Resistance to fatigue	Increased tooth fragility Reduced retention/stability of the prosthesis

Compositional changes in nonvital teeth and the influence of endodontic therapy

The loss of pulpal vitality is accompanied by a slight change in tooth moisture content. This loss of moisture (9%) is attributed to a change in free water but not in water bonded to the organic and inorganic components.[65,69] This alteration was associated with a slight change in values for the Young modulus and proportional limit.[75] However, no decrease in compressive and tensile strength values was associated with this change in water content.[75] Only one study showed no difference in moisture content between vital and nonvital teeth.[123] No difference in collagen cross-linkage was found between vital and nonvital dentin.[140] Thus nonvital teeth undergo rather minor changes in physical characteristics.

Sodium hypochlorite and chelators such as ethylenediamine tetra-acetic acid (EDTA), cyclohexane-1,2-diaminetetra-acetic acid (CDTA), ethylene glycol-bis-(β-amino-ethyl ether) *N*,*N*,*N*,N-tetra-acetic acid (EGTA), and calcium hydroxide ($Ca[OH]_2$) commonly used for canal irrigation and disinfection interact with root dentin, with either mineral content (chelators) or organic substrate (sodium hypochlorite).[78,116,119] Chelators mainly deplete calcium by complex formation and also affect noncollagenous proteins (NCPs), leading to dentin erosion and surface softening.[78,82,144] Depending on concentration, duration of exposure, and other factors, sodium hypochlorite can demonstrate a proteolytic action by hydrolysis of long peptide chains such as collagen.[68] These alterations are likely to impact dentin and root structure and alter bonding properties of this substrate.

Telegram: @dental_k

www.konkur.in

Dentin structure and properties in nonvital and endodontically treated teeth

It is important to know that dentin displays a range of normal variations in its physical properties, which must be distinguished from alterations related to loss of vitality or endodontic treatment. For instance, dentin microhardness and elasticity actually vary between peritubular and intertubular dentin and depend on tooth location. Peritubular dentin presents an elasticity modulus of 29.8 GPa, whereas intertubular dentin ranges from 17.7 GPa (close to pulp) to 21.1 GPa (close to the root surface).[70,85,101] Most if not all the decreases in hardness on approaching the pulp can be attributed to changes in hardness of the intertubular dentin.[84,85] Overall dentin elasticity modulus is considered to be in the range of 16.5 to 18.5 GPa.[15,32,50,86,121,138]

The changes in mineral density due to the variation in the number and diameter of tubules within the tooth may also contribute to variations in the properties of dentin. Unsurprisingly, dentin hardness values are inversely related to dentin tubule density.[124] Ultra microindentation measurements also demonstrated significantly higher values for hardness and elasticity modulus when forces were parallel to the tubules rather than perpendicular.[133] Differences in maximum strength and compressive strength were also found to vary according to tubule orientation.[121] The ultimate tensile strength (UTS) of human dentin is lowest when the tensile force is parallel to tubule orientation, showing the influence of dentin microstructure and anisotropy of the tissue.[93] No difference was found in the Young modulus of aged, transparent dentin (also called *sclerotic*) and normal dentin,[19,87,167] but the mineral concentration significantly increases and crystallite size is slightly smaller in transparent dentin, in relation with closure of the tubule lumens. Transparent dentin, unlike normal dentin, exhibits almost no yielding before failure. Its fracture toughness is also lowered by about 20%, whereas the fatigue lifetime is deleteriously affected.[87]

Interestingly, comparisons between vital and nonvital dentin of contralateral teeth demonstrate no or only minor differences in microhardness values after periods ranging up to 10 years after treatment.[94,154] Thus the literature does not support a widely held belief that attributes particular weakness or brittleness to nonvital dentin. Others have suggested that

Telegram: @dental_k

www.konkur.in

nonvital teeth in older patients may have greater risk for fracture because the age-related generation of secondary or tertiary dentin would be lost. However, this is not the case because the only impact of age-related tissue changes is the aforementioned reduction in fracture toughness and fatigue lifetime attributed to dentin sclerosis.[87]

The chemicals used for canal irrigation and disinfection, as already mentioned, interact with mineral and organic contents and then reduce dentin elasticity and flexural strength to a significant extent,[64,157] as well as microhardness.[33,77,146] On the contrary, disinfectants like eugenol and formocresol increase dentin tensile strength by way of protein coagulation and chelation with hydroxyapatite (eugenol). Dentin hardness, however, did not prove to be influenced by the latter products.[112]

In conclusion, a possible decrease in tooth strength can be attributed to dentin aging and to a smaller extent to dentin alteration by endodontic irrigants.

Fracture resistance and tooth stiffness of nonvital and endodontically treated teeth

In contrast to the aforementioned factors, the major changes in tooth biomechanics appear to be due to the loss of hard tissue following decay, fracture, or cavity preparation (including the access cavity prior to endodontic therapy).

The loss of hard tooth structure following a conservative access cavity preparation affects tooth stiffness by only 5%.[91,169] The influence of subsequent canal instrumentation and obturation lead only to a slight reduction in the resistance to fracture[91,169] and ultimately have little effect on tooth biomechanics.[91,137,169] From a clinical perspective, one can expect alteration of tooth biomechanics only in cases of nonconservative canal preparation or through the chemical or structural alteration triggered by endodontic irrigants, as previously mentioned.

In fact, the largest reduction in tooth stiffness results from excessive access preparation, especially the loss of marginal ridges. The literature reports a 20% to 63% and a 14% to 44% reduction in tooth stiffness following occlusal and MOD cavity preparations, respectively.[44,92,137] It has been shown that an

Telegram: @dental_k

www.konkur.in

endodontic access cavity combined with an MOD preparation results in maximum tooth fragilization. The cavity depth, isthmus width, and configuration are therefore highly critical to the reduction in tooth stiffness and risk of fracture (Fig. 23.1).[74,83,96,122] This important point has profound clinical implications.

FIG. 23.1 The negative impact of poor initial biomechanical status on restoration success. **A** and **B,** Preoperative radiographic views following the removal of the old metallic foundation. **C,** A new amalgam core, using post and self-anchorage into mesial root structure, was performed. **D,** Prosthetic restorations on working model. **E,** Full arch view after 3 years. **F,** The tooth is symptomatic due to furcation involvement and periapical lesion. **G,** This untreatable tooth was finally

extracted and replaced by an implant. **H,** Eight-year postoperative radiograph showing a stable situation. Other teeth with less extensive biomechanical damage overcame functional stresses.

A) Radiograph shows three teeth. The first tooth has radiolucent root canal with a hard-density patch on the enamel and a radiolucent round patch on the crown. The second and third teeth have radiopaque crowns.

B) Radiograph shows three teeth with filled root canals. Part of the crown of first and second teeth has less-density tissue.

C) Radiograph shows teeth with filled root canals.

D) Occlusal view of teeth with slight yellow stains.

E) Close-up view of lower jaw with slight yellow stains. Some teeth are not properly aligned.

F) Radiograph shows four teeth. The first tooth has radiolucent root canal with radiopaque patch on the crown. All other teeth have radiopaque crowns and root canals. The root canal of the second tooth is half-filled.

G) Radiograph shows the third tooth missing.

H) Radiograph shows the implantation of new tooth. Its U-shaped root is properly radiopaque with a hole at the base.

The presence of residual hard tissue in the cervical area (which constitutes the *ferrule* for restorations) and a larger amount of residual mineralized tissue in general increase tooth resistance to fracture. It actually allows the axial walls of the crown to encircle the tooth, providing restoration retention and stabilization and reducing cervical tensile stresses.[6,23,161] Crown preparations with as little as 1 mm coronal extension of dentin above the margin double the fracture resistance of preparations, compared to those where the core terminates on a flat surface immediately above the margin[103,161]; therefore a minimal 1-mm ferrule (and ideally 2 to 3 mm) is considered necessary to stabilize the restoration.[161] However, the widths of preparation shoulder and crown margin do not appear to influence fracture strength.[2] Taken together, the height of the ferrule is one of the most important elements in the long-term survival of restorations. These considerations have led to the conclusion that the most important part of the restored tooth is the tooth itself, and no contemporary restorative material or combination of materials will perfectly substitute for lost tooth structure.

www.konkur.in

Aesthetic changes in nonvital and endodontically treated teeth

Several aesthetic changes may also occur in nonvital or endodontically treated teeth. For example, color change or the darkening of nonvital teeth is a common clinical observation (Fig. 23.2). In addition, incomplete endodontic treatment can contribute to discoloration. For instance, inadequate cleaning and shaping can leave necrotic tissue in coronal pulp horns, resulting in tooth darkening. In addition, root canal filling materials (gutta-percha and root canal sealer cements, MTA-like materials) retained in the coronal aspect of anterior teeth can detract from the aesthetic appearance. Opaque substances also adversely affect the color and translucency of most uncrowned teeth. Biochemically altered dentin modifies tooth color and appearance. It is generally accepted that organic substances present in dentin (e.g., hemoglobin) might play an important role in this color change and also food and drink pigment penetration triggered by the absence of pulpal pressure. However, the respective contribution of these two phenomena and precise physicochemical mechanisms leading to discoloration are poorly understood or described in the literature.[34,67,131]

FIG. 23.2 Severe discoloration can significantly disturb aesthetics, even in the lateral area of the smile. When not treatable with bleaching agents or veneers, this condition might justify tooth preparation for a full crown.

Telegram: @dental_k

www.konkur.in

Close-up view shows teeth with yellow stains on them. The tooth at the center has grayish stain as well extending from the gum line.

Thin gingival tissue or, in general, thin biotype, is considered a negative factor for the aesthetic outcome of restorative and prosthetic treatment of discolored teeth.[110,111,118]

Endodontic treatment and subsequent restoration of teeth in the aesthetic zone require careful control of procedures and materials to retain a translucent, natural appearance. It is therefore strongly recommended that one avoid the use of potentially staining endodontic cements and clean all material residues left in the pulpal chamber and access cavity.

Restorative materials and options

As described previously, endodontic treatment, particularly excessive access preparations, can result in significant loss and weakening of tooth structure. Tooth structure lost during endodontic treatment increases the risk of crown fracture, with fatigue mechanisms mediating the fracture of roots over time. Restorations of endodontically treated teeth are designed to (1) protect the remaining tooth from fracture, (2) prevent reinfection of the root canal system, and (3) replace the missing tooth structure.

According to the amount of tissue to be replaced, restorations of endodontically treated teeth rely on different materials and clinical procedures. As a general rule, most structurally damaged teeth should be restored with an artificial crown.

Although the use of a crown built on post and core is a traditional approach, others have advocated the use of direct composite resins for restoring small defects in endodontically treated teeth. More recently, indirect restorations, such as overlays or endocrowns made of composite resins or ceramics, have also been used. The selection of appropriate restorative materials and techniques is dictated by the amount of remaining tooth structure. This is far more relevant to the long-term prognosis of endodontically treated teeth than any properties of post, core, or crown materials.

Direct composite restorations

Telegram: @dental_k

www.konkur.in

When a minimal amount of coronal tooth structure has been lost after endodontic therapy, a direct resin composite restoration may be indicated. Composite resins are a mixture of a polymerized resin network reinforced by inorganic fillers. Contemporary composites have compressive strengths of about 280 MPa, and the Young modulus of composite resins is generally about 10 to 16 GPa, which is close to that of dentin.[134]

When properly cured, resin composites are highly aesthetic, exhibit high mechanical properties, and can reinforce the remaining tooth structure through bonding mechanisms. Typically, 500 to 800 mW/cm^2 of blue light for 30 to 40 seconds is necessary to polymerize an increment of composite that must be 1 to 3 mm thick. Unfortunately, the shrinkage that accompanies polymerization of contemporary composite resins remains a significant problem to the long-term success of these restorations. The use of an incremental filling technique, which helps to reduce shrinkage stresses during polymerization, is highly recommended. The amount of shrinkage will also depend on the shape of the cavity preparation and the ratio of bonded to unbonded (or free) surfaces.[36] This so-called C-factor is a clinically relevant predictor of the risk of debonding and leakage; restorations with high C-factors (>3.0) are at greatest risk for debonding.[175] In other words, a direct composite restoration may be indicated when only one proximal surface of the tooth has been lost; using an incremental filling technique is mandatory.

Classically, direct composite restorations have been placed in anterior teeth that have not lost tooth structure beyond the endodontic access preparation. In such cases, the placement of a direct composite restoration offers an immediate sealing of the tooth, which prevents coronal leakage and recontamination of the root canal system with bacteria. In vitro studies have demonstrated that the fracture resistance of small bonded restorations is nearly as great as that of intact teeth.[57,136]

Although direct composite resins may also be used for small restorations in posterior teeth, they are contraindicated when more than a third of coronal tissue has been lost. In one study,[136] it was reported that the resistance to fracture of endodontically treated teeth is reduced by 69% in cases where MOD cavities are present.[137] Under such conditions, a direct composite restoration may not be appropriate to prevent the tooth structure from fracture and reinfection. Furthermore, resin composite materials may require the use

Telegram: @dental_k

www.konkur.in

of reinforcing in vitro fibers to increase their mechanical resistance. Although most studies on the clinical performance of direct composite restorations were conducted on vital teeth, one clinical report indicates that direct in vitro fiber-reinforced composite restorations may represent a valuable alternative to conventional restorations of endodontically treated teeth.[37] On the contrary, inserting an in vitro fiber post in the root canal of an endodontically treated tooth before bonding a direct MOD restoration significantly reduces its fracture resistance compared to the same composite restoration without a post.[160]

Indirect restorations: Composite or ceramic onlays and overlays

Ceramic or resin composite onlays and endocrowns can also be used to restore endodontically treated teeth. Whereas overlays incorporate a cusp or cusps by covering the missing tissue, endocrowns combine the post in the canal, the core, and the crown in one component.[88,142] Both onlays and endocrowns allow for conservation of remaining tooth structure, whereas the alternative would be to completely eliminate cusps and perimeter walls for restoration with a full crown.[58] Onlays and overlays are generally constructed in the laboratory from either hybrid resin composite or ceramics.

Ceramics are a material of choice for long-term aesthetic indirect restorations because their translucency and light transmission mimic enamel. Whereas traditional feldspathic porcelains were sintered from a slurry, new ceramic materials may be cast, machined, pressed, or slip-cast, in addition to being sintered. New materials either are variations of feldspathic porcelains (e.g., In-Ceram, Cerec, IPS Empress) or may be fabricated from other ceramic systems, including alumina, zirconia, or silica.[3,38] Among these newer compositions is lithium disilicate, which offers high strength, high fracture toughness, and a high degree of translucency. Physical properties of these materials have improved to the point where they can survive high stress-bearing situations such as posterior restorations in endodontically treated teeth.[46,73] Researchers have examined 140 partial Cerec restorations (Vita MKII, feldspathic porcelain) adhesively cemented to endodontically treated teeth and found this treatment approach satisfactory after an

Telegram: @dental_k

www.konkur.in

observation period of 55 months.[9] Their results indicate that survival rates are higher for molars than for premolars.

Onlays, overlays, and endocrowns can also be fabricated from resin composites processed in the laboratory. Using various combinations of light, pressure, and vacuum, these fabrication techniques are claimed to increase the conversion rate of the polymer and, consequently, the mechanical properties of the restorative material. Other investigations have described the application of glass fiber–reinforced composite endocrowns on premolars and molars as single restorations or as abutment for fixed partial dentures.[58,59] One in vitro study by another research team indicates that composite inlays can partially restore the resistance to fracture of endodontically treated molars and prevent catastrophic fractures after loading.[28] Other investigators reported that composite resin MZ100 increased the fatigue resistance of overlay-type restorations in endodontically treated molars when compared to porcelain MKII.[97] Another study used three-dimensional finite element analysis to estimate bone resorption around endocrowns made up of high- (alumina) or low-elastic modulus materials (resin composites). They concluded that the higher resilience of resin composite restorations acts positively against the risk of periodontal bone resorption by reducing the amount of force transferred to root dentin.[4]

Full crowns

When a significant amount of coronal tooth structure has been lost by caries, restorative procedures, and endodontics, a full crown may be the restoration of choice. In a few cases, the crown can be directly built on the remaining coronal structure, which has been prepared accordingly (see the Core Materials section). More frequently, the cementation of a post inside the root canal is necessary to retain the core material and the crown.[164] The core is anchored to the tooth by extension into the root canal through the post and replaces missing coronal structure. The crown covers the core and restores the aesthetics and function of the tooth.

An additional role of the post and core is to protect the crown margins from deformation under function and thereby to prevent coronal leakage. Because most endodontic sealers do not completely seal the root canal space, the coronal seal provided by the placement of a post and core will positively

Telegram: @dental_k

www.konkur.in

influence the outcome of the endodontic treatment.[148] The post's ability to anchor the core is also an important factor for successful reconstruction, because the core and the post are usually fabricated of different materials. Finally, the luting material used to cement the post, the core, and the crown to the tooth will also influence the longevity of the restoration. The post, the core, and their luting or bonding agents together form a *foundation restoration* to support the future crown.[106]

The foundation restoration: General considerations

Although many materials and techniques can be used to fabricate a foundation restoration, no combination of materials can substitute for tooth structure. As a general rule, the more tooth structure that remains, the better the long-term prognosis of the restoration. The coronal tooth structure located above the gingival level will help to create a ferrule.[6,100,128] The *ferrule* is formed by the walls and margins of the crown, encasing at least 2 to 3 mm of sound tooth structure. A properly executed ferrule significantly reduces the incidence of fracture in endodontically treated teeth by reinforcing the tooth at its external surface and dissipating forces that concentrate at the narrowest circumference of the tooth.[95,173] A longer ferrule increases fracture resistance significantly. The ferrule also resists lateral forces from posts and leverage from the crown in function and increases the retention and resistance of the restoration. To be successful, the crown and crown preparation together must meet five requirements:

1. The ferrule (dentin axial wall height) must be at least 2 to 3 mm.
2. The axial walls must be parallel.
3. The restoration must completely encircle the tooth.
4. The margin must be on solid tooth structure.
5. The crown and crown preparation must not invade the attachment apparatus.

Root anatomy can also have significant influence over post placement and selection. Root curvature, furcations, developmental depressions, and root concavities observed at the external surface of the root are all likely to be reproduced inside the root canal. Within the same root, the shape of the canal

Telegram: @dental_k

www.konkur.in

will vary between the cervical level and the apical foramen.[62] As a result, severe alteration of the natural shape of the canal is often necessary to adapt a circular post inside the root. This increases the risk of root perforation, especially in mesial roots of maxillary and mandibular molars that exhibit deep concavities on the furcal surface of their mesial root.[16,89] The tooth is also weakened if root dentin is sacrificed to place a larger-diameter post. A study using three-dimensional electronic speckle-pattern interferometry (ESPI) evaluated the effects of root canal preparation and post placement on the rigidity of human roots.[93] ESPI has the major advantage of being able to assess tooth deformation in real time and can be used repeatedly on the same root because of the nondestructive nature of the test. Study results indicate that root deformability increases significantly after the preparation of a post space. Thus preservation of root structure is also a guiding principle in the decision to use a post, the selection of the post, and the preparation of the post space. This is a reason why not every endodontically treated tooth needs a post and why more conservative approaches that do not rely on the use of a post are currently being developed. However, a post may be used in the root of a structurally damaged tooth in which additional retention is needed for the core and coronal restoration. Posts should provide as many of the following clinical features as possible:

- Maximal protection of the root from fracture
- Maximal retention within the root and retrievability
- Maximal retention of the core and crown
- Maximal protection of the crown margin seal from coronal leakage
- Pleasing aesthetics, when indicated
- High radiographic visibility
- Biocompatibility

From a mechanical point of view, an endodontic post should not break, should not break the root, and should not distort or allow movement of the core and crown. An ideal post would have an optimal combination of resilience, stiffness, flexibility, and strength. *Resilience* is the ability to deflect elastically under force without permanent damage. It is a valuable quality in endodontic posts, but too much flexibility in a narrow post

Telegram: @dental_k

www.konkur.in

compromises its ability to retain the core and crown under functional forces. *Stiffness* describes a material's ability to resist deformation when stressed. The stiffness of a material is an inherent physical property of that material, regardless of size. However, the actual flexibility of a post depends both on the diameter of a specific post and on the modulus of elasticity of the post's material. Posts with a lower modulus of elasticity are more flexible than posts of the same diameter with a higher modulus of elasticity. Posts made of nonstiff materials (low modulus of elasticity) are more resilient, absorb more impact force, and transmit less force to the root than stiff posts, but low-modulus posts fail at lower levels of force than do high-modulus posts.[99,120,143]

Excessive flexing of the post and micromovement of the core are particular risks in teeth with minimal remaining tooth structure, because these teeth lack their own cervical stiffness as a result of the missing dentin. Post flexion can also distort and open crown margins. Open margins can result in potentially devastating caries or endodontic leakage and apical reinfection. Extensive caries extending into the root can be as irreparable as root fracture. Because rigid posts flex and bend less than nonrigid posts, they can limit movement of the core and possible disruption of the crown margins and cement seal. However, the force must go somewhere. Force from a stiff post is transmitted to the root, next to the apex of the post. An attempt to strengthen a weak root by adding a stiff post can instead make the root weaker as a result of the force concentration of a stiff rod in a more flexible material. Stress concentration in the post/root complex can lead to the self-destructive processes of cracking and fracturing. Root fracture is particularly a risk in teeth with minimal remaining tooth structure to support a ferrule.

Roots also flex under force, which is a function of both the modulus of elasticity of dentin and the diameter of the root. Dentin is relatively flexible, and posts can be flexible or stiff. Although no material can behave exactly like dentin, a post with functional behavior similar to that of dentin is beneficial when the post must be placed next to dentin. Posts have been developed with a modulus of elasticity closer to dentin than that offered by traditional metal posts. But posts are significantly narrower than roots, and the actual deflection of a post within dentin is a function of both the modulus of elasticity and the diameter. The modulus of elasticity of various posts,

Telegram: @dental_k

www.konkur.in

compared with that of dentin, represents only one aspect of flexion.

In summary, an ideal post would be resilient enough to cushion an impact by stretching elastically, thereby reducing the resulting stress to the root. It would then return to normal without permanent distortion. At the same time, this ideal post would be stiff enough not to distort, permanently bend, or structurally fail under mastication forces. Finally, the perfect post would combine the ideal level of flexibility and strength in a narrow-diameter structure, which is dictated by root canal morphology. Current post systems are designed to provide the best compromise between the desired properties and inherent limitations of available materials.

Why roots fracture

Structures subjected to low but repeated forces can appear to fracture suddenly for no apparent reason. This phenomenon, also known as *fatigue failure,* occurs when a material or a tissue is subjected to cyclic loading. Fatigue may be characterized as a progressive failure phenomenon that proceeds by the initiation and propagation of cracks; many failures of teeth or materials observed in the mouth are fatigue-related. Because teeth are subjected to fluctuating cycles of loading and unloading during mastication, fatigue failure of dentin, posts, cores, crown margins, or adhesive components is likely to occur.[153] Mechanical loading will favor the propagation of microcracks that will progress from the coronal to the apical region of the tooth.

Initial failure of crown margins from fatigue loading is clinically undetectable. However, when measured in vitro, early failure resulted in significant leakage of crown margins, extending between the tooth, restoration, and post space. Particularly in teeth with minimal remaining tooth structure, fatigue can cause endodontic posts to bend permanently or break, or it can cause a fiber-matrix complex to disintegrate.

Fatigue failure of nonvital teeth restored with a post is more catastrophic because it may result in a complete fracture of the root. A post placed into a dentin root will function physically like any structural rod anchored in another material. This means that the forces applied on the post are transmitted to the root dentin with characteristic patterns depending on the modulus of elasticity of both the post and the dentin. If the post has a higher

Telegram: @dental_k

www.konkur.in

modulus than the dentin, the stress concentration is adjacent to the bottom of the post (Fig. 23.3). This is evident in clinical cases of root fracture originating at the apex of a rigid post.

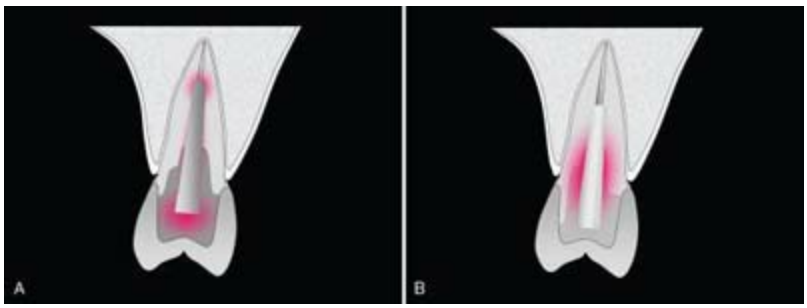

FIG. 23.3 **A,** Stress distribution within a metallic post and core foundation and residual tooth structure, according to photoelastic studies. The post is cemented and usually penetrates the apical portion of the root. Functional stresses accumulate inside the foundation, slightly around the post and further inside the canal, around the apex of the post; there is less stress buildup in the cervical area compared to that with a fiber post (as shown in Fig. 23.3, *B*). This configuration more ideally protects the coronocervical structures, but when failing, it results in severe untreatable root fractures. **B,** Stress distribution within a fiber post/composite foundation and residual tooth structure, according to photoelastic and FEM studies. The post is bonded to the canal walls and penetrates the canal less apically. Functional stresses mainly accumulate around the post in the cervical area. This configuration protects the cervical area less efficiently but tends to prevent untreatable root fractures. The presence of a ferrule is mandatory.

A) Tooth has grey root canal with pink spots at the root tip and pulp chamber.

B) Tooth has white root canal and pink spots along the lateral sides of the root canal.

Source: (Adapted from Dietschi D, Duc O, Krejci I, Sadan A: Biomechanical considerations for the restoration of endodontically treated teeth: a systematic review of the literature—part 1. Composition and micro- and macrostructure alterations, *Quintessence Int* 38:733, 2007.)

When the stiffness of the endodontic post is similar to that of dentin, stresses are not concentrated in the dentin adjacent to the apex of the post but rather are dissipated by both the coronal and the root dentin (see Fig. 23.3). A resilient post can also prevent a sudden blow by stretching elastically, which

Telegram: @dental_k

www.konkur.in

reduces the transient forces against the tooth, but a post that is too elastic becomes too flexible for retaining a core and a crown when the tooth cannot do so on its own. A resilient post that is overloaded fails with less force than a stiffer post. This limits the amount of resilience that can be designed into a post.

Direct foundation restorations

In general, the evolution of foundation restorations has been to diminish invasiveness and eliminate some components in selected cases. When a sufficient amount of tissue is present at the periphery of the prepared tooth, a direct foundation restoration is indicated. In the direct technique, a prefabricated post is cemented inside the root canal, and the core is built directly on the prepared tooth. For other clinical situations, an indirect custom-cast post and core may be indicated.

Various materials can be used to fabricate a direct foundation restoration. Although there is growing interest in using resin-based materials such as resin composites or fiber-reinforced resin posts, more traditional materials such as amalgam are still used for that purpose.[27] For clarity, the components used for fabricating a direct foundation restoration (e.g., the endodontic post and core material) are described individually.

Posts.

The large number of post designs and materials available on the market reflects the absence of consensus in that field. Based on what manufacturers or clinicians consider the most important properties, posts can be fabricated from metal (gold, titanium, stainless steel), ceramic, or fiber-reinforced resins. As a general rule, a post needs retention and resistance. Whereas *post retention* refers to the ability of a post to resist vertical forces, *resistance* refers to the ability of the tooth/post combination to withstand lateral and rotational forces. Resistance is influenced by the presence of a ferrule, the post's length and rigidity, and the presence of antirotational features. A restoration lacking resistance form is not likely to be a long-term success, regardless of the retentiveness of the post.

Prefabricated metallic posts.

Telegram: @dental_k

www.konkur.in

Prefabricated metallic posts are frequently used for the fabrication of a direct foundation restoration. These posts are classified several ways, including by alloy composition, retention mode, and shape. Materials used to fabricate metallic posts include gold alloys, stainless steel, or titanium alloys. Metallic posts are very strong and, with the exception of the titanium alloys, very rigid.[90] One study indicates that the flexural strength of stainless steel posts is about 1430 MPa and that flexural modulus approximates 110 GPa.[130] On the other hand, titanium posts are less rigid (66 GPa) but exhibit a flexural strength (1280 MPa) similar to stainless steel.

The retention of prefabricated posts inside the root canal is also essential for successful restorations. Two basic concepts have been used to promote the retention of endodontic posts: active posts and passive posts. Active posts derive their primary retention directly from the root dentin by the use of threads. Most active posts are threaded and are intended to be screwed into the walls of the root canal. A major concern about threaded posts has been the potential for vertical root fracture during placement. As the post is screwed into place, it introduces great stresses within the root, causing a wedging effect.[163] It is therefore generally accepted that *the use of threaded posts should be avoided.* Furthermore, the improved retention once offered by threaded posts can now be achieved with adhesive luting cements (discussed later).[117] Passive posts are passively placed in close contact to the dentin walls, and their retention primarily relies on the luting cement used for cementation. The shape of a passive post may be either tapered or parallel.[139] A parallel post is more retentive than a tapered post but also requires removal of more root dentin during the preparation of the post space. Parallel posts are reported to be less likely to cause root fractures than tapered posts, although they are less conforming to the original shape of the root.[79,152,161] Unfortunately, modern techniques for root canal preparation use tapered nickel-titanium (NiTi) rotary shaping files, which result in a very wide tapered and unretentive canal exhibiting a significant divergence from apical to coronal.[145] Longer posts are often necessary to accommodate this problem and offer adequate retention; adequate length in the root canal is considered to be greater than 6 mm. When teeth are protected by crowns with an adequate ferrule, longer posts do not further increase fracture resistance.[80] Posts designed with mechanical locking features in the heads and roughened

Telegram: @dental_k

www.konkur.in

surface texture can show better retention of the core.[29]

Fiber posts.

A fiber post consists of reinforcing fibers embedded in a resin-polymerized matrix. Monomers used to form the resin matrix are typically bifunctional methacrylates (Bis-GMA, UDMA, TEGDMA), but epoxies have also been used. Common fibers in today's fiber posts are made of carbon, glass, silica, or quartz but the type, volume content, and uniformity of the fibers and the matrix are proprietary and vary among fiber post systems. These differences in the manufacturing process may reflect the large variations observed among different types of fiber posts subjected to a fatigue-resistance test.[63] Fibers are commonly 7 to 20 μm in diameter and are used in a number of configurations, including braided, woven, and longitudinal. The original fiber posts consisted of carbon fibers embedded in epoxy resin, but quartz-fiber posts are currently preferred for their favorable mechanical properties, aesthetic qualities, and ability to chemically bond to the polymer matrix.[49] One study indicates that the flexural strength of glass-, silica-, or quartz-fiber posts approximates 1000 MPa and that flexural modulus is about 23 GPa.[35] Current fiber posts are radiopaque and may also conduct the light for polymerization of resin-based luting cements. A light-transmitting post results in better polymerization of resin composites in the apical area of simulated root canals, as measured by hardness values.[141,174] To enhance bonding at the post/core/cement interfaces, several physicochemical pretreatments such as silanization or sand blasting of the post surface have been described. Research indicates that silanization, hydrofluoric etching, and sandblasting (with 30 to 50 μm Al_2O_3) do not modify the mechanical properties of different glass-, silica-, or quartz-fiber posts.[5]

It is generally accepted that bonding fiber posts to root canal dentin can improve the distribution of forces applied along the root, thereby decreasing the risk of root fracture and contributing to the reinforcement of the remaining tooth structure.[12,18] A well-adapted adhesively cemented fiber post is considered the most retentive with the least stress generated on the canal walls. In a retrospective study that evaluated three types of bonded fiber posts, investigators reported a 3.2% failure of 1306 fiber posts in recalls of 1 to 6 years.[54] More recently, another study reported survival rates of 98.6%

Telegram: @dental_k

www.konkur.in

and 96.8% for parallel-sided and tapered fiber posts, respectively, placed in anterior teeth covered with full-ceramic crowns after a mean observation period of 5.3 years.[156]

Zirconia posts are composed of zirconium dioxide (ZrO_2) partially stabilized with yttrium oxide and exhibit a high flexural strength. Zirconia posts are aesthetic, partially adhesive, rigid, but also brittle. Zirconia posts cannot be etched, and available literature suggests that bonding resins to these materials is less predictable and requires substantially different bonding methods than conventional ceramics.[11] When a composite core is built on a zirconia post, core retention may also be a problem. Controversies exist about the efficiency of airborne particle abrasion at establishing a durable resin bond to zirconia posts treated or not treated with a coupling agent.[1,127] Overall, there are concerns about the rigidity of zirconia posts, which tends to make those posts too brittle. Other reports indicate that the rigidity of zirconia posts negatively affects the quality of the interface between the resin core material and dentin when subjected to fatigue testing.[40,43]

Core materials.

The core replaces carious, fractured, or missing coronal structure and helps to retain the final restoration. Desirable physical characteristics of a core include (1) high compressive and flexural strength, (2) dimensional stability, (3) ease of manipulation, (4) short setting time, and (5) the ability to bond to both tooth and post. Core materials include composite resin, cast metal or ceramic, amalgam, and sometimes glass-ionomer materials. The core is anchored to the tooth by extension into the coronal aspect of the canal or through the endodontic post. The importance of retention between the post, the core, and the tooth increases as remaining tooth structure decreases.

Composite resin core.

Composite core materials (see Figs. 23.12–23.14, located further in the chapter) take a number of strategies to enhance their strength and resistance; metal may be added, filler levels may be greater, or faster-setting ionomers may be used.[134] Composite core materials have been shown to exhibit slightly better mechanical values than conventional materials, but improvements are negligible.[176] However, they appear to be superior to

Telegram: @dental_k

www.konkur.in

silver-glass-ionomer cement and amalgam.[30] The advantages of composite core resins are adhesive bonding to tooth structure and many posts, ease of manipulation, rapid setting, and translucent or highly opaque formulations. Composite cores have been shown to protect the strength of all-ceramic crowns equally to amalgam cores. The bond strength of composite cores to dentin depends on a complete curing of the resin materials, so dentin bonding agents must be chemically compatible with composite core materials. Self-cure composite resins require self-cure adhesives and are mostly incompatible with light-cure adhesives.[26] However, no adhesive has been shown to completely eliminate microleakage at the margins of the restoration.[17] A degradation of the resin core or the marginal integrity of the crown can result in invasion of oral fluids. Therefore as with all buildup materials for decimated teeth, more than 2 mm of sound tooth structure should remain at the margin for optimal composite resin core function.

Composite core materials can be used in association with metallic, fiber, or zirconia posts. This is frequently observed in the presence of structurally compromised teeth. They may provide some protection from root fracture in teeth restored with metal posts compared with amalgam or gold cores. Loosening of the post, core, and crown with composite core can occur, but composite cores have been shown to fail more favorably than amalgam or gold.[129] A retrospective study of the clinical performance of fiber posts indicates that fiber posts and cores have a failure rate ranging between 7% and 11% after a service period of 7 to 11 years and that post loosening may also occur.[53] Composite core materials are typically two-paste, self-cured composites, but light-curing materials are also available. The use of light-curing composite core materials generally eliminates the risk of chemical incompatibility between adhesives and self-curing resin core materials. Bonding light-cured resin composites to the irregular structure of the pulp chamber and canal orifices might eliminate the need for a post when sufficient tooth structure remains. Research indicates that bonding to the dentin walls of the pulp chamber is easier and superior to resin dentin bonds made on dentin canal walls.[7]

Amalgam core.

Dental amalgam is a traditional core buildup material with a long history of

Telegram: @dental_k

www.konkur.in

clinical success. Although there are many variations in the alloy's composition, more recent formulations have high compressive strength (400 MPa after 24 hours), high tensile strength, and a high modulus of elasticity. High-copper alloys tend to be stiffer (60 GPa) than low-copper alloys.

Amalgam can be used with or without a post. In the 1980s, investigators described the amalcore.[113] With the amalcore technique, amalgam is compacted into the pulp chamber and 2 to 3 mm coronally of each canal. The following criteria were considered for the application of this technique: the remaining pulp chamber should be of sufficient width and depth to provide adequate bulk and retention of the amalgam restoration, and an adequate dentin thickness around the pulp chamber was required for the tooth-restoration continuum rigidity and strength. The fracture resistance of the amalgam coronal-radicular restoration with 4+ mm of chamber wall was shown to be adequate, although the extension into the root canal space had little influence.[81]

Amalgam can also be used in combination with a prefabricated metallic post when the retention offered by the remaining coronal tissue needs to be increased. Amalgam cores are highly retentive when used with a preformed metal post in posterior teeth; they require more force to dislodge than cast posts and cores.[102] Others have suggested the use of adhesive resins to bond amalgam to coronal tissue.[155]

Significant disadvantages of amalgam cores are the "nonadhesive nature" of the material, the potential for corrosion, and subsequent discoloration of the gingiva or dentin. Amalgam use is declining worldwide because of legislative, safety, and environmental issues.

Glass ionomer core and modified glass ionomer core.

Glass ionomer and resin-modified glass ionomer cements are adhesive materials useful for small buildups or to fill undercuts in prepared teeth. The rationale for using glass ionomer materials is based on their cariostatic effect resulting from fluoride release. However, their low strength and fracture toughness result in brittleness, which contraindicates the use of glass-ionomer buildups in thin anterior teeth or to replace unsupported cusps. They may be indicated in posterior teeth in which (1) a bulk of core material is possible, (2) significant sound dentin remains, and (3) caries control is indicated.[172]

Telegram: @dental_k

www.konkur.in

Resin-modified glass ionomer materials are a combination of glass ionomer and composite resin technologies and have properties of both materials. Resin-modified glass ionomers have moderate strength, greater than glass ionomers but less than composite resins. As a core material, they are adequate for moderate-sized buildups, but hygroscopic expansion can cause the fracture of ceramic crowns and fragilized roots.[158] The bond to dentin is close to that of dentin-bonded composite resin and significantly higher than traditional glass ionomers. Today, resin composites have replaced glass ionomer materials for core fabrication.

Indirect foundation restorations: Cast post and core

For many years, use of the cast metal post and core has been the traditional method for fabricating the foundation restoration of a prosthetic crown. Classically, smooth-sided, tapered posts conforming to the taper of the root canal are fabricated from high noble alloys, although noble and base-metal classes of dental alloys have also been used. Noble alloys used for post and core fabrication have high stiffness (approximately 80 to 100 GPa), strength (1500 MPa), hardness, and excellent resistance to corrosion.[31]

One advantage of the cast post/core system is that the core is an integral extension of the post and that the core does not depend on mechanical means for retention on the post. This construction prevents dislodgment of the core from the post and root when minimal tooth structure remains. However, the cast post/core system also has several disadvantages. Valuable tooth structure must be removed to create a path of insertion or withdrawal. Second, the procedure is expensive because two appointments are needed, and laboratory costs may be significant. The laboratory phase is technique sensitive. Metal casting of a pattern with a large core and a small-diameter post can result in porosity in the gold at the post/core interface. Fracture of the metal at this interface under function results in failure of the restoration. Most importantly, the cast post/core system has a higher clinical rate of root fracture than preformed posts.[47,159]

Studies on cast post retention have shown that the post must fit the prepared root canal as closely as possible to be perfectly retained. When a ferrule is present, custom cast posts and cores exhibit a higher fracture resistance compared to composite cores built on prefabricated metallic posts

Telegram: @dental_k

www.konkur.in

or carbon posts.[98] Cast posts are also known to exhibit the least amount of retention and are associated with a higher failure rate compared to prefabricated parallel-sided posts. In a classic retrospective study (1 to 20 years) of 1273 endodontically treated teeth in general practice, 245 (19.2%) were restored with tapered cast posts and cores. Among these, 12.7% were deemed failures. This failure rate was higher than that for the other passive post systems used. Of particular concern was the fact that 39% of the failures led to unrestorable teeth requiring extraction. Thirty-six percent of the failures were due to loss of retention, and 58% were due to the fracture of the root. It has been suggested that tapered smooth-sided posts have a “wedging” effect under functional loading, and it is this that leads to increased risk of root fracture.[162]

One 6-year retrospective study reported a success rate higher than 90% using a cast post and core as a foundation restoration.[8] The lower failure rate and fewer root fractures were attributed to the presence of an adequate ferrule and careful tooth preparation. Attention has also been drawn to the fact that the higher failure rate may be due to the fact that nearly half of the posts were shorter than recommended from the literature. A venting groove for the cement along the axis of the post results in less stress on residual tissues.

Luting cements

A variety of cements have been used to cement endodontic posts and include traditional cements, glass ionomer cements, and resin-based luting cements.

Traditional cements

Zinc phosphate cements or polycarboxylate cements are still used for cementation of posts and crowns. They are generally supplied as a powder and a liquid, and their physical properties are highly influenced by the mixing ratio of the components. Their compressive strength is about 100 MPa, and elastic moduli are lower than that of dentin (5 to 12 GPa). Zinc phosphate cement is mostly used for cementing metal restorations and posts; film thickness of the zinc phosphate cement is less than 25 μm. These cements provide retention through mechanical means and have no chemical bond to the post or to dentin but provide clinically sufficient retention for posts in teeth with adequate tooth structure.

Telegram: @dental_k

www.konkur.in

Glass ionomer luting cements

Glass ionomer cements are a mixture of glass particles and polyacids, but resin monomers may also be added. Depending on the resin content, glass ionomer cements can be classified as either conventional or resin-modified glass ionomer cements. Conventional glass ionomer cements have compressive strengths ranging between 100 and 200 MPa; the Young modulus is generally about 5 GPa. They are mechanically more resistant than zinc phosphate cements, and they can bond to dentin with values ranging between 3 and 5 MPa. Some authors still recommend the use of glass ionomer cements for the cementation of metallic posts. Major advantages of conventional glass ionomer cements are their ease of manipulation, chemical setting, and ability to bond to both tooth and post. On the contrary, resin-modified glass ionomer cements are not indicated for post cementation because these cements exhibit hygroscopic expansion that can promote fracture of the root.

Resin-based luting cements

Today there is a trend toward the use of adhesive cements for bonding endodontic posts during the restoration of nonvital teeth. The rationale for using adhesive cements is based on the premise that bonding posts to root canal dentin will reinforce the tooth and help retain the post and the restoration.[48] Contemporary resin-based luting cements have been shown to exhibit compressive strengths around 200 MPa and elastic moduli between 4 and 10 GPa.[24] These materials may be polymerized through a chemical reaction, a photopolymerization process, or a combination of both mechanisms. Photo-polymerization of these resin-based materials is often necessary to maximize strength and rigidity.

Most luting cements require a pretreatment of the root canal dentin with either etch-and-rinse or self-etching adhesives. Both types of adhesives have been shown to form hybrid layers along the walls of the post spaces.[10] However, bonding to root canal dentin may be compromised by the use of endodontic irrigants such as sodium hypochlorite, hydrogen peroxide, or their combination.[115] Because these chemicals are strong oxidizing agents, they leave behind an oxygen-rich layer on the dentin surface that inhibits the polymerization of the resin.[151] Previous research has shown that the bond

Telegram: @dental_k

www.konkur.in

strength of C&B Metabond to root canal dentin was reduced by half when the dentin was previously treated with 5% sodium hypochlorite (NaOCl) or 15% EDTA/10% urea peroxide (RC Prep, Premier Dental, Plymouth Meeting, PA).[107] Other reports indicate that the contamination of the dentin walls by eugenol diffusing from endodontic sealers may also affect the retention of bonded posts.[66,168] Furthermore, it is difficult to control the amount of moisture left in a root canal after acid etching, making impregnation of collagen fibers with etch-and-rinse adhesives problematic. The use of self-etching adhesives has been proposed as an alternative for the cementation of endodontic posts, because self-etching adhesives are generally used on dry dentin and do not require rinsing of the etchant. However, their efficiency at infiltrating thick smear layers like those produced during post space preparation remains controversial.[104,171] More recently, dual-curing adhesives have been developed to ensure a better polymerization of the resin deep inside the root canal. Dual-cured adhesives contain ternary catalysts to offset the acid-base reaction between the acidic monomers and the basic amines along the composite/adhesive interface.[105]

Although both self-curing and light-curing luting cements can be used for cementation of prefabricated endodontic posts, most resin cements have a dual-curing process that requires light exposure to initiate the polymerization reaction. Dual-curing cements are preferred because there are concerns as to whether light-curing materials are properly cured, especially in areas of difficult light access, such as the apical portion of the root canal. However, it has been reported that photocured composites generate more shrinkage stress and exhibit less flow than chemically cured composites.[52] Contraction stresses induced by polymerization also depend on the geometry of the post space and the thickness of the resin film. Previous research indicates that the restriction of flow of resin cements by the configuration of the root canal can significantly increase the contraction stress at the adhesive interface.[51,166]

In recent years, a number of techniques have been used to measure the adhesion of resin-based luting cements to root canal dentin. These methods include the pull-out tests, the microtensile bond strength tests, and the push-out tests.[45,61] Although laboratory tests confirmed that bond strengths ranging between 10 and 15 MPa can be obtained with modern resin-based luting cement, there is also evidence that frictional retention is a factor contributing

Telegram: @dental_k

www.konkur.in

to post retention.[14] It is generally accepted that bonding to dentin of the pulp chamber is more reliable than bonding to root canal dentin, especially at the apical level.[126] The lowered bond strength values recorded at the apical third of the root canal are likely to be related to the reduced number of dentinal tubules available for dentin hybridization. Shorter posts may be used when successful bonding occurs between fiber-reinforced posts and root dentin, because current adhesive luting cements can assist in the retention of posts in the root canal space.[132]

Another factor that may influence the performance of resin-based luting cements is the thickness of the cement layer. The cementation of endodontic fiber posts with thicker cement layers might be required when posts do not perfectly fit inside the root canal. Although a slight increase in cement thickness (up to 150 microns) does not significantly affect the performance of adhesive luting cements applied to root canal dentin, thicker layers may be detrimental to bond quality.[76,150]

One study indicates that bond strength to radicular dentin might be maximized by adopting procedures that compensate for polymerization stresses.[13] The bonding procedures are realized in two separate steps. The initial step allows optimal resin film formation and polymerization along the root canal walls, leading to more ideal resin-dentin hybridization without stresses imposed by the placement of the post. A second step bonds the post to the cured resin film. The polymerization shrinkage that occurs during the initial adhesive coating step reduces the effects of stress imposed when the resin-coated post polymerizes, thereby preserving the bond integrity.

Although the bonding performance of resin-based luting cements is well documented, other reports indicate that resin-dentin bonds degrade over time.[22,56] The loss of bond strength and seal are attributed to the degradation of the hybrid layer created at the dentin-adhesive interface. This is particularly true for etch-and-rinse adhesives, because the gelatinization of collagen fibers caused by phosphoric acids may restrict the diffusion of the resin within the interfibrillar spaces and may leave unprotected fibers available for degradation. Removing organic components from the demineralized dentin prior to bonding procedures has been suggested. The use of dilute NaOCl (0.5%) after acid etching or the conditioning of dentin smear layers with EDTA (0.1 M, pH 7.4) has been shown to produce more

Telegram: @dental_k

www.konkur.in

durable resin-dentin bonds made with single-step etch-and-rinse adhesives.[149]

Other research indicates that the degradation of denuded collagen fibrils exposed in incompletely infiltrated hybrid layers is driven by an endogenous proteolytic mechanism involving the activity of matrix metalloproteinases (MMPs).[21,125] The release of MMPs such as collagenases has been evidenced in both coronal and root dentin of fully developed teeth of young patients.[147] Researchers suggest that conditioning root canal dentin with a broad-spectrum protease inhibitor such as chlorhexidine (2 wt% chlorhexidine digluconate solution) might be useful for the preservation of dentin bond strength over time.[20]

Interestingly, these dentin-conditioning procedures, which may improve the resistance of the resin-dentin bond to chemical degradation, also act as antibacterial agents; this might be of interest in the endodontic context.

Self-adhesive cements

More recently, self-adhesive resin cements have been introduced as an alternative to conventional resin-based luting cements. Self-adhesive luting cements contain multifunctional phosphoric acid methacrylates that react with hydroxyapatite and simultaneously demineralize and infiltrate dental hard tissue.[108] They do not require any pretreatment of the tooth substrates, and their clinical application is accomplished in a single step. Therefore the self-etching capability of these new cements reduces the risk for incomplete impregnation of the conditioned tissue by the resins and reduces technique sensitivity. The elastic moduli of chemically cured self-adhesive resin cements are relatively low (4 to 8 GPa) but generally increase when a dual-curing process is used. It is therefore recommended that all dual-cured resin cements receive maximal light to achieve superior material properties wherever clinically possible.[135] Adhesion performance to dentin was found comparable to multistep luting cements but bonding to enamel without prior phosphoric acid etching is not recommended.[72] However, their long-term clinical performances need to be assessed before making a general recommendation for their use.

Pretreatment evaluation and treatment

Telegram: @dental_k

www.konkur.in

strategy

Before any therapy is initiated, the tooth must be thoroughly evaluated to ensure treatment success. Each tooth must be examined individually and in the context of its contribution to the overall treatment plan and rehabilitation. This assessment includes endodontic, periodontal, biomechanical, and aesthetic evaluations. Planning of the restoration for endodontically treated teeth brings together all aforementioned biomechanical and clinical factors, as well as the various materials and procedures designed to address them.

Pretreatment evaluation

Endodontic evaluation

The prerestorative examination should include an inspection of the quality of existing endodontic treatment. New restorations, particularly complex restorations, should not be placed on abutment teeth with a questionable endodontic prognosis. Endodontic retreatment is indicated for teeth showing radiographic signs of apical periodontitis or clinical symptoms of inflammation. Restorations that require a post need a post space, which is prepared by removal of gutta-percha from the canal. Canals obturated with a silver cone or other inappropriate filling material should be endodontically retreated before starting any restorative therapy. Because the probability for periapical tissue to heal after endodontic retreatment is reasonably high, the chances to retain a well-restored tooth in asymptomatic function over time are excellent.[119]

Periodontal evaluation

Maintenance of periodontal health is also critical to the long-term success of endodontically treated teeth. The periodontal condition of the tooth must therefore be determined before the start of endodontic therapy and restorative phase. The following conditions are to be considered as critical for treatment success:

- Healthy gingival tissue
- Normal bone architecture and attachment levels to favor periodontal health

Telegram: @dental_k

www.konkur.in

- Maintenance of biologic width and ferrule effect before and after endodontic and restorative phases

If one or more of the aforementioned conditions are not met, owing to preexisting pathology or structural defects, treatment success or even feasibility can be compromised, sometimes suggesting extraction of weak teeth and replacement with dental implants rather than conventional therapy.

Biomechanical evaluation

All previous events, from initial decay or trauma to final root canal therapy, influence the biomechanical status of the tooth and the selection of restorative materials and procedures. The biomechanical status can even justify the decision to extract extremely mutilated teeth that do not deserve extensive treatments and that carry a limited probability of success. Important clinical factors include the following:

- The amount and quality of remaining tooth structure
- The anatomic position of the tooth
- The occlusal forces on the tooth
- The restorative requirements of the tooth

Teeth with minimal remaining tooth structure are at increased risk for the following clinical complications[114,165,170] (Fig. 23.4; also see Fig. 23.1):

- Root fracture
- Coronal-apical leakage
- Recurrent caries
- Dislodgment or loss of the core/prosthesis
- Periodontal injury from biologic width invasion

Telegram: @dental_k

www.konkur.in

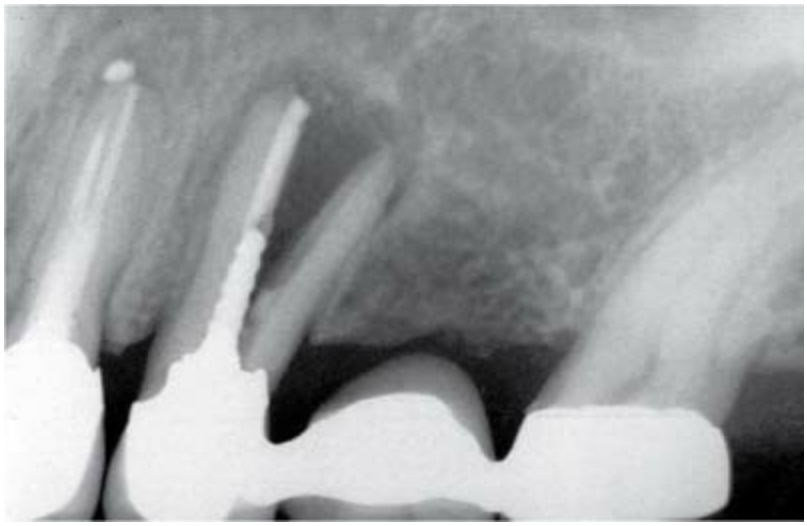

FIG. 23.4 Failure of prosthetic foundations can have dramatic consequences on both overlying restorations and surrounding tissues. A better understanding of compositional and structural changes that affect tooth resistance to repeated functional forces is mandatory to improve treatment success in endodontically treated teeth.

Radiograph shows four teeth. The first tooth has filled root canals with a globular mass close to the root tip. In the second tooth, only one root canal is filled and less-density tissue in-between the root canals. The roots of third tooth are missing. The fourth tooth has radiopaque crown and hard-density root.

The amount and quality of remaining tooth substrate are far more important to the long-term prognosis of the restored tooth than any restorative material properties. One must consider that no restorative material can truly substitute for dentin or enamel and that a minimal amount of intact structure is mandatory to justify tooth maintenance and its strategic importance to the overall treatment plan. The presence of healthy adjacent teeth available as abutments or the option of dental implants are additional factors to be analyzed when justifying the restoration of endodontically treated teeth.

Tooth position, occlusal forces, and parafunctions

Teeth are subjected to cyclic axial and nonaxial forces. The teeth and associated restorations must resist these forces to limit potential damages such as wear or fracture. The degree and direction of forces depend on the location of the tooth in the arch, the occlusal scheme, and the patient's functional status.

Telegram: @dental_k

www.konkur.in

In most occlusal schemes, anterior teeth protect posterior teeth from lateral forces through anterolateral guidance. In the context of very steep anterior guidance and deep vertical overbite, maxillary anterior teeth are sustaining higher protrusive and lateral forces from the mandibular anterior teeth. Restorations of damaged anterior teeth with heavy function should therefore be designed to resist flexion. Restorative components should be stronger than would be required for teeth with an edge-to-edge relationship and therefore vertical forces.

Posterior teeth normally carry more vertical forces, especially when maintaining canine and anterior guidance; they also sustain greater occlusal loads than anterior teeth, and restorations must be planned to protect posterior teeth against fracture. In the case of parafunctions, protection by anterior contacts is likely to be reduced or lost and posterior teeth then submitted to more lateral stresses, generating a higher demand for restorative materials.

The literature reports that average biting forces vary between 25 and 75 N in the anterior region and between 40 and 125 N for the posterior region of the mouth, depending on food type, dental status (dentate or edentulous), and patient anatomy and functional habits.[55,71] Those forces can easily reach 1000 N or above in case of parafunctions, showing how potentially destructive they can be for intact teeth and even more so for nonvital, fragilized teeth. Parafunctional habits (clenching and bruxism) are major causes of fatigue or traumatic injury to teeth, including wear, cracks, and fractures. Teeth that show extensive wear or sequelae from parafunctions, especially heavy lateral function, require components with the highest physical properties to protect restored teeth against fracture.

In general, modern strategy focuses on tissue preservation and on the use of adhesion to stabilize the restoration for improved short- and long-term service. However, in certain conditions like reduced tooth support, conventional materials are not obsolete.

Aesthetic evaluation and requirements

Anterior teeth, premolars, and often the maxillary first molar, along with the surrounding gingiva, compose the aesthetic zone of the mouth. Changes in the color or translucency of the visible tooth structure, along with thin soft tissues or biotype, diminish the chance for a successful aesthetic treatment

Telegram: @dental_k

www.konkur.in

outcome.

Potential aesthetic complications should be investigated before endodontic therapy is initiated. For instance, metal or dark carbon fiber posts or amalgam placed in the pulpal chamber can result in unacceptable aesthetic results, such as a grayish appearance of the overlying prosthetic restoration (especially with modern, more translucent full-ceramic crowns) or gingival discoloration from the underlying cervical area or root (see Fig. 23.1). All teeth located in the aesthetic zone also require critical control of endodontic filling materials in the coronal third of the canal and the pulp chamber to avoid or reduce the risk of discoloration. Careful selection of restorative materials, careful handling of tissues, and timely endodontic intervention are important for preserving the natural appearance of nonvital teeth and gingiva.

Treatment strategy

General principles and guidelines

The post, the core, and their luting or bonding agents together form the *foundation restoration* to support the coronal restoration of endodontically treated teeth. The evolution of foundation restorations has been to diminish invasiveness, to use adhesion rather than macromechanical anchorage, and to eliminate intraradicular components in selected cases. These changing clinical concepts derive from both an improved understanding of tooth biomechanics and advances in restorative materials.

The foundation and its different constituents are then aimed at providing the best protection against leakage-related caries, fracture, or restoration dislodgment. Therefore all aforementioned local and general parameters are to be systematically analyzed in order to select the best treatment approach and restorative materials. Prosthetic requirements are also to be taken into consideration to complete each case analysis. In general, abutments for fixed or removable partial dentures clearly dictate more extensive protective and retentive features than do single crowns, owing to greater transverse and torquing forces. This modern biomechanical treatment strategy is summarized in Fig. 23.5.

Protective approach: The column headers are limited over bite and functional stresses, and deep over bite and increased functional stresses. The row headers are large decay but greater than equal to half residual tooth structure and ferrule effect and smaller than equal to half residual tooth structure and/or limited ferrule effect. Large decay shows adhesive core plus full chamber in the first column and fiber, ceramic, or metal post and core plus full crown in the second column. Limited ferrule effect has fiber or metal post and core plus full crown.

A two-panel figure is as follows:

First panel: The column headers are clinical conditions, Small cavity size or conservative approach and large cavity size or protective approach under limited functional and lateral stresses; Increased functional and lateral stresses. The row headers under clinical conditions are class 1, class 2 MO or OD, and class 2 MOD. Class 1 shows class 1 direct composite or inlay in the first column and overlay in the second column. Class 2 and 3 each show class 2 direct composite or inlay in the first column and overlay in the second column.

Second column: The column headers are conservative and conventional or aesthetic indication. The row headers are greater than or equal to half residual tooth structure and smaller than or equal to residual tooth structure. The first row shows endocrowns (ceramic or composite) in the first column and composite core plus full crown in the second column. The second row shows post and core plus full crown.

Structurally sound anterior teeth

Anterior teeth can lose vitality as a result of a trauma with no or minimal structural damage. They generally do not require a crown, core, or post; restorative treatment is limited to sealing the access cavity and direct composite fillings. Discoloration, whenever present, is addressed by nonvital bleaching, or, for untreatable or relapsing ones, with conservative restorative approaches such as direct or indirect veneers (Table 23.2).

		INTERFACE TREATMENT			
Treatment Approach	**Indications**	**Tooth Preparation (Critical Guidelines)**	**Tooth**	**Restoration**	**Restoration Fabrication**
Composite restoration	Minimal tissue loss	None	DBA	—	Direct multilayer
Veneer	Limited tissue loss	≥1 mm Buccal reduction, lingual enamel present, minimal to moderate discoloration only	DBA	1. Sandblasting or etching 2. Silane 3. Bonding resin	CP direct multilayer *or In laboratory:* Etchable CER: fired, pressed, or CAD-CAM
Overlay (composite/ceramics)	Thin remaining walls	Minimum 2 mm occlusal reduction	DBA + composite lining	1. Sandblasting or etching 2. Silane 3. Bonding resin	*In laboratory:* CP: hand-shaped, light or heat cured, CAD-CAMEtchable CER: fired, pressed, or CAD-CAM
Endocrown (composite/ceramics)	Loss of occlusal anatomy	Minimum 2 mm occlusal reduction, extension into pulpal chamber	DBA + composite lining	1. Sandblasting or etching 2. Silane 3. Bonding resin	*In laboratory:* CP: hand-shaped, light or heat cured, CAD-CAMEtchable CER: fired, pressed, or CAD-CAM

CAD-CAM, Computer-aided design/computer-aided machined; *CER,* ceramic; *CP,* composite; *DBA,* dentin bonding agent.

Nonvital posterior teeth with minimal/reduced tissue loss

The loss of vitality in posterior teeth resulting from trauma, decay, or a restorative procedure does not necessarily lead to extreme biomechanical involvement and therefore allows, in certain conditions, for conservative restorations.

Occlusal cavities or mesio/disto-occlusal cavities can be restored with either direct- or indirect-adhesive intracoronal restorations, providing residual walls are thick enough (proximal ridges and buccolingual walls more than 1.5-mm thickness). The three additional clinical factors that must be analyzed to ensure optimal treatment success are the configuration factor (C-factor), cavity volume, and dentin quality. For instance, a large class I cavity with contaminated and sclerotic dentin would clearly be a contraindication to the direct approach, despite the fact that it apparently falls within the indications of direct techniques. Conservative options, however, must always be analyzed under the light of functional and occlusal environment. They can

Telegram: @dental_k

www.konkur.in

only be considered in the absence of parafunctions and with anterior guidance, which limits overall functional loading and lateral or flexural forces. In less favorable biomechanical conditions (e.g., group guidance, steep occlusal anatomy, bruxism, clenching), a protective approach with full occlusal coverage (onlay or overlay) is mandated to minimize the risk of fatigue failures (see Table 23.2).

Structurally compromised teeth

The decision for placing a post as well as the selection of a post system (rigid or nonrigid) depends once again on the amount and quality of remaining tooth structure and the anticipated forces sustained by this tooth (Table 23.3).

Table 23.3

Clinical Protocols for Restoring Nonvital Teeth With Full Prosthetic Restorations (Most Likely Procedures)

		FOUNDATION			RESTORATION	
Treatment Approach	**Indications**	**Tooth Preparation (Critical Guidelines)**	**Post**	**Core**	**Fabrication**	**Luting**
Composite core	Reduced walls but >½ crown height	Maintain all residual structures >1 mm thickness (after core prep.)	—	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + ceramic post	More than ½ coronal structure lost, reduced wall height	Maintain all residual structures >1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + in vitro fiber post	More than ½ coronal structure lost, reduced wall height	Maintain all residual structures >1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + metal post	More than 2/3 coronal structure lost, reduced wall height	Maintain all residual structures >1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Amalgam core (± metal post)	Alternative to composite core with metal post	Maintain all residual structures >1 mm thickness (after core prep.)	No tt + nonadhesive cement or sandblasting/coating/silane + DBA + Dual cement or SA cement	Amalgam placement in retentive tooth preparation	*In laboratory:* PFM restoration	Coating, sandblasting, or etching + silane and Dual or SA cement
Cast gold post and core (± porcelain)	More than ¾ coronal structure lost	Maintain all residual structures >1 mm thickness (after core prep.) Internal walls are divergent	No tt/sandblasting + nonadhesive cement or sandblasting/coating/silane + DBA + Dual cement or SA cement	No tt + nonadhesive cement or DBA + Dual cement or SA cement	*In laboratory:* PFM or full ceramic restoration: Zirconia/CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement

CAD-CAM, Computer-aided design/computer-aided machined; *CER,* ceramic; *DBA,* dentin bonding agent; *Dual,* dual curing; *LC,* light curing; *PFM,* porcelain fused to metal; *SA,* self-adhesive.

In general, rigid posts made of stiff materials (metal and ceramics) are indicated for teeth with minimal tooth structure that rely on the post to hold the core and crown. Because rigid posts flex and bend less than other types of posts, they are supposed to limit movement of the core and possible disruption of the crown margins and cement seal. But one must remember that stiff posts transmit more stresses to the root, next to the post apex, when

Telegram: @dental_k

www.konkur.in

conventionally cemented. An attempt to strengthen a weak root by adding a stiff post can instead make the root weaker as a result of the force concentration behavior of a stiff rod in a more flexible material. Adhesion therefore plays a crucial role, because a well-bonded post can help absorb stresses more evenly throughout the remaining tooth structure. Benefit and increased risk of fissure and fracture must then be appropriately weighed against adhesion potential inside the root and post type, composition, and surface treatment.

In structurally sound teeth, nonrigid posts flex with the tooth under functional forces, reducing the transfer of force to the root and reducing the risk of root fracture. Flexion is of course related to post diameter. In structurally compromised teeth, which lack cervical stiffness from dentin and ferrule effect, excessive post flexion can be detrimental to the marginal seal and prosthesis longevity, so fiber posts are generally contraindicated.

White or translucent fiber posts are generally preferred underneath full-ceramic restorations, whereas stronger black carbon fiber posts, which can reflect through gingiva, tooth structure, or ceramic restorations, are usually used in teeth to be restored with gold or porcelain fused to metal crowns, as well as in zirconia-based restorations. The literature has largely overemphasized the impact of post color on restoration aesthetics. Metal or carbon post color can be masked with resin opaquer and gold post and core ceramized to enhance aesthetic integration. Such procedures can help to approach a more ideal restoration biomechanical behavior through the fabrication of rigid but more aesthetic foundations. Upper lateral and lower incisors, together with extremely thin biotype, are probably the only real aesthetic contraindication for metal or carbon fiber posts.

In cases of extreme tooth fragility secondary to caries, fracture, previous overenlargement of the root canal system, or immaturity, residual root structure can be unified and reinforced with adhesive bonding and composite before placing a normal-diameter post, forming an altogether cohesive unit, as previously described.

In conclusion, in a damaged tooth that is to be restored with a nonrigid post, 2 to 3 mm of cervical tooth structure must ideally remain to allow creation of a restoration as a whole that is resistant to flexion. Teeth with minimal tooth structure and limited ferrule effect need additional cervical stiffness from a more rigid post to resist distortion. In this situation, adhesive

Telegram: @dental_k

www.konkur.in

cementation is preferred to conventional cementation.

Structurally compromised anterior teeth

Restoration of endodontically treated teeth becomes more complex as teeth or supporting structures become increasingly affected. A nonvital anterior tooth that has lost significant tooth structure requires restoration with a crown, supported and retained by a core and possibly a post as well.

When less than half the core height is present, or when remaining walls are extremely thin (<1 mm on more than three-fourths of the tooth circumference), a post is needed to increase retention and stabilize and reinforce the foundation. Many post options are available nowadays, including titanium, fiber-reinforced resin, and ceramics. Adhesion is now the preferred mode of post cementation unless a long-term contamination of root dentin is obvious (e.g., with eugenol), making adhesion highly questionable.

In the latter situation or in the presence of flared canals (possibly as well when a limited ferrule effect is present), cast gold post and core are still considered feasible options. Actually, in this extremely unfavorable biomechanical environment, this traditional treatment approach provides a higher rigidity in the cervical area, which is mandatory for restoration stability. Here, a fiber-reinforced composite foundation having higher flexibility might present less favorable biomechanical behavior, such as suggested by FEM studies (see Fig. 23.3 and Table 23.2).[42] Tooth extraction and implant placement or bonded bridge (particularly for lateral incisors) are also to be considered in this situation.

In the aesthetic zone, the post should not detract from the aesthetics of the coronal tooth structure, ceramic crown, or gingiva. Current restorative procedures allow fabrication of highly aesthetic ceramic coronal restorations that have no metal substructure. When such restorations with remarkably lifelike color and vitality are selected, it usually implies the use of nonmetal aesthetic posts, either ceramic or resin fiber-reinforced ones.

Structurally compromised posterior teeth

Slightly decayed posterior teeth in the context of parafunctions or significantly fragilized premolars and molars require cuspal protection afforded by onlay restoration, endocrown, or a full crown. The need for a

Telegram: @dental_k

www.konkur.in

post and core depends on the amount of remaining tooth structure. When remaining walls (buccal and lingual) provide more than 3 to 4 mm height (from the pulpal chamber floor) and 1.5 to 2 mm thickness, core and restoration stability are granted through macromechanical retention or adhesion; then, posts are not needed (see Fig. 23.5). With current treatment strategy, *the post has become the exception rather than the rule for the restoration of nonvital posterior teeth*.

Additional procedures

Periodontal crown lengthening surgery or orthodontic extrusion can expose additional root structure to allow restoration of a severely damaged tooth. In the smile frame, crown lengthening might, however, be limited by aesthetically adverse consequences (proximal attachment reduction); basically, buccal crown lengthening can only be considered as a potential indication for this procedure. In the posterior region, crown lengthening is limited by tooth and furcation anatomy or by loss of bone structure, which complicates future implant placement. With regard to orthodontic extrusion, root length and anatomy are the limiting factors of this procedure; short roots or conical anatomy are contraindications to orthodontic extrusion. Once again, when a long-lasting, functional restoration cannot be predictably created, it might be better to extract the tooth than to pursue heroic efforts to restore an extremely weak tooth, using complex, expensive, and unpredictable procedures.

Clinical procedures

The restoration of a nonvital tooth may include several restorative components such as the post, the core, and the overlying restoration. Within the same tooth, several interfaces such as post to radicular dentin, core to coronal dentin, core to post, and core to overlying restoration will be created. According to the biomechanical status, some or all restorative components and interfaces will be present and need to be addressed.

General clinical guidelines for restoring endodontically treated teeth with either partial or full crown restorations are presented in Table 23.2, with specific procedures for tooth preparation and treatment of the different interfaces involved. Clinical steps for all recommended treatment options are

Telegram: @dental_k

www.konkur.in

presented in Figs. 23.6–23.14.

FIG. 23.6 Direct composite restorations on front teeth (following bleaching). Nonvital anterior tooth with sufficient amount of residual tissue and intact, healthy neighboring teeth, usually in rather young patients. **A,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha were removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. **B,** Bleaching procedures. Two sessions of internal bleaching were needed to adapt the color of both traumatized anterior teeth (tooth #11), using a mixture of 3% hydrogen peroxide and sodium perborate powder. Each bleaching session extended over a 10-day period. Between sessions and until the given delay to proceed with final restoration (1 to 2 weeks up to 6 to 8 weeks), access cavity is closed with either a temporary filling material or flowable resin composite. **C** and **D,** Restorative procedures. A layer of adhesive is applied over all cavity surfaces. An etch-and-rinse system is frequently preferred when the dentinal tissue is highly sclerotic or was contaminated (e.g., by eugenol). A hard cement such as glass ionomer

Telegram: @dental_k

www.konkur.in

(not a resin-modified glass ionomer because of water uptake and further expansion) was used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. Two or three layers are usually used to replace the missing tissue, preferably following the "natural layering concept," which aims to build up the restoration with two basic masses, namely dentin and enamel, with the help of a silicone index. **E** and **F,** Postoperative views. The two conservative restorations are shown after finishing and polishing, with the rubber dam still in place **(E)** and after several weeks **(F)**. Note that aesthetic integration cannot be evaluated before full rehydration has occurred (4 to 6 hours at least).

Six close-up views of teeth, marked A through F, show the changes taking place during the conversion of yellowish and chipped front teeth into healthy white teeth.

Telegram: @dental_k

www.konkur.in

FIG. 23.7 Direct composite restoration on posterior tooth. Nonvital posterior tooth with sufficient amount of residual tissue and mostly intact, rather healthy, neighboring teeth. No significant discoloration of buccal tooth substrate and absence of severe parafunctions or group guidance or other unfavorable occluso-functional condition. **A,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for a later placement of a post. **B,** Adhesive procedure. An etch-and-rinse adhesive system was used here owing to the presence of sclerotic and contaminated dentin. **C** to **E,** Restoration base and layering technique. Resins or glass ionomer cements can be used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. A dentin composite mass is used to replace missing dentinal tissue, and enamel composite is used to build up proximal walls and the occlusal anatomy. **F,** The postoperative view demonstrates the advantage of this

Telegram: @dental_k

www.konkur.in

conservative approach in the context of teeth with appropriate biomechanical status.

A) Radiograph shows three teeth. The third tooth has radiopaque crown with three filled root canals.

B) Close-up view of teeth isolated with rubber dam clamp shows the central tooth with a large cavity that has pink residues and brownish tissue.

C) The cavity of tooth is clear without any residues and brownish tissue.

D) The tooth with cavity is isolated with rubber dam clamp.

E) The cavity of tooth is filled.

F) Close-up view of jaw shows clean and normal tooth with filled cavity at the center.

FIG. 23.8 Veneer. Nonvital anterior tooth with sufficient amount of residual tissue and rather healthy neighboring teeth. Discoloration

Telegram: @dental_k

www.konkur.in

resisted bleaching or relapsed, despite several retreatments. Preferably thick biotype to limit the risk of gingival recession and loss of aesthetic integration. **A,** Closing the lingual cavity. A hard cement such as glass ionomer (not resin-modified glass ionomer because of water uptake and possible expansion) can be used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. **B,** Preparation. A sufficient amount of buccal tooth structure must be removed to allow for a good aesthetic result (preparation depth is dictated by the discoloration severity). Cervical margins closely follow gingival contours, preventing soft-tissue impingement, but they assume complete coverage of discolored tooth structure. **C** and **D,** Adhesive procedure. Hydrophobic bonding systems are preferred to wet-etched enamel when no dentin is exposed. An etch-and-rinse adhesive system is preferred when dentin is exposed (here, in the presence of significant areas of sclerotic dentin). Restoration. Ceramic is etched and silanated. Just before cementation, a last layer of bonding resin is applied but not light-cured until placement. **E,** Luting technique. A light-curing, highly filled, translucent and fluorescent restorative material is preferably used for cementation. This allows better control of restoration placement and minimal wear and fatigue of the cement layer. **F,** Postoperative view. The postoperative view demonstrates satisfactory aesthetics. This approach is sometimes suitable to meet a patient's high aesthetic demands.

Set of six close-up views, marked A through F, shows the conversion of worn front teeth into normal healthy teeth without any crack by using veneer technique.

www.konkur.in

FIG. 23.9 Onlay/overlay. Nonvital posterior tooth with sufficient amount of residual tissue to justify partial restoration. Preparation involves both proximal surfaces or only two surfaces, but in a less favorable occluso-functional environment (thin walls). No significant discoloration of visible buccal tooth substrate. Option is favorable for short clinical crowns. **A** and **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. Thin and weak occlusal walls are removed until reaching sufficient thickness for the restoration (1.5 to 2 mm in occlusal-free and occlusal areas, respectively). Adhesive procedure: an etch-and-rinse adhesive system is preferably used here owing to the presence of sclerotic and contaminated dentin (a self-etch adhesive system can also be used). A resin composite base is made with a restorative composite or preferably with flowable composite (for limited volume and thickness) to smooth internal angles, fill undercuts, and, when needed, relocate cervical margins occlusally. **C** and **D,** After impression and model fabrication, the restoration is generated in the laboratory to optimize restoration anatomy, function, and aesthetics. The restoration can be made of different tooth-colored materials: ceramics (fired, pressed, or CAD-CAM generated) or resin composite. This treatment option provides optimal tissue conservation, function, and aesthetics and is a good alternative to full crowns.

A) Radiograph shows cavities in teeth.

B) Close-up view shows three teeth isolated with a rubber dam clamp. They are filled with metal, white, and pinkish materials.

Telegram: @dental_k

www.konkur.in

C and D) shows occlusal view of filled cavities.

FIG. 23.10 Endocrown. Nonvital posterior tooth with reduced amount of residual cervical tissue but sufficient tissue to provide supragingival restoration margins and good stabilization within former pulpal chamber. No or limited discoloration in visible buccal tooth substrate. Favorable option for short clinical crowns. **A** and **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. Thin and weak walls are removed until reaching sufficient thickness (1.5 mm minimum); as much residual cervical structure as possible is then maintained to avoid restoration interference with periodontal tissues. **C,** Prosthetic restoration on working model. **D,** Restoration base. Adhesive procedures: An etch-and-rinse adhesive system is preferably used here owing to the presence of sclerotic and contaminated dentin (a self-etch adhesive system can also be used). Restoration base: A resin composite base is made with a restorative

Telegram: @dental_k

www.konkur.in

composite or preferably with flowable composite (for limited volume and thickness) to smooth internal angles, fill undercuts, and, when needed, relocate cervical margins occlusally. **E,** Impression and restoration fabrication. After impression and model fabrication, the restoration is generated in the laboratory to optimize restoration anatomy, function, and aesthetics. The restoration can be made of different tooth-colored materials: ceramics (fired, pressed, or CAD-CAM generated) or resin composite. **F,** Postoperative result. Despite their relatively rare application, endocrowns combine biomechanical advantages with facilitation of clinical procedures and minimal if any involvement of biologic width. It is an interesting alternative to full crowns.

A) Close-up view shows the second tooth with dead and soft tissues in the cavity.

B) The tooth has pink residues along with some fluid in the cavity.

C) Occlusal view of two teeth shows brown lines in pits. The third tooth is covered.

D) Tooth teeth with deep and clear cavities.

E) The second tooth undergoes fabrication.

F) Occlusal view of four teeth with deep lines.

www.konkur.in

FIG. 23.11 Amalgam core. Nonvital posterior teeth with reduced tooth structure and wall height. Amalgam core stability is granted by extension of the restoration into the coronal portion of the canal (curved roots) and post (only if straight root anatomy) and remaining pulpal chamber undercuts. Today, this option is considered obsolete or historical because of the intrinsic staining of amalgam, the nonadhesive technique, and the less-than-ideal biomechanical behavior of amalgam. **A** and **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Thin and weak walls are removed until reaching sufficient thickness (1.5 to 2 mm); existing retentions are used to stabilize the amalgam core, together with a post. The metal post (with passive and anatomic design, preferably made of titanium) extends into the root for about the same length as its coronal extension. **C** to **E,** Restoration fabrication. After placing a matrix or cupper ring to envelop the preparation, amalgam is compacted into the cavity, superior root canal portion, and around the post until the appropriate coronal volume is restored. Preparation of cores is made to manage optimal space for porcelain fused to metal (PFM) crowns. **F,** Posttreatment result. This treatment approach is feasible for teeth already restored with amalgam cores and when PFM restorations are mandated. Satisfactory aesthetics can be attained with intrasulcular

Telegram: @dental_k

www.konkur.in

restoration margins.

B) Radiograph shows first and third teeth with partially filled root canals. The central tooth has unfilled root canals.

C) Close-up view shows smooth surface of silver fillings.

D) Radiograph shows three teeth with filled root canals.

E) Occlusal view of teeth where gums are covered.

F) Close-up view of teeth shows yellowish stains at the center with cracks.

FIG. 23.12 Composite core (without post). Nonvital tooth with more than half the coronal structure left and sufficient wall thickness. Core stability is granted by adhesion, remaining pulpal chamber, and residual wall height. **A** and **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. The tooth is prepared to evaluate precisely the height and thickness of residual tooth structure. Half of the abutment height and more than 1.5 mm wall thickness must be present to restore the tooth without a post. If aforementioned conditions are met, a thin layer of hard cement (calcium hydroxide, zinc phosphate, or glass ionomer; not resin-modified glass ionomer) is applied at the entrance of the root canal to enable possible retreatment in the future. **C,** Adhesive procedures and core fabrication. All walls are covered with the adhesive system (etch-

Telegram: @dental_k

www.konkur.in

and-rinse or self-etch) before applying in layers a direct light-curing restorative composite or a self-curing material, in case of limited restoration volume. **D,** Postoperative view. The advantage of this approach is the ease of application and excellent aesthetics. It is considered a good restorative solution for highly aesthetic ceramic crowns placed on teeth with limited tissue loss and discoloration.

A) Panoramic view of closed teeth. The second left tooth on the upper jaw is yellowish near the gum line.

B) Occlusal view of three teeth where the second tooth has a cavity at the center.

C) Close-up view of three upper teeth where the second tooth is abnormally small.

D) Close-up view of normal and healthy upper teeth.

FIG. 23.13 Composite core with white post (resin-reinforced fiber or zirconia post). Nonvital tooth with less than half the coronal structure

Telegram: @dental_k

www.konkur.in

left or insufficient wall thickness. Core stability is improved through adhesion and a tooth-colored post (resin-reinforced fiber or ceramic posts). **A,** Preoperative view. **B** and **C,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. The tooth is prepared to evaluate precisely the height and thickness of residual tooth structure. If less than half of the abutment height or 1.5-mm wall thickness remain, the abutment requires a post to increase core retention and foundation stability. **D** and **E,** Post-and-core fabrication. Post placement: The post space is prepared with ad hoc instruments until reaching a length equivalent to core height or slightly less depending on remaining wall height. Increased length is not needed, because retention is predominantly achieved through adhesion. Any tooth-colored post can be used, but fiber posts are usually preferred to limit stress buildup into the root structure, even though they provide less rigidity to the foundation. Post cementation: A self-curing adhesive system is applied on all cavity walls and into post preparation before luting the post with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). Core fabrication: The remaining core volume is built up in layers, using a direct light-curing restorative composite or with a single increment of a self-curing material when only limited volume is to be completed. **F,** Postoperative view. The primary advantage of this approach is the excellent aesthetic outcome. It is considered a good restorative solution for highly aesthetic ceramic crowns placed on teeth with more tissue loss but moderate discoloration.

Six close-up views are marked A through F.

A) Panoramic view of teeth shows a black stain on the center incisor.

B) Almost half of the crown in the central incisor is broken.

C) Occlusal view of three teeth shows a deep hole in the central tooth.

D) The central incisor on the right is comparatively smaller and has black stains. The central incisor on the left has an oblique fracture on one side.

E) Interior view of jaw shows the fractured edge of the left tooth and filling in the right tooth.

F) Upper jaw shows normal and clean teeth.

Telegram: @dental_k

www.konkur.in

FIG. 23.14 Composite core with prefabricated metal post. Nonvital tooth with reduced coronal structure and ferrule effect or insufficient wall thickness. Core stability is improved through adhesion and a metal (opacified) post (titanium posts are usually preferred). **A,** Preoperative view. **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose the remaining tooth structure and a clean dentin substrate. The absence of coronal tissue and ferrule effect mandates the use of a more rigid post (ceramic posts are considered too rigid and contraindicated in this situation). **C** to **F,** Post and core fabrication. Post space preparation: The post space is prepared with ad hoc instruments until reaching a length equivalent to about core height. More length is not needed, because retention is predominantly achieved through adhesion. Post preparation: The metal post (titanium here) is sandblasted (silicoating can be used to increase adhesion; i.e., Rocatec or CoJet systems, 3M), followed by silane application. An opaque resin or flowable composite can be used to mask metal dark color and improve aesthetics. Post cementation: A self-curing adhesive system is applied on all cavity walls and into post preparation before luting the post with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). Core fabrication: The remaining core volume is built up in layers, using a

Telegram: @dental_k

www.konkur.in

direct light-curing restorative composite or a single increment of a self-curing material when only limited volume is to be completed.

Six close-up views are marked A through F.

A) Closed teeth show yellow stains on left incisors.

B) The incisor marked in blue shows dentine tissue.

C) An instrument is implanted into the dentine.

D) The tooth shows an oval structure.

E) The oval structure resembles tooth but with decreased length.

F) It's similar to E, but has smooth edges.

Tooth preparation

The most important part of the restored tooth is the tooth itself. As described earlier, thickness and height of remaining dentin walls or cusps along with functional occlusal conditions are the determining factors in choosing the most appropriate restorative solution.

For partial intracoronal restorations, maximal tissue conservation is the only consideration for the clinician. In other situations, the selected restorative approach will usually necessitate some tooth preparation to comply with restoration design and thickness. Onlays, overlays, and endocrowns require about 1.5 to 2 mm occlusal space to guarantee restoration resistance to functional loads. For full crowns, a ferrule is needed to encircle the vertical walls of sound tooth structure above the restoration margin (1.5 to 3 mm), thus preventing a coincidence between core and restoration limits. Other preparation requirements presented in this chapter are to be respected to ensure treatment success. This means that a 4- to 5-mm height and 1-mm thickness of sound, suprabony tooth structure should be available to accommodate both the periodontal biologic width and the restorative ferrule.

Post placement

The post is an extension of the foundation into the root of structurally damaged teeth, which is necessary for core and coronal restoration stability and retention. The post is cemented or bonded into the root, according to

Telegram: @dental_k

www.konkur.in

tissue quality and post and core choice. The post performs both a mechanical and biologic function by protecting the apical seal from bacterial contamination in case of coronal leakage. These functions should not be attained at the expense of tooth strength; post space preparation should be as conservative as possible to avoid an increased risk of root fracture. It is important to point out again that a post does not strengthen or reinforce a tooth. This elusive goal would only be achieved in a case of perfect cohesion between post and tooth substrate, nowadays only partially achievable. The clinician must therefore keep in mind that inherent strength of the tooth and its resistance to root fracture comes mostly from the remaining tooth structure and the surrounding alveolar bone. The tooth is weakened if dentin is sacrificed to place a larger-diameter post.

The post should be long enough to meet aforementioned biomechanical demands without jeopardizing root integrity. The standard parameters for post placement in a tooth with normal periodontal support are as follows:

1. In case of nonadhesive cementation (metal posts only)[60]:
   - Two-thirds the length of the canal
   - A radicular extension at least equal to the coronal length of the core
   - One half the bone-supported length of the root
2. In case of adhesive cementation (fiber posts)[41,136]:
   - One-third to one half the length of the canal, maximum
   - A radicular extension about the coronal length of the core

The first step for all types of post and core restorations is removal of gutta-percha and endodontic cement from the future post space. This procedure generally is best accomplished by the clinician providing the endodontic service, because that person has a clear knowledge of the size and form of the canal system. The initial post space preparation procedure is similar for most standardized post and core systems. The space, cleared of gutta-percha, has the form of the canal after cleaning and shaping. Proprietary systems are supplied with a series of drills to prepare the internal surface of the canal. The goal of post space formation is to remove little or no dentin from the root canal.

www.konkur.in

Adhesive procedures

In general, both self-etch and etch-and-rinse adhesive systems can be used successfully on root dentin, both systems having a well-documented proof of efficacy. However, the use of etch-and-rinse adhesive systems may be advantageous in the presence of highly sclerotic or contaminated dentin, because phosphoric acids will etch dentin more deeply than self-etching primers. When treating the canal in the perspective of post cementation, a dual-curing adhesive system is preferably used to optimize polymerization. Self-adhesive cements have also demonstrated satisfactory performance for post cementation.

Partial restorations

In the case of limited to moderate coronal substance loss, the restorative strategy for endodontically treated front teeth varies, from direct composite restoration using the same layering or application techniques as for vital teeth (possibly with the contribution of intracoronal or extracoronal bleaching) to full veneers, when discoloration is not fully treatable or tends to relapse. From a restorative standpoint, it is only necessary to mention that a 1- to 2-week delay is mandatory prior to adhesively restoring a bleached tooth. For more extensive restoration, it is even advised to wait up to 6 weeks or more (depending on the extent and duration of bleaching treatment) to allow for tooth final color stabilization and to proceed with shade selection.[39] Figs. 23.6 and 23.7 describe the clinical steps involved in the restoration of moderately decayed front teeth using direct composite and bleaching or veneers.

In posterior teeth exhibiting limited to moderate tissue loss, direct to indirect partial or full occlusal restorations are proposed. Their benefit is to take advantage of residual tooth structure to stabilize the restoration and minimize the potential impact of a prosthetic rehabilitation on periodontal tissues. For instance, second molars definitely profit from a conservative approach using adhesively luted intracoronal and full occlusal coverage restorations. An endocrown is a modification of the aforementioned concept, with extension of the restoration into the pulpal chamber as an additional retentive and stabilization structure. Figs. 23.8–23.10 describe the clinical steps involved in the restoration of moderately decayed posterior teeth using

Telegram: @dental_k

www.konkur.in

onlays, overlays, and endocrowns.

Foundation restoration underneath full crowns

If significant coronal substance loss justifies a full-tooth coverage, the strategy for foundation fabrication varies as follows:

- Amalgam core with/without metal post
- Composite core without post
- Composite post with fiber or ceramic post
- Composite with prefabricated metal post
- Cast gold post and core

Amalgam core

A coronal-radicular amalgam foundation may be realized with or without a post (see Fig. 23.11). The amalgam coronal-radicular core without a post is indicated for posterior teeth that have a large pulp chamber and lateral walls at least 4 mm high. This restoration extends slightly into the coronal portion of the canals (1 to 1.5 mm). The core is then retained by a combination of the divergence of the canals and natural undercuts in the pulp chamber. A single, homogeneous material is used for the entire restoration, rather than the dual phases of a conventional preformed post and core.

When shorter lateral walls are present, a post is mandatory to improve core stability and retention. The preferred roots for post placement for molars are the palatal root in the upper jaw and the distal root in the lower jaw. Other roots, thinner and presenting more pronounced curvatures, are normally not indicated for post placement. Coronal-radicular amalgam foundations are not indicated for premolars owing to their smaller dimensions; adhesive foundations or cast gold post and core are preferred.

Cast gold post and core

Cast gold post and core restorations can be fabricated with either direct or indirect techniques.

Direct technique.

In the direct technique, a castable post and core pattern is fabricated in the

Telegram: @dental_k

www.konkur.in

mouth on the prepared tooth. A preformed plastic post pattern is seated in the post space. To gain a path of withdrawal, undercuts are blocked out with resin composite rather than by removing healthy dentin structure. Acrylic resin is added to create a core directly attached to the post pattern. The finished pattern is removed from the tooth and cast in the laboratory.

Indirect technique.

With the indirect technique, a final impression of the prepared tooth and post space is made (Fig. 23.15). As with the direct technique, the path of withdrawal is made by undercut blockout, not by dentin removal. The castable final post and core pattern are fabricated on a die from this impression. The crown margins need not be accurately reproduced at this stage. Proprietary systems provide matched drills, impression posts, and laboratory casting patterns of various diameters. An impression post (preferably a repositionable one) is fitted to the post space, and a final impression is made that captures the form of the remaining coronal tooth structure and picks up the impression post. In the laboratory, a die reproduces the post space and the residual coronal tooth structure for fabrication of the post and core pattern.

Telegram: @dental_k

www.konkur.in

FIG. 23.15 Nonvital teeth with limited coronal structure or numerous abutments. Indirect post and core fabrication helps to achieve proper parallelism and core anatomy. Core retention is assumed by a conventional or adhesive cement. Today, this solution is considered mostly for extended metal-ceramic restorations or sometimes for multiple full-ceramic restorations. **A,** Preoperative view. **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose the remaining tooth structure and a clean dentin substrate. Despite the indirect approach, all healthy coronal structures must be maintained to improve foundation stability. Access cavity and coronal walls are prepared with minimal convergence (6 to 10 degrees) to allow for easy insertion. **C** and **D,** Cast gold post and core fabrication and luting. Post space preparation: The post space is prepared with ad hoc instruments until reaching a length equivalent to about core height or more. More length is needed here, as retention cannot always be achieved through adhesion (endodontic retreatment or highly sclerotic contaminated dentin). Then a conventional glass ionomer or zinc phosphate cement is used. Post and core preparation: The gold post is sandblasted (or eventually sandblasted and coated if adhesive procedures are possible) using Rocatec or CoJet systems, 3M + silane. Post cementation: The post and core is luted with the aforementioned conventional cements or adhesive technique. Next, a self-curing adhesive system is applied on all cavity walls and into post preparation (before the insertion of the post and core) and covered with a dual-

Telegram: @dental_k

www.konkur.in

cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). **E** and **F,** Restoration fabrication and placement. A second impression is needed for the final prosthetic work to optimize restoration precision and quality. Lab-made PFM or full ceramic crowns are made with optimal foundation design and alignment.

Six close-up views are marked A through F.

A) Closed teeth show black gum line and yellow stains on the teeth.

B) Upper jaw shows teeth with removed crowns and cavities.

C) Metal tooth-like structures are implanted in the cavities.

D) Upper jaw shows front view of silver teeth.

E) Interior view of upper jaw shows teeth with little yellow stains.

F) Mouth shows restored and normal teeth.

With both techniques, the fabrication of a temporary crown with intraradicular retention is needed. This provisional restoration must stay in the mouth only for a limited time to prevent decementation or canal reinfection. This is why this approach is less popular today and is replaced by direct techniques in most cases.

The cast post and core is cemented at the second appointment. The cementation process must be passive in nature and an evacuation groove made on post side to facilitate cement expulsion and limit seating pressure. Rapid seating, excessive cement, and heavy seating pressure (e.g., occlusal force) can produce high hydraulic pressures inside the root that may be great enough to crack the root.

Crown preparation and temporary restoration

When a coronal restoration is indicated, the amount of tooth structure remaining after final preparation is the most important determinant of the design of the post and core. In addition, the underlying sound tooth structure provides greater resistance to fracture than any post and core type, design, or material. Natural tooth structure should always be carefully preserved during all phases of post space and crown preparation. Otherwise, preparation of endodontically treated teeth is not different from that for vital teeth, with the

Telegram: @dental_k

www.konkur.in

exception of severely discolored teeth, which require a slightly deeper chamfer to hide discoloration with the prosthetic structure and intrasulcular margins to reduce the visibility of a dark cervical tooth structure.

Provisional crowns for endodontically treated teeth must be used only for short periods of time because the loss of cement seal—which is, of course, symptom-free—can lead to leakage, canal reinfection, and even serious carious invasion, thereby jeopardizing the success of endodontic treatment and even resulting in tooth loss.

Summary

Endodontically treated teeth represent a singular situation because of the attendant qualitative and quantitative alterations of the dental substrate. Current literature indicates that treatment success relies on an effective coronal seal that will prevent canal reinfection and an adequate restoration that will resist functional stresses applied to the remaining tooth structure. The purpose of this chapter is to help the clinician make treatment planning decisions concerning the restorative options available for endodontically treated teeth.

24: Vital pulp therapy

George Bogen, Till Dammaschke, Nicholas Chandler

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

"There is nothing permanent except change."

—Heraclitus

Vital pulp therapy aims to preserve and maintain pulpal health in teeth challenged by trauma, caries, restorative procedures, and anatomic anomalies. The treatment can be completed for permanent teeth that show reversible pulpal injuries, and outcomes depend on several factors.[87,192,252] The primary objective is to initiate the formation of new mineralized tissue. This procedure is essential for the preservation of involved immature permanent teeth where root development is incomplete, and maintenance of arch integrity is critical during maxillofacial development.[73]

From the first description of direct pulp capping using gold foil by Philipp Pfaff in 1756, dentistry has recognized the ability of the injured pulp to

Telegram: @dental_k

www.konkur.in

repair.[308] New materials now provide superior sealing properties to protect the pulp from microorganisms and their toxic by-products. Mineral trioxide aggregate (MTA) and other hydraulic calcium silicate cements (CSCs) partnered with advanced treatment strategies have changed the long-held concept that pulp capping after carious exposure should be avoided. The perception that outcomes for direct pulp capping in a carious field are inconsistent is based on traditional protocols and materials that did not generate a favorable environment for hard tissue formation.[168,229,271,382] This has encouraged clinicians towards alternative treatments, such as pulpotomy or pulpectomy, particularly in immature permanent teeth.[74,396] This is further complicated by diagnostic difficulties, because clinical signs, symptoms, and radiographs may not accurately reflect the histologic condition of the pulp (Fig. 24.1).[196] However, based on a better understanding of pulp physiology, caries microbiology, and the inflammatory mechanisms responsible for irreversible changes, teeth with the potential for repair and continued vitality can now be more readily identified and predictably treated.[54]

FIG. 24.1 Radiographs of carious molars in patients aged 12 to 38 years. **A,** Mandibular left first molar in a 23-year-old with minor symptoms. **B,** Asymptomatic maxillary right second molar in a 16-year-old. **C,** Asymptomatic maxillary left first molar in a 38-year-old. **D,** Deep caries in the mandibular right first molar of a 12-year-old. All patients were referred to the endodontist for root canal treatment based on radiographic appearance. They exhibited normal vitality with cold testing, and all were treated successfully with vital pulp therapy.

Telegram: @dental_k

www.konkur.in

Four radiographs are marked A through D.

A) Three teeth are shown. Two teeth have radiolucent root canals. One tooth on the left is blurred.

B) Right tooth has radiolucent patch on lateral side of the crown. All teeth have radiolucent root canals.

C) The central tooth has large radiolucent patch covering most of the part of crown.

D) Three teeth are shown with radiolucent root canals. The enamel is removed from one side of the right tooth.

Source: (© Dr. George Bogen.)

Maintaining pulp vitality is in contrast to root canal treatment where remaining pulp tissue is removed and the canal system shaped, disinfected, and obturated using root canal filling materials. Although success rates of over 90% can be achieved after approximately 5 years with careful treatment after vital extirpation the complete loss of function of the pulp tissue occurs, which can be disadvantageous.[21] Proprioceptive protection is partially lost after orthograde treatment, permitting more than double the normal occlusal load before a provoked neuromuscular response occurs.[32,314] This proprioceptive deficit can threaten long-term tooth function and survival. In contrast, vital tooth therapy provides a conservative option that exploits bioactive materials and strategies to save the dentition.

This chapter describes the microbiology of caries and the associated physiologic reactivity of pulp tissue. Understanding that pulp tissue has an innate potential for repair in the absence of bacterial contamination, new treatments in vital pulp therapy for the preservation of the pulpally involved permanent tooth are discussed.[97,201]

The living pulp

Vital pulp tissue comprises cells including fibroblasts, undifferentiated mesenchymal cells, odontoblasts, macrophages, dendritic cells, and other immunocompetent cells. The cells of the subodontoblastic layer and odontoblasts form a thin border between the dentin and the periphery of the pulp known as the *Höhl cell layer*.[106,158] The odontoblasts are elongated

Telegram: @dental_k

www.konkur.in

columnar-shaped cells separated from the mineralized dentin by predentin and characterized by processes that extend into the dentin and possibly to the dentinoenamel junction.[167,348,372,403] Odontoblasts form the mineralized predentin-dentin matrix, which includes phosphoproteins, glycoproteins, proteoglycans, and sialoproteins.[220] Repair mechanisms in the pulp are similar to those in normal connective tissue injured by trauma. When the enamel and dentin are challenged and the pulp is exposed to advancing microorganisms, inflammatory changes can induce pulp necrosis, which precedes problems including infection and its complications.[50,61] The pulp undergoes physiologic, pathologic, and defensive changes during its life.[240,276,381] These include continued dentin apposition, causing reduction of coronal pulp volume and circumference and canal lumen dimensions.[125,277] Atrophy results in fibrosis, dystrophic calcification, degeneration of odontoblasts, and increased cellular apoptosis.[46,125] Aging of human pulp cells is primarily characterized by the formation of reactive oxygen species and senescence-related beta (β)-galactosidase activity.[233] Pain sensitivity is reduced due to a decrease in fast-conducting A-δ fibers and diminished pulp repair, partly attributed to decreases in the levels of substances such as alkaline phosphatase.[254,345]

A comparison analysis of gene expression levels reflecting cell function, proliferation, differentiation, and development found them markedly higher in young pulps.[381] Young dental pulps show greater cell and tissue differentiation, proliferation, and development of the lymphatic, hematologic, and immune systems compared to older pulps where the apoptosis pathway is highly expressed.[381] Although A-β fiber function remains constant with aging, a decrease in A-δ fibers with age may reduce the perception of pain by these fibers.[254]

In summary, the main functions of the dental pulp include dentin formation during development and life of the tooth, the transmission of stimuli via proprio- and pain receptors, and immune responses. The pulp also produces reparative dentin as a defense mechanism against external stimuli, and tissue during the formation and closure of the root apex.

Loss of pulp vitality

Telegram: @dental_k

www.konkur.in

Pulpless teeth with minimal remaining tooth structure that undergo root-canal-filling procedures and are heavily restored become more vulnerable to irreparable fracture because of the loss of proprioceptive mechanisms.[32,262,314,358] Moisture depletion from dentin and reduction of tooth stiffness are minimal after root canal treatment.[186,204,241] Although root canal treatment can prolong tooth survival, the cumulative loss of tooth structure from endodontic and restorative treatment weakens teeth.[64,76,118,393] Changes in root canal geometry are inevitable in the course of canal preparation and may lead to a higher incidence of fractures.[151,235] Other potential problems are tooth discoloration and increased caries risk because of plaque accumulation and altered microflora or due to the absence of the defenses of the pulp-dentin complex.[224,263] Root-canal-filled teeth demonstrate an increased susceptibility to recurrent caries because of poor marginal integrity of restorations or modification of their biologic environment.[78,263] Root canal treatments may be more complex than initially thought, while procedures for maintaining vitality are conservative, easy to implement, and often cost-effective.[198,339]

Pulpal response to caries[a]

The microbial advance in carious lesions is the primary cause of pulpal inflammation and potential necrosis. Acidogenic gram-positive bacteria, predominately oral streptococci and lactobacilli, produce lactic acid as the main metabolic by-product in active lesions that demineralizes enamel and dentin.[136,176] Immune responses and inflammation occur when the caries front is within 1.5 mm of the pulp and bacterial antigens and metabolites diffuse through dentinal tubules.[43,136,203,293] If bacterial challenge continues, immune cell responses lead to increased inflammation and edema, initially characterized clinically by pulpal pain. In the low-compliance environment of the pulp space, inflammation eventually leads to pulp disintegration and apical pathosis.[176,376]

Advancing caries is initially confronted by protective innate immune responses, progressing to an adaptive response when bacteria directly approach the pulp.[175] The pioneer microbes first encounter a positive outward flow of dentinal fluid, characterized by the deposition of immunoglobulins

Telegram: @dental_k

www.konkur.in

and serum proteins that slow the diffusion of antigens.[176] Potent microbial metabolites, such as lipoteichoic acid and lipopolysaccharide, also activate the innate immune system. The by-products stimulate signaling by Toll-like receptors in odontoblasts when these cells first encounter the carious front. They also stimulate proinflammatory cytokines, including interleukin-1, interleukin-8, interleukin-12, tumor necrosis factor alpha, vascular endothelial growth factor (VEGF), and transforming growth factor beta (TGF-β).[137,187,411] VEGF promotes vascular permeability and angiogenesis. Dentin mineralization and matrix metalloproteinase secretion are also induced by the increased expression of TGF-β. Cariogenic bacteria also activate complement pathways and induce the proinflammatory cytokine interferon γ, responsible for killing phagocytosed bacteria by activated macrophages.[190] Odontoblasts also participate in the adaptive response by the synthesis of reactionary dentin, which features diminished tubularity.[86] As microorganisms advance, the modified helical structure in reparative dentin constricts lumen diameter, forming a barrier against pathogens.[85]

As pulpitis progresses, vasoactive neuropeptides contribute to increased vascular permeability and intrapulpal blood flow. Increases in neuropeptide concentration and nerve sprouting characterize neurogenic inflammation, which can cause a transient increase in interstitial tissue pressure and contribute to painful pulpitis.[65,323] Immune cells attempt to control neurogenic inflammation with the secretion of peptides such as somatostatin and β-endorphin.[280] The primary effector cells in innate responses include natural killer cells, neutrophils, monocytes, and macrophages. Immature dendritic cells and T cells contribute to immunosurveillance during the progression of caries. Macrophages eliminate both pathogens and senescent cells while contributing to tissue homeostasis by repairing and remodeling tissue after inflammation.[175]

Cytokines are small, cell-signaling proteins secreted by innate immune cells that induce phagocyte extravasation during inflammation. Chemokines secreted by odontoblasts, fibroblasts, immature dendritic cells, and macrophages stimulate leukocyte recruitment by directing monocyte and neutrophil migration extravascularly to sites of infection.[175] Prompt intervention, through removal of caries and bacterial antigens before irreversible pulpitis commences, can resolve inflammation (Fig. 24.2).

FIG. 24.2 A 15-year-old female patient presented with full orthodontic banding and deep cervical caries of the mandibular right first molar (tooth #30). The tooth was sensitive to cold and biting pressure. **A,** Periapical radiograph revealing large carious lesion and normal periapical structures. **B,** Clinical photograph showing advanced cervical caries extending below crestal gingiva. **C,** View of initial pulp exposure during caries excavation guided by caries detector dye. **D,** Photograph after complete caries removal, large pulp exposure and 6% sodium hypochlorite hemostasis. **E,** Clinical photograph after placement of thick white mineral trioxide aggregate aliquot over entire pulp and surrounding dentin. **F,** Radiograph showing pulp capped molar with temporary restoration (Photocore). **G,** Four-year radiographic control showing recurrent caries and fractured distal marginal ridge tooth #30. **H,** Five-year radiographic review showing no detectable apical pathosis and recently cemented full coverage porcelain fused to metal crown. The molar was asymptomatic and responded normally to sensibility testing.

Telegram: @dental_k

www.konkur.in

Radiograph A shows 30th tooth with radiolucent crown, pulp chamber, and root canal. Three close-up views, marked B to D, show 30th tooth with white soft tissue, blood, and clean cavity, respectively. Close-up view E shows white filling in the cavity. Three radiographs, marked F to H, show gradual changes in the cavity after filling. Radiograph F has rough radiopaque surface in crown, whereas radiograph H has smooth surface.

Dentin regeneration and reparative tissue formation

Mammalian dentin can be subdivided into primary, secondary, and tertiary types. Primary dentin is regular, tubular, and develops before eruption. Secondary dentin is also regular and formed throughout life. Tertiary dentin is more or less irregular and forms locally in response to caries or cavity preparation.[228] It is also referred to as irritation dentin. Secondary dentin formation is slower than that of primary dentin as odontoblast activity is presumably downregulated by autophagocytosis after eruption.[95] A mild external stimulus to the odontoblasts leads to upregulated activity and tertiary dentin formation.[350,353] Unlike bone, which is able to adapt to physiological changes throughout life, dentin is neither remodeled nor replaced once lost.[319]

Tertiary dentin formation

Once dentin is exposed by caries, trauma, or cavity preparation, the tubules are opened and odontoblasts injured or even destroyed. If these challenges are of moderate intensity, they lead to a brief inflammation, which subsides when the irritant is removed. Thereafter, tertiary dentin is formed in the affected region.[319,353] Minor trauma to the pulp stimulates undamaged primary odontoblasts to form new dentin.[236,353,354] This tertiary dentin is therefore also referred to as a reactionary dentin, defined as dentin whose matrix is secreted by primary postmitotic odontoblasts in response to an adequate stimulus.[236,353,354]

Injury to the dentin and odontoblast processes leads to a release of growth factors, which in turn leads to the upregulation of odontoblast activity.[350,353]

Telegram: @dental_k

www.konkur.in

The probable control mechanism includes a series of tissue factors or signaling molecules, mainly from the TGF-β family released from the dentin matrix following injury.[156,157] These growth factors can also be secreted by odontoblasts, promoted by acidogenic bacteria, or removed from the dentin by different rinsing solutions used during treatment such as ethylenediaminetetraacetic acid (EDTA), sodium hypochlorite (NaOCl), or citric acid.[352,353] In addition, the application of calcium hydroxide (CH) or silicate cements (e.g., MTA or Biodentine) to dentin or onto pulp tissue leads to TGF-β1 release.[164,232,374] Residual dentin thickness has a significant influence on dentin formation. Even if the dentin above the pulp remains intact, not all odontoblasts will survive. In cavities with a residual dentin thickness of less than 0.25 mm, approximately 50% of cells survive; in shallower cavities, this figure is 85% or more.[281] Despite odontoblast death, hard tissue formation can be observed. The reactionary dentin formation by the primary, postmitotic odontoblasts under these conditions is therefore a specific form of tertiary dentin.

Mineralized tissue formation after loss of the primary odontoblasts

The formation of mineralized tissue after loss of the odontoblasts is more complex than that of reactionary dentin. Dentin formation is not possible without odontoblasts. Nevertheless, after direct capping of a healthy, noninflamed pulp, hard tissue formation occurs. This mineralized tissue is heterogeneous, amorphous, and atubular. Therefore it differs histologically from primary and secondary dentin, but also from reactionary dentin. It is questionable whether this tissue can be called a “dentin bridge,” as it is not dentin from a histological viewpoint. If it really was further formation of dentin, a new type of cell would have to replace the destroyed primary odontoblast. The origin and differentiation of these initial cells remains unclear.[319]

Recent investigations have found no histological evidence for the formation of replacement odontoblasts or new odontoblast-like cells after direct pulp capping (DPC) of human teeth with either CH or MTA.[111,319,320] Secondary odontoblasts or odontoblast-like cells are therefore histologically not detectable in human teeth. It is uncertain whether the hard tissue

Telegram: @dental_k

www.konkur.in

formation is really dentin or just a dystrophic intrapulpal mineralization in response to inflammation.[111,320] However, it is important to emphasize that both reactionary dentin (formed by primary odontoblasts) and hard mineralized repair tissue can form simultaneously in the same lesion.[319,353]

Indications for vital pulp therapy

The penetration of microorganisms and their metabolic products through dentin leads to an inflammation in the pulp. Mediated via cell receptors on odontoblasts, dendritic cells, and pulp fibroblasts, an immune response is initiated. This leads to hyperemia; the reaction is characterized by a decrease in cell number, a flattening of the odontoblasts, and the immigration of lymphocytes and plasma cells.[321] Clinically, this correlates with the development of reversible pulpitis, where healing could be facilitated by therapeutic intervention. If the stimulus persists, bacterial colonization in the pulp chamber can be detected, microabscesses and tissue necrosis lined with polymorphonuclear neutrophilic granulocytes become present, and inflammatory infiltrates are found in the periphery.[321] This is considered to be irreversible pulpitis.

Signs of a reversible pulpitis are a positive response to cold sensibility testing with radiating pain. An irreversible pulpitis is diagnosed on the (enhanced) positive sensibility test, on radiating irritant-persistent pain or lingering pain, pain on heat, and possibly on the patient's inability to localize the problem tooth. However, irreversible pulpitis may be asymptomatic.[14] The correct diagnosis of pulp condition before DPC plays an important role in the outcome. Therefore, assessing the possible the degree of inflammation and/or infection is required.[211] It is challenging to assess pulp health accurately via clinical tests and to distinguish between altered and healthy pulps.[11]

A positive sensibility test (cold) can give a variety of different diagnoses, depending on the severity and duration of response, guiding clinicians to different diagnoses. Teeth responding to cold test may lead to a preoperative diagnosis of normal pulp, reversible pulpitis, or irreversible pulpitis dependent on subjective responses.[301] Sensibility testing does not precisely mirror the condition of the pulp, with 10% to 16% of results being false.[19]

Telegram: @dental_k

www.konkur.in

Besides pain history and sensibility testing, hemorrhage after pulp exposure should be assessed. This may be a more reliable way to determine the status of pulpal infection than clinical signs and symptoms or sensibility testing.[252] Bleeding may reflect the level of inflammation of the pulp, with excessive hemorrhage usually indicating a pulp with a decreased or no chance of recovery.[88] The inflammatory response extends deeper into the pulp tissue when carious dentin is present during exposure, with possible bacterial penetration, compared to superficial inflammation when the pulp is just mechanically exposed.[229]

Pulps with profuse and lingering hemorrhaging had a significantly poorer outcome than those with modest bleeding or bleeding of short duration.[252] Clinically, bleeding should be controlled within 5 to 10 minutes.[211] According to current recommendations in cases of irreversible pulpitis, the healing of the pulp tissue cannot be achieved predictably after removal of the triggering stimulus (e.g., caries). The diagnosis “irreversible pulpitis” often leads to the initiation of pulpectomy and root canal treatment. Although there is evidence that the histological observations described earlier correlate well with the clinical diagnosis, it should be noted that the clinical pattern of the complaint does not indicate the tissue’s ability to regenerate.[321] In a paradigm shift, current clinical investigations using CSCs for full pulpotomies in adult teeth diagnosed with irreversible pulpitis and demonstrating radiographic periapical rarefaction have been treated successfully without pulpectomy and conventional orthograde treatments.[22,23,25,211,242,363,364,386] Refer to the section Pulpotomy With Calcium Silicate Cements.

Maintaining pulp vitality can only be successful if bacterial infection of the tissue during and after the therapy is eliminated. Vital pulp treatments should generally be performed on teeth that do not show pronounced and unprovoked pain symptoms or severe pain on percussion. Vital pulp therapy should not be performed without a response to the sensibility test (in which the pulp status must be verified after pulp exposure) alongside radiographic evidence of periapical disease. In cases diagnosed with irreversible pulpitis, advanced treatment options such as CSC pulpotomy should be considered, especially in younger patients. All vital pulp treatment procedures require a quality bacteria-tight coronal restoration to preclude infection, with dental dam placement, the use of sterile instruments and complete excavation of

Telegram: @dental_k

www.konkur.in

caries. If not, root canal treatment should be given preference or extraction for teeth deemed unrestorable.[107]

Favorable conditions exist in young patients with pulps without previous damage.[334] With increasing age, a reduced ability for repair is expected due to pulpal changes characterized by a cell-poorer and more fibrous pulp tissue.[161,285] Nevertheless, the age of the patient seems to play only a minor role in treatment success.[23,101–103,206,211,242,243,248,258,363] The same applies to factors such as the sex of the patient, tooth position (posterior or anterior), and the size or location of the pulp exposure.[110,206,244,260,301] The success rates of vital pulp therapies in the literature vary widely, especially in the case of DPC after caries excavation. Early clinical failures (within days or weeks) are multifactorial, but certainly correlate with improper pulpal diagnosis or inability to identify and remove necrotic pulp tissue. An inaccurate pulpal diagnosis can underestimate the inflammatory status of the pulp, leading to irreversible pulpitis and pulp necrosis with postoperative pain.

The introduction of new bioactive materials, along with modified protocols, make more teeth with deep caries, traumatic injuries, and mechanical exposures viable candidates for innovative pulp therapies designed to maintain pulp survival. Outcomes depend on case selection, hemostatic agents, choice of pulp capping material, and the integrity of the sealed permanent restoration. The purpose in vital pulp therapy is to avoid or delay root canal treatment and advanced restorative care because these procedures, together, reduce long-term tooth survival compared to teeth with vital pulps.[76,77,118,270,289,328,366,380,385]

Procedures generating mineralized tissue barriers

Indirect pulp capping

Indirect pulp capping is defined by the American Association for Pediatric Dentistry (AAPD) as “a procedure performed in a tooth with a deep carious lesion approximating the pulp but without signs or symptoms of pulp degeneration. Indirect pulp treatment is indicated in a permanent tooth diagnosed with a normal pulp with no signs or symptoms of pulpitis or with a

Telegram: @dental_k

www.konkur.in

diagnosis of reversible pulpitis."[13] Hence indirect pulp capping is the permanent capping of a thin, pulp-nigh, cariously altered dentin layer, without complete excavation of the caries.[33] This may differ from the definition in other countries, for example, in the German-language literature, "indirect pulp capping" is defined as the treatment of a thin layer of caries-free dentin remaining above the pulp chamber with a medication.[332] The French definition of indirect pulp capping implies the covering of both healthy or carious dentin.[230] These definitions may lead to confusion when interpreting the literature.

Clinically, this situation usually arises in the excavation of an extensive carious lesion, so that indirect capping is also called *treatment of deep carious lesions*. A more general term would be "treatment of the pulp-nigh dentin," since indirect pulp capping may be necessary even in caries-free teeth, for example, after dental trauma.[357] Because only a minimal dentin layer remains above the pulp tissue, there is a risk of irreversible inflammation of the pulp via the dentinal tubules.[284] This can result from remaining bacteria or microorganisms actively entering the tissue and by cytotoxic components from restorative materials diffusing across thin residual dentin. Pulp-nigh dentin should be disinfected and bacteria-sealed with a capping material, stimulating the formation of tertiary dentin.[319] The indirect capping thus serves to protect the vital pulp, especially after caries removal. If there is already reversible pulpitis, a favorable environment for pulpal healing should be generated by indirect pulp capping (Fig. 24.3).

Advancing microorganisms and their by-products during the carious process pose a threat to the pulp.[322] Therefore, during caries excavation, the number of microorganisms in the cavity and near the pulp should be reduced, with indirect capping completed under dental dam isolation. To prevent spread of microorganisms, it is recommended to disinfect the clinical crown with NaOCl (1% to 5%) or chlorhexidine digluconate (CHX, 2%) prior to

Telegram: @dental_k

www.konkur.in

excavation. After caries excavation, the cavity should be cleaned with NaOCl or CHX and water spray.[53,75] Damage to vital tissue when using NaOCl is not of concern.[31] Nevertheless, it remains unclear how much altered dentin can be left while allowing the pulp to heal.[50,338] Hence indirect capping materials should eliminate potential residual microorganisms, neutralize any acidic (due to the carious defect) tissues, remineralize dentin, and stimulate the pulp to form tertiary dentin. Due to the disadvantages of aqueous CH suspensions, the use of CSCs can be seen as an improved alternative for indirect capping.[9]

Direct pulp capping

Direct pulp capping is defined as "placing a dental material directly on a mechanical or traumatic vital pulp exposure" and "sealing the pulpal wound to facilitate the formation of reparative dentin and maintenance of a vital pulp."[14] The procedure is indicated for pulp exposures incurred as a result of caries removal, trauma, or tooth preparation. When mechanical exposures occur during tooth preparation, the exposed tissue is generally not inflamed. However, in cases of trauma or carious exposure, the degree of inflammation is the key predetermining prognostic factor. According to the American Association of Endodontists (AAE), "In a carious pulp exposure, underlying pulp is inflamed to a varying or unknown extent."[14] The major challenge in DPC is the proper identification and removal of the acutely inflamed or necrotic tissue compromised by longstanding proximity to oral microorganisms.[247] Direct capping is therefore geared towards the healing of the pulp and the preservation of the tooth. If the pulp survives this treatment (remains vital), this can be considered a clinical success. Direct capping is a noninvasive, relatively simple and inexpensive treatment technique that, unlike root canal treatment, often does not require extensive restorative care.[198]

Since Hermann's first publications in the late 1920s, CH has been used as an aqueous suspension for direct capping.[189] However, the published success outcomes of DPC in a carious field show significant variation and the procedure remains controversial. Some recent publications therefore recommend selective excavation and leaving carious tissue in the tooth, suggesting improved performance over direct capping. For a direct

Telegram: @dental_k

www.konkur.in

comparison of the two treatments, there are currently only three clinical studies available, two comparing 1- and 5-year data and the third showing 1-year data.[25,51,52] In the second study, the prognosis of the two-stage excavation was compared with complete caries excavation treated by DPC or partial pulpotomy.[51] Five years after two-step caries excavation, the pulp was vital in 60% of the cases, whereas in the same period the success rates after direct capping were only 6% and after partial pulpotomy 11%.[51] The reason for lower success rates may include the absence of disinfection after pulp exposures, the choice of Dycal (Dentsply, Konstanz, Germany) as capping material, and the use of long-term provisional restorations.[181] However, in the third study, where no pulp exposures were detected after complete caries removal, indirect pulp capping resulted in a 100% success rate at 12 months. The results indicate that CSCs may be preferable in indirect pulp capping procedures and that hard setting CH cements do not provide long- or short-term pulpal protection.[181]

Partial pulpotomy

Partial pulpotomy (shallow or Cvek pulpotomy) is defined as the removal of a small portion of the vital coronal pulp as a means of preserving the remaining coronal and radicular pulp tissues.[14] During clinical treatment, the decision to remove a small or large portion of the coronal pulp is based on visual inspection of the tissue after pulp exposure during either caries excavation or exposure as a result of trauma (partial or shallow pulpotomy).[145] The incorporation of the dental operating microscope (DOM) is highly recommended. The coronal pulp is reduced from the exposed site by approximately 2 to 3 mm in order to remove necrotic or potentially inflamed and irreversibly damaged tissue, keeping the remaining pulp vital.[49] Partial pulpotomy is preferably performed with a high-speed handpiece and a small round diamond bur with copious water spray or continuous rinsing with physiological saline solution.[135,140,165]

After partial tissue removal, if bleeding cannot be controlled after 5 to 10 minutes of direct exposure to NaOCl, complete removal of the coronal pulp to the pulp floor is the preferred option.[211] NaOCl is a valuable diagnostic as well as clinical tool to differentiate irreversible from reversible pulpitis in the

Telegram: @dental_k

www.konkur.in

coronal pulp in order to help determine whether to proceed with partial pulpotomy, complete pulpotomy, or pulpectomy. This decision can be of paramount importance in young permanent teeth with open apices, in which removal of tissue contaminated by microorganisms can reverse symptoms and stabilize inflamed tissue.[89,130,390]

A recent study that examined MTA complete pulptomies suggested that a hemorrhage "control time" parameter is not an accurate indicator of pulpal inflammatory conditions, contrary to other investigations.[242] However, the study did not benefit from recommended protocols including verified necrotic tissue removal using the DOM. Investigations have shown that the inflammatory response of pulp tissue challenged by bacterial by-products can progress several millimeters into the coronal pulp or advance further, thus affecting the radicular pulp tissue distant from the injury site.[320] The removal of 2 to 3 mm of exposed coronal tissue or radicular tissue to access the deeper, healthy tissue, in cases of trauma, carious exposures or complete pulptomies can ensure pulp survival (Fig. 24.4).[101]

The amputation site is covered with a NaOCl soaked cotton pellet until hemorrhage ceases. If the formation of a blood coagulum is prevented, the same pulpal repair mechanisms associated with DPC are expected.[102,191] If the remaining pulp is healthy, bleeding can be stopped within 5 to 10 minutes. If hemostasis does not succeed within this time, it indicates that the

Telegram: @dental_k

www.konkur.in

pulp is irreversibly inflamed, and a complete pulpotomy (the removal of the entire coronal pulp) may be considered as a last resort to maintain vitality.[225] A CH suspension or CSC is applied to the newly exposed pulp surface and covered with a cement (for the CH suspension) or a thin layer of flowable composite, compomer, or RMGI (for the CSC).[92] A current study examining MTA versus CH pulpotomy has shown superior performance by MTA in mature permanent teeth compared with a hard-setting CH (Dycal). Since the capping material is used in larger quantities in the partial pulpotomy than in the DPC, the risk of tooth staining is considered higher when using a bismuth oxide containing CSC.[225] Partial pulpotomy and DPC are similar procedures, differing only in the amount of vital pulp tissue remaining after treatment. Partial pulpotomy is the preferred option in elective treatment procedures for teeth diagnosed with anatomic anomalies, such as dens evaginatus and invaginatus.

Complete pulpotomy

Complete pulpotomy, or complete *pulp amputation*, is a more intrusive procedure defined by the AAE as "the removal of the coronal portion of the vital pulp as a means of preserving the vitality of the remaining radicular portion: may be performed as emergency procedure for temporary relief of symptoms or therapeutic measure, as in the instance of a Cvek pulpotomy."[14] The entire coronal pulp is removed and the vital pulp tissue capped at the entrance level of the root canal orifice. After successful hemostasis, it is treated analogously to DPC (Fig. 24.5).[225]

The assessment, selection, and amount of tissue removal are dependent on observer experience and completed on a case-by-case basis using magnification. Generally, after necrotic coronal tissue is completely removed, the inflamed pulp can be partially or completely amputated to the pulp floor or cervical area (pulpotomy) in the case of molars and some premolars.[144,147] The remaining tissue requires hemostasis before the placement of a CSC. The AAPD guidelines state, "A pulpotomy is performed in a tooth with extensive caries but without evidence of radicular pathology when caries removal results in a carious or mechanical pulp exposure."[13] However, the guideline requiring an absence of apical pathosis before pulp exposure for pulpotomy procedures may be outdated and require modification. Growing evidence from contemporary studies shows resolution of radicular lesions after pulpotomy treatments using CSCs in adult teeth diagnosed with irreversible pulpitis.[20,22,23,25,242,361–363]

Complete pulpotomy has traditionally been recommended for primary and immature permanent teeth for which short-term outcomes are generally favorable. However, the treatment of mature permanent teeth can be traced to Roman times around 200 BC.[415] Since the introduction of CSCs, there has been a renewed interest in pulpotomy as an alternative option to conventional orthograde root canal treatment, particularly in mature adult permanent teeth. Ongoing clinical investigations strongly support the use of CSCs for pulpotomy procedures in these teeth and show acceptable outcomes in pain reduction with continued normal function.[21–23,25,211,242,363,364,386]

Materials for vital pulp therapy

For successful pulp capping outcomes, the removal of noxious stimuli, control of any infection, and the biocompatibility of the capping material are important prerequisites.[55,75] It has been shown that rat pulp, in the absence of microorganisms, has the regenerative power to seal an exposed pulp with mineralized tissue even without medication or the use of restorative

Telegram: @dental_k

www.konkur.in

materials.[210,306] The presence or absence of microorganisms is the determining factor in the healing of pulp tissue.[210] The tissue reactions that follow capping (for instance, collagen synthesis and secretion) are generally similar to connective tissue injuries.[334,353] While excavating a deep caries lesion or during trauma, dentin or pulp tissue areas can be directly exposed, which are particularly permeable due to the structure of dentin. Closer to the pulp chamber, dentinal tubules occur more frequently per square millimeter and have larger diameters than further from the pulp.[336]

Since microorganisms, bacterial toxins (lipopolysaccharides), and many restorative materials can damage the exposed pulp tissue or diffuse via the dentinal tubules, causing irritation, both the pulp and the surrounding dentin should therefore be covered with the indicated capping material. Alternatively, pulp capping materials must create an artificial barrier between the vital pulp and the oral cavity to prevent the ingress of microorganisms. Moreover, the capping material should have antimicrobial properties without being toxic to the pulp.[108] In addition to the disinfection and sealing of dentin, another requirement of the capping material is hard tissue regeneration by pulp cell induction and thus preservation of pulpal vitality.[128,273,334] Mineralized tissue regeneration can occur in healthy pulps beneath a variety of capping materials.[15] The healing of pulp wounds is therefore not associated with a special drug or wound dressing.[44] However, medications to treat an exposed pulp should promote the innate capacity of pulpal cells to form hard tissue.[334]

Aqueous calcium hydroxide suspensions

CH has long been considered the universal standard material for vital pulp therapy. Although the material demonstrates many advantageous properties, long-term study outcomes in vital pulp therapy have been inconsistent.[30,40,42,196] Desirable characteristics of CH include an initial high alkaline pH, which is responsible for stimulating fibroblasts and enzyme systems. It neutralizes the low pH of acids, shows antibacterial properties, and promotes pulp tissue defense mechanisms and repair. The drawbacks of CH include weak marginal adaptation to dentin, degradation and dissolution over time, and resorption in primary teeth. Histologically, CH demonstrates

Telegram: @dental_k

www.konkur.in

cytotoxicity in cell cultures and has been shown to induce pulp cell apoptosis.[15,159,335]

Tunnel defects have also been demonstrated in hard tissue barriers generated over pulp wounds associated with both CH and CSCs.[10,15,38,98,99,159,162,275,334] However, the primary difference between the two agents is that CH products are absorbable over time and dimensionally unstable. The slow disintegration of the CH after mineralized tissue formation can allow microleakage, permitting a slow ingress of microorganisms through defects. This can induce subsequent pulpal degeneration and lead to potential dystrophic calcification and pulp necrosis. Over extended periods, this problematic outcome can complicate any necessary nonsurgical root canal treatment at a later date.[274]

Clinical retrospective investigations have shown variable success rates over 2- to 10-year recall periods for direct CH pulp capping in humans.[30,40,42,196] Two current studies have examined the efficacy of CH as a DPC agent. One examined the survival of 248 pulp-capped teeth that were diagnosed either as having normal pulps or exhibiting spontaneous pain; the researchers found an overall survival rate of 76.3% with an average recall period of 6.1 years.[110] Outcomes were less favorable for teeth showing spontaneous pain, in older compared to younger patients, and in teeth restored with glass ionomer cements (GIC). The probability of pulps becoming nonvital after CH pulp capping was greater within the first 5 years of treatment.

The second study observed 1075 teeth directly pulp capped with a CH-based agent; these teeth had either healthy pulps or showed signs of reversible pulpitis.[288] Inclusion criteria limited pulp chamber roof exposures to no larger than 2 mm in diameter. Successful outcomes were 80.1% after 1 year and 68% after 5 years; this diminished to 58.7% after a 9-year observation period.[395] The results demonstrate increasing failure rates over time, attributable to absorption of the material under permanent restorations proximal to hard tissue bridges with tunnel defects. Another investigation has confirmed decreasing success rates with CH pulp capping with extended recall periods.[258] CH clearly has many favorable characteristics, but it can no longer be considered the preferred agent in vital pulp therapy (Fig. 24.6).[134,193,258,260,286]

Hard setting calcium hydroxide cements

In contrast to aqueous CH suspensions, other CH combinations such as cements (calcium salicylate ester cements) as well as liners or putties are less suitable for pulp capping due to a lower release of hydroxyl ions. In these

Telegram: @dental_k

www.konkur.in

preparations, the resulting pH is lower and the antimicrobial effect is significantly weaker.[139] In addition, hardening calcium salicylate ester cements (e.g., Dycal; Life, KerrHawe, Bioggio, Switzerland) are characterized by long-term disintegration.[38] They also fail to provide permanent support for the final restoration.[99] New mineralized tissue formation below CH-salicylate ester cements can be slow to generate and be less uniform in shape. Hard tissue regeneration may therefore be weaker using these CH preparations. In addition, inflammation is more common than with CH suspensions.[334] Some additives that harden the CH preparations may even have a toxic effect on the pulp.[99,334] For direct capping or pulpotomy, hard setting CH cements based on calcium salicylate esters cannot be recommended.

Light-curing liners and cements

To compensate for the disadvantages of proven CH preparations, light-curing liners and cements with CH additives were developed (e.g., Ultrablend Plus, Ultradent, South Jordan; Calcimol LC, VOCO, Cuxhaven, Germany). These materials do not have sufficient mechanical strength despite their composite content, and specific CH effects are minimal.[359] Moreover, the pH of these products is significantly lower compared to other CH products.[359] Nonetheless, antibacterial effects can be detected in vitro, although this has not been confirmed by other studies.[309,402] The cytotoxicity of these products, which is due to the composite component, has been clearly demonstrated.[184,309,310] Therefore according to the manufacturer's instructions, the direct contact of Calcimol LC to pulp cells should be avoided.

Another light-curing product is TheraCal LC (Bisco, Schaumburg, IL). The spectrum of indications according to the manufacturer corresponds to that of MTA and other CSCs. Unlike all other CSC products, where a cement powder must be mixed with a liquid (water), TheraCal LC consists of 45% Portland cement CEM III and 45% composite resin and is therefore photopolymerizable, significantly simplifying its clinical use.[154,155] However, it is known that all the monomers in TheraCal LC are cytotoxic in vitro.[180,202,207] After 1 day of direct contact with TheraCal LC, the fibroblast

Telegram: @dental_k

www.konkur.in

cell turnover rate decreased by 31.5% and after 1 week to 45.9%.[184] After 72 hours of contact with TheraCal LC there was a marked decrease in the percentage survival of the cells.[310] For tissue healing (hard tissue formation after pulp capping), it is crucial that there is no decrease but an increase in the cell turnover rate. In contrast to TheraCal LC, other calcium silicate products and CH have been shown to induce pulpal cell proliferation.[112,113]

Similar to other light-curing liners using CH, TheraCal LC exhibits a significant cell-damaging effect when in direct contact with human dental pulp stem cells.[58,184,309,310] It is also unclear how much Portland cement can be released from the resin matrix when the material is polymerized. After curing, TheraCal LC shows a heterogeneous structure with a high proportion of large, unhydrogenated particles, since the resin additives do not provide enough moisture to allow hydration. The hydration of TheraCal LC (the reaction of cement with water) is incomplete because of limited moisture diffusion within the material. Thus, no CH and only a small amount of calcium ions are released.[70] Light-curing liners and cements with added CH or MTA are collectively cytotoxic.[309,310] It is currently inadvisable to use photopolymerizable CH or calcium silicate-containing materials for indirect or DPC.

Composite resins, dentin adhesives, and resin-modified glass ionomer cements

Adhesive systems were introduced in the early 1980s as potential agents for DPC of cariously and mechanically exposed pulps.[200,253,404] Dentin adhesives, hydrophilic resins, and RMGI cements initially showed favorable outcomes in preliminary pulp capping investigations with nonhuman primates, based on standards set by the International Organization for Standardization.[96,367–369] However, the transitional use of these materials in human subjects did not demonstrate the corresponding biocompatibility or consistent reparative bridge formation.[5,119,159,183,197,271] Investigations that have examined responses to resin-based materials in human teeth have demonstrated unfavorable histologic reactions when the material is placed directly or in close proximity to pulp tissue.[5,124,172,272,315] Histological material typically demonstrates inflammatory cell infiltrates consistent with

Telegram: @dental_k

www.konkur.in

pulp cell cytotoxicity, subclinical adhesive failures at the pulp interface, and a profound absence of biocompatibility.[5,119,272,296,315,349]

The application of dentin adhesive to a thin layer of dentin (0.5 mm) leads to an expansion of the blood vessels and chronic inflammation of the pulp tissue.[183] Nonpolymerized or partially polymerized dentin adhesives cause apoptosis in various pulp cells, such as macrophages and undifferentiated pulp cells.[246] Besides monomers from dentin adhesives, identical cytotoxic components can also be released from composites, which then penetrate through dentinal tubules to pulp tissue causing damage.[59] Also, deep cavities (without pulp exposure) are problematic because the residual dentin thickness over the pulp can be thin, and tubular fluid can prevent complete polymerization. In addition, complete polymerization can be prevented by an excessively thick composite layer that is insufficiently penetrated by curing lights.[272] Both factors lead to an increased proportion of residual-free monomers, which are then released from the composite resin and diffuse into the pulp tissue. In clinical studies the use of dentin adhesives in deep cavities results in relatively frequent pulp necrosis.[337]

Unpolymerized, polymerized, and aged dentin adhesives release cytotoxic components that are responsible for inferior performance in human and animal experiments.[5,94,112] In addition, monomers from restorative materials (dentin adhesives/composites) may interact with the immune system of the pulp, weakening its defense against invading microorganisms.[44,268] Direct contact with dentin adhesives or composite resins is thought to reduce pulpal defense, either due to cytotoxicity or specific changes in the immune response.[207,267,268] Adhesive components thus inhibit the proliferation of immunocompetent cells and cause chemical immunosuppression, which promotes the development of pathological changes in the pulp.[44,207] Dentin adhesives and composites are essentially not biocompatible and should not be used for indirect or DPC.[9,94] However, hydrophilic resins and RMGI cements provide excellent seals when they are combined with light-cured composites as permanent restorations and placed directly over pulp capping materials such as MTA and other CSCs.[27,131,288]

Mineral trioxide aggregate

MTA was introduced as a pulp capping agent by Torabinejad and associates in the mid-1990s.[141] Most preliminary experimental and current clinical data in vital pulp therapy are based on the proprietary material ProRoot MTA (Tulsa/Dentsply, Tulsa, OK). The cement consists of a hydraulic calcium silicate powder containing oxide compounds, including calcium oxide, ferric oxide, silicon oxide, sodium and potassium oxides, magnesium oxide, and aluminum oxide.[71] The material exhibits favorable physicochemical characteristics that stimulate reparative dentinogenesis by recruitment and activation of hard tissue–forming cells, contributing to matrix formation and mineralization.[298] Soluble cytokines and growth factors that mediate wound repair of the dentin-pulp complex are nested in the extracellular matrix. MTA stimulates reparative hard tissue formation by sequestering these growth factors and cytokines embedded in the surrounding dentin.[222,223,375,385]

CH and calcium silicate hydrate, the principal by-products formed during hydration of mixed MTA, contribute to a sustained alkaline pH.[68,143] The setting properties of the hydroscopic silicate cements are not affected by the presence of tissue fluids or blood.[377] They are therefore also referred to as "hydraulic" cements, as they are hard setting both in contact with air and water.[47] During the setting process, the gradual release of calcium ions encourages reparative barrier formation by promoting signaling molecules, such as VEGF, macrophage colony-stimulating factor, TGF-β, and interleukins IL-β and IL-1α.[251,300]

MTA demonstrates superior marginal adaptation to dentin compared to CH-based agents and forms a dense bond to dentin. Mineral components from the cement penetrate into the tubules, producing adhesion to dentin comparable to GICs.[29,216] MTA also forms an adherent interfacial layer during mineral nucleation at the dentin surface that appears similar in composition to hydroxyapatite when examined with x-ray diffraction, energy-dispersive x-ray analysis, and scanning electron microscopy (SEM).[298,329,379] Similar to CH, MTA induces an inflammatory cascade that results from calcium ion release and the creation of an alkaline environment, producing tissue necrosis. Both MTA and CH have been shown to stimulate and increase the Höhl cell mitosis index in rodents.[114,115]

MTA activates the migration of progenitor cells (fibroblasts) from the central pulp to the injury site and promotes their proliferation and

Telegram: @dental_k

www.konkur.in

differentiation into odontoblast-like cells without inducing pulp cell apoptosis.[298] MTA also stimulates in vitro the production of messenger RNA and increases protein expression of the mineralized matrix genes and cellular markers crucial for mineralization after matrix formation.[298] In a human study, odontoblast-like cells and the formation of a dentin or dentin-like tissue could not been proven after DPC with MTA (RetroMTA; BioMTA, Daejeon, Korea). Hence the new calcified hard tissue was not "regular dentin" and did not seem to be the product of genuine odontoblast differentiation. This observation is identical to results after DPC with CH. Hard tissue formation after DPC appears to be a dystrophic intrapulpal mineralization in response to the capping procedure.[111]

Gray MTA has been shown to enhance cell proliferation and survival of cultured human dental pulp stromal cells.[300] The biocompatibility of set MTA upregulates the expression of transcription factors, angiogenic factors, and gene products, such as dentin sialoprotein, osteocalcin, and alkaline phosphatase.[299] Odontoblast signaling proteins are essential in the differentiation of progenitor cells into cells responsible for repair and hard tissue deposition.[299,300] After MTA pulp capping, both sialoprotein and osteopontin have been observed in the mineralized hard tissue matrix at the exposure site during the process of reparative hard tissue formation.[227]

Dental pulp cells differentiate into the odontoblastic cell line in the presence of the signaling molecules, such as TGF-β, heme oxygenase-1 enzyme, and bone morphogenetic proteins BMP-2, BMP-4, and BMP-7.[171] MTA most likely upregulates fibroblast secretion of BMP-2 and TGF-β1 and therefore stimulates and promotes mineralization and hard tissue regeneration.[117,170,171,178,340,365,406] MTA induces a time-dependent environment that is proinflammatory and promotes wound regeneration through upregulation of cytokines.[318] Immunohistochemical analyses show that cytokines, including myeloperoxidase, inducible nitric oxide synthase, VEGF, nuclear factor-kappa B, activating protein-1, and cyclooxygenase-2, show increased expression in the presence of MTA. Cytokine upregulation is responsible for inducing biomineralization by producing apatite-like clusters on collagen fibrils at the MTA-dentin interface. MTA does not affect the generation of reactive oxygen species, thereby positively influencing cell survival. MTA also has been shown to improve the secretion of IL-1β, IL-6,

Telegram: @dental_k

www.konkur.in

and IL-8.[67,81,91] However, an inhibitory effect on dental pulp cells has been demonstrated in the presence of MTA, which may be attributed to the release of aluminum ions.[267] Overall, the data indicate that MTA promotes a biocompatible, noncytotoxic, antibacterial environment and surface morphology that is favorable for reparative calcific bridge formation. MTA stimulates the release of the dentin matrix components necessary for hard tissue repair and regeneration in mechanically exposed healthy and partially inflamed pulps (Figs. 24.7–24.9).[6,141,170,266,286,317,374]

One disadvantage of MTA is that it can lead to discoloration of the hard tooth tissue. This may be problematic, particularly in anterior teeth during trauma management.[279] It is due to heavy metals contained in MTA, such as bismuth oxide used for radiopacity or iron.[45,123,347] The discoloration is mainly induced by the oxidation of these metals after contact with NaOCl or the uptake of blood components.[69,234,347] Other CSCs contain less or minute levels of heavy metals and their potential to discolor teeth is minimal. CSCs containing zirconium oxide or tantalum oxide, which are used as radiopacifiers, are particularly color-stable.[279]

www.konkur.in

Calcium silicate cements

A variety of new CSCs have developed since the introduction of MTA.[116,153,232,302] Preliminary investigations have demonstrated physicochemical and bioinductive properties comparable to MTA, indicating promise for their application in vital pulp therapy.[18,57,127] Some of these tricalcium-based materials include BioAggregate (Innovative Bioceramix, Vancouver, BC, Canada), Biodentine (Septodont, Saint-Maur-des-Fossés, France), MTA-Angelus (Angelus, Londrina PR, Brazil), MTA Bio, and MTA Branco (Angelus).[160,237] Other formulations include EndocemMTA (Maruchi, Wonju-si, Gangwon-do, South Korea) and EndoSequence BC root repair material (Brasseler USA, Savannah, GA). Currently, there are more than 40 different CSC formulations from international manufacturers. Some other silicate cement products include EndoBinder, iRoot BP, MicroMega MTA, MTA Bio, MTA Plus, NeoMTA Plus, RetroMTA, Tech Biosealer Capping, TheraCal LC, CEM Cement (calcium-enriched mixture), Grey MTA Plus, MEDCEM MTA, EndoCem Zr, Channels MTA, DiaRoot Bioaggregate, and Harvard MTA.[302] Additional compounds are currently undergoing clinical investigations to establish their safety and efficacy.[219,278,302,378]

The main components of MTA and the new CSCs are tricalcium silicate and dicalcium silicate, the major components of Portland cement. Hydraulic tricalcium silicates promote reparative barrier formation by the upregulation of transcription factors after gaining immediate strength on hydration. The cements also encourage hydroxyapatite crystal formation on the cement surface when in contact with calcium- and phosphate-containing fluids.[155,179] Moreover, the release of CH from CSCs during hydration has a positive effect on cell regeneration. Osteoblasts, cementoblasts, periodontal ligament cells, and pulp cells are deposited directly on the CSC surface, as the material is recognized as “non-foreign,” which affirms the high biocompatibility of these cements.[378]

In addition to CH, silicon is released during CSC cement hardening. The exact function of silicon in the metabolic processes of hard tissue formation is unclear, but it is believed to play a role in the early stages of mineralization.[80] It is also known that silicon positively influences the rate of

Telegram: @dental_k

www.konkur.in

new hard tissue deposition when it is released from bioactive materials such as MTA.[304] In addition, silicon can remineralize demineralized dentin in vitro and this has also been demonstrated for CSCs.[28,304,327] It can be concluded that the release of silicon from calcium silicate-containing materials contributes to the induction of mineralized tissue formation.[179]

BioAggregate is a bioinductive tricalcium cement that can induce mineralization in osteoblast cells by increasing levels of osteocalcin, collagen type 1, and osteopontin gene expression.[412] Hydration of the cement results in the formation of calcium silicate hydrate and CH, showing high concentrations of silica and calcium phosphate.[166] This characteristic is consistent with materials used in vital pulp therapy to promote hard tissue formation. Investigations using x-ray diffraction show the material to have a composition similar to that of MTA, but BioAggregate contains tantalum rather than bismuth oxide for radiopacity.[303] It demonstrates remarkable biocompatibility compared to MTA, inducing cell differentiation in both human periodontal ligament and gingival fibroblasts.[361,405] Both fresh and set mixtures of MTA and BioAggregate have shown antimicrobial properties effective against *Enterococcus faecalis* in vitro when combined with equal amounts of human dentin powder.[414] The material also shows a greater resistance to dislodgement in an acidic environment compared to MTA, and higher fracture resistance when used as a filling material.[182,383]

Biodentine is a tricalcium silicate–based cement that also demonstrates exceptional bioactive properties.[2] Whereas MTA is more or less comparable to a refined Portland cement, Biodentine consists mainly of pure tricalcium silicate (about 80%) with calcium carbonate as filler (about 15%).[47,109] Zirconium oxide is added as radiopacifier (about 5%). In contrast to other CSCs and MTA, Biodentine does not contain dicalcium silicate or metal oxides except the radiopacifier.[72,341] The liquid consists of calcium chloride in an aqueous solution with an admixture of modified polycarboxylate. The powder is mixed in a triturator with the liquid in a capsule. Once mixed, Biodentine sets in about 15 minutes minimum, and hardens completely in 85 minutes.[217]

Biodentine does not induce genotoxic or cytotoxic effects when measured with the Ames mutagenicity test. It is considered a biocompatible dentin

Telegram: @dental_k

www.konkur.in

replacement material for use under restorative materials as a base.[232] During setting, Biodentine releases calcium ions forming CH that lead to an alkaline pH in the surrounding tissues, inhibiting the growth of microorganisms.[48,70] Furthermore, when Biodentine is applied onto pulp cells ex vivo, TGF-β1 is released.[231,250] In vitro Biodentine induces proliferation, migration, and differentiation of human dental pulp cells and induces cell proliferation in osteoblasts and periodontal ligament cells.[17,209,232,307]

These factors may explain hard tissue formation after DPC with Biodentine.[2] The material stimulates biomineralization and encourages hard tissue formation when used as a capping material.[343,413] Histological evaluation in humans revealed complete mineralized tissue formation 6 weeks after DPC with mild to absent pulp inflammatory reactions, comparable to MTA.[295,297] Biodentine forms needle-like crystals resembling apatite at the dentin interface.[120] Identically to MTA, Biodentine seals dentin by micromechanical retention with a shear bond strength comparable to GICs.[29,216] Different light-curing adhesive lining materials are able to bond to Biodentine and may prevent bacterial leakage.[2,333] After indirect capping with Biodentine, a reversible pulpitis can reproducibly heal.[182] Success rates of human DPC with Biodentine are between 82.6% and 86% after 1.5 to 2.3 years and thus in the range given for ProRoot MTA (Figs. 24.10 and 24.11).[181,193,206,226,244,248,260]

Another promising material for vital pulp therapy is MTA-Angelus, which has a basic formulation of 25% bismuth oxide and 75% Portland cement. The composition eliminates calcium sulfate, providing a short setting time of 15 minutes, preferable for pulp capping or pulpotomy procedures.[57] Variations in bismuth oxide and the presence of iron characterize the chemical composition of MTA-Angelus, and the crystalline structures formed on hydration are similar to gray and white ProRoot MTA.[355] These materials have been compared experimentally as pulp capping agents in intact, caries-free human teeth. Histomorphologic examination of the extracted teeth revealed similar inflammation and hard tissue formation responses.[4] MTA-Angelus also demonstrates antifungal properties and a lower compressive strength than ProRoot MTA.[41,212,219] Many CSC materials demonstrate acceptable antibacterial products; however, *E. faecalis* has shown resistance to some cements when measured with disc diffusion tests.[219]

EndoSequence BC root repair material shows low cytotoxicity, antibacterial activity against *Enterococcus faecalis*, and potential as a pulp capping material.[105,416] Another material, calcium-enriched mixture (CEM) cement, has also demonstrated excellent physical and biologic properties in vital pulp therapy investigations.[20–24,26,294] The advantages of these calcium silicate materials over the typically used CH products lie in the higher mechanical strength, lower solubility, and tighter sealing to dentine. Major disadvantages of CH are avoided when using CSCs: dissolution of the capping material as well as the mechanical instability and consequent lack of long-term protection against bacterial microleakage.[108] The new generation of CSCs appear promising when used as vital pulp therapeutic agents, and current investigations appear to support their future potential and expanded use in vital pulp therapy.

Calcium silicate cement applications in vital pulp therapy

Direct pulp capping with calcium silicate cements

Controlled prospective investigations on DPC in humans using MTA and other CSCs against cariously exposed pulps are limited but expanding. Collectively, most studies are inconsistent with regard to case selection, treatment strategies, and clinical protocols.[268] The spectrum of outcomes reflects the absence of standardized guidelines for caries removal, hemostatic agents, choice and placement of the capping material, and single- versus two-visit delivery sequences. With the advent of quicker setting CSC formulations, indications for two-visit pulp capping are declining in favor of one-visit procedures. Moreover, although the concept of DPC in a carious field is gaining universal acceptance using MTA and other CSCs, clinical recommendations for avoiding and treating pulp exposures in permanent teeth as an accepted management strategy persist, despite contrary evidence.[129,316] Current international guidelines are variable because the research and technological advances within the field are moving exponentially without a universal consensus.

Human studies using CSCs other than MTA are showing the mutual biocompatibility of new bioceramic materials, indicating that conjointly, the cements exhibit similar properties and cellular responses when exposed to vital pulp tissues. Comparable outcomes are evident when pulp capped teeth are examined for mineralized tissue barrier formation, lack of inflammatory cells, and continued vitality in DPC.[31,62,181,185,206,211,214,219,243,301] Analysis has shown that initial pulp capping treatment is also cost-effective compared to root canal treatment in younger patients with pulp exposures due to caries.[63]

Current and past investigations comparing newer CSC formulations have shown clinical and radiographic success in permanent teeth treated with carious exposures ranging from 83.4% to 100% at 1 to 7.4 years.[31,62,181,185,214,243,244,301] In a larger study using Biodentine as a DPC agent, 245 teeth recalled with an average recall period of 2.3 years showed continued vitality in 86% of the cases. In one study where Biodentine was compared against MTA in a split mouth model or randomly allocated in different patients, outcomes at recall periods of 18 to 36 months were comparable for both materials when examined in permanent mature teeth with carious exposures.[214] Impressive results have also been demonstrated in

Telegram: @dental_k

www.konkur.in

several other contemporary studies.[3,6,238,258] An investigation examined 30 immature permanent teeth exhibiting wide-open apices directly pulp capped with MTA and restored temporarily with intermediate restorative material (IRM).[138] Definitive permanent composite restorations were placed 2 weeks later, after confirmation of pulp vitality. In these cariously exposed immature permanent teeth, the success rate at a 2-year review was 93%.

One notable factor revealed in a recent study with a broad sample size was that treatment outcomes were negatively influenced when restored with a GIC compared to all other restorative materials.[181] The outcome is a likely indicator that GIC should not be considered as a definitive restoration in DPC cases.[181] The outcomes of these current studies strongly suggest that MTA and introduction of new CSC capping agents show capable biocompatibility and sealing properties and can make the outcome of DPC techniques in mature permanent teeth with carious exposures increasingly reliable.

Another observational investigation examined DPC of carious exposures of mature and immature permanent teeth using slow-set MTA in a two-visit sequence.[56] Forty-nine teeth were examined in patients aged 7 to 45 years over a 1- to 9-year period, with an average 3.94-year observation time. The study protocol used detector dye-aided caries excavation using the DOM, 5.25% to 6% NaOCl hemostasis, bulk MTA placement on pulp exposures, and surrounding dentin, coupled with bonded composite restorations placed at a second visit to compensate for the delayed setting properties of ProRoot MTA. Based on subjective symptomology, cold testing, and radiographic evaluation, 97.96% of teeth showed continued vitality. All patients with immature apices showed continued root formation and apical closure within a 1- to 6-year period (Fig. 24.12).

Telegram: @dental_k

www.konkur.in

A related DPC investigation using a two-step protocol in permanent teeth using MTA with bonded restorations with slight variations in procedural execution registered similar outcomes. Sixty-four teeth recalled after 3.6 years showed an overall success rate of 91.3%. The success in patients older than 40 years of age was 80% and for those younger than 40 years was 100%.[248] In a corresponding study, 33 patients with DPC after carious exposures and provisionalized for 1 week (two-visit protocol) showed a 85% success rate at 3 years.[226] The same study also compared outcomes with patients that received direct CH capping and demonstrated a survival rate of 52% at 3 years. The majority of human studies that compare MTA/CSC direct capping in permanent teeth with CH suggest MTA/CSCs offer more predictable long-term benefits.[78,226,239] Moreover, larger scale pulp capping studies comparing MTA/CSCs with CH corroborate previous data that demonstrate superior results when MTA/CSCs are applied in a clinical setting (Figs. 24.13 and 24.14).[66,193,238,260]

The unique physicochemical properties of MTA and CSC also promote a superior environment for pulpal repair and bridge formation, compared to CH products.[193,238,260,286] MTA and CSC are hygroscopic cements that set in the presence of blood and serum, produce a gap-free interface with dentin, and generate a sustained alkaline pH; in addition, the surface morphology of the hardened cement allows for predictable bonding with current adhesion systems. Growth factors necessary for hard tissue formation are activated by CSCs through the gradual release of calcium ions during curing.[222] The small particle size and alkaline pH contribute to the entombment of remaining cariogenic bacteria at the dentin-MTA and CSC interface, impeding bacterial ingression and caries progression and discouraging continued pulpal injury (Fig. 24.15).[288,409,414]

Pulpotomy with calcium silicate cements

It has been recommended that pulpectomy be avoided in immature permanent teeth with vital canal tissue so as to protect the remaining radicular pulp tissue and thus encourage continued root development and apexogenesis.[140,335] Partial pulpotomy to treat direct pulp exposures in immature permanent teeth using CH products has been shown to be a reliable treatment option with proper case selection.[73,335] However, comparable success rates ranging from 83% to 100% have been demonstrated using CSCs for pulpotomies in both immature and mature permanent teeth.[23,25,39,242,313,361–363,398,399] Moreover, pulpotomies completed with MTA/CSCs do not show complications such as internal resorption, typically seen with CH, formocresol, and ferric sulfate pulpotomies (Fig. 24.16).[126,195,324]

Adult pulpotomy using CSCs is a promising treatment strategy of considerable interest. More important is the inclusion of symptomatic teeth in clinical investigations that exhibit irreversible pulpitis and show apical radiolucencies consistent with advanced pulp inflammation or partial pulp necrosis.[23,25,39,242,313,361–363,398,399] The potential for resolution of apical disease in teeth with inflamed pulps displaying apical rarefaction after pulpotomy procedures has been previously documented.[66,208] One multicentered randomized controlled trial complemented by an earlier study evaluated randomly allocated MTA and CEM adult pulpotomies at 2 and 5 years. The clinical outcomes for both materials were ≥98%, showing equal effectiveness for both CSCs in permanent molars associated with irreversible

Telegram: @dental_k

www.konkur.in

pulpitis and apical periodontitis.[22,24] Another investigation by the same group examined pulpotomy outcomes for CEM measured against conventional orthograde root canal therapy in mature molars diagnosed with irreversible pulpitis. It demonstrated comparable outcomes in pain reduction and the resolution of apical periodontitis, with continued tooth function and survival after 5 years (Fig. 24.17).[23] Both studies showed postoperative pain reduction and the resolution of apical pathosis in the majority of cases. Other investigations have confirmed significant pain reduction in symptomatic permanent teeth with deep caries using CSC pulpotomy.[152,361] Concurrent studies corroborate findings that pulpotomy treatments performed in mature permanent teeth with irreversible pulpitis and advanced caries using CSCs are a viable future treatment alternative.[22,23,25,242,361–363]

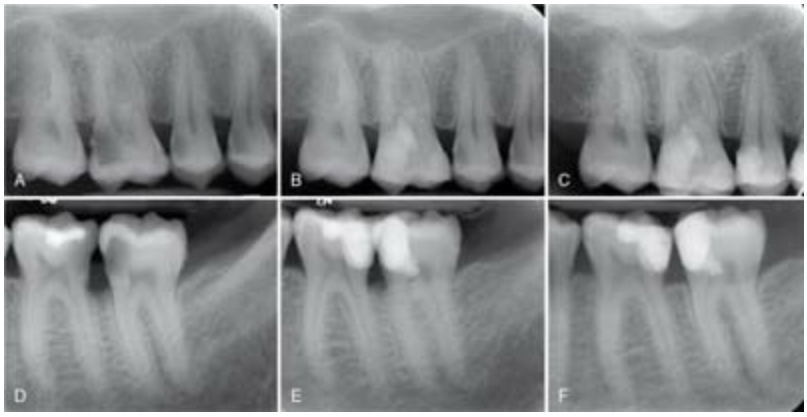

FIG. 24.17 Pulpotomy procedures completed for two patients clinically diagnosed with irreversible pulpitis using calcium enriched mixture (CEM) cement (BioniqueDent, Tehran, Iran). **A,** Preoperative radiograph from 27-year-old male patient with deep caries associated with maxillary right quadrant. The first molar was symptomatic with calcified tissue evident in the pulp chamber. **B,** Radiograph after complete pulpotomy using CEM cement restored with bonded composite. **C,** Five-year radiographic recall. The tooth was asymptomatic, firm, with normal probings. **D,** Preoperative radiograph showing deep caries in the mandibular left first (#19) and second (#18) molars in a 41-year-old male patient. Both teeth demonstrated lingering pain to cold testing and tooth #18 was sensitive to percussion. **E,** Postoperative radiograph showing completed miniature pulpotomy #19 and partial pulpotomy #18 after sodium hypochlorite hemostasis and application of CEM cement. Both molars were restored with bonded composites. Tooth #18 demonstrated resolution of symptoms after 24 hours. **F,** Six-year radiographic recall, patient remained asymptomatic

Indications for pulpotomy have recently transitioned from immature to mature teeth using CSCs, which may improve consumer acceptance and retention rates for patients seeking alternatives to conventional root canal therapy and protective ancillary care. Teeth that present with irreversible pulpitis and experience carious pulp exposures are normally treated with pulpectomy and orthograde root canal treatment coupled with restorative procedures designed to protect the tooth from fracture and microleakage. However, issues with cost effectiveness, holistic concerns, pain management, treatment time, and need for additional appointments when compared to orthograde root canal therapy are strong arguments in favor of this newer treatment option. Pulpotomy in permanent teeth using CSC materials can be recommended as a minimally invasive alternative to traditional root canal treatment.

Vital pulp therapy techniques

Diagnosis

A differential diagnosis based on clinical symptoms and radiographic findings is the aim in assessing pulp vitality. However, an accurate determination of the pulpal condition before treatment initiation is more challenging in younger patients.[356] Establishing a diagnosis of reversible versus irreversible pulpitis in immature teeth can be complicated by subjective symptoms and testing responses that may not accurately reflect pulp histopathology.[73] However, efforts should be directed toward the ultimate goal of pulpal preservation and continued apexogenesis in immature permanent teeth.[53,54] A diagnosis of irreversible pulpitis, based on signs and symptoms, along with clinical testing procedures, does not preclude vital pulp therapy options. Regardless of the treatment choice of pulp capping or partial or complete pulpotomy, preservation of the radicular pulp and apical

Telegram: @dental_k

www.konkur.in

papilla allows for root maturation in cases of trauma or deep caries.[146,147,169,342]

Diagnostic quality intraoral radiographs of the involved tooth must be taken to evaluate accurately the extent of root formation and periradicular or furcation changes associated with the periodontal ligament and supporting bone.[256] In young permanent teeth, the stage of root development directly influences the diagnosis and treatment options.[74] Because the faciolingual dimension of most immature roots is greater than the mesiodistal dimension, apical closure may be difficult to determine radiographically.[74,221] Teeth that demonstrate radiographic evidence of deep caries should not be planned for aggressive procedures, such as pulpectomy, without the benefit of thermal (cold) testing (see Fig. 24.1).

Before arriving at treatment decisions, the clinician should carefully assess all available information; the medical history, patient report, radiographic evidence, clinical evaluation, and vitality (cold) testing are recommended. Periodontal probing, mobility assessment, and the presence of any localized swelling or sinus tracts should be recorded during the evaluation. Radiographs, including bitewings and periapical views, should be evaluated for periapical and furcation pathosis, resorptive defects, and pulpal calcification resulting from trauma or previous restorations.

Patients with deep carious lesions often experience sensitivity to cold, heat, or sweet or acidic foods, and cold tests may evoke a short lingering response of 1 to 2 seconds. This may not be a definitive indicator that the pulp is irreversibly damaged. Determination of the pulpal condition with the aid of contemporary testing methods can be challenging, even for experienced clinicians, because of possible excessive responses to pulp percussion and palpation testing in children.[148,213,396] Clinical evidence indicates that cold testing with carbon dioxide ice is a more reliable prognosticator of pulp status in immature permanent teeth than electronic testing devices.[54] However, a diagnosis of irreversible pulpitis or pulp necrosis should be considered for teeth that generate pain on percussion.

Clinically, the difference between reversible and irreversible pulpitis is often determined on the basis of the duration and intensity of pain.[147] Unprovoked, spontaneous pain of long duration or unrelenting symptoms forcing sleep deprivation are consistent with irreversible pulp inflammation

Telegram: @dental_k

www.konkur.in

or an acute periapical abscess.[50] The difficulty in predictably assessing pulpal health and potential degrees of inflammation has been recently addressed in an attempt to improve current terminology that may not accurately reflect pulp conditions during the inflammatory process.[401] It has been proposed that the terms *initial*, *mild*, *moderate*, and *severe pulpitis* be used to replace current terminology for reversible and irreversible pulpitis, better reflecting conditions encountered in the clinical setting. The recategorization of stages of pulpal inflammation attempts to better direct minimally invasive treatment selections using CSCs and is designed to improve outcomes for pulp tissue preservation. However, these assessments can be more complicated than previously proposed, as diagnosed pulp conditions are not always consistent with clinical findings during treatment.[321,401]

Another consideration in a patient with displacement trauma is transient apical breakdown, which mimics periapical radiolucencies.[16] Teeth that experience luxation-type injuries can discolor and may not respond to cold testing for up to 4 months before they recover normal color and vitality. Also, biologically or pharmacokinetically immunosuppressed patients may not respond to conventional treatments because of abnormal function of related repair mechanisms.[245,389] Most clinical investigations clearly indicate that successful outcomes for vital pulp therapy decrease as the patient's age increases. Although aging of the pulp diminishes pulpal volume, vascularity, and host immune responses, functional repair mechanisms can still provide favorable treatment outcomes in older patients (Fig. 24.18).[1,270]

The initial pulpal diagnosis can be confirmed after visualization of the exposed pulp and assessed during tissue hemostasis. If no hemorrhaging is seen, this area of the tissue is most likely necrotic and must be removed with a high-speed round diamond bur until bleeding is evident (Fig. 24.19). After hemostasis with NaOCl, a large bulk of CSC can be placed directly against the remaining tissue. Alternatively, if hemorrhage control cannot be achieved after 5 to 10 minutes of direct contact with 3% to 6% NaOCl, the pulp is likely to be irreversibly involved, and a full pulpotomy or pulpectomy is recommended.

Although the size of the pulp exposure has no significant bearing on the final outcome, some clinicians falsely assume that larger exposures have an unfavorable prognosis.[252] Pulp sizes are underestimated on radiographs.[82–84] The size of the pulp exposures may also be overestimated, which could affect the decision-making process, leading clinicians to abandon more conservative vital pulp treatment options.[163] Pulp dimensions may also vary between various racial groups and genders.[83,346,392]

Teeth that have a history of trauma or previous restorations or that display pulpal calcification have a poorer prognosis than teeth showing only initial caries. In the selection of a specific vital pulp treatment, it is important to consider the remaining tooth structure and future restorative plan. In patients with uncontrolled caries or extensive loss of coronal structure in which full coverage is indicated, pulpotomy rather than pulp capping is recommended.[60,73,373]

Caries removal

The main objective in caries removal is the identification and complete removal of infected tissue while preserving sound tooth structure; this contributes to pulpal protection and continued vitality. Caries removal is enhanced with the aid of a caries detector dye and optical magnification; however, it must be understood that dyes can cause excessive and unnecessary removal of healthy tooth structure.[37,255,408]

Caries removal has traditionally been completed somewhat subjectively using hand instruments and slow-speed burs. The procedure is performed using an explorer and tactile sense to differentiate soft from hard dentin to determine infected from noninfected dental tissue. However, this method has shortcomings because clinicians may leave decay at the dentinoenamel junction and unnecessarily remove dentin that has the potential to remineralize under a sealed restoration.[149] Furthermore, it has been found that the ability to remove caries varies among operators and during different time periods for the same operator.[149,150]

Investigators in the early 1970s used SEM to identify two different layers of carious dentin.[150] Teeth show two layers as the result of gram-positive bacteria releasing lactic acid as their main by-product. The outside carious layer subjacent to the enamel-dentin junction exhibited demineralized hydroxyapatite crystals that were dissolved by acidic bacterial by-products; this layer also featured unbound and altered collagen denatured by microbial proteolytic enzymes.[312] The second demineralized carious layer proximal to the pulp featured degraded hydroxyapatite crystals but contained collagen with intact intermolecular cross links unaffected by cariogenic acids.[149,150,331] If this deeper layer can be preserved during caries excavation, the remaining pulp tissue and odontoblasts will be subjected to less trauma, contributing to pulpal protection and survival. [282,326] This layer has a stronger capacity to remineralize when paired with bonded composite restorations to prevent bacterial microleakage.[269,282]

The two carious layers have been further classified into four zones when analyzed by atomic force microscopy and transverse digital microradiography.[312] Consistent with previous investigations, the four zones reinforce the concept that increasing levels of demineralization decrease the

Telegram: @dental_k

www.konkur.in

peritubular dentin rating and mechanical properties of dentin.[312]

Investigations in human, dog, and nonhuman primate models have demonstrated this regenerative characteristic in caries-affected dentin.[208,215,269,370,371] Several studies have questioned the efficacy of caries removal using a caries detector dye. Not all stainable dentin can be classified as infected, and the absence of staining does not eliminate the potential for residual cariogenic bacteria.[218,312] However, dyes allow the operator to visually inspect, with the aid of the DOM, infected dentin that may have been overlooked, particularly at the dentinoenamel junction, where it may compromise treatment outcome.[218,407] Although a compromise, it may be clinically preferable to inadvertently remove a small excess of dentin than to leave infected tissue.

Hemostatic agents

A wide range of hemostatic solutions and methods have been recommended to control a bleeding pulp exposure. These include various concentrations of NaOCl; 2% CHX; MTAD (Tulsa/Dentsply, Tulsa, OK); 30% hydrogen peroxide (Superoxol); ferric sulfate; disinfectants, such as Tubulicid (Global Dental Products, North Bellmore, NY); epinephrine; direct pressure with cotton pellets soaked in sterile water or saline; and the use of lasers.[8] NaOCl in concentrations of 1.5% to 5.25% is currently regarded as the most effective, safe, and inexpensive hemostatic solution for pulp capping and partial and complete pulpotomy procedures.[174,397] First used as a wound antiseptic during World War I and referred to as Dakin's solution, it was soon introduced for root canal irrigation.[100,104] NaOCl became a valuable hemostatic agent for direct pulp exposures in the late 1950s.[173,194,360] The antimicrobial solution provides hemostasis and disinfection of the dentin-pulp interface, chemical amputation of the blood clot and fibrin, biofilm removal, clearance of dentinal chips, and removal of damaged cells at the mechanical exposure site.[39,126,173,249] Concentrations of 1.5% to 5.25% in direct contact with pulp tissue do not appear to adversely alter pulp cell recruitment, cytodifferentiation, and hard tissue deposition.[121] Rinsing the exposed pulp tissue for 15 minutes with 5 mL NaOCl 5.25% (Clorox) leads to dissolution effects, but these effects are limited to the 3 to 5 upper cell

Telegram: @dental_k

www.konkur.in

layers without any changes in deeper pulp areas or the dentin. Perfused vital pulp tissue also buffers the chemical activity of NaOCl.[325]

An investigation into pulp-capped human third molars treated with either CH or a self-etching adhesive system examined pulps histologically at 30 and 60 days after the use of 2.5% NaOCl for hemostasis.[133] Histologic evidence demonstrated no impairment of the repair process after the use of NaOCl, although CH appeared to outperform the resin-based pulp capping agent. Current data clearly support the use of 1.25% to 5.25% NaOCl solutions in humans as a safe and appropriate hemostatic agent for DPC and pulpotomies.[5,34,121,133,173,192,252,384,388,397]

When pulp exposures occur in a carious field, the ability to attain hemostasis remains the most crucial factor in the success of vital pulp therapy. This was demonstrated in an innovative study that examined outcomes of teeth directly pulp capped with a hard setting CH after exposures were generated during caries excavation.[252] Caries removal during the investigation was aided by a caries detector dye with 10% NaOCl for hemostasis. The 2-year success rate was 81.8%. A statistical analysis of key factors revealed that preoperative thermal responses, percussion sensitivity, the diameter of the exposure, the age of the patient, and the tooth type and location had no significant influence on the outcome. The degree of bleeding and its control at the time of exposure constituted the most critical predictor of outcome. When hemostasis can be attained, pulpal repair and reparative dentin formation can proceed normally, in the absence of microbial challenges, when MTA and other CSCs are used as the pulp dressing.[87,210]

Sodium hypochlorite is an effective hemostatic agent and a valuable tool for assessing the difference between irreversibly and reversibly inflamed pulps as continued hemorrhaging after a 10-minute exposure strongly indicates irreversible pulpitis (Fig. 24.20).

Treatment considerations

An important and often unrecognized aspect of DPC in a carious field is the potential survival of undetected bacteria in tubules adjacent to the exposure site even after caries removal. These microorganisms can compromise treatment even after meticulous excavation and disinfection. Unfortunately, traditional pulp capping protocols have directed clinicians to place pulp dressings only at the exposure site, without considering the adjacent dentin. It is therefore recommended that CSCs be placed over the exposure sites and onto the surrounding dentin to entomb residual microorganisms (see Fig. 24.15).[409,410]

The concept of biomineralization and bacterial entombment is particularly important when caries removal protocols are ineffective at completely removing undetected acidogenic microorganisms. During the CSC hydration process, calcium-deficient crystalline formation within the dentinal tubules produces bacterial entrapment, entombment, and neutralization.[409,414] This notable change in pulp capping strategy, based on CSC crystallization properties, can improve treatment outcomes in symptomatic and asymptomatic teeth featuring extensive caries. This includes cavities with multiple exposures after caries excavation or partial and complete pulptomies when indicated.[54] Together with an extensive bulk application of MTA/CSC to provide a cement thickness of 1.5 mm or greater, there is an increased likelihood of bacterial neutralization, minimizing further microbial challenges.

A disadvantage of CSCs is their long setting time of up to 228 minutes for ProRoot MTA and up to 85 minutes for Biodentine.[217] Thus according to the manufacturers' recommendation, CSCs should be allowed to set for a 15-minute minimum (e.g., Biodentine) or 2.5 hours (ProRoot MTA) before a permanent restoration can be placed. Nevertheless, in clinical use waiting even 15 minutes for set can lead to complications. To overcome these clinical drawbacks and to bypass the long setting time, it has been suggested to cover the MTA or CSC with an RMGI, compomer, or flowable composite resin.

Telegram: @dental_k

www.konkur.in

The final restoration is then placed allowing the cement to set beneath the interlayer.[53,75]

Recently it was shown that 3 minutes after mixing MTA or Biodentine, it may be covered with a thin layer of a self-etching, self-bonding flowable composite resin (Vertise flow), an RGMI, or composite resin in combination with a self-etching dentin adhesive. All these restorative materials achieved shear bond strengths to Biodentine or MTA that were similar to those after 15 minutes and 2 days. A longer waiting time after mixing did not increase the adhesion of the lining materials to MTA or Biodentine.[333] Furthermore, the results of previous studies indicated that when placing RMGI on these cements, the time span between the mixing of CSCs and the application of RMGI did not influence the setting reaction of the cement. The moisture of the CSC had no impact on the setting reaction or setting time of RMGI or on the MTA-RMGI structural interface.[35,131,287] A final permanent restoration can therefore be provided at the same appointment.

Treatment recommendations†

Pulp capping and pulpotomy

1. After profound local anesthesia is achieved, the clinical crown is disinfected with NaOCl or CHX after dental dam isolation. Optical magnification and illumination (ideally with a DOM) are highly recommended. The cavity outline is completed using high-speed burs under constant water cooling.
2. Caries excavation is completed using long shank #2-6 round burs in a slow-speed handpiece augmented by hand instrumentation. Removal of caries may be guided by a detector dye if a DOM is used.
3. The cavity and exposure site(s) are immersed with 1.5% to 5.25% NaOCl. Heavy bleeding may be controlled with a cotton pellet moistened with NaOCl under moderate pressure for 5 minutes. If no bleeding is present after the pulp exposure, the area must be examined for necrotic tissue. This is removed with a high-speed round diamond bur under water coolant until bleeding tissue is exposed. Uncontrolled hemorrhaging after 10 minutes can be

Telegram: @dental_k

www.konkur.in

managed with a full pulpotomy or pulpectomy after assessing the radicular tissue condition. It is CRITICAL that all necrotic tissue is removed (see Fig. 24.19).

4. Prepare MTA or CSC according to the manufacturers' instructions.
5. Using a suitable instrument (composite instrument, Glick #1 endodontic instrument, or MTA carrier gun), apply a large bulk of CSC over the exposure side, including most of the surrounding dentin at a thickness of 1.5 to 3 mm.
6. Remove excess moisture at the site with a dry cotton pellet and leave a clear periphery of dentin for adhesive bonding. A total etch and rinse technique with a phosphoric acid gel is not possible at this stage because the MTA or CSC can be washed away. Either the CSC must show a firm set or a flowable composite/RMGI material must been accurately placed and completely cover the cement.
7. Apply a small amount of a light-curing flowable compomer, an RMGI (or an equivalent light-cured resin–glass ionomer liner), a self-etching, self-bonding flowable composite resin or a flowable composite resin in combination with a self-etching dentin adhesive to cover the CSC and light-cure according to the material's instructions. NOTE: Placement of flowable resins can be more challenging in cases of DPC than indirect pulp capping and pulpotomy procedures.
8. Etch the remaining cavity walls with 34% to 37% phosphoric acid gel for 60 seconds, rinse thoroughly and apply a dentin adhesive (fourth generation, two-bottle systems are highly recommended). Avoid using self-etching dentin adhesives (single-bottle systems).[290] Cure according to manufacturers' instructions.
9. Place a composite resin material incrementally as a permanent, final restoration. Light-cure according to manufacturer's instructions.
10. Pulp vitality should be assessed at the next appointment, preferably at 7 to 10 days using a cold test. Radiographic assessment is only needed in case of negative sensibility testing or onset of pain during the first year. Assessments can be made yearly or every 2 years, if indicated.

The permanent restoration

Telegram: @dental_k

www.konkur.in

A definitive restoration should be provided during the pulp treatment appointment. Temporary restorations over MTA or CSC may lead to significantly lower success rates.[181,260] It has been reported that teeth which were permanently restored more than 2 days after DPC with MTA exhibited a diminished prognosis.[260] The negative impact of the time between DPC and placement of the permanent restoration was also shown for Biodentine and CH.[110,181] However, if the permanent restoration cannot be placed at the time of definitive pulp treatment due to management concerns, nonbonded translucent core materials such as Photocore (Kuraray Co. Ltd., Osaka, Japan) can provide acceptable protection for extended periods when used in conjunction with CSCs.[39]

The placement and quality of the permanent restoration can be crucial to the long-term maintenance of pulp vitality and may be more significant than the actual pulp treatment.[12,142,188,257,264] The aim of the final restoration is to complement the sealing ability of the pulp capping/pulpotomy material and defend the pulp from further microbial challenges. The selection of the restorative material, procedure execution, and adherence to proper restorative protocols can all contribute to minimizing potential restorative microleakage. Microleakage around restorations may be more detrimental to vital pulp tissue than unfilled cavity preparations directly exposed to the oral environment.[330] An important consideration in both mature and immature permanent teeth is the conservation of the remaining tooth structure, which ultimately contributes to favorable long-term retention and function.[93,122,199,351] The incorporation of adhesive restorative materials as definitive final restorations minimizes tooth reduction, encourages anatomic preservation, and thus provides better pulpal protection and repair potential.[149,172]

Advances in dental materials have increased treatment options in the restoration of teeth that have undergone vital pulp procedures. Permanent restorations for pulp capped or pulpotomized permanent teeth can include composite resins, bonded or unbonded amalgam restorations, and cuspal coverage restorations. However, the more conservative the restorative treatment, the greater the probability of pulp survival.[149] Vital pulp therapy must be considered an injury to an already challenged connective tissue, and every effort should be directed toward minimizing further injurious

Telegram: @dental_k

www.konkur.in

procedures.[1] Factors that affect the repair mechanisms in pulp tissue can include the age of the patient, the depth and size of the cavity preparation, and the choice of restorative material.[283]

Total etch and self-etching systems produce excellent bond strengths to enamel, dentin, and cured CSCs.[27,288] The most durable bond strengths generated with contemporary materials are achieved using selective etching of the enamel with 34% to 37% phosphoric acid, followed by two-step, two-bottle, self-etching adhesive systems.[79,291,387] Current advances in adhesive technology have also shown that beneath the resin-interfused hybrid layer, an acid-base–resistant zone is formed that enhances the resistance of normal dentin to recurrent caries. This reinforced layer forms when monomer penetration and polymerization occur, and it demonstrates an ability to restrict (inhibit) primary and secondary caries.[290,291] As a result of their simplifications and improved bonding strengths, modern adhesives complement vital pulp therapy. Bonding procedures must strictly follow manufacturers' recommendations and be paired with dental dam placement.[79]

Postoperative follow-up and recall

After treatment completion, the pulp status must be assessed periodically to ensure continued pulp vitality, normal function, and apical closure in immature teeth. Cold testing and radiographic evaluation most accurately assess continued pulp health and are excellent predicators for measuring survival rates. Recalls can address postoperative sensitivity, pulpal degeneration or necrosis, and indications for further endodontic and restorative care. Review also allows detection of emerging complications such as recurrent caries, poor hygiene, restoration failures, and cuspal fractures.

Patient compliance for recall in asymptomatic cases can be challenging. Because some parents do not practice regular preventive care and may not have a strong background in basic oral health care, recall compliance rates for children can be unpredictable.[205,311] Although recall has been traditionally based on a 6-month checkup and oral prophylaxis period, this has come into question.[265] Recalls can be tailored individually, based on patient need, symptomology, caries indices, periodontal status, and craniofacial

Telegram: @dental_k

www.konkur.in

development assessment in younger patients.[292,391]

A tentative diagnosis of tooth survivability can be made at the 3-month recall.[252] One study demonstrated that the prognosis for long-term pulp survival can be established at an observation period of 21 to 24 months.[252]

Radiographic evidence of root-end closure in immature adult teeth is a reliable prognostic marker of continued pulp vitality (Fig. 24.21).[36] Apexogenesis after DPC or pulpotomy procedures using CSCs should proceed normally in healthy patients at a progressive rate.[39,305,394,400] The observed root maturation should also follow a predictable pattern of tooth development that coincides with the contralateral teeth in the same patient when the teeth are compared radiographically and viewed chronologically.[36]

FIG. 24.21 An 8-year-old male presented following a traumatic injury to the maxillary left central incisor 2 months earlier. **A,** Periapical radiograph revealed an open apex with a developing radiolucency. The tooth was sensitive to palpation, percussion and negative to cold testing. The diagnosis was necrotic pulp and acute apical periodontitis. **B,** Clinical photograph after access cavity preparation, vital pulp tissue visible coronally. Observation of contralateral tooth development can be an invaluable method of measuring the success of vital pulp therapy when using CSCs. Alternatively by comparison, in traumatized teeth that exhibit necrotic pulps and periradicular pathosis, CSCs can be used as an apical plug to stimulate the apical papilla to promote barrier formation, which may require 5 to 20 months for completion (apexification).[7,90,344] If MTA or another CSC is substituted for CH in vital pulp therapy procedures or apexification, similar time periods for apical maturation or barrier formation can be anticipated (Fig. 24.22).[132,259 261]

FIG. 24.22 **A,** Preoperative radiograph of a 7-year-old male patient exhibiting a dens evaginatus anatomical anomaly associated with the maxillary right lateral incisor. The parents had been advised to extract

the tooth, which was symptomatic and nonresponsive to vitality tests. **B,** A periapical radiograph after cleaning the coronal portion of the canal and irrigation with 2.12% sodium hypochlorite. A coronal plug using ProRoot MTA (Tulsa/Dentsply, Tulsa, OK) was placed and sealed with a provisional restoration. **C,** Four-year radiographic review demonstrates complete root formation with maturation and apical root closure. The tooth was asymptomatic with normal mobility and probings.

Three radiographs are marked A through C.

A) Three teeth are shown with wide open root canals.

B) The central tooth with improper half-filled root canal. The root canal is wide.

C) The central tooth with closed root apex with half-filled root canal.

Source: (Courtesy Dr. Mahmoud Torabinejad.)

In the absence of microbial challenges, the human dental pulp demonstrates an exceptional regenerative capacity when treated with CSCs independent of patient age. Together with our advances in pulp biology and dental materials, changes in treatment protocols that encourage dental pulp preservation and survival will ultimately contribute to improved dental health for all patients requiring vital pulp therapy.

CHAPTER OUTLINE

The interrelationships between pulpal and periodontal disease primarily occur

Telegram: @dental_k

www.konkur.in

by way of the intimate anatomic and vascular connections between the pulp and the periodontium; these interrelationships have been traditionally demonstrated using radiographic, histologic, and clinical criteria. Pulpal and periodontal problems are responsible for more than 50% of tooth loss.[17] Diagnosis is often challenging because these diseases have been primarily studied as separate entities, and each primary disease may mimic clinical characteristics of the other disease. Some studies suggest that these two diseases may have etiologic influences on the progression of the other disorder. Pulp tissue succumbs to degeneration by way of a multitude of insults, such as caries, restorative procedures, chemical and thermal insults, trauma, and periodontal disease. When products from pulp degeneration reach the supporting periodontium, rapid inflammatory responses can ensue that are characterized by bone loss, tooth mobility, and sometimes sinus tract formation. If this occurs in the apical region, a periradicular lesion forms. If this occurs with crestal extension of the inflammation, a retrograde periodontitis or reverse pocket is formed. However, the lesion formed has little anatomic similarity to a periodontally induced defect.

The 2017 World Workshop, jointly held by the American Academy of Periodontology and European Federation of Periodontology, developed an evidence-based classification of periodontal and peri-implant diseases and conditions.[16] The classification of periodontitis has been clarified to include staging, extent, and grading.[62] The staging system indicates whether there is stage 1 (mild disease), stage 2 (moderate disease), stage 3 (severe disease with ≤ four missing teeth), and stage 4 (severe disease with ≥ five missing teeth and complex needs) disease.[62] The pathophysiology of the disease stages is similar and includes a dysbiosis of the plaque biofilm in response to the host response and energizing this response. Independent of the dysbiosis of the biofilm, the loss of connective tissue attachment and the associated bone resorption are attributed to the proinflammatory cytokines, prostaglandins, and matrixmetalloproteinases elicited by the host response.[81] The severity of the staging system also includes the extent of disease presentation from localized (less than 30% of teeth involved), generalized (greater than 30% of teeth involved) to a molar/incisor pattern (previously termed localized aggressive periodontitis).[81] In addition, the new classification system includes grading, which is an indication of the rate of

Telegram: @dental_k

www.konkur.in

disease progression from grade A (slow rate), grade B (moderate rate), to grade C (rapid rate).[62]

Regardless of the staging of periodontitis, endo-periodontal lesions occur at teeth with or without root damage (e.g., fracture, root perforation) and in patients with or without periodontitis.[37] Although there is a lack of evidence indicating a unique pathophysiology between a periodontal lesion and an endo-periodontal lesion, the combined lesion adversely affects the successful management of the involved teeth.[37,62] This chapter discusses the intercommunication between pulpal and periodontal tissues; the effects of pulpal disease on the periodontium; periodontal disease and its effects on the pulp; and the classification, differential diagnosis, and management and prognosis of endodontic and periodontal problems.

Intercommunication between pulpal and periodontal tissue

Several possible channels between the pulp and periodontium that lead to the interaction of the disease process in both tissues have been suggested. These include neural (i.e., reflex) pathways, lateral canals, dentinal tubules, palatogingival grooves, periodontal ligament, alveolar bone, apical foramina, and common vasculolymphatic drainage pathways. The most interconnected and evidenced relationship between the two tissues is by way of the vascular system, as illustrated anatomically by the presence of the apical foramen, lateral (i.e., accessory) canals, and dentinal tubules.[7,19,47,56,71,79] These communications, when they exist, may serve as paths for inflammatory reciprocity.[13,34,47,49,56,69]

The apical foramen is the most direct route of communication to the periodontium, but by no means is it the only location where pulpal and periodontal tissues communicate with each other. Lateral and accessory canals, mainly in the apical area and in the furcation of molars, also connect the dental pulp with the periodontal ligament. Table 25.1 lists the incidence of furcation canals. These have been suggested as a direct pathway between pulp and periodontium and typically contain connective tissue and vessels that connect the circulatory system of the pulp with that of the periodontium. Research has demonstrated that inflammation in the interradicular periodontal

Telegram: @dental_k

www.konkur.in

tissues may develop after the induction of pulpal inflammation.[73,74] Serial sectioning of 74 teeth revealed that 45% of accessory canals were present, primarily in the apical region.[69] More significantly, lateral accessory canals in eight teeth were located more coronally on the roots. Among them, connection of the accessory canals with periodontal pockets was microscopically demonstrable in five of the specimens. Gutmann[34] introduced safranin dye into 102 molar teeth that were placed in a vacuum chamber and found that 28% of the teeth had furcation canals, although only 10% of the total group showed canals on the lateral root surface.

Table 25.1

Incidence of Furcation Canals

Investigators	Techniques	Incidence
Rubach and Mitchell (1965)[69]	Sectioned teeth	45%
Lowman et al. (1973)[56]	Dissecting microscope	Maxillary molars: 59% Mandibular molars: 55%
Burch and Hulen (1974)[13]	Radiopaque dye	Accessory furcal canals: 76%
Vertucci and Williams (1974)[84]	Hematoxylin dye	46%
Kirkham (1975)[45]	Radiopaque dye	23%
Gutmann (1978)[34]	Safranin dye	Maxillary molars: 28.4% Mandibular molars: 27.4%

In addition to the apical foramen and lateral accessory canals, dentinal tubules have been suggested as another common pathway between the periodontium and pulpal tissue. Dentinal tubules contain cytoplasmic extensions or odontoblastic processes that extend from the odontoblasts at the pulpodentin interface to the dentinoenamel junction (DEJ) or the cementodentinal junction (CDJ). It has been reported that the pulp chamber can communicate with the external root surface by way of dentinal tubules, especially when the cementum is denuded.[34,88]

Palatogingival grooves are developmental anomalies of the maxillary incisor teeth; lateral incisors are more often affected than central incisors

Telegram: @dental_k

www.konkur.in

(4.4% vs. 0.28%, respectively).[88] These grooves usually begin in the central fossa, cross the cingulum, and extend apically for varying distances. Generally, the incidence of palatogingival grooves ranges from 1.9% to 8.5%.[27,88] In their study, Everett and Kramer[27] reported that 0.5% of the teeth examined had a palatogingival groove extension to the root apex, thus contributing to an endodontic pathologic condition. Bilateral buccal radicular grooves have also been reported on maxillary incisors.[43]

Perforation of the root creates a communication between the root canal system and the periodontal ligament. This may occur as a result of overinstrumentation during endodontic procedures, internal or external root resorption, or caries invading through the floor of the pulp chamber. The prognosis for teeth with root perforation is usually determined by the location of the perforation, the time left unsealed, the ability to seal the perforation, the chance of building new attachments, and the accessibility of the remaining root canals. Teeth that have perforations in the middle or apical third of the root have the greatest chance of healing. The closer the perforation is to the gingival sulcus, particularly into the coronal third of the root or the furcation region, the greater the likelihood of apical migration of the gingival epithelium in the initiation of a periodontal lesion.[4]

A vertical root fracture can produce a “halo” effect around the tooth radiographically (see also Chapter 2).[67] Deep periodontal pocketing and localized destruction of alveolar bone are often related to longstanding root fractures. The fractured root can mimic a radiographic profile of occlusal trauma, with localized loss of lamina dura, altered trabecular pattern, and a widened periodontal ligament. The fracture site provides a portal of entry for irritants from the root canal system to the surrounding periodontal ligament. Vertical root fractures have contributed to the progression of periodontal destruction in the presence of apparently successful endodontic tooth therapy and overall periodontal site stability.[68]

Influence of pulpal pathologic condition on the periodontium

Pulpal pathosis as a cause of periodontal disease has received much attention during the past decade. Pulpal degeneration results in necrotic debris,

Telegram: @dental_k

www.konkur.in

bacterial by-products, and other toxic irritants that can move toward the apical foramen, causing periodontal tissue destruction apically and potentially migrating toward the gingival margin. Investigators termed this *retrograde periodontitis* to differentiate the process from *marginal periodontitis*, in which the disease proceeds physically from the gingival margin toward the root apex. When pulpal disease progresses beyond the confines of the tooth, inflammation extends and affects the adjacent periodontal attachment apparatus.[77] This inflammatory process often results in dysfunction of the periodontal ligament and resorption of alveolar bone, cementum, and even dentin.

The endodontic infection has been regarded as a local modifying risk factor for periodontitis progression if left untreated.[24] It is believed that an unresolved periapical infection could sustain endodontic pathogen growth, and infectious products would egress into the periodontium by way of the apex and lateral or accessory canals, as well as encourage osteoclastic activity. These may aggravate periodontal pocket formation and bone loss and impair wound healing to accelerate further periodontal disease development and progression. In addition, the high concentrations of the medicaments used for root canal therapy (e.g., calcium hydroxide, corticosteroids, and antibiotics) can irritate the periodontal attachment apparatus.[10,11] The nature and extent of periodontal destruction depend on several factors, including the virulence of the irritating stimuli present in the root canal system (e.g., microbiota, medications, foreign body reactions), the duration of the disease, and host defense mechanisms.[17] The rare development of endodontic-periodontal lesions argues that periradicular pathoses in general have little effect on localized inflammatory bone resorption, given that few combined lesions are seen in cases of apical periodontitis.

The ability of the periodontium to regenerate lost attachment apparatus on pulpless teeth has been questioned, especially if these teeth contain a root canal filling and have been denuded of cementum. One investigator suggested that endodontically treated teeth may not respond as well as untreated teeth to periodontal procedures. He found 60% osseous regeneration of periodontal defects in teeth not treated endodontically, compared with 33% defect fill in endodontically treated teeth.[70] However, in

Telegram: @dental_k

www.konkur.in

a monkey study, others reported that all tissue of the periodontium had the potential for regeneration after periodontal surgery, regardless of the status of the pulp (vital, filled, medicated, or open).[21] Another study reported that pulpal status has little influence on initial cementogenesis and that substances leaching from certain root canal filling materials do not alter deposition of new cementum.[65]

Although endodontic infections have been highly correlated with deeper periodontal pockets and furcation involvement in mandibular molars, the causal relationship between the two pathoses has not yet been established.[41] It has been suggested that endodontic treatment should occur before treatment of furcation lesions (i.e., bone regeneration) to ensure successful results. Extensive evidence is lacking to prove this hypothesis, but there is general agreement that with the proper endodontic treatment, periodontal disease of pulpal origin should heal. The question of whether endodontic infections play a significant role in affecting the health of the periodontium remains to be further elucidated.[59]

Influence of periodontal inflammation on the pulp

Clinically, it is not uncommon to observe a stage 3 or 4 periodontitis spreading to the apical foramen, with associated pulp necrosis. It is also recognized that infection from a periodontal pocket may spread to the pulp through accessory canals, which occur most often in the furcation and closer to the apex of teeth.[60] Investigators proved that pulpitis and pulp necrosis can occur as a result of periodontal inflammation involving accessory and apical canals.[69] Bacterial products and toxins may also gain access to the pulp by way of exposed dentinal tubules. The pulpal reaction is influenced not only by the stages of periodontal disease, but also by the type of periodontal treatment, such as scaling, root planing, and administration of medication.[33] Inflammatory lesions of varying severity and necrotic pulp tissue are usually found in teeth with large canals or in cases in which periodontal breakdown has extended to the apex.[33] Whyman[87] stated that during periodontal therapy, the blood vessels supplying the pulp by way of accessory canals may be damaged. Another animal study found that 70% of root specimens examined

Telegram: @dental_k

www.konkur.in

showed no pathologic changes despite the fact that 30% to 40% of the periodontal attachment was lost.[8] The remaining 30% of roots displayed only small inflammatory cell infiltrates or the formation of reparative dentin, or both, in areas where pulp was adjacent to root exposed through periodontal destruction. These tissue changes were frequently associated with root surface resorption, which suggests that dentinal tubules must be uncovered before irritation can be transmitted.

These observations suggest that the presence of an intact cementum layer is important for the protection of the pulp from toxic elements produced by the plaque biofilm microbiota, so periodontal disease and periodontal treatments should be regarded as potential causes of pulpitis and pulpal necrosis. It has also been reported that the pulps of teeth with longstanding periodontal disease develop fibrosis and various forms of mineralization. Canals associated with periodontally involved teeth were reported to be narrower than canals of teeth that were not periodontally involved. This result is thought to be a reparative process rather than an inflammatory response.[7,51]

Although consensus supports the theory that a degenerating or an inflamed pulp can affect the periodontium, not all researchers agree about the effect of periodontal disease on the pulp. Specifically, inflammatory alterations and localized pulp necrosis have been observed adjacent to lateral canals in roots exposed by periodontal disease.[69,73,74] Additional studies have failed to confirm a direct correlation between periodontal disease and pulp tissue changes.[20,58,82] When pathologic changes occur in the pulp as a result of periodontal disease, the pulp usually does not degenerate so long as the main canal is not involved.[50] It seems plausible to assume that periodontal disease rarely jeopardizes the vital function of the pulp. Generally, if the blood supply through the apical foramen remains intact, the pulp is usually capable of withstanding physiologic insults induced by periodontal disease.

Theoretic pathways of osseous lesion formation

For the clinician, the close relationship between pulpal and periodontal disease is reasonably established on clinical and radiographic levels. Because interpretations vary as to which came first (the proverbial “chicken or egg”

Telegram: @dental_k

www.konkur.in

controversy), clinical data gathering in endodontic and periodontal problems is often complex, requiring a medical history review, pulp vitality testing, pocket and furcation probing, tooth mobility determinations, and critical examination of radiographs. When formulating a differential diagnosis, the clinician should first consider both the periodontal and pulpal status of the affected tooth. If an interrelationship in disease entities exists, appropriate treatment must be rendered to remove true causative factors and enhance the prognosis for tooth retention.[76] Fig. 25.1 shows interrelationships between pulpal and periodontal disease.

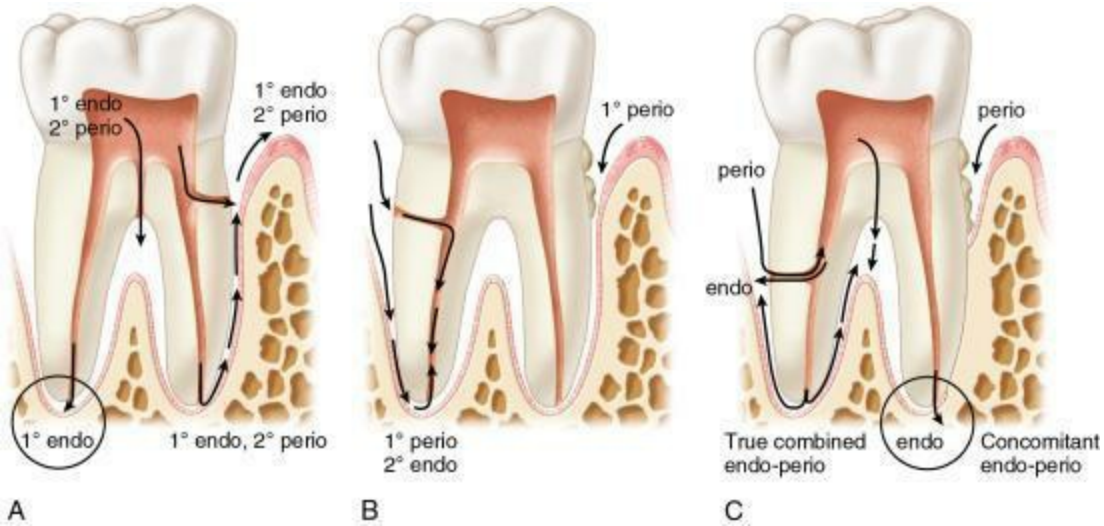

FIG. 25.1 Endodontic and periodontal pathways. **A,** Endodontic lesions. The pathway of inflammation is through the apical foramen, furcation canals, and lateral accessory canals to the periodontium. This results in a primary endodontic lesion, sometimes progressing to secondary periodontal involvement. **B,** Periodontal lesions. This is the progression of periodontitis by way of the lateral canal and apex to induce a secondary endodontic lesion. **C,** True combined endodontic and periodontal lesion and concomitant endodontic and periodontal lesions.

A) Pathway for primary endo and secondary perio from the center of the root below the pulp chamber leads to gum line on the right. A primary endo lesion is encircled at the tip of one root canal.

B) Pathway for primary perio and secondary endo from the root tip of right canal and above the mid root meets slightly above the root tip. A pathway of primary perio from the gum line on the right leads toward the root.

C) It shows true combined endo-perio and concomitant endo-perio. An

www.konkur.in

endolesion is encircled at the right root tip.

Primary endodontic lesions

Disease processes of the dental pulp frequently involve inflammatory changes. Caries, restorative procedures, and traumatic injuries are the most common causes. Typically, endodontic lesions resorb bone apically and laterally and destroy the attachment apparatus adjacent to a nonvital tooth. Inflammatory processes in the periodontium that occur as a result of root canal infection not only may be localized at the apex, but also may appear along the lateral aspects of the root (Fig. 25.2) and in furcation areas of two- and three-rooted teeth (Fig. 25.3).

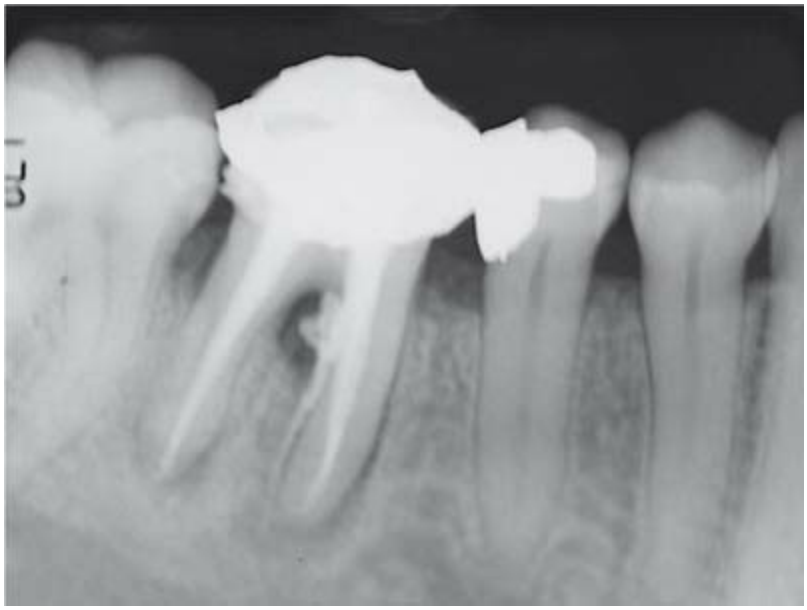

FIG. 25.2 Primary endodontic lesion. Mandibular molar showing endodontic filling material extending into the furcation and along the lateral root surface because of inadequate canal preparation. Furcation could be probed.

Radiograph of lower jaw shows molar with radiolucent patch at the center of beginning of root system. The canal on the left has less-bone density at the tip.

The emergence of these processes may be associated with clinical signs of inflammation: pain, tenderness to pressure and percussion, increased tooth mobility, and swelling of the marginal gingiva, simulating a periodontal abscess. The suppurative process may cause a sinus tract along the periodontal ligament space or through patent channels (including the apical foramen and lateral accessory canals). This usually results in a narrow opening of the sinus tract into the gingival sulcus and pocket that can be easily traced with a gutta-percha cone or a periodontal probe. Such a tract can readily be probed down to the tooth apex, where no increased probing depth would otherwise exist around the tooth. In multirooted teeth, a periodontal ligament sinus tract can drain off into the furcation area and resemble a grade III through-and-through furcation defect resulting from periodontal disease.

Clinically, endodontic testing procedures should reveal a necrotic pulp or,

Telegram: @dental_k

www.konkur.in

in multirooted teeth, at least an abnormal response, indicating that the pulp is degenerating. Because the primary lesion is an endodontic problem that has merely manifested itself through the periodontal ligament, complete resolution is usually anticipated after nonsurgical endodontic therapy, without any periodontal treatment.

Primary endodontic lesions with secondary periodontal involvement

When a lesion of endodontic origin is not treated, pathosis usually continues, leading to destruction of the periapical alveolar bone and progression into the interradicular area, causing breakdown of surrounding hard and soft tissues (Fig. 25.4). As drainage persists through the gingival sulcus, accumulation of plaque biofilm and calculus in the purulent pocket results in periodontal disease and further apical migration of the attachment. When this occurs, not only does the diagnosis become more difficult, but the prognosis and treatment may be altered. Diagnostically, these lesions have a necrotic root canal and plaque biofilm or calculus accumulation, demonstrable by a probe and radiograph. Radiographs may show generalized periodontal disease with angular defects at the initial site of the endodontic involvement.

FIG. 25.4 Primary endodontic lesion with secondary periodontal

Telegram: @dental_k

www.konkur.in

involvement. **A,** The mesial aspect of the mandibular second premolar had deep periodontal pocketing (a periodontal probe in place demonstrated 6 mm of probing depth), even after periodontal therapy. **B,** Pulp tests were performed on the premolar; the tooth was nonresponsive. After endodontic treatment, the periodontal pocket resolved (filling of a lateral accessory canal after obturation is demonstrated).

Four radiographs are shown as follows:

A: Three teeth are shown the central tooth has a large radiolucent patch on the right of root.

Radiograph on top-right: A tube is inserted into the radiolucent patch.

B radiograph: The tissue at the root tip of tooth has somewhat high density as compared to first two radiographs.

Radiograph at bottom-right: The radiolucent patch has high density as compared to first three radiographs.

Resolution of the primary endodontic and secondary periodontal lesion relies on treatment of both conditions. When only endodontic therapy is provided, only part of the lesion can be expected to heal. If endodontic therapy is adequate, the prognosis depends on the severity of periodontal involvement and the efficacy of periodontal therapy.

Primary periodontal lesions

Periodontal disease has a progressive nature. It begins in the sulcus and migrates to the apex as deposits of plaque biofilm and calculus produce inflammation, causing loss of surrounding alveolar bone and supporting periodontal soft tissues. This leads to a loss of clinical attachment and the formation of a periodontal abscess during the acute phase of destruction.[75] The progression of periodontal disease to the formation of osseous defects and subsequent radiographic appearance along lateral aspects of roots and in furcation areas is well known. These defects may or may not be in association with trauma from occlusion, which can often be the cause of an isolated periodontal problem. Osseous lesions of periodontal origin are usually associated with tooth mobility, and the affected teeth respond positively to pulp testing. In addition, careful periodontal examination usually reveals broad-based pocket formation and an accumulation of plaque biofilm

Telegram: @dental_k

www.konkur.in

and calculus. The bony lesion is usually more widespread and generalized than are lesions of endodontic origin (Fig. 25.5).

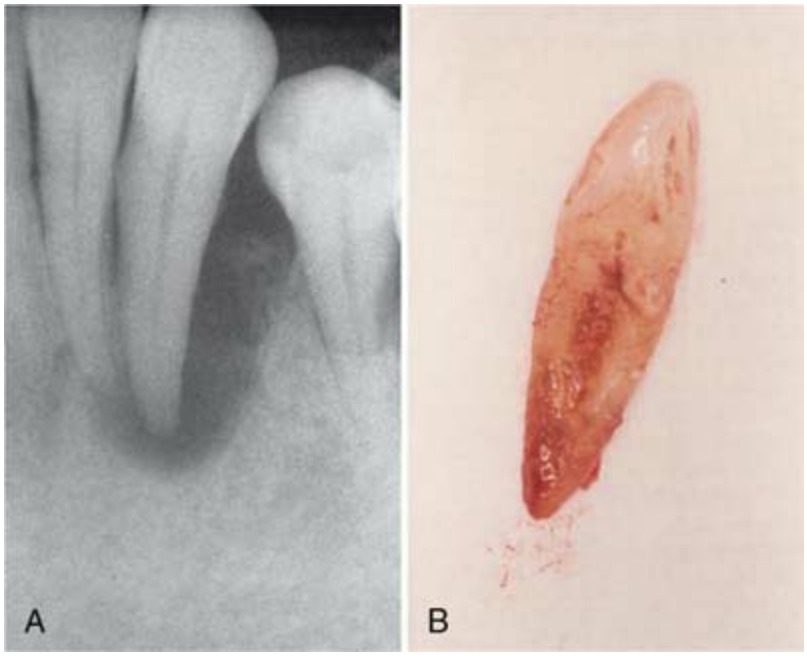

FIG. 25.5 Primary periodontal lesion. **A,** Mandibular cuspid exhibits extensive periodontal destruction; the tooth responded normally to pulp tests. **B,** Extracted tooth depicts extensive calculus accumulation and root concavity.

A) Radiograph shows J-shaped radiolucency along the root of tooth.

B) Extracted tooth with blood stain is kept on a platform.

The prognosis for teeth affected by periodontitis worsens as the disease process and periodontal destruction progress. Treatment depends on the extent of the periodontitis and on the patient's ability to comply with potential long-term treatment and maintenance therapy. Because this is purely a periodontal problem, the prognosis depends exclusively on the outcome of periodontal therapy.

Primary periodontal lesions with secondary endodontic involvement

As stated earlier, periodontal disease can have an effect on the pulp through dentinal tubules, lateral canals, or both. Primary periodontal lesions with

Telegram: @dental_k

www.konkur.in

secondary endodontic involvement differ from the primary endodontic lesion with secondary periodontal involvement only by the temporal sequence of the disease processes. The tooth with primary periodontal and secondary endodontic disease exhibits deep pocketing, with a history of extensive periodontal disease and, possibly, past treatment. When the pulp becomes involved, the patient often reports accentuated pain and clinical signs of pulpal disease. This situation exists when the apical progression of periodontal disease is sufficient to open and expose the pulp to the oral environment by way of lateral canals or dentinal tubules. On radiographs, these lesions may be indistinguishable from primary endodontic lesions with secondary periodontal involvement. The prognosis depends on continuing periodontal treatment subsequent to endodontic therapy.

True combined lesions

Pulpal and periodontal disease may occur independently or concomitantly in and around the same tooth. Once the endodontic and periodontal lesions coalesce, they may be clinically indistinguishable (Fig. 25.6). The prognosis of multirooted teeth with combined pulpal and periodontal lesions depends largely on the extent of the destruction caused by the periodontal disease component. A necrotic pulp or a failing endodontic treatment, plaque biofilm, calculus, and periodontitis will be present in varying degrees.

FIG. 25.6 True combined pulpal and periodontal lesions on the

Telegram: @dental_k

www.konkur.in

mandibular second premolar and first molar. Periodontal probing depths were to the apices in both teeth.

Radiograph shows four teeth where the surrounding and bifurcation region of central two teeth are completely radiolucent.

Concomitant pulpal and periodontal lesions

An additional classification has been proposed for lesions that may commonly be seen clinically and reflect the presence of two separate and distinct entities.[6] This is referred to as the *concomitant pulpal and periodontal lesion* (Fig. 25.7). In essence, both disease states exist, but with different causative factors and with no clinical evidence that either disease state has influenced the other. This situation often goes undiagnosed, and treatment is rendered to only one of the diseased tissues in the hope that the other responds favorably. In actuality, the two disease processes must be treated concomitantly, and the prognosis depends on the removal of the individual etiologic factors and the prevention of any further factors that may affect the respective disease processes.

FIG. 25.7 Concomitant pulpal and periodontal lesion on the maxillary second premolar. An endodontic lesion was noted at the apex, with a noncommunicating periodontal pocket on the distal side.

Radiograph shows the posterior view of four teeth where the second premolar has radiolucent pockets on the gum line and a radiolucent patch at the root tip.

With the application of research findings and clinical experience, pathways of osseous lesion formation may be theorized. These concepts are intended as a guide for the evaluation and understanding of the clinician's successes and failures in treating teeth with osseous lesions. By understanding the nature of their formation, the clinician can better anticipate the healing potential after treatment.

Differential diagnosis

During the course of treatment, clinicians are frequently presented with the dilemma of accurately assessing the contribution of endodontic and periodontal lesions. These lesions may be very separate from each other and present no extraordinary therapeutic consideration. In a few other situations, there is no obvious demarcation between the two lesions, which appear as one, both on radiographs and clinically. In the diagnosis of radiographic osseous lesions, the clinician must resist the temptation to label everything a "combined lesion." Table 25.2 summarizes the differential diagnosis between pulpal and periodontal lesions and highlights a number of common characteristics of these lesions.

Table 25.2

Differential Diagnosis Between Pulpal and Periodontal Disease

Telegram: @dental_k

www.konkur.in

	Pulpal	Periodontal
CLINICAL		
Etiology	Pulp infection	Periodontal infection
Vitality	Nonvital	Vital
Restorative	Deep or extensive	Not related
Plaque biofilm/calculus	Not related	Primary cause
Inflammation	Acute	Chronic
Pockets	Single, narrow	Multiple, wide coronally
pH value	Often acid	Usually alkaline
Trauma	Primary or secondary	Contributing factor
Microbial	Few	Complex
RADIOGRAPHIC		
Pattern	Localized	Generalized
Bone loss	Wider apically	Wider coronally
Periapical	Radiolucent	Not often related
Vertical bone loss	No	Yes
HISTOPATHOLOGIC		
Junctional epithelium	No apical migration	Apical migration
Granulation tissues	Apical (minimal)	Coronal (larger)
Gingival	Normal	Some recession
THERAPY		
Treatment	Root canal therapy	Periodontal treatment

Root fractures, especially vertical root fractures, present particular problems in diagnosis (Fig. 25.8). Symptoms and signs associated with vertical root fractures show a varying character and are frequently difficult to distinguish from those associated with periodontal and endodontic lesions. Breakdown can manifest itself on radiographs in a number of different ways. This may be anything from nothing detectable on radiographs to an area of rapid vertical bone loss, given that there is no way to predict when a patient may present for treatment. It is imperative for the clinician to take more than one radiograph at different angles, especially when no clear diagnosis emerges. In these cases, a minor alteration in the angulation may reveal a tooth fracture or periodontal furcation involvement. The diagnosis of vertical root fractures is often difficult because the fracture is usually not detectable by clinical inspection and radiographic examination unless there is a clear separation of the root fragments. Cemental tears or detachment of cementum from a root surface by means of trauma or aging has been reported.[14,53] The lesion often results in periodontal destruction and endodontic involvement (Fig. 25.9).[54,55]

breakdown; the tooth was very tender to both percussion and palpation. **B,** An "eggshell" piece of cementum on the buccal surface of the root before root-end resection; the cementum was removed with curettage. **C,** Postoperative radiographs after root-end resection, root-end preparation, and root-end filling. **D,** Six-month follow-up radiographs demonstrate periapical healing; the tooth was asymptomatic.

Set of six radiographs and a photograph marked A through D shows the cemental tear in tooth along with its healing.

Sometimes, the definitive diagnosis of vertical root fractures has to be confirmed by exploratory surgical exposure of the root for direct visual examination.[85] Vertical root fractures have been associated with root-filled teeth where excessive lateral forces were applied during compaction or possibly with stress induced by post placement in root-filled teeth.[61] A clinical survey of fractured teeth also reveals that fractures are more common in teeth with extensive restorations, in older patients, and in mandibular posterior teeth.[31] The prognosis for teeth with vertical root fractures that involve the gingival sulcus and periodontal pocket usually is hopeless because of continuous bacterial invasion of the fracture space from the oral environment. Single-rooted teeth are generally extracted. In multirooted teeth, a treatment alternative is hemisection or resection of the fractured root. (See Chapter 22 for further discussion of vertical root fractures.)

Developmental grooves, primarily found in maxillary central and lateral incisors, are also capable of initiating localized periodontal destruction along the root surface.[27,43,52] It is thought that they may be a genetic attempt to form an accessory root, but once plaque biofilm and calculus invade the epithelial attachment, the groove becomes a pathway for microbes and their noxious allies (toxins), with ample substrate from food debris to create a self-supporting periodontal lesion. Bone demineralization follows the path of the groove. Palatogingival grooves are often associated with poor periodontal health because of patients' inability to keep these areas clean, and a poor prognosis is usually assigned regardless of proper conventional therapy.[31,88] It is easy to identify these grooves if the clinician is aware of their existence. Clinically, these grooves may be asymptomatic, or symptomatic periodontal problems (either acute or chronic) may occur. It is thought that the pulp of these teeth may become secondarily involved and demonstrate symptoms of

Telegram: @dental_k

www.konkur.in

pulpal disease (Fig. 25.10). These lesions are often confused with the enamel projections in the furcation area of mandibular molars.[58] The prevalence of cervical enamel projections (Fig. 25.11) ranges from 18% to 45%.[38,58] Depending on the apical extent of these cervical grooves, some authors[38,58] also find a high association with pathologic furcation involvement (up to 82.5%[38]).

Lateral periodontal cysts

The clinical presentation of a lateral periodontal cyst is often without symptoms (Fig. 25.12). It may present as a gingival swelling on the facial aspect that may show pain and tenderness on palpation. Radiographic features are a well-circumscribed round or ovoid radiolucent area that usually has a sclerotic margin. Most lateral periodontal cysts are less than 1 cm in diameter and lie somewhere between the apex and cervical margin of a tooth. Three possible etiologies are reported in the literature: (1) reduced enamel epithelium, (2) remnants of dental lamina, or (3) cell rests of Malassez. Histologic evaluation reveals that these cysts are lined by epithelium that closely resembles reduced enamel epithelium lining. The lesion occurs predominantly in the fifth to seventh decades of life, with a predilection for males.[3] The lesion is usually slow growing. Treatment consists of careful excision to help prevent recurrence. The most common location is the mandibular cuspid-bicuspid area, although numerous cases have been reported in the anterior maxilla.

FIG. 25.12 Lateral periodontal cyst. **A,** Clinical photograph showing mild gingivitis around tooth #24; there is a 5-mm probing defect on the mesial aspect of tooth #24. **B,** A radiograph depicts the beginning lesion 2 years earlier. **C,** A radiograph shows the extent of the lesion at the time of referral to the periodontist. **D,** Initial flap reflection; the lesion is present interproximally between teeth #24 and #25. **E,** The lesion was enucleated and submitted for histologic evaluation; the diagnosis was a lateral periodontal cyst. **F,** Three-month posttreatment clinical photograph; tooth #24 was nonvital and symptomatic and was referred for root canal treatment. **G,** One-year posttreatment radiograph showing completed root canal treatment and osseous defect still present; continuous recall recommended. **H,** One-year posttreatment clinical photograph; probing depths were within normal limits; continuous recall was recommended.

Set of radiographs and photographs marked A through D shows the changes in fluid filled lesion below the gum line of teeth 24 and 25.

Set of photographs and radiographs marked E through H shows a cavity with two oval structures below teeth 24 and 25 and its partial healing after treatment.

Altini and Shear[3] reported finding unicystic and multicystic (including botryoid) varieties. They found that lateral periodontal cysts were lined predominantly or exclusively by thin, reduced enamel, epithelium-like tissue that contained many clear cells, and epithelial thickenings referred to as *plaque biofilms*. Glycogen was present in the epithelium of two thirds of the cases, although not exclusively in the clear cells, many of which were not positive for glycogen. Some of their botryoid variety differed histologically, being lined predominantly by nonkeratinizing stratified squamous epithelium with crowded and pyknotic nuclei and no clear cells. One case contained melanin, and another showed epithelial crypt formation and superficial palisaded low columnar cells, as seen in the glandular odontogenic cyst. This raised the question of whether the latter may form part of the clinicopathologic spectrum of a lateral periodontal cyst. The histogenesis of lateral periodontal cysts is uncertain, but these cysts favor origin from reduced enamel epithelium. Some cases either do not fit a characteristic endodontic or periodontal lesion or do not respond to treatment as expected. A biopsy and histologic analysis are often recommended. Systemic diseases such as scleroderma, metastatic carcinoma, and osteosarcoma can mimic endodontic and periodontal disease visible on a radiograph. *The*

Telegram: @dental_k

www.konkur.in

conscientious clinician must always be alert for lesions of nonendodontic or nonperiodontal origin and look for other causes.

Treatment alternatives

When traditional endodontic and periodontal treatments prove insufficient to stabilize an affected tooth, the clinician must consider treatment alternatives. Generally, a localized periodontal defect associated with an endodontically untreatable tooth or an iatrogenic tooth problem is reason to explore other treatment options. Alternate treatments often consist of resection or regenerative approaches. Resection techniques focus on eliminating the diseased roots or teeth, while regenerative efforts are aimed at restoring lost biologic structures. Resection methods involve removal of affected roots or extraction of involved teeth. When a tooth requires extraction, one of the first options for restoring occlusal function should include placement of dental implants with hybrid prostheses. Bone replacement grafts using guided tissue and bone regeneration techniques are ways to reestablish biologic structures that were lost during this disease process. Fixed partial dentures are still a viable option for some patients and certainly should be considered if abutment teeth already have restorations or endodontic treatment.

Root resection is the removal of a root, with accompanying odontoplasty before or preferably after endodontic treatment.[28] Formerly, it was used when root canal therapy was considered too difficult, but now its indications are restricted to multirooted teeth in which one or more roots cannot be saved. The indications for root resection often include (but are not limited to) root fracture, perforation, root caries, dehiscence, fenestration, external root resorption involving one root, incomplete endodontic treatment of a particular root, stage 3 or 4 periodontitis affecting only one root, and severe grade II or grade III furcation involvement. Root resection is a technique-sensitive procedure (Fig. 25.13) requiring a careful diagnostic process for selection of teeth that would likely be successful candidates, followed by meticulous interdisciplinary treatment. Factors such as occlusal forces, tooth restorability, and the value of the remaining roots must be examined before treatment. A carefully constructed treatment plan is crucial to the success of this resection procedure.[32] Proper reshaping of the occlusal table and

Telegram: @dental_k

www.konkur.in

restoration of the clinical crown are essential, and the root surface must be recontoured to remove the root stump, thus preventing formation of a potential food trap.[44]

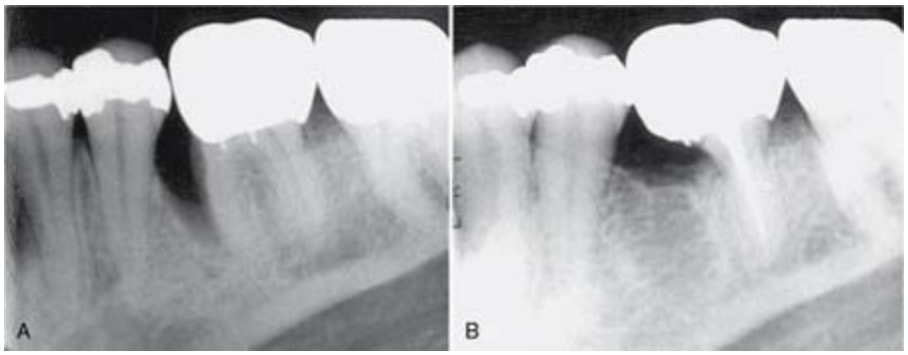

FIG. 25.13 Root resection to correct endodontic and periodontal defect. **A,** Pretreatment radiograph depicts severe periodontal involvement on the mesial. Endodontic treatment was performed before surgical removal of the mesial root. **B,** Five-year follow-up shows the remaining tooth well maintained.

A) Radiograph shows a V-shaped pocket between two teeth.

B) Radiograph shows porous tissue in place of the pocket.

The effectiveness of this approach remains controversial, owing to the disparity of results reported in several long-term studies.[4,10,12,15,25,28,46] Retrospective longitudinal studies have observed the fate of sectioned teeth for time frames ranging from 3 to 12 years and have reported success rates ranging from 62% to 100%, with a low incidence (i.e., 10%) of periodontal breakdown. However, as most long-term studies will point out, the major cause of failure of resection procedures resides in failure of the endodontic and restorative components. Unique anatomic features, such as root length, curvature, shape, size, position of adjacent teeth, and bone density, may influence the end result. For example, root fusion makes resection all but impossible. The removal of roots purely to eliminate a resorptive or traumatic perforation defect, fractured root, or endodontically inoperable root usually results in definitive treatment. If, however, localized or generalized periodontal disease is present, conditions favorable for healing must be created, and concomitant periodontal therapeutic procedures can be

Telegram: @dental_k

www.konkur.in

implemented to restore the health of the periodontium.[32] The final restoration of root-resected teeth depends significantly on the nature of the resection, the amount of remaining tooth structure, the periodontal status, and the patient's occlusion. The prosthetic aspects of tooth restoration must be carefully assessed and integrated into the anticipated surgical procedure to ensure proper positioning of tooth margins relative to the osseous crest and also to manage the anticipated changes in occlusal relationships and masticatory forces.[86] Hemisection is the surgical separation of a multirooted tooth, usually a mandibular molar with severe furcation involvement, through the furcation in such a way that a root and associated portion of the crown may be removed or retained. A fixed partial denture often is placed in the area to restore the lost portion of the occlusal table (Fig. 25.14).

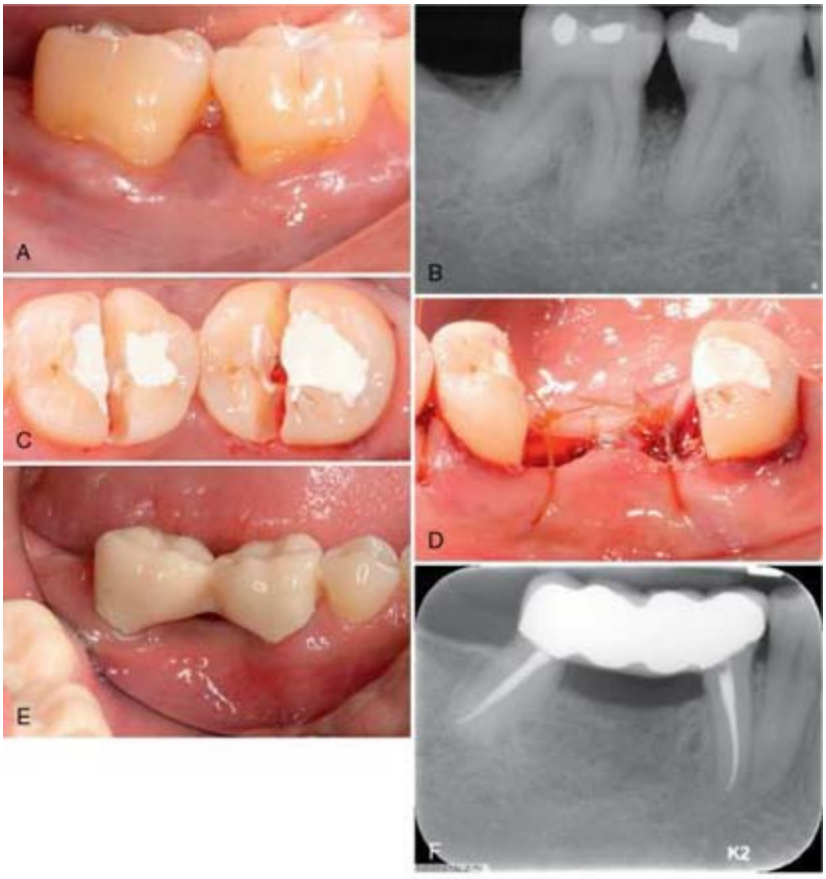

FIG. 25.14 Hemisection. **A,** Initial presentation of mandibular molars with severe attachment loss on the mesial aspect of tooth #31 and the distal aspect of tooth #30. **B,** Radiograph exhibiting interproximal periodontal defects. **C,** Occlusal view of hemisection after endodontic

treatment. **D,** Suturing after removal of mesial half of tooth #31 and distal half of tooth #30. **E,** Eighteen-month follow-up with fixed restoration in place. **F,** Postoperative radiograph at 18 months showing normal bony and periodontal architecture.

Set of photographs and radiographs marked A through F shows two multi-rooted teeth, followed by the removal of their half parts, resulting in single rooted teeth with fused crowns.

Controversy has also existed regarding the benefits of and need for endodontic therapy before root resection. Instances develop in which exploratory surgery is necessary; should the periodontal problem be more extensive than determined presurgically, removal of a root should be carried out at that time. In these instances, removal of the involved root without endodontic treatment would be acceptable, but root canal therapy should be performed as soon as possible after root removal.[30,78,80] After resection of a vital root, the pulpal opening in the crown may be sealed and restored with a permanent amalgam restoration or sedative base material (e.g., Dycal) as a temporary solution. Investigators evaluated vital-root resection in maxillary molar teeth for 9 years.[28] Amputated pulps were covered with Dycal base and amalgam. At 1 year, 38% of molar teeth remained vital, but at 5 years only 13% maintained vitality. These findings imply that the long-term prognosis for vital-root resection is poor, so *endodontic therapy should be done before or immediately after resection*. However, Haskell[36] reported that vitality of resected teeth can be maintained even after 16 years. Nonetheless, it is generally agreed that whenever possible, endodontics should be performed in advance (before root resection). If this is not possible, the endodontic treatment should be performed as soon as possible after vital-root amputation. Otherwise, pulpal complications may occur, such as internal resorption, pulpal inflammation, and necrosis.[2,79]

The concepts of guided tissue regeneration (GTR) and guided bone regeneration (GBR) have been used to promote bone healing after endodontic surgery.[29,64] Fig. 25.15 illustrates an endodontic defect successfully treated with the GTR approach. Theoretically, the GTR barrier prevents contact of connective tissue with the osseous walls of the defect, protecting the underlying blood clot and stabilizing the wound.[35] An investigator treated large periradicular lesions with GTR barrier membranes and demonstrated

Telegram: @dental_k

www.konkur.in

that periradicular healing occurred more rapidly at membrane sites than at control sites.[63,64] The quality and quantity of the regenerated bone were superior with adjunctive use of the membrane than without such use. Similar findings were published in a case report with histologic examination of biopsy material obtained at barrier removal.[66] In addition, during examination of clinical cases, the closer the lesion is to the gingival margin, the greater the fluid and bacterial contamination from the sulcus (and the greater the risk of mechanical trauma). When GTR is considered, the combined endodontic and periodontal lesion probably has the least favorable prognosis compared with cases having only a periodontal lesion.[63]

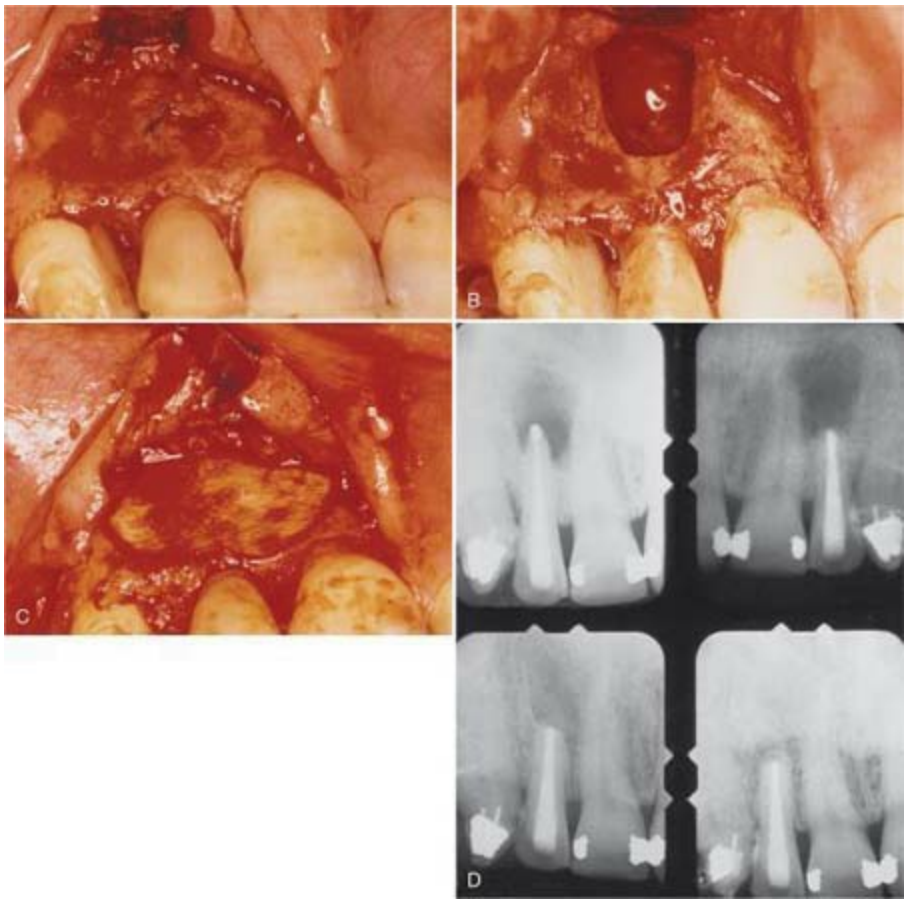

FIG. 25.15 Periradicular endodontic surgery using the combination of bone replacement grafts and collagen guided tissue regeneration barrier membranes. **A,** A buccal flap was reflected (note extensive apical lesion). **B,** An osseous window was created with a bur. **C,** The defect was repaired with demineralized freeze-dried bone allograft and covered with a collagen membrane. **D,** Radiographs show condition

before surgery, at the time of surgery, and at 6 months and 2 years after surgery. At 2 years, the radiograph reveals complete bone regeneration.

Set of photographs and radiographs marked A through D shows the restoration of tissue damage at the root apex of tooth.

Many varieties of GTR membranes are available for clinical use, but it is logical to use bioresorbable collagen and polymer membranes in endodontic surgeries because there is often no need for a second surgery to retrieve the membrane. Studies reveal similar results achieved with nonresorbable and resorbable membranes.[18] Long-term studies need to be completed to evaluate the success of this approach.

For more than 40 years, bone grafts have been used to treat osseous defects associated with periodontal disease.[70,72] Because the "apicoectomy" (i.e., root-end resection) defect has a surrounding bony wall, the need for adjunctive bone grafting during this procedure is questionable (unless the lesion is exceptionally large in diameter). With the introduction of the GTR concept, a combination of bone replacement graft and GTR membrane (Fig. 25.16) has shown promising results.[1,22,42,66,83] Further studies are required to explore the true benefit of this combination treatment approach in root-end resection procedures.

Forced eruption or extrusion

Teeth that have fractured, undergone extensive decay, or experienced internal or external root resorption or lateral perforation may be candidates for a forced eruption procedure, especially straight, tapering, single-rooted teeth (Fig. 25.17). To obtain good access for endodontic or restorative procedures, along with reduced probing depths, it may be necessary to perform extensive resection surgery to gain crown lengthening. Forced eruption may offer a better solution than surgical crown lengthening, which may produce poor aesthetics in some cases. A review of the literature reveals that most successfully treated cases are extrusions of less than 4 mm.[5,9,48] The infrequently used treatment method of forced eruption serves as an alternative to the sacrifice of the natural root system. Forced eruption can preserve the natural root system and related periodontal architecture, resulting in years of additional service for the patient. It also can maintain adjacent tooth structure while retaining the option for future implant reconstruction, if needed. Given the reported success of forced eruption, the technique should be used more often by dentists.[23,26] The increased use of implants in clinical treatments has stimulated clinicians' interest in augmenting bone in patients who have deficient alveolar ridges that might preclude ideal implant placement.

FIG. 25.17 Clinical case of forced eruption. **A,** Initial presentation of tooth #29 (buccal view). **B,** Bonded wire to help extrude tooth #29. **C,**

Four close-up views of interior of mouth marked A through D shows the restoration of tooth 29 affected with fractured crown and black residues in the cavity.

A nonsurgical technique for using the available bone for implant site development and fixture placement is orthodontic extrusion or forced eruption. The concept of extruding a tooth coronally by orthodontic forces and the clinical alterations in the soft tissue architecture of the periodontium demonstrated during orthodontic extrusive movement of periodontally compromised teeth have demonstrated probing depth reduction in some cases.[57] An investigator reported that tooth movement in the presence of inflammation might cause deepening of osseous defects. Often, extrusions are accompanied by an immature-appearing tissue that is red compared with adjacent tissue. This results from the eversion of junctional epithelium, which is nonkeratinized in the sulcus; the vasculature is more readily visible until the newly exposed tissue has a chance to keratinize, in about 28 days.[39,40] Most extruded teeth should be retained in place twice as long as it took to force-erupt them to minimize relapse before attempting definitive restorative procedures.

Summary

Endodontic and periodontal lesions result from the close interrelationship of pulp tissue and the periodontium. The major pathways of communication between the two types of tissue are the apical foramina, lateral and accessory canals, and dentinal tubules. The differential diagnosis of endodontic and periodontal lesions is not always straightforward and requires clinical data accumulation from a number of diagnostic tests to obtain a correct diagnosis. When examining and treating the combined or individual lesion in endodontics and periodontics, the clinician must bear in mind that successful treatment depends on a correct diagnosis. Lesions with combined causes require both endodontic and periodontal therapy, and endodontic therapy should usually be completed first. Root resection and regenerative techniques

Telegram: @dental_k

www.konkur.in

offer alternative approaches, enhancing the clinician’s ability to deal with these complex clinical problems.

26: Bleaching procedures

Frank Setzer

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Beauty and perfect appearance have a great value in society. The “perfect smile” is important to many people,[185] including straight and light-colored teeth. Tooth whitening has become an established practice, both in the dental office by providing nonvital and vital in-office bleaching procedures as well as by commercial companies that sell over-the-counter tooth “whitening” products. Vital tooth bleaching aims to lighten entire arches. Nonvital bleaching procedures are most often used to treat individual discolored teeth

Telegram: @dental_k

www.konkur.in

so that they blend in with adjacent teeth.

Etiology of tooth discolorations

A great variety of etiologies may be responsible for tooth discolorations. Discoloration was described as "any change in the hue, color, or translucency of a tooth due to any cause."[196] Great differences exist in severity, localization, and appearance. Intrinsic discolorations are incorporated into the tooth structure. Extrinsic discolorations are attached to the tooth surface. Both intrinsic and extrinsic discolorations can exist in combination and may affect enamel, dentin, or pulp. Some tooth discolorations are caused by hereditary causes, while others are related to patient behavior, age, and disease, or are created iatrogenically by dental or medical treatments (Table 26.1).

Table 26.1

Overview of Intrinsic and Extrinsic Discolorations

Color of Stain	Extrinsic	Intrinsic (Single Tooth)	Intrinsic (Multiple Teeth)

MTA, Mineral trioxide aggregate.

Systemic intrinsic causes

Genetic causes

Amelogenesis imperfecta (AI) describes a group of hereditary conditions associated with mutations in five genes—*AMEL* (amelogenin), *ENAM* (enamelin), *MMP20* (matrix metalloproteinaise-20), *KLK4* (kallikrein-4), and *FAM83H*—affecting the structure and appearance of enamel in the primary and secondary dentition.[77] Enamelin defects may cause variable hypoplasia, ranging from local pitting to generalized thinning of the enamel. Amelogenin defects can lead to abnormal maturation and mineralization defects; disorganized, hypoplastic enamel; or other phenotypic variations ranging

Telegram: @dental_k

www.konkur.in

from hypoplasia to hypomaturation or hypomineralization.[77] Based on this clinical appearance, this has led to the classification of four subtypes of AI[70]: AI type 1, hypoplastic enamel, which presents very thin, yet hard and translucent with normal radiographic appearance[251]; AI type 2, hypomaturation, softer than normal enamel, which is prone to rapid wear, and a radiographic density comparable to dentin; AI type 2, hypocalcified enamel of normal thickness, but extremely brittle, very susceptible to staining and rapid wear, and less radioopaque than dentin; and AI type 4, hypomature and hypoplastic enamel associated with taurodontism. The impaired mineralization due to the developmental changes in the enamel matrix formation may allow discoloring agents from the oral cavity easy access to the mineral structure. The tooth color may be brown or yellow. Bleaching attempts may be, although successful, of a temporary nature and often seen as an adjunct to comprehensive restorative treatment. Resin infiltration has been proposed as an alternative treatment for the white opacities present in the hypomature enamel of patients with type 2 AI.[39] Besides discolorations, the clinical appearance and morphologic structure of the enamel may result as well in increased sensitivity and fragility.

Dentinogenesis imperfecta (DGI) and dentin dysplasia (DD) are a group of hereditary autosomal dominant genetic dentin disorders characterized by an abnormal dentin structure.[19] Either the primary dentition solitarily or both primary and secondary dentitions may be affected.[19] DGI is most commonly categorized into three subtypes: DGI type I, DGI type II, and DGI type III; DD is categorized into two subtypes: DD type I and DD type II. DGI type I is associated with osteogenesis imperfecta and involves mutations in the collagen type 1 encoding genes COL1A1 and COL1A2. With the exception of DD type I, all other forms of DGI and DD are related to mutations in the gene encoding dentin sialophosphoprotein (DSPP).[19] All patients affected by osteogenesis imperfecta also suffer from brittle bones. Patients with DGI have weaker teeth that are more prone to fracture. Patients suffering from DGI type I, DGI type II, and DGI type III have teeth with yellow-brown, deep amber, or blue-gray discolorations and higher translucency. Bleaching treatment will have minimal to no effect; comprehensive restorative treatment is indicated, but it is difficult to execute due to the compromised tooth structure.

Telegram: @dental_k

www.konkur.in

Other hereditary diseases causing tooth discoloration include porphyria, erythroblastosis fetalis or thalassemia, and sickle cell anemia. Congenital erythropoietic porphyria is a disease resulting from abnormalities in the synthesis of porphyrins, organic compounds essential for the function of hemoglobin. It may result in reddish or brownish tooth discoloration. Erythroblastosis fetalis is a hemolytic disease wherein fetal erythrocytes in Rh-positive fetuses or newborns of Rh-negative mothers are destroyed by antigens that cross the placenta, leading to hyperbilirubinemia. Bilirubin, a yellow breakdown product of hemoglobin, is incorporated into developing teeth, creating yellow-green and blue-green discolorations. Thalassemia, a blood disease causing characteristic malformations of the skull and long bones, and sickle cell anemia, a hereditary blood disorder displaying an abnormality of the oxygen-carrying hemoglobin molecule causing red blood cell malformations, may result in intrinsic blue, green, or brown discolorations.

Disease-related causes

High fevers experienced during the ages of tooth development may cause chronologic enamel hypoplasia leading to banding type discolorations on the tooth surface. Vitamin and mineral deficiencies may induce hypoplasia. Rickets, a vitamin D deficiency, may lead to white hypoplasias resulting from osteomalacia, developmental anomalies in the bones. Scurvy, a vitamin C deficiency in conjunction with vitamin A deficiency, and disturbances of phosphorus uptake can cause enamel hypoplasias.

Metabolic causes

Enamel hypoplasia may also occur after excessive exposure to fluoride during tooth formation. Fluoride exposure can lead to alterations in the mineralized tooth structure, especially in the enamel matrix, giving the appearance of a mottled tooth. The extent of hypoplasia directly correlates with the fluoride uptake during tooth formation and will impact the degree of discoloration.[46] Shades of discoloration may vary greatly and can range from white spots with opaque or chalky appearances to yellow or brown stains on the facial side of the affected tooth, in severe cases with surface pitting of the enamel. No damage to the shape of the crown can be found. It can be related

Telegram: @dental_k

www.konkur.in

to AI or hereditary hypophosphatemia. Tumors, infections, or trauma may be contributing factors. In situations of moderate severity, external bleaching may be sufficient, whereas in severe cases, a restorative approach may be indicated.

Drug-related causes

Tetracycline is an antibiotic used to treat diseases such as urinary tract infections, chlamydia, acne, and cystic fibrosis. It was frequently used from the 1950s through the early 1980s. In particular in young children, it causes gray or brown, deep, dark stains that may affect the entire tooth or occur as a pattern of horizontal stripes. Many adults also currently suffer from tetracycline stains on their teeth. Tetracycline-induced discolorations in permanent teeth manifest during tooth development, when tetracycline becomes calcified in the tooth, generating the characteristic stains. The discolorations are embedded in enamel and dentin. Children are susceptible to tetracycline discolorations from the time they are in utero until the age of 8. Because tooth development starts prior to birth, women are advised to avoid taking tetracycline during pregnancy. Tetracycline stains are obvious and were viewed as always permanent in the past. However, several studies reported successful cases after application of a walking bleach technique[2,4,7,12,68,95,143,256] and even prolonged bleaching with carbamide peroxide.[30,125,137,151,174,228,253] The walking bleach technique will, however, require intentional devitalization and endodontic treatment of the tooth to allow for the application of the bleaching agent into the pulp chamber.[2,4] A patient must be thoroughly informed about the risks, advantages, and disadvantages of this treatment.[2,4] Today, “power bleaching” and veneers are among the suggested treatments for tetracycline stains. Nevertheless, great care must be taken to avoid issues with bonding systems after the application of bleaching agents. Severe cases of tetracycline discoloration may require full coverage restorations.

Local intrinsic causes

Pulpal hemorrhage

Dental trauma may lead to the rupture of intrapulpal blood vessels with

Telegram: @dental_k

www.konkur.in

subsequent intrapulpal hemorrhage and the release of blood components into the dentinal tubules.[13] The hemolysis of erythrocytes will result in the degradation of hemoglobin into globin and the heme protein, containing an iron atom.[162] The iron, in the form of iron sulfides, may reach dentinal tubules, causing brown/reddish or black stains and discolorations in the surrounding dentin. Depending on whether the pulp recovers or becomes necrotic, the discoloration may revert or persist. If the pulp survives, the tooth may eventually revert to its initial shade; however, in situations where pulp necrosis takes place, the discoloration may remain and become worse. Intracoronal bleaching has proven effective in these situations.[71,206,258]

Pulp necrosis

The dental pulp may be irritated chemically, mechanically, or by microbial insult, especially by bacteria and their toxic by-products. After initial inflammation, the pulp develops local microabscesses followed by tissue necrosis and eventually complete necrosis. Disintegration products from pulp necrosis may become incorporated into dentinal tubules and cause discoloration of the surrounding dentin. The intensity of the discoloration appears proportional to the time the discoloring agents remain in the pulp chamber. These types of discolorations tend to respond favorably to intracoronal bleaching.[196]

Pulp tissue remnants

Remnant pulp tissue that was left behind after endodontic therapy will eventually disintegrate and may discolor tooth structure. As a clinical consequence, pulp horns and all other pulp tissues in the access chambers should be carefully removed during treatment.

Restorative materials

Metallic filling materials, such as amalgam or gold, may cause discolorations. Gold fillings, including gold foil compaction fillings, inlays, or onlays, but also pins or posts, mostly cause color changes, reducing tooth translucency and adding dark hues through thin remaining tooth portions. Amalgam fillings, however, over time, will undergo corrosive changes and degradation, with by-products causing color alterations within the tooth structure.[175] For

Telegram: @dental_k

www.konkur.in

any metallic filling that remains visible through existing tooth structure, removal of the filling and exchange with an esthetic filling material is the preferred choice. Effectively, dentin discolorations by amalgam can be bleached but may be prone to recurrence. Composite resin restorations may leak at the margins and allow for discoloring agents to penetrate into the tooth and dentinal tubules.

Intracanal medicaments and root filling materials

A variety of endodontic medications and filling materials may be responsible for discolorations. Silver points, historically used for root fillings, can cause gray, dark discolorations in teeth and the surrounding tissues due to corrosive processes.[3,33] Gutta-percha was reported to cause a light pink discoloration.[182,250] Resorcinol-formaldehyde resin paste ("Russian Red") was reported to cause discolorations ranging from pink to dark burgundy.[163,212] Phenols or iodine-containing intracanal medications (e.g., camphorated monochlorophenol [CMCP] or iodine-potassium-iodine [IKI]) may reside in the root canal space and start gradual discolorations by penetration of dentinal tubules through oxidation.

Endodontic sealers, particularly those containing metallic compounds (e.g., silver), can cause dark discoloration, either if the material is incompletely removed from pulp chambers and access cavities or because some components interact with moisture from dentin over time (Fig. 26.1).[8,181,255] For example, AH26 (Dentsply De Trey, Konstanz, Germany), an epoxy resin cement, contains bismuth trioxide as a filler and radiopacifier. Within dentin, various bismuth compounds that range in color from green to black may occur and cause discoloration.[255] The corrosion of silver in the sealer may cause a gray to black discoloration.[8,56] Also, incomplete removal of AH26 can cause discoloration in reaction with intracanal medicaments.[232] Epiphany (SybronEndo, Orange, CA), an adhesive root canal cement, showed signs of tooth discoloration.[214]

FIG. 26.1 Clinical case of a 19-year-old female patient illustrating discolorations from endodontic filling materials. **A,** Preoperative situation with history of endodontic treatment on both maxillary lateral incisors. **B and C,** Preoperative radiographs prior to nonsurgical retreatment and bleaching procedures. **D,** Postoperative situation after endodontic retreatment, bleaching procedures and new coronal restorations. Shades now match the maxillary arch with A2 (shade guide not shown). **E and F,** Postoperative radiographic control of procedures ca. 4 weeks after completion of endodontic treatment and new restorations.

A) Close-up view of upper teeth shows black spots on the lateral incisors.

B) Radiograph shows a dark patch at the root of lateral incisor.

C) Radiograph shows a high-density tissue in place of the dark patch.

D) Close-up view of teeth shows disappearance of black spots post procedure.

E) Radiograph shows the central tooth with filled root canal and a dark patch at the root tip. The neck region has radiolucent region. The adjacent tooth shows radiolucent root canal and central part of the crown.

F) Radiograph shows two teeth with radiolucent root canal and central part of the crown. The third tooth has a filled radiocanal.

Mineral trioxide aggregate (MTA), a dental material known for excellent biocompatibility, is used for apexifications, perforation repair, root-end

Telegram: @dental_k

www.konkur.in

filling, and revascularization procedures. MTA may discolor teeth and adjacent soft tissues.[22,29,31,114,120,173,222,259] The discoloring effects were shown for both gray and white formulations.

Antibiotic pastes in various combinations are used to initiate revascularization of immature necrotic teeth. Tooth discoloration after regenerative endodontic therapy was extensively reviewed by Kahler and Rossi-Fedele in 2015.[119] In particular, the use of the triple antibiotic combination (clinically used as triple antibiotic paste [TAP]) of metronidazole, minocycline, and ciprofloxacin has produced cases of dark discolorations of hard tissue structure.[119,126] Minocycline, a tetracycline derivate, binds calcium ions of the root dentin and forms an insoluble complex. Discoloration by minocycline-containing pastes affects both teeth with closed apices as well as teeth with open apices.[130] While intracoronal bleaching with sodium perborate has demonstrated whitening after several weeks,[130] these effects cannot be guaranteed. Thus minocyline-containing pastes should be avoided for regenerative therapies if these are addressed from a patient-centered perspective.[119] Other medications shown to induce discolorations include corticosteroid preparations[127] or formocresol and iodoform-based medications.[91,139] Repeated applications of formocresol will penetrate dentin and cementum, particularly in the teeth of younger patients.

Discolorations may also occur due to irrigation solutions. Sodium hypochlorite can discolor dentin based on its destructive effect on erythrocytes and the ability to crystallize on the dentin surface.[91] In contact with chlorhexidine, sodium hypochlorite may form a dark brown precipitate containing para-chloroaniline, which can only be removed by mechanical action.[20,21,109,133,252] MTAD (a mixture of a tetracycline isomer, citric acid, and a detergent; Dentsply Tulsa Dental, Tulsa, OK) has been described as a cause for brown discoloration,[238] probably due to dentinal absorption and the release of doxycycline.

Dental caries

Progressing caries can cause tooth discoloration. Early stages of caries are characterized by white, opaque enamel lesions. If caries arrests, the lesion may darken by taking up pigments from exogenous sources, frequently

Telegram: @dental_k

www.konkur.in

rendering it a deep dark brown or black color.[231] Explanations for discoloration include the formation of melanin or lipofuscin; the sugar-protein reaction also known as the Maillard reaction or nonenzymatic browning[17]; melanin[132] or food dye[124] uptake into the carious defect, or compounds diffusing ahead of the bacterial penetration of demineralized dentin. Dietary chromogens entering the dentin is seen at least as a co-staining factor facilitated by the increased porosity of the hard tissue structures by the carious process. Silver compounds, such as silver diamine fluoride, used to arrest caries may also result in the dark gray or black discolorations typical for silver. These discolorations have been shown not to be very esthetically tolerable by parents if children's anterior teeth are being treated.[45] The use and effects of silver compounds utilized in dentistry for caries management was critically reviewed by Peng et al. in 2012.[188] The addition of the Glutathione Bio-Molecule to the silver diamine fluoride solution has demonstrated some effects in minimizing tooth discoloration in vitro.[210]

Calcific metamorphosis/dystrophic calcification

Calcific metamorphosis can be caused by trauma, resulting in obliteration of the pulp with mineralized tissue. Odontoblasts can become destroyed by the traumatic impact and replaced by cells from adult stem cell populations in the pulp. These cells may initiate rapid deposition of reparative dentin, resulting in yellowish or yellow-brownish discolorations. Anterior teeth are mostly affected. Reparative dentin may occupy the entire pulp chamber, and in certain situations also major parts of the root canal system, resulting in a loss of translucency of the crown. Depending on whether or not the remaining uncalcified portions of the pulp remain vital, endodontic therapy may be indicated, yet difficult to execute, depending on the extent of the calcification.[258] Dystrophic calcification involves the formation of foci of calcification frequently found in the aging pulp, usually in perivascular or perineural locations. Bleaching procedures are not expected to render positive results as the underlying color changes for calcific metamorphosis dystrophic calcification are primarily related to translucency and not actual discolorations. Veneers or full coronal coverage restorations may be indicated in severe situations.

Telegram: @dental_k

www.konkur.in

Root resorption

Cervical root resorptions can lead to pink discolorations of teeth. The granulation tissue of the resorptive defect may be visible through a thin dental enamel layer, giving the characteristic “pink spot” appearance. Treatment involves the removal if the granulation tissue, etching with trichloroacetic acid to remove tissue remnants and an adhesive restoration of the defect. The treatment may involve a surgical exposure of the resorption or, in severe cases, extraction of the tooth.

Aging

Aging-related tooth discolorations are the result of a physiologic process attributed to the uptake of discoloring agents into the hard tissue structure over time.[253] Age-related changes such as incisal wear, craze lines, or cracks allow for easier penetration of discoloring agents. Furthermore, over time, enamel becomes thinner, and the change in ratio between dentin and enamel structure results in additional optical darkening of the teeth. Extracoronal bleaching can partially whiten age-related stains.

Extrinsic causes

Extrinsic stains are food-, beverage-, or smoking-related superficial stains and discolorations. Pigments from beverages such as coffee or tea or tar from smoking may cause dark, brownish discolorations. Extensive consumption of oranges, carrots, licorice, or chocolate may lead to food-related stains. In areas with diverse populations, betel chewing and areca nut use may be prevalent. In particular, people with origins from Southeast and East Asia, India, Nepal, Bangladesh, Sri Lanka, Pakistan, and parts of China, Melanesia, Taiwan, and the Pacific Islands may be affected. Consistent chewing of betel nut and related substances may cause large-scale black discolorations. Discoloring agents are also included in marijuana. The effects of staining may be accelerated or enhanced if demineralization from acidic food or poor oral hygiene created rougher tooth surfaces. In general, extrinsic stains respond well to scaling, polishing, or bleaching.

Treatment planning for internal bleaching

Telegram: @dental_k

www.konkur.in

The etiology of tooth discolorations may vary greatly. Thus the outcome of bleaching procedures is very dependent on the etiology of the discoloration. Prior to any bleaching procedures, the situation must be carefully assessed and potential bleaching outcomes discussed with the patient, together with the patient's expectations.[85] If bleaching procedures are indicated, then they should be integrated into the overall treatment plan.[217] A referring dentist should be made part of the conversation, if applicable. To establish a correct diagnosis, the patient's dental and medical histories need to be reviewed, including family history, genetic or systemic disorders, past and current medications, as well as any history of dental or facial trauma or orthodontic, restorative, and endodontic treatment. Radiographic analysis, including periapical and bitewing radiographs (as well as, if applicable, cone-beam computed tomography [CBCT]) is indicated. The assessment of the pulpal and periapical status is a prerequisite. Particular to treatment planning bleaching procedures, the dentition must be evaluated for caries prevalence and type, plaque control, and tooth surface stains, as well as the type, quality, and extent of existing restorations. Transillumination may aid in finding dental decay or pulp chamber calcifications.

Contraindications of bleaching

Tooth bleaching is not indicated for every situation and every patient. A thorough investigation and diagnosis of the patient's history and clinical situation may bring to the surface issues with the underlying stain that imply that a good esthetic outcome is either impossible or difficult to achieve.[44,189] The patient's esthetic expectations should be critically evaluated and the prognosis for the treatment discussed thoroughly. This includes potentially unrealistic expectations by the patient, either due to the clinical facts or the patient's overexpectations. The clinicians should be aware of any psychological or emotional problems that a patient may have with the current clinical situation and should advise patients if a bleaching procedure is not in their best interest. All findings and discussions with the patient should be well documented for legal purposes and future reference.

The patient must be made aware of additional dental procedures, such as restorative, periodontal, endodontic, or orthodontic treatments that may be

Telegram: @dental_k

www.konkur.in

necessary to achieve a desired esthetic goal.[189,217] Bleaching of teeth with white[26,88] or brown spot[123] discolorations could increase the existing contrast.[225] Teeth with existing decay or discolored or leaking older restorations may require technique variations[61] or new restorative procedures to remove diseased hard tissue structures to match the adjacent tooth esthetically.

Patients with confirmed severe attrition, abrasion, abfractions or erosion, caries, or insufficient restorations may experience dentin hypersensitivity prior to a bleaching procedure. This sensitivity could be strongly increased by an in-office or at-home external bleaching procedure, particularly if patients can control the amount of bleaching agent used. Clinicians are advised to resolve the underlying issues prior to engaging in tooth whitening procedures. Patients with suspected or confirmed bulimia should not receive bleaching procedures. The underlying psychological condition must be resolved prior to treatment. Most patients suffering from bulimia require veneers or full coverage restorations.

If orthodontic treatment with fixed orthodontic appliances is scheduled, no bleaching procedures should take place 2 to 3 weeks prior to any adhesive placement of brackets.[225] The oxygen released from the peroxide compounds will interfere with the bonding strength of the composite resins to hard-tissue structure.[61,171]

Alternatives to bleaching

Microabrasion is an alternative to bleaching with peroxide compounds for superficial irregularities and shallow intrinsic stains in the enamel surface.[90] Briefly, the technique involves mixing 18% hydrochloric acid solution with fine pumice powder to form a thick paste and applying it to the stained tooth surface. A rotating rubber cup in a slow speed handpiece with light pressure is used to distribute the paste. Liquid or sheet rubber dam placement is mandatory. Prior to using the rubber cup, the paste should be placed on the tooth for about 5 seconds, followed by the rubber cup activation for 15 seconds. While the enamel is carefully monitored for any damages, this procedure is repeated for up to 12 to 15 times, depending on the effectiveness of the stain removal. If the stain is not fully removed after this many

Telegram: @dental_k

www.konkur.in

applications, the procedure should be terminated to avoid permanent enamel damage. Copious irrigation with water is used to remove excessive paste material. The application of topical fluoride for several minutes concludes the procedure.[192] Several case reports with successful long-term follow-up have been reported.[223]

Chemistry of bleaching

The most common classification for tooth discoloration was described by Nathoo[175] and includes three classes:

- Nathoo type 1 (N1): The discoloring agent (chromogen) binds to the tooth surface, with a color similar to that of dental stains caused by chromogenic bacteria, coffee, tea, wine, and metals.
- Nathoo type 2 (N2): The discoloring agent is a Nathoo type 1 food stain that changes color to darker after binding to the tooth surface for a certain amount of time.
- Nathoo type 3 (N3): A prechromogen or, in its base state, colorless material binds to the tooth and causes a stain after a chemical reaction. These types of stains are often due to carbohydrate-rich foods (e.g., apples, potatoes), stannous fluoride, or chlorhexidine.

Tooth bleaching involves the alteration of light-absorbing or light-reflecting properties of enamel and dentin stains, resulting in apparent whitening. In-office bleaching, internally and externally, has been practiced since the early 20th century employing peroxide compounds. At-home bleaching procedures were only introduced in the 1980s. Historically, a variety of bleaching materials has been tried, including substances such as oxalic acid or chlorine.[26,83,175] Requirements for active tooth bleaching ingredients include a quick reaction with the stain components, fewer reactions with oral hard and soft tissues, ease of use, and an acceptable shelf life. Alkaline bleaching solutions may cause less demineralization damage than acidic solutions and are less likely to penetrate the pulp.[75,76] Bleaching materials should cause as minimal oxidative damage to tissues as possible (Fig. 26.2).[69,200]

Telegram: @dental_k

www.konkur.in

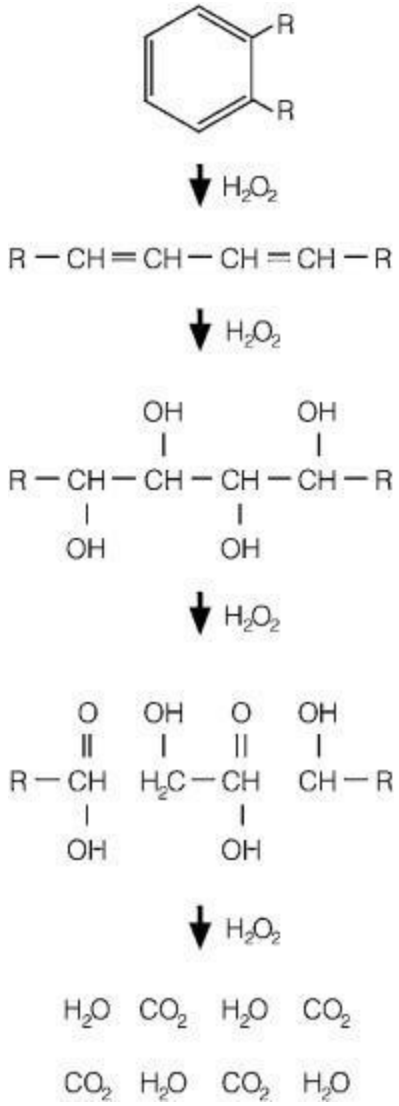

FIG. 26.2 Chemistry of tooth whitening with hydrogen peroxide. Breakdown of pigmented organic materials consisting of carbon ring structures with unsaturated, double carbon bonds to hydrophilic, nonpigmented carbon structures with saturated carbon bonds, resulting in effective whitening. Further degradation over this step may complete disintegration of the organic matrix with the release of carbon dioxide and water.

A benzene ring with two R groups at C1 and C2 in the presence of hydrogen peroxide leads to R single bonded to CH double bonded to CH single bonded to CH double bonded to CH single bonded to CH, which further in the presence of hydrogen peroxide leads to a compound that has a 4-carbon chain. Each carbon is single bonded to a hydroxyl group. The terminal carbon atoms are each single bonded to an R group. This compound further in the presence of hydrogen peroxide yields three compounds. The first compound has a central CH group double bonded to an oxygen atom, single bonded to a hydroxyl group and an R group. The second compound has a methylene group

Telegram: @dental_k

www.konkur.in

single bonded to a hydroxyl group and a CH group, which is double bonded to an oxygen atom and single bonded to a hydroxyl group. The third compound has a CH group single bonded to a hydroxyl group and an R group. Further, these compounds in the presence of hydrogen peroxide yield four water molecules and four carbon dioxide molecules each.

Contemporary bleaching techniques rely on oxidative processes that actively break down large pigmenting molecules. Oxidation is initiated by active peroxide compounds.[84,96] Peroxides and oxygen radicals are reactive free agents that are formed in all body cells that use oxygen. Reactive oxygen is, however, usually only found in low concentrations. Natural antioxidants, such as vitamin E, prevent the accumulation.[40,154] Cell damage may occur if reactive oxygen reacts with iron or copper ions.[69]

The active peroxides utilized by contemporary bleaching techniques primarily derive from hydrogen peroxide and carbamide peroxide for external, vital bleaching and sodium peroxide for internal, nonvital bleaching. Hydrogen peroxide (H_2O_2) is the simplest peroxide. In its pure form, it is a colorless liquid of a slightly higher viscosity than water. It is suitable for in-office as well as at-home bleaching procedures. Temperature increase accelerates the speed of the bleaching reaction. Hydrogen peroxide is more effective as a bleaching agent at pH values that are close to the dissociation constant.[65] Enzymes such as peroxidases can break down hydrogen peroxide into oxygen and water. High concentrations of hydrogen peroxide must be handled with great care. If accidentally brought into contact with soft tissues, it is caustic and may cause chemical burns by free oxygen radicals. For external bleaching procedures, the use of rubber dam with additional block out isolation around the gingival margins is mandatory to avoid iatrogenic complications. Typically, at-home concentrations range from 3% to 7.5%; however, some exceptionally strong concentrations can reach 14%. In-office concentrations may range from 25% to 38%. Hydrogen peroxide was shown not to induce significant changes in the organic and inorganic relative contents of enamel, but to whiten teeth by oxidizing the organic matrix.[62]

Carbamide peroxide ($CH_6N_2O_3$), or urea hydrogen peroxide, will break

Telegram: @dental_k

www.konkur.in

down into carbamide and hydrogen peroxide in aqueous solution.[175] It is an efficient bleaching agent.[248] The carbamide portion urea is well tolerated by the human body.[202] Carbamide peroxide is available as crystallized powder or white crystals that contain H_2O_2 in a concentration of about 35%. Most common home bleaching products contain carbamide peroxide at about 10% strength, but it can reach up to 30% (equivalent to 3.5% to 8.6% hydrogen peroxide). Carbamide peroxide can be used for internal bleaching.[248] At 35%, it shows very low extraradicular diffusion rates compared to hydrogen peroxide and sodium perborate.[145,158] Common bleaching preparations may contain glycerin or propylene glycol, sodium stannate, phosphoric or citric acid, and flavor additives. Carbopol, a water-soluble polyacrylic acid polymer, may be added as a thickening agent. It prolongs the release of active peroxide. At room and oral temperatures, the reaction of carbamyl peroxide takes place at a slower rate compared to hydrogen peroxide.[98] The release of oxygen from hydrogen peroxide occurs within seconds of contacting tooth surfaces, whereas carbamide peroxide remains active for 40 to 90 minutes.[175]

Sodium perborate ($NaBO_3$) comes in different preparations, mostly as a stable, dry powder or as a gel. It is available as a monohydrate, trihydrate, and tetrahydrate, with varying contents of oxygen. Depending on the oxygen content of the preparation, the compounds have a different bleaching efficiacy.[260] The perborate ion comprises 95% of the molecule and provides close to 10% of the available oxygen. Acids, water, and warm air initiate its decomposition to sodium metaborate, hydrogen peroxide, and nascent oxygen. The pH of sodium perborate solutions used for dental bleaching is alkaline. Because sodium perborate can be more easily controlled, it is considered safer to work with than hydrogen peroxide and more popular for intracoronal bleaching.

In an aqueous solution, due to heat or in an acidic environment, both carbamide peroxide and sodium perborate decompose and release hydrogen peroxide. Hydrogen peroxide release from sodium perborate has been shown to reach a peak concentration within 27 hours of mixing it with distilled deionized water, reaching a plateau after about 3 days, with only low levels of hydrogen peroxide present up to 28 days.[241] Hydrogen peroxide then diffuses through enamel and dentin. Subsequently, the oxidative processes

Telegram: @dental_k

www.konkur.in

provide for lightening of stains in comparison to the surrounding tooth structure. Double bonds of complex molecular chains with high-molecular-weight pigments are broken down by the chemical reactions with the free radicals. As a consequence, the change in pigment configuration and size leads to a change in the wavelength of the reflected light and the change of the stain to a lighter color.[75,76,175] In an ideal scenario, this leads to an effective reduction or elimination of the discoloration. However, after the bleaching process, a shade rebound effect may be observed, resulting from a reformation of double bonds of the molecules.

Walking bleach technique

Early accounts of the walking bleach technique described it as leaving a mix of sodium perborate and distilled water in the pulp chamber for a period of several days, with the access cavity sealed with a temporary restoration.[208,220] Later, the use of 30% hydrogen peroxide instead of water was suggested to provide better bleaching effectiveness.[179] A mix of sodium perborate and water or, alternatively, anesthetic solution remains the most commonly used technique for internal bleaching of nonvital teeth. The enhancement of the mixture with 30% hydrogen peroxide is being used less due to concerns of cervical root resorptions but remains an option for stains resistant to whitening that require stronger chemical compounds to achieve good bleaching results.[16,27,170,180,213]

Walking bleach clinical protocol

1. Prior to initiating a bleaching procedure, a diagnosis must be made following thorough evaluation of the etiology and origin of the stain. The patient must be informed about the history, the procedures involved in the treatment, the expected outcome of the procedure, and a potential for rediscoloration.
2. The endodontic status of the tooth must be assessed clinically and radiographically. In case of clinical symptoms, the presence of periapical pathology, or an insufficient root filling, retreatment of the existing endodontic filling is advised, unless the apical periodontitis is on a tooth with a history of recent, well-executed root canal

treatment or is verifiably in the process of healing.

3. Existing coronal restorations need be checked for adequate seal and shade and replaced if defective. In certain situations, the reason for discoloration may be a leaking restoration or discolored filling materials. Replacement of a defective restoration and cleaning of the access chamber may resolve the discoloration.
4. Clinical photographs should be taken at the beginning, throughout, and at the end of the treatment, with the tooth next to a shade guide to act as a reference for the practitioner and the patient.
5. Rubber dam isolation is mandatory. It is important to provide a seal at the gingival margin to prevent leakage of bleaching agents into the surrounding soft tissues. Depending on whether a single tooth or multiple teeth are being isolated, this may involve the placement of clamps, wedges, ligatures, floss, or light curing blockout material. Local or topical anesthesia may be applied if the patient is sensitive to the discomfort exerted during the isolation procedures.
6. The access cavity needs to be prepared so that all restorative filling materials, root-filling material and sealer remnants, and necrotic pulp tissues remnants are completely removed. This procedure requires good visualization through cavity refinement and the elimination of all undercuts, especially in the area of pulp horns. The practitioner should exercise care to avoid labial perforations.
7. Intracoronal materials should be removed to a level just below the labial gingival margin. Solvents such as xylene, eucalyptus oil, or orange solvent may be used to help clean the pulp chamber. Also, rinsing the cavity with sodium hypochlorite was suggested for cleanliness and disinfection or, alternatively, with alcohol to reduce surface tension.[16] Although some authors have recommended cavity treatment with 37% phosphoric acid or ethylenediaminetetraacetic acid (EDTA) to allow for deeper penetration of the bleaching agents, others have suggested that phosphoric acid was unnecessary and offered no better prognosis and no improvement in the bleaching effectiveness of either sodium perborate or a high concentration of hydrogen peroxide.[16,41] Acidic pretreatment may increase the risk adverse effects on the periodontium.[110]

Telegram: @dental_k

www.konkur.in

8. A protective layer of at least a 2-mm thickness should be placed over the root filling material. To avoid further pigmentation the protective layer should be white or tooth colored. Without this protective layer, bleaching materials may penetrate the root filling toward the apical foramen.[52,93,218] Materials that had been suggested include glass-ionomer cements, intermediate restorative material (IRM), Cavit and Coltosol, resin composites, photo-activated temporary resin materials such as Fermit, zinc oxide–eugenol cements, polycarboxylate cements, and zinc phosphate cements.[221] Cavit and IRM provide better sealing than zinc phosphate cement,[165] and Cavit offers a better leakage barrier than IRM.[93] Cavit and Coltosol also provided the most favorable seal when tightly compacted and proved to be superior to Fermit.[111] A protective barrier at the cementoenamel junction (CEJ) will furthermore reduce the risk of cervical root resorption and damage to the periodontal ligament.[221] Ideally, the vertical outline of the protective barrier should be 1 mm coronally to the CEJ to cover lingual, labial, and proximal CEJ areas.[207] Clinically, however, this may be difficult to achieve in confined spaces. A barrier at level with the labial CEJ will leave a substantial area of proximal dentinal tubules unprotected. Clinically, Cavit is also easily removable using ultrasonic instruments and chlorhexidine, thus minimizing the amount of tooth structure loss. Glass-ionomer cements may remain in place after the bleaching procedure is completed and do not need to be removed (Figs. 26.3 and 26.4).
9. Sodium perborate (tetrahydrate) is mixed with an inert liquid (distilled water, saline, or anesthetic solution) to achieve the consistency of wet sand. Mixing the paste instead with hydrogen peroxide is an option to accelerate the speed of the bleaching process, yet this technique is risky due to the increased possibility of cervical root resorptions. If it is required, due to the severity of the stain, then it should be used at 3% strength,[179] and it should be refrained from being increased to a 30% solution. The long-term results of a sodium perborate and water mix do not significantly differ from mixes with hydrogen peroxide.[108,202,206] A plastic instrument or amalgam carrier can be used to place the material in the pulp chamber. It is then

Telegram: @dental_k

www.konkur.in

carefully condensed with a plugger, without missing areas such as pulp horns (Fig. 26.5).

10. Excessive bleaching material should be removed, the paste carefully dapped with a cotton pellet without removing too much moisture, and a temporary filling material that is ideally 3 mm thick with well sealing margins placed (IRM, Cavit). Though some have advocated the use an acid-etched adhesive as a temporary filling to avoid recontamination, restaining, and to offer the best possible prevention from leaking walking bleach,[254] this may not be practical in small cavities where it becomes difficult to selectively etch the enamel without the risk of opening dentinal tubules for hydrogen peroxide and the subsequent risk of cervical resorption. Moreover, because this procedure would have to be repeated at every visit, it would add to the amount of tooth structure loss. Any walking bleach remnants on the external tooth surfaces or the rubber dam isolation need to be removed to avoid irritation of the soft tissues.
11. The rubber dam is removed and all tissues inspected.
12. The patient should be informed about the procedure. Depending on the reaction of the stain to the bleaching agent, the time to expect results may vary. Usually, a patient should be instructed to return between 3 and 10 days to evaluate the results and to change the walking bleach if necessary. To avoid overbleaching,[16] the patient needs to be instructed to self-monitor the color status of the tooth and to report back earlier than the scheduled appointment date if the color change has reached the desired result or if the temporary filling material is starting to wash out. Although a rarely documented event, it was advocated to instruct the patient about an increased susceptibility to tooth fracture in the time that the tooth is filled with a bleaching agent and not a supportive buildup.[18]
13. If desired results cannot be obtained, a mix with 3% H_2O_2 can be considered. However, the patient needs to be informed about the risks and that most good bleaching results can be accomplished by a sodium perborate and water/anesthetic mix.[206] If the esthetic outcome with the results is acceptable, a potential for resorption may be minimized.

Telegram: @dental_k

www.konkur.in

14. If a clinical case does not show improvement after three to four attempts, the diagnosis and treatment plan should be reevaluated for a different etiology.
15. At the conclusion of the bleaching procedure, a postoperative radiograph should be taken to check for any adverse effects of the bleaching agents. A definitive adhesive restoration should be placed about 1 to 3 weeks after the last appointment[42,215,216,246] (see the separate paragraph regarding definitive restoration after bleaching procedures a bit later).
16. The patient should be scheduled for yearly follow-ups to include a clinical examination and periapical radiographs.[49]

Thermocatalytic bleaching

Heat-activated Superoxol had been advocated for its increased bleaching effect for nonvital bleaching of endodontically treated teeth.[112] Hydrogen peroxide with a concentration of 30% to 35% is placed in the pulp chamber and activated via heat application with electric heating devices or special lamps.[27,28,37,113,134,162,230] All preparatory steps follow the clinical protocol described previously for the walking bleach technique. However, in lieu of placing a sodium perborate/water mix, the pulp chamber is filled with 30% to 35% hydrogen peroxide and a heating device applied (e.g., Touch'n Heat, System B; Analytic Technology, Orange, CA; SuperEndo Alpha, B&L, Fairfax, VA). The application of heat will result in foaming of the hydrogen peroxide, with a subsequent release of free radical oxygen. This procedure is repeated in three to four office visits. In addition, some protocols advocate the placement of 30% to 35% hydrogen peroxide in the pulp chamber between chair-side appointments.[47,160,261] Temporary filling placement follows the same steps as outlined earlier for the walking bleach technique. If this technique is used, great care needs to be taken to avoid overheating of teeth, periodontal ligament, and gingival tissues. Regular cooling breaks are recommended. Products such as Vaseline, Orabase, or cocoa butter have been suggested for additional thermal insulation. However, due to the increased risk of cervical root resorption when using this clinical technique, the walking bleach technique is seen as more favorable today. If a decision is made to apply the thermocatalytic technique, the patient must be thoroughly informed about the risks and potential long-term consequences.

Definitive restoration of teeth following internal bleaching

Telegram: @dental_k

www.konkur.in

A well-sealing definitive restoration is one of the foundations for long-term success, as it prevents coronal microleakage from the access cavity and avoids the risk of renewed discoloration through open dentinal tubules.[18,264] It is generally accepted that an acid-etched and bonded composite resin restoration provides the most favorable results. For preexisting resin composite restorations, a rebonding of the filling has been suggested to reduce the risk of microleakage at the dentinal margins after bleaching with 15% carbamide peroxide.[169] The restoration must be placed at a depth that provides both the adequate seal for the access cavity as well as incisal support. The placement of a white base material below the resin restoration was viewed favorably in situations where the composite resin restoration may compromise the translucency of the tooth. Lighter shade composites were suggested for teeth with a not entirely satisfactory bleaching result.[4,81] Consensus exists that the adhesive bond strength between glass-ionomer cements and composite resins to dentin and enamel is temporarily compromised following bleaching procedures[60,78,117,234–236] due to remnants of peroxide or free oxygen, which inhibit resin polymerization.[60,239] Several remediation techniques have been suggested to overcome the negative influence of hydrogen peroxide containing bleaching agents, including dehydrating agents such as 80% alcohol and the use of acetone-containing adhesives,[118] the application of sodium hypochlorite to dissolve remnants of peroxide,[202] catalases,[195] the antioxidant sodium ascorbate,[121,142] or the use of alpha-tocopherol.[262] At least 1 week of contact with an aqueous solution was recommended to achieve adequate bonding.[5,234,240] Optimal bonding to bleached dentin and enamel was shown to be reestablished after 3 weeks.[42,216] Calcium hydroxide medication in the pulp cavity was advocated to achieve a buffering effect for an acidic pH that may be present after internal bleaching[18,122]; however, it may be unnecessary after a walking bleach technique, due to weaker nature of sodium perborate compared to Superoxol. Light curing of the composite resin restoration should occur from labial so that shrinkage toward the axial walls can reduce a potential risk of microleakage.[147]

External bleaching

Telegram: @dental_k

www.konkur.in

External bleaching may involve single teeth or entire arches. Whereas internal bleaching requires endodontic treatment of the tooth, external bleaching can also be applied to vital teeth. Steady advancements have been made in external bleaching techniques since their inception.[100,115] Various techniques exist, including in-office and at-home methods.

In-office external bleaching

The in-office or chairside techniques are completely in the hand of the dental professional. Almost all techniques involve the application of hydrogen peroxide gels of concentrations between 25% and 38%. Liquid solutions at higher concentrations are associated with higher complication rates of soft-tissue damage, as they are more difficult to control in terms of handling. High concentrations of hydrogen peroxide solutions are thermodynamically unstable and may explode if not stored in dark bottles in a refrigerator. It was also demonstrated in vitro that hydrogen peroxide gel concentrations above the 15% level did not increase bleaching effectiveness; they may, however, negatively affect enamel hardness.[87]

Although early techniques also employed heat activation, electric currents, or combinations with other chemicals to make hydrogen peroxide more effective,[153] contemporary techniques commonly use bleaching gels applied on their own or in combination with light activation by special lamps. Patients should undergo a hygiene treatment with cleaning and polishing of the tooth surfaces prior to external bleaching, as well as a careful evaluation of the nature of the stain or the possibility that the discoloration is related to an existing restoration.

If external bleaching is indicated, the treatment involves the placement of rubber dam, as described in the protocol for the walking bleach technique. Great care must be taken to avoid soft-tissue damage. If liquid hydrogen peroxide solutions and no gels are used, the additional placement of gauze to act as a reservoir for hydrogen peroxide is recommended to keep the solution in the proximity of the teeth. More gauze can be placed underneath the rubber dam as an additional safety to catch excess solution before it can damage gingiva, mucosa, or lips. However, these complications can be greatly reduced by a gel application with or without light activation.

Light sources used for bleaching include conventional ultraviolet (UV)

Telegram: @dental_k

www.konkur.in

bleaching lights, tungsten-halogen and Xe-halogen lights, plasma arc lamps, light-emitting diodes (LEDs), or laser lights. The wavelengths of the various light sources may range from the high UV to low visible blue light spectra, and invisible infrared light, such as employed by a CO_2 laser.[37,194] Although all of these lights have been used to activate the bleaching agent or expedite the whitening effect, there are great differences among them. Limited research on bleaching lights exists, sometimes with controversial results. Although some studies emphasized certain effects after light-activated bleaching, others reported no differences between teeth bleached with and without light activation.[37,138,194,227] In the 1980s, the Fuji HiLite dual-cure material containing 35% hydrogen peroxide was used. When the paste was mixed, it had a green color that would turn white upon activation with a standard UV light upon the release of oxygen. In comparison to other light activation techniques, this was a more time-consuming process and less comfortable for the patient. In addition to light activation alone, various photocatalysts had been suggested, including methylene blue and UV or visible light-activated titanium dioxide.[224]

Traditionally, tungsten-halogen curing lights are the standard dental curing lights that provide heat and stimulate the initiation of the chemical reaction by activating light-sensitive chemicals in the bleaching agent. Depending on manufacturer recommendations, the individual bleaching time with activation of the gel is up to 30 to 60 seconds per application per tooth, which is rather time consuming for the patient and the dental professional because up to three passes are recommended. Some products available were based on a premixed 35% hydrogen peroxide gel with carotene that converts light energy to heat upon activation and increased the breakdown of the bleaching agent into active free radicals. Xenon-halogen curing lights are newer generation dental curing lights used to the same effect. Some specialized bleaching lights offer full-arch adaptors. A randomized clinical trial of in-office tooth whitening identified blue light-activated bleaching as the one technique with results most favored by patients.[9]

Xenon Plasma Arc Lamp systems are primarily based on thermal activation and the activation of chemical catalysts in the bleaching gel. The light employed is of high intensity, produces great heat energy, and limits the application to 3-second intervals for up to three passes. Due to the high heat

Telegram: @dental_k

www.konkur.in

intensity, there is a potential for dental trauma to the pulp and the surrounding tissues, which is why these lights have to be used with great care. Some manufacturers produced lights that allowed an on-off mode setting over 5-second bursts to have a safer and lower-intensity output.

LED lamps emit cold blue light with a wavelength of around 465 nm, which allows activation of hydrogen peroxide gels and accelerates the bleaching process. LED lights are placed close to the patient's teeth for 15- to 20-minute treatments, which may have to be repeated up to three times. Cosmetic specialists with no dental background have adopted this method of bleaching because it offers low risk, as no heat activation is involved. Green LED lights demonstrated the lowest intrapulpal temperature increase compared to conventional halogen, hybrid lights with or without a laser component, or high-intensity LED lights.[167] However, a systematic review investigating the influence of the light source on pulpal responses during bleaching procedures concluded that there was not sufficient evidence to extrapolate the true human situation.[23]

Lasers have been in use for tooth bleaching at around 810 to 830 nm and 970 to 980 nm wavelengths in combination with 30% to 35% hydrogen peroxide gel. Gels prepared for laser activation may contain fumed silica and a blue dye, the latter absorbing the laser wavelength, leading to an increase in temperature and a controlled breakdown of the hydrogen peroxide. Gels are commonly applied in a 2- to 3-mm thickness over the teeth. An application of 1 to 2 W of laser energy for 30 seconds per tooth has been recommended. Dental professionals and patients are required to wear protective eyewear while operating lasers. Some studies reported no significant advantage to using laser light for bleaching,[37] whereas others demonstrated a significant increase in whiteness and decrease in yellowness compared to conventional power bleaching[66] or showed a decrease in color regression after a combination of at-home bleaching with an in-office laser-assisted bleaching session in comparison to an at-home bleaching regimen on its own.[6]

Power bleaching

The technique normally termed *power bleaching* refers to accelerated vital in-office tooth whitening procedures that employ xenon plasma arc-curing lights or lasers. Dental hygienists or assistants may carry out this procedure,

Telegram: @dental_k

www.konkur.in

depending on individual state licensing regulations. The use of laser lights might be more strictly regulated and may not be permitted to be performed by dental professionals other than the dentist. For a delegated procedure, liquid rubber dam is often applied in lieu of a sheet of rubber dam, which would require active retention techniques, such as wedges, floss, or ligatures. Liquid rubber dam can be applied more easily without assistance, but it does not give additional protection to gingival tissues or the mucosa.

Power bleaching clinical protocol

1. Prior to initiating the bleaching procedure, a diagnosis must confirm that the discolorations can be resolved by external bleaching. The patient must be informed about the history, the procedures involved in the treatment, the expected outcome of the procedure, and the potential for rediscoloration.
2. A thorough clinical examination should be performed to detect caries, developmental defects, endodontic or periodontal diseases, and other pathologic conditions in the oral cavity. Existing restorations need be checked for quality and shade and replaced if defective. For certain teeth, the reason for discoloration may be leaking restorations or discolored filling materials. Replacement of a defective restoration may resolve most of the discoloration.
3. Patients should have a hygiene appointment prior to the bleaching session to check for sound gingival tissues and ensure that areas to be bleached are free of calculus or plaque.
4. Clinical photographs should be taken in the beginning, throughout, and at the end of the treatment with the tooth next to a shade guide to act as a reference for the practitioner and the patient.
5. The patient and dental professionals should wear proper protective eyewear (sunglasses). The patient should be prepared to signal if a tingling sensation to the gingiva, mucosa, lips, or teeth is felt or if the temperature is perceived as too hot. As a precaution, vitamin E capsules, a powerful antioxidant, should be ready at hand. In case of an emergency, these can be cut open and the oil inside the capsules applied to the injured tissues with a cotton pellet.
6. The teeth should be cleaned again with rubber cups and pumice. The

Telegram: @dental_k

www.konkur.in

cheeks should be retracted with photo retractors or cotton rolls. The cotton rolls serve as an additional safety feature if any hydrogen peroxide is leaking. Rubber dam isolation is mandatory. This can be either liquid rubber dam (light-cured resin dam) around the gingival margins or ligated sheet rubber dam. Liquid rubber dam bears a higher risk of tissue injury. It is important to create a tight seal at the gingival margin to prevent leakage of bleaching agents. If a sheet rubber dam is used, the inversion of the rubber dam in the sulcus with an air syringe followed by dental loss ligature is recommended.

7. The power bleach gel is mixed according to the manufacturer's recommendation and applied on the labial surfaces of the teeth in a 2- to 3-mm thickness with a disposable brush.
8. Depending on the light source, each individual tooth is exposed for up to three passes for 3 to 10 seconds, according to manufacturers' recommendations. The gel may stay on the teeth for another 3 to 5 minutes without light activation.
9. The gel should be removed with a wet gauze and copious amounts of water, then cleaned with pumice for a second time, and rinsed again to ensure all remnants of the bleaching gel were removed.
10. The rubber dam and any remaining cotton rolls and retractors are removed. Water rinsed is used again, and all tissues inspected.
11. The teeth should be polished and a neutral pH sodium fluoride gel be applied.
12. The patient should be informed about the procedure. Depending on the individual situation, results may vary. The patient should be instructed that increased sensitivity of the teeth may be present for 2 to 3 days.
13. The patient ought to be instructed to refrain from tobacco, coffee, tea, cola, and wine for a period of 2 weeks.[51]

At-home external bleaching

For patients who do not want to undergo an in-office procedure, the possibility of at-home external bleaching with custom-made bleaching trays exist. These may be readily available from a pharmacy, requiring only crude adaptation after softening in hot water, or can be custom-fabricated in a

Telegram: @dental_k

www.konkur.in

dental laboratory. Over-the-counter products typically come with bleaching gels, although some come with pastes. Some products are offered as simple, low-strength hydrogen peroxide strips or pastes that can be brushed onto the teeth. Occasionally, pre-rinses are offered. However, pre-rinses may have a rather acidic pH, as the solutions may become unstable more easily.

Professional home bleaching involves the fabrication of a well-adapted custom tray after impressions are taken and models are poured. The patient will wear gel loaded in a tray that slowly releases the bleaching agents for several hours or overnight every day for 2 to 6 weeks until a satisfactory result has been achieved.[44,96–100]

Trays are usually made using alginate impressions. Upon delivery, trays must be checked for fit, smoothness at the margins, and occlusion. The patient should place several drops of bleaching gel into the tray before every application. The most common bleaching agent for at-home bleaching is 10% to 22% carbamide peroxide with an effective yield of 4% to 7.5% hydrogen peroxide. Patients who wear the trays during the daytime may choose to replace the gel every 2 hours. If any disturbance (e.g., thermal sensitivity, abnormal taste, or tissue irritation) occurs, the patient should stop the procedure and seek advice from the dentist. Patients who use the trays in the daytime should be seen once per week for 3 weeks; nighttime users should be seen every other week for 6 weeks.

The success of at-home bleaching mostly depends on the patient's cooperation. Risks include potential compliance issues and the possibility of overuse of the bleaching agent. Results with at-home bleaching techniques tend to remain stable for 1 to 10 years.[149]

Risks and complications associated with tooth bleaching

Risks associated with internal tooth bleaching

Tooth bleaching may cause localized adverse effects on hard and soft tissues, such as the risk of external cervical resorption, interaction with adhesive bonding systems, and dental material solubility.[11]

Telegram: @dental_k

www.konkur.in

Cervical root resorption

External or cervical root resorption is a serious complication of whitening procedures with peroxide compounds (Fig. 26.6). Cervical root resorptions were seen in 6% to 8% of cases when 35% hydrogen peroxide was used, and 18% to 25% if the hydrogen peroxide was heat activated.[54,73,74,94,104,141,204] The etiology for external root resorption to occur is complex.[86,94,136,141] It is suggested that a combination of predisposing factors—such as a cementum deficiency exposing dentin, a periodontal ligament injury that is triggering an inflammatory response, or an infection that is sustaining inflammation—has to be present.[18,74,178,244] Cervical resorptions are also often seen in patients who had bleaching treatment at a young age[7,12,74,104,108,141] or who suffered from a traumatic injury.[94,242]

FIG. 26.6 Clinical case of a 33-year-old female patient illustrating extensive resorptive defects after nonvital bleaching efforts. **A,** Postoperative situation after endodontic treatments of the maxillary right canine and first premolar. The patient was referred back to the primary care provider for definitive restorations. **B,** Situation 12 months after the original endodontic treatments. The patient had spent 1 year overseas and received endodontic treatment on the second premolar, root-end surgery on the canine, as well as nonvital bleaching of the maxillary right canine and first premolar. Note the extensive resorptive defects on both teeth that received bleaching procedures and the missing restoration on the canine. **C** and **D,** Coronal CBCT views of canine and first premolar. Note location and dimensions of the resorptions *(arrows)*.

Source: (Courtesy Dr. Mariana Lis Robles, Mendoza, Argentina.)

Hydrogen peroxide itself was suggested to be responsible for the induction of the resorptive process.[94] The body can handle hydrogen peroxide effectively at lower concentrations.[92]

Proinflammatory agents activate reduced nicotinamide adenine dinucleotide phosphate oxidase, which produces superoxides that can react with hydrogen peroxide in the presence of inflammation.[89] This may allow the formation of hypochlorous acid, N-chloramines, and reactive hydroxyl ions, and cause a resorptive process.[89] Hydrogen peroxide may reach the bone by diffusion via dentinal tubules, cementum, and the periodontal ligament.[89,184,257] Within the bone, the acidic environment induced by the low pH value of hydrogen peroxide at high concentrations may facilitate osteoclastic activity.[74,249] Significant increases in the levels of the bone resorption markers RANK-L and IL-1β were observed in the gingival crevicular fluid of teeth undergoing nonvital bleaching with either 35% hydrogen peroxide or 37% carbamide peroxide.[24] After application to the enamel surface, 25% hydrogen peroxide was also shown to cross enamel and the dentinoenamel junction (DEJ), reaching the dentin.[245]

About 10% of all teeth have a natural defect at the cementoenamel junction, exposing dentin.[229] These cementum defects, as well as unusual morphology at the CEJ, can favor the penetration of hydrogen peroxide into the cervical area of a tooth.[135,177,204] The placement of 30% hydrogen peroxide in the pulp chamber of teeth with missing parts of the cementum layer resulted in the diffusion of 82% of the bleaching agent.[204] Dentin exposure may also be a result of defects in the cementum layer following traumatic injuries or an incomplete formation of the cementoenamel junction.[161,168] The permeability of the dentin can then facilitate the penetration of bacteria or bacterial endotoxins from an infected root canal

Telegram: @dental_k

www.konkur.in

system or pulp chambers to the surface of the root, potentially causing inflammatory processes in the periodontal ligament.[105,170] If highly concentrated bleaching agents are used, in particular, 30% to 35% hydrogen peroxide, a diffusion of highly reactive hydroxyl radicals via unprotected dentinal tubules and cemental defects has been suggested.[135,204]

Free oxygen radicals are also able to break down constituents of connective tissue, in particular collagen and hyaluronic acid, which may be another likely mechanism responsible for periodontal tissue destruction and root resorptions after internal bleaching.[55] The oxidizing agents were shown to induce dentin protein denaturation,[141] either by local changes in the pH[58,80,168] or by heat.[71,94,161] Pretreatment is with EDTA, a chelating complex binding iron. Heat activation of 30% to 35% hydrogen peroxide is the characteristic step of the thermocatalytic method. It may result in widening of the dentinal tubules, allowing for a diffusion of free radicals into the dentin[183,203] and an enhancement of resorptive processes.[203] The hydroxyl radicals released from hydrogen peroxide are extremely reactive and have been shown to degrade components of connective tissue.[55] As a consequence, the thermocatalytic technique is nowadays disfavored due to the high risk of external root resorption.

The potential for cervical resorption may be minimized by using sodium perborate with water instead of hydrogen peroxide for internal bleaching techniques, because similar acceptable outcomes have been reported[206] and because it did not cause cervical resorption, even 1 year after bleaching.[161] Sodium perborate-water suspensions were also shown to be less toxic to periodontal ligament cells than 30% hydrogen peroxide or sodium perborate mixed with 30% hydrogen peroxide.[129,181] Moreover, a strong association was found between tooth discoloration related to blood components and an increased presence of hydroxyl radicals.[55]

Treatment of cervical resorption may range from simple fillings to extraction, depending on the severity of the resorptive defect. An early detection of a resorptive process increases the chances of avoiding unnecessary tooth loss because the prognosis for cases with advanced resorptions is doubtful.[59] Evaluation by means of a CBCT may greatly enhance the ability for correct treatment planning.[64] If resorptions are related

Telegram: @dental_k

www.konkur.in

to internal bleaching, the placement of calcium hydroxide into the root canal space has been suggested[74] to change the low pH present in inflammatory osteolytic processes characteristic for hard-tissue resorption.[164] Reparative hard-tissue formation was suggested to take place following this treatment.[243] Some cervical resorption can be repaired with direct restorations, such as composite resin or glass ionomer-composite compomers (e.g., Geristore, DenMat, Lompoc, CA). This treatment requires a surgical exposure of the defect, followed by degranulation by curettage and the application of 90% trichloroacetic acid to remove remnant tissues prior to adhesive restorations.[72,166] Patients should be informed about the potential for gingival recession if the surgical access requires a full thickness flap in the anterior area.[64,80] Rapid orthodontic extrusion in combination with fiberotomy and restoration was suggested for resorptions with a substantial subcrestal component.[103,144]

The free radicals released by peroxides can cause chemical burns and tissue sloughing on gingiva, mucosa, or other oral soft tissues. This may occur during the internal bleaching procedure in the dental chair during both walking bleach and thermocatalytic technique appointments after a patient has left the office if a walking bleach technique is used. In any case, prevention is the best cure, and avoiding accidents is the priority. In general, the use of higher concentrations of peroxides, such as 30% to 35% hydrogen peroxide, in particular in liquid form, is more dangerous than the use of a mixed paste or gel of sodium carbamide peroxides that have lower effective hydrogen peroxide concentrations and can be used in a more controlled way. However, in the dental office, great care has to be taken so that the bleaching agents do not leak through the rubber dam and all excessive bleaching material is carefully removed after the end of the procedure (see details in Walking Bleach Clinical Protocol). For emergency situations, clinicians should have vitamin E on hand, because this tough antioxidant reverses the strong oxidation processes on oral soft tissues and minimizes damage (see details in Power Bleaching Clinical Protocol). To avoid out-of-office accidents, it must be assured that the temporary filling material is sealing tightly and is placed in an adequate thickness to cover the bleaching agent. Patients should be advised to return immediately after a temporary restoration starts to fail or wash out.

Enamel and dentin damage

A number of in vitro studies reported changes in enamel microhardness and morphology,[25,43,87,159,172,197,199,263,266] as well as in the cementum.[237,265] It has been suggested that peroxide components alter the proportions of organic to inorganic hard tissue components.[96,105,152,191,] A treatment with 10% carbamide peroxide and 7.5% hydrogen peroxide did alter the enamel surface micromorphology but not its microhardness.[209] Hydrogen peroxide demonstrated a different chemical affinity to each specific dental tissue, rather than just to diffuse through interprismatic spaces into the dentinal tubules when applied to the enamel surface.[245] It was also shown to modify the organic compounds of dentin.[245]

At least in vital teeth, however, these changes appear not to be permanent[15,79] and can be reduced by the application of fluoride before or during remineralization.[36,79] Bleaching with hydrogen peroxide increased the demineralization in teeth affected by incipient caries lesions.[34] The bleached enamel surface may show an increased porosity and slight erosion when observed under scanning electron microscopy (SEM). These changes were mostly seen when acidic prerinses or bleaching gels with a low pH had been applied.[247] One study found no differences between bleached and unbleached human enamel over a 6-month period when a 10% carbamide peroxide gel was used.[102] No significant clinical evidence of negative effects on enamel by professionally administered at-home bleaching techniques was seen. A few case reports described significant enamel damage after over-the-counter products had been applied by patients, possibly the result of overuse.[53]

Inhibition of adhesive bonding

Polymerization and bonding strength of composite resins to dentin and enamel are temporarily compromised by the oxygen released during a bleaching process.[14,60,226,233,] Scanning electron microscope images have shown an increased porosity of the enamel after bleaching.[235] This may present a clinical issue in terms of leaking restorations with the potential for caries activity and rediscoloration. Several remedial solutions were suggested, including rinsing the cavity with sodium hypochlorite,[202] which, however, was demonstrated to have similar effects on bonding, alcohol,[118]

Telegram: @dental_k

www.konkur.in

chlorhexidine, catalase, and sodium ascorbate.[48,121,142] Clinicians are generally advised to wait for 2 to 3 weeks prior to placing a definitive adhesive restoration to allow time to reverse the effects and have all remnants of hydrogen peroxide removed from the pulp chamber.[48]

Risks associated with external tooth bleaching

External tooth bleaching (including professional at-home tray bleaching techniques) is, generally speaking, a safe procedure that allows tooth whitening to be retained for several years.[149] Nevertheless, concerns have been raised since the introduction of external bleaching,[101,154–157] mostly related to the caustic effects of free oxygen radicals that may cause tissue damage in oral soft and hard tissues. The reaction with proteins, lipids, and nucleic acids may eventually lead to cell damage. Human dental pulp cells in contact with enamel/dentine discs treated with 17.5% hydrogen peroxide gel demonstrated significant overexpression of inflammatory mediators, as well as significant cell viability reduction.[219] At-home external bleaching did not demonstrate significant long-term complications if 10% carbamide peroxide was used as the bleaching agent. However, since at-home bleaching does not give the practitioner control over the patient's behavior, higher concentrations of carbamide peroxide than recommended may be used and could more likely cause damage to the gingival and periodontal tissues.[106] In general, caution is advised with regard to the quality of product, techniques used, and treatment rendered.

Tooth sensitivity

The presence of hypersensitivity is an indication of inflammatory changes in the dental pulp.[156] Histologically, however, few pulps have demonstrated actual signs of inflammation after external bleaching with hydrogen peroxide gels.[128] Nevertheless, changes in sensitivity after external bleaching of vital teeth have been reported in up to 50% of the teeth.[101,153] Most of the time the change in sensitivity is mild to moderate and is transient over a period of 2 to 3 days.[116,150,190] The use of 37% carbide peroxide compared to 35% hydrogen peroxide for in-office bleaching demonstrated reduced sensitivity in a randomized controlled trial.[187] A systematic review and meta-analysis

Telegram: @dental_k

www.konkur.in

assessing in-office versus at-home vital bleaching in adult patients did not identify differences regarding the risk or intensity of tooth sensitivity nor the effectiveness of the bleaching treatment.[57] In the case of at-home bleaching, the incidence of hypersensitivity increases with the frequency of changing the bleaching trays, particularly if they are changed more than once daily.[150] For the best immediate remediation, the bleaching periods should be shortened. Both topical fluoridation and desensitizing toothpaste may aid in reducing the hypersensitivity after bleaching.

Hydrogen peroxide that is released from the bleaching trays or from the gel during power bleaching may reach the pulp chamber via craze lines, enamel defects, as well as enamel and dentin cracks.[32,50,82,193] However, it was shown that 50,000 µg of hydrogen peroxide are required to inhibit pulpal enzymes.[92] From bleaching gels containing 12% carbamide peroxide, less than 30 µg of hydrogen peroxide were shown to reach the pulp chamber after tray applications for up to 7 hours. Therefore at least for at-home external bleaching, it is unlikely to create long-term or significant damage. Nevertheless, to avoid complications, active bleaching should be avoided whenever restorations with ill-adapting margins or exposed dentin areas are present. The microhardness of methacrylate-based composite resins can be affected by carbamide peroxide in home bleaching concentrations.[63] It has been suggested that desensitizers be used in addition to the bleaching gel. Fluoride, casein phosphopeptide-amorphous calcium phosphate, potassium nitrate, or nano-hydroxyapatite suspension applied after the in-office bleaching process or mixed into bleaching agent were shown to recover the microhardness of the enamel after 14 days.[140] Caution should also be applied regarding children and adolescents due to the larger pulpal volume present in immature, respectively younger teeth.[146]

Gingival irritation

The most commonly observed adverse effect after external bleaching is gingival irritation, which may be associated with an increase in tooth sensitivity.[148,205,211] Most of the gingival irritations are mild to moderate and disappear after 2 to 3 days without causing significant discomfort for the patient. For in-office bleaching, these issues are mostly related to soft-tissue exposures to excessive bleaching gel or liquid hydrogen peroxide in amounts

Telegram: @dental_k

www.konkur.in

less than necessary to cause severe discomfort or tissue damage. However, when a patient reports tissue irritation, the soft tissues should be checked immediately. Warning signs other than the patient's sensation are air bubbles rising from the gingival margins. The area should be copiously rinsed without delay. A vitamin E preparation should be on hand to serve as an emergency dressing that will provide an immediate antioxidative effect. If an at-home technique is used, gingival irritations may be related to badly adapting trays, and the issue should be resolved after correcting the defective trays. As for gingival hypersensitivity, the increase of gingival irritation is related to the frequency of changing the gel in the custom trays. For more severe cases, topical anesthesia, limited movement, and good oral hygiene can increase the speed of soft-tissue healing.

Mercury release from amalgam restorations

Several studies have reported an increased mercury release from amalgam restorations after the application of bleaching agents, in particular carbamide peroxide.[198,201] Although mercury is toxic and can cause damage in larger doses, no health implications due to the induced release of mercury by tooth bleaching have been reported.

Prognosis of bleaching

Most studies addressing the prognosis of internal bleaching refer to the immediate postoperative whitening result.[4,7,12,108,112,162,178] The higher concentrations of bleaching agents used for in-office vital bleaching versus at-home bleaching products were demonstrated to produce greater bleaching effectiveness.[131] A long-term follow-up of teeth bleached with the thermocatalytic technique reported an 80% success rate after 1 year and a 45% success rate after 6 years, confirming the redarkening of bleached teeth in many instances.[67] External bleaching may show color regressions after 1 to 3 years.[38] A randomized clinical trial evaluating CIELab parameters of teeth bleached using the walking bleach or an inside-outside technique demonstrated no significant changes in color and lightness comparing the short-term bleaching results with the 1-year follow-up.[186] Al-Tarakemah and Darvell reevaluated a data set of 300 patients, coming to the conclusion that some patients who started out with lighter color shades at the beginning of a

Telegram: @dental_k

www.konkur.in

bleaching procedures may be worse off after 1 year of follow-up, attributing this to cumulative damages to the organic matrix of the enamel.[10] Discolorations induced by trauma or pulp necrosis appear to have a good prognosis of around 95%, indicating that bleaching reaches the desired result, whereas discolorations due to medications or restorations have a much less successful outcome.[176] Discoloration caused by restorative materials has an uncertain prognosis,[250] particularly if metallic ions such as silver, mercury, copper, or iodine are involved. Although some authors disagree,[1,35,113] there may be a higher possibility for successful bleaching in younger patients due to the wider open dentinal tubuli when compared to older patients.[2,107,178] Gray or light yellow discolorations may be easier to bleach than other discolorations.[1] Well-sealing composite restorations are recommended to prevent renewed discoloration.[1]

Endodontic record excellence

Importance

Endodontic therapy records serve as an important map to document and guide the clinician's journey down the correct diagnostic and treatment path. Documentation is essential to attaining endodontic excellence.

The dental record must contain sufficient information to identify the patient, support the diagnosis, justify the treatment, and document the course and result of treatment, and it should be designed to protect the patient's welfare. Records also are fundamental means of communication among health care professionals.

Content

Telegram: @dental_k

www.konkur.in

Endodontic treatment records should include the following information:

1. Name of patient
2. Date of visit
3. Medical (periodically updated) and dental history
4. Allergies and adverse drug reactions
5. Chief complaints
6. Radiographs of diagnostic quality
7. Pulpal and periodontal diagnostic tests performed
8. Clinical examination findings
9. Differential diagnoses and final diagnosis
10. Treatment plan
11. Prognosis
12. Referrals, including patient refusals (if any)
13. Communications with other health care providers
14. Progress notes (including complications)
15. Completion notes
16. Canceled or missed appointments and stated reasons
17. Emergency treatment
18. Patient concerns and dissatisfactions
19. Planned follow-ups
20. Drug and laboratory prescriptions
21. Patient noncompliance
22. Consent and informed refusal forms
23. Accounting ledger
24. Recall notifications
25. Name or initials of author for each treatment entry
26. E-mail address of patient
27. Emergency contact persons, addresses, and phone numbers
28. Patient phone numbers including home, work, and cell
29. Log of records and radiographs received or sent

Office records

1. Sign-in and discharge sheets (optimal)
2. Periodic bacteriological monitoring of waterlines

Telegram: @dental_k

www.konkur.in

3. Continuing Education certificates[a]
4. Office procedure manuals, that is, tray setups
5. Weekly spore testing of autoclaves

Function

Dental records should document the following information:

1. Course of therapy by recorded diagnosis, including differential diagnoses, informed consent or refusal, treatment, and prognosis
2. Communications among the treating clinician, other health care providers, consultants, subsequent treating practitioners, and third-party carriers
3. Necessity and reasonableness of diagnosis and treatment capable of peer review and dental insurance carrier evaluation
4. Standard of care compliance
5. Adverse reactions or events with explanation
6. Follow-up comments to medical history–positive responses

Patient information form

A patient information form provides essential data for patient identification and office communication, which should be updated periodically (Fig. 27.1). The patient's name; home, business, and e-mail addresses; and telephone and fax numbers are needed to contact the patient for scheduling purposes and inquire about postoperative sequelae.[178] Location information about the patient's spouse, relative, or a close friend who can be notified in an emergency is also suggested. In the event the patient is a minor, the responsible parent or guardian should provide the information. Questions about dental insurance and financial responsibility are included on the form to avoid any later misunderstandings and help fulfill federal requirements of the Truth in Lending law, applicable if four or more installment payments are arranged (whether or not there are interest or late-payment charges).[104]

Relationship to patient: _____

Date: _____ Signature: _____

FIG. 27.1 Patient information form.

Form, titled patient account information, is as follows:

Name, social security number, today's date, birth date, responsible parent or guardian's name, marital status: (single, married, widowed, or divorced), address, city, state, zip code, e-mail address, phone, fax.

Referred By: Patient driver's license number, occupation, employer, how long, business address, city, state, zip code, e-mail address, phone, fax, spouse's Name, occupation, employer, how long, business address, city, state, zip code, e-mail address, phone, fax.

Person financially responsible for account: Address (if different from patient), city, state, zip Code, phone, relationship to patient.

Dental insurance carriers: Group number, local number, name of insured person, social security number, relationship to patient.

Telegram: @dental_k

www.konkur.in

Second dental insurance carrier (if dual coverage): Group number, local number, name of insured person, social security number, and relationship to patient.

Each option is followed by blank space.

At the bottom, blank spaces for date and signature are given.

Medical health history

The clinician should thoroughly review the patient's past and present health status before proceeding so that dental treatment can be safely initiated. Health questionnaires open avenues for discussion about problems of major organ systems and important biochemical mechanisms, such as blood coagulation, allergy, immunocompromised status, need for antibiotic prophylaxis, and disease susceptibility. The clinician may request that the patient be examined by a physician or undergo laboratory testing under medical supervision to determine whether a suspected medical problem may require attention before endodontic therapy proceeds or if drug sensitivity or an allergy mandates treatment modifications.[43,165,188] Knowledge about current medications, medical therapy, and the name and address of the treating physician is essential.

Medical histories must be updated periodically (or at least annually or sooner, as the need arises). The patient should be asked to review the previous and current medical history (Fig. 27.2). If no changes are necessary, the patient should date and sign the history form. If any changes occurred, the patient should identify each updated medical change, the date, and sign the form where indicated for medical update information. Periodically the patient should provide an entirely new updated form rather than changing data on the old form. Earlier medical histories should be retained in the chart for future reference. If physician communication for treatment occurs, the clinician should record these contacts. In addition, the clinician should verify physician approvals for treatment by fax, with verification of receipt or letter or preferably both, and retain copies in the chart.

www.konkur.in

Please circle any present or past illness you now have or had in the past:

Alcoholism, blood pressure, epilepsy, hepatitis, kidney or liver, rheumatic fever, allergies, cancer, glaucoma, herpes, mental, sinusitis, anemia, diabetes, head/neck injuries, immunodeficiency (HIV), migraine, ulcers, asthma, drug dependency, Heart or valve disease, infectious diseases, respiratory, and venereal disease.

Are you allergic to Latex or any other substances or materials? (Yes or no), If so, please explain. If female, are you pregnant? (Yes or no), Is there any other information that should be known about your health?

Each query or option is followed by blank space.

At the bottom, blank spaces for signature of patient (or parent) and date are given.

Updating the medical history requires the practitioner to be apprised of changes in the patient's medical condition and any new medications the patient is taking, including over-the-counter or herbal medications or supplements.[257] A patient untrained in medical science may not appreciate the fact that new medications may suggest new diseases or changes in existing disease status. For instance, certain regurgitating valvular heart diseases may require antibiotic prophylaxis.[334] New medications may also cause a synergistic effect with other medications the patient is using or another treating clinician is prescribing.

Clinicians who pass the buck by claiming, "Oh it was my secretary or my new assistant—I could do nothing about it," are nonetheless legally liable for their staff's actions or inactions.[335] A clinician exclusively relying on staff members to obtain medical histories in a waiting room full of patients is making a mistake. Instead, the clinician must check and then follow up regarding the accuracy of the histories. Training and monitoring staff are duties clinicians cannot afford to ignore. President Harry Truman's sage advice, "The buck stops here," applies to treating clinicians who overdelegate to nonclinician staff members who lack the requisite dental education for adequate medical history follow-up.

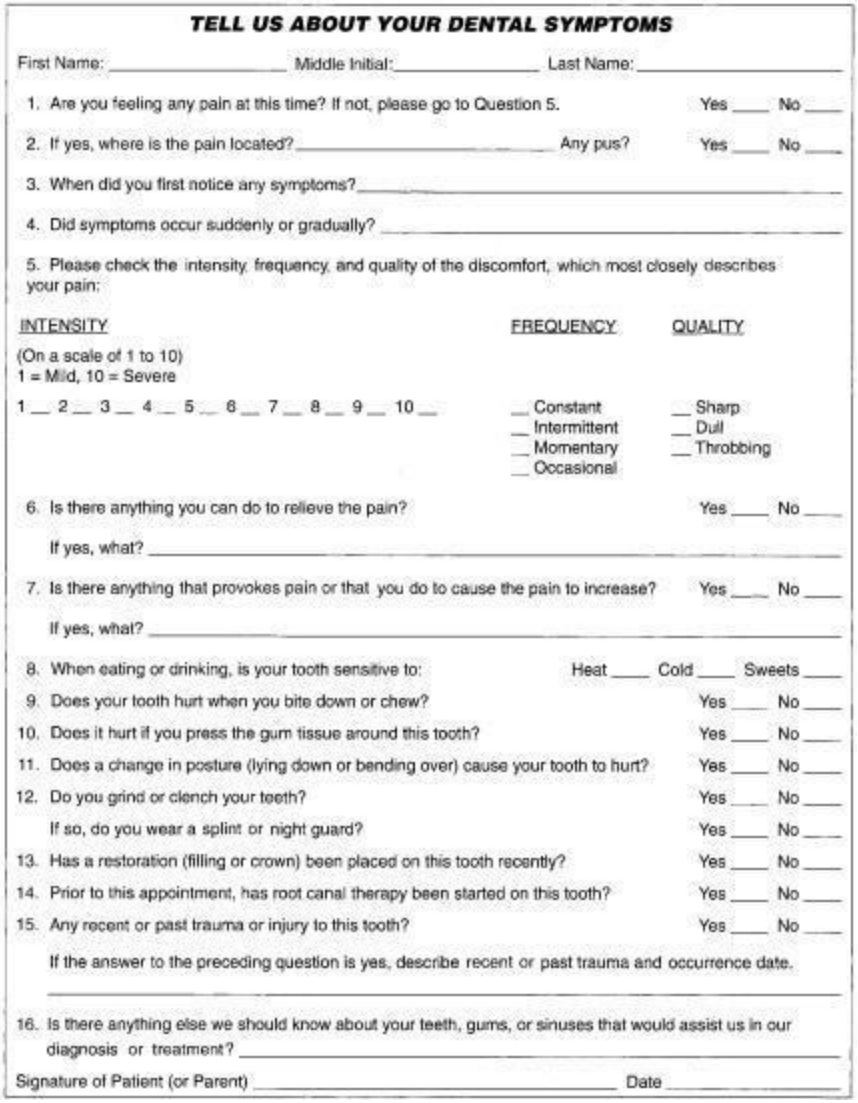
Dental history

The dental history should include past dental difficulties, name and address

Telegram: @dental_k

www.konkur.in

of current or most recent treating clinician, chief complaint (including onset, duration, frequency, type, and intensity of any pain or numbness), relevant prior dental treatment, and attitude regarding teeth retention. Positive responses suggest further patient consultation and consideration for obtaining records (by written release) for elucidation from the patient's previous or present treating clinician.[227] After receiving positive responses, the clinician may also wish to obtain prior and concurrent treaters' radiographs for current comparison with any progressive changes (Fig. 27.3).



TELL US ABOUT YOUR DENTAL SYMPTOMS

First Name: _____ Middle Initial: _____ Last Name: _____

1. Are you feeling any pain at this time? If not, please go to Question 5. Yes ___ No ___
2. If yes, where is the pain located? _____ Any pus? Yes ___ No ___
3. When did you first notice any symptoms? _____
4. Did symptoms occur suddenly or gradually? _____
5. Please check the intensity, frequency, and quality of the discomfort, which most closely describes your pain:

INTENSITY	FREQUENCY	QUALITY
(On a scale of 1 to 10) 1 = Mild, 10 = Severe		
1 __ 2 __ 3 __ 4 __ 5 __ 6 __ 7 __ 8 __ 9 __ 10 __	__ Constant __ Intermittent __ Momentary __ Occasional	__ Sharp __ Dull __ Throbbing

6. Is there anything you can do to relieve the pain? Yes ___ No ___
   If yes, what? _____
7. Is there anything that provokes pain or that you do to cause the pain to increase? Yes ___ No ___
   If yes, what? _____
8. When eating or drinking, is your tooth sensitive to: Heat ___ Cold ___ Sweets ___
9. Does your tooth hurt when you bite down or chew? Yes ___ No ___
10. Does it hurt if you press the gum tissue around this tooth? Yes ___ No ___
11. Does a change in posture (lying down or bending over) cause your tooth to hurt? Yes ___ No ___
12. Do you grind or clench your teeth? Yes ___ No ___
    If so, do you wear a splint or night guard? Yes ___ No ___
13. Has a restoration (filling or crown) been placed on this tooth recently? Yes ___ No ___
14. Prior to this appointment, has root canal therapy been started on this tooth? Yes ___ No ___
15. Any recent or past trauma or injury to this tooth? Yes ___ No ___
    If the answer to the preceding question is yes, describe recent or past trauma and occurrence date.
    _____
16. Is there anything else we should know about your teeth, gums, or sinuses that would assist us in our diagnosis or treatment? _____

(Yes or no) If the answer to the preceding question is yes, describe recent or past trauma and occurrence date. 16. Is there anything else we should know about your teeth, gums, or sinuses that would assist us in our diagnosis or treatment?

Each query or option is followed by blank space.

At the bottom, blank spaces for signature of patient (or parent) and date are given.

Diagnostic and progress records

Diagnostic and progress records often combine fill-in and check-off types of forms. Fill-in or essay forms allow greater latitude of response to a question, resulting in a more detailed description. However, one drawback is that these forms are open to oversights unless a clinician is conscientious in following up with further clinical information.

Using only an essay-type health history is insufficient. Often a patient may not appreciate the significance of important symptoms. A check-off format is efficient and more practical. Forms with questions that reveal pertinent data alert the clinician to medical or dental conditions that warrant further evaluation or consultation.[43] Moreover, such records can document any missing medical information the patient failed to provide orally. At the end of the check-off portion of the medical history, an essay question allows the

Telegram: @dental_k

www.konkur.in

patient to provide any omitted pertinent medical information or elaborate on checkmarked items.[273,286]

Electronic records

Electronic records represent current methodology for recording patient information (see Chapter 28 for details).[307] Several safeguards are essential for their use. First, patient confidentiality and security must be protected. Consider using advanced encryption standard (AES) encryption with at least 2048 bit key. Be certain that only the clinician and authorized staff view patient data in conformance with the Health Insurance Portability and Accountability Act (HIPAA) security standards, effective April 2005.[149] Second, data backup of patient records, including digital radiographs and account ledgers, should be stored off site. The entire hard drive should be periodically backed up for additional protection, which can be accomplished with cloud technology autosave backup systems.[94] Multiple copies of the backup data should be stored in more than one geographic location, and fault protection such as redundant array of inexpensive disks (RAID) level 1 or 5 should be installed to prevent data loss.

Radiographs

Radiographs are essential for diagnosis and also serve as additional documentation of the patient's pretreatment condition. A panographic radiograph is not diagnostically accurate for endodontics and therefore should be used only as a screening device (see Chapter 2).[143,271,344] Diagnostic-quality periapical plain film or digital radiographs are essential aids for diagnosis, for working films (e.g., measuring the length of root canals, fitting gutta-percha cones), to verify the final fill, and for follow-up comparisons at recall examinations. Therefore the clinician should retake any radiographs that lack diagnostic quality. Retain all radiographs, including working films.

Digital radiography is recommended because it increases endodontic efficiency at the chair. Also, images may be forwarded via e-mail to either the patient or another clinician. No developing time is needed, so procedural radiographs can be viewed instantly and approved or retaken with little time in between (no downtime is required to wait for a film to exit the film

Telegram: @dental_k

www.konkur.in

processor). Newer digital x-rays with improved sensor technology use high-resolution charged coupling device (CCD) chips, rather than complementary metal-oxide semiconductor (CMOS) technology and provide close-up zooming with improved image quality as described in Chapters 5 and 28.

Three-dimensional (3D) cone-beam computed tomography (CBCT) imaging has greater information compared with conventional radiography. Conventional periapical radiographs do not facilitate accurate predictions in the preoperative assessment for the potential perforation of the maxillary sinus. CBCT has greatly aided the diagnosis of pain sources caused by root fractures or incompletely filled, overfilled, or missed extra canals that two-dimensional (2D) periapical imaging may obscure.[20,75,97,157,169,201,204]

According to the U.S. Food and Drug Administration (FDA), switching from D to E speed results in a 30% to 40% reduction in radiation exposure. F-speed film reduces exposure 20% to 50% compared to E-speed film, without compromising diagnostic quality.[19] Digital imaging reduces radiation dose by 40% to 60%.[5,124]

A rectangular collimator decreases the radiation dose by up to fivefold compared with a circular one.[126] Radiographic equipment should provide rectangular collimation for exposure of periapical and bitewing radiographs.

Evaluation and differential diagnosis

Diagnosis includes evaluating pertinent history of the current problem, clinical examination, pulpal testing, periodontal probe charting, and recorded radiographic results. If therapy is indicated, the reasons should be discussed with the patient in an organized way. When other factors affect the prognosis (e.g., strategic importance, restorability of the tooth, or proximity to vital structures), the clinician should consider further consultation with the referring clinician or specialists, including a prosthodontist, periodontist, or radiologist with CBCT imaging, before initiating endodontic treatment.

Diagnosis is essential in treatment decisions. Recommending extractions for undiagnosed pain etiology is generally contraindicated. Chronic idiopathic orofacial pain warrants referrals and consultation with other health care professionals, lest wholesale extractions worsen the patient's dental state and not relieve pain (see Chapter 4).[7] For instance, in a long-term follow-up study of patients with chronic facial pain and without a recognizable

Telegram: @dental_k

www.konkur.in

odontologic pathosis, some patients were subsequently diagnosed with maladies ranging from cracked-tooth syndrome to medication-mediated illnesses.[7] Accordingly, referral to other specialists is essential, lest a patient be misdiagnosed with idiopathic or atypical facial pain when instead the pain etiology was misdiagnosed.[238,255]

About 5.3% of patients have postendodontic pain 6 months or more after nonsurgical and surgical endodontic treatment. Nonodontogenic pain may account for about 57% to 64% of the total causes of postendodontic pain that persists after 6 months. Therefore of patients being treated with endodontic procedures, about 3.4% (64% of 5.3%) will have posttreatment pain that arises from a nonodontogenic cause.[41,237]

Fig. 27.4, *A* and *B*, demonstrates the advantage of CBCT 3D imaging compared to 2D imaging. In *A*, the nail appears inside the cranium, contrasted with *B*, which shows the nail taped outside the skull.

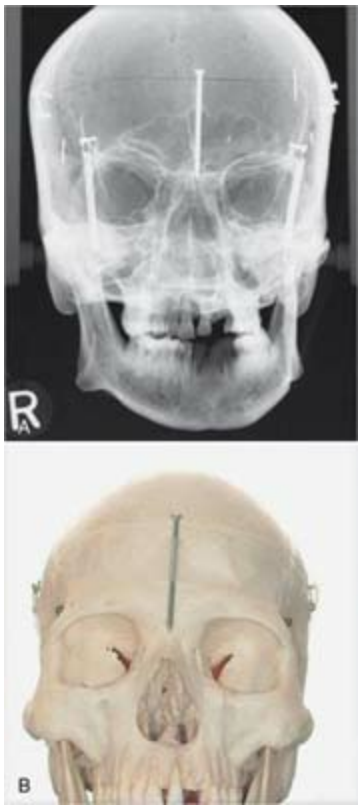

FIG. 27.4 **A,** Nail inside cranium? **B,** Nail in same patient as in **(A)**, showing nail taped to outside of skull. Alas, poor Yorick!

A) Scan of front view of skull shows a nail placed vertically at the center of

Telegram: @dental_k

www.konkur.in

forehead.

B) 3D image shows the skull with the same nail.

Diagnostic tests

Sound endodontics begins with a proper diagnosis. Otherwise, unnecessary or risky treatment with a compromised prognosis follows. Generally, as described in greater detail in Chapter 1, the following endodontic tests should be performed to arrive at a correct and accurate endodontic diagnosis, including adjacent teeth for comparison:

1. Percussion
2. Thermal testing
3. Electrical testing (optional)
4. Palpation
5. Mobility
6. Periodontal assessment (pockets, mobility, furcations, gingival recession)

Both positive and negative pulpal testing results should be recorded. Juries, peer-review committees, and insurance consultants often disbelieve unrecorded test results. Uncharted test findings may be regarded as never having been done. Consequently, reasonable clinicians should record all testing results, both positive and negative. Evaluation of the temporomandibular apparatus is necessary to diagnose or rule out pain producing temporomandibular disorders (TMDs).

Treatment plan

Treatment records should contain a written plan that considers all aspects of the patient's oral health. Treatment plans should be coordinated, preferably in writing, with other concurrent or jointly treating clinicians. For instance, endodontic treatment will probably fail if underlying periodontal pathosis is ignored or untreated. Thus the clinician should assess the patient's entire dentition and not just a single root canal system. The clinician should also recommend a periodontal consultation to both the patient and the referring

Telegram: @dental_k

www.konkur.in

clinician if periodontal therapy is required. The patient should approve the treatment plan. Remember the maxim: If you fail to plan, plan to fail.

Examination

After gathering the dental and medical history, findings obtained from the various phases of the clinical and radiographic examinations are recorded as shown in Fig. 27.5. Lists in each category afford the clinician a systematic format for recording details pertinent to an accurate diagnosis. Appropriate descriptions are circled, followed by the necessary notations in the accompanying spaces. Tabular arrangement allows easier recording and comparison of diagnostic test data acquired from one tooth on different dates or from different teeth on the same visit. A pain intensity index (i.e., 0 to 10) or pain classification (i.e., mild +, moderate ++, severe +++) should be used to differentiate diagnostic test results.

Telegram: @dental_k

www.konkur.in

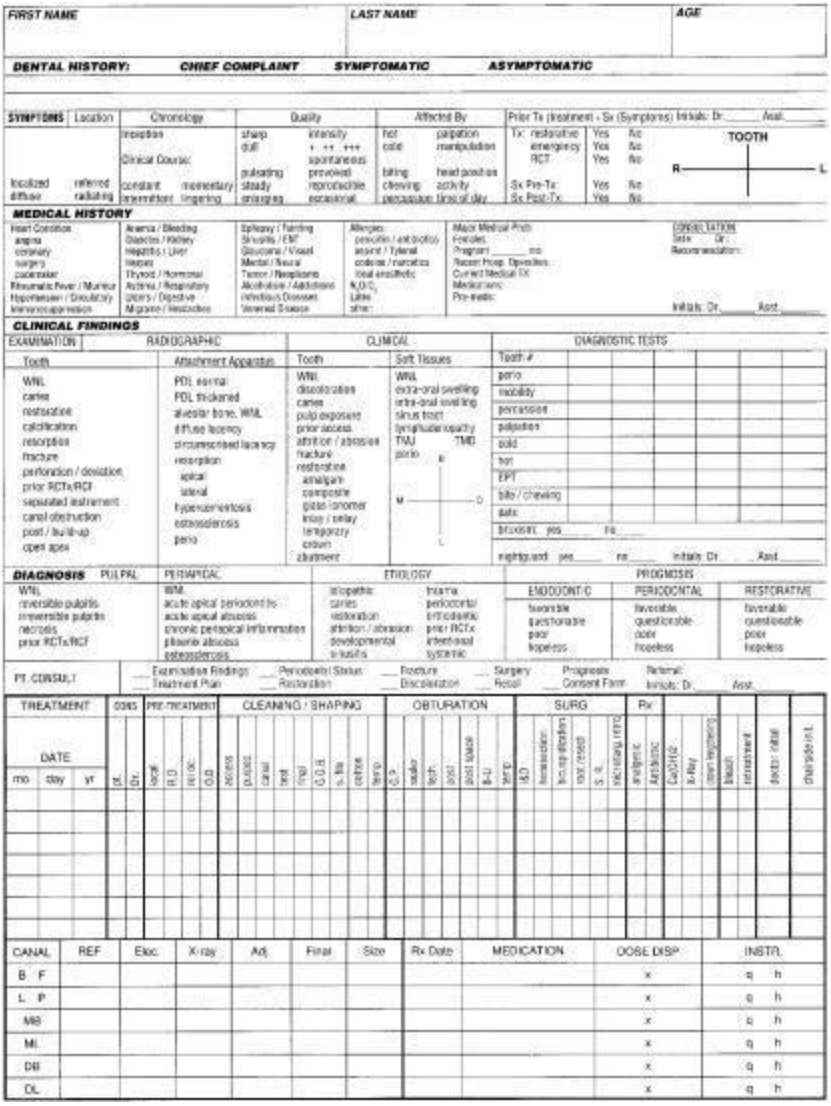

FIG. 27.5 Diagnosis and treatment form.

Diagnosis and treatment form shows spaces for first name, last name, and age, followed by spaces for chief complaint, symptomatic, and asymptomatic options under dental history. Next to it, symptoms panel shows sub-options under location, chronology, quality, affected by, prior treatment plus symptoms, initials: doctor and assistant. It is followed by medical history and clinical findings with sub-options under examination, radiographic, clinical, and diagnostic tests column headers. Further, the next panel shows diagnosis with sub-options under pulpal, periapical, etiology, prognosis (endodontic, periodontal, and restorative) column headers. Next panel shows data for treatment, consultation, pre-treatment, cleaning or shaping, obturation, surgery, and Rx. The bottom panel shows data for canal, ref. elec, X-ray, adj, final, size, Rx date, medication, dose tip, and instrument.

Telegram: @dental_k

www.konkur.in

Diagnosis

Careful analysis of accumulated examination data should result in the determination of an accurate pulpal and periapical diagnosis. Clinical conditions and the probable etiologic factors for the presenting problem are circled. Alternative modalities of therapy are considered and analyzed. The recommended treatment plan is circled, followed by a prognostic assessment of the intended therapeutic course.

Patient consultation

Patients should be advised of each diagnosis and should consent to the treatment plan before therapy is instituted. Consultation should include an explanation of reasonable alternative treatment approaches and rationales and treatment consequences of each alternative therapy, including risks from nontreatment or delayed treatment that may affect the outcome of intended therapy. This discussion is documented by completing the checklist items.

Treatment

All treatment provided on a given date is documented by placing a checkmark (✓) within the designated procedural category. Only the most frequent retreatment procedures are included for tabulation. Descriptions of occasional procedures or explanatory treatment remarks should be entered in writing. A separate dated entry should be made for each patient visit, phone call, e-mail message, and fax communication (e.g., consultations with the patient or other clinicians) or correspondence (e.g., biopsy report, treatment completion letters).

Individual root canal lengths are recorded by (1) circling the corresponding anatomic designation and the method of length determination (e.g., radiograph or electronic measuring device), (2) writing the measurement (in millimeters), and (3) indicating the reference point. For any medication prescribed, refilled, or dispensed, the treatment record should show the date and type of drug (including dose, quantity, and instructions for use) in the treatment table under the heading “Rx.” Fig. 27.6 also shows a sample medication log. Periodic recall intervals, dates, and findings are entered in the spaces provided.

Telegram: @dental_k

www.konkur.in

MEDICATION LOG: P. Ulp (Patient name) (415) 391-5353 (Phone number)

6/29/20	Acetaminophen	12	1000 mg	Y	W			MZ
6/29/20	Ibuprofen	12	400 mg	Y	W			MZ

FIG. 27.6 Medication log.

Template of medication log is as follows:

It begins with patient name, followed by phone number, and medication allergies.

Further, the template has ten rows and nine columns with the following column headers: date; medication; number of tabs/ caps/ gel, dosage/quantity; refill question mark (yes or no); R sub x written-W, Dispen-D, and phone-P; phoned R sub x question mark (pharmacy and phone hash); staff initial, and Doctor initial.

If the scope of the examination or treatment is intentionally limited, such as a screening examination or emergency endodontic therapy, the limited scope of the visit should be recorded. Otherwise, the chart appears as if the

Telegram: @dental_k

www.konkur.in

examination were superficial and treatment incomplete. If a suspicious apical lesion requires subsequent reevaluation, the clinician should record the future reevaluation date and differential diagnosis—for example, “Small apical lesion on #28. Reevaluate for changes in 2 months. Also, check for any root fractures.” If this is not done, it appears (on the chart) as if the clinician ignored potential pathosis, such as suspected root fracture. A soft-tissue examination (including cancer check) is a standard part of any complete dental examination. E-mail, prescriptions, and correspondence should be documented with hard copies in the chart unless virtually all treatment records are stored in electronic format.[191,307]

Informed consent form

After endodontic diagnosis, the benefits, risks, treatment plan, and alternatives to endodontic treatment—including any patient refusal of recommended treatment and consequences of refused treatment—should be presented to the patient or the patient’s guardian. This will document acceptance or rejection of treatment recommendations. The patient or guardian, along with a witness (who can be a staff member), should sign and date the consent form. Any informed-consent video should similarly be noted, if viewed. Subsequent changes in the proposed treatment plan should also be discussed and initialed by the patient to indicate continued acceptance and acknowledge the patient’s understanding of any newly disclosed risks, alternatives, or referrals.

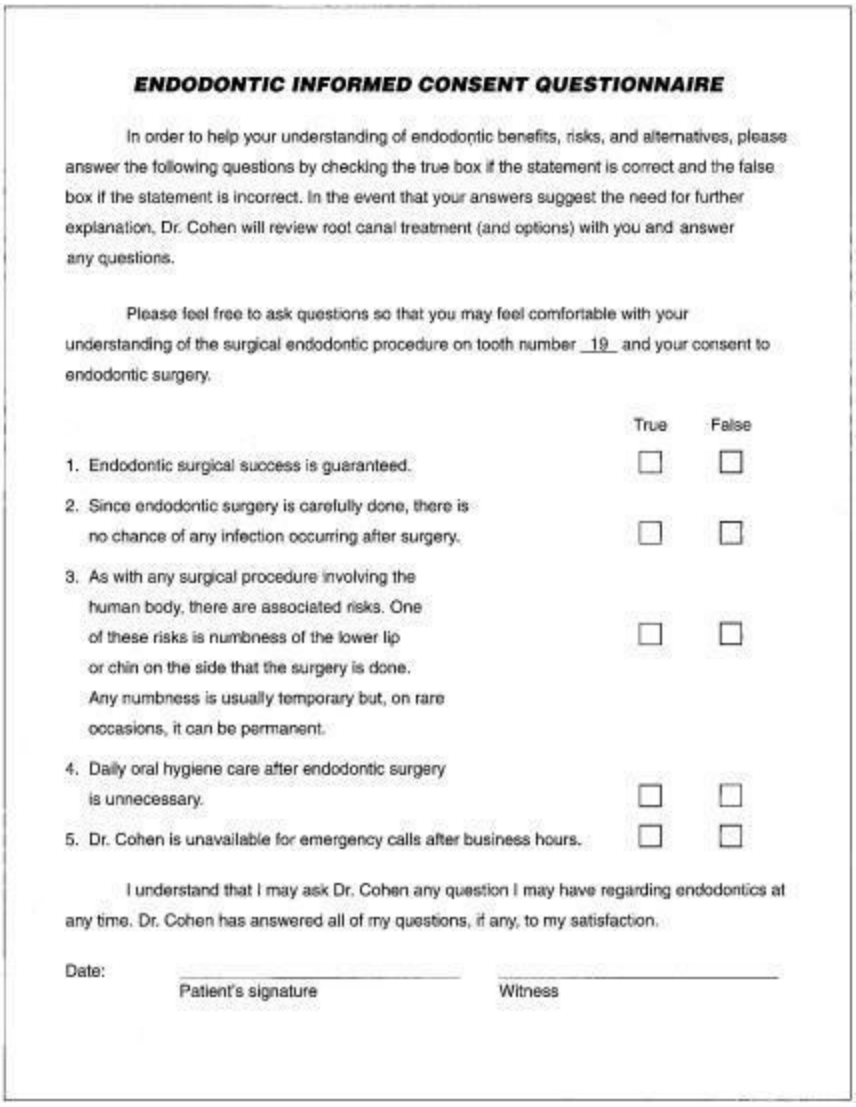
Despite a patient’s confirmed signature on an informed consent form, a jury is free to decide that the patient never read the informed consent form’s content before signing. For instance, the patient may claim it was impossible to have read the consent form, because he or she did not have reading glasses when signing and no clinician ever explained the form contents. Another frequent factual scenario is when the patient claims the staff stated it was a standard consent form that was a mere procedural formality requiring a patient signature, rather than a detailed informed consent form. Consequently, numerous legal cases have been lost at trial on the issue of inadequate informed consent despite a signed patient consent form.

To obviate a patient’s claim that no explanation ever occurred, a patient questionnaire can additionally be used. Patients can be instructed that unless

Telegram: @dental_k

www.konkur.in

they score 100%, proposed procedures will not be done (because patient understanding is imperative and essential for cooperation, including postoperative care). To be effective, the patient questionnaire should be relatively short and simple (Fig. 27.7). Also, the patient should be given an opportunity to correct any incorrect answers after the clinician reviews with the patient the reasons why the patient answered incorrectly. Note that the majority of answers are false. This precludes a patient from guessing the correct answer by assuming that all test questions are necessarily true.



ENDODONTIC INFORMED CONSENT QUESTIONNAIRE

In order to help your understanding of endodontic benefits, risks, and alternatives, please answer the following questions by checking the true box if the statement is correct and the false box if the statement is incorrect. In the event that your answers suggest the need for further explanation, Dr. Cohen will review root canal treatment (and options) with you and answer any questions.

Please feel free to ask questions so that you may feel comfortable with your understanding of the surgical endodontic procedure on tooth number 19 and your consent to endodontic surgery.

	True	False
1. Endodontic surgical success is guaranteed.	☐	☐
2. Since endodontic surgery is carefully done, there is no chance of any infection occurring after surgery.	☐	☐
3. As with any surgical procedure involving the human body, there are associated risks. One of these risks is numbness of the lower lip or chin on the side that the surgery is done. Any numbness is usually temporary but, on rare occasions, it can be permanent.	☐	☐
4. Daily oral hygiene care after endodontic surgery is unnecessary.	☐	☐
5. Dr. Cohen is unavailable for emergency calls after business hours.	☐	☐

I understand that I may ask Dr. Cohen any question I may have regarding endodontics at any time. Dr. Cohen has answered all of my questions, if any, to my satisfaction.

Date: _____ Patient's signature _____ Witness

FIG. 27.7 True/false endodontic informed consent form.

The form titled, "Endodontic informed consent questionnaire" is as follows:

I understand that I may ask Dr. Cohen any question I may have regarding endodontics at any time. Dr. Cohen has answered all of my questions, if any, to my satisfaction.

At the base, date and blank spaces for Patient's signature as well as witness are given.

Treatment record: Endodontic chart

A suggested chart is presented in Fig. 27.8 to facilitate recording of information pertinent to the diagnosis, recommendations, and treatment of the endodontic patient. Systematic acquisition and arrangement of data from the patient questionnaire, along with clinical and radiographic examinations and careful recording of treatment performed, expedites accurate diagnosis and maximizes clinician efficiency. Suggested chart format and use are described in the sections that follow.

FIG. 27.8 **A,** Progress notes. **B,** Diagnosis and treatment form with notes.

It begins with last name, first name, address, home phone, and business phone. The next row shows information about ref Doctor, ref doctor address, ref doctor phone, followed by tooth location and number with fee, treatment plan, and special instructions in the next row.

Next section shows arrays with row headings as follows: insurance, pre-auth, percent covered, verified, form signed, pt. informed, pt. portion, and ins sent. The columns are as follows: amount due, rec'd, date, day, time, pro-cedure, x-ray, and remarks.

Next section has data as follows: date (month, day, year), remarks, and signature.

Filled diagnosis and treatment form is shown. First name, last name, and age of the patient, followed by chief complaint, symptomatic, or asymptomatic

Telegram: @dental_k

www.konkur.in

dental history. Next to it, symptoms panel shows sub-options under location, chronology, quality, affected by, prior treatment plus symptoms, initials: doctor and assistant. It is followed by medical history and clinical findings with sub-options under examination, radiographic, clinical, and diagnostic tests column headers. Further, the next panel shows diagnosis with sub-options under pulpal, periapical, etiology, prognosis (endodontic, periodontal, and restorative) column headers. Next panel shows data for treatment, consultation, pre-treatment, cleaning or shaping, obturation, surgery, and Rx. The bottom panel shows data for canal, ref. elec, X-ray, adj, final, size, Rx date, medication, dose tip, and instrument.

General patient data

Patient name, address, phone numbers, referring clinician, and chief complaint are printed or typed in the corresponding space at the patient's initial office visit. The patient's appointment and financial record are divided into two parts as follows:

1. The treating clinician or staff completes the first portion after the diagnosis and treatment plan have been formulated and presented to the patient. Tooth number and quoted fee are posted. The treatment plan is recorded by circling the appropriate description. Under "Special Instructions," specific treatment requests by the referring clinician are circled. Details of planned adjunctive procedures (e.g., hemisection, root resection) may be written in the adjacent space, along with information from the patient data section. The clinician can then use this information for general reference during future treatment. The secretary or treatment coordinator can also use this information when scheduling appointments and establishing financial arrangements.
2. Business personnel complete the second portion. Financial agreements, third-party coverage, account status, and appointment data (including the day, date, and scheduled procedure) are recorded.

Either the clinician or the assistant may complete portions of the diagnosis and treatment sections, but *the clinician should review and approve all entries*.

Telegram: @dental_k

www.konkur.in

Dental history

The chief complaint should include whether the patient is symptomatic at the time of examination or in the recent past and what medications the patient is currently taking for pain relief. Narrative facts regarding the presenting problem are then recorded. Additional details of the chief complaint obtained during successive questioning are recorded by circling the applicable word within each symptom parameter. The pain intensity index (i.e., 0 to 10) or pain classification (i.e., mild +, moderate ++, severe +++) should be registered alongside the appropriate description. For accurate assessment of the effects of prior dental treatment pertaining to the examination site, a summarized account of these procedures should be documented. In addition, all pretreatment signs and symptoms should be described. It is essential that the patient comprehend all communications with the clinician and staff. If there is any language comprehension difficulty, the clinician should ask the patient whether he or she understands completely the language the clinician is speaking. To verify patient comprehension, the clinician should ask the patient to repeat important information that has been conveyed. A clinician- or patient-provided interpreter may be necessary if language problems exist.

Medical history

More medical history information is obtained from a patient-administered questionnaire than from the clinician obtaining an oral history solely from the patient.[43,286] Maximum information is obtained if the clinician reviews with the patient the written health history form the patient has completed.

Information (e.g., personal physician's name, address, and phone number; patient's age; date of last medical examination) is recorded for reference. The clinician can obtain a detailed medical history by completing a survey of common diseases and disorders along with a comprehensive review of corresponding organ systems and related pathosis. Specific entities that have affected the patient are circled. Essential remarks regarding these entries (e.g., details of consultations with the patient's physician) should be documented on an attached blank sheet with dated treatment notes attached to the back of the chart (see Fig. 27.2). A review of the patient's medical status (including recent or current conditions, treatments, and medications) completes the medical history. Updated medical histories that the patient

Telegram: @dental_k

www.konkur.in

signs or initials should be done at least annually and at reevaluation visits.

Excessive alcohol consumption can contribute to a higher incidence of restoration corrosion from chronic regurgitation and vomiting from gastritis associated with alcohol abuse.[139] Corrosion can lead to coronal marginal leakage predisposing to endodontic failure.[305] Accordingly, medical histories should include histories of gastric reflux disease, bulimia with associated habitual vomiting, gastritis, and excessive alcohol intake.

Periodontal disease

Nearly half of American adults older than age 30 years have periodontal disease.[241] Periodontal disease was higher in men than in women (56.4% vs. 38.4%) and was highest among Mexican Americans (66.7%).

Periodontal examination

Competent endodontic treatment begins with adequate diagnostic procedures. An adequate periodontal evaluation must accompany each endodontic diagnosis, which requires a diagnostic radiograph, clinical visualization, mobility recordings, evaluation of the periodontal tissues, and probing for periodontal pockets with a calibrated periodontal probe, particularly in furcation areas.[9,117a,211]

Periodontal chart documentation should include pocket recordings, extent of furcation, bleeding on probing, mobility, areas of gingival recession, and any inadequate attached gingiva.[93,218,241]

Although endodontic treatment may be successful, tooth loss may result from progression of any residual, untreated periodontitis. Consequently, periodontal evaluation and prognosis are mandatory so that the patient and clinician can make an informed and intelligent choice about whether to proceed with endodontics, a combination of periodontal and endodontic treatment, or extraction.

Each tooth undergoing endodontic therapy (and adjacent teeth) should be probed with a calibrated periodontal instrument to obtain six measurements per tooth. Pockets of 4 mm or greater should be recorded on the patient's chart. If no pockets exist, WNL (within normal limits) or a similar abbreviation should be noted. Mobility should also be charted and classified class I, II, or III. Gingival recession, furcations, and mucogingival

Telegram: @dental_k

www.konkur.in

deficiencies should also be recorded.[9,117a]

A clinician who treats with endodontic success but ignores loss of periodontal attachment may misdiagnose or fail to appreciate the risk of failure because of poor periodontal prognosis. It bears repeating that the endodontic treating clinician should not assume an adequate periodontal evaluation has been performed by another clinician or the referring clinician. Instead, an independent periodontal evaluation should be done with a calibrated periodontal probe and results recorded before initiating endodontics, including noting the absence of pockets or within normal limits.

If clinically significant periodontal disease is present, the endodontic treating clinician should consult with the restorative clinician to determine whether the periodontal disease will be properly treated or referred to a periodontist in conjunction with endodontic treatment. A patient should be advised of any compromise of the endodontically treated tooth's periodontal status to comply with required informed consent disclosure.

Drug history

A current drug history, both written and oral, is necessary to alert the clinician to any potential for interaction between any newly prescribed drugs and any other medication, supplements, or over-the-counter medication the patient is already taking.

In patients aged 57 through 85, 40% are potentially at risk of a major drug reaction—half involving various prescription medications and the other half involving anticoagulant drug reactions. About half of prescription users also concurrently take over-the-counter medications plus dietary supplements.[190,235]

Risks of drug interactions or side effects incidence may not be discovered or appreciated in premarket research-controlled drug trials for newly marketed drugs, despite FDA approval. For example, rofecoxib (Vioxx) was withdrawn from the market in September 2004 after increased incidences of myocardial infarcts and strokes manifested in a postmarket research study of 2600 patients. Merck's voluntary recall followed an FDA researcher's claim that the FDA tried to ostracize and intimidate him after he raised safety concerns over Vioxx.[33] Currently, pharmaceutical manufacturers budget more for marketing than research and development.[121] Some drug

Telegram: @dental_k

www.konkur.in

manufacturers have suppressed publication of adverse research.[55,208,337] The Patient Protection and Affordable Care Act of 2010 (Section 6002) requires drug companies to disclose payments to medical/dental professionals who tout their drugs in seminars or publications and receive compensation greater than $500.[245]

For newly marketed drugs, the small number of premarket patients studied may lack sufficient statistical power to expose serious side effects that occur infrequently but are nonetheless life threatening.[337] For instance, mibefradil (Posicor) was withdrawn from the market after 1 year because it increased plasma concentrations of 25 other co-administered drugs, including erythromycin.[235,239] In another example, the popular prescription nighttime heartburn drug Propulsid (cisapride) was linked to 70 deaths and more than 270 significant negative reactions.[328] Other examples include the risk of esophageal cancer with bisphosphonate[337,341] and bisphosphonate-associated osteonecrosis.[92,287] In 2008, the FDA added a black box warning label for Levaquin-associated risks of tendonitis (www.levaquin.com/levaquin/medication).

Preoperative and postoperative radiographs

Pretreatment, midtreatment, and posttreatment radiographs or digital images are essential for endodontic diagnosis and treatment:

1. A current, pretreatment, interpretable periapical radiograph of adequate diagnostic quality is mandatory.
2. Measurement films or digital images are necessary to verify canal length (which can be supplemented with an electronic canal-measuring device) and the apical extent of the gutta-percha fill to the radiographic apex.
3. Posttreatment radiographs are essential for determining the adequacy of the endodontic seal or if further treatment is necessary (see Chapter 10).

Digital radiography

Digital radiographic endodontic applications are ever increasing in

Telegram: @dental_k

www.konkur.in

accuracy.[142] The standard of care does not currently require digital imaging, because traditional silver halide radiographic film is a reasonable alternative. When there is more than one reasonably acceptable practice modality, a clinician who chooses either modality meets the standard of care. Fig. 27.9, *A*, represents a distal open margin on tooth #30 (shown digitally) that is not evident in part *B* with plain-film radiography.

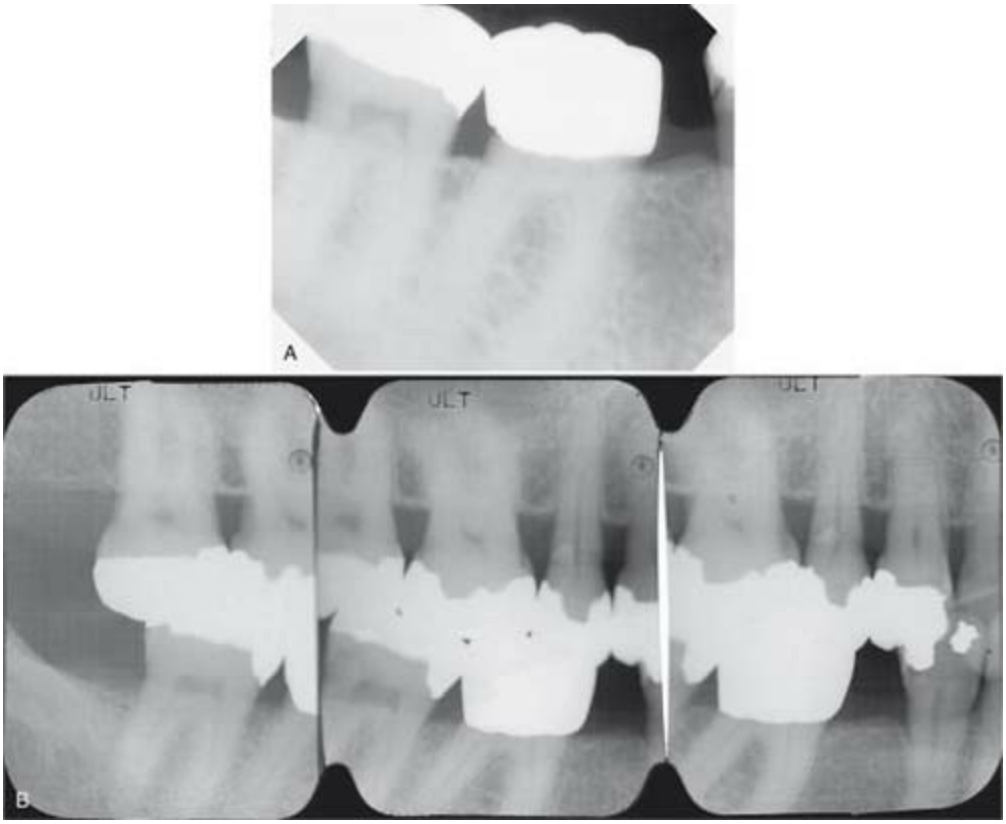

FIG. 27.9 **A,** Distal open margin on tooth #30 (shown digitally). **B,** Distal open margin on tooth #30 not evident with plain-film radiography.

Set of four radiographs marked A through B evaluates the distal open margin of tooth 30 using digital and plain-film radiography.

Advertised claims of 80% reduction in radiation with direct digital radiography (rather than film) assume the following[53,142]:

1. Ultraspeed D-speed film is used. (Ektaspeed E-speed film and the newer F-speed film reduce radiation 50% and 60%, respectively, while producing images of comparable quality to D speed.)[4]

Telegram: @dental_k

www.konkur.in

2. No rectangular collimation is used, which reduces exposure another 30%.
3. No extra radiographs are taken to compensate for a smaller area. For instance, a 2 CCD sensor has an active area smaller than size 1 film and may require an extra image with additional radiation exposure.

A digital x-ray image should never be modified to “enhance” the radiographic appearance of the original image. X-ray modification can be detected. In litigation, it can prove devastating to the clinician’s defense because the clinician’s credibility of events or recorded entries are not believable, particularly if the radiograph is Photoshopped.

Periapical (PA) radiography is limited to only two dimensions. Newer 3D imaging systems for dental radiology use x-ray beams that are cone shaped. CBCT can provide a more nearly accurate diagnosis.[75,122,157] In Fig. 27.10, *A–C*, the PA does not show the transported canal and extent of short fill, which is more evident in the CBCT. Each CBCT scan produces three image views: axial, coronal, and sagittal.

Telegram: @dental_k

www.konkur.in

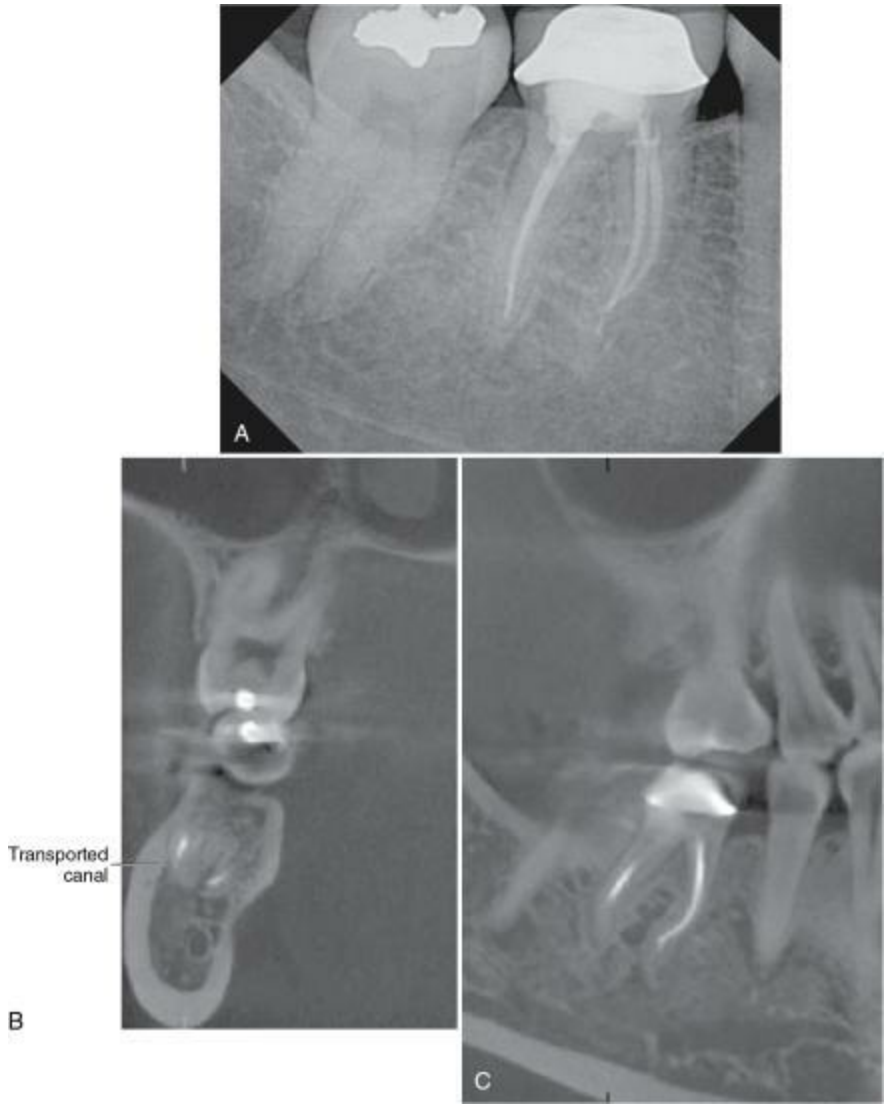

FIG. 27.10 **A,** Periapical (PA) view, which does not show full extent of transported and short-filled canal. Both deficiencies evident in **B** and **C** with cone-beam computed tomography (CBCT). **B,** CBCT Accuitomo of transported canal. **C,** CBCT Accuitomo of short-filled canal.

A) Periapical radiograph shows filled root canals.

B) CBCT image shows transported canal in tooth.

C) CBCT image shows right canal one-fourth filled at the center and left canal completely filled in the tooth.

Radiation safety

The American Dental Association (ADA) Council on Scientific Affairs

Telegram: @dental_k

www.konkur.in

recommends the dentist recognize the importance of keeping radiation exposure as low as reasonably achievable (ALARA). Accordingly, CBCT imaging should not be performed for screening purposes but rather for specific diagnostic and treatment usage.[20]

The Food and Drug Administration provides recommendations for dental CBCT.[99] The American Academy of Oral and Maxillofacial Radiology provides indicated use of the CBCT for implant placement.[317] In the future, magnetic resonance imaging (MRI) may supplant or augment CBCT because its imaging quality equals and in certain instances surpasses that of CBCT.[189]

Children have greater radiosensitivity because of developing cells in their young bodies. Thus CBCT imaging radiation dosage should be considered for young patients in assessing the need for a CBCT.

Computed tomography (CT) scans enable evaluation of the true extent of lesions and their spatial relationship to important anatomic landmarks.[97] Fig. 27.11, *A–C*, shows a bifid inferior alveolar nerve canal (IANC) that is not apparent on Panorexes. CT scans may provide information important for retreatment decisions, especially apical surgery. CBCT[75,201,204] showed significantly more lesions than PA radiography, including expansion of lesions into the maxillary sinus, sinus membrane thickening, and missed canals; PA radiography missed 34% of these lesions.[201,204] Artificial bone defects in the antral surface were not detected with PA radiography. Because of overlapping roots, only 1 out of 14 furcation defects in upper molars were seen on PA radiography, but CT scans were able to identify all furcal defects. Second molars proved to be the most difficult for detecting lesions with PA radiography alone. Twenty-three teeth with lesions expanding into the maxillary sinus were detected by CBCT, of which only two teeth were seen with PA radiography. Thirty-five teeth with membrane thickening were identified with CBCT, of which 16 teeth were also detected with PA radiography. Fifteen teeth with missing canals were detected with CBCT, of which only four teeth were identified with PA radiography. In a study that compared the efficacy of PA radiography and CBCT in detecting periapical lesions in maxillary premolars and molars for apical surgery,[204] Lofthag-Hansen showed that 38% of maxillary posterior teeth lesions were undetected by PA radiography, despite the fact that an additional different angulated PA radiograph was taken.[201] Lesions associated with apices near the sinus floor

Telegram: @dental_k

www.konkur.in

had a higher probability of being missed with PA than lesions associated with apices located away from or overlapping the sinus floor. Expansion of the lesion into the maxillary sinus, thickening of the sinus membrane, missed canals, and presence of apicomarginal communications were more frequently detected with CBCT than with PA radiography.[201]

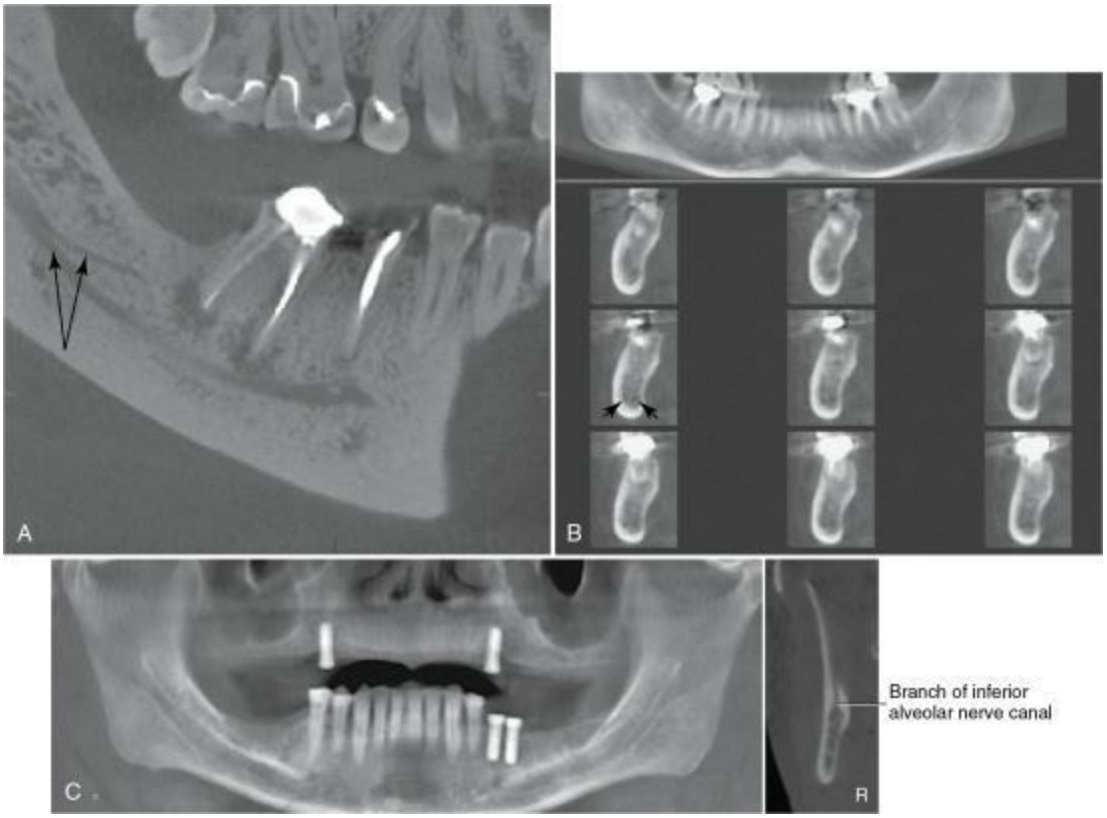

FIG. 27.11 **A,** Bifid inferior alveolar nerve canal (IANC) visible with cone-beam computed tomography (CBCT). **B,** Bifid canal visible with CBCT but not shown on Panorex. **C,** Branch of IANC apparent on CBCT but not shown on Panorex.

A) Radiograph shows IANC on right side of lower jaw.

B) Panoramic view of lower jaw is followed by nine coronal sections. In one coronal section, bifid IANC is marked.

C) Panoramic view of both jaws is shown. Branch of inferior alveolar nerve canal is marked separately.

Source: (Courtesy Gurminder Sidhu, DDS, MS.)

Apicomarginal communication is an important predictor for the success

Telegram: @dental_k

www.konkur.in

rate of apical surgery, including evidence of undetected vertical fractures necessitating extraction; 83% of apicomarginal communications were not seen with PA radiography in the Lofthag-Hansen study.

If the radiograph shows a small distance between the periapical lesion and the sinus floor when the bony wall is thin, there is a high probability that an oral antral communication (OAC) can result, unless skillful care avoids sinus penetration during apical surgery. CBCT also allows the clinician to study the topography of the bony defect and assess whether the use of guided tissue membranes would be beneficial. Precise morphometric assessment of osseous relationships to the sinus is often inadequate with periapical radiography. Thus CBCT is invaluable in treatment planning for apical surgery, as 70% of cases studied revealed clinically relevant information not found in PA radiography.[204]

The probability of detecting lesions with PA alone was limited for teeth with apices in close contact with the floor of the maxillary sinus, for molars (in particular second molars), and when bone thickness between lesion and sinus was less than or equal to 1 mm. Findings of lesion expansion into the sinus, sinus membrane thickening, missed canals, and presence of apicomarginal defects are more frequently diagnosed with CBCT than PA.[75,204]

Endodontics and heart disease

Associations between chronic infections such as periodontal diseases and coronary heart disease (CHD) have been suggested.[280] Conversely, supporting evidence linking root canal–filled teeth or teeth with periapical disease to CHD is lacking.[119]

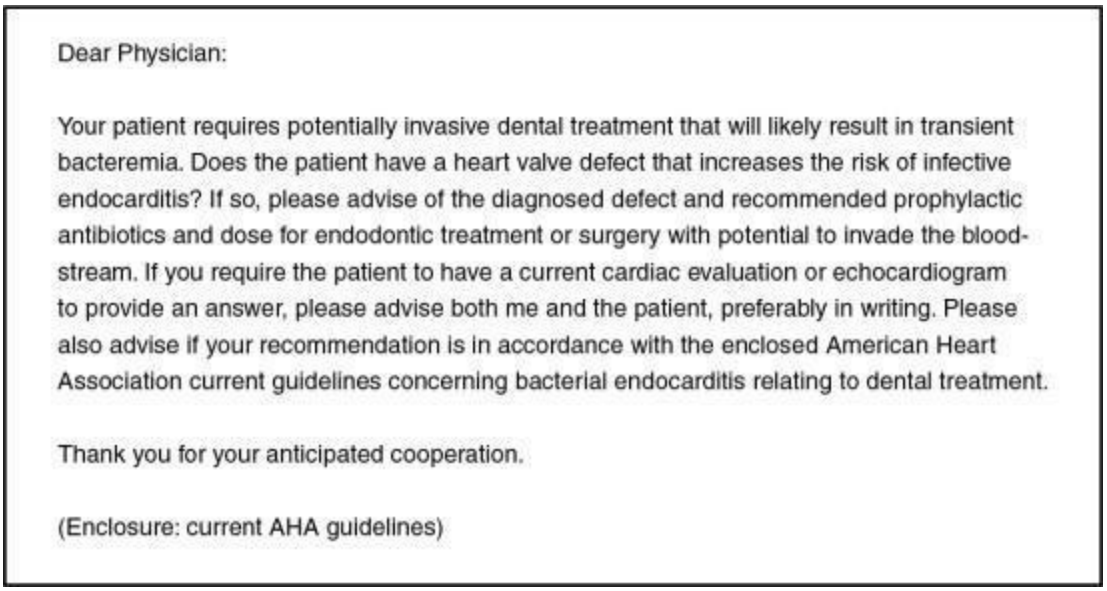
If a patient's medical history shows valvular heart defects with regurgitation, the clinician should consult with the patient's physician to determine the necessity of antibiotic prophylaxis against infective endocarditis in accordance with current American Heart Association (AHA) guidelines.[334] If the physician does not appear knowledgeable about those guidelines, the clinician should provide a copy of the guidelines to the physician. If the physician advises deviation from AHA guidelines, the clinician should inquire why the physician feels that this is appropriate. The

Telegram: @dental_k

www.konkur.in

clinician should also record any discussions with the physician in the patient's chart and confirm the discussion and the physician's recommendation in writing (by fax and letter to the physician).

Communications with the physician should be specific, because dental treatment risks, such as overextension of files or filling material sealants that occur nonsurgically and may enter the bloodstream, may not be fully understood or appreciated. A sample format is shown in Fig. 27.12.



Dear Physician:

Your patient requires potentially invasive dental treatment that will likely result in transient bacteremia. Does the patient have a heart valve defect that increases the risk of infective endocarditis? If so, please advise of the diagnosed defect and recommended prophylactic antibiotics and dose for endodontic treatment or surgery with potential to invade the blood-stream. If you require the patient to have a current cardiac evaluation or echocardiogram to provide an answer, please advise both me and the patient, preferably in writing. Please also advise if your recommendation is in accordance with the enclosed American Heart Association current guidelines concerning bacterial endocarditis relating to dental treatment.

Thank you for your anticipated cooperation.

(Enclosure: current AHA guidelines)

FIG. 27.12 Sample of written physician recommendations.

Sample of written physician recommendations is as follows:

Abbreviations

Abbreviated records can be frustrating if the clinician is unable to decipher his or her own or other clinicians' handwritten entries, so the clinician should use standard or easily understood abbreviations. Pencil entries are legally valid, but ink entries are less vulnerable to a plaintiff's claim of erasure or alteration. A short pencil is better than a long memory; records remember, but patients and clinicians may forget.

A sample of a completed endodontic chart (Fig. 27.13) illustrates its proper use. Box 27.1 lists a key to the abbreviations.

Computerized treatment records

Clinicians are increasingly using computerized record storage as described in this chapter.[282] To avoid a claim of record falsification, whatever computer system is used should be able to demonstrate that records indicating earlier treatment were not recently falsified. Software technology, such as the “write only read memory” (WORM) system, used to identify computer data tampering, is not foolproof because it cannot detect tampering where an entire disk of recent origin has been substituted for an earlier version. Periodically, a hard copy of computer data should be printed out, hand initialed, dated in ink, and stored in the chart to provide written verification of the computer records if the office is a virtual paperless office.[307]

Health information technology for economic and clinical health act pitfalls

Affected patients must be notified if there is a breach in the electronic record storage system.[148] Electronic records have the following pitfalls:

- Data entry in the wrong patient record
- Incorrect data entry in the patient record

Telegram: @dental_k

www.konkur.in

Incorrectly entered information or information that was not entered at all was reported as the cause of the majority of errors. The absence of an undecipherable scrawl is designed to reduce errors. Whether the result of fat fingers or providers pushed for time, mistakes will still occasionally occur. Some of the things that make paperless electronic records desirable—transparency, the ability of more people to view the same information, and more immediate accessibility—may cause any electronic record mistakes risk to be amplified.

Health Insurance Portability and Accountability Act

The Department of Health and Human Services' Security and Electronic Signature Standards rule is part of the HIPAA of 1996. This act emphasizes the safeguarding of clinicians' health care information and permits a patient to obtain a copy of the requesting patient's records. Most states have authorized digital electronic signatures as binding for most contracts and orders. Digital signatures with electronic transactions are authorized by the Third Millennium Electronic Commerce Act (also called the Electronic Signature in Global and National Commerce Act).[323]

Pertinent HIPAA requirements follow:

1. Original records and radiographs should not be released but only copies provided to the patient. A reasonable copying charge may be requested before or after release of the copies.
2. A patient may amend health information in the chart that the patient believes to be incorrect or incomplete. The clinician may respond to the patient's proposed chart amendments.
3. Notice of office privacy practices should be provided to the patient, and the patient should acknowledge receipt in writing.
4. If privacy rights are violated, the patient can file a grievance with the secretary of the Department of Health and Human Services. Patients cannot be penalized for complaining.
5. Confidential dental and medical information may be shared with other clinicians, based on a need-to-know.
6. All e-mail communications between clinician and patient must use a secure network and be stored on a secure server.[282] A patient may

Telegram: @dental_k

www.konkur.in

waive this requirement and request communications and copies of records be sent via unencrypted email.

Record size

Although there is little harm in recording too much information, there is great danger in recording too little. Standard 8½ × 11 inch or larger clinical records possess the advantage of providing the treating clinician adequate space for clinical notes.

Identity of entry author

Either a clinician or an auxiliary can chart clinical entries unless state law indicates otherwise. Some states require clinicians and assistants to sign or initial each treatment entry.[58] What is important is that the correct clinical information is recorded. Each person who makes a clinical chart entry should record the date and initial the entry. Otherwise, the author's identity may be forgotten if the individual who recorded the entry is needed in a legal proceeding. For instance, initialing the entry makes it easier to identify the particular clinician or auxiliary who, after the original recording, is now employed elsewhere. A separate log of clinician and staff initials should be created and stored for later comparison to identify the entrant's initials (see Fig. 27.13).

Patient record request

Patient requests for record transfers or copies must be honored. It is unethical to refuse to transfer patient records, on the patient's request, to another treating clinician.[18] Moreover, refusing to provide patient records is illegal in some states, subjecting the clinician to discipline and fines should the records not be provided to the patient upon written request, even if the balance is outstanding.[62]

Patient education materials

Patient education pamphlets may be used in litigation as evidence that a patient was properly informed and given endodontic alternatives but instead chose extraction. Such pamphlets include the ADA's *Your Teeth Can Be*

Telegram: @dental_k

www.konkur.in

Saved by Endodontic Root Canal Treatment and the American Association of Endodontists' (AAE's) *Your Guide to Endodontic Treatment, Your Guide to Endodontic Retreatment,* and *Your Guide to Endodontic Surgery*. The clinician should indicate in the patient's chart which particular pamphlets the patient was provided or which video was shown, because this may prove useful should the patient later deny being informed of endodontic alternatives.

The use of educational materials may improve health behavior, enhance patient satisfaction, and facilitate the consultation processes. Consequently, the patient is better informed if patient questions are answered after prompting with informative educational materials.

Postoperative instructions

It is unlikely a patient will remember oral postoperative instructions unless accompanied with written instructions. After endodontic procedures, the patient may be sedated or affected by analgesic drugs. Accordingly, written postoperative instructions are beneficial. Emergency phone numbers to contact the treating clinician should be included on the form. Written instructions reduce postoperative morbidity and pain and improve patient compliance.[6] Document that both written and oral postoperative instructions were provided. If treating in close proximity to the IANC, place a precaution, such as seen in Fig. 27.14, in the postoperative instruction sheet.

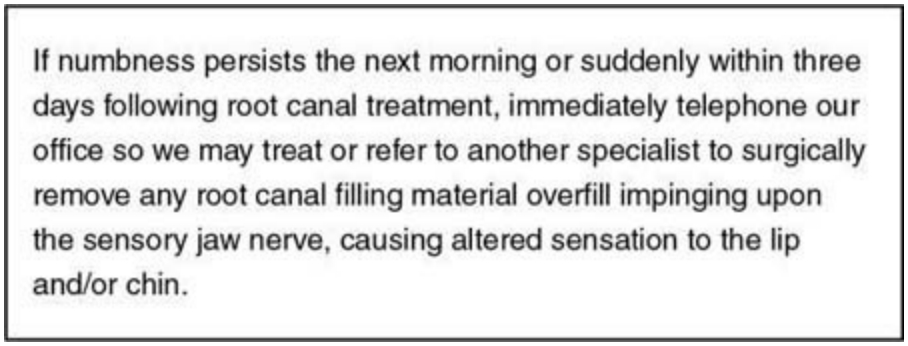

FIG. 27.14 Postoperative instruction sheet.

The text reads:

If numbness persists the next morning or suddenly within three days following root canal treatment, immediately telephone our office sol we may treat or

Telegram: @dental_k

www.konkur.in

refer to another specialist to surgically remove any root canal filling material overfill impinging upon the sensory jaw nerve, causing altered sensation to the lip and/or chin.

Recording referrals

Every clinician, including the endodontic specialist, has a duty to refer under appropriate circumstances. If consultations with additional experts or specialists become necessary, referrals should be recorded lest they be forgotten or refused. Carbonless, two-part referral cards allow the clinician to provide an original referral slip to the patient while retaining a copy for the patient's chart. The clinician or staff member should document the fact that the original referral card was given or mailed to the patient and record the name of the person who provided the referral card and the date on which it was provided. A copy of the referral card should also be sent to the referred doctor. If the patient fails to keep the referral appointment, this copy will provide proof that a referral was made. The clinician should request that the patient and the referred clinician report back if the referral appointment is canceled. Staff should calendar to verify that the referral consultation occurred.

Dental fees related to quality care

The link between health care fees and the quality of health care remains unclear.[156]

Record correction

Records must be complete, accurate, legible, and dated. All diagnoses, treatments, and referrals should be recorded. Chart additions may expand, correct, define, modify, or clarify (as long as they are currently dated to indicate a belated entry).

To correct an entry, the clinician should draw a line through (but not erase or obscure) the erroneous entry. The correction should then be written on the next available line and dated. Handwriting and ink experts use ink chemical tags, age dating, and infrared technology to prove falsified additions, deletions, or substitutions. If records are proved to be falsified, the clinician

Telegram: @dental_k

www.konkur.in

may be subject to punitive damages in civil litigation. In addition, the clinician may be subject to license revocation for intentional misconduct.[58] Professional liability insurance policies may defend but will usually not indemnify punitive damages if the clinician is found to have committed fraud or deceit.[56,57,61,77] In addition, insurance carriers may deny renewal of professional liability coverage to a clinician who fraudulently alters dental records.

If an erroneous entry occurs, the clinician should add another entry dated as a late entry to demonstrate later corrected information. Fig. 27.15 gives an example of the proper method of belated record correction.

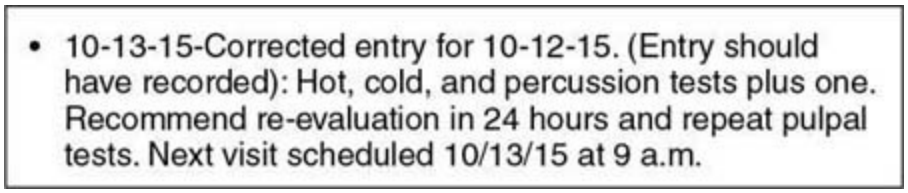

FIG. 27.15 Belated record correction.

The record correction is as follows:

• 10-13-15-Corrected entry for 10-12-15. (Entry should have recorded): Hot, cold, and percussion tests plus one. Recommend re-evaluation in 24 hours and repeat pulpal tests. Next visit scheduled 10/13/15 at 9 a.m.

When patient records have been requested or subpoenaed, it is wise to refrain from examining in detail prior to copying to avoid the temptation to clarify or belatedly add an entry. Alteration of clinical records is a cause of large settlements because the clinician's credibility is suspect. Also the jury may be similarly instructed. For instance, California Jury Instruction 204 regarding "Willful Suppression of Evidence" states as follows:

You may consider whether one party intentionally concealed or destroyed evidence. If you decide that a party did so, you may decide that the evidence would have been unfavorable to that party.

Spoliation

Spoliation is the destruction or significant alteration of evidence, or the failure to preserve property for another's use as evidence, in pending or

Telegram: @dental_k

www.konkur.in

reasonably foreseeable litigation under Fed. R. Civ. P. 37(b)(2)(C).[103]

Spoliation occurs when the wrongdoer alters, changes, or substitutes dental records in an attempt to defeat a civil lawsuit.[64,322] It is far easier to defend a dental negligence lawsuit with poor records compared to attempting to justifiably defend altered (falsified) records. A jury and/or a judge will likely conclude the clinician acted with consciousness of guilt for falsifying records compared with excusing staff clerical oversight if records are poorly maintained. Dental records, like all business records, deserve accuracy and completeness.

Questioned document experts utilize ink age dating, examine watermarks, or apply infrared techniques to ascertain substituted pages and additions or deletions in records, including prior erasures, entries underneath whiteouts, and indentations made when one page is overwritten on another page. Infrared technique analyzes these patterns of indentations underneath the altered pages that detect belated second entries. In one case, the defendant clinician claimed a written referral was made to a specialist in 1998, but the patient refused the referral. During litigation, the patient denied the referral and subpoenaed records of the print shop where the specialist's referral forms were printed. These subpoenaed records proved the carbon copy of the form used for the purported 1998 referral was instead first printed in 2000, which was 2 years after the alleged specialist referral was made (Fig. 27.16, *A* and *B*).

periodontist copy.

B) Falsified record are as follows: introducing (black bar), date (3/02), telephone (black bar) (please include), referred by doctor (black bar), appointment date, time.

Doctor's recommendations:

Complete periodontal examination crown lengthening, ridge preservation, other, limited periodontal examination (25) (crossed mark), gingival graft on, implant consultation.

Has root planning been performed? Yes, No (cross mark), date.

Patient status: radiographs, accompany patient, mailed, please take (cross mark). Restorative plans. If it becomes necessary to change this appointment, kindly give 72 hours notice. Pink-patient, yellow-referring dentist copy, white-periodontist copy.

In another example, altered records were detected in nine different entries in one medical negligence case involving an undiagnosed malignancy. The physician's carrier subsequently settled for $1 million. Also, the defendant personally paid a separate fine to the court. As part of the settlement, the defendant authored an article for the Washington Medical Association detailing why records falsification is wrong.[29]

Records are subjected to (1) audits by insurance carriers for documentation that treatment was performed, (2) review by peer review committees, and (3) subpoena by state licensing boards or agencies for disciplinary proceedings. Accordingly, falsified records expose the clinician not only to civil liability for professional negligence but also to criminal penalties for criminal offenses, such as insurance fraud.[64,313,318,322,323]

Deliberate record alteration with intent to deceive may also subject the clinician to licensing[58] and ethical discipline as well as punitive damages for deceitful misconduct. Insurance carriers may defend but not indemnify a verdict for intentional material alteration of dental records done with intent to deceive.

Digital radiography may have dental advantages, but because the digital images originally may be computer manipulated, they may be legally suspect as altered.[168,313] Therefore hard copies of the digital images may also be printed and dated in ink to show the informational baseline upon which the

Telegram: @dental_k

www.konkur.in

clinician based diagnostic or therapeutic decisions. This also protects against computer glitches, such as disk drive crashes, electrical power surges, computer viruses, and operator delete errors.

In one instance, a judgment of $641,541.65 was awarded for negligently designed and prepared veneers and crowns with resulting endodontics from some teepee appearing restorations. The dentist claimed she spilled Diet Coke on her records, which compromised inspection by a questioned document expert. Her defense that the flood of muddy water caused the dentist to discard plaintiff's study models was refuted by demonstrating that the models could have been easily washed and preserved.[324] Subsequently the dentist surrendered her dental license with pending disciplinary allegations concerning the patient who obtained the judgment along with six other patients of which some were alleged to be have had unnecessary dental restorations necessitating root canals and restoration remake.

False claims

Performing or billing for unnecessary endodontic therapy, such as prophylactic endodontic therapy with every crown preparation, subjects the clinician to fraud. In non–pulpal exposure crown preparation, the likely incidence of subsequent endodontic therapy is approximately 3%. Therefore performing prophylactic endodontics on the other 97% of patients represents unnecessary and therefore fraudulent treatment. Another example of doing unnecessary endodontic therapy is treating incipient caries of a deciduous molar with pulpotomy rather than a filling or monitoring for caries progression until the tooth exfoliates. Excessive unnecessary treatment also ethically violates the Hippocratic oath of "primum non nocere" ("first, do no harm"). The ADA Code of Professional Conduct, Section 5—Principle: Veracity ("truthfulness") in 5.A requires "dentists shall not represent the care being rendered to their patients in a false or misleading manner."

The Federal False Claims Act carries both civil and general penalties of treble damages, fines, and attorneys' fees for fraudulently billing government programs, such as the Civilian Health and Medical Program of the Uniformed Services (CHAMPUS) or Medicare. Fines between $5000 and $10,000 per claim form apply if the U.S. mail was used for a false-claim submission. If any portion of the claimed treatment was fraudulently misrepresented, even if

Telegram: @dental_k

www.konkur.in

a small minority, a violation results.[322] Fraudulent intent need not be conclusively proved. Reckless disregard for the accuracy of submitted data is all that is necessary to obtain a federal criminal conviction or prove civil wrongdoing.[314]

Legal responsibilities

Malpractice claims

More than 42% of physicians have been sued over the course of their careers. Before reaching the age of 40, more than half of obstetricians/gynecologists have already been sued. About 90% of general surgeons aged 55 and over have been sued.[22]

Incidence of negligence

Medical errors or adverse events are estimated to occur in almost one out of four patient visits to a family practitioner.[270] A U.S. government study of the Institute of Medicine found that 152,000 avoidable deaths occur annually because of medical negligence.[118,120] In this government study, injury from medical care occurred in 3.7% of hospital admissions. Some 58% of these injuries were concluded to be preventable, and 13.6% were fatal injuries. The actual fatality numbers may be underestimated, because calculations were based solely on hospital chart review.

Malpractice prophylaxis: Importance of records

Good clinicians keep good records. Records represent the single most critical evidence a clinician can present in court as confirmation that an accurate diagnosis, properly planned treatment, and informed consent were provided.

Prevention is the goal of modern dental care. Competent endodontic treatment performed within the requisite standard of care not only saves endodontically treated teeth but also helps prevent a lawsuit for professional negligence. Thus sound and carefully applied endodontic principles protect both patient and clinician. Prudent practices reduce avoidable and unreasonable risks associated with imprudent or careless endodontic diagnosis or therapy.

Telegram: @dental_k

www.konkur.in

Not all examples of negligent endodontic treatment are included in this chapter, because the myriad of malpractice incidents far exceeds its scope and length. Rather, only select examples are elucidated for educational purposes.

Standard of care

Good endodontic practice, as defined by the courts, is the standard of reasonable care that reasonably careful clinicians legally are required to comply. The standard of care does not require perfection. Instead, the legal standard is the reasonable degree of skill, knowledge, and care ordinarily possessed and exercised by reasonably careful clinicians under the same or similar circumstances.[172]

Although the standard of care is flexible to accommodate individual variations in treatment, it is objectively tested based on what a reasonable clinician would do under the same or similar circumstances. Reasonable conduct represents a minimum standard required for legal due care. Reasonable care is care based on reasoning supported by sound science such as evidence-based, peer-reviewed literature. Additional precautionary steps that rise above this minimal floor of reasonableness and ascend to achieve ideal care are laudable but not legally mandated. Again, the standard of care does not require perfection; nor does it require ideal endodontics. Nevertheless, prudent clinicians should always strive to achieve a higher level of care than barely or minimally adequate care. Excellent clinicians always strive to do their best and practice endodontics at the highest level. Some have criticized this concept by contending that average care is below average, because 49% of clinicians represent a minority compared to the majority of clinicians. Careful clinicians should strive to avoid the mediocrity of minimally acceptable care and instead zealously pursue a goal of endodontic excellence. Endodontists set the standard of care in endodontics. Accordingly, a general dentist and endodontist must each meet the same standard of care in rendering endodontic therapy.

Negligent errors are unintended acts, either of omission or commission. Some errors do not lead to patient injury if intercepted. Failure to mitigate factors that contribute to errors or near misses may combine with human fallibilities of mood, inattention, carelessness, and forgetfulness to cause error repetition or a future more serious injury.

Telegram: @dental_k

www.konkur.in

The written policies and procedures of a clinician, institution, or organization may be used as evidence of standard of care. An expert may consider these the appropriate standard of care in testifying about alleged breaches of standard of care on that issue. For instance, an expert may rely upon AAE's 1998 position paper on paraformaldehyde-containing root canal filling materials as substandard practice, as well as the fact that all U.S. dental schools teach that toxic paraformaldehyde substances should not be used for adult patients as a root canal obturant.

Standards of care: Generalist versus endodontist

A general practitioner performing treatment ordinarily performed exclusively by specialists—such as apical endodontic surgery, periodontal surgical grafting, or full bony impaction surgery—will be held to the specialist's standard of care.[131,132] To avoid performing treatment that is below the specialist's standard, a generalist should refer to a specialist rather than perform procedures that are beyond the general practitioner's training or competency. The three levels of clinical skill are (1) competency or beginning level, (2) proficiency, and (3) mastery. To err is human. Even specialists may not always know what they believe they know.[98,179] Approximately 80% of general practitioners in the United States provide some endodontic therapy. Endodontic expansion into the realm of the generalist can be linked to (1) refinements in root canal preparation and improved obturation (i.e., packing) techniques currently taught in dental schools, (2) continuing education courses, and (3) significant improvements in the armamentarium of instruments, equipment, and materials available to all clinicians to optimize efficiencies in endodontics.

The AAE's Guidelines Case Difficulty Assessment Form and Guidelines provide a road map for when a generalist should treat or refer to an endodontist. Levels of difficulty range from minimal to moderate and high difficulty (Fig. 27.17). General dentists are competent to treat cases of minimal difficulty. Experienced general dentists may treat the moderate-difficulty cases but should refer high-difficulty patients.

Guidelines for Using the AAE Endodontic Case Difficulty Assessment Form

The AAE designed the Endodontic Case Difficulty Assessment Form for use in endodontic curricula. The Assessment Form makes case selection more efficient, more consistent and easier to document. Dentists may also choose to use the Assessment Form to help with referral decision making and record keeping.

Conditions listed in this form should be considered potential risk factors that may complicate treatment and adversely affect the outcome. Levels of difficulty are sets of conditions that may not be controllable by the dentist. Risk factors can influence the ability to provide care at a consistently predictable level and impact the appropriate provision of care and quality assurance.

The Assessment Form enables a practitioner to assign a level of difficulty to a particular case.

LEVELS OF DIFFICULTY

MINIMAL DIFFICULTY	Preoperative condition indicates routine complexity (uncomplicated). These types of cases would exhibit only those factors listed in the MINIMAL DIFFICULTY category. Achieving a predictable treatment outcome should be attainable by a competent practitioner with limited experience.
MODERATE DIFFICULTY	Preoperative condition is complicated, exhibiting one or more patient or treatment factors listed in the MODERATE DIFFICULTY category. Achieving a predictable treatment outcome will be challenging for a competent, experienced practitioner.
HIGH DIFFICULTY	Preoperative condition is exceptionally complicated, exhibiting several factors listed in the MODERATE DIFFICULTY category or at least one in the HIGH DIFFICULTY category. Achieving a predictable treatment outcome will be challenging for even the most experienced practitioner with an extensive history of favorable outcomes.

Review your assessment of each case to determine the level of difficulty. If the level of difficulty exceeds your experience and comfort, you might consider referral to an endodontist.

The contribution of the Canadian Academy of Endodontics and others to the development of this form is gratefully acknowledged.

The AAE Endodontic Case Difficulty Assessment Form is designed to aid the practitioner in determining appropriate case disposition. The American Association of Endodontists neither expressly nor implicitly warrants any positive results associated with the use of this form. This form may be reproduced but may not be amended or altered in any way.

AAE Endodontic Case Difficulty Assessment Form

Criteria and Subcriteria	Minimal Difficulty	Moderate Difficulty	High Difficulty
A. PATIENT CONSIDERATIONS			
Medical history	☐ No medical problem (ASA Class 1*)	☐ One or more medical problems (ASA Class 2*)	☐ Complex medical history/serious illness/disability (ASA Classes 3-5*)
Anesthesia	☐ No history of anesthesia problems	☐ Vasoconstrictor intolerance	☐ Difficulty achieving anesthesia
Patient disposition	☐ Cooperative and compliant	☐ Anxious but cooperative	☐ Uncooperative
Ability to open mouth	☐ No limitation	☐ Slight limitation in opening	☐ Significant limitation in opening
Gag reflex	☐ None	☐ Gags occasionally with radiographs/treatment	☐ Extreme gag reflex which has compromised past dental care
Emergency condition	☐ Minimum pain or swelling	☐ Moderate pain or swelling	☐ Severe pain or swelling
B. DIAGNOSTIC AND TREATMENT CONSIDERATIONS			
Diagnosis	☐ Signs and symptoms consistent with recognized pulpal and periapical conditions	☐ Extensive differential diagnosis of usual signs and symptoms required	☐ Confusing and complex signs and symptoms; difficult diagnosis ☐ History of chronic orofacial pain
Radiographic difficulties	☐ Minimal difficulty obtaining/interpreting radiographs	☐ Moderate difficulty obtaining/interpreting radiographs (e.g., high floor of mouth, narrow or low palatal vault, presence of tori)	☐ Extreme difficulty obtaining/interpreting radiographs (e.g., superimposed anatomical structures)
Position in the arch	☐ Anterior/premolar ☐ Slight inclination (<10°) ☐ Slight rotation (<10°)	☐ 1st molar ☐ Moderate inclination (10-30°) ☐ Moderate rotation (10-30°)	☐ 2nd or 3rd molar ☐ Extreme inclination (>30°) ☐ Extreme rotation (>30°)
Tooth isolation	☐ Routine rubber dam placement	☐ Simple pretreatment modification required for rubber dam isolation	☐ Extensive pretreatment modification required for rubber dam isolation
Crown morphology	☐ Normal original crown morphology	☐ Full coverage restoration ☐ Porcelain restoration ☐ Bridge abutment ☐ Moderate deviation from normal tooth/root form (e.g., taurodontism, microdens) ☐ Teeth with extensive coronal destruction	☐ Restoration does not reflect original anatomy/alignment ☐ Significant deviation from normal tooth/root form (e.g., fusion, dens in dente)
Canal and root morphology	☐ Slight or no curvature (<10°) ☐ Closed apex (<1 mm in diameter)	☐ Moderate curvature (10-30°) ☐ Crown axis differs moderately from root axis. Apical opening 1-1.5 mm in diameter	☐ Extreme curvature (>30°) or S-shaped curve ☐ Mandibular premolar or anterior with 2 roots ☐ Maxillary premolar with 3 roots ☐ Canal divides in the middle or apical third ☐ Very long tooth (>25 mm) ☐ Open apex (>1.5 mm in diameter)
Radiographic appearance of canal(s)	☐ Canal(s) visible and not reduced in size	☐ Canal(s) and chamber visible but reduced in size ☐ Pulp stones	☐ Indistinct canal path ☐ Canal(s) not visible
Resorption	☐ No resorption evident	☐ Minimal apical resorption	☐ Extensive apical resorption ☐ Internal resorption ☐ External resorption
C. ADDITIONAL CONSIDERATIONS			
Trauma history	☐ Uncomplicated crown fracture of mature or immature teeth	☐ Complicated crown fracture of mature teeth ☐ Subluxation	☐ Complicated crown fracture of immature teeth ☐ Horizontal root fracture ☐ Alveolar fracture ☐ Intrusive, extrusive or lateral luxation ☐ Avulsion
Endodontic treatment history	☐ No previous treatment	☐ Previous access without complications	☐ Previous access with complications (e.g., perforation, non-negotiated canal, ledge, separated instrument) ☐ Previous surgical or nonsurgical endodontic treatment completed
Periodontal-endodontic condition	☐ None or mild periodontal disease	☐ Concurrent moderate periodontal disease	☐ Concurrent severe periodontal disease ☐ Cracked teeth with periodontal complications ☐ Combined endodontic/periodontic lesion ☐ Root amputation prior to endodontic treatment

*American Society of Anesthesiologists (ASA) Classification System

Class 1: No systemic illness. Patient healthy.
Class 2: Patient with mild degree of systemic illness, but without functional restriction, e.g., well-controlled hypertension.
Class 3: Patient with severe degree of systemic illness which limits activities, but does not incapacitate the patient.
Class 4: Patient with severe systemic illness that immobilizes and is sometimes life threatening.
Class 5: Patient will not survive more than 24 hours whether or not surgical intervention takes place.

www.konkur.in

keeping.

Conditions listed in this form should be considered potential risk factors that may complicate treatment and adversely affect the outcome. Levels of difficulty are sets of conditions that may not be controllable by the dentist. Risk factors can influence the ability to provide care at a consistently predictable level and impact the appropriate provision of care and quality assurance.

The Assessment Form enables a practitioner to assign a level of difficulty to a particular case.

Levels of difficulty are as follows:

Minimal difficulty: Preoperative condition indicates routine complexity (uncomplicated). These types of cases would exhibit only those factors listed in the minimal difficulty category. Achieving a predictable treatment outcome should be attainable by a competent practitioner with limited experience.

Moderate difficulty: Preoperative condition is complicated, exhibiting one or more patient or treatment factors listed in the moderate difficulty category. Achieving a predictable treatment outcome will be challenging for a competent, experienced practitioner.

High difficulty: Preoperative condition is exceptionally complicated, exhibiting several factors listed in the moderate difficulty category or at least one in the high difficulty category. Achieving a predictable treatment outcome will be challenging for even the most experienced practitioner with an extensive history of favorable outcomes.

Review your assessment of each case to determine the level of difficulty. If the level of difficulty exceeds your experience and comfort, you might consider referral to an endodontist.

Text at the bottom reads, The contribution of the Canadian academy of endodontics and others to the development of this form is gratefully acknowledged.

The AAE Endodontic Case Difficulty Assessment Form is designed to aid the practitioner in determining appropriate case disposition. The American Association of Endodontists neither expressly nor implicitly warrants any positive results associated with the use of this form. This form may be reproduced but may not be amended or altered in any way. It is followed by the address of AAE.

The continuation of AAE Endodontic Case Difficulty Assessment Form shows three sections as follows: A) Patient considerations, B) Diagnostic and treatment considerations, C) Additional considerations. Each section has list of queries under criteria and subcriteria, minimal difficulty, moderate difficulty,

Telegram: @dental_k

www.konkur.in

and high difficulty columns.

Ethical guidelines

The ADA's Code of Ethics guides conduct that distinguishes the dental profession from a trade by placing patient service paramount and profit secondary.[122] Section 5 of the ADA Code of Ethics regarding veracity ("truthfulness") states, "Professionals have a duty to be honest and trustworthy in their dealings with people." Accordingly, both ethically and legally,[159] clinicians are obligated to communicate truthfully and without deception to patients. Announcements to the public must be truthful so that the average person is not materially misled. Truth in dentistry is the rule and not the exception.[122]

Section 5.I of the ADA Code of Ethics provides the following:

> *General Practitioner Announcement... general clinicians who wish to announce the services available in their practices are permitted to announce the availability of those services so long as they avoid any communications that express or imply specialization.*

Thus clinicians should not misrepresent or overstate the facts of their training and competence in any way that would be false or misleading in any material or significant manner to the public or their peers. General clinicians should avoid false and misleading self-representation regarding endodontic "superiority." Implying credentials that the generalist lacks misrepresents a general clinician's endodontic skill and knowledge as equivalent to a board-eligible or board-certified endodontist. A generalist's 30-year experience may be little more than 1 year of experience repeated 30 times. Every state has specific laws governing advertising. Consult your state's law, because each state deals differently with specialty announcements.

Telephone directory listings are organized into categories based on types of procedure, such as endodontics. Generalists must also state in such ads that endodontic services are being provided by general clinicians. The public is entitled to be informed of the distinction between an endodontist specialist

Telegram: @dental_k

www.konkur.in

and a generalist, although each provides endodontics. Only an ADA-recognized board-eligible or board-certified clinician is entitled to represent him or herself as an endodontist. With this distinction in mind, the ADA-recognized endodontic specialty organization is titled the American Association of Endodontists, not the American Association of Endodontics.

Standard of care for endodontics

Endodontists set the standard for routine endodontics. Therefore if the endodontist's standard of care cannot be met, such as the need for microscopy or apical surgery, the generalist should refer the patient to an endodontist.[76,131,132,183]

Endodontists should not forget their general dentist training. Even though a patient may be referred for a specific procedure or undertaking, the endodontist should not overlook sound biologic principles inherent in the overall treatment. A specialist may also be held liable for relying solely on the information referral card or radiographs of the referring clinician if the diagnosis or therapeutic recommendations prove incorrect, unnecessary, or the referral card lists the wrong tooth for treatment. Therefore conduct a "time-out" with patient and staff to verify which tooth is to be treated.[167]

Fig. 27.18 demonstrates a general clinician's radiograph showing apparent complete endodontic fill within the canal space, whereas Fig. 27.19 demonstrates an endodontist's radiograph showing a transported canal. This difference is explained by radiographic quality and angulation. Taking radiographs at different angles improves radiographic accuracy.[201,204]

Telegram: @dental_k

www.konkur.in

FIG. 27.18 A general clinician's radiograph that ostensibly shows a complete endodontic fill within the root canal space.

Radiograph shows three teeth where the central tooth has filled root canals and the adjacent teeth on both sides each have unfilled root canals. The tooth on the right is extremely radiopaque. The surrounding tissue of all teeth has less bone density.

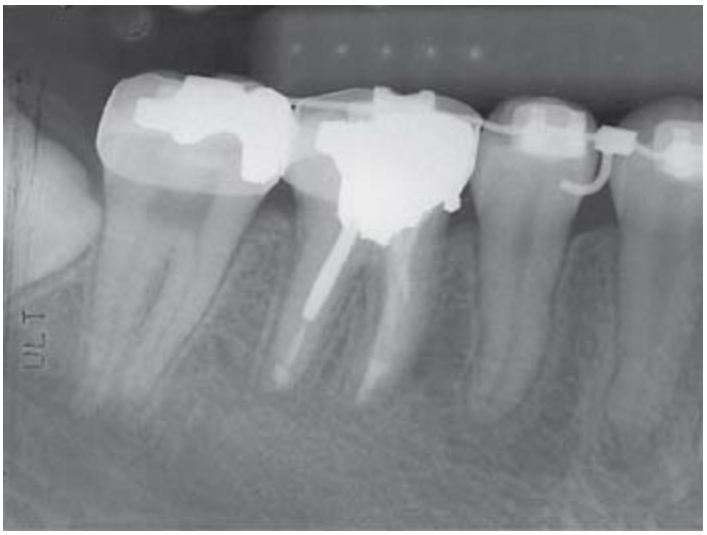

FIG. 27.19 Endodontist's radiograph demonstrating a transported canal.

Radiograph shows transported canal passing horizontally above the crowns of teeth. All teeth except second have unfilled root canals.

Telegram: @dental_k

www.konkur.in

Endodontists should not provide rubber-stamp treatment to whatever the clinician refers or recommends. Without performing an independent examination, the endodontist risks misdiagnosis and resulting incorrect treatment. Prevention of misdiagnosis or incorrect treatment requires an accurate medical and dental history preceding a clinical examination (not only of the specific tooth or teeth involved but also of the general oral condition). Obvious problems such as oral lesions, periodontitis, or gross decay should be noted in the chart and the patient advised regarding a referral for further examination, testing, or another specialist's consultation.

Radiographs from the referring clinician should be reviewed for completeness, clarity, and diagnostic accuracy. An endodontist should expose a new radiograph to verify current status before treatment and only use the referring clinician's radiograph for historical comparison. Unfortunately, the referring clinician may surreptitiously forward a pretreatment film with the referred patient, rather than the referring clinician's own posttreatment film depicting a perforation or broken file that necessitated the referral. This may occur whenever an errant clinician attempts to fraudulently conceal negligently performed endodontic treatment in an attempt to shift blame for bungled treatment to the endodontist. In such cases, a valuable lesson is learned when the endodontist exposes independent pretreatment radiographs, rather than relying exclusively on the referring clinician's radiographs to determine current status of endodontic treatment.

Poor oral hygiene may contribute to periodontal disease. In such cases, endodontic treatment may be compromised unless the associated periodontal condition, along with the tooth being treated endodontically, is brought under periodontal disease control, including any crown-lengthening needs (see Chapter 25 for more information). Referral to a periodontist may be necessary before or contemporaneous with completion of endodontic treatment.

In summary, it is necessary for the endodontist to do the following:

1. Be alert to any contributory medical or dental condition within the operative area of endodontic treatment that can affect treatment.
2. Undertake an independent diagnostic and radiographic examination of the treatment area and treatment plan rather than relying solely on

the referring clinician.
3. Perform a general dental examination (at least a screening) to diagnose any hard- and soft-tissue pathosis.
4. Evaluate status and prognosis of adjacent and opposing teeth.
5. Advise the referring clinician and patient of pertinent findings.

Ordinary care equals prudent care

Ordinary is commonly understood (outside its legal context) to mean "lacking in excellence" or "being of poor or mediocre quality."[217] As expressed in the context of actions for negligence, however, ordinary care has assumed a technical legal definition that differs somewhat from its common meaning. The eighth edition of *Black's Law Dictionary* describes ordinary care as "that degree which persons of ordinary care and prudence are accustomed to use or employ... that is, reasonable care."[46]

In adopting this distinction, the courts have defined *ordinary care* as "that degree of care which people ordinarily prudent could be reasonably expected to exercise under circumstances of a given case."[108] It has been equated with the reasonable care and prudence exercised by ordinarily prudent clinicians under similar circumstances.[136,265] It is not extraordinary or ideal care. Thus ordinary care is not average care but instead equates with prudently careful care. Stated otherwise, average care may be below the average of what all reasonable clinicians should practice.

Although the standard required of a professional cannot be only that of the most highly skilled practitioner, neither can it be limited to the arithmetic-average member of the profession, because those who possess somewhat less than median skill may still be competent and qualified to treat.[265] By such an illogical definition of average care, half of all clinicians would automatically fall short of the mark and be negligent as a matter of law. As one court explained, "We are not permitted to aggregate into a common class the quacks, the young men who have not practiced, the old ones who have dropped out of practice, the good, and the very best, and then strike an average between them."[281] Thus the standard of care equates with reasonable care and not average care.

Customary practice versus negligence

Telegram: @dental_k

www.konkur.in

Customary practice may constitute evidence of the standard of care, but it is not the only determinant. Moreover, if the customary practice constitutes negligence, it is not considered reasonable (although or even if customarily practiced by a majority of clinicians).[38] Rather, the reasonably careful clinician is the standard of care and not an average or mediocre practitioner. For instance, a majority of clinicians did not perform biologic testing of the dental unit waterlines despite ADA recommendations to do so.[220,222] However, careful clinicians did follow the ADA's recommendation (Box 27.2 and Fig. 27.20).

FIG. 27.20 Implant "harpooned" inferior alveolar nerve canal.

Radiograph shows a teeth quadrant where harpoons are implanted in three teeth of lower jaw.

Box 27.2

Typical Examples of Negligent Customs

- Failing to probe and record periodontal pockets

Telegram: @dental_k

www.konkur.in

- Failing to take diagnostic-quality radiographs
- Failing to refer patients for complicated procedures
- Failing to use aseptic practices such as gloves, facemasks, and sterile fluids for surgery
- Failing to use rubber dams for root canal therapy
- Failing to install or periodically check valves in dental units to prevent water retraction, suck-back, and cross-contamination
- Failing to do thermal pulp testing as an aid to diagnosing pulpal disease (see Chapter 1)
- Failing to discontinue quaternary ammonium chloride–based products for precleaning or disinfection of environmental surfaces
- Failing to use a microscope for fractured file retrieval and PRS
- Failure to include CAMBRA in a comprehensive new patient exam
- Failure to use CBCT technology to guide implant placement when placement is in close proximity to the IANC (see Fig. 27.21 for implant "harpooning" of IANC)
- Not informing CT radiation risks to patient [171]

CAMBRA, Caries management by risk assessment; CBCT, cone-beam computed tomography; IANC, inferior alveolar nerve canal.

Merely because a majority of clinicians in a community practice a particular method does not establish it as the standard of care if the practice is unreasonable or imprudent.[38] Ultimately, the courts determine what constitutes reasonable practice by considering available dental knowledge and evaluating the relative risks versus benefits of a particular procedure.

Again, the law does not require dental perfection.[311] Instead, the legal yardstick by which prudent conduct is measured is what a reasonably prudent clinician should do under the same or similar circumstances, regardless of how many or how few clinicians conform to this standard.

In a seminal case, it was not customary practice in the state of Washington for ophthalmologists to test patients under 40 years old for glaucoma, because the incidence was only 1 in 25,000 patients. Nevertheless, the Supreme Court of Washington State held that the defendant ophthalmologist was negligent as a matter of law, irrespective of customary medical practice, as a negligent customary practice is no defense.[150,213]

Little excuse exists for failing to routinely probe and chart periodontal pockets before rendering endodontic therapy, no matter how many other clinicians in the community may fail to do so. The benefit of probing for periodontal disease substantially outweighs the virtually nonexistent risk of conducting this valuable diagnostic procedure. A legal defense likely to invoke a jury's wrath is to claim that a necessary diagnostic or prophylactic procedure is "too time consuming," when dental and medical patient health are placed at risk if not done. If the benefit outweighs the risk, a reasonable clinician complying with the standard of care should opt for the beneficial diagnostic test or treatment. For instance, the Accuitomo and Kodak 9000

Telegram: @dental_k

www.konkur.in

CBCT may prove an invaluable benefit for diagnosing the etiology and source of endodontic pain when compared to the relatively low radiation risk. Thus the CBCT diagnostic benefit outweighs the radiation risk if a differential diagnosis cannot accurately rule in or rule out a final diagnosis.[203]

Another example of negligent customary practice includes a majority of general dentists not using a rubber dam for all root canal therapy despite virtually all endodontists who do so. The AAE's 2010 Position Statement mandates that "tooth isolation using the dental dam is the standard of care; it is integral and essential for any nonsurgical endodontic treatment."

A further instance of a customary but nevertheless negligent practice concerns the majority of dentists who did not adhere to the 2003 CDC Guidelines for Infection Control in Dental Health-Care Settings.[70]

Health maintenance organization care versus standard of care

Reasonably careful or prudent practitioners (not insurance carriers) set the standard of care. Third-party payers may limit reimbursement but should not limit access to quality care. Clinicians have an affirmative duty on behalf of patients to appeal insurance carrier care denial decisions and, in some states, are protected against retaliation.[332] The clinician who complies (without protest) with restrictive limitations or denials imposed by a third-party payer when sound judgment dictates otherwise cannot avoid ultimate responsibility for the patient's care.[332]

Although dental insurance companies do not set the standard of care, insurance carriers may contractually limit dental benefits. Therefore a clinician is obligated to inform patients of their dental needs, regardless of carrier reimbursement. Patients may then elect to pay out of pocket for noncovered treatment or decline uninsured services. Informed choice is uninformed if the clinician fails to provide patients with all reasonable options and alternatives.[209] Follow the adage to not x-ray the patient's pocket book or wallet to determine what options the patient should be presented. Instead offer the patient all reasonable treatment options.

Notwithstanding that an insurance carrier denies endodontic therapy or limits endodontics to only certain clinical conditions, a prudent clinician must nevertheless, both legally and ethically, provide an informed consent option to the patient that a tooth may be endodontically treated and retained rather

Telegram: @dental_k

www.konkur.in

than extracted.[71,220,288,303,346] The California Dental Association's Dental Patient Bill of Rights advises patients: "You have the right to ask your clinician to explain all treatment options regardless of coverage or cost."[60]

Clinicians may agree to a discounted fee with a health maintenance organization (HMO) carrier but must never discount the quality of care provided. Peer reviews and the courts recognize only one standard of care. A lower, double, or different standard of care for reduced-fee HMO plans is not legally recognized. Expediency should not be exercised at the expense of quality patient care. Section 3 of the ADA Code of Ethics affirms, "Managed care contract obligations do not excuse clinicians from their ethical duty to put the patient's welfare first."

Plans that delay treatment approval, resulting in endodontic complications or tooth nontreatability, may be subject to liability.[233,303]

Capitation systems have a built-in incentive to undertreat, delay, or discourage treatment and access to care. For the HMO-paid clinician, the patient may be perceived as a threat to profits. Thus capitation creates incentives that can transform clinicians from the patient's advocate to the patient's adversary. Conversely, the federal Patient Protection and Affordable Care Act compensates based on the quality of care rather than the quantity.[244]

Although clinicians seem like double agents serving two masters (i.e., managed care carriers and patients), the law is clear that the clinician must always act in the patient's best interest, because the clinician owes a fiduciary obligation to the patient. Should the carrier deny requested care, the clinician is legally obligated to appeal the decision to protect the patient's dental health.[332] A patient's best interest is always paramount, both legally and ethically, to a clinician's financial interest.[122,333]

Although profitable to insurance carriers, the success of denying or limiting benefits has created an era of rightfully indignant patients and frustrated clinicians. Consequently, the clinician must guard against patient disappointment with limited insurance benefits by explaining that although insurance carriers determine coverage under their patients' insurance policy, carriers do not set the standard of care. Regardless of how much or how little is covered by the patient's insurance carrier, prudent and reasonably careful clinicians set the standard of care. The legal doctrine of informed consent mandates the patient be informed of alternative therapy choices that the

Telegram: @dental_k

www.konkur.in

patient may pay privately even though the HMO denies approval for alternative therapies. Follow the maxim: Do not x-ray a patient's pocketbook. Reasonable informed consent is premised on patient choice and not cost alone.

Employment law

An employer may fire an employee for a bad reason or no reason at all, as long as termination was not done for discriminatory reasons.[236,326]

Dental negligence defined

Dental negligence is defined as a violation of the standard of care (i.e., an act or omission that a reasonably careful or prudent clinician under similar circumstances would not have done).[172] *Negligence* is equated with carelessness or inattentiveness.[179] *Malpractice* is a lay term for such professional negligence. Dental negligence occurs for two reasons:

1. A clinician does not possess a reasonable degree of education and training to act prudently.
2. Despite reasonable schooling, additional training, and continuing education, the clinician acts with unreasonable carelessness or imprudently fails to act as a reasonably careful clinician would act.

One simple test to determine if an adverse outcome results from negligence is to ask the following question: Was the treatment result reasonably avoidable? If the answer is yes, then it is probably malpractice. If the answer is no, then it is instead an unfortunate maloccurrence that resulted despite reasonable care attempts.

Locality rule

The locality rule, which provides for a different standard of care in different communities, is rapidly becoming outdated. Originating in the 19th century, the rule was designed to acknowledge differences in facilities, training, and equipment between rural and urban communities.[198,347]

The trend across the United States is to move from a locally based standard

Telegram: @dental_k

www.konkur.in

to a statewide standard, at least for generalists. For endodontists, a national standard of care is applied, as the AAE Board is national in scope.[290] Because of nationally published endodontic literature, advances in Internet communication, continuing education courses, and reasonably available transportation for patients, no disparity generally exists between rural and urban endodontic standards. A current exception may be the limited geographic availability of specific CBCT technology such as the Accuitomo or Kodak 9000. Their higher resolution provides superior radiographic endodontic diagnosis compared with 2D imaging and even other CBCT devices. As CBCT machine pricing is lowered and availability increases, the locality rule may be broadened beyond a local community for CBCT technology. On the other hand, time is critical during the first 48 hours of symptomatic numbness if an endodontic overfill enters the IANC.[254] In such instances, a referral to a distant CBCT facility may be required to assess the need for immediate microsurgical removal or instead obtain, at the very least, a medical CT in the local geographic area if a CBCT facility is unavailable.[75,97,157,169,201,204]

A clinician should provide reasonably careful endodontic care to a patient regardless of treatment locality. Rather than focusing on different standards for different communities, more important considerations include knowledge of endodontic advances in the field gained with continuing education to utilize improved diagnostics, instrumentation, and therapeutic interventions.

The locality rule has two major drawbacks. In areas with small populations, clinicians may be reluctant to testify as expert witnesses against other local clinicians. Also, the locality rule allows a small group of clinicians in an area to establish a local standard of care inferior to what the law requires of larger urban areas. Peer-reviewed publications are available to all clinicians in print and online. Clinicians can easily travel great distances to attend continuing education courses or attend webcasts in their own office. Blaming technologic ignorance on a clinician's rural location is inexcusable with modern media, computer technology, continuing education courses, and travel ease.

Continuing education

Continuing education should not add new skills at the expense of

Telegram: @dental_k

www.konkur.in

compromising or eliminating core clinical values. A prudent practitioner should be cautious adding a new methodology that is counterintuitive to basic biomechanical principles.[224] As a general maxim, don't be the first or the last to adopt new technology.

A clinician is legally obligated to maintain current knowledge in the field of endodontics. If not, the clinician may have only 1 year of knowledge (repeated 30 times) during the span of a 30-year career. By not maintaining continuing education knowledge and updating clinical skills, a clinician may unreasonably condemn otherwise salvageable teeth because of inadequate diagnosis or treatment.

State dental board relicensing continuing education requirements range from 0 in Colorado to 100 continuing education units in South Dakota.

Evidence-based endodontics

Although much emphasis is currently placed on evidence-based medicine and dentistry, most clinical practices are not based on data derived from randomized clinical trials.[240] It is virtually impossible to conduct a trial to test the validity of every possible patient-management option. Many therapeutic choices are so compelling that a test would be unethical; others are so trivial that a test might not be worth the time or effort. Clinicians do not always practice in conformity to evidence-based research, even when evidence is available from randomized clinical trials. This is because knowing the right answer is only the first step in the process of adopting a new treatment methodology. Many clinicians will not use a new drug simply because supporting research data suggest its efficacy. Instead, identification of the probable mechanism of action is often a prerequisite before adopting a new treatment. Moreover, the test of time may eventually reveal an adverse effect of a particular drug or device (e.g., defects that were not identified before marketing). Even if the new product's research proves beneficial, comparative effectiveness studies with other time-proven and tested products are needed to determine a new product's relative worthiness.[137,196,253,295]

Clinicians should not avoid using certain drugs if the data supporting their use are overwhelming. When the results of a clinical trial conflict with a widely held mechanistic model, many clinicians doubt research-based evidence.[226] However, when the results from well-researched clinical trials

Telegram: @dental_k

www.konkur.in

become so convincing that the evidence can no longer be ignored, a prudent clinician embraces the new paradigm and discards previously held concepts. Endodontic science advances as disproved older concepts retreat. For example, delaying extractions until after several days of antibiotic use to reduce infection is no longer the accepted practice. Rather, immediate extraction, along with any necessary antibiotics, is the preferred current therapy.[6] Another example is one-visit endodontics, which has been proved to be as effective as two-visit endodontics.[109,225,250]

Holistic dentistry

Evidence-based dentistry is reached when there is a consensus of the majority of practitioners relying upon peer-reviewed research published in respectable dental journals with adequate statistical power that has been replicated. In contrast, pseudoscientific research and/or publications are typically espoused by a very small minority of dentists belonging to international dental or medical organizations that number less than 1000 practitioners. By contrast, the ADA membership is 170,000.

Examples of holistic teachings and preaching to patients include that root canals are toxic foci of infections, which cause systemic maladies. Thus perfectly healthy root-canaled teeth are unnecessarily extracted and the underlying alveolar bone excessively removed by cavitation therapy. More than 70 years ago, the ADA published refutation of such holistic hokum in its *Journal of the American Dental Association*.[b] AAE offers scientific refutation of holistic therapies for extracting healthy root-canaled teeth.[c] Moreover, state dental boards have disciplined dentists for promoting in advertisements and/or performing unnecessary holistic therapies.[d]

A dentist is not necessarily negligent just because he or she chooses one dentally accepted method of treatment or diagnosis and it turns out that another dentally accepted method would have been a better choice.[e] This defense jury instruction for acceptable alternative treatment method does not excuse extraction of healthy root-canaled teeth. Such treatment is an **unacceptable,** negligent choice of treatment. Nor is it acceptable within the standard of care to ask a patient to consent to negligent care.

Ozone therapy

Telegram: @dental_k

www.konkur.in

Ozone's antibacterial efficacy is not comparable with that of NaOCl.[f] Treatment of apical periodontitis involves elimination of root canal infection by a combination of mechanical and chemical means. Mechanical instrumentation alone does not completely eliminate bacteria from the root canal system because not all of the root canal surfaces are planed by the action of files. Consequently, antibacterial irrigants are employed to penetrate the noninstrumented surfaces. Sodium hypochlorite (NaOCl) is the current irrigant of choice due to its antibacterial and tissue-dissolving effects.

Food and Drug Administration Department of Health and Human Services subchapter H—Medical Devices, Section 801.415 Maximum acceptable level of ozone states:

> *(a) Ozone is a toxic gas with no known useful medical application in specific, adjunctive, or preventive therapy. In order for ozone to be effective as a germicide, it must be present in a concentration far greater than that which can be safely tolerated by man and animals.*
>
> *(b) Although undesirable physiological effects on the central nervous system, heart, and vision have been reported, the predominant physiological effect of ozone is primary irritation of the mucous membranes. Inhalation of ozone can cause sufficient irritation to the lungs to result in pulmonary edema. The onset of pulmonary edema is usually delayed for some hours after exposure; thus, symptomatic response is not a reliable warning of exposure to toxic concentrations of ozone. Since olfactory fatigue develops readily, the odor of ozone is not a reliable index of atmospheric ozone concentration.*

New products

New devices that lack definitive research studies should be used cautiously. For instance, high-intensity, wireless, fast-curing lights may generate heat at the wand tip and cause pulpal pathosis. First-generation halogen bulbs require longer composite curing time to achieve polymerization but generate only 400 to 800 mW/cm. Plasma arc bulbs reduce curing time but generate 2000

Telegram: @dental_k

www.konkur.in

mW/cm.

Hydron was marketed without long-term clinical testing. Its purported biocompatibility and reduced inflammation portended an improved endodontic drug for obturation. Postmarketing failures resulted from inadequate premarket testing that lacked long-term research. Thus Hydron's inability to obturate canals with a durable filling material resulted in both clinicians and patients being harmed as postmarket guinea pigs. Hydron's in vitro research did not match in vivo patients' experiences.

Other examples include Endocal 10 (formerly Biocalex 6/9), which proved ineffective. Arsenic to promote devitalization of the pulp resulted in local osteonecrosis. Thermafil metal carriers proved difficult to remove and were replaced with plastic carriers. Advance cement was touted as an improved luting cement for retaining permanent restorations. The high incidence of marginal leakage with Advance resulted in its withdrawal from the market in 2000. A multimillion-dollar class action settlement resulted against the manufacturer on behalf of California clinicians with unsealed margins of crowns cemented with the Advance luting agent.[128]

Older devices, over time and with sufficient patient experience, may manifest adverse events. Overheating with ultrasonic tips for post removal has resulted in teeth and tissue loss (Fig. 27.21). Accordingly, despite insufficient label warnings on some ultrasonic devices, copious water coolant, rest periods, and avoidance of prolonged ultrasonic device use are needed for safe post removal.[90,95,130]

FIG. 27.21 Results of overheating a post with an ultrasonic device

Telegram: @dental_k

www.konkur.in

during post removal.

A) Close-up shows top view of yellow stained teeth with whitish tissue on the black gum line.

B) Close-up view shows pale teeth with greater loss of tissue compared to A at gum line. The black line is diminished.

Today's clinician who is exploring ways to improve the quality and success of endodontic therapy is constantly presented with new dental products and techniques. For prescribing and using drugs or other agents, the ADA's Principles of Ethics, Section 5D, provide this guideline[18]:

> *Except for formal investigative studies, dentists shall be obliged to prescribe, dispense, or promote only those devices, drugs and other agents whose complete formulae are available to the dental profession. Dentists shall have the further obligation of not holding out as exclusive any device, agent, method or technique if that representation would be false or misleading in any material respect.*

Ethical clinicians should not indiscriminately adopt every new product. Instead, the supporting research should be reviewed, rather than risk the patient's welfare with inadequately tested products or researched products only tested in vitro. Again, do not be the first or the last to adopt new technology.

U.S. food and drug administration approval

Despite FDA approval, some drugs are marketed with fraudulent concealment of the number and nature of adverse event incidents.[117a]

U.S. food and drug administration's drug approval

Until 1962, drug companies were allowed to promote their products for any use so long as they were shown to be "safe" for one use. Manufacturers were marketing drugs with serious side effects for minor conditions and to vulnerable populations, resulting in many injuries and deaths. Ineffective drugs were the rule rather than the exception. When a retrospective review of

Telegram: @dental_k

www.konkur.in

all drugs was conducted after 1962, the National Academy of Sciences found that fully 80% of the uses for which drugs were being promoted could not be shown to be effective. Since 1962, the FDA has required prescription drug manufacturers to demonstrate safety and efficacy with animal and randomly controlled research trials conducted with FDA-approved protocols. FDA "approval" to market new drugs for specific uses is termed *premarket approval* (PMA).

In a new drug application (NDA) to the FDA, findings from many clinical studies are used to assess a new drug's efficacy and safety and to gain the FDA's PMA to market the drug. An NDA judges whether the proposed new drug (1) causes more good than harm (benefit outweighs the risk), (2) is comparatively more effective than already existing marketed drugs, or (3) has unreasonably frequent or severe side effects (risk outweighs the benefit).[35,321]

The Pharmaceutical Research and Manufacturers Association of America has created an online database that summarizes clinical study results involving hundreds of prescription medicines. Notwithstanding, the sheer volume of clinical testing has overwhelmed the FDA's ability to independently assess commercial trials and make all test results public. Deceptive marketing, unreported side effects, and hidden payments to medical/dental researchers highlight the gap between the number of clinical trials conducted and the number published.[27,181,196,216,256,269,274,284,295,316,337]

U.S. food and drug administration clearance

The applicant must receive FDA approval of its PMA application prior to marketing the device as FDA approved. PMA approval is based on an FDA determination that the PMA contains sufficient valid scientific evidence to assure that the device is safe and effective for its intended uses.

The FDA lists certain products that are exempt from premarket notification requirements under the Food and Drug Administration Modernization Act of 1997 (the Modernization Act),[116] which include the following endodontic products:

- Root canal posts
- Gutta-percha

Telegram: @dental_k

www.konkur.in

Adverse drug events

Adverse drug events (ADEs) include "injury due to medications."[39] In 1999, the Institute of Medicine identified medication errors as a significant and preventable source of ADEs. Warning labels represent a quick reminder to highlight the most important instructions for the safe and effective use of prescribed medications. In one study, 50% of participants looked directly at the warning labels; 22% did not look at any. The recommendation was to move all of the warnings from the colored stickers to the main, white label.[304] More than 30% of those 65 and older take 10 medications daily.[304]

Primary medication nonadherence: Unfilled prescriptions

Primary medication nonadherence occurs when a noncompliant patient fails to fill a prescription. Up to 25% of children discharged from a hospital with a prescription do not have those prescriptions filled.[348] Other data from emergency departments suggest that the frequency of unfilled prescriptions is between 7% and 35%.[348] Electronic prescriptions are more likely to be filled. When a prescription is electronically prescribed, the patient does not have an opportunity to lose or misplace it. Data suggest that clinicians should explore whether a patient actually filled the medication prescribed or was taking it properly when the patient does not appear to be responding adequately to prescribed treatment.[199]

U.S. food and drug administration medwatch

Newly marketed drugs may not list all potential adverse drug reactions or events because of the limited number of patients in research trials before marketing. Therefore the FDA's MedWatch program encourages clinicians to report known or suspected drug reactions. MedWatch encourages reporting of serious unexpected adverse drug reactions whose nature and severity are inconsistent with or absent from the drug's labeled warnings.[111–113,115,235] Clinician reporting to the FDA is confidential and voluntary. The patient's identity need not be disclosed. Clinicians should contact the FDA by telephone at (800) FDA-1088 or fax at (800) FDA-0178 to obtain the FDA Medical Products Reporting Program (MedWatch) form (FDA form #3500). The back portion of the *Physicians' Desk Reference* (PDR) contains a

Telegram: @dental_k

www.konkur.in

MedWatch form. Clinicians can also download the MedWatch reporting form at www.fda.gov/medwatch/getforms.htm; request the form by mail via MedWatch, 5600 Fishers Lane, Rockville, Maryland 20852-9787; and report suspected drug interactions, reactions, or adverse product events at www.fda.gov/medwatch/report.htm. Other electronic drug databases are available to report and access important drug interaction information.[340] For FDA-approved safety-related drug labeling online, see www.fda.gov/MedWatch.

Adverse drug reactions are injuries occurring when drugs are administered at usual doses. These reactions represent the primary focus of regulatory agencies and postmarketing surveillance. An adverse drug event suggests medication prescribing or dispensing errors that compromise patient safety. Unfortunately, clinicians report only between 1% and 5% of adverse drug incidents to the FDA, because clinician reporting is voluntary.[184] On the other hand, drug manufacturers must report known adverse drug incidents to the FDA.[113]

Clinicians should document adverse drug reactions not only in the progress notes but also in the allergy section of the chart in order to assess whether future use of the same drug is contraindicated and to prevent a harmful recurrence. Predictable adverse drug reactions that manifest should also be recorded as consideration for future disuse of the involved particular drug.

The Weber effect is a known phenomenon in the epidemiology literature in which the number of spontaneously reported adverse events for a drug tends to peak around the second year after a drug's initial marketing.[80] The influence of the Weber effect suggests that an increase in adverse events may be attributed to epidemiologic reporting bias, which may not reflect a true difference in adverse events.[80]

Compounding pharmacies

More than 500 cases of fungal meningitis, including 44 fatalities, were attributed to injectable steroid solutions prepared by the New England Compounding Center (NECC), which subsequently filed for bankruptcy.[297]

Contamination is only one of five categories of risk associated with compounding pharmacies. The other four are subpotency, superpotency, overmedication, and medication replacement.[47]

Telegram: @dental_k

www.konkur.in

Many patients received sterile injections for back and joint pain for procedures that lack high-quality evidence-based efficacy.[299] FDA-approved methylprednisolone acetate is sold by Pfizer and two generics companies. NECC's version did not contain preservatives, which avoided the FDA's regulatory process.

Compounding involves the preparation of medications on prescription to meet unique patient health care needs that cannot be met with commercially manufactured and marketed drug products. Compounding includes providing different strengths of a drug with different nonactive excipients for allergy patients or creating dosage forms that are more palatable for a patient. Compounding pharmacies and pharmacists work directly with the prescribing dentist to create customized personalized medication solutions for patients in doses and formulations that the pharmaceutical industry does not manufacture.

The Food and Drug Administration Modernization Act (FDAMA), enacted November 21, 1997, amended the Federal Food, Drug, and Cosmetic Act relating to the regulation of food, drugs, devices, and biologic products. FDAMA exempted individualized compounded drug products from the rigid federal current goods manufacturing practices. Under federal law, drugs that are not manufactured in conformity with federal current goods manufacturing practices are deemed to be "adulterated" under 21 U.S.C. 351(a)(2)(B) and subject to federal sanction. FDAMA, 21 U.S.C. 351(a)(2)(B) does not apply to a drug product compounded by a licensed pharmacist in a state-licensed pharmacy for an identified individual patient with a valid prescription order —or in limited quantities before receipt of the valid prescription order.[299]

Federal law prohibits compounding of drugs previously removed from the market because such drug products, or one or more of their components, have been found to be unsafe or ineffective. Compounding drugs that are copies of a commercially available drug product are also prohibited.

After the 1937 sulfanilamide disaster that killed more than 100 people, Congress passed the Food, Drug, and Cosmetic Act (FDCA), requiring drugs to be safe and properly labeled. In 1962, a requirement was introduced for proof of drug efficacy through "adequate and well-controlled investigations," in response to thalidomide's fatal side effects causing impaired limb development.

Telegram: @dental_k

www.konkur.in

Traditional compounding pharmacies are not registered with the FDA as drug manufacturers. The FDA does not approve compounding pharmacy prescriptions before marketing. Nor does the FDA require compounding pharmacies to report adverse events. Instead, state law generally controls recordkeeping, certifications, and licensing for compounding pharmacies.

Dietary supplements

The Dietary Supplements Health and Education (DSHE) Act allows dietary supplements to be sold directly to consumers without any oversight or FDA regulation. In response to intense lobbying by the multibillion-dollar dietary supplement industry, Congress in 1994 exempted these products from FDA regulation.[190,205,342] Products may contain amounts claimed, but they need not, and nothing can prevent their sale if they do not. For example, an analysis of ginseng[205] products showed no ginseng at all in some products. The DSHE Act places the burden of proof for dietary supplements' safety on the FDA and not the manufacturer. As a result, consumers of herbal supplements must depend on self-regulation within the industry for assurance of product quality, consistency, potency, and purity.[164,342] An understaffed and overworked FDA can hardly be expected to be a vigorous enforcer.

An herbal product label can state the way the product is intended to affect "the structure or function" of the body but cannot claim its use for a specific disease. Manufacturers thus use creative language that complies technically with the statute but generally is confusing or deceptive.[205]

A current medication history form should include over-the-counter, herbal, and illicit drugs, many of which have the potential for synergistic or antagonistic interaction with clinician-prescribed drugs.[342]

Negligence per se

Violation of a health safety statute constitutes negligence per se if the patient was in the class of persons the statute was designed to protect.[292] Compliance with a health safety statute does not conclusively establish due care, because regulations require only minimal care and not (necessarily) prudent care or what the law regards as due care.[79,308]

Telegram: @dental_k

www.konkur.in

Prescription drugs

Clinicians should exercise extreme caution when administering or prescribing dangerous drugs. For sedative or narcotic drugs, cautionary directions should be written on prescriptions, and the pharmacist should place these directions on the prescription container as a patient reminder. For example, for the appropriate drugs, the clinician should prepare a prescription rubber stamp or obtain preprinted prescriptions that state the following:

> *Do not drive or operate dangerous machinery after taking medication because drowsiness is likely to occur. Alcohol, sedative, or tranquilizing drugs will cause drowsiness if taken in combination with this prescribed drug.*

The ADA and American Medical Association (AMA) provide prescription drug warning pads. Clinicians should document each drug information form provided with the prescription in the patient's chart.

The overuse of antibiotics risks resistant-strain development and side effects. Studies demonstrate generally no increased therapeutic efficiency of endodontic therapy with antibiotics when performed in the absence of facial swelling.[327] Unless persistent infections occur or compelling systemic reasons exist (e.g., uncontrolled diabetes, antibiotic prophylaxis necessary because of mitral valve regurgitation), antibiotics should not be prescribed prophylactically.[163,227] Neither pain nor localized swelling alone justifies antibiotics. However, extraoral swelling, cellulitis, or lymphadenopathy may require surgical drainage, antibiotics, or both. The U.S. Centers for Disease Control and Prevention (CDC) estimates about one third of all antibiotic outpatient prescriptions are unnecessary.[12]

Ability to foresee unreasonable risk

Each endodontic procedure has a variable degree of inherent risk. The standard of care requires that the clinician avoid unreasonable risks that may harm the patient (Fig. 27.22). Treatment is deemed negligent when a reasonably careful clinician would have foreseen some unreasonable risk of harm to the patient. Failure to follow the dictates of sound endodontic

Telegram: @dental_k

www.konkur.in

practice increases the risk of negligently induced deleterious results. Accordingly, prophylactic endodontic practice is designed to prevent foreseeable or reasonably avoidable injury risks. Foreseeability connotes predictability.

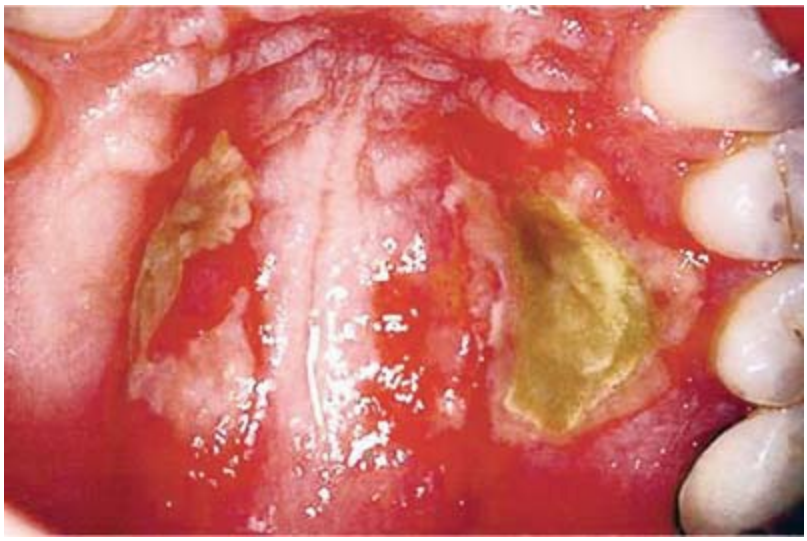

FIG. 27.22 Excessive local anesthetic resulting in palatal tissue sloughing with anterior middle superior alveolar (AMSA) (wand) injection.

Close-up view of interior of teeth shows greenish patches on palatal region little above the gums.

It is not necessary that the exact injuries that occur be foreseeable. Nor is it necessary to foresee the precise manner or circumstances under which injuries are inflicted. It is enough that a reasonably prudent clinician would foresee that injuries of the same general type would likely result in the absence of adequate safeguards.[265]

Consent

Simple consent occurs when the clinician makes the treatment decision unilaterally and obtains the patient's consent without offering the patient a choice. Conversely, informed consent is a joint decisional process whether to proceed with treatment or not after the dentist informs the patient of reasonable alternatives, benefits, and potential complications. Unconsented treatment constitutes a battery in legal parlance.

Telegram: @dental_k

www.konkur.in

Emergency endodontic treatment often requires that the patient be provided pain relief. Acute pain clouds the patient's decisional process; palliative treatment provides immediate pain relief so that on a return visit, the patient can rationally decide among treatment choices. With ample time, the patient can rationally decide and compare choices such as completion of endodontics and a crown versus extraction followed by an implant with crown. Also, an extraction that may result in progressive alveolar ridge bone loss and the need for bone grafting are considerations the clinician should explain to the patient.

Patient choices may be influenced by cost, convenience, time off work, travel needs, esthetics, or a myriad of other reasons. The clinician plants the seeds of the decisional tree, but the patient decides which branch of the tree should be followed.

Informed consent principles

The legal doctrine of informed consent requires that the patient be advised of reasonably foreseeable material risks of endodontic therapy, the nature of the treatment, reasonable alternatives, and the consequences of nontreatment.[71,173,221] This doctrine is based on the legal principle that, as individuals, patients have the right to do with their own bodies as they see fit, including the right to prematurely lose teeth regardless of recommended dental treatment. Once the clinician has informed the patient of the diagnosis, treatment risks, prognosis, and nontreatment risks, as well as recommendations for corrective treatment or alternative therapy, the patient has the right to decide how, when, or if to proceed. An adult of sound mind is entitled to elect to do nothing about existing endodontic disease. Rather than elect corrective treatment, the patient may elect to suffer nontreatment consequences, including present or future tooth loss or apical abscess.

To be legally effective, a patient's consent to treatment involving potentially serious injury complications must include informed consent. Accordingly, a clinician has a fiduciary duty to disclose all material or essential information necessary for the patient to make a decision.[71,173,221] The scope of a clinician's duty to disclose information is measured by the amount of knowledge a reasonable patient requires to make an informed choice. Material information is the disclosure a clinician knows (or should

Telegram: @dental_k

www.konkur.in

know) would be regarded as significant by a reasonable person in the patient's position who must decide whether to accept or reject a recommended endodontic procedure.

If a clinician fails to reasonably disclose information that would make a reasonable person in the patient's position decline the procedure, the clinician may be liable should an undisclosed risk manifest. Beyond the foregoing minimal disclosure, a clinician must also reveal such additional information as a skilled practitioner of good standing would provide under similar circumstances.

Informed consent

Adequate informed consent requires that a patient be informed of the ABC's —the alternatives, benefits, and complications—of a proposed treatment, along with the pros and cons of the alternative therapies or options.[71,173,221] A patient has a right to be informed of these ABC's from the treating clinician and not solely from an informed consent form or by a front office staff person who lacks a dental license. Informed consent must be presented in layperson's language, so that the patient can appreciate and understand what the treatment risks are.

A patient cannot legally consent to negligent care.[315] Accordingly, informed consent applies only to treatment that complies within the standard of care. If the clinician is reasonably careful during treatment but an untoward result occurs, the clinician is not liable so long as the patient was forewarned of the potentially unavoidable risk prior to treatment.

A reasonably unavoidable risk that manifests during treatment represents a maloccurrence and not malpractice. For example, a small percentage of endodontic failures occur for nonnegligent reasons. The clinician should be sensitive to the patient's feelings of disappointment. When endodontics fails, regardless of cause, it is a 100% failure rate for the patient. On the other hand, if the risk was reasonably avoidable, then informed consent does not apply to reasonably avoidable risks.

Patient treatment refusals should be documented. Some states require informed refusal disclosures advising the patient about the consequences of refusing treatment or diagnostic modalities.

Telegram: @dental_k

www.konkur.in

Informed consent application

Informed consent is a flexible standard that considers reasonably foreseeable consequences, depending on the clinical situation present both before and during treatment. For instance, a fractured or separated endodontic instrument left in the root canal creates the possibility of root canal failure or impaired success (depending on whether the fracture occurred in the coronal, middle [least favorable], or apical third of the root canal). The clinician must advise the patient of the relative risk of future failure and suggest treatment alternatives to correct the problem. An adequately informed patient can better make an intelligent choice among apicoectomy, referral to an endodontist utilizing microscopy for attempted retrieval, or periodic radiographic observation at recall visits.[76,183,197] In Fig. 27.23, the clinician overinstrumented and perforated the inferior alveolar nerve (IAN), causing both a permanent dysesthesia and paresthesia. The clinician should have immediately referred the patient to an endodontist for attempted gutta-percha retrieval before the endodontic sealant containing eugenol set, which caused more deleterious chemical injury to the IAN. If retrieval was unsuccessful, the patient should have then been referred to a microsurgeon within 48 hours from occurrence for optimal opportunity to prevent chemical cytotoxic injury to the IAN.[262]

Telegram: @dental_k

www.konkur.in

Adequate disclosure includes clinical judgment and experience, which assesses current research and applies it to the clinical needs of each patient. Today's advance may be tomorrow's retreat if materials, devices, or instruments lacking adequate long-term study of safety and efficacy predictably fail. For instance, the one-component bonding agent is more technique sensitive than its two-component predecessor. This is because the one-component agent contains acetone that desiccates the tooth surface and requires a moist surface to avoid postoperative sensitivity. Long-term testing before marketing would have revealed that the two-step system is more reliable and forgiving.[312] Reasonable clinicians do not sacrifice patient safety for speed and profit and then compensate with desensitizing agents. Clinicians should be sensitive to limited research on new products or devices lest the patient be the injured guinea pig patient with products that were inadequately tested before marketing.

Material disclosure concerns whether the patient was provided sufficient information for a reasonable patient to achieve a general understanding of the proposed treatment or procedure. This disclosure includes information concerning any dentally acceptable alternatives, any predictable risks of serious injury, and any likely consequences should the patient refuse the proposed therapy. The standard to be applied is whether a reasonable person in the patient's position would have consented to the procedure or treatment in question if adequately informed of all significant perils.[66] Informed consent applies only to inherent risks of nonnegligent treatment, because a patient's consent to negligent treatment is voidable as being contrary to public policy.[315] Accordingly, a patient who refuses necessary diagnostic radiographs should be refused treatment.

If warnings are limited to some risks but not others, some courts have held that the patient can recover for all surgical injuries including warned risks.[160]

Endodontic informed consent

If the practitioner's own statistical experience varies significantly from national statistics, using statistics presented in national literature regarding success rates for endodontic procedures is considered insufficient disclosure and does not fulfill the legal requirements of informed consent (Fig. 27.24).[145,291]

INFORMED CONSENT

We are concerned not only about your dental health and endodontic treatment needs, but also about your right as a patient to make the treatment decision that you feel is best for you. Our commitment to you is to provide you with detailed and complete information about your dental needs as we diagnose them. We will share our diagnostic processes with you, and we invite and welcome all of your questions regarding our treatment.

Towards this aim of a mutual sharing of information, we feel it is important to advise you of the reasonably foreseeable risks of endodontic therapy. The following is important information you should consider to aid your treatment decision.

- Root canal therapy is a procedure designed to retain a tooth that may otherwise require extraction. Root canal therapy has a very high degree of success. However, it is a biological procedure, and results cannot therefore be guaranteed.
- Approximately 5% to 10% of teeth that have undergone nonsurgical root canal therapy may require retreatment or root-end surgery.
- Despite our best efforts, approximately 5% of endodontically treated teeth may fail and require extraction.
- Final restoration (crown) of the tooth that has undergone root canal therapy is essential to root canal success and retention of the tooth. A final restoration should be completed within 30 days of root canal therapy. This restoration should be done by your restorative dentist.

Signature of Patient (or Parent) _____ Date _____

Witness _____ Date _____

FIG. 27.24 Informed consent form.

Form of informed consent is as follows:

We are concerned not only about your dental health and endodontic treatment needs, but also about your right as a patient to make the treatment decision that you feel is best for you. Our commitment to you is to provide you with detailed and complete information about your dental needs as we diagnose them. We will share our diagnostic processes with you, and we invite and welcome all of your questions regarding our treatment.

Towards this aim of a mutual sharing of information, we feel it is important to advise you of the reasonably foreseeable risks of endodontic therapy. The following is important information you should consider to aid your treatment decision.

1) Root canal therapy is a procedure designed to retain a tooth that may

Telegram: @dental_k

www.konkur.in

otherwise require extraction. Root canal therapy has a very high degree of success. However, it is a biological procedure, and results cannot therefore be guaranteed.

2) Approximately 5 percent to 10 percent of teeth that have undergone nonsurgical root canal therapy may require retreatment or root-end surgery.

3) Despite our best efforts, approximately 5 percent of endodontically treated teeth may fail and require extraction.

4) Final restoration (crown) of the tooth that has undergone root canal therapy is essential to root canal success and retention of the tooth. A final restoration should be completed within 30 days of root canal therapy. This restoration should be done by your restorative dentist.

At the bottom, the blank spaces for signature of patient (or parent), date, witness, and date are given.

Among specialists, the reported incidence of treatment complications in endodontics is relatively low. Based on a Southwest Endodontic Society retrospective study, a reasonable endodontist or a practitioner with similar abilities should disclose the following facts to patients[288]:

1. Endodontic therapy cannot be guaranteed.
2. Although endodontic therapy is usually successful, a small percentage of teeth are lost due to complications or treatment failure, despite competent endodontic care.
3. Slight overextending or underfilling of root canals occurs in 2% to 4% of cases, which may contribute to treatment failure.
4. Slight to moderate transient postoperative pain may occur. Severe postoperative pain rarely occurs.
5. Irreparable damage to the existing crown or restoration secondary to endodontic treatment is uncommon after the access opening is restored.

Video-informed consent.

Animated video-informed consent shown to the patient is a dynamic method of providing informed consent. Because the video-informed consent is considered part of the clinician’s records, in the event the patient disputes having ever been advised of (1) the nature of endodontic disease, (2) the

Telegram: @dental_k

www.konkur.in

availability of endodontic specialists, or (3) the relative indications for nonsurgical versus surgical endodontic care, the videotape can be played back to the jury as proof that the patient was informed. It is doubtful that a jury would believe a forgetful patient who admits having previously viewed the videotape, because the videotape refreshes the stream of memories that may have otherwise faded into the unconscious.

A patient viewing the videotape is more likely to understand the informed consent disclosure of a technical procedure, particularly if the video contains illustrated animation. After viewing the videotape and discussing its contents with the clinician, the patient should sign a video consent form to verify that the video was viewed and all the patient's questions were answered.

Alternative technique choices

Currently taught methodologies include filling the root canal with the lateral compaction method or using vertical warm gutta-percha carrier delivery systems, such as heat-transfer units for warm gutta-percha.[197] Each technique has zealous advocates. Both methods are reasonable and acceptable choices, and each method conforms to the standard of care. The choice of techniques changes as new products are introduced and scientific research is conducted. The vertical warm gutta-percha technique promises to deliver improved flow to fill lateral canals and is likely to predominate in the 21st century as the preferred methodology. Nonetheless, lateral compaction has a long-term proven track record, particularly with less-experienced practitioners, and is less technique sensitive. Regenerative endodontics will have greater utilization as this scientific application increases.[16]

Different schools of thought.

After the clinician advises treatment, if other reasonable clinicians would disagree or if there are other respectable schools of thought on the correct treatment, this material information should be disclosed to the patient.[325,346] For example, there may be two schools of thought concerning the optimal treatment for retrofilling and apicoectomy. One school posits that a retrograde with mineral trioxide aggregate (MTA) or Biodentine is the appropriate procedure, whereas another school asserts that retrograde with Super EBA is a reasonable choice.[343] One can assume further that an

Telegram: @dental_k

www.konkur.in

explanation of these two different methods of treatment constitutes material information for the purposes of informed consent. The mere fact that there is a disagreement within the relevant endodontic community does not establish that the selection of one procedure as opposed to the other constitutes negligent endodontic therapy. Because competent endodontists regularly use both procedures, a patient would have a difficult time proving dental negligence (i.e., that the endodontist failed "to have the knowledge and skill ordinarily possessed, and to use the care and skill ordinarily used, by reputable specialists practicing in the same field and in the same or a similar locality and under similar circumstances"). Moreover, neither school of thought possesses long-term clinical research results to prognosticate apical sealant insolubility rates in an 18-year-old patient with an additional 60-year life expectancy.[293] Long-term durability depends on an insoluble seal to reduce the risk of bacterial leakage.[66,228] Fig. 27.25 represents a preoperative and postoperative radiograph of a successful apicoectomy and retrograde in a 14-year-old.

FIG. 27.25 **A,** Preoperative panoramic radiograph showing a

B) Radiograph shows high-density tissue in place of the ovoid chamber. The braces are slightly curved at the center of teeth.

Source: (Courtesy Edmond Bedrossian, DDS.)

On the other hand, the specialist would have a duty under the previous hypothetical circumstances to disclose the two recognized schools of treatment so that the patient could be sufficiently informed to make the final personal decision. An endodontist, being the expert, appreciates the risks inherent in the procedure prescribed, the risks of a decision not to undergo the treatment, and the probability of a successful outcome of the treatment. Once this information has been disclosed, this aspect of the endodontist's expert function has been performed. The weighing of these risks against the individual subjective fears and hopes of the patient is not an expert skill. This evaluation and decision constitute a nondental judgment reserved for the patient alone.[71,173] In this hypothetical situation, failure to disclose such material information would deprive the patient of the opportunity to weigh the risks versus the benefit. Consequently, the clinician would have failed in the duty of disclosure, which the doctrine of informed consent requires.

When improved technology offers clearly superior results, it no longer becomes a patient choice issue but rather a requisite requirement to fulfill the standard of care. Apical microsurgery with ultrasonic tips for retrofilling exemplifies improved technology and the current standard of practice. Likewise, apical retrogrades should be done with MTA and not with amalgam.[66] Finally, microscopic endodontics represents the current standard of care for apical surgery or fractured instrument retrieval.[76,86,166,183,197]

Avoiding patient claims.

If a clinician fails to obtain adequate informed consent, a plaintiff can recover damages (even in the absence of any negligent treatment) should the patient testify that performed treatment would have been refused if the clinician had

Telegram: @dental_k

www.konkur.in

provided information concerning possible risks. Therefore discussions of treatment risks with the patient should be documented. Informed consent forms are very helpful, although not legally mandated. A jury may believe that the patient was informed orally although the patient's attorney may argue that if it is not documented it did not happen. Equally, if not more important than consent forms, is a chart notation indicating that the clinician discussed informed-consent risks and alternatives (and that the patient understood and accepted this information).

Patients may mentally block out frightening information. Trauma and a potent anesthetic agent can create retrograde amnesia. Therefore clinicians must document (in the patient's chart) any risks, benefits, alternatives, and consequences of nontreatment provided to the alert patient before sedation.

Clinicians should follow only the patient-authorized and consented treatment plan. If an emergency precludes advising treatment risks to the minor patient, lack of informed consent may be defensible as implied consent (because no reasonable parent would refuse necessary emergency treatment).

The following example demonstrates how a clinician should record any recommended treatment the patient has refused and the reason for refusal:

> *Patient refused endodontic referral for consultation with endodontist (Dr. Goodguy) because husband was laid off work last month and cannot afford treatment. After Dr. G. provided explanation, patient states she understands detrimental delay risks but is willing to assume these risks.*

Patients may initial any referral refusal on the chart. Although patient signature is not mandatory, it will enhance the clinician's credibility should the patient later dispute a referral was made.

Reasonable familiarity with a new product or technique is required before it is used. In addition, a patient is entitled to know the clinician's personal experience with a particular modality because the patient has a right to choose between reasonable alternatives or to seek care from a clinician who has more extensive experience with a particular modality or new product. A clinician who fails to obtain informed consent may be liable for injury caused by a product or instrument. The fact that the clinician followed the

Telegram: @dental_k

www.konkur.in

manufacturer's instructions is no defense if the clinician did not provide adequate information concerning a product or instrument risk (to permit the patient to intelligently weigh the disclosed information and choose among treatment options).

Referrals to other specialists

Every clinician, including specialists, will at some time need to refer a patient to another specialist for treatment to comply with the standard of care required of a reasonably careful clinician.[123]

Generally, if the referral takes place within the same dental practice, the legal doctrine of respondeat superior ("let the master answer") may be applicable. Under this doctrine, a clinician is liable for the dental negligence of a person acting as his or her agent, employee, or partner.[264] Liability is determined by whether the principal clinician controls the agent clinician's activities or methodology, regardless of whether such control is actually exercised.

If the referral is made (even within the same physical environment) to an "independent contractor" endodontist who does not diagnose or treat under the direction or supervision of the referring clinician, and that referring clinician has no right of control as to the mode of performing the treatment, the principle of agency and responsibility for the acts of another does not apply.[223] The legal test for agency is the principal's right to control, regardless of whether the control is exercised over the agent. However, if the independent contractor or referring clinician in the same practice does not provide adequate notice of this independent relationship to the patient, the independent contractor will still be liable under the legal doctrine of ostensible agency. Thus despite an independent contractor agreement, a patient can legally infer the so-called independent clinician is instead an employee, because neither clinician in the group practice disclosed an independent contractor relationship to the patient.

To ensure that the referred clinician is not considered the agent of the referring clinician within the same facility, fees for the referred clinician should not be set by the referring clinician nor should the fees be divided equally or shared based on some other arrangement. Also, the referred clinician should bill separately and exercise independent diagnostic and

Telegram: @dental_k

www.konkur.in

therapeutic judgment. The patient should be advised that the referred clinician is independent of the referring clinician. Otherwise, the referred clinician or specialist may be regarded or inferred to be the ostensible agent of the referring clinician in the same office although not intended. The legal test for agency is how the facts or circumstances appear to a reasonable patient, regardless of the clinician's understanding or written contract intent that the other treating clinician is to be considered an independent contractor. Thus agency may be actual in fact or, alternatively, ostensible (i.e., implied by circumstantial conduct).[174]

Surgical versus nonsurgical endodontics

Litigation to determine whether nonsurgical or surgical endodontics was the proper treatment choice will not be decided by any one clinician, the ADA, the AAE, or the ablest of judges. Rather, after considering all the evidence and the opinions of experts, a jury of the patient's peers will decide the disputed matter. Depending on the individual case, the jury may decide that either a combination of nonsurgical and surgical endodontic therapy, rather than one method exclusively, should have been attempted. The jury may also decide that the patient should have been advised of the availability of such alternative therapy. Similarly, the jury may determine that apical surgery should have been done microscopically rather than macroscopically, depending on expert testimony regarding the relative advantages of each method or upon presenting clinical circumstances (e.g., suspected calcification, viewing a separated instrument).

Microscopic endodontics

Microscopic endodontics improves posture and reduces neck and back fatigue.[25] Identification of microfractures in teeth[76,183,197,230] and removal of diseased dental tissue are easier and more accurate when done microscopically.

> *The operating microscope is an indispensable tool for state-of-the-art endodontic treatment. The specialty practice should not be without a microscope; this instrument is useful in all phases of endodontic*

Telegram: @dental_k

www.konkur.in

treatment from diagnosis to placement of the final restoration.[166]

Microscope

A 2007 survey of 1091 endodontists indicated that 90% of endodontists have access to and use the OM in their practice, a dramatic increase from 52% in use in 1999.[15] The 2012 AAE Position Statement is that the microscope is an integral and important part of the performance of modern endodontic techniques.[15]

According to the AAE, microscope benefits are as follows:

- Locating hidden canals obstructed by calcifications or reduced in size
- Removing materials such as solid obturation materials (silver points and carrier-based materials), posts, or separated files
- Removing canal obstructions
- Assisting in access preparation to avoid unnecessary destruction of mineralized tissue
- Repairing perforations
- Locating cracks and fractures that not clinically visible or palpable with an endodontic explorer
- Facilitating all aspects of endodontic surgery, particularly in root-end resection and placement of retrofilling material
- Photographic documentation enhancement
- Ergonomic benefit[15]

Magnification.

The modern approach to periradicular surgery (PRS) is through magnification, illumination, and microsurgery. Prognosis is greatly improved when these techniques are employed. Although loupes are helpful, improved illumination and magnification of the surgical operating microscope are essential for PRS. Microscopy provides a more detailed examination of the root apex anatomic features such as isthmuses, accessory canals, fracture cracks, and crazing. Failure to shape, clean, and fill the root canal system is acknowledged as the main reason for failure of root canal treatment. The

Telegram: @dental_k

www.konkur.in

same principle applies to apical surgery. A disadvantage of MTA for retrograde sealant is handling and placement. MTA is hydrophilic and requires moisture to set with up to 3 hours of setting time. Newer agents to replace MTA include Biodentine, containing tricalcium silicate.

Root canal systems have much greater complexity at the level of root resection than previously recognized. At least 3 mm of the root apex should be removed to ensure successful retrograde obturation of all portals of exit. Angle of resection should be close to horizontal.

The floor of the sinus may be only 1 or 2 mm above root apices of the posterior dentition. Accordingly, the risk of sinus perforation increases when apical pathosis is present. Care must be taken to prevent debris from entering the sinus during maxillary posterior root canal therapy.

Separated instruments

The risk of broken files can be reduced if all hand and rotary nickel and titanium (NiTi) cleaning and shaping files are not resterilized and reused but are discarded after single-tooth use. Efficiency also increases, because approximately 50% of cutting efficiency is lost after initial use. Episodes of broken instruments will be dramatically reduced and nearly eliminated when files are used correctly and discarded after single-tooth use. Breakage increases sharply when hand or rotary shaping files are reused. Therefore the clinician should discard rotary instruments after a single-use visit. Chair and staff time efficiency, along with improved safety, dictates single-visit use of files.[228]

The clinician should save broken or defective instruments (e.g., a file that was broken inside a canal) (Fig. 27.26). The instrument manufacturer may be liable because the product was defective, rather than the clinician being liable for dental negligence.[266] Electron microscopy spectrographic analysis can determine if manufacturing defects with contaminants caused the break, rather than the clinician excessively stressing the instrument.

Equipment and supplies

Equipment should be kept in good repair by checking and following the manufacturer's recommended maintenance schedule. The clinician should carefully read the manufacturer's instruction warnings on instruments and

Telegram: @dental_k

www.konkur.in

inform staff of any important points. Infection control in operating dental equipment is mandatory, such as updating and maintaining dental units with check valves to prevent water retraction or suck-back.[70] The clinician should inspect check valves monthly and change clogged valves immediately.[287] Water retraction testers, at no charge to the clinician, are available from some manufacturers (A-dec [Newberg, OR], for instance).

The clinician or a staff member should also disassemble the unit's handpiece, run water through the line for a few seconds, and then stop. If a bubble of water is visible at the end of the water hose holes, the check valve is operating properly. If a bubble of water is not visible, water may be sucked back because of an absent or clogged check valve. An absent or clogged check valve is a source of cross-contamination, so it is important for the clinician or staff to perform weekly spore testing of the autoclave and monthly bacteriologic testing of waterlines.[17] The clinician or staff should consider using filters and should flush dental-unit waterlines between patients and also daily with FDA-approved chemical disinfectants to reduce water tubing biofilm. Some chemical disinfectants claim improved cost effectiveness by increasing handpiece and bur longevity concomitant with waterline purging or with continual use during treatment. Currently available waterline delivery systems, such as AquaSept, provide for safe water delivery or coolant to the handpiece or sonic scaler with autoclavable tubing.

Waterlines

Dental unit waterlines, typically, are constructed from a polymer or silicone rubber tubing, to provide water for irrigation, cooling, and flushing during dental procedures. Dental units are class I, FDA-regulated medical devices, which require FDA premarket clearance (510[k]).

Water stagnates in dental unit waterlines. Stagnant water contributes to biofilm buildup in the dental unit tubing, which can cause cross-contamination between patients. Dental unit waterlines connected to municipal water sources or closed-bottle systems typically cannot be sterilized. Without disinfection, waterborne microorganisms can collect in the dental unit waterline and form a biofilm. A layer of microorganisms adherent to the dental unit waterline tubing can also become biofilm, then dislodged and enabled to enter the output water stream to the handpiece and water

Telegram: @dental_k

www.konkur.in

syringe. Contaminated dental unit waterlines pose a risk of infection to the patient by direct exposure of waterborne pathogens and to dental professionals due to inhalation of aerosols.

The ADA[g] recommends routine monitoring of the water to demonstrate bacteria count of less than or equal to 500 colony forming units (CFU)/mL of heterotrophic bacteria. Sampling locations include the connection to the water source, dental handpiece connection, and air/water syringe. Organization for Safety Asepsis and Prevention (OSAP) recommends quarterly bacteriological test monitoring.

Flushing the waterline between patients as well as at the end of the day and before each day's first dental patient alone does not eliminate all biofilm. Therefore chemical disinfection of the waterlines is required to achieve water of potable drinking water quantity of no more than 500 CFU/mL. Germicidals that are automatically applied daily appear to be the most efficacious means of maintaining potable water quality. The CDC recommends that the dentist check with the dental unit manufacturer for recommendations for achieving and maintaining waterline quality to prevent contaminated dental water emanating from the dental drill and/or air/water syringe.[h]

Dental staff should not attach dental handpieces or dental instruments to dental unit waterlines that have not been cleaned or disinfected.

Dentists should establish written standard operating procedures to guide dental personnel in performing infection control procedures for dental unit waterlines.

To verify that the dental office complies with waterline quality maintenance, an infection control log should be kept.

Since 2003, the CDC in its Guidelines for Infection Control in Dental Health-Care Settings has recommended that the dentist test and monitor waterline quality with periodic bacteriological testing.[i]

Pulpotomy

California Dental Board requires that the dentist who performs procedures on exposed dental pulp, water, or other methods used for irrigation must be "sterile or contain recognized disinfecting or antibacterial properties."[j]

Examples of infection outbreaks from inadequately disinfected waterlines

Telegram: @dental_k

www.konkur.in

during pediatric pulpotomies include Georgia[k] in 2012 and Anaheim, California[l] in 2016. In each instance, dozens of children in the same dental clinic office suffered from mycobacterium abscessus infections. Consequently, dozens of young children who had not yet become immunocompetent lost significant portions of their maxilla or mandible and were hospitalized, administered IV PIC lines for 6 weeks, and suffered psychological damages including being fearful of future medical and dental care.

For surgical endodontic procedures, sterile water is required in accordance with CDC Guidelines for Infection Prevention.[m] Ultrasonic unit waterlines contained in the inner mechanisms of the device cannot be sterilized. Unless the device has autoclavable or disposable tubing rather than inaccessible inner waterline tubings, such devices can only deliver disinfected coolants and not sterile water. Consequently, such devices are contraindicated for surgical endodontic procedures. Thus during surgical procedures, use only sterile solutions as a coolant/irrigant using an appropriate delivery device, such as a sterile bulb syringe, sterile tubing that bypasses dental unit waterlines, or sterile single-use devices.

D) Patient's tongue has white tissue along with the wound on lower lip.

Clinician's liability for staff's acts or omissions

A clinician is liable for the acts or omissions of the clinician's staff under the doctrine of respondeat superior ("let the master answer"). This is termed *vicarious liability*, which means that the clinician is responsible not because

Telegram: @dental_k

www.konkur.in

of personal wrongdoing but because the clinician assumes legal responsibility for the conduct of employees and agents who act in the course and scope of their employment.

The clinician should instruct the staff in advising patients regarding posttreatment complaints. For example, if the staff ignores signs of infection, such as difficulty in swallowing or breathing or elevated temperature, and dismisses the patient's complaints as normal postoperative swelling, the clinician may be held liable for injury to the patient, such as delayed cellulitis, diagnosis or treatment of Ludwig angina, brain abscess, or other serious complications.

A clinician must be cautious when delegating responsibilities and give clear instructions to ensure that staff members properly represent the clinician and the chosen practice methods. Auxiliaries should not be allowed to practice beyond their competency level or license. For example, in states where assistant-placed restorations are legally permissible, the clinician should check any assistant-placed restoration before patient dismissal. Staff members should not make final diagnoses or handle patient clinical complaints without the clinician's involvement and consultation. Staff should be instructed to ask appropriate questions and relay the patient's answers to the clinician so the clinician can adequately determine what should be done.

Abandonment

Once endodontic treatment is initiated, the clinician is legally obligated to complete the treatment regardless of the patient's payment of any outstanding balance. This requirement is posited on the legal premise that any person who attempts to rescue another from harm must reasonably complete the rescue with beneficial intervention unless another rescuer (i.e., clinician) is willing to assume the undertaking.[69,195] Another view is that should a patient be placed in a position of danger unless further treatment is performed, the clinician must institute reasonable therapeutic measures to ensure that adverse consequences do not result.[212,296]

A clinician performing endodontic therapy should have reasonable means of communicating with patients after regular office hours to avoid a claim for abandonment. A recorded message is inadequate if the clinician fails to check for recorded messages frequently. Therefore answering services, pagers, or

Telegram: @dental_k

www.konkur.in

cell phones are required by the standard of care.

If the clinician providing endodontic therapy is away from the office for an extended period, a substitute on-call clinician should be available for any endodontic emergency and to answer patients' emergency calls. The endodontic treating clinician should arrange in advance for emergency service with a covering clinician. Leaving a name on the office answering machine or with the answering service without first determining the availability of the covering clinician is a mistake.

To avoid an abandonment claim, several prophylactic measures apply:

1. No legal duty requires a clinician to accept all patients for treatment. A private practice clinician may legally refuse to treat a new patient, despite severe pain or infection, except on the grounds of race or disability.[49,329] If treatment is limited to emergency measures only, the clinician must advise the patient that only temporary emergency endodontic therapy is being provided and that endodontic treatment is incomplete. The clinician should record this information in the patient's chart. For example:

Emergency palliative treatment only. Patient advised endodontic treatment of tooth #8 needs to be completed, either here or with another clinician. Explained complications likely if not soon completed, including infection recurrence, tooth loss, or both.

The patient should also be asked to acknowledge that treatment is limited to the existing emergency by endorsing an informed consent to emergency endodontics statement as follows:

I agree to emergency endodontic treatment of my tooth #8 and have been advised that (1) emergency treatment is for temporary relief of pain and (2) further root canal treatment of tooth #8 after emergency treatment is necessary to avoid further complications, including, but not limited to, pain, infection, swelling, tooth fracture, abscess, or tooth loss.

Telegram: @dental_k

www.konkur.in

2. No legal duty requires a clinician to continue treating former patients on recalls or subsequent emergency care once treatment is complete. Thus completion of endodontic treatment for tooth #19 does not legally obligate the clinician to initiate endodontic therapy for tooth #3 if endodontic disease of #3 began months after the clinician completed treatment of tooth #19.
3. Any patient may be discharged from a practice for any arbitrary reason, except on the grounds of race or disability, so long as all initiated treatment is completed. Accordingly, a former patient who evokes memories of a "frictional" relationship, who is financially irresponsible, or who arrives at the office after an absence of several years with an acute apical abscess in a site where previous care was not rendered may legally be refused treatment.
4. It is not considered abandonment if a patient is given reasonable notice to seek endodontic treatment with another clinician, and the patient is willing to seek endodontic services elsewhere.[229] Thus if rapport with the patient dissolves, the clinician should not hesitate to suggest that the patient would be better served if any remaining endodontic treatment were performed by a different clinician.

The clinician may discontinue treatment, provided it is not done at a time when the patient's dental health will be jeopardized (e.g., in the middle of treatment). To discontinue treatment, the clinician should do the following:

1. Notify the patient of the plan to discontinue treatment after a certain date.
2. Allow enough time for the patient to obtain care with another clinician, usually 30 days.
3. Offer to make emergency service available during the interim 30 days until a new clinician is obtained.
4. Provide diagnostic-quality records, copies of radiographs, and other pertinent clinical information in transfer records to the new treating clinician.
5. Allow the patient to select a new clinician or suggest referral by the local dental society if a referral service exists.
6. Document all of this in the patient's records, including a copy of a

Telegram: @dental_k

www.konkur.in

certified letter sent to the patient notifying discontinuance of further treatment.

Expert testimony

The standard of care that a clinician must possess and exercise is particularly within the knowledge of dental experts. However, there are occasional exceptions where the conduct involved is within the common knowledge of laypersons, in which case expert testimony is not required. In determining whether expert testimony is required to establish negligence, one California court commented: "The correct rule on the necessity of expert testimony has been summarized by Bob Dylan: 'You don't need a weatherman to know which way the wind blows.'"[170]

Incorrectly operating on the contralateral side because of mismounted radiographs or marking the wrong tooth on an endodontic referral card is an example of negligent conduct within the common knowledge of laypersons for which expert testimony is not required. The tort of battery results from unconsented treatment.

Increasingly, courts act as gatekeepers regarding the admissibility of scientific expert testimony. Anecdotal comparisons appear compelling, but such evidence may be judicially excluded in the courtroom. Some experts rely solely on their skill for experience-based observation rather than research testing of risk factors, such as that which occurs with epidemiologic research.

The U.S. Supreme Court (in the Daubert four-factors checklist[78]) held that in federal court an expert's testimony may be reliably admitted into evidence based on the following:

1. Whether the expert's technique or theory may be tested or refuted
2. Whether the technique or theory has been the subject of peer review or publication
3. Known or potential rate of technique error
4. Degree of acceptance of a theory or technique within the relevant scientific community

Courts determine whether testimony is based on the application of scientific principle or clinical experience. In general, courts are flexible and

Telegram: @dental_k

www.konkur.in

adaptable in determining whether a bright line separates scientific and unsupported nonscientific evidence. Often technical and specialized knowledge gained through continuing education and scientific journals, rather than an expert performing the research, is considered sufficient.

State courts are not bound to follow the Federal Rules of Evidence, but many do comply.[30] Nonetheless, U.S. Supreme Court decisions influence state courts that consider placing limitations on expert testimony. State court trial judges may either be more liberal or more restrictive in admitting expert witness testimony. If the trial court judge denies admission of scientific evidence as unreliable, untrustworthy, or irrelevant, the result may be to preclude an expert offering any opinion. On the other hand, the court may admit such evidence and instruct the jury members that they may consider the scientific basis for the expert opinions and give such evidence the evidentiary weight it deserves.

National Practitioner Data Bank

Insurance carriers are obligated to report all settlements to the National Practitioner Data Bank. These data are only accessible to hospitals for staff privilege credentialing and state licensing boards but not individual patients.

Medical negligence occurring in hospitals is too often underreported.[81] The Public Citizens' Health Research Group reports that more than half of U.S. hospitals have never reported an adverse incident to the National Practitioner Data Bank, an incredulous occurrence rate.[72]

Malpractice incidents

What to do if you are sued

If served with a summons or complaint, call your carrier immediately. Your carrier will assign an attorney. Be candid with the attorney. You will be asked to provide and interpret your dental records. Assemble all available records regarding your patient's treatment and review them thoroughly with your attorney prior to your deposition. Cell and office phone records can confirm calls to the patient, pharmacy, or specialists.

Telegram: @dental_k

www.konkur.in

Screw posts

Screw posts represent a restorative anachronism. The risk of root fracture is too great compared with the benefit, particularly when reasonable and superior passive alternatives exist (see Chapter 23). Even if the screw post is initially placed passively, the temptation to turn the screw is too great, considering human nature. Therefore screw posts are not a reasonable and prudent treatment choice.[68]

Paresthesia prevention

Endodontic surgery in the vicinity of the mandibular canal or mental foramen carries with it the significant risk of irreversible injury to the inferior alveolar or mental nerve. Consequently, the clinician must advise the patient in lay terms of the risk of temporary or permanent anesthesia or paresthesia before any surgery near these structures is performed. To document that adequate informed consent was provided, the clinician should have the patient execute a written informed consent form confirming that the patient was so advised. Informed consent is no defense if the surgery was negligently chosen or performed, because informed consent only applies to nonnegligent treatment risks. CBCT imaging has greatly reduced, if not eliminated entirely, the likelihood of IANC perforation. CBCT provides diagnostic guidance before therapy. Also, a final diagnosis with CBCT can confirm or rule out IANC penetration post treatment to facilitate prompt removal of foreign materials that have penetrated into the IANC. Also, sealants can chemically leak through the paper-thin porous (5% to 10%) IANC cortical borders even if the initial overfill only reaches but does not penetrate the underlying IANC. Delayed onset of paresthesia or dysesthesia up to 4 days can occur with sealant chemicals such as eugenol or resin components.

A clinician initiating root canal therapy on a mandibular posterior tooth must have (1) an awareness of the vital neurovascular bundle containing the IAN, which commonly approximates the ends of these roots, and (2) a diagnostic-quality image that accurately demonstrates both crestal borders of the IANC. Should the radiograph only demonstrate one border of the IANC, it is highly likely the evident border is the inferior crest of the IANC and not the superior crest.[206] If endodontics is done without adequate diagnostic radiographs, the patient is placed at great risk if there is anatomic variation or

Telegram: @dental_k

www.konkur.in

vital neural bundles lie in close proximity to these roots.[110,180,206,289,336] Also be mindful that as the IAN ascends toward the mental foramen, the IAN may have an anterior loop before exiting the mental foramen.[138,175,176,277] Overfilling or overinstrumentation of the root ends can cause traumatic or chemical injury to the IAN bundle, resulting in potentially permanent altered or total loss of sensation from paresthesia (partial numbness), anesthesia (total anesthesia), or dysesthesia (burning pain).[261]

The risk of overfills containing toxic materials causing irreversible neuropathies results from (1) inadequate imaging of the proximity of both borders of the IANC (Fig. 27.28, *A–C*), (2) inadequate measurements during cone measurement, (3) not limiting filling materials to within the confines of the shaped root canal space, and (4) not utilizing CBCT when instrumenting or performing surgery adjacent to vital structures such as the IANC and maxillary sinus.

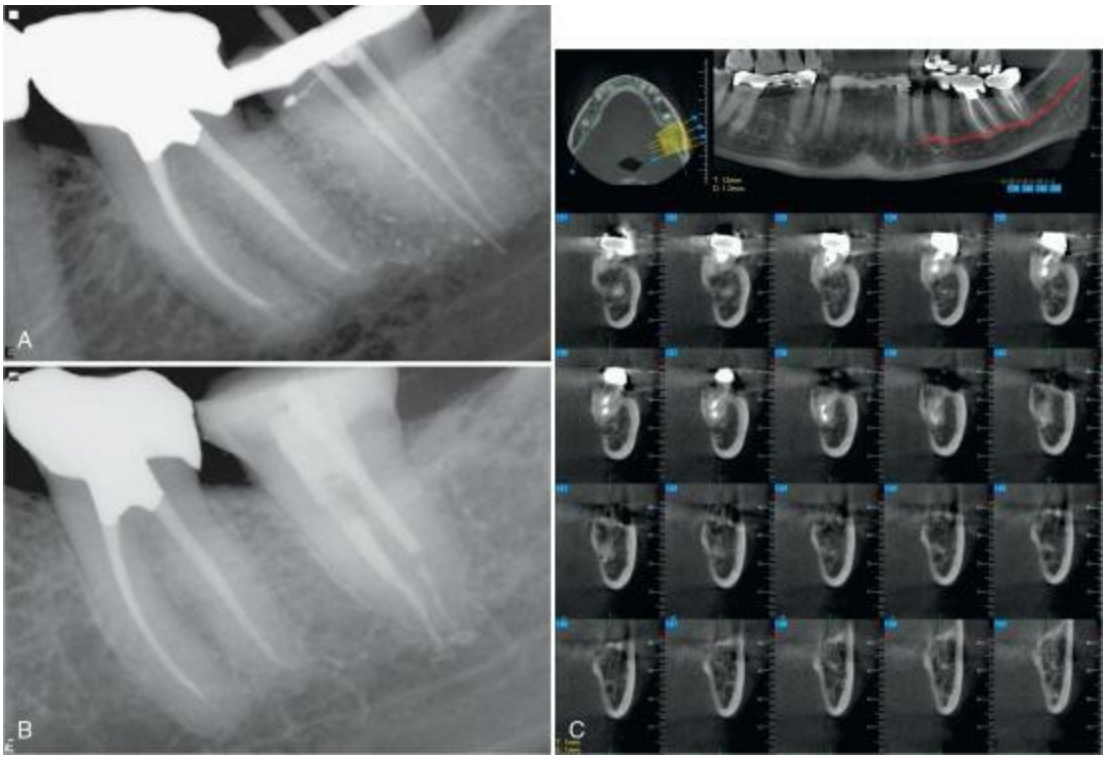

FIG. 27.28 **A,** Unclear periapical radiograph shows both cortical borders of inferior alveolar nerve canal (IANC). **B,** Cones placed into IANC, showing measurements beyond apices. **C,** Overfill into IANC better shown on cone-beam computed tomography (CBCT) than periapicals of **A** and **B.**

Telegram: @dental_k

www.konkur.in

A) Radiograph shows left tooth with radiolucent crown and IAN canals in front of the tooth.

B) Radiograph shows tooth with radiopaque crown and filled root canals.

C) Series of CBCT images show axial and panoramic view of teeth along with twenty coronal views of the first left tooth in the lower jaw.

The eugenol component of the root canal sealer part of the overfill is known to be cytotoxic. Consequently, endodontic overfill of the root apex is capable of producing not only mechanical damage[219] but also chemical injury. Accordingly, a prompt microsurgery referral to remove the injurious materials from the IAN inside the IANC nerve space before overfill material toxins are chemically set is mandatory.[254] Better yet is to take precautions to prevent *any* significant injurious overfill.

The use of electronic measuring devices such as an electronic apex locator is standard technology for accuracy when working deep within the root canal system. Combined with diagnostic quality radiographs, an apex locator helps provide accurate length readings. If it is determined that the apex is in extremely close proximity to the IANC, extra precaution must be taken to prevent overextension of instruments or materials, including slightly short fills and apical packing techniques.

Overfills

A general dentist utilized an electronic apex locator (EAL) to measure his file lengths during cleaning and shaping of the molar root canals. Relying exclusively on the accuracy of his EAL, the dentist did not take any midtreatment radiographs to verify that his EAL measurements were accurate. Unfortunately for both dentist and patient, the dentist had transported one of the root canals with resultant root perforation. Consequently, during obturation with a calcium hydroxide sealant, the root canal was overfilled into the underlying IANC. The patient suffered permanent paresthesia and dysesthesia. The Virgina verdict was $1.5 million (Brenner v. Khalil, Virginia Circuit Court, Arlington County, No. 013CL17000341-00) (see Fig. 27.32, later in this chapter).

Precise measurements during cleaning, shaping, and obturation compacting stages of endodontics minimize significant overfill incidents. Obturating

Telegram: @dental_k

www.konkur.in

filling materials with sealants may be not only toxic to nerve cells but also create a mechanical pressure injury to the nerve cells themselves. Immediate microsurgical referral should be done on a stat basis within the first 48 hours of neuropathic symptoms for retrieval of any overfill materials that "harpoon" the IANC to protect against irreversible neuropathies (see Fig. 27.30, *C,* presented later).[254] Also see animation of an adverse overfill.

Serious mechanical and chemical injury to the IAN results from a lack of recognition of the overfill piercing the IANC or disregard for neuropathic symptoms the patient reports any time between 4 hours and 4 days postoperatively that are consistent with neurologic deficits such as paresthesia or burning pain dysesthesia.

Referral to an oral surgeon/microsurgeon is time-dependent. Pogrel's study demonstrated complete reversal of neuropathic symptoms secondary to overfill if microsurgery was done within 48 hours.[254] Two thirds of Pogrel's patients gained significant improvement if microsurgery was done within 3 months of IAN overfill injuries. Delaying expeditious referral to a microsurgeon for removal of overfilled materials progressively worsens the toxic effects of the chemical injury over time. Delaying microsurgical referral risks permanent injury, owing to the time-dependent 48-hour window for complete reversal or within several weeks to greatly diminish the cytotoxic effects of overfill errors.

Microsurgical delay will close the window of opportunity to prevent permanent neurologic deficits of altered sensation, with resulting persistent chronic pain, numbness, and painful burning symptoms that extrusion overfills into the IANC can cause. Stat referral for microsurgical removal of paraformaldehyde-containing root canal filling materials and sealants is even more critically time dependent because of the greater toxicity and mummifying effects of these powders when mixed into pastes (e.g., N2 and RC2B). Risks include anaphylactic shock.[50,125,144,192]

For needed stat referrals, the referring clinician should phone, fax, and e-mail the microsurgeon. Patients lack the expertise to promptly obtain critically time-dependent referrals. When time is of the essence, the clinician and staff must assume direct responsibility to assure the stat referral to a microsurgeon is promptly appointed. Remind the patient that microsurgical delay is detrimental to corrective care.

www.konkur.in

Sealant overfills

Neurotoxic and compressive effects of sealants are the most frequent causes of paresthesia after endodontic overfill.[129,185,262]

Additionally created injuries occur to the maxillary division of the trigeminal nerve or into the maxillary sinus membranes when sealants or bleach is extruded through maxillary teeth. Obturation and sealant materials should be used cautiously in all circumstances, especially in teeth in close proximity to the IANC and maxillary sinus.

The use of syringes for applying endodontic sealers, or obturation with the Lentulo spiral, requires extra precaution when application is done in close proximity to neural structures because precise control is compromised.

Short fills contribute to apical infections and may cause temporary paresthesia. Paresthesia reversal can occur with retreatment, gaining improved cleaning, shaping, and obturation to the anatomic apex.[3]

Standard of care requires that the clinician avoid unreasonable risks to prevent potentially serious or permanent harm to the patient. Treatment is negligent when a reasonably careful clinician should have foreseen and prevented unreasonable patient harm risks.

Treatment failure

A clinician should not guarantee treatment success. It is foolish to assure the patient of a perfect result.[67] Endodontic failures may occasionally occur despite adequate endodontic care.[161,311] Nevertheless, negligent contributing factors to endodontic failures include perforation, missed or transported canal, uninstrumented portion of a root canal, bacterial infiltrates by way of a leaky coronal restoration contaminating the root canal filling,[66,293,298] overextension errors, and inadequate isolation of the tooth from salivary contaminants during instrumentation due to lack of a dental dam.

Successful root canal treatment requires the prevention of microorganism toxins from the oral flora penetrating through the root canal system into the periapical tissues. Inadequate obturation of the root canal system is the most frequent cause of failure. Either coronal or apical leakage adversely affects success.[84,85,298]

Failing endodontics that necessitate endodontic disassembly should first be

Telegram: @dental_k

www.konkur.in

considered for a nonsurgical option because it is less invasive and therefore represents risk reduction. The clinician should first evaluate for coronal leakage, fractures, missed canals, silver point corrosion, and incomplete obturation. Root canal systems can then be recleaned, or correctly transported and then thoroughly disinfected, reshaped, and packed in three dimensions to avoid apical surgery by providing instead adequate coronal, lateral, and apical seal nonsurgically.

To avoid claims based on failed endodontics, the patient should be advised in advance of treatment of the inherent (but relatively small) risk of failure (i.e., about 5% to 10%). It may be adequate to advise the patient of the high statistical probability of success in endodontics if the clinical condition of the tooth and the clinician's past success rate warrant such representation.[145,291] Clinicians should avoid quoting the national success rate of endodontics when (1) the patient's tooth is of questionable endodontic and periodontal status and (2) the clinician is known to have an unusually high endodontic failure rate. A rate that varies markedly from national statistics suggests referral to an endodontist.

An endodontic treating clinician is also liable for failure to disclose evidence of other pathosis in the quadrant being treated. The patient should be advised of any periodontal disease that adversely affects the prognosis of abutment teeth for partial dentures, bridges, or an implant with a need for grafting if the endodontically treated tooth is lost. A clinician should also advise of cysts, fractures, or lesions of suspected neoplasms. In addition, the clinician must be careful not to ignore any evident pathosis that, if untreated, may adversely affect the dental or medical health of the patient. Again, a clinician who fails to plan treatment properly is planning for treatment failure.

Full disclosure

Disclosing a nonharmful mistake will not erode patient confidence. On the contrary, it bolsters trust by reassuring the patient that the dentist is honest and truthful. Increased trust through full transparency mitigates against legal action. Patients who trust their dentist are less likely to bring a malpractice suit. Truthful disclosures, sincere apologies, and appropriate acceptance of responsibility, including reimbursing corrective care, decreases litigation.

Telegram: @dental_k

www.konkur.in

Disclosing is ethical and preserves integrity. “No harm, no foul” is a misguided approach. It is the patient’s right to be informed of any intervention administered in the course of treatment that *could* have caused harm. On the other hand, major errors must be prudently disclosed to the patient for the sake of transparency, trust, integrity, and ethical responsibility.

Slips of the drill

A slip of the drill, like a slip of the tongue, may be unintentional. Nevertheless, it can cause harm. When a cut tongue or lip occurs, it is usually the result of operator error. To paraquote Alexander Pope, “to err is human, to forgive, divine.” To increase the likelihood that a patient will forego filing suit because of a cut lip or tongue, the clinician should follow these steps:

1. Inform the patient that the clinician regrets having injured the patient. This is not a legal admission of guilt in 29 states with “I’m sorry” protective statutes, but rather an admission that the clinician is a compassionate human being. In 2005, federal legislation to apply “I’m sorry” to all 50 states was proposed. The Senate bill sponsored by senators Clinton and Obama did not pass in Congress.
2. Repair the injured tissues or refer the patient to an oral or plastic surgeon, depending on the extent of the injury and whether a plastic revision is necessary if scarring is likely.
3. Advise the patient that the clinician will pay the bill for the referred treatment of the oral or plastic surgeon. Request the oral or plastic surgeon to send the bill directly to the clinician for payment. Send the oral or plastic surgeon’s bill to the clinician’s professional liability carrier. Some carriers will pay the claim under the medical payments provisions of the general liability policy for an “accident” rather than as a malpractice incident compensable under the professional liability policy. Call the patient periodically to check on healing, recovery, and any follow-up plastic or other surgeries.

Telegram: @dental_k

www.konkur.in

Fear factor

U.S. Centers for Disease Control and Prevention's National Center for Health Statistics report that cost is the overriding factor preventing adults from seeking dental care. Fear is the second reason for delayed dental care. Medicaid recipients were at five times greater risk for worse dental health than those with private coverage. Adults on Medicaid were twice as likely to have not visited a dentist in more than 5 years.[319]

Dental fear may result in patients delaying or avoiding dental care.[199] Frequent cancellations and missed appointments are characteristically associated with fearful dental patients. Although it is ordinarily a defense of contributory negligence if patients do not follow a clinician's treatment recommendations, the patient's advocate may contend that the defendant clinician negligently failed to diagnose a fearful patient. Fearful patients tend to avoid dental treatment because they believe it may exacerbate a prior traumatic dental experience. Referral to clinicians who specialize in treating fearful patients should be considered to facilitate comprehensive dental treatment and to avoid future emergency endodontic care because of repeatedly canceled treatment visits.

Dental anxiety and finances are the two most important barriers to patients obtaining regular dental care. Fearful dental patients avoid necessary treatment, delay recalls, and are reluctant to undergo painful procedures. Therefore it is essential that such patients be identified for proper management or referral for fear-reduction therapy. A patient who experiences intense anxiety in the dental chair, together with a history of avoiding dental care, suggests a diagnosis of dental phobia. Fearful dental patients fear loss of control during clinical treatment and require reassurance and reaffirmation that they have the power to halt the procedure by raising a hand or using another appropriate gesture. After trust is gained, additional procedures may be performed.

In addition to desensitizing techniques, the use of proven topical-anesthesia delivery systems helps to ensure a relatively painless injection of local anesthetics. Topical-anesthetic patches and oral-anesthetic rinses may prove a valuable aid for pain management of the fearful patient.

The use of psychological questionnaires, such as the Dental Anxiety Scale

Telegram: @dental_k

www.konkur.in

or the Modified Dental Anxiety Scale, may help to identify such individuals.[154] These simple questionnaires are short, quick, and easy to complete, and users are provided with cutoff scores that help the clinician identify patients who have psychological special needs. In this way, the clinician will be in a position to assist the dentally anxious or dentally phobic patient in accessing dental health care.

Pain management

Buffered local anesthetics are more effective than nonbuffered local anesthetics when used for mandibular or maxillary anesthesia in pulpally involved teeth. Buffering of local anesthetics has 2.29 times greater likelihood of achieving successful anesthesia.[n]

Every day, more than 130 people in the United States die after overdosing on opioids. The Centers for Disease Control and Prevention estimates that the total "economic burden" of prescription opioid misuse alone in the United States is $78.5 billion a year, including the costs of health care, lost productivity, addiction treatment, and criminal justice involvement. In 2017, more than 47,000 Americans died as a result of an opioid overdose, including prescription opioids, heroin, and illicitly manufactured fentanyl. Approximately 21% to 29% of patients prescribed opioids for chronic pain misuse them.[o]

To reduce the risk of opioid addiction, ibuprofen and acetaminophen are the preferred postoperative analgesics. A seminal research study showed that 400 mg ibuprofen/1000 mg acetaminophen was more efficacious than placebo, acetaminophen/codeine and ibuprofen/codeine.[p] See also CDC Guidelines for prescribing opioids for chronic pain.[q]

Leakage

Long-term seal of the root canal system is determined apically by the sealer and coronally by the final restoration.[36,134,228,293] Root canal–filled teeth should be permanently restored without undue delay to prevent leakage contamination of the previously obturated canal system, because varying canal shapes from round to oval prevent a 100% seal.[84,85,202] Bonded seals covering the canal surfaces should be used to control any leakage after

Telegram: @dental_k

www.konkur.in

compaction until a permanent restoration is cemented.[305] Besides an adequate coronal sealing, an adequate apical sealer should be well adhered to the canal walls.

The endodontic goal is to prevent bacterial contamination of the periradicular tissue by predictably providing adequately cleaned, shaped, and filled root canal systems. Any residual bacteria should be entombed in the root canal filling. A bacteria-tight apical seal should be designed to last long term with sealed portals to prevent reentry of microorganisms, which cause reentry recontamination and lead to endodontic failure.[84,298] Younger patients are more susceptible to bacterial penetration inside dentin tubules and thus recurring infections.[177]

Implant risk factors

Patient risk factors such as grinding teeth or diabetes increase the odds of implant failure.[166] Higher implant failure rates occur with surgeons who have less than 5 years of implant experience.[166]

Fluoride for caries prevention

In 2006, the ADA Council on Scientific Affairs published evidence-based research with fluoride recommendations for caries prevention. The ADA recommends that fluoride varnish treatments for at-risk patients should be done between two to four times annually, depending on risk classification. Fluoride varnish containing 5% sodium fluoride with 22,600 ppm fluoride ions help occlude dentin tubules and aid remineralization. Silver diamine fluoride is recognized as safe[r] and effective[s] to reduce the risk of progressive caries causing pulpal exposure.

Reasonable versus unreasonable errors in judgment

Although a clinician is legally responsible for unreasonable errors in judgment, mistakes occasionally happen despite adherence to the standards of reasonable care. A mistake does not prove malpractice unless it is caused by a malpractice error or omission.[141] For example, accessory or fourth canals on molar teeth are frequently difficult to locate and may tax the best clinicians. Failure to locate an accessory or fourth canal does not conclusively

Telegram: @dental_k

www.konkur.in

constitute an unreasonable error of judgment. Rather, this may represent a reasonable error of judgment in the performance of endodontics. Nevertheless, if the additional canal could have been diagnosed radiographically with diagnostic quality radiographs at different angles, the existence of a fourth canal should have been considered. Instrument and seal the extra canal for successful obturation.

Incorrect tooth treatment

A reasonable, nonnegligent mistake in judgment may occur because the clinician has difficulty localizing the source of endodontic pain. Vital pulps may, on occasion, be sacrificed in an attempt to diagnose the pain source, but it is unreasonable and therefore inexcusable to treat the wrong tooth if it is inadequately tested with pulp tests, misidentified on the referral slip, or if radiographs are mounted or read incorrectly. Also, treating large numbers of teeth endodontically (e.g., an entire quadrant) when attempting to localize chronic pain suggests pain is probably not of pulpal origin, and other differential diagnoses should be ruled out including atypical facial pain, referred pain, or TMD pain.

If the wrong tooth is treated because of an unreasonable mistake in judgment, the clinician should be compassionate, waive payment for all endodontic treatment, and offer to pay the fee for crowning the unnecessarily treated tooth.

Post retrieval

Ultrasonic instruments will vibrate and loosen the cement around posts.[68] The clinician can avoid overheating the post by proceeding slowly with a water coolant, periodically resting for cool down, and checking the post temperature periodically to be reasonably certain overheating is not occurring.[96,130,230] Fig. 27.21 demonstrates what happened when an endodontist negligently overheated the post during attempted removal, causing tissue necrosis, bone loss, need for augmentation procedures, irreversible pulpitis in an adjacent tooth, and the loss of two teeth.[252]

Broken files

Leaving broken files behind without referring the patient to an endodontist

Telegram: @dental_k

www.konkur.in

for attempted microscopic retrieval and not advising the patient of leakage potential may constitute fraudulent concealment (Figs. 27.29 and 27.30). Patients should be informed of such mishaps for (1) referral consultation or treatment; (2) advising the patient, who on his or her own may seek a second opinion; or (3) disclosure, so as to return if a flare-up occurs.

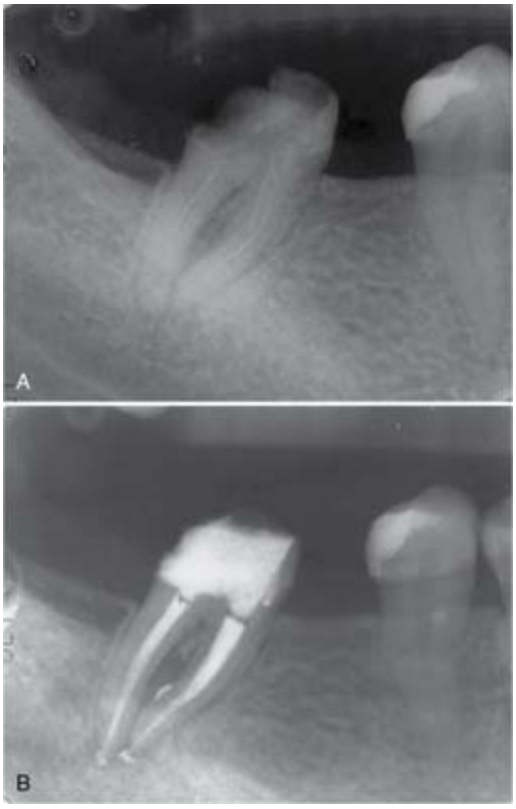

FIG. 27.29 **A,** Tooth #31 with three separated files, one in each canal. K-files used for cleaning canals and also obturation (1996). **B,** No apparent radiographic changes in 1998.

Swallowing or aspirating an endodontic instrument

Use of a rubber dam in endodontics is mandatory.[14,294] Even if the endodontically treated tooth is broken down and cannot be clamped, a rubber dam, regardless of required modification, should be used in all instances (see Chapter 7). Not only is microbial contamination reduced with the use of a

Telegram: @dental_k

www.konkur.in

rubber dam, but the risk of a patient's aspirating or swallowing an endodontic instrument is eliminated (Fig. 27.31). Accordingly, if a patient swallows or aspirates a file, it is likely because of the clinician's failure to observe the standard of care. If a swallowing or inhalation incident does occur, the clinician should do the following:

1. Advise the patient that the clinician regrets and is sorry about what occurred.
2. Refer the patient for immediate medical care, including radiographic imaging, to determine if the instrument is lodged in the bronchus, esophagus, or stomach so that appropriate medical measures are taken promptly to remove it.
3. Offer to pay for the patient's out-of-pocket medical expenses and wage loss. Some professional liability policies will cover the incident as "medical payment" for an accident and not as a malpractice claim.

FIG. 27.31 Swallowed endodontic instrument demonstrates the wisdom of using a dental dam.

Overextensions and overfills

A common error in utilizing periapical or Panorex imaging is presuming that when only one cortical border of the IANC is visible, the sole visible border is the superior border. Instead, virtually always when only one cortical border is clearly visible, it is the inferior cortical border.[206] (See Fig. 27.30, *B,* periapical, which may appear to show only one cortical border, and Fig. 27.30, *C,* a clearer CBCT image of the same area showing both cortical borders.)

Misassumption of the IANC borders results in mismeasurement of the IANC location. Because the IANC is approximately 3 mm in diameter, misassuming the sole observable cortical canal border to be the superior border (rather than the inferior border) can result in an imprudent treatment decision to delay microsurgery if overfill occurs and belated CBCT confirms an overfill inside the IANC. In Fig. 27.30, *B,* the defendant endodontist misdiagnosed the overfill as being superior to the IANC rather than inside the IAN canal. Resultant permanent paresthesia occurred from watching and waiting for sensory return rather than referring to a microsurgeon for a stat microsurgical removal.

A slight overextension of root canal filling with conventional obturation or sealants can occur without violating the standard of care if not in close proximity to the IANC or sinus (see Chapters 2 and 27). Gross overfill usually indicates faulty technique. Fig. 27.32, *A* and *B,* illustrates gross overfill of calcium hydroxide, causing permanent paresthesia. Nevertheless, so long as the overextension is not in contact with vital structures such as the IANC or sinuses, permanent harm is unlikely. An exception is paraformaldehyde-containing sealants, which cause a neurotoxic chemical burn type of injury that chemically diffuses through bone and soft-tissue spaces.

Telegram: @dental_k

www.konkur.in

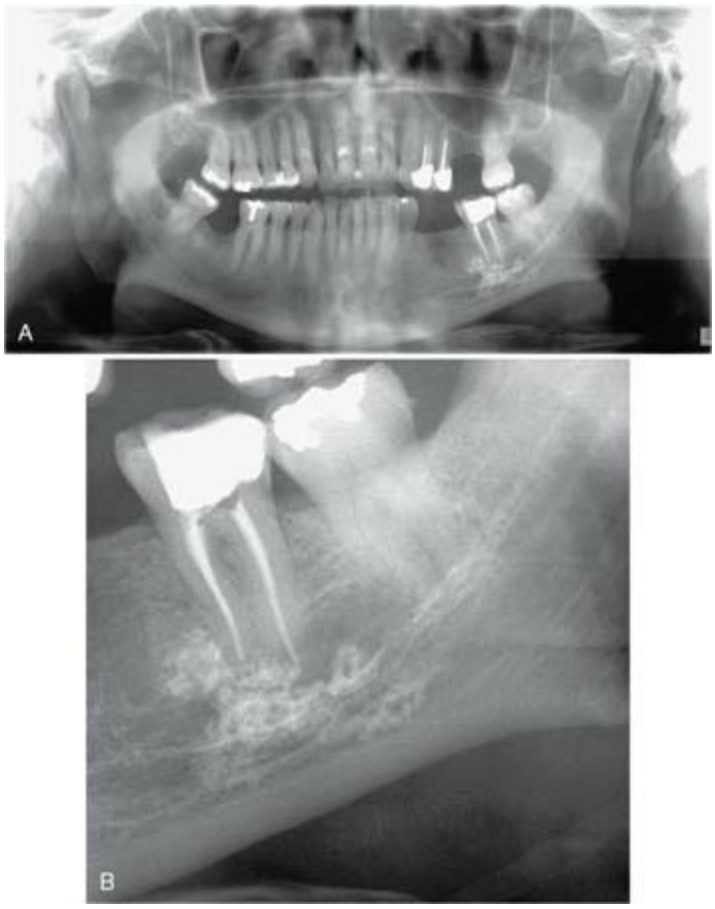

FIG. 27.32 **A–B,** Calcium hydroxide overfill, causing permanent paresthesia.

A) Panoramic radiograph shows the deposition of calcium hydroxide in lower left quadrant.

B) Radiograph shows the calcium hydroxide deposition below the second molar that has radiopaque crown and filled root canals.

If, however, postoperative pain is foreseeable as a result of overextension, the patient should be advised with postoperative written instructions of the likelihood of postoperative discomfort or paresthesia because of suspected contact of the sealant material with surrounding vital structures. A note should be made on the patient's chart of the overextension should symptoms later manifest. The clinician should observe with close follow-up visits and patient phone calls that evening, the next morning, and the following 3 days to rule out postoperative persistent numbness or dysesthesia pain resulting from any overfill. Slight overextensions with inert conventional endodontic sealers, such as gutta-percha with Grossman's sealant, can repair themselves

Telegram: @dental_k

www.konkur.in

and produce no irreversible changes if done without direct contact with the sinus or IANC or indirectly through chemical leakage and seepage beyond the initial area of operation.

Overextending the root canal filling material risks permanent consequences if the underlying IAN is initially "harpooned" with files. A portal of entry into the IANC results from overinstrumentation penetration. Flexible gutta-percha alone probably will not penetrate beyond the mature root into the IANC or other vital structures without prior excessive instrument perforation into the IANC.

Mental foramen distances can be overestimated on the panoramic radiograph. Panoramic radiography may show more deviation (+0.6 mm) from the perioperative measurement.[110,289] Paraformaldehyde-containing sealants can create cytotoxic chemical destruction of the IAN if placed in close proximity to, even though not directly contacting, the underlying IAN (see reference, Sargenti Opposition Society [SOS]).[278] On the other hand, conventional obturators and sealants usually require coming closer to contact with the IAN before resulting permanent anesthesia, paresthesia, or dysesthesia occurs (Fig. 27.33). Consequently, the incidence of permanent sequelae with conventional filling materials is lower than the greater cytotoxic potential with paraformaldehyde-containing sealants.[234] Because of the higher risks associated with paraformaldehyde-containing endodontic materials, use of N2, RC2B, or similar toxic pastes is contraindicated and violates the standard of care.[11] Permanent injury risk is substantially less likely with traditional eugenol-containing filling materials, less toxic chemicals than paraformaldehyde, which destroys and mummifies nerve tissues. When safer, less risky alternative effective therapy exists, it is unreasonable (and substandard) to elect an unsafe alternative methodology. Also, the doctrine of informed consent is highly relevant because it is contrary to public policy to request a patient to assume inherently dangerous treatment risks that are reasonably avoidable with safer and more predictable methodologies. When the risk exceeds the benefits, such risks are regarded as negligent and thus should be avoided and not undertaken.

Telegram: @dental_k

www.konkur.in

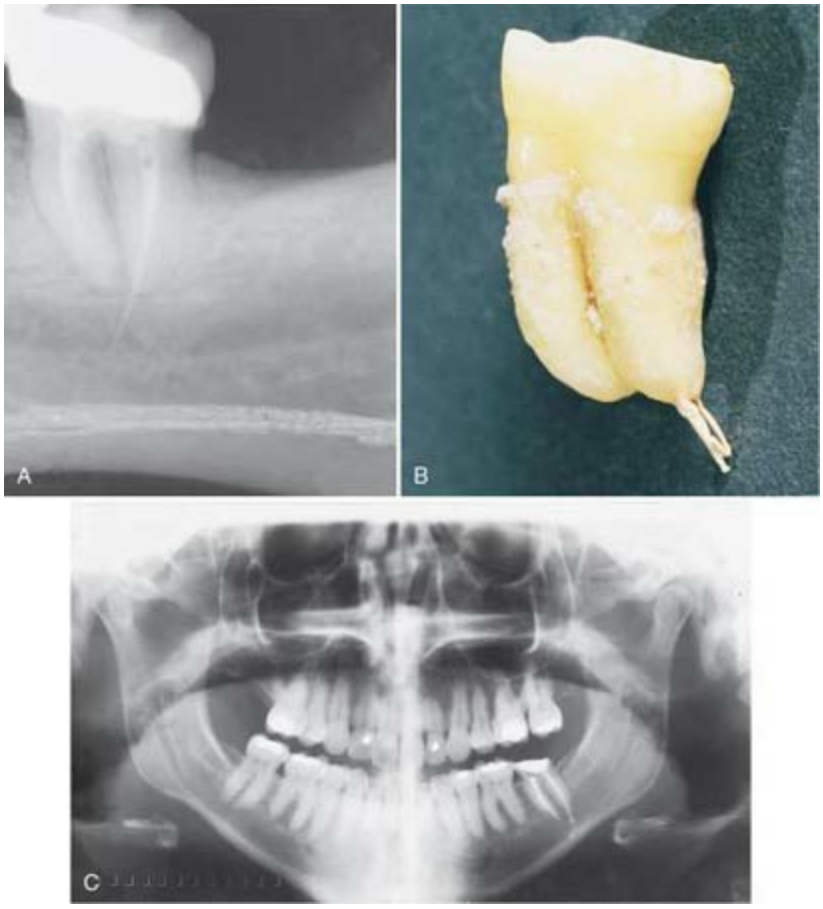

FIG. 27.33 **A-C,** Overextended gutta-percha and extracted tooth with gutta-percha intact.

A) Radiograph shows a tooth, in which the left root canal has extended gutta percha.

B) Specimen shows tooth with gutta percha protruding from the root apex.

C) Panoramic radiograph shows first molar with long gutta-percha in the lower left jaw.

Any significant overextension should be considered for immediate retreatment by attempted retrieval of overextended gutta-percha and sealant.[135] The clinician also has the option of immediately referring the patient to an endodontist for retrieval before the sealant sets. Conventional filling agents such as gutta-percha do not penetrate the cortical walls of the IANC unless probably preceded by prior penetration with overinstrumentation. This principle can apply to sinus perforation. If, despite local anesthesia, the patient feels an electric shock during mandibular molar

Telegram: @dental_k

www.konkur.in

or premolar instrumentation, this may be a warning sign that the IAN was pierced with endodontic files. If this occurs, the root canal should not be filled; instead, periapical radiographs at different angles should be exposed with instruments in place to confirm whether any IAN penetration resulted. Removal of gutta-percha and sealants that have entered the IANC should be attempted as soon as possible (preferably no later than within the first 24 hours).[254] The eugenol component of the sealant causes an inflammatory reaction in a constricted space, which is best relieved by retrieval. If retrieval fails, a decortication microsurgical procedure with an oral surgeon is indicated at the earliest possible time (preferably within the first 24 hours) owing not only to eugenol chemical toxicity but also eugenol reaction with gutta-percha, which causes expansion and thus a mechanical compression ischemic injury.[219,254]

Compartment syndrome

Inflammatory edema that compresses and compromises blood supply to soft tissues and nerves in limited spaces with resulting ischemia is termed *compartment syndrome*.[285,339] Compartment syndromes are a group of conditions that result from increased pressure within a limited anatomic space, acutely compromising the circulation and ultimately threatening the function of the tissue within that space. Compartment syndrome occurs from an elevation of the interstitial pressure in a closed osseofascial compartment that results in microvascular compromise. The pathophysiology of compartment syndrome is an insult to normal local tissue homeostasis that results in increased tissue pressure, decreased capillary blood flow, and local tissue necrosis caused by oxygen deprivation. Compartment syndrome is caused by localized hemorrhage or postischemic swelling. The pathophysiology of compartment syndrome is a consequence of closure of small vessels. Increased compartment pressure increases the pressure on the walls of arterioles within the compartment. Increased local pressure also occludes small veins, resulting in venous hypertension within the compartment. The arteriovenous gradient in the region of the pressurized tissue becomes insufficient for tissue perfusion.

The clinician should have a high index of suspicion whenever a nerve is located inside a closed bony compartment where nerve injury within the

Telegram: @dental_k

www.konkur.in

surrounding neurovascular bundle has the potential for bleeding or swelling. Compartment syndromes are characterized by pain beyond what should be experienced from the initial injury. Also, diminished sensation may be noted in the distribution of the nerve within a compartment that is being compressed, such as the IAN, which is enclosed by bone on all sides.

Root canal followed by root resection without an adequate retrograde restoration will likely fail. Open drainage is no longer recommended. Dissect out subapical granulation tissue cleanly and without damage to vital structures. Caution should be taken when granulation tissues are attached to vital anatomic structures such as neurovascular bundles or sinus linings. A potential for recontamination exists unless the root apex is removed. Apical resection of 3 mm will remove potential problems. This resection will additionally permit inspection. A straight fissure bur design with appropriate air venting is recommended rather than a conventional air rotor to prevent air emphysema.

Currently preferred methodology utilizes specifically designed ultrasonic tips inserted into a piezoelectric ultrasonic handpiece. Amalgam is no longer recommended as a material for root-end filling. MTA and newer silicate trioxide materials are recommended.[243]

Periradicular surgery

Accessing mandibular posterior teeth can generate increased heat during removal of significant quantities of bone to gain apical access. Thus copious coolants must be applied to avoid risking injury to adjacent structures. Molar teeth surgical access should avoid the facial artery as it crosses the border of the mandible adjacent to the first molar.

Avoiding the inferior alveolar nerve canal

When placing implants or performing apicoectomies in close proximity to the mental foramen in the bicuspid region, the clinician should consider the anterior loop of the IAN.[277] The IAN ascends as it approaches the mental foramen, compared with the IAN's more inferior location in the molar region. The IANC varies from buccal to lingual as it courses the length of the mandible. Thus CBCT imaging aids in assessing the IANC location for planning implant placement or apical surgery[75,97] (Fig. 27.34, *A–C*[138]; this

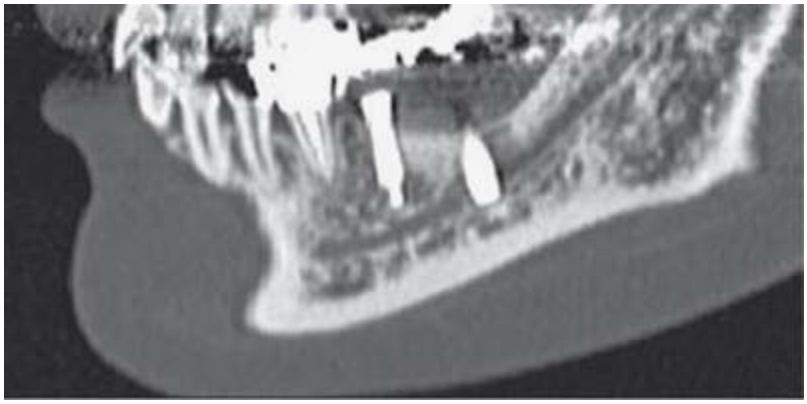

FIG. 27.38 Implant “harpooned” the inferior alveolar nerve canal.

Radiograph shows lower jaw with implants in the inferior alveolar nerve canal.

Mental nerve injuries

The mental nerve, as the terminal branch of the IAN, is at risk during elevation of the mandibular mucoperiosteum. Careful flap design and elevation are important to avoid mental nerve injury while working on the buccal surface of the mandible in the region of the mental foramen.[207] In performing incision and drainage in the region of the mental foramen, a diagnostically accurate radiograph is necessary to avoid incising through the course of the mental nerve.[84,180]

When carrying out PRS in the mandible, consideration must be given to the path of the inferior dental nerve bundle in the mandibular canal, which lies in close proximity to the root apices.[277] Be aware of the position of the mental nerve exiting through the mental foramen. A shallow sulcus, coupled with a prominent mandibular protuberance, together with the lingual inclination of the roots may make access to the root apices difficult. Approximately 40% of lower incisors have two root canals, which may preclude adequate resection and retrograde filling of the root apex, which may ultimately lead to treatment failure.

Local anesthesia: Septocaine

Septocaine and Articaine are not suitable for an inferior dental nerve block due to the potential increased risk of paresthesia and nerve damage.[91] Prudent practice is to avoid utilizing 4% solutions of local anesthetics, such as

Telegram: @dental_k

www.konkur.in

Septocaine and Articaine, during inferior alveolar block injections. When the risk exceeds the benefit, the reasonably careful dentist wisely chooses to not subject the patient to such an unreasonable risk of harm. Both Septocaine and Articaine are associated with increased risks of permanent neuropathic injuries of paresthesia and/or dysesthesia resulting from mandibular block injections with these 4% solutions. Since efficacious results can be achieved with conventional 2% local anesthetics such as lidocaine, Septocaine and Articaine are contraindicated for mandibular blocks.[t]

It is the dentist's choice and decision which local anesthetic to utilize for a particular endodontic procedure. A patient should not be offered a choice between a reasonably acceptable local anesthetic and an unreasonable choice of a 4% solution for a mandibular block. Informed consent only applies to nonnegligent treatment risks and alternative choices. A patient therefore should not be asked to consent to a negligent choice of Septocaine or Articaine for a mandibular block injection.

Implant versus endodontics

A natural tooth with its periodontal support, function, and proprioception is superior to an implant-retained restoration. Whenever reasonably feasible, teeth should be retained.

Reasonable clinicians may differ in recommending extraction versus PRS depending on location near vital structures and clinical conditions. Extraction of the diseased tooth and placement of a dental implant has a better long-term prognosis and thus should be the treatment of choice is one author's conclusion.[275] Conversely, every reasonable effort should be made to retain the natural tooth with its periodontal support, function, and proprioception. Thus an implant-retained restoration should be considered as the last possible treatment option as concluded by other clinicians.[24,73,310]

Infraocclusion of the implant restoration in teenage patients with residual craniofacial growth occurs as the adjacent teeth erupt. Therefore delay implant placement until dental and skeletal maturation occurs.[309]

Aesthetics is an important outcome for patients receiving implant-supported restorations. To achieve this outcome, patients require good bone volume and quality, as well as soft-tissue height. Following extraction, the alveolar bone resorbs vertically, as well as horizontally (buccolingually).

Telegram: @dental_k

www.konkur.in

Socket preservation intervention grafting may aid in reducing the bony dimensional changes after tooth extraction, but ridge resorption is not completely prevented. Intervention techniques including autografts, allografts, xenografts, guided bone regeneration (GBR) and growth factors accomplish varying degrees of success in maintaining the anatomic dimensions of the alveolus before implantation.[54]

Current use of silver points

Based on what has been known for more than 3 decades, use of silver points in lieu of gutta-percha or other conventional endodontic filling materials represents a departure from the current standard of care.[13] This is because silver points corrode in time, and a tight 3D apical seal is lost. Fig. 27.36, *A–C*, represents gross overextension with a silver point that ultimately caused the loss of tooth #14 as a result of endodontic failure.

Telegram: @dental_k

www.konkur.in

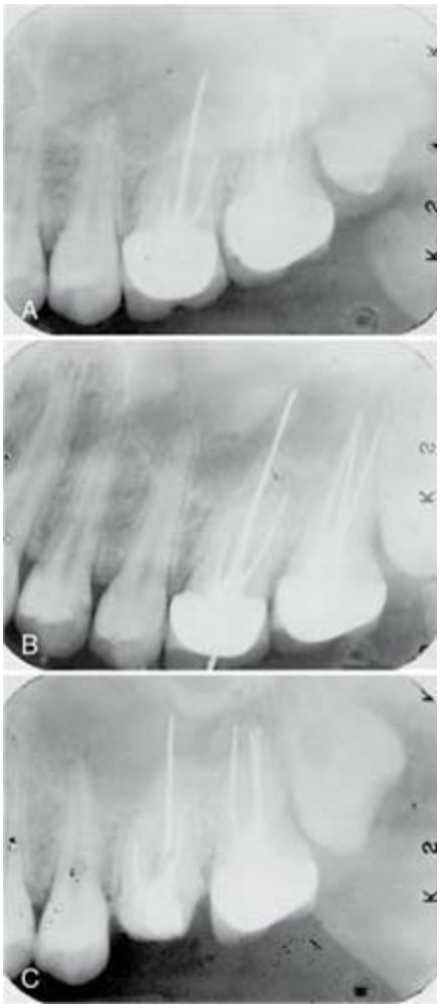

FIG. 27.36 Gross overfill into sinus with a silver point, which ultimately caused sinusitis and loss of tooth #14 as a result of endodontic failure.

Set of three radiographs, marked A through C, shows the changes in length of gutta-percha taking place during the loss of fourteenth tooth.

The AAE Position Statement does not recommend the prophylactic revision of silver point obturation, unless there is clear evidence of endodontic pathosis or if the silver points complicate proper restoration of the tooth.[13]

N2 (sargenti paste)

Dental literature reports that permanent paresthesias are associated with gross overfilling with paraformaldehyde sealant (N2) (Fig. 27.37).[200,234] Current use of paraformaldehyde-containing endodontic sealants is not merely the result of a philosophic difference between two respectable schools of thought.

Telegram: @dental_k

www.konkur.in

Rather, the distinction is between the reasonable and prudent school of thought that advocates conservative conventional endodontics and the imprudent and radical school of paraformaldehyde providers who unreasonably risk permanent, deleterious injury with N2 overextensions. Regardless of the small number of clinicians professing to use N2, it is cytotoxically unsafe and should be avoided. A customary negligent practice by some clinicians is no defense to safe and prudent practice, which the standard of care requires. No matter how few or how many do it wrong, this never makes it right.

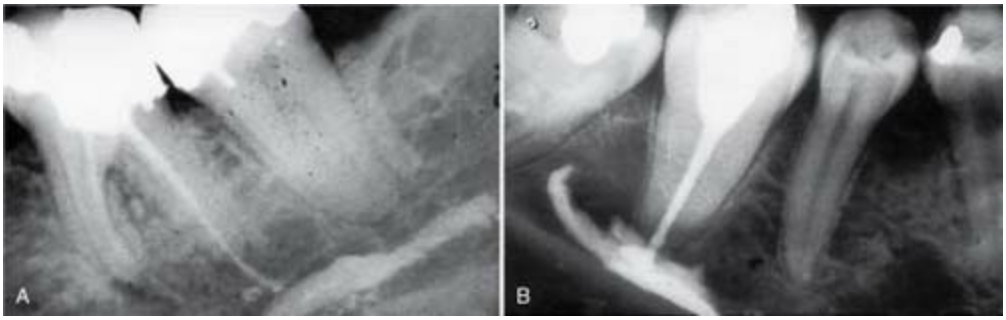

FIG. 27.37 **A** and **B,** Overextensions of Sargenti paste filling the inferior alveolar nerve canal. Both cases could have been avoided if the practitioners had selected a conventional sealing material and used a technique that emphasizes working length control.

Set of two radiographs, marked A and B, shows two different teeth with extended N2 sealant.

The AAE recommends against the use of paraformaldehyde-containing materials as they have proved to be both unsafe and ineffective. Accordingly, the use of such materials is below the standard of care for endodontic treatment.[11]

Clinicians may be liable for fraudulent concealment, intentional misrepresentation, or co-conspiracy if they discovered that a previous clinician's negligence is the cause of dental disease and both the prior clinician and subsequent treater concealed the prior clinician's negligence. For instance, if a gross overextension of a paraformaldehyde packing or sealant is evident radiographically and the patient reports that another clinician caused the overfill (that resulted in permanent lip and chin anesthesia), subsequent treating clinicians may be liable for fraudulent

Telegram: @dental_k

www.konkur.in

concealment if they misinform the patient that the anesthesia will probably disappear shortly and that using N2 merely reflects a philosophic difference rather than substandard practice. Some clinicians who differ on therapies regard such differences as controversial. The difference between standard of care and substandard practice is not controversial but rather an indisputable difference between right and wrong. For instance, quackery based on pseudoscience is not controversial. Instead it is fraudulent practice.[37,224] Likewise, if the radiographs indicate sealant is inside the IANC and the patient complains of persistent anesthesia, the patient should not be told to wait for return of sensation. The clinician should refer the patient immediately for microsurgical consultation for decortication and decompression surgery.[263]

The Federal Food, Drug, and Cosmetic Act prohibits interstate shipment of an unapproved drug or individual components used to compound the drug.[100] On February 12, 1993, the FDA Dental Advisory Panel confirmed that N2's safety and effectiveness remain unproven. N2 may not be shipped interstate or distributed intrastate if any of the N2 ingredients were acquired interstate. Mail-order shipments of N2 from out-of-state pharmacies in quantities greater than for single-patient use are considered a bulk sales order rather than a prescription, thus violating FDA regulations.[63] A San Francisco jury awarded punitive damages against an N2-distributing New York pharmacy for knowingly shipping N2 in violation of FDA regulations, done with deliberate disregard for patient safety.[162]

Defective restorations

Marginal gaps greater than 50 μm lead to cement dissolution and cause 10% of crown failures within 7 years after cementation. Dull or worn explorers substantially increase the likelihood of nondetection of open margins. A sharp explorer can detect margin defects as small as a 35-μm opening.[36] Accordingly, a sharp clinician should utilize a sharp explorer to detect open margins. Open crown margins contribute to endodontic failure and should be avoided (see Chapter 23).

Restoration marginal integrity

A pathologic apical lesion will resolve when the origin of infection is

Telegram: @dental_k

www.konkur.in

eradicated, the root canal system effectively sealed, and a satisfactory coronal restoration placed. Many clinical studies report a high success rate for nonsurgical root canal treatment (NSRCT) of greater than 90% but a weighted long-term average of 83%.[u]

Malpractice prophylaxis

Most negligently injured patients do not sue.[51] Nonetheless, litigation serves a prophylactic purpose because litigation fears make some clinicians more careful and help promote professional guidelines. For example, after the American Society of Anesthesiologists adopted practice guidelines to reduce patient harm, deaths and professional liability premiums decreased dramatically.[252,283]

Allergies

All dentists must be periodically trained in handling dental emergencies. Dental Practice Acts typically require training in Basic Life Support for dental license renewal. A common misconception by both patient and dentist is that reactions to local anesthetics were due to an allergic reaction. Allergic reactions from local anesthetics are extremely rare. Instead the patient more likely has experienced an overdose of local anesthetic from inadvertent injection into the bloodstream. Such syncope reactions require reassuring the patient and administering oxygen.

To avoid overdosing with local anesthetics or causing a toxic dosage of a vasoconstrictor such as epinephrine, two precautions are necessary. First, aspirate the local anesthetic syringe in two planes perpendicular to each other. Second, inject slowly. Both precautions are designed to prevent the injection of local anesthetics into adjacent blood vessels.[v]

One-visit versus two-visit endodontics

One-visit endodontics, if done well, will allow disinfection of the canals and obturation without risk of recontamination through the coronal seal between visits. Treatment of apical periodontitis with signs or symptoms of a beginning lesion is determined by the sound judgment choice of the clinician. Either one or two visits will comply with the endodontic standard of care.[242]

Telegram: @dental_k

www.konkur.in

Disclosure errors

Should dental negligence harm a patient, then full disclosure, including accepting the clinician's responsibility along with providing an apology and explanation, results in the best outcome for the clinician and patient. Also, assurance of efforts to prevent a recurrence results in greater patient satisfaction and retains trust with the disclosing clinician to sustain a continuing clinician-patient relationship. Patients want to be told of treatment errors, regardless of whether the error can be corrected. One study in which there was full disclosure of negligently caused therapeutic errors resulted in only one patient thereafter seeking legal advice.[210] In the same study, patients paradoxically acknowledged, "It is realistic to expect that doctors will make errors.... Patients have a right to expect that their doctors will not make errors." Nonetheless, virtually all patients concluded, "Patients should be able to trust their doctors to give them the right care." As noted earlier, apologetic expressions of sorrow or empathy for a patient's injuries are barred in evidence from being construed as admissions of fault in 29 states.[182] Protecting the patient's best interest includes telling the patient when negligent errors occur.

Temporomandibular disorders

Occlusal prematurities can trigger TMDs in patients with a prior TMD history, so during or following endodontic therapy for such a patient, it is essential that temporary and final restorations not open the bite or significantly alter existing occlusion.[194] Hyperocclusion is a potential TMD trigger that can result from open bite or on a contralateral side, when a terminal abutment tooth is taken out of occlusion.

Patient rapport

Good patient relations are 15% dependent on the clinician's competency to cure and 85% dependent on the clinician's ability to assure the patient that the treatment being given will be done with the clinician's best judgment and care.

Rapport between clinician and patient reduces the likelihood the patient will sue, despite an adverse result. The clinician can develop rapport by

Telegram: @dental_k

www.konkur.in

demonstrating genuine interest in the patient and making the patient feel valued. Patients feel important if they are seated in the operatory within a reasonable time after arriving. The longer a patient is kept waiting, the more frustration and animosity build. If the patient cannot be seen within a reasonable time, a staff member should communicate the reason and, if appropriate, offer to reschedule the appointment. Staff or the clinician should telephone the patient at the end of the day after any difficult procedure or surgery to check on the patient's status and remind the patient to follow postoperative instructions. The clinician should record any patient complaints, symptoms, and noncompliance with instructions. The latter can be used as evidence of patient contributory negligence if litigation occurs.

Rapport building blocks

The best communicators listen more than they speak. When they do speak, it is mostly to clarify what the patient has said.

In discussing the patient's complaints, the clinician should ask, "What do you think is causing the problem?" Otherwise, the clinician may solve the patient's dental problem while failing to solve the patient's perceived problem. For instance, a patient may fear that a retained endodontic file is carcinogenic unless this fear is allayed with a careful explanation that it is not.

Telephone communications

Good telephone communication is a matter of asking the right questions, such as asking a patient complaining of postoperative swelling if there is difficulty breathing or swallowing, as well as the degree and location of swelling. In cases of suspected infection, clinicians should ask the patient or family member to call back with a temperature reading to verify the patient is afebrile.

Post perforation

Post selection is important for minimizing the risk of perforations.[68] Generally, posts should not exceed one third of the mesiodistal width of a tooth, should follow the canal anatomy, and should leave 4 to 5 mm for sealant in the opened post space; this is described more thoroughly in Chapter

Telegram: @dental_k

www.konkur.in

23. When a tooth is already crowned, access to the root canal entrance surface should be located before rubber dam placement. This will aid in orienting the root's long axis, which may vary from the prosthetic crown's long axis. Fig. 27.39, *A* and *B*, represents an endodontist's perforation of tooth #7 because of difficulty locating the entrance into the root canal apical to the pulp chamber.[107] Fig. 27.40 shows a general clinician's misaligned post and perforation of tooth #5.

www.konkur.in

FIG. 27.40 Post perforation of tooth #5.

Radiograph shows four teeth with the second tooth having implant extended up to mid of the root and third tooth having oblique implant.

Ordinarily, a careful clinician performing endodontic therapy should be able to avoid post perforations. If post perforation occurs, early diagnosis and treatment are important. Belated diagnosis and treatment substantially increase the risk of endodontic failure. If the perforation is relatively small (i.e., 1 mm or less) and promptly diagnosed at the time of the post perforation, immediate treatment with intracanal sealants (MTA) or tricalcium silicate in the area of the perforation will probably succeed. However, delayed diagnosis and treatment (beyond 24 to 72 hours) result in bacterial contamination in the area surrounding the perforation. Delayed perforation repair therapy can cause periodontal or endodontic lesions and lateral periodontal abscesses occurring secondary to delayed diagnosis, which usually prognosticate a high failure risk.

Perforation prevention

Irreversible endodontic complication, such as furcation perforation during pulpal chamber access, is usually preventable with due care.[228] Furcation perforations are avoided by adhering to basic principles of pulpal chamber removal such as cleaning and shaping in a coronal rather than an apical direction. Innovative bur designs can access the pulp chamber without risking

Telegram: @dental_k

www.konkur.in

furcation perforation by preventing cutting or ditching of the pulp chamber by use of a non-end-cutting bur.[87]

Bleach injury

Because of the varying shapes of the root canal system in the apical third after cleaning, shaping, and obturation, some residual bacteria may remain, which are entombed. Sodium hypochlorite is the usual disinfectant irrigant used to minimize these remaining bacteria.[268] Apical or lateral extrusion occurs when bleach is extruded past the protective apical constriction or through a root perforation. The common denominators of bleach injuries are sudden severe pain and facial swelling.[2,101,186,214,249,260,268,336] Because of the clinician's concern for emergency treatment and the patient's pain, further endodontic therapy is deferred and usually not completed at the same visit. However, two cases report that compaction was completed during the same visit, despite a bleach injury.[215,276] One article reports that subsequent flare-up may be related to the original bleach injury.[52]

Prevention of bleach extrusion is done with bleach syringes with safe, side-venting needles constantly moving to prevent hydrostatic pressure buildup from bleach fluid. Sodium hypochlorite is extruded into the periapical tissues during root canal therapy if excessive pressure is placed on the irrigating syringe, resulting in an expression of sodium hypochlorite beyond the apex. Subsequent pain is caused by the solution diffusing into the surrounding bone and thire, causing swelling, tissue necrosis, and paresthesia. Surgery is usually contraindicated, and palliative treatment such as cold compresses accompanied by reassurance that most symptoms will dissipate is usually adequate.[186] However, if the bleach diffuses into vital nerve tissue of the infraorbital or IANs, permanent paresthesia and occasional dysesthesia may result.[101,214,249,336] Figs. 27.41 and 27.42, *A–C,* represent bleach injuries secondary to a root canal perforation. Paresthesia persists. Note the periapical film does not show the perforation, but the CBCT does.

www.konkur.in

Esthetic bleaching

Use of 35% H_2O_2 as a bleaching agent can be clinically adverse in the long term or after recurring bleaching treatments.

Precautions include the following:

- Reduce hydrogen peroxide concentration
- Reduce the time of each application, and increase the time between applications
- Avoid reaction catalysts, such as lamps or lasers
- Apply with a dental dam

Post-bleaching sensitivity is mostly due to reversible pulpitis that may progress in some cases to irreversible pulpitis.

Cores

Incorrect choice of cores can contribute to failure, including fractures. Some manufacturers (e.g., 3M ESPE, St. Paul, MN, for Ketac silver) recommend against use of their core material unless at least two thirds of the tooth remains before buildup. Failure to follow the manufacturer's directions can be considered when an expert determines whether the standard of care was met.

Resin-reinforced post-and-core systems show promise for structurally weakened incisors, but long-term longevity has not been reported. A ferrule or other counterrotational core design is an important consideration for fracture resistance and retention,[155] although it has not been proven to be statistically significant for the resin-reinforced core systems.[279]

Absorbable hemostatic agents causing neuropathy

Absorbable collagen hemostatic agents should not be placed on or adjacent to peripheral nerves because of the potential for neural injuries, particularly in bony nerve canals.[105,200] Also, as this material is absorbed, its chemotactic properties promote collagen formation and scarring. Compression injuries of peripheral nerves in bony canals can result from expanding scar tissue. FDA adverse incident reports list 11 patients with severe neural defects, including

Telegram: @dental_k

www.konkur.in

paraplegia secondary to absorbable collagen products placed in the spinal canal for hemorrhage control. Thus the FDA warned of paralysis from absorbable hemostatic agents.[105,200] Accordingly, after hemorrhage is controlled with hemostatic agents, absorbable collagen agents should not be left in situ or near bony neural spaces. This will avoid having remaining hemostatic material cause swelling, pressure, or migration to adjacent neural tissues. The minimum amount of collagen agents necessary to achieve hemostasis should be used.

Pneumomediastinum (air embolus)

When performing endodontic surgery, a surgical handpiece should be used that ventilates air through the back of the handpiece rather than an air turbine that directs air into open tissue spaces. Pneumomediastinum, also known as *mediastinal emphysema*, may result from air embolisms dissecting down the neck facial planes from air forced into the submandibular or sublingual spaces contiguous with neck spaces.[40,301]

Broken needle

Scanning electron microscopy (SEM) with an energy-dispersive x-ray spectrometer attachment can analyze whether a broken instrument is due to excessive operator trauma or a manufacturing defect. Fig. 27.43 represents a combination of low-cycle bending fatigue and tensile overload. Accordingly, the local anesthetic needle likely fractured because of bending deformation as it struck the ramus.

Telegram: @dental_k

www.konkur.in

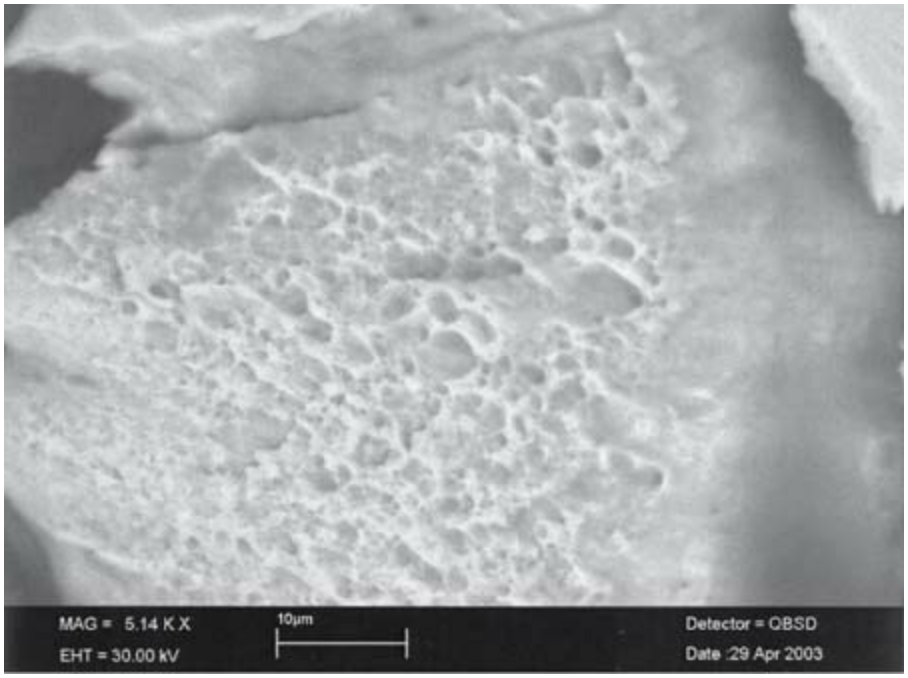

FIG. 27.43 Tensile overload shown in elongated ductile dimple voids.

Scanning electron micrograph shows ductile fracture. The scale reads, 10 micrometers.

Ductile rupture in metals results from shearing along planes that are oriented at 45 degrees to the tensile stress. Tensile "necking" results from multiple slipping deformations in all the 45-degree planes to the needle axis because of significant overload. Final rupture results from a combination of bending and tension. Fig. 27.44 shows the needle tip bent and blunted as it hit a hard object. No manufacturing defects were found. Fig. 27.45, *A* and *B*, shows SEM views of the fracture. Fig. 27.45, *C*, is a SEM view of the needle fracture taken at the hub side of the fracture. These illustrations demonstrate why longer 25-gauge needles should be used for mandibular blocks rather than shorter 30-gauge needles.[207]

Telegram: @dental_k

www.konkur.in

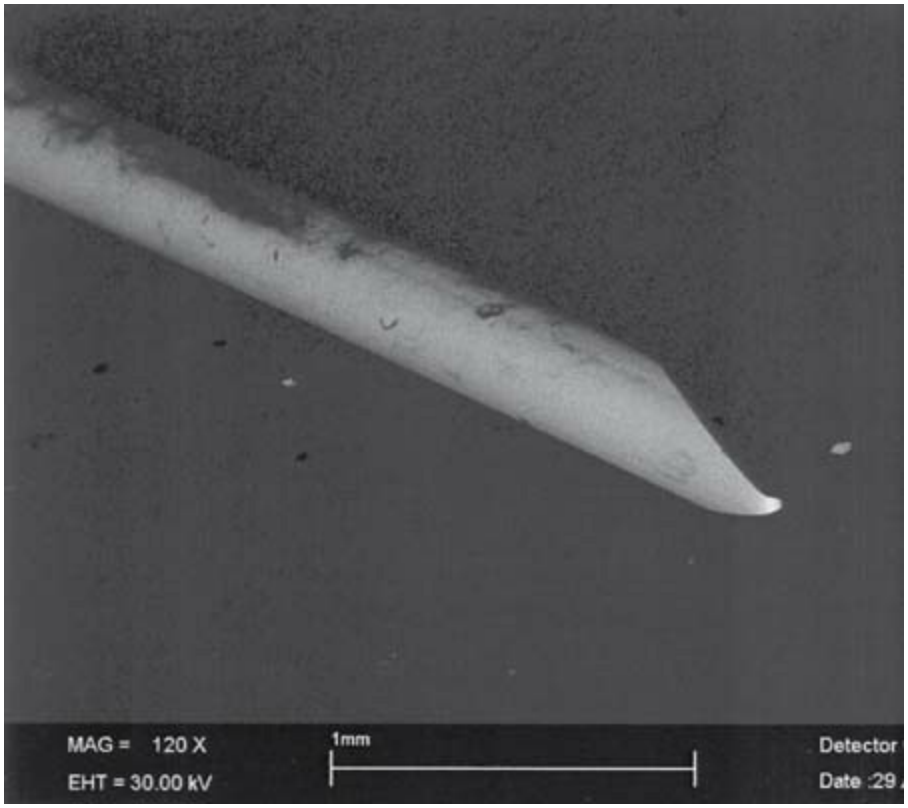

FIG. 27.44 Needle blunting of broken needle tip demonstrating striking hard object (ramus).

Scan shows curved tip of the needle. The scale reads, 1 millimeter.

Telegram: @dental_k

www.konkur.in

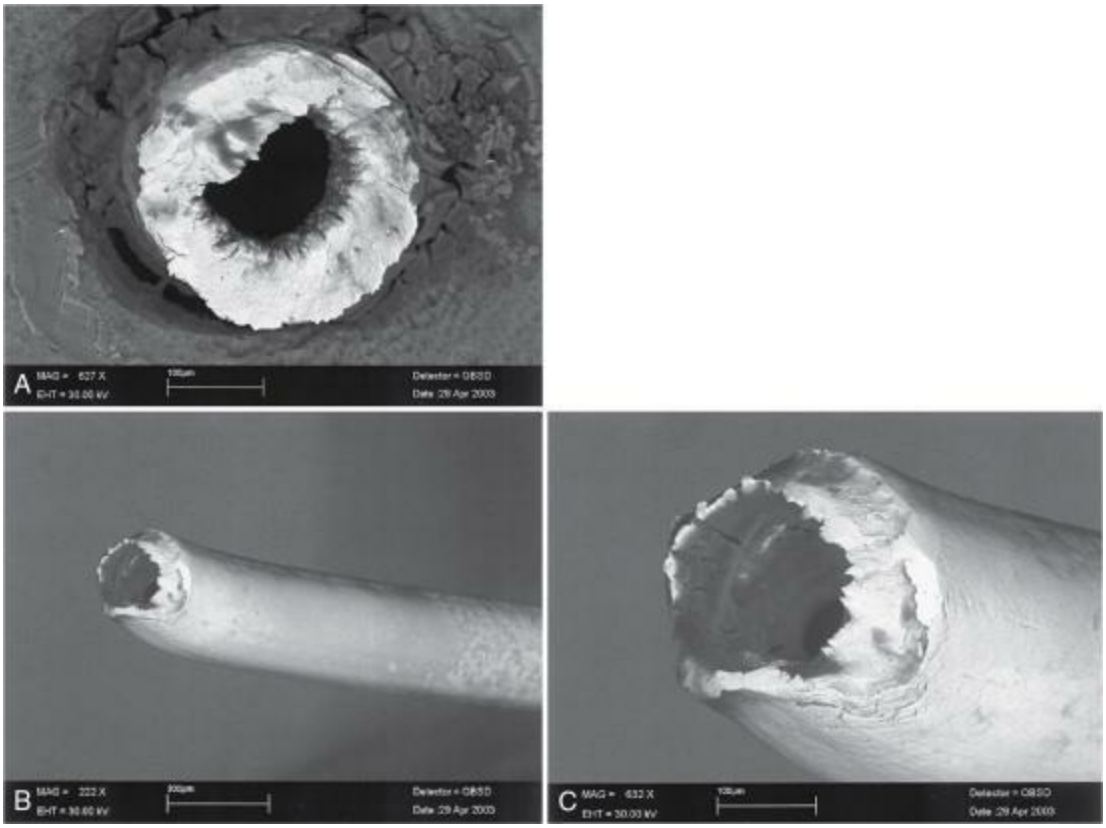

FIG. 27.45 **A,** Needle fracture with scanning electron microscopy (SEM). **B,** Needle fracture, side view (SEM). **C,** Needle fracture at high SEM magnification.

Set of three scanning electron micrographs, marked A through C, shows top, side, and highly magnified view of fractures at needle tips.

Causes of a broken local anesthesia needle that are preventable are as follows[207]:

- Use of a 30-gauge needle for mandibular block
- Bending needle
- Insertion of needle to the hub
- Multiple use of the same needle

Sterilization

The nonsurgical use of the dental unit water supply should comply with the Environmental Protection Agency regulatory standard to not exceed 500 CFU/mL.[188]

Telegram: @dental_k

www.konkur.in

CDC guidelines require sterile water or sterile solutions for all surgical procedures.[188] Disinfected water from handpieces or ultrasonic devices is no longer acceptable as a water coolant during surgery. Instead, an ultrasonic device that can deliver a sterile irrigant during surgery should be used. Dental unit waterlines are available with tubing that can be disposed or autoclaved for surgery. Some ultrasonic devices are also available with disposable tubing to maintain a sterile water coolant delivery system.

Rotary NiTi files likely contain bioburden material that, after sterilization, may act as a foreign body. Efficiency degradation after sterilization should suggest to the prudent clinician a single-use philosophy.[31]

Digital radiographic devices that contact the oral mucosa region require a combination of barrier protective sheath and chemical disinfection in accordance with prudent manufacturers' directions.[151]

Medication errors

The FDA has received more than 95,000 reports of medication errors since the year 2000. Medication errors involve the wrong drug, an extra or wrong dose, omission of a drug, or administering a drug by the wrong route or at an incorrect time.[190]

Medication errors are often preventable.[306] Two major sources of errors in prescribing are poor penmanship and the use of error-prone abbreviations. Writing "1.0 mg" can be read as "10 mg" if the decimal point is not clearly visible. The FDA recommends that no trailing zeros be used when denoting doses expressed as whole numbers and that preceding zeros be used whenever a decimal point is needed for a dose that must be administered as a fraction of a whole number (e.g., 1 mg, 0.5 mg). Recent drug label changes can be readily accessed on the National Library of Medicine's DailyMed website.

Posttrauma therapy

The reader is referred to Chapter 21 for a full discussion of how to treat and manage patients who have sustained a traumatic injury.

Millennium management of endodontic advances

Telegram: @dental_k

www.konkur.in

Microsurgical endodontics is an example of improved endodontic technology; use of magnifying loupes or similar devices may prove inadequate for apical surgery or fractured instrument retrieval compared with microscopes. Therefore the clinician should adopt proven improvements in the endodontic field. Three-dimensional reconstruction of mandibles can be accomplished with cone-beam volumetric tomography to accurately locate the course of the IANC or mental foramen. Fig. 27.46 shows an example of volumetric tomography usage for implant placement or apical surgery.

FIG. 27.46 Cone-beam computed tomography usage for implant placement or apical surgery.

Specimen shows lower jaw with stained implant.

If studies demonstrate significantly superior results for some alternative to surgical endodontics, the informed consent standard of care may require that the patient be advised of the alternative technique, even if it is more expensive. There may be more than one path to success. So long as the clinician uses reasonably acceptable techniques and informs the patient of reasonable alternatives, the standard of care is met. Microscopic apical surgery has gained general acceptance, is performed by the majority of endodontists, and represents the current standard of care.[15,76,166,183]

Statistical research

Telegram: @dental_k

www.konkur.in

The standard of care usually does not mandate incorporation of every new technology. However, in those states with informed consent laws that are based on what a prudent patient would want to know rather than what prudent clinicians should do, the patient may argue that an alternative technology or technique used by a different clinician would have been chosen had the clinician provided the patient with such information. Microscopic endodontics for broken file retrieval and CBCT to aid apical surgeries and implant placement are pertinent examples of what a reasonable patient would wish to know.[75,157]

Other clinicians' substandard treatment

Clinicians should not be overly protective of blatant examples of another clinician's substandard dental treatment. On discovery of apparent negligent treatment by a previous clinician, the clinician should consider investigation. Begin by obtaining the patient's written authorization for transfer of a copy of the previous clinician's records, including radiographs. If negligence is still suspected after reviewing the records, the clinician should consider talking with the previous clinician to learn the circumstances of what occurred during the patient's past treatment (after obtaining the patient's written consent pursuant to HIPAA).

On discovery of a gross violation of the standard of care, a clinician has an ethical responsibility to report the matter to the local dental society, peer review, dental licensing board, or agency.[18,122] If the patient was misinformed and later discovers patently obvious negligent treatment, the subsequent clinician could arguably be sued as a co-conspirator to fraudulent concealment of the prior clinician's neglect.

Peer review

If, despite good rapport, candid disclosure, and an offer to pay corrective medical or surgical bills, the patient is still unsatisfied, the clinician should consider referring the patient to peer review. Peer-review committees award damages for out-of-pocket losses but not for pain and suffering or lost wages. Consequently, even if the committee's decision is adverse to the clinician, the damage award will probably be less than a jury's verdict. If peer review finds for the clinician, the patient may be discouraged from proceeding further with

Telegram: @dental_k

www.konkur.in

litigation. Peer review proceedings, including the committee's decision, are not admissible in court.[61] Insurance carriers usually honor and pay a peer-review committee award, because a fair adjudication of the merits has been determined; the award is usually less than a jury would award. Also defense costs, including attorney's fees, are saved with peer review.

Human Immunodeficiency Virus and Endodontics

A clinician may not ethically refuse to treat an HIV-seropositive patient solely because of such diagnosis.[82] Although in the 1980s, no federal law had clearly extended the protection of the handicapped laws to patients with AIDS, federal congressional action in 1990 extended this protection to the dental office setting with the passage of the Americans with Disabilities Act.[23] Many states already offer additional protection under state law.[59,83]

Confidentiality for patients disclosing their HIV status is important. An inadvertent disclosure to an insurance carrier or to other third parties without any need to know may result in cancellation of the patient's health, disability, or life insurance. This cancellation could result in a claim against the clinician whose office disclosed the information without authorization. Therefore employees should sign the confidentiality agreement shown in Fig. 27.47. In signing this agreement, the staff may be alerted to the seriousness and importance of maintaining the confidentiality of patient health histories, because these histories may document AIDS, venereal disease, or other socially stigmatizing diseases.

DENTAL AUXILIARY CONFIDENTIALITY AGREEMENT

I, _____, have been informed by
(Dental Assistant)
_____, DDS, that all dental, medical, and
(Dentist Name)
financial information concerning patients is confidential.

As a condition of employment, I agree to maintain the confidentiality of all oral and written information, including treatment charts, and to not disclose such information to any unauthorized outside persons, including any family members, except upon request and authorization by the patient, the patient's agent, or supervising dentist.

I understand and agree that breach of this employment agreement shall constitute good cause for my discharge from employment. I acknowledge that I may be personally liable for any violation of a patient's privacy or civil rights including HIPAA committed by me without consent of the patient, or the patient's agent, or approval by above-named dentist.

Date: _____ _____
Signature of Dental Assistant

Witness: _____

FIG. 27.47 Dental auxiliary confidentiality agreement.

Dental auxiliary confidentiality agreement is as follows:

I, blank space (dental assistant), have been informed by blank name (dentist name), DDS, that all dental, medical, and financial information concerning patients is confidential. As a condition of employment, I agree to maintain the confidentiality of all oral and written information, including treatment charts, and to not disclose such information to any unauthorized outside persons, including any family members, except upon request and authorization by the patient, the patient's agent, or supervising dentist.

I understand and agree that breach of this employment agreement shall constitute good cause for my discharge from employment. I acknowledge that I may be personally liable for any violation of a patient's privacy or civil rights including HIPAA committed by me without consent of the patient, or the patient's agent, or approval by above-named dentist.

Date: Blank space.

Witness: Blank space.

Signature of Dental Assistant with a blank space above.

If a patient requests that the clinician not inform the staff of his or her HIV status, the clinician should refuse to treat that patient. This information is

Telegram: @dental_k

www.konkur.in

essential to staff members who may come in contact with the infection.[48] An accidental needle stick with HIV-infected blood, which carries a risk of approximately 1 in 250 chances of seroconversion, may occur. Current medical protocol includes prophylactic administration of zidovudine (also known as azidothymidine [AZT]), either to prevent or to slow the manifestation of AIDS from a deep, penetrating, accidental needle-stick exposure.

Although a treating clinician risks devastating a dental practice by informing patients that the clinician has contracted AIDS, the legal risk of not informing patients is much greater. The health care provider may be required to advise patients of positive HIV test results under the doctrine of informed consent (i.e., advising of a known risk of harm from accidental exposure).[88] Even if an uninformed patient never contracts AIDS, in those states that use a reasonable patient standard for disclosure of material risks of treatment (which could include accidental direct contact such as an unintended cut or needle stick), the patient may decide to bring an action for intentional concealment as a variant of informed consent and seek to recover emotional distress and punitive damages. Conversely, patients may be legally liable for intentionally misrepresenting their health history regarding their HIV status.[51]

Summary

If the clinician performs endodontics within the standard of care as described in this chapter, there should be little concern that a lawsuit for professional negligence will be successful. Prophylactic measures suggested in this chapter should lessen the likelihood of litigation by reducing, if not eliminating, avoidable risks associated with endodontic care.

Both the patient and the clinician benefit from risk reduction.[119] To do it wrong does not take long, but it is far better for the clinician to take the extra precautionary time to do it right. We are in a profession that deserves the public's trust, but only if that trust is earned. Clinicians deservedly earn public trust by providing safe and excellent quality patient care. The best prophylaxis against being sued is to make protecting the patient's best interest our paramount goal. No matter how many others do it wrong, this

Telegram: @dental_k

www.konkur.in

never makes it right. Our ethical and legal obligation adheres to the identical bedrock principle, which is service to our patients first and foremost.

28: Key principles of endodontic practice management

Roger P. Levin

CHAPTER OUTLINE

Telegram: @dental_k

www.konkur.in

Operating a successful endodontic practice requires both excellent clinical *and* management skills (Fig. 28.1). Endodontists are extremely well trained in their clinical specialty, but most do not receive extensive business training prior to becoming a practice owner. This scenario is beginning to change as more in the dental profession recognize the value of practice management skills and the role they play in an endodontist's ability to have a successful and rewarding career.

Telegram: @dental_k

www.konkur.in

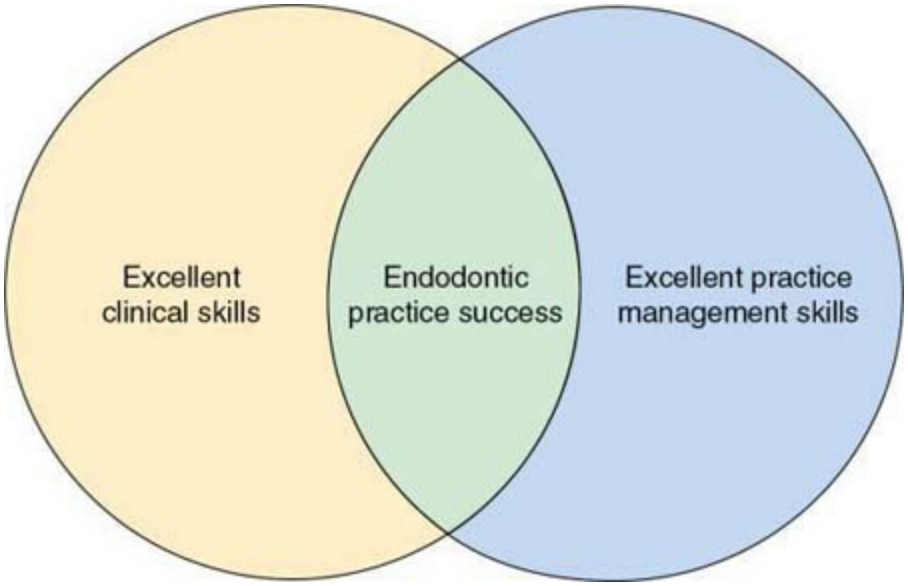

FIG. 28.1 The keys to achieving practice management success.

Venn diagram of practice management success shows two overlapping circles as excellent clinical skills (left) and excellent practice management skills (right), with common region labeled as endodontic practice success.

Endodontists who possess management skills are better positioned to handle the demands of operating an endodontic practice—a business that can generate significant revenue. Historically, there was a time when endodontists could enter practice without strong business skills and enjoy a long, prosperous career, but the business side of endodontics has become more complicated due to the difficult economy.

Young endodontists are leaving dental school and residency with far more debt than even a decade ago. The cost of purchasing or opening an endodontic practice continues to rise. In addition, endodontists face increased competition from other doctors who perform root canal treatments. The success of endodontic practices can also be affected by the development of new clinical techniques or services. For example, some doctors believe that dental implants represent a better treatment option than root canals, depending on the difficulty of saving the infected tooth. As dental implant procedures become easier and more common, this trend may continue to grow.

To meet these and other challenges, endodontists need to supplement their clinical expertise with excellent practice management skills. *Practice management* involves the use of documented systems to achieve superior

Telegram: @dental_k

www.konkur.in

business results. Effective practice management allows endodontists to provide optimal patient care while creating a highly productive, low-stress office environment. The design and implementation of effective practice management and marketing systems enables endodontists to operate their practices as successful businesses with steady growth and maximum efficiency. Endodontists who can combine excellent clinical skills with strong practice management skills will experience greater practice success (see Fig. 28.1).

Endodontic management systems

Written, documented systems are the basic foundation for all successful operations within an endodontic practice. Step-by-step, reproducible systems enable a practice to consistently operate and be successful as both a provider of patient care and a business enterprise. Documented systems reduce unnecessary stress and allow endodontists to remain chairside so they can focus on providing exceptional quality of care. As each system is established, every step in that system must be clearly documented and then implemented. Many endodontists fail to establish efficient systems in the early years of a new practice, and inefficient systems can hinder the practice's growth, increasing stress for the doctor and team.

Endodontists should begin their careers by developing and implementing effective practice systems. This way, when an endodontic practice begins to grow, the office has a solid management foundation in place to handle the growth with low stress as well as to reach more challenging goals. If the practice waits until it becomes more established, there is less time to design effective systems, and the endodontist often becomes less motivated to do so owing to an increasingly busy office and other responsibilities in life.

Systems design

New endodontic practice owners have an excellent opportunity to design systems because the office is nowhere near its capacity. This type of foresight sets the stage for practice growth in the years to come. However, systems should be evaluated and updated throughout an endodontist's career. It will be necessary to replace most major endodontic practice systems on a 5-year

Telegram: @dental_k

www.konkur.in

cycle to maintain growth and profitability. The reason is that practices regularly outgrow their systems as a result of changes in staff, equipment, technologies, referral relationships, and the economy.

Immersed in the day-to-day pressures of running the practice, evaluating systems can be difficult. Therefore endodontic practices are well advised to seek outside experts to help them determine the "state of the practice." An in-office practice analysis should include the following:

- First-hand observations of the team and practice operations
- Interviews with the doctor and key team members
- In-depth assessment of all key production indicators (KPIs)
- Thorough evaluation of all practice systems, physical layout, and patient flow

Through such careful analysis, it is possible to accurately determine the effectiveness of practice systems that are in place.

Systems should be designed based on the specific characteristics of each practice. Areas to be considered include the following:

- Days of operation
- Hours of operation
- Number of staff
- Number of patients
- Number of true emergencies
- Average daily patient flow
- Types of procedures offered
- Number of chairs

Effective management systems can make the difference between a successful endo practice and a *highly* successful endodontic practice. Many endodontists cannot fathom how they could see any more patients, produce any more revenue, or work any harder. Yet, there exist similar practices that have much higher production in the same number of days per week with the same number of staff. It is always interesting to reflect on why one endodontic practice can be so much more financially successful than another practice in similar circumstances.

Telegram: @dental_k

www.konkur.in

Assuming a sufficient patient flow, the answer always comes down to management systems. It is not about working harder or faster, but it is about creating systems that allow the practice to operate at a specific production and profitability level in a low-stress environment. Key systems and principles for effective endodontic management and marketing include these:

1. Vision
2. Mission
3. Goal setting
4. Target setting
5. Key production indicators
6. Staff training and development
7. Scheduling
8. Customer service

Management

Vision

The first question endodontists should answer before opening or purchasing an endodontic practice is, “What kind of endodontic practice do I want to have?” This question requires the endodontist to take some time and identify a vision, which is a description of where the doctor wants the practice to be in 3 years. Whereas some vision statements may reflect a longer period, this shorter time frame works well for most endodontists because it is difficult to predict changes in dentistry, the economy, and other events more than 3 years into the future. In addition, after 3 years, it is time for the doctor to review what has been accomplished and possibly establish a new vision for the practice.

To create a vision statement, the following questions should be answered:

- What location is most suitable for the practice?
- What size should the practice be in 3 years?
- Does the doctor want to be in solo practice or multidoctor practice?
- What working days and hours will be satisfactory for the practice?
- What services will the practice provide?

Telegram: @dental_k

www.konkur.in

- Is the intent to have only one practice or to have more than one location?

These are just examples of questions that can stimulate the design of a vision statement.

A vision statement clearly articulates where the practice is going. The length of a vision statement can vary between a short, single paragraph and several paragraphs. It is probably counterproductive to have a multipage vision statement; it will be difficult for both the endodontist and the staff to fully grasp such a lengthy and complex vision.

The vision guides the long-term development and growth of the endo practice. Once the vision statement has been created, it should be shared with the staff on a regular basis. Good leaders always communicate their vision to their staff. When team members understand where the practice is headed, they are empowered to help the endodontist achieve his or her vision. Sharing the vision inspires commitment and participation in achieving the vision. The following are two examples of vision statements.

Short vision statement

In 3 years, we will be the leading endodontic practice in the area. We will be known for exceptional quality of care and outstanding customer service. We will grow by 15% per year. Our staff is motivated and committed to continuously improving our management systems and to a lifelong learning process. We strive to meet or exceed our goals in a low-stress work environment.

Long vision statement

In 3 years, we will be known in the community for being the most comprehensive and skilled endodontic practice in the area, offering our patients an atmosphere of compassion and comfort.

Our excellent management skills create an environment that is low-stress and productive. We consistently meet our production goals without creating a rushed atmosphere, and our days are fulfilling.

We provide exceptional customer service that consistently generates spontaneous, positive comments. Team members have a clear understanding

Telegram: @dental_k

www.konkur.in

of their roles and responsibilities. We have developed practice systems that foster a sense of fulfillment and accomplishment for all. In year 3, we will engage an associate doctor.

Mission

Once the vision statement has been created, the next step is the development of a mission statement.

Whereas the vision statement is about where the practice will be in the future, the mission statement is focused on where the practice is today.

Once again, a strong leader has a clear practice mission and shares it with the team. Because of the similar services provided by endodontic practices, many mission statements resemble one another—they talk about quality, patient care, practice services, and customer satisfaction. It is not important to have a mission that differentiates one practice from another, but it *is* essential to have a mission that reflects the doctor's true vision. Here is an example of a mission statement:

> *Our endodontic practice is dedicated to delivering quality care to meet the endodontic needs of our patients and referring doctors. We provide exceptional clinical care and customer service in a comfortable, relaxed environment.*

One way to keep the mission statement on everyone's mind is to display it prominently in several places throughout the office, as well as on the practice's website. The most powerful reason for displaying the mission statement is to reinforce to the team that the mission is a living document that guides the practice. An added benefit of displaying the mission statement is the opportunity to let patients know that they are important to the practice.

The endodontist should refer to the mission statement on a regular basis. Reinforcing the mission during meetings helps staff members focus on why the practice exists and the difference the team is trying to make in the lives of patients.

Goal setting

Telegram: @dental_k

www.konkur.in

Goal setting represents one of the most important business activities for endodontists. It is critical to achieving success in a doctor's professional and personal life. Once a vision and mission are established, annual goals are the method to make the vision and mission realities. Goal setting is a step-by-step methodology that leads to the achievement of the overall vision. To be effective, a goal must be

1. Written
2. Deadline driven
3. Measurable

Goals that lack these three characteristics cannot be considered goals and are much less likely to be achieved. Be sure that all of the goals are aligned with the practice's vision and mission to achieve the desired results.

The pace of today's endodontic practice forces many doctors to focus on day-to-day operations. In doing so, they cannot see the big picture until many years have gone by. Goal setting and regular goal reviews can help endodontists manage their practice—instead of being managed by it.

Far more than just a motivational concept, goal setting acts as a timeline, benchmark, and directional process to achieve the vision and mission. A vision or mission without specific goals is merely an idea. Endodontists who set goals are much more likely to succeed.

Target setting

Targets measure whether you are accomplishing your short-term and long-term goals. Each year, endodontists need to set 12 to 15 specific targets to be achieved for the next year. This helps motivate the team to reach goals and drive practice growth. Targets should be reviewed on a weekly basis. For example, if the practice is only collecting 85% of its fees, then the office needs to implement more effective financial procedures to reach the 99% target (if that is the target that has been set).

Sample endodontic targets to achieve include the following:

- *Increase practice production by 15% in the next 12 months.*
- *Ensure that 98% of all nonemergency patients are scheduled at all*

Telegram: @dental_k

www.konkur.in

times.
- *Collect 99% of all money owed to the practice.*
- *Maintain a less than 1% no-show/last-minute cancellation rate.*

Key production indicators

Without data, an endodontic practice cannot be well managed. To obtain a clear picture of current and potential practice performance, practice goals must be monitored and measured. Key production indicators (KPIs) provide an accurate assessment of the practice's most critical functions, including the following:

- Production
- Collections
- Profit
- Overhead
- New patients
- Accounts receivable
- Number of re-treats versus initial root canal treatments
- Insurance percentages
- Production per hour

These KPIs offer endodontists a starting point for analyzing their practices. Once the information has been collected, weekly measurement and analysis are necessary. Although this may sound arduous, a weekly review should take only a few minutes. Such frequent analyses can bring substantial benefits to the practice.

Evaluating KPIs every week allows endodontists to rapidly identify trends or performance deviations that may be difficult to discern otherwise. With accurate practice data, endodontists are then able to take appropriate actions.

Staff training and development

Establishing practice systems will only be effective if team members understand their roles in making those systems work. Training the endodontic team begins with the development of job descriptions that list the skills, responsibilities, and accountabilities for each staff position.

Telegram: @dental_k

www.konkur.in

Bear in mind that the majority of staff will be hired without previous endodontic or dental experience and must be trained on the job. Training is specific to each position so that all team members can perform their duties as independently and effectively as possible. During training, it is critical that practices document training policies and procedures so they can be clearly communicated to new staff and regularly reinforced with established team members.

One frequent problem is that many staff members fail to fully understand their job responsibilities and are not held accountable for their performance. As a result, the endodontist will continue to handle numerous responsibilities that should be performed by other team members.

Although this type of behavior may be common in the early stages of an endo practice, endodontists who become effective leaders learn how to delegate appropriate tasks to the team. The goal for all endodontists should be to spend 98% of their workday involved in direct patient care or communication with referring doctors. To reach this goal, it is recommended that endodontists make a list of all activities they perform and which of those responsibilities can be assigned to the staff. This exercise will enable the endodontist to clearly identify which activities should be handled by the doctor only and which should be delegated to the team.

Delegation empowers the team to take ownership of their roles in contributing to practice success. The concept involves giving responsibilities to staff members so that endodontists can concentrate on what they do best. Without delegation, endodontists often carry out numerous responsibilities that can easily be performed by others. To spend more time in direct patient care, endodontists must delegate appropriate responsibilities to specific staff members. In addition, the team should be cross-trained on systems to cover for any illnesses, vacations, or turnover.

Once all team members have achieved a high level of expertise and independence, the endodontic practice can operate at peak performance. Efficiency, professional satisfaction, and quality of care steadily climb to maximum levels. At this stage, endodontists trust their teams to effectively perform their duties with minimal oversight. Best of all, doctors can focus on providing exceptional patient care without distractions and unnecessary stress.

In highly successful endodontic practices, the doctor focuses 98% of

Telegram: @dental_k

www.konkur.in

working hours strictly on patient care, interdisciplinary treatment, and referring-doctor communication. These practices will typically reach 90% to 100% of their production potential.

Scheduling

Making changes in the area of practice management should begin with a thorough evaluation of the schedule because of its impact on all other major systems. If the schedule is integrated properly with all other endodontic management systems, the practice has the best opportunity to achieve the endodontist's targets.

Schedules are created to achieve specific practice production in a low-stress environment. This means that an endodontic practice must establish a target for annual production and design the schedule accordingly. Each year, endodontic practices should calculate the desired level of growth and create a schedule that allows for that growth. The greatest challenge to increasing production is scheduling inefficiencies that make it all but impossible for the practice to grow.

The following principles are essential when designing the ideal schedule for any endo office.

Schedule for production

Design the schedule to achieve a specific production target. Endodontic practices are typically capable of growing between 5% and 15% annually. Less than 4% growth represents moving onto a plateau. There are endodontic practices that can grow by as much as 20% to 25% in a single year as optimal systems are implemented.

Scheduling is a quantitative and mathematical activity because time is quantitative and therefore measurable. The schedule should answer questions like these: *How many root canals will we need to perform this year? Will those numbers allow for the production goal to be achieved?* Benchmark these production goals against the hours and days per week the practice is available for patient care and adjust the schedule accordingly.

Set the daily production target

Setting the daily goal is a reflection of the annual production target. To

Telegram: @dental_k

www.konkur.in

determine the daily goal, simply take the annual production goal and divide it by the number of days the practice will operate that year. Then build the schedule around this key number. Front desk personnel should become aware that the top practice management priority is to achieve the daily goal. By implementing an excellent scheduling system, they will have a far greater chance of successfully accomplishing this task.

Perform procedural time studies

Many endodontic practices are unrealistic about how much time they actually need for procedures. One common example is for root canals to simply be scheduled for one set length of time, regardless of the level of complexity involved. Performing “procedural time studies” is recommended to determine the exact amount of time needed for each appointment.

During procedural time studies, each type of treatment performed by the office should be measured approximately 10 times to develop an average procedure time. Once these studies are performed and the schedule is updated, most endodontists will usually be able to increase their endodontic workload by using time more efficiently.

Young endodontists should perform procedural time studies once a year for the first 5 years they are in practice. After that, studies can be conducted at less frequent intervals (every 3 to 5 years) to evaluate whether the endodontist has become faster or more efficient in terms of experience, technique, or the use of new technologies in the practice. Procedural time studies play a critical role in building an effective and accurate schedule, which directly affects the success of the endodontic practice.

Create the ideal day

The schedule should be designed to perform larger and more complex appointments in the morning whenever possible. This can be extremely challenging, owing to the number of emergencies endodontists see during a normal day. By scheduling larger procedures in the morning, practices can take advantage of the high energy level for both the endodontist and the team earlier in the day. Of course, emergencies will continue to occur, but effectively managing other appointments will better position the practice to handle end-of-day emergencies. Other recommendations for creating the

Telegram: @dental_k

www.konkur.in

ideal day include the following:

- Handle less complex cases in the early afternoon.
- Perform consults and diagnoses in the midafternoon.
- Schedule all minor procedures, such as posttreatment evaluations, for the end of the day.

Basically, this means that the more difficult or larger cases will occur in the morning when the doctor and team are fresh. As the day goes forward, the doctor and staff have the opportunity to work on less complex cases, such as second visits and patient consultations, with all minor procedures taking place at the end of the day. A highly organized schedule will allow for increased productivity and higher profitability while decreasing stress for the endodontist and the team throughout the day.

Manage emergencies

No discussion of endodontic scheduling would be complete without focusing on emergency management. Obviously, emergency procedures are a frequent occurrence in endodontic practices. Managing emergencies well requires a combination of referring-doctor management, setting patient expectations, and effective scheduling. The result will be a highly productive, satisfying professional environment for any endodontic practice.

The first step in managing emergencies is to develop a schedule that allows some flexibility. It does not benefit the practice to create a schedule that is 100% maximized without accounting for emergencies. Instead, analyze how many genuine emergencies occur on an average day, and then leave time for that number of emergencies in the schedule. Many high-level endodontic practices will schedule only 80% of their day, leaving time slots for emergencies. The key is to not ignore the time slots and invite every emergency patient to visit the office immediately, but to manage each situation appropriately.

For example, a patient who is in mild discomfort calls at 10 a.m. The practice does not have an opening until noon. If the patient is allowed to come in immediately, the office feels a need to work the patient into the schedule, not only causing stress for the doctor and team but possibly forcing already-scheduled patients to wait longer than expected. If the practice

Telegram: @dental_k

www.konkur.in

instead schedules the patient in an emergency time slot, there is a much greater opportunity to maintain excellent flow for the day and create a positive customer service experience for every patient. The main point is to provide optimal care and exceptional customer service without disrupting the daily schedule.

The keys to effective emergency management are as follows:

- Evaluate each call from a patient or referring office to determine the level of emergency. Many calls are not true emergencies, and these patients do not need to be seen immediately. Scripting and training can help staff members elicit specific information from patients about the level of discomfort (mild tenderness versus extreme pain) while providing excellent customer service.
- If it is a true emergency, bring the patient in immediately, but still evaluate the schedule to facilitate the overall process. Highly systemized endodontic practices use trained staff to evaluate emergency situations as much as possible, including preliminary assessment and x-rays.
- If the emergency call does not constitute a true emergency, it is important to use effective scripting to move the patient into an emergency time slot that will prevent the appointment from disrupting the entire schedule. This approach can be used with either a referring office or a patient.
- If the practice notices ongoing disruptions from emergencies, it should reevaluate the emergency policy and scripting to create a more effective methodology. Many endodontic practices tell every emergency patient to come in immediately. The problem arises from mistaking high-level customer service with providing immediate treatment. It is much more effective to manage the emergency patient into a time slot reserved for emergencies, unless the patient is experiencing an endodontic problem that necessitates immediate treatment. Staff training is critical for effectively managing emergencies while providing quality customer service.

Scheduling is the single most important system because it integrates with all other systems. When an effective scheduling system has been established

Telegram: @dental_k

www.konkur.in

and properly implemented, the practice will immediately see an increase in productivity and a decrease in stress. Most stress in endodontic practices is based on poor scheduling methods that overwhelm the doctor and team and lower customer service. Even though the endodontist and team are actually working harder, profitability will be lower. An efficient schedule enables the endodontic practice to provide a high level of care and customer service to all patients.

Customer service

Customer service today means much more than just “being nice” to patients. It is a system focused on managing the patient experience from the initial referral to treatment to postoperative care. Outstanding customer service is critical to exceeding patient expectations and building strong relationships with referring doctors.

The majority of endodontic patients are referred to the practice by general dentists. The growth of the endodontic practice therefore depends on the satisfaction and confidence of referring doctors. General dentists want to know that their patients’ expectations, as well as their own, are being met. When patients receive excellent clinical treatment and superior customer service, they are likely to provide positive feedback when returning to their general dentist. Positive feedback from patients reinforces the dentist’s confidence in the endodontist and leads to continuing referrals.

Developing a customer service system is more complex than simply telling the staff to be nice to patients and referral sources. A customer service system requires that patients consistently receive the same level of responsiveness, caring, and concern from every member of the endodontic practice. Consistency and quality are at the core of a practice’s customer service system.

Although the patient’s time in the endodontic practice may be limited, the endodontist must realize that the patient will be returning to the referral source and sharing his or her experience with the referring doctor or the clinician’s staff. The patient will also share information about the experience with family, friends, and others. Negative word-of-mouth descriptions about the office will obviously hurt the endodontic practice’s reputation within the community.

Telegram: @dental_k

www.konkur.in

Patients want to believe they are the practice's *only* priority when they come in for their appointments. Endodontic practices with excellent customer service strive to meet this expectation. If a practice fails to return phone calls quickly, is running late when patients arrive, or does not seem prepared for appointments, patient confidence and trust disappears, as does the patient's perception of quality care.

Endodontic practices should manage expectations by making everything about the patient's treatment plan value based. Do patients fully understand the value of their treatment plans? Do they know exactly what the treatment entails, what the fees are, and why the treatment must be done? Does the patient know the projected outcome? All these questions must be satisfactorily answered before treatment starts.

Endodontic practices have an opportunity to exceed expectations when the following occurs:

- There is complete understanding about why, how, and when endodontic treatment will take place
- Patients have realistic expectations of outcomes
- Patients and referring doctors receive accurate and timely information about the treatment process
- The practice has timely follow-up posttreatment communication with patients

Marketing

Endodontic marketing

The science of endodontic marketing has evolved considerably. For many years, endodontic practices were in such high demand that referral marketing was relatively unimportant. In fact, endodontists felt that they couldn't handle any additional patients.

Today's supply and demand scenario has changed dramatically with the great expansion of different sources (read: competition) for endodontic procedures. Factors that have added to the competitive challenges of endodontists include:

Telegram: @dental_k

www.konkur.in

- *General dentists.* General dentists are performing more root canals than ever. The 2008 recession slowed general practice production leaving general dentists scrambling to make up for lost revenue. According to the Levin Group Data Center, the first specialty service that general dentists typically expand in their practices during a downturn is root canals. All indications are that this trend will continue.
- *Dental support organizations (DSOs).* Corporate dentistry also benefits from offering root canal treatment. One of today's largest DSOs has an in-house training program for the GPs in their practices to learn and perform endodontics.
- *Dental implants.* Dental implants have changed the referral pattern for endodontic procedures. Many implant procedures are no longer being referred out and are simply being treatment-planned for extraction and root canal.
- *Endodontic retreatment.* Retreatment by endodontists is on the decline. When general dentists perform root canals that fail years later, they do not necessarily refer treatment to an endodontist. More GPs are opting to perform implant procedures in-house.

All of these factors are changing the referral patterns of endodontics for the foreseeable future and causing practices to rethink their referral marketing strategy.

Endodontic referral marketing

Emerging competitive factors are having a profound effect on how endodontic practices approach referral marketing. While referral marketing (Fig. 28.2) may have been an afterthought in previous years, it's now a crucial part of endodontic practice success that can be described in two highly effective parts—quality and quantity.

Telegram: @dental_k

www.konkur.in

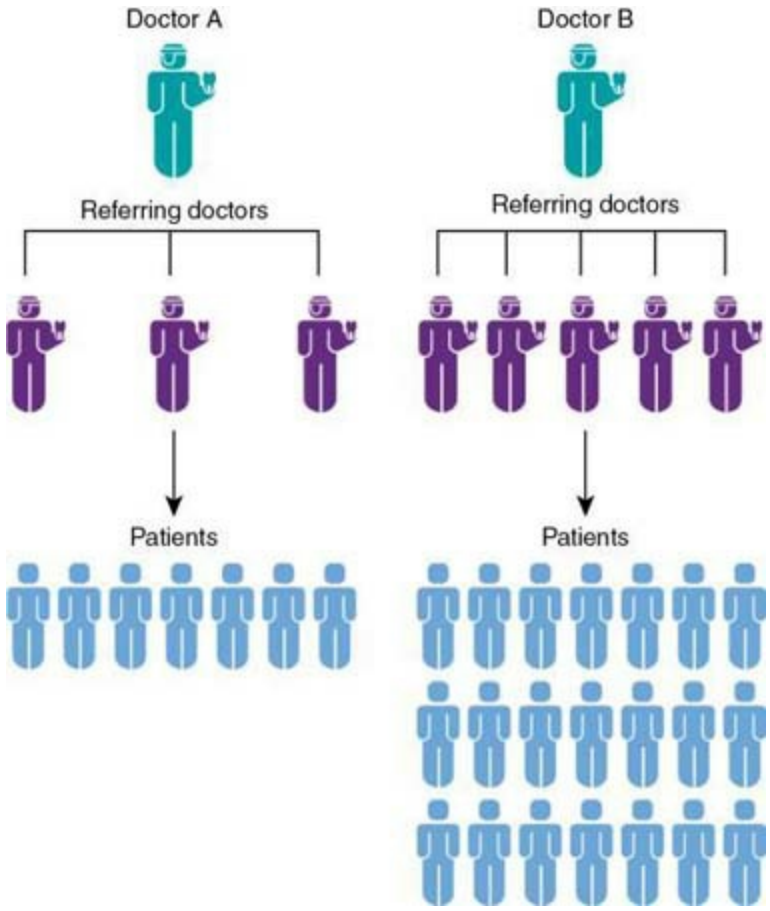

FIG. 28.2 The impact of referral marketing. *Doctor A* does not have a formal referral marketing program in place. *Doctor B* does have a formal referral marketing program in place. The results are dramatic. *Doctor B* has many more referring doctors, who refer more patients for treatment.

Doctor A leads to three referring doctors, which further leads to seven patients. Doctor B leads to five referring doctors, which further leads to twenty one patients.

Quality refers to the type of strategies that are employed in referral marketing such as education, events, branding, and relationship-building. The quantity of strategies is the part that is far less understood. Practices often employ two or three strategies, believing that will be enough. However, it has been clearly demonstrated that a minimum of 15 different referral marketing strategies targeted to referring doctors should be performed on an on-going basis. The key is to select the proper 15 (or more) that represents the quality and quantity necessary for the referral marketing program to be successful.

This outreach is best performed by a marketing coordinator who can carry

Telegram: @dental_k

www.konkur.in

out 95% of the referral marketing program activities, allowing the endodontist to continue to focus heavily on practice production. These activities can include hosting seminars, visiting referring offices, or creating fun contests and events for referring doctors and staff. A strong referral marketing program of this nature run by a focused marketing coordinator will increase referrals and maintain a strong referral base. Typically this will be a part-time position, typically 16 to 20 hours a week for a one- to two-doctor practice or 22 to 24 hours for a three-doctor practice. Practices with four more doctors will require a full-time marketing coordinator.

An endodontic referral marketing program should focus on four key areas —referring doctors, patients, social media, and the community. These areas work great together in order to create a synergistic affect where the whole is greater than the sum of the parts.

Social media

Social media has become a major marketing vehicle if not *the* major marketing vehicle in the world today. Unfortunately, the benefits of social media are fewer for endodontic practices as most endodontic patients are referred by other doctors and do not directly seek endodontic services on their own. However, social media can play a major role in an endodontic referral marketing program by helping practices connect to the community, build their brand, and create name recognition so that their practices will be top of mind with referring doctors that have patients who need endodontic services or individuals seeking endodontic treatment.

While it may be tempting, the social media component of an endodontist referral marketing program should not focus on constantly posting information, pictures, or videos. In fact, that may be counterproductive. Instead, having a small but steady flow of content related to endodontics and dentistry will effectively create name recognition and branding.

Transitions

In the past, endodontic practices typically reached a certain production level and remained at that level throughout the endodontist’s career. When the time came for the sale of the practice, the endodontist could count on a strong valuation for the sale.

Telegram: @dental_k

www.konkur.in

Today is a very different era. When endodontic practices reach a point of sale or transition, the owners are finding that their valuation is not as strong as they had hoped. This is typically due to having fewer referrals or lower production than in the past due—competitive factors outlined earlier in this chapter. Valuations are typically based on 3 years of information demonstrating whether or not the practice has had consistent growth and performance. For example, a practice that is strong in production but demonstrating a declining number of referrals will have a lower valuation.

One of the most important factors in preparing for a practice transition or sale is to keep the practice strong. As they edge toward retirement, many doctors tend to lose focus. And while it may feel good to cut back, they will be in for a lower practice valuation when the time comes for a sale. Keeping a practice strong in the last few years will allow for an excellent valuation and a higher sale price, which contributes to the endodontist's retirement funding. If the practice has demonstrated weaknesses or decline in the last 3 years, the endodontist will either have to accept a lower sale price or delay selling the practice if financially necessary.

A strong marketing program that aids in increasing and maintaining patient and referring doctor relationships will add to the value of an endodontic practice. Unlike other businesses that have ongoing customers when the business is sold, an endodontic practice is often dependent on the endodontist and his or her relationships with referring offices. When selling a practice, it is often prudent to offer to remain with the practice for 6 months or more to help ensure a smooth transition of referral sources to the new doctor. The more time the selling endodontist stays to endorse and help the buying doctor transition, the better. If possible, it makes sense to hire an associate who can buy in over a number of years and develop relationships with the referring doctors.

Leadership

Leaders possess many skills, qualities, and attributes that are the result of learning, experience, and self-motivation. Many people have great ideas or vision, but true leaders are able to implement those ideas or carry out the steps necessary to achieve predetermined goals. They have the ability to inspire others to do their best. The most successful endodontic practices are

Telegram: @dental_k

www.konkur.in

guided by strong leaders.

Becoming an excellent leader starts with the desire to have an outstanding practice. Most endodontists are highly motivated to be excellent clinicians. Endodontic continuing education is focused mainly on clinical topics, which is appropriate, given that doctors have an obligation to provide the best possible care to patients. This makes it even more important for endodontists to seek out opportunities to develop leadership, business management, and marketing skills.

The endodontic leader

As practice owners, endodontists are automatically viewed as leaders by team members. The more leadership skills endodontists master, the better leaders they become. Though not an exhaustive list, the following leadership skills are critical for endodontists.

Interpersonal communication

Interpersonal skills are the foundation of leadership. Endodontists work with a small group of people in a fairly limited space. Good interpersonal skills are essential for a smoothly functioning office environment. In business, there are many successful, “tough” bosses. Even though they may be disliked, they are respected. However, being tough or inflexible is not always the best strategy, especially in dentistry. Few endodontists can be tough leaders in a very small office environment and still expect to have happy team members and a successful practice.

The best practice leaders can motivate their staff, accomplish goals, and earn the respect of team members. Regular morning meetings and monthly staff meetings provide excellent opportunities to communicate with the team, increase awareness of practice challenges and goals, and build stronger interpersonal relationships with team members.

Decision making

As the CEOs of their practices, endodontists must make business decisions. There are many people who do not progress in business simply because they vacillate between two choices and fail to make a decision in a timely manner. No matter what the issue, excellent leaders make decisions and trust their

Telegram: @dental_k

www.konkur.in

instincts, based on analysis, education, and experience. Why? Strong leaders believe in themselves and their knowledge. They are confident that they have the ability to make decisions that are in their best interest and that of their teams.

Motivation

The ability to motivate is one of the most important leadership skills. By earning the trust and respect of the team, the endodontic leader is able to bring together the individuals to achieve shared goals and move toward the practice vision. Many people are not self-motivated. Instead, some external force motivates them. In this case, the external force is the practice leader.

Pursuit of knowledge

Practice leaders are usually in constant pursuit of knowledge. They want to excel in the management of the endodontic practice and will read, listen, and learn as much as possible about the subject of practice management. Leaders are typically lifelong learners who do not seek knowledge sporadically but take advantage of opportunities to learn new ideas and strategies on an ongoing basis.

Teamwork

An endodontic leader never works on his or her own. These leaders rely on their team to help achieve practice goals. However, many people mistake the concept of being a leader with being a “ruler.” This approach is not an effective one when working closely with a team whose performance is tied to the ultimate success of the practice. Therefore endodontic leaders must remember that they are part of a group dynamic. In fact, the practice leader is like the coach of a basketball or football team. He or she creates a game plan, guides the team, and facilitates teamwork.

Time management

Time is one of the leader’s most important assets. Endodontic leaders must not only manage their own schedule but their team’s as well. However, good leaders do not micromanage their team. They educate staff members, provide guidance, set expectations, and hold the team accountable for the results.

Telegram: @dental_k

www.konkur.in

Successful leaders effectively and efficiently use their time, creating positive outcomes for themselves, their teams, and their practices. Good leaders also eliminate extraneous items from their lives that take time away from achieving their goals.

Leading by example

The best way to earn the team's respect is to "talk the talk and walk the walk." The way the endodontist behaves will have a significant effect on how the team acts. The professionalism exhibited toward patients, the doctor's attitude and interactions with individual staff members—all of these behaviors send messages to the team. The team is looking to the endodontist for guidance, and the best strategy is to serve as an effective role model. If the team is expected to show up on time, the endodontist cannot stroll in 15 minutes late every day without causing resentment. Good leaders adhere to the rules others are expected to follow.

Leadership is a way of thinking and acting based on desire, skills, training, and specific behaviors. Endodontists who are willing to develop leadership skills will inevitably build better teams with lower turnover and higher efficiency.

Summary

Effective practice management involves management and referral marketing systems that enable an endodontic practice to provide outstanding patient care while operating as a successful business enterprise (Fig. 28.3). The number one source of practice stress is the lack of efficient systems. When an endo practice operates year after year without strong systems, the endodontist experiences increased stress and frustration. On the other hand, endodontists who implement documented, high-performance systems enjoy greater satisfaction (and profitability) throughout their careers.
